AWARD LECTURE / CONFÉRENCE D'HONNEUR

2003 Alfred Bader Award Lecture
Predicting the rates of chemical reactions

J. Peter Guthrie

Abstract: The dream of being able to predict the rate of a chemical reaction corresponding to a detailed mechanism is now almost within our grasp. No barrier theory (NBT), which makes the calculations relatively facile, is described, as are various applications of the approach to date. Illustrations are given of the use of NBT not just as a quantitative tool for predicting rates, but as a qualitative tool for thinking about which of a pair of reactions will have the higher intrinsic barrier, and thus be slower for similar thermodynamic driving force.

Key words: rate, equilibrium, thermodynamics, kinetics, no barrier theory, computational chemistry, chemical reactivity.

Résumé : Le rêve de pouvoir être capable de prédire la vitesse de réaction d'une réaction chimique correspondant à un mécanisme détaillé est à la portée de la main. On décrit la théorie sans barrière qui rend les calculs relativement faciles, comme c'est aussi le cas pour diverses applications de l'approche jusqu'à maintenant. On donne des exemples de l'utilisation de la théorie sans barrière non seulement comme un outil quantitatif permettant de prédire des vitesses, mais aussi comme outil qualitatif permettant de faire un choix entre deux réactions pour définir laquelle aura la barrière intrinsèque la plus élevée et, en conséquence, sera la plus lente pour des forces motrices thermodynamiques semblables.

Mots clés : vitesse, équilibre, thermodynamique, cinétique, théorie sans barrière, chimie quantique, réactivité chimique.

[Traduit par la Rédaction]

Introduction

The goal of my current research is to develop general methods for predicting the rates of chemical reactions. In reviewing the progress that has been made, and the research currently underway in my laboratory, I wish also to share with you the dream that motivates this research. "Dream" is a flexible word, with various meanings, of which I wish to focus on two:

"Dream: (n) 1.···2. A visionary creation of the imagination. 3.···4. A goal or purpose ardently desired" (1).

What then is this visionary creation, ardently desired? To have a general method, which any chemist could apply, to proceed from structures of starting material and products (written out in the detailed form of an organic reaction mechanism, as is illustrated in Fig. 1), to the free energy of activation for the corresponding reaction in the solvent of interest. This is an ambitious goal, and we will have to start with less ambitious targets, but this remains the ultimate dream.

Received 20 July 2004. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 3 February 2005.

Suppose for a moment that it were possible to achieve this dream. We would then have predictive power not just to say how fast a proposed reaction (perhaps never yet attempted in the laboratory) would be, but also to say how fast the likely alternative reactions were likely to be, and thus to predict whether the reaction would be clean or not. We would also have a mechanistic criterion, an unambiguous way to say how a reaction occurs, and which of the plausible mechanisms that could be written were viable contenders. The questions to ask would be: which mechanism leads to the fastest reaction, since this is the one that will be observed; and which predicted rate matches the experimental rate — they had better be the same or there is something badly wrong with the approach! Finally, we would have a new way of thinking about reactions, because the method that makes the dream possible imposes a new and different way of thinking about reactions, and why they have kinetic barriers.

To go from structure to rate is an ambitious goal; as a first stage one might think about going from equilibrium to rate. Would it be possible, given an equilibrium constant in solution, to calculate the corresponding rate constant by some manageably small computation? There is in fact a long history of using equilibrium constants as a guide to predicting rate constants. This began with linear free energy relations (LFER) such as the Bronsted relation (2). As Bronsted and Petersen recognized from the start (2), such a linear free energy relation is only an approximation, valid over a short

 doi: 10.1139/V04-172 © 2005 NRC Canada

Fig. 1. A typical organic reaction, with a detailed mechanism for the overall transformation, which is believed to occur in a single reactive collision, transforming one encounter complex into another.

range, to what must over the full range of possibility be a nonlinear relation. Nevertheless, LFERs have been very useful in organic chemistry, and can often be used for interpolative (or, with less confidence, extrapolative) estimation of rate constants. There was a considerable pause before this expected nonlinearity could be demonstrated, first by Bell (3) and Eigen (4). Marcus (5–11) developed a theory leading to quadratic relationships between rate and equilibrium constants; the theory was developed for electron transfer reactions (5–8), but has proven to be a very general description of the relation of rate to equilibrium (9–11), and Murdoch (12) has shown that a Marcus relationship is a logical consequence of the Hammond Postulate (13), Leffler's equation (14), and the assumption that interactions between substituents and reaction center are present in either starting material or products. Many of the extensions have been purely empirical (15–25).

If we accept that it will be necessary to start by calculating rate constants from equilibrium constants, what are the prospects for being able to calculate equilibrium constants from structure? In fact, this is now almost possible. For neutrals there are now fairly general and affordable procedures by which one can calculate $\Delta H_f^\circ(g)$ (26, 27) and $S^\circ(g)$ (28, 29). The solvation energy, or free energy of transfer from the gas phase to solution (ΔG_t) is still a bit trickier; sometimes the available methods work very well, but sometimes they fail badly. For ions it is much harder, both to match experimental precision in the gas phase, and to calculate solvation energies. Nonetheless it is almost possible, and a little more progress should bring this part of the dream within reach.

Results and discussion

No barrier theory (NBT)— The shape of the dream

The method that I have developed for calculating rates of reactions is called no barrier theory (NBT) to emphasize the key idea, namely that if only one thing were to happen in a chemical reaction there would be no kinetic barrier.[2] The reason that almost all real chemical reactions have an associated kinetic barrier is that most reactions require two or more things to happen in order for reaction to take place. This theory uses the same conceptual framework as Marcus Theory, namely that reaction proceeds from encounter complex of starting materials to encounter complex of products. Marcus Theory leads to the well-known eqs. [1] and [2]. The encounter complex of starting materials has them in position to begin the bond transformation, and the encounter complex of products has them in the position immediately resulting from bond transformation. The free energy cost of bringing reactants together, the work term, is called w_R, and the corresponding energy for the products is w_P. It should be possible to estimate the values of these work terms based on the entropic, electrostatic, desolvational, etc., contributions. Marcus Theory uses an intrinsic barrier ($\tilde{G}$), which operationally is the kinetic barrier when the thermodynamic barrier, within the encounter complex, is zero. Although the intrinsic barrier is often transferable within a family of similar reactions, it becomes a function of the equilibrium constant for large variation in equilibrium constant (24, 25, 30, 31). If the intrinsic barrier were constant for a family of reactions then it would be straightforward to calculate rate constants from equilibrium constants for further members of the family; if the intrinsic barrier is not constant this becomes impossible unless the intrinsic barrier is correlated with the equilibrium constant and even then is less satisfactory. The Marcus equation relating $\Delta G^\ddagger$, ΔG°, and, $\tilde{G}$ means that knowing any two allows one to calculate the third. Thus, if the free energy of activation can be calculated by some means from the standard free energy change, then in effect we have calculated the intrinsic barrier.

$$[1] \qquad \Delta G^\ddagger = w_r + \tilde{G}\left(1 + \frac{\Delta G^\circ - w_r + w_p}{4\tilde{G}}\right)^2$$

$$[2] \qquad \Delta G^\ddagger_{corr} = \tilde{G}\left(1 + \frac{\Delta G^\circ_{corr}}{4\tilde{G}}\right)$$

where

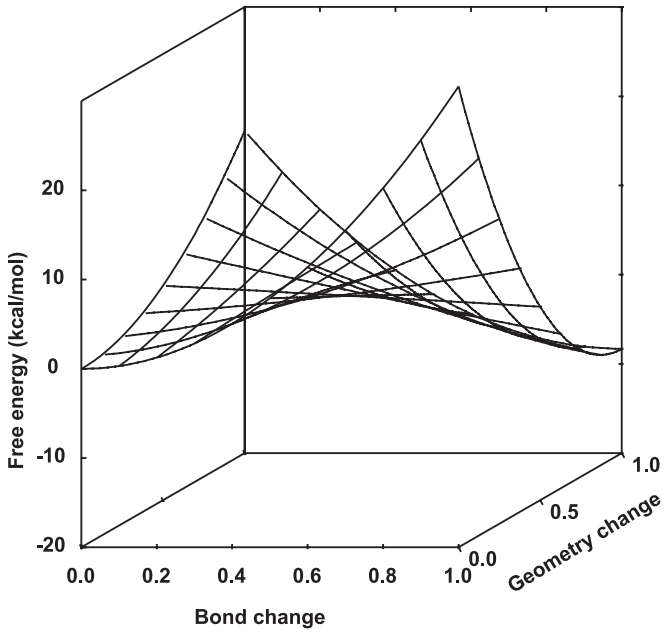
$$\Delta G^\ddagger_{corr} = \Delta G^\ddagger - w_r$$

$$\Delta G^\circ_{corr} = \Delta G^\circ - w_r + w_p$$

$\tilde{G}$ = the intrinsic barrier

w_r = work term for reactants

w_p = work term for products



[2] "Kinetic barrier" is equivalent to free energy of activation and easily transformed into rate constant. This expression is used to emphasize that there is a barrier to overcome if reaction is to take place, even when the reaction is thermodynamically favorable.

© 2005 NRC Canada

The suggestion that "if only one thing happens then there is a quadratic relation between energy and the reaction coordinate" sounds like lunacy, because it is well-known that most reactions have a kinetic barrier, and that the energy as a function of reaction coordinate looks far more like a quartic (minima at starting material and product, maximum at transition state) than like a quadratic through initial and final energies. The saving thing is the clause "if only one thing happens" because the viewpoint of the theory is that for almost all real reactions more than one thing must happen. This is illustrated in Fig. 2; in this figure and in higher dimensional versions of it, such as Fig. 3, the origin (0,...,0) represents the initial state, while (1,...,1) represents the final state, and the other corners represent hypothetical states where one (or two or more in higher dimensional cases) of the simple reaction dimensions have gone to completion. The dimensions are chosen so that they run from 0 to 1 and so that the energy is a quadratic function of each dimension. Even when only two things happen, if the energy is a quadratic function of the reaction coordinate for any section, parallel to an axis, through the square reaction diagram, then there will be a barrier, and the simplest path from starting material to saddle point to product will look approximately quartic.

What kinds of simple, one thing at a time processes are we talking about? First, there is geometry change, from one hybridization to another. This is the same sort of change as a bending vibration, for which we expect Hooke's Law behavior; an appropriate coordinate would be some simple function of bond angles set up to run from 0 to 1, such as $(\theta - \theta_0)/(\theta_1 - \theta_0)$, where θ_0 is the initial angle, θ_1 is the final angle, and θ is any intermediate value. Then there are bond length changes, where again we expect Hooke's Law behavior, and an appropriate coordinate would be a simple function of bond length, scaled to run from 0 to 1, such as $(r - r_0)/(r_1 - r_0)$. Next there are bond making or breaking processes. For a pure bond making or breaking (with no accompanying geometry change) we would expect a Morse curve (32) (eq. [3]), which does not look much like a quadratic. However, if the bond length in the Morse curve is transformed into a bond order using the Pauling bond length – bond order relationship (33) (eq. [4]), then we obtain a quadratic in a coordinate related to bond order. Finally, proton transfer between two atoms (with no accompanying geometry change, as for oxygen to oxygen transfer) is at least an approximation to a simple process, because it is known that these reactions can be ultra-fast with rate constants greater than 10^{11} s^{-1} (34). However, it is also clear that this is only an approximation and that this is not truly a no barrier process. Reactions such as the water-mediated proton switch, which involve only proton transfers between electronegative atoms, and which are successfully described by Multidimensional Marcus Theory (with an intrinsic barrier for proton transfer between two atoms of 1 kcal/mol) are not satisfactorily treated by NBT with these proton transfers treated as simple processes. On the other hand, the approximation that proton transfer between two atoms can be treated as a simple process is quite satisfactory for reactions involving heavy atom bond making and geometry change coordinates, as for various carbonyl hydration reactions.

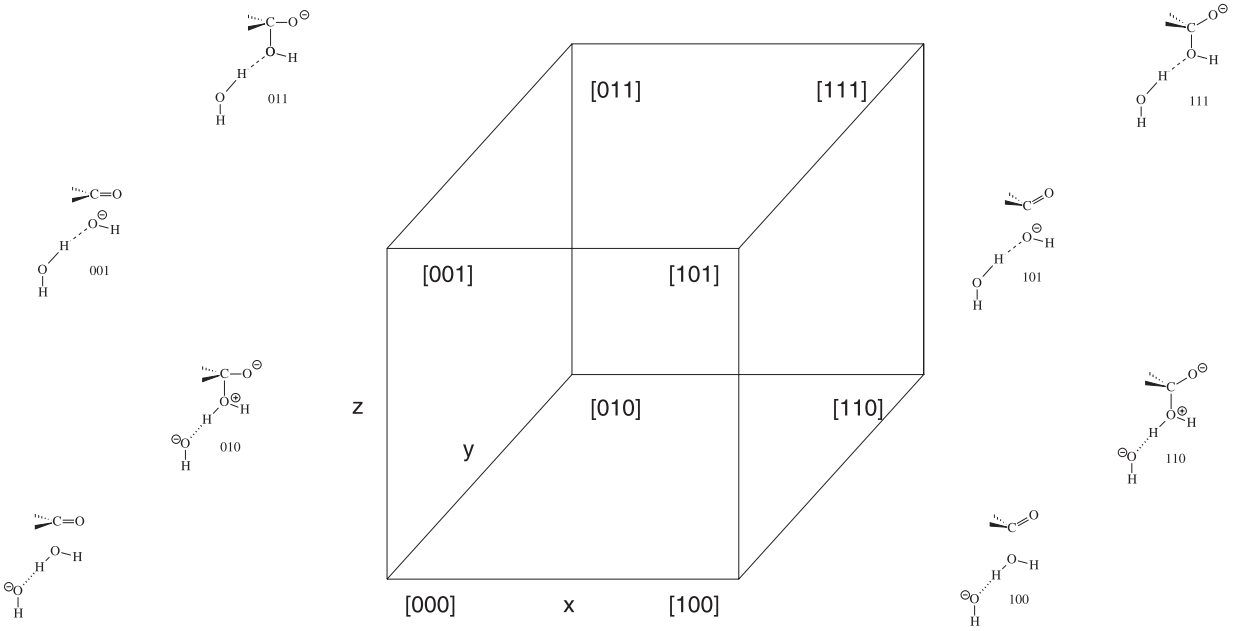
Fig. 2. The kind of energy surface implied by NBT. In this case, a two-dimensional reaction diagram was used, with one bond change and one geometry change dimension.

$$[3] \qquad E = D_e[1 - \exp(-\beta(r - r_0))]^2$$

$$[4] \qquad r_n = r_1 - \alpha \log(n)$$

The theory can be summarized in a few postulates:

(1) Reactants[3] are in equilibrium with starting material or product at each point along each reaction coordinate, with the minimum at the lower energy end of the coordinate.
(2) For any process where only one elementary reaction coordinate changes, the energy will be a quadratic function of the corresponding reaction coordinate with the minimum at the lower energy end of the coordinate.
(3) Heterolytic bond cleavage constitutes an elementary reaction coordinate.
(4) Proton transfer between two atoms constitutes an elementary reaction coordinate.



The first is the assumption underlying transition state theory. The second is the key assumption of the theory; if it is accepted then all else follows. The last two make explicit how reactions will be described. For convenience, all coordinates are defined to run from 0 to 1.

For an overall chemical reaction involving two or more simple reaction dimensions, we can construct a two, three, four,... dimensional reaction diagram (square, cube, hypercube,...). Once we have calculated the energy of each corner of the diagram, as will be illustrated in what follows, then, by postulate 2, we have defined the energy surface (or hypersurface) for the reaction. By finding the energy of the lowest saddle point on this surface between initial and final states we will determine the free energy of activation. This has been done for hundreds of reactions, and it works.

[3] Here we are using "reactants" to mean the molecular system involved in the chemical reaction at any point on the reaction hypersurface.

Fig. 3. The three-dimensional reaction diagram needed to describe addition of hydroxide to a reactive carbonyl compound. The structures corresponding to each corner are shown. Energy would be a fourth dimension, orthogonal to the three shown.

The assumptions stated above permit the calculation of rate constants for any reaction provided that the energies of all corners of the appropriate diagram can be calculated and that energy is a quadratic function of each coordinate: electron transfer or electronic state changes will not fit this pattern. The equilibrium constant in solution is a crucial input datum. Distortion energies are calculated relative to equilibrium species with the same bonding arrangement. This procedure leads to the rate constant for a particular step in a reaction. If the mechanism is complicated, and the rate-determining step is not known, then similar calculations for several different steps may be needed to determine the overall rate constant for the observable reaction.

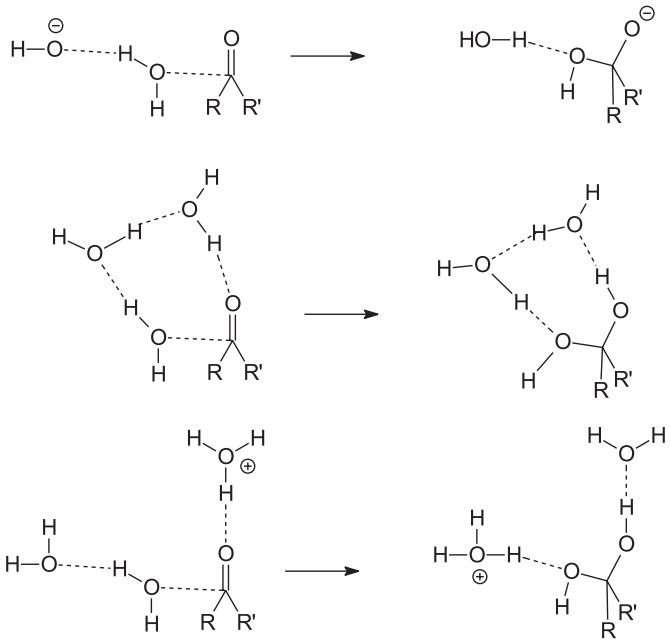
To illustrate the process of calculating a free energy of activation, I will work through an example, the addition of hydroxide to acetaldehyde.

Three things happen in this transformation: there is a proton transfer between two oxygens; a carbon–oxygen bond forms; and there is a geometry change at the reaction center from sp^2 to sp^3. The first of these may seem superfluous — why not simply start with hydroxide in contact with the carbonyl carbon? The problem is that hydroxide is strongly solvated, by approximately three water molecules, and for hydroxide to be in contact with the carbonyl carbon, with one lone pair ready to begin bond formation, requires loss of one of these solvating water molecules. Comparison of the pK_a of water in water and in DMSO as solvent shows that losing hydrogen bonding solvation is very expensive. On the other hand, the carbonyl compound, dissolved in water, must have water molecules in contact with it, and thus the cost of putting a water molecule in contact is zero. The more elaborate process shown above avoids the cost of bringing hydroxide into contact with the carbonyl before reaction begins, but at the cost of a more elaborate transition state. The advantage of using a general model is that it allows the molecules to tell us what the lowest energy path is: if the cost of bringing hydroxide into contact with the carbonyl carbon is small with respect to the overall kinetic barrier, then it is found that progress along the proton transfer dimension is complete at the transition state. If this cost is high with respect to the kinetic barrier, then the more elaborate three-dimensional path is followed: this is the case for the more reactive carbonyl compounds. The three-dimensional reaction diagram, which is sufficient for all of the compounds discussed here, is shown in Fig. 3.

Now the energy of each corner of the diagram must be calculated. The starting material is the reference; from the overall equilibrium constant for the reaction, we know the free energy of the product corner. By using the experimental equilibrium constants we avoid the tough computational task of calculating solvation energies. Now the energy of each distorted form is calculated using the difference in MO energies between distorted and equilibrium structures. If the difference is calculated for structures differing only in geometry and not in bonding, then relatively low level molecular orbital calculations will suffice. To calculate the energy differences between structures differing in bonding would be much more difficult. If a proton transfer has taken place the free energy change is calculated from the pK_a values of the species involved (either measured or estimated using linear free energy relations). If hydrogen bonds are present, their free energies of formation from the separate species are calculated using the Stahl–Jencks equation (35). Electrostatic interactions, if present, are calculated using a simple model, scaled to the experimental ion-pairing energies in the solvent of interest. The statistical effects of encounter (if more than one nonsolvent species is present in

© 2005 NRC Canada

the corner species) are calculated using the simple model proposed by Hine (15).



The corner energies, by postulate 2, define the free energy hypersurface for the reaction. Now we find the lowest saddle point between starting materials and products, by systematically searching the hyperspace. Computer programs have been written to do this. First, all candidate saddle points are found, which are points higher than a nearby point closer to the starting point and than a nearby point closer to the final point. These candidates are ranked in terms of energy level and tested starting with the lowest. The first one for which one can find both a path leading to starting point without going higher than the candidate, and a path leading to final point without going higher than the candidate is the lowest energy transition state on the energy surface.

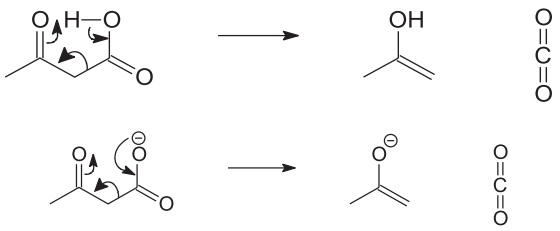
At this stage, my dream may be sounding like your nightmare. There are lots of details to take care of, lots of fussy calculations, lots of corner structures to account for. (For a two-dimensional reaction diagram, there are four corners; for a 3-D diagram, eight corners; for a 4-D diagram, 16 corners; for a 5-D diagram, 32 corners;...). The solution is found in words of wisdom from Kernighan and Plauger: "Let the machine do the dirty work" (36). I am engaged in writing computer programs to make the calculations easier to perform. The initial implementation involved a sequence of four programs to carry out the four stages of the analysis. (1) To identify the reaction dimensions. (2) To generate structures of the corner intermediates, in the form of data files suitable for MO calculations: this allows calculation of the distortion energies. (3) To calculate energies for each corner species as described above. (4) To search for the transition state. The next revision, now underway, will combine the first two programs into one, which will set up the calculation of distortion energies. In addition, this revision will correct various deficiencies in the initial versions of the programs, which became quite apparent as we used them. Once the data files for the MO calculations of distortion energies are set up, there is a pause while these calculations are carried out, a pause that can take a while depending on the level of theory used and the size of the molecular species.

Dreams are all very well: does it work? A review of published examples

We have reported a thorough investigation of the application of NBT to carbonyl hydration reactions, examining the hydroxide-catalyzed, uncatalyzed, and acid-catalyzed paths, and covering the range of compounds for which rate and equilibrium constants are available (31). In all 121 rate constants were calculated, spanning a range of 16 powers of 10. For each path, a general mechanism was used, more complicated than necessary for some, but sufficient to cover all cases. The lowest energy transition state can easily involve fewer than the maximum number of reaction dimensions in the model. For hydroxide, the standard model involves a water molecule as actual nucleophile, with hydroxide acting as general base, although for unreactive carbonyl compounds the lowest energy path involves the simpler direct hydroxide attack path, which is a subset of the full mechanism. For uncatalyzed attack, the cyclic path shown is the most general, even though for many compounds a simpler two water

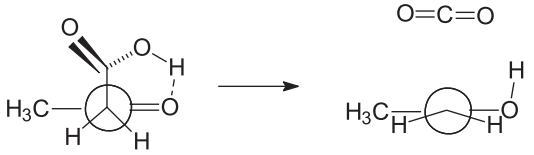
Fig. 4. The general mechanisms for hydroxide-catalyzed, uncatalyzed, and acid-catalyzed addition of water to carbonyl compounds. In particular cases, a simpler subset of these mechanisms may suffice to describe the transition state.

mechanism, leading to the hydronium ion complex of the anionic tetrahedral intermediate (with a water separating the charges) is preferred. For acid-catalyzed attack, the most general mechanism starts with a hydronium ion complexed with the carbonyl oxygen and involves two water molecules, one as nucleophile and one as general base. These three mechanisms are illustrated in Fig. 4. Again for many compounds a simper version, starting with the protonated carbonyl, may be the lowest energy transition state. In each case, the standard procedure allows the molecule to tell us if one of the possible dimensions should have a value of zero or one at the transition state, i.e., if the actual process should be of lower dimensionality than the general mechanism. For 121 reactions, the rms deviation was 1.1 in log k, or 1.4 kcal/mol in $\Delta G^{\ddagger}$. Although most of these reactions could also be described by Multidimensional Marcus Theory, with a constant intrinsic barrier for C—O bond formation, for the most reactive compounds the reactions with hydroxide required that the intrinsic barrier depend on the equilibrium constant (37).



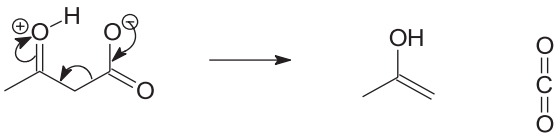
The first application of NBT was to the reaction of water or hydroxide as base removing the α hydrogen from carbonyl compounds to give enolates (38). Again, it was possible to cover the entire range of compounds for which both rate and equilibrium constants were available, and do so with an rms error of 1.08 in log k for monocarbonyl compounds and 0.65 in log k for dicarbonyl compounds.

Cyanohydrin formation, a simple carbon–carbon bond forming reaction, could also be treated by NBT, with an rms error of 1.3 in log k (39).



Thus far, the focus has been on demonstrating that the NBT method could calculate rate constants from equilibrium constants and distortion energies. In the case of decarboxylation

© 2005 NRC Canada



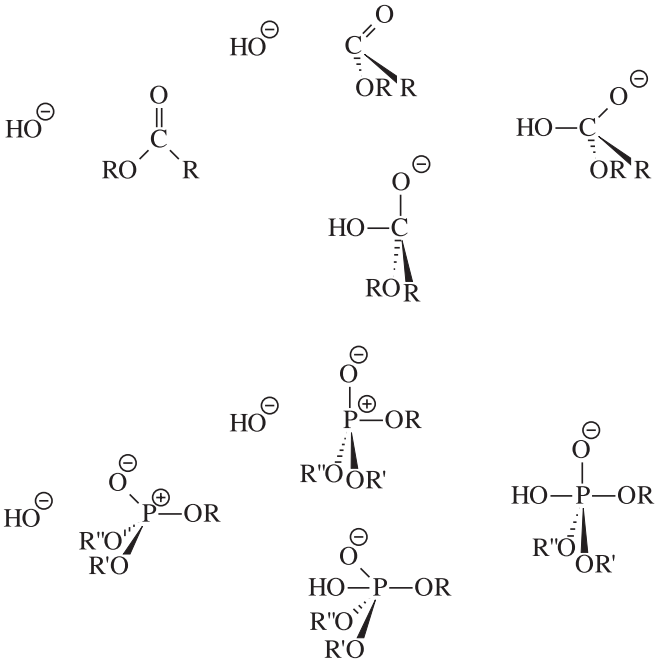
reactions, it could also be used as a mechanistic criterion to show that the textbook mechanism is incorrect (40). For the decarboxylation of acetoacetic acid, the commonly written mechanisms are:

For acetoacetate anion, the mechanism is unambiguous, and the observed rate constant is reproduced by NBT. For neutral acetoacetic acid, there is a problem with the mechanism shown if one considers it in stereoelectronic detail.

For direct proton transfer accompanying decarboxylation, not only is the carboxylic acid in the less stable conformation, with the H syn to the CH_2, but if the C—C bond, which breaks, is to be aligned parallel to the *p* orbitals of the ketone, then the proton must be transferred to the π bond and not to the lone pair. This is all energetically expensive, and if one follows through then the calculated free energy of activation is too high by 15 kcal/mol (40). In fact, the correct free energy of activation is obtained if one starts with the zwitterionic form of the starting material.

Current efforts

Currently, I am looking at the application of NBT to S_N1 reactions. As a part of that effort I have examined the feasibility of calculating the equilibrium constant for conversion of an alcohol of the type ArCRR′OH to the corresponding cation, the process measured by pK_R. pK_R values are now available for a number of such compounds (41–44). What we have found, in work which is nearing completion (45),[4] is that the absolute equilibrium constant can be calculated if the gas-phase thermodynamics are determined by calculations at the G3MP2B3 level (46), and solvation energies are calculated by the IPCM continuum model. These G3MP2B3 calculations are quite demanding of computer resources, and with the facilities available to me become impractical much beyond 100 valence shell electrons. For larger systems only lower level calculations are practical, and these do not lead to satisfactory absolute equilibrium constants. Instead, I found that calculated relative equilibrium constants, using cumyl alcohol and cation as the reference system, are linearly correlated with values derived from experiment. Presumably, there is massive cancellation of errors when one uses such a relative equilibrium constant. In any event, this made it possible to estimate pK_R values for a number of cases where no experimental values were available.



Given equilibrium constants, whether experimental or calculated, it is then possible to calculate the rate constants for trapping of the cation by water, for which numerous values are available from the work of Richard and co-workers (41–43, 47, 48), and McClelland and co-workers (49, 50). The model for these reactions involves three dimensions: (1) formation of the C—O bond; (2) change of the geometry at the reaction center from sp^2 to sp^3; (3) change of the bond lengths in the conjugated system from the alternating bonds of the cation to the aromatic ring arrangement of the alcohol. We considered adding a proton transfer step with a second water molecule acting as a general base, but when this four-dimensional model was tried the proton transfer was only advanced to a very small extent in the transition states and the free energy of activation was essentially the same as for the three-dimensional model. The first paper on this work has now been published (45).

Work on phosphate ester hydrolyses is incomplete, but I am encouraged to think that rates of phosphate ester reactions can also be treated by NBT. Phosphate esters also provide a nice example of the power of NBT as a qualitative way of thinking about how reactions happen. One of the striking things about phosphate esters is how unreactive they are relative to carboxylate esters. Phosphate diesters are anionic at physiological pH, which renders them even less reactive, and this unreactivity has been suggested as the reason why DNA is based on a phosphate sugar backbone. What is less widely recognized is that this unreactivity, even for neutral phosphate triesters, occurs despite the more favorable equilibrium constant for addition of hydroxide to trimethyl phosphate than for addition of hydroxide to methyl acetate. In Marcus language, the intrinsic barrier for addition to trimethyl phosphate must be considerably larger than for addition to methyl acetate to overcome the equilibrium constant effect, which would make phosphate more reactive if the intrinsic barriers were similar. Why then are phosphate esters inherently less reactive than carboxylate esters? This might be an embarrassment for an instructor teaching introductory organic chemistry, except that one can say: "This is easily explained by qualitative application of no barrier theory". Consider the two addition reactions in terms of NBT, as shown in Fig. 5. For the carboxylic ester, distortion of the starting material to the geometry of the product of addition involves the change of three angles from 120° to 109.5°, for a change of 10.5° each. For the corresponding distortion of trimethyl phosphate, three angles change from 109.5° to 120°, for a change of 10.5° each, and three angles change from 109.5° to 90°, for a change of 19.5° each. To the crude approximation that all bending force constants are the same (and in fact the force constants in molecular mechanics vary relatively little, which is why it is possible to use generalized values where no experimental data are available), it is clear that the distortion energy is larger for the phosphate es-

[4] Additional work is in progress.

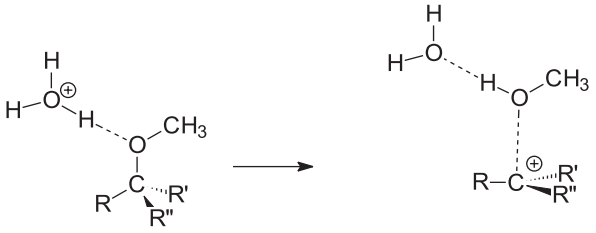
Fig. 5. Comparison of the addition of hydroxide to a carboxylate and a phosphate ester in terms of NBT. Qualitatively, one can see that the total angular distortion is greater in the phosphate case, and thus that the intrinsic barrier for addition to phosphate will be greater.



ter. The same conclusion follows from the analogous analysis of distortions of the adducts. If both distortions are larger for the phosphate ester, then for the same equilibrium constant it is clear that the free energy of activation will be larger for the phosphate ester, thereby explaining the phenomenon in qualitative terms. If the appropriate MO calculations are carried out, the distortions are indeed larger for phosphates, and lead to good values for the rate constants of the various methyl phosphate esters.

Leonardo Leandro[5] is examining the application of NBT to E2 elimination reactions. For simple alkyl halides, this requires a five-dimensional model: (1) C—Br bond breaking; (2) geometry at the carbon that makes or loses the bond to bromine; (3) C—C bond length; (4) proton transfer from C to O; (5) geometry at the carbon that makes or loses the bond to proton. With this model, the free energies of activation for ethyl bromide, isopropyl bromide, *tert*-butyl bromide, 1-phenethyl bromide, and 2-phenethyl bromide have been calculated with an rms deviation of 1.4. A manuscript describing this work is now in preparation.

Ian Greig[6] spent a month in my laboratory, and in this time was able to show that the rate constants for the hydrolysis of acetals and ortho esters could be calculated by NBT.

There were a few complications along the way. The pK_{BH^+} values for the acetals or orthoesters are not directly measurable, nor easily calculated (protonated acetals tend to fall apart in the gas phase), so values had to be estimated by linear free energy relations. Fortunately, the final results are quite insensitive to the pK_{BH^+} values used. To calculate distortion energies for protonated acetals or orthoesters, it was necessary to lock the C—O bond length at the value in the neutrals, again because otherwise this bond would simple stretch and break. With these provisos, it was possible to calculate the free energies of activation for acid-catalyzed hydrolysis for a set of compounds ranging from formaldehyde dimethyl acetal to tetramethyl orthocarbonate. A manuscript describing this work is now in preparation.

Conclusions and prospects

Although the dream is still far from achieved, the prospects are encouraging. No Barrier Theory (NBT) seems to be a general way to calculate rate constants. The programs I am developing, however imperfect and unfriendly they are at present, are already helping the research move forward. The prospects for being able to calculate equilibrium constants in solution from first principle are encouraging, even though this remains a challenging problem. There is abundant motivation to keep going, and the goal is still ardently desired.

Computational investigation of isomeric and conformeric structures of methyl iodoperoxide

Evangelos Drougas and Agnie M. Kosmas

Abstract: Quantum mechanical electronic structure methods are employed to investigate the isomeric and conformeric stuctures of methyl iodoperoxide. Optimized geometries and harmonic vibrational frequencies are calculated at the MP2 level of theory using two types of basis sets, the 6-311G(d,p) for all atoms and the 6-311G(d,p) combined with the LANL2DZ relativistic ECP procedure for iodine. Refinement of the energetics has been accomplished by performing single-point CCSD(T) calculations. Five isomers were determined in total among which iodomethyl hydroperoxide (ICH_2OOH) is found to be the lowest energy structure. Conformational barriers and transition states that connect the isomeric forms have been characterized.

Key words: methyl iodoperoxide, isomers, conformers.

Résumé : Méthodes quantomechaniques de structure electronique sont employées pour l' investigation des structures isomeriques and conformeriques de methyl iodoperoxide. Des géométries optimizées et des fréquances harmoniques vibrationales sont calculées à la méthode théorique MP2 avec l' usage de deux types de basis sets, 6-311G(d,p) et 6-311G(d,p) avec le procédé relativistique ECP de méthode LANL2DZ pour l' iodine. Des énergies totales et rélatives sont calculées avec CCSD(T). Cinq isomers sont determinés en total. Iodomethyl hydroperoxide (ICH_2OOH) est trouvé d' être la structure la plus stable. Des barrières conformeriques et des états de transition qui connectent les formes isomeriques sont characterizés.

Mots clés : methyl iodoperoxide, isomers, conformers.

Introduction

Iodine polyoxides (1) have been implicated in the atmospheric chemistry of iodine (2, 3) in the reactivity of iodine–ozone mixtures (4), in the reactions between iodine-containing compounds in the marine boundary layer (5, 6), and in the mechanism of oxygen–iodine lasers (7). Methyl iodoperoxide is an interesting relevant species suggested to be involved in the mechanism of the self-reaction of CH_3O_2 radicals formed in the photolysis of iodomethane (8) and the reactions of CH_3O radicals with iodine monoxide (9). It is the methyl analog of hydrogen iodoperoxide (HOOI) recently investigated theoretically (10) and similarly involved in the mechanism of HO + IO reaction (11). Other related systems include the isomeric forms of methyl hypoiodide (CH_3OI, CH_3IO, and ICH_2OH), extensively studied in the work of Misra et al. (12) where the novel species CH_2IOH has been computed at the MP2 level of theory that has no counterpart in the chemistry of lighter halomethanes.

In the current work we present the computational investigation of the isomeric structures of CH_3OOI species and the isomerization and conformational barriers. Five isomers, four interisomerization transition state configurations, and two conformational barriers were determined in total. Among the isomeric minimum energy structures, another novel species, the CH_2IOOH isomer, was found, which like the CH_2IOH species mentioned above, presents no analogs in the chemistry of lighter halo-methylperoxides (13, 14).

Methodology

The computations have been carried out using the Gaussian 98 A.9 series of programs (15). The main part of our work has been to select a suitable methodology and the appropriate basis sets to handle iodine-containing compounds. Two series of optimizations were performed at the MP2 level of theory. In the first series, the 6-311G(d,p) basis set, denoted hereafter as basis set A, was employed for all atoms involved in the system including iodine. In the second series of optimizations, all atoms except iodine were handled in the same way, i.e., with the 6-311G(d,p) basis set, but the iodine atom was treated differently using the relativistic effective-core-potential (ECP) LANL2DZ procedure of Wadt and Hay (16), which includes first-order relativistic effects. The LANL2DZ basis set was augmented with *d* and *f* polarization functions (exponents 0.292 and 0.441, respectively) and it is denoted hereafter as basis set B. The necessity of including extra polarization functions for the proper quantum description of I has been recognized on several occasions (10, 17–19). To refine the energetics, a final series of calculations were performed using coupled cluster techniques. Thus, the relative stability order among the various isomers was established by CCSD(T)/B computations carried out at the basis set B optimized geometries. All infor-

mation about the basis sets was obtained from the Extensible computational chemistry environment basis set database, version 1.0 (20).

Full optimizations and harmonic vibrational frequency calculations were performed using both basis sets to identify the computed stationary points as energy minima or transition states. The transition states were characterized by one imaginary frequency and they were further confirmed as first-order saddle points by intrinsic reaction coordinate (IRC) calculations where they have shown to connect the appropriate isomeric species.

Geometry and frequency results

The structural results at both optimization levels are listed in Tables 1 and 2. Table 1 contains the optimized geometrical parameters of the minimum energy structures and the conformeric forms of CH_3OOI, while Table 2 lists the geometries of the isomerization barriers determined. Figure 1 displays the basis set B optimized structures for all species examined and Table 3 lists the harmonic frequency results from both optimization procedures. Table 4 lists the calculated electronic energies including the zero-point-energy (ZPE) corrections and the energy differences with respect to CH_3OOI, as well as the explicit ZPE values at the MP2/B level. Finally, Fig. 2 contains an energy profile of all species involved with respect to the most stable adduct, iodomethyl hydroperoxide (ICH_2OOH), based on the CCSD(T)/B single-point energy calculations.

The geometries obtained by both optimization procedures are, in general, fairly consistent with each other. However, the basis B results do exhibit significant overall tightening of the optimized structures wherever iodine bonding is involved, a tendency that reflects the considerable improve-

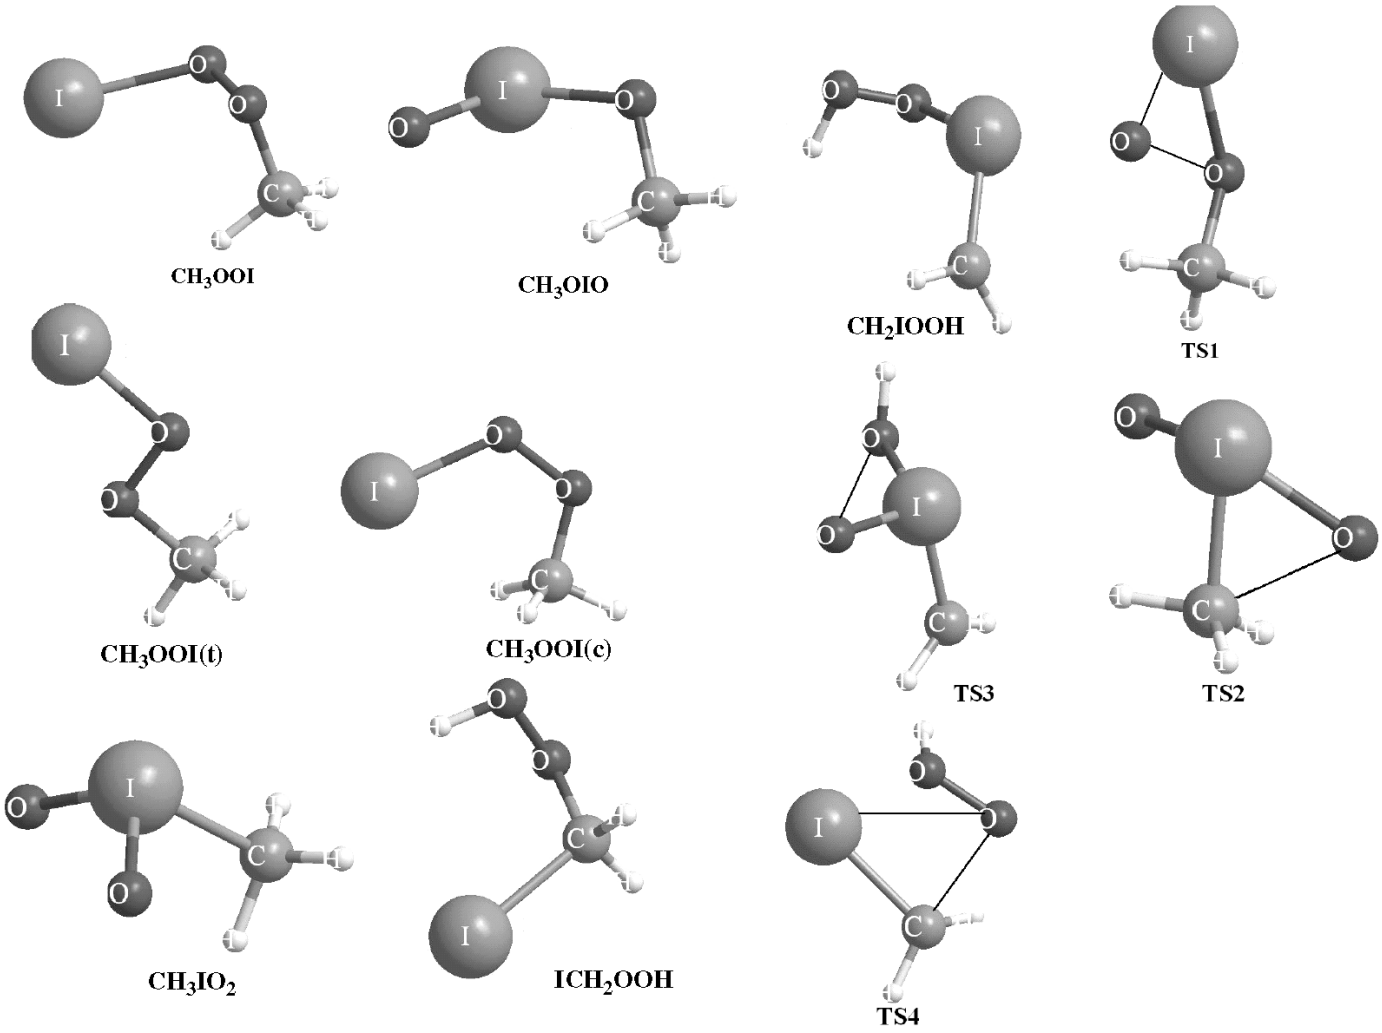
ment achieved by the use of the LANL2DZ approach implicitly including first-order relativistic effects, and the employment of the extra *d* and *f* polarization functions.



Energy minima

Five types of plausible connectivity for the isomeric forms of methyl iodoperoxide were examined: CH_3OOI, CH_3OIO, CH_3IO_2, ICH_2OOH, and CH_2IOOH.

The peroxide form (CH_3OOI) is one of the two nascent association minima that may be formed in the CH_3O + IO reaction. In the equilibrium state it possesses C_1 symmetry and shows a skew configuration with a COOI dihedral angle

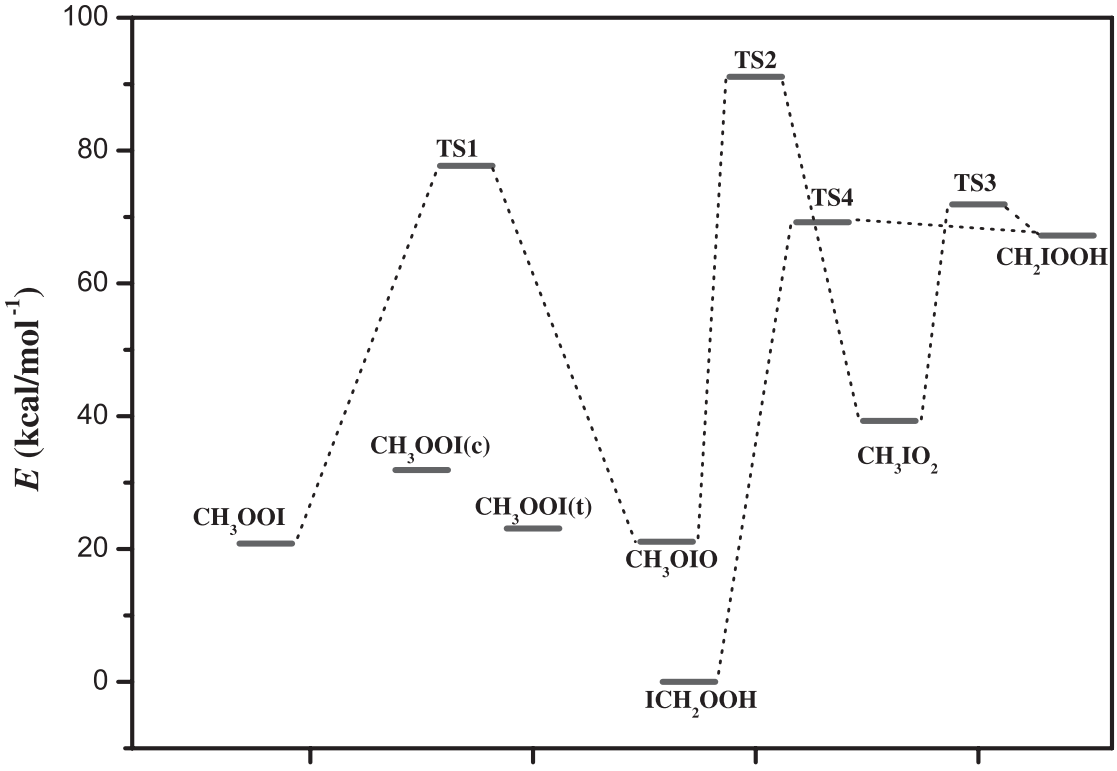
Fig. 1. Optimized structures for CH_3OOI isomers and isomerization and conformational barriers at the MP2/B level of theory.

of 89.8° with basis set A and 89.6° with basis set B. The O-O-I bond angle is calculated to be 109.8° and the O—O and O—I bond distances are 1.438 and 2.005 Å, respectively, with the B basis set. The MP2/6-311G(d,p) calculations (basis A results) agree overall with the MP2/B results, e.g., 110.6° for the O-O-I bond angle and 1.416 and 2.103 Å for the O—O and O—I bond distances. The differences exhibit the tightening observed because of the LANL2DZ approach used for I, which shortens the O—I distance by 0.1 Å, and results in a slight enlargement of the O—O distance by 0.02 Å. The present results are consistent with the corresponding data for HOOI (10) where the LANL2DZ methodology augmented with extra polarization functions has also been used and where the O—O and O—I bond distances were found to be 1.428 and 2.058 Å, respectively.



The other two isomeric forms that preserve the CH_3 group entity are CH_3OIO and CH_3IO_2, resulting from the hypervalent bonding of the I atom. CH_3OIO like CH_3OOI may also be formed as a nascent intermediate in the CH_3O + IO reaction and presents similar characteristics with the HOIO isomer. For example, the bond distances CO—I and OI—O at the MP2/B level were found to be 1.948 and 1.777 Å, respectively, in good agreement with the corresponding distances 1.989 and 1.812 Å in HOIO (10), but significantly shorter than the corresponding MP2/A values (2.038 and 1.831 Å). However, both basis sets' results show the interesting shrinkage that the iodine-terminal oxygen bond distance suffers compared to iodine-bridged oxygen bond length, as in all-bridged, halogen-terminal oxygen bonds, because of the partial double bond character that these bonds exhibit (21). The third isomer CH_3IO_2 with a C_s symmetry, presents the I-O multiple bond characteristics more enhanced because of the double pair of electrons that are shared with the terminal oxygen atoms. Thus, it presents the shortest I—O bond distance (1.807 Å with basis set A and 1.749 Å with basis set B) following the same trend as all X—O distances in the analogous YXO_2, X = Cl, Br structures (13, 14). The nature of the hypervalent halogen-terminal oxygen multiple bonding has been analyzed in great detail by Lee et al. (21) and it has found to present important consequences not only

Fig. 2. Energy stability profile at the CCSD(T)/B level of theory with respect to CH_3OOI.

in the bond distances, but in the relative stability of the isomers as well, as we shall see in the next section.

The final isomeric structures examined are ICH_2OOH and CH_2IOOH, which contain the iodomethyl group and may be considered as possible intermediates in the reaction of the iodomethyl radical (ICH_2) with the hydroperoxy radical (HO_2). Iodomethyl hydroperoxide (ICH_2OOH) is found to be a very stable species, the most stable structure among all isomers of the CH_3OOI family. The compound presents interesting similarities with the $ClCH_2OOH$ species (22), found to be one of the products in the experimental investigation of the $ClCH_2O_2 + HO_2$ reaction (23). The equilibrium geometries using both basis sets are consistent and show the same structural and stability features observed in the $ClCH_2OOH$, CH_3OOCl system, namely the decrease in C—O bond distance and the lower energy of the halomethyl isomer, indicating a stronger interaction of the halogenated methylic group with the -OOH part, compared to the interaction of the plain methylic group with the -OOX fragment. Indeed, we have for example, C—O = 1.418 Å in CH_3OOI and C—O = 1.384 Å in ICH_2OOH (basis set B). The effect results in a very high stability for ICH_2OOH as we shall see in the next section.

The novel species CH_2IOOH presents the same type of C—I bonding as the CH_2IOH compound calculated by Misra et al. (12) at the MP2(full)/6-31G(d) level. In the present work, CH_2IOOH has been also optimized at the MP2 level using both types of basis sets. Both structures result from the hypervalent bonding of iodine with the carbon atom and present significantly shorter C—I bond distances compared

© 2005 NRC Canada

to the C—I single bonds in the iodomethyl C-O type derivatives. Thus, the C—I bond distances in CH_2IOOH and ICH_2OOH were found to be 1.958 and 1.929 Å, and 2.201, and 2.162 Å, with basis sets A and B, respectively. The results are consistent with the CH_2IOH and ICH_2OH cases (12) where the values 1.959 and 2.225 Å have been determined, respectively, at the MP2/6-31G(d) level. The partially double C—I bond is also demonstrated by the slight biradical character that the molecule appears to possess as reflected in the instability of the spin-restricted (RHF) wavefunction compared to the spin-unrestricted (UHF) one (12).

Isomerization and conformation barriers

Four transition state configurations have been determined for the following isomerization processes: CH_3OOI <–> CH_3OIO (TS1), CH_3OIO <–> CH_3IO_2 (TS2), CH_3IO_2 <–> CH_2IOOH (TS3), and ICH_2OOH <–> CH_2IOOH (TS4). The geometries calculated with basis set B are included in Fig. 1 and they are characterized by one imaginary frequency (Table 3) as first-order saddle-points. All transition state structures exhibit triangular geometries, and TS1 is characterized by the I atom migration to the carbon-bonded oxygen atom, while TS2, TS3, and TS4 result from the the I atom migration to the carbon atom and insertion between the oxygen atom and the carbon atom.

The cis and trans conformeric structures of CH_3OOI with respect to C, O, O, and I atoms are also depicted in Fig. 1. They are well-characterized as conformational barriers by the imaginary frequencies, 249i, 235i and 19i, 40i, respectively, with bases A and B and present the same variations in O—O bond distance and O-O-I bond angle with the torsional angle as the CH_3OOBr, CH_3OOCl conformational barriers (13, 14). Thus, the O—O bond varies from its largest value, 1.475 Å, 1.480 Å in the conformers to its shortest, 1.416 Å, 1.438 Å in the minimum, while the C-O-O bond angle decreases from a maximum value (116.2°, 115.9°) in the cis conformer to a minimum value (102.0°, 101.9°) in the trans, through an intermediate value in the minimum energy structure (107.2°, 106.4°) in the two basis sets, respectively. The same type of variation is followed by the I-O-O bond angle.

Electronic energy and relative stability results

Table 4 summarizes the electronic (including zero point energy corrections) and the relative energies at the MP2 level combined with both basis sets and also the CCSD(T)/B//MP2/B single point energy calculations, while Fig. 2 presents a relative energy profile based on the CCSD(T) procedure. All three series of energy calculations predict the iodomethyl hydroperoxide (ICH_2OOH) to be by far the most stable isomer. However, inspection of Table 2 also demonstrates significant discrepancies in the relative stability order among the various isomers, despite the general overall consistency in the structural results. The most striking difference is observed in the relative stability order between the CH_3OOI and the CH_3OIO forms. The MP2/A results locate CH_3OIO 12.2 kcal mol^{-1} higher than CH_3OOI, while the MP2/B calculations reverse this order and predict CH_3OIO to be more stable than CH_3OOI by 5 kcal mol^{-1}. This order is similar to that predicted for the HOOI, HOIO isomers where the latter is calculated to be lower by 13 kcal mol^{-1} using DFT techniques combined with the LANL2DZ procedure (10). The CCSD(T)/B results place both isomers at similar energy levels, locating CH_3OIO higher only by 0.2 kcal mol^{-1}. We attribute the considerable stability of the CH_3OIO structure to the stabilization acquired by the bonding between the highly positively charged I and the electronegative CH_3O partner. The comparison with the analogous Cl, Br species indicates indeed a progressive stabilization of the CH_3OXO form as the electronegativity of the halogen decreases. Thus, the energy difference (8.4 kcal mol^{-1}) of CH_3OClO decreases to 6.3 kcal mol^{-1} for Br and drops to 0.2 kcal mol^{-1} for I.

With the same reasoning, the CH_3IO_2 structure is clearly found to be the highest in energy at all levels of theory since, in this case, the bonding between the positively charged hypervalent iodine and the electropositive moiety CH_3 considerably increases the instability of the structure. Thus, CH_3IO_2 is higher located than CH_3OOI at the MP2 level by 44.2 kcal mol^{-1} with basis set A, 10.9 kcal mol^{-1} with basis set B, and 18.5 kcal mol^{-1} at the CCSD(T)/B level in agreement with the corresponding $XClO_2$, $XBrO_2$ species, whose stability has been found to depend strongly on the electronegativity of the X partner (13, 14, 21, 24–26). The results are consistent with the relative stability order of the HIO_2 isomer, which is also the most unstable in the HOOI family, calculated to be 26.5 kcal mol^{-1} higher compared to the peroxide isomer HOOI.

The two iodomethyl isomers, ICH_2OOH and CH_2IOOH, are found to be the most stable and unstable isomers, respectively. In particular, CH_2IOOH is found to be unstable compared to CH_3OOI by more than 40 kcal mol^{-1} in all three levels of energy calculations. Similar energy order is found also in the CH_3OI family where CH_2IOH is calculated to be 42 kcal mol^{-1} higher than CH_3OI.

The calculated isomerization barriers TS1–TS4 are very high located to allow any interconversion process in all series of energy calculations without notable differences in the results. No differences are observed for the cis and trans energy barriers, which range from 11.8 to 2.2 kcal mol^{-1}, respectively, at the CCSD(T)/B level.

Summary

Five isomeric forms have been optimized for methyl iodoperoxide at the MP2 level of theory using two basis sets, the 6-311G(d,p) for all atoms and the 6-311G(d,p) for all atoms combined with the LANL2DZ method for I augmented with additional *d* and *f* polarization functions. Consistent overall structural and harmonic frequency results are obtained by both methods, but the relativistic corrections and the additional polarization produces tighter O—I and C—I bond lengths.

The refinement of the energetics has been accomplished carrying out CCSD(T) calculations at the MP2/6-311G(d,p) + LANL2DZdf optimized geometries. The more stable isomer is found to be the iodomethyl hydroperoxide. Among the three CH_3- isomeric forms, competing stability is found for the CH_3OOI and CH_3OIO structures. The CH_3IO_2 adduct is the highest in energy among the three. The most unstable

© 2005 NRC Canada

structure is found to be the novel species CH_2IOOH containing hypervalent iodine–carbon bonding that presents no analog in the corresponding families of the lighter halogens.

The interisomerization transition states are very high located to present any probability for such processes to take place and they thus, reflect the stability of each isomeric form with respect to the others. Finally, the cis and trans torsional barriers are also calculated and they are found to be consistent in all three methods of energy calculations.

$InCl_3 \cdot 4H_2O$-promoted green preparation of xanthenedione derivatives in ionic liquids

Xuesen Fan, Xueyuan Hu, Xinying Zhang, and Jianji Wang

Abstract: A green procedure for the synthesis of xanthenedione derivatives (**3**) through $InCl_3 \cdot 4H_2O$-promoted condensation of aldehydes (**1**) and 5,5-dimethyl-1,3-cyclohexanedione (**2**) in ionic liquids is described in this paper. This novel method has such advantages as operational simplicity and environmental benignancy together with enhanced atom utilization. Moreover, the reaction media and the catalyst can be recovered conveniently and reused effectively for at least six times.

Key words: ionic liquid, xanthenedione derivatives, indium trichloride, green synthesis.

Résumé : Dans ce travail, on décrit une méthode verte de synthèse de dérivés **3** de la xanthènedione par le biais d'une condensation, catalysée par le $InCl_3 \cdot 4H_2O$, des aldéhydes (**1**) avec la 5,5-diméthylcyclohexane-1,3-dione (**2**), dans des liquides ioniques. Cette nouvelle méthode allie la simplicité d'opération et un caractère bénin pour l'environnement avec une utilisation accrue des atomes. De plus, le milieu réactionnel ainsi que le catalyseur peuvent être facilement récupérés et réutilisés d'une façon efficace jusqu'à six fois.

Mots clés : liquide ionique, dérivés de la xanthènedione, trichlorure d'indium, synthèse verte.

[Traduit par la Rédaction]

Introduction

Xanthene derivatives have attracted considerable interest in recent years because of their promising activity as positive allosteric modulators of metabotropic (mGlu) receptors (1) and potent nonpeptidic inhibitors of recombinant human calpain I (2). They have been used as rigid carbon skeletons for the construction of new chiral bidentate phosphine ligands with potential applications in catalytic processes (3). In particular, xanthenediones constitute a structural unit in a number of natural products (4) and have been used as versatile synthons because of the inherent reactivity of the inbuilt pyran ring (5). Up to now, several methods have been developed for the preparation of xanthenediones. Among them, the conventional procedures involve acid- or base-catalyzed condensation of appropriate active methylene carbonyl compounds with aldehydes (6). However, these methods are plagued by the limitation of prolonged reaction times, poor yields, and side reactions of aldehydes. Recently, Singh et al. (7*a*) reported a new method for the preparation of xanthenediones through carbon transfer reactions of 1,3-oxazinanes and oxazolidines with carbon nucleophiles. It has also been reported that xanthenedione derivatives could be obtained through condensation of aldehydes and 5,5-dimethyl-1,3-cyclohexanedione in glycol under microwave irradiation (7*b*). Most recently, Jin et al. (7*c*) reported a novel and interesting procedure in which the above condensation process was realized in water in the presence of a dodecylbenzenesulphonic acid catalyst. However, due to their great importance, there still needs to be development of novel methods for the preparation of xanthenediones.

The development of environmentally friendly catalysts and solvents for organic chemistry is an area of considerable importance. From both economical and environmental points of view, the use of nonvolatile solvents is very promising. In the last few years, room-temperature ionic liquids (RTILs), especially those based on 1,3-dialkylimidaxolium cations, have been recognized as a possible environmentally benign alternative to chemically volatile solvents. They are nonvolatile, recyclable, nonexplosive, easy to handle, and thermally robust. In many cases, the products are weakly soluble in the ionic liquid phase so that the products can be easily separated by simple filtration or extraction with ether. Because of the great potential of RTILs as novel reaction media for catalytic processes, much attention has currently been focused on their applications as novel media for various kinds of organic reactions (8). As a continuation of our interest in the area of clean synthesis using ionic liquids as a green recyclable alternative to classical molecular solvents (9), we report here a very simple and green procedure for the preparation of xanthenediones (**3**, Scheme 1) through a $InCl_3 \cdot 4H_2O$-promoted cascade reaction between aldehydes (**1**) and 5,5-

dimethyl-1,3-cyclohexanedione (**2**) in ionic liquid 1-butyl-3-methylimidazolium tetra-fluoroborate ([bmim][BF_4]).

Results and discussion

The mixture of 5,5-dimethyl-1,3-cyclohexanedione (**2**) and 4-chlorobenzaldehyde (**1a**) in [bmim][BF_4] was prepared and stirred at room temperature. After 0.5 h, some solid was observed and TLC analysis gave a positive result for the formation of a new compound together with the remaining aldehyde **1a**. To have a complete conversion, stirring of the mixture was continued for 1 h. To our surprise, another compound was formed as indicated by the TLC analysis. At this stage, the reaction was quenched by the addition of 5 mL H_2O to the mixture. Then, the solid compound was collected and separated through column chromatography. Subsequent analysis in terms of physical and spectral data (IR, ^{1}H NMR, and MS) showed that these two compounds were 9-(4 chlorophenyl)-3,3,6,6-tetramethyl-3,4,5,6,7,9-exahydro-1*H*-xanthene-1,8(2*H*)-dione (**3a**) and bis(5,5-dimethyl-3-hydroxy-1-oxa-2-cyclohexen-2-yl)-4′-chlorophenylmethane (**4a**). Their yields were found to be 5% and 20%, respectively. In addition, it should be noted that the compound formed first in this process was **4a**. The reaction process is shown in Scheme 2.

To obtain **3a** alone, rather than the mixture of **3a** and **4a**, with more increased yield, the reaction mixture of **1a** and **2** was then stirred at different elevated reaction temperatures and (or) over a prolonged reaction time. The results obtained are shown in Table 1. It can be seen that with increased reaction temperature and (or) prolonged reaction time, although **3a** could be obtained in higher yields, the yields of **4a** were also increased to some extent. Thus, it seems impossible to get **3a** alone just by adjusting such factors as temperature and reaction time. Considering the fact that $InCl_3·4H_2O$, as an efficient Lewis acid catalyst, has been successfully used in promoting many kinds of organic reactions (10), especially in several condensation processes, we then added a catalytic amount of $InCl_3·4H_2O$ into the reaction mixture with the hope of obtaining an improved result in terms of both yield and selectivity of **3a**. To our delight, $InCl_3·4H_2O$ showed high efficiency for this process by affording **3a** not only in high yield, but also with excellent selectivity (entries 7–10, Table 1).

Based on the above results, this process was then extended to other structurally varied aldehydes to investigate its scope and generality. The results are listed in Table 2. It

is shown that under the similar fashion, a wide range of aldehydes underwent smooth condensation with 5,5-dimethyl-1,3-cyclohexanedione (**2**) to give xanthenedione derivatives in high yields. One feature of the present procedure is that aldehydes both with electron-withdrawing groups and with electron-donating groups afforded the corresponding product in good yields, and para- and meta-substituted substrates reacted almost equally well. However, aldehydes bearing an ortho group turned out to be reluctant to undergo the condensation reaction probably because of steric hindrance. Thus, longer reaction time is required for these substrates to get the corresponding products in high yields (entries 5 and 8, Table 2).

Our attention was then directed toward the possibility of recycling the reaction media since the recovery and reuse of catalyst and solvent are highly preferable for a greener process. At completion, water was added into the reaction mixture, and the solid was collected by filtration to give the product. The filtrate containing [bmim][BF_4] and the dissolved In(III) was concentrated under reduced pressure to recover the ionic liquid and the catalyst. Then, their reusability was investigated by using **1a** and **2** again as the model substrates. It has been observed that even in the sixth round, the corresponding product could still be obtained with fairly good yield by using the ionic liquid and the catalyst recovered from the fifth (Table 3, entry 6).

For the sake of comparison with [bmim][BF_4], several conventional organic solvents including methanol, ethanol, toluene, and ethyl acetate, were also used in this catalytic process with **1c** (*p*-nitrobenzaldehyde) and **2** as model substrates. The results are summarized in Table 4.

Table 4. Reaction of **1c** and **2** in different solvents.[a]

				Isolated yield (%)	
Entry	Solvent	Reaction temp. (°C)	Reaction time (h)	**3c**	**4c**
1	Ethanol	Reflux	5	29	31
2	Methanol	Reflux	5	24	23
3	Toluene	80	5	25	27
4	Ethyl acetate	Reflux	5	59	Traces
5	[bmim][BF_4]	80	5	86	0

[a]Reaction conditions: 1 mL solvent, 0.5 mmol **1c**, and 1 mmol **2**.

It has been shown that of the five solvents used, [bmim][BF_4] gave the best result in terms of both yield and selectivity. In fact, only when [bmim][BF_4] was used as the reaction medium, can **3c** be obtained with a high yield (86%, Table 4, entry 5). On the other hand, when toluene, methanol, ethanol, or ethyl acetate was used, not only was the reaction incomplete after being stirred at reflux or at 80 °C for 5 h, but a mixture of **3c** and **4c** was also obtained with much lower yields (Table 4, entries 1–4). Actually, **3c** is in the solid state when the reaction is complete and therefore can be obtained through simple filtration because of its poor solubility in [bmim][BF_4]. On the contrary, when toluene, methanol, ethanol, or ethyl acetate was used, the product was dissolved in the solution. Therefore, with toluene or ethyl acetate as solvent, the product has to be obtained through tedious experimental operations, such as washing with water, drying over anhydrous sodium sulfate, concentrating under vacuum, and subsequent separation on column chromatography. When ethanol or methanol was used, the separation procedure turned out to be even more complicated. First, the solvent had to be removed and the residue was redissolved in another solvent immiscible with water. Then the solution was washed with water, dried, concentrated, and finally separated on column. Considering all of these differences, it may be safe to say that using [bmim][BF_4] in place of conventional organic solvents as the reaction medium actually results in a much enhanced reactivity, and avoids the disadvantages such as tedious operational procedure and potential experimental pollution in relation to the organic solvents.

It has been reported that another green solvent, water, has also been used as reaction medium for this procedure (11). However, due to the poor solubility of substrates in water, a

phase-transfer catalyst (quaternary ammonium salt) and a strong acid catalyst (such as TsOH) have to be used to facilitate the cyclodehydration reaction. Even so, xanthenedione derivatives **3** (Scheme 2) can only be obtained from para-substituted aromatic aldehydes through a much longer reaction period. In the case of ortho- and meta-substituted aromatic aldehydes, non-cyclodehydrated products **4** (Scheme 2) instead of **3** were obtained. In contrast, the substrates are well-dissolved in the [bmim][BF_4]/In^{3+} system, no phase-transfer catalyst is needed, and the reaction time is much shorter in our situation. Moreover, aromatic aldehydes with ortho- or meta-substituents can react smoothly with **2** to produce xanthenedione derivates **3** in good yields (Table 2, entries 5 and 10). In another case, microwave irradiation technique has also been successfully used in the condensation of aldehydes with 5,5-dimethyl-1,3-cyclohexanedione to give xanthenedione (7*b*). However, its potential use for larger scale preparation may be rather limited compared to the method presented in this paper.

In conclusion, we have found a novel procedure for the preparation of xanthenedione derivatives. The main advantages of this procedure include high yields, simple experimental procedure, and ease of recovering and reusing of the catalyst and the reaction media. Therefore, the present method is expected to serve as an alternative process for the preparation of xanthenedione derivatives.

Experimental

Melting points were measured by a Kofler micromelting point apparatus and the results were uncorrected. IR spectra were recorded on a Bruker Vector 22 spectrometer in KBr with absorption in cm^{-1}. ^1H NMR spectra were determined on a Bruker AC 400 spectrometer as $CDCl_3$ solutions. Chemical shifts (δ) are expressed in ppm downfield from the internal standard tetramethylsilane, and coupling constants (*J*) are given in Hz. Elemental analyses were performed on an EA-1110 instrument.

The ionic liquid [bmim][BF_4] was prepared and purified according to literature procedure (12). Other reagents were of reagent grade and were used without further purification.

General procedure for the preparation of xanthenedione derivatives

Aldehyde (**1**, 1 mmol), 5,5-dimethyl-1,3-cyclohexanedione (**2**, 2 mmol), and $InCl_3 \cdot 4H_2O$ (0.1 mmol) were added to a 10 mL round-bottomed flask containing 1 mL [bmim][BF_4]. Then the mixture was stirred at 80 °C for a certain period of time (shown in Table 2) to complete the reaction (monitored by TLC). At completion, water was added into the reaction mixture and the solid was collected by suction and rinsed with cold ethanol to give the product **3**. All the products were fully characterized by IR, ^1H NMR, and elemental analysis. The aqueous solution of ionic liquid together with the catalyst was concentrated under reduced pressure to recover the ionic liquid and catalyst for subsequent use.

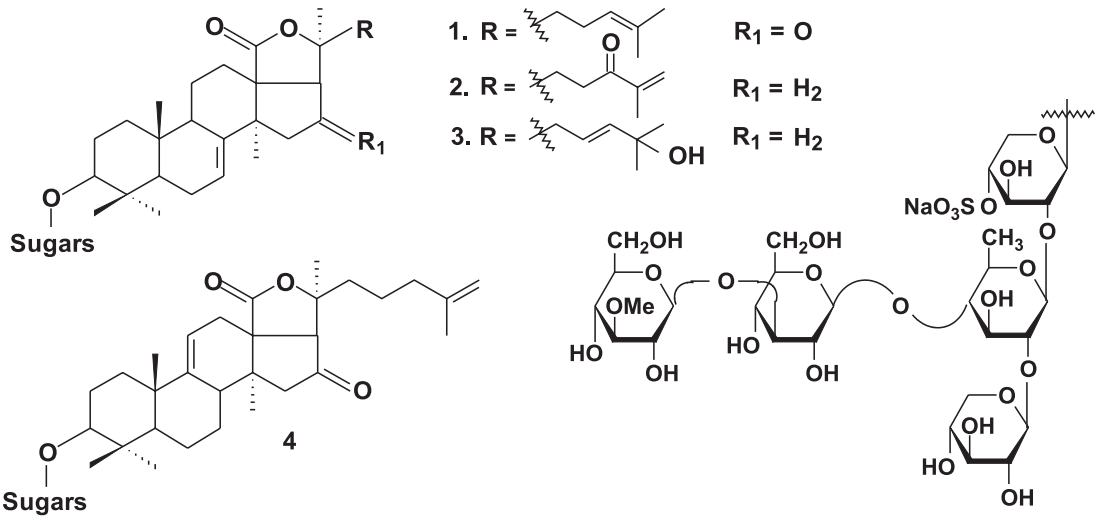
Glycosides from the sea cucumber *Cucumaria frondosa*. III. Structure of frondosides A_2-1, A_2-2, A_2-3, and A_2-6, four new minor monosulfated triterpene glycosides

Alexandra S. Silchenko, Sergey A. Avilov, Alexandr S. Antonov, Anatoly I. Kalinovsky, Pavel S. Dmitrenok, Vladimir I. Kalinin, Valentin A. Stonik, Carl Woodward, and Peter D. Collin

Abstract: Frondosides A_2-1 (**1**), A_2-2 (**2**), A_2-3 (**3**), and A_2-6 (**4**) are new monosulfated holostane pentaosides isolated from the sea cucumber *Cucumaria frondosa*. Their structures have been elucidated on the basis of spectral data (2D NMR and MS). Frondoside A_2-2 (**2**) contains an α,β-unsaturated ketone fragment in the side chain of the aglycon, unique for triterpene glycosides of sea cucumbers.



Key words: Cucumaria frondosa, sea cucumbers, frondosides, triterpene glycosides.

Résumé : Les frondosides A_2-1 (**1**), A_2-2 (**2**), A_2-3 (**3**) et A_2-6 (**4**) sont des pentaosides monosulfatés d'holostane isolés du concombre de mer *Cucumaria frondosa*. On a élucidé leurs structures sur la base de données spectrales (RMN 2D et SM). La chaîne latérale de l'aglycone du frondoside A_2-2 (**2**) comporte un fragment de cétone α,β-insaturée qui est unique pour les glycosides triterpéniques des concombres de mer.

Mots clés : Cucumaria frondosa, concombres de mer, frondosides, glycosides triterpéniques.

[Traduit par la Rédaction]

The sea cucumber *Cucumaria frondosa* Gunnerus (Cucumariidae, Dendrochirotida) is a widespread benthic animal common in the North Atlantic and Western Arctic seas that is harvested commercially. Although previous studies of this sea cucumber have yielded a series of new triterpene glycosides, *C. frondosa* remains poorly investigated because of the extreme complexity of its glycoside fraction (1–6). Previously, we isolated and reported a new minor monosulfated tetraoside frondoside A_1 along with the known frondoside A from the specimens of *C. frondosa* collected in the Barents

Sea (3). We also elucidated the structure of a novel and more polar trisulfated non-holostane (having no lactone cycle in the aglycon) pentaoside from this animal (4).

In continuation of our investigations on *C. frondosa* triterpene glycosides, we report herein results of the study on monosulfated pentaosides having a glucose residue as the third monosaccharide unit in the carbohydrate moiety in contrast to the major component of the glycoside fraction, frondoside A, having xylose as the corresponding residue.

Sea cucumbers were collected in the Gulf of Maine, Penobscot Bay, Maine, USA. Column chromatography on polychrom-1 (powdered Teflon) of the ethanolic extract of *C. frondosa* gave a mixture of glycosides that was separated by column chromatography on silica gel, affording a crude mixture of monosulfated pentaosides. Separation of the fraction by HPLC yielded four individual glycosides, frondosides A_2-1 (**1**), A_2-2 (**2**), A_2-3 (**3**), and A_2-6 (**4**) belonging to the cucumarioside A_2 group (7).

Signals of the carbohydrate chains in the NMR spectra of isolated glycosides (**1–4**) were coincident in all of them indicating the identity of the sugar parts of these compounds (Table 1). The presence of five characteristic doublets (J = 6.7–7.8 Hz) in the ^{1}H NMR spectra of **1–4** and corresponding signals of anomeric carbons in the ^{13}C NMR were indicative of a pentasaccharide chain and the β-configuration of glycosidic bonds (8). The characteristic proton resonances of methyl groups at δ 1.67 ppm (d, J = 5.6 Hz) and δ 3.89 ppm (s) suggested the presence of quinovose and 3-*O*-methyl glucose residues in the oligosaccharide chain. The comparison of carbon resonances belonging to the carbohydrate chains

[a]Recorded at 125.77 MHz in C_5D_5N.
[b]Recorded at 500 MHz in C_5D_5N.

of **1**–**4** (Table 1) showed complete coincidence with those in the spectrum of monosulfated pentaoside cucumarioside A_2-2 isolated from *Cucumaria japonica* (7). The structure of the carbohydrate chains of **1**–**4** was corroborated by HMBC and NOESY correlations (Table 1). Specifically, interglycosidic bonds were confirmed by NOESY cross peaks between H-1 of the first xylose residue and H-3 of the aglycon; between H-2 of quinovose and H-1 of the terminal xylose residue; between H-4 of quinovose and H-1 of the glucose residue; and between H-3 of the glucose residue and H-1 of the terminal 3-*O*-methyl-glucose residue.

The MALDI TOF MS of glycoside **1** exhibited pseudomolecular ion peaks at *m/z* 1341 $[M_{Na} + Na]^+$, 1342 $[M_{Na} + Na + H]^+$ along with the peak at *m/z* 1239 $[M_{Na} - SO_3Na + Na + H]^+$ in the positive ion mode, and pseudomolecular ion peaks at *m/z* 1295 $[M_{Na} - Na]^-$, 1296 $[M_{Na} - Na + H]^-$, and 1163 $[M_{Na} - Na - Xyl + H]^-$, and a peak at *m/z* 1119 $[M_{Na} - Na - 3\text{-O-Me-Glc} + H]^-$ (because of the loss of terminal monosaccharide residues) in the negative ion mode. The HR MALDI TOF MS (positive ion mode) showed the pseudomolecular ion $[M_{Na} + Na]^+$ at *m/z* 1341.5098, calculated for $C_{59}H_{91}O_{29}SNa_2$ as 1341.5160, which allowed us to determine the molecular formula of frondoside A_2-1 (**1**) as $C_{59}H_{91}O_{29}SNa$.

The aglycon moiety of glycoside **1** was found by extensive NMR spectroscopy (^1H and ^{13}C NMR, HMQC, HMBC, ^1H–^1H COSY, and NOESY) (Table 2) to be very similar with that of cucumarioside A_2-2 isolated from *C. japonica* (7). It is distinguished only by the presence of a 24(25)-double bond instead of a 25(26) one (7). The presence of a 7(8)-double bond was confirmed by signals at 121.82 (C-7) and 143.92 (C-8) ppm in the ^{13}C NMR spectrum and 5.80 ppm (m, H-7) in the ^1H NMR spectrum (7). The presence of a 24(25)-double bond was confirmed by the signals at 123.92 ppm (C-24) and 132.01 ppm (C-25) in the ^{13}C NMR spectrum and 5.14 ppm (m, H-24) in the ^1H NMR spectrum. Signals of the terminal methyl groups of the aglycon side chain at 17.50 ppm (C-26) and 25.53 ppm (C-27) in the ^{13}C NMR and 1.63 (s, H-26) and 1.66 (s, H-27) in the ^1H NMR spectra also indicated the position of a double

bond at C-24 (9). The signal at 214.32 ppm (C-16) in the ^{13}C NMR spectrum was characteristic for a C-16 keto group (7). The structure of the aglycon moiety was also confirmed by HMBC and NOESY data. In particular, the cross-peak between H-24 and H-27 corresponding to the 24(25)-double bond was observed in NOESY. Hence, frondoside A_2-1 (**1**) is 3-*O*-{3-*O*-methyl-β-D-glucopyranosyl-(1→3)-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-16-keto-3β-hydroxy-holosta-7,24-diene.

The MALDI TOF MS of glycoside **2** exhibited a pseudomolecular ion at *m/z* 1341 $[M_{Na} + Na]^+$ and 1239 $[M_{Na} - SO_3Na + Na + H]^+$ in the positive ion mode and a pseudomolecular ion at *m/z* 1295 $[M_{Na} - Na]^-$ and fragmentation peaks at *m/z* 1163 $[M_{Na} - Na - Xyl + H]^-$ and 1119 $[M_{Na} - Na - 3\text{-O-Me-Glc} + H]^-$ (because of the loss of terminal monosaccharide residues) in the negative ion mode. The HR MALDI TOF MS (positive ion mode) showed the pseudomolecular ion $[M_{Na} + Na]^+$ at *m/z* 1341.5148 ($C_{59}H_{91}O_{29}SNa_2$, calcd. 1341.5160), which allowed us to determine the molecular formula of frondoside A_2-2 (**2**) as $C_{59}H_{91}O_{29}SNa$.

The aglycon moiety of glycoside **2** was found by extensive NMR spectroscopy (^1H and ^{13}C NMR, HMBC, HMQC, ^1H–^1H COSY, and NOESY) (Table 3) to be very similar to that of cucumarioside A_7-3 isolated from *C. japonica*, having no oxygen functional group at C-16 and distinguished only by signals of the side chain (10). The signals of C-25 and C-26 at 144.50 and 124.80 ppm in the ^{13}C NMR spectrum and at 5.75 (s, H-26) and 6.06 (s, H-26′) ppm in the ^1H NMR spectrum indicated the presence of a terminal double bond. The signal at 200.32 ppm in the ^{13}C NMR spectrum showed the presence of a ketone group in the side chain. The position of a ketone group at C-24 was indicated by the cross-peaks between C-24 and protons H-26 and H-27 in the HMBC spectrum. The presence of an α,β-unsaturated ketone fragment in the side chain was also confirmed by the UV spectrum of glycoside **2** (λ_{max} = 249.6 nm, ε = 2127). Hence, frondoside A_2-2 (**2**) is 3-*O*-{3-*O*-methyl-β-D-glucopyranosyl-(1→3)-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β-hydroxy-holosta-7,25-diene-24-one.

The MALDI TOF MS of glycoside **3** exhibited a pseudomolecular ion at *m/z* 1343 $[M_{Na} + Na]^+$ and the ion peak at *m/z* 1241 $[M_{Na} - SO_3Na + Na + H]^+$ in the positive ion mode, and a pseudomolecular ion at *m/z* 1297 $[M_{Na} - Na]^-$ and fragmentation peaks at 1165 $[M_{Na} - Na - Xyl + H]^-$ and 1121 $[M_{Na} - Na - 3\text{-O-Me-Glc} + H]^-$ (because of the

loss of terminal monosaccharide residues) in the negative ion mode. In the HR MALDI TOF MS (positive ion mode), the pseudomolecular ion $[M_{Na} + Na]^+$ at *m/z* 1343.5387 ($C_{59}H_{93}O_{29}SNa_2$, calcd. 1343.5317) was observed, allowing us to determine the molecular formula of frondoside A_2-3 (**3**) as $C_{59}H_{93}O_{29}SNa$.

The aglycon moiety of glycoside **3** was found by extensive NMR spectroscopy (^1H and ^{13}C NMR, HMBC, HMQC, ^1H–^1H COSY, and NOESY) (Table 4) also to be very similar with that of cucumarioside A_7-3 isolated from *C. japonica*, having no oxygen functional group at C-16 and distinguished only by signals of the side chain (10). However, signals of the side chain in the ^{13}C NMR spectrum were very similar with those of the known cucumarioside G_4 from *Eupentacta fraudatrix* (11) and eximisoside A from *Psolus eximius* (12) showing the presence of a 23(24)-double bond and a hydroxy group at C-25. Indeed, the position of the 23(24)-double bond was confirmed by cross-peaks between H-23 and C-25; H-24 and C-25; H_3-26 and H_3-27 of the terminal methyl groups, and C-24 in HMBC. The signal of C-25 was shifted downfield to 69.60 ppm in the ^{13}C NMR spectrum, indicating the presence of a hydroxy group in this position. Hence, frondoside A_2-3 (**3**) is 3-*O*-{3-*O*-methyl-β-D-glucopyranosyl-(1→3)-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β,25-dihydroxy-holosta-7,23-diene.

The MALDI TOF MS of glycoside **4** exhibited a pseudomolecular ion at *m/z* 1341 $[M_{Na} + Na]^+$ and a characteristic ion peak at *m/z* 1239 $[M_{Na} - SO_3Na + Na + H]^+$ in the positive ion mode, and a pseudomolecular ion at *m/z* 1295 $[M_{Na} - Na]^-$ along with fragmentation ion peaks at *m/z* 1163 $[M_{Na} - Na - Xyl + H]^-$ and 1119 $[M_{Na} - Na - 3\text{-}O\text{-}Me\text{-}Glc + H]^-$ (because of the loss of terminal monosaccharide residues) in the negative ion mode. In the HR MALDI TOF MS (positive ion mode), the pseudomolecular ion $[M_{Na} + Na]^+$ at *m/z* 1341.5160 was observed (calculated for $C_{59}H_{91}O_{29}SNa_2$ 1341.5145), which allowed us to determine the molecular formula of frondoside A_2-6 (**4**) as $C_{59}H_{91}O_{29}SNa$.

The aglycon moiety of glycoside **4** was found by extensive NMR spectroscopy (^1H and ^{13}C NMR, HMBC, HMQC, ^1H–^1H COSY, and NOESY) (Table 5) to be holotoxinogenin, already known from holotoxins A_1 and B_1 from *Stichopus* (= *Apostichopus*) *japonicus* (13) and widely distributed in sea cucumber glycosides (14), having 9(11)-, and 25(26)-double bonds and a 16-ketone group. Indeed, the signals at 151.17 (C-9) and 110.93 (C-11) ppm in the ^{13}C NMR spectrum and 5.33 (m, H-11) ppm in the ^1H NMR spectrum indi-

cated the presence of a 9(11)-double bond. The signals at 145.46 (C-25) and 110.39 (C-26) ppm in the ^{13}C NMR spectrum and at δ 4.79 (br s, H-26) ppm in the ^{1}H NMR spectrum showed the presence of a terminal 25(26)-double bond. The signal at 213.12 (C-16) ppm in the ^{13}C NMR spectrum was indicative of a keto-group at C-16. Hence, frondoside A_2-6 (**4**) is 3-*O*-{3-*O*-methyl-β-D-glucopyranosyl-(1→3)-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β-hydroxy-holosta-9,25-diene-16-one.

The glycosides **1**–**4** are new ones, the glycosides **1**–**3** have new aglycones, while **4** represents a new combination of a previously known carbohydrate chain and aglycone. The simultaneous presence of a 24-ketone group and the 25(26)-double bond as an α,β-unsaturated ketone fragment in the side chain of the aglycon of frondoside A_2-2 (**2**) is unique for sea cucumber glycosides.

Experimental section

General experimental procedures

All melting points were determined with a Kofler–Thermogenerate apparatus. Optical rotation was measured on a PerkinElmer 343 polarimeter. NMR spectra were recorded on a AMX Bruker 500 spectrometer at 500.12/125.67 MHz ($^{1}H/^{13}C$) and a Bruker DPX 300 spectrometer at 300/75 MHz ($^{1}H/^{13}C$) in C_5D_5N with TMS as an internal reference (δ = 0). The MALDI TOF MS (positive and negative ion modes) were recorded using a Bruker apparatus, model BIFLEX III, with impulse extraction of ions, on an α-cyano-4-hydroxycinnamic acid matrix. UV spectrum was recorded on a CECIL, CE 7250, 7000 series spectrophotometer in water solution. HPLC was performed using an Agilent 1100 chromatograph equipped with a differential refractometer on Diasphere-110 C_{18} and Chiradex 5 mμ columns.

Animal material

The sea cucumber *C. frondosa* (the family Cucumariidae; the order Dendrochirotida) was collected in Penobscot Bay (Gulf of Maine, Maine, USA) in September 2000 by commercial dragging. Taxonomic identification was carried out by Dr. E.N. Gudimova. A voucher specimen CF-09–2000 is on deposit in the collection of the Murmansk Marine Biological Institute of the Kolsky Scientific Center of the Russian Academy of Sciences, Murmansk, Russia.

Extraction and isolation of the fraction of glycosides belonging to the cucumarioside A_2 group

Body walls of 40 specimens of the sea cucumbers were separated, cut very small, and lyophylized to dryness and extracted twice with hot ethanol. The dry weight of the residue was 943 g. The combined extracts were concentrated to dryness and chromatographed on a polychrom-1 column (powdered Teflon, Biolar, Latvia) previously loaded in EtOH and washed with distilled water to give inorganic salts and polar impurities at elution with H_2O and the fraction containing glycosides at elution with 50% acetone. This fraction was twice chromatographed on silica gel columns eluting with $CHCl_3$–EtOH–H_2O (100:100:17 and 100:75:10) solvent systems to obtain a homogenous on TLC crude subfraction of glycosides belonging to the cucumarioside A_2 group (500 mg).

Isolation of glycosides 1–4

The subfraction was subsequently submitted for HPLC on a Diasphere-110 C_{18} (4 × 250) column (MeOH, water, $Na_2HPO_4 \cdot 12H_2O$ (540 mg in 100 mL of water) (72:27:3)) and a Chiradex 5 mμ (4 × 250) column (MeOH, water, $Na_2HPO_4 \cdot 12H_2O$ (540 mg in 100 mL of water) (60:37:3)) followed by desalting on a Teflon column as described above to give 2.4 mg of frondoside A_2-1 (**1**), $[\alpha]_D^{20}$ –70 (*c* 0.1, pyridine), mp 218–220 °C (see Tables 1 and 2 for ^{13}C and ^1H NMR data). MALDI TOF MS (positive ion mode) *m/z* (rel. intensity): 1341 ($C_{59}H_{91}O_{29}SNa_2$ $[M_{Na} + Na]^+$, 0.7), 1342 ($C_{59}H_{92}O_{29}SNa_2$ $[M_{Na} + Na + H]^+$, 1), 1239 ($[M_{Na} – SO_3Na + Na + H]^+$, 0.3). MALDI TOF MS (negative ion mode) *m/z* (rel. intensity): 1295 ($C_{59}H_{91}O_{29}S$ $[M_{Na} – Na]^–$, 1), 1296 ($C_{59}H_{92}O_{29}S$ $[M_{Na} – Na + H]^–$, 0.6), 1163 ($[M_{Na} – Na – Xyl + H]^–$, 0.03), 1119 ($[M_{Na} – Na – 3\text{-O-Me-Glc} + H]^–$, 0.03); 2.4 mg of frondoside A_2-2 (**2**), $[\alpha]_D^{20}$ –36 (*c* 0.1, pyridine), mp 198–200 °C (see Tables 1 and 3 for ^{13}C and ^1H NMR data). UV (λ_{max}, nm): 249.6, ε = 2127. MALDI TOF MS (positive ion mode) *m/z* (rel. intensity): 1341 ($C_{59}H_{91}O_{29}SNa_2$ $[M_{Na} + Na]^+$, 1) 1239 ($[M_{Na} – SO_3Na + Na + H]^+$, 0.3). MALDI TOF MS (negative ion mode) *m/z* (rel. intensity): 1295 ($C_{59}H_{91}O_{29}S$ $[M_{Na} – Na]^–$, 1), 1163 ($[M_{Na} – Na – Xyl + H]^–$, 0.04), 1119 ($[M_{Na} – Na – 3\text{-O-Me-Glc} + H]^–$, 0.04); 1.8 mg of frondoside A_2-3 (**3**), $[\alpha]_D^{20}$ –15 (*c* 0.1, pyridine), mp 213–215 °C (see Tables 1 and 4 for ^{13}C and ^1H NMR data). MALDI TOF MS (positive ion mode) *m/z* (rel. intensity): 1343 ($C_{59}H_{93}O_{29}SNa_2$ $[M_{Na} + Na]^+$, 1) 1241 ($[M_{Na} – SO_3Na + Na + H]^+$, 0.3), 1167 ($[M_{Na} – 3\text{-O-Me-Glc} + Na + H]^+$, 0.2). MALDI TOF MS (negative ion mode) *m/z* (rel. intensity): 1297 ($C_{59}H_{93}O_{29}S$ $[M_{Na} – Na]^–$, 1), 1165 ($[M_{Na} – Na – Xyl + H]^–$, 0.2), 1121 ($[M_{Na} – Na – 3\text{-O-Me-Glc} + H]^–$, 0.3); 3.1 mg of frondoside A_2-6 (**4**), $[\alpha]_D^{20}$ –51 (*c* 0.1, pyridine), mp 220–222 °C (see Tables 1 and 5 for ^{13}C and ^1H NMR data). Synthesis of novel optically pure β-lactams

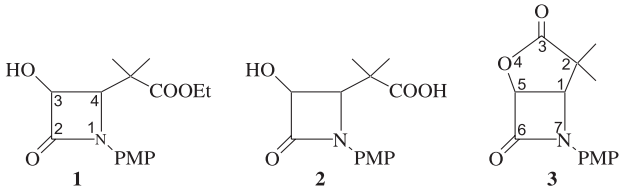
Yan Yang, Fengyun Wang, Fernande D. Rochon, and Margaret M. Kayser

Abstract: Several new β-lactams were synthesized as racemates via a Staudinger reaction. The corresponding optically pure compounds were obtained in subsequent biotransformation steps either through baker's yeast reduction or lipase resolution. Their absolute configurations were established. The X-ray crystal structures of three new substituted β-lactams are reported here. These compounds represent key building blocks for a variety of medicinally important molecules, including inhibitors of aspartyl proteases and Taxol® analogues.

Key words: optically pure β-lactams, lipase resolutions, baker's yeast reductions, Staudinger reaction.

Résumé : Faisant appel à la réaction de Staudinger, on a réalisé la synthèse de plusieurs nouvelles β-lactames racémiques. On a obtenu les composés correspondants optiquement purs par le biais de biotransformations subséquentes impliquant une réduction par la levure de boulanger ou par résolution avec une lipase. On en a déterminé les configurations absolues. On a déterminé les structures cristallines de trois β-lactames substituées par diffraction des rayons X. Ces composés sont des unités pouvant servir à la synthèse de plusieurs molécules médicinalement importantes, y compris des inhibiteurs de protéases de l'aspartyle et des analogues du Taxol®.



Mots clés : β-lactames optiquement pures, résolutions à la lipase, réductions avec de la levure de boulanger, réaction de Staudinger.

[Traduit par la Rédaction]

Introduction

The β-lactam skeleton represents a core structure of numerous natural and synthetic antibiotics (1). The 3-hydroxy-substituted β-lactams are convenient precursors of β-amino-α-hydroxy esters that constitute key fragments of many biologically important natural products such as aminosugars, α-hydroxy-β-amino acids, glycosphingolipids, peptidic enzyme inhibitors, and alkaloids (2). Furthermore, 3-hydroxy-β-lactams are used for the construction of analogues of the anticancer drug Taxol® (3). It is not surprising, therefore, that the development of enantioselective syntheses of such β-lactams has been pursued by numerous laboratories around the world.

The extensive structure–activity relationship (SAR) studies have shown that the phenylisoserine C-13 side chain of paclitaxel (Taxol®, Fig. 1), essential for anticancer activity, tolerates a variety of modifications (4), and even small changes significantly influence the bioactive properties of the drug (3, 5). The therapeutic potential of paclitaxel is limited by its high hydrophobicity and development of resistance. Search for analogues with better water solubility, easier to administer, fewer side effects, and active on multidrug-resistant (MDR) cells is an on-going process (6). We have been interested in developing the synthesis of optically pure C-13 side chains in which 3′-phenyl is replaced with bulky, polar groups. The preparation of side chains in the form of 3-hydroxy-β-lactams is particularly appealing since it is in this form that the prospective side chains are generally coupled with baccatin III. Here, we report the syntheses and characterizations of several isomers of 4-(1-ethoxycarbonyl-1-methylethyl)-3-hydroxy-β-lactam (**1**), the 4-(1-carboxy-1-methylethyl)-3-hydroxy-β-lactam (**2**), and the corresponding lactone (**3**).

A number of methods for the preparation of β-lactams, such as ketene–imine cycloaddition (1*a*, 7), metalloester enolate–imine condensation (8), isocyanate–alkene cycloaddition (9), and alkyne–nitrone cycloaddition (10), have been developed over the years. Among these, the most widely used is the Staudinger reaction, in which ketene–imine addition leads to a β-lactam ring system. Optically pure β-lactams prepared via asymmetric synthesis employed either a combination of chiral imine and achiral ketenes, achiral imines and chiral ketenes (1*a*, 11), or a direct cyclization of ketene–imine in the presence of a chiral catalyst (12). Only a few studies resorted to biocatalytic approaches such as lipase-catalyzed resolution (13) or baker's yeast reduction (14). Since our preliminary goal was to syn-

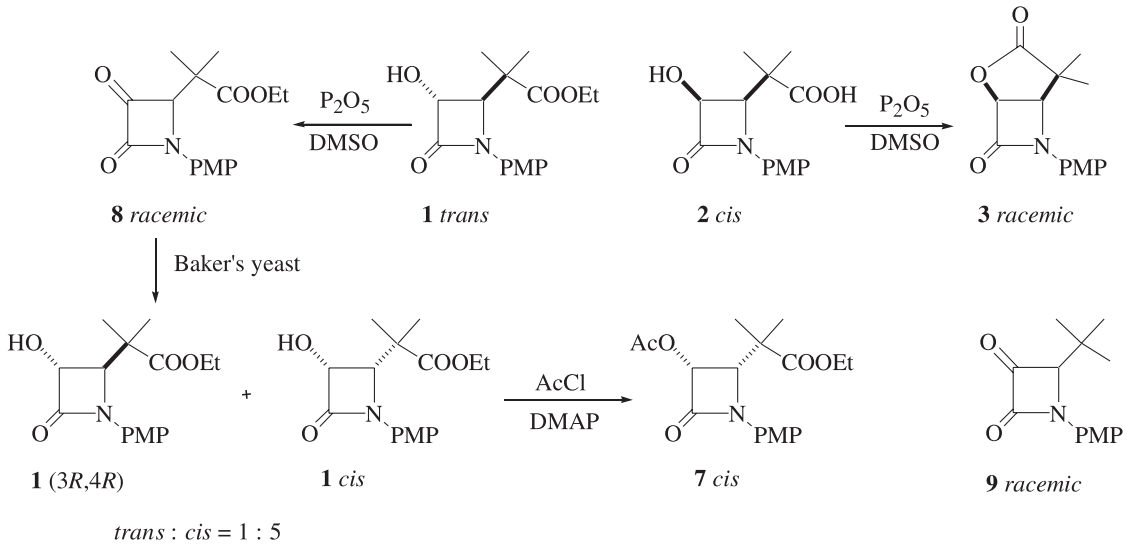
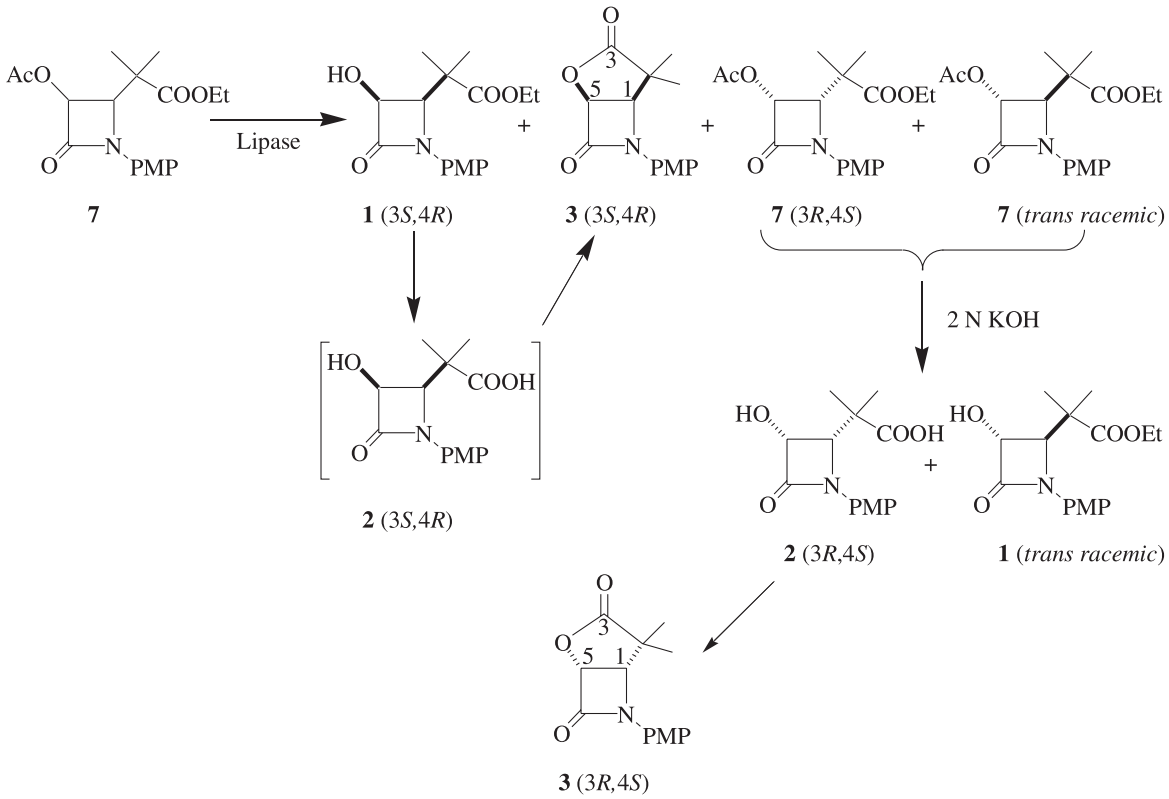
thesize and characterize all the diastereomers and enantiomers, we decided to prepare the racemic β-lactams through Staudinger cyclization (Scheme 1) and to obtain enantiopure β-lactams in the subsequent biotransformation steps.

Results and discussion



Condensation of 3,3-diethoxy-2,2-dimethylpropionic acid ethyl ester (**4**) (15) with *p*-anisidine gave 3-(4-methoxyphenylimino)-2,2-dimethylpropionic acid ethyl ester (**5**), which was used in the following step without purification. Cycloaddition of **5** with the in-situ-generated acetoxyacetyl chloride in the presence of anhydrous triethylamine gave acetyl β-lactam **7** (PMP = *p*-methoxyphenyl) in 53% yield after two steps. The β-lactam product **7** consisted of trans and cis diastereomers in the ratio of 2:1 based on the ^{1}H NMR spectrum of the product mixture. Hydrolysis of **7** (2 N KOH) gave two compounds as shown in Scheme 1. It was interesting to note that while the *trans*-acetyl β-lactam was selectively hydrolyzed to the corresponding *trans*-3-hydroxy β-lactam (**1**) as expected, its cis diastereomer was hydrolyzed at both acetyl and acetate groups, yielding *cis*-3-hydroxy β-lactam (**2**). Apparently in the cis isomer, the hindered ester function undergoes hydrolysis aided by the strategically located 3-OH group. The two compounds were easily separated during the extraction process (see Experimental). This turned out to be very useful in the characterization of **7**-*trans* and **7**-*cis*, since the original mixture from the Staudinger reaction was inseparable by chromatography. The pure sample of **7**-*trans* was prepared by acylation of **1**-*trans* (Scheme 1), while **7**-*cis* was obtained from baker's yeast reduction of the α-keto-β-lactam (**8**, Scheme 2). Their stereochemistry was assigned on the basis of coupling constants for the *cis*- and t*rans*-β-lactams (16). Oxidation of compound **1** with DMSO/phosphorus pentoxide provided the α-keto-β-lactam (**8**). Under the same conditions, **2**-*cis* was dehydrated to a racemic mixture of fused lactone–lactams **3** as shown in Scheme 2.

In an initial attempt to obtain optically pure 3-hydroxy-β-lactams (**1**), we performed baker's yeast reduction of the racemic 3-oxo-β-lactam (**8**). This strategy was successful for the *tert*-butyl analogue **9**, where it yielded easily separable 3-hydroxy diastereomers 3*R*,4*S*-*cis* and 3*R*,4*R*-*trans* (14). Unfortunately, in the case of ketone **8**, the reduction product consisted of an inseparable mixture of essentially racemic **1**-*cis* and an optically pure **1**-*trans* isomer, tentatively identified as 3*R*,4*R* (Scheme 2). The ratio of cis to trans (5:1) was measured from the ^{1}H NMR spectrum of the product mixture.



Since a racemic mixture of *cis*-3-acetoxy-4-phenyl-β-lactams was reported to be enantioselectively hydrolyzed by Amano lipase (13*a*), we decided to test the ability of this enzyme to resolve the mixture of lactams **7**. It turned out that the mixture of the isomers of **7** could be resolved efficiently, particularly since the **7**-*trans* is not a suitable substrate for the lipase PS "Amano" (Scheme 3).

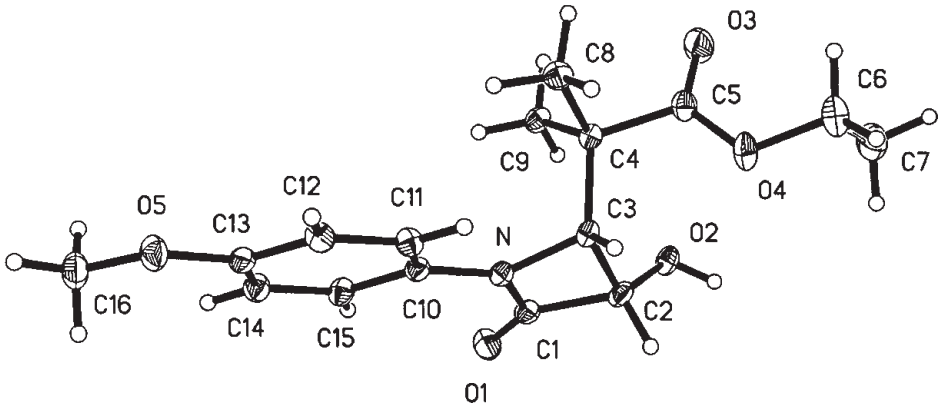
Scheme 2.

Scheme 3.

Of the four products formed in the course of the lipase resolution, compounds **1** and **3** were easily separated by chromatography and the absolute configuration of **1** (3*S*,4*R*) was established with certainty by X-ray diffraction methods. The whole diffraction sphere was measured with Cu-Kα radiation. The absolute structure parameter (Flack) determined using the option TWIN/BASF 0.5 indicated the right configuration (Table 1).

The molecular structure of **1** (3*S*,4*R*) is shown in Fig. 2. The internal angles in the four-membered ring vary between 85.4(1)° and 95.1(2)°. The N—C and O—C bond distances close to the carbonyl groups are shorter than the others. For example, the distances N—C1 = 1.360(3) Å and O4—C5 = 1.335(3) Å, while N—C3 = 1.488(3) Å and O4—C6 = 1.461(3) Å.



The lactone–lactam **3** (1*R*,5*S*), apparently resulting from hydrolysis of the ethoxy carbonyl group followed by cyclization, was isolated and its absolute configuration was initially established by chiral-phase HPLC analysis. This was possible because the four isomers of **7** are clearly re-

solved on the chiral-phase HPLC. Furthermore, in the course of the HPLC-monitored lipase resolution we were able to observe that only *one* of the cis enantiomers was hydrolyzed; its antipode and the two trans diastereomers were unaffected. Additional evidence for the configuration of **3** (1*R*,5*S*) was obtained when a mixture of **1** (3*S*,4*R*) and **3** (1*R*,5*S*) under extended treatment with an excess of the lipase was transformed entirely into the lactone **3** (1*R*,5*S*). Finally, we were able to obtain a suitable crystal, and the proposed absolute configuration of **3** (1*R*,5*S*) was confirmed by X-ray diffraction. Again, the absolute structure parameter (Flack) confirmed the correct enantiomer (Table 1). The compound crystallized with two independent molecules in the unit cell. The two molecules are very similar as shown by identical equivalent bond distances and angles. The molecular structure of one of the two molecules is shown in Fig. 3.

The conformations of the two molecules are slightly different, especially in the region of the five-membered ring. For example, the torsion angles in the first molecule N1-C3-C4-C5 = –91.9(2)°, N1-C3-C4-C7 = 27.5(3)°, and N1-C3-C4-C6 = 153.8(2)°, while the corresponding angles in the second molecule are N2-C17-C19-C18 = –82.4(2)°, N2-C17-C19-C20 = 38.7(3)°, and N2-C17-C19-C27 = 165.3(2)°. Again, the N—C and O—C bond distances close to the carbonyl bonds are shorter than the others.

The remaining products from the lipase resolution, **7** (3*R*,4*S*) and **7**-*trans* (racemic), were hydrolyzed with 2 N

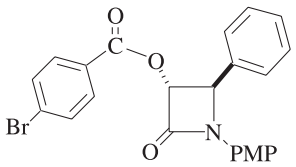
KOH to give **2** (3*R*,4*S*) and **1**-*trans* (racemic), which were separated during the work-up. The subsequent treatment of **2** (3*R*,4*S*) with DMSO/phosphorous pentoxide gave lactone **3** (1*S*,5*R*), which is clearly distinguishable from its antipode on the chiral-phase HPLC and has opposite specific rotation (Scheme 3).



The attempts to resolve racemic **1**-*trans* using lipases PS "Amano", PS-C "Amano" II, AY "Amano", and AK "Amano" were not successful. To characterize fully and to establish unambiguously the absolute configurations of the trans products, we decided to separate and identify the **1**-*trans* enantiomer from the baker's yeast reduction (Scheme 2). We were unable to separate the overlapping cis and trans isomers, however, on treatment with 2 N KOH, only the racemic **1**-*cis* was hydrolysed to the corresponding acid and the enantiopure **1**-*trans* was separated during the work-up. Unfortunately, neither **1**-*trans* nor its *p*-bromobenzoyl derivative **10** could produce crystals suitable for X-ray crystallographic analysis. Thus, the (3*R*,4*R*) absolute configuration was tentatively assigned by analogy to other related *trans*-β-lactams obtained from yeast-catalyzed reductions: the phenyl-substituted **11** (3*R*,4*R*) (17) whose crystal structure was determined and is shown in Fig. 4 (Table 1), and *tert*-butyl-substituted lactam **12** (3*R*,4*R*) reported earlier (14).

In summary, we have synthesized and fully characterized several new β-lactams. The absolute configurations were deduced from chiral-phase HPLC and confirmed through X-ray crystal structure determination. We are currently developing and optimizing more efficient and better-yielding

protocols for the preparations of these and several other related compounds.

Experimental

The X-ray crystallographic data for compounds **1** and **3** were collected using a Bruker Platform diffractometer, equipped with a Bruker SMART 2K charged-coupled device (CCD) area detector using the program SMART and normal focus sealed tube source graphite-monochromated Cu-Kα radiation. The crystal-to-detector distance was 4.908 cm, and the data collection was carried out in 512 pixel × 512 pixel mode, utilizing 4 pixel × 4 pixel binning. The initial unit cell parameters were determined by a least-squares fit of the angular setting of strong reflections, collected by a 9.0° scan in 30 frames over four different parts of the reciprocal space (120 frames total). One complete sphere of data was collected, to better than 0.8\Å resolution. Upon completion of the data collection, the first 101 frames were recollected to improve the decay correction analysis. The crystal structure of the bromo compound (**11**) was determined on a Siemens P4 instrument using graphite-monochromated Mo-Kα radiation and the XSCANS program (18). The intensity data were corrected for the effects of Lorentz and polarization. An absorption correction based on the equations of the crystal faces was applied for crystal **11**. The coordinates of the first set of atoms (Br for **11**) were determined by direct methods and the positions of all the other atoms were found by the standard Fourier methods. The structures were refined on F_0^2 using all reflections. The H atoms were fixed in idealized positions using a riding model with displacement parameters = $1.2U_{eq}$ (1.5 for methyl groups) of the parent atom. The SHELXTL system (19) was used for all calculations and drawings. The experimental details and crystal data are listed in Table 1. The absolute structure of the three compounds was established with certainty. For crystals **1** and **3**, the data were measured with Cu-Kα radiation on the entire sphere. Crystal **11** was measured with Mo-Kα, but it contains a heavy atom, which makes it very easy to determine the absolute configuration. The absolute Flack parameter was obtained using the option TWIN/BASF 0.5 in the refinement program. The crystal of compound **3** contains two independent molecules in the unit cell.

All chemicals were purchased from commercial suppliers and were used as received except where noted. Dry methylene chloride was freshly prepared by distillation from calcium hydride. Triethylamine was freshly distilled from sodium hydride. Commercially available DMSO was treated with molecular sieves (4 Å). Thin layer chromatography was performed on Sigma-Aldrich 0.2 mm aluminum-backed silica gel plates with UV indicator and was visualized under a UV lamp. Flash chromatography was performed on 230–400 mesh silica gel (Silicycle). Chiral-phase HPLC analyses were performed on a Chiracel OD-H column (4.6 mm × 150 mm) using hexane:iso-propanol (90:10) as the mobile phase. A UV detector set at 254 nm was used to monitor the reactions. Capillary gas chromatography was performed on a DB-1301 (15 m × 0.53 mm × 1.0 μm) column from J & W Scientific. Lipases were generous gifts from Amano Enzyme USA Co., Ltd. Commercial baker's yeast was obtained from a local grocery chain.

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Specific rotation ($[\alpha]_D$) was measured on a PerkinElmer 241 polarimeter at room temperature with energy source Na 589 and is given in $10^{-1\circ}$ cm^2 g^{-1}. IR spectra were recorded as thin films on a Mattson Satellite FT IR spectrometer. ^{1}H NMR and ^{13}C NMR spectra were recorded in $CDCl_3$ solution, except where otherwise specified, at room temperature either on a Bruker AC-250 FT-NMR spectrometer or a Varian Unity 400 FT-NMR spectrometer; chemical shifts (δ) are reported in ppm using Me_4Si as the internal standard. *J* values are expressed in Hz. The high-resolution mass spectra were obtained on a Kratos MS50TC mass spectrometer.

(±)-3-Acetoxy-4-(1-ethoxycarbonyl-1-methylethyl)-1-(4-methoxyphenyl)-2-azetidinone (7)

A mixture containing *p*-anisidine (15.4 g, 0.125 mol), ethyl 3,3-diethoxy-2,2-dimethylpropanoate (**4**) (30.0 g, 0.137 mol), and *p*-toluenesulfonic acid monohydrate (0.100 g, 0.526 mmol) was heated at reflux for 5 h. The reaction mixture was cooled and evaporated under vacuum to remove the resulting ethanol. The imine **5** thus obtained was used in the next step without purification. Phosphorus oxychloride (28.0 g, 0.182 mol) in dry methylene chloride (100 mL) was added dropwise to a solution of imine **5**, acetoxyacetic acid **6** (23.4 g, 0.198 mol), and triethylamine (69.9 mL, 0.502 mol) in methylene chloride (500 mL) maintained at 5 °C. The stirred reaction was warmed to room temperature and monitored by TLC until complete disappearance of the imine (48 h). The reaction was quenched with 2 N HCl (400 mL) solution, and extracted with methylene chloride (3 × 400 mL). The combined organic layers were washed sequentially with a saturated solution of $NaHCO_3$ and brine, dried over magnesium sulfate, and concentrated under reduced pressure. The residue was purified by flash chromatography on silica gel to give compound **7** as a mixture of diastereomers (trans:cis = 2:1) with a yield of 23.0 g (53%) over two steps from *p*-anisidine. **7**-*trans*: IR ($CHCl_3$, cm^{-1}): 2981, 2940, 1765, 1731, 1513, 1372, 1221, 1149. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.17 (3H, t, *J* = 7.2, CH_2CH_3), 1.21 (3H, s, CCH_3), 1.29 (3H, s, CCH_3), 2.17 (3H, s, $COCH_3$), 3.78 (3H, s, OCH_3), 4.03 (2H, q, *J* = 7.0, CH_2CH_3), 4.49 (1H, d, *J* = 1.8, NC*H*), 5.74 (1H, d, *J* = 1.8, OC*H*), 6.86 (2H, d, *J* = 9.1, Ar*H*), 7.21 (2H, d, *J* = 8.9, Ar*H*). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.9 (CH_2CH_3), 20.0 (CCH_3), 20.7

HR-MS calcd. for $C_{18}H_{23}NO_6$ (M^+): 349.1525; found: 349.1511.

3-Hydroxy-1-(4-methoxyphenyl)-2-azetidinone (1)

A solution of **7** (mixture) (5.0 g, 0.014 mol) in THF (100 mL) was slowly treated with 2 N KOH (50 mL) at 0 °C. The reaction was stirred at 0 °C until TLC indicated complete conversion (2 h). The solution was extracted with ethyl acetate (3 × 80 mL). The combined organic layers were washed with brine, dried over magnesium sulfate, filtered, and evaporated to dryness to afford racemic **1**-*trans* (2.8 g) as a colorless solid. The water layer was acidified with 2 N HCl to pH 2 ~ 3, and then extracted with ethyl acetate. The organic layers were combined and washed with brine, dried over magnesium sulfate, filtered, and evaporated to dryness to afford racemic **2**-*cis* (1.2 g) as a colorless solid. (±)-*trans*-4-(1-Ethoxycarbonyl-1-methylethyl)-3-hydroxy-1-(4-methoxyphenyl)-2-azetidinone (**1**): mp 78 to 79 °C. IR ($CHCl_3$, cm^{-1}): 3387, 2939, 1730, 1513, 1249, 1150. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.16 (3H, s, CCH_3), 1.18 (3H, t, *J* = 7.2, CH_2CH_3), 1.27 (3H, s, CCH_3), 3.78 (3H, s, OCH_3), 4.05 (2H, q, *J* = 7.2, CH_2), 4.38 (1H, d, *J* = 1.7, NCH), 4.73 (1H, d, *J* = 1.7, HOCH), 6.84 (2H, d, *J* = 9.0, ArH), 7.16 (2H, d, *J* = 8.9, ArH). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.0 (CH_2CH_3), 20.4 (CCH_3), 22.8 (CCH_3), 43.6 (CCH_3), 55.5 (OCH_3), 61.2 (OCH_2), 68.6 (NCH), 76.7 (OHCH), 114.4, 123.0, 129.0, 157.7, 167.2 (*C*O), 175.6 (*C*O). HR-MS calcd. for $C_{16}H_{21}NO_5$ (M^+): 307.1420; found: 307.1428. (±)-*cis*-4-(1-Carboxy-1-methylethyl)-3-hydroxy-1-(4-methoxyphenyl)-2-azetidinone (**2**): mp 168 to 169 °C. IR ($CHCl_3$, cm^{-1}): 3373, 2979, 2839, 1724, 1513, 1248, 1170. ^{1}H NMR (400 MHz, d_6-acetone) δ: 1.32 (3H, s, CCH_3), 1.35 (3H, s, CCH_3), 3.79 (3H, s, OCH_3), 4.74 (1H, d, *J* = 5.3, NCH), 5.16 (1H, d, *J* = 5.3, OHCH), 6.92 (2H, d, *J* = 9.0), 7.40 (2H, d, *J* = 9.0). ^{13}C NMR (100 MHz, d_6-acetone) δ: 22.1 (CCH_3), 26.8 (CCH_3), 45.6 (CCH_3), 56.5 (OCH_3), 65.7 (NCH), 77.7 (OCH), 115.7, 122.7, 132.8, 158.4, 168.8 (*C*O), 178.6 (*C*O). HR-MS calcd. for $C_{14}H_{17}NO_5$ (M^+): 279.1107; found: 279.1113.

(±)-4-(1-Ethoxycarbonyl-1-methylethyl)-1-(4-methoxyphenyl)-3-oxo-2-azetidinone (8)

Phosphorus pentoxide (6.0 g, 0.042 mol) was added to dry DMSO (90 mL) and stirred at room temperature for 30 min. Racemic **1**-*trans* (7.5 g, 0.025 mol) in DMSO (45 mL) was added over an 1 h period. The resulting mixture was stirred at room temperature until TLC showed complete conversion (48 h). The reaction was quenched with a cold saturated aqueous solution of sodium bicarbonate (100 mL) and extracted with ethyl acetate (3 × 100 mL). The combined organic phases were washed with water (5 × 150 mL), followed by brine and dried over sodium sulfate. The solvent was removed under vacuum. The residue was purified by flash chromatography on silica gel and crystallized from ethyl acetate – hexane to give 5.3 g (71%) of **8** as yellow crystals; mp 64 to 65 °C. IR ($CHCl_3$, cm^{-1}): 2981, 1815, 1764, 1513, 1253, 1149. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.18 (3H, t, *J* = 7.0, CH_2CH_3), 1.27 (3H, s, CCH_3), 1.37 (3H, s, CCH_3), 3.82 (3H, s, OCH_3), 4.07 (2H, q, *J* = 7.2, CH_2), 4.95 (1H, s, NCH), 6.92 (2H, d, *J* = 9.0), 7.38 (2H, d, *J* = 9.2). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.8 (CH_2CH_3), 21.0 (CCH_3), 23.6 (CCH_3), 44.9 (CCH_3), 55.5 (OCH_3), 61.7 (OCH_2), 76.7 (NCH), 114.6, 121.5, 128.9, 158.4, 161.0 (*C*O), 174.4 (*C*O), 193.3 (*C*O). HR-MS calcd. for $C_{16}H_{19}NO_5$ (M^+): 305.1263; found: 305.1274.

(±)-*cis*-7-(4-Methoxyphenyl)-2,2-dimethyl-4-oxa-7-aza-bicyclo[3.2.0]heptane-3,6-dione (3)

Phosphorus pentoxide 1.8 g (0.013 mmol) was added to dry DMSO (35 mL) and stirred at room temperature for 30 min. Racemic **2**-*cis* (2.4 g, 0.0090 mol) in DMSO (15 mL) was added over 30 min. The resulting mixture was stirred at room temperature until TLC indicated complete conversion (48 h). The reaction was quenched with a cold saturated aqueous solution of sodium bicarbonate (40 mL) and extracted with ethyl acetate (3 × 40 mL). The combined organic phases were washed with water (5 × 80 mL) and brine, dried over sodium sulfate, and concentrated under reduced pressure. Crystallization of the crude residue from ethyl acetate – hexane afforded 1.9 g (85%) of **3** as a colorless crystalline solid; mp 169–169.5 °C. IR ($CHCl_3$, cm^{-1}): 2976, 2936, 2838, 1781, 1513, 1385, 1247, 1149. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.28 (3H, s, CCH_3), 1.39 (3H, s, CCH_3), 3.80 (3H, s, OCH_3), 4.49 (1H, d, *J* = 4.6, NCH), 5.44 (1H, d, *J* = 4.6, OCH), 6.90 (2H, d, *J* = 8.9), 7.31 (2H, d, *J* = 8.9). ^{13}C NMR (62.9 MHz, $CDCl_3$) δ: 20.4 (CCH_3), 25.1 (CCH_3), 42.8 (CCH_3), 55.5 (OCH_3), 61.2 (NCH), 79.8 (OCH), 114.6, 118.7, 130.3, 157.1, 160.7 (*C*O), 180.1 (*C*O). HR-MS calcd. for $C_{14}H_{15}NO_4$ (M^+): 261.1001; found: 261.1006.

Lipase-catalyzed hydrolysis of 7

The reaction was carried out in a 0.2 mol L^{-1} potassium phosphate buffer (pH 7.5, 50 mL) containing a mixture of cis and trans diastereomers of **7** (2.1 g, 0.006 mol) and lipase PS "Amano" (2.1 g). The reaction mixture was stirred at room temperature. The kinetic resolution of **7**-*cis* was monitored by chiral HPLC (the **7**-*trans* diastereomers were not hydrolysed by the lipase). After 26 h, 50% conversion of **7**-*cis* was observed. The mixture was extracted with ethyl acetate, and the combined ethyl acetate layers were washed with brine and dried over magnesium sulfate. Removal of the solvent afforded a mixture of unreacted **7** (3*R*,4*S*) and racemic **7**-*trans* as well as the compounds **1** (3S,4*R*) and **3** (1*R*,5*S*). Separation on a silica gel column gave unreacted material **7** (1.2 g), optically pure 3-hydroxy-β-lactam (**1**) (3S,4*R*) as a colorless crystal (0.080 g), and lactone **3** (1*R*,5*S*) as a colorless crystal (0.18 g). The recovered mixture **7** (7.5 g, 0.022 mol) was hydrolyzed with 2 N KOH, as described above, to yield optically pure **2** (3*R*,4*S*) as a white solid (1.1 g) and racemic **7**-*trans* as a colorless solid (5.0 g).

1 (3*S*,4*R*): mp 139–139.8 °C. $[\alpha]_D$ = –170 (*c* 1.00 in CH_2Cl_2). **3** (1*R*, 5*S*): mp 140 to 141 °C. $[\alpha]_D$ = –110 (*c* 1.00 in CH_2Cl_2). **3** (1*S*, 5*R*) prepared from **2** (3*R*,4*S*) in 91% yield: mp 139 to 140 °C. $[\alpha]_D$ = +108 (*c* 1.00 in CH_2Cl_2). **2** (3*R*, 4*S*): mp 158 to 159 °C. $[\alpha]_D$ = +13.4 (*c* 1.00 in CH_3COCH_3).

Procedure for baker's yeast reduction of 8

A suspension of baker's yeast (10 g) and dextrose (40 g) in sterilized water (500 mL) was stirred at 30 °C in a fermentor with aeration for 15 min. Compound **8** (1.00 g) was added and stirring continued for 26 h. The reaction was monitored by chiral HPLC. After complete conversion, the reaction mixture was saturated with salt and centrifuged at 3000× *g* for 10 min to remove yeast cells. The supernatant was extracted with ethyl acetate. The cell pellet was extracted three times with ethyl acetate. The combined organic layers were washed with brine, dried over magnesium sulfate, and filtered. Vacuum evaporation afforded the crude mixture (0.82 g) of optically pure **1**-*trans*, and mixtures of **1**-*cis* and **3**. The crude reaction product (0.29 g) was hydrolyzed with 2 N KOH as described before. Optically pure **1**-*trans* (3*R*,4*R*) was isolated as a colorless oil (0.029 g); **1**-*cis* and **3** were hydrolyzed to the racemic acid **2** and were isolated from the aqueous layer as a colorless solid (0.17 g). **1** (3*R*,4*R*): $[\alpha]_D$ = +84.9 (*c* 1.65 in CH_2Cl_2). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.17 (3H, s, CCH_3), 1.18 (3H, t, *J* = 7.10, CH_2CH_3), 1.28 (3H, s, CCH_3), 3.78 (3H, s, OCH_3), 4.05 (2H, q, *J* = 7.05, CH_2CH_3), 4.35 (H, d, *J* = 1.70, NC*H*), 4.75 (1H, d, *J* = 1.6, OHC*H*), 6.82 (2H, d, *J* = 9.2, Ar*H*), 7.14 (2H, d, *J* = 9.2).[2]

A quantitative structure–activity relationship study for α-substituted acetamido-*N*-benzylacetamide derivatives — A novel anticonvulsant drug class

Albert Y. Jin, Harold Kohn, Cécile Béguin, Shridhar V. Andurkar, James P. Stables, and Donald F. Weaver

Abstract: A library of 35 benzylacetamide derivatives was evaluated for anticonvulsant activity as reflected in the ED_{50} (mg/kg) required to suppress seizure activity in the maximal electroshock seizure (MES) test. Using the method of partial least-squares regression in conjunction with cross-validation, the influence of 31 topological, electronic, physicochemical, and structural properties on anticonvulsant activity was investigated. A QSAR model of the $\log ED_{50}$ in the MES test was established ($R^2_{adj} = 0.77$) as a function of the following seven properties: the Wiener index on distance code (Wmean), the mean information index on atomic composition (rIac), the partial charge at the C-terminal carbonyl carbon (qCC), the sum of partial charges in the α substituent (qαtotal), the number of hydrogen bond donors and acceptors in the α substituent (Hdα and Haα), and the calculated value of the squared *n*-octanol/water partition coefficient. Based on this model, two new amido ketone compounds — (*R*,*S*)-2-acetamido-5-phenyl-3-pentanone and *cis*/*trans*-(*R*,*S*)-2-acetamido-5-phenyl-4-penten-3-one — were synthesized and shown to have significant anticonvulsant activity in the MES test.

Key words: QSAR, anticonvulsant, benzylacetamide, functionalized amino acid, amido ketones.

Résumé : On a évalué 35 dérivés du benzylacétamide pour leur activité anticonvulsivante telle que reflétée dans les ED_{50} (mg/kg) requises pour supprimer l'activité de crise dans le test de crise maximale d'électrochoc (MES). Faisant appel à la méthode de régression partielle des moindres carrés en conjonction avec contre validation, on a évalué l'influence de 31 propriétés topologiques, électroniques, physicochimiques et structurales sur l'activité anticonvulsivante. Dans le test MES, on a pu établir un modèle QSAR du $\log ED_{50}$ ($R^2_{adj} = 0{,}77$) en fonction des sept propriétés suivantes: l'indice de Wiener sur la distance code (Wmean), l'indice d'information moyenne sur la composition atomique (rIac), la charge partielle au niveau de l'atome de carbone du carbonyle C-terminal (qCC), la somme des charges partielles dans le substituant α (qαtotal), le nombre de donneurs et d'accepteurs de liaison hydrogène dans le substituant α (Hdα et Haα) et la valeur calculée du coefficient de partition *n*-octanol/eau mise au carré. Sur la base de ce modèle, on a synthétisé deux nouvelles amidocétones, les (*R*,*S*)-2-acétamido-5-phénylpentan-3-one et les *cis*/*trans*-(*R*,*S*)-2-acétamido-5-phénylpent-4-én-3-one, qui ont montré des activités anticonvulsivantes élevées dans le test de MES.

Mots clés : QSAR, anticonvulsivante, benzylacétamide, acide aminé fonctionnalisé, amidocétones.

[Traduit par la Rédaction]

Introduction

The search for safer and more potent anticonvulsant medications remains a drug design priority (1, 2). Quantitative structure–activity relationship (QSAR) studies have received widespread attention as a powerful drug design tool for the optimization of promising drug candidates (3–11). In this study, QSAR methodology was used to elucidate the structural correlates of anticonvulsant activity in a series of α-substituted acetamido-*N*-benzylacetamide compounds shown by Kohn et al. (12) to be a promising novel anticonvulsant class.

The putative benzylacetamide anticonvulsant pharmacophore or "bioactive face", shown in Fig. 1, consists of: a vicinal diamine linkage; an oxygen atom on the ethylene chain bridging two amino groups; and an aromatic ring one carbon removed from an amide group. Exploitation of this anticonvulsant design led to a diverse array of structural analogues with promising activity and low neurotoxicity (13–21), including *N*-acetyl-DL-alanine-*N*-benzylamide, and (*R*,*S*)-α-acetamido-*N*-benzyl-2-furancetamide. These and the discovery of several other highly active analogues suggest that the current anticonvulsant paradigm offers numerous avenues for improvement. However, the plethora of simultaneous synthetic changes embodied within the variety of active compounds can obscure potential directions for further structural modification. Multivariable regression through the method of partial least-squares regression (PLSR) provides an ideal approach to reveal physicochemical features that can be correlated with bioactivity. The substituted acetamido-*N*-benzylacetamide derivatives examined in this study were shown to influence anticonvulsant activity through seven physical and chemical properties. Through this QSAR study, promising directions for future drug design have lead to the synthesis of two new functionalized amido ketone compounds — (*R*,*S*)-2-acetamido-5-phenyl-3-pentanone and *trans*-(*R*,*S*)-2-acetamido-5-phenyl-4-penten-3-one — that show significant anticonvulsant activity.

Fig. 1. A novel anticonvulsant paradigm: α-substituted acetamido-*N*-benzylacetamides. Bioactivity expressed as ED_{50} (mg/kg) in the maximal electroshock seizure test.

R_1	Compound	ED_{50} (mg/kg)
	**11**	10.3
	**27**	8.3
	**30**	8.1

Methods

All compounds shown in Table 1 were synthesized and the racemates were pharmacologically evaluated as previously described (12–21). Anticonvulsant activity, measured as the ED_{50} (mg/kg) in the maximal electroshock seizure (MES) test, was evaluated through the Anticonvulsant Drug Development program at the National Institute of Neurologic Disorders and Stroke, Bethesda, Maryland, USA. All experiments with animals were performed with protocols that have received ethics approval for the humane treatment of experimental animals. These compounds displayed an $ED_{50} \leq 100$ mg/kg. By restricting the compound selection to those that displayed reasonable bioactivity, the confounding effect of including irrelevant and nonactive compounds was minimized.

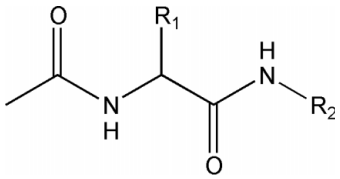
Calculations were performed on an IBM RS/6000 RISC 550 workstation operating under AIX 3.2, and an IBM parallel 8-node SP2 computer operating under AIX4.1. Topological indices were calculated using the TOPOLOGY program provided by H.L. Gordon (22). Molecular volumes based on van der Waals' volume fragmental constants (23, 24) were calculated using the software package QUANTA, version 4.1 from Accelrys Inc. Molecular mechanics calculations were performed using the CHARMm force field (25, 26). Semiempirical molecular orbital calculations were done using the software package Gaussian94 (revision E3) from Gaussian, Inc. (27). Log *P* values were estimated using the fragment approach of Leo and Hansch (28) implemented in the MaclogP program (version 1.0.0) from Biobyte Corporation. Calculations for exploratory data analysis, modeling, and model analysis were done using the Splus (version 3.4) statistical analysis program from MathSoft Inc. The Splus function "pls1a" — an implementation of the algorithm presented by Marten and Naes (29) — was modified and used for partial least-squares regression during model development. Leave-one-out cross-validation was carried out using the modified Splus function "cv".

QSAR — Partial least-squares regression and leave-one-out cross-validation

Standard QSAR terminology is used (30, 31). "Property" refers to any characteristic of a molecule. "Response" refers to a property that is to be expressed in terms of other properties called "predictors" or "descriptors". A "model" expresses the response as a function of the set of predictors. In this study, bioactivity expressed as the $\log(ED_{50})$ in the MES test provided the response variable.

Partial least-squares regression (PLSR) in conjunction with cross-validation (CV) provides a robust means of revealing linear predictor–response relationships (32–37). In this study, PLSR and CV were used to develop and evaluate the QSAR model based on improvements in the adjusted R^2 (R^2_{adj}), the root mean square error of calibration (RMSEC), the predicted error sum of squares (PRESS), and the root mean square error of prediction (RMSEP):

$$[1] \qquad R^2_{adj} = 1 - (n - 1)/(n - p) \times (1 - R^2)$$



(where n = the number of observations, p = the number of PLSR components used in the model, and R^2 = the square of the correlation coefficient),

$$[2] \qquad \text{RMSEC} = \sum (y'_i - y_i)^2/n$$

(where the sum is over all compounds $i = 1$ to n, y'_i is the predicted bioactivity from the PLSR model, and y_i is the corresponding measured bioactivity),

Table 1 (*concluded*).

Compound	R_1 substituent	R_2 substituent	MES ED_{50}
35			~30

Note: All compounds were isolated as racemates. Compounds were orally administered to albino Sprague–Dawley rats and ED_{50} (mg/kg) was measured in the MES test, as conducted under the auspices of the National Institutes of Health's Anticonvulsant Screening Project.

$$[3] \quad \text{PRESS} = \sum (y'_{i(\text{cv})} - y_i)^2$$

$$[4] \quad \text{RMSEP} = (\text{PRESS}/n)^{1/2}$$

(where the sum is over all observations $i = 1$ to n, $y'_{i(\text{cv})}$ = the predicted $\log(ED_{50})$ obtained from leave-one-out CV, and y_i = the actual $\log(ED_{50})$).

In QSAR studies, the assumption of normality in the data distribution is tenuous as the large variety of data types are often not distributed evenly around a mean value. Also, the set of compounds in this study is not representative of the *entire* set of anticonvulsant compounds that contain the pharmacophore shown in Fig. 1. For example, the effect of a long alkyl R_1 substituent on anticonvulsant activity was not explored in this study. Also, the effect of benzyl substituents at the benzylacetamido moiety was examined only with respect to the arrangement of fluoro groups on the aromatic ring. Unlike random sampling done from a large population, the "sample" of compounds in this study was chosen based on the availability of accurate bioactivity data. Therefore, the application of "bootstrapping" methods to calculate population statistics, e.g., confidence intervals from limited samples cannot be justified. In this study, the uncertainty in the regression coefficients for the autoscaled data (see Data pretreatment section) was described using the range in the regression coefficients obtained during cross-validation.

Predictor selection

A set of 31 predictors was used to describe each compound. These predictors were chosen based on their ability to differentiate properties amongst a wide range of compounds. Four predictor categories were employed to describe topological, electronic, physicochemical, and ad hoc properties.

The topological predictors used in this study have been shown by Todeschini et al. (38) to differentiate a wide variety of molecules based on structural branching and elemental diversity. These included: the mean Randić connectivity index "r1mean"; the Kier–Hall flexibility index "phi"; the Wiener index on distance code "Wmean"; and the Balaban distance connectivity index "BJ". The following topological indices were based on the application of Shannon statistical information theory to both molecular graphs and atomic composition (39): the mean information content of the mag-

© 2005 NRC Canada

nitude of the distance degree "rIwdd"; the mean information on equality of the distance degree "rIedd"; the mean information index on atomic composition "rIac"; the multigraph information content index "rIc"; the bonding information content index "bIc"; and the complementary information content "cIc".

Electronic predictors were used to differentiate topologically similar compounds by elemental composition. These predictors were chosen to reflect changes in the local electronic environment near positions where substituents were frequently altered. Since there is a conformational dependence for properties based on the distribution of electron density, partial charges were used strictly as a means to differentiate molecules, and not as a reflection of the electron density distribution associated with an in vivo state. In the CHARMm force field, unfavorable steric contacts were removed through energy minimization starting from extended conformations (i.e., ϕ and ψ torsional angles at the α-carbon were initially set to 180°). For the subsequent semi-empirical molecular orbital calculations (27), each molecule was then further energy minimized using the PM3 Hamiltonian (40). Mulliken partial charges at selected atoms and molecular orbital energies were tabulated for each compound to generate the following predictors: partial charges at the α-carbon (qαC), the C-terminal carbonyl carbon (qCC), and the N-terminal amide nitrogen (qNN); the sum of the partial charges in the α-carbon substituent(s) (qαtotal); and the difference in energy ($\Delta E_{\text{LUMO–HOMO}}$) between the lowest unoccupied and highest occupied molecular orbitals (referred to as LUMO and HOMO, respectively).

Physicochemical predictors were based on estimated values of log *P*, where *P* is the *n*-octanol/water partition coefficient. Using the method originally proposed by Leo et al. (28) as implemented in the ClogP program, the predictors ClogP and ClogP^2 represented the estimated log *P* and (log *P*)^2, respectively. The log *P* has been strongly correlated to the extent of passive diffusion across the blood–brain barrier (41–45). Therefore, this predictor was included to delimit the hydrophobic constraints that must be considered in future syntheses.

Ad hoc predictors were devised to examine the influence of regiospecific substitutions. These included: molecular weight (MW); molecular volume calculated using van der Waals' volume fragmental constants (Vtotal); α-carbon substituent volume (Vαtotal); C-terminal substituent volume (VCterm) and N-terminal substituent volume (VNterm); the number of hydrogen bond donors and acceptors in the α-carbon substituent (Hdα and Haα, respectively), the C-terminal substituent (HdC and HaC) and the N-terminal substituent (HdN and HaN); the number of atoms between the α-carbon and the nearest heteroatom in the α-carbon substituent (*n*-α-het); and the number of nitrogen and oxygen atoms in the α-carbon substituent (Nα and Oα).

Data pretreatment

The predictor data was analyzed to minimize confounding effects. Predictors that showed little or no variance were discarded. These predictors contain information pertaining only to a few compounds and contribute greatly to data noise, thus obscuring trends in the data. Correlation among predictor variables with a correlation coefficient $|r| > 0.8$ were also identified. Predictor variables were then removed to reduce the number of highly correlated variables within the predictor data set. By removing these predictors, the likelihood of developing spurious predictor–response relationships can be greatly reduced. The remaining predictor data was then scaled and normalized through an "autoscaling" procedure, in which the data was scaled to the predictor's standard deviation and centered about the mean. This procedure allowed the predictors to carry approximately the same weight in model development, despite differences in their measurement scales.

Model development

The model was generated in a stepwise fashion using the following procedure:

1. The correlation between each predictor variable and the response variable was calculated.
2. A linear model was derived using the predictor with the highest correlation coefficient.
3. The R^2 was calculated for the model.
4. PLSR models were derived using all previously used predictor data plus one of the remaining predictors. For each model, the R^2_{adj} was calculated.
5. The added predictor was replaced with another one of the remaining predictors. R^2_{adj} was recalculated. This last step was repeated until all of the remaining predictors had been tested. Leave-one-out cross-validation was also performed on each model.
6. From all of the models generated, the one with the most improved R^2_{adj} and smallest PRESS was accepted. Steps 4 to 6 were then repeated until the improvement in R^2_{adj} was less than 0.02, yielding the final model. This limit was set to avoid overfitting.

Results

Of the 31 predictor variables initially evaluated in this study, six showed insignificant variance and were discarded. These variables were: VCterm, VNterm, HdC, HaC, HdN, and HaN. In addition, five variables were removed to eliminate excessive correlation within the predictor data set. The five discarded predictors were: BJ, rIwdd, cIc, MW, and Vtotal. The remaining 20 variables used in the study were: r1mean, Wmean, rIedd, rIac, rIc, bIc, phi, $\Delta E_{\text{LUMO–HOMO}}$, V$\alpha$total, q$\alpha$C, qCC, qNN, q$\alpha$total, Hd$\alpha$, Ha$\alpha$, *n*-$\alpha$-het, N$\alpha$, O α, ClogP, and ClogP^2. Of the 35 compounds used in the analysis, approximately 50% had $\log(ED_{50}) < 1.5$, with a $\log(ED_{50})$ range between 0.9 and 2.0. Exploratory analysis of the predictor data showed that most of the variables were not described by a normal distribution; similarly, the bioactivities were also not normally distributed (data not shown).

The majority of the compounds in Table 1 contain a benzylamide moiety at the C-terminal. Among these, the most active compounds incorporated a variety of different α-carbon groups, including: -CH_2OCH_3 (**27**, ED_{50} = 8.3 mg/kg), 2-pyrimidyl (**30**, ED_{50} = 8.1 mg/kg), and 2-furanyl (**11**, ED_{50} = 10.3 mg/kg). There was no consistent trend in the activity data on changing the α substituent from acyclic to cyclic or nonaromatic to aromatic structures. At the C-terminal, seven compounds with either fluoro-

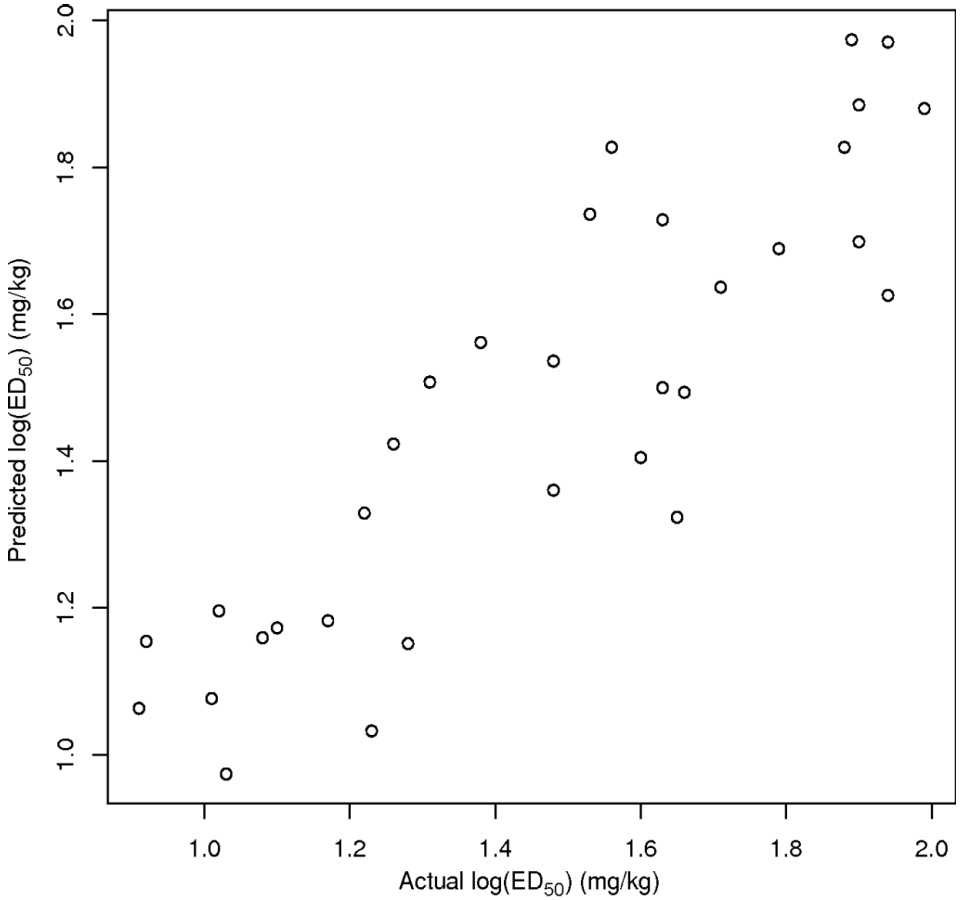
Table 2. QSAR model statistics and regression coefficients.

Statistic	PLSR model (complete data set)	PLSR model (three outliers removed)
RMSEC	0.19	0.16
PRESS	2.29	1.31
RMSEP	0.25	0.20
R^2_{adj}	0.66	0.77
q^2	0.42	0.63
Regression coefficients for the autoscaled data (range of coefficients derived during cross-validation in brackets):		
Wmean	–0.27 (–0.38,–0.23)	–0.25 (–0.33, –0.22)
rIac	0.38 (0.27, 0.41)	0.26 (0.22, 0.29)
qCC	–0.37 (–0.44, –0.29)	–0.44 (–0.51, –0.37)
qαtotal	0.27 (0.16, 0.31)	0.21 (0.11, 0.24)
Hdα	0.58 (0.38, 0.62)	0.63 (0.46, 0.66)
Haα	–0.43 (–0.52, –0.37)	–0.52 (–0.56, –0.49)
$(ClogP)^2$	0.37 (0.29, 0.44)	0.29 (0.20, 0.34)

substituted phenyl rings or a pyridinyl ring also did not show any consistent trend in anticonvulsant activity when compared with the benzylamide-substituted compounds. There were also no consistent topological, electronic, or physicochemical trends in comparing acyclic and cyclic α substituents. The acyclic-containing structures generally showed a smaller α-substituent volume, as expected.

The initial PLSR model employed seven predictors and three PLSR components: Wmean, rIac, qCC, qαtotal, Hdα, $ClogP^2$, and Haα. The fit to the response data was good, with an R^2_{adj} value of 0.66. Predictions based on the first PLSR component alone accounted for 48% of the bioactivity displayed in Table 1. The contribution of each predictor to a PLSR component can be assessed by the predictor's "weighting" that arises from the PLSR algorithm. Weightings range from –1 to +1, with positive values indicating a positive correlation to the response variable. The predictor weightings for the first PLSR component showed the involvement of Hdα, Haα, qCC, rIac, qαtotal, and Wmean with corresponding weights of 0.567, –0.384, –0.553, 0.176, 0.309, and –0.312, respectively. The second PLSR component accounted for an additional 16% of the bioactivity in Table 1 and was weighted heavily towards $ClogP^2$, with a weight of 0.837. The third component accounted for about 2% of the bioactivity and was derived mainly from Hdα, Haα, rIac, and qαtotal, with minor contributions from the remaining predictors qCC, $ClogP^2$, and Wmean. Using three PLSR components, the RMSEC was 0.19 (see Table 2). The cross-validated q^2 value was 0.42 and the PRESS was 2.29, forewarning of poor predictive ability. Thus, from the RMSEP value of 0.25, one could expect that future predictions of $\log(ED_{50})$ will vary by ±0.25, a significant error for a logarithmic scale. One cause of this was the presence of three outliers identified as compounds **4**, **7**, and **13**. For compounds **4** and **13**, the $\log(ED_{50})$ was overestimated by 0.34 and 0.48, respectively. Compound **7** was estimated to have a $\log(ED_{50}) = 1.45$, compared to its actual value of 1.79. Removal of these outliers from the data set resulted in a second model with a slight change in the regression coefficients, as shown in Table 2. The cross-validated q^2 improved to 0.63, suggesting that the second model would be expected to account for approximately 60% of the variance in the anticonvulsant activity of newly synthesized compounds. Three components were also found to be ideal in the second model. The predictor weightings for the first and second components were similar to that seen in the initial model, whereas the third component was derived mainly from Hdα, Haα, and rIac, with minor contributions from qCC, qαtotal, and $ClogP^2$. The percentage of the bioactivity in Table 1 accounted for by the first and second components was 62% and 13%, respectively. The third component accounted for an additional 2%. From cross-validation, the range for each regression coefficient using the autoscaled data is shown in Table 2. Quantile–quantile plots of the regression coefficients derived during cross-validation showed significant deviations from a normal distribution suggesting that the use of standard error would be inappropriate (data not shown).



Using the approach outlined by Golbraikh and Tropsha (46), a measure of model robustness can be obtained by comparing the q^2 statistic of the PLSR model against q^2 values derived from models using randomly shuffled bioactivity data. For 10 sets of data with randomly shuffled $\log(ED_{50})$ values, models containing up to seven predictors and up to three removed outliers were generated using the same modeling strategy. The q^2 values for the random data sets varied from 0.26 to 0.59, with a mean value of 0.36 and a standard deviation of 0.13. The *Z*-score was calculated using $Z = (h - \mu)/\sigma$, where h is the q^2 for the PLSR model, μ is the mean q^2, and σ is the standard deviation in q^2 for the random data sets. For the PLSR model, $Z = 2.1$, indicating that the likelihood the model was derived by chance is 0.018, or 1 in 56. However, among the random data sets, the presence of two models with q^2 values of 0.58 and 0.59 indicated some instability in the model, perhaps reflecting the small size of the data set. This forewarns that predictions based on the model should be of a qualitative nature.

The chemical interpretation of the PLSR model can be facilitated by deriving the regression coefficients to generate the following prediction relation for the unscaled and uncentred data:

$$[5]\quad \log(ED_{50}) = (-0.434)\text{Wmean} + (0.738)\text{rIac} + (-7.36)\text{qCC} + (0.520)\text{q}\alpha\text{total} + (0.285)\text{Hd}\alpha + (0.163)\text{ClogP}^2 + (-0.272)\text{Ha}\alpha + 4.60$$

© 2005 NRC Canada

Fig. 2. Predicted log(ED_{50}) vs. actual log(ED_{50}) for 32 α-substituted acetamido-*N*-benzylacetamide derivatives. Predicted log(ED_{50}) = (–0.434)Wmean + (0.738)rIac + (–7.36)qCC + (0.520)qαtotal + (0.285)Hdα + (0.163)ClogP^2 + (–0.272)Haα + 4.60 (R^2_{adj} = 0.77; cross-validated q^2 = 0.63, three PLSR components).

(R^2_{adj} = 0.77; RMSEC = 0.16; cross-validated q^2 = 0.63; RMSEP = 0.20; three PLSR components).

A plot of the predicted log(ED_{50}) against the actual log(ED_{50}) is shown in Fig. 2. The statistical relevance in this QSAR equation can be summarized as follows: (*a*) from an original set of 31 predictors, seven predictors were found to be useful in describing anticonvulsant activity; (*b*) as suggested by R^2_{adj} = 0.77, this QSAR can account for 77% of the variance in the anticonvulsant activity displayed in Table 1; (*c*) for Table 1, this QSAR calculates the log(ED_{50}) within an error of ±0.16; (*d*) one can expect the QSAR equation to predict about 60% of the variance in the anticonvulsant activity of a new set of compounds (cross-validated q^2 = 0.63), with an error of ±0.20 in the predicted log(ED_{50}) (RMSEP = 0.20); (*e*) from the original 31 predictors examined (a potentially 31-dimensional data space), the "essential" data *that is relevant to anticonvulsant activity* can be described by a three-dimensional data space represented by the three PLSR components, which are mutually orthogonal.

Discussion

The potential of a QSAR analysis lays not only in the statistical characterization of favorable structure–activity trends, but also in the identification of irrelevance or redundancy among the many structural properties of initial interest. A well-constructed QSAR model should provide not only a range in which structural properties are correlated to some measure of bioactivity, but also a set of boundaries within which toxicity and bioavailability issues may be examined.

Chemical and structural interpretation of the model

The seven predictors employed by the PLSR model cover a range of topological, electronic, physicochemical, and ad hoc properties. Although the chemical meaning of predictors such as Hdα is self-evident, for others such as Wmean, the structural implications are less intuitive. Through examples drawn from Table 1, the significance of these predictors can be clearly illustrated.

The predictor Wmean spanned a range from 4.26 to 5.18. At the high end, compounds **5**, **24**, and **33** possess heteroatom-containing cyclic α substituents. Heteroatoms in the C-terminal benzylamide groups of **5** also increased Wmean. Thus, the presence of heteroatoms in either large branched α substituents or at the C-terminal benzylamide group was associated with a large Wmean value, which favoured anticonvulsant activity. Countering this, a large rIac value disfavours anticonvulsant activity. High values for rIac arose from the introduction of heteroatoms in small α-carbon and C-terminal substituents. Compounds such as **2**, **6**, and **20** possessed high rIac values of 1.40, 1.40, and 1.32, re-

© 2005 NRC Canada

spectively. Low values were seen in large compounds with little heteroatom diversity. For example, compounds **8**, **10**, and **19** displayed rIac values of 0.99, 0.89, and 1.02. As the size of a molecule increases, the probability of elemental diversity at a given nucleus diminishes, thus lowering rIac. This illustrates the interdependence of rIac and Wmean. This interpretation does not account for the possible influence of other possible R_1 moieties, such as alkyl chains of varying lengths. Thus, one cannot exclude that the current model is biased towards favouring large heteroatom-containing substituents.

The large difference in the regression coefficients for the electronic predictors qCC and qαtotal reflects the difference in the ranges for these variables. When this is taken into account, the contributions of the qCC and qαtotal terms are of comparable magnitude. Anticonvulsant activity was associated with increasing values of qCC. Large qCC values above 0.28 were attributed to the presence of electron-withdrawing centres adjacent to the α-carbon. For example, in compounds **5** (ED_{50} = 12.7 mg/kg, qCC = 0.282) and **11** (ED_{50} = 10.3 mg/kg, qCC = 0.281) the 2-furanyl α substituent places an aromatic center next to the α-carbon. In contrast, a low qCC value in compound **26** (ED_{50} = 62 mg/kg, qCC = 0.202) was due to the placement of an electron-rich -OCH_2CH_3 group next to the α-carbon. Differences in qαtotal were more difficult to interpret as most qαtotal values were close to zero. Both qαtotal and qCC were calculated using Mulliken population analysis and are therefore strongly dependent on conformation. For each molecule in the present study, in the absence of biologically relevant conformational data, the extended conformation was used to calculate the electron density distribution. This does not necessarily correspond to an in vivo state. Therefore, while qαtotal and qCC in this study were useful in distinguishing different compounds, it would be inappropriate to attribute any biological significance to these partial charges, e.g., with respect to receptor interactions. Clearly, for future analyses, it would be preferrable to substitute more relevant electronic predictors should the appropriate conformational data become available.

The physicochemical predictor $ClogP^2$ provided an indication of the hydrophobic requirements for activity. Most of the compounds in Table 1 showed a $ClogP^2$ value between 0 and 1. For compounds with $ClogP^2 < 1$, the small $ClogP^2$ coefficient of 0.163 indicates that the impact of the $ClogP^2$ term on $\log(ED_{50})$ is weak. This suggests that favourable activity is compatible with a wide range in hydrophobicity.

The chemical and physical interpretation of the current PLSR model complements the structure–activity relationship study of functionalized amino acids reported by Shen et al. (47). In that study, data sets using topological indices and atom pair descriptors were used to construct models employing up to 50 predictors using either the "k-nearest-neighbor" QSAR (kNN-QSAR) method or a "simulated annealing" partial least-squares (SA-PLS) approach. These techniques were capable of generating models with high q^2 values and good prediction capabilities. In addition, the use of atom pair descriptors was useful for revealing chemical substructures that were present in only the most active compounds. However, the relation between chemical *properties* and anticonvulsant activity can be obscured through the simultaneous use of many predictors, which have only an indirect correlation to physicochemical quantities. The current PLSR model complements the kNN-QSAR and SA-PLS models by revealing *chemical trends* that may be exploited by the synthetic chemist to design new compounds. Thus, for example, the PLSR model suggested that anticonvulsant activity may be enhanced by eliminating α-substituent hydrogen bond donors, incorporating α-substituent hydrogen bond acceptors, and increasing the partial positive charge at the C-terminal carbon. This information is difficult to obtain from the use of topological descriptors alone.

Outlier analysis

Compounds **4**, **7**, and **13** have been identified as outliers. The ED_{50} for compounds **4** and **13** are overestimated (i.e., the model predicts that they are less active than they actually are) while the ED_{50} for compound **7** is underestimated (i.e., the model predicts greater bioactivity than is actually seen). Compound **4** (R_2 = *meta*-fluorobenzyl) is comparable to compounds **3** (R_2 = *ortho*-fluorobenzyl) and **5** (R_2 = *para*-fluorobenzyl), with experimental ED_{50} values of 13.3, 40, and 12.7, respectively. The calculated ED_{50} values for **4**, **3**, and **5** are 28.7, 27.0, and 16.4. Thus, the model fails to recognise the favourable *meta*-fluorobenzyl group, and treats this as equivalent to the unfavourable ortho analogue.

Compound **7** contains a 2-furanyl group at R_1 and a -CH_2-2,6-$F_2C_6H_3$ group at R_2. It is comparable to compound **6**, which differs by having a -CH_2-2,5-$F_2C_6H_3$ group at R_2. The calculated and actual ED_{50} values for **7** are 27.9 and 63, respectively. The corresponding values for **6** are 41.4 and 23.8. The model fails to recognize the detrimental effect of two *ortho*-fluoro groups at the R_2 benzyl moiety. In fact, the model predicts the *opposite* trend for compounds **6** and **7**. As for compounds **3**, **4**, and **5**, the model fails to recognise the detrimental effect of the *ortho*-fluorobenzyl group.

Compound **13** contains a 2-pyrrolyl group at R_1 and a benzyl group at R_2, and is comparable to **14** (R_1 = 2-pyrrolyl-5-CH_3). Compounds **13** and **14** possess calculated ED_{50} values of 49.2 and 48.1, respectively. From the experimental ED_{50} values in Table 1, the presence of a 5-methyl group on the pyrrole ring in **14** is associated with lower activity. This suggests that the model doesn't account for the steric effect of the methyl group attached to the pyrrolyl ring in compound **14**.

This outlier analysis illustrates an inherent inability of this QSAR method to account for specific pharmacodynamic interactions. The substituent position in the R_2 benzyl moiety or in the R_1 2-pyrrolyl group was not specifically characterized in the original descriptor set. Specific descriptors focused on substituent effects would be appropriate in QSAR studies of future drug candidates containing an array of modifications at these sites. Additionally, this QSAR study did not utilize three-dimensional conformational data, which may be relevant to model specific drug–receptor interactions. The use of detailed conformational data is dependent on availability and the relevance of the structural information to the specific drug–receptor milieu. Conformational data is most useful in exploring trends within a series of closely related structural analogues. Consequently, this would not be appropriate in the present QSAR study, which examined a wide variety of α-substituted acetamido-*N*-benzylacetamide structures. It is certainly possible that for

compounds **4**, **7**, and **13** specific steric and nonbonding interactions within the receptor microenvironment directly affected anticonvulsant activity. A future exploration of benzyl group substituent effects at the R_2 position or 2-pyrrolyl substituents at the R_1 position may be promising.

Functionalized amido ketones — a new anticonvulsant class

The PLSR model suggested that certain chemical modifications would be compatible with increased anticonvulsant activity. Increasing positive charge at the C-terminal carbonyl carbon and the removal of hydrogen bond donors in the α substituent could be obtained by modifications at either the α-carbon or at the C-terminal. Therefore, two functionalized amido ketones — (*R*,*S*)-2-acetamido-5-phenyl-3-pentanone, and *trans*-(*R*,*S*)-2-acetamido-5-phenyl-4-penten-3-one — were proposed to explore these possibilities (Fig. 3). The absence of a C-terminal benzylamide moiety not only increased the positive charge at the C-terminal carbonyl carbon, but also represented a substantial structural departure from the original pharmacophore shown in Fig. 1, removing a site for amide bond hydrolysis. These compounds satisfied the following structural guidelines derived from the model: (*a*) both had a large Wmean value of 4.258; (*b*) both had a low rIac value of 0.87; (*c*) both had qCC values greater than 0.28; (*d*) neither compound had a hydrogen bond donor in the α substituent. Using the PLSR model in conjunction with the previous experience with functionalized amino acid anticonvulsants, the synthesis, characterization, and pharmacologic testing of several substituted amido ketones was completed by Béguin et al. (48).

Significant anticonvulsant activity was seen in the MES test for (*R*,*S*)-2-acetamido-5-phenyl-3-pentanone, and *trans*-(*R*,*S*)-2-acetamido-5-phenyl-4-penten-3-one (see Table 3). Additionally, (*R*)-2-acetamido-5-phenyl-3-pentanone showed greater potency than the (*S*)-isomer. This finding mirrored the stereochemical influence exerted at the α-carbon in *N*-acetyl-DL-alanine-*N*-benzylamide, in which the D-isomer possessed 10 times the pharmacologic activity of the L-isomer (12). This suggested that anticonvulsant activity is mediated by a molecular scale interaction. The vinylic amido ketone *trans*-(*R*,*S*)-2-acetamido-5-phenyl-4-penten-3-one also demonstrated significant activity. The similar activities exhibited by functionalized amino acid, saturated amido ketone, and vinylic amido ketone anticonvulsants indicated the biological equivalence of the terminal substituents -N(H)CH_2Ph, -CH_2CH_2Ph, and *trans*-CH=CHPh. This raises the possibility that these groups attain a similar bioactive conformation.

Conclusions

The aim of the exploratory phase of rational drug design is to identify the most promising strategies for the future optimization of the lead compound. In the present study, a chemometric approach employing QSAR methodology was used to extract novel insight from a diverse collection of structural analogues. The resulting structure–activity model suggested possible directions for future synthetic design.

Modeling with the compounds shown in Table 1 yielded the following linear relationship after the removal of three outliers: log(ED_{50}) = (–0.434)Wmean + (0.738)rIac + (–7.36)qCC + (0.520)qαtotal + (0.285)Hdα + (0.163)ClogP^2 + (–0.272)Haα + 4.60 (R^2_{adj} = 0.77; cross-validated q^2 = 0.63; three PLSR components). This model explained 77% of the variance in the calibration set as a function of seven predictors. Through leave-one-out cross-validation, it was shown that the relevant structural and chemical information in Table 1 was described by three components, i.e., a three-dimensional predictor space. The cross-validated q^2 statistic of 0.63 indicated that the model should account for ~60% of the variance in future test set predictions.

The model provided statistical support for the validity of the proposed anticonvulsant pharmacophore for α-substituted acetamido-*N*-benzylacetamide compounds. From a structural perspective, favourable bioactivity was correlated with: highly branched, cyclic α substituents and a large *N*-benzylacetamido moiety (indicated by Wmean and rIac); the presence of α-substituent hydrogen-bond acceptors (from Ha

© 2005 NRC Canada

α); the absence of hydrogen-bond donors (Hdα); and, the presence of electron-withdrawing substituents at either the α-position or the benzyl moiety (from the qCC term). The ClogP[2] coefficient suggests that a wide range of hydrophobic compounds can be accomodated by the present pharmacophore. The synthesis of functionalized amido ketones represents a synthetic priority consistent with this QSAR study. These compounds possess appreciable activity in the maximal electroshock seizure test and represent a newly discovered class of anticonvulsant agents.

Re-evaluation of the second thermodynamic dissociation constants of α-alanine, valine, and leucine using potentiometric data measured for aqueous potassium chloride solutions at 298.15 K

Jaakko I. Partanen, Pekka M. Juusola, and Virginie Verraes

Abstract: Equations were developed for the calculation of the second stoichiometric (molality scale) dissociation constants (K_{m2}) of α-alanine, valine, and leucine in aq. KCl solutions at 298.15 K from the revised thermodynamic dissociation constants (K_{a2}) of these acids and the ionic strength (I_m) of the solutions. The ionic strength of the solutions considered in this study is determined mostly by KCl alone, and the equations for K_{m2} were based on the single-ion activity coefficient equations of the Hückel type. The existing literature data obtained from Harned cell measurements and new potentiometric titration data were used to revise the K_{a2} values of the three amino acids. The values $(1.295 \pm 0.013) \times 10^{-10}$, $(1.894 \pm 0.009) \times 10^{-10}$, and $(1.685 \pm 0.011) \times 10^{-10}$ were obtained from the new potentiometric titration data for α-alanine, valine, and leucine, respectively. For alanine and valine, the new K_{a2} values are also supported by the Harned cell data used, but the value $(1.80 \pm 0.02) \times 10^{-10}$ obtained for leucine from these data is significantly different. The potentiometric values are recommended here. The activity coefficient equations for the calculation of K_{m2} values were also determined from the new potentiometric data. By means of the activity coefficient equations obtained for these three amino acids for KCl solutions, K_{m2} can be evaluated almost within experimental error up to an I_m of about 1.0 mol kg^{-1}. The K_{m2} values calculated by this method are also compared with the values suggested in the literature.

Key words: ionic strength dependence, stoichiometric dissociation constant, Debye–Hückel equation, potentiometry, α-alanine, valine, leucine.

Résumé : Des équations sont développées pour le calcul de K_{m2}, la deuxième constante de dissociation stœchiométrique (en molalité) de l'α-alanine, la valine et la leucine en solutions aqueuses de KCl à 298,15 K, à partir des constantes thermodynamiques révisées (K_{a2}) de ces acides et de la force ionique de la solution (I_m). La force ionique des solutions considérées dans la présente étude est imposée presque en totalité par KCl, et les équations des constantes K_{m2} sont déduites d'équations de type Hückel pour la détermination du coefficient d'activité d'un seul type d'ions en solution. Les données bibliographiques existantes, obtenues à partir de mesures faites sur des cellules de Harned, ainsi que de nouvelles données potentiométriques ont été utilizées pour réévaluer les valeurs des coefficients K_{a2} des ces trois acides aminés. Des valeurs de $(1{,}295 \pm 0{,}013) \times 10^{-10}$, $(1{,}894 \pm 0{,}009) \times 10^{-10}$ et $(1{,}685 \pm 0{,}011) \times 10^{-10}$ ont ainsi été obtenues pour l'α-alanine, la valine et la leucine, respectivement, à partir de nouvelles titrations potentiométriques. Pour l'alanine et la valine, les nouvelles valeurs de K_{a2} sont confirmées par les valeurs utilizées provenant de valeurs obtenues avec des cellules de Harned, mais la valeur de $(1{,}80 \pm 0{,}02) \times 10^{-10}$ obtenue pour la leucine diffère considérablement. Les valeurs potentiométriques sont recommandées dans la présente étude. Les équations pour les coefficients d'activités utilizées pour le calcul des constantes K_{a2} ont aussi été déterminées à partir de nouvelles données potentiométriques. Au moyen de la méthode de calcul obtenue pour ces trois acides aminés en solutions de KCl, leur constante K_{m2} peut être calculée dans la limites des erreurs expérimentales jusqu'à des valeurs de force ionique au moins de 1.0 mol kg^{-1}. Les valeurs de K_{m2} calculées par cette méthode sont aussi comparées aux valeurs suggérées dans la bibliographie.

Mots clés : dépendance à la force ionique, constante de dissociation stœchiométrique, équation de Debye–Hückel, potentiométrie, α-alanine, valine, leucine.

Introduction

In this manuscript, we continue studies (ref. 1 and see refs. 1–17 therein) dealing with the thermodynamics of weak acid solutions. The purpose of these studies is to determine the stoichiometric dissociation constants (for example, the molality scale dissociation constants (K_m)) for salt solutions of different weak acids as reliably as possible from potentiometric titration data measured with glass electrodes. Additionally in these studies, calculation methods for experimental K_m values for weak acids are also developed for literature data measured with galvanic cells without a liquid junction. The used cells of this type (Harned cells) contain a hydrogen electrode and a silver–silver chloride electrode.

The other motivation for studies in this field is to develop equations for correlating experimental K_m values for different weak acids with the composition variables of salt solutions at 298.15 K and also at other temperatures (2, 3). In the present study, a Hückel equation is used for the analysis of potentiometric titration data for aq. KCl solutions of alanine, valine, and leucine, as well as Harned cell data for NaCl solutions of these three amino acids. Pitzer equations, which are nowadays most often used for interpretation of thermodynamic data, were not considered in this study because the necessary Pitzer parameters are missing for the component salts of sodium and potassium alaninate, valinate, and leucinate, and these parameters cannot be accurately determined solely from the existing data.

α-Alanine ($CH_3CH(NH_2)COOH$ = ala), valine ($(CH_3)_2CHCH(NH_2)COOH$ = val), and leucine ($(CH_3)_2CHCH_2CH(NH_2)COOH$ = leu) are simple aliphatic amino acids. Many studies have been published on the dissociation of these acids in aqueous solutions. A review of this research by IUPAC (4) shows, however, that only a few systematic studies on the influence of ionic strength I_m or other composition variables on K_{m1} and K_{m2} (i.e., on the first and second stoichiometric dissociation constant) of these three amino acids have been carried out. Systematic studies for other weak acids are also rare, and the existing studies in this field are usually concentrated on acids used as pH buffer substances. The existing systematic glass electrode studies have been considered in the reviews written by Daniele et al. (5) and Sastre de Vicente (6).

Stoichiometric dissociation constants of ala have been studied by Brandariz et al. (7) in aq. KNO_3 solutions (I_m = 0.3–1.6 mol kg^{-1}), by Fiol et al. (8) in NaCl solutions (I_m = 0.05–1.25 mol kg^{-1}), and by Fiol et al. (9) in artificial sea water (I_m = 0.087–0.62 mol kg^{-1}). K_{m1} and K_{m2} values for val have been investigated by Brandariz et al. (10) in KCl and KBr solutions (I_m = 0.1–1.7 mol kg^{-1}) and by Fiol et al. (11) in artificial sea water (I_m = 0.10–0.72 mol kg^{-1}). The existing systematic leu studies are the following: Rey et al. (12) in KNO_3 solutions (I_c = 0.025–0.5 mol dm^{-3}, I_c is the ionic strength on the molarity scale) and Fiol et al. (9) in artificial sea water (I_m = 0.087–0.62 mol kg^{-1}).

Harned cells have been used in the determination of the thermodynamic dissociation constants of amino acids. Though old, these studies are nowadays very important because the resulting K_a values at various temperatures are still the best values available for most of the amino acids. This is true also for ala, val, and leu. Nims and Smith (13) determined in this way the value 1.35×10^{-10} for the second thermodynamic dissociation constant (= K_{a2}) of ala at 298.15 K, and Smith et al. (14) determined the values of 1.36×10^{-10}, 1.91×10^{-10}, and 1.80×10^{-10} for K_{a2} of ala, val, and leu, respectively, at this temperature. In the present study, the calculation of these values is revised, and for the first time the K_{m2} values for the solutions of these three amino acids are calculated from the Harned cell data.

In the determination of the second dissociation constants of ala, val, and leu, the pH during titration was above 8, as in a recent glycine study (1). The solutions titrated had, therefore, to be protected against atmospheric carbon dioxide. This was achieved, as in the glycine study, by bubbling argon through the solution before titration. An argon blanket was thus formed over the solution and it protected the solution from absorption of CO_2. The glycine study (1) and the present study show that this experimental technique allows the determination of K_m values with a glass electrode for alkaline solutions almost with the same accuracy obtained by the best glass electrode techniques for acidic solutions.

Experimental

Potentiometric titrations of ala, val, and leu were carried out in aq. KCl solutions at 298.15 K. A series of KCl (pro analysi, Riedel–de Haën) solutions for each acid was prepared in RO-filtered water (Millipore). The concentrations in this series were as follows: 0.080, 0.160, 0.240, 0.320, 0.400, 0.500, 0.700, and 1.350 mol L^{-1}. Solutions at 0.0100 mol L^{-1} of L-ala (Aldrich), of L-val (Fluka), and of L-leu (Fluka) were prepared. A 0.1000 mol L^{-1} KOH (Titrisol, Merck) solution was also prepared in RO-filtered water (Millipore), and this solution was protected during titrations from atmospheric CO_2. The concentration of this solution was standardized using titrations of a potassium hydrogen phthalate solution, and the result of nine replicate determinations was (0.100 02 ± 0.000 03) mol L^{-1} where the standard deviation is given. The experimental data from the ala titrations are shown in Table 1, from the val titrations in Table 2, and from the leu titrations in Table 3.

The solutions for titration were prepared by mixing a volume of 100.0 cm^3 of a KCl solution, 25.00 cm^3 of water, and 10.00 cm^3 of the ala, val, or leu solution (for details, see ref. 15). The amino acid solutions were titrated with the KOH solution, and details of the titrations are given in ref. 1. The molalities were calculated from the experimental molarities (see below and ref. 15) using an equation reported by Harned and Owen (16) for this conversion in KCl solutions. To verify the stability of the measuring system, a titration of formic acid was carried out under similar conditions before the amino acid titration in each KCl solution. An argon gas blanket was also adjusted over the formic acid solutions before titration. From the results of these formic acid titrations, the K_m values were determined by the method suggested in ref. 17. This method is principally the same as the one used here for the three amino acids. The resulting K_m values are shown in Tables 1, 2, and 3 for ala, val, and leu cases, respectively. These K_m values from the formic acid titrations were very close to those calculated from the equations recommended in ref. 17 for K_m of this acid in KCl solutions (shown Table 1). The good agreement between the

observed and recommended K_m values for this acid guarantees the quality of the new data for the amino acids considered.

Theory

In the Hückel method, the following equation is generally used for the calculation of the activity coefficient (γ) of a univalent ion i on the molality scale.

$$[1] \qquad \ln \gamma_i = -\frac{\alpha\sqrt{I_m}}{1 + B_i\sqrt{I_m}} + b_{i,MCl}\left(\frac{I_m}{m^o}\right)$$

where m^o = 1 mol kg^{-1}, I_m is the ionic strength on the molality scale, and α is the Debye–Hückel parameter at 298.15 K, equal to 1.174 44 (mol $kg^{-1})^{-1/2}$; see Archer and Wang (18). B_i and $b_{i,MCl}$ are the parameters that are dependent on ion i, and $b_{i,MCl}$ is also dependent on the salt MCl present in the system. Table 4 gives the parameter values determined previously for this equation and used here.

The thermodynamic value of the second dissociation constant (K_{a2}) of ala, val, or leu is given by

$$[2] \qquad K_{a2} = \frac{a_H a_A}{a_{HA}} = \left(\frac{\gamma_H \gamma_A}{\gamma_{HA}}\right) K_{m2}$$

where a is the activity, HA refers to amino acid molecules or zwitterions, and A to the anion resulted from the amino acid, i.e., to alaninate, valinate, or leucinate. It is assumed that the activity coefficient of the neutral species HA follows the Kirkwood equation (22, 23)

$$[3] \qquad \ln \gamma_{HA} = b_{HA}\left(\frac{I_m}{m^o}\right)$$

for zwitterions, where b_{HA} is a constant. The second stoichiometric dissociation constant of the amino acid, K_{m2} in eq. [2], is defined by $K_{m2} = m_H m_A/(m_{HA} m^o)$. The following equation can be derived from eqs. [1]–[3] for K_{m2} of these acids in aq. NaCl or KCl solutions:

$$[4] \qquad \ln K_{m2,MCl} = \ln K_{a2} + \alpha\sqrt{I_m}\left(\frac{1}{1 + B_H\sqrt{I_m}} + \frac{1}{1 + B_A\sqrt{I_m}}\right) - [b_{H,MCl} + (b_{A,MCl} - b_{HA,MCl})]\left(\frac{I_m}{m^o}\right)$$

where MCl refers to either NaCl or KCl. Here, the values of B_H = 1.25 (mol $kg^{-1})^{-1/2}$, B_A = 2.2 (mol $kg^{-1})^{-1/2}$, $b_{H,NaCl}$ = 0.238, and $b_{H,KCl}$ = 0.178 were used in this equation (see Table 4). The thermodynamic dissociation constants (K_{a2}) and the parameters $b_{A,KCl} - b_{HA,KCl}$ (= q_{KCl}) and $b_{A,NaCl} - b_{HA,NaCl}$ (= q_{NaCl}) were determined from the new potentiometric titration data and from the Harned cell data for the amino acids considered. The value of B_A = 2.2 (mol $kg^{-1})^{-1/2}$ was determined previously for glycine species (1), and it also applies to alaninate, valinate, and leucinate ions (see below).

[a]Recommended value of the second thermodynamic dissociation constant for the corresponding acid.
[b]$pK_{a2} = -\log K_{a2}$.
[c]Experimental value of K_{a2} of the corresponding amino acid (see also footnote *b*). It was estimated from the K_{m2} values obtained from glass electrode data (Tables 1–3) in this study, and the standard deviation is also given.
[d]Experimental value of K_{a2} of α-alanine (see also footnote *b*). It was estimated from the K_{m2} values obtained from hydrogen electrode data (Table 5) of Nims and Smith (13), and the standard deviation is also given.
[e]Experimental value of K_{a2} of of the corresponding amino acid (see also footnote *b*). It was estimated from the K_{m2} values obtained from hydrogen electrode data (Tables 6–8) of Smith et al. (14), and the standard deviation is also given.
[f]Determined from Harned cell data (19).
[g]Determined for glycine species from Harned cell data (20). The same value is used here for the anions considered.
[h]Determined from Harned cell data (21).
[i]Recommended in this study ($q = b_A - b_{HA}$).
[j]Estimated from the K_{m2} values obtained from glass electrode data (Tables 1–3) in this study, and the standard deviation is also given ($q = b_A - b_{HA}$).
[k]Estimated from the K_{m2} values obtained in this study from hydrogen electrode data (Table 5) of Nims and Smith (13), and the standard deviation is also given ($q = b_A - b_{HA}$).
[l]Estimated from the K_{m2} values obtained in this study from hydrogen electrode data (Tables 6–8) of Smith et al. (14), and the standard deviation is also given ($q = b_A - b_{HA}$).

The thermodynamic value of the ionic product of water ($K_{a,w}$) is defined by

$$[5] \qquad K_{a,w} = \frac{\gamma_H \gamma_{OH} m_H m_{OH}}{a_w (m^o)^2} = \frac{g_w m_H m_{OH}}{(m^o)^2}$$

where OH refers to hydroxide ions, w refers to water, and the quantity g_w is defined by $g_w = \gamma_H\gamma_{OH} / a_w$. Harned and Hamer (24) determined the value 1.008×10^{-14} for $K_{a,w}$ at 298.15 K. In a previous study (1), the following equation containing only one salt-dependent parameter (b_w) was used for $\ln g_w$ for KCl and NaCl solutions at 298.15 K:

$$[6] \qquad \ln g_w = \ln\left(\frac{\gamma_H\gamma_{OH}}{a_w}\right) = -\frac{2\alpha\sqrt{I_m}}{1 + B_H\sqrt{I_m}} + b_w\left(\frac{I_m}{m^o}\right)$$

For NaCl solutions, the value of parameter b_w is 0.412 (obtained in ref. 1 from the Harned cell data of Harned and Mannweiler (25)), and eq. [6] is valid up to an ionic strength of about 3 mol kg^{-1}. For KCl solutions, the value of this parameter is 0.482 (obtained from the data of Harned and Hamer (24)), and eq. [6] is valid in this case up to an I_m of about 2 mol kg^{-1}.

Results

Redetermination of the second thermodynamic dissociation constants of amino acids from Harned cell data

Nims and Smith (13) and Smith et al. (14) have measured cell potential differences (cpd = E) for ala, val, and leu solutions using cells of the type

$$[7] \qquad \text{Pt(s)} \mid H_2(g, f = 101.325\ \text{kPa}) \mid \text{HA(aq, } m_a\text{)}, \text{NaA(aq, } m_b\text{)}, \text{NaCl(aq, } m_s\text{)} \mid \text{AgCl(s)} \mid \text{Ag(s)}$$

where f is the fugacity. In the actual cell used (13, 14), the amino acid was partially neutralized by sodium hydroxide and the composition shown in cell [7] resulted from this neutralization. The ionic strength of the solutions varied from 0.010 to 0.151 mol kg^{-1}, and the molalities m_a, m_b, and m_s were approximately equal. Nims and Smith (13) measured 22 ala solutions, Smith et al. (14) seven ala, six val,

and five leu solutions. The cell potential differences (E) of cell [7] are given by

$$[8] \qquad E = E^{o} - \frac{RT}{F}\ln\left(\frac{\gamma_H\gamma_{Cl}m_Hm_{Cl}}{(m^{o})^2}\right)$$

where Cl refers to chloride ions, and E^o is the standard cpd. A value of 0.222 50 V was used for E^o (see Harned and Ehlers (26)). In addition, these cpd data were updated by using the conversion factor 1 V = 1.000 34 int. V. The data in these sets were used to determine K_{a2} as follows.

The observed K_{m2} value was first calculated from each experimental point by using eq. [6] and the equations

$$[9] \qquad \ln\left(\frac{m_H}{m^{o}}\right) = \frac{(E^{o} - E)F}{RT} - \ln\left(\frac{\gamma_H\gamma_{Cl}m_{Cl}}{m^{o}}\right)$$

$$[10] \qquad m_{OH} = \frac{K_{a,w}(m^{o})^2}{g_w m_H}$$

$$[11] \qquad K_{m2} = \frac{m_H(m_b - m_{OH})}{(m_a + m_{OH})m^{o}}$$

For the activity coefficients of hydrogen and chloride ions in eq. [9], eq. [1] was used with the parameters given in Table 4. The experimental K_{m2} values calculated in this way from the data of Nims and Smith (13) and Smith et al. (14) are presented in Tables 5–8.

The values for K_{a2} of the three amino acids were determined from the K_{m2} values in Tables 5–8 using the equation:

[a]Calculated by eq. [27].

$$[12] \qquad \ln K_{m2,MCl} - \alpha\sqrt{I_m}\left(\frac{1}{1 + B_H\sqrt{I_m}} + \frac{1}{1 + B_A\sqrt{I_m}}\right) = y = \ln K_{a2} - (b_{H,MCl} + q_{MCl})\left(\frac{I_m}{m^{o}}\right)$$

where, in this case, MCl is NaCl. In preliminary calculations, it was observed that the value of B_A = 2.2 (mol kg^{-1})$^{-1/2}$ applies also to the three amino acids studied. This value has been determined for glycine species from the large Harned cell data sets of King (27) in ref. 20. Equation [12] represents an equation of the straight-line y vs. (I_m/m^o). K_{a2} can be obtained from the intercept of the line with the y-axis, and the slope of the straight line is $b_{H,NaCl} + q_{NaCl}$. The resulting K_{a2} values for the amino acids are shown in Table 4. As can also be seen in this table, each value obtained for q_{NaCl} of the amino acid species has a wide confidence interval, and thus is not very reliable. This is due to the fact that the Harned cell data are only for dilute solutions and the two

© 2005 NRC Canada

Debye–Hückel terms on the left hand side of eq. [12] are dominant in these solutions and the slope term on the right hand side is thus small. Therefore, the q_{NaCl} values obtained from Harned cell data were not used here.

Determination of the experimental values for the stoichiometric dissociation constants from potentiometric glass electrode data

In ref. 1, the following equation was derived for the molality of hydroxide ions (m_{OH}) at each point of the glycine titrations

$$[13] \quad m_{OH}^2 + \left(m_t - m_b + \frac{K_{a,w}m^o}{g_w K_{m2}}\right)m_{OH} - \frac{K_{a,w}m^o}{g_w K_{m2}}m_b = 0$$

The same equation can now be used for the ala, val, and leu titration data in Tables 1–3. In this equation, m_b is the molality of KOH, in the solution titrated and $m_b = c_b V / w_1$, where c_b is the concentration, V is the volume of the base solution added in the titration, and w_1 is the mass of water in the solution titrated. In eq. [13], m_t is the total molality of amino acid in the solution titrated, and $m_t = n_t/w_1$ where n_t is the total amount of this substance. Equation [13] is of the second degree in the molality of OH^- ions and can therefore be easily solved.

For the determination of K_{m2} of ala, val, and leu from the titration data, a glass electrode parameter (E_0) was estimated from each titration data set in addition to this dissociation constant. In the present titrations, the following equation is valid (see ref. 1) for the cell potential differences (E) measured with the glass electrode cell

$$[14] \quad E = E_0 + \frac{RT}{F}\ln\left(\frac{m_H}{m^o}\right)$$

where E_0 is constant during each titration at a constant ionic strength and must be estimated from the titration data.

K_{m2} and E_0 were calculated for each amino acid data set of N points presented in Tables 1–3 by the following set of equations:

$$[15] \quad \sum_{i=1}^{N}(E_i - E_{pred,i}) = 0$$

$$[16] \quad \ln\left(\frac{x_i}{m^o}\right) = \frac{(E_i - E_0)F}{RT}$$

$$[17] \quad o_i = \frac{K_{a,w}(m^o)^2}{g_w x_i}$$

$$[18] \quad K_{m2,i} = \frac{x_i(m_{b,i} - o_i)}{\left(\frac{n_t}{w_{1,i}} - m_{b,i} + o_i\right)m^o}$$

$$[19] \quad K_{m2} = \frac{\left(\sum_{i=1}^{N} K_{m2,i}\right)}{N}$$

$$[20] \quad y_i = \left(\frac{n_t}{w_{1,i}} - m_{b,i} + \frac{K_{a,w}m^o}{g_w K_{m2}}\right)^2 + 4m_{b,i}\left(\frac{K_{a,w}m^o}{g_w K_{m2}}\right)$$

$$[21] \quad m_{OH,i} = \frac{\left[\sqrt{y_i} - \left(\frac{n_t}{w_{1,i}} - m_{b,i} + \frac{K_{a,w}m^o}{g_w K_{m2}}\right)\right]}{2}$$

$$[22] \quad m_{H,i} = \frac{K_{a,w}(m^o)^2}{g_w m_{OH,i}}$$

$$[23] \quad E_{pred,i} = E_0 + \left(\frac{RT}{F}\right)\ln\left(\frac{m_{H,i}}{m^o}\right)$$

where x_i and o_i are the experimental molalities of hydrogen and hydroxide ions at point i, respectively. The results from the calculations of the titration data of Tables 1–3 are shown in Tables 9 (for ala), 10 (for val), and 11 (for leu).

Determination of the thermodynamic dissociation constants for amino acids and the activity parameters for the amino acid species from the experimental K_{m2} values obtained from titration data

The activity parameter q_{KCl} (= $b_{A,KCl} - b_{HA,KCl}$) and K_{a2} were determined from the new titration data. The experimental K_{m2} values shown in Tables 9–11 were used in these determinations with eq. [12] where, in this case, MCl is KCl. The results from these linear regressions are shown in Table 4.

The K_{a2} estimates from the titration data and from the Harned cell data (see Table 4) for ala and val agree quite well. On the other hand, the K_{a2} estimates for leu do not agree. The K_{a2} value 1.80×10^{-10} was obtained for leu from the data of Smith et al. (14), whereas the K_{a2} value 1.68×10^{-10} resulted from the new titration data. The new potentiometric K_{a2} values are recommended here because of the following arguments: (1) Good agreement was obtained between glass electrode and Harned cell values of K_{a2} for ala and val (see Table 4); (2) the glass electrode data for leu seem to be as reliable as those for ala and val; (3) the glass electrode K_{a2} value for leu was based on eight experimental potentiometric K_{m2} values (each of them was based on 17 titration points) instead of the five K_{m2} values from which the Harned cell value for K_{a2} was estimated (see Table 8). The recommended values are thus 1.29×10^{-10} (ala), 1.89×10^{-10} (val), and 1.68×10^{-10} (leu). The resulting values of q_{KCl} for the three amino acids and their standard deviations are also shown in Table 4.

Discussion

The Hückel parameters recommended above were tested with the titration data presented in Tables 1–3. The recommended K_{m2} values given in Tables 9–11 were used in these tests. Parameter E_0 for eq. [14] was calculated for each data set by using eqs. [20]–[22] and the following equations:

$$[24] \quad E_{0,i} = E_i - \left(\frac{RT}{F}\right)\ln\left(\frac{m_{H,i}}{m^o}\right)$$

[a]Second stoichiometric dissociation constant of leucine determined from the titration data by means of the method described in the text.
[b]Second stoichiometric dissociation constant of leucine calculated by eq. [4] with $K_{a2} = 1.68 \times 10^{-10}$ and with the recommended activity parameters.
[c]Value of the glass electrode parameter E_0 used in the calculation of the errors for Fig. 3. It was determined by requiring that the sum of errors in the data set is zero (i.e., by eqs. [20]–[22], [24], and [25]).

$$[25] \qquad E_0 = \frac{\left(\sum_{i=1}^{N} E_{0,i}\right)}{N}$$

The resulting E_0 values are included in Tables 9–11. The results of the tests are shown as error plots in Figs. 1*a* (ala), 2*a* (val), and 3*a* (leu) where the cpd error defined by

$$[26] \qquad e_E = E(\text{observed}) - E(\text{predicted})$$

is presented for each data set as a function of the added volume of the KOH solution. The error plots in these graphs are random and almost all of the errors are comparable to the resolution of the pH meter (i.e., to 0.1 mV). Therefore, the titration data presented in Tables 1–3 support quite well the calculation method.

From each point of the titrations presented in Tables 1–3, an experimental value of K_{m2} can also be calculated from eqs. [16]–[18] with the E_0 values shown in Tables 9–11. All of these values are compared with the recommended values in Figs. 1*b*, 2*b*, and 3*b*. In these graphs, the pK_m (= –log(K_m)) errors, defined by

$$[27] \qquad e(\text{p}K_{m2}) = \text{p}K_{m2}(\text{observed}) - \text{p}K_{m2}(\text{predicted})$$

are presented as a function of the added volume of the KOH solution. All pK_{m2} errors in Figs. 1*b*, 2*b*, and 3*b* are smaller than ±0.015 and they form a random pattern in almost every data set. The maximum error can also be compared to the conventional pK_m error of 0.06 suggested by Albert and Serjeant (28). These considerations also reveal how valuable the new activity coefficient models are.

The Harned cell data considered above were also compared with the results obtained using recommended models for ala, val, and leu. These data were measured in NaCl solutions, but the recommended values of q_{KCl} must be used for q_{NaCl} in these calculations because of the lack of better values (see Table 4). On the other hand, the solutions used to obtain these data were rather dilute and thus specific interactions between species in those were probably not very important. The predicted K_{m2} values and the pK_{m2} errors defined by eq. [27] are presented in Tables 5–8 as a function

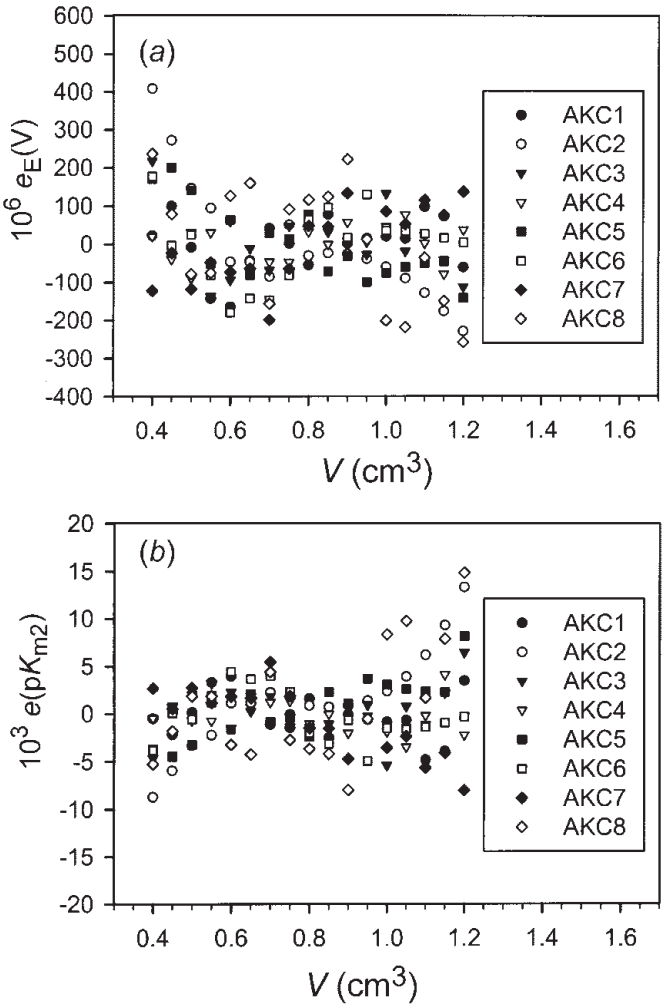
Fig. 1. (*a*) The difference between the observed and predicted cpd values (e_E in eq. [26]), and (*b*) the difference between the observed and predicted pK_{m2} values (e(pK_{m2}) in eq. [27]) as a function of the titrant volume in the titrations of α-alanine with the KOH solution. The predicted cpd for (*a*) was calculated by eqs. [4]–[6], [13], and [14] using the thermodynamic value of 1.29×10^{-10} for the second dissociation constant, the recommended activity parameters, and the value of the glass electrode parameter E_0 shown in Table 9. The observed K_{m2} value for (*b*) was calculated from each titration point by eqs. [5], [6], [16]–[18] with the glass electrode parameter shown in Table 9, and the predicted K_{m2} value was calculated by eq. [4]. Symbols of the different sets are shown in the graphs.



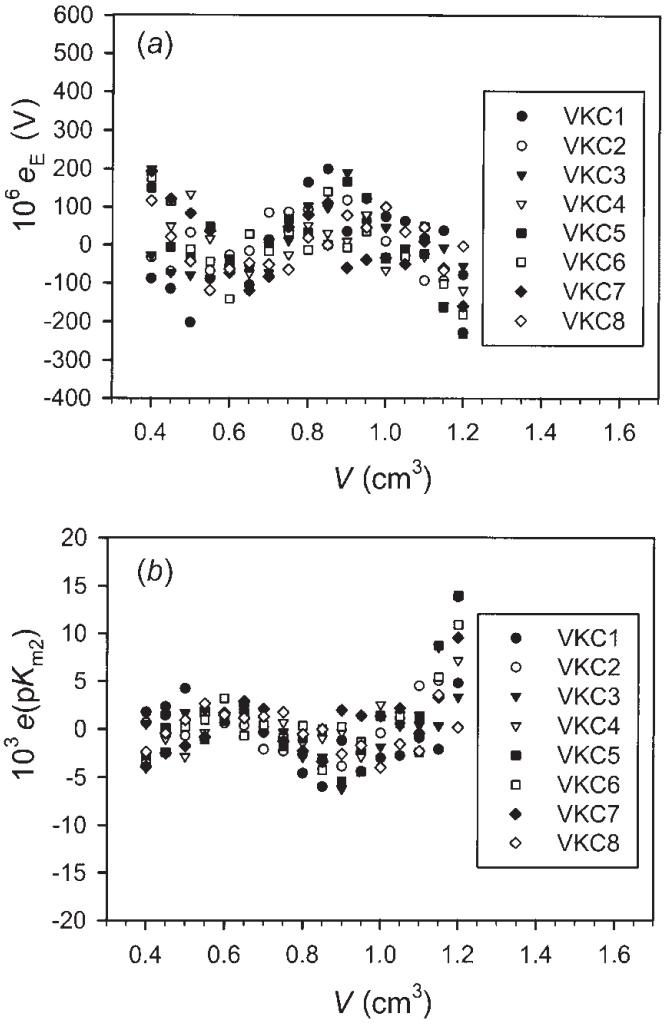


Fig. 2. (*a*) The difference between the observed and predicted cpd values (e_E in eq. [26]), and (*b*) the difference between the observed and predicted pK_{m2} values (e(pK_{m2}) in eq. [27]) as a function of the titrant volume in the titrations of valine with the KOH solution. The predicted cpd for (*a*) was calculated by eqs. [4]–[6], [13], and [14] using the thermodynamic value of 1.89×10^{-10} for the second dissociation constant, the recommended activity parameters, and the value of the glass electrode parameter E_0 shown in Table 10. The observed K_{m2} value for (*b*) was calculated from each titration point by eqs. [5], [6], [16]–[18] with the glass electrode parameter shown in Table 10, and the predicted K_{m2} value was calculated by eq. [4]. Symbols of the different sets are shown in the graphs.

of the ionic strength of the solution. The recommended K_{a2} values were used in these calculations. The errors in these tables also support quite well the new models for ala and val, but not for leu (see Table 8 and the discussion above).

Brandariz et al. (10) have determined K_{m1} and K_{m2} values for val in aq. KCl and KBr solutions at 298.15 K using potentiometric titrations. The experimental K_{m2} values in KCl solutions were tested with the present Hückel model. The results are shown as error plots in Fig. 4. In this figure, the pK_{m2} errors defined by eq. [27] are presented as a function of the ionic strength of the solution. The results in this figure show that the experimental data support only satisfactorily the new model. It can be seen by comparing Figs. 2*b* and 4 that the precision of the data of Brandariz et al. (10) is less than that of the present study. Therefore, it seems that more reliable K_{m2} values are obtained by using the new model.

Table 12 shows the recommended K_{m2} values for ala, val, and leu in aq. KCl solutions at 298.15 K at rounded ionic strengths. These values apply to the case where KCl alone determines the ionic strength of the solution. The K_{m2} values were calculated using eq. [4] with the recommended K_{a2} val-

[a] I_m is the same as m_{KCl} and m^o = 1 mol kg^{-1}.

Fig. 4. The difference (e(pK_{m2}) in eq. [27]) between the pK_{m2} values determined by Brandariz et al. (10) for valine in KCl solutions and those predicted by the recommended Hückel method (i.e., by eq. [4] with $K_{a2} = 1.89 \times 10^{-10}$ and with the recommended activity parameters) as a function of I_m.

ues and with the recommended parameter values shown in Table 4.

In Table 13, we have collected the parameters for the Hückel equations determined previously for the calculation of K_m values of various weak acids in aq. NaCl, KCl, and LiCl solutions at 298.15 K. The new parameter values for alaninate, valinate, and leucinate species in this table are close to the values obtained previously (1) for glycinate species. The present values for the difference of q_{KCl} (= $b_{A,KCl} - b_{HA,KCl}$) are also rather close to the b values of anions resulting from the light aliphatic carboxylic acids in KCl solutions. Therefore, the second stoichiometric dissociation constants of ala, val, and leu depend on the ionic strength in these solutions qualitatively, in the same way as the dissociation constants of aliphatic acids. In dilute solutions, the Debye–Hückel terms in the Hückel equations of ions (see eq. [1]) are dominant, and a strong dependence was observed (see Table 12). At molalities higher than about 0.05 mol kg^{-1}, the influence of these terms decreases and the terms taking into account the specific interactions between

New cycloaddition of diarylazines with 1,2-dehydrobenzene, 1,1,2,2-tetracyanoethylene, and dibenzoylacetylene — Facile synthesis of acridinones, pyrazolidine, and pyridazine derivatives

Ashraf A. Aly and Mohsen A.-M. Gomaa

Abstract: Diarylazines were reacted with 1,2-dehydrobenzene (*o*-benzyne) to give 10-amino-3-substituted-9(10*H*)-acridinones. On the other hand, 1,1,2,2-tetracyanoethylene was reacted with diarylazines through Michael addition to yield 5-arylpyrazolidine-3,3,4,4-tetracarbonitriles. On reacting the same azines with dibenzoylacetylene, pyridazine derivatives were obtained via a Diels–Alder reaction.

Key words: diarylazines, 1,2-dehydrobenzene, tetracyanoethylene, dibenzoylacetylene.

Résumé : Les diarylazines réagissent avec le 1,2-dihydrobenzène (*o*-benzyne) pour conduire à la formation des 10-amino-9(10*H*)-acridones substituées en position 3. Par ailleurs, le 1,1,2,2-tétracyanoéthylène réagit avec les diarylazines par le biais d'une addition de Michael qui conduit à la formation de 5-arylpyrazolidine-3,3,4,4-tétracarbonitriles. Les mêmes azines, par réaction avec le dibenzoylacétylène, conduisent à la formation de dérivés de la pyridazine par le biais d'une réaction de Diels–Alder.

Mots clés : diarylazines, 1,2-dihydrobenzène, tétracyanoéthylène, dibenzoylacétylène.

[Traduit par la Rédaction]

Introduction

The reaction of diarylazines with various dienophiles has been valuable in the field of heterocyclic compounds (1–3). Azines derived from aromatic aldehydes undergo the so-called criss-cross addition with 2 equiv. of the dienophile to yield 1,5-diaza-bicyclo[3,3,0]octane of pyrazole derivatives (2, 3). On the basis that the reactions of azines with dienophiles are found to be susceptible to electronic and steric factors, various types of intramolecular rearrangements have been observed (4–6). Therefore, the chemistry of azines towards various dienophiles still needs more light shed on it because of the abnormality that sometimes accompanies their reactions. In this context, we aim to develop efficient, facile, and elegant syntheses of various heterocycles of biological interest, which basically depend upon cycloaddition reactions (7–11). As an extension of this strategy, we have now explored the chemistry of the aromatic azines towards some dienophiles such as 1,2-dehydrobenzene (*o*-benzyne), 1,1,2,2-tetracyanoethylene, and dibenzoylacetylene, which are known to undergo various types of cycloadditions (12–14).

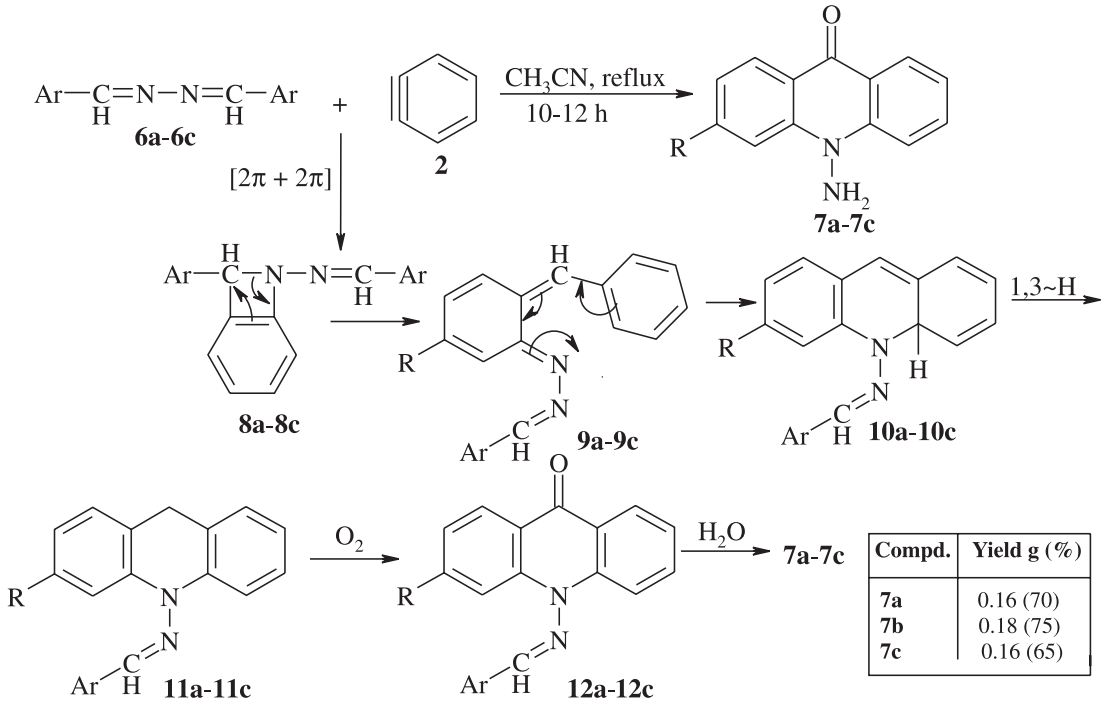
Results and discussion



Some years ago, we examined the reaction of *N*,*N*′-bis-(aryl)-benzene-1,4-diyldimethylidene-diamines (**1a**, **1b**) with 1,2-dehydrobenzene (*o*-benzyne, **2**). The reaction gave 1,4-bis(2′-substituted-acridine-10-yl)benzenes (**3a**, **3b**), 10-(4′-formylphenyl)-2-substituted-acridines (**4a**, **4b**), and *N*-phenyl-arylamines (**5a**, **5b**) (Scheme 1). The reaction mechanism was described via [2π + 2π] cycloaddition between 2 mol of **2** and the azomethine groups in **1a** and **1b** (Scheme 1) (7). The formation of compounds **4a** and **4b** was explained as being due to the hydrolysis of one azomethine during the course of the reaction (Scheme 1) (7). 1,2-Dehydrobenzene (*o*-benzyne, **2**), which was generated by diazotization of 1,2-anthranilic acid, (7, 8, 11, 15) reacted with **6a**–**6c** (16) to afford **7a**–**7c** in yields of 65%–75% (Scheme 2). Mechanistically, the reaction of **2** with imines is undoubtedly based initially upon [2π + 2π] cycloaddition forming a benzazetidine ring (7, 8). Thus, we postulated that cycloaddition occurred between 1 mol of **2** and one azomethine group in **6a**–**6c** to form cycloadducts **8a**–**8c**. The benzazetidines **8a**–**8c** were converted by ring opening into their valence tautomers **9a**–**9c**. Subsequently, ring closure of **9a**–**9c** via electrocyclization, followed by a 1,3-hydrogen shift, would give the dehydroacridines **11a**–**11c**. One can expect that the acridinones **12a**–**12c** were obtained by aerial oxidation of **11a**–**11c**. Presumably, during chromatographic purification, the imine group is hydrolyzed to yield, ultimately, 10-amino-3-substituted-9(10*H*)-acridinones **7a**–**7c** (Scheme 2). It is worthwhile to mention that the reactions of

2 with diarylazines possessing electron-donating substitutents in the arylidene groups (such as **6a** and **6b**) yielded **7a** and **7b** in higher yields than **7c**. NMR spectra as well as COSY H-H and C-H spectral data of compounds **7a**–**7c** supported their structural proof. Additionally, NMR spectra of the isolated compounds **7a**–**7c** were compared with those of the known 3-substituted acridinones (17). Accordingly, some distinctive δ values of the protons and carbons of **7a**–**7c** were easily analyzed. For example, the ^{13}C NMR spectrum of **7a** showed 14 signals; seven signals were attributed to aromatic CH, one signal at higher field was identified as a methyl carbon atom, and six quaternary carbon atoms, one of them resonating downfield at δ = 178.80 was assigned as the carbonyl carbon atom C-9. In the IR spectrum of **7a**, absorptions at 3250 and 1695 cm^{-1} were assigned to the NH_2 and carbonyl groups, respectively. The importance of the

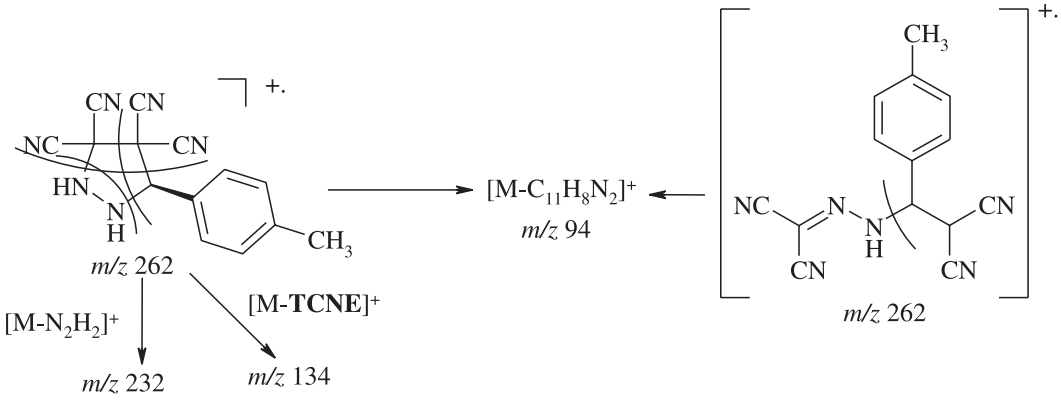
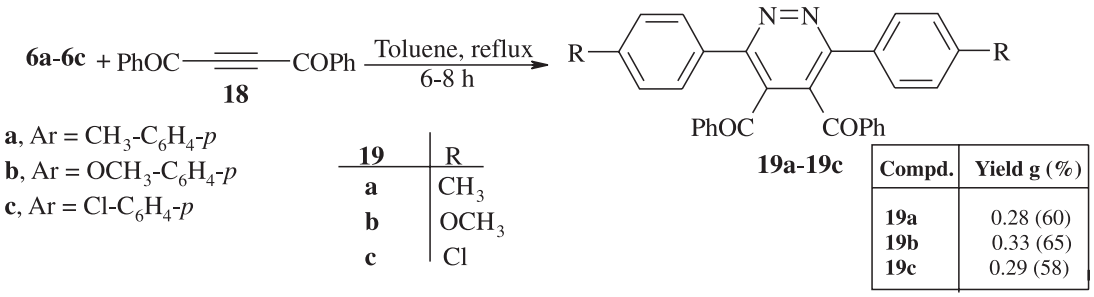
acridines' synthesis comes from their medical and industrial value (17, 18). Moreover, *N*-substituted acridinones have anticancer activity (19). Therefore, work is still directed towards utilization of facile methods such as microwave to synthesize acridine derivatives (20).



Recently, the synthesis of various pyrazolidines has been reported via 1,3-dipolar cycloaddition of azomethine-iminoylidene derivatives (21). However, on reacting **6a–6c** with 1,1,2,2-tetracyanoethylene (TCNE, **13**) in ethyl acetate, we obtained 5-aryl-pyrazolidine-3,3,4,4-tetracarbonitriles **17a–17c** (Scheme 3). Herein, the reaction can be described as being due to Michael addition followed by cyclization to form intermediate iminium ions **15a–15c**. Addition of moisture to **15a–15c** would, therefore, produce **16a–16c** (Scheme 3). Finally, elimination of arylaldehydes from **16a–16c** yielded **17a–17c** (Scheme 3). The structural assignment of **17a–17c** is unequivocally confirmed by mass, IR, ^{1}H NMR, and ^{13}C NMR, as well as elemental analysis. For example, mass spectra and elemental analysis of **17a** established its molecular formula as $C_{14}H_{10}N_6$. Particularly interesting is the ^{1}H NMR spectrum of **17a**, which showed a singlet at δ_H = 4.60 corresponding to H-5. The NH–NH proton signals were superimposed upon the aromatic ones at δ_H = 6.20–6.50. The ^{13}C NMR spectrum of **17a** showed four signals at δ_C = 20.90, 52.00, 54.60, and 60.40, which were assigned to the CH_3 group, C-4, C-3, and C-5, respectively. The ^{13}C DEPT 135/90 spectrum of **17a** showed a signal with a positive amplitude at δ_C = 60.40 confirming the existence of the methine carbon atom C-5. Conclusive evidence for the proposed structure of compounds **17a–17c** was obtained from COSY H-H and C-H experiments. The molecular modeling (MM2) (22) of **17a**, as an example, indicated the presence of its most stable geometric form in which the phenyl group in the same plane of the formed five-member ring as plotted in Scheme 3. Therefore, compounds **17a–17c** were identified as 5-aryl-pyrazolidine-3,3,4,4-tetracarbonitriles.

Earlier reports (23, 24) investigated the fragmentation patterns of 3,3,4,4,5-pentasubstituted pyrazolidines. Similar fragmentation processes were observed in the mass spectroscopy of compounds **17a–17c**. For example, the mass spectrum of **17a** showed a molecular ion at *m*/*z* 262 (Fig. 1). The fragmentation pattern of this compound also includes heterocycle cleavages with loss of $C_{11}H_8N_2^+$ (*m*/*z* = 94), which might indicate the existence of $M^{+\cdot}$ in its linear form. Figure 1 indicates the most expected fragmentation patterns of the mass spectrum in **17a**. For example, the ion peaks at *m*/*z* = 232 and 134 appeared in the mass spectrum of **17a** corresponding to the fragmentation patterns [$M^+ - N_2H_4$] and [M^+ – TCNE], respectively. Fragmentation through the N—N bond cleavage also appears, but less intensely (*m*/*z* 246, Fig. 1).



Surprisingly, reaction of **6a–6c** with dibenzoylacetylene (DBA, **18**) produced pyridazine derivatives **19a–19c** (Scheme 4). Apparently, the reaction between **6a–6c** and **18** occurred via [4π + 2π] cycloaddition followed by aromatization. The symmetrical structure of **19a–19c** was easily deduced from mass and NMR spectra (see Experimental). For example, mass spectroscopy of compound **19a**

showed a strong fragment ion at *m/z* 234 (60%) corresponding to half the molecular weight of this compound. The ^{13}C NMR spectrum of **19a** showed 16 signals, half the number of carbon atoms existing in the molecular formula. The carbonyl group, C-3, and C-4 appeared at δ_C = 190.20, 154.00, and 140.90, respectively (see Experimental). In the case of **19b**, the ^{13}C NMR spectrum revealed five characteristic carbon signals at δ_C = 188.00, 153.90, 148.20, 142.00, and 50.90 corresponding to the carbonyl group, C-3, Ar-C-OMe, C-4, and OCH_3, respectively. The obtained products **19a**–**19c** constitute a new class of pyridazine derivatives. Pyridazines have been reported to have antihypertensive activity (25), in addition to analgesic and anti-inflammatory activities (26).

Experimental

Melting points are uncorrected. NMR spectra were recorded in $CDCl_3$ or DMSO-d_6 on a Bruker AM 400 instrument (400.134 MHz for ^1H, 100.60 MHz for ^{13}C). The chemical shifts (δ) were measured relative to internal TMS. Coupling constants were expressed in Hz. Elemental analyses were performed by the Microanalysis Center of the Institut für Anorganische Chemie, Technische Universität Braunschweig. Mass spectra were obtained on a Finnigan MAT 8430 spectrometer at 70 eV. IR spectra were obtained on a Nicolet 320 FT-IR using KBr pellets. UV spectra were recorded on a Beckman UV 5230 spectrophotometer. For preparative layer chromatography (TLC), glass plates (20 cm × 48 cm) were covered by a slurry of silica gel PF254 (Merck) and air dried.

Reaction of 6a–6c with 2 — Synthesis of 10-amino-3-substituted-acridin-9(10*H*)-ones (7a–7c)

Benzenediazonium carboxylate was prepared by a published procedure (7, 8, 11, 14). Under a nitrogen atmosphere, 2 mmol of **2** precursor was slowly added to the stirred and refluxed solutions of **6a**–**6c** (2 mmol) in dry acetonitrile (250 mL) over 1 h. The reaction mixture was stirred at reflux until the consumption of the starting materials (monitored by TLC) in 10–12 h. The solvent was concentrated and the residue was filtered off. The precipitate was washed with dichloromethane (250 mL). The filtrate was concentrated in vacuum and the residue was separated by PLC using toluene as the eluant. The first migrating zones contained the arylaldehyde derivatives R_f 0.80 (CH_2Cl_2), which were identified by TLC comparison to authentic samples and were isolated in 3%–7% yields. This was followed by the zones containing compounds **7a**–**7c**. All zones were extracted with acetone and the recovered products were recrystallized from the stated solvents.

N-Iodosuccinimide — An effective reagent for regioselective heterocyclization of *o*-cyclohex-2′-enylanilines for the synthesis of hexahydrocarbazoles

K.C. Majumdar, U.K. Kundu, U. Das, N.K. Jana, and B. Roy

Abstract: A number of carbazoles are synthesized in good yields by the *N*-iodosuccinimide mediated heterocyclization of *o*-cyclohex-2′-enylanilines in acetonitrile at –10 °C for 45 min followed by heating with palladium–charcoal (10%) in benzene (80 °C) for 18–20 h.

Key words: N-iodosuccinimide, hexahydrocarbazole, heterocyclization, carbazole, Claisen rearrangement.

Résumé : On a réalisé la synthèse de plusieurs carbazoles avec de bons rendements en faisant appel à une hétérocyclisation, catalysée par le *N*-iodosuccinimide, de *o*-cyclohex-2′-énylanilines, à –10 °C pendant 45 min, suivie par un chauffage avec du palladium sur charbon (10 %), dans le benzène, à 80 °C, pendant une période de 18 à 20 heures.

Mots clés : N-iodosuccinimide, hexahydrocarbazole, hétérocyclisation, carbazole, réarrangement de Claisen.

[Traduit par la Rédaction]

Introduction

There are several reports for the synthesis of carbazoles (1). Carbazole has been synthesized from diphenylamine either by photochemical cyclization (2) or by thermal cyclization (3), and also in the presence of iodine (4) at 350 °C. We have reported the synthesis of 1-alkoxy tetrahydrocarbazoles by the Hg(II)-mediated heterocyclization (5) of *o*-cyclohex-2′-enylanilines. This prompted the evaluation of the efficacy of *N*-iodosuccinimide for the heterocyclization of *o*-cyclohex-2′-enylanilines.

o-Cyclohex-2′-enylanilines **1a**–**1g** were prepared in 50%–90% yields by the acid-catalyzed aza-Claisen rearrangement of 3-*N*-alkyl, *N*-arylamino cyclohexene in refluxing ethanolic hydrochloric acid following the literature procedure (5).

Results and discussion

It was envisaged that heterocyclization of *o*-cyclohex-2′-enylanilines (**1a**–**1g**) would afford hexahydrocarbazoles. Previously, we have successfully utilized pyridinehydrotribromide (6) and hexaminehydrotribromide (7) for the heterocyclization of *o*-cyclohex-2′-enylphenols. However, our attempts at cyclization of *o*-cyclohex-2′-enylanilines with these reagents were of no avail (8). At this point our attention was drawn to *N*-iodosuccinimide, which is reported to effect the cyclization of unsaturated nitrogen-containing substrates. Electron-poor nitrogen species like amides and hydroxylic amines have so far been employed (9) for the preparation of *N*-*p*-toluenesulfonyl-3-hydroxy-4-pentenamides, *N*-protected 3-hydroxy-4-pentenyl-amines, 4-hydroxy-5-hexenylamines, and dialkylsubstituted pyrrolidines and piperidines from hydroxylic amines. Intramolecular cyclization of substrates by electron-poor nitrogen nucleophiles has been accomplished under various reaction conditions. However, there is no report so far on the iodoamination where arylamines have been used as electron-poor nucleophiles with *N*-iodosuccinimide. Therefore, substrate **1a** was stirred with 1 equiv. of *N*-iodosuccinimide in acetonitrile at –10 °C. The reaction was completed in ~45 min to give a viscous oil in 60% yield. This was characterized as 1,2,3,4,4a,9a-hexahydro-1-iodo-9-methylcarbazole (**2a**) from its elemental analysis and spectroscopic data. ^{13}C NMR spectral data and DEPT experiment corroborated the proposed structure for product **2a**. The degree of protonation of the 10 carbons were determined by DEPT experiment, which showed one -CH_3, three -CH_2-, and six >CH-. Substrates **1b**–**1g** were also similarly treated to give products **2b**–**2g** in 55%–70% yield (Scheme 1). It was found that the iodoamines (**2a**–**2g**) are not very stable and on standing decompose to intractable products. The products **2a**–**2e** were dehydrogenated with palladium-charcoal (10%) in refluxing benzene for 18–20 h to give corresponding carbazoles **3a**–**3e** in 60%–65% yield (10–13). These were characterized as substituted 9-methylcarbazoles (**3**) from their elemental analyses and spectroscopic data. The products **2f** and **2g** were similarly treated with 5% palladium–charcoal to give products **4f** and **4g** in 60% and 62% yield, respectively, contaminated with minor amounts of fully aromatized products. These minor products could not be isolated in pure form. The products (**4f** and **4g**) were characterized as 1,2,3,4-tetra-

hydrocarbazoles from their elemental analyses and spectroscopic data (Scheme 2).

The regioselective formation of hexahydrocarbazoles **2a**–**2g** from substrates **1a**–**1g** may be easily explained by the initial formation of an intermediate iodonium ion (**5a**–**5g**), which may undergo a "5-*exo*" cyclization to give products **2a**–**2g**. An alternative "6-*endo*" cyclization to give bicyclic products is ruled out as no such product could be isolated from the reaction mixture (Scheme 3).

The relative stereochemistry of the product could not be determined from the observed coupling constants of protons (C4a-*H*, C9a-*H*, and C1-*H*) alone. However, we could assign

© 2005 NRC Canada

Fig. 1. Stereostructure of compound **2**.

the stereochemistry of the product by considering the mechanism of the reaction. As the product **2a** is formed via an iodonium intermediate, the N9—C9a and C1—I bonds in **2a** are antiperiplanar. Again, Pd-C-catalyzed dehydrogenation occurs via cis-elimination. Therefore, the C9a—*H* and C1—I bonds are expected to be cis. C4a-*H* is suggested to be axial because shifting of the double bond is facilitated by the axial hydrogen. Hence, C9a-*H* and C4a-*H* should be trans (J = 6.5 Hz because of the presence of nitrogen heteroatom). The iodine atom and N-R groups are bulky and likely to occupy equatorial positions (Fig. 1). The same heterocyclization was attempted with *N*-bromosuccinimide without any success, while pyridine hydrotribromide and hexamine hydrotribromide afforded the addition products along with ring-brominated products, and there also, no cyclization was observed (8). *N*-Iodosuccinimide is a mild reagent and reacts at low temperature bringing about regioselective heterocyclization of *o*-cyclohex-2′-enylanilines to give hexahydrocarbazoles. For the cases where pyridine hydrotribromide and hexamine hydrotribromide afforded bicyclic products, cyclizations occurred by a 6-*endo* mode. In contrast, *N*-iodosuccinimide gave linear hexahydrocarbazoles by a 5-*exo* cyclization. Recently, we reported the formation of bicylic heterocycles by *N*-iodosuccinimide-mediated reactions in cases of 2-cyclohex-2′-enyl phenols (14) and 3-cyclohex-2′-enyl-4-hydroxy coumarins (15). 2-(Cyclopent-2′-enyl)anilines have recently been cyclized using iodine (16) in the presence of $NaHCO_3$. Synthesis of tetrahydrocarbazoles by Ullmann cross coupling of *o*-halonitrobenzene and various related nitrobenzenes with a range of α-halo cyclohexenones followed by reaction with hydrogen in the presence of Pd on C has also been recently reported (17). The present work clearly demonstrates the viability of *N*-iodosuccinimide as an effective reagent for regioselective heterocyclization of *o*-allylanilines. In the cases of cyclization of electron-poor nitrogen species like amides and hydroxylic amines, different types of stereoisomers were obtained (9). However, in the present study only one type of regioselective product was obtained. Therefore, this is an effective reagent for the synthesis of hexahydrocarbazoles. We have, therefore, successfully demonstrated the use of aryl amines as electron-poor nucleophiles in the *N*-iodosuccinimide-mediated iodoaminations for the first time.

Experimental

Melting points were determined in an open capillary and are uncorrected. UV absorption spectra were recorded in EtOH on a Shimadzu UV-2401 PC spectrophotometer (λ_{max} in nm), and IR spectra were obtained on a PerkinElmer L 120-000A grating IR spectrophotometer and the frequency reported in cm^{-1}. ^1H NMR (300 MHz) and ^{13}C NMR (75.5 MHz) spectra were recorded in $CDCl_3$ (TMS was used as an internal standard) on a Bruker DPX-300 instrument at the Indian Institute of Chemical Biology, Kolkata, India (chemical shifts in δ ppm). Elemental analyses and recording of mass spectra were carried out by RSIC (CDRI) Lucknow on a JEOL D-300 (El) instrument. Silica gel (60–120 mesh, Spectrochem, India) was used for chromatographic separation. Petroleum ether refers to the fraction boiling between 40 and 60 °C. Palladium on activated charcoal (5% and 10%) was procured from S.D. Fine Chemicals Ltd. (India) and Loba Chemie, respectively.

General procedure for the synthesis of compounds 2a–2g

A solution of compound **1** (**1a**–**1g**) (1 mmol) in dry CH_3CN (50 mL) was stirred at –10 °C with *N*-iodosuccinimide (0.23 g, 1 mmol) for 45 min. The solvent was removed under reduced pressure at room temperature. The residual mass was dissolved in $CHCl_3$ (50 mL). The $CHCl_3$ was washed with a saturated solution of $NaHSO_3$ (2 × 25mL), water (2 × 25 mL), and dried (Na_2SO_4). A gummy residue was obtained after evaporation of the solvent. This was purified by column chromatography over silica gel. Elution of the column with petroleum ether (40–60 °C) gave compounds **2a**–**2g** as viscous oils.

Compound 2a

Viscous oil; yield 60%. UV (EtOH, nm) λ_{max}: 217, 265, 303. IR (neat, cm^{-1}) ν_{max}: 530, 1260, 1500, 1590, 2940, 3120. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.73–1.89 (m, 4H), 1.97–2.01 (m, 2H), 2.75 (s, 3H, N-*Me*), 3.29 (dt, J = 6.5, 11.4 Hz, 1H, ArC*H*), 3.57 (dd, J = 6.5, 2.5 Hz, 1H, -NC*H*), 4.86 (d, J = 2.5 Hz, 1H, -C*H*I), 6.40–6.43 (m, 1H, Ar*H*), 7.14–7.21 (m, 2H, Ar*H*). ^{13}C NMR ($CDCl_3$, 75.5 MHz) δ: at 21.24 (C3), 29.89 (C4), 30.83 (C1), 31.28 (C2), 35.19 (>N*C*H_3), 38.57 (C4a), 74.30 (C9a), 110.82 (C8), 126.37 (C5), 130.49 (C7), 137.03 (C6), 138.12 (C4b), and 148.03 (C8a). MS *m*/*z*: 391, 393 (M^+, M^+ + 2). Anal. calcd. for $C_{13}H_{15}BrIN$ (%): C 39.79, H 3.82, N 3.57; found: C 39.95, H 3.72, N 3.43.

Compound 2b

Viscous oil; yield 67%. UV (EtOH, nm) λ_{max}: 217, 264, 303. IR (neat, cm^{-1}) ν_{max}: 555, 1266, 1506, 1615, 2929, 3132. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.15 (t, J = 7.5 Hz, 3H), 1.28–1.89 (m, 4H), 2.28–2.33 (m, 2H), 2.46 (q, J = 7.5 Hz, 2H), 2.88 (s, 3H, N-*Me*), 3.29 (brs, 1H, -NC*H*), 3.83 (brs, 1H, ArC*H*), 4.84 (brs, 1H, -C*H*I), 6.43 (d, J = 8.7 Hz, 1H, Ar*H*), 6.67–7.22 (m, 2H, Ar*H*). MS *m*/*z*: 341 (M^+). Anal. calcd. for $C_{15}H_{20}IN$ (%): C 52.78, H 5.86, N 4.10; found: C 52.68, H 5.79, N 4.15.

Compound 2c

Viscous oil; yield 65%. UV (EtOH, nm) λ_{max}: 217, 264, 303. IR (neat, cm^{-1}) ν_{max}: 550, 1260, 1500, 1610, 2921, 3130. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.22–1.91 (m, 4H), 2.20 (s, 3H), 2.24–2.38 (m, 2H), 2.88 (s, 3H, N-*Me*), 3.05 (brs, 1H, -NC*H*), 3.48 (brs, 1H, ArC*H*), 4.83 (brs, 1H, -C*H*I), 6.42 (d, J = 8.7 Hz, 1H, Ar*H*) 6.65–6.93 (m, 2H,

Ar*H*). MS *m*/*z*: 327 (M^+). Anal. calcd. for $C_{14}H_{18}IN$ (%): C 51.37, H 5.50, N 4.28; found: C 51.29, H 5.48, N 4.32.

Compound 2d

Viscous oil; yield 58%. UV (EtOH, nm) λ_{max}: 218, 265, 304. IR (neat, cm^{-1}) ν_{max}: 590, 1261, 1470, 1600, 2924, 3132. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.28–2.00 (m, 4H), 2.20–2.50 (m, 2H), 2.88 (s, 3H, N-*Me*), 3.04 (brs, 1H, -NC*H*), 3.49 (brs, 1H, ArC*H*), 4.75 (brs, 1H, -C*H*I), 6.39 (d, *J* = 8.7 Hz, 1H, Ar*H*), 6.80–7.03 (m, 2H, Ar*H*). MS *m*/*z*: 347, 349 (M^+, $M^+ + 2$). Anal. calcd. for $C_{13}H_{15}ClIN$ (%): C 44.89, H 4.31, N 4.02; found: C 44.78, H 4.29, N 4.12.

Compound 2e

Viscous oil; yield 55%. UV (EtOH, nm) λ_{max}: 218, 264, 303. IR (neat, cm^{-1}) ν_{max}: 560, 1260, 1470, 1630, 2920, 3130. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.26–2.01 (m, 4H), 2.23–2.49 (m, 2H), 2.87 (s, 3H, N-*Me*), 3.08 (brs, 1H, -NC*H*), 3.42 (brs, 1H, ArC*H*), 4.76 (brs, 1H, -C*H*I), 6.53–7.49 (m, 4H, Ar*H*). MS *m*/*z*: 313 (M^+). Anal. calcd. for $C_{13}H_{16}IN$ (%): C 49.84, H 5.11, N 4.47; found: C 49.83, H 5.08, N 4.52.

Compound 2f

Viscous oil; yield 70%. UV (EtOH, nm) λ_{max}: 217, 264, 304. IR (neat, cm^{-1}) ν_{max}: 550, 1250, 1500, 1610, 2920, 3110. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.14–1.19 (m, 3H), 1.30–1.89 (m, 4H), 2.30–2.34 (m, 2H), 2.98 (brs, 1H, -NC*H*), 3.05–3.42 (m, 2H), 3.52 (brs, 1H, ArC*H*), 4.75 (brs, 1H, -C*H*I), 6.50–7.09 (m, 4H, Ar*H*). MS *m*/*z*: 327 (M^+). Anal. calcd. for $C_{14}H_{18}IN$ (%): C 51.37, H 5.50, N 4.28; found: C 51.28, H 5.43, N 4.32.

Compound 2g

Viscous oil; yield 63%. UV (EtOH, nm) λ_{max}: 217, 265, 303. IR (neat, cm^{-1}) ν_{max}: 560, 1260, 1490, 1590, 2930, 3100. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.13–1.17 (m, 3H), 1.28–1.80 (m, 4H), 2.26–2.40 (m, 2H), 2.99 (brs, 1H, -NC*H*), 3.14–3.36 (m, 2H), 3.51 (brs, 1H, ArC*H*), 4.65 (brs, 1H, -C*H*I), 6.30 (d, *J* = 8.7 Hz, 1H, Ar*H*), 7.09–7.31 (m, 2H, Ar*H*). MS *m*/*z*: 361, 363 (M^+, $M^+ + 2$). Anal. calcd. for $C_{14}H_{17}ClIN$ (%): C 46.47, H 4.70, N 3.87; found: C 46.52, H 4.68, N 3.79.

General procedure for the synthesis of compounds 3a–3e and 4f and 4g

Compound **2** (**2a**–**2e**, 0.2 g) was refluxed with 10% palladium on charcoal (0.02 g), and in the case of compounds **2f** and **2g**, 5% palladium on charcoal was used in benzene (20 mL) for 18–20 h. The mixture was filtered and benzene was distilled off. The residual mass was directly chromatographed over silica gel. Elution of the column with petroleum ether (40–60 °C) gave the compounds **3a**–**3e** and **4f** and **4g.** The solid compounds were recrystallized from ethanol.

Compound 3a

White crystalline solid, mp 76 to 77 °C (lit. value (10) mp 78 to 79 °C); yield 63%. UV (EtOH, nm) λ_{max}: 222, 265, 297. IR (KBr, cm^{-1}) ν_{max}: 1246, 1493, 1605, 2925, 3134. ^1H NMR ($CDCl_3$, 300 MHz) δ: 3.86 (s, 3H, N-*Me*), 7.71–7.48 (m, 4H, Ar*H*), 7.50–8.11 (m, 3H, Ar*H*). MS *m*/*z*: 259, 261 (M^+, $M^+ + 2$). Anal. calcd. for $C_{13}H_{10}BrN$ (%): C 60.00, H 3.84, N 5.38; found: C 60.11, H 3.76, N 5.32.

Compound 3b

Viscous oil; yield 60%. UV (EtOH, nm) λ_{max}: 222, 265, 297. IR (neat, cm^{-1}) ν_{max}: 1247, 1488, 1605, 2926, 3133. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.31 (t, *J* = 7.5 Hz, 3H), 2.79 (q, *J* = 7.5 Hz, 2H), 3.88 (s, 3H, N-*Me*), 7.17–7.47 (m, 5H, Ar*H*), 7.91–8.08 (m, 2H, Ar*H*). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: at 17.03 (C12), 29.37 (C11), 29.50 (>NCH_3), 108.60 (C1), 108.75 (C8), 118.95 (C6), 119.47 (C5), 120.61 (C2), 123.10 (C4a), 123.25 (C4b), 125.86 (C7), 126.37 (C4), 135.29 (C3), 139.91 (C9a), and 141.66 (C8a). MS *m*/*z*: 209 (M^+). Anal. calcd. for $C_{15}H_{15}N$ (%): C 86.12, H 7.17, N 6.69; found: C 86.22, H 7.11, N 6.60.

Compound 3c

Pale yellow crystalline solid, mp 81 to 82 °C (lit. value (11) mp 84 °C); yield 61%. UV (EtOH, nm) λ_{max}: 222, 265, 297. IR (KBr, cm^{-1}) ν_{max}: 1264, 1494, 1590, 2931, 3134. ^1H NMR ($CDCl_3$, 300 MHz) δ: 2.53 (s, 3H, ArCH_3), 3.83 (s, 3H, N-*Me*), 7.17–7.47 (m, 5H, Ar*H*), 7.89–8.07 (m, 2H, Ar*H*). MS *m*/*z*: 195 (M^+). Anal. calcd. for $C_{14}H_{13}N$ (%): C 86.15, H, 6.66, N 7.17; found: C 86.31, H 6.59, N 7.23.

Compound 3d

Pale yellow crystalline solid, mp 38–40 °C (lit. value (12) mp 38–40 °C); yield 55%. UV (EtOH, nm) λ_{max}: 221, 266, 297. IR (KBr, cm^{-1}) ν_{max}: 1246, 1474, 1596, 2939, 3130. ^1H NMR ($CDCl_3$, 300 MHz) δ: 3.84 (s, 3H, N-*Me*), 7.22–7.44 (m, 4H, Ar*H*), 7.47–8.05 (m, 3H, Ar*H*). MS *m*/*z*: 215, 217 (M^+, $M^+ + 2$). Anal. calcd. for $C_{13}H_{10}ClN$ (%): C 72.38, H 4.64, N 6.49; found: C 72.29, H 4.61, N 6.42.

Compound 3e

Pale yellow crystalline solid, mp 83 to 84 °C (lit. value (13) mp 85 °C); yield 65%. UV (EtOH, nm) λ_{max}: 222, 265, 297. IR (KBr, cm^{-1}) ν_{max}: 1245, 1468, 1600, 2926, 3133. ^1H NMR ($CDCl_3$, 300 MHz) δ: 3.86 (s, 3H, N-*Me*), 7.20–7.46 (m, 4H, Ar*H*), 7.48–8.11 (m, 4H, Ar*H*). MS *m*/*z*: 181 (M^+); Anal. calcd. for $C_{13}H_{11}N$ (%): C 86.18, H 6.07, N 7.73; found: C 86.12, H 6.11, N 7.68.

Compound 4f

Viscous oil; yield 60%. UV (EtOH, nm) λ_{max}: 229, 263, 293. IR (neat, cm^{-1}) ν_{max}: 1231, 1484, 1598, 2928, 3053. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.40–1.45 (m, 3H), 1.54–1.93 (m, 4H), 2.70–2.72 (m, 2H), 4.02–4.09 (m, 2H), 4.33–4.40 (m, 2H), 7.02–8.11 (m, 4H, Ar*H*). MS *m*/*z*: 199 (M^+). Anal. calcd. for $C_{14}H_{17}N$ (%): C 84.42, H 8.54, N 7.03; found: C 84.48, H 8.48, N 7.12.

Compound 4g

Viscous oil; yield 62%. UV (EtOH, nm) λ_{max}: 221, 265, 293. IR (neat, cm^{-1}) ν_{max}: 1231, 1485, 1599, 2928, 3052. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.41–1.45 (m, 3H), 1.60–2.02 (m, 4H), 2.71–2.74 (m, 2H), 4.03–4.13 (m, 2H, =CCH_2), 4.23–4.41 (m, 2H), 7.05–8.11 (m, 3H, Ar*H*). MS *m*/*z*: 233, 235 (M^+, $M^+ + 2$). Anal. calcd. for $C_{14}H_{16}ClN$ (%): C 71.94, H 6.85, N 5.99; found: C 71.83, H 6.87, N 5.23.

The 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid keto–enol system in aqueous solution — Generation of the enol by flash photolytic Wolff rearrangement of 2-diazo-4,4,6,6-tetramethylcyclohexane-1,3-dione followed by hydration of the acylketene thus formed

Y. Chiang, A.J. Kresge, V.A. Nikolaev, I. Onyido, and X. Zeng

Abstract: Flash photolysis of 2-diazo-4,4,6,6-tetramethylcyclohexane-1,3-dione in aqueous solution produced 2-oxo-3,3,5,5-tetramethylcyclopentylideneketene, which underwent hydration to the enol of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid; the enol then isomerized to the keto form of the acid. Rates of hydration of the ketene and rates of ketonization of the enol were measured in perchloric acid, sodium hydroxide, and buffer solutions, and rate profiles were constructed. Rates of enolization of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboyxlic acid were also measured, using bromine to scavenge the enol as it formed, and rates of enolization and ketonization were then combined to give the keto–enol equilibrium constant $pK_E = 1.65$. This and other results are discussed in comparison with the behavior of the unmethylated 2-oxocyclopentanecarboxylic acid system.

Key words: flash photolysis, photo-Wolff reaction, ketene hydration, enolization, ketonization, keto–enol equilibria, β-oxocarboxylic acids.

Résumé : La photolyse éclair de la 2-diazo-4,4,6,6-tétraméthylcyclohexane-1,3-dione en solution aqueuse conduit à la formation du 2-oxo-3,3,5,5-tétraméthylcyclopentylidènecétène qui subit ensuite une hydratation conduisant à l'énol de l'acide 2-oxo-3,3,5,5-tétraméthylcyclopentanecarboxylique qui se transforme éventuellement en forme cétonique de l'acide. On a mesuré les vitesses d'hydratation du cétène et les vitesses de cétonisation de l'énol dans des solutions d'acide perchlorique, d'hydroxyde de sodium et de tampons et on a construit des profils de vitesse. On a aussi mesuré les vitesses d'énolisation de l'acide 2-oxo-3,3,5,5-tétraméthylcyclopentanecarboxylique à l'aide de brome pour piéger l'énol qui se forme; ensuite on a combiné les vitesses d'énolisation et de cétonisation pour calculer la constante d'équilibre céto–énolique, $pK_E = 1{,}65$. On discute de ce résultat et d'autres en comparaison avec le comportement du système l'acide 2-oxocyclopentanecarboxylique non méthylé.

Mots clés : photolyse éclair, réaction de photo-Wolff, hydratation d'un cétène, énolisation, cétonisation, équilibre céto–énolique, acides β-oxocarboxyliques.

Introduction

Keto–enol tautomerizm of β-ketoesters has been investigated for more than a century and about which there is consequently an impressively large body of information.[2] In striking contrast to this, comparatively little is known about keto–enol tautomerizm of the parent keto acids themselves. In an effort to rectify this imbalanced situation, we have examined keto–enol tautomerizm of acetoacetic acid (**1**) (3), 2-oxocyclopentanecarboxylic acid (**2**) (4), trifluoroacetoacetic acid (**3**) (5), and 2-oxo-cyclohexanecarboxylic acid (**4**) (6). We now add to that a study of keto–enol tautomerizm of 2-oxo-3,3,5,5-teteramethylcyclopentane carboxylic acid (**5**).

We generated the enol of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid (**8**) by hydration of 2-oxo-3,3,5,5-tetramethylcyclopentylideneketene (**7**), itself produced by flash photolytic photo-Wolff reaction of 2-diazo-4,4,6,6-tetramethylcyclohexane-1,3-dione (**6**), as shown in eq. [1]. We were able to observe both the enol and the preceeding ketene as short-lived transient species, and we consequently

could study the chemistry of both. Our results provide some interesting comparisons with the behavior of the unmethylated 2-oxocyclopentanecarboxylic acid keto–enol system.

β-Ketocarboxylic acids such as that investigated here can, at least in principle, form two isomeric enols: a ketone enol and a carboxylic acid enol. High level ab initio calculations show, however, that the ketone enol is the more stable isomer by a considerable margin (7), and this is consistent with the much greater enol content of simple ketones than that of simple carboxylic acids, i.e., pK_E = 8.3 for acetone (8) vs. the reliable estimate pK_E = 20 for acetic acid (9). The enol studied here was consequently a ketone enol, as shown in eq. [1].

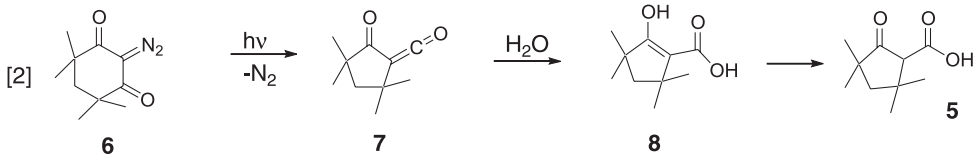
Experimental section

Materials

2-Diazo-4,4,6,6-tetramethylcyclohexane-1,3-dione (**6**) was prepared by diazo group transfer from *p*-toluenesulfonyl azide to 4,4,6,6-tetramethylcyclohexane-1,3-dione (10), and 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid (**5**) was prepared by the photo-Wolff reaction of this diazo compound in the presence of water (11). All other materials were best available commercial grades.

Kinetics, ketone enolization

Rates of enolization of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid were measured under first-order conditions by bromine scavenging of the enol as it formed, with an excess of bromine over ketone substrate. Determinations were made in aqueous hydrobromic acid solutions and acetic acid buffers using sodium bromide to maintain a constant ionic strength (0.10 mol L^{-1}). At the concentrations employed, bromine existed largely as the tribromide ion, and reactions were followed by monitoring the absorbance of this ion at λ = 330 nm. Measurements were made using either a Cary 2200 spectrometer, with ketone substrate concentration = 5 × 10^{-5} mol L^{-1} or a Hi-Tech SF-51 stopped-flow system, with substrate concentration = 1 × 10^{-4} mol L^{-1}. In both cases, the temperature of the reacting solutions was controlled at 25.1 ± 0.05 °C. The data obtained using the stopped-flow system conformed to the first-order rate law well, and observed first-order rate constants were determined by least-squares fitting of a single exponential function. In the slower runs monitored with the Cary spectrometer, on the other hand, an exponential absorbance drop was followed by a considerably slower downward drift;[3] these data conformed well to a single exponential plus linear expression, and observed first-order rate constants were obtained by fitting of such a function.

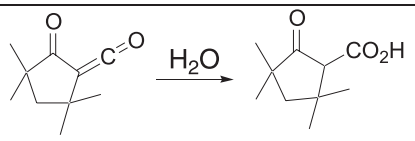


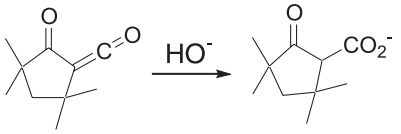
Kinetics, ketene hydration, and enol ketonization

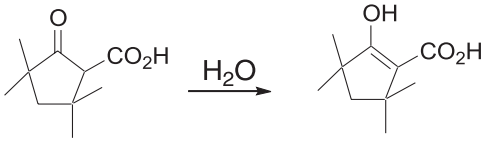
Rates of hydration of 2-oxo-3,3,5,5-tetramethylcyclopentylideneketene were measured using a nanosecond laser flash photolysis system, operating at λ = 248 nm that has already been described (14), and rates of ketonization of 2-oxo-3,3,6,6-tetramethylcyclopentanecarboxylic acid enol were measured using a microsecond flash lamp system that has also already been described (15). Substrate concentrations were in the range (3–10) × 10^{-5} mol L^{-1}, and the temperature of all reacting solutions was maintained at 25.0 ± 0.1 °C. The data obtained conformed to the first-order rate law well, and observed first-order rate constants were determined by least-squares fitting of a single exponential function.

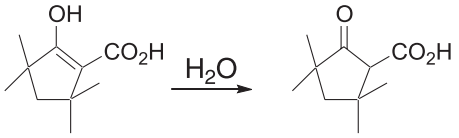
Results and discussion

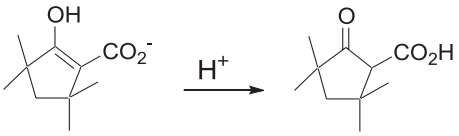
Reaction identification

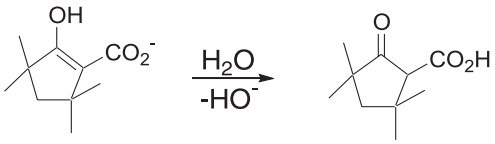


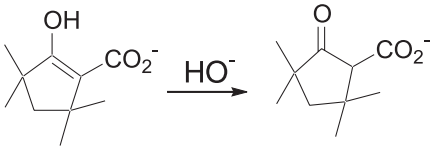


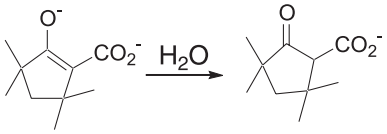


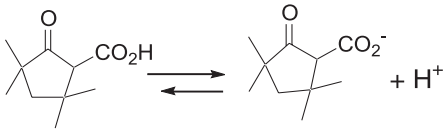


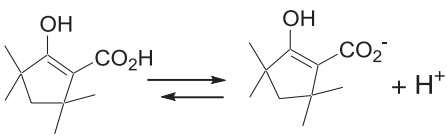












It was already known (11) that irradiation of 2-diazo-4,4,6–6-tetramethylcyclohexane-1,3-dione (**6**) with UV light gave a photo-Wolff rearrangement producing 2-oxo-3,3,5–5-tetramethylcyclopentylideneketene (**7**), which, in the presence of water, underwent rapid hydration to the enol of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid (**8**); ketonization of this enol then furnished 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid itself (**5**) as the final

[3] Such consumption of additional amounts of halogen in enolization reaction studies has been observed before (4, 12) and has been attributed to subsequent hydrolysis and oxidation reactions of the initial halogenated products (12*a*); in the case of β-keto acids, such as the present substrate, decarboxylation followed by additional rapid halogenation is also known to occur (13).

reaction product (eq. [2]). We had observed analogous sequences of reactions before in previous flash photolytic studies of 2-diazo-1,3-diketones (3–6), where they appeared as a rapid microsecond absorbance rise in the region λ = 250–300 nm, attributable to ketene hydration, followed by a much slower millisecond decay of this absorbance, attributable to enol ketonization. Similar absorbance changes were observed in the present study. That and the chemistry provided by these absorbance changes, plus the known occurrence of the reactions of eq. [2], established the processes that we were monitoring as the hydration of 2-oxo-3,3,5–5-tetramethylcyclopentylideneketene (**7**), and the ketonization of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid enol (**8**).

Ketene hydration

Rates of hydration of 2-oxo-3,3,5,5-tetramethylcyclopentylideneketene were measured in aqueous perchloric acid and sodium hydroxide solutions and in acetic acid, biphosphate ion, and tris(hydroxymethyl)methylammonium ion buffers. The ionic strength of these solutions was maintained at 0.10 mol L^{-1}, except for four sodium hydroxide concentrations in the range 0.2–0.5 mol L^{-1} where ionic strength = [NaOH]: hydroxide ion catalysis of this reaction was weak, and measurements at hydroxide ion concentrations above 0.10 mol L^{-1} were required to obtain reliable values of the hydroxide ion catalytic coefficient. These data are summarized in Tables S1–S3.[4]

The measurements in buffers were made in a series of solutions of constant buffer ratio, and therefore constant hydronium ion concentration, but varying total buffer concentration. The data were analyzed by linear least-squares fitting of the buffer dilution expression shown as eq. [3]. Buffer catalysis proved to be either weak or

$$[3] \qquad k_{obs} = k_{int} + k_{buff}[\text{buffer}]$$

nonexistant, and buffer catalytic coefficients (k_{buff}) were not well-determined. This is typical of ketene reactions in the buffers employed, inasmuch as the buffer bases react as nucleophiles and the nucleophilic strength of the present buffer bases is weak (16). The zero-buffer-concentration intercepts (k_{int}), on the other hand, were accurately fixed. These, plus the rate constants determined in perchloric acid and sodium hydroxide solutions, are displayed as the upper rate profile of Fig. 1. Hydronium ion concentrations (written here as $[H^+]$) of the buffer solutions needed for this purpose were obtained by calculation using acidity constants of the buffer acids from the literature and activity coefficients recommended by Bates (17).

The present rate profile is typical of ketene hydrations, which generally show long uncatalyzed portions, weak hydroxide ion catalysis, and weak or nonexistant hydronium

[4]Tables of rate data (Tables S1–S10) may be purchased from the Depository of Unpublished data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A OS2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically).

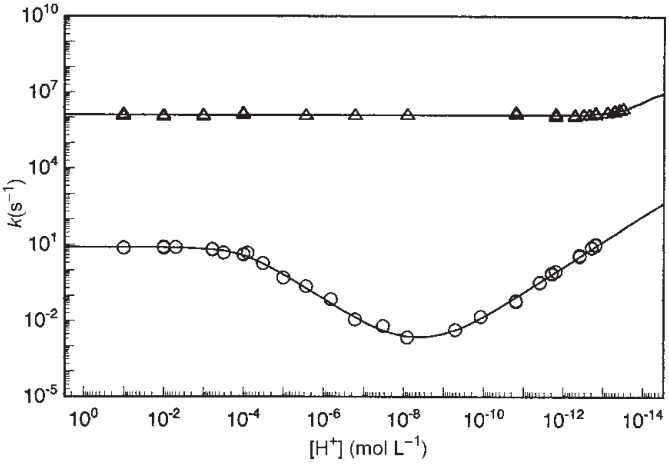
ion catalysis (18). The rate law that applies in the present case is shown as eq. [4],

$$[4] \qquad k_{obs} = k_o + k_{HO}[HO^-]$$

and least-squares fitting of this expression gave $k_o = (1.34 \pm 0.01) \times 10^6$ s^{-1} and $k_{HO} = (2.06 \pm 0.113) \times 10^6$ M^{-1} s^{-1} (Table 1).

Enol ketonization



Rates of ketonization of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid enol were measured in aqueous perchloric acid and sodium hydroxide solutions and also in formic acid, acetic acid, biphosphate ion, tris(hydroxymethyl)methylammonium ion, ammonium ion, and bicarbonate ion buffers. The ionic strength of these solutions was maintained at 0.10 mol L^{-1}. The data are summarized in Tables S4–S6.[4]

The measurements in buffers were once again done in a series of solutions of constant buffer ratio, and therefore constant hydronium ion concentration, but varying total buffer concentration, and the data were analyzed by least-squares fitting of the buffer dilution expression of eq. [3]. Buffer catalysis was now strong, which is typical of enol ketonization reactions where buffers serve as proton transfer reagents. The zero-buffer-concentration intercepts together with the rate constants measured in perchloric acid and sodium hydroxide solutions are displayed as the lower rate profile shown in Fig. 1.

This rate profile is characteristic of enol ketonizations and may be understood in terms of the accepted mechanism for this reaction, which involves rate-determining β-carbon protonation of enol or enolate ion by any available acid (19). Because this profile refers to solvent-related species, the protonating acid will be either the hydronium ion or a water molecule. Since ketonization is an electrophilic addition reaction, successively ionized forms of the enol will be more reactive than their precursors, and ketonization will take place through them even when they are relatively minor substrate species.

Over the acidity range represented by the present rate profiles, the enol will react through either its monoanionic or dianionic form, as shown in eq. [5]. This produces a horizontal uncatalyzed rate profile segment at the high acidity end, where ketonization is through carbon protonation of the enol carboxylate ion by H$^+$ while un-ionized enol is still the major substrate species. Such a reaction produces H$^+$ in the rapidly established pre-equilibrium step and then uses it up in the rate-determining step, giving an overall process independent of H$^+$ concentration.

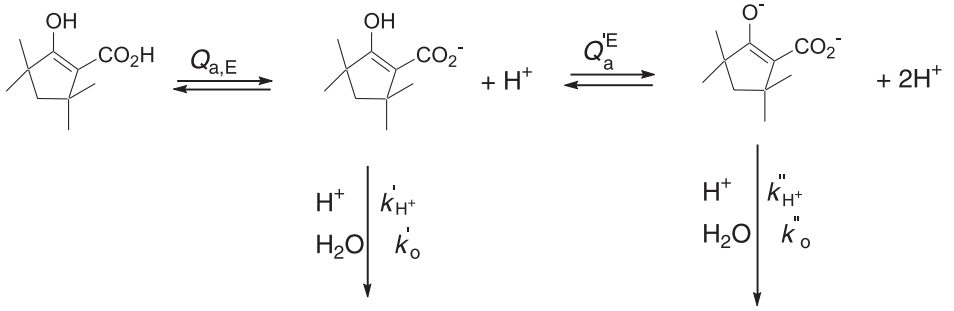


Fig. 1. Rate profiles for the hydration of 2-oxo-3,3,5,5-tetramethylcyclopentylideneketene (Δ) and the ketonization of 2-oxo-3,3,5,5-tetramethylcyclo-pentanecarboxylic acid enol (O) in aqueous solution at 25 °C.

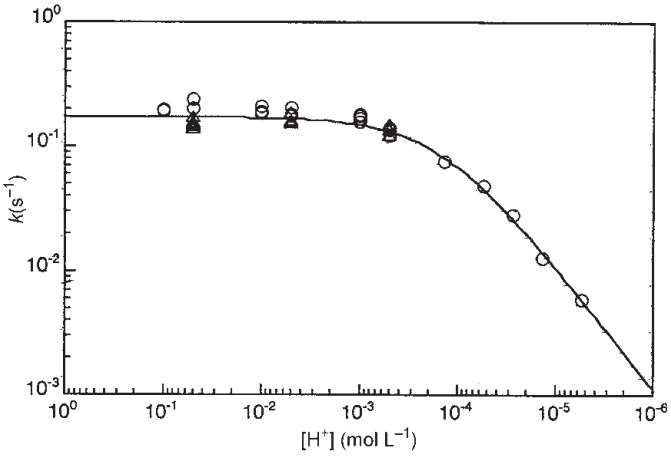
As the acidity drops this uncatalyzed ketonization gives way to a reaction where H$^+$ is still the protonating agent, but now the enol exits mainly in its carboxylate ion form. This produces a downward bend in the profile, corresponding to the carboxylic acid group ionization constant $Q_{a,E}$, and leading to a diagonal acid-catalyzed segment of slope = –1. At sufficiently low acidity, this acid catalysis gives way to a narrow second horizontal plateau, whose origin is sometimes uncertain, as discussed below. Beyond this plateau, ketonization takes place through the dianionic form of the enol while its monoanion is still the dominant substrate form, with water as the carbon-protonating agent. This gives a pre-equilibrium that produces H$^+$, but the latter is now not used up in the rate-determining step; this produces a process whose rate is inversely proportional to H$^+$ concentration and has the appearance of hydroxide ion catalysis.

In the rate profiles for ketonization of some of the previous β-oxocarboxylic acid enols that we investigated, this apparent hydroxide ion catalysis became saturated and gave way to a third horizontal plateau as the fully ionized enol became the dominant substrate species (3–5). This did not happen in the present case because the acidity constant of this enol ($pQ'^{E}_{a} = 14.4$, vide infra) is well beyond the rate profile limit (p[H$^+$] = 12.8) imposed by the requirement that ionic strength be kept constant at 0.10 mol L^{-1}.

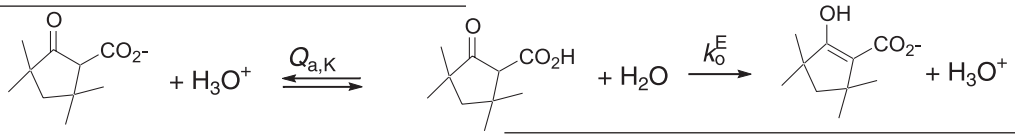
[5]

© 2005 NRC Canada



The rate law that corresponds to this reaction scheme is given in eq. [6],

$$[6] \qquad k_{obs} = \frac{k'_{H^+}Q_{a,E}[H^+]}{Q_{a,E} + [H^+]} + k'_{uc} + k'_{HO^-}[HO^-]$$



with (k'_{uc}) as the rate constant for the process of uncertain origin responsible for the horizontal plateau at the center of the rate profile, and k'_{HO^-} as the rate constant for the apparent hydroxide ion catalysis; the other constants are defined by eq. [5]. Least-squares fitting of this expression gave $k'_{H^+} = (7.60 \pm 0.63) \times 10^4$ M^{-1} s^{-1}, $Q_{a,E} = (1.03 \pm 0.11) \times 10^{-4}$ mol L^{-1}, $pQ_{a,E} = 3.99 \pm 0.05$,[5] $k'_{uc} = (1.74 \pm 0.37) \times 10^{-3}$ s^{-1}, and $k'_{HO^-} = (8.49 \pm 0.34) \times 10^1$ M^{-1} s^{-1}.

It was pointed out above that the origin of the rate profile plateau with rate constant k'_{uc} is sometimes uncertain. This is because it could be due either to ketonization of the monoanionic form of the enol through carbon protonation by a water molecule or to equilibrium ionization of the monoanion to the dianion followed by carbon protonation of that by H^+. In the latter case, k'_{uc} would be equal to $k''_{H^+}Q'^{E}_{a}$, and use of the estimate $pQ'^{E}_{a} = 14.4$ (vide infra) then provides $k''_{H^+} = (4.0 \pm 2.1) \times 10^{11}$ M^{-1} s^{-1}. This is a very large rate constant whose value exceeds the encounter-controlled limit ($k \cong 10^{10}$ M^{-1} s^{-1}) for two particles in aqueous solution at 25 °C (20). This suggests that k'_{uc} does not represent reaction of the dianionic form of the enol with H^+, but is rather due to carbon protonation of the monoanionc form by a water molecule.

Fig. 2. Rate profile for the enolization of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid in aqueous solution at 25 °C based on rate constants measured with conventional (O) and stopped-flow (Δ) spectrometers.

that involved rate-determining carbon protonation of the carboxylate ion form of the enol by hydronium ion, providing un-ionized 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid and a water molecule as reaction products (vide supra). Enolization will therefore occur by the rate-determining reaction of the un-ionized carboxylic acid with a water molecule, giving the horizontal uncatalyzed region seen at the high acidity end of the rate profile of Fig. 2. The un-ionized acid, however, will also be in equilibrium with its less reactive carboxylate ion, as shown in eq. [7], and the

[7] 

need to convert this ion to the more reactive un-ionized acid before enolization can take place will give the acid-catalyzed region seen at the lower acidity end of the rate profile of Fig. 2. The bend in the profile connecting these two regions, of course, corresponds to the ionization constant of the substrate acid.

The rate law that fits this reaction scheme is shown as eq. [8] whose rate and

$$[8] \qquad k_{obs} = k_o^E[H^+]/([H^+] + Q_{a,K})$$

equilibrium constants are defined in eq. [7]. Least-squares analysis of the data using this expression gave $k_o^E = (1.73 \pm 0.04) \times 10^{-1}$ s^{-1} and $Q_{a,K} = (1.55 \pm 0.11) \times 10^{-4}$ mol^{-1}, $pQ_{a,K} = 3.81 \pm 0.03$.[5]

The acidity constant $Q_{a,K}$ of the carboxylic acid group of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid was also determined spectrophotometrically by monitoring the reversible absorbance change at λ = 225 nm that occurred as this acid ionized. Absorbance measurements (A) were made in aqueous perchloric acid solutions and acetic acid and biphosphate ion buffers, using a fixed stoichiometric concentration (7.15×10^{-4} mol L^{-1}) of the cyclopentanecarboxylic

Ketone enolization

Rates of enolization of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid were measured in aqueous hydrobromic acid solutions over the concentration range [HBr] = 0.1–0.0005 mol L^{-1} and in acetic acid buffers that extended this acidity range down to 5×10^{-6} mol L^{-1}. The data so obtained are summarized in Tables S7 and S8.[4]

The measurements in buffers were once again made in a series of solutions of constant buffer ratio, and therefore constant hydronium ion concentration, but varying total buffer concentration. Buffer catalysis was strong, and the data were analyzed by least-squares fitting of the buffer dilution expression given in eq. [3]. The k_{int} obtained in this way, together with the rate constants measured in hydrobromic acid solution, are displayed as the rate profile shown in Fig. 2. It may be seen that rate constants measured using conventional and stopped-flow spectrometers agree very well with one another.

This enolization reaction is the microscopic reverse of the ketonization of 2-oxo-3,3,5–5-tetramethylcyclopentanecarboxylic acid enol, which was assigned a reaction mechanism in the acidity region of these enolization rate measurements

[5] This is a concentration acidity constant applicable at ionic strength = 0.10 mol L^{-1}.

© 2005 NRC Canada

acid substrate. The ionic strength of these solutions was maintained at 0.10 mol L^{-1}. The data so obtained are summarized in Table S9.[5]

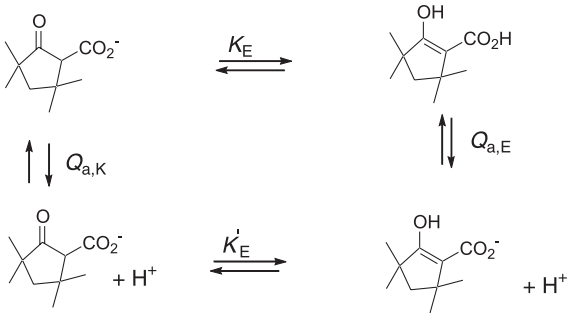
These results were analysed by least-squares fitting of the titration curve expression shown as eq. [9], in which A_{HA} is the absorbance of un-ionized acid and A_A is

$$[9] \qquad A = (A_{HA}[H^+] + A_A Q_{a,K})/(Q_{a,K} + [H^+])$$

the absorbance of its carboxylate ion. This gave $Q_{a,K}$ = (1.59 ± 0.08) ×10^{-4} mol L^{-1}, in very good agreement with the result obtained from the enolization rate measurements ($Q_{a,K}$ = (1.55 ± 0.11) × 10^{-4} mol L^{-1}). The weighted average of the two values is (1.58 ± 0.06) × 10^{-4} mol L^{-1}, $pQ_{a,K}$ = 3.80 ± 0.02.[5]

Keto–enol equilibria

The enolization and ketonization rate constants determined here can be combined to provide keto–enol equilibrium constants for the 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid system. Two such equilibrium constants may be defined: one (K_E), relating keto and enol isomers with the carboxylic acid group in its un-ionized form and another (K'_E), with this group in its ionizied carboxylate form.

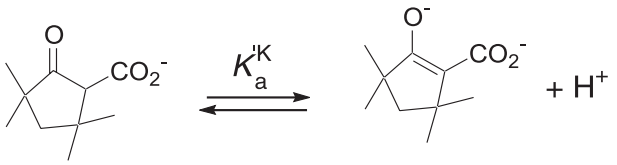


The first of these equilibrium constants can be formulated as the ratio of enolization to ketonization rate constants, as shown in eq. [10], using rate constants that

$$[10] \qquad K_E = k_o^E/k_o^K$$

refer to enolization in the uncatalyzed reaction of the rate profile shown in Fig. 2 and ketonization in the corresponding region of the rate profile of Fig. 1. The rate profile of Fig. 1, however, was constructed using rates of decay of enol, which, because ketonization is slightly reversible (K_E = 0.02, vide infra) are actually rates of approach to equilibrium and contain a small (2%) enolization component. The quantity $k'^K_{H^+}Q_{a,E}$ that represents the acid-region plateau of the profile in Fig. 1 must therefore be corrected by subtracting off k_o^E to convert it into a pure ketonization rate constant: $k_o^K = k'^K_{H^+}Q_{a,E} - k_o^E$ = (7.66 ± 0.44) s^{-1}. Rates of enolization, of course, require no correction because they were determined by bromine scavenging under nonreversible conditions. The rate and equilibrium constants determined here when applied in this way then lead to K_E = (2.26 ± 0.14) × 10^{-2}, pK_E = 1.65 ± 0.03.

The second keto–enol equilibrium constant (K'_E) involving carboxylate ion species, can be evaluated from K_E using the thermodynamic cycle shown in eq. [11]. The relationship $K'_E = K_E Q_{a,E}/Q_{a,K}$ using values of $Q_{a,E}$ and $Q_{a,K}$ determined here then leads to K'_E = (1.48 ± 0.20) × 10^{-2}, pK'_E = 1.83 ± 0.06.



[11]

Carbon acid strength

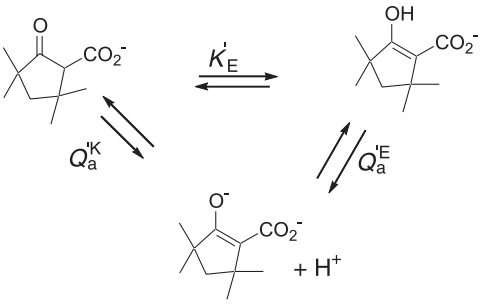
The acidity constant of 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylate ion ionizing further as a carbon acid (eq. [12]) was determined spectrophotometrically by monitoring the reversible absorbance change at λ = 280 nm that accompanies this reaction. Absorbance measurements were made in aqueous potassium hydroxide solutions over the concentration range [KOH] = 0.2–14 mol L^{-1} using a constant stoichiometric concentration (7.2 × 10^{-5} mol L^{-1}) of substrate. The data so obtained are summarized in Table S10.[4]

[12]

Because these measurements were made in concentrated potassium hydroxide solutions, the results should be analyzed using a basicity function to express solvent basic strength. Three basicity functions were tried: an H_- scale based on neutral indole indicators (21), an $H_=$ scale based on indoles bearing carboxylate groups (21), and an $H_=$ scale based on aromatic amines bearing carboxylate and sulfonate groups (22). The absorbance data were first transformed into values of I (= [basic form]/[acidic form]) and the fit of log I to each of these basicity scales was determined. Each basicity scale gave an adequately linear plot of log I vs. the basicity function. The slope of the plot using H_-, however, was significantly different from unity (1.26 ± 0.02), and this function was consequently deemed unsuitable for analyzing the present results. The slopes of the two plots using $H_=$ scales, on the other hand, were both indistinguishable from unity and were in fact the same: 1.02 ± 0.02. The data were therefore analyzed using each of these functions: least-squares fitting using eq. [9] with $10^{-H_=}$ in place of $[H^+]$ gave K_a = (3.65 ± 0.09) × 10^{-17} mol L^{-1} with the Yagil $H_=$ scale and K_a = (1.34 ± 0.03) × 10^{-17} mol L^{-1} with the Halle $H_=$ scale.

It is not clear which of these results is to be preferred. We therefore took the simple average, which gave K_a = (2.50 ± 1.16) × 10^{-17} mol L^{-1}, pK_a = 16.60 ± 0.20. It is unfortunate that this gives a result with a rather large uncertainty (ca. 50%), but this value is still sufficiently precise to allow some interesting conclusions to be drawn (vide infra).

Basicity functions such as the $H_=$ scales used here are anchored to an infinitely dilute standard state, and the acidity constant K_a determined here is therefore a thermodynamic value applicable at zero ionic strength. It may be converted to a concentration dissociation constant (Q'^K_a) appropriate to the ionic strength (0.10 mol L^{-1}) used for the other measurements made here, by applying appropriate activity coefficients. Use of f = 0.83 for the hydronium ion (17), plus the



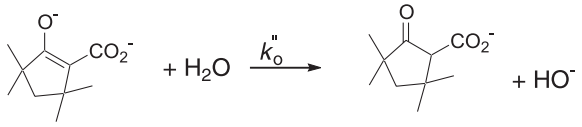
© 2005 NRC Canada

acetate ($f = 0.775$) (17) and hydrogen citrate ($f = 0.36$) (17) values as surrogates for the mono- and dianions of eq. [12], then gives $Q_a'^K = (6.48 \pm 3.00) \times 10^{-17}$ mol L^{-1}, $pQ_a'^K = 16.19 \pm 0.20$.[5]

pK_E' and k_0'' determination

The thermodynamic cycle given in eq. [13] shows that $Q_a'^K = K_E' Q_a'^E$. This relationship then allows the enol acidity constant $Q_a'^E$ to be determined from the now known values of

[13]

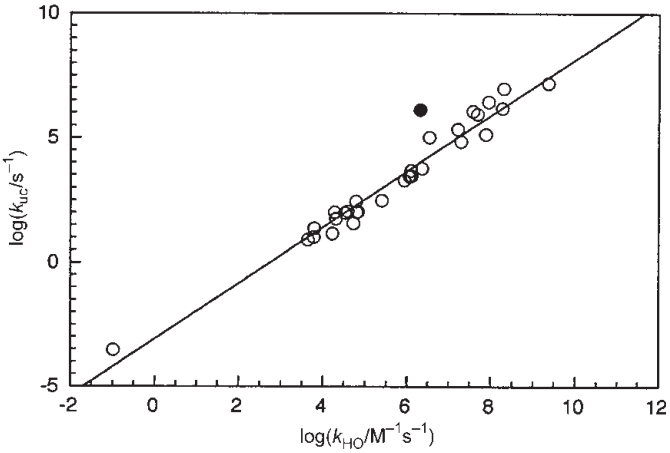


K_E' and $Q_a'^K$: $Q_a'^E = Q_a'^K/K_E' = (4.38 \pm 2.11) \times 10^{-15}$ mol L^{-1}, $pQ_a'^E = 14.36 \pm 0.21$.[5]

It was pointed out above that values of this acidity constant for some other β-oxocarboxylic acid systems were obtained from bends at the low acidity ends of their rate profiles. The very low value of this acidity constant estimated here for the present system shows why such a rate-profile-derived determination could not be made in this case: the relevant bend would have come well beyond the lowest acidity available ([H$^+$] = 10^{-13} mol L^{-1}), consistent with maintaining an ionic strength of 0.10 mol L^{-1}.

This presently determined estimate of $Q_a'^E$ can in turn be used to obtain a value of the rate constant k_0'' for ketonization by the uncatalyzed route beyond the unobserved rate profile bend, i.e., through carbon protonation of the enol dianion by a water molecule, as shown in eq. [14]. This

[14]



rate constant is related to the hydroxide ion rate constant of eq. [6], $k'^K_{HO^-}$: $k'^K_{HO^-} = k_0'' Q_a'^E / Q_w$, and use of the known values of $Q_a'^E$ and the autoprotolysis constant of water (Q_w) gives $k_0'' = (3.07 \pm 1.48) \times 10^2$ s^{-1}. This result is considerably above the largest rate constant measured at the low acidity end of the rate profile of Fig. 1, which again points to the incompatibility of making measurements in this profile region while maintaining an ionic strength of 0.10 mol L^{-1}.

Comparison with the unmethylated cyclopentyl system

The rate of uncatalyzed hydration of 2-oxo-3,3,5,5-tetramethylcyclopentylideneketene determined here is virtually the same as that for the unmethylated 2-oxocyclopentylideneketene (4): the two rate constants differ by less than 5%. The rates of the hydroxide-ion-catalyzed hydrations of the ketenes, on the other hand, differ by a factor of 37, with the present ketene being the more slowly reacting substrate.

Fig. 3. Correlation of rate constants for the hydroxide-ion-catalyzed and uncatalyzed hydration reactions of ketenes. The filled circle represents hydration of the presently examined substrate.

The reason for this striking difference in behavior of the uncatalyzed and hydroxide-ion-catalyzed reactions is not at all clear. The methylated ketene would, of course, be expected to be the more slowly reacting substrate, inasmuch as both water and hydroxide ion serve as nucleophiles in these reactions, adding to the ketene carbonyl carbon atom through approach in the ketene molecular plane (23); such approach is hindered by the methyl groups in the methylated cyclopentyl system. Some difference in the hindrance encountered by water and hydroxide ion is also to be expected, for hydroxide is strongly solvated in aqueous solution and is consequently a considerably larger nucleophile than is a water molecule. A change from identical rate constants to a factor of 37 difference in going from water to hydroxide ion is, however, surprising.

At any rate, this retardation of the hydroxide-ion-catalyzed ketene hydration, but not of the water reaction, produces a striking deviation from a correlation of rate constants for the hydroxide ion and water reactions of some 30 other ketenes (24). This deviation is shown in Fig. 3.

There are also interesting differences between the methylated and unmethylated systems in their keto–enol interconversions. The rate of water-catalyzed enolization, for example, in the methylated system is 3.3 times faster than in the unmethylated system. The rate of enol ketonization, on the other hand, is 2.2 times slower in the methylated than in the unmethylated system. These differences propagate into a difference in keto–enol equilibrium constants through the relationship that expresses the equilibrium constant as a ratio of enolization to ketonization rate constants: $K_E = k_E/k_K : K_E$ for the methylated system is 7.3 times that for the unmethylated system, which is nicely consistent with the product $3.3 \times 2.2 = 7.3$.

This difference can be understood in terms of strain produced by eclipsing interactions in the keto isomer between the carboxylic acid group and hydrogen atom at position 1 and the substituents at position 5. This strain is relieved as the keto form isomerizes to the enol form and the state of

© 2005 NRC Canada

hybridization of carbon number 1 changes from sp^3 to sp^2. This eclipsing strain is, of course, greater in the methylated system with its methyl groups at position 5 than in the unmethylated system with only hydrogen atoms at this location. The methylated system consequently has more to gain from this relief of strain, thus making its keto–enol equilibrium constants greater than that for the unmethylated system.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2004 Alcan Award Lecture
From dinuclear to triakontahexanuclear complexes — Adventures in supramolecular coordination chemistry[1]

Laurence K. Thompson

Abstract: Polynuclear coordination complexes result from the interplay between the arrangement of the binding sites of a ligand, and their donor content, and the coordination preferences of the metal ion involved. Rational control of the ligand properties, such as denticity, geometry, and size, can lead to large, and sometimes predictable, polynuclear assemblies. This Alcan Award Lecture highlights our "adventures" with polynucleating ligands over the last 25 years, with examples ranging from simple dinucleating to more exotic high-denticity ligands. Complexes with nuclearities ranging from 2 to 36 have been produced, many of which have novel magnetic, electrochemical, and spectroscopic properties. Self-assembly strategies using relatively simple "polytopic" ligands have been very successful in producing high-nuclearity clusters in high yield. For example, linear "tritopic" ligands produce M_9 (M = Mn(II), Fe(II), Fe(III), Co(II), Ni(II), Cu(II), Zn(II)) [3 × 3], flat grid-like molecules, which have quantum dot-like arrays of nine closely spaced metal centers in electronic communication. Some of these grids are discussed in terms of their novel magnetic and electrochemical properties, and also as multistable nanometer-scale platforms for potential molecular device behaviour. Bigger ligands with extended arrays of coordination pockets, and the capacity to self-assemble into much larger grids, are highlighted to illustrate our current and longer term goals of generating polymetallic molecular two-dimensional layers on surfaces.

Key words: Alcan Award Lecture, transition metal, polynuclear, structure, magnetism, electrochemistry, surface studies, molecular device.

Résumé : Les complexes de coordination polynucléaires résultent de l'interaction entre l'arrangement des sites de fixation d'un ligand et leur contenu en donneur et les préférences de coordination de l'ion métallique impliqué. Un contrôle rationnel des propriétés du ligand, par exemple, la denticité, la géométrie et la taille, peuvent conduire à d'importants assemblages polynucléaires qui quelquefois peuvent être prédites. Cette conférence du prix Alcan met en relief notre aventure de plus de ving-cinq ans avec les ligands de polynucléation et comporte des exemples allant de simples dinucléations à des ligands plus exotiques de denticité plus élevée. On a produit des complexes comportant des nucléarités allant de deux à trente-six dont plusieurs présentent de nouvelles propriétés magnétiques, électrochimiques et spectroscopiques. Les stratégies d'autoassemblage faisant appel à des ligands polytopes relativement simples ont connu de grands succès dans la production d'agrégats de nucléarité élevée avec d'excellents rendements. Par exemple, les ligands tritopiques conduisent à la formation de M_9 [M = Mn(II), Fe(II), Fe(III), Co(II), Ni(II), Cu(II), Zn(II)] [3 × 3], des molécules planes et en forme de réseaux qui possèdent des arrangements pointillés quantiques de neuf centres métalliques en proche proximité et en communication électronique. Certains de ces réseaux peuvent être discutés en termes de leurs nouvelles propriétés magnétiques et électrochimiques ainsi que leur rôle potentiel de plates-formes multistables d'échelle nanométrique pour le comportement de dispositifs moléculaires. Afin d'illustrer nos objectifs tant courant que ceux à long terme relatif à la génération de molécules polynucléaires à couches bidimensionnelles sur des surfaces, on présentera des ligands plus gros comportant des arrangements plus étendus de poches de coordination ayant la capacité de s'autoassembler en réseaux plus grands.

Mots clés : conférence du prix Alcan, métal de transition, polynucléaire, structure, magnétisme, électrochimie, études de surface, dispositif moléculaire.

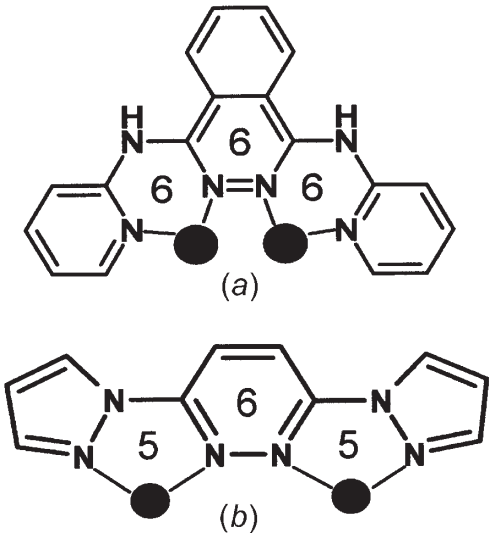
Fig. 1. Academic family tree and portrait of August Hofmann.

August Wilhelm Hofmann (1818-1892)



Introduction

A major influence in one's approach to research inevitably stems from the research interests of one's Ph.D. advisor, and also on one's academic lineage. My academic family tree (Fig. 1) shows that organic chemistry is a strong influence in this background, with connections through Sir Reginald P. Linstead and Sir Jocelyn Thorpe to August W. Hofmann. In this context, it is interesting to note that Hofmann attended the University of Giessen in the 1830s with the intention of studying law and philosophy but, after attending Liebig's lectures, became most interested in chemistry. In the mid 1800s, he was instrumental in establishing the Royal College of Chemistry in London.

As an undergraduate at UMIST (University of Manchester Institute of Science and Technology) in the mid 1960s,

blending core science and "technology" was a natural focus. It is perhaps ironic that in the current chemical "arena" this is suddenly seen as an important direction, with e.g., "Materials Applications" being a major platform in departmental and university strategic plans. Barry Lever (Ph.D. advisor) had broad interests in coordination chemistry and spectroscopy and provided a rich opportunity for a raw graduate student to get a quick start in an interesting and productive research area. I chose a project on phthalazine coordination chemistry (Fig. 2*a*), which started my journey into the realm of polynuclear complexes, with the interesting properties provided by the presence of more than one metal ion in a molecule, e.g., electronic and magnetic communication.

Research summary

Complexes derived directly from polyfunctional ligands

The successful developments and advances in X-ray crystallography in the 1950s, coupled with improvements in computing power, expanded the scope of biological chemistry, and in particular metallo-protein chemistry, with the successful solution of the structures of a number of metal-containing proteins and enzymes. These were restricted to fairly small systems, and yet interest in probing and understanding active-site protein structure and function led to the emergence of a new field combining biological and inorganic chemistry — bioinorganic chemistry. "Model" compounds were synthesized in their thousands by coordination chemists trying to "mimic" metallo-protein active-site structures on the basis of, e.g., spectroscopic and magnetic properties.

Polydentate aromatic diazine ligands, e.g., phthalazines (Fig. 2*a*; 1,4-di(2′-pyridyl)aminophthalazine (pap); defined as a 6–6–6 system based on the sequence of chelate ring and diazine ring sizes) provided a unique platform for the systematic examination of magnetic properties as a function of structure in a series of dinuclear copper(II) complexes. These were studied as active-site models for the dinuclear centers in, e.g., hemocyanin, laccase, and ascorbate oxidase. The parent compound in this class, $[Cu_2(pap)(\mu_2\text{-}OH)(\mu_2\text{-}Cl)Cl_2]\cdot 1.5H_2O$ (**1**) (Fig. 3), is formed by simply reacting pap with $CuCl_2\cdot 2H_2O$ in water. A crystal structure revealed a dinuclear center, with two square-pyramidal copper(II) ions spaced at 2.99 Å (avg.), with μ_2-OH (Cu-O-Cu bridge angle 100.9° (avg.)) and phthalazine N_2 groups bridging the metals (1). The copper(II) ions are antiferromagnetically exchange-coupled through the diazine and hydroxide bridges with a singlet–triplet splitting ($-2J$) of 200 cm^{-1} (2). It was observed that changing the anion in a series of related complexes led to a variation in exchange coupling. The anionic replacement occurred at the apical bridging position and caused a dramatic change in the dinuclear center dimensions, with increasing Cu–Cu distances (3.14–3.22 Å) and Cu-OH-Cu bridge angles (111–116°) as single-atom bridges (e.g., Cl) were replaced by triatomic bridges (e.g., SO_4^{2-}, ClO_4^-, IO_3^-, NO_3^-) (see Fig. 4 for the IO_3^--bridged complex $[Cu_2(pap)(\mu_2\text{-}OH)(\mu\text{-}IO_3)(IO_3)_2]\cdot 4H_2O$ (**2**); Cu-OH-Cu 113.8(2)°). The $-2J$ values increased accordingly (280–600 cm^{-1}) (3–6), and in all cases the hydroxide bridge remained intact.

To increase the dinuclear dimensions further, a ligand modification strategy was employed, which involved changing the size of the chelate rings formed on coordination. Reducing the ring size from six in the phthalazine ligands to five in ligands like 3,6-bis(1-pyrazolyl)pyridazine (ppd) (Fig. 2*b*; 5–6–5 system) results in a dramatic expansion of the dinuclear center with a much larger increase in dinuclear center dimensions (Cu–Cu 3.29–3.46 Å; Cu-OH-Cu 117–127°), and a resulting increase in exchange coupling ($-2J$ =

Fig. 5. Structural representation of $[Cu_2(ppd)(\mu_2\text{-}OH)Br_3(H_2O)]$ (**3**).

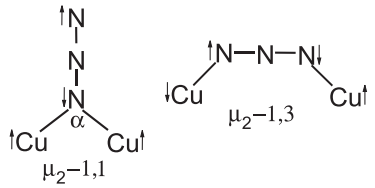
770–1305 cm^{-1}) (5, 6). A typical example, $[Cu_2(ppd)(\mu_2\text{-}OH)Br_3(H_2O)]$ (**3**), is shown in Fig. 5. In all cases, the copper ions are bridged by the diazine (N_2) and hydroxide groups.

The magnetic exchange interactions in the diazine complexes result from alignment and overlap of the copper magnetic orbitals with appropriate symmetry orbitals (e.g., *p* orbitals) on the bridging groups. In most cases, the copper ions have square-pyramidal geometries resulting in $d_{x^2-y^2}$ magnetic ground states, which places the unpaired *d* electron in an ideal molecular orbital environment for exchange coupling via both equatorial bridges in the copper basal planes (e.g., as in Fig. 5). In cases where an axial bridge exists, e.g., in **1**, this results in an orthogonal magnetic connection and does not contribute to antiferromagnetic exchange. The exchange integrals for a large number of complexes in this class were analyzed as a function of hydroxide bridge angle, and a reasonable straight line plot gave the relationship $-2J = 23.06\alpha - 2143$ cm^{-1} (where α is the Cu-OH-Cu bridge angle, and the diazine bridge is assumed to make a small, and roughly constant, contribution to overall exchange) (6).

Studies on laccase (*Rhus vernicifera*) ($-2J \geq 1000$ cm^{-1}) and oxy-hemocyanin (*Megathura crenulata*) ($-2J \geq 1250$ cm^{-1}) extracts in the late 1970s using superconducting quantum interference device (SQUID) measurements revealed very strong antiferromagnetic exchange between the two copper(II) ions at the dinuclear active-site centers (7, 8). The limited structural information available at that time suggested oxygen bridge(s) between the copper(II) centers, and given estimates of copper–copper separations of ~3.5 Å, a projected Cu-O-Cu bridge angle of ~140° results. Substituting this angle into the correlation equation above gives $-2J \approx 1100$ cm^{-1}, consistent with the experimentally observed protein values, strongly supporting an oxygen-based bridge between the copper centers. Definitive model studies (9), and ultimately an X-ray structure on oxy-hemocyanin (*Limulus polyphemus*) (10), revealed that this structural motif is correct, although two oxygen atoms are found between the copper ions, in the form of bridging η_2–η_2 peroxide.

In the early 1980s, the chemistry of azide-bridged dicopper complexes attracted much attention because of the unusual ferromagnetic properties of a few μ_2-1,1-azide bridged dicopper(II) systems (Fig. 6) reported by Kahn and co-workers (11–14) and the suggestion by those authors that, owing to a "spin-polarization" mechanism, ferromagnetic exchange would persist at all Cu-N_3-Cu angles (12). This was based on the interaction of *d* electron spin in the copper

Fig. 6. Spin polarization models for μ_2-1,1 and μ_2-1,3 bridging azides.



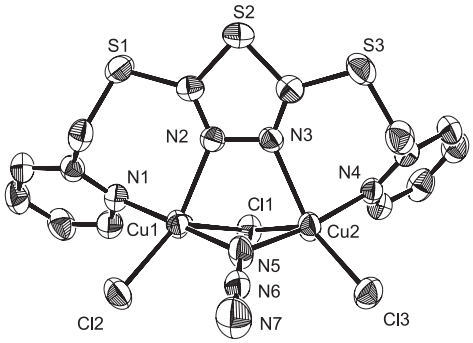


Fig. 7. Structural representation of $[Cu_2(dmptd)(\mu_2\text{-}1,1\text{-}N_3)(\mu_2\text{-}Cl)Cl_2]\cdot CH_3CN$ (**4**).

ion with a π_g symmetry MO on azide, which has a preponderance of α and β spin localized at the end nitrogen atoms. The antiferromagnetic behaviour of "all known" μ_2-1,3-azide bridged dicopper(II) complexes was explained conveniently using the same model (Fig. 6).

Our interest in azide-bridged systems rested with our ability to adjust dinuclear center dimensions successfully in hydroxide-bridged dinuclear copper(II) complexes and the knowledge that azide would replace hydroxide as a μ_2-1,1 bridge. We were therefore able to produce a large series of μ_2-1,1-azide bridged diazine complexes and were able to vary the Cu-N_3-Cu angle in a very broad range (98°–125°), in complexes where the $d_{x^2-y^2}$ copper electrons overlapped directly with the azide bridge orbitals. The 2,5-bis((pyridylmethyl)thio)thiadiazole (dmptd) ligand in the complex $[Cu_2(dmptd)(\mu_2\text{-}1,1\text{-}N_3)(\mu_2\text{-}Cl)Cl_2]\cdot CH_3CN$ (**4**) (Fig. 7; Cu-N_3-Cu 105.9(1)°) is a 7–5–7 ring system, which forces the copper ions to be quite close together (Cu–Cu 3.1215(7) Å), leading to a small azide bridge angle (15, 16). This complex exhibits strong intramolecular ferromagnetic exchange ($2J = 118(3)$ cm^{-1}), consistent with the observations of Kahn and co-workers. The complex $[Cu_2(pap)(\mu_2\text{-}1,1\text{-}N_3)(\mu\text{-}Br)Br_2]\cdot CHCl_3$ (**5**) (Fig. 8; Cu-N_3-Cu 108.7°) and others with the 6–6–6 ring configuration have somewhat larger Cu-N_3-Cu bridge angles than their hydroxide counterparts (108–112°) and exhibit intramolecular antiferromagnetic exchange ($-2J > 100$ cm^{-1}) (16). The 5–6–5 complex $[Cu_2(ppd)(\mu_2\text{-}1,1\text{-}N_3)(ClO_4)(N_3)_2(H_2O)]$ (**6**) (Fig. 9; Cu-N_3-Cu 123.2(2)°, Cu–Cu 3.409(2) Å) has a much larger dinuclear center owing to the presence of five-membered chelate rings, typical of similar systems in this group, which exhibit very strong antiferromagnetic exchange ($-2J = 770$–1100 cm^{-1}) (16).

A magnetostructural analysis of the exchange data for the 1,1-azide-bridged complexes shows a good straight line relationship between exchange integral ($2J$) and Cu-N_3-Cu

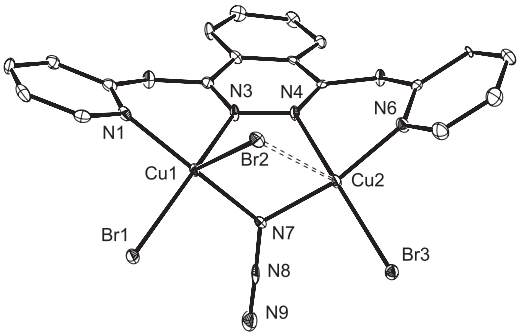
Fig. 8. Structural representation of $[Cu_2(pap)(\mu_2\text{-}1,1\text{-}N_3)(\mu\text{-}Br)Br_2]\cdot CHCl_3$ (**5**).



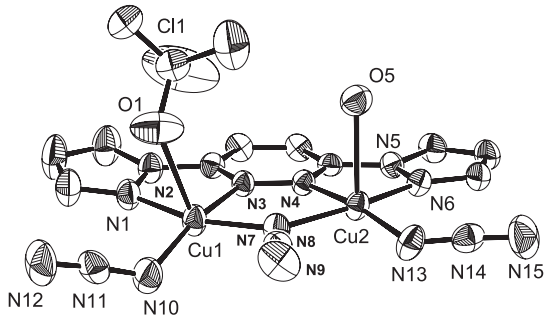


Fig. 9. Structural representation of $[Cu_2(ppd)(\mu_2\text{-}1,1\text{-}N_3)(ClO_4)(N_3)_2(H_2O)]$ (**6**).

bridge angle, with $2J = -41.94\alpha + 4440$ cm^{-1} (17). The changeover from antiferromagnetic to ferromagnetic behavior occurs at ~106° ($2J = 0$ cm^{-1}). Since in all cases the exchange is mediated by two bridging groups (azide and diazine), a correction for the diazine contribution must be included. This is estimated to be of the order $2J \approx -100$ cm^{-1} in all cases from baseline studies of dinuclear complexes with just diazine bridges. This therefore means that the actual angle at which the azide bridge causes a change in sign of the magnetic exchange behavior is ~108°, consistent with the angle of accidental orthogonality of 103° calculated using extended Hückel theory (11, 18). These results indicate that an orbital overlap model involving metal *d* orbital and bridge atom *p* orbital participation is the controlling influence in the exchange process for μ_2-1,1-azide bridged dicopper(II) systems and that it is not necessary to invoke spin polarization theory. It is of interest to note that a polarized neutron diffraction study on the complex $[Cu_2(t\text{-bupy})_4(\mu_2\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ (**7**; *t*-bupy = *p-tert*-butylpyridine) (12) shows positive spin density on the copper ions and the azide bridging nitrogen atoms, thus contradicting spin polarization theory (19).

Increasing the nuclearity in a complex can be achieved by increasing the number of donor pockets in the ligand. This becomes more difficult to achieve and control with increasing nuclearity, but ligands like pap (Fig. 2*a*) can effectively be doubled by starting with tetracyanobenzene, rather than dicyanobenzene, to produce a tetrapyridyl-benzodipyridazine ligand (Fig. 10). Reaction of this and related ligands with copper(II) salts produces novel tetranuclear complexes with two dinuclear halves connected by the planar, fused aromatic network. Figure 11 illustrates the structure of the complex

Fig. 10. Synthetic scheme for tetranuclear benzodipyridazine complexes.

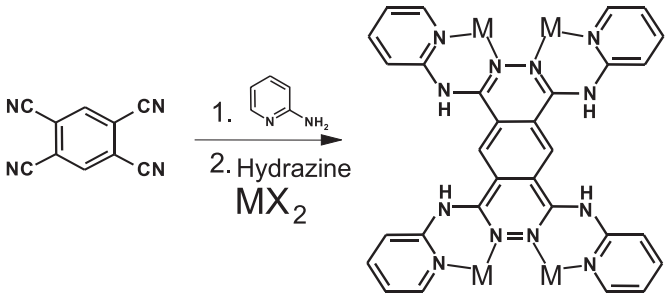

Fig. 11. Structural representation of $[Cu_4(tnl4)(\mu_2\text{-}OH)_2(H_2O)_8](CF_3SO_3)_6\cdot 6H_2O$ (**8**).

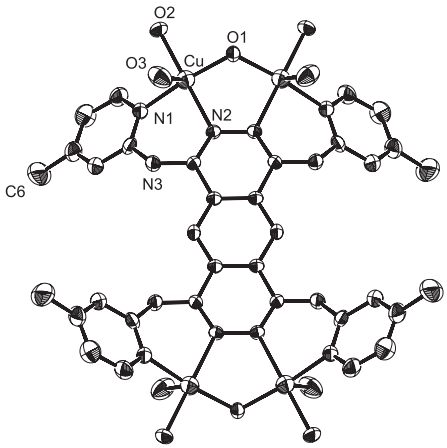

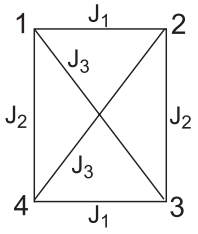

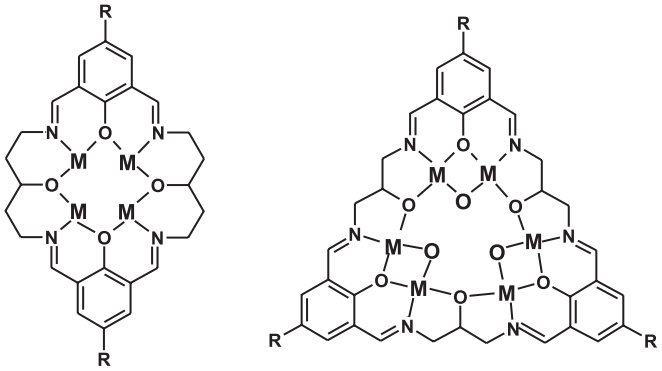

Fig. 12. Magnetic exchange model for a rectangular tetranuclear complex.

$[Cu_4(tnl4)(\mu_2\text{-}OH)_2(H_2O)_8](CF_3SO_3)_6\cdot 6H_2O$ (**8**) (where tnl4 is a tetrapyridyl-benzodipyridazine ligand with a 4-methyl substituent on each pyridine ring) (20, 21). Fairly large Cu-OH-Cu bridge angles lead to intramolecular antiferromagnetic exchange; however, the magnetic data for this class of compound cannot be fitted successfully to a simple dinuclear exchange expression ($H_{ex} = -2JS_1\cdot S_2$) but can instead be fitted successfully to a rectangular exchange scheme (Fig. 12), in which $J_2 = J_3$ ($H_{ex} = -2J_1(S_1\cdot S_2 + S_3\cdot S_4) - 2J_2(S_2\cdot S_3 + S_1\cdot S_4)$). Fairly large $-J_1$ values (167–338 cm^{-1}) and substantial $-J_2$ values (36–210 cm^{-1}) indicate that exchange coupling is split between the direct diazine/hydroxide interaction and the cross-ligand interaction. While μ-OH/μ-diazine interactions are well documented (4–6), the long coupling pathway across the fused aromatic network is most unusual.

Template cyclization as a method to achieve higher nuclearity

Increasing the nuclearity of a complex beyond four metals with a single ligand approach presents special synthetic challenges, and so other routes, e.g., metal ion templating and self-assembly, are more desirable. With appropriately chosen precursor subunits, this can lead to novel, and in some cases "predictable", outcomes. Macrocyclic ligands based on the diformyl-phenol building block are well known, and reaction with 1,5-diamino-3-pentanol in the presence of metal ions like copper(II) readily templates the formation of 2:2 tetranuclear complexes (22–24) (Fig. 13*a*; e.g., R = CH_3). The alkoxide and phenoxide bridges lead to intramolecular antiferromagnetic exchange between the copper(II) ions. The chelate rings are all six-membered.

The use of a smaller diamino-alcohol linker, e.g., 1,3-diaminopropan-2-ol, would generate five-membered chelate rings and prevent the formation of a 2:2 macrocycle, and one would expect that if a macrocycle formed on reaction with a diformyl phenol, the ring size would be larger. In reality, template condensation of 2,6-diformyl-4-methylphenol with 1,3-diaminopropan-2-ol in the presence of $Cu(NO_3)_2$ leads to a 3:3 condensation and the formation of a hexanuclear complex $[Cu_6(L)(\mu_2\text{-}OH)_3]_2(NO_3)_6\cdot 10H_2O$ (**9**) in high yield (Fig. 13*b*) (25, 26). The X-ray structure (Fig. 14) shows the square-planar copper(II) centers connected by an alternation of phenoxide and alkoxide bridges around the hexagonal copper ring. The structure also reveals that adventitious hydroxide bridges (O(7), O(8), O(9)) between Cu(1) and Cu(2), Cu(3) and Cu(4), and Cu(5) and Cu(6) actually lead to an alternation of single and double oxygen bridges. The overall structure is, in fact, a dodecanuclear dimer (Fig. 15), with two saucer-shaped hexagonal macrocyclic rings joined at their bases by axial Cu–O interactions (e.g., Cu(4)′-O(7) 2.43 Å, Cu(3)′-O(9) 2.45 Å). Oxygen bridge angles (alkoxide 131°–136°, phenoxide 96°–98°, hydroxide 96°–99°) are in ranges that would suggest that intramolecular spin exchange would be dominated by antiferromagnetic coupling, and this is borne out by experiment. Variable-temperature magnetic data were fitted to an alternating exchange Hamiltonian (eq. [1]),

$$[1] \qquad H_{ex} = -2J_1\{S_i\cdot S_{i-1}\} - 2J_2\{S_i\cdot S_{i+1}\}$$

and best fit results were obtained for $-2J_1 = -2J_2 = 318$ cm^{-1} (g = 2.05). An alternate fitting procedure suggested weak antiferromagnetic exchange between the rings in the dimer structure (26). The results suggest that electron delocalization occurs throughout the whole Cu_6 ring structure via the oxygen bridges, which connect the copper magnetic orbitals directly, and the ring can be considered as a metallacyclic analogue of the benzene structure.

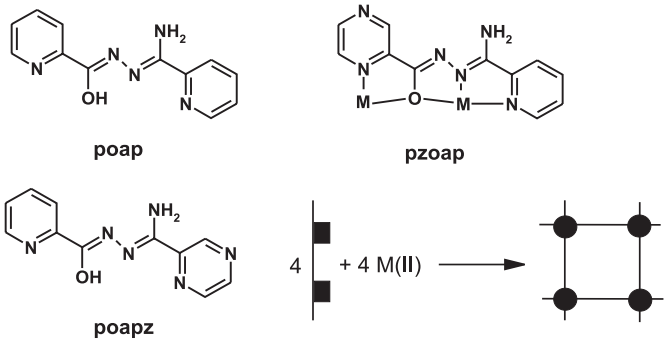
Self-assembly as a strategy to higher nuclearity

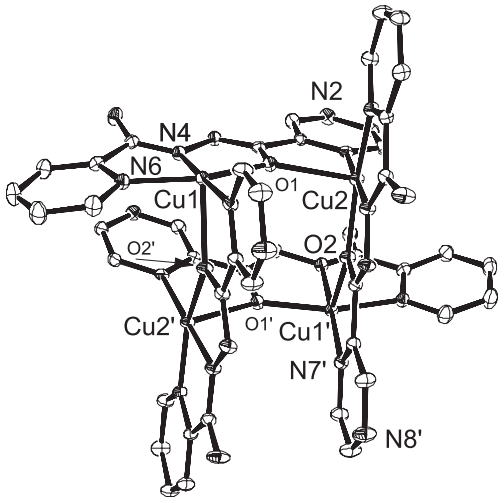
Large polynuclear systems can be approached by the method of self-assembly, in which coordination information is encoded into a ligand by the creation of suitable coordination pockets in an appropriate spatial arrangement. On reaction with a metal ion, the metal decodes this information according to its own coordination preferences.

This is illustrated in the simplest example by considering the hydrazone ligands poap, pzoap, and poapz (Fig. 16), which contain two coordination pockets (ditopic) and form five-membered chelate rings on coordination, as shown in Fig. 16 for pzoap. The proximity of these rings and the presence of a bridging oxygen atom allow the high-yield self-assembly of [2 × 2] square-based grid complexes with a variety of transition-metal ions (Fig. 16). The complex $[Cu_4(pzoap\text{-}H)_4](NO_3)_4\cdot 3H_2O$ (**10**) (Fig. 17) shows a [2 × 2]

© 2005 NRC Canada

Fig. 16. Ditopic hydrazone ligands, bonding mode, and self-assembly model.





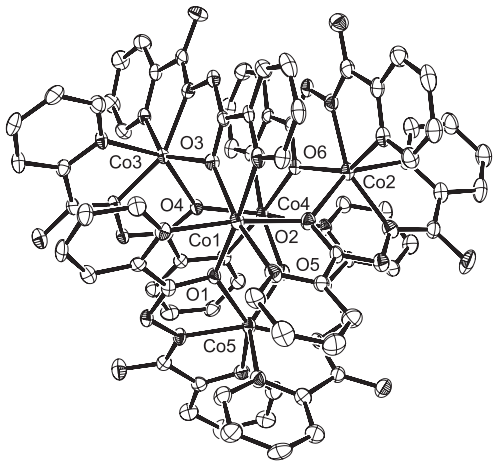


Fig. 17. Structural representation of $[Cu_4(pzoap\text{-}H)_4](NO_3)_4{\cdot}3H_2O$ (**10**).

square grid arrangement of four ligands and four five-coordinate square-pyramidal copper(II) ions, with the four copper ions bridged by four μ_2-O (deprotonated hydrazone) oxygen atoms (27). The tetradentate ligands are arranged in parallel pairs above and below the metal plane. Cu–Cu distances are ~4.05 Å, with Cu-O-Cu angles in the range 140°–141°.

A close examination of the Cu—O bond lengths in the square core reveals that they alternate short–long (Cu(1)—O(1) 2.015(1) Å; Cu(2)—O(1) 2.294(2) Å; Cu(2)—O(2) 2.036(2) Å; Cu(1)—O(2) 2.261(1) Å), with the copper-ion basal planes twisted by 90° from neighbouring copper centers. Since in a square-pyramidal ($d_{x^2-y^2}$ ground state) copper ion the unpaired electron resides in the $d_{x^2-y^2}$ orbital, it follows that there can be no magnetic overlap of the copper ion spin through the oxygen bridge connections, and so there can be no significant intramolecular antiferromagnetic exchange. Given the large Cu-O-Cu angles, this would not be expected. Variable-temperature magnetic data are in accord with this prediction, with a magnetic moment (per mole) increasing from a value of 4.0 μ_B at 300 K to 5.0 μ_B at 5 K. Fitting of the data to the exchange Hamiltonian shown in eq. [2] (which assumes all exchange couplings are the same) for a sequence of four S = 1/2 spin centers arranged in a square gave g = 2.221(5), J = 8.2(4) cm^{-1}, TIP (temperature-independent paramagnetism) = 242 × 10^{-6} cm^3 mol^{-1}, and θ (Weiss-like correction) = –0.4 K. The presence of intramolecular ferromagnetic coupling is clear proof of the internal orthogonal connectivity between the copper(II) ions. Other similar examples have also been studied (27).

Fig. 18. Structural representation of $[Co_5(poap\text{-}H)_6](ClO_4)_4{\cdot}3H_2O$ (**14**).

[2] $$H_{ex} = -J\{S_1{\cdot}S_2 + S_2{\cdot}S_3 + S_3{\cdot}S_4 + S_1{\cdot}S_4\}$$

Nickel(II) and manganese(II) square grid complexes, e.g., $[Ni_4(poap\text{-}H)_4(H_2O)_4](NO_3)_4{\cdot}8H_2O$ (**11**) and $[Mn_4(poapz\text{-}H)_4(H_2O)_4](NO_3)_4{\cdot}H_2O$ (**12**), have also been obtained, with similar [2 × 2] $M_4(\mu_2\text{-}O)_4$ structures and dimensions (27, 28). Orthogonality issues do not arise with these metal ions, and the large M-O-M bridge angles (Ni complex: 132°–140°; Mn complex: 127–130°) lead to intramolecular antiferromagnetic exchange (–J = 10–16 cm^{-1} (Ni); –J = 2.9 cm^{-1} (Mn)). Six-coordinate metal-ion geometries occur in these systems, and since each ligand only fills five donor positions, heteroleptic structures result with co-ligands (e.g., water or an anion) occupying the four vacant coordination sites. Self-assembly leaves the structural outcome to the whims of nature in large measure, and while square [2 × 2] grids are one outcome, there are theoretically others. The lowest ligand/metal combination that would satisfy the bonding requirements for a homoleptic assembly would be 6/5 (i.e., 30 coordination sites for each). It has been found that in some cases, where weakly coordinating anions are involved (e.g., perchlorate), homoleptic pentanuclear clusters are formed in preference to the [2 × 2] square grids (29, 30). Typical examples are $[Mn_5(poap\text{-}H)_6](ClO_4)_4$ (**13**) and $[Co_5(poap\text{-}H)_6](ClO_4)_4{\cdot}3H_2O$ (**14**). The structure of **14** is shown in Fig. 18. The pentanuclear cation has a trigonal bipyramidal arrangement of cobalt(II) ions bonded to six tetradentate ligands, with the core comprising a $Co_5(\mu_2\text{-}O)_6$ subunit. The core structure is shown in Fig. 19. M-O-M bridge angles fall in the range 125–136°, suggesting significant intramolecular antiferromagnetic exchange. Magnetic moments fall from 13.4 μ_B at 300 K to 5.8 μ_B at 5 K (**13**) and from 10.6 μ_B at 300 K to 2.7 μ_B at 2 K (**14**), confirming the expected behavior. Analysis of the magnetic data for the manganese complex, using a full isotropic model (eq. [3]; atom numbering as in Fig. 19), gave g = 2.02 and J = –1.8 cm^{-1}.

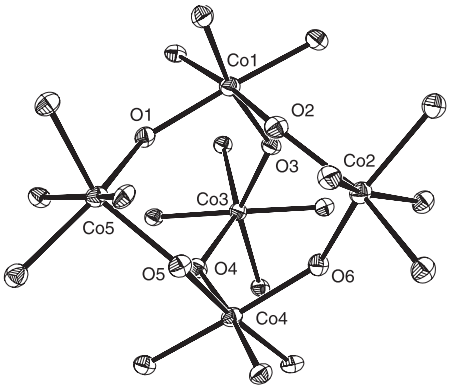

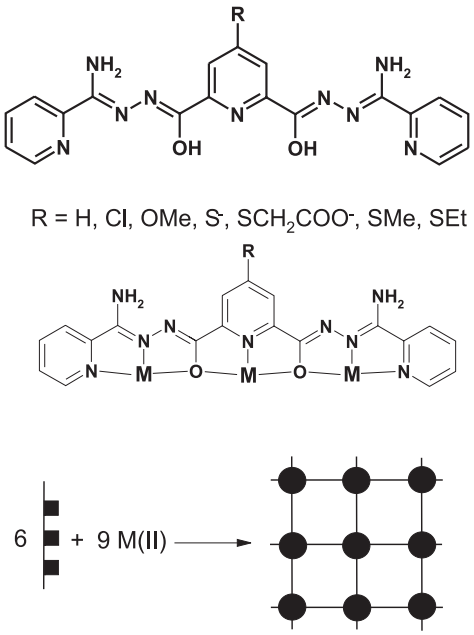

Fig. 20. Tritopic pyridine-dihydrazone ligands, bonding mode, and self-assembly model.

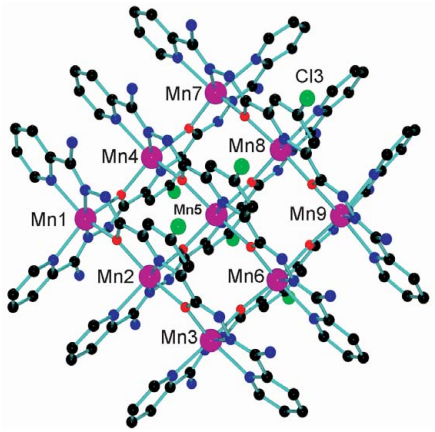
[3] $$H_{ex} = -J\{S_1 \cdot S_2 + S_1 \cdot S_3 + S_1 \cdot S_5 + S_4 \cdot S_5 + S_4 \cdot S_3 + S_4 \cdot S_2\}$$

The creation of larger grid molecules requires the incorporation of extra coordination sites in the ligand. This can be achieved by extending the ligand backbone in Fig. 16 using substituted 2,6-picolinic dihydrazones as the building blocks. Extension with capping pyridine ends can be achieved simply by reaction of the dihydrazone with methyl-2-pyridyl imidate to produce the tritopic ligands shown in Fig. 20 (R = H). Variants of this ligand type can readily be made by changing R, and also incorporating other end groups, e.g., pyrazine. The formation of five-membered chelate rings on coordination ensures that the metal ions are arranged in a roughly linear fashion. Self-assembly in the presence of, e.g., Mn(II), Fe(II), Fe(III), Ni(II), Co(II), Cu(II), and Zn(II) occurs in high yield to produce [3 × 3] nonanuclear grid complexes (31–42). A typical grid structure of the complex $[Mn_9(Cl2poap\text{-}2H)_6](ClO_4)_6 \cdot 10H_2O$ (**15**)

Fig. 21. Structural representation of $[Mn_9(Cl2poap\text{-}2H)_6](ClO_4)_6 \cdot 10H_2O$ (**15**). Colour code: Mn, magenta; C, black; O, red; N, blue; Cl, green.



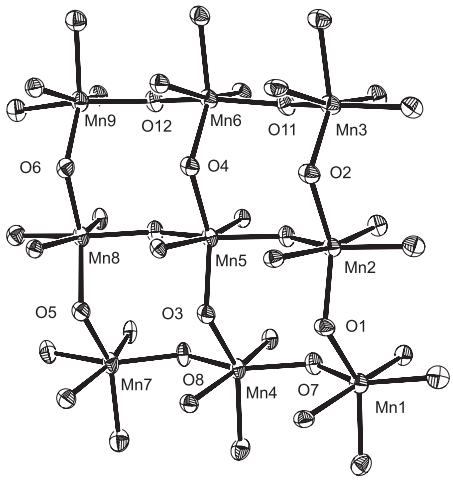


Fig. 22. Core structure of $[Mn_9(Cl2poap\text{-}2H)_6](ClO_4)_6 \cdot 10H_2O$ (**15**).

is shown in Fig. 21. The $[Mn_9(\mu_2\text{-}O)_{12}]$ core structure is shown in Fig. 22 (35). The grid consists of a pseudo-square core with nine six-coordinate Mn(II) centers bridged by 12 deprotonated hydrazone oxygen atoms, with Mn–Mn separations in the range 3.88–4.06 Å and Mn-O-Mn angles in the range 126.4°–130.7°. Six ligands are arranged in two parallel groups above and below the metal plane, with separations between the rings in the range 3.5–4.0 Å, indicating the likely contribution of π interactions to the overall stability of the grid.

The magnetic properties of the $Mn(II)_9$ grids are typified by **15,** which shows a drop in magnetic moment from 17 μ_B at 300 K to close to 6 μ_B at 2 K (Fig. 23), indicating dominant intramolecular antiferromagnetic exchange. The ground state is confirmed by M/H (magnetization at variable field) measurements (2 K) for this and all other $Mn(II)_9$ grids to be $S = 5/2$. The full isotropic magnetic exchange model (Fig. 24; eq. [4]) involves two J values but cannot be conveniently solved because of the enormous dimensions of the matrices involved.

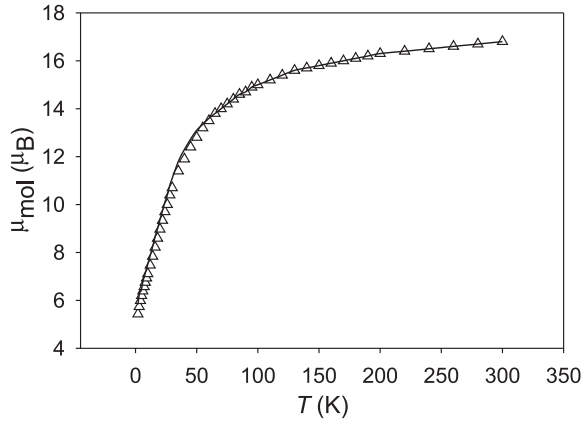
Fig. 23. Magnetic moment as a function of temperature for $[Mn_9(Cl2poap\text{-}2H)_6](ClO_4)_6 \cdot 10H_2O$ (**15**). The solid line represents the best fit of the magnetic data to a chain model. See text for fitted parameters.



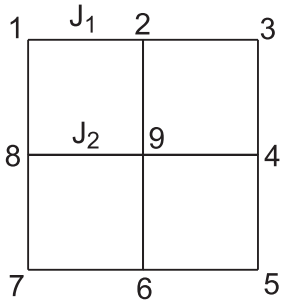


Fig. 24. Magnetic model for [3 × 3] nonanuclear grid.

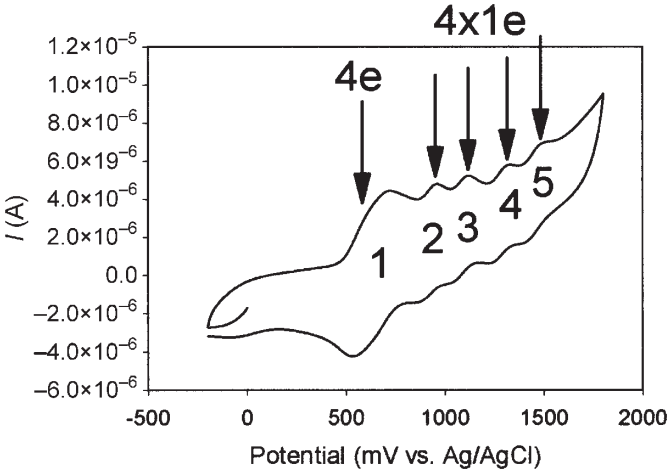
$$[4] \quad H_{ex} = -J_1\{S_1 \cdot S_2 + S_2 \cdot S_3 + S_3 \cdot S_4 + S_4 \cdot S_5 + S_5 \cdot S_6 + S_6 \cdot S_7 + S_7 \cdot S_8 + S_1 \cdot S_8\} - J_2\{S_2 \cdot S_9 + S_4 \cdot S_9 + S_6 \cdot S_9 + S_8 \cdot S_9\}$$

Even when D_4 rotational symmetry is employed, the computer memory (RAM) requirement is ~4 GB. In the low-temperature antiferromagnetic limit, the ground state for the outer ring of eight Mn(II) centers is $S = 0$, and so a reasonable simplification of the model involves the assumption that J_2 can be ignored in comparison with J_1. A further simplification includes the representation of the ring as a chain using an $S = 5/2$ chain model (38). Typically, $-J_1$ values are found in the range 4–5 cm^{-1} ($g = 2.0$, $J_1 = -4.6$ cm^{-1} for **15**) for $Mn(II)_9$ grids in this class. The solid line in Fig. 23 represents the best fit of the data using this model for **15**.

Three different metal-ion chromophores are found in the M_9 grids: *trans*-N_2O_4 at the center, *cis*-N_4O_2 at the corners, and *mer*-N_3O_3 on the sides (Figs. 21 and 22). This should lead to different electronic properties at these sites, and this is reflected quite clearly in the electrochemical properties. Figure 25 illustrates the cyclic voltammetry for the complex $[Mn_9(MeS2poap\text{-}2H)_6](CF_3SO_3)_6$ (**16**) (Fig. 20; R = SMe) in acetonitrile solution (Pt electrode). The large, fairly broad quasi-reversible single wave at $E_{1/2} = 0.62$ V corresponds to a four-electron process associated with oxidation of the four isolated, but similar, corner Mn(II) centers to Mn(III). The

Fig. 25. Cyclic voltammetry in acetontirile for $[Mn_9(MeS2poap\text{-}2H)_6](CF_3SO_3)_6$ (**16**) (Pt electrode).



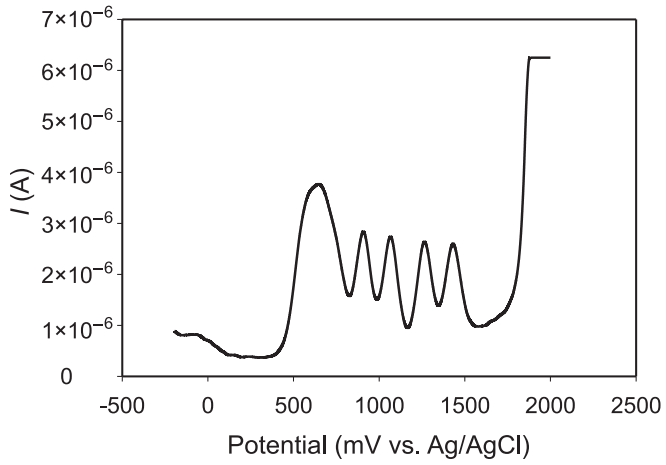


Fig. 26. Differential pulse voltammetry in acetonitrile for $[Mn_9(MeS2poap\text{-}2H)_6](CF_3SO_3)_6$ (**16**).

four higher potential waves are reversible in nature and correspond to one-electron oxidations of four Mn(II) centers, which are clearly in communication, in that as one Mn(II) center oxidizes, it influences the potential at which a neighbour is oxidized. These waves are assigned to the side Mn centers, which can communicate electronically through the central metal ion and also by electrostatic coulombic interactions. Differential pulse voltammetry (Fig. 26) shows these redox events much more clearly. All other $Mn(II)_9$ grid complexes have similar voltammetric responses, with $E_{1/2}$ values varying with the 4-pyridine ring substituent (Fig. 20).[2]

Oxidation of the $Mn(II)_9$ grids proceeds smoothly using bulk electrolysis, to produce examples with $[Mn(III)_3Mn(II)_6]$ and $[Mn(III)_4Mn(II)_5]$ cores. Chemical oxidants, e.g., Cl_2(aq.) and Br_2(aq.), can also be used. The complex $[Mn(III)_3Mn(II)_6(Cl2poap\text{-}2H)_6](ClO_4)_9 \cdot 7H_2O$ (**17**), isolated from the reaction of the complex $[Mn(II)_9(Cl2poap\text{-}2H)_6](ClO_4)_6 \cdot 10H_2O$ (**15**) with Cl_2(aq.), has three corner metal-ion centers oxidized to Mn(III), with considerably shortened Mn—L distances (M—$L_{avg.}$ 2.055–2.066 Å), but

[2] References 31 and 38; V.A. Milway, D.J. Pond, and L.K. Thompson. Unpublished results.

© 2005 NRC Canada

the Mn—L distance for the fourth corner metal ion is much longer (M—$L_{avg.}$ 2.174 Å) and closer to expected values for Mn(II) (38). Complete corner metal-ion oxidation can be achieved using bulk electrolysis (applied potential of +20 V in CH_3CN) of the complex $[Mn_9(2poap\text{-}2H)_6](ClO_4)_6\cdot 10H_2O$ (**18**) (31). An X-ray structure shows the space group symmetry $I\bar{4}$ with four equivalent corner centers oxidized to Mn(III) (M—$L_{avg.}$ 2.062(4) Å) in the complex $[Mn(III)_4Mn(II)_5(2poap\text{-}2H)_6](ClO_4)_{10}\cdot 18H_2O$ (**19**) (43). The grid structures remain intact on oxidation with almost no change in the overall grid dimensions, leading to slightly higher Mn-O-Mn angles in all oxidized cases. Oxidation of the side Mn(II) centers has not yet been clearly documented, although with persulfate oxidation preliminary evidence indicates removal of more than four electrons.

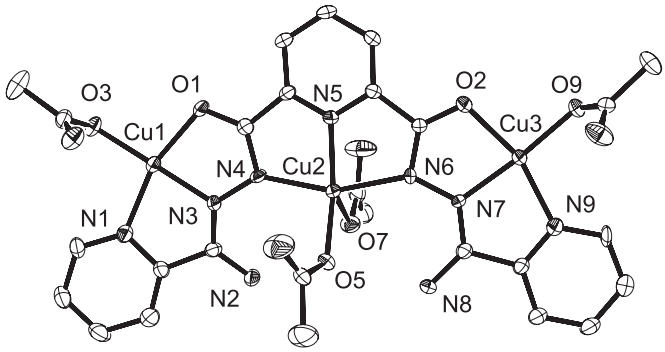
As each metal ion is oxidized to Mn(III), the electron complement of the grid diminishes, with $S = 4/2$ spin centers replacing $S = 5/2$ spin centers at the corners. This leads not only to lowered room temperature magnetic moments but also to changes in the ground-state spin. For compound **17** with three $S = 4/2$ centers at the corners (Fig. 24; $S = 4/2$ at sites 1, 3, and 5) in the low-temperature antiferromagnetic limit ($J_1 < 0$ cm^{-1}), the ground-state spin of the outer eight-membered metallic ring is $S = 3/2$. Coupling of the ring to the central Mn(II) for $J_2 < 0$ cm^{-1} results in an overall ground state spin of 5/2 – 3/2 = 2/2. Magnetization studies at 2 K as a function of field confirm the $S = 2/2$ ground state (38). Variable-temperature and variable-field magnetic data for **18**, which has all four corner sites oxidized (Fig. 24; $S = 4/2$ at sites 1, 3, 5, and 7), reveals that the ground state has $S = 1/2$, as a result of antiferromagnetic exchange between the $S = 4/2$ ring and the central $S = 5/2$ site. Magnetic data are thus definitive in assessing the state of oxidation of the grids.

Reaction of copper(II) salts with ligands in this class provides some surprises, in that examples of trinuclear, octanuclear, and nonanuclear complexes can be obtained depending on the anion used and the synthetic conditions. Copper acetate forms a linear trinuclear complex, $[Cu_3(2poap\text{-}2H)(CH_3COO)_4]\cdot 3H_2O$ (**19**), on reaction with 2poap, in which the ligand adopts a different coordination conformation, with a copper ion bound to a N_3 central ligand pocket and bridged to its neighbours by N_2 diazine groups (Fig. 27). The hydrazone oxygen atoms are bound terminally to the peripheral copper ions. This and related complexes exhibit magnetic properties typical of linear trinuclear systems with intramolecular antiferromagnetic exchange. Fitting of the variable-temperature magnetic data for **19** to the exchange expression derived from the Hamiltonian (eq. [5]) gave $g = 2.19(1)$ and $J = -75.5(2)$ cm^{-1} (44).

$$[5] \qquad H_{ex} = -2J\{S_1\cdot S_2 + S_2\cdot S_3\}$$

Reaction of other copper salts, e.g., $Cu(NO_3)_2\cdot 3H_2O$ and $Cu(ClO_4)_2\cdot 6H_2O$, under mild (room temperature) conditions in CH_3CN/MeOH and MeOH/H_2O mixtures leads to octanuclear complexes as the major products. $[Cu_8(Cl2poap\text{-}2H)_4(NO_3)_8]\cdot 20H_2O$ (**20**) (Fig. 28) is a typical example. Four heptadentate Cl2poap ligands (Fig. 20; R = Cl) intersect via their end pockets to produce a $Cu_4(\mu_2\text{-}O)_4$ inner core involving six-coordinate Cu(II) ions, with the ends of the ligands radiating outwards in a "pinwheel" shape to bind four extra

Fig. 27. Structural representation of $[Cu_3(2poap\text{-}2H)(CH_3COO)_4]\cdot 3H_2O$ (**19**).



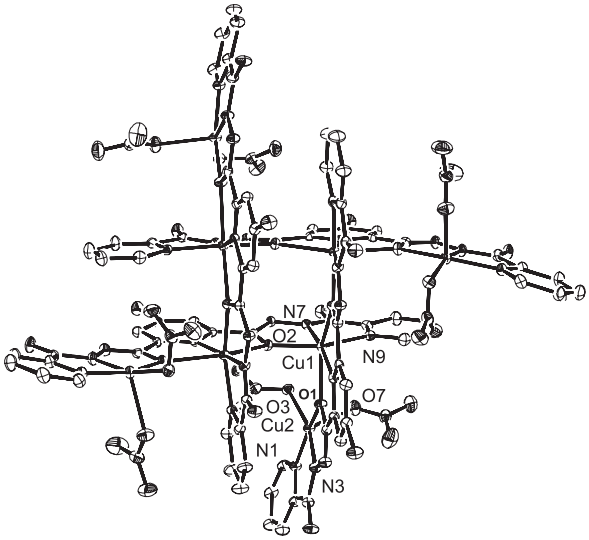


Fig. 28. Structural representation of $[Cu_8(Cl2poap\text{-}2H)_4(NO_3)_8]\cdot 20H_2O$ (**20**).

square-pyramidal Cu(II) ions. The terminal ligand pockets provide three donors (N_2O), and two monodentate nitrates fill the two remaining coordination sites. The terminal copper ions are bridged to the core with μ_2-O connections. The core structure is shown more clearly in Fig. 29. Cu–Cu distances vary from 4.01 to 4.06 Å, with Cu-O-Cu angles in the range 138.6–140.0°. Cu—O bond distances throughout the cluster alternate between long (axial) and short (equatorial) from one copper center to the next. This leads to strict magnetic orbital orthogonality between adjacent pairs of $d_{x^2-y^2}$ ground-state metal ions (45).

More forcing conditions lead to the formation of Cu_9 grids, and in the case of M2poap (Fig. 20; R = OMe), reaction with $Cu(NO_3)_2\cdot 3H_2O$ in MeOH/H_2O with heating to reflux forms the complex $[Cu_9(M2poap\text{-}H)_2(M2poap\text{-}2H)_4](NO_3)_8\cdot 17H_2O$ (**21**) (45). The structure (Fig. 30) shows the familiar [3 × 3] square grid arrangement, with nine six-coordinate Cu(II) centers bridged by μ_2-O hydrazone oxygen atoms. The core structure is shown in Fig. 31. The grid dimensions are similar to those of the Mn(II) systems, with Cu–Cu separations in the range 3.97–4.21 Å and Cu-O-Cu angles in the range 135.4°–142.4°. An examination of the bond distances at the eight metal ions in the outer ring re-

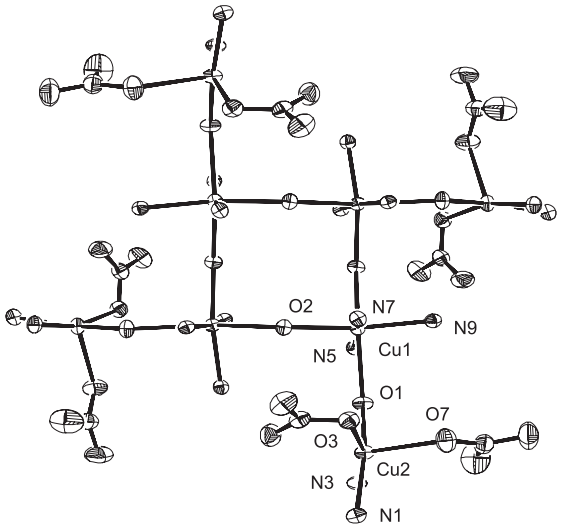
Fig. 29. Core structural representation of $[Cu_8(Cl2poap\text{-}2H)_4(NO_3)_8]\cdot 20H_2O$ (**20**).



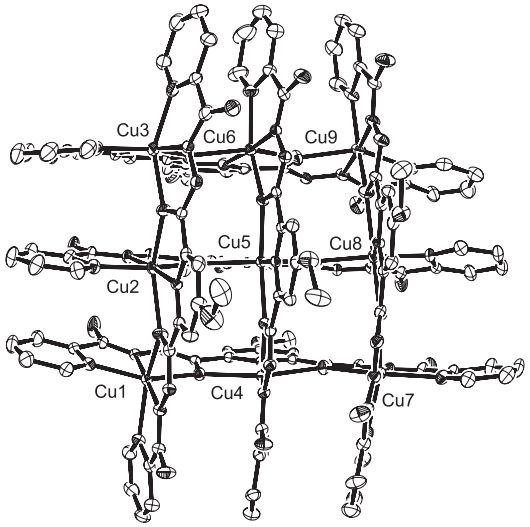


Fig. 30. Structural representation of $[Cu_9(M2poap\text{-}H)_2(M2poap\text{-}2H)_4](NO_3)_8\cdot 17H_2O$ (**21**).

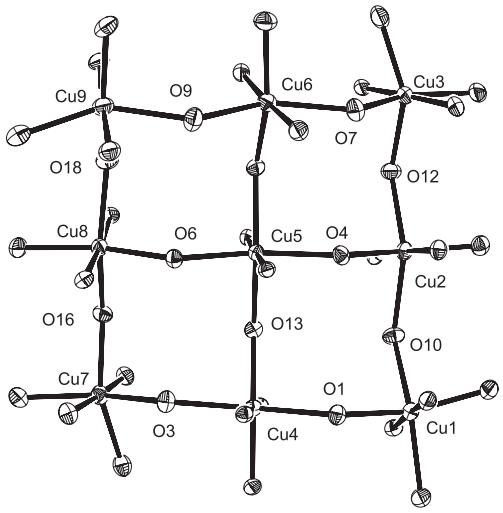
veals axially elongated geometries indicating $d_{x^2-y^2}$ ground states, with the central atom having a compressed tetragonal geometry, suggestive of a d_{z^2} ground state. The magnetic orbital arrangement in the ring is most unusual but parallels that in the "pinwheel" complexes, with all copper magnetic planes arranged with strict magnetic orbital orthogonality. This leads to ferromagnetic exchange within the ring (vide infra). All other Cu_9 grid molecules in this class have similar magnetic orbital topologies. The central d_{z^2} copper ion is also expected to be orthogonally connected, but magnetic studies indicate that this is not the case (32, 39, 45).

The magnetic exchange models for the copper "grid" and "pinwheel" complexes (see eqs. [4] and [6] for the exchange

Fig. 31. Core structural representation of $[Cu_9(M2poap\text{-}H)_2(M2poap\text{-}2H)_4](NO_3)_8\cdot 17H_2O$ (**21**).



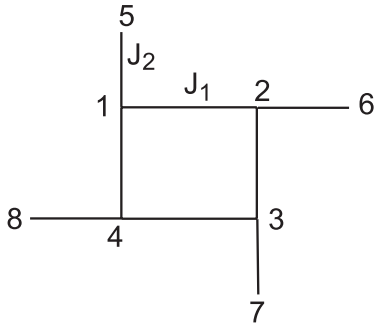


Fig. 32. Magnetic exchange model for Cu_8 pinwheel cluster.

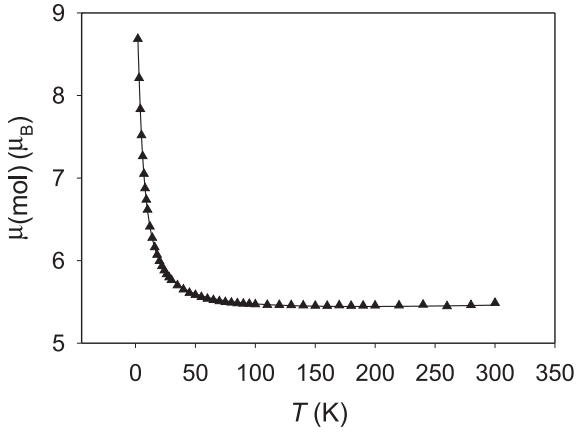
Hamiltonian expressions and Figs. 24 and 32) are quite different.

$$[6]\qquad H_{ex} = -J_1\{S_1\cdot S_2 + S_2\cdot S_3 + S_3\cdot S_4 + S_1\cdot S_4\} - J_2\{S_1\cdot S_5 + S_2\cdot S_6 + S_3\cdot S_7 + S_4\cdot S_8\}$$

A reasonable simplification for the Cu_8 systems is to assume that $J_1 \approx J_2$, since the Cu–Cu separations and Cu-O-Cu angles are similar throughout the cluster. The large number of spin centers in these and other high-nuclearity clusters prompted us to create a software package that would deal with the complex calculations of the total spin quantum number situations and their energies using a typical Kambe vector summation approach (46) and then substitute these internally into the van Vleck equation (eq. [7]) to generate a theoretical magnetic susceptibility (χ_m)/temperature profile.



$$[7]\qquad \chi_m = \frac{N\beta^2 g^2[\Sigma S'(S'+1)(2S'+1)\,e^{-E(S')/kT}}{3k(T-\theta)[\Sigma(2S'+1)e^{-E(S')/kT}} + \text{TIP}$$

The software package that we created, MAGMUN4.0,[3] runs on a Windows™ platform, deals with a variety of spin-

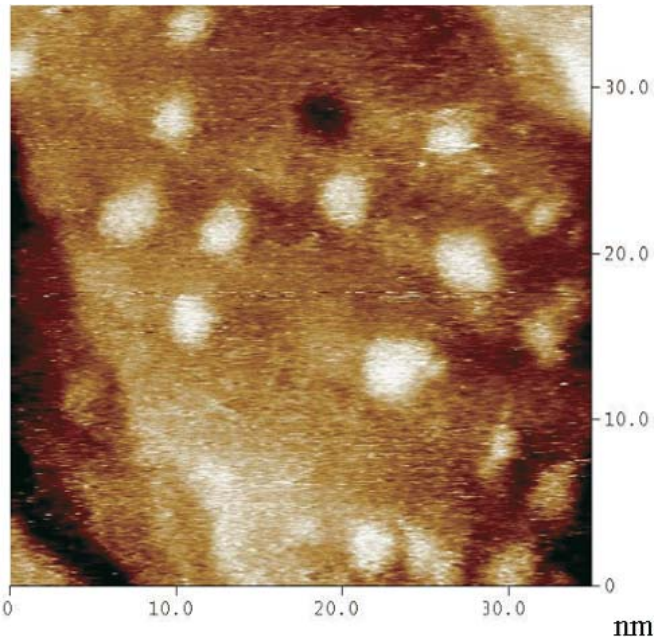

Fig. 33. Magnetic moment variation as a function of temperature for **20** (solid line calculated using fitted parameters quoted in the text).

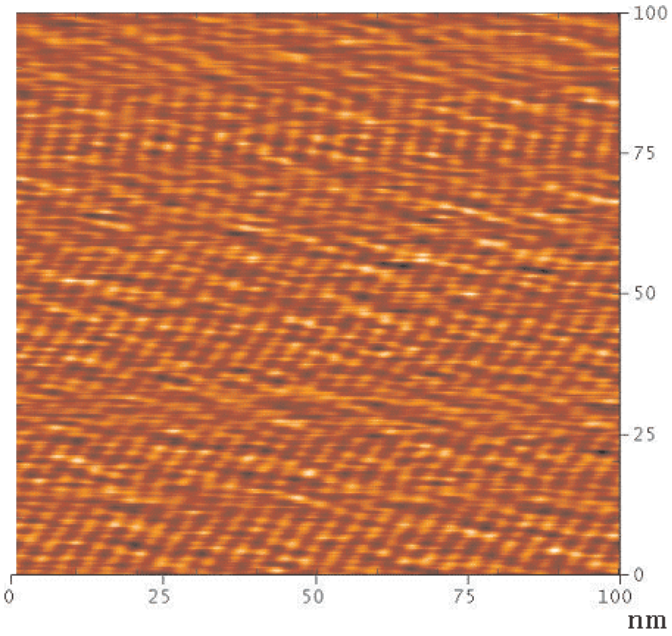
coupled situations irrespective of geometry, and can provide a full fitting of both simple and quite complex exchange situations using nonlinear regression fitting procedures. Such calculations are, however limited by the computer RAM available (vide supra), because of the size of the matrices involved in the spin coupling schemes. As an illustration, for a fully isotropic calculation based on eq. [4] ($J_1 = J_2$), the RAM requirements for $S = 3/2$ (largest dimension 5300), 4/2 (largest dimension 25 200), and 5/2 (largest dimension 88 900) [3 × 3] grids are 215 MB, 4.8 GB, and 60.3 GB, respectively. Imposing D_4 rotational symmetry can reduce the requirements significantly, and for the $S = 5/2$ case (largest dimension 22 210), only 3.8 GB are required. This still places such calculations beyond the capability of most PCs.

The magnetic exchange for the Cu_8 clusters and Cu_9 grids can be solved successfully using MAGMUN4.0. For compound **20**, the magnetic moment rises from 5.5 μ_B at 300 K to 8.7 μ_B at 2 K, which is indicative of intramolecular ferromagnetic exchange (Fig. 33). Fitting of the data to eqs. [6] and [7] gave $g = 2.15(1)$, $J = 7.8(5)$ cm^{-1}, and TIP = 540 × 10^{-6} cm^3 mol^{-1} for a system with an $S = 8/2$ ground state (M/H data at 2K) (the solid line in Fig. 33 corresponds to this data fitting). This is entirely consistent with strict *d* orbital orthogonality within the cluster. The magnetic moment of compound **21** exhibits a different response as a function of temperature, with a room temperature moment of 5.84 μ_B, dropping steadily to 5.16 μ_B at 26 K, followed by a sharp rise to 6.39 μ_B at 2 K. Such a profile, which is typical of all the $Cu(II)_9$ grids studied, implies the presence of both antiferromagnetic and ferromagnetic exchange within the grids. Analysis of the variable-temperature magnetic data for **21** according to eqs. [4] and [7] gave $g = 2.17(1)$, $J_1 = 0.5(1)$ cm^{-1}, $J_2 = -23(1)$ cm^{-1}, and TIP = 790 × 10^{-6} cm^3 mol^{-1}, confirming the presence of ferromagnetic coupling in the Cu_8 ring. The negative J_2, which is typical of all Cu_9 grids, indicates that despite an expected ferromagnetic J_2 term based on magnetic orbital orthogonality arguments, the central copper ion plays an unusual role in the overall coupling scheme and must undergo some sort of dynamic Jahn–Teller distortion, which allows it to interact in an antiferromagnetic sense with its four neighbours. The net reduction in total spin is therefore 2/2, which means that the overall spin ground state for the grid is 9/2 – 2/2 = 7/2. This is confirmed by magnetization data as a function of field at 2 K.

Fig. 34. STM imagery for complex **15** attached to a Au(111) surface. The bright spots represent grid molecular ions attached in a flat conformation to the surface.



The [3 × 3] grid molecules have generated great interest in the physics community, as simple quantum dot models, and in the case of Mn(II) quantum oscillation effects have been demonstrated in the field dependence of the magnetic torque at low temperature (41). The novel, and close to reversible, electrochemical properties observed in bulk solution, and the demonstrated ability of these systems to exist in mixed oxidation state structures, suggests that an individual molecule may exhibit similar properties if it can be appropriately addressed in the solid state. The flat nature of the grids implies that they may adhere well to certain surfaces. As a simple test, electrochemistry was carried out on compound **15**, which has chlorine atoms exposed prominently on both faces of the grid (Fig. 21), using a gold electrode in place of platinum. Similar redox responses were observed to those obtained with platinum. The gold electrode was then thoroughly cleaned and immersed in a solution of **15** in acetonitrile for an extended period. The electrode was then rinsed thoroughly, and cyclic voltammetry performed on the electrode in the absence of dissolved grid. Redox responses in the 0–1.2 V range clearly indicated gold-bound grid molecules.

Surface studies were then carried out on Au(111) films formed on mica substrates, and imaging performed using scanning tunneling microscopy (STM) techniques. Compound **15** was deposited from a dilute solution in acetonitrile. STM imagery shows that individual molecules are attached to the gold surface (Fig. 34). The grid dimensions are consistent with the "footprint" of the grid observed from the X-ray structural determination and indicate that the mol-

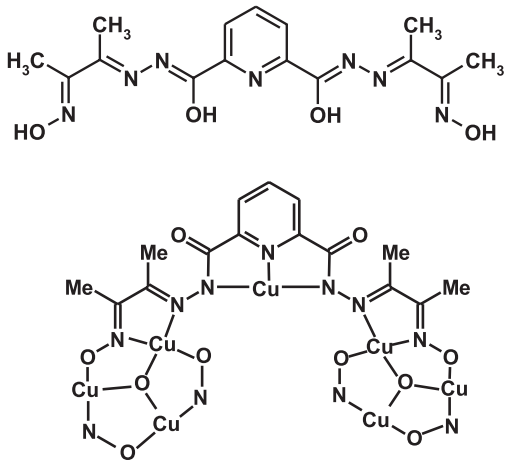
Fig. 35. STM imagery for complex $[Mn_9(S2poap)_6](ClO_4)_{10}\cdot 12H_2O$ (**22**) bound as a self-assembled monolayer (SAM) to Au(111).

ecules are bound in a flat conformation, with the chlorine atoms as the likely points of surface attachment (47). Surface binding on gold would be much stronger with sulphur-based groups attached at the 4-position of the central ligand pyridine ring. This has been achieved with a $Mn(II)_9$ grid complex of the ligand S2poap (Fig. 20; R = S^-), $[Mn_9(S2poap)_6](ClO_4)_{10}\cdot 12H_2O$ (**22**). The Au(111) surface imagery in this case is quite remarkable (Fig. 35) and indicates that a self-assembled monolayer (SAM) has formed from a dilute acetonitrile solution of the complex. The bright spots have dimensions on the order of 2.6 nm across, completely consistent with the molecular structural dimensions obtained for grids in this class by X-ray crystallographic techniques (48). Spaces between the grids (dark spots) are comparable in size to the grids themselves.

The [2 × 2] and [3 × 3] grids are novel systems with molecular-based properties that rely on the close juxtaposition of the metal ions themselves and the simple oxygen atom bridges that connect them. This leads to considerable electron delocalization within the grids, and electronic properties that are manifested in terms of rich electrochemistry in the case of the Mn_9 systems and magnetic properties that reflect electron communication throughout the grids. Future and ongoing studies are aimed at addressing individual molecules on surfaces, as already demonstrated by STM imagery, by probing the electronic properties at the molecular level, and even detecting individual molecules based on the presence of unpaired spins. This has recently been demonstrated using a combination of STM and ESR on organic radicals bound to a highly oriented pyrolytic graphite (HOPG) surface (49). The Mn_9 grids are considered to have significant potential for device behaviour at the molecular level, in, e.g., a switching or data storage capacity.

Fig. 36. The extended ligand dpocco and bonding motif with copper(II).



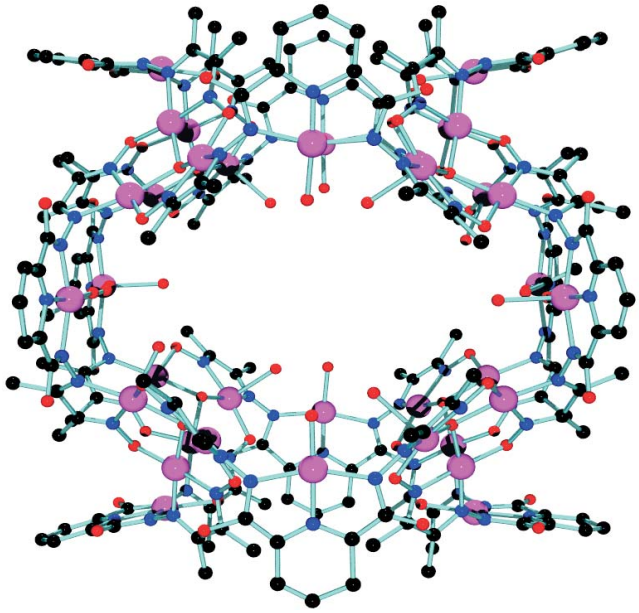


Fig. 37. Structural representation of $[Cu_{36}(dpocco\text{-}4H)_{12}(\mu_3\text{-}OH)_8](CH_3COO)_{16}\cdot xH_2O$ (**23**). Colour code: Cu, magenta; C, black; O, red; N, blue.

Larger grids and clusters are a logical extension of the work achieved so far, and they can be approached in a more or less systematic way using extended ligands. Extension of the 2,6-picolinic-dihydrazone core by reaction with butanedione monoxime leads to the ligand dpocco (Fig. 36), which has the tritopic core found in, e.g., 2poap, but with peripheral ligating groups capable of additional coordination. Reaction of dpocco with $[Cu(OAc)_2(H_2O)]_2$ led to dark crystals whose structure revealed a most unusual Cu_{36} cluster $[Cu_{36}(dpocco\text{-}4H)_{12}(\mu_3\text{-}OH)_8](CH_3COO)_{16}\cdot xH_2O$ (**23**) (50). The ligand adopts a different conformation from that observed in the [3 × 3] grids, with a copper bound in a central N_3 pocket, but bridged via μ_2-N–N groups to two peripheral copper ions (Fig. 37). The oxime function at the end of each ligand takes part in additional bonding to two more similar

copper subunits, forming a μ_3-OH bridged trinuclear, triangular fragment. This arrangement extends throughout the collection of 12 such subunits forming the Cu_{36} cluster (Fig. 37). A simplified core representation is shown in Fig. 38. The magnetic properties of this unique cluster indicate intramolecular antiferromagnetic exchange, with a moment at room temperature of 10.1 μ_B dropping to 4.5 μ_B at 2 K. The large spin state associated with this cluster has thus far prevented solution of the exchange problem.

Conclusion

The formation of polynuclear coordination complexes can be achieved up to a certain size by combining metal ions with single ligands, providing they have a large number of coordination pockets. Synthetic difficulties with large ligands, and adverse entropy situations, seriously impede the formation of systems with high nuclearities, and in our case four was the largest number. Metal-ion template cyclizations can produce larger systems by the controlled organization of appropriate subunits into, e.g., large macrocycles, and nuclearities up to six have been achieved in this way. The pursuit of higher nuclearity clusters and grids has been a challenge, but the design and synthesis of polyfunctional ligands with appropriately arranged coordination pockets can lead to nuclearities up to 36 by taking advantage of, for instance, self-assembly processes. Generally, this approach produces stable clusters and grids in high yield and provides a thermodynamic driving force to counterbalance the negative entropy effects involved in organizing large numbers of particles into the same unit. This method is again based on ligand synthesis, but in principle it is a simpler way to

© 2005 NRC Canada

achieve novel high-nuclearity systems. The M_9 grids, particularly those with manganese, have proven to be unique systems in terms of their magnetic and electronic properties.

The synthesis of larger [$n \times n$] grids (e.g., $n = 4$, 5) and compartmental grids (e.g., $4 \times [3 \times 3]$) based on 2,6-picolinic-dihydrazone subunits (Fig. 39) depends on the extension of this type of ligand with suitable additional coordination pockets. This would involve maintaining the linear sequence of five-membered chelate rings, and also the repeating arrangement of "enolic" oxygen donors. Figure 40 illustrates examples of tetratopic, pentatopic, and hexatopic ligands (*a*, *b*, and *c*, respectively), which could be synthesized by extension of the picolinic hydrazone framework. Examples of ligands in all three classes have been synthesized, and preliminary results indicate that extended [4 × 4] grids can be produced.

Acknowledgements

The work described in this paper has been the result of many contributions from undergraduate students, high school students, graduate students, postdoctoral fellows, research associates, and sabbatical associates with whom I have had the privilege of working over the years. Also I must thank and acknowledge numerous collaborators both within and outside Canada, whose expertise and interest have fostered, advanced and encouraged our work. These numerous researchers should all share in the Alcan Lecture Award.

Pursuing research in a smaller university always presents special challenges, but Memorial University has always been supportive financially, logistically and in terms of teaching loads. Generous financial support from the Natural Sciences and Enginerring Research Council of Canada (NSERC) over the years has been a major component in financing our research programme, but international support via collaborative research projects from NATO, the Engineering and Physical Sciences Research Council (UK) Monbusho, and the Norwegian Research Council has also played a significant role.

Finally, it is indeed an honour to have been chosen to receive the Alcan Lecture Award. Thanks are extended to the Aluminum Company of Canada for providing the award and to the Canadian Society for Chemistry for sponsoring it.

Stereoselective synthesis of multiply substituted [1,2]oxazinan-3-ones via ring-closing metathesis

Gennady V. Shustov, Melanie K. Chandler, and Saul Wolfe

Abstract: The title compounds are α-amino acids whose nitrogen atoms are enclosed within 4,5-disubstituted, six-membered cyclic hydroxamates and they are of interest as potential β-lactam surrogates. The compounds have been synthesized in the present work by functionalization of the double bonds of *N*-substituted 6*H*-[1,2]oxazin-3-ones, which are obtained upon successive reaction of the triflates of *S*-α-hydroxy esters with *O*-allylhydroxylamine and acryloyl chloride, followed by cyclization of the resulting *R*-α-*N*-acryloyl-*N*-allyloxyamino esters in the presence of the ring-closing metathesis (RCM) catalyst bis(tricyclohexylphosphine)benzylideneruthenium dichloride. The olefins are also accessible, but less efficiently so, by a Wittig sequence that employs bromoacetyl bromide in place of acryloyl chloride, followed successively by triphenylphosphine, silver triflate, ozonolysis, and cyclization. Asymmetric dihydroxylation of these chiral olefins affords a single diastereomer in high yield having either the α*R*,4*S*,5*S*- or the α*R*,4*R*,5*R* configuration, depending on the auxiliary. The configuration of the α*R*,4*R*,5*R* isomer has been confirmed by its conversion to (α*R*,4*S*,5*R*)-2-(α-carboxyethyl)-4-phenylacetylamino-5-hydroxy-1,2-oxazinan-3-one, whose α*R*,4*R*,5*S* diastereomer was previously prepared from L-ascorbic acid. With *N*-bromosuccinimide in aqueous dimethylformamide, a 6*H*-[1,2]oxazin-3-one afforded a separable 1:1 mixture of bromohydrins, which could be cyclized to epoxides or hydrogenolyzed to 5-hydroxy-1,2-oxazinan-3-ones.

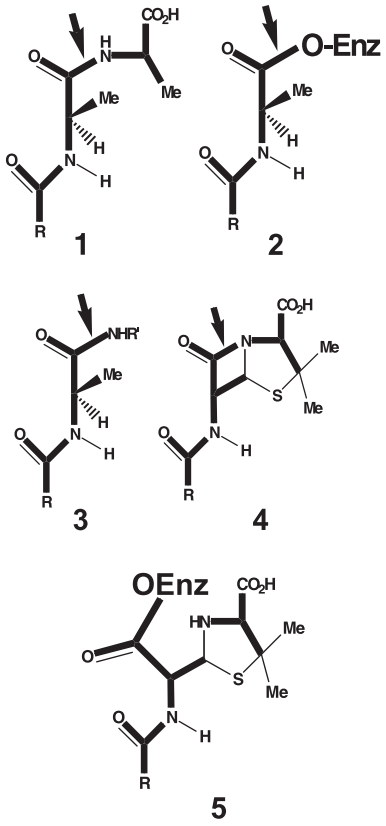
Key words: penicillin surrogates, asymmetric dihydroxylation, bis(tricyclohexylphosphine)benzylideneruthenium dichloride, cyclic sulfite, epoxides, azidohydrin, bromohydrin.

Résumé : Les composés mentionnés dans le titre sont des acides α-aminés dont l'atome d'azote fait partie d'hydroxamates cycliques à six chaînons substitués dans les positions 4 et 5 qui présentent de l'intérêt comme substituts de β-lactames. Dans ce travail, les composés ont été synthétisés par le biais d'une fonctionnalisation de doubles liaisons de 6*H*-[1,2]oxazin-3-ones *N*-substituées qui sont obtenues par la réaction successive des triflates des esters *S*-α-hydroxylés avec de la *O*-allylhydroxylamine et du chlorure d'acryloyle, suivie d'une cyclisation des esters *R*-α-*N*-acryloyl-*N*-allyloxyamino en présence du catalyseur RCM, dichlorure du bis(tricyclohexylphosphine)benzylidène ruthénium. Les oléfines sont aussi accessibles, mais d'une façon moins efficace, par le biais d'une séquence de Wittig faisant appel au bromure de bromoacétyle, à la place du chlorure d'acryloyle, suivie successivement d'une réaction avec le triphénylphosphine, le triflate d'argent, d'une ozonolyse et d'une cyclisation. La dihydroxylation asymétrique de ces oléfines chirales conduit à un seul diastéréoisomère, avec un rendement élevé, de configuration α*R*,4*S*,5*S*- ou α*R*,4*R*,5*R*- suivant la nature de l'auxiliaire. La configuration de l'isomère α*R*,4*R*,5*R* a été confirmée par sa conversion en (α*R*,4*S*,5*R*)-2-(α-carboxyéthyl)-4-phénylacétylamino-5-hydroxy-1,2-oxaziran-3-one, dont le diastéréoisomère a antérieurement été préparé à partir de l'acide L-ascorbique. La réaction du *N*-bromosuccinimide, dans le diméthylformamide aqueux, avec une 6*H*-[1,2]oxazin-3-one conduit à la formation d'un mélange 1 : 1 de bromohydrines qui peut facilement être séparé alors que les deux isomères peuvent être cyclisés en époxydes ou hydrogénolysés en 5-hydroxy-1,2-oxazinan-3-ones.

Mots clés : substituts de pénicilline, dihydroxylation asymétrique, dichlorure de bis(tricyclohexylphosphine)benzylidèneruthénium, sulfite cyclique, époxydes, azidohydrine, bromohydrine.

[Traduit par la Rédaction]

The final stage of bacterial cell wall peptidoglycan biosynthesis proceeds in two steps (1). The first is displacement of the terminal D-alanine from an RCO-D-ala-D-ala chain by the hydroxyl group of a serine peptidase (**1** → **2**). The second is a cross-linking reaction in which the enzyme is displaced from the depsipeptide by an amino group of another chain (**2** → **3**). These serine peptidases, also known as penicillin-binding proteins (PBPs) (2), are the targets of β-lactam antibiotics (**4** → **5**).



It has been recognized for many years that **1** and **4** are structural analogs (3), i.e., that β-lactam antibiotics are *N*-acyl-D-ala-D-ala surrogates. Since lactivicin (**6**), an antibiotic

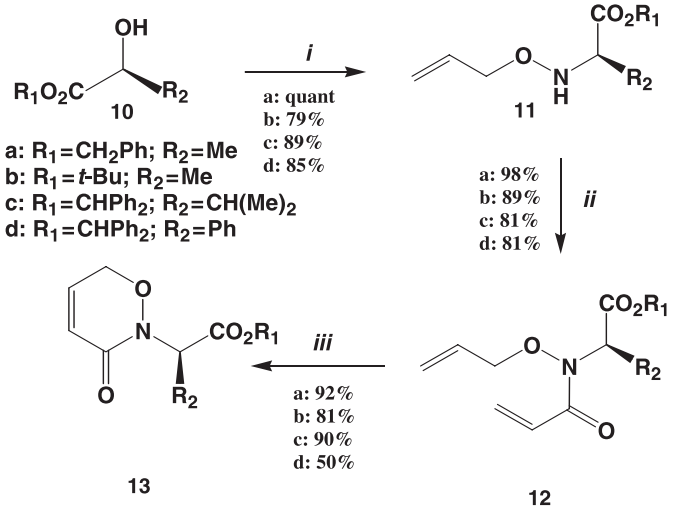
isolated from culture filtrates of *Empedobacter lactagenus* YK-258 and *Lysobacter albus* YK-422, also functions by acylation of the serine hydroxyl groups of PBPs and other penicillin-recognizing enzymes (4), it seems likely that lactivicin is a penicillin and *N*-acyl-D-ala-D-ala analog, and that an isoxazolidin-3-one ring, a five-membered cyclic hydroxamate, is a β-lactam surrogate.

We have recently reported that *six*-membered cyclic hydroxamates of general structure **7** may also serve as β-lactam and D-ala-D-ala surrogates. In a first synthetic approach to such compounds (**8**, Z = H, Me) (5), based on disconnection **a**, protected *N*-hydroxyglycine and *N*-hydroxyalanine were coupled to racemic protected β-hydroxy-γ-bromobutyric acid, and the cyclic hydroxamate was generated by O1-C5 ring closure. In a second approach (6), based on disconnection **b** (**9**), the cyclic hydroxamate was prepared by trimethylaluminium-promoted cyclization of an ε-aminooxyester. These initial syntheses suggested that a stereocontrolled approach to **7**, with extensive variation of X, Y, and Z via **a** would be difficult, because of significant competing *O*-acylation when Z ≠ H, and that syntheses via **b** would also be unsatisfactory because of the large number of steps (11 steps from L-ascorbic acid to **7**, Z = Me, X = α-hydroxy, Y = β-phenylacetamido) and low overall yield (0.9%).

This paper reports a stereocontrolled route to **7**, based on **c**, the functionalization of olefins **13**, which are accessible in three steps from the benzyl, benzhydryl or *tert*-butyl L-α-hydroxyesters **10** by a ring-closing metathesis (RCM) strategy (7).

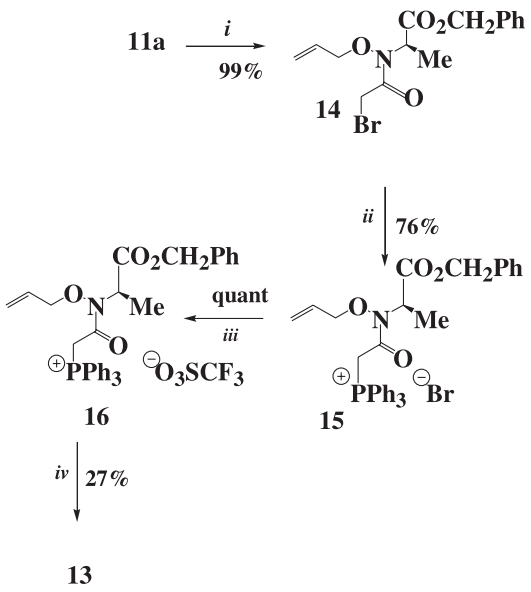
Scheme 1 summarizes the results obtained starting with the α-hydroxy acids available from the nitrous acid deaminations of L-alanine, L-valine and L-phenylglycine. In situ reaction of allyloxyamine (8) with the triflates of **10** proceeded with inversion of configuration (6, 9) to yield the *R*-α-allyloxyamino esters **11**, which were converted to the RCM precursors **12** with acryloyl chloride. With the exception of the phenyl compound (R_2 = Ph), cyclization to **13** was achieved in 80%–90% yield in refluxing methylene chloride in the presence of the first generation Grubbs catalyst bis(tricyclohexylphosphine)benzylideneruthenium dichloride (4 to 5 mol%).

The synthetic improvement provided by the RCM approach can be seen upon comparison of the cyclizations of **12a** and of the Wittig precursor **16**. Thus (Scheme 2), successive reaction of **11a** with bromoacetyl bromide, triphenylphosphine, and silver triflate, followed by ozonolysis and treatment with potassium carbonate led to cyclization to **13a** in 27% yield.



Schemes 3 and 4 exemplify reaction sequences that have been applied to the olefins **13**. In Scheme 3, Sharpless asymmetric dihydroxylation (10) leads, depending on the auxiliary, either to a β-diol **17** or an α-diol **19** as a single diastereomer in each case, and these diols can be deprotected to carboxylic acids **18** or **20**, respectively. The cyclic sulfi*te* (11) of **19** afforded the *trans*-azidohydrin **22** (12),[2] which was converted in 81% overall yield, into **25**, the (α*R*,4*S*,5*R*)-isomer of 2-(α-carboxyethyl)-4-phenylacetylamino-5-hydroxy-1,2-oxazinan-3-one (**25**), which was different from the (α*R*,4*R*,5*S*)-isomer (**7**) synthesized previously from L-ascorbic acid.

As summarized in Scheme 4, **26**, the 6*H*-[1,2]oxazin-3-one prepared from benzhydryl *S*-lactate, reacted with *N*-bromosuccinimide in aqueous dimethylformamide to give, in addition to the dibromides **27**, a separable mixture of bromo-



[2] No attempt was made to improve the (nonoptimized) 18% yield of this reaction (11). Cyclic sulfates (13) are, in general, more effective substrates for this reaction than cyclic sulfites, but this route was also not pursued (14).

dried (140 °C, 24 h) glassware. The glassware was allowed to cool in a desiccator under vacuum and assembled cold, capped with rubber septa, and evacuated with dry nitrogen gas. Both ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Bruker model AMX 400 spectrometer operating at 400.1 and 100.6 MHz, respectively. Chemical shifts (δ) are reported in parts per million (ppm) relative to tetramethylsilane (TMS) in an appropriate deuterated solvent. ^{1}HMR data are reported in the following manner: chemical shift, integration, peak multiplicity, coupling constants, and identification. The peak multiplicities are abbreviated as s (singlet), d (doublet), t (triplet), q (quartet), dd (doublet of doublets), ddd (doublet of doublets of doublets), m (multiplet), etc. ^{13}CMR data are reported as δ values in ppm downfield from tetramethylsilane. Infrared (IR)

spectra were recorded on a Bomen-Hartmann-Braun spectrometer (1% KBr or 1% solution). Mass spectra refer to direct inlet EI measurements or CI measurements, using isobutane, or fast-atom bombardment (FAB) employing xenon gas, on a Kratos MS50 spectrometer operated at 70 eV by G. Owens at Simon Fraser University. Melting points (mp) were determined on a Fisher-Johns apparatus, and are uncorrected. Analytical thin layer chromatography (TLC) was carried out on precoated Merck silica gel 60 F-254 plates with aluminium backing. Spots were observed under short-wavelength UV light, or were visualized with iodine vapour, ninhydrin, or ceric sulfate. Flash column chromatography (16*a*) and dry-column flash chromatography (16*b*) were carried out on Merck silica gel 60 (230–400 mesh), using only distilled solvents under dry nitrogen gas. Elemental analyses were performed by M.K. Yang on a Carlo Erba model 1106 elemental analyzer at Simon Fraser University.

Allyloxyamine

DBU (46.36 mL, 0.31 mol) was added in one portion, with stirring, to a cooled solution (5–10 °C) of *N*-hydroxyphthalimide (53.80 g, 0.33 mol) in DMF (120 mL). After 10 min, allyl bromide (25.96 mL, 0.30 mol) was added dropwise. When the addition was complete, the cooling bath was removed and the reaction mixture was stirred at room temperature for 1 h, until the color turned from dark burgundy to yellow. Ethyl acetate (300 mL) and water (150 mL) were added, the aqueous phase was separated, and the organic phase was washed with water (4 × 50 mL). The combined aqueous extracts were back-extracted with EtOAc (3 × 50 mL) and the combined organic layers were washed with satd. $NaHCO_3$ (10 × 50 mL) until the aqueous phase was pale yellow, then with brine (2 × 75 mL), dried over anhydr. $MgSO_4$ and concentrated to give *N*-allyloxyphthalimide 58.83 g (96%), mp 59 to 60 °C (lit. value (3) mp 59 to 60 °C) as a white solid. A solution of the *N*-allyloxyphthalimide (58.70 g, 0.289 mol) in dry ethanol (295 mL) was treated dropwise, with stirring, with a solution of hydrazine hydrate (14.01 mL, 0.289 mol) in EtOH (44 mL). The reaction mixture immediately turned yellow and a white precipitate formed. The mixture was refluxed for 2 h, stirred at room temperature for 17 h, cooled (10–15 °C), concentrated, and concd. HCl (30.24 mL, 0.37 mol) was added dropwise. The white precipitate was removed by filtration and washed with water (160 mL). The filtrate was concentrated under reduced pressure and the residue was maintained at 1 torr (1 torr = 133.322 4 Pa) for 3 h. Water (100 mL) was added, the solution was filtered, and the filtrate was concentrated to 50 mL and added portionwise to KOH pellets in a distillation apparatus. The product was collected at 80–100 °C. A second distillation over KOH pellets afforded 18.96 g (89%) of allyloxyamine as a colorless liquid, bp 94–97 °C (lit. value (17) bp 98 to 99 °C).

(*R*)-*N*-Allyloxyalanine benzyl ester (11a)

A solution of triflic anhydride (10.86 g, 38.5 mmol) in dry CH_2Cl_2 (20 mL) was added dropwise to a solution of benzyl (*S*)-lactate (**10a**) (6.31 g, 35 mmol) in dry CH_2Cl_2 (100 mL) with cooling (–68 to –72 °C) and stirring. After 5–7 min, a solution of 2,6-lutidine (4.31 g, 40.3 mmol) in dry CH_2Cl_2 (15 mL) was added dropwise at the same temperature and the reaction mixture was stirred for 30 min at –68 to –72 °C. A solution of allyloxyamine (4.55 g, 77 mmol) in dry CH_2Cl_2 (15 mL) was then added dropwise, with cooling (–68 to –72 °C) and stirring. The reaction mixture was stirred for 15 min at ca. –72 °C and then was allowed to warm to room temperature. Stirring was continued for 15 h and the reaction mixture was then shaken with satd. $NaHCO_3$ (200 mL) and dried over $MgSO_4$. After removal of the solvent, the residue was purified by dry flash chromatography (silica gel 60H for TLC, 10% EtOAc – hexanes) to afford 8.20 g (quant) of the product as a pale yellowish oil. IR (film, cm^{-1}): 3264, 1740, 1456, 1208, 1170. ^{1}H NMR (100 MHz, $CDCl_3$ + 1 drop of D_2O) δ: 1.28 (3H, d, ^3J = 7.1 Hz, *Me*CH), 3.82 (1H, q, ^3J = 7.1 Hz, MeC*H*), 4.22 (2H, dt, ^3J = 5.7 Hz, ^4J = 1.2 Hz, OCH_2CH=CH$_2$), 5.16–5.37 (2H, m, CH=CH_2), 5.23 (2H, CH_2Ph), 5.76–6.15 (1H, m, ^3J = 5.7 Hz, $^3J^{cis}$ = 9.9 Hz, $^3J^{trans}$ = 17.1 Hz, C*H*=CH$_2$), 7.38 (5H, *Ph*).^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.81, 59.09, 66.63, 75.22, 117.53, 128.06, 128.24, 128.56, 134.37, 135.84, 174.01. (*R*)-*N*-Acryloyl-*N*-allyloxyalanine benzyl ester (12a)

A solution of acryloyl chloride (3.26 g, 36 mmol) in dry CH_2Cl_2 (20 mL) was added dropwise with cooling (–5 to –10 °C) and stirring to a solution of (*R*)-*N*-allyloxyalanine benzyl ester (**11a**) (7.06 g, 30 mmol) and Et_3N (4.55 g, 45 mmol) in dry CH_2Cl_2 (80 mL). The reaction mixture was stirred for 1 h at 0–5 °C and then for 4.5 h at room temperature. After dilution with CH_2Cl_2 (ca. 150 mL), the mixture was washed successively with water (3 × 50 mL), 1 N HCl (50 mL), brine (100 mL), and dried over $MgSO_4$. Removal of the solvent gave 9.16 g of a yellow oil, which was purified by dry flash chromatography (silica gel 60H for TLC, 3% EtOAc – hexanes to 15% EtOAc – hexanes) to afford 8.52 g (98%) of the product as a colorless oil. IR (film, cm^{-1}): 1746, 1667, 1621, 1411. ^{1}H NMR (100 MHz, $CDCl_3$) δ: 1.61 (3H, d, ^3J = 7.3 Hz, *Me*CH), 4.45 (2H, dq, ^3J = 6.0 Hz, ^4J = 1.1 Hz, OCH_2CH=CH$_2$), 5.09 (1H, q, ^3J = 7.3 Hz, MeC*H*,), 5.21 (2H, CH_2Ph), 5.25–5.47 (2H, m, CH=CH_2, allyl), 5.76–6.15 (1H, m, ^3J = 6.0 Hz, $^3J^{cis}$ = 10.0 Hz, $^3J^{trans}$ = 17.3 Hz, C*H*=CH$_2$, allyl), 5.83 (1H, dd, ^2J = 2.7 Hz, $^3J^{cis}$ = 7.6 Hz, CH=CH_AH$_B$, acryloyl), 6.48 (1H, dd, ^2J = 2.7 Hz, $^3J^{trans}$ = 17.2 Hz, CH=CH$_A$$H_B$, acryloyl), 6.80 (1H, dd, $^3J^{cis}$ = 7.6 Hz, $^3J^{trans}$ = 17.2 Hz, C*H*=CH$_2$, acryloyl) 7.39 (5H, *Ph*). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.06, 56.45, 67.10, 78.27, 120.28, 126.21, 128.07, 128.21, 128.48, 130.04, 130.91, 135.47, 168.22, 170.35. MS (CI, isobutane), *m/z*: 290 (M^+ + 1). Anal. calcd. for $C_{16}H_{19}NO_4$ (%): C 66.4, H 6.6, N 4.8; found: C 66.4, H 6.7, N 5.1.

(*R*)-2-(3-Oxo-3,6-dihydro[1,2]oxazin-2-yl)-propionic acid benzyl ester (13a)

A solution of (*R*)-*N*-acryloyl-*N*-allyloxyalanine benzyl ester (**12a**) (7.32 g, 25.3 mmol) and bis(tricyclohexylphosphine)benzylideneruthenium dichloride (1.04 g, 1.26 mmol, 5 mol%) in dry CH_2Cl_2 (250 mL) was refluxed for 6 h under nitrogen, with stirring. Stirring was continued for 20 h at room temperature and the dark brown reaction mixture was then filtered through a short pad of silica gel 60H (for TLC), which was washed with CH_2Cl_2 (50 mL). After concentra-

tion of the filrate, the dark oily residue was purified by dry flash chromatography (silica gel 60H for TLC, 5% EtOAc – hexanes to 15% EtOAc – hexanes) to afford 6.05 g (92%) of the product. IR (film, cm^{-1}): 1745, 1675, 1214, 1189. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.53 (3H, d, ^3J = 7.3 Hz, *Me*CH), 4.46 (1H, dq, ^2J = –15.9 Hz, ^3J = 3.4 Hz, ^4J = 1.8 Hz, OCH_ACH=CH), 4.56 (1H, dq, ^2J = 15.9 Hz, ^3J = 3.4 Hz, ^4J = 1.8 Hz, OCH_BCH=CH), 5.15 (1H, d, ^2J = 12.4 Hz, CH_APh), 5.19 (1H, q, MeC*H*, ^3J = 7.3 Hz), 5.22 (1H, d, ^2J = 12.4 Hz, CH_BPh), 6.04 (1H, dt, $^3J^{cis}$ = 10.0 Hz, ^4J = 1.8 Hz, CH=C*H*CO), 6.72 (1H, dt, $^3J^{cis}$ = 10.0 Hz, ^3J = 3.4 Hz, CH_2C*H*=CHCO), 7.27–7.40 (5H, m, *Ph*). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.71, 53.57, 67.08, 67.57, 122.32, 128.02, 128.26, 128.52, 135.49, 139.67, 164.64, 170.09. MS (CI, isobutane), *m*/*z*: 262 (M^+ + 1). Anal. calcd. for $C_{14}H_{15}NO_4$ (%): C 64.4, H 5.8, N 5.4; found: C 64.3, H 5.85, N 5.6.

(*R*)-*N*-(Bromoacetyl)-*N*-allyloxyalanine benzyl ester (14)

A solution of bromoacetyl bromide (2.22 g, 11 mmol) in dry CH_2Cl_2 (20 mL) was added dropwise with cooling (–25 to –30 °C) and stirring to a solution of (*R*)-*N*-allyloxyalanine benzyl ester (**11a**) (2.59 g, 11 mmol) and Et_3N (1.11 g, 11 mmol) in dry CH_2Cl_2 (30 mL). The reaction mixture was stirred for 1 h at 0–5 °C and then allowed to warm to room temperature. After dilution with CH_2Cl_2 (ca. 30 mL), the mixture was washed successively with water (2 × 30 mL), 1 N HCl (30 mL), satd. $NaHCO_3$ (30 mL), dried over $MgSO_4$, and evaporated to yield **14** as a yellowish oil. IR (film, cm^{-1}): 1746, 1678, 1455, 1214. ^1H NMR (100 MHz, $CDCl_3$) δ: 1.60 (3H, d, ^3J = 7.3 Hz, *Me*CH), 4.08 (2H, CH_2Br), 4.49 (2H, dt, ^3J = 6.1 Hz, ^4J = 0.9 Hz, OCH_2CH=CH_2), 4.98 (1H, q, MeC*H*, ^3J = 7.3 Hz), 5.16–5.48 (2H, m, CH=CH_2), 5.20 (2H, CH_2Ph), 5.76–6.15 (1H, m, ^3J = 6.1 Hz, $^3J^{cis}$ = 10.0 Hz, $^3J^{trans}$ = 17.3 Hz, C*H*=CH_2), 7.29–7.41 (5H, m, *Ph*). MS (CI, isobutane), *m*/*z*: 358, 356 (M^+ + 1).

Conversion of 14 to 15

A solution of **14** (3.90 g, 11 mmol) in dry toluene (10 mL) was added dropwise to a solution of triphenylphosphine (2.88 g, 11 mmol) in dry toluene (20 mL), and the reaction mixture was stirred for 24 h at room temperature. The precipitated yellow oil was separated, washed with toluene, and dried in vacuo to give a solid yellowish hygroscopic foam, which was reprecipitated from a mixture of dry CH_2Cl_2 (10 mL) and absolute ether (ca. 100 mL) to afford 5.16 g (76%) of **15** as a white hygroscopic foam.

Conversion of the bromide salt 15 to the triflate salt 16

A solution of silver trifluoromethanesulfonate (2.56 g, 10 mmol) in dry MeCN (20 mL) was added dropwise with stirring to a solution of **15** (6.18 g, 10 mmol) in dry MeCN (25 mL). The yellow precipitate was collected on a sintered glass funnel using a short pad of Celite® 545, and washed with MeCN (ca. 50 mL). The filtrate was concentrated under reduced pressure and the residual yellow foam was dissolved in CH_2Cl_2 (100 mL) and a small amount of $MgSO_4$ was added to coagulate small particles of AgBr. The solution was filtered again and the filtrate was concentrated to provide 6.52 g (quant) of **16** as a yellow highly hygroscopic foam. ^1H NMR (400 MHz, $CDCl_3$, major isomer) δ: 1.50 (3H, d, ^3J = 7.4 Hz, *Me*CH), 4.84 (1H, dd, ^2J = 11.5 Hz, ^3J = 6.1 Hz, OCH_ACH=CH_2), 4.80 (1H, q, MeC*H*, ^3J = 7.4 Hz), 4.84 (1H, dd, ^2J = 11.5 Hz, ^3J = 6.1 Hz, OCH_BCH=CH_2), 4.89 (1H, dd, $^2J_{HH}$ = 17.8 Hz, $^2J_{HP}$ = 12.7 Hz, CH_AP), 5.06 (1H, d, ^2J = 12.4 Hz, CH_APh), 5.10 (1H, d, ^2J = 12.4 Hz, CH_BPh), 5.31 (1H, br.d, $^3J^{cis}$ = 10.4 Hz, CH=CH_D), 5.35 (1H, dd, $^2J_{HH}$ = 17.8 Hz, $^2J_{HP}$ = 13.8 Hz, CH_BP), 5.49 (1H, dd, $^3J^{trans}$ = 17.2 Hz, ^2J = 1.2 Hz, CH=CH_E), 5.92–6.02 (1H, m, ^3J = 6.1 Hz, $^3J^{cis}$ = 10.4 Hz, $^3J^{trans}$ = 17.2 Hz, C*H*=CH_2), 7.4–7.8 (5H, m, *Ph*CH_2), 7.6–7.7 (15H, m, *Ph*$_3$P).

Ozonolysis and cyclization of 16

A solution of **16** (6.52 g, 9.95 mmol) in CH_2Cl_2 (180 mL) was cooled to –76 to –78 °C, stirred, and saturated with ozone (moderate bubbling until a persistent blue color remained). Excess ozone was removed by bubbling nitrogen through the reaction mixture at –76 to –78 °C, and Me_2S (3.1 g, 50 mmol) was added dropwise with stirring. The reaction mixture was allowed to warm to room temperature and a solution of K_2CO_3 (6.91 g, 50 mmol) in water (20 mL) was added with vigorous stirring. Water (100 mL) was added and the organic layer was separated, washed with water (2 × 30 mL), dried over $MgSO_4$, and concentrated to a yellow semisolid, which was purified by flash chromatography (silica gel 60H, 20% EtOAc – hexanes) to afford 0.70 g (27%) of **13** as a colorless oil, identical with the material prepared previously.

(*R*)-*N*-Acryloyl-*N*-allyloxyalanine *tert*-butyl ester (12b)

A solution of triflic anhydride (15.52 g, 55 mmol) in dry CH_2Cl_2 (25 mL) was added dropwise to a solution of *tert*-butyl (*S*)-lactate (**10b**) (6.71 g, 46 mmol) in dry CH_2Cl_2 (130 mL) with cooling (–68 to –72 °C) and stirring. After 5–7 min, a solution of 2,6-lutidine (6.16 g, 57.5 mmol) in dry CH_2Cl_2 (20 mL) was added dropwise and stirring was continued for 1.5 h at –68 to –72 °C. A solution of allyloxyamine (6.57 g, 90 mmol) in dry CH_2Cl_2 (20 mL) was then added dropwise, with continued cooling and stirring. After an additional 15 min stirring at –72 °C, the reaction mixture was allowed to warm to room temperature, and stirring was continued for 15 h. The reaction mixture was then shaken with satd. $NaHCO_3$ and the organic layer was dried over magnesium sulfate and evaporated to give 14.31 g (79% yield) of a 1.0:0.97 mixture of (*R*)-*N*-allyloxyalanine *tert*-butyl ester (**11b**) and 2,6-lutidine. Additional 2,6-lutidine (2.66 g, 24.8 mmol) was added to a solution of this mixture in dry CH_2Cl_2 (100 mL), the solution was cooled to –15 to –20 °C, and a solution of acryloyl chloride (5.09 g, 56.3 mmol) in dry CH_2Cl_2 (20 mL) was added dropwise, with stirring. Stirring was continued for 1 h at 0–5 °C and then 20 h at room temperature. After dilution with CH_2Cl_2 (ca. 150 mL), the mixture was washed successively with water (4 × 50 mL), 1 mol L^{-1} citric acid (2 × 50 mL), satd. $NaHCO_3$ (2 × 50 mL), dried over $MgSO_4$, and concentrated to give 12.73 g of a red oil, which was purified by dry flash chromatography (silica gel 60H for TLC, 1% EtOAc – hexanes to 7% EtOAc – hexanes) to afford 8.91 g (70% over the two steps) of **12b** as a colorless oil. IR (film, cm^{-1}): 2981, 1738, 1667, 1622, 1411. ^1H NMR (100 MHz, $CDCl_3$) δ: 1.47 (9H, *Me*$_3$C), 1.53 (3H, d, ^3J = 7.3 Hz, *Me*CH), 4.48 (2H, dq,

^3J = 5.9 Hz, ^4J = 1.2 Hz, OCH_2CH=CH_2), 4.93 (1H, q, ^3J = 7.3 Hz, MeC*H*,), 5.26–5.50 (2H, m, CH=CH_2, allyl), 5.76–6.18 (1H, m, ^3J = 5.9 Hz, $^3J^{cis}$ = 10.1 Hz, $^3J^{trans}$ = 15.6 Hz, C*H*=CH_2, allyl), 5.81 (1H, dd, ^2J = 2.6 Hz, $^3J^{cis}$ = 9.5 Hz, CH=CH_AH$_B$, acryloyl), 6.46 (1H, dd, ^2J = 2.6 Hz, $^3J^{trans}$ = 17.0 Hz, CH=CH$_A$$H_B$, acryloyl), 6.80 (1H, dd, $^3J^{cis}$ = 9.5 Hz, $^3J^{trans}$ = 17.0 Hz, C*H*=CH_2, acryloyl). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.12, 27.91, 57.28, 78.22, 81.83, 120.02, 126.42, 129.75, 131.09, 132.41, 168.34, 169.55. MS (CI, isobutane), *m*/*z*: 256 (M^+ + 1).

Cyclization of 12b to 13b

A solution of (*R*)-*N*-acryloyl-*N*-allyloxyalanine *tert*-butyl ester (**12b**) (3.39 g, 13.27 mmol) and bis(tricyclohexylphosphine)benzylideneruthenium dichloride (Grubbs' catalyst) (0.48 g, 0.58 mmol, 4.4 mol%) in dry benzene (120 mL) was refluxed with stirring under nitrogen for 6 h. Additional amounts (0.23 g, 0.28 mmol and 0.21 g, 0.25 mmol) of the catalyst were added and the reaction mixture was refluxed for 8 h after each of these additions. The dark brown reaction mixture was then filtered through a short pad of silica gel 60H (for TLC), which was washed with CH_2Cl_2 (100 mL). The filtrate was concentrated and the dark oily residue was purified by dry flash chromatography (silica gel 60H for TLC, 5% EtOAc – hexanes to 20% EtOAc – hexanes) to afford 2.45 g (81%) of **13b** as an oil. IR (film, cm^{-1}): 2979, 1737, 1677, 1368, 1162. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.46 (9H, *Me*$_3$C), 1.53 (3H, d, ^3J = 7.3 Hz, *Me*CH), 4.49 (1H, dq, ^2J = 15.8 Hz, ^3J = 3.4 Hz, ^4J = 1.8 Hz, OCH_ACH=CH), 4.64 (1H, dq, ^2J = –15.8 Hz, ^3J = 3.4 Hz, ^4J = 1.8 Hz, OCH_BCH=CH), 5.03 (1H, q, MeC*H*, ^3J = 7.3 Hz), 6.05 (1H, dt, $^3J^{cis}$ = 10.0 Hz, ^4J = 1.8 Hz, CH=C*H*CO), 6.74 (1H, dt, $^3J^{cis}$ = 10.0 Hz, ^3J = 3.4 Hz, CH_2C*H*=CHCO). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.77, 27.95, 54.16, 67.53, 81.82, 122.46, 139.47, 164.67, 169.28. MS (CI, isobutane), *m*/*z*: 228 (M^+ + 1). Anal. calcd. for $C_{11}H_{17}NO_4$ (%): C 58.1, H 7.5, N 6.2; found: C 58.4, H 7.7, N 6.3.

(*R*)-3-Methyl-2-(3-oxo-3,6-dihydro[1,2]oxazin-2-yl)-butyric acid (13, R_1 = H, R_2 = CH(Me)$_2$)

A solution of **13c** (2.00 g, 5.47 mmol) in 98% formic acid (120 mL) was stirred vigorously at room temperature for 6 h. The solvent was then removed in vacuo, and the residue, in dry CH_2Cl_2 (100 mL), was dried over anhydr. $MgSO_4$. Removal of the solvent gave 2.22 g of a yellow oil, which was purified via dry flash chromatography (silica gel 60H for TLC, 30% EtOAc – hexanes → 100% EtOAc) to afford 0.82 g (75%) of the product as a yellow solid. ^{1}H NMR (100 MHz, $CDCl_3$) δ: 1.10 (d, 3H, -CH_3), 1.15 (d, 3H, -CH_3), 2.20–2.80 (m, 1H, C*H*Me$_2$), 4.40–4.75 (m, 2H, NOCH_2), 4.90 (d, 1H, NC*H*), 6.15 (dt, 1H, NOCH$_2$CH=C*H*), 6.81 (dt, 1H, NOCH$_2$C*H*), 8.33 (br. s, 1H, CO_2H). MS (CI, isobutane), *m*/*z*: 200 (M^+ + 1).

(*S*)-2-Hydroxy-3-methylbutyric acid benzhydryl ester (10c)

A solution of diphenyldiazomethane (0.70 g, 3.60 mmol) in EtOAc (5 mL) was added portionwise with cooling (ice bath) and stirring to a solution of (*S*)-2-hydroxy-3-methylbutyric acid (0.51 g, 4.36 mmol) in EtOAc (5 mL). The resulting purple solution was stirred at room temperature for 6 h until the color faded to pale yellow, and then was washed successively with satd. $NaHCO_3$ (3 × 5 mL) and brine (2 × 5 mL), dried over anhydr. $MgSO_4$, and concentrated to give 0.99 g of a yellow solid. Recrystallization from hexanes yielded 0.82 g (80%) of **10c** as white crystals, mp 71 to 72 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.76 (d, 3H, -CH_3), 1.02 (d, 3H, -CH_3), 2.12–2.23 (m, 1H, C*H*Me$_2$), 2.68 (br. s, 1H, OH), 4.16 (d, 1H, C*H*OH), 6.96 (s, 1H, C*H*Ph$_2$), 7.20–7.45 (m, 10H, Ar*H*). MS (CI, isobutane), *m*/*z*: 285 (M^+ + 1). Anal. calcd. for $C_{18}H_{20}O_3$ (%): C 76.03, H 7.09; found: C 76.13, H 7.12.

(*R*)-2-Allyloxyamino-3-methylbutryic acid benzhydryl ester (11c)

A solution of triflic anhydride (4.42 mL, 26.29 mmol) in dry CH_2Cl_2 (12 mL) was added dropwise via syringe to a solution of **10c** (6.50 g, 22.86 mmol) in dry CH_2Cl_2 (70 mL), with cooling (–68 to –70 °C) and stirring. After 5 min, a solution of 2,6-lutidine (3.19 mL, 27.43 mmol) in dry CH_2Cl_2 (10 mL) was added dropwise. The pale yellow reaction mixture was stirred at –68 °C for 1 h, warmed to room temperature, and stirred for an additional 17 h. The solvent was removed under reduced pressure and the residue (in EtOAc) was washed with 1 N citric acid (5 × 100 mL), dried over anhydr. $MgSO_4$, and evaporated to give 9 g of a red semisolid. This was purified via dry flash chromatography (silica gel 60H for TLC, 5% EtOAc – hexanes) to afford 8.04 g of the triflate as a pale yellow solid. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.89 (d, 3H, -CH_3), 1.05 (d, 3H, -CH_3), 2.38–2.46 (m, 1H, C*H*Me$_2$), 5.04 (d, 1H, C*H*OSO$_2$CF$_3$), 7.00 (s, 1H, C*H*Ph$_2$), 7.20–7.42 (m, 10H, Ar*H*). MS (CI, isobutane), *m*/*z*: 417 (M^+ + 1). Anal. calcd. for $C_{19}H_{19}O_5SF_3$ (%): C 54.80, H 4.60; found: C 54.55, H 4.63.

A solution of allyloxylamine (5.41 g, 0.074 mol) in dry CH_3CN (35 mL) was added, with stirring, to a solution of the above triflate (7.71 g, 0.018 mol) in dry CH_3CN (80 mL). The reaction mixture was refluxed for 3 h, cooled to room temperature, and evaporated under reduced pressure. The residue, in EtOAc (100 mL), was washed successively with satd. $NaHCO_3$ (3 × 100 mL) and brine (2 × 100 mL), dried over anhydr. $MgSO_4$, and concentrated to give 6.67 g of a pale yellow oil. Purification by dry flash chromatography (silica gel 60H for TLC, 10% EtOAc – hexanes) afforded 5.62 g (89%) of **11c** as a colorless oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.86 (d, 3H, -CH_3), 0.92 (d, 3H, -CH_3), 1.85–1.94 (m, 1H, C*H*Me$_2$), 3.57 (d, 1H, NC*H*), 4.17–4.19 (m, 2H, OCH_2), 5.14–5.18 (m, 1H, OCH$_2$CH=C*H*H), 5.22 (dd, 1H, OCH$_2$CH=CH*H*), 5.83–5.93 (m, 1H, OCH$_2$C*H*), 6.98 (s, 1H, C*H*Ph$_2$), 7.23–7.40 (m, 10H, Ar*H*). MS (CI, isobutane), *m*/*z*: 340 (M^+ + 1). Anal. calcd. for $C_{21}H_{25}NO_3$ (%): C 74.31, H 7.42, N 4.13; found: C 74.49, H 7.46, N 4.40.

(*R*)-2-(*N*-Acryloyl, *N*-allyloxyamino)-3-methylbutyric acid benzhydryl ester (12c)

A solution of **11c** (5.08 g, 14.98 mmol) in dry CH_2Cl_2 (50 mL) was treated in one portion with triethylamine (3.13 mL, 22.47 mmol). The solution was stirred at room temperature for 5 min, cooled to 0 °C, and 97% acryloyl chloride (1.50 mL, 17.98 mmol) was added dropwise via syringe. This mixture was stirred at 0 °C for 45 min, then allowed to warm to room temperature, and stirring was continued for 2.5 h. The light orange reaction mixture was

© 2005 NRC Canada

then diluted with CH_2Cl_2 (150 mL) and washed successively with water (3 × 50 mL), 1 N HCl (50 mL), and brine (100 mL), dried over anhydr. $MgSO_4$, and evaporated to 5.67g of an orange oil. Purification by dry flash chromatography (silica gel 60H for TLC, 3% EtOAc – hexanes → 5% EtOAc – hexanes) gave 4.79 g (81%) of **12c** as a yellow oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.95 (d, 3H, -CH_3), 0.96 (d, 3H, -CH_3), 2.44–2.54 (m, 1H, C*H*Me_2), 4.15 (dd, 1H, OC*H*H), 4.32 (dd, 1H, OCH*H*), 4.87 (d, 1H, NC*H*), 5.17–5.22 (m, 2H, OCH_2CH=CH_2), 5.73–5.82 (m, 2H, OCH_2CH + NC=OC*H*), 6.48 (dd, 1H, NC=OCH=C*H*H), 6.71 (dd, 1H, NC=OCH=CH*H*), 6.91 (s, 1H, C*H*Ph_2), 7.20–7.40 (m, 10H, Ar*H*). MS (CI, isobutane), *m*/*z*: 394 (M^+ + 1).

(*R*)-3-Methyl-2-(3-oxo-3,6-dihydro[1,2]oxazin-2-yl)-butyric acid benzhydryl ester (13c)

Bis(tricyclohexylphosphine)benzylideneruthenium dichloride (0.34 g, 0.42 mmol) was weighed directly into a 250 mL flask, placed under a nitrogen atmosphere, and dry CH_2Cl_2 (25 mL) was added, followed by a solution of **12c** (3.28 g, 8.33 mmol) in dry CH_2Cl_2 (60 mL). The dark purple reaction mixture was refluxed for 4 h, cooled to room temperature, filtered through a short, densely packed pad of silica gel 60H for TLC (ϕ ~ 3.8 cm, *l* ~ 2 cm), which was washed with CH_2Cl_2 (5 × 20 mL). Removal of the solvent gave 3.18 g of a brown oil, which was purified via dry flash chromatography (silica gel 60H for TLC, 5% EtOAc – hexanes → 20% EtOAc – hexanes) to afford 3.57 g (90%) of the product as a brown oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.99 (d, 3H, -CH_3), 1.01 (d, 3H, -CH_3), 2.44–2.53 (m, 1H, C*H*Me_2), 4.38 (ddd, 2H, NOCH_2), 4.97 (d, 1H, NC*H*), 6.05 (dt, 1H, $NOCH_2CH$=C*H*), 6.68 (dt, 1H, $NOCH_2$C*H*), 6.92 (s, 1H, C*H*Ph_2), 7.20–7.40 (m, 10H, Ar*H*). MS (CI, isobutane), *m*/*z*: 366 (M^+ + 1).

(*S*)-α-Hydroxyphenylacetic acid benzhydryl ester (10d)

A solution of diphenyldiazomethane (0.53 g, 2.72 mmol) in EtOAc (5 mL) was added portionwise with cooling (ice bath) and stirring to a solution of (*S*)-mandelic acid (0.50 g, 3.29 mmol) in EtOAc (5 mL). The purple reaction mixture was stirred at room temperature for 1 h and was then washed successively with satd. $NaHCO_3$ (3 × 5 mL) and brine (2 × 5 mL), dried over anhydr. $MgSO_4$, and concentrated to 0.99 g of a yellow solid, which was recrystallized from hexanes to give 0.67 g (80%) of the ester, mp 87 to 88 °C (lit. value (18) mp 87 to 88 °C). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.45 (d, 1H, O*H*), 5.28 (d, 1H, C*H*OH), 6.75 (s, 1H, C*H*Ph_2), 7.20–7.45 (m, 15H, Ar*H*).

(*R*)-α-Allyloxyaminophenylacetic acid benzhydryl ester (11d)

A solution of triflic anyhydride (10.80 mL, 64.47 mmol) in dry CH_2Cl_2 (25 mL) was added dropwise via syringe to a solution of **10d** (17.85 g, 56.1 mmol) in dry CH_2Cl_2 (175 mL), with cooling (–68 to –70 °C) and stirring. After 5 min, a solution of 2,6-lutidine (7.80 mL, 67.28 mmol) in dry CH_2Cl_2 (25 mL) was added dropwise. The pale yellow reaction mixture was stirred at –68 °C for 1 h, and a solution of allyloxyamine (7.29 g, 99.8 mmol) in dry CH_2Cl_2 (25 mL) was added dropwise with continued cooling and stirring. The yellow reaction mixture was stirred for 30 min and the cooling bath was then removed and the mixture allowed to warm to room temperature. Stirring was continued at room temperature for 17 h and the dark yellow solution was mixed in a separatory funnel with 250 mL of satd. $NaHCO_3$. The two layers were gently mixed by bubbling nitrogen for 20 min, and then shaken manually. The organic phase was separated, washed successively with satd. $NaHCO_3$ (2 × 250 mL) and brine (250 mL), dried over $MgSO_4$, and evaporated to 24.05 g of a mixture of **11d** and 2,6-lutidine (1:0.37, mol:mol), which was used in the next step without further purification. ^{1}H NMR (100 MHz, $CDCl_3$) δ: 4.28 (dt, 2H, NOCH_2), 4.95 (br. d, 1H, NC*H*), 5.10–5.45 (m, 2H, $NOCH_2CH$=CH_2), 5.72–6.15 (m, 1H, $NOCH_2$C*H*), 6.22 (br. d, 1H, N*H*), 6.98 (s, 1H, C*H*Ph_2), 7.02–7.50 (m, 10H, Ar*H*).

(*R*)-(*N*-Acryloyl, *N*-α-allyloxyamino)phenylacetic acid benzhydryl ester (12d)

2,6-Lutidine (4.24 mL, 36.4 mmol) was added dropwise, with stirring, to a solution of **11d** (9.06 g, 24.26 mmol) in dry CH_2Cl_2 (75 mL). After 5 min at room temperature, the reaction mixture was cooled to 0 °C and a solution of 97% acryloyl chloride (2.44 mL, 29.12 mmol) in dry CH_2Cl_2 (25 mL) was added dropwise with stirring. This mixture was stirred at 0 °C for 45 min, then allowed to warm to room temperature and stirred for 17 h. The reaction mixture was diluted with CH_2Cl_2 (50 mL) and washed successively with water (50 mL), 1 N citric acid (2 × 100 mL), satd. $NaHCO_3$ (2 × 75 mL), and brine (100 mL), dried over anhydr. $MgSO_4$, and evaporated to a dark orange oil, which was purified via dry flash chromatography (silica gel 60H for TLC, 3% EtOAc – hexanes → 20% EtOAc – hexanes) to afford 8.36 g (81%) of **12d** as a yellow oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.60 (dd, 1H, NOC*H*H), 4.07 (dd, 1H, NOCH*H*), 5.04 (dd, 1H, $NOCH_2CH$=C*H*H), 5.10 (dd, 1H, $NOCH_2CH$=CH*H*), 5.53–5.63 (m, 1H, $NOCH_2$C*H*), 5.84 (dd, 1H, C=OC*H*), 6.28 (s, 1H, NC*H*), 6.49 (dd, C=OCHC*H*H), 6.77 (dd, 1H, C=OCHCH*H*), 6.94 (s, 1H, C*H*Ph_2), 7.02–7.46 (m, 15H, Ar*H*). MS (CI, isobutane), *m*/*z*: 428 (M^+ + 1).

(*R*)-(3-Oxo-3,6-dihydro[1,2]oxazin-2-yl)-phenylacetic acid benzhydryl ester (13d)

Bis(tricyclohexylphosphine)benzylideneruthenium dichloride (0.11 g, 0.13 mmol) was weighed directly into a 50 mL flask, placed under a nitrogen atmosphere, and dry CH_2Cl_2 (10 mL) was added, followed by a solution of **12d** (1.10 g, 2.58 mmol) in dry CH_2Cl_2 (15 mL). The purple reaction mixture was refluxed for 3 h, an additional 0.11 g of the catalyst was added, and refluxing was continued for another 2 h. The mixture was then allowed to cool to room temperature and filtered through a short, densely packed pad of silica gel 60H for TLC (ϕ ~ 3.8 cm, *l* ~ 2 cm), which was washed with CH_2Cl_2 (5 × 20 mL). Evaporation gave a brown oil, which was purified via column chromatography (5% EtOAc – hexanes → 30% EtOAc – hexanes) to afford 0.50 g (50%) of **13d** as a brown oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.34 (ddd, 1H, NOC*H*H), 4.61 (ddd, 1H, NOCH*H*), 6.04 (dt, 1H, $NOCH_2CH$=C*H*), 6.37 (s, 1H, NC*H*), 6.70 (dt, 1H, $NOCH_2$C*H*), 6.96 (s, 1H, C*H*Ph_2), 7.10–7.40 (m, 15H, Ar*H*). MS (CI, isobutane), *m*/*z*: 410 (M^+ + 1).

(α*R*,4*S*,5*S*)-2-(α-Benzoxycarbonylethyl)-4,5-dihydroxy-1,2-oxazinan-3-one (17)

A mixture of $K_2OsO_2(OH)_4$ (0.0063 g, 0.017 mmol), $(DHQD)_2PHAL$ (0.032 g, 0.041 mmol), and AD-mix-β (1.41 g) was dissolved in a mixture of *tert*-butanol (5 mL) and water (5 mL). After dissolution of the salts, methanesulfonamide (0.099 g, 1.04 mmol) was added and the mixture was cooled to –2 °C. The benzyl ester **13a** (0.26 g, 1.01 mmol) was added in one portion and the heterogeneous slurry was stirred vigorously for 14 h at –2 to +2 °C. Sodium sulfite (1.5 g) was added to quench the reaction and stirring was continued for 1 h at room temperature. Methylene chloride (10 mL) was added and the organic layer was separated. The aqueous phase was extracted with CH_2Cl_2 (5 × 5 mL) and the combined organic extracts were dried over $MgSO_4$. After removal of the solvent, the yellowish semisolid residue was purified by dry flash chromatography (silica gel 60H for TLC, 15% EtOAc – hexanes to EtOAc) to afford 0.158 g (81%) of the product as a white solid. ^{1}H NMR (400 MHz, $CDCl_3$ + 2 drops of CD_3OD) δ: 1.53 (3H, d, ^3J = 7.3 Hz, α-*Me*CH), 3.96 (1H, dd, ^2J = –11.8 Hz, ^3J = 2.5 Hz, 6-H_A), 4.41 (1H, d, ^3J = 4.1 Hz, 4-*H*), 4.44 (1H, dd, ^2J = –11.8 Hz, ^3J = 6.8 Hz, 6-H_B), 4.55–4.51 (1H, m, 5-H), 5.11 (1H, q, ^3J = 7.3 Hz, -C*H*), 5.13 (1H, s, CH_2Ph), 7.34–7.24 (5H, m, *Ph*).

(α*R*,4*S*,5*S*)-2-(α-Carboxyethyl)-4,5-dihydroxy-1,2-oxazinan-3-one (18)

A suspension of 5% Pd-C (0.137 g) in EtOAc (10 mL) was stirred for 1 h in a hydrogen atmosphere and a solution of the benzyl ester **17** (0.137 g, 0.464 mmol) in EtOAc (15 mL) was added dropwise. The reaction mixture was stirred for 8 h under hydrogen and filtered through a short pad of silica gel 60H (for TLC) followed by washing with MeOH (7 × 5 mL). After evaporation of the filtrate under reduced pressure, the residue was triturated with dry ether and dried in vacuo to provide 0.093 g (98%) of the product as a white solid. ^{1}H NMR (400 MHz, CD_3CN) δ: 1.44 (3H, d, ^3J = 7.3 Hz, α-*Me*CH), 3.00 (2H, br. s, O*H*, O*H*), 3.90 (1H, m, 6-H_A), 4.37 (1H, d, ^3J = 4.4 Hz, 4-*H*), 4.49–4.43 (2H, m, 6-H_B, 5-H), 5.01 (1H, q, ^3J = 7.3 Hz, -C*H*), 5.31 (1H, br. s, COO*H*). ^{13}C NMR (100 MHz, CD_3CN) δ: 13.55, 54.34, 70.15, 70.64, 78.41, 171.22, 172.85.

(α*R*,4*R*,5*R*)-2-(α-*tert*-Butoxycarbonylethyl)-4,5-dihydroxy-1,2-oxazinan-3-one (19)

This compound was obtained in 83% yield from **13b** as a white solid (mp 93 to 94 °C) as described above, but with $(DHQ)_2PHAL$ as the auxiliary. ^{1}H NMR (400 MHz, $CDCl_3$ + 2 drops of CD_3OD) δ: 1.44 (3H, d, ^3J = 7.3 Hz, α-*Me*CH), 1.45 (9H, *Me*$_3$C), 2.25 (2H, br. s, O*H*, O*H*), 4.30 (1H, dd, ^2J = –11.9 Hz, ^3J = 2.8 Hz, 6-H_A), 4.37 (1H, d, ^3J = 4.5 Hz, 4-*H*), 4.38 (1H, dd, ^2J = –11.9 Hz, ^3J = 7.3 Hz, 6-H_B), 4.56–4.52 (1H, br. m, 5-H), 4.96 (1H, q, ^3J = 7.3 Hz, α-C*H*). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.96, 27.92, 54.89, 68.89, 69.98, 76.55, 83.01, 169.46, 169.94. IR (KBr), cm^{-1}: 3423, 2985, 1739, 1662, 1415, 1152. MS (CI, isobutane), *m/z*: 262 (M^+ + 1). Anal. calcd. for $C_{11}H_{19}NO_6$ (%): C 50.6, H 7.3, N 5.4; found: C 50.5, H 7.4, N 5.4.

(α*R*,4*R*,5*R*)-2-(α-Carboxyethyl)-4,5-dihydroxy-1,2-oxazinan-3-one (20)

Trifluoroacetic acid (0.9 mL) was added in one portion to a cooled (ca. 0 °C) stirred solution of the *tert*-butyl ester **19** (0.0467 g, 0.179 mmol) in CH_2Cl_2 (0.9 mL). The reaction mixture was maintained at room temperature for 1 h and was concentrated under reduced pressure. The semisolid residue was triturated with dry ether and dried in vacuo to afford 0.0295 g (80%) of the product as a white solid. ^{1}H NMR (400 MHz, CD_3CN) δ: 1.41 (3H, d, ^3J = 7.3 Hz, α-*Me*CH), 3.60 (2H, br. s, O*H*, O*H*, COO*H*), 4.14 (1H, dd, ^2J = –11.6 Hz, ^3J = 2.3 Hz, 6-H_A), 4.34 (1H, d, ^3J = 4.1 Hz, 4-*H*), 4.40 (1H, dd, ^2J = –11.6 Hz, ^3J = 7.4 Hz, 6-H_B), 4.49–4.45 (2H, m, 5-H), 5.01 (1H, q, ^3J = 7.3 Hz, α-C*H*), 5.31 (1H, br. s, COO*H*). ^{13}C NMR (100 MHz, CD_3CN) δ: 14.45, 54.48, 70.05, 70.99, 77.77, 167.30, 171.82.

(α*R*,1*R*,6*R*)-2-(α-*tert*-Butoxycarbonylethyl)-8-thia-3,7,9-trioxa-4-azabicyclo[4.3.0]nona-5,8-dione (21)

A solution of thionyl chloride (1.64 g, 13.75 mmol) in dry CH_2Cl_2 (15 mL) was added dropwise with cooling (–15 to –20 °C) and stirring to a solution of the diol **19** (2.40 g, 9.17 mmol) and Et_3N (3.71 g, 36.67 mmol) in dry CH_2Cl_2 (45 mL). After stirring for 1 h at –2 to 2 °C, the reaction mixture was diluted with CH_2Cl_2 (60 mL) and washed successively with water (20 mL), 1 mol L^{-1} citric acid (20 mL), satd. $NaHCO_3$ (20 mL), dried over $MgSO_4$, and evaporated to give the cyclic sulfite **21** (2.52 g, 90%) as a 1:1 mixture of diastereomers. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.45 (9H, *Me*$_3$C), 1.46 (9H, *Me*$_3$′C), 1.47 (3H, d, ^3J = 7.3 Hz, α-*Me*CH), 1.49 (3H, d, ^3J = 7.3 Hz, α-*Me*′CH), 4.43 (1H, dd, ^2J = –12.4 Hz, ^3J = 5.5 Hz, 2-H_A), 4.48 (1H, dd, ^2J = –11.5 Hz, ^3J = 5.0 Hz, 2-H_A′), 4.51 (1H, dd, ^2J = –11.5 Hz, ^3J = 5.0 Hz, 2-H_B), 4.60 (1H, dd, ^2J = –12.4 Hz, ^3J = 6.5 Hz, 2-H_B′), 5.01 (1H, q, ^3J = 7.3 Hz, α-C*H*), 5.05 (1H, q, α-C*H*, ^3J = 7.3 Hz), 5.18 (1H, d, ^3J = 8.2 Hz, 6-*H*), 5.22 (1H, m, ^3J = 8.2, 6.5, 5.5 Hz, 1-*H*), 5.37 (1H, d, ^3J = 7.3 Hz, 6-*H*′), 5.50 (1H, m, ^3J = 7.3, 5.0 Hz, 1-*H*′). The compound was used in the next reaction without further purification.

(α*R*,4*S*,5*R*)-2-(α-*tert*-Butoxycarbonylethyl)-4-azido-5-hydroxy-1,2-oxazinan-3-one (22)

Sodium azide (1.60 g, 24.6 mmol) was added in one portion to a stirred solution of the cyclic sulfite (2.52 g, 8.21 mmol) in HMPA (15 mL), and the solution was stirred for 24 h at room temperature. Then EtOAc (50 mL) was added and the resultant mixture was washed successively with water (2 × 15 mL) and 1 mol L^{-1} citric acid (15 mL). The combined aqueous layers were extracted with EtOAc (3 × 15 mL). The combined organic extracts were washed successively with satd. $NaHCO_3$ (50 mL), brine (2 × 50 mL), dried over $MgSO_4$, and concentrated. The dark oily residue was purified by flash chromatography (silica gel 60H, 1% MeCN – CH_2Cl_2 to 10% MeCN – CH_2Cl_2) to afford 0.37 g (16%) of the product as a yellowish oil. IR (film, cm^{-1}): 3436, 2981, 2116, 1739, 1685, 1256, 1158. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.46 (9H, *Me*$_3$C), 1.48 (3H, d, ^3J = 7.3 Hz, α-*Me*CH), 2.65 (1H, d, ^3J = 4.5 Hz, O*H*), 4.08–4.02 (1H, m, 5-H), 4.08 (1H, dd, ^2J = –11.6 Hz, ^3J = 3.5 Hz, 6-H_A), 4.27 (1H, dd, ^2J = –11.6 Hz, ^3J = 6.1 Hz, 6-H_B), 4.37

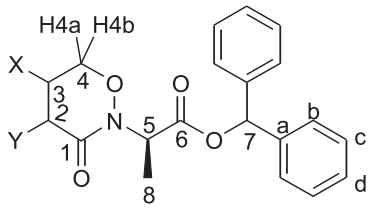
MS (CI, isobutane), *m*/*z*: 231 (M^+ + 1). The compound was used in the next reaction without further purification.



(α*R*,4*S*,5*R*)-2-(α-Carboxyethyl)-4-amino-5-hydroxy-1,2-oxazinan-3-one (24)

A suspension of 5% Pd-C (0.175 g) in EtOAc (10 mL) was stirred for 1.5 h under a hydrogen atmosphere and a solution of the azido alcohol **23** (0.37 g, 1.62 mmol) in EtOAc (15 mL) was added dropwise. The reaction mixture was stirred under hydrogen for 17 h and then evaporated to dryness. The residue was washed with dry ether (3 × 15 mL) and the product was extracted from the dried residue with hot (ca. 70 °C) water (30 mL). The aqueous solution was filtered through a paper filter and the black solid was washed with hot water (3 × 10 mL). Evaporation of the filtrate provided 0.296 g (90%) of the product **24** as a white solid, mp 200–202 °C (dec.). IR (KBr, cm^{-1}): 3158, 1684, 1599, 1568, 1400. ^{1}H NMR (400 MHz, CD_3OD + 1 drop of CF_3CO_2H) δ: 1.52 (3H, d, ^3J = 7.4 Hz, α-*Me*CH), 4.08 (1H, dd, ^2J = –11.7 Hz, ^3J = 2.5 Hz, 6-H_A), 4.18–4.16 (2H, m, 4-H, 5-H), 4.46–4.41 (1H, dd, ^2J = –11.7 Hz, ^3J = 6.4 Hz, 6-H_B), 4.98 (1H, q, ^3J = 7.4 Hz, α-C*H*). ^{13}C NMR (100 MHz, D_2O) δ: 17.62, 59.62, 61.42, 73.69, 82.48, 169.06, 180.86. MS (CI, isobutane), *m*/*z*: 205 (M^+ + 1). Anal. calcd. for $C_7H_{12}N_2O_5 \cdot 0.5H_2O$ (%): C 39.4, H 6.1, N 13.1; found: C 39.3, H 6.2, N 13.2.

(α*R*,4*S*,5*R*)-2-(α-Carboxyethyl)-4-phenylacetylamino-5-hydroxy-1,2-oxazinan-3-one (25)

A solution of phenylacetyl chloride (0.191 g, 1.24 mmol) in dry MeCN (3 mL) was added dropwise with cooling (–5 to –6 °C) and stirring to a solution of the amino acid **24** (0.290 g, 1.36 mmol) and $NaHCO_3$ (0.343 g, 4.08 mmol) in water (7 mL). The reaction mixture was stirred for 2 h at 0 to –2 °C and for 1 h at room temperature and was then concentrated under reduced pressure to a volume of ca. 5 mL, cooled to ca. 5 °C and the pH was adjusted to 2 to 3 with 1 mol L^{-1} HCl (2.8 mL). The white precipitate was collected, washed with water, and dried in vacuo to afford 0.364 g (91%) of **25** as a white solid, mp 194 to 195 °C (dec.) (from isopropanol). IR (KBr, cm^{-1}): 3361, 2913, 1729, 1666, 1630, 1542, 1440, 1233. ^{1}H NMR (400 MHz, CD_3OD) δ: 1.47 (3H, d, ^3J = 7.3 Hz, α-*Me*CH), 3.62 (1H, d, ^2J = –14.8 Hz, CH_APh), 3.67 (1H, d, ^2J = –14.8 Hz, CH_BPh), 4.06 (1H, dd, ^2J = –11.4 Hz, ^3J = 3.7 Hz, 6-H_A), 4.12–4.06 (1H, m, 5-H), 4.33 (1H, dd, ^2J = –11.4 Hz, ^3J = 5.6 Hz, 6-H_B), 4.66 (1H, d, ^3J = 8.0 Hz, 4-H), 4.96 (1H, q, ^3J = 7.3 Hz, α-C*H*), 7.38–7.17 (5H, m, *Ph*). ^{13}C NMR (100 MHz, CD_3OD) δ: 13.71, 43.63, 55.70, 57.54, 71.84, 79.10, 127.85, 129.51, 130.37, 136.63, 169.61, 172.71, 174.89. MS (CI, isobutane), *m*/*z*: 323 (M^+ + 1). Anal. calcd. for $C_{15}H_{18}N_2O_6$ (%): C 55.9, H 5.6, N 8.7; found: C 55.7, H 5.7, N 8.6.

Functionalization of a 6*H*[1,2]oxazin-3-one with aq. *N*-bromosuccinimide — Bromohydrins, epoxides, and alcohols

The olefin **26** was prepared from the triflate of benzhydryl *S*-lactate by sequential reactions with allyloxyamine, acryloyl chloride, and bis(tricyclohexylphosphine)benzylideneruthenium dichloride. ^{1}H NMR (100 MHz, $CDCl_3$) δ: 1.60 (3H), 4.40 (2H), 4.57 (1H), 6.05 (1H), 6.68 (1H), 6.91 (1H) 7.35 (10H). *N*-Bromosuccinimide (1.06 g, 2 equiv., 5.92 mmol) was added with rapid stirring to a solution of **26** (1.00 g, 2.96 mmol) in DMF (2.3 mL, 10 equiv., 29.6 mmol) and H_2O (110 μL, 2 equiv., 5.92 mmol). The resulting mixture was stirred for 24 h at room temperature. Water (20 mL) was then added and the mixture was extracted with Et_2O (3 × 30 mL). The combined organic extracts were dried over $MgSO_4$, and concentrated under reduced pressure to an oil. Flash column chromatography (5%–30% EtOAc – hexanes, gradient) provided, in order of elution, a mixture of dibromides (**27**) (199 mg), unreacted starting material (212 mg), and two diastereomeric bromohydrins **28** (268 and 206 mg, 26% and 20%, respectively). There was no reaction after 48 h when the experiment was performed in aq. THF.

Dibromides 27

^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.33–7.34 (m, Ar-H), 6.92 (s, H-7), 6.91 (s, H-7′), 5.30 (q, *J* = 7.3 Hz, H-5), 5.27 (q, *J* = 7.3 Hz, H-5′), 4.73 (d, *J* = 4.0 Hz, H-2), 4.68 (d, *J* = 4.1 Hz, H-2′), 4.54–4.65 (m, containing 4.63 (dd, *J* = 4.3, 12.6 Hz, H-4a), 4.51 (dd, *J* = 5.7, 12.3 Hz, H-4a′)), 4.31 (dd, *J* = 12.3, 5.8 Hz, H-4b′), 4.15 (dd, *J* = 12.7, 4.1 Hz, H-4b), 1.58 (d, *J* = 7.3 Hz, H-8), 1.56 (d, *J* = 7.3 Hz, H-8′).^{13}C NMR (75 MHz, $CDCl_3$) δ: 168.4 and 138.3 (C-6, C-6′), 163.5 and 162.5 (C-1, C-1′), 139.5 and 139.3 (Ar-a, Ar-a′), 128.6, 128.5, 128.3, 128.2, 128.1, 127.4, 127.3, 127.2,

126.9, 126.8, 126.5, 78.5 and 78.4 (C-7, C-7′), 73.5 and 72.4 (C-4, C-4′), 54.5 and 54.3 (C-5, C-5′), 46.5 and 45.6 (C-2, C-2′), 43.5 and 43.3 (C-3, C-3′), 13.3 (C-8, C-8′).

28 (Less polar isomer)

^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.29–7.34 (m, Ar-H), 6.89 (s, H-7), 5.27 (q, *J* = 7.3 Hz, H-5), 4.44 (dd, *J* = 5.0, 11.7 Hz, H-4a), 4.42 (dd, *J* = 0.7, 4.6 Hz, H-2), 4.34–4.36 (br m, H-3), 4.06 (dd, *J* = 11.7, 2.5 Hz, H-4b), 3.25 (br s, -OH), 1.59 (d, *J* = 7.3 Hz, H-8). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 169.3 (C-6), 167.0 (C-1), 139.2, 139.1 (Ar-a), 128.6 (Ar-c), 128.3, 128.1 (Ar-d), 127.2, 126.8 (Ar-b), 78.8 (C-7), 73.0 (C-3), 71.6 (C-4), 54.6 (C-5), 44.7 (C-1), 13.2 (C-8). MS (CI, isobutane), *m/z*: 435, 433 (M^+ + 1).

28 (More polar isomer)

^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.29–7.35 (m, Ar-H), 6.89 (s, H-7), 5.23 (q, *J* = 7.3 Hz, H-5), 4.56 (d, *J* = 6.1 Hz, H-2), 4.46 (dd, *J* = 11.7, 5.8 Hz, H-4a), 4.28–4.35 (br m, H-3), 3.90 (dd, *J* = 11.7, 3.5 Hz, H-4b), 2.86 (br s, -OH), 1.56 (d, *J* = 7.3 Hz, H-8). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 168.7 (C-6), 164.0 (C-1), 139.3 (Ar-a), 128.6 (Ar-c), 128.3, 128.1 (Ar-d), 127.3, 126.8 (Ar-b), 78.5 (C-7), 74.4 (C-3), 73.0 (C-4), 54.6 (C-5), 49.0 (C-1), 13.7 (C-8). MS (CI, isobutane), *m/z*: 435, 433 (M^+ + 1).

Epoxides 29

Potassium carbonate (62 mg, 1.1 equiv.) was added to a solution of **28** (171 mg, 0.41 mmol) in acetone (2 mL). The resulting mixture was stirred at room temperature for 24 h, concentrated under reduced pressure, and the residue shaken with a mixture of 10% NH_4Cl (50 mL) and Et_2O (50 mL). The aqueous phase was extracted with Et_2O (3 × 20 mL) and the combined ether layers were dried over $MgSO_4$ and evaporated. Flash column chromatography of the residue (20%–25% EtOAc – hexanes) afforded the appropriate epoxide (39.6 mg, 29%).

***29** Isomer I (from the less polar **28**)*

^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.31–7.37 (m, Ar-H), 6.83 (s, H-7), 5.16 (q, *J* = 7.3 Hz, H-5), 4.40 (d, *J* = 12.5 Hz, H-4a), 4.02 (d, *J* = 12.5 Hz, H-4b), 3.65–3.67 (m, H-2 and H-3), 1.50 (d, *J* = 7.3 Hz, H-8). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 168.1 (C-6), 165.2 (C-1), 139.8, 139.7 (Ar-a), 128.5, 128.4 (Ar-c), 127.9, 127.8 (Ar-d), 127.0, 126.9 (Ar-b), 78.3 (C-7), 67.3 (C-4), 53.9 (C-2), 52.6 (C-5), 48.7 (C-3), 13.1 (C-8).

***29** Isomer II (from the more polar **28**)*

^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.30–7.37 (m, Ar-H), 6.89 (s, H-7), 5.31 (q, *J* = 7.3 Hz, H-5), 4.18 (d of multiplets, *J* = 12.7 Hz, H-4a), 4.06 (d, *J* = 12.7 Hz, H-4b), 3.63 (d, *J* = 4.1 Hz, H-2), 3.60 (dd, *J* = 4.1, 1.3 Hz, H-3), 1.55 (d, *J* = 7.3 Hz, H-8). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 169.0 (C-6), 163.7 (C-1), 139.4, 139.3 (Ar-a), 128.5, 128.5 (Ar-c), 128.3, 128.1 (Ar-d), 127.3, 126.7 (Ar-b), 78.3 (C-7), 66.9 (C-4), 53.8 (C-2), 53.3 (C-5), 48.9 (C-3), 13.8 (C-8).

Debromination of 28

A solution of the less polar isomer of **28** (200 mg, 0.196 mmol) in MeOH (1.5 mL) containing Et_3N (36 μL) and 10% Pd-C (10 mg) was stirred under hydrogen for 18 h and then filtered through a pad of Celite®. The pad was washed with ethanol and the combined filtrates were concentrated. The residue was partitioned between H_2O (10 mL) and Et_2O (10 mL). The ether layer was dried ($MgSO_4$) and evaporated to a viscous yellow oil. Flash column chromatography (10%–80% EtOAc – hexanes) provided the debromination product **30** (27 mg). ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.31–7.37 (m, Ar-H), 6.90 (s, H7-), 5.32 (q, *J* = 7.3 Hz, H-5), 4.35–4.42 (m, H-3), 4.13 (dd, *J* = 11.8, 5.4 Hz, H-2a), 4.01 (ddd, *J* = 11.8, 3.2, 1.0 Hz, H-2b), 2.77 (dd, *J* = 15.7, 5.0 Hz, H-4a), 2.64 (ddd, *J* = 15.7, 3.8, 1.0 Hz, H-4b), 1.56 (d, *J* = 7.3 Hz, H-8). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 169.9 (C-6), 169.2 (C-1), 139.4, 139.3 (Ar-a), 128.6, 128.6 (Ar-c), 128.2, 128.1 (Ar-d), 127.2, 126.8 (Ar-b), 78.5 (C-7), 76.2 (C-4), 66.2 (C-3), 53.5 (C-5), 38.6 (C-2), 13.6 (C-8).

Synthesis, characterization, and biological activity of a new palladium(II) complex with deoxyalliin

Pedro P. Corbi, Antonio C. Massabni, Andréia G. Moreira, Francisco J. Medrano, Miriam G. Jasiulionis, and Claudio M. Costa-Neto

Abstract: Synthesis, characterization, and biological activity of a new water-soluble Pd(II)–deoxyalliin (*S*-allyl-L-cysteine) complex are described in this article. Elemental and thermal analysis for the complex are consistent with the formula $[Pd(C_6H_{10}NO_2S)_2]$. ^{13}C NMR, ^1H NMR, and IR spectroscopy show coordination of the ligand to Pd(II) through S and N atoms in a square planar geometry. Final residue of the thermal treatment was identified as a mixture of PdO and metallic Pd. Antiproliferative assays using aqueous solutions of the complex against HeLa and TM5 tumor cells showed a pronounced activity of the complex even at low concentrations. After incubation for 24 h, the complex induced cytotoxic effect over HeLa cells when used at concentrations higher than 0.40 mmol/L. At lower concentrations, the complex was nontoxic, indicating its action is probably due to cell cycle arrest, rather than cell death. In agreement with these results, the flow cytometric analysis indicated that after incubation for 24 h at low concentrations of the complex cells are arrested in G0/G1.

Key words: palladium(II), deoxyalliin, *S*-allyl-L-cysteine, tumor cells, cancer.

Résumé : On décrit la synthèse, la caractérisation et l'activité biologique d'un nouveau complexe, soluble dans l'eau, de Pd(II)–désoxyalliine (*S*-allyl-L-cystéine). Les analyses élémentaire et thermique du complexe sont en accord avec la formule $[Pd(C_6H_{10}NO_2S)_2]$. Les spectres de RMN du ^{13}C et du ^1H ainsi que la spectroscopie infrarouge permettent de montrer que la coordination du ligand au Pd(II) se fait par les atomes de soufre et d'azote dans une géométrie plan carré. Le résidu final du traitement thermique a été identifié comme un mélange de PdO et de Pd métallique. Des essais antiprolifération à l'aide de solutions aqueuses du complexe ont permis de démontrer l'activité prononcée du complexe contre les cellules cancéreuses HeLa et TM5, même à faibles concentrations. Après une incubation de 24 h, le complexe utilisé à des concentrations supérieures à 0,40 mmol/L induit un effet cytotoxique vis-à-vis des cellules HeLa. À des concentrations plus faibles, le complexe n'est pas toxique, ce qui indique que son action est probablement due à un arrêt du cycle cellulaire plutôt qu'à une mort de la cellule. En accord avec ces résultats, l'analyse de l'écoulement cytométrique indique que, après une incubation de 24 h à de faibles concentrations de complexe, les cellules de G0/G1 s'arrêtent.

Mots clés : palladium(II), désoxyalliine, *S*-allyl-L-cystéine, cellules cancéreuses, cancer.

Introduction

The most largely used metal-based drug is cisplatin (*cis*-diammindichloroplatinum(II)), which has been used for the treatment of several human cancers, particularly testicular, ovarian, bladder, head, and neck (1, 2). For a review see ref. 3. The anticancer properties of cisplatin were first observed by Barnet Rosenberg at the Michigan State University in 1965 (4), but only in 1978 was this compound approved worldwide for cancer treatment (5). Toxic side effects of cisplatin, mainly nephrotoxicity, neurotoxicity (2), and ototoxicity (6), have limited its use and led to the development of second generation drugs. Interest in developing new complexes with lower side effects than cisplatin, but at the same time with high activity against tumors, has stimulated syntheses of many new complexes of platinum(II) and

also of palladium(II) (7, 8). Pd(II) complexes containing S and N donor ligands have been prepared and biological assays showed their activities against several tumor lines (HL-60, HeLa, 3T3, JURKAT, Pam212, and Pam-ras) (7).

Deoxyalliin (*S*-allyl-L-cysteine, $C_6H_{11}NO_2S$), a sulfur-containing amino acid derived from cysteine, is a product of vegetal origin present in onion and garlic bulbs (9, 10). More recent studies have shown that deoxyalliin may be considered a biological antagonist of nitrosomorpholine, the substance responsible for the development of hepatic cancer in humans (11). It also exhibits the capacity to inhibit proliferation of malignant cells from the human nervous system and thorax (12, 13).

Complexes containing Pt(II) or Pd(II) with mixed ligands such as amino acids and 1,10-phenanthroline displayed cytotoxic activities in vitro against Molt-4, a human leukaemia cell line (1). A study of *S*-alkyl and *S*-alkylaryl cysteine complexes with platinum(II) characterized by ^{13}C NMR, ^{1}H NMR, and IR absorption spectroscopy has also been reported (14). Biological tests were not performed for the latter complexes. The present article describes the synthesis and characterization of a new palladium(II) complex with deoxyalliin and its biological action against proliferation of tumor cells.[2]

Experimental

Materials

L-Deoxyalliin of analytical purity was purchased from LKT Laboratories. Palladium(II) chloride and lithium chloride of analytical purity were purchased respectively from Acros and Mallinckrodt Laboratories. Elemental analyses for carbon, hydrogen, nitrogen, and sulfur were performed with a CHNS-O EA1110 analyzer (CE Instruments); cystine was used as a reference substance. IR spectra were recorded on a FT-IR spectrophotometer spectrum 2000 (PerkinElmer) with samples prepared as KBr or CsI pellets. ^{13}C NMR and ^{1}H NMR were recorded on a Varian 500 MHz spectrometer; samples were analyzed in deuterium oxide solutions. Thermal analyses were performed on a Thermoanalyzer TG/DTA simultaneous SDT 2960 (TA Instruments) in the following conditions: synthetic air, 100 cm^3/min and heating rate of 10 °C/min, from 40 to 1100 °C. Palladium content was determinated by analyzing the residue of the thermal treatment at 900 °C. Powder X-ray analysis was performed on a D 5000 Siemens diffractometer using $CuK_{\alpha 1}$ radiation (λ = 1.5406 Å) with a graphite diffracted beam monochromator. The sample was scanned over the 2θ range from 4° to 70° in 0.05° steps. The counting time was 1.0 s/step. Cisplatin was purchased from Acros and MTT from Sigma. Media (DMEM and RPMI) and antibiotics for cell culture were purchased from Life Technologies, Inc. (Gaithersburg, Maryland) and FCS from Cultilab (Campinas, Brazil). Flasks and 24-well plates for cell culture were purchased from Costar (Corning Inc., Corning, N.Y.).

Preparation of the Pd(II) complex

The potassium salt solution of deoxyalliin was prepared by adding 1.12×10^{-3} mol of potassium hydroxide to a methanolic solution containing 1.12×10^{-3} mol of deoxyalliin (molar proportion of 1:1). This reaction was carried out at room temperature with stirring for 1 h.

The Pd(II) complex was synthesized by adding 5.6×10^{-4} mol of a freshly prepared methanolic solution of Li_2PdCl_4 to the solution of the potassium salt of deoxyalliin previously prepared, containing 1.12×10^{-3} mol of the ligand (molar proportion Pd(II):deoxyalliin of 1:2). This reaction was carried out at room temperature with stirring. A pale yellowish solid of the complex was precipitated slowly. After 2 h of constant stirring, the complex was filtered, washed with cooled methanol, and dried in a desiccator under P_4O_{10}. Final yield of the synthesis was about 70%. Anal. calcd. for $[Pd(C_6H_{10}NO_2S)_2]$ (%): C 33.8, H 4.72, N 6.56, S 15.0, Pd 24.9; found: C 33.4, H 4.60, N 6.40, S 14.7, Pd 23.7. No single crystals of the complex were obtained for X-ray structure determination. The lithium tetrachloropalladate solution was prepared by the reaction of $PdCl_2$ and LiCl in methanol under stirring and reflux for 30 min.

Cell culture

HeLa (human cervix cancer, ATCC CCL-2) and TM5 (murine melanoma, (15)) cell lines were cultured at 37 °C in a humidified atmosphere containing 5% CO_2, using, respectively, DMEM supplemented with 10% of Fetal Calf Serum (FCS) and RPMI at pH 6.9 with 5% FCS. Penicillin (100 U/mL) and streptomycin (100 µg/mL) were used as antibiotics.

Determination of the cell number and cell viability

A stock sample solution was prepared by dissolving the Pd(II) complex in a phosphate-buffered saline solution (PBS). PBS was used as the vehicle for the Pd(II) complex in all biological experimental procedures. Final different concentrations of the complex were achieved by dilution of the stock solution directly into the cell's medium. Cells were plated (25×10^4 cells/60 mm dish) 24 h prior to the beginning of the experiment. 48 h after addition of the complex or the vehicle, cells were detached and counted in individual samples using an impedance-based automated counter (CELM, Barueri, Brazil). To evaluate the immediate cytotoxic action of the Pd(II) complex, the MTT method (16) was applied to the cells after incubation for 24 h. Briefly, 24 h after plating 2.5×10^4 cells/well in a 24-well plate, the complex or the vehicle was added and the cells incubated for 24 h in culture conditions. After that, 100 µL of a MTT solution (5 mg/mL in PBS) were added and the cells were incubated for another period of 3 h. After washing with PBS, 200 µL of isopropanol were added, and cell viability was determined by absorbance measurements at 570 nm.

Cell cycle analysis by flow cytometry

Flow cytometric analysis of the Pd(II)-complex-treated TM5 cells was performed using a FACScan (Becton Dickinson). For synchronization, the cells were submitted to

[2] Abbreviations: phosphate-buffered saline (PBS), Dulbecco's modified Eagle's medium (DMEM), Roswell Park Memorial Institute medium (RPMI), fetal calf serum (FCS), American type cell collection (ATCC).

© 2005 NRC Canada

a serum depletion for 24 h to induce M block, followed by addition of fresh serum to stimulate growth in the presence (0.20 mmol/L) or absence of the Pd(II) complex. After 24 h, cells were washed, fixed with ice-cold ethanol (70% final concentration), resuspended in 0.5 mL of a solution of propidium iodide (20 µg/mL) and 200 µg/mL of Dnase-free Rnase in PBS, and incubated for 30 min at 37 °C. For flow cytometric analysis, at least 10 000 cells were evaluated using a FACSCalibur™. Cell cycle distribution and pre-G1 fraction were determined and quantified using the CellQUEST™ program.

Effect of the complex on melanoma growth in C57BL/6 mice

Groups of six C57BL/6 mice weighing between 25 and 30 g were selected. For tumor induction, melanoma TM5 cells (2×10^5) were injected subcutaneously into the dorsal-side of each mouse. In the subsequent 5 days, the complex (24 mg/kg and 72 mg/kg) or the vehicle (PBS) was administrated subcutaneously into the dorsal-side of each animal at a distance (1 cm) from the site of the cells injection. Detection of tumors were followed for 30 days, after which animals were sacrificed. C57BL/6 mice were kept at Centro de Desenvolvimento de Modelos Experimentais para Medicina e Biologia (CEDEME, UNIFESP, SP, Brasil) under the International Guiding Principles for Biomedical Research Involving Animals (CIOMS), Genebra (1985), and the Guide to the Care and Use of Experimental Animals, Canadian Council on Animal Care (www.ccac.ca).

Results and discussion

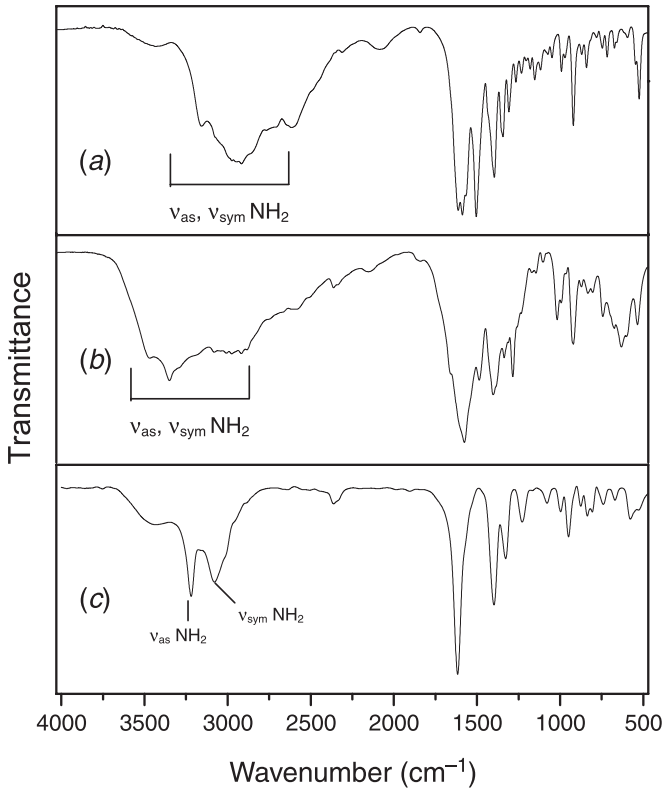
IR spectroscopy

The IR spectra of deoxyalliin, potassium *S*-allyl-L-cysteinate, and $[Pd(C_6H_{10}NO_2S)_2]$ complex are shown in Fig. 1.

Two very well resolved bands in the range 3400–3000 cm^{-1} are an indication of coordination of the amino group to Pd(II) (17). The IR spectrum of potassium *S*-allyl-L-cysteinate shows a broad band at 3350–2575 cm^{-1}, which corresponds to the NH_2 vibrational frequencies, while in the spectrum of deoxyalliin, the frequencies related to the amino group are observed in the range 3160–2675 cm^{-1} (broad band). Enlargement and shifting of the band show that the two hydrogen atoms of the amino group are involved in the formation of hydrogen bonds, which occur with cysteine and its derivatives, as deoxyalliin (17). The amino group involvement in the ligand coordination is attested by the presence of two very well resolved bands at 3220 and 3079 cm^{-1} for the Pd(II) complex (17). Moreover, the absence of the band at 2050–2150 cm^{-1} in the complex spectrum, in comparison to the free ligand and its potassium salt, confirms coordination through the amino group. The band at 2050–2150 cm^{-1} is assigned to a noncoordinated NH_2 group, as it occurs for the free ligand (18).

The IR spectrum of $[Pd(C_6H_{10}NO_2S)_2]$ also shows a strong absorption band at 1617 cm^{-1}, which can be assigned to a free ionized carboxylate group. In the case of Pt(II) complexes with *S*-alkyl cysteine derivatives, in which the carboxylate group was not coordinated to the metal ion, the band attributed to the free ionized carboxylate group appears at 1620 cm^{-1} (14).

Fig. 1. IR absorption spectra for: (*a*) deoxyalliin, (*b*) potassium *S*-allyl-L-cysteinate, and (*c*) the Pd(II) complex.



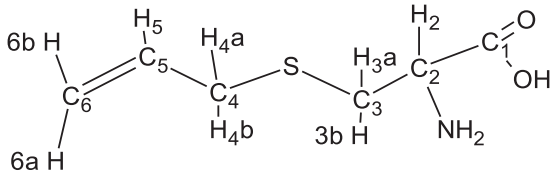


Fig. 2. The schematic structure of deoxyalliin.

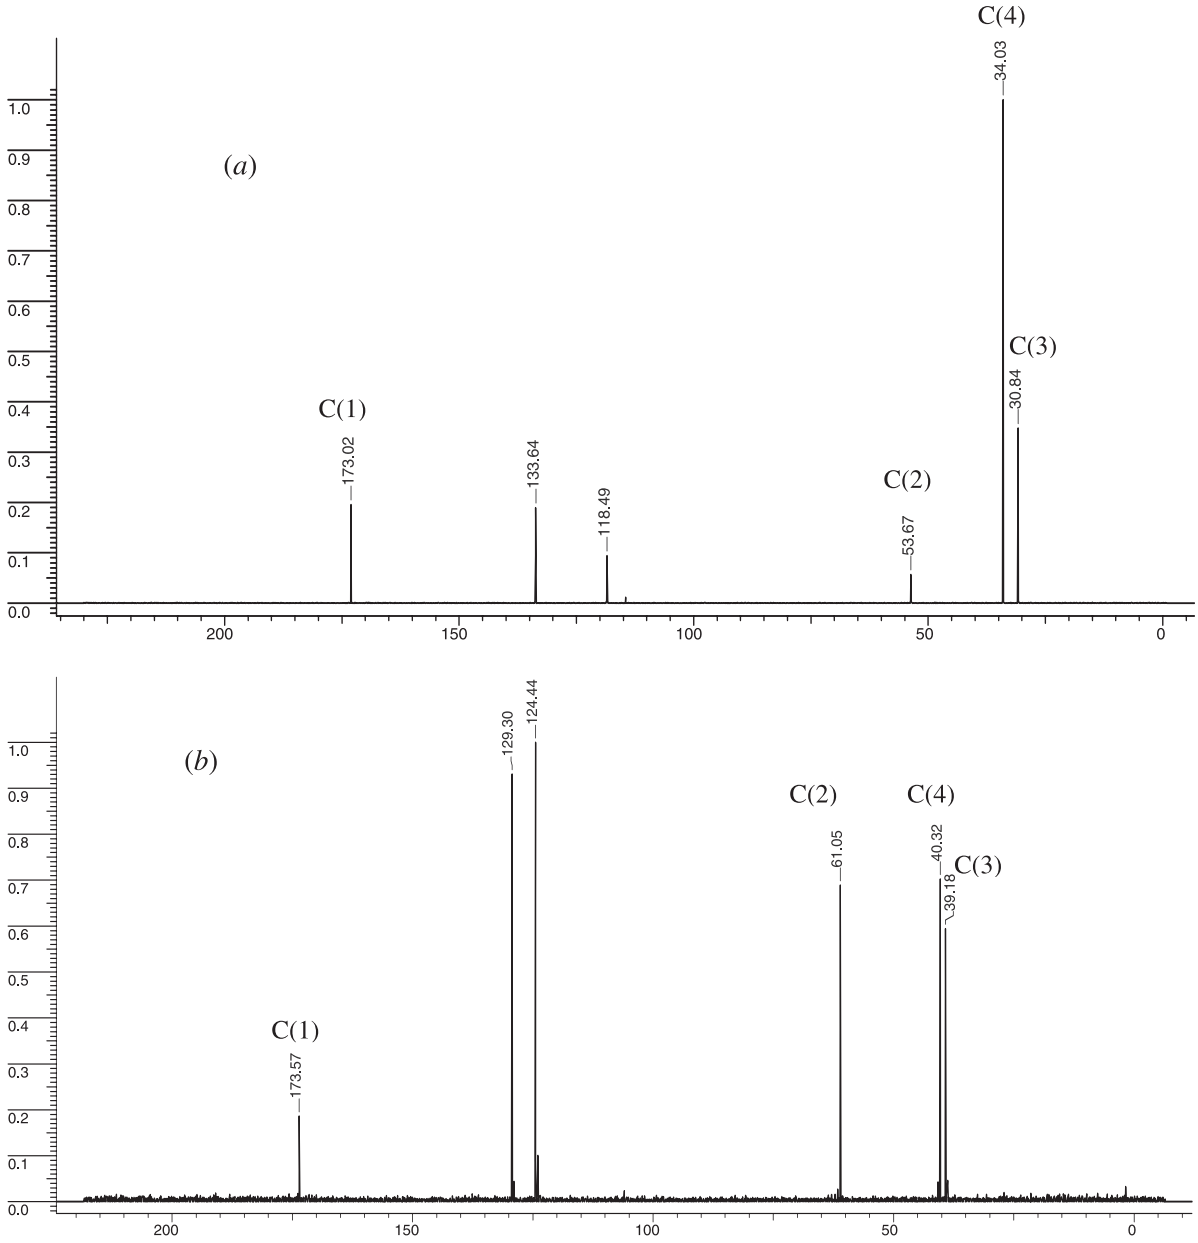
The IR spectra of the complexes were also measured in the region 700–150 cm^{-1} to identify frequencies related to M—S and M—N bonds. The IR spectrum shows frequencies at 342 cm^{-1} and at 554 cm^{-1}, which could be assigned to ν(M-S) and ν(M-N), respectively. These attributions are in agreement with the literature values, being similar to those found for an ethyl cysteinate complex of palladium(II) (19) and for other metal complexes with amino acids (14). Considering the presence of two well-defined bands for ν(M-N) and ν(M-S), a trans configuration could be proposed for the Pd(II) complex, as it occurs for complexes of the type $[Pt(L\text{-}H^+)_2]$, where L is an *S*-alkyl-L-cysteine derivative (14).



^1H and ^{13}C NMR spectrometry

^1H NMR and ^{13}C NMR spectra of the Pd(II) complex are useful for assigning ligand to metal bonding sites. The NMR spectra of the complex were analyzed in comparison to the spectra of the free ligand. The ligand structure is shown in Fig. 2.

The ^1H NMR spectrum of the Pd(II) complex with deoxyalliin is consistent with coordination of the ligand to

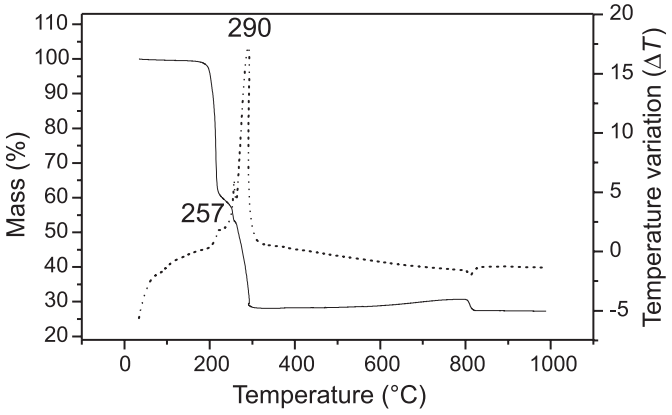
© 2005 NRC Canada

Fig. 3. ^{13}C NMR for: (*a*) deoxyalliin and (*b*) the Pd(II) complex.

the metal through the S and N atoms. Protons near the coordination sites are shifted downfield by 0.2–0.7 ppm. It was also observed that the chemical shifts for H(4a, 4b) (see Fig. 2) varies from 2.9 ppm for the ligand spectrum to 3.6 ppm for the complex. It was also observed that H(2a) varies from 3.8 ppm for the ligand to 4.0 ppm for the complex. These results are in agreement with the literature for Pd(II) and Pt(II) complexes involving amino acid derivatives showing *S*,*N*-coordination sites to the metal ions (14).

^{13}C NMR data are in agreement with S and N coordination proposed by analyzing the ^{1}H NMR and IR spectra. ^{13}C NMR chemical shifts for deoxyalliin and the Pd(II) complex are shown in Fig. 3.

According to the ^{13}C NMR data, the chemical shift at 173 ppm in the spectrum of the ligand is assigned to the carbon atom of the COOH group (C1 in Figs. 2, 3*a*, and 3*b*). In the spectrum of the complex, no changes are observed for the chemical shift of the COOH group. Pronounced changes are observed for the chemical shifts of C2, C3, and C4 in the spectrum of the Pd(II) complex when compared to the free ligand (see Figs. 2, 3*a*, and 3*b*). These changes are other indications for coordination of deoxyalliin to Pd(II) through the N and S atoms of the amino acid structure.



Thermal analysis

TG and DTA curves for the Pd(II) complex are shown in Fig. 4. According to the thermogravimetric data, the composition of the complex formulated as $[Pd(C_6H_{10}NO_2S)_2]$ is confirmed. Oxidation of the coordinated ligand starts at temperatures near 200 °C. The residue formed after the thermal treatment of the Pd(II) complex at 900 °C was identified by powder X-ray diffractometry as a mixture of PdO (20) and metallic Pd (21).

DTA of the Pd(II) complex shows a strong exothermic

© 2005 NRC Canada

Fig. 4. TG (solid) and DTA (dot) curves for $[Pd(C_6H_{10}NO_2S)_2]$.

peak with a maximum at 290 °C and a weak peak at 257 °C (see Fig. 4). These effects are assigned to ligand oxidation of the complex in two steps.

Powder X-ray diffractometry

Powder X-ray diffraction data for $[Pd(C_6H_{10}NO_2S)_2]$ have been successfully indexed in supposition of an orthorhombic system with the following lattice cell parameters: a = 10.740 Å, b = 19.999 Å, and c = 5.2470 Å. A complete discussion of the powder X-ray indexation of this new complex has already been described (22).

Antiproliferative and cell viability analyses

The profile of the cell proliferation assays using HeLa and TM5 cells (Fig. 5) shows a blockage action of the Pd(II) complex starting at low concentrations such as 0.050 mmol/L, especially for HeLa cells. At 0.40 mmol/L, HeLa proliferation was totally eliminated and TM5 cell proliferation was only about 25% when compared to the control. Similar results were obtained when cisplatin was used: ~70% inhibition at 0.40 mmol/L (data not shown here).

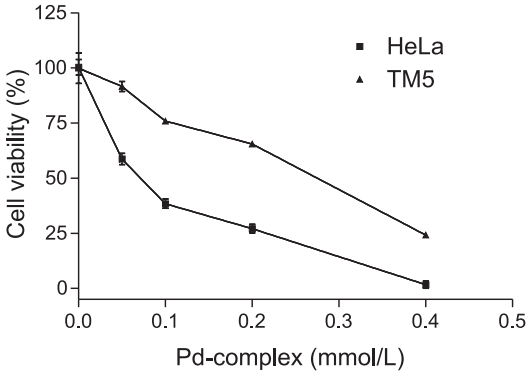
The Pd(II) complex was also analyzed for HeLa cells after a longer exposure period of time (Fig. 6). The results showed that after 7 days of exposure to the Pd(II) complex (concentrations of 0.10 and 0.20 mmol/L), cell proliferation was about 75% inhibited. When the concentration was increased to 0.40 or 0.80 mmol/L, cell proliferation was completely inhibited.

The evaluation of the immediate cytotoxic action of the Pd(II) complex was analyzed after an incubation time of 24 h. After this period of incubation, a relevant effect was found only at high concentrations of the complex (0.40 and 0.80 mmol/L) suggesting that the antiproliferative action of the Pd(II) complex observed at lower concentrations is probably due to cell cycle arrest rather than cell death. In the case of cell death, cell viability would appear reduced at lower concentrations of the complex when compared to the control.

Flow cytometry analysis

As can be observed in Fig. 7, TM5 melanoma cells treated during 24 h with the Pd(II) complex at the concentration of 0.20 mmol/L did not present an apoptosis pattern, as seen by the low level of hypodiploid cells, which are detected when DNA fragmentation and (or) loss of DNA is occurring. On the other hand, cells were mainly arrested in G0/G1, when compared to the vehicle treated group. These results corroborate the data discussed here for the cytotoxic action of the compound after an incubation time of 24 h.

Fig. 5. Proliferation profiles for HeLa and TM5 cells after treatment with the Pd(II) complex in different concentrations for 48 h. The data represent an average of three to six independent experiments done in duplicate.



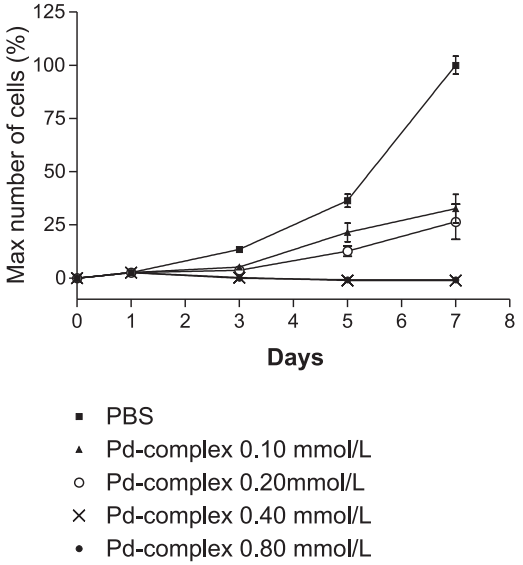


Fig. 6. Profiles for HeLa proliferation after treatment with the Pd(II) complex in different concentrations. The data represent an average of three independent experiments done in duplicate.

In vivo assays

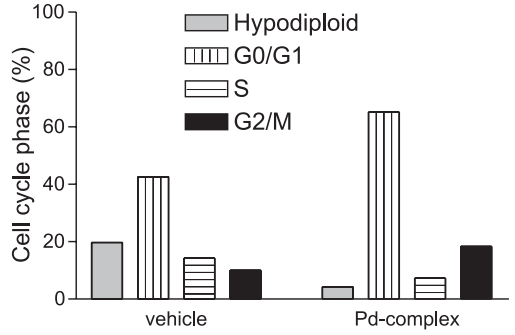
The results obtained for the melanoma growth assay using C57/BL6 mice were considered nonsignificant due to the short delay (~48 h) observed for the appearance of tumors in the group treated with the complex (72 mg/kg body weight) when compared to the control group. No side effects, e.g., weight loss, were detected. This modest result warrants further in vivo investigation and optimization of dosage of the complex.

Final conclusions

Based on the chemical and spectroscopic results, a schematic structure for the Pd(II) complex with deoxyalliin is proposed in Fig. 8.

© 2005 NRC Canada

Fig. 7. Flow cytometric analysis of TM5 cells subjected to 0.20 mmol/L of Pd(II) complex or the vehicle (PBS) for 24 h. Hypodiploid cells correspond to cells that are undergoing apoptosis. The data represent an average of two independent experiments.



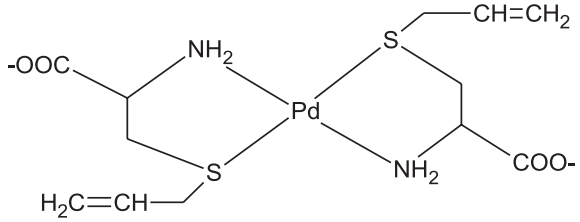


Fig. 8. The schematic structural formula proposed for $[Pd(C_6H_{10}NO_2S)_2]$.

Antiproliferative activity of the Pd(II) complex with deoxyalliin over HeLa and TM5 cells started at the concentration 0.050 mmol/L leading to a proliferation inhibition of about 40% for HeLa and 10% for TM5 cells. At the concentration 0.40 mmol/L, proliferation of HeLa cells was totally eliminated while inhibition of the proliferation of TM5 cells was about 75%. The MTT assay, used to evaluate the immediate cytotoxic effect of the complex, after an incubation of 24 h, indicated that at low concentrations, the Pd(II) complex action is probably due to cell cycle arrest rather than cell death, which was observed only under concentrations equal or higher than 0.40 mmol/L. In agreement with this conclusion, the flow cytometry analysis indicated that TM5 cells are mainly arrested at G0/G1 after a period of 24 h of incubation for the concentration 0.20 mmol/L of the complex. It is well-established that cisplatin treatment arrests cells in G2 with subsequent induction of apoptosis (3). In the present work, it was also possible to observe that, using the concentration 0.20 mmol/L of the Pd(II) complex, an apoptosis pattern was not triggered, as evidenced by a low percentage of hypodiploid cells (see Fig. 7). To our knowledge up to this date, a pattern of cell arresting by palladium complexes has not been described in the literature. We have also tested this Pd(II) complex against the development of melanoma tumors in mice in a preliminary trial. A slight delay (~48 h compared to untreated controls) in tumor appearance for the 72 mg/kg Pd(II)-complex-treated group was observed.

This work describes a new palladium(II) complex with in vitro biological activity in the μmol/L concentration. Its action is similar to other palladium complexes and also to cisplatin when tested against HeLa cells (8, 23–25).

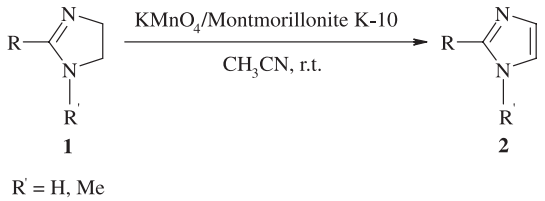
Mild, efficient, and chemoselective dehydrogenation of 2-imidazolines, bis-imidazolines, and *N*-substituted-2-imidazolines with potassium permanganate supported on montmorillonite K-10

Iraj Mohammadpoor-Baltork and Mohammad Abdollahi-Alibeik

Abstract: Different types of 2-imidazolines, bis-imidazolines, and *N*-substituted-2-imidazolines are efficiently oxidized to their corresponding imidazoles with potassium permanganate ($KMnO_4$) supported on montmorillonite K-10 under very mild conditions. The procedure is very simple and no strict conditions were required. Selective dehydrogenation of 2-alkyl-2-imidazolines in the presence of 2-aryl-2-imidazolines is a noteworthy advantage of this method and can be considered as a useful practical achievement in these reactions.

Key words: 2-imidazolines, imidazoles, dehydrogenation, potassium permanganate, montmorillonite K-10.

Résumé : Utilizant des conditions réactionnelles très douces impliquant du permanganate de potassium ($KMnO_4$) déposé sur de la montmorillonite K-10, il est possible d'oxyder divers types de 2-imidazolines, de bis-imidazolines et de 2-imidazolines substituées en imidazoles correspondants. La méthode est simple et ne demande pas de conditions strictes. La déshydrogénation sélective des 2-alkyl-2-imidazolines en présence de 2-aryl-2-imidazolines est un avantage important de cette méthode et elle peut être considérée comme la plus grande réalisation de ces réactions.



Mots clés : 2-imidazolines, imidazoles, déshydrogénation, permanganate de potassium, montmorillonite K-10.

[Traduit par la Rédaction]

Introduction

Compounds with an imidazole ring system have many pharmaceutical and biological activities including antihypertensive, antiinflammatory, antibacterial, and antidiabetic (1). Several methodologies for the direct synthesis of substituted imidazoles have been published (2–4). 2-Substituted imidazoles are also prepared by the oxidation of the corresponding 2-imidazolines. However, the oxidation of 2-imidazolines to the resonance-stabilized imidazoles is surprisingly difficult. Several methods and reagents such as Zn-Al_2O_3 (5), Ni (6), Se (7), Pd/C (8), MnO_2 (9), $BaMnO_4$ (10), and DMSO (11) have been developed for this purpose in the literature. The reported reagents suffer from one or more of the following disadvantages such as low yields of the products, very long reaction times, toxicity, harsh reaction conditions, and the use of large excess of the reagents. Also, some of these methods are not effective for the oxidation of 2-alkyl-2-imidazolines. Potassium permanganate has also been used for the oxidation of 2-imidazolines (12). However, this method suffers from drawbacks such as long reaction times (12–16 h), low yields of the products (40%–72%), and strict reaction conditions (reflux in dioxane). Thus, the development of a new improved protocol for a high yielding oxidation of 2-imidazolines and bis-imidazolines to their corresponding imidazoles using inexpensive reagents such as $KMnO_4$ under very mild reaction conditions is still in demand.

Scheme 1.

Results and discussion

It was recently shown that adsorption onto solid supports can change the reactivity and selectivity of $KMnO_4$ in oxidation reactions (13). Along this line, herein, we wish to disclose that $KMnO_4$ adsorbed on the very inexpensive and readily available support, montmorillonite K-10, oxidizes 2-imidazolines, bis-imidazolines, and *N*-substituted-2-imidazolines to their corresponding imidazoles efficiently under very mild reaction conditions (Scheme 1).

[d]Reaction was performed in mixture of CH_3CN–DMF (1:2) at room temperature.

Our goals in undertaking this work were: (*i*) to achieve rapid reaction rates, higher yields, and milder reaction conditions; (*ii*) to overcome the drawbacks of the reported methods; (*iii*) to develop a high-yielding synthesis of imidazoles using a cheap commercially available reagent. We first examined the oxidation of 2-phenyl-2-imidazoline (**1a**) using $KMnO_4$ (2 equiv.) alone in CH_3CN at room temperature. Only 20% of the 2-phenylimidazole was isolated from the

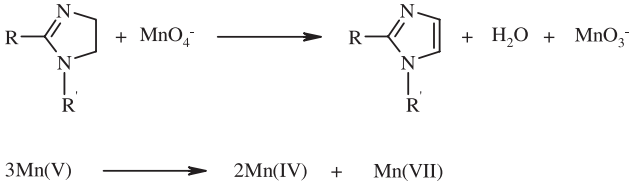
Table 2. Comparison of some of the results obtained from $KMnO_4$ – montmorillonite K-10 (I) and some of those reported with DMSO (II) (11), 10%Pd/C (III) (11), and $KMnO_4$ – refluxing dioxane (IV) (12).



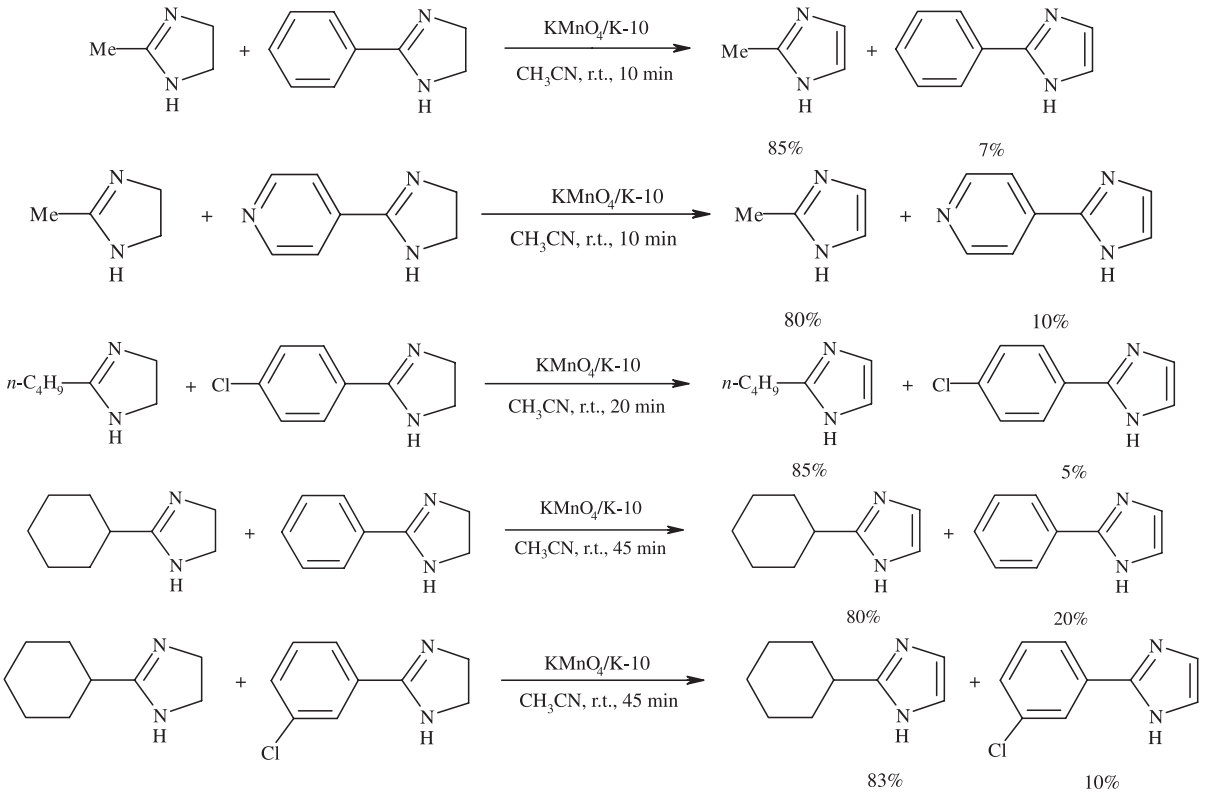
Substrate	Product	Yield (%) (Time, h)			
		I	II	III	IV
		88 (0.16)	0 (48)	0 (48)	72 (12)
		95 (1)	51 (48)	77 (48)	40 (16)
		89 (1.9)	51(48)	30 (48)	—
		95 (0.75)	71 (48)	57 (48)	—

reaction mixture after 2 h. Once again, we attempted a similar reaction with $KMnO_4$ (2 equiv.) in the presence of different amounts of montmorillonite K-10 and observed that to achieve a quantitative yield of the corresponding imidazole, the weight ratio 1:2 of $KMnO_4$:montmorillonite K-10 is required (entry 1, Table 1). It is worth mentioning that in the oxidation of 2-phenyl-2-imidazoline with $KMnO_4$ (3 equiv.) in refluxing dioxane, only 40% of the related imidazole was obtained after 16 h (12).

Similarly, different types of 2-aryl-2-imidazolines (**1b**–**1h**) were reacted with $KMnO_4$ in the presence of montmorillonite K-10 and their corresponding imidazoles **2b**–**2h** were obtained in good to excellent yields. Under these conditions, the 2-aryl-2-imidazolines do not exhibit significantly different reactivities. The influence of the substituents on the yields of the products is also not significant. Bis-imidazolines (**1i**–**1j**) were also oxidized with this reagent system, affording the corresponding bis-imidazoles (**2i**–**2j**) in high yields. The oxidation of 2-alkyl-2-imidazolines (**1k**–**1m**) was also investigated. It was found that in comparison with 2-aryl-2-imidazolines, the oxidation of 2-alkyl-2-imidazolines can proceed effectively with lower amounts of $KMnO_4$ (1–1.5 equiv.) in the presence of montmorillonite K-10 in CH_3CN at room temperature. Under these conditions, 2-alkylimidazoles (**2k**–**2m**) were obtained in excellent yields (Table 1). *N*-Substituted-2-imidazolines such as *N*-methyl-2-phenylimidazoline (**1n**) underwent oxidation with $KMnO_4$ – montmorillonite K-10 to afford the corresponding imidazole **2n** in 85% yield. Therefore, in addition to oxidation of 2-imidazolines and bis-imidazolines, it seems that this method can be applied successfully for the oxidation of *N*-substituted 2-imidazolines.

To show the efficiency of montmorillonite K-10 in these reactions, the dehydrogenation of 2-phenylimidazoline (**1a**) and 2-(4-chlorophenyl)imidazoline (**1d**) was investigated with potassium permanganate in the presence of untreated montmorillonite clay. Under these conditions, the corresponding imidazoles **2a** and **2d** were obtained in 50% and 35% yields, respectively. This difference seems to indicate the importance of the acidity of montmorillonite K-10 in the dehydrogenation of 2-imidazolines.

Scheme 2.



After completion of the reaction, the waste brown MnO_2 precipitate is formed, which is removed by filtration. The exact mechanism of these reactions is unclear at present. However, on the basis of the above observation, a plausible explanation is that 2-imidazolines are oxidized to their corresponding imidazoles and permanganate ion is reduced from Mn(VII) to Mn(V). The Mn(V) ion formed disproportionates to Mn(VII) and Mn(IV) (Scheme 2). Thus, the end product of manganese in these dehydrogenation reactions is MnO_2 (14).

In Table 2, some of the results of our experiments are compared with those reported by other methods. As can be seen, this method is superior to the previously reported methods in terms of yields, reaction times, the amount of the reagent used for successful oxidation, and reaction conditions. Also, this is the first report in which the reactions have been carried out at room temperature and under very mild conditions.

To extend the scope of this reagent system further, the competitive oxidation of 2-alkyl-2-imidazolines and 2-aryl-2-imidazolines was also examined. The results are shown in Scheme 3 and the product ratios were determined by NMR spectroscopy. It was found that 2-alkyl-2-imidazolines are oxidized in the presence of 2-aryl-2-imidazolines with high selectivity. It is worth mentioning that such a selectivity has not been reported previously and can be considered as a useful practical achievement in oxidation of 2-imidazolines.

Scheme 3.

In conclusion, we have demonstrated a remarkably mild, efficient, and simple method for the oxidation of 2-imidazolines, bis-imidazolines, and *N*-substituted-2-imidazolines using $KMnO_4$ – montmorillonite K-10 at room temperature. In addition, short reaction times, low cost of the reagents, the ease of use, high yields of the products, and chemoselectivity are noteworthy advantages of this method and offer significant improvements over the existing procedures for the oxidation of 2-imidazolines.

Experimental

Melting points were determined using a Stuart Scientific apparatus and are uncorrected. IR spectra were run on a Shimadzu IR-435 spectrophotometer. ^{1}H NMR spectra were recorded in DMSO-d_6 solvent on a Brucker 500 MHz spectrometer. Yields refer to isolated products. 2-Imidazolines, bis-imidazolines, and *N*-methyl-2-phenylimidazoline were prepared according to the described procedure (15).

Dehydrogenation of 2-imidazolines, bis-imidazolines, and *N*-substituted-2-imidazolines — General procedure

Potassium permanganate (1.58 g, 10 mmol) and montmorillonite K-10 (3.16 g) were ground together in a mortar until a fine homogeneous powder was obtained.

To a solution of substrate (1 mmol) in CH_3CN (25 mL), $KMnO_4$ – montmorillonite K-10 (0.474–1.90 g, 1–4 mmol) was added portionwise and the mixture was stirred at room temperature for 10–115 min. The progress of the reaction was monitored by TLC (eluent: EtOAc–MeOH, 4:1). Ethanol (1 mL) was added to reduce excess oxidant and after stirring for an additional 20 min, the mixture was filtered through a short pad of Celite or silica gel and the solid material was washed with CH_3CN (20 mL). The filtrate was evaporated and the resulting crude material was purified by chromatography on SiO_2 or Al_2O_3 with an appropriate eluent. The pure products were obtained in 70%–97% yields (Table 1). Selected physical and spectroscopy data: Compound **2b**: mp 218–220 °C (lit. value (11) mp 223 °C). IR ν_{max} (KBr, cm^{-1}): 3435, 3150, 2985, 1658, 1610, 1575, 1514, 1435, 1100, 815, 725. ^{1}H NMR (500 MHz, DMSO-d_6) δ_H: 12.39 (s, 1H, NH), 7.81 (d, J = 8 Hz, 2H, Ar), 7.23 (d, J = 7.5 Hz, 2H, Ar), 7.18 (br s, 1H, =CH), 6.99 (br s, 1H, =CH), 2.31 (s, 3H, CH_3). Compound **2i**: mp 290–292 °C (lit. value (18) mp 287 to 288 °C). IR ν_{max} (KBr, cm^{-1}): 3400, 3105, 3010, 1610, 1592, 1517, 1496, 1478, 1370, 1108, 968, 938, 745, 704. ^{1}H NMR (500 MHz, DMSO-d_6) δ_H: 12.63 (s, 2H, 2NH), 8.57 (d, J = 1.1 Hz, 1H, Ar), 7.86 (d, J = 7.7 Hz, 2H, Ar), 7.49 (t, J = 7.7 Hz, 1H, Ar), 7.23 (br s, 2H, 2 × =CH), 7.07 (br s, 2H, 2 × =CH). Compound **2k**: mp 139–141 °C (lit. value (12) mp 140–142 °C). IR ν_{max} (KBr, cm^{-1}): 3115, 3012, 1670, 1595, 1440, 1298, 1110, 990, 935, 750, 738. ^{1}H NMR (500 MHz, DMSO-d_6) δ_H: 9.00 (s, 1H, NH), 6.82 (s, 2H, 2 × =CH), 2.24 (s, 3H, CH_3).

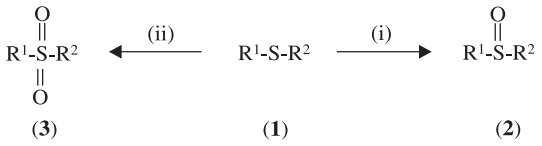
3-Carboxypyridinium chlorochromate – aluminium chloride — An efficient and inexpensive reagent system for the selective oxidation of sulfides to sulfoxides and sulfones in solution and under microwave irradiation

Iraj Mohammadpoor-Baltork, Hamid R. Memarian, and Kiumars Bahrami

Abstract: 3-Carboxypyridinium chlorochromate (CPCC) in the presence of aluminium chloride is a very efficient reagent for the selective oxidation of sulfides to sulfoxide and sulfones in solution and under microwave irradiation. It is noteworthy that different functional groups including carbon–carbon double bonds, ketones, oximes, aldehydes, ethers, and acetals were tolerated under these reaction conditions.

Key words: sulfoxides, sulfones, oxidation, chlorochromate, Lewis acid.

Résumé : Le chlorochromate de 3-carboxypyridinium (CCCP) en présence de chlorure d'aluminium est un réactif très efficace pour l'oxydation des sulfures en sulfoxydes et en sulfones effectuée en solution et sous irradiation de micro-ondes. Il est notable que divers groupes fonctionnels, y compris les doubles liaisons carbone–carbone, les cétones, les oximes, les aldéhydes, les éthers et les acétals, sont tolérés dans les conditions de la réaction.



Mots clés : sulfoxydes, sulfones, oxydation, chlorochromate, acide de Lewis.

[Traduit par la Rédaction]

Introduction

Sulfoxides and sulfones are useful synthetic intermediates for the construction of various chemically and biologically significant molecules (1). The most popular and straightforward method for preparing sulfoxides or sulfones involves the oxidation of sulfides. Various methods are available for the oxidation of sulfides to sulfoxides and (or) sulfones (2–29). However, some of these methods suffer from drawbacks such as long reaction times, low yields of the products, the use of expensive reagents, and undesired reactions of other functional groups. On the other hand, selective oxidation of sulfides to sulfoxides and sulfides to sulfones with the same reagent system under the adjusted reaction conditions is an important process in synthetic organic chemistry, and only a few reports are available in the literature for this purpose (30). Consequently, introduction of a new method and inexpensive reagent for the oxidation of sulfides to sulfoxides and sulfones is still in demand. The chemoselective oxidation of sulfides without affecting the other functional groups is also another point of interest. Along this line, we wish to report that sulfides are efficiently oxidized to their corresponding sulfoxides and sulfones with 3-carboxypyridinium chlorochromate in solution and under microwave irradiation.

Scheme 1. (*i*) CPCC (0.8–1 equiv.), $AlCl_3$ (1 equiv.), CH_3CN, reflux or MW; (*ii*) CPCC (1–2.5 equiv.), $AlCl_3$ (1 equiv.), CH_3CN, reflux or MW.

Results and discussion

3-Carboxypyridinium chlorochromate (CPCC) is an inexpensive reagent and is easily prepared from the commercially available starting materials. We have recently reported CPCC as a convenient reagent for the oxidative cleavage of carbon–nitrogen double bonds, oxidative deprotection of trimethylsilyl and tetrahydropyranyl ethers, oxidation of 1,4-dihydropyridines, and deprotection of thiocarbonyl compounds (31). In the course of further exploration on the application in synthetic organic chemistry, we found that CPCC in the presence of aluminium chloride can be used as an efficient reagent for the oxidation of sulfides to sulfoxides and sulfones (Scheme 1).

Initially, benzyl 4-methylphenyl sulfide (entry **1g**, Table 1) was used as a model compound for sulfoxidation by CPCC alone in refluxing acetonitrile. It was found that the reaction did not proceed at all after 2 h.

Recently, Lewis-acid-promoted oxidation of organic compounds has been reported in the literature (32). Therefore, the oxidation of benzyl 4-methylphenyl sulfide to the corresponding sulfoxide with CPCC in the presence of different Lewis acids such as $AlCl_3$, $BiCl_3$, $FeCl_3{\cdot}6H_2O$, $SnCl_2{\cdot}2H_2O$, $NiCl_2{\cdot}6H_2O$, and $CoCl_2{\cdot}6H_2O$ in refluxing acetonitrile was investigated. The best result was achieved using $AlCl_3$ (Table 2).

We have also examined this reaction in different solvents such as CH_2Cl_2, $CHCl_3$, CH_3CN, CH_3COCH_3, and *n*-hexane, and it was observed that CH_3CN is the only solvent of choice for this purpose (Table 3).

The applicability of the CPCC–$AlCl_3$ system was then examined for sulfoxidation of diaryl, dibenzyl, aryl benzyl, dialkyl, and cyclic sulfides in refluxing acetonitrile. The optimum molar ratio of sulfide to CPCC to $AlCl_3$ was found to be 1:1:1. Under these conditions, the corresponding sulfoxides were obtained in high yields (Table 1).

Recently, there has been a growing interest in the application of microwave irradiation in chemical reactions (33). The salient features of the microwave approach are the much im-

© 2005 NRC Canada

proved reaction rates, formation of cleaner products, and operational simplicity. Therefore, the sulfoxidation of the above-mentioned sulfides with CPCC–$AlCl_3$ was performed under microwave irradiation with a dramatic reduction of reaction time. Under these conditions, the optimum molar ratio of sulfide to CPCC to $AlCl_3$ was found to be 1:0.8:1. When the sulfides, dissolved in 2 mL of CH_3CN, were treated with CPCC–$AlCl_3$ and irradiated for 0.33–4 min, the corresponding sulfoxides were obtained in high yields (Table 1).

However, in the oxidation of alkyl aryl sulfides such as 4-chlorophenyl methyl sulfide and methyl phenyl sulfide, a mixture of sulfoxide (~55%) and sulfone (~40%) were isolated from the reaction mixture.

To show the efficiency and applicability of the CPCC–$AlCl_3$ system further, the oxidation of sulfides to their corresponding sulfones was also carried out in solution and under microwave irradiation. The reaction conditions specified in Table 4 were optimized for use in both solution (sulfide to CPCC to $AlCl_3$ = 1:1.5–2.5:1) and under microwave irradiation (sulfide to CPCC to $AlCl_3$ = 1:1–2:1). It was found that a wide variety of diaryl, dialkyl, dibenzyl, aryl benzyl, alkyl aryl, and cyclic sulfides were oxidized to their sulfones in excellent yields in refluxing acetonitriles. It should be noted that some of these oxidation reactions were also performed in dry acetonitrile and no improvement was observed under these conditions. The oxidation of these sulfides with the CPCC–$AlCl_3$ system under microwave irradiation afforded the corresponding sulfones in excellent yields in very short reaction times (0.25–4.5 min) without any special precautions. The results are presented in Table 4. Under microwave irradiation, acetonitrile was used for the homogenization of the reaction mixture. The polar character of this solvent also seems to increase the reaction temperature, so the reaction is completed in a short time (33*c*). Inspection of the data in Tables 1 and 4 show that the yields of the reactions in solution and under microwave irradiation are comparable, but under microwave irradiation, the reaction times are considerably shorter. Also, the molar ratio of CPCC to sulfide is lower under microwave irradiation.

We investigated some of these reactions with 3-carboxypyridine–$AlCl_3$ and it was found that the reactions did not proceed at all. Also, during the reaction with CPCC, the colour of the mixture turned from yellow-orange to green. Further, the reaction times and yields were comparable when the reactions were carried out in air and under an inert atmosphere. These are good indications that the oxygens transferred to sulfides are those bound to chromium in the CPCC reagent.

As mentioned in our previous publications (32), some of the reagents under investigation were effective oxidizing agents only in the presence of aluminium chloride. This trend has been also observed in the oxidation of sulfides with CPCC. Unfortunately, we have not been able to assign a reasonable mechanism for these reactions at present.

It is worth mentioning that the CPCC–$AlCl_3$ system is chemoselective, tolerating various functional groups such as carbon–carbon double bonds, ketones (Table 4, entries **1t**, **1c′**, and **1d′**), oximes, aldehydes, ethers, and acetals (Scheme 2). These observations clearly suggest that this method can be applied for the chemoselective oxidation of sulfides in the presence of the above-mentioned functional groups in multifunctional molecules.

To show the advantage of 3-carboxypyridinium chlorochromate (CPCC) over pyridinium chlorochromate (PCC), we compared the results obtained for some of the reactions using these two reagents. It was found that the yields of the reactions are higher with CPCC (Table 5).

In conclusion, we have demonstrated that the CPCC–$AlCl_3$ system is an inexpensive and excellent reagent for the oxidation of a variety of structurally diverse sulfides to their corresponding sulfoxides and sulfones. It is noteworthy that the reaction can tolerate oxidatively sensitive functional groups and that the sulfur atom is selectively oxidized.

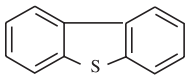
Experimental

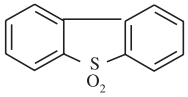
The sulfides **1a**, **1p**, **1q**, **1s**, **1t**, and **1d′** were purchased from the Merck chemical company. The other sulfides were prepared according to the described procedure (34). Microwave irradiation was carried out using a commercial microwave oven (Samsung M9G45) operating at 2450 MHz (900 W). The yields refer to isolated pure products. Melting points were determined using a Mettler FP5 apparatus and are uncorrected. IR spectra were run on a Philips PU9716 spectrophotometer. ^1H NMR spectra were recorded on a Bruker 80 or 200 and (or) 500 MHz spectrometer with $CDCl_3$ as the solvent and TMS as the internal standard. The elemental analysis was performed by the Research Institute of Petroleum Industry, Tehran, Iran. CPCC was prepared according to the reported procedure (31*a*).

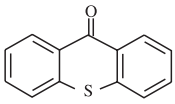
General procedure for the oxidation of sulfides to sulfoxides in solution

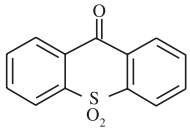
In a round-bottomed flask (50 mL) equipped with a condenser and a magnetic stirrer, a solution of sulfide (1 mmol) in CH_3CN (10 mL) was prepared. CPCC (1 mmol) and $AlCl_3$ (1 mmol) were added and the mixture was stirred under reflux conditions for the time indicated in Table 1. The progress of the reaction was monitored by TLC (eluent: *n*-hexane – ethyl acetate, 7:2). The mixture was filtered and the solid material was washed with CH_3CN (10 mL). The filtrate was evaporated and the crude product was purified by recrystallization or chromatography on silica gel to afford the pure sulfoxide (Table 1).

General procedure for the oxidation of sulfides to sulfoxides under microwave irradiation









A mixture of sulfide (1 mmol), CPCC (0.8 mmol), and $AlCl_3$ (1 mmol) and CH_3CN (2 mL) was exposed to microwave irradiation (900 W) for 0.33–4 min (at 20 s intervals). The progress of the reaction was followed by TLC. After completion of the reaction, the mixture was extracted with ethyl acetate (2 × 20 mL). Evaporation of the solvent followed by recrystallization or chromatography on silica gel afforded the pure sulfoxide (Table 1).

General procedure for the oxidation of sulfides to sulfones in solution

To a solution of sulfide (1 mmol) in CH_3CN (10 mL) in a round-bottomed flask (50 mL) equipped with a condenser and a magnetic stirrer, CPCC (1.5–2.5 mmol) and $AlCl_3$

[a]All products were identified by comparison of their physical and spectral data with those of authentic samples.
[b]Sulfide:CPCC:$AlCl_3$ = 1:2.5:1 and 1:1.5:1 for entries **1a**–**1v** and **1w**–**1d′**, respectively.
[c]Sulfide:CPCC:$AlCl_3$ = 1:2:1 and 1:1:1 for entries **1a**–**1v** and **1w**–**1d′**, respectively.
[d]Isolated yields.

(1 mmol) were added and the mixture was stirred under reflux conditions for the appropriate time according to Table 4. The progress of the reaction was monitored by TLC (eluent: *n*-hexane – ethyl acetate, 7:1). The reaction mixture was filtered and the solid material was washed with CH_3CN (10 mL). Evaporation of the solvent, followed by recrystallization or chromatography on silica gel afforded the pure sulfone (Table 4).

General procedure for the oxidation of sulfides to sulfones under microwave irradiation

A mixture of sulfide (1 mmol), CPCC (1 to 2 mmol), $AlCl_3$ (1 mmol), and CH_3CN (2 mL) was prepared. The mixture was irradiated (900 W) for 0.25–4.5 min (at 20 s intervals) and the completion of the reaction was monitored by TLC examination. After completion of the reaction, the mixture was extracted with ethyl acetate (2 × 20 mL). The

Conformational study of internally retrograde and quasi-retrograde molecules — An ab initio and DFT study

Miguel A. Zamora, Luis N. Santágata, Marcelo F. Masman, José A. Bombasaro, Mónica L. Freile, and Ricardo D. Enriz

Abstract: A conformational study of the symmetrical and nonsymmetrical homologue series was carried out. In this study, ab initio (RHF/3-21G and RHF/6-31G(d)) and density functional theory (B3LYP/6-31G(d)) calculations were performed. The presence of two symmetrical aromatic systems (identical or not) reduces notably the conformational possibilities of these compounds. Our results indicate that RHF/3-21G calculations are sufficient to use in a preliminary form. However, from our results it is prudent to use this technique only for a preliminary or exploratory conformational analysis. Thus, at least, the HF level of theory in conjunction with more extended basis sets and the inclusion of electron correlation appear to be necessary to confirm critical points at the potential energy hyper surfaces (PEHSs) and to assign the conformational preferences of these compounds. In the present paper, we report a complete and comprehensive picture of the conformational intricacies of the compounds with a small flexible connecting chain (n = 1–5). In addition, an "educated guess" for the conformational behaviour of large-size homologues (n = 6–10) is also reported.

Key words: ab initio and DFT calculations, conformational study, homologue series.

Résumé : On a effectué une étude conformationnelle de séries homologues symétrique et non-symétrique en procédant à des calculs ab initio (RHF/3-21G et RHF/6-31G(d)) et à des calculs de densité fonctionnelle (B3LYP/6-31G(d)). La présence de deux systèmes aromatiques symétriques (identiques ou pas) réduit considérablement les possibilités conformationnelles de ces composés. Nos résultats indiquent que les calculs RHF/3-21G sont suffisants pour être utilisés dans une forme préliminaire. Toutefois, sur la base de nos résultats, il serait prudent de n'utiliser cette technique que pour une analyse conformationnelle préliminaire ou exploratoire. Il semble en effet nécessaire d'utiliser au moins le niveau HF de la théorie en combinaison avec des ensembles de bases plus étendus et d'inclure une corrélation d'électron pour confirmer les points critiques des hypersurfaces d'énergie potentielle (HSEP) et pour attribuer les préférences conformationnelles de ces composés. Dans ce travail, on rapporte une image complète de la complexité de ces composés comportant de petites chaînes de liaison flexibles (n = 1–5). On rapporte de plus une évaluation probable du comportement conformationnel des homologues plus grands (n = 6–10).

Mots clés : calculs ab initio et de la théorie de la densité fonctionnelle, étude conformationelle, séries homologues.

Introduction

Life disfavours symmetry, just look at a familiar face as it is reflected by the mirror and you immediately recognize that the apparent symmetry of the human body is nothing but a disguise. Life's dislike of symmetry is even more evident at the molecular level. Our body uses D-glucose, L-amino acids, and many more molecules chosen discriminatively from the two mirror-image forms of chiral molecules. In contrast, for computational calculation purposes, symmetry is a very advantageous situation because it reduces notably the conformational possibilities of symmetrical compounds.

On the other hand, nature is efficient in producing compounds with a high degree of symmetry. It is now claimed that symmetry involving forces, including electromagnetic forces, are important in biology, particularly for the assembly of macromolecules. In addition, the ordering of water in organized systems and the symmetry of interactions may play important roles in biological processes (1, 2). Symmetrical natural compounds present generally a C_2 or C_{2v} symmetry axis; examples are the alkaloids lobelanine and sparteine, the anticoagulant dicumarol, and the antispermatogenic gossypol (Fig. 1).

Besides drugs of natural origin, twin drugs combining two structural components in a single molecule have been de-

scribed in numerous domains of medicinal chemistry. Identical twin drugs acting on receptors have been efficient in several cases. The development of polyamine disulphides such as APC or benextramine (Fig. 2) allowed the hypothesis of symmetrical properties of α-adrenergic receptors (3). Melthoctramine (Fig. 2) is a useful probe for characterizing acetylcholine muscarinic receptor subtypes where it appears as a selective M_2 antagonist (4). In addition, many twin drugs have been reported acting as enzyme inhibitors (HIV-enzyme (5), protein kinase (6, 7)), DNA ligands (8, 9), as well as surface-active antibacterial agents (9).

It should be noted that, in general, the twin drugs of interest in medicinal chemistry are large; implying that relatively large compounds possess a great number of different spatial orderings. Thus, a complete conformational analysis for these compounds appears to be, at least in principle, a very difficult task. However, it is well-known that symmetry reduces notably the conformational possibilities of a symmetrical homologue series. The question that arises is: is the number of identical or enantiomeric conformations by symmetrical reasons enough to keep the number of different conformations "manageable" using high levels of theory calculations?

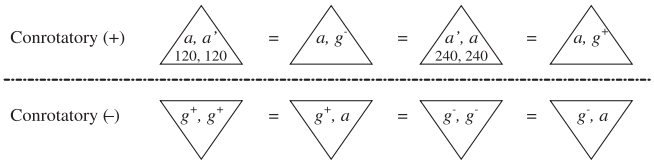
To better understand how the presence of symmetrical aromatic systems reduces the conformational possibilities in a homologue series, we performed a comparative conformational study for four series of compounds possessing different degrees of symmetry (Fig. 3).

Method of calculation

Molecular geometry optimizations were performed at three levels of theory, RHF/3-21G, RHF/6-31G(d), and B3LYP/6-31G(d), for the compounds **Ia**, **IIa**, **IIIa**, **IVa**, **IIb**, **IIc**, and **IId** (Fig. 3). The rest of the compounds reported here were evaluated only from RHF/3-21G calculations. Partially relaxed potential energy surface (PES) scan calculations for compounds **Ia**, **IIa**, **IIIa**, **IVa**, **IIb**, **IIc**, and **IId** (Fig. 3) were calculated at the RHF/3-21G level of theory. In the partially relaxed PES scan calculations, the variables were rotated with 30° increments to produce plots consisting of 13 × 13 = 169 points, keeping the bond lengths and internal angles fixed. The partially relaxed PES scan calculations (opt = z-matrix), were all critical points possessing gradients less than 4.5×10^{-4} a.u.

All the calculations reported here were carried out with the GAUSSIAN 03 program (10).

Results and discussion



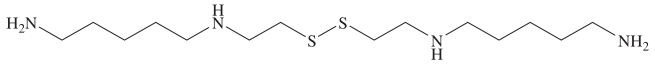
Compounds Ia, IIa, IIIa, and IVa (n = 1)

These compounds look like a simple conformational problem with two torsional angles (θ and ϕ). When a planar moiety of twofold symmetry is connected to a tetrahedral carbon of threefold symmetry, the torsional conformational potential about that single bond does not necessarily have three minima; in principle it may have six minima, as in the case of methylbenzene. In ethylbenzene (11), however, the six degenerate minima are reduced to two unique structures.

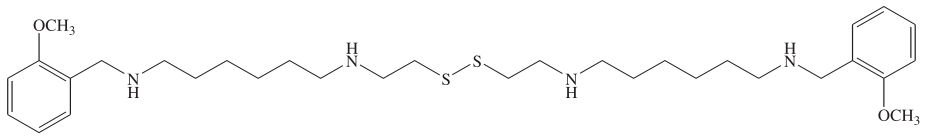
Compounds **Ia** (12, 13) and **IIa** (14) have been studied previously from ab initio and DFT calculations. In these compounds, the rotation along θ and ϕ are expected to show some symmetry since the two sides of the aromatic rings are identical. By the same rationale, such symmetry is not expected to be present when rotations are carried out along θ in compound **IIIa** and along θ and ϕ in compound **IVa**.

Figure 4 shows the PES obtained for compound **Ia**. This surface possesses eight clearly defined potential wells; however, the eight minima energy values obtained are degenerate, implying that we can have only identity and enantiomeric relationships, but not diastereoisomerism.

Observing Fig. 4, we can note that the pair of minima, located in one of the quadrants, is repeated four times in the full cycle of rotation. The pairs of minima are lying along the conrotatory mode of motion. Thus, we can classify the eight minima to two sets of four structures. In each set, the four structures are identical and the two sets imply an enantiomeric relationship.



The -·-·-·-·- line symbolizes a mirror, which is called upon to indicate the enantiomeric relationship. The results obtained for compound **Ia** are identical to those reported earlier (12, 13).



The conformational PES of **IIa** looks quite different from that of compound **Ia** (Fig. 4). Each of the four pairs of minima, together with their corresponding TS, collapsed to a single minimum. The result of such annihilation of critical points is that instead of eight only four minima are located on the conformational PES. The θ and ϕ values for these four

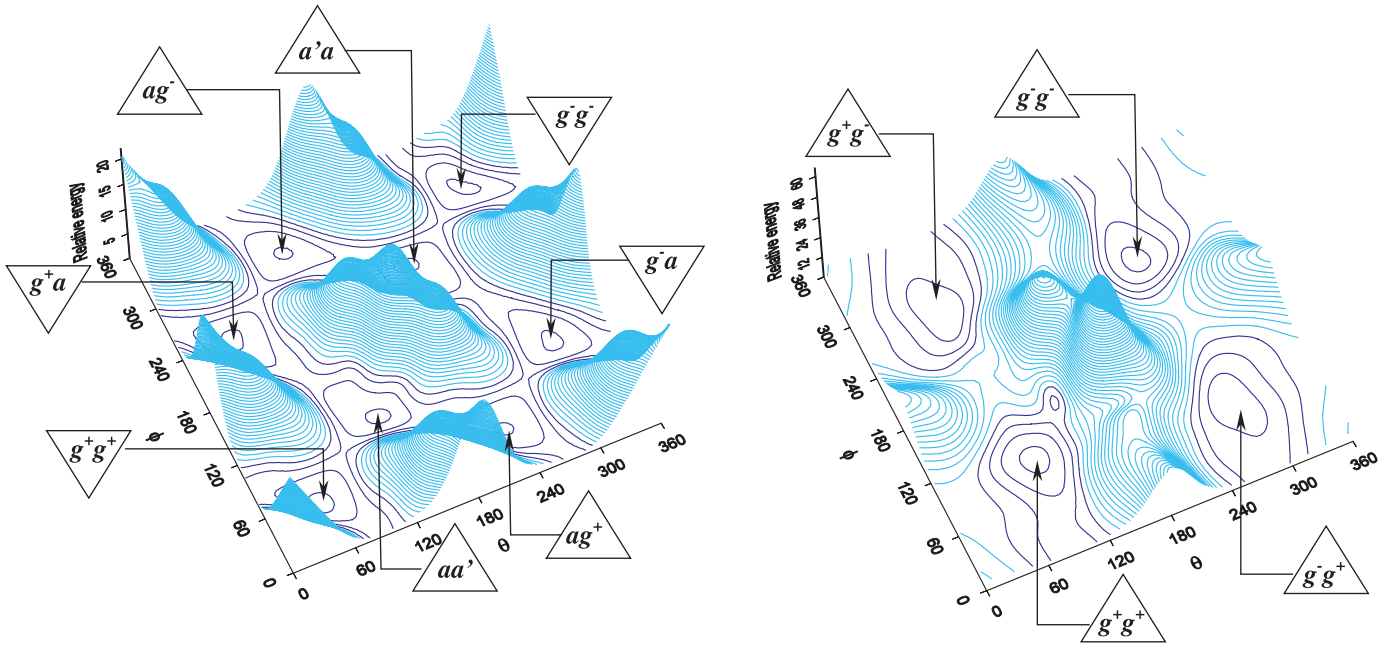
Fig. 3. General structural features of the four homologue series reported here. The torsional angles θ, ψ_1, ψ_2, ψ_3, ψ_4, ψ_5, and ϕ are also shown. n = number of methylenes; $N = 3^{(n-1)}$: number of backbone conformers without rotation about the θ and ϕ angles; $N_T = 2^2 \times 3^{(n-1)}$: total number of conformers.



minima are close to the location of the annihilated TS, namely ±90°. Interestingly enough, the four minima are identical.

The PES obtained for compound **IIIa** (Fig. 5) displays six potential wells. It is interesting to note that the total energetic degeneracy observed in the above compounds is now removed. This implies that we now have a diastereoisomeric relationship as the result of axis chirality. The form g^+, g^+ is identical to g^+, g^-, whereas g^-, g^- is identical to g^-, g^+; in turn, a, g^+ is identical to a, g^-, which is 0.4 kcal/mol above

the global minima at the RHF/3-21G level. However, the global minimum varies as a function of the basis set or level of theory; g^+, g^+ at the RHF/3-21G and *a*, g^+ at the RHF/6-31G(d) and DFT levels (Table 1). From Fig. 5 and Table 1, it is easy to note that g^+, g^+ is the enantiomeric form of g^-, g^- and g^+, g^- is the enantiomeric form of g^-, g^+.

The PES obtained for compound **IVa** is shown in Fig. 5. This PES looks quite different from those obtained for compound **Ia**, showing six critical points that were confirmed at higher levels of theory. The global minimum at the three levels of theory reported here is the conformer g^+, g^+, which has a mirror image in the form g^-, g^-. Conformation *a*, g^+

possesses a mirror image in the form a, g^-, and is 1.02 and 0.42 kcal/mol above the global minimum at RHF/3-21G and DFT levels, respectively. This form is not a minimum at the RHF/6-31G(d) level of calculation. Conformation g^+, a was found at the three levels of theory and possesses a mirror image in the form g^-, a.

To avoid misleading terminology, from now on the term "different conformations" will be used only for different spatial orderings with different energies (the so-called diastereoisomers) without consideration of the mirror images. Thus, the enantiomeric forms will be considered "equivalent conformations". In summary, compounds **Ia** and **IIa** have only one conformation, whereas compounds **IIIa** and **IVa** display two and three different conformations, respectively.

Compounds Ib, IIb, IIIb, and IVb (n = 2)

In these compounds, the orientations of the ring systems are described by the dihedral angles θ and ϕ; whereas the orientations of the alkyl chain are described by the dihedral angle ψ_1. The multidimensional conformational analysis (MDCA) (15–17) predicts the existence of 2 × 3 × 2 = 12 legitimate minima for triple rotors with these multiplicities.

The three torsional angles (θ, ψ_1, ϕ) span a three-dimensional (i.e., 3D) conformational hyper surface. The PEHS is therefore labelled as a 3D-PEHS even though such a PEHS is, in fact, a four-dimensional where the dependent variable, the energy, is the fourth dimension. We, of course, may generate 2D cross-sections of this 3D-PEHS by singling out one torsional angle (for example, ψ_1).

The overall expression for the 3D-PEHS in which energy is the function of the three independent variables, can thus be partitioned into three 2D-PES of the type:

$$[1] \qquad E^{\psi_1 = g^+} = E(\theta, \phi)$$

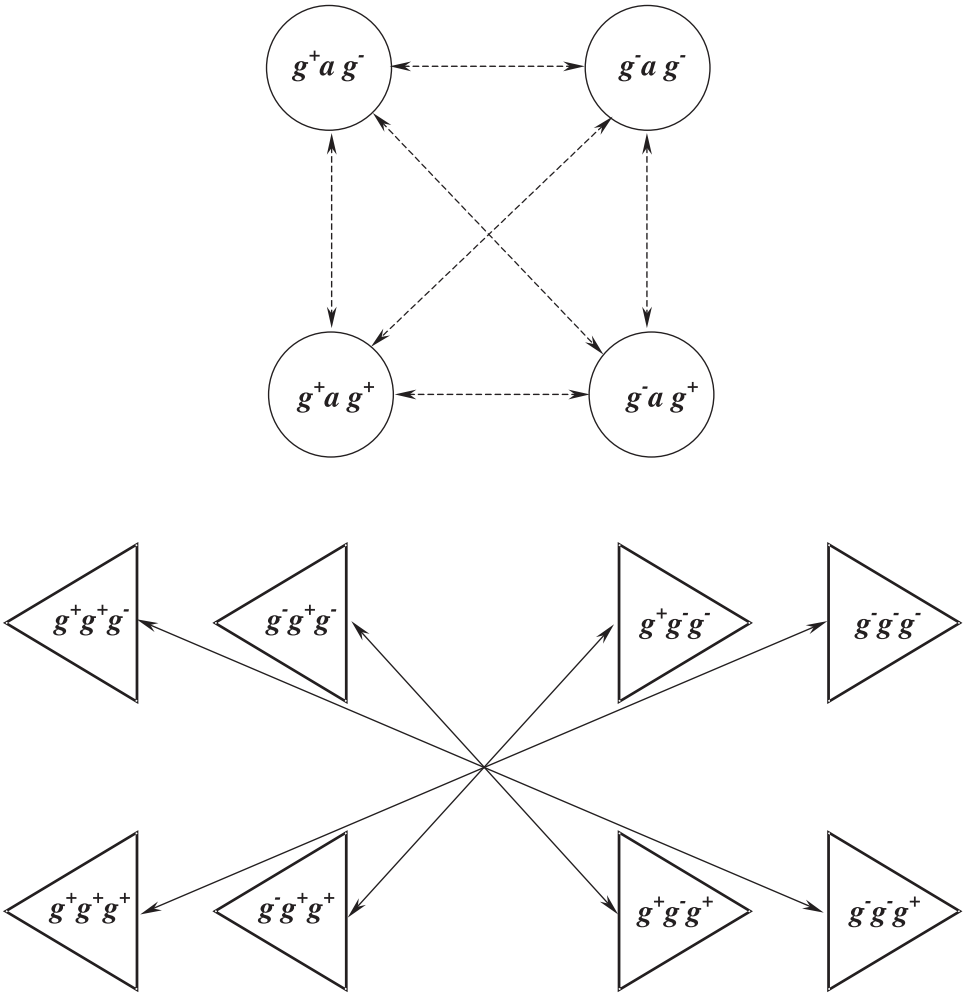
$$[2] \qquad E^{\psi_1 = a} = E(\theta, \phi)$$

$$[3] \qquad E^{\psi_1 = g^-} = E(\theta, \phi)$$

where g^+ (gauche plus) ≅ 60°, a (anti) ≅ 180°, and g^- (gauche minus) ≅ 300°.

Each of the above equations represents a 2D-PES for compounds **Ib** and **IIb**. These surfaces are shown topologically in Fig. 6.

Using RHF/3-21G calculations, 12 forms were found. However, observing the results shown in Fig. 6, it is clear from the topology of the hyper surface $E = E(\theta, \psi_1, \phi)$ that the four minima obtained in each 2D-PES (eqs. [1]–[3]) are identical. Figure 7 illustrates this situation very well for eq. [2]. It is interesting to note that the four forms with ψ_1 in g^+ (eq. [1]) are equivalents (enantiomeric forms) to those with ψ_1 in g^- (eq. [3]). Thus, compounds **Ib** and **IIb** possess only two different spatial orderings: a folded conformation ("gauche") and an extended one ("anti"), which are shown in Fig. 8. These conformations were also obtained using RHF/6-31G(d) and DFT calculations (Table 2).



Compound **IIIb** possesses six different conformations as a function of the planar (pln), perpendicular (perp), or antiperpendicular (antp) position of the benzene ring (Table 2). Compound **IVb**, in turn, possesses 11 different conformations owing to the lack of symmetry between A and B rings (Table 2).

Compounds Ic, IIc, IIIc, and IVc (n = 3)

These compounds are, in principle, a quadruple rotor and therefore its conformational change is governed by four cir-

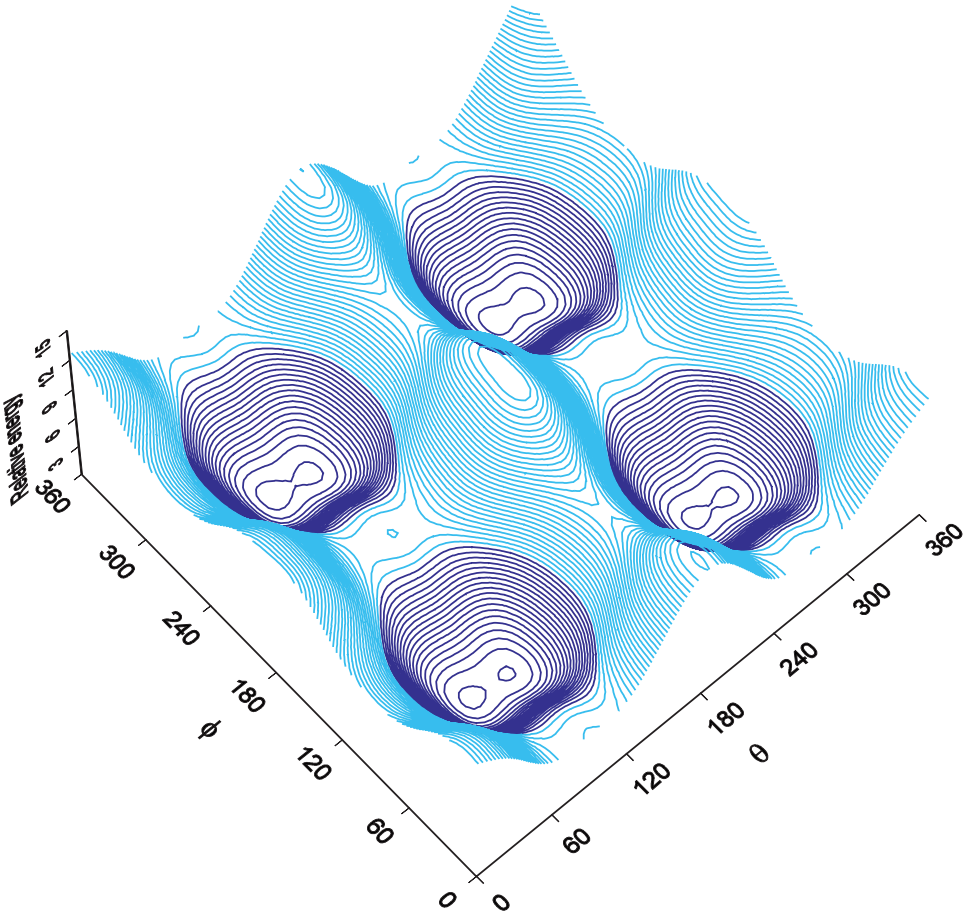

Fig. 6. Topological view for the three 2D-PESs represented in eqs. [1]–[3]. The enantiomeric conformers are shown with the same geometrical figure.

cular motions involving θ, ψ_1, ψ_2, and ϕ torsional angles. MDCA predicts the existence of 2 × 3 × 3 × 2 = 36 legitimate minima for a quadruple rotor with these multiplicities. Observing the results obtained for compounds **Ic**, **IIc**, and **IIIc** in Table 3, it is clear that the conformational intricacies of these compounds are mainly determined by two torsional angles (ψ_1 and ψ_2) instead of four dihedrals. In contrast to the idealized topology, instead of 36, only three different conformations were found for compound **Ic**. In principle, it appears to be nine conformations, however, fully relaxed computations indicate only three different conformations for this molecule. The topological features of the ψ_1 vs. ψ_2 surface is given in Fig. 9; these nine stable conformations, however, encompass only three unique conformers. The degenerate conformations (enantiomeric and identical forms) are denoted by circles and squares, in this figure. To categorize the different structures obtained for this compound, we introduced, intuitively rather than by a precise definition, three forms: fully folded (FF), partially folded (PF), and fully extended (FE). By the FF form,we mean a closed structure with relatively short distances between the aromatic rings. By the FE form, we mean a form with a linearized connecting chain. By PF, we denote a form intermediate between folded and extended (Fig. 8). The PES scanning ψ_1 vs. ψ_2 for compound **IIc** is shown in Fig. 10. In principle, it appears to be nine conformations, however, fully relaxed computations indicate only five different conformations for this molecule. The topological features of this surface is given in Fig. 9. It is interesting to note that RHF/3-21G calculations found six different conformations the last one being a conformation with the torsional angle ϕ in a planar form (g^+ *a* g^+ *a*) (Table 3). However, this conformation was not found at high levels of theory. Considering that the g^+ *a* g^+ *a* conformation only exists on the RHF/3-21G less accurate PES, it is reasonable to assume that this form is a very flat minimum on the hypersurface and at higher levels of calculation this minimum just disappears. Again, the global minimum varies as a function of the basis set or level of theory: FF (g^+ g^+ g^+ g^+) at RHF/3-21G and FE (g^+ *a* *a* g^+) at RHF/6-31G(d) and B3LYP/6-31G(d). It should be noted that the torsional angles obtained for the different conformations using different levels of theory are closely related suggesting that RHF/3-21G calculations are sufficient to use in a preliminary and exploratory form. However, RHF/6-31G(d) or DFT calculations appear to be necessary to confirm critical points and to assign conformational preferences. This is par-

Compound IIb *anti*

ticularly apparent considering that the number of conformations and the global minimum varies as a function of the basis set or level of theory.

RHF/3-21G calculations predict 13 and 20 different conformations for compounds **IIIc** and **IVc**, respectively. It is instructive to note that for these compounds several planar conformations for both aromatic rings are allowed (Table 3). This is a striking difference with respect to the above results suggesting that from now on the planar forms for the aromatic rings would be taken into account in the conformational analysis.

Compounds Id, IId, IIId, and IVd (n = 4)

These compounds are a quintuple rotor and therefore its conformational change is governed by five circular motions involving θ, ψ_1, ψ_2, ψ_3, and φ torsional angles. MDCA predicts the existence of 2 × 3 × 3 × 3 × 2 = 108 legitimate minima for a quintuple rotor with the above multiplicities. In the particular case of compounds **Id** and **IId**, the overall expression for the 5D-PEHS in which energy is the function of the five independent variables (θ, ψ_1, ψ_2, ψ_3, and φ), can be partitioned into three 2D-PES keeping θ and φ ≅90°. In contrast, this is not the case of compounds **IIId** and **IVd**, where the torsional angles θ and φ can adopt planar forms. Instead of 108, only seven different conformations were found for compound **Id**, one of them possessing the torsional angle θ at about 180° (Table 4).

Figure 8 gives the spatial view for the seven different conformations obtained for compound **Id**. The following types of structures were found:

(1) Fully extended (FE) structures with three torsional angles (ψ_1–ψ_3) in anti (≅ ± 180°).
(2) Open extended (OE) structures with one torsional angle in gauche (≅ ± 60°) and two in anti.
(3) Open folded (OF) structures with two torsional angles in gauche and one in anti.
(4) Fully folded (FF) structures with the three torsional angles in gauche.

Figure 11 gives the topological features obtained for the respective PESs (eqs. [4]–[6]) of compound **IId**.

[4] $E^{\psi_2 = g^+} = E(\psi_1, \psi_3)$

[5] $E^{\psi_2 = a} = E(\psi_1, \psi_3)$

[6] $E^{\psi_2 = g^-} = E(\psi_1, \psi_3)$

The 25 stable conformations encompass only 13 unique conformers. The energetically degenerated conformations (identical and enantiomeric forms) are denoted by double arrows and with the same notation. Figure 12 shows the PES ob-

Compound Ic

Compound IIc

tained for eq. [5] using RHF/3-21G calculations; the symmetry of this surface might be appreciated in this figure.

In addition to the 13 conformations with torsional angles θ and ϕ in perpendicular or antiperpendicular form, another conformation with ϕ = 164.6° (quasi-planar) was found (Table 4).

The 14 different conformations attained for compound **IId** from RHF/3-21G computations were also obtained using RHF/6-31G(d) and DFT calculations. Whereas for RHF/3-21G calculations, the global minimum is the $g^+\ g^+\ g^+\ a\ g^-$ conformation, for RHF/6-31G(d) and DFT calculations, the preferred form is the $g^+\ a\ a\ a\ g^+$ (Table 4).

Compound **IIId** possess 32 different conformations from RHF/3-21G calculations. Obviously, the conformational behaviour of compound **IVd** is even more complex considering the lack of symmetry of ring B. Thus, 59 different conformations were obtained for this compound from RHF/3-21G calculations.

Compounds Ie and IIe (n = 5)

These compounds are a sextuple rotor and therefore its conformational change is governed by six circular motions involving θ, ψ_1, ψ_2, ψ_3, ψ_4, and ϕ torsional angles. MDCA predicts the existence of $2 \times 3 \times 3 \times 3 \times 3 \times 2 = 324$ minima for a sextuple rotor with these multiplicities. RHF/3-21G calculations found 14 and 37 different conformations for compounds **Ie** and **IIe**, respectively (Table 5).

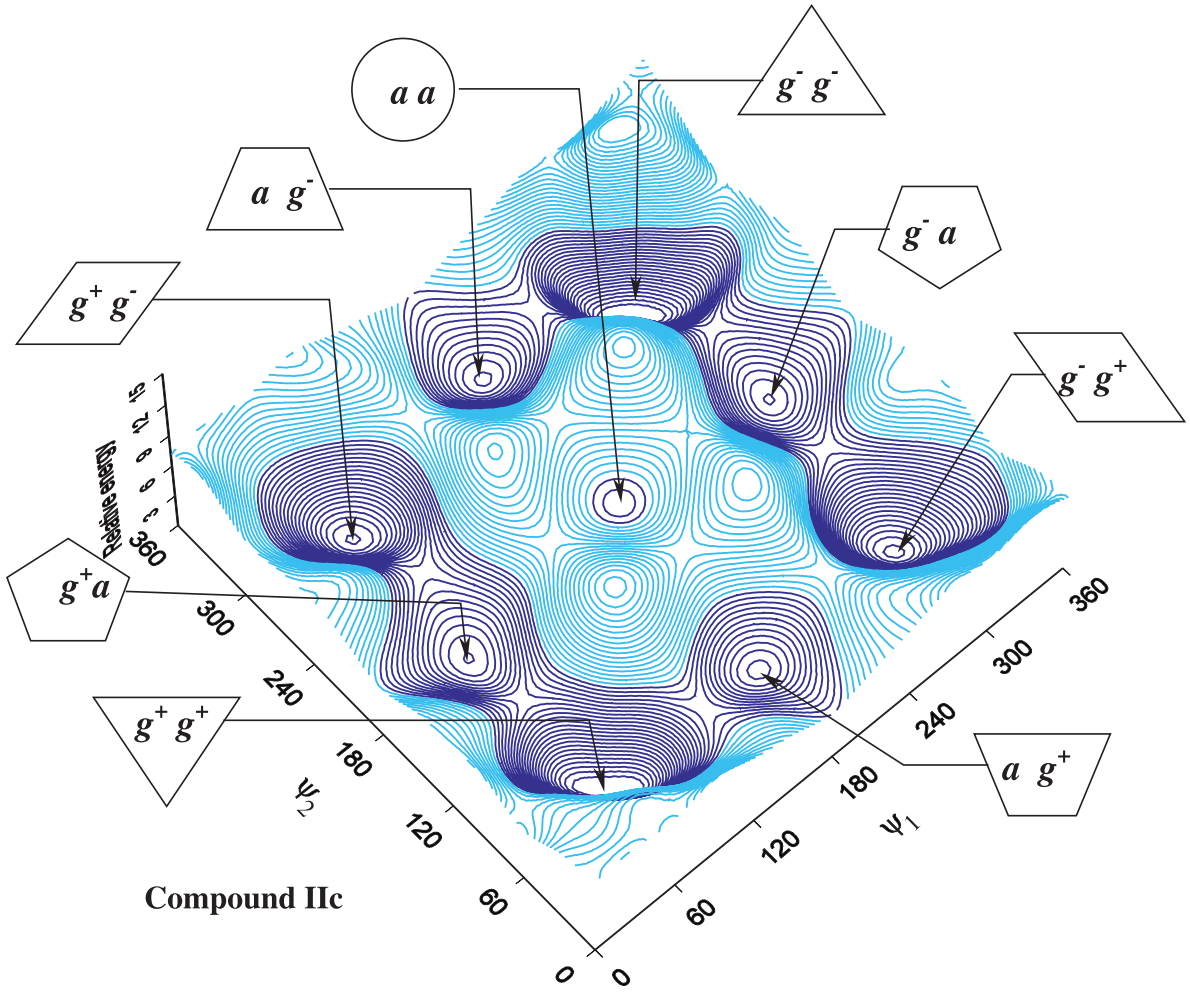
Since the PEHS of large and flexible homologues is highly multidimensional, it is not an easy task to explore all possibilities from ab initio calculations. Thus, we cannot be absolutely sure that the conformations reported here are the only possible structures for these compounds. This is particularly apparent considering that the criterion chosen to obtain the starting geometries was that postulated by MDCA. It is instructive to note that MDCA is not a fool-proof strategy (18). However, to ameliorate such situations we have performed additional calculations considering, for example, different planar forms for the aromatic ring systems. Thus, we have carried out sufficient calculations to feel confident that the results reported here possess an adequate degree of accuracy.

At this stage of our work, some observations can be made with respect to the conformational intricacies of compounds reported here. Table 5 shows the conformations predicted by MDCA and also those obtained from RHF/3-21G calculations (denoted in italics). Figure 13 gives a graphic representation of the values shown in Table 5. This figure shows the increasing complexity of conformational space as a function of the lengthening of the saturated carbon connecting chain for the different series reported here.

What about the large-size homologues?

Our results indicate that conformationally restricted retrograde or quasi-retrograde molecules (n = 1) have only one structure; small-size compounds have an enumerable number of conformers. However, nobody can make even an "educated guess" how many conformers might be associated with a medium- or large-size flexible twin drug ($n = 5 - n$) taking into account redundancy owing to symmetry. We have not performed ab initio calculations for large-size homologues, therefore it is not yet possible to do more than speculate.

Let us first consider the case of MDCA. This approach predicts the possible total number of different conformations (f) using a general equation that might be expressed as:



$$[7] \qquad N_T = 2^2 \times 3^{(n-1)}$$

where $N_T = f$ (total number of different conformations) and numbers 2 and 3 are due to the sp^2 and sp^3 torsional modes, respectively (see Fig. 3).

In the case of series **I–IV**, we may assume that the total number of different conformers ($f(n)$) of these compounds

Fig. 10. PES obtained for compound **IIc** varying ψ_1 vs. ψ_2. Computations were performed using RHF/3-21G calculations. Enantiomeric forms are denoted with the same geometrical figure.

follows a similar behaviour to that given in eq. [7]. Thus, we can obtain a general equation as follows:

$$[8] \qquad f_{\mathrm{MDCA}} = \alpha 3^{\beta(n-1)}$$

However, in this case, both constants α and β loose the significance given by MDCA and therefore, they only play a mathematical role, adjusting in a convenient way the corresponding function with the calculated $f(n)$ values in each series. Thus, it would be possible to compare the respective equations of each series with eq. [8].

The potential number of different conformations $f(n)$ for the different series may be adjusted using a linear-regression equation such that:

$$[9] \qquad \log_{10} f(n) = (\log_{10} \alpha - \beta \log_{10} 3) + (\beta \log_{10} 3)n$$

Equation [9] may be summarized in the following form:

$$[10] \qquad \log_{10} f(n) = A + B \times n$$

It is necessary to adjust A and B to obtain the corresponding α and β constants. These results are shown in Table 6 where in the last column the correlation coefficients (r) are also given.

The small value obtained for β in the series **I** is a direct consequence of the slight increase of $f(n)$ in **I** with respect to the other series reported here.

On the basis of results shown in Table 6, it is possible now to predict the possible total number of different conformations ($f(n)$) for any homologue of each series. Thus, Table 5 gives the number of $f(n)$ obtained from RHF/3-21G calculations (grey zone), and the predicted number of $f(n)$ (white zone) for the four series.

Figure 13 gives a graphic representation of the values shown in Table 5. The increasing complexity of the conformational space as a function of the lengthening of the saturated carbon connecting chain from $n = 1$ to $n = 10$ might be appreciated in this figure. It is clear, however, that the symmetry reduces notably the conformational possibilities in series **I** and **II**; this is particularly apparent in the case of identical twin compounds (series **I**).

Table 7 gives the percentage relative differences obtained for the calculated values of $f(n)$. These values were obtained from eq. [11]

$$[11] \qquad \Delta\% = [|f_{\mathrm{eq.[8]}}(n) - f(n)| \,/\, f(n)]100$$

where $f_{\mathrm{eq.[8]}}(n)$ is obtained from eq. [8] and $f(n)$ is obtained from the RHF/3-21G calculations.

Note: For compound **IId**, RHF/6-31G(d) and B3LYP/6-31G(d) computations are also included.

It is interesting to note that $f(n)$ functions displayed bigger differences for $n = 1$ and 2 with respect to $n = 3$–5. It appears that there is more difficult to simulate the conformational intricacies of torsional angles θ and ϕ than those of the connecting flexible chain. On the other hand, it is clear that more ab initio calculations performed on medium- and large-size homologues will help us to obtain more accurate predictive equations.

There exists the possibility that eq. [8] itself is perhaps inappropriate for obtaining the total number of different conformations in the series reported here. If, however, this equation is correct in postulating the above conformations,

$f_{II}(n)$	*1*	*2*	*6*	*14*	*37*	90	225	562	1 405	3 514	3.37×10^{7}	2.96×10^{19}
$f_{III}(n)$	*2*	*6*	*13*	*32*	81	201	497	1230	3 047	7 549	6.56×10^{7}	4.32×10^{19}
$f_{IV}(n)$	*3*	*11*	*20*	*59*	152	395	1026	2661	6 904	17 914	2.47×10^{8}	6.55×10^{20}

Note: RHF/3-21G calculations were performed in the zone denoted in italics; the rest of the values were obtained from eq. [8]. MDCA values are shown in bold.

we can obtain the possible number of different conformations of any large homologue in each series. For example, eq. [8] predicts about 99 698 different conformations for $\mathbf{I}_{n=20}$ and the amazing number of 7.60×10^{12} different conformations for homologue $\mathbf{I}_{n=50}$.

It is clear that eq. [8] is highly speculative, therefore further calculations to confirm its validity are necessary. However, accepting the validity of this equation, we may form at least a superficial idea about the conformational possibilities of large-size homologues possessing symmetrical or non-symmetrical aromatic rings.

Conclusions

The presence of two symmetrical rings (identical or not) reduces notably the conformational possibilities of flexible

Note: The last column shows the respective correlation coeficient (*r*).

homologues. Thus, the conformational behaviour of compounds, which in principle appears to be a very complex problem, could be evaluated using relatively high levels of theory.

The three levels of theory reported here (RHF/3-21G, RHF/6-31G(d)), and B3LYP/6-31G(d)) displayed closely related results indicating that RHF/3-21G calculations are sufficient to use in a preliminary form. However, caution is needed when using RHF level of theory with a modest basis set for a final and complete conformational analysis involving flexible homologues. From our results, it is prudent to use this technique only for a preliminary or exploratory conformational analysis. At least, the HF level of theory in conjunction with more extended basis sets and the inclusion of electron correlation appear to be necessary to confirm critical points at the PEHSs and to assign the conformational preferences of these compounds.

Chemists working in the field of twin drugs, in particular with flexible homologue series, must have been frequently exposed to the problem of multiconformation the most. How many conformers are expected for flexible homologues considering the redundancy owing to symmetry?

For compounds with a small-size connecting chain (*n* = 1–5), our results give a complete and comprehensive picture

Échelles pK_{HB} et enthalpique du pouvoir accepteur de liaison hydrogène de thioéthers, thiols et disulfures

Christian Laurence, Michel Berthelot, Karine Evain et Bertrand Illien

Résumé : Le pouvoir accepteur de liaison hydrogène (liaison H) de 31 bases soufrées tétraédriques (thioéthers, thiols, disulfures) a été mesuré par spectrométrie infrarouge à partir (*i*) de leurs constantes de complexation 1 : 1 avec le 4-fluorophénol dans CCl_4 à 25 °C (échelle pK_{HB}), (*ii*) de l'enthalpie de liaison H, et (*iii*) du déplacement de fréquence $\Delta\nu$(OH) du 4-fluorophénol par liaison H. La comparaison des échelles pK_{HB}, $\Delta H°$ et $\Delta\nu$(OH) met en évidence certaines particularités de chaque échelle. Le pouvoir accepteur de liaison H dépend (*i*) de la nature de l'atome accepteur (O > S, en accord avec le principe des acides et des bases durs et mous), (*ii*) de sa fonctionnalité (pour les bases soufrées : sulfure de phosphine > thioamide > thiocétone > thioéther > thiol > isothiocyanate ~ disulfure) et (*iii*) des effets de substituant sur la fonction. Les principaux effets de substituant sont (*i*) l'effet de polarisabilité des substituants alkyles, (*ii*) l'effet inductif, (*iii*) l'effet de résonance, et (*iv*) l'effet de cyclisation, qui fait varier le pourcentage de caractère *s* des paires libres du soufre. Les spectres infrarouges montrent que le 4-fluorophénol, outre sa fixation sur le soufre, établit également une liaison H avec l'atome de chlore de $MeSCH_2Cl$ et $MeSCH_2CH_2Cl$ et avec le nuage π de PhSMe, Ph_2S, $PhCH_2SMe$ et $EtSCH{=}CH_2$.

Mots clés : liaison hydrogène, thioéthers, thiols, disulfures, échelle pK_{HB}.

Abstract: The hydrogen bond acceptor (HBA) strength of 31 tetrahedral sulfur bases (thioethers, thiols, disulfides) has been measured by IR spectrometry from: (*i*) their 1:1 complexation constants with 4-fluorophenol in CCl_4 at 25 °C (the pK_{HB} scale); (*ii*) their HB enthalpies; and (*iii*) the frequency shifts, $\Delta\nu$(OH), of the ν(OH) band of 4-fluorophenol hydrogen bonded to sulfur. The comparison of the pK_{HB}, $\Delta H°$, and $\Delta\nu$(OH) scales points to their distinctive features. The HBA strength depends on: (*i*) the nature of the atomic site: oxygen bases are always stronger than sulfur bases, in agreement with the hard and soft acids and bases principle; (*ii*) the functionality of this atom (for sulfur bases: phosphine sulfur > thioamide > thioketone > thioether > thiol > isothiocyanate ~ disulfide); and (*iii*) the substituent effects on the function. The main substituent effects are: (*i*) the polarizability effect of alkyl groups; (*ii*) the field-inductive effect; (*iii*) the resonance effect; and (*iv*) the cyclization effect, which changes the percentage of the *s* character of sulfur lone pairs. In addition to the attachment to the sulfur atom, IR spectra show the attachment of 4-fluorophenol to the chlorine of $MeSCH_2Cl$ and $MeSCH_2CH_2Cl$, and the interaction to the π cloud of PhSMe, Ph_2S, $PhCH_2SMe$, and $EtSCH{=}CH_2$.

Key words: hydrogen bond, thioethers, thiols, disulfides, pK_{HB} scale.

Introduction

Nous construisons actuellement (1) une échelle thermodynamique du pouvoir accepteur de liaison hydrogène (liaison H) des molécules organiques. Reprenant l'idée initiale de Gurka et Taft (2), cette échelle, notée pK_{HB}, repose sur la constante de formation de liaison H entre des bases organiques B et un donneur de liaison H de référence, le 4-fluorophénol, dans des conditions standard de solvant (CCl_4), de température (298 K) et de stœchiométrie (1 : 1) (équations [1]–[3]). Le choix de ces conditions permet de mesurer la constante d'équilibre K_c

$$[1] \qquad B + 4\text{-}FC_6H_4OH \rightleftarrows 4\text{-}FC_6H_4OH\cdots B$$

$$[2] \qquad K_c = \frac{[4\text{-}FC_6H_4OH\cdots B]}{[B][4\text{-}FC_6H_4OH]} \text{ en } M^{-1}$$

$$[3] \qquad pK_{HB} = \log_{10} K_c$$

avec précision dans une large gamme s'étendant d'environ pK_{HB} = –1 pour les bases très faibles à pK_{HB} = +4 pour les bases fortes. Il suffit de déterminer la concentration de 4-fluorophénol non lié à l'équilibre, par exemple par spectrométrie infrarouge (IR) à l'aide de la bande ν(OH) à 3614 cm^{-1} (3). L'échelle pK_{HB} permet une comparaison

quantitative des énergies de Gibbs (ΔG° = –5,7 pK_{HB}, ΔG° en kJ mol^{-1}) de formation de liaison H, interaction moléculaire omniprésente en chimie (4) et en biologie (5).

Nous avons déjà mesuré pK_{HB} pour un grand nombre de bases carbonées, halogénées, oxygénées, azotées et soufrées (1). Dans cette dernière famille, nous avons étudié une série de molécules à soufre trigonal : thioamides et thiourées (6), isothiocyanate de méthyle (7) et thiocamphre (7). Le présent travail concerne la mesure par spectrométrie infrarouge à transformée de Fourier (IRTF) de l'échelle pK_{HB} de bases soufrées tétraédriques : 27 thioéthers, deux disulfures et deux thiols.

De manière à déterminer les principaux effets structuraux modifiant le pouvoir accepteur de liaison H des bases soufrées tétraédriques, nous avons sélectionné 11 thioéthers avec des groupes alkyles de longueur et de ramification différentes, huit thioéthers cycliques, cinq thioéthers substitués par différents groupes inductifs électroattracteurs et trois thioéthers où les paires libres du soufre peuvent se conjuguer avec un système π. Nous obtenons ainsi une échelle qui s'étend sur 1,3 unité de pK_{HB}, soit environ 7,6 kJ mol^{-1}, du sulfure de diphényle (pK_{HB} = –0,93) au sulfure de di-*tert*-butyle (pK_{HB} = +0,40).

La mesure de la constante d'équilibre à différentes températures permet de déterminer l'enthalpie et l'entropie de complexation du 4-fluorophénol par ces bases soufrées, en vue d'étudier l'existence de la relation de compensation enthalpie–entropie (8).

La spectrométrie IRTF permet la mesure des déplacements par liaison H, Δν(OH), de la fréquence d'élongation OH du 4-fluorophénol. Ces déplacements constituent une échelle spectroscopique du pouvoir accepteur de liaison H. Ils permettent de tester l'existence de la relation controversée de Badger–Bauer (9, 10) entre enthalpies de complexation et déplacements de fréquence OH. De plus la spectrométrie IRTF est une méthode de choix pour révéler d'autres sites accepteurs de liaison H que l'atome de soufre. Par exemple, elle met en évidence deux complexes pour la molécule $MeSCH_2Cl$, l'un sur l'atome de soufre, l'autre sur l'atome de chlore, et permet de séparer les contributions respectives de ces deux sites à la constante de complexation globale.

Partie expérimentale

Produits

Toutes les bases soufrées, le solvant CCl_4, et le donneur de liaison H 4-fluorophénol sont des composés commerciaux soigneusement purifiés et desséchés. Ils sont manipulés en boîte sèche pour préparer les solutions et remplir la cellule IR.

Spectres IR

Ils sont enregistrés sur un spectromètre Bruker Vector 22 avec une résolution de 1 cm^{-1}. La cellule en quartz possède un trajet optique de 1 cm pour permettre l'étude de solutions très diluées de 4-fluorophénol (4 mmol L^{-1}) et donc éviter l'autoassociation de ce dernier. À cette concentration il n'y a effectivement aucune bande ν(OH···O) à 3480 cm^{-1} correspondant au dimère du 4-fluorophénol (11). La cellule est thermorégulée à 25,0 ± 0,2 °C, pour la mesure de pK_{HB} et Δν(OH). Sa température est variée de –5 à +60 °C, pour les déterminations d'enthalpie, à l'aide d'un système thermoélectrique.

Constantes K_c, enthalpies ΔH°, entropies ΔS° et déplacements $\Delta\nu$(OH)

Les méthodes de détermination ont déjà été publiées (12, 13). Un choix rigoureux des concentrations initiales en 4-fluorophénol et base soufrée, dans CCl_4, permet de former essentiellement des complexes de liaison H de stœchiométrie 1 : 1 (c.-à-d. l'équilibre [1] prédomine très largement). Par exemple, un excès de base soufrée permet de rendre minimale la présence de complexes 1 : 2 (1 base : 2 phénols) pour les composés à plusieurs sites accepteurs de liaison H.

Résultats

Nous rapportons les valeurs pK_{HB}, $\Delta G^\circ_{x,298}$, ΔH°_{298}, $\Delta S^\circ_{x,298}$ et Δν(OH) pour la liaison H du 4-fluorophénol avec 31 bases soufrées dans le tableau 1. Les constantes K_c relatives aux concentrations molaires sont transformées en K_x relatives aux fractions molaires (14), et les grandeurs thermodynamiques sont calculées par les équations [4]–[6]. Le déplacement Δν(OH) en passant du 4-fluorophénol libre au 4-fluorophénol lié au soufre est donné par l'équation [7].

$$[4] \qquad \Delta G^0_x = -RT \ln K_x$$

$$[5] \qquad \Delta H^0 = RT^2 \, [d(\ln K_x)/dT]$$

$$[6] \qquad \Delta S^0_x = (\Delta H^0 - \Delta G^0_x)/T$$

$$[7] \qquad \Delta\nu(OH) = \nu(OH \text{ libre}) - \nu(OH\cdots S) = 3614 - \nu(OH\cdots S)$$

Pour six thioéthers possédant un site potentiel accepteur de liaison H supplémentaire (site π ou Cl), nous observons sur le spectre IR, entre la bande fine ν(OH) du 4-fluorophénol libre à 3614 cm^{-1} (fig. 1, bande 1) et la bande large ν(OH···S) (fig. 1, bande 3) correspondant au complexe sur le soufre, une bande supplémentaire (fig. 1, bande 2). Nous attribuons cette bande supplémentaire à un deuxième complexe de liaison H se formant soit sur un atome de chlore (composés **19** et **20**), soit sur un nuage π aromatique (**17**, **21** et **22**) ou éthylénique (**23**). En effet ces bandes supplémentaires sont bien aux positions attendues pour une liaison H sur un atome de chlore (15) ou sur un site π aromatique (16) ou éthylénique (16).

Puisque nous avons contrarié la formation de complexes 2:1 par un excès de base soufrée, nous avons essentiellement en solution deux complexes 1 : 1, un complexe OH···S sur l'atome de soufre et un complexe OH···X (π ou Cl) sur le site supplémentaire. Dans ce cas la constante de complexation mesurée à partir de l'absorbance de la bande ν(OH) du 4-fluorophénol libre correspond à la formation de ces deux complexes, et il est facile de montrer (18) qu'elle est la somme de deux constantes, K_c(S) et K_c(X), ou 2K_c(X) pour Ph_2S. La constante propre à l'atome de soufre peut donc être calculée à partir de l'équation [8], s'il

$$[8] \qquad K_c(\text{totale}) = K_c(S) + xK_c(X) \; (x = 1 \text{ ou } 2)$$

[a]Valeur par atome de soufre (supposés équivalents) après correction statistique de log 2 (pK_{HB}), RT ln 2(ΔG) et $-R$ ln 2(ΔS).
[b]Valeur indicative à cause du deuxième site.
[c]Après soustraction de la contribution du site π (voir tableau 2).
[d]Après soustraction de la contribution du chlore (voir tableau 2).
[e]Un épaulement, observé à $\Delta\nu$ = 186 cm^{-1}, pourrait être attribué à une stéréochimie de complexation (voir réf. 17 pour les éthers).

est possible d'évaluer K_c(X). Nous l'avons fait à partir des déplacements de fréquence IR $\Delta\nu$(OH), en utilisant les corrélations entre pK_{HB} et $\Delta\nu$(OH) établies dans des travaux précédents pour les familles des chloroalcanes (15) et des bases π aromatiques (16) et éthyléniques (16). Le détail des calculs est donné dans le tableau 2.

Nous n'avons trouvé dans la littérature que des travaux partiels et hétérogènes (se rapportant à des donneurs de liaison H et des solvants différents) sur les paramètres thermodynamiques de liaison H des bases soufrées tétraédriques (19–26). Ils ne permettent pas de construire une échelle homogène du pouvoir accepteur de liaison H des bases soufrées.

Avec le 4-fluorophénol dans CCl_4, nous n'avons trouvé que la valeur pK_{HB} = 0,11 pour Et_2S (2) qui diffère sensiblement de notre valeur 0,25. Nous pensons que la valeur 0,11 déterminée par RMN du ^{19}F est moins précise que notre valeur IR, car la méthode RMN se rapporte à deux inconnues (K_c et résonance ^{19}F du complexe) au lieu d'une en IR (K_c).

Par contre Arnett et al. (27) ont déterminé par calorimétrie les enthalpies de complexation du 4-fluorophénol avec six thioéthers (tableau 3), par la méthode (approchée) de la base pure. Pour trois thioéthers, les écarts relatifs entre les valeurs calorimétriques et les valeurs IR (van't Hoff) ne dépassent pas 8 %. Trois autres thioéthers ont un autre site accepteur de liaison H, et la calorimétrie montre ici ses limites, puisqu'elle ne peut mettre en évidence l'existence de deux complexes 1 : 1 (S et π ou S et Cl) à la différence de l'IR.

Nous considérons donc que ce travail constitue quasiment la première étude thermodynamique cohérente sur le pouvoir accepteur de liaison H des thioéthers, thiols et disulfures. Les données sont nombreuses et structuralement diversifiées. De plus, elles nous semblent fiables dans la mesure où la précision photométrique de l'IRTF et la méthode de détermination des enthalpies et des entropies (13) doivent garantir des résultats reproductibles et probablement précis. La reproductibilité est de l'ordre de ±0,03 sur pK_{HB}, de ±0,5 kJ mol^{-1} sur ΔH°, et de ±1,5 J K^{-1} mol^{-1} sur ΔS°.

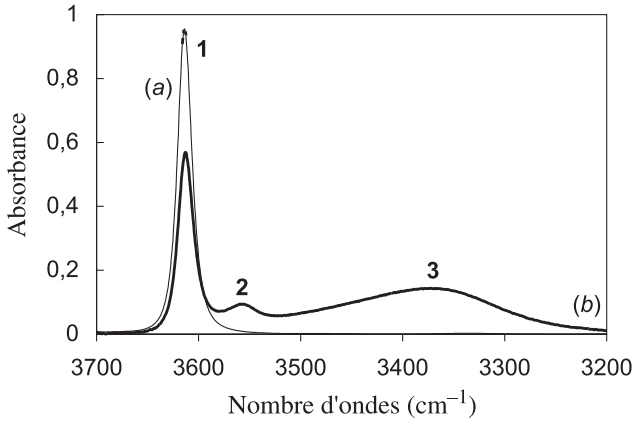
Tableau 2. Évaluation de la constante de complexation (M^{-1}) sur le soufre, K_c(S), dans le cas des thioéthers possédant un autre site X accepteur de liaison H.

N°	Base	X	K_c (totale)[a]	Δν(OH)[b]	K_c(X)[c]	K_c(S)[d]	pK_{HB}(S)
17	$MeSCH_2Ph$	π	1,33	55	0,38	0,95	–0,02
19	$MeSCH_2CH_2Cl$	Cl	1,07	52	0,30	0,77	–0,12
20	$MeSCH_2Cl$	Cl	0,69	46	0,26	0,43	–0,37
21	PhSMe	π	0,81	50	0,33	0,48	–0,32
22	PhSPh	2π	0,74	47	0,62	0,12	–0,93
23	$EtSCH=CH_2$	π	0,88	61	0,15	0,73	–0,13

[a]Valeur mesurée.
[b]Déplacement (cm^{-1}) de fréquence de la bande OH du 4-fluorophénol lié sur le site X.
[c]Calculée à partir des relations pK_{HB} = 1,04 [Δν(OH)/100] – 1,06 pour les bases chlorées, pK_{HB} = 1,09 [Δν(OH)/100] – 1,02 pour les bases π aromatiques et pK_{HB} = 1,26 [Δν(OH)/100] – 1,60 pour les bases π éthyléniques.
[d]$K_c(S) = K_c(\text{totale}) - xK_c(X)$.

Discussion

Position des bases soufrées sur les échelles pK_{HB} et enthalpique du pouvoir accepteur de liaison H



Pour les bases soufrées tétraédriques nous observons :

Fonction	Disulfure	<	Thiol	<	Thioéther
Composé	Me_2S_2		EtSH		Me_2S
$-\Delta H°$ (kJ mol^{-1})	8,8		10,4		12,8

Ces valeurs sont intéressantes pour comparer les enthalpies de liaison H de donneurs OH aux résidus cystine, cystéine, et méthionine dans la reconnaissance moléculaire de ligands par des récepteurs biologiques. Elles sont par ailleurs en accord avec un travail (28) soulignant que, dans l'organisation des cristaux organiques, les contacts intermoléculaires par liaison H à un soufre tétraédrique, quoique peu fréquents, ne peuvent être négligés.

Pour l'ensemble des bases soufrées, à part la fonction isothiocyanate le soufre tétraédrique est moins accepteur que le soufre trigonal :

Fig. 1. Spectres IR dans la région ν(OH) (*a*, traits fins) d'une solution 4 mmol L^{-1} de 4-fluorophénol dans CCl_4 (*b*, traits gras) de la même solution après ajout de 0,49 mol L^{-1} de $PhCH_2SMe$, montrant (1) la bande ν(OH) du 4-fluorophénol libre à 3614 cm^{-1}, (2) la bande ν(OH···π) d'un premier complexe 1 : 1 à 3559 cm^{-1}, et (3) la bande ν(OH···S) très large d'un deuxième complexe 1 : 1 à 3376 cm^{-1}.

Fonction	Isothiocyanate	<	Thioéther	<	Thiocétone	<	Thioamide	<	Sulfure de phosphine
Composé	MeN=C=S		Me_2S		Thiocamphre		$HCSNMe_2$[2]		$(n\text{-Oct})_3PS$[2]
$-\Delta H°$ (kJ mol^{-1})	9,0		12,8		14,7		19,1		20,7

Ces résultats sont en accord avec les calculs MP2/6-311++G(d,p) de Platts et al. (29) sur le pouvoir accepteur de liaison hydrogène de H_2S et $H_2C=S$.

Comme le montre le tableau 4, quelle que soit la fonctionalité du chalcogène, les bases soufrées sont toujours de moins bons accepteurs de liaison H que les bases oxygénées correspondantes. Ceci vérifie banalement le principe HSAB des acides et des bases durs et mous (30), puisque les donneurs de liaison H sont des acides durs dans la classification de Pearson (30) et que l'oxygène est plus dur (η(H_2O) = 7,0 eV) que le soufre (η(H_2S) = 5,3 eV) (31). D'une manière plus intéressante, les données du tableau 4 permettent de quantifier le principe HSAB : pour les complexes de liaison H considérés, la perte d'énergie de Gibbs en passant d'une base dure oxygénée à une base molle soufrée varie de 2,0 kJ mol^{-1} (0,35 pK_{HB}) pour le couple *t*-Bu_2S–*t*-Bu_2O à 12,5 kJ mol^{-1} (2,2 pK_{HB}) pour le couple Et_3PS–Et_3PO.

Relation de Badger–Bauer entre Δ*H* et Δν(OH)

Badger et Bauer (9, 10) ont proposé que le déplacement Δν(OH) pouvait permettre d'estimer l'enthalpie de la liaison H. Cette proposition a été très controversée (3, 27, 34–40). Nous observons sur la figure 2 une bonne relation pour beaucoup de bases soufrées tétraédriques; le 1,3-dithiane **30** et le 1,3-dithiolane **28** dévient de cette relation, probablement à cause de la non-équivalence de leurs deux atomes de soufre, et donc de l'inadaptation de l'équation de van't Hoff pour décrire la variation avec la température d'une constante d'équilibre qui est la somme de deux constantes différentes (vide supra). De même les thiols **3** et **4** et le disulfure **1**

[a]Ce travail.

n'obéissent pas à la relation des thioéthers. En excluant ces cinq composés, nous observons l'équation [9] de coefficient de correlation r = 0,941 et d'écart type s = 0,65 kJ mol^{-1} pour

[9] $-\Delta H° = 8{,}04\ (\Delta\nu(OH)/100) - 7{,}08$

n = 18 thioéthers. La relation de Badger–Bauer peut donc rendre des services, puisque l'écart type de l'estimation est de l'ordre de grandeur des erreurs expérimentales. Cependant il faut prendre garde à son caractère très dépendant de la famille (thiols, thioéthers et disulfures forment ici des familles différentes).

Fig. 2. Relation entre l'enthalpie de liaison H, $-\Delta H°$, et le déplacement Δν(OH) pour les complexes du 4-fluorophénol avec des bases soufrées. Le disulfure **1** et les thiols **3** et **4** n'appartiennent pas à la famille des thioéthers. Dans celle-ci, le 1,3-dithiane **30** et le 1,3-dithiolane **28** dévient (voir texte).

Relation de compensation entre l'enthalpie et l'entropie

Il existe un dilemme dans la construction des échelles de basicité. Doit-on les définir à partir d'énergies de Gibbs, comme l'échelle pK_{BH}^{+}, ou d'enthalpies, comme l'échelle du nombre donneur de Gutmann (41) ? Cette question ne se pose pas s'il existe une relation extrathermodynamique, appelée relation de compensation, entre l'enthalpie et l'entropie (équation [10] dans laquelle δ est un opérateur de variation de structure) dans la série de réactions considérées, car alors ΔH et ΔG sont reliés par l'équation [11]. Cette dernière

[10] $\delta\Delta H = \beta\delta\Delta S$

[11] $\delta\Delta G = [1 - (T/\beta)]\delta\Delta H$

équation est appelée relation d'isoéquilibre, car lorsque T = β, $\delta\Delta G$ = 0.

Le système de coordonnées ΔH, ΔS est à éviter pour étudier l'existence de la relation de compensation, car une relation entre ces deux grandeurs peut ne traduire que leurs erreurs liées quand elles ont été déterminées par la loi de van't Hoff. Exner a montré (8) que le système de coordonnées ln K, T^{-1}, c'est-à-dire l'équation [12], était mathématiquement équivalent au système ΔH, ΔS, c'est-à-dire à l'équation [10], mais qu'il était cette fois

© 2005 CNRC Canada

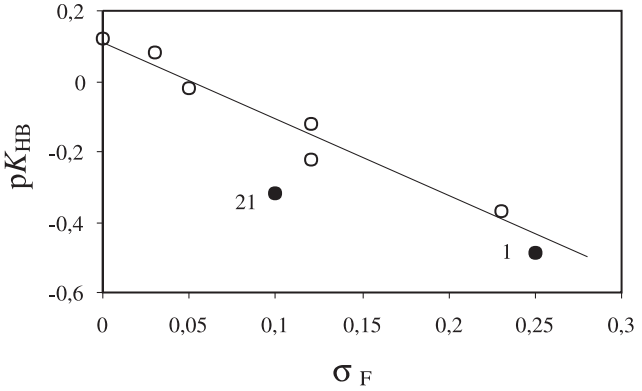
[12] $\ln K_{ij} = (\Delta H_i^\circ / R)(\beta^{-1} - T_{ij}^{-1}) + y_0$

statistiquement correct, puisque ln K et T^{-1} sont des coordonnées a priori indépendantes. L'équation [12], dans laquelle i et j se rapportent respectivement au thioéther et à la température, correspond à celle d'un faisceau de droites de van't Hoff se coupant en un point commun de coordonnées β^{-1} et y_0. Le problème se réduit donc à la démonstration de l'existence d'un point commun à plusieurs droites de régression (ici droites de van't Hoff). Ouvrard et al. (42) ont développé un programme permettant de répondre à cette question.

Nous avons appliqué ce programme aux thiols, thioéthers et disulfures de notre étude (sauf aux thioéthers possédant un site π ou Cl secondaire ou deux atomes de soufre suspectés d'être non équivalents). Avec cet échantillonnage le test F de Fischer au niveau 95 % rejette l'existence d'un point d'intersection unique. Nous avons essayé d'autres échantillonnages et trouvons qu'il faut enlever les quatre thioéthers Et_2S, n-Bu_2S, i-Pr_2S et t-Bu_2S pour que l'existence de la relation d'isoéquilibre [11] soit statistiquement démontrée. La température d'isoéquilibre β est alors égale à 778 K, et son intervalle d'erreur est 685 à 931 K.

Les statistiques indiquent donc que dans la famille des bases soufrées tétraédriques, la relation d'isoéquilibre est obéie par (*i*) les thiols, (*ii*) les thioéthers cycliques et (*iii*) les thioéthers aliphatiques, dont un des substituants alkyles est moins volumineux que le groupe éthyle (ce qui inclut MeSEt et même *t*-BuMeS, mais exclut EtSEt). Une explication moléculaire, qui pourrait être basée sur l'effet stérique, reste à trouver pour ces observations statistiques sur l'entropie de liaison H.

Effet des substituants alkyles sur le pouvoir accepteur de liaison H



Les substituants alkyles peuvent *augmenter* le pouvoir accepteur de liaison H du soufre par leur effet de polarisabilité ou le *diminuer* par leur effet stérique. Ces deux effets sont corrélés significativement pour les substituants alkyles, car l'augmentation du nombre d'atomes (de carbone et d'hydrogène) augmente à la fois le nombre d'électrons (la polarisabilité) et la taille (l'effet stérique). Pour l'échantillon de substituants alkyles considéré (Me, Et, *n*-Pr, *n*-Bu, *n*-Oct, *c*-Hex, *i*-Pr, *t*-Bu) et l'hydrogène, c.-à-d. pour neuf points, il existe un coefficient de corrélation significatif (0,935) entre la constante σ_α de polarisabilité (43, 44) et la constante υ d'effet stérique (45). Un seul paramètre peut donc être utilisé pour décrire l'effet des groupes alkyles; nous avons choisi la constante σ_α de polarisabilité (43, 44). C'est le signe du coefficient de la régression de ΔH° en σ_α qui déterminera si les groupes alkyles agissent majoritairement par effet stérique (coefficient négatif, diminution de $-\Delta H^\circ$) ou par effet de polarisabilité (coefficient positif, augmentation de $-\Delta H^\circ$). L'équation [13] montre que pour 11 thioéthers RSR′ **5**–**15** et deux thiols RSH **3**, **4**, le pouvoir accepteur de liaison H

[13] $-\Delta H^\circ = 6{,}92\ (-\Sigma\sigma_\alpha) + 7{,}4$

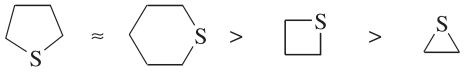
$n = 13$, $r = 0{,}983$, $s = 0{,}38$

augmente quand le nombre, la longueur et la ramification des substituants alkyles R et R′ (c.-à-d. $-\Sigma\sigma_\alpha$) du soufre augmentent. Ceci indique que l'effet de polarisabilité l'emporte sur l'effet stérique pour l'enthalpie de liaison H. Grâce à cette relation on estime à environ 7,4 kJ mol^{-1} l'enthalpie de complexation avec H_2S (pour lequel $\Sigma\sigma_\alpha = 0$) dont l'état gazeux rend l'étude expérimentale difficile.

Fig. 3. Relation entre pK_{HB} et la constante inductive σ_F du substituant XCH_2 dans la série XCH_2SMe : pK_{HB} = –2,189 σ_F + 0,11; n = 6; r = 0,977. Le disulfure MeSSMe **1** obéit à cette corrélation, tandis que le thioanisole PhSMe **21** dévie vers le bas (voir texte).

Effet inductif

Nous avons étudié l'effet inductif de substituants électroattracteurs dans la série XCH_2SMe (**5**, **16**, **17**, **18**, **19** et **20**). La figure 3 montre que la diminution de pK_{HB} par cet effet électroattracteur est bien reliée à la constante inductive σ_F du groupe XCH_2 (44). Le thioanisole PhSMe **21** dévie vers le bas, car à l'effet inductif du substituant Ph s'ajoute son effet de résonance électroattracteur. Au contraire le disulfure MeSSMe **1** se place sur la droite de régression. Ceci indique que la diminution du pouvoir accepteur de liaison H en passant d'un thioéther à un disulfure est principalement due à l'effet inductif du substituant SR. Ainsi la constante σ_F = +0,25 du substituant SMe en fait le substituant inductif le plus électroattracteur de notre échantillon; en conséquence le disulfure MeSSMe a la valeur pK_{HB} la plus faible (–0,49) de la série. Il a également l'enthalpie de liaison H la plus petite de toutes les bases soufrées, dont l'enthalpie a été mesurée dans ce travail.



Effet de résonance

L'effet de résonance électroattracteur des groupes Ph et $CH{=}CH_2$ s'ajoute à leur effet inductif électroattracteur pour diminuer la densité électronique des paires libres du soufre dans les thioéthers aromatiques et éthyléniques PhSMe, Ph_2S et $EtSCH{=}CH_2$. Ces derniers sont donc significativement moins accepteurs de liaison H que leurs analogues aliphatiques. Ainsi l'écart entre PhSMe et *c*-HexSMe est de 0,56 unité de pK (3,2 kJ mol^{-1}) et celui entre $EtSCH{=}CH_2$ et EtSEt de 0,38 unité de pK (2,2 kJ mol^{-1}).

Effet de cyclisation

La cyclisation modifie le pouvoir accepteur de liaison H des thioéthers cycliques. L'ordre observé sur l'échelle enthalpique est le suivant :

© 2005 CNRC Canada

$-\Delta H°$ (kJ mol^{-1})	14,3	≈	14,2	>	12,7	>	11,6
% *s* moyen des paires libres du S	35,6	≈	35,2	<	37,5	<	41,4

Une explication simple pourrait provenir d'une modification de l'hybridation des paires libres du soufre par variation de l'angle CSC. Quand celui-ci se ferme en allant vers les plus petits cycles, leur pourcentage de caractère *s* augmente. En conséquence le pouvoir accepteur de liaison H diminue, puisque la basicité de liaison H d'une paire libre diminue généralement avec l'augmentation de son caractère *s* (par exemple, pour l'azote la basicité diminue dans l'ordre Me_3N > pyridine > acétonitrile). Nous avons analysé les paires libres du soufre par la méthode NBO (« natural bond orbital ») (46, 47) au niveau B3LYP/6-31+G** (48). Nous trouvons un accord satisfaisant (r = 0,967, n = 4) entre le pourcentage moyen de caractère *s* des paires libres calculé par cette méthode et l'enthalpie de complexation.

An intriguing effect of lithium perchlorate dispersed on silica gel in the bromination of aromatic compounds by *N*-bromosuccinimide

Mojtaba Bagheri, Najmedin Azizi, and Mohammad R. Saidi

Abstract: A convenient and efficient procedure for electrophilic aromatic bromination has been developed by mixing of *N*-bromosuccinimide and an aromatic compound at room temperature on the surface of silica gel mixed with solid anhydrous $LiClO_4$. All of the substrates examined underwent clean electrophilic aromatic bromination in reaction times of a few minutes to afford the corresponding bromoarenes under neutral conditions in excellent yield. In the case of thiophenol, no substitution reaction occurred, and the corresponding disulfide was obtained in excellent yield.

Key words: LP-SiO_2, NBS, arenes, electrophilic bromination, regioselectivity.

Résumé : On a mis au point une méthode pratique et efficace d'effectuer une bromation aromatique électrophile donnant d'excellents rendements et qui implique la mise en contact, à la température ambiante et pendant quelques minutes, de *N*-bromosuccinimide et d'un composé aromatique à la surface d'un gel de silice mélangé avec du $LiClO_4$ anhydre solide. Tous les substrats ont donné lieu à des bromations aromatiques électrophiles propres conduisant, dans des conditions neutres, aux bromoarènes correspondants. Dans le cas du thiophénol, il ne se produit pas de réaction de substitution et le disulfure correspondant est obtenu avec un excellent rendement.

Mots clés : LP-SiO_2, NBS, arènes, bromation électrophile, régiosélectivité.

[Traduit par la Rédaction]

Introduction

Brominated arenes are versatile intermediates in the synthesis of a wide variety of biologically active compounds. They are also widely used for the preparation of products of commercial importance such as pharmaceuticals, agrochemicals, synthetic colorants, and performance chemicals (1). A popular method for the bromination of aromatic compounds is the reaction of molecular bromine with an arene, in a halogenated hydrocarbon (2) or acetic acid (3). However, in many cases, mixtures of mono-, di-, and polybrominated products are obtained. Another popular and mild, less hazardous, and inexpensive reagent that has been used for electrophilic aromatic bromination is *N*-bromosuccinimide (NBS) in CCl_4 (4). The major advantage of the use of NBS as a brominating agent is that the by-product succinimide can be easily recovered, converted to NBS, and reused. A variety of methods for such a reaction with NBS have been reported in the literature, including NBS-PTZ (5), NBS-PTSA (5), NBS-Amberlyst (6), NBS-NaOH (7), NBS-HZSM (8), and NBS-HBF_4/Et_2O (9). In addition, electrophilic bromination of activated aromatic compounds has been reported to be favored in polar solvents such as propylene carbonate (10), DMF (11), CH_3CN (12), and ionic liquids (13). Despite the apparent utility of these reagents, they have not been widely used for electrophilic aromatic bromination, which may be due to the variable results reported in terms of both products and yields. More recently, green protocols such as solid-state bromination (14) and Oxone®/sodium bromide (15) have been reported in the literature.

Results and discussion

In recent years, the use of lithium perchlorate in diethyl ether (LPDE) as a polar medium has attracted attention owing to the enhanced rate and selectivity observed for various organic transformations in this medium (16). The LPDE medium provides a convenient means to carry out reactions under neutral and easy workup conditions.

In continuation of our interest on the application of lithium perchlorate for various organic transformations (17), we herein describe a simple, efficient, and general method for the electrophilic bromination of aromatic rings by using NBS in CH_2Cl_2 catalyzed by solid lithium perchlorate dispersed on silica gel ($LiClO_4$–SiO_2). The general applicability of this reagent for a large number of aromatic compounds was investigated, and the results are summarized in Tables 1 and 2. The brominated compounds were identified on the basis of their ^{1}H NMR and mass spectral data, and by comparison of these data with those reported in the literature. The

starting materials used in this study were commercially available. The bromination reaction was studied at different temperatures and in solvents of different polarities (CH_3CN, CH_2Cl_2, CCl_4, MeOH, and 5 mol/L LPDE), using different molar ratios of NBS/arene. The optimized reaction conditions were found to be the simple stirring of a solution of arene (1 equiv.), NBS (1 equiv.), and 0.4 g $LiClO_4$–SiO_2 (1:4) in CH_2Cl_2 at room temperature, which afforded the product in good yield (Table 1). Without using solid $LiClO_4$ or SiO_2, the reaction is less selective and the reaction time is longer.

The data in Table 1 clearly show the general applicability of this method for a variety of aromatic compounds. In most cases, one product (either the monobromo- or the

Scheme 1.

dibromoarene) was formed in a short reaction time and in good yield. In all cases, the crude products were monitored by GC and checked for the presence of any by-products. Some general trends are apparent from the data in Table 1. First, the reactivity of the substrate seems to be related to the electron density on the aromatic ring. Thus, the nucleus must be sufficiently activated before significant reactions occurred. This reagent is not effective for benzene, toluene, or naphthalene, and amino derivatives give slightly easier and cleaner reaction than hydroxyl derivatives. The presence of electron-donating or electron-withdrawing groups on the aniline or phenol did not affect the rates or the yields of the reactions. For example, *p*-methylaniline, *p*-nitroaniline, *N,N*-dimethylaniline, and *p*-(*N,N*-dimethylamino)benzaldehyde gave the monobromo product in short reaction times and in high yields (Table 1, entries 4, 8, 10, and 11). *p*-*S*ubstituted anilines were brominated at the ortho position. In the case of aniline (Table 1, entry 2), 1-naphthylamine (Table 2, entry 3), and 4-aminoacetophenone (Table 1, entry 6), as well as 8-aminoquinoline (see Table 3, entry 2), in the presence of 2 equiv. of NBS dibromination occurred at the 2 and 4 positions in high yields. It is noteworthy that the direct bromination of aniline with bromine in solution often results in polybromination and requires the protection of amino groups. The results with the derivatives of phenol are somewhat different. For example, under the above reaction conditions, phenol gave dibromophenol (Table 1, entry 1), while 2-naphthol (Table 2, entry 1), 2,7-dihydroxynaphthalene (Table 2, entry 4), and *p*-substituted phenols gave only monobrominated products in short reaction times and with high yields (except in the case of 4-nitrophenol). 1-Naphthol (Table 2, entry 2) and 3-anisidine (Table 1, entry 13) produced the corresponding dibromo derivatives. The bromination of methoxybenzene required a long reaction time with 1 g of $LiClO_4$–SiO_2 (Table 1, entry 9), but 2-methoxynaphthalene gave the dibromo product in excellent yield with 1 g of $LiClO_4$–SiO_2 (Table 1, entry 13). Comparison of our results with those reported in the literature clearly shows that higher reactivity and higher selectivity are obtained with $LiClO_4$–SiO_2 than with SiO_2 (18).

We next investigated bromination of 2-aminopyridine and 8-aminoquinoline. The most direct approach to the bromination of pyridine derivatives is the direct electrophilic halogenation of the activated pyridines in polar protic solvents, such as water and ethanol. In the reported procedures, with the use of common organic solvents such as CH_3CN, CS_2, CH_2Cl_2, and CCl_4, mixtures of monobromo and dibromo products were formed, with long reaction times (19, 20). We have found that NBS/$LiClO_4$–SiO_2 is suitable for the regioselective monobromination of aminopyridine and dibromination of 8-aminoquioline with excellent yields and a reaction time of a few minutes (Table 3).

To extend the scope of this reagent, we have also investigated bromination of anthracene and thiophenol. NBS in CCl_4 is a common brominating agent for anthracene and affords a mixture of mono- and dibromoanthracene in good yields (21). We found that bromination of anthracene with 2 equiv. of NBS using the NBS/$LiClO_4$–SiO_2 reagent yieled 9,10-dibromoanthracene as the sole product. On the other hand, bromination of thiophenol was not successful, and coupling of thiol groups to form the disulfide in excellent yields was observed (Scheme 1).

In conclusion, we have developed a simple, general, and efficient method for electrophilic bromination of activated arenes under mild conditions, mediated by $LiClO_4$ dispersed on SiO_2 in CH_2Cl_2. The absence of side-chain bromination products in this procedure clearly indicates that an electrophilic aromatic substitution mechanism operates in this reaction medium; the remarkable enhancement in reaction rates and regioselectivity could be explained by increased polarization of the N—Br bond of NBS in this ionic process. This procedure also can be applied to polycyclic aromatic compounds. Furthermore, the $LiClO_4$–SiO_2 reagent is cheap, stable, easy to handle, and nontoxic. The present method would be useful in organic synthesis. We are currently extending this methodology to the use of NXS (X = Cl, I).

Experimental

General procedure for the bromination of aromatic compounds with NBS

NBS (1–2 eqiuv.) was added slowly to a stirred solution of an aromatic compound (2 mmol) and 0.4 g of $LiClO_4$–SiO_2 (1:4) in CH_2Cl_2 (20 mL). When the addition was complete, the reaction mixture was stirred at room temperature and the progress of the reaction monitored by TLC and GC. Complete conversion was achieved for most of the substrates. The reaction mixture was filtered, and the catalyst

© 2005 NRC Canada

was recovered and washed with CH_2Cl_2 (2 × 10 mL). The combined organic layer was washed with water and dried over anhydrous sodium sulfate and concentrated under reduced pressure using a rotary evaporator. Almost pure crude product was obtained in most cases. Further purification was carried out by short column chromatography on silica gel (ethyl acetate: petroleum ether). All compounds are known and were characterized on the basis of their spectroscopic data (GC, MS, NMR) and by comparison of these data with those reported in the literature.

Synthesis, characterization, and coordination chemistry of phosphines with ethylenedioxythiophene substituents

M'hamed Chahma, Daniel J.T. Myles, and Robin G. Hicks

Abstract: The preparation of several new phosphines bearing one or more 3,4-ethylenedioxythiophene (EDOT) units as substituents linked at the 2-thienyl position is described. The phosphines were prepared by reaction of lithiated EDOT intermediates with appropriate chlorophosphines to afford (3,4-ethylenedioxy-2-thienyl)diphenylphosphine (**1**), (bis(3,4-ethylenedioxy-2-thienyl)phenylphosphine (**2**), tris(3,4-ethylenedioxy-2-thienyl)phosphine (**3**), 2,5-bis(diphenylphosphino)-3,4-ethylenedioxythiophene (**4**), and 2-diphenylphosphino-5-mesitylthio-3,4-ethylenedioxythiophene (**5**). Molybdenum carbonyl complexes of compounds **1**–**3** were prepared by reaction of the phosphine ligands with *cis*-$Mo(CO)_4(pip)_2$. In all cases, spectroscopic evidence is fully consistent with the phosphines acting as monodentate, P-bound ligands. Electrochemical studies on the phosphines as well as their metal complexes indicate that the normal electrochemical redox robustness of the EDOT group is dramatically decreased by the presence of phosphine substituents: all compounds exhibited irreversible oxidation processes and no evidence of electropolymerization was observed for the phosphines bearing two or three EDOT groups.

Key words: phosphines, thiophene, 3,4-ethylenedioxythiophene, EDOT, electrochemistry, coordination complexes.

Résumé : On décrit la préparation de plusieurs nouvelles phosphines portant un ou plusieurs unités de 3,4-éthylènedioxythiophène (EDOT) comme substituants liés à la position 2-thiényle. On a préparé les phosphines par la réaction d'intermédiaires EDOT lithiés avec les chlorophosphines appropriées qui ont conduit à la formation des (3,4-éthylènedioxy-2-thiényl)diphénylphosphine (**1**), bis(3,4-éthylènedioxy-2-thiényl)phénylphosphine (**2**), tris(3,4-éthylènedioxy-2-thiényl)phosphine (**3**), 2,5-bis(diphénylphosphino)-3,4-éthylènedioxythiophène (**4**) et 2-diphénylphosphino-5-mésitylthio-3,4-éthylènedioxythiophène (**5**). La réaction des ligands phosphines avec les *cis*-$Mo(CO)_4(pip)_2$ a permis de préparer les complexes du molybdène carbonyle des composés **1**–**3**. Dans tous les cas, les données spectroscopiques sont en total accord avec le fait que les phosphines agissent comme des ligands monodentates liés par le phosphore. Des études électrochimiques sur les phosphines ainsi que sur leurs complexes métalliques indiquent que la solidité redox électrochimique normale du groupe EDOT est dramatiquement abaissée par la présence des substituants phosphines : tous les composés donnent lieu à des processus d'oxydation irréversibles et aucune électropolymérisation n'a été observée avec les phosphines portant deux ou trois groupes EDOT.

Mots clés : phosphines, thiophène, 3,4-éthylènedioxythiophène, EDOT, électrochimie, complexes de coordination.

[Traduit par la Rédaction]

Introduction

The importance of phosphine ligands in (organo)transition metal chemistry cannot be overstated. The ability to modulate steric and electronic properties of phosphines (1) and their resulting metal complexes has facilitated the development of metal phosphine-based catalysis in a wide range of forums, particularly in late metal-catalyzed cross-coupling reactions (Suzuki, Stille, Kumada–Corriu, etc.) (2). As one of the prototypical members of this ligand class, triphenylphosphine is a true benchmark ligand. In recent years, other arylphosphine derivatives have been explored in which some or all of the phenyl groups have been replaced by heteroaromatic rings such as pyridine (3) and furan (4). Phosphines containing thiophene subtitutents have also received attention. Although they typically behave as simple P-monodentate ligands (5), thienylphosphines can also act as bridging ligands via the thiophene sulfur atom (6), or as chelating ligands involving cyclometallation of one of the thiophene rings (7).

Thienylphosphine complexes have also attracted interest because of the possibility of making phosphine-substituted conjugated polythiophenes in which the electronic properties of the polymer can be tuned via metal coordination at the phosphine (8). Metal–organic polymers have received a great deal of interest stemming from the potential properties that may arise from polymers containing both organic and inorganic elements (9). There has been a particularly strong emphasis on polymers containing metals as part of, or attached to, conjugated frameworks (10). The main motivation behind

Scheme 1.

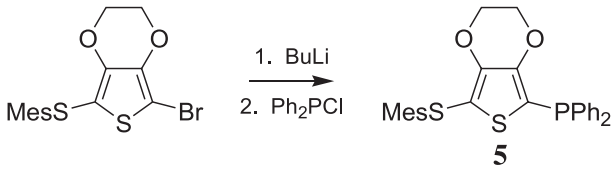
these studies is to explore the possibilities of making new materials, which combine inherent functional properties of purely organic conjugated polymers (11) such as conductivity, electrochromism, and light emission with the electronically interesting features of metal complexes (magnetic, optical, etc.).

Among the many thiophenes that have been incorporated into conjugated organic polymers, 3,4-ethylendioxythiophene (EDOT) stands out as an electron-rich derivative. The strongly electron-donating oxygen atoms render EDOT relatively easily oxidized and impart exceptional stability to the resulting homopolymer. The outstanding properties of poly(EDOT) have led to the synthesis and study of a wide range of hybrid materials of EDOT with other organic and inorganic moieties (12). However, no EDOT-substituted phosphines have been reported. It occurred to us that such species should be useful ligands and may lead to interesting materials from hybrid EDOT–phosphine–metal complexes and polymers. To this end, herein we describe the synthesis, characterization, and preliminary coordination chemistry of triarylphosphine derivatives bearing 3,4-ethylenedioxy-2-thienyl groups as substituents.

Synthesis and characterization of EDOT phosphines

The EDOT–phosphine derivatives were prepared by reactions of in-situ-generated, lithiated EDOT compounds with the appropriate chlorophosphine (Scheme 1). Thus, Li^+EDOT^- reacts with chlorodiphenylphosphine, dichlorophenylphosphine, and trichlorophosphine to give $Ph_2P(EDOT)$ (**1**), $PhP(EDOT)_2$ (**2**), and $P(EDOT)_3$ (**3**), respectively. In addition, 2,5-bis(diphenylphosphino)-3,4-ethylenedioxythiophene (Ph_2P-EDOT-PPh_2) (**4**) was prepared by reaction of chlorodiphenylphosphine with doubly lithiated EDOT.

Scheme 2.



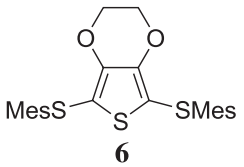


Table 1. Characterization data for EDOT–phosphines **1**–**5** and related compounds.

Compound	λ_{max} (nm)	^{31}P NMR δ (ppm)	E_p (V vs. Fc/Fc^+)
EDOT	260	—	+0.93
$EDOT–PPh_2$ (**1**)	274	–28.1	+0.79
$(EDOT)_2PPh$ (**2**)	274	–50.5	+0.68
$(EDOT)_3P$ (**3**)	277	–68.5	+0.60
Ph_2P-EDOT-PPh_2 (**4**)	292	–26.5	+0.52
MesS-EDOT-PPh_2 (**5**)	288, 305	–27.6	+0.57
MesS-EDOT-SMes (**6**)	305	—	+0.40[a]

[a]Reversible.

In addition to compounds **1**–**4**, an EDOT derivative with one diphenylphosphine (Ph_2P) and one mesitylthio (MesS) substituent was prepared for comparison of electrochemical properties. Compound **5** was synthesized from 5-bromo-2-(mesitylthio)-3,4-ethylenedioxythiophene) (13) via lithium–halogen exchange followed by treatment with Ph_2PCl using analogous protocols employed in the synthesis of **1**–**4**. (Scheme 2).

Although some EDOT derivatives with unsubstituted thiophene α-carbon atoms are unstable to air and moisture, all of the EDOT phosphines are air-stable compounds. Table 1 summarizes pertinent physicochemical data for the new EDOT-substituted phosphines as well as EDOT itself and 2,5-bis(mesitylthio)3,4-ethylenedioxythiophene (**6**), a disubstituted EDOT derivative previously made in our lab.(13) The UV–vis spectra all have lowest energy absorption maxima in the neighborhood of 277–290 nm. These are all slightly red-shifted relative to EDOT itself (λmax = 260 nm) indicative of a weak electronic perturbation of the EDOT chromophore by the phosphine moieties. The ^{31}P NMR chemical shifts of the series $(EDOT)_nPPh_{3-n}$ progress smoothly to more negative values as phenyl groups are successively replaced by more electron-rich EDOT moieties. Analogous behaviour is observed in the related series of unsubstituted 2-thienyl–phenylphosphines $(2\text{-Th})_nPPh_{3-n}$ (Fig. 1) (6*a*). Similar trends can also be found in triarylphosphines bearing para substituents, for which the more electron-donating groups give rise to more negative δ ^{31}P NMR values (14).

The redox properties of compounds **1**–**5** were examined by cyclic voltammetry. All new compounds **1**–**5** exhibited irreversible oxidation waves at the potentials given in Table 1.

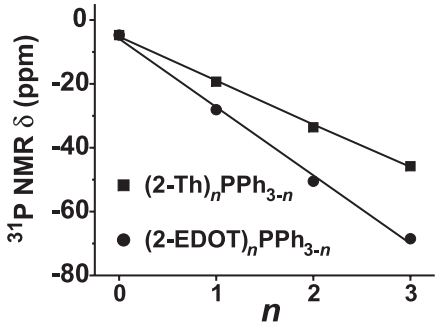

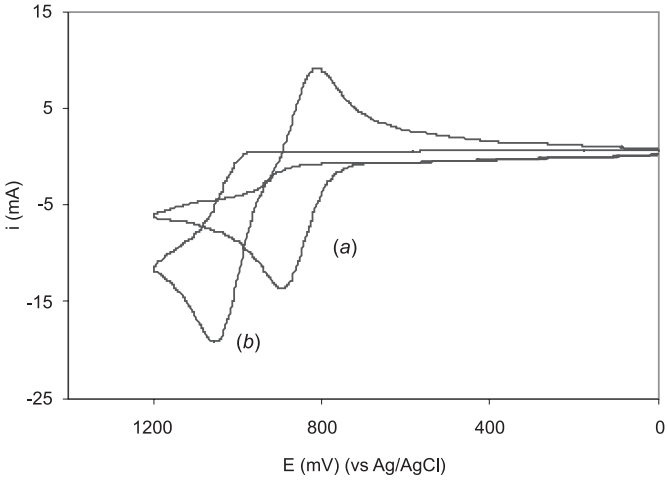

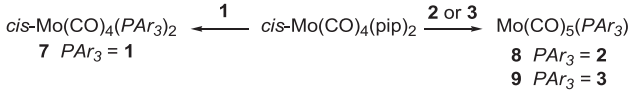

Fig. 2. CV of 2 × 10^{-4} mol/L of **6** (*a*) alone and (*b*) with 1 equiv. of Ph$_3$P added.

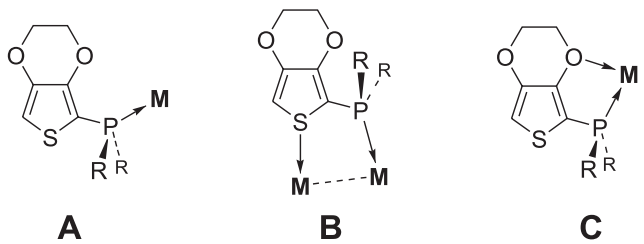
For compounds **1**–**3**, the irreversible nature of the oxidation was not unexpected because the EDOT groups in these compounds contain unsubstituted positions on the thiophene ring. These unsubstituted positions are known to be highly reactive sites in oxidized thiophenes. However, the bis(phosphine)-substituted EDOT **4** and 5-mesitylthio-2-diphenylphosphine-3,4-ethylenedioxythiohene (**5**) also exhibited irreversible behaviour upon oxidation. Thiophenes containing substituents at all the 2 (or 5) positions generally can be electrochemically oxidized to give radical cations that are stable at least on electrochemical timescales, For example, bis(mesitylthio)EDOT **6** undergoes a fully reversible oxidation to its radical cation at +0.40 mV. Evidently, the presence of a phosphine group on one of the a carbon atoms of EDOT render the oxidation of the latter moiety irreversible. In general, the oxidation of thiophene derivatives bearing two or more unsubstituted α-carbon atoms are irreversibly oxidized because the resulting radical cations couple at these carbons — this is the first step in the electropolymerization of thiophene and its derivatives. The source of instability in compounds **1**–**5** appears to arise from reactions specific to phosphine-containing thiophenes: although, in principle, compounds **2** and **3** could lead to poly(thiophene–phosphine) materials upon oxidation, repeated electrochemical cycling lead to passivation of the electrode and no formation of polymer was observed. Similar behavior was observed in related phosphinoterthiophenes (8*e*). As a final piece of supporting evidence, the reversibility of the electrochemical oxidation of **6** is dramatically decreased upon addition of triphenylphosphine (Fig. 2).

Coordination complexes

Preliminary investigations into the coordination chemistry of the phosphines involved reactions with molybdenum carbonyl species; related complexes of other 2-thienylphosphines have been reported (6*b*, 6*c*, 6*f*). Reactions of **1** with the reagent *cis*-Mo(CO)$_4$(piperidine)$_2$ (15) led to the expected cis-disubstituted product *cis*-Mo(CO)$_4$(EPPh$_2$)$_2$ (**7**). However, reactions of **2** or **3** with *cis*-Mo(CO)$_4$(piperidine)$_2$ in a 2:1 ratio did gave mixtures of products, which appeared to contain the *mono*substituted products Mo(CO)$_5$(PAr$_3$) in addition to the anticipated disubstituted products. Changing the stoichiometric ratio of phosphines to Mo to 1:1 produced the monosubstituted products **8** and **9** in high yields. These unexpected products must result from intermolecular CO transfer and may be a consequence of the larger steric bulk of the phosphines bearing multiple EDOT substituents. The qualitative similarity of an EDOT group to a naphthyl group would lead to approximately similar steric features between (EDOT)$_3$P (**3**) and tris(1-naphthyl)phosphine, the latter of which has a cone angle of ~200° (1*c*).

The product identities were confirmed through a combination of IR, NMR, and mass spectroscopies. The ^{31}P NMR chemical shifts (see Table 2) of the complexes are 52–60 ppm upfield relative to the chemical shifts of the free ligand, indicative of P-coordinated phosphines. The proton and carbon NMR suggest simple P-monodentate coordination modes for all three phosphines; no evidence of either cyclometallation of S-donating binding is detected. The ^{13}C



© 2005 NRC Canada

NMR spectra were particularly informative as the magnitude of the carbon–phosphorus coupling constants to the carbonyl groups provided strong support for the cis-disubstituted geometry of **7** as well as the monosubstituted nature of **8** and **9**. Parent molecular anions were observed in the mass spectra of all three complexes. However, these are all relatively weak compared with the base peaks, which in each case correspond to the loss of two carbonyls. This process may well be facilitated by chelation of an ethylenedioxy oxygen atom of the EDOT–phosphines (see the following). The ν(CO) frequencies are quite similar to those observed in related molybdenum carbonyl complexes of 2-thienylphosphines, a feature that suggests that the π-electron-rich nature of the EDOT moiety is not strongly felt by the metal center in these complexes.

Cyclic voltammetry studies on complexes **7**–**9** revealed irreversible oxidations for all three compounds. Interestingly, the oxidation peak potential for complexes **8** and **9** are very similar to the peak potentials for the corresponding free ligand, whereas the peak potential for **7** is some 0.4 V lower than its free phosphine ligand. This may be related to the fact that **7** has two EDOT phosphine ligands whereas **8** and **9** have one each, although the irreversibility of the oxidations renders direct comparisons difficult owing to the scan rate dependence of these processes. Attempts to electropolymerize **7**–**9** by repeated electrochemical cycling failed, instead leading to electrode passivation.

Conclusions

We have described the synthesis and characterization of a new series of phosphines bearing ethylenedioxythiophene substituents. Characterization of the phosphines as well as metal complexes thereof suggest there is little electronic perturbation of the EDOT group by the phosphine and vice versa. In sharp contrast to other lone-pair-containing substituents (e.g., -OR, -SR) that can enhance the redox stability of thiophenes, phosphine groups do not offer much in the way of electrochemical stability at all and in fact can destabilize the otherwise inherently robust redox characteristics of the EDOT moiety. In a similar vein, it appears that the electron richness of the EDOT ring is not manifested in a more "electron-rich" metal center in coordination complexes — at least for the ones presented herein. Nonetheless, these compounds should be useful additions to the stable of arylphosphine ligands because of their ease of synthesis, variable steric bulk, and in particular because of the potential modes of coordination they offer: As simple monodentate mode **A**, bidentate (P/S) bridging ligands in polynuclear systems **B**, or chelating (P/O) chelating **C** — the latter two having the potential to be hemilabile coordination modes (16). Studies aimed at exploring the potential coordinative versatility of these ligands are in progress.

Experimental

General considerations

All reagents were purchased from Aldrich and used as received; $Mo(CO)_4(piperdine)_2$ was prepared according to literature procedures (15). All reactions were performed under an atmosphere of dry argon using standard Schlenk or glove box techniques. Solvents were dried and distilled under argon prior to use (CH_2Cl_2, CaH_2; THF, Na–benzophenone). Mass spectra were recorded on a Kratos Concept IH mass spectrometer system. IR spectra were recorded as Nujol mulls or KBr presses on a PerkinElmer Spectrum One spectrometer. NMR spectra were recorded on a Bruker AMX360 spectrometer. Cyclic voltammetry experiments were performed using a CV-50W voltammetric analyzer (BAS) at room temperature (22 ± 2 °C). Voltammetric measurements were performed in CH_2Cl_2 containing 1 mol/L of *n*-Bu_4NBF_4. The platinum electrode (BAS, diameter 1.6 mm) was used as the working electrode. Platinum and silver wires were used as auxiliary and reference electrodes, respectively. The reference electrode was calibrated vs. ferrocene/ferrocenium redox ($E°$ = 0.440 vs. Ag/AgCl) internal reference. The working electrode was polished on alumina before use. *iR* compensations were applied for all experiments.

General synthesis of (3,4-ethylenedioxy-2-thienyl) phosphine derivatives

The synthesis of EDOT-substituted phosphines **1**–**4** is exemplified by the synthesis of **1**. EDOT (1.313 g, 9.25 mmol) was dissolved in THF (50 mL) and treated with *n*-BuLi (1.6 mol/L, 3 mL, 9.36 mmol) at room temperature. After 2 h of stirring, the mixture was cooled to –78 °C and chlorodiphenylphosphine (3 mL, 3.1 mmol) was added dropwise to the reaction mixture. The mixture was stirred at –78 °C for 2 h and gradually brought to room temperature. The mixture was then poured into water (100 mL) and extracted using CH_2Cl_2 (2 × 100 mL). The organic layers were combined and dried over anhydr. $MgSO_4$. Removal of the solvent gave a crude product, which was purified by chromatography using silica gel and chloroform as the eluent. The product was then recrystallized in CH_2Cl_2–methanol.

(3,4-Ethylenedioxy-2-thienyl)diphenylphosphine (EDOT-PPh_2, 1)

Yield: 74%; mp 84 °C. UV–vis (CH_2Cl_2): λ_{max} (ε) 274 nm (16 450 M^{-1} cm^{-1}). ^1H NMR (CD_2Cl_2, 300 MHz) δ: 4.20 (m, 4H), 6.60 (s, 1H), 7.40 (m, 10H). ^{13}C NMR (CD_2Cl_2, 125 MHz) δ: 64.94 (CH_2), 65.41 (CH_2), 106.22 (CH), 109.95 (C, d, J = 28.6 Hz), 128.75 (4CH, d, J = 6.8 Hz), 129.23 (2CH), 133.54 (4CH, d, J = 20.2 Hz), 137.24 (2C, d, J = 8.6 Hz), 142.72 (C, d, J = 3.7 Hz), 147.01 (2C, d, J = 18.9 Hz). ^{31}P NMR (CD_2Cl_2, 145 MHz) δ: –28.12. HR-MS calcd. for $C_{18}H_{15}O_2PS$: 326.0530; found: 326.0535. Anal. calcd. for $C_{18}H_{15}O_2P$ (%): C 66.25, H 4.63, O 9.80; found: C 66.21, H 4.17, O 9.95.

^{1}H NMR studies on the solution conformation of the [L-Ser^{10}] and [D-Ser^{10}] analogues of contulakin-G

Lill Kindahl, Lennart Kenne, and Corine Sandström

Abstract: The synthesis of the *O*-glycosylated serine-10 analogue of contulakin-G yielded both the [L-] and the [D-Ser^{10}] analogues. The ^{1}H NMR study indicated that the sugars of the two Ser^{10}-glycosylated peptides lacked the hydrogen bond to the peptide backbone that exists in contulakin-G. NOEs showed that the glycan part of the [D-Ser^{10}] analogue had a different orientation to the peptide backbone than that of the [L-Ser^{10}] analogue. The peptide backbones in the two compounds were found to exist mainly in random coil conformations, with transient turns at the site of glycosylation. A transient turn was also found at the C-terminus of the [D-Ser^{10}] glycopeptide. The NMR data indicated that the average conformation of the [D-Ser^{10}] analogue resembles the conformation of contulakin-G more than the [L-Ser] does. Since biological data showed that the [D-Ser^{10}] glycopeptide was as active as contulakin-G, while the [L-Ser^{10}] glycopeptide was only slightly active at more than 100 times the dose, it is possible that it is the orientation of the glycan relative to the peptide chain that is actually recognized by the proteolytic enzyme.

Key words: conformation, contulakin-G analogues, NMR, *O*-linked glycopeptide.

Résumé : La synthèse de l'analogue sérine-10 *O*-glycosylée de la contulakine-G conduit à la formation des deux analogues [L-] et [D-Ser^{10}]. Une étude de RMN du ^{1}H indique que dans les sucres des deux peptides Ser^{10}-glucosylés on ne retrouve pas la liaison hydrogène avec le squelette du peptique qui existe dans la contulakine-G. Des études d'effet Overhauser nucléaire montrent que l'orientation de la partie glycane de l'analogue [D-Ser^{10}] par rapport au squelette du peptide est différente de celle de l'analogue avec [L-Ser^{10}]. On a trouvé que les squelettes peptidiques des deux composés existent principalement sous la forme de pelote aléatoire avec des revirements transitoires au site de la glycosylation. On a aussi observé un revirement transitoire au C-terminal de l'analogue [D-Ser^{10}] du glycopeptide. Les données de la RMN indiquent la conformation moyenne de l'analogue [D-Ser^{10}] ressemble plus à la conformation de la contulakine-G que celle de l'analogue [L-Ser]. Comme les données biologiques montrent que l'analogue [D-Ser^{10}] du glycopeptide est aussi actif que la contulakine-G alors que l'analogue [L-Ser^{10}] du glycopeptide n'est que faiblement actif à plus de cent fois la dose, il est possible que ce soit l'orientation du glycane par rapport à la chaîne peptidique qui soit reconnue par l'enzyme protéolytique.

Mots clés : conformation, analogues de la contulakine-G, RMN, glycopeptide à liaison par l'oxygène.

[Traduit par la Rédaction]

Introduction

Contulakin-G (**1**, Scheme 1) is an invertebrate neurotensin analogue, which has recently entered phase II clinical trials for short-term management of postoperative pain (1–3). Contulakin-G is a 16 amino acid *O*-glycosylated glycopeptide, which was isolated from the venom of the Cone snail *Conus geographus*. In a previous study, the conformations of contulakin-G (**1**) and three analogues (**2**–**4**, Scheme 1) were investigated by ^{1}H NMR spectroscopy, and an attempt was made to correlate the NMR data to the biological activity of these compounds (4). The analogues were the nonglycosylated peptide (**2**), one analogue with the monosaccharide α-D-Gal*p*NAc at Thr^{10} (**3**), and one analogue with the disaccharide β-D-Gal*p*-(1→3)-α-D-Gal*p*NAc at Ser^7 (**4**).

The potency of compounds **1**–**4** was assessed by testing their ability to induce latency of tail flick in mice in an assay of acute pain.[2] Contulakin-G (**1**) was found to be significantly more potent than the analogue with the monosaccharide α-D-Gal*p*NAc at Thr^{10} (**3**). The latter was in turn more potent than the nonglycosylated peptide **2**, which was found to have an activity comparable to that of the analogue *O*-glycosylated at Ser^7 (**4**). These results suggested that the presence of the glycan, its size and position are important factors for the activity of contulakin-G. The NMR study showed that contulakin-G and the three analogues mainly existed in random coil conformations (4). Some transient populations of folded conformations were also present in the glycopeptides, and turns, probably induced by the sugars, were found in the peptide chain around the site of

glycosylation. In the two peptides *O*-glycosylated at Thr[10] (**1** and **3**), the presence of a transient hydrogen bond between the α-D-Gal*p*NAc residue and the peptide was found. An intramolecular hydrogen bond between the carbohydrate and the peptide chain did not exist in the peptide *O*-glycosylated at the Ser[7] residue (**4**). In contulakin-G (**1**), an additional transient turn was formed at the C-terminal end of the peptide chain. When the stability towards enzymatic degradation with proline specific endopeptidase was investigated,[2] the nonglycosylated peptide (**2**) and the peptide *O*-glycosylated at the Ser[7] residue (**4**) showed significantly more susceptibility to enzymatic hydrolysis than contulakin-G (**1**) and the analogue with the monosaccharide α-D-Gal*p*NAc at Thr[10] (**3**). It was concluded that the glycan was able to exert significant protection against enzymatic degradation, and this protection appeared to be completely abolished in the Ser[7]-glycosylated analogue (**4**). The analogue **3**, which is glycosylated with the monosaccharide α-D-Gal*p*, was also more readily degraded than contulakin-G (**1**), which is glycosylated with the disaccharide β-D-Gal*p*-(1→3)-α-D-Gal*p*NAc. This indicated that the glycan might sterically inhibit the enzyme from inactivating the peptide by hydrolysis of the linkage between Pro[13] and Tyr[14]. The stabilization against enzymatic degradation correlated with the increased

© 2005 NRC Canada

antinociceptive activity of the compounds,[2] and it is possible that the reduced proteolysis of contulakin-G, as compared to that of the nonglycosylated peptide, may be responsible for the increased activity of this peptide. Since the data obtained in the proteolysis study indicated that the main role of the glycan is a steric inhibition of enzymatic degradation, it was of interest to study the Ser^{10}-glycosylated analogue of contulakin-G (Scheme 1). Previous NMR studies have reported differences in glycan mobility and orientation relative to the peptide backbone depending on if the glycosylated residue was a threonine or a serine (5, 6). In this work, we have studied the solution conformations of [Ser^{10}]-contulakin-G by ^{1}H NMR spectroscopy.

Results and discussion

The synthesis of [Ser^{10}]-contulakin-G was performed in a similar way as previously described (1). As the synthetic product was purified with reverse phase HPLC, two components with different retention times were found; one fraction with shorter retention time containing compound **5**, and one fraction with longer retention time containing compound **6**. The mass spectrum showed that both compounds had the correct mass, and that both were glycopeptides. In the antinociceptive assay of acute pain (7) of the two samples, it was found that glycopeptide **5** was active at about the same potency as contulakin-G (**1**), whereas glycopeptide **6** only was slightly active at more than 100 times the dose.[3] The structures of the two compounds were determined by ^{1}H NMR spectroscopy using a combination of standard two-dimensional COSY, DQF-COSY, TOCSY, and NOESY experiments. The chemical shifts of the signals from the protons of the peptide chains are given in Table 1, and those of the sugars in Table 2.

Structure determination

The disaccharide

Figure 1 shows the one-dimensional proton NMR spectra of compounds **5** and **6** in D_2O recorded at 25 °C. In both spectra, the downfield signal at δ 4.90 ppm in **5** and 4.89 ppm in **6** ($^3J_{1,2}$ = 3.8 Hz) was assigned to the anomeric proton of α-D-Gal*p*NAc. The signal from the anomeric proton of the β-D-Gal*p* residue was found at δ 4.48 ppm in **5** and 4.46 ppm in **6** ($^3J_{1,2}$ = 7.8 Hz). In the 2D NOESY spectra, the strong NOE between H-1 of β-D-Gal*p* and H-3 of α-D-Gal*p*NAc confirmed that the two sugars are connected through a 1,3-linkage (β-D-Gal*p*-(1→3)-α-D-Gal*p*NAc).

The primary structure of the peptide chain

The amino acid sequence of the peptide was confirmed by sequential assignment using the $d_{\alpha N}(i,i+1)$ NOE connectivities. The primary structure at the Lys^{12}–Pro^{13} junction was confirmed by the observation of an NOE between the α-H of Lys^{12} and the δ-CH_2 protons of Pro^{13}.

The site of glycosylation

The site of glycosylation at Ser^{10} of compounds **5** and **6** was confirmed by the existence of an NOE between the H-1 of α-D-Gal*p*NAc and the β-H of Ser^{10}. The two β protons of Ser^{10} in compounds **5** and **6** had signals that were slightly more separated than those of Ser^2 and Ser^7. This separation was also observed for the methine protons of the Ser^7 residue in compound **4**, and is due to the effect of glycosylation.

Differences in NMR spectra

The 2D COSY, TOCSY, and NOESY spectra of compounds **5** and **6** were very similar and Table 1 shows that most of the chemical shift differences between the signals from the amino acid protons in **5** and **6** were <0.04 ppm. An exception was found for the α-H signal of Ser^{10}, which showed a difference of 0.06 ppm between compounds **5** and **6**. Also, the NH signals of Lys^{11} and α-D-Gal*p*NAc showed differences between compounds **5** and **6** of 0.16 and 0.17 ppm, respectively. A major difference was found in the fine structure of the α-H–β-H and α-H–β′-H cross-peaks of Ser^{10} in the phase-sensitive DQF–COSY spectra. In the spectrum of compound **5**, the downfield proton had a $^3J_{H\alpha,H\beta}$ = 6 Hz, whereas the upfield proton had a $^3J_{H\alpha,H\beta}$ = 4 Hz (no stereospecific assignments of the geminal β-H protons of Ser^{10} were made). In the spectrum of compound **6**, the peak pattern of these two cross-peaks was reversed; the downfield proton had a *J* value of 4 Hz, while the upfield proton had a *J* value of 6 Hz. These data indicated that the structure of the two compounds differed by the configuration of α-C of the Ser^{10} amino acid, which means that the serine residue substituted by the glycan would have been racemized during peptide synthesis.

Determination of configuration at [Ser^{10}]

The absolute configuration of the serine residues in the peptide chains of **5** and **6** was determined using the GC–MS method of Ström et al. (8) (see Experimental). The analysis showed that **5** contained L-Ser and D-Ser in the ratio 2:1, while **6** only contained L-Ser. Since two L-serine are present at the 2 and 7 positions in the peptide chain of compounds **5** and **6**, this indicates that **5** has a D-Ser at the site of glycosylation, whereas **6** has a L-Ser.

Conformational analysis of the peptide chain

Chemical shifts

The ^{1}H NMR chemical shifts measured for most of the amino acid residues in compounds **5** and **6** (Table 1) had values similar to those in random coils (9, 10). An exception was found for the α-protons of the residues at and around the glycosylation sites, α-H of Lys^{12} and α-H of Leu^{16} (Table 1, Fig. 2). The α-H signal of Ser^{10} in **5** and **6** showed downfield shifts of 0.17 and 0.11 ppm, respectively, as compared to the random coil values. In the Ser^{10}-glycosylated peptides **5** and **6**, the α-H signal of the preceding residue, Ala^9, had a chemical shift value close to that of random coil, whereas in the Thr^{10}-glycosylated peptides **1** and **3**, the α-H

[3] The mice were administrated intrathecally with a constant volume (5 μL) and then gently wrapped in a towel with the tail exposed. At various time points following the intrathecal injection, the tail was dipped in a water bath maintained at 54 °C and the time taken for the mouse to withdraw its tail recorded. If there was no withdrawal by 8 s, the tail was withdrawn to avoid tissue damage (A.G. Craig, unpublished results).

[a]Taken from ref. 4.

signal showed a large downfield shift of 0.17 and 0.13 ppm, respectively (4). The α-H signal of the second residue from the site of glycosylation (α-H Lys[12]) in **5** and **6** showed a large downfield shift of 0.20 and 0.25 ppm, respectively, as compared to the random coil value. This signal of Lys[12] was also shifted downfield with 0.25 ppm for the nonglycosylated peptide **2**, 0.24 ppm for the Ser[7] analogue **4**, and 0.14 and 0.15 ppm for the Thr[10] analogues **3** and **4**, respectively (4). This suggests that the downfield shift is mainly due to the neighbouring Pro[13], which is known to be "turn-inducing". In **5** and **6**, the α-H signal of Leu[16] is shifted upfield 0.17 and 0.19 ppm, respectively, as compared to the random coil values.

$^3\mathbf{J}_{NH,\alpha H}$ values

The $^3J_{NH,\alpha H}$ values were in the range 5.7–9.0 Hz in **5** and

[a]Taken from ref. 4.

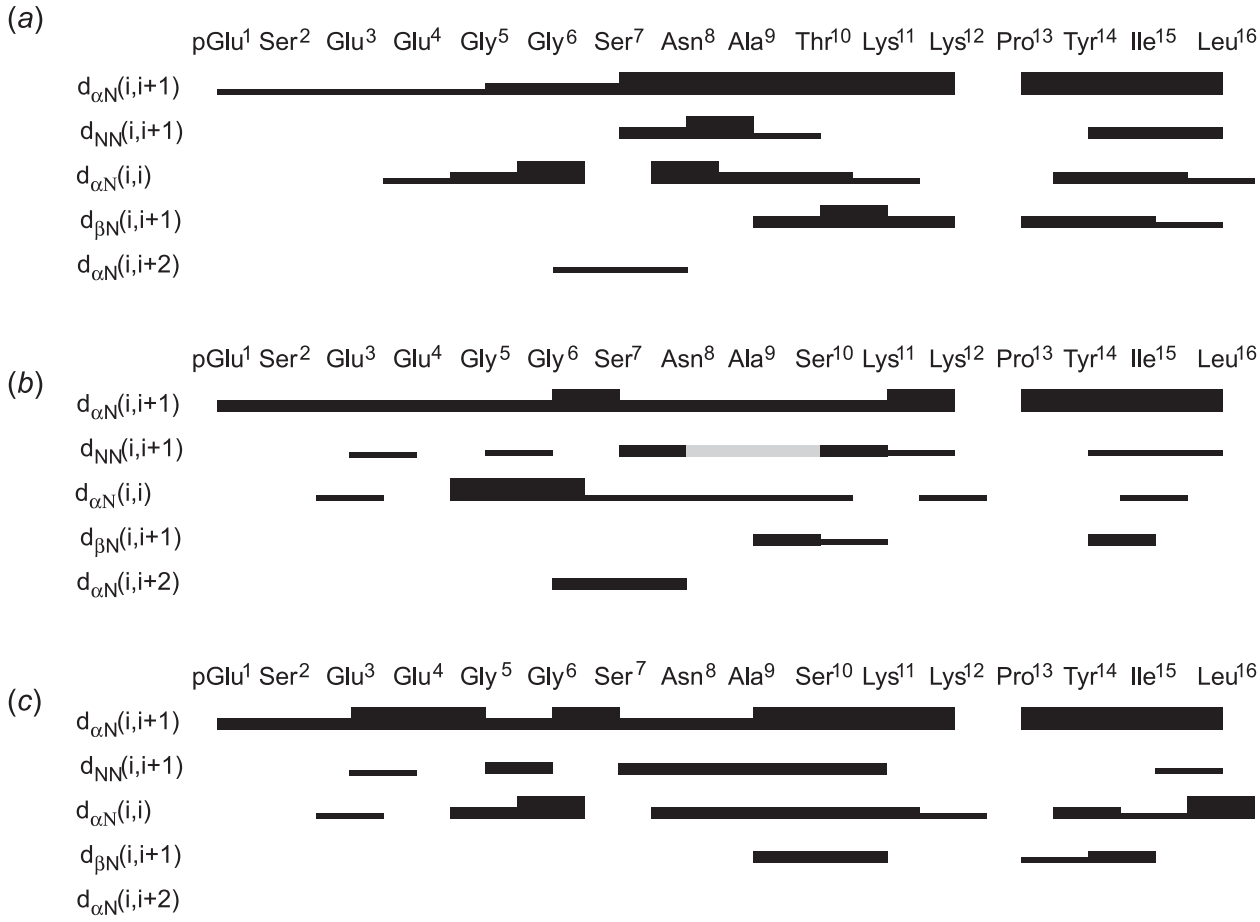
Fig. 1. One-dimensional ^{1}H NMR spectra of (*a*) **5** and (*b*) **6** recorded at 25 °C in D_2O. The arrows show the anomeric H-1 of α-D-Gal*p*NAc and β-D-Gal*p*, and the α-H of Ser^{10}.

6 (Table 3) and were very similar to the values measured in the (glyco-)peptide analogues **1**–**4** (4). These values suggested random coil or extended conformations. The $^3J_{NH,\alpha H}$ values of 8.6 and 9.0 Hz measured for Thr^{10} in contulakin-G (**1**) and in the analogue with α-D-Gal*p*NAc at Thr^{10}(**3**) were slightly larger than the corresponding value of 7.5 Hz measured in the nonglycosylated peptide (**2**) (4). This increase in the *J* value of **1** and **3** as compared to **2** was attributed to the presence of some ordered secondary structures in **1** and **3**. A larger $^3J_{NH,\alpha H}$ value was also measured for [D-Ser^{10}] in **5** (8.5 Hz) as compared to [L-Ser^{10}] in **6** (6.6 Hz) (Table 3). It should be noted that in analogue **4**, a value of 6.4 Hz was measured for the glycosylated Ser^7 (4). Furthermore all the nonglycosylated Ser residues in **1**–**6** had *J* values from 6.0 to 6.8 Hz.

Temperature coefficients for the NH protons

The temperature coefficients ($\Delta\delta/\Delta T$) for the NH proton signals from **5** and **6** were obtained in 95% H_2O – 5% D_2O solutions from a series of one-dimensional spectra recorded at sample temperatures between 5 and 45 °C (Table 3). The large $\Delta\delta/\Delta T$ values indicated that no hydrogen bonds or amide protons protected from solvent were present in the peptide chains.

NOEs in the peptide chain



In **5** and **6**, the sequential $d_{\alpha N}(i,i+1)$ NOE pattern characteristic of extended conformations was observed along the whole peptide chain (Fig. 2). Sequential $d_{NN}(i,i+1)$ NOEs were observed for residues 7–12 and 14–16 in **5**, and 7–11 in **6** (Fig. 3). However, none of the $d_{NN}(i,i+1)$ NOEs found in **5** and **6** were strong, suggesting a high degree of flexibility in glycopeptides **5** and **6**. The [D-Ser^{10}] glycopeptide **5** had a Gly^6-Asn^8 $d_{NN}(i,i+2)$ NOE indicative of a turn, also found in contulakin-G (**1**), but not in the [L-Ser^{10}] analogue **6**.

Carbohydrate–peptide interaction

In contulakin-G (**1**) and the α-D-Gal*p*NAc analogue **3**, a $\Delta\delta/\Delta T$ of –5.8 ppb/°C was measured for the NH of α-D-

Fig. 2. Intra- and inter-residue NOE signals involving the backbone NH protons in (*a*) contulakin-G (**1**) (taken from ref. 4), (*b*) **5**, and (*c*) **6**. The thickness of the lines represents the relative intensities of the NOE signals. Greyish lines represent overlapping NOEs. The NOESY were recorded at 5 °C with a mixing time of 300 ms.

Gal*p*NAc in water solution. This together with the NOEs between the glycan and the peptide chain and with the small $^3J_{H\alpha,H\beta}$(Thr^{10}) value (1.5 Hz in **1** and 2 Hz in **3**) indicated a torsional rigidity between the sugar and the peptide, enforced by a hydrogen bond interaction between the NH of α-D-Gal*p*NAc and Thr^{10}. In **5** and **6**, *O*-glycosylated at a serine residue, the large $\Delta\delta/\Delta T$ value obtained for the NH of α-D-Gal*p*NAc (–11.3 ppb/°C in **5** and –8.3 ppb/°C in **6**) showed that these protons are not protected from exchange with the solvent through hydrogen bond formation. Also, in **5** and **6**, the two $^3J_{H\alpha,H\beta}$ of Ser^7 had values in the range 4–6 Hz and the relative intensities of the two α-H–βH NOEs were similar. This indicated that the C_α—C_β bond is subject to conformational averaging, and that there is motion around the sugar–peptide linkage. The $^3J_{H\alpha,H\beta}$ value characteristic for conformational averaging ($^3J_{H\alpha,H\beta}$ ~ 6–8 Hz) is, however, not easy to distinguish from the corresponding value for the gauche rotamer ($^3J_{H\alpha,H\beta}$ ~ 4 Hz) only from the fine structure of the DQF-COSY cross-peaks, since there is a limitation in digital resolution and line widths. A few NOEs were found between the peptide and the carbohydrate moiety in **5** and **6** (Fig. 4). These were the NH(Ser^{10})–H-1(α-D-Gal*p*NAc), β-H(Ser^{10})–H-1(α-D-Gal*p*NAc), β′-H(Ser^{10})–H-1(α-D-Gal*p*NAc), β-H(Ser^{10})–H2(α-D-Gal*p*NAc), β′-H(Ser^{10})–H-2(α-D-Gal*p*NAc), and NH(Lys^{11})–H-1(α-D-Gal*p*NAc) NOEs. Two additional NOEs, NH(Ser^{10})–NH(α-D-Gal*p*NAc) and NH(Ser^{10})–CH_3CO(α-D-Gal*p*NAc), were found for compound **5**. These additional NOEs together with a larger $^3J_{NH,\alpha H}$(Ser^{10}) value of 8.5 Hz indicated that the average orientations of the glycan in the [D-Ser^{10}] analogue **5** and in the [L-Ser^{10}] analogue **6** were different. The $^3J_{NH,H2}$ of 9.7 Hz measured for Gal*p*NAc of **5** and **6** demonstrated a trans orientation of NH relative to C(2)H.

Our previous NMR study (4) on contulakin-G and analogues **1**–**4** together with the present work on **5** and **6** suggest that there is more local rigidity around the threonine segment, as in **1** and **3**, than around the serine segment, as in **4**–**6**. These conformational differences have previously been shown from NMR and molecular modelling studies for other *O*-linked glycopeptides (5, 6). In these studies, the galactosamine units at the Thr residue were in close contact with several peptide atoms, whereas the galactosamine units attached to Ser residues assumed more apical positions with the surrounding peptide backbones distanced from the sugar, allowing more rotational freedom around the glycosidic bond. On the other hand, another study showed that a Thr-linked glycan was positioned perpendicular to the peptide backbone, and had no hydrogen bond to the peptide (11). A recent NMR study on MUC1 glycopeptides also showed that glycosylation produced only localized effects on the confor-

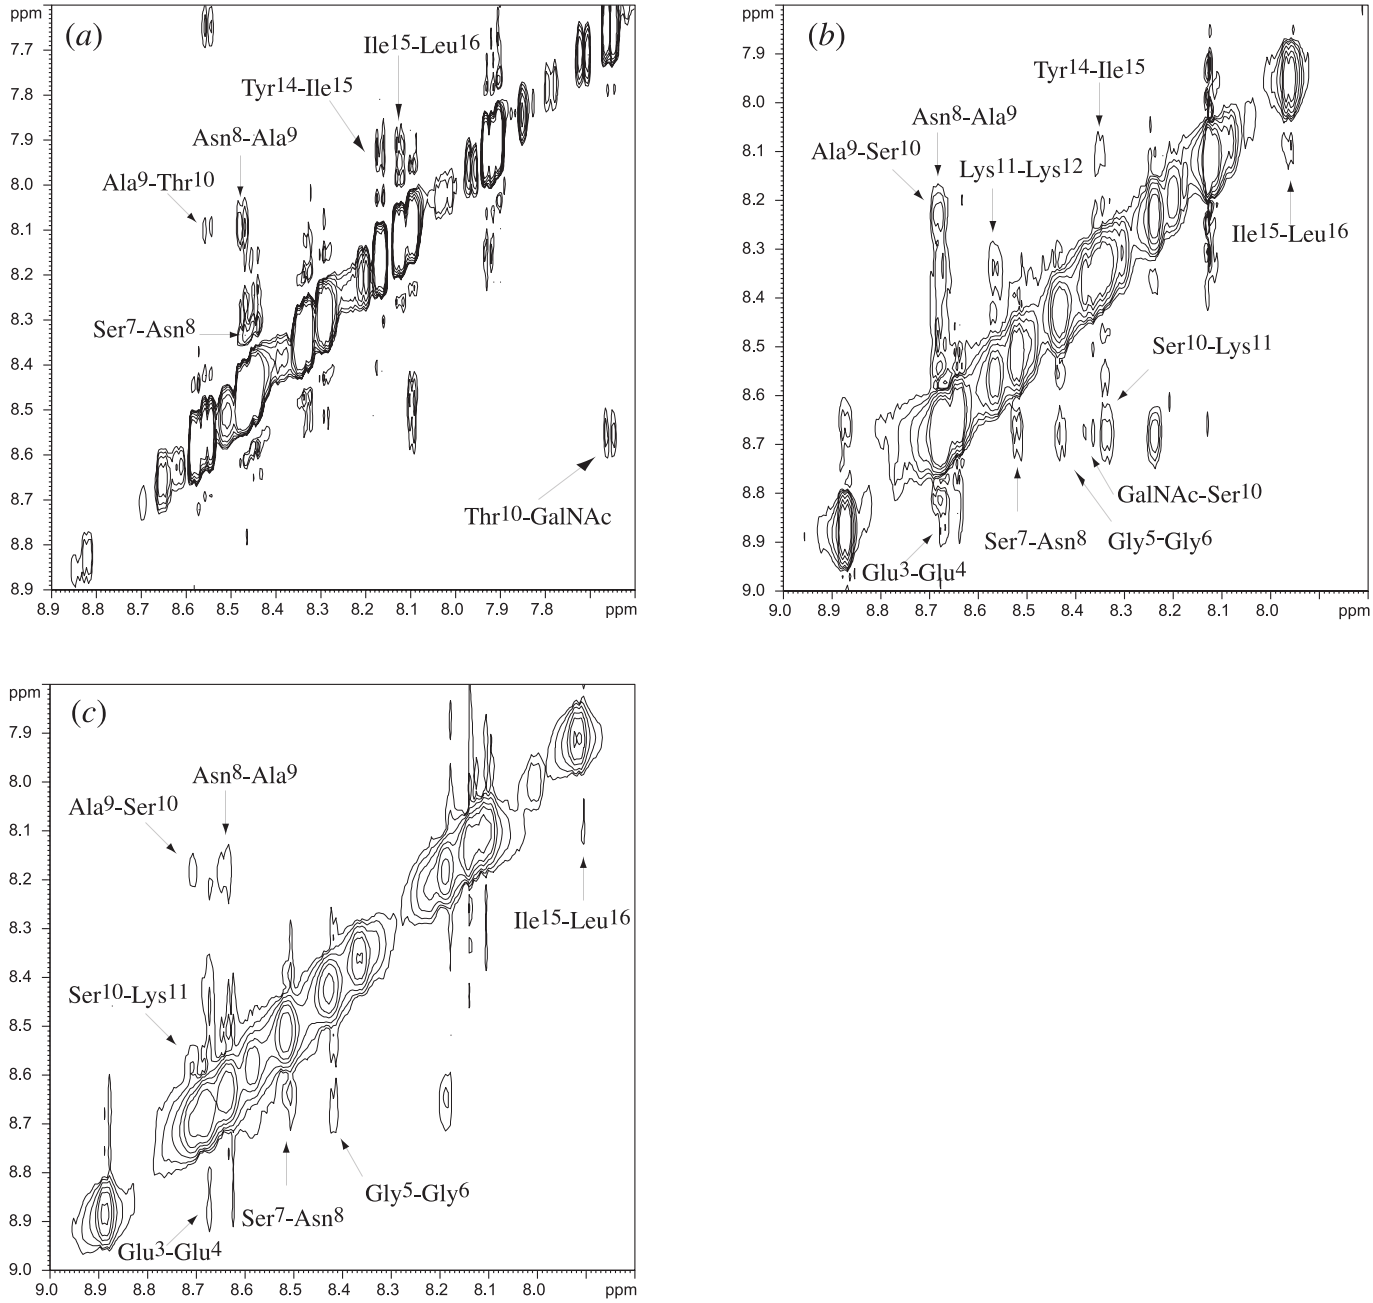
mation and the backbone dynamics of residues at or close to the site of glycosylation (12). The NMR data for **5** and **6** together with models obtained by MM2 suggested that, while there was no hydrogen bond interaction in the L- and D-serine analogues, the contacts between the peptide chain and the glycan were closer with a D-serine that with an L-serine. Because of the difference in chirality of the Ser[10] residue of **5** as compared to **6**, the backbone from Ser[10] to the amino acid 16 extended in opposite directions relative to the glycan in these two compounds. The disaccharide was bent away from the peptide chain in the [L-Ser[7]] enantiomer (**6**) whereas in the [D-Ser[7]] enantiomer (**5**), the glycan was positioned over the Lys[10]–Leu[16] chain.

Conclusions

Because of racemization, the synthesis of [Ser[10]]-contulakin-G yielded two diatereoisomers that have been characterized by ^{1}H NMR spectroscopy and GC–MS as the [D-Ser[10]]- and [L-Ser[10]]-contulakin-G. The absence of strong $d_{NN}(i,i+1)$ NOEs together with the temperature coefficients and $^3J_{NH,\alpha H}$ values indicated that the peptide chain in glycopeptides **5** and **6** predominantly existed in random coil or extended conformations. The NMR data also showed that there was no hydrogen bond between the peptide chain and the glycan. Thus, the hydrogen bond previously found in contulakin-G (4) does not seem to be of crucial importance for the biological activity. In contulakin-G (**1**) and in the [D-Ser[10]] analogue **5**, the NH(Ser[10])–NH(Gal*p*NAc), αH(Glu[6])–NH(Asn[8]), and consecutive NH(Tyr[14])–NH(Ile[15]) and NH(Ile[15])–NH(Leu[16]) NOEs were found, but these NOEs were not found in the [L-Ser[10]] analogue **6**. These differences in NOEs, together with the larger $^3J_{NH,\alpha H}$-value of 8.6 Hz for Thr[10] in contulakin-G (**1**) and of 8.5 Hz for D-Ser[10] in **5**, suggest that the ensemble average conformation of the [D-Ser[10]] analogue **5** resembles the conformation of contulakin-G (**1**) more than the [L-Ser[10]] analogue **6** does. The transient turn between residues 14 to 16 found in contulakin-G (**1**) and in [D-ser[10]]-contulakin-G (**5**), both with high biological activity, is probably not of importance for the biological activity. Previously, Craig et al. (1) concluded that *O*-glycosylation was a strategy of contulakin-G to enhance the binding affinity to neurotensin receptors. If the biological activity was due to binding of the glycopeptides to neurotensin receptors, and this transient C-terminal turn would be beneficial in the binding to these receptors, the turn would probably also have been found in conformational studies of this neurotensin. This is, however, not the case (13, 14). Previous proteolytic degradation studies showed that the glycan sterically inhibited the enzyme from hydrolysing the Pro[13]—Tyr[14] bond, and that this was a likely explanation to the high biological activity of contulakin-G.[2] The difference in the biological activity of [D-Ser[10]]-contulakin-G and [L-Ser[10]]-contulakin-G indicates that the orientation of the sugar relative to the peptide chain is important to protect against proteolytic degradation.



Experimental

Synthesis

Glycopeptides **5** and **6** were manually synthesized using a solid phase approach and Fmoc protection strategy, in a similar fashion as previously described (1). After cleavage of the peptide from the resin (100 °C, 2 h), the precipitate from the diethylether was dried. The product was then dissolved in 0.1% trifluoroacetic acid (TFA) and separated by HPLC

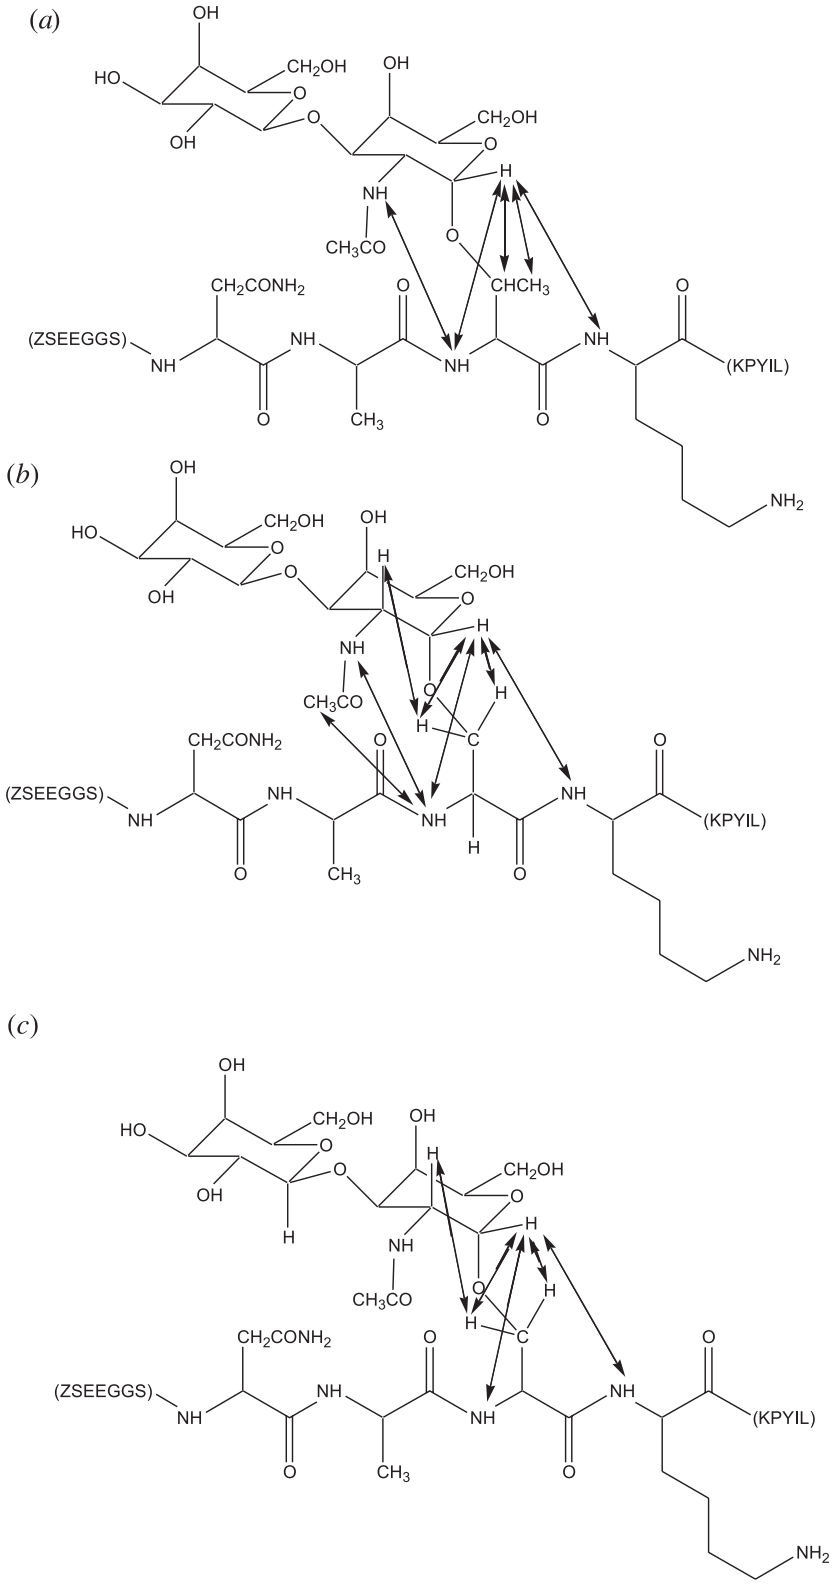
Fig. 3. The NH–NH region of the 2D NOESY spectra (mixing time 300 ms) of the glycopeptides **1**, **5**, and **6** in 95% H_2O – 5% D_2O. (*a*) Contulakin-G (**1**) (25 °C) (from ref. 4), (*b*) [D-Ser^{10}] analogue **5** (5 °C), and (*c*) [L-Ser^{10}] analogue **6** (5 °C).



using a C18 column, a buffer A = 0.1% TFA and a buffer B = 60% acetonitrile in 1% TFA; 1 min gradient from 20% B to 60% B. Two separate HPLC fractions eluted, the first at approximately the same time as contulakin-G and the second about 2 min later. The samples were lyophilised separately, and the glycan deprotected in a similar way as previously described (1). The samples were again purified by HPLC under the same conditions as described above. The purity of the final samples was >95% based on RP-HPLC with triethylamine (pH 6) as the ion pairing agent, and capillary zone electrophoresis. Analysis of the protected glyco amino acid on TLC indicated a pure starting material. The mass spectrum yielded the information that both compounds had the correct mass, and that both were glycopeptides. The samples were characterized with electrospray-MS on an ion trap instrument and MALDI-TOF MS, and both samples were found to have identical monoisotopic masses and superimposable isotope distributions.

Determination of absolute configuration by GC–MS

The absolute configuration of the serine residues in the peptide chains of **5** and **6** was determined by using the GC–MS method of Ström et al. (8). A small amount (<0.1 mg) of each peptide was hydrolysed by 6 mol L^{-1} hydrochloric acid.

Fig. 4. Schematic representation of inter-residual NOEs observed at the junction between the peptide and the glycan in (*a*) **1**, (from ref. 4), (*b*) **5**, and (*c*) **6**.

Prior to injection on the column, the acid function was esterified with (*S*)-(+)-butanol, and perfluoropropanoic acid was allowed to react with the amine and alcohol functions to make the amino acids more volatile. Reference samples were prepared by derivatisation of commercially available D- and L-serine as outlined above.

© 2005 NRC Canada

NMR spectroscopy

The samples were prepared by dissolving ~1 mg of glycopeptide in 50 µL 99.98% D_2O, H_2O–D_2O (95:5), or in a pH 5.6 buffer containing H_2O–D_2O (95:5, v:v), 100 mmol L^{-1} sodium chloride and 13.5 mmol L^{-1} sodium acetate. The solutions were then transferred into 1.7 mm NMR capillaries. All NMR experiments were performed on a Bruker DRX-600 spectrometer equipped with a 2.5 mm microprobe. The NMR spectra, unless specified, were recorded at 5, 15, or 25 °C. The temperature coefficients were calculated for the amide protons in H_2O–D_2O solutions using ^{1}H NMR chemical shift data measured by variation of the temperature from 5 to 45 °C in steps of 5 °C. The two-dimensional NMR spectra were recorded in the phase-sensitive mode using the TPPI method (15). For experiments on samples in D_2O, the residual HDO peak was suppressed by preirradiation at low decoupler power. For experiments in 95% H_2O – 5% D_2O, the WATERGATE pulse sequence was used for water suppression (16). The DQF–COSY and TOCSY spectra were typically acquired with 4K data points in t_2 and 512 points in t_1, and a repetition delay of 1.5 s. TOCSY were recorded with a mixing time of 100 ms. NOESY and ROESY spectra were recorded with mixing times (t_m) from 100 to 600 ms for NOESY and 150 ms for ROESY. 256 Spectra of 4K data points were acquired, and a repetition delay of 2.5 s was used. The ^{1}H NMR chemical shifts were measured relative to the resonance of the methyl signal of acetone (δ 2.225 ppm) added as an internal reference.

MM2 representations

Chem3D (R) version 4.0 for Windows 95 and NT was used. Minimization was performed with the "MM2" force field. The default convergence criterion was used (rms (root mean square) force 0.1 kcal mol^{-1} $Å^{-1}$).

Acknowledgements

This work was supported by grants from the Swedish Research Council. Professor Thomas Norberg is acknowledged for providing the sugars used in the synthesis of the glycopeptides. Many thanks to Dr. A.G. Craig for providing the two glycosylated contulakin-G analogues and the biological data.

Theoretical studies on the absorption and luminescent properties of a series of derivatives of 1,3-diphenyl-5-pyrene-2-yl-4,5-dihydro-1*H*-pyrazole

Xiao-Juan Liu, Ji-Kang Feng, Ai-Min Ren, Xin Zhou, and Hong Cheng

Abstract: The absorption and emission spectra for a series of substituted 1,3-diphenyl-5-pyrene-2-yl-4,5-dihydro-1*H*-pyrazole (DPPyP) molecules are computed by TDDFT methods. The solvent effect is modeled using the self-consistent reaction field (SCRF) method with Tomasi's polarized continuum model (PCM). The ground-state geometries were optimized by the Hartree–Fock method with the 6-31G basis set (and also with 3-21G* for molecule A) (HF/6-31G), and the lowest singlet excited-state geometries were optimized at the ab initio CIS level with the 6-31G basis set (CIS/6-31G). The calculated results indicate that the TDDFT method can reproduce the experimental values. We consider the effects of different basis sets on the optimization of the ground-state geometries. Specially, some insights on the differences observed for these compounds in changing the substituted donors (H, CH_3, and NH_2) and acceptor group (CN) are given; the results indicate that introduction of the donor groups will lead emission to be red-shifted, while introduction of the acceptor will induce the emission to be blue-shifted, which provides useful information for modulating light-emitting material colors.

Key words: absorption and emission, TDDFT, CIS, SCRF–PCM.

Résumé : Les spectres d'absorption et d'émission d'une série de 1,3-diphényl-5-pyrène-2-yl-4,5-dihydro-1*H*-pyrazole (DPPyP) ont été calculés par des méthodes « TDDFT ». On a modélisé l'effet du solvant faisant appel à la méthode de champ réactionnel autocohérent (« SCRF ») avec le modèle du continuum polarisé de Tomasi (« PCM »). On a optimizé les géométries de l'état fondamental par la méthode de Hartree–Fock, avec l'ensemble de base 6-31G (ainsi q'avec l'ensemble 3-21G* pour la molécule A) (HF/6-31G), et les géométries de l'état excité singulet d'énergie la plus faible ont été optimizées au niveau ab initio CIS avec un ensemble de base 6-31G (CIS/6-31G). Les résultats calculés indiquent que la méthode TDDFT permet de reproduire les valeurs expérimentales. Les effets des différents ensembles de base sur l'optimization des géométries de l'état fondamental ont été considérés. En particulier, on discute quelques explications possibles des différences observées pour ces composés lorsqu'on remplace des substituants donneurs (H, CH_3 ou NH_2) par un groupe accepteur (CN); les résultats indiquent que l'introduction de groupes donneurs conduit à une émission déplacée vers le rouge alors que l'introduction d'un groupe accepteur induit un déplacement de l'émission vers le bleu et que ces différences fournissent une méthode de moduler les couleurs émises par les matériaux qui émettent de la lumière.

Mots clés : adsorption, émission, TDDFT, CIS, SCRF–PCM.

Introduction

Considerable research efforts in recent years have been dedicated to the development of electroluminescent polymers and organic materials for use in light-emitting diodes (LEDs). The efforts were stimulated by the potential applications of these devices in the electronics industry. The main advantages of such LEDs over inorganic ones are that they are lightweight and have a large active area and flexibility. These factors favor their use in display technology. For ex-

ample in 1987, Tang and Van Slyke (1) reported on the interesting electroluminescent properties of multilayer devices using an organic material (Alq_3) as an emitter.

The basic structure of these stacked light-emitting devices typically has up to four organic semiconductor layers. Starting from the anode, the construction of a hole-injection layer (HIL) with a low ionization potential lowers the barrier controlling the injection of holes. It is covered by a hole-transport layer (HTL), which conducts the positive carriers to the confinement zone. In a symmetrical fashion, an electron-transport layer (ETL) and an electron-injection layer (EIL) just below the cathode perform the same functions but for negative carriers. The emitting layer is generally one of the transport layers. It can be intrinsically luminescent or doped with fluorescent molecules. The discovery of several important classes of organic materials with excellent transport, injection, and luminescent properties has enabled fabrication of high-performance multilayer device structures (2, 3). Recently, many hole-transport materials (HTM) with high glass transition temperatures (T_g), including starburst amines (4), spiro-linked amines (5), and those with rigid groups (6), have been investigated, such as *N*,*N*′-di-1-naphthenyl-*N*,*N*′-diphenyl-1,1′-bephenyl-4,4′-damine (α-NPD) (7) and 1,3,5-triaryl-2-pyrazoline compounds. But most of these compounds have low melting points and show poor thermal stability. Sano et al. (8) have demonstrated that pyrazoline dimers have higher melting points than pyrazoline monomers, and that stable amorphous films can be obtained by using these dimers. Some other works found that the introduction of condensed rings into the pyrazoline ring could also increase the melting point of the compounds (9–11). In these experiments, phenanthryl and pyrene groups were introduced into the 5-position of the pyrazoline ring. X-ray diffraction analysis shows that these molecules have nonplanar structure (10), and that there is strong π-stacking interaction in the solid state. This particular structure endues these molecules with good film forming ability and a high T_g of 96 °C. One popular approach to modulating the emissive color of organic materials is to introduce electron-withdrawing and (or) electron-releasing groups into the molecules. For example, tris (4-methyl-8-hydroxyquinoline) aluminum(III) (4-$Almq_3$) has received attention, because it has significantly higher photoluminescence and electroluminescence quantum yields.

However, few theoretical investigations of the luminescent properties for the pyrazoline derivatives mentioned above have appeared in the literature owing to the fact that the calculation of excited-state properties typically requires significantly more computational effort than is needed for the ground states. In present work, the geometries, absorption and emission properties of 1,3-diphenyl-5-pyrene-2-yl-4,5-dihydro-1*H*-pyrazole (DPPyP) derivatives, with the pyrene group introduced into the 5-position of the pyrazoline, were theoretically studied with the quantum chemical calculations. The transition energies were calculated at the ground-state and excited-state geometries using time-dependent density functional theory (TDDFT), and the results are compared with the available experimental data. The excited-state geometries were optimized at the ab initio CIS level of theory. Since the introduction of electron-withdrawing and (or) electron-releasing groups can modulate the emissive color, we connected donors (amino and methyl) and acceptor (cyanic) to the two phenyls to investigate their effects on the absorption and emission properties.

Fig. 1. The investigated molecules and the numbers for the pyrazoline ring.

Calculation details

The ground-state structures of the molecules were optimized at the Hartree–Fock level with the 6-31G basis set (HF/6-31G). The ab initio CIS (12) method was adopted to obtain the first singlet excited-state structures of the molecules. Vertical transition energies were evaluated with TDDFT (B3LYP/6-31G) as implemented in GAUSSIAN 98 at the optimized geometries obtained with 6-31G basis sets. The solvent effect is modeled using the self-consistent reaction field (SCRF) method with the Tomasi's polarized continuum model (PCM). The PCM model defines the solvent cavity as the union of a series of interlocking atomic spheres. The effect of the polarization of the solvent continuum is represented numerically: it is computed by numerical integration rather than by an approximation to the analytical form used in the Onsager model. Ionization potentials are obtained by calculating energy differences in the neutral ground-state and the cation ground-state geometries (the cation ground-state geometries are calculated using the restricted open shell Hartree–Fock–ROHF/6-31G method). These calculations were all carried out with the program package GAUSSIAN 98 (13).

Results and discussion

Molecular ground-state structures

The investigated molecules are shown in Fig. 1, their ground-state geometries are predicted at HF levels with 6-31G basis sets. Taking molecule A as an example, its equilibrium geometry is optimized using the HF method with both 3-21G* and 6-31G basis sets to investigate the basis set effect on the geometrical and electronic structures. Some selected interatomic bond lengths and bond angles of molecule A (DPPyP) are listed in Table 1, along with those of 1,3-diphenyl-5-(9-phenanthryl)-4,5-dihydro-1*H*-pyrazole (DPPhP), which is an analog of our investigated molecules given in the literature (14), while the dihedral angles among the planes of DPPyP are listed in Table 2. It can be seen that the calculated geometrical parameters are in good agreement

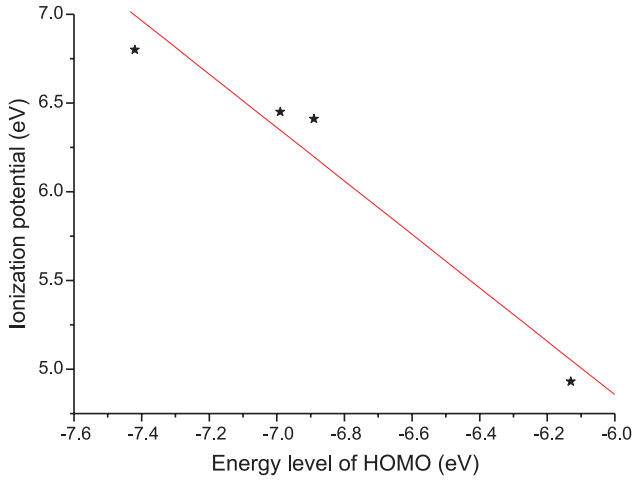
Fig. 2. Molecular orbital diagram summarizing the HF predicted energies and the main excitations.

with the X-ray diffraction experimental values. The bond length differences between molecule DPPyP and its analog DPPhP are 0.01~0.02 Å and the angles have a discrepancy within 1.5° except for the angles C(1)-C(6)-C(5), C(6)-C(7)-H(43), and C(6)-C(5)-C(19). Considering the different sterical effect between phenanthryl and pyrene, the discrepancy is reasonable. Table 2 shows that the two phenyl groups are conjugated with the pyrazoline ring and form a large conjugated π system, just like DPP. The dihedral angles formed by planes IV and I, II, III (see Fig. 1) in the investigated molecules are all a little larger than those in the analog DPPhP. These discrepancies between the two molecules are due to the sterically hindered group difference between phenanthryl and pyrene.



The bond angle of C(6)-C(7)-H(43) of 107.11° and the dihedral angle between planes II and IV of 81.0° suggest that the pyrene group extends outside the pyrazoline ring. Therefore, the introduction of the large polycyclic pyrene group decreases the symmetry of the compound and the resultant compounds A and other investigated molecules have nonplanar molecular structures, which is in agreement with the experimental results (10). Experimental results indicated that the nonplanar structure can prevent regular packing of molecules, and hence allows the formation of stable, amorphous films (10).

Molecular electronic structure

Electronic structures are fundamental to the interpretation and understanding of the absorption spectra. It has been found that the relative ordering of the occupied and virtual orbitals provides a reasonable qualitative indication of the excitation energies. The five highest occupied and five lowest virtual orbital energies for all the studied molecules calculated by HF/6-31G are given in Table 3. For a simple comparison, the schematic representation of the energy level of the orbitals and the main related electronic energy transitions are shown in Fig. 2. In Fig. 2, the solid lines represent that the molecular orbital is mainly made up of the atomic orbitals on pyrazoline; the dotted lines represent that the molecular orbital is mainly made up of the atomic orbitals on the pyrene. It can be found from Fig. 2 that introduction of donor groups (molecules B-CH_3 and C-NH_2) raises the

Fig. 3. The relationship between the energy of the HOMOs and ionization potentials.

HOMO a little, while introduction of an acceptor (molecule D-CN) lowers the frontier orbitals, when compared to molecule A, which has no substituted group.

Ionization energy (IP) is defined as the minimum energy necessary to bring an electron from the material into vacuum. According to Koopmans theorem, this energy value can be compared to the computed highest occupied molecular orbital energy level (HOMO). In this paper, the IPs are obtained by differences in the total self-consistent energies of the cation and the neutral states at the cation and neutral ground-state optimized geometries, respectively. The calculated values are also listed in Table 3. The calculated ionization potential energies are 6.45, 6.41, and 4.93 eV for molecules A, B, and C, respectively, and the 6.45 eV for molecule A corresponds to its experimental value of –5.61 eV. As for molecule D, its ionization potential is 6.80 eV. Comparing the values of IP with the energy values of HOMO, we found that they are indeed approximately equivalent with each other. To indicate their relationship, we plot the lines of IP vs. the energy of HOMO in Fig. 3. Fig. 3 shows that these points are almost in line, which verifies the Koopmans theory. In photoluminescent materials, the ionization potential of HTL is higher than that of HIL, so holes would enter from the HIL to the HTL layer freely after being injected from ITO (indium tin oxide). From this point of view, molecule C is a better candidate for use in a device than molecules B and D.

Electronic absorption spectra

Since the accuracy of the computed spectra are dependent upon the structural parameters used in the calculations, it is important to establish the quality of the computed structures by comparing the calculated spectra to available experimental data. Taking molecule A as an example, we calculated the absorptions on the optimized ground-state (S_0) geometries obtained with the HF/6-31G and HF/3-21G* methods, respectively. The calculated results are listed in Table 4, along with the experimental values. The TDDFT results indicate that there is a comparatively large discrepancy between the absorptions for the two geometries. This phenomenon indicates that the TDDFT method is sensitive to the molecular geometries, and comparing both the calculated absolute geometrical parameters and absorption with the experimental values, it was found that the 6-31G basis set based on the HF method is suitable for our investigated molecules, and the TDDFT (B3LYP/6-31G) model is good enough to predict the investigated molecular absorption spectra.

Table 4. The TDDFT calculated absorption properties in the gas phase, based on the HF-optimized geometries with 6-31G and 3-21G* basis sets.

It is well-known, both experimentally (15–20) and theoretically (21–26), that the presence of solvent strongly influences the optical response for many polar and nonpolar molecules compared to the gas phase. For our investigated molecules, based on the HF/6-31G optimized geometries, using the SCRF–PCM model, we calculated the absorptions both in the gas phase and in the acetonitrile (CH_3CN) solvent. The results are tabulated in Table 5. Firstly, we found that the solvent has a much stronger effect on molecule C than the other molecules. This result indicates that the introduction of a strong donor group (-NH_2) makes the molecule more polarized. Secondly, it was found that only when the solvent effect is considered in the calculation, the calculated results are in agreement with the change tendency with the substituent group. And the tendency is that with the substituent group strength increasing, the absorption is red-shifted (the absorption is 336, 338, and 360 nm for molecules A, B, and C, respectively). So it is necessary for our investigated molecules that the solvent effect should be considered in the spectra calculation. For all the studied molecules, the calculated excited energies (in nm), dominant orbital excitations, and oscillator strengths (*f*) from TDDFT calculations in the CH_3CN solvent are listed in Table 6. In the table we have reported only the active bands that are important for a complete characterization for the compounds. We begin with the spectrum of molecule A, and then discuss the donors (amine and methyl) and acceptor (cyanyl) substitution effects.

The strongest absorption of molecule A is located at 336 nm with 0.51 oscillator strength, which is in accordance with the experimental value of 345 nm, and this excited state mainly involves the transition from HOMO to LUMO + 1; the other two absorptions of 314 and 254 nm are mainly from the transitions of HOMO – 1 to LUMO and HOMO – 2 to LUMO, respectively (this also is shown in Fig. 2). In Fig. 4*a*, these molecular orbitals are plotted to provide a qualitative indication of the excitations. From Fig. 4, it can be easily found that the absorption at 336 nm comes from

the electron transition within the pyrazoline, while the other two absorptions of 314 and 254 nm can be seen as coming from the electron transitions within the pyrene. This result indicates that the absorption of molecule A is the combination of the absorption of the two chromophores (the pyrene and pyrazoline groups). This opinion is consistent with the experiment (10, 11). In the experiment (10), it was found that the absorption and emission are not affected by the introduction of the bulky phenanthryl substitution both in acetonitrile solution and in the solid film when comparing molecules DPPhP and DPP.

Similarly, the absorption characters of other molecules are analyzed in the same way as molecule A. Such as in molecule C (shown in Fig. 4*b*), the 360 nm absorption comes from the electron transition within the pyrazoline; the 268 and 247 nm absorptions come from the electron transitions within the pyrene, while the 306 nm absorption comes from the electron transition from pyrazoline to pyrene. In all, the introduction of the substituent of the amino group induces more electrons to distribute on the pyrazoline group. For molecule B from Fig. 2, we found that its absorptions are all within its constituent chromophores. Molecule D's absorption occurs mainly as an electron transition within constituent chromophores, with an absorption coming from pyrazoline to pyrene. In all, for our investigated molecules, their absorptions mainly come from the electron transitions within individual chromophores; and if a strong substituent group is introduced on pyrazoline, there exists some electron transition between the two chromophores, such as in molecules C and D.

Excited-state geometry calculations

Excited-state optimized geometries are important for the investigation of emission properties because structural relaxation after photoexcitation cannot be reproduced by ground-state optimization. The excited-state geometries were optimized at the ab initio CIS levels with the 6-31G basis set. We found that the geometry changes mainly happen on the pyrazoline group, especially on plane II (see Fig. 1), such as the R bond (18, 21) length is decreased by 0.037 Å from ground to excited state, and the angles related to plane II are all changed about 0.5°. We investigated the geometry relaxations upon excitation by consideration of the nodal patterns of the HOMO and LUMO orbitals (15). It is considered that if there are no nodes across the bond on HOMO, while there are nodes across the same bond on LUMO, then this bond will be elongated when the molecule changes from the ground state to the excited state; in contrast, if there is no nodal across the bond on LUMO, while there is a nodal across the same bond on HOMO, then this bond will be contracted. According to this rule, we investigated the bond length changes in molecule A. The nodal patterns are plotted in Fig. 5*b*, only plane II being shown. The HOMO has nodes across C(5)-C(19), C(5)-C(20), and C(18)-C(19) on plane II (for labelling see Fig. 5*a*), while LUMO has no nodes across these bonds; one would expect contraction of these bonds. Fig. 5*a* shows that these bonds are in fact considerably shorter in the excited state. The HOMO has no node across C(18)-C(28), while on LUMO this bond shows a node across it, and the data in Fig. 5*a* confirms the anticipated elongation of these bonds.

Emission properties

Based on the excited-state geometry optimization by CIS/6-31G, we carried out the emission calculation using TDDFT/6-31G in the CH_3CN solvent (using the same model as absorption). The calculated results are shown in Table 7; the experimental data are included for comparison. The TDDFT calculated value of molecule A is located at 423 nm, which is in agreement with the experimental value of 440 nm in CH_3CN solvent. When the substituent groups are amine and methyl for molecules B and C, their emissions are red-shifted, positioned at 431 and 501 nm, respectively, while the cyanyl substituent makes the emission blue-shift (418 nm).

The calculated Stokes shift values, the differences between the absorption and emission λ_{max} values, are compared with the experimental values. TDDFT calculated results (B3LYP/6-31G model) based on the excited-state optimized geometries by CIS/6-31G reproduced experimental emission well. The TDDFT-calculated Stokes shift (87 nm) for molecule A is in good agreement with the experimental data (95 nm). Furthermore, molecule C has the largest Stokes shift in these molecules, indicating that during the excitation the nuclei position has a comparatively large change in molecule C than incompared with the other molecules.

Conclusions

We have calculated the ground- and excited-state geometries using the HF/6-31G and CIS/6-31G methods, respectively. The calculated geometrical parameters are in good agreement with available X-ray diffraction data. Comparison of the CIS/6-31G optimized excited-state structures and the

HF/6-31G ground-state structures indicates that the geometric shift is mainly confined to the pyrazoline part (plane II). Basis sets effects on the absorption properties are discussed taking molecule A as an example. The absorptions on these two geometries (optimized here using HF/6-31G and HF/3-21G*) were calculated by TDDFT methods, the results indicating that the TDDFT method is sensitive to the geometries and can give reliable results for the absorption values. Using the CIS-optimized structure of the excited state, TDDFT calculations predict an emission wavelength of 423 nm, which is comparable to 440 nm, which is observed experimentally in the acetonitrile solvent. The Stokes shift calculated by TDDFT is 87 nm, in agreement with the observed value of 95 nm. The TDDFT provides a good method to calculate the Stokes shift for these molecules.

The calculated results indicate that the introduction of donor groups will lead the molecular emissions to be red-shifted, and introduction of an acceptor will lead the luminescence to be blue-shifted, which is useful for modulating the emission color in practical light-emitting materials and the holes transition.

A synthetic, structural, and ^{113}Cd NMR study of cadmium complexes of 1,3-thiazolidine-2-thionate, including the structures of $Cd(C_3H_4NS_2)_2$, $(Cd(C_3H_4NS_2)_2(C_5H_5N)_3 \cdot C_5H_5N$, and $(Ph_4P)_2[I_2Cd(\mu\text{-}C_3H_4NS_2)_2CdI_2]$

Donald C. Craig, Ian G. Dance, Philip A.W. Dean, James M. Hook, Hilary A. Jenkins, Christopher W. Kirby, Marcia L. Scudder, and Umarani Rajalingam

Abstract: The crystallization of cadmium bis(1,3-thiazolidine-2-thionate), $Cd(C_3H_4NS_2)_2$ (**1**), is reported. Freshly prepared **1** reacts with $Ph_4P^+X^-$ in a 1:2 ratio to give $(Ph_4P)_2[Cd_2(C_3H_4NS_2)_2X_4]$ (X = I (**4**) or Br (**5**)). Crystallization of **1** from pyridine produces a solvate **7**, which loses pyridine readily. X-ray analyses show that **1** has a polymeric sheet structure in which the $C_3H_4NS_2^-$ ligands act as bidentate bridges through N and the exocyclic S and the Cd has a CdN_2S_2 kernel; **5** is isomorphous with **4**, which contains a dimeric anion again with bridging through the N and exocyclic S of the heterocyclic ligands; and **7** is $Cd(C_3H_4NS_2)_2(C_5H_5N)_3 \cdot C_5H_5N$, containing trigonal bipyramidal $Cd(C_3H_4NS_2)_2(C_5H_5N)_3$ molecules, in which the $C_3H_4NS_2^-$ ligands, both of which are monodentate and in equatorial positions, occur as a unique combination of S- and N-bound. Cadmium-113 NMR data for **1** in pyridine solution and solid-state CP-MAS ^{113}Cd data for **1**, **7**, bis(pyridinium-4-thiolate)cadmium, and tetrakis(pyridinium-2-thiolate)cadmium nitrate are reported and discussed. The compound **1** has chemical and NMR spectroscopic properties that make it a useful standard for solid-state CP-MAS ^{113}Cd NMR spectroscopy.

Key words: cadmium, 1,3-thiazolidine-2-thionate, X-ray analysis, solid-state ^{113}Cd NMR, ^{113}Cd NMR standard compound.

Résumé : On a effectué la cristallisation du bis(1,3-thiazolidine-2-thionate) de cadmium, $Cd(C_3H_4NS_2)_2$ (**1**). Le composé **1** fraîchement préparé réagit avec le $Ph_4P^+X^-$ dans un rapport 1 : 2 pour conduire à la formation de $(Ph_4P)_2[Cd_2(C_3H_4NS_2)_2X_4]$ (X = I (**4**) et Br (**5**)). La cristallisation du composé **1** dans la pyridine conduit à la formation du produit solvaté **7** qui perd facilement de la pyridine. Les données de la diffraction des rayons X montrent que le composé **1** existe dans une structure en feuillets polymériques dans laquelle les ligands $C_3H_4NS_2^-$ agissent comme ponts bidentates entre l'azote et le soufre exocyclique et que le cadmium se trouve dans un noyau CdN_2S_2; que le composé **5** est isomorphe de **4** qui contient un anion dimère qui se lie lui aussi par des ponts à l'azote et au soufre exocyclique des ligands hétérocycliques; que **7**, $Cd(C_3H_4NS_2)_2(C_5H_5N)_3 \cdot C_5H_5N$, comporte des molécules bipyramidales trigonales $Cd(C_3H_4NS_2)_2(C_5H_5N)_3$ dans lesquelles les ligands $C_3H_4NS_2^-$, qui sont tous les deux monodentates et dans des positions équatoriales, se retrouvent comme une combinaison unique avec des liaisons au soufre et à l'azote. On a obtenu et on discute des données de RMN du ^{113}Cd pour le composé **1**, en solution dans la pyridine, et des données de « CP-MAS » à l'état solide du ^{113}Cd pour les composés **1** et **7**, le bis(pyridinium-4-thiolate)cadmium et le nitrate de tétrakis(pyridinium-2-thiolate)cadmium. Le composé **1** a des propriétés chimiques et spectroscopiques qui pourraient le rendre utile comme standard pour la spectroscopie RMN ^{113}Cd « CP-MAS » à l'état solide.

Mots clés : cadmium, 1,3-thiazolidine-2-thionate, diffraction des rayons X, RMN du ^{113}Cd à l'état solide, composé standard pour la RMN du ^{113}Cd.

Introduction

An interest (1) in cadmium complexes of heterocyclic thione donor ligands, including 1,3-thiazolidine-2-thione (tztH), has led us into an investigation of complexes containing cadmium and the 1,3-thiazolidine-2-thionate anion (tzt^-). The compound $Cd(tzt)_2$ was first reported in this journal in 1976 (2*a*). It was suggested that the structure was polymeric and based on tetrahedrally coordinated metal ions. However, the compound has never been characterized structurally, and to our knowledge there are no other structurally characterized examples of complexes of Cd with the tzt^- ligand either.

Heterocyclic thionates, including tzt^-, are known to be versatile ligands (3, 4). A search of the Cambridge Structural Database[4] (CSD) (5) revealed that the following bonding modes occur for the tzt^- ligand in structurally characterized examples: monodentate bonding through sulfur (found in only two examples, MeHg(tzt) (6) and $(Ph_3P)Au(tzt)$ (7)); a single example of monodentate bonding through N, reported since the completion of our work (8); N,S-chelation; and bridging, which usually involves both N and the exocyclic S, although a single example of bridging solely through the exocyclic S is known (9). Of these, the N,S-bridging mode predominates.

In this paper, we describe the structure of $Cd(tzt)_2$, as well as the synthesis and characterization of two other cadmium complexes of tzt^-.

Experimental

Materials

Tetraphenylphosphonium bromide and iodide, pyridine-2- and pyridine-4-thiols (py2SH and py4SH), $Cd(NO_3)_2{\cdot}4H_2O$, and $Cd(OAc)_2{\cdot}2H_2O$ were commercial products and used as received. Thiazolidine-2-thione (Aldrich) was recrystallized from water before use. Spectroscopic-grade pyridine was dried over NaOH before use. All other solvents were spectroscopic grade and were stored over 3 Å molecular sieves.

Synthesis of $Cd(tzt)_2$ (1) and $Cd(py2S)_2$ (2)

Compounds **1** and **2** were synthesized (and, for **2**, recrystallized) by the literature methods (2, 10). The salt $[Cd(py2SH)_4](NO_3)_2$ was prepared as reported previously (1*a*, 11).

Synthesis of $Cd(py4S)_2$ (3)

Compound **3** was prepared in the same way as **2**. Anal. calcd. for $C_{10}H_8CdN_2S_2$: C 36.08, H 2.42, N 8.42; found: C 35.85, H 2.38, N 8.48.

Synthesis of $(Ph_4P)_2[I_2Cd(\mu\text{-}C_3H_4NS_2)_2CdI_2]$ (4)

A solution of tztH (0.066 g, 0.55 mmol) and Et_3N (0.075 mL, 0.53 mmol) in CH_2Cl_2 (3 mL) was added with stirring to a mixture of $Cd(NO_3)_2{\cdot}4H_2O$ (0.076 g, 0.27 mmol) in 10 mL of MeCN, causing formation of a white precipitate. To the mixture was added solid Ph_4PI (0.233 g, 0.500 mmol), causing the precipitate to dissolve. Diethyl ether was added until turbidity was apparent, at which point the container and contents were placed in a freezer for several days. The colourless crystals that formed were washed with diethyl ether and dried in vacuo. Yield: 0.029 g, 14%. Anal. calcd. for $C_{54}H_{48}Cd_2I_4N_2P_2S_4$: C 39.36, H 2.94, N 1.70; found: C 40.29, H 2.87, N 2.11. The formulation of the compound was confirmed by a single-crystal X-ray analysis (see below).

Synthesis of $(Ph_4P)_2[Br_2Cd(\mu\text{-}C_3H_4NS_2)_2CdBr_2]$ (5)

A solution of $Cd(NO_3)_2{\cdot}4H_2O$ (0.076 g, 0.25 mmol) in 3 mL of MeCN was added with stirring to a mixture of tztH (0.058 g, 0.49 mol) and Et_3N (0.069 mL, 0.49 mmol) in 3 mL of MeCN. To the white precipitate was added solid Ph_4PBr (0.206 g, 0.491 mmol), causing dissolution of the precipitate. Thereafter, diethyl ether was added, and colourless crystals were obtained and isolated as for **4**. Yield: 0.074 g, 41%. Anal. calcd. for $C_{54}H_{48}Br_4Cd_2N_2P_2S_4$: C 44.43, H 3.31, N 1.92; found: C 44.77, 44.89, H 3.04, 2.82, N 2.07, 2.07. Unit cell parameters for **5** at 294 K: monoclinic, a = 9.650(2) Å; b = 16.156(3) Å; c = 18.361 Å; β = 102.78(1)°.

Other attempted syntheses of $(Ph_4P)_2$ $[Cd_2(tzt)_2X_4]$

Attempts to prepare **4** and **5** rationally, by the stoichiometric reaction of $Cd(tzt)_2$, Ph_4PX, and CdX_2 (X = Br or I) in MeCN, were not successful; dissolution of the reactants was incomplete, and the colourless crystals isolated from the supernatant liquor were found by X-ray analysis to be $(Ph_4P)_2[Cd_2X_6]$.

Crystallization of 1

Colourless crystals of **1** were obtained by liquid diffusion at room temperature: in a vial of approximate dimensions 2.5 cm o.d. × 8 cm, a solution of tztH (0.120 g, 1.01 mmol) in a mixture of EtOH (8.5 mL) and DMSO (1.5 mL) was allowed to diffuse into a solution of $Cd(OAc)_2{\cdot}2H_2O$ (0.135 g, 0.51 mmol) in 10 mL of water, through an intervening 10 mL layer of EtOH and H_2O (1:1 (*v*/*v*)).

Attempted crystallization of 3

An attempt was made to crystallize **3**, by the method used to crystallize **1** (see preceding section). The yellow crystals that were produced were found, by complete X-ray analysis, to be $Cd(py4S)_2(py4SH)_2$ (**6**), which had been characterized independently (12).

Crystallization of 7, the pyridine solvate of 1

Following ref. 10, an attempt was made to crystallize **1** from pyridine. The colourless crystals that were produced were shown by X-ray analysis to be $Cd(tzt)_2(py)_3{\cdot}py$ (**7**) (see below). This adduct loses pyridine on standing at room temperature, although the loss is not complete even after pumping the adduct under preparative vacuum for 24 h. Anal. calcd. for $3Cd(tzt)_2{\cdot}py$, $C_{23}H_{29}Cd_3N_7S_{12}$ of the pumped product: C 24.54, H 2.60, N 8.71; found: C 24.54, 24.27, H 2.62, 2.28, N 9.12, 8.72.

NMR spectra

Solutions of $Cd(tzt)_2$ in pyridine were prepared in 10 mm o.d. NMR tubes under an atmosphere of argon. Their ^{113}Cd NMR spectra were measured using a Varian INOVA 400

[4] Version 5.25, including three updates.

© 2005 NRC Canada

spectrometer system, at 88.663 MHz, without a field-frequency lock; negligible field drift occurred. Decoupling was inverse-gated since ^{113}Cd has a negative Overhauser effect. The pulse width used was 9.5 μs (68°), the acquisition time was 1 s, and the re-cycle time was 4 s. After each temperature change, 30 min was allowed to reach a steady state before the spectrum was measured. External referencing was carried out by sample interchange using an aqueous solution of $Cd(ClO_4)_2$ (0.1 mol/L), at 299 K. Temperatures were calibrated using the ^{1}H NMR spectrum of MeOH (13) when no decoupling was used, and the heating effect of decoupling was measured using a 1:1 (*v*/*v*) CCl_4–Me_2CO mixture (14).

CP-MAS solid-state ^{113}Cd NMR spectra were measured at either the University of New South Wales (UNSW), using a Varian Inova-300 spectrometer system operating at 66.5 MHz, or the University of Western Ontario (UWO), using a Varian Infinity Plus 400WB spectrometer system operating at 88.6 MHz, at 303 and 293 K, respectively, with a range of spinning speeds. The samples, dry powders, except for microcrystalline **7**, which was damp with pyridine, were contained in 4 mm (UNSW) or 7.5 mm (UWO) pencil-design spinners made of partially stabilized ZrO_2. Optimal conditions were found by experimentation. Typical conditions (MAS rates, ^{1}H pulsewidth (μs and degrees), contact time, re-cycle time, acquisition time, spectral window) used at UNSW were: 2–8 kHz, 3.3 μs (90°), 20 ms, 60 s, 10 ms, and 100 kHz. Those at UWO were 3–6 kHz, 6 μs (90°), 15 ms, 60 s, 3.0 ms, and 166.67 kHz. Referencing was by sample interchange with solid $CdSO_4{\cdot}8H_2O$ (δ_{Cd} = –64.6/–77.4 relative to 0.1 mol/L $Cd(ClO_4)_2$ (aq) (15)) and with solid $Cd(tzt)_2$ at UNSW and UWO, respectively. Isotropic signal positions were found by comparing spectra measured at two or more spinning rates.

All simulations of the MAS spectra were carried out by first converting to Bruker format and then using the Bruker WINFIT program to obtain the following parameters: the principal components δ_{11}, δ_{22}, and δ_{33} with $\delta_{11} > \delta_{22} > \delta_{33}$; δ_{iso} (= $1/3(\delta_{11} + \delta_{22} + \delta_{33})$); and asymmetry factor η (= $(\delta_{11} - \delta_{22})/(\delta_{iso} - \delta_{33})$). The span Ω and the skew κ were calculated as $\Omega = \delta_{33} - \delta_{11}$, and $\kappa = 3(\delta_{iso} - \delta_{22})/\Omega$. (16). The values of δ have an estimated error of ±1 ppm.

X-ray structure determinations

Crystals of **1**, **6**, and **7** were obtained as described above. Crystals of **4** were obtained from a saturated solution in CH_2Cl_2, while crystals of **5** were obtained during the synthesis. The data crystals were mounted on silica (UNSW), glass (UWO), or mohair (University of Sydney) fibres.

Data for **1** and **6** were collected at ambient temperature (294 K) at UNSW using a Nonius CAD4 diffractometer, equipped with CAD4 software.[5] Data reduction used the CAD4 software and a local program. Structure solution and refinement on *F* were accomplished using SIR92 (17) and RAELS (18), respectively. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and were assigned the isotropic equivalent thermal parameter of the atom to which they are bonded.

Data for **4** and unit cell data for **5** were obtained at 294(2) K at UWO with a Siemens P4 diffractometer, using XSCANS software. The data for **4** were processed, and full-matrix least-squares refinement on F^2 was performed, using direct methods and the SHELXTL 5.03 program package (19). All non-hydrogen atoms of both the cations and the anion were refined with anisotropic thermal parameters. Hydrogen atoms were included in positions calculated on geometric grounds and were included as riding atoms in the structure factor calculations.

Data for **7** were collected at Sydney University using a Bruker SMART 1000 CCD diffractometer. The temperature used was 250(2) K, with the crystal being cooled by a cold nitrogen gas stream from an Oxford Cryosystems Cryostream. (Crystals of **7** lose pyridine at room temperature, as noted above, and were also observed, during setting up of the X-ray diffractometer for data collection at reduced temperature, to undergo a destructive phase transition at approximately 212 K). Data processing, structure solution, and refinement for **7** were as for **1** and **6**, except that TLX group thermal parameters were used for the four independent pyridine rings (where T is the translation tensor, L is the libration tensor, and X is the origin of libration).

Details of data collection and refinement for **1**, **4**, and **7** are given in Table 1. Selected interatomic distances and angles for the three structures appear in Tables 2, 3, and 4, respectively. Full crystallographic data for **1**, **4**, **6**, and **7** have been deposited as Supplementary data.[6] All figures resulting from the X-ray analyses were created using CrystalMaker (20).

Elemental microanalyses

C, H, and N microanalyses were carried out by Campbell Microanalytical Laboratory (University of Otago, New Zealand) (for **3**) and Guelph Analytical Laboratories Ltd. (Guelph, Ont.) (for **4** and **5**, and for **7** after pumping).

Results and discussion

Bulk **1** is easily prepared but, once isolated, is intractable, and a polymeric structure has been suggested (2); that suggestion is confirmed in the present work. Our attempts to solubilize pre-prepared **1**, by addition of $Ph_4P^+X^-$ (X = Br or I) in a $Cd(tzt)_2$:$Ph_4P^+X^-$ ratio of 1:2 to break up the polymeric structure as $Cd(tzt)_2X_2^-$, were unsuccessful. However, mixtures in which Cd^{2+}:tzt^-:$Ph_4P^+X^-$ = 1:2:2, with the $Cd(tzt)_2$ freshly prepared in situ, gave $(Ph_4P)_2[X_2Cd(tzt)_2CdX_2]$ (X = I (**4**) or Br (**5**)) in low yield as the unexpected products. The compound **4** has been characterized structurally in this work, and **5** has been found to be isomorphous, and presumably

$3Cd(tzt)_2{\cdot}py$ remains after **7** has been pumped for 24 h. The pumped material gave no solid-state ^{113}Cd NMR spectrum in our hands; thus, it is not simply a mixture of **1** and **7**.

Crystal structure of $Cd(tzt)_2$ (1)

The structure of **1** is polymeric, as predicted (2), with puckered sheets lying perpendicular to the *c* axis (Figs. 1 and 2). Within a sheet (Fig 1*a*), each tzt^- ligand acts in an N,S-bridging manner, through N and the exocyclic S, as is commonly found for this ligand (see Introduction). Accordingly, each cadmium atom is four-coordinate, the coordination kernel being CdN_2S_2. The organic moieties are on the surface of the layers and "insulate" each layer from the next (Fig 1*b*), as is frequently observed in metal–organic layer structures. Selected bond distances and angles are given in Table 2.

Within the CdN_2S_2 kernels of **1**, the Cd—S1A and Cd—S1B distances are 2.498(1) and 2.557(1) Å, respectively, which can be compared with the known ranges of 2.41–2.68 Å for Cd bound to a terminal thiolate S atom and 2.45–2.65 Å for Cd bound to a terminal thione S atom, as reported in the CSD, and with Cd—S bond distances of 2.531(2) Å in **4** and 2.551(1) Å in **7** (see below). The Cd—N1A and Cd—N1B distances, 2.259(3)and 2.201(3) Å, can be compared with the Cd—N distance of 2.245(5) Å found for the bridging ligands in **4** and that of 2.227(2) Å found for the monodentate N-bound tzt^- in **7** (see below). The bond angles at Cd range from 100.86(9)° to 123.37(9)°, so that the geometry is distorted tetrahedral, a common situation for Cd.

In the structure, there are eight-membered Cd-S-C-N-Cd-S-C-N rings in the boat conformation, with twofold symmetry. The two heterocyclic rings (A) that are joined to the eight-membered ring are in *syn* positions. Each A ring together with its exocyclic S is essentially planar (the maximum deviation from the least-squares plane is 0.04 Å). The N1A–Cd vector makes an angle of 77.9(1)° with the perpendicular to the plane. The C1A-S1A-Cd bond angle is 97.3(1)°.

Within the tzt^- ligands B, which are not involved in the eight-membered Cd-S-C-N-Cd-S-C-N rings, the twisted conformation is found, with C2B and C3B on opposite sides of the N1B,C1B,(S1B),S2B plane (for which the maximum deviation is 0.01 Å) and 0.24 and 0.32 Å out of the plane. The N1B–Cd vector makes an angle of 81.8(1)° with the perpendicular to the N1B,C1B,(S1B),S2B plane. The C1B-S1B-Cd bond angle is 103.7(1)°.

Crystal structure of $(Ph_4P)_2[I_2Cd(tzt)_2CdI_2]$ (4)

The crystal structure of **4** contains segregated columns of Ph_4P^+ cations and $[I_2Cd(tzt)_2CdI_2]^{2-}$ anions, along the *a* direction (Fig. 3). The cation chains are made up of pairs of Ph_4P^+ ions linked through sixfold phenyl embraces (21), with a P···P distance of 5.96 Å; adjacent pairs are linked through offset face-to-face interactions (21) with a longer

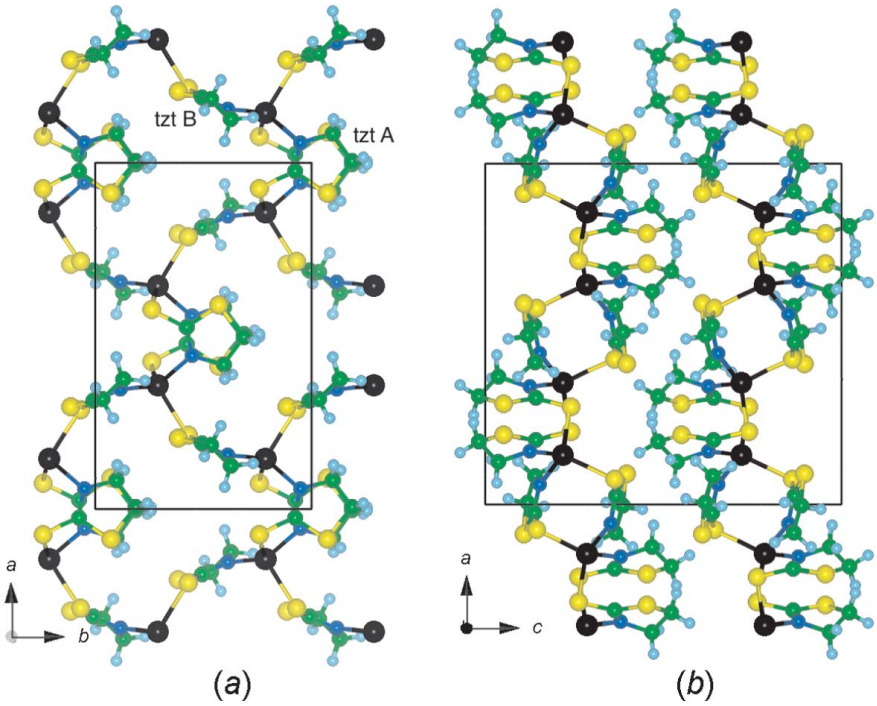
Fig. 1. Views of the structure of $Cd(tzt)_2$ (**1**): (*a*) along *c* showing a sheet and the two different types of tzt^- ligands; (*b*) along *b*, showing the corrugated sheets. Colour code: Cd, black; S, yellow; N, blue; C, green; H, cyan.



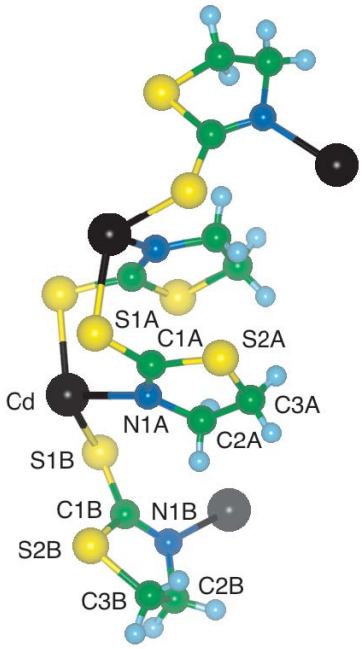


Fig. 2. A fragment of the structure of $Cd(tzt)_2$, giving the numbering scheme and showing the eight-membered Cd-S-C-N-Cd-S-C-N ring in the boat conformation.

P···P distance of 8.14 Å. The cations are otherwise unremarkable. Within the chains of anions, the repeat distance is *a* (9.87 Å). Figure 4 shows an anion, with the numbering scheme used. Selected bond distances and angles for the anion in **4** are presented in Table 3.

The centrosymmetric anion contains an eight-membered Cd-S-C-N-Cd-S-C-N ring in the chair conformation, with the tzt rings bonded through N and exocyclic S and occupying *anti* positions at the head and the foot of the chair. We note that eight-membered rings are found in the structure of **1** also; however, the conformation of the eight-membered rings in the (discrete) anions of **4** differs from that found for the eight-membered rings found in (polymeric) **1**. Within the anion, the tzt rings have an envelope conformation (the flap, C3, is 0.39 Å out of the least-squares plane of C2,N1,C1,(S1),S2; the N1–Cd vector lies essentially *in* this plane, the mean deviation of the atoms in the C2,N1,Cd,C1,(S1),S2 plane being 0.014 Å. The coordination kernel of Cd is $CdNSI_2$. The Cd—S distance is 2.531(2) Å, which falls between the two Cd—S distances of **1**. The Cd—N distance, 2.245(5) Å, is not statistically different from the longer Cd—N distance of **1** (2.259(3) Å) but is longer than the Cd—N distance of 2.227(2) Å found for the N-bonded tzt^- in **7** (see below). The Cd—I1 and Cd—I2 distances, 2.8057(7) and 2.7222(7) Å, fall within the range reported in the CSD for the terminal bonds of $[I_2CdI_2CdI_2]^{2-}$ and $[I_2Cd(\mu\text{-}SEt)(\mu\text{-}I)CdI_2]^{2-}$ (2.68–2.81 Å). The bond angles at Cd range from 96.19(5)° to 117.86(5)°, and the coordination geometry about Cd is again distorted tetrahedral. The C1-S1-Cd bond angle is 105.8(2)°, while the C1-N1-Cd angle is 122.2(4)°.

Crystal structure of $Cd(tzt)_2(py)_3{\cdot}py$ (7)

The structure of **7** consists of discrete $Cd(tzt)_2(py)_3$ molecules and lattice py molecules. As can be seen in Fig. 5 (in which the C atoms of bound and lattice py molecules are coloured orange and magenta, respectively), the crystal structure reveals regions that are rich in free and bound py and regions within which tzt^- ligands of adjacent $Cd(tzt)_2(py)_3$ molecules interdigitate. Each Cd-containing molecule is associated with four lattice py molecules. The

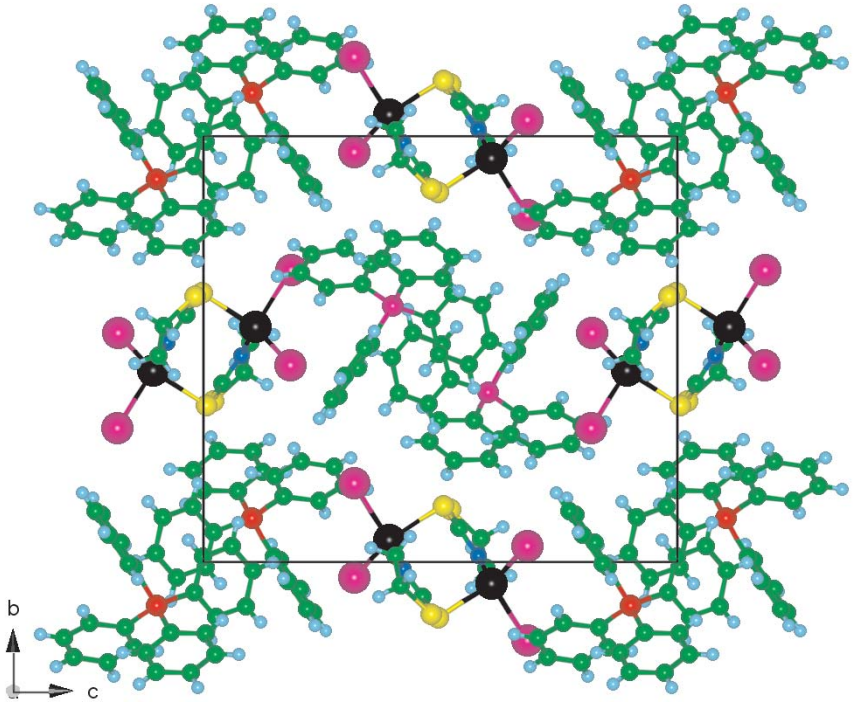
Fig. 3. A view along *a* of the structure of $(Ph_4P)_2[I_2Cd(\mu\text{-}tzt)_2CdI_2]$ (**4**), showing segregated columns of cations and anions. Colour code: Cd, black; I, magenta; P, red; S, yellow; N, blue; C, green; H, cyan.



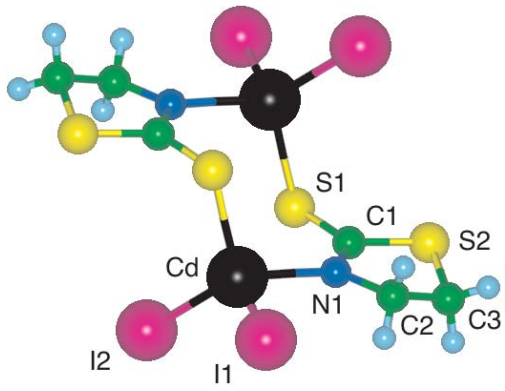


Fig. 4. The anion in $(Ph_4P)_2[I_2Cd(\mu\text{-}tzt)_2CdI_2]$ (**4**), giving the numbering scheme and showing the eight-membered Cd-S-C-N-Cd-S-C-N ring in the chair conformation.

geometry of the lattice py molecules is normal. Figure 6 shows a $Cd(tzt)_2(py)_3$ molecule and gives a partial numbering scheme. Table 4 gives selected bond distances and angles for this molecule.

As can be seen in Fig. 6, the Cd atom in $Cd(tzt)_2(py)_3$ exhibits distorted trigonal bipyramidal geometry, neither the coordination number nor the coordination geometry being unusual for Cd, according to a search of the CSD. We regard the Cd···S1B distance of 3.3 Å as indicating a nonbonding interaction — the sum of the Cd and S van der Waals radii is 3.38 Å (22) — but if the additional S were included in the first coordination sphere of Cd (within the angle $N1_{Py2}$-Cd-N1B), the coordination geometry of the Cd would be distorted octahedral, with S1B approximately *trans* to S1A. A unique feature of the $Cd(tzt)_2(py)_3$ molecule is that it contains examples of *both* rare S-bonded monodentate tzt^- (tzt(A)) *and* rare N-bonded monodentate tzt^- (tzt(B)).

Within $Cd(tzt)_2(py)_3$, pyridine molecules 1 and 3 occupy the axial positions, the $N1_{Py1}$-Cd-$N1_{Py3}$ bond angle being 169.39(7)°. The Cd is close to being coplanar with the atoms $N1_{Py2}$, S1A, and N1B, which occupy the equatorial sites of $Cd(tzt)_2(py)_3$ (the maximum deviation of the four atoms from the least-squares plane is 0.06 Å). The angles between the perpendicular to the mean Cd,$N1_{Py2}$,S1A,N1B plane and the $N1_{Py1}$–Cd and $N1_{Py3}$–Cd vectors are 8.7° and 2.3°, respectively.

The Cd—$N1_{Py1}$ and Cd—$N1_{Py3}$ distances are 2.471(2) and 2.455(2) Å, respectively, which fall in the known range for Cd–py bonds in the CSD (2.276–2.554 Å). In the equatorial plane, the Cd—$N1_{Py2}$, Cd—S1A, and Cd—N1B distances are 2.365(2), 2.551(1) and 2.227(2), respectively. Thus, the bond between Cd and the equatorial pyridine molecule, Py2, is significantly shorter than those to the axial pyridine molecules; such a relationship between equatorial and axial bond lengths is not unusual (23). The Cd—S1A bond length does not differ significantly from the longer Cd—S distance in **1**, while the Cd—N1B distance falls between the two Cd—N distances observed in **1**. Within the equatorial plane, the S1A-Cd-$N1_{Py2}$ angle is 90.49(4)°, while the N1B-Cd-$N1_{Py2}$ and S1A-Cd-$N1_{Py2}$ angles are considerably larger (135.79(6)° and 133.35(4)°, respectively). The origin of this difference is probably steric: the S1A-Cd-$N1_{Py2}$ angle can close up because the Py2 and tzt(A) rings are relatively far apart, as a result of the bend-back at S1A, the exocyclic sulfur atom of tzt(A). In addition, the presence of the nonbonded S1B (see above) may cause the $N1_{Py2}$-Cd-N1B angle to open up.

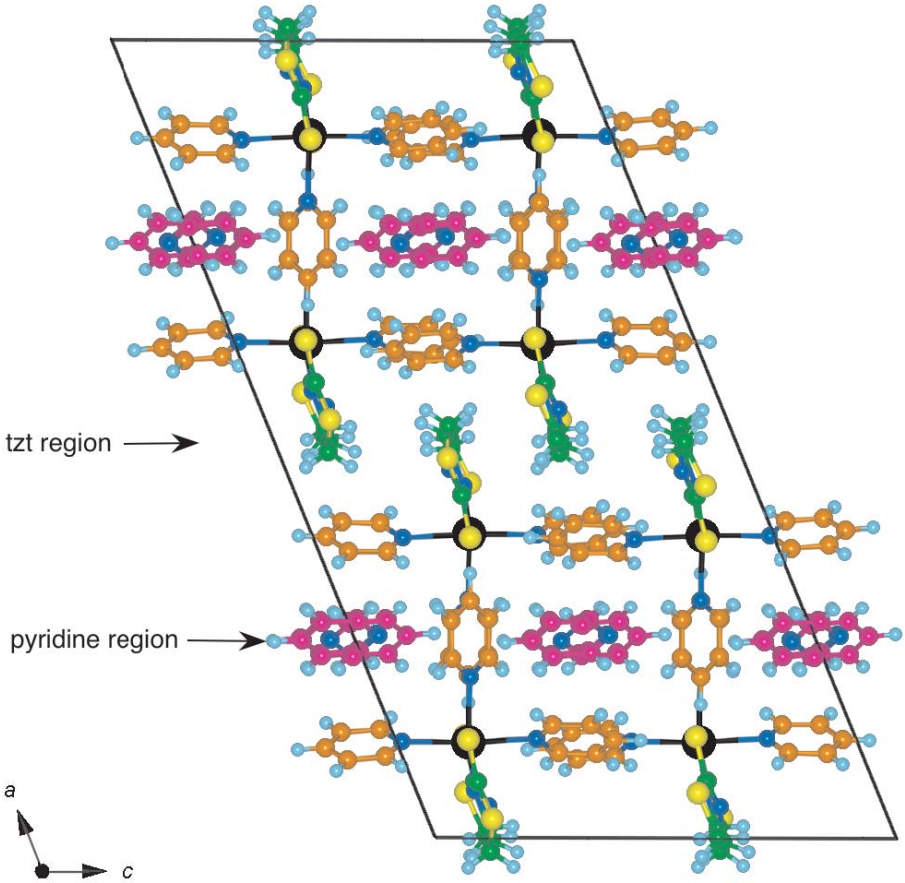
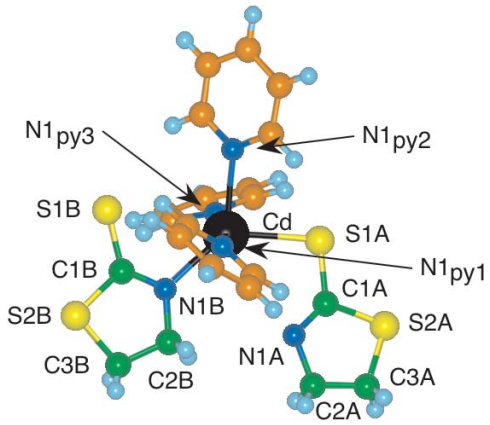
Fig. 5. A view along *b* of the structure of $Cd(tzt)_2(py)_3$·py (**7**), revealing pyridine-rich regions and tzt-rich regions. Colour code: Cd, black; S, yellow; N, blue; bound-pyridine C, orange; lattice-pyridine C, magenta; non-pyridine C, green; H, cyan.





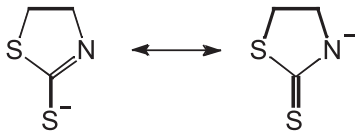


Fig. 6. The trigonal bipyramidal $Cd(tzt)_2(py)_3$ molecule found in $Cd(tzt)_2(py)_3$·py (**7**), viewed in the axial direction, giving a partial numbering scheme and showing the S- and N-bound tzt^- ligands in the equatorial plane.

Both tzt rings have the envelope conformation (the flaps C3A and C3B are 0.21 and 0.24 Å out of their respective C2,N1,C1,(S1),S2 planes). The Cd–N1B vector makes an angle of 78.4° with the C2B,N1B,C1B,(S1B),S2B mean plane.

The structure of **7** provides a unique opportunity to compare the geometries of S- and N-bound tzt^- ligands within the same complex. In both ligands, the expected planar geometry occurs at C1. The changes in the thioamide region are quite small but are in the direction expected from a consideration of the resonance structures of tzt^-, **IA** and **IB** (Scheme 1): more C–N multiple bonding and less C–(exocyclic)S multiple bonding in the S-bound ligand (labelled A), which promotes resonance structure **IA**, than in the N-bound ligand (labelled B), which promotes resonance structure **IB**. Thus, the C1—N1 distance in the A ring is 1.270(3) Å, while that in the B ring is 1.294(3) Å, and the C1—S1 distance is 1.727(2) Å in the A ring and 1.701(2) Å in the B ring. In addition, the N1-C1-S2 and S1-C1-N1 angles are larger in the S-bound (A) ligand (116.8(2)° and 127.2(2)°, respectively) than in the N-bound (B) ligand (114.6(2)° and 125.9(2)°, respectively), while C1-N1-C2 and S1-C1-S2 angles are larger in the N-bound ligand (115.5(2)° and 119.5(1)°, respectively) than in the S-bound ligand (111.5(2)° and 115.5(1)°, respectively).

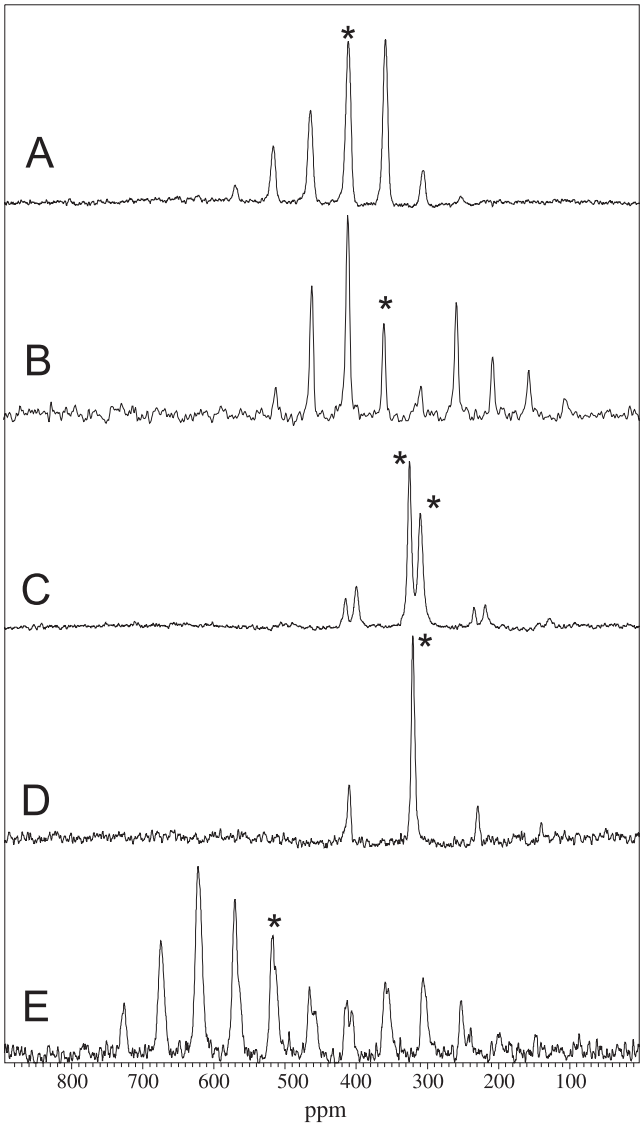
by the fact that the structures were measured at different temperatures. In addition, the supporting ligands at Cd differ in these complexes, and this must have an effect. However, we note that planarity at C1 is maintained, as expected, and also that the C1-N1-C2 angle in the bridging ligands is remarkably constant at 113.1(3)°–113.5(3)°, a value intermediate between those found in tzt(A) and tzt(B) in **7**.

Cadmium-113 NMR spectra of 1, 7, and related compounds

Solid-state (SS) ^{113}Cd NMR spectra of **1** and **7** have been measured, together with the variable-temperature solution ^{113}Cd NMR spectrum of **1** in pyridine and several other solid-state ^{113}Cd NMR spectra, for comparison. The NMR results are detailed in Table 5, and Fig. 7 shows representative solid-state NMR spectra.

Compound **1** gives a CP-MAS ^{113}Cd NMR spectrum with a single isotropic chemical shift, consistent with the finding of a single Cd atom in the single-crystal X-ray analysis. The chemical shift, 411 ppm, can be compared with the values of 557–586 ppm found for $[Cd(tztH)_4]^{2+}$ in solid compounds containing the S-bound neutral thione, and hence a CdS_4 kernel (1*b*). In **1**, the kernel is CdS_2N_2, and replacement of an S-donor by an N-donor is expected to lead to increased shielding, as is observed. (Few ^{113}Cd NMR data are available for established CdN_4 kernels, but a tetrahedral CdN_4 kernel in statically disordered $Cd(CN)_2$ has a ^{113}Cd NMR chemical shift of ca. 360 ppm (24), while, perhaps coincidentally, the *square-planar* CdN_4 kernel in (*meso*-tetraphenylporphyrinato)cadmium has an isotropic ^{113}Cd NMR chemical shift of 399 ppm (25)). Compound **1** has many of the properties that are desirable in a ^{113}Cd NMR reference material useful for solid-state ^{113}Cd NMR, including: ease of preparation, stability (we have kept **1** for months in a refrigerator with no obvious change in its CP-MAS ^{113}Cd NMR spectrum), and a single Cd environment giving a relatively sharp signal (e.g., ca. 750 Hz, S/N ≈ 18 after 8 transients, at UWO).



When **1** is converted into its pyridine adduct, which contains $Cd(py)_3$(tzt-*N*)(tzt-*S*) molecules (see above), the ^{113}Cd NMR chemical shift in the solid state changes to 361 ppm. Though the observed shielding is relatively slight, both increasing coordination number and increasing nitrogen/sulfur ratio in the coordination kernel are expected to lead to shielding. We were unable to find a ^{113}Cd NMR signal for the compound "3Cd(tzt)$_2$·(py)" that is obtained by pumping on **7**; certainly, it is not simply a mixture of **1** and **7**.

The change in chemical shift when **1** is dissolved in pyridine is surprisingly large: the ^{113}Cd NMR signal is found at 191 ppm at 244 K, at which temperature the linewidth is relatively narrow (ca. 40 Hz). This chemical shift is more shielded than δ_{iso} of $Cd(py)_3$(tzt-*N*)(tzt-*S*), by an amount that exceeds expectation for an effect of the medium only. Tentatively, we suggest that either the tzt$^-$ ligands are both N-bound in solution or the number of bound pyridines exceeds three in the solution in pyridine, or both.

The ^{113}Cd NMR chemical shift of solid **1** is larger than that of solid $Cd(btzS)_2$ (btzS$^-$ = mercaptobenzothiazolate), in which a $CdN_2S_2S'_2$ kernel occurs (10). Thus, it seems that of the two competing effects — larger coordination number, producing shielding, versus larger sulfur/nitrogen ratio in the coordination sphere. producing deshielding — the former is dominant for $Cd(btzS)_2$, although the effect on the chemical shift of N,S-chelation, which occurs in the solid, is an unknown and complicating factor in this comparison. As expected from its similar structure, again with a $CdN_2S_2S'_2$ kernel (10), solid $Cd(py2S)_2$ has an isotropic chemical shift similar to that of $Cd(btzS)_2$; the similarity between the two compounds extends even to the simplification of their solid-state ^{113}Cd NMR spectra from two signals to a single isotropic signal that occurs when the samples are recrystallized from pyridine. The CP-MAS ^{113}Cd NMR spectrum of

© 2005 NRC Canada

Fig. 7. CP-MAS ^{113}Cd NMR spectra of: (A) compound **1**, $Cd(ttz)_2$, 3.5 kHz, 66.5 MHz, 303 K; (B) compound **7**, $Cd(tzt)_2py$, 4.5 kHz, 88.6 MHz, 293 K; (C) compound **2**, $Cd(py2S)_2$, before recrystallization, 6 kHz, 66.5 MHz, 303 K; (D) compound **2**, $Cd(py2S)_2$, after recrystallization from pyridine, 6 kHz, 66.5 MHz, 303 K; and (E) compound **3**, $Cd(py4S)_2$, 3.5 kHz, 66.5 MHz, 303 K. An asterisk indicates the isotropic signal.

$Cd(py2S)_2$ could not be observed by the previous workers (10), but insufficient experimental detail is available in ref. 10 to explain the discrepancy between the previous work and our current work. The $[Cd(py2SH)_4]^{2+}$ cation in its solid nitrate salt has a CdS_4 kernel (1*a*); its isotropic ^{113}Cd NMR signal is considerably deshielded, by ≈300 ppm relative to that of either $Cd(py2S)_2$ or $Cd(btzS)_2$, consistent with both the smaller coordination number and the larger sulfur/nitrogen ratio found in the coordination sphere of $[Cd(py2SH)_4]^{2+}$.

Finally, the isotropic ^{113}Cd NMR chemical shift of $Cd(py4S)_2$ is significantly deshielded, by ≈200 ppm, compared with those of $Cd(py2S)_2$ and $Cd(btzS)_2$, and the 4-thiolate must therefore have a different structure from the other two thiolates. Although the structure of $Cd(py4S)_2$ remains unknown — as noted above, attempts to crystallize this compound by the method used for $Cd(tzt)_2$ yielded $Cd(py4SH)_2(py4S)_2$ — the chemical shift approaches the region where resonances from CdS_4 kernels are found (see, e.g., Table 5 and refs. 26 and 27), although it is smaller than those found (12) for $[Cd(py4S)_{4-n}(py4SH)_n]^{(2-n)+}$ (n = 0, 2, 4) in a DMF–MeOH solvent mixture (616–617 ppm at 213 K).

Acknowledgements

We thank Dr. Peter Turner, Professional Officer, Crystallography, School of Chemistry, University of Sydney, Australia, for collecting single-crystal X-ray data on compound **7**, and Dr. Michael Jennings, Manager, Crystallography Facility, Department of Chemistry, UWO, for assistance in preparing the manuscript. Much progress with this work was made possible by a sabbatical leave from UWO, and by Visiting Professorships at UNSW in 2001–2002 and 2004, for which PAWD is grateful. IGD acknowledges the support of the Australian Research Council.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2002 W.A.E. McBryde Award Lecture — Affinity recognition, capillary electrophoresis, and laser-induced fluorescence polarization for ultrasensitive bioanalysis

X. Chris Le, Victor Pavski, and Hailin Wang

Abstract: The combination of affinity recognition, capillary electrophoresis (CE), laser-induced fluorescence (LIF), and fluorescence polarization for the ultrasensitive determination of compounds of biological interest is described. Competitive immunoassays using CE–LIF eliminate the need for fluorescently labeling trace analytes of interest and are particularly useful for determination of small molecules, such as cyclosporine, gentamicin, vancomycin, and digoxin. Fluorescence polarization allows for differentiation of the antibody-bound from the unbound small molecules. Noncompetitive affinity CE–LIF assays are shown to be highly effective in the determination of biomarkers for DNA damage and HIV-1 infection. An antibody (or aptamer) is used as a fluorescent probe to bind with a target DNA adduct (or the reverse transcriptase of the HIV-1 virus), with the fluorescent reaction products being separated by CE and detected by LIF. Aptamers are attractive affinity probes for protein analysis because of high affinity, high specificity, and the potential for a wide range of target proteins. Fluorescence polarization provides unique information for studying molecular interactions. Innovative integrations of these technologies will have broad applications ranging from cancer research, to biomedical diagnosis, to pharmaceutical and environmental analyses.

Key words: capillary electrophoresis, laser-induced fluorescence, fluorescence polarization, immunoassay, affinity probes, antibodies, aptamers, DNA damage, toxins, therapeutic drugs.

Résumé : On décrit une méthode de détermination ultrasensible de l'intérêt biologique de composés qui est basée sur une combinaison de la reconnaissance d'affinité, l'électrophorèse capillaire (EC), de la fluorescence induite au laser (FIL) et de la polarisation de fluorescence. Les essais immunologiques compétitifs faisant appel à la combinaison EC–FIL éliminent la nécessité de marquages fluorescents de traces de l'analyte examiné. Aussi, ils sont particulièrement utiles pour la détermination de petites molécules, telle la cyclosporine, la gentamicine, la vancomycine et le digoxine. La polarisation de fluorescence permet de différencier de l'anticorps lié des petites molécules non liées. On a montré que les essais EC–FIL d'affinité non compétitive sont très efficaces dans la détermination de biomarqueurs pour le dommage à l'ADN et les infections du HIV-1. On a utilisé un anticorps (ou aptamère) comme sonde fluorescente qui se lie à un adduit d'ADN cible (ou la transcriptase inverse du virus HIV-1), alors que les produits fluorescents de la réaction sont séparés par EC et détectées par FIL. Les aptamères sont des sondes d'affinité qui présentent de l'attrait pour l'analyse des protéines en raison de leur grande affinité, de leur spécificité élevée et du potentiel pour un large éventail de protéines cibles. La polarisation de fluorescence permet de recueillir de l'information unique pour l'étude des interactions moléculaires. Des intégrations innovatrices de ces technologies donneront lieu à un vaste éventail d'applications allant de la cancérologie aux diagnostics biomédicaux et aux analyses pharmaceutiques et environnementales.

Mots clés : électrophorèse capillaire, fluorescence induite au laser, polarisation de fluorescence, essai immunologique, sondes d'affinité, anticorps, aptamères, dommage à l'ADN, toxines, médicaments.

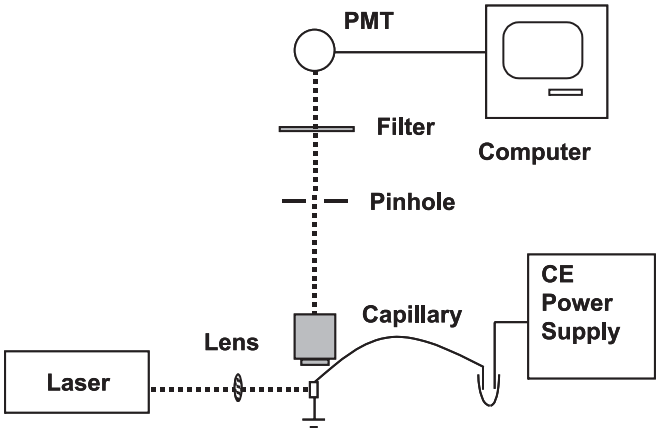
Introduction

Affinity recognition is widely used as a means of achieving specificity for a range of bioanalytical applications. As an example, immunoassays that make use of the preferential binding affinity of antibody to specific antigen (or hapten) are widely used for the ultrasensitive and selective detection of a large variety of biological substances, including, but not limited to, whole microorganisms, viruses, proteins and peptides, therapeutic drugs, chemical warfare agents, natural and man-made toxins, and environmental contaminants (1–3). In an immunoassay, antibodies are used as analytical reagents to bind with a target analyte. The distribution of the analyte between bound and free forms is related to the total analyte concentration.



Immunological recognition is based on the spatial complementarity of the epitope of the antigen with the paratope in the antibody. Because antibodies target epitopes, not the whole antigen, antibodies can fail to discriminate structurally similar species by cross-reacting. One way to improve the specificity of the technique is to combine the immunoassay with chromatography–electrophoresis separation. Capillary electrophoresis (CE) is a high efficiency analytical separation technique (4, 5). Fast and efficient separation and a small sample volume requirement make CE a powerful technique for bioanalysis (6–8). Laser-induced fluorescence (LIF) offers extremely sensitive detection for CE, leading to a single molecule detection limit (9–13). However, fluorescent labeling of trace levels of analyte in the presence of a sample matrix can be problematic because of nonquantitative derivatization at trace levels and matrix interference on the labeling reactions.

By developing innovative combinations of affinity recognition with CE–LIF, these problems can be circumvented. Ourselves and others have demonstrated the potential of competitive immunoassay using CE with LIF or laser-induced fluorescence polarization (LIFP) detection, and affinity capillary electrophoresis (14–20). Affinity CE–LIF has been demonstrated for biological and environmental applications, including studies of antibody–antigen interactions, determination of therapeutic drugs and natural toxins, and assays for DNA damage (see refs. 17–20 for reviews). This paper describes recent work in this area, part of which has been presented in the W.A.E. McBryde Medal address at the 85th Canadian Society for Chemistry Conference held in Vancouver. Here, we summarize CE–LIF, competitive immunoassays, noncompetitive immunoassays, aptamers as affinity probes, and fluorescence polarization.

Capillary electrophoresis with laser-induced fluorescence detection (CE–LIF)

Electrophoresis is defined as the movement of ions in an applied electric field, typically through an anticonvective medium. Fused silica capillaries, essentially the polyimide-coated fused silica tubing produced for gas chromatography, are attractive as anticonvective media, and are relatively inexpensive. Although the earliest prototypes of capillary electrophoresis (CE) systems were developed between 1958 and 1965 (21), it was not until the early 1980s that potential detection systems became sufficiently affordable to permit the development of CE on a practical basis (4, 5). In a typical free zone CE experiment, the capillary ends are inserted into electrophoretic buffer reservoirs, into which electrodes are also inserted. Samples are introduced either hydrodynamically (pressure injection) or electrophoretically using a short (5–10 s) application of voltage from a high voltage (5–30 kV) power supply. When voltage is once more applied, during the electrophoresis of the sample, electroosmotic flow (EOF) develops as the result of the negatively charged silanol groups on the fused silica walls. Driven by the EOF, analyte species migrate to the detection window according to their respective electrophoretic mobilities, effectively their charge to mass ratios. The plug flow character of the EOF permits separation efficiencies of a million theoretical plates (5).

Fig. 1. A schematic diagram showing a CE–LIF system used in this laboratory (adapted from ref. 48).

Owing to their small inner diameter (typically 10–100 μm), fused silica capillaries have very small internal volumes. Samples injected into the capillary have volumes of around 1–10 nL. To provide high sensitivity detection, the detection system must be compatible with the small sample volume. Because absorbance is dependent on the path length (Beer's law, $A \propto L$), it is not a very sensitive detection mode for CE, owing to the very small path length (i.e., internal diameter) of the capillary.

Fluorescence, however, is independent of sample path length. Because of this, laser-induced fluorescence (LIF) excitation of the CE sample volume, provided the analyte is natively fluorescent or fluorescently labeled, has provided the best detection limits in CE applications. A schematic diagram of a CE–LIF system used in our laboratory is given in Fig. 1. The set-up consists of a CE unit and an LIF detection system. The LIF detection system consists of a laser for excitation (e.g., argon ion laser, primary laser line 488 nm or green helium–neon laser at 543.5 nm), laser beam focusing and fluorescence collection optics (lens, filter, aperture, microscope objective), and a detector (e.g., a photomultiplier tube (PMT)). Output from the PMT is passed through an analogue-to-digital (A/D) converter into a data acquisition board in a personal computer. Fluorescence intensity is usually obtained from the peak area of the species of interest, and calibration plots of fluorescence intensity vs. the concentration of standard solutions of the species of interest are used to quantify the analyte.

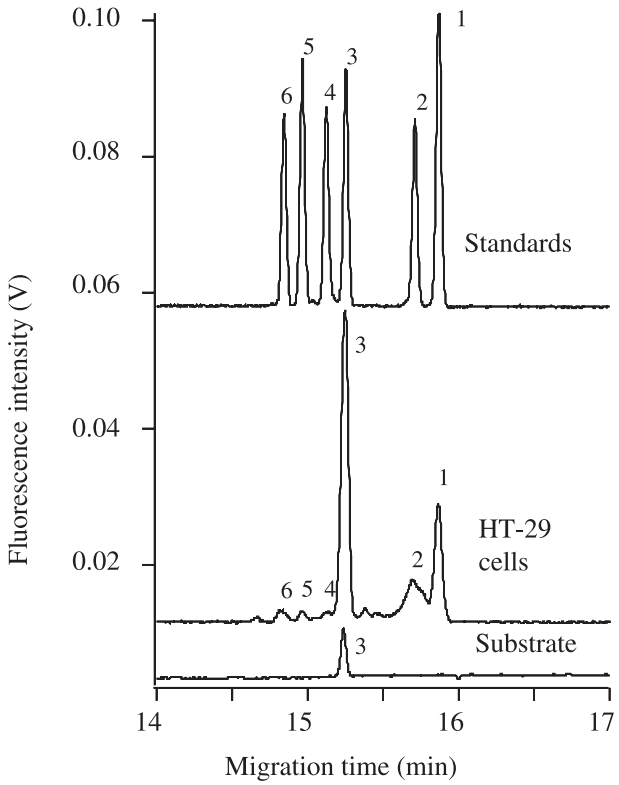
We have demonstrated the sensitivity of CE–LIF in studies of oligosaccharides (22, 23). Because of the very low UV absorption of oligosaccharides, their direct spectrophotometric detection is problematic. Improvements in sensitivity have been obtained mainly through derivatization with chromophores or fluorophores, with fluorophore labeling and LIF detection providing the best limits of detection (24–26). We chose tetramethylrhodamine (TMR) as the fluorescent label because of its high molar absorptivity and quantum yield. The oligosaccharides were aminated and then reacted with the *N*-hydroxysuccinimide ester of tetramethylrhodamine to produce TMR-labeled compounds. Using an inexpensive green helium–neon laser with an excitation wavelength of 543.5 nm, we were able to generate intense orange fluorescence, which was collected through a 580 nm bandpass filter and detected by a PMT. The limit of detection was 8×10^{-23} mol (80 yoctomol) or 50 molecules of TMR-labeled saccharides (22).

Figure 2 shows an example of the detection of βGal(1→3)βGlcNAc and βGal(1→4)βGlcNAc (LacNAc) series oligosaccharide standards and enzyme products from human colon adenocarcinoma HT-29 cells by CE–LIF. A TMR-labeled oligosaccharide (βGal(1→4)βGlcNAc (LacNAc)) was used as a substrate and incubated with the cells for 20 h. The cells were then centrifuged and lysed, with the purified lysate being isolated for analysis. Unreacted substrate (βGal(1→4)βGlcNAc-O-TMR) is the major component of the cell sample, with minor components being the linker arm ($HO(CH_2)_8CONHCH_2CH_2NHCO$-TMR), βGlcNAc-O-TMR, αFuc(1→2)βGal(1→4)βGlcNAc-O-TMR, βGal(1→4)[αFuc(1→3)]βGlcNAc-O-TMR, and αFuc(1→2)βGal(1→4)[αFuc(1→3)]βGlcNAc-O-TMR.

Because CE requires only minute amounts of sample and LIF provides excellent detections, we have further developed the CE–LIF technique for the analysis of single cells. Analysis of single cells is important because it may permit the study of cell heterogeneity from the same cell line as a function of age and culturing conditions. We studied enzymatic hydrolysis of TMR-labeled trisaccharides in Baker's yeast cells (23). Cells (*Saccharomyces cerevisiae*, baker's yeast) were incubated with the TMR-labeled trisaccharide, α-D-Glc(1→2)α-D-Glc(1→3)α-D-Glc-O-$(CH_2)_8$CO-$NHCH_2CH_2$-NHCO-TMR, with shaking at 25 °C for 24 h. At various intervals during the incubation, microlitres of the cell suspension were removed and washed thoroughly with phosphate-buffered saline (PBS), prior to analysis by confocal laser scanning microscopy to ascertain the degree of uptake in the cells of the TMR-labeled trisaccharide. Fluorescence from the cells increased with time, and short-term incubations of cells with the TMR-labeled substrate exhibited no detectable fluorescence, indicating the increased fluorescence over time is related to actual incorporation of the substrate, rather than simple adsorption of the fluorescent dye at the cell surface. To facilitate the insertion of single cells into the CE, the bare capillary end was etched with hydrofluoric acid. A 2–5 μL volume of spheroplast suspension was placed on a glass slide under an inverted fluorescence microscope. An appropriate spheroplast was located, the capillary was moved proximate to it with the micromanipulators, and an airtight syringe or syringe pump was used to provide gentle suction from the detection end of the capillary. After a single spheroplast was introduced into the capillary, suction was stopped, the capillary was placed in running buffer, and a high (20–25 kV) voltage was applied for 10 s to drive the electrophoresis buffer into the capillary. The nonphysiological pH running buffer (containing SDS) lyses the cell. The CE separates the trisaccharide substrate and its enzymatic products that are originated from the single spheroplast.

Fig. 2. Electropherogram of oligosaccharide standards (top trace), the enzyme products from the HT-29 cells (middle trace), and the fluorescent substrate (bottom trace). The major component of the cell sample is unreacted substrate, βGal(1→4)βGlcNAc-O-TMR (peak 3), with minor components being the linker arm ($HO(CH_2)_8CONHCH_2CH_2NHCO$-TMR (peak 1)), βGlcNAc-O-TMR (peak 2), αFuc(1→2)βGal(1→4)βGlcNAc-O-TMR (peak 4), βGal(1→4)[αFuc(1→3)]βGlcNAc-O-TMR (peak 5), and αFuc(1→2)βGal(1→4)[αFuc(1→3)]βGlcNAc-O-TMR (peak 6) (adapted from ref. 22).



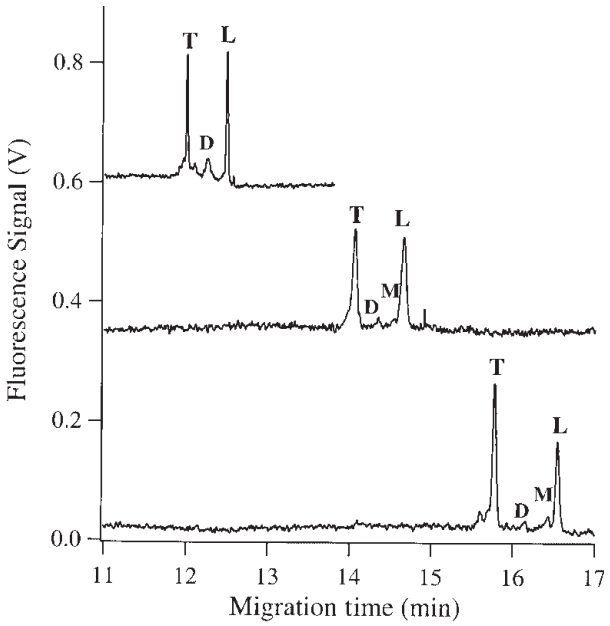


Figure 3 shows the electropherograms obtained from different individual spheroplasts. The major fluorescent compounds, the TMR-labeled trisaccharide and free linker arm, were detected at a concentration of approximately 500–1000 molecules. TMR-labeled disaccharide and monosaccharide were also detected at concentrations of less than 100 molecules. The variations among the electropherograms presumably reflect the heterogeneity of the cell population and their different stages of maturity. This methodology can be expanded to any class of enzymes for which a fluorescent substrate may be synthesized, ultimately permitting enzyme activity to be assayed on a cell-by-cell basis. Determining the distribution of enzyme activity in a cell population may prove useful in the diagnostic and prognostic determination of cancer and other diseases, as well as in in vivo studies on

Fig. 3. Electrophoresis of the contents of three different single yeast spheroplasts introduced into the capillary. The major fluorescent compounds, the TMR-labeled trisaccharide (T) and free linker arm (L), are present at a concentration of approximately 500–1000 molecules. TMR-labeled disaccharide (D) and monosaccharide (M) are also detected, at concentrations of less than 100 molecules (adapted from ref. 23).

the development of enzyme inhibitors in the pharmaceutical industry.

Other groups have also developed highly sensitive CE–LIF techniques for single cell analysis (27–33). These included analyses of amino acids in a single giant neuron from a snail (27), glutathione in single human erythrocytes (28), amines in individual rat pheochromocytoma cells (29), carbohydrate metabolites in single cancer cells (30), kinase activities (31), RNA synthesis (32), and protein fingerprint (33) in single cells.

Competitive CE–LIF immunoassays

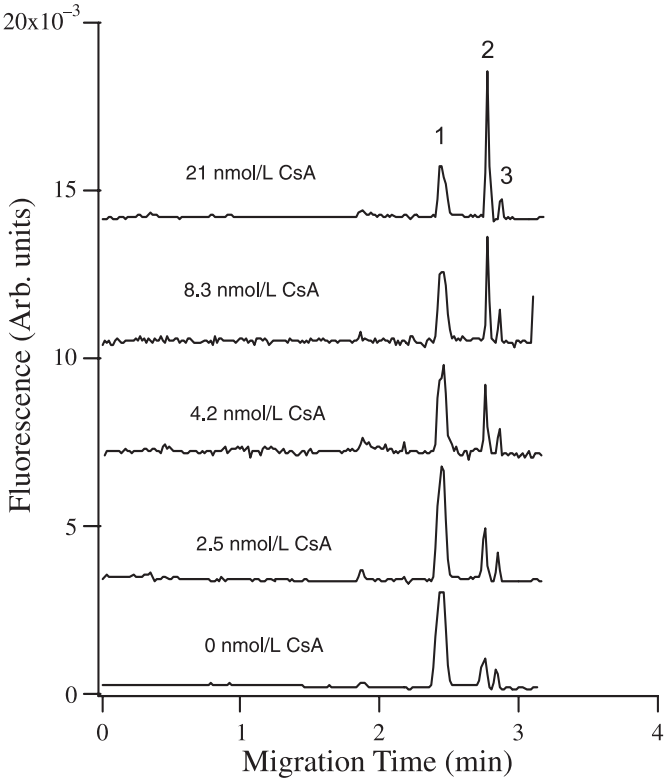
Although CE–LIF permits the study of single molecules and single cells, it usually requires the analyte of interest to be fluorescently labeled. While some biological analytes exhibit native fluorescence (34), the fluorescent wavelengths required tend to be in the UV, where commercial lasers are few, expensive, and have limited excitation wavelengths. While it is possible to fluorescently label the target analyte, in practice fluorescent labeling of trace or ultratrace levels of analyte in the presence of the sample matrix is challenging owing to nonquantitative labeling and poor specificity. One way to overcome this limitation and be able to detect (directly or indirectly) nonfluorescent analytes is to form complexes between them and a fluorescently labeled partner. Immunoassays are an elegant way of accomplishing this.

Two immunoassay formats combined with CE–LIF are discussed in the following two sections. In a competitive immunoassay, a fluorescently labeled antigen (analyte; Ag*) is used, and the unlabeled target analyte (Ag) competes with labeled Ag* for binding to a limiting amount of unlabeled antibody (Ab), as illustrated by eq. [1].

$$[1] \qquad Ag^* + Ag + 2Ab \leftrightarrows Ab\text{–}Ag + Ab\text{–}Ag^*$$

Provided they possess sufficiently different electrophoretic mobilities, two peaks corresponding to the free Ag* and bound Ab–Ag* complex should be observed. As the concentration of unlabeled analyte (Ag) increases, more Ag* is displaced from the Ab–Ag* complex, and the fluorescence intensity of the complex peak decreases with increasing analyte concentration, while the free Ag* peak increases. Both peaks may be used for quantitation.

The first CE–LIF immunoassay was reported by Schultz and Kennedy (14). They used a fluorescein isothiocyanate (FITC) labeled insulin as a probe and Fab fragments of anti-insulin mouse monoclonal antibody IgG_{2a} served as the analyte. A calibration curve constructed from both the free FITC-insulin and the bound FTIC-insulin-Fab complex exhibited linear dynamic ranges of two orders of magnitude. The concentration detection limit for Fab was 2 nmol/L, and the mass detection limit was 2.8×10^{-19} mol (280 zeptomol). These authors also performed a competitive assay in which unlabeled insulin competed with FITC-insulin for a limiting amount of anti-insulin antibody, attaining linear dynamic ranges and limits of detection similar to those found with their initial immunoassay for antibody IgG_{2a}.



Using a competitive immunoassay and CE–LIF detection, we were able to detect the immunosuppressive drug, cylcosporine A (CsA), in the whole blood of organ transplant patients (16). Cyclosporine is believed to suppress T-cell activation (35), and must be maintained within a narrow therapeutic concentration range in blood (150–450 ng/mL) (36), or adverse effects such as nephrotoxicity, hepatoxicity, and neurotoxicity may result. Using the fluorescently labeled tracer (CsA*) and antibody (Ab) from a commercially available cyclosporine test kit, we were able to quantify CsA in whole blood samples with a limit of detection of 0.9 nmol/L and a mass detection limit of 9×10^{-19} mol. Figure 4 displays electropherograms that illustrate the effect of increasing nonfluorescent CsA (analyte) concentration at fixed concentrations of Ab and CsA*. In the presence of a limiting amount of Ab, CsA and fluorescently labeled CsA* react as shown in eq. [2].

$$[2] \qquad 2Ab + CsA^* + CsA \leftrightarrows Ab\text{–}CsA^* + Ab\text{–}CsA$$

As the CsA concentration increases, more fluorescently labeled CsA* is displaced from the immunocomplex, and the peak corresponding to the Ab–CsA* complex decreases, while the free CsA* peak increases. CsA was quantified from a calibration curve using the free CsA* peak in the electropherogram. Methanol, used in preparation of the blood samples, was found to weaken the stability of the Ab–CsA* complex somewhat, but otherwise did not interfere with the analysis. Similarly, binding of the antibody (Ab) with two CsA metabolites, AM9 and AM19, which were reported to have the highest cross reactivity (37), was assessed and the antibody was found to exhibit a cross reactivity of only 13.3 ± 0.1% with AM9 and 2.0 ± 0.1% with AM19 (16). Excellent agreement for the quantification of CsA in

whole blood was found for our assay and for CsA obtained by a standard fluorescence polarization immunoassay.

We have also applied the competitive CE–LIF assay to the analysis of digoxin (38), gentamicin (38), and vancomycin (39). A minimum detectable concentration of vancomycin in clinical samples (heparinized plasma) was found to be 0.98 ng/mL (1.1 fg of vancomycin), which is approximately 10 times better than conventional assays. Like cyclosporine A, digoxin and gentamicin are drugs whose therapeutic serum concentrations fall into narrow ranges. Digoxin, prescribed for congestive heart failure and supraventricular arrhythmias, must be monitored not to exceed the range of 0.8–2.0 ng/mL, whereas gentamicin, prescribed to treat infections caused by Gram-negative bacteria, must be maintained in the range of 5–10 μg/mL. Fluorescently labeled tracers (digoxin* and gentamicin*) and corresponding antibodies for digoxin and gentamicin were obtained from commercially available test kits. At pH below 11.1, the Ab–digoxin* complex was poorly resolved and subsequent experiments were performed at a running buffer pH of 12. Calibration curves were readily constructed from both free digoxin* and bound Ab–digoxin* complex peaks, with a concentration limit of detection of 0.02 ng/mL (26 pmol/L) and a mass detection limit of 2.6×10^{-20} mol (26 zeptomol) being attained for digoxin. Cross-calibration with another commercially available digoxin immunoassay showed good agreement with our assay for the determination of digoxin in whole blood. Calibration curves could be constructed as with digoxin and a concentration limit of detection of 25 ng/mL (52 nmol/L) and a mass detection limit of 5.2×10^{-19} mol was obtained for gentamicin. Because of the incomplete resolution of the gentamicin* and bound Ab–gentamicin* complex, as well as the tendency of the immunocomplex to dissociate at high pH, it was not possible to determine gentamicin levels in whole blood samples.

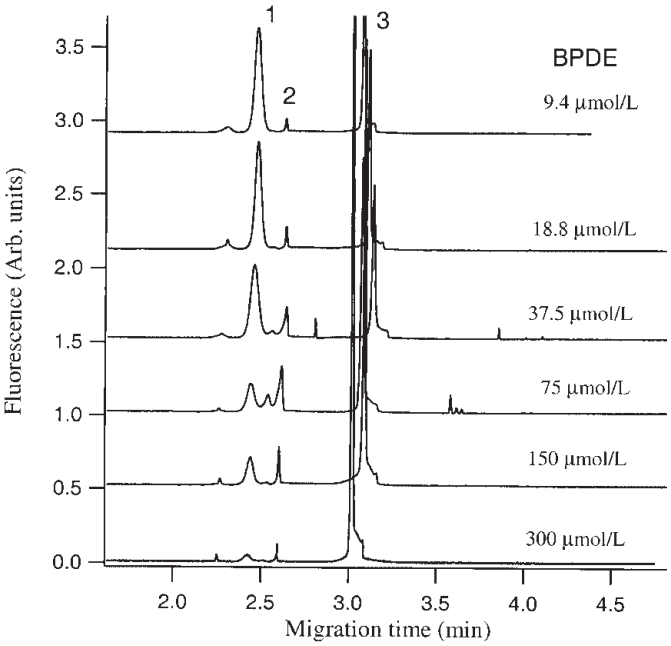
While the above examples deal with the analysis of relatively small molecules, we have also applied competitive immunoassay and CE–LIF to the detection of larger molecules, such as toxins. Staphylococcal enterotoxins (SE) are a family of serologically distinct proteins capable of causing food poisoning when ingested at levels as low as 1 μg (40). In particular, we investigated the detection of staphylococcal enterotoxins A and B (SEA and SEB) (41, 42). Fluorescently labeled SEA (SEA*) was obtained by incubating SEA at room temperature with FITC for 30 min. The Ab–SEA* complex forms at 3 min in the electropherogram, roughly 1 min before the free SEA* peak. Using the Ab–SEA* complex peak for quantitation, a calibration curve linear from 0.3–6.5 nmol/L SEA was obtained. As little as 3×10^{-18} mol of SEA could be detected, for a concentration detection limit of 0.3 nmol/L. No cross-reactivity of the SEA antibody with SEB was observed. For detection of SEB, tetramethylrhodamine isothiocyanate (TRITC) was used to label SEB. It was found that TRITC-labeled SEB (SEB*) exhibited the highest binding affinity with the SEB antibody at pH 7.0. The addition of 5 mmol/L phytic acid to the running buffer increased the resolution between the bound Ab–SEB* and free SEB* peaks sufficiently that both peaks could be used for quantitation. It is possible that the ion-pairing properties of phytic acid reduce the adsorption of proteins to the capillary wall, thus improving both peak shape and resolution. Calibration plots exhibited linear dynamic ranges of nearly two orders of magnitude, and recovery of SEB spiked into a skim milk sample matrix was essentially quantitative.

Our group has also employed competitive CE–LIF immunoassay in our extensive studies of DNA damage and repair. DNA damage by environmental and endogenous agents is considered to be a critical step leading to mutation and subsequent neoplastic transformation and cancer induction. Damage to DNA is also critical in the cytotoxicity induced by anti-cancer treatments such as ionizing radiation and chemotherapeutic agents. In reaction to the insult to their DNA caused by genotoxic agents, cells have adapted a number of DNA repair pathways, each of which deals with a different type of lesion (43). Because DNA damage and repair plays a critical role in cancer development and treatment, it is important to be able to detect and quantify the damage. Assays for DNA damage are important not only for general studies in biochemistry and genetics of mutagenesis and DNA repair, but also because they present the potential to use DNA damage as an endpoint in monitoring environmental and occupational exposure to carcinogens, as well as cellular exposure to anti-cancer agents in clinical dosimetry.

Tan et al. (44) developed a competitive CE–LIF immunoassay for DNA adducts of benzo[*a*]pyrene diol epoxide in a human lung carcinoma cell line (A549). Benzo[*a*]pyrene-7,8-diol 9,10-epoxide (BPDE) is a reactive carcinogenic species produced in vivo when benzo[*a*]pyrene is metabolized by cytochrome P450 and epoxide hydrolase. The reactive epoxide moiety of BPDE binds to DNA, primarily at the N^2

© 2005 NRC Canada

position of deoxyguanosine, forming the bulky adduct BPDE-N^2-dG, which can affect DNA replication and transcription. To detect this DNA damage, a fluorescently labeled single-stranded DNA oligonucleotide (90-mer*) containing a BDPE-N^2 deoxyguanosine (dG) adduct in the middle of the strand was synthesized and used as a detection probe (45). Such an oligonucleotide, which contains a known amount of specific damage type, functions effectively as a fluorescent probe that can be used for sensitive, selective, and specific detection of DNA damage by CE–LIF. The assay itself involves binding of the fluorescently labeled 90-mer DNA probe (90-mer*) with an unlabeled anti-BPDE antibody, typically mouse monoclonal 8E11. BPDE–DNA adducts in a sample compete with the fluorescently labeled probe for the limiting amount of antibody. Electropherograms of the unbound DNA probe (90-mer*) and DNA–antibody complex (Ab–90-mer*) obtained from DNA from A549 cells incubated with 9.4–300 μmol/L BPDE, appear in Fig. 5. The Ab–90-mer* complex is observed to migrate before the unbound DNA. This is because both antibody-bound and unbound DNA are negatively charged and the direction of their electrophoretic mobilities is opposite to that of the electroosmotic flow (EOF). The decrease in total charge-to-mass ratio after antibody binding decreases the mobility of the bound DNA adduct moving toward the injection end of the capillary (positive polarity). Because the magnitude of EOF is larger than that of the electrophoretic mobility, the net result is faster migration directed towards the detector end of the capillary (direction of EOF). As DNA from cells subjected to incubation with increasing levels of BPDE are used, more fluorescently labeled DNA probe (90-mer*) is displaced from the DNA–antibody complex (Ab–90-mer*), and the complex peak decreases while the free 90-mer* peak increases. In this instance, the affinity complex is composed of two distinct peaks (peaks 1 and 2 in Fig. 5). Since antibodies are bidentate, they are capable of binding with up to two antigen molecules. Peak 1 corresponds to the complex formed between the antibody and one DNA adduct (1:1 complex), whereas peak 2 corresponds to the complex formed between the antibody and two DNA adducts (1:2 complex). Therefore, antibody binding stoichiometry can be studied using rationally designed fluorescent oligonucleotide probes (46).



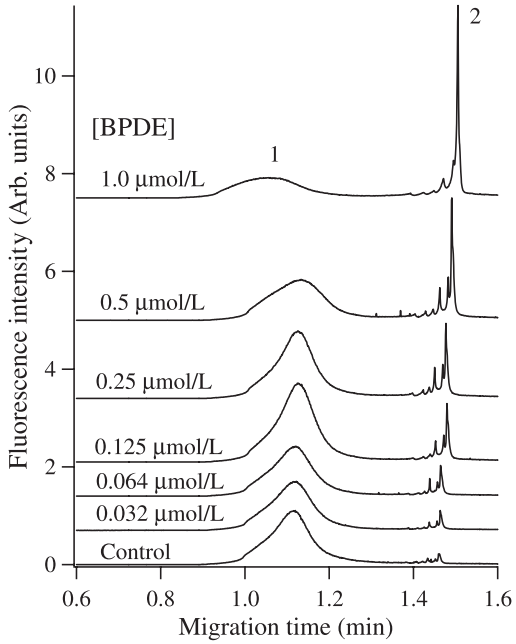
Noncompetitive CE–LIF immunoassays

In a noncompetitive immunoassay, a probe (usually an antibody) is fluorescently labeled (Ab*) and is used to bind with the analyte (Ag), forming a fluorescent Ab*–Ag complex. The chemical reaction illustrating this behavior is given in eq. [3].

$$[3] \qquad Ab^* + Ag \leftrightarrows Ab^*\text{–}Ag$$

The Ab*–Ag complex and uncomplexed free Ab* are separated by CE and detectable by LIF. As the analyte (Ag) concentration increases, more free Ab* (which is held at a constant or limiting concentration) is consumed in binding to form the Ab*–Ag complex, the fluorescence of which increases. Ultimately, all the free Ab* should be consumed into the bound Ab*–Ag complex. On electrophoresis, the Ab* and Ab*–Ag species appear as separate peaks and the

Fig. 5. Electropherograms showing the competitive assays for DNA adducts of BPDE in A549 cells. The cells had been incubated with 9.4–300 μmol/L BPDE for 2 h prior to extraction of the DNA for adduct analysis. Peaks 1 and 2 correspond to the 1:1 and 1:2 stoichiometric complexes formed by the 8E11 antibody and the BPDE–90mer* oligonucleotide. Peak 3 represents the free BPDE–90mer* probe (adapted from ref. 44).



analyte concentration in an unknown sample may be obtained by a calibration curve against known standards. Either the increase in the fluorescence intensity of the Ab*–Ag peak, or the decrease in fluorescence intensity of the Ab* peak with increasing analyte concentration, may be used for quantitation.

Our group has also developed a noncompetitive CE–LIF immunoassay for BDPE–DNA adducts (47, 48). Instead of using the synthetic 90-mer DNA as a probe, a fluorescently labeled antibody (secondary antibody, $F(ab')_2$ fragment of goat anti-mouse IgG, Ab''_{IgG}*) is used to bind to the anti-BDPE antibody (primary antibody, mouse monoclonal 8E11, Ab'_{8E11}), rendering the Ab'_{8E11}–BPDE adduct complex fluorescent. Electropherograms for the fluorescent secondary antibody, the secondary antibody bound to the primary antibody, and the immunocomplex of the two antibodies with the DNA damage are shown in Fig. 6. To maximize formation of the fluorescent complex so that DNA damage may be quantified, excess amounts of secondary antibody (Ab''_{IgG}*) were used to saturate the primary antibody (Ab'_{8E11}), which in turn was added in excess to saturate the DNA damage. Peak 1 corresponds to the primary–secondary antibody species, and peak 2 corresponds to the Ab''_{IgG}*–Ab'_{8E11}–BPDE adduct affinity complex. The BPDE–DNA adducts from A549 human lung carcinoma cells were formed by incubating the cells with BPDE (0.032–1.0 μmol/L) for 2 h (48). With increasing concentration of BPDE, the fluorescence signal from the DNA adducts (peak 2) increases, indicating a clear dose–response relationship. Using the results from the complex that had been incubated with 0.032 μmol/L BPDE,

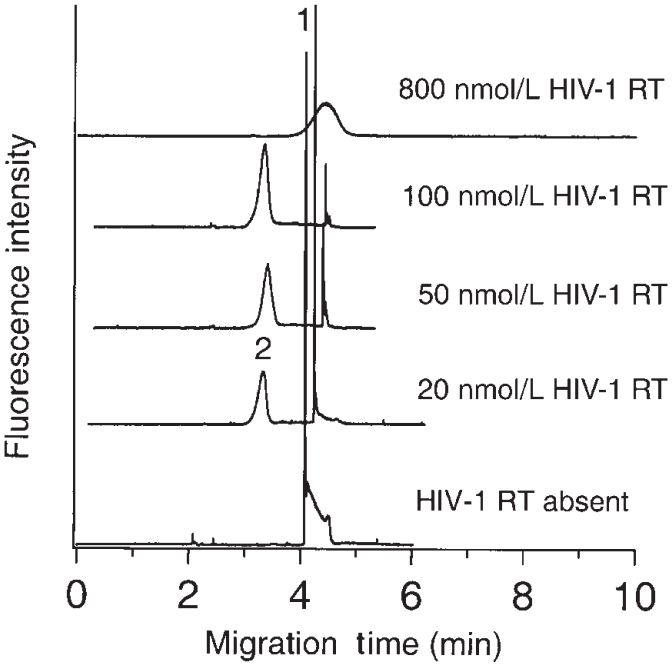
Fig. 6. Electropherograms showing the noncompetitive assays for BPDE–DNA adducts in A549 cells. The cells had been incubated with 0.032–1.0 µmol/L BPDE for 2 h prior to extraction of the DNA for adduct analysis. Peak 1 corresponds to the complex formed between the primary 8E11 antibody (Ab'_{8E11}) and the fluorescently labeled secondary antibody, the $F(ab')_2$ fragment of goat anti-mouse IgG (Ab''_{IgG}*). Peak 2 corresponds to the affinity complex of BPDE–DNA adducts with the two antibodies (Ab''_{IgG}*–Ab'_{8E11}–BPDE adducts) (adapted from ref. 48).

a detection limit of approximately three BPDE adducts per 10^9 nucleotides was obtained. This is comparable with the most sensitive method available for detecting DNA damage, the ^{32}P post-labeling assay (49).

Use of aptamers as affinity probes



Most immunoassays or affinity assays use antibodies as probes. Although antibodies are highly selective and sensitive probes for immunoassays, they have shortcomings. For example, fluorescent labeling of proteins is not always facile, and a fluorescent label can interfere with binding if it is too close to the binding site. Because they need to be generated within an organism, the binding characteristics and analytical performance of antibodies can vary from lot to lot. Finally, antibodies must be carefully handled as they denature at much lower temperatures than oligonucleotides. Recently, there has been much interest in generating, as alternatives to antibodies, synthetic oligonucleotides, which have binding properties similar to antibodies. Termed aptamers from the Latin *aptus* meaning "fitting", these are synthetic RNA or DNA molecules generated in vitro from a combinatorial chemistry process termed SELEX or systematic evolution of ligands by exponential enrichment (50, 51). A large pool of oligonucleotides of the same length with randomized sequences is tested for binding, typically by filter assays, to a specific target ligand. The oligonucleotides that bind most tightly to the target ligand are then separated and amplified by the polymerase chain reaction (PCR), and the process is repeated until the pool evolves to a subset of sequences with the highest binding affinity to the target ligand. At the end of the process, the aptamers produced have binding constants typically many orders of magnitude greater than the original oligonucleotide mixture (typically nmol/L to pmol/L) (50), making the aptamers highly selective for their target ligands. Aptamers may be produced in a matter of weeks to months with the traditional SELEX process, or in a matter of days with the automated SELEX process (52) and the modified capillary electrophoresis process (53). Once the sequence of the aptamer is known, it can be easily synthesized and readily and specifically labeled. Because of this specificity in synthesis, aptamers should not be subject to the lot-to-lot variability that can sometimes be problematic with antibody production. Although both RNA and DNA aptamers are produced, successful analytical applications have overwhelmingly employed DNA aptamers, likely because RNA aptamers are particularly vulnerable to degradation by ribonucleases because of the presence of the 2′-hydroxyl group on the ribose sugar.

German et al. (54) first used a fluorescently labeled DNA aptamer and CE–LIF for the determination of nanomolar levels of IgE in reconstituted human serum, and thrombin in standard solution, yielding calibration curves having linearity of five orders of magnitude. Although used in a number of applications including being immobilized on stationary phases in capillary electrochromatography (55–57), affinity chromatography (58), and affinity mass spectrometry (59), aptamers have been sparingly used in affinity CE–LIF (60, 61). Schneider et al. (62) described the synthesis of single-stranded DNA aptamers for the reverse transcriptase (RT) of the type 1 human immunodeficiency virus (HIV-1). Two oligonucleotides, an 81-mer termed RT 26 and an 84-mer termed RT 12, were developed. They have binding constants with HIV-1 RT of 1 nmol/L and 2 nmol/L, respectively. This represents a 1000-fold increase over binding to wild-type DNA. These aptamers represent excellent potential probes for binding to HIV-1 RT, which is significant in that HIV-1 RT is a biomarker for the HIV-1 virus, and HIV-1 RT activity is used to determine HIV-1 viral load.

Figure 7 illustrates the formation of the RT26-HIV-1 RT affinity complex as HIV-1 RT concentration is increased at a constant concentration of aptamer (61). As expected, the affinity complex increases with HIV-1 RT concentration, whereas the free aptamer peak decreases, ultimately completely being incorporated into the affinity complex at 800 nmol/L HIV-1 RT. Calibration curves were linear to 6 µg/mL HIV-1 RT. The aptamer-based assay provides the first sensitive, selective, and rapid assay for HIV-1 RT, although the extremely low levels of HIV-1 RT present in the sera of HIV-positive individuals (9×10^{-4} to 1 pg/mL) (63), would restrict its application to cell culture. Other current HIV-1 RT assays are laborious and time-consuming, typically involving PCR and gel electrophoresis of the PCR products. None detect HIV-1 RT directly. They also suffer interference from the human T-cell leukemia virus type 1 (HTLV-1), the avian myeloblastosis virus (AMV), and the Moloney murine leukemia virus (MMLV), among others. In contrast, the CE–LIF assay using aptamer showed no cross reaction to AMV-RT, or MMLV-RT, or heat-denatured HIV-1 RT.

Fig. 7. Electropherograms demonstrating the effect of increasing HIV-1 RT concentration (0–800 nmol/L) at a fixed concentration (17 nmol/L) of fluorescently labeled RT 26 aptamer. The bottom electropherogram contains data representing only the RT 26 aptamer. Peak 1 corresponds to the unbound aptamer and Peak 2 corresponds to the affinity complex formed between the aptamer and the HIV-1 RT protein (adapted from ref. 60).

Fluorescence polarization

An additional property that can be used to enhance detection and studies of molecular binding is fluorescence polarization. Fluorescence polarization is governed by the orientation of a molecule in the excited state relative to the electric vector of excitation (64–67). A molecule that loses its orientation as the result of rotational diffusion is said to be depolarized. A fluorescent molecule, when excited by polarized light, emits fluorescence with its polarization (P) controlled by rotational correlation time (ϕ), and fluorescence lifetime (τ) as shown below (65).

$$[4] \qquad \frac{1}{P} - \frac{1}{3} = \left(\frac{1}{P_o} - \frac{1}{3}\right)\left(1 + \frac{\tau}{\phi}\right)$$

where P_o is the intrinsic polarization in the absence of rotational diffusion. The fluorescence is depolarized when the rotational correlation time is small relative to the fluorescence lifetime. When the fluorescence lifetime is constant for a given fluorophore, an increase in fluorescence polarization may be observed with increasing rotational correlation time. The Debye–Stokes–Einstein equation (68) permits an estimation of rotational correlation time.

$$[5] \qquad \phi = \frac{M\eta(v + h)}{RT}$$

where M is the mass of the molecule, η is the viscosity of the solution, v is the specific volume of the molecule, h is the degree of hydration, T is the absolute temperature, and R is the ideal gas constant.

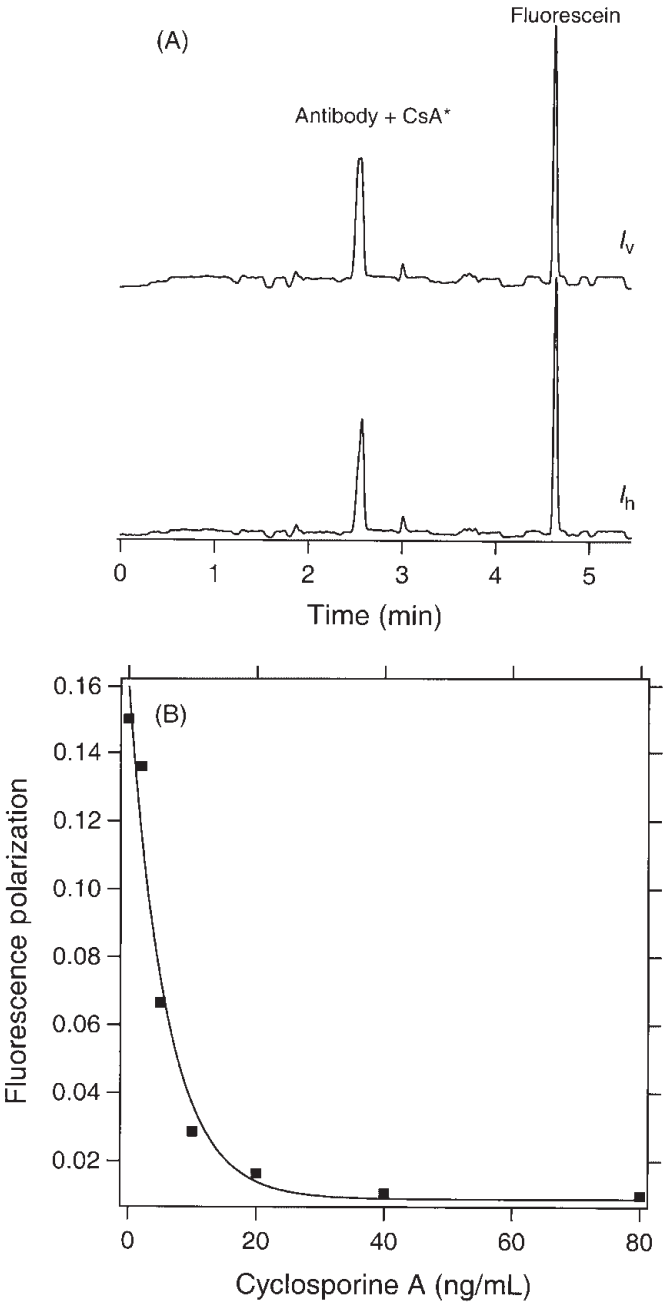
When vertically polarized light is used for excitation, I_v is the intensity of the vertically polarized fluorescence and I_h is the intensity of the horizontally polarized fluorescence.

The degree of polarization (P) is defined as follows:

$$[6] \qquad P = \frac{I_v - I_h}{I_v + I_h}$$

Similarly, fluorescence anisotropy (A) can be obtained from I_v and I_h as follows:

$$[7] \qquad A = \frac{I_v - I_h}{I_v + 2I_h}$$



Measurement of fluorescence polarization provides additional analytical information because polarization is affected by changes in molecular size. When a molecule is excited by polarized light, it fluoresces with a degree of polarization that is primarily determined by the rotational motion of the molecule, which is inversely proportional to molecular size. Small molecules rotate rapidly in solution, causing the molecule's fluorescence to be depolarized (low fluorescence polarization). In contrast, when a small fluorescent molecule binds to a much larger molecule (e.g., antibody, ~150 000 Da), the rotational motion slows down and the fluorescence polarization of the large bound complex is higher. Changes in fluorescence polarization can therefore be used to monitor binding or dissociation of molecules, making polarization very useful in affinity binding studies.

We utilized fluorescence polarization in a competitive immunoassay to quantify CsA in electrophoretic conditions under which free fluorescently labeled tracer (CsA*) and bound tracer–antibody complex (Ab–CsA*) co-eluted (i.e., homogeneous immunoassay) (69). As antibody concentration is increased, fluorescence polarization increases, consistent with the small fluorescent tracer (CsA*) binding to the much larger antibody (Ab). The resulting increase in molecular size, coupled with restricted molecular motion, is responsible for the fluorescence polarization. When the concentration of unlabeled analyte (CsA) is increased, CsA displaces CsA* from the Ab–CsA* complex, and the fluorescence polarization decreases as a result. An electropherogram of the co-eluted antibody–tracer complex, along with the calibration curve appears in Fig. 8.

We also examined the fluorescence polarization in fluorescently labeled vancomycin binding to its antibody (70). The binding of vancomycin to its antibody results in an increase in molecular volume and a slower rotation of the molecule; consequently, the vancomycin–antibody immunocomplex exhibits significant polarization. A mean fluorescence polarization was found to be 0.28 ± 0.02. This value represents the intrinsic polarization of the complex, which is dependent on the rotational diffusion of the molecule, but is independent of the concentration of vancomycin and antibody added. We also investigated the polarization of fluorescently labeled Staphylococcal enterotoxin A (SEA). Free labeled SEA exhibited appreciable polarization (0.14), making it identifiable in the presence of residual dyes. This finding suggests that CE–LIFP may be used to monitor the

Fig. 8. (A) Electropherograms of a mixture containing fluorescently labeled cyclosporine A (CsA*) and its antibody in a 1:1 volume ratio. The upper and lower traces correspond to vertically (I_v) and horizontally (I_h) polarized fluorescence, respectively. The unbound CsA* and the Ab–CsA* complex were made to co-elute. (B) Fluorescence polarization as a function of unlabeled cyclosporine A. This represents a homogeneous competitive immunoassay (adapted from ref. 69).

progress of labeling reactions to verify the purity of reaction products.

LIFP is capable of providing information on the formation of affinity complexes prior to or during CE separation. An example of on-line monitoring of affinity complex formation was demonstrated in a study of protein–DNA interaction (71). Because of lower binding affinity, dynamic formation of the affinity complexes was achieved and was monitored using LIFP. Both the fluorescence polarization and mobility shift information enabled studies of the DNA–protein binding. Unlike the mobility shift method that required the use of an internal marker to correct for unwanted changes of mobility, the LIFP method does not have this limitation. Prior to our studies, most fluorescence measurements for CE detection have been based on the fluorescence intensity. The CE–LIFP technique maintains the advantage of excellent sensitivity as in the case of laser-induced fluorescence detection. It provides the additional capability of identifying complex formation, suitable for studies of molecular interactions. Applications of the CE–LIFP technique to such binding systems as vancomycin and its antibody, staphylococcal enterotoxin and its antibody, and *trp* operator and *trp* repressor represent peptide–protein, protein–protein, and DNA–protein interactions (70, 72). The affinity complexes were readily distinguished from the unbound molecules on the basis of their fluorescence polarization. Studies of these common binding systems demonstrate potential wide applications of CE–LIFP.

Conclusions

CE–LIF provides an excellent means for the rapid and ultrasensitive (tens to hundreds of molecules) determination of bioanalytical compounds of interest from a wide variety of samples. The application of immunoassay by CE–LIF permits the determination of unlabeled analyte in a sensitive and selective manner, in the presence of many potential interfering components in the sample matrix. The range of immunoassays or affinity CE–LIF assays is limited only by the ability to generate a suitable antibody or aptamer to a target of interest. We have successfully used CE–LIF for the analysis of components of single cells, for the determination of therapeutic drugs in human sera, for the determination of natural toxins, and for the detection of biomarkers for DNA damage and HIV-1 infection. The use of LIFP provides additional benefits in studying molecular interactions and improving affinity assays. The use of aptamers as affinity probes presents new opportunities for a wide range of analytical applications.

Kinetic and spectroscopic studies on α- and β-cyclodextrin rotaxanes with (μ-*N*,*N*′-bis(4-pyridinylmethylene)-α,ω-alkanediimine)bis[pentacyanoferrate(II)] threads

Victor X. Jin, Donal H. Macartney, and Erwin Buncel

Abstract: [2]Pseudorotaxanes have been prepared by threading *N*,*N*′-bis(4-pyridinylmethylene)-1,2-ethanediimine (**L2**), -1,4-butanediimine (**L4**), and -1,6-hexanediimine (**L6**) ligands through α-cyclodextrin (α-CD) and β-cyclodextrin (β-CD), and have subsequently been converted to the corresponding [2]rotaxane species by coordinating bulky $[Fe(CN)_5]^{3-}$ end groups. The stability constants for the [2]pseudorotaxanes were determined by ^{1}H NMR chemical shift titrations and increase with the polymethylene chain length *n*. The rate constants for both the formation of the $[Fe(CN)_5(\mathbf{Ln})]^{3-}$ complexes from the $[Fe(CN)_5OH_2]^{3-}$ ion and **Ln**, and the rate constants for the dissociation of **Ln** from the metal complexes, exhibit significant diminutions in the presence of α- and β-CD, owing to inclusions of the free and coordinated ligands, respectively. The lability of the iron(II)–pyridine bonds also permits the spontaneous self-assembly of the [2]rotaxane upon the addition of cyclodextrin to the iron dimer complexes. The mechanism for this process involves the rate-determining dissociation of a $[Fe(CN)_5]^{3-}$ unit from $[(NC)_5Fe(\mathbf{Ln})Fe(CN)_5]^{6-}$, followed by CD inclusion of the **Ln** ligand to form a semirotaxane, and subsequent recomplexation by the $[Fe(CN)_5OH_2]^{3-}$ ion.

Key words: cyclodextrins, rotaxanes, pentacyanoferrate(II), ligand substitution, kinetics.

Résumé : En enfilant les ligands *N*,*N*′-bis(4-pyrimidylméthylène)-éthane-1,2-diimine (**L2**), -butane-1,4-diimine (**L4**) et -hexane-1,6-diimine (**L6**) à travers la α-cyclodextrine (α-CD) et la β-cyclodextrine (β-CD), il y a formation de [2]pseudorotaxanes qui ont été subséquemment transformés en espèces [2]rotaxanes par coordination avec les groupes terminaux volumineux, $[Fe(CN)_5]^{3-}$. On a déterminé les constantes de stabilité des [2]pseudorotaxanes titrages des déplacements chimiques en RMN du ^{1}H et par augmentation avec la longueur de la chaîne polyméthylène, *n*. Les constantes de formation des complexes de $[Fe(CN)_5(\mathbf{Ln})]^{3-}$ à partir de l'ion $[Fe(CN)_5OH_2]^{3-}$ et de **Ln** ainsi que de dissociation de **Ln** à partir des complexes métalliques présentent toutes des diminutions significatives en présence de α-CD et de β-CD en raison des inclusions respectivement de ligands libres et coordinés. La labilité des liaisons fer(II)–pyridine permet aussi l'auto-assemblage du [2]rotaxane lors de l'addition de cyclodextrine aux complexes dimère du fer. Le mécanisme de ce processus implique une dissociation qui détermine la vitesse d'une unité de $[Fe(CN)_5]^{3-}$ de $[(NC)_5Fe(\mathbf{Ln})Fe(CN)_5]^{6-}$, suivie d'une inclusion de CD du ligand **Ln** pour former une semirotaxane et une recomplexation subséquente par l'ion $[Fe(CN)_5OH_2]^{3-}$.

Mots clés : cyclodextrines, rotaxanes, pentacyanoferrate(II), substitution de ligand, cinétique.

[Traduit par la Rédaction]

Introduction

Rotaxanes (1, 2) are supramolecular species (3) in which a cyclic molecular bead is threaded by a linear chain and stoppered by bulky end units, thus preventing the complex from dissociating into its cyclic and linear molecular components. The syntheses of a number of [2]rotaxanes ([*n*] indicates the number of components in the rotaxane) containing a variety of cyclic beads, with alkyl or polyether chains as the threads and bulky organic groups or metal complexes as the end groups, have been reported (4–10). The cyclodextrins (CD) (11, 12), a class of cyclic oligosaccharides normally comprising six (α-CD), seven (β-CD), or eight (γ-CD) α-(1→4)-linked D(+)-glucopyranose units with a toroidal hydrophobic cavity capable of including a wide variety of guest substances (13), have also been employed as the cyclic component in the syntheses of rotaxanes in recent years (14). [2]Rotaxanes, stoppered by transition metal complexes (15–20), have generally been prepared by reacting a semirotaxane (bearing one bulky end unit) with a second metal complex or organic end unit.

In our laboratory, we have investigated the kinetics and mechanisms of the formation of a series of stable α-cyclodextrin rotaxanes of the type $[(NC)_5Fe\{R(CH_2)_nR'\text{-}CD\}Fe(CN)_5]^{4-}$, with symmetric and asymmetric threads where R and R′ = 3- and 4-cyanopyridine or 4,4′-bipyridine and (or) pyrazine, with *n* = 8–12 (20–23). These [2]rotaxanes will

self-assemble irrespective of the order of the addition of the α-CD, the $[R(CH_2)_nR']^{2+}$ ligand, and the $[Fe(CN)_5]^{3-}$ stopper components. The slower route involves initial formation of an iron dimer complex, $[(NC)_5Fe(R(CH_2)_nR')Fe(CN)_5]^{4-}$, which will not permit direct threading through α-CD because of the bulky pentacyanoferrate(II) stoppers. Slow dissociation of a $[Fe(CN)_5]^{3-}$ unit, however, followed by the α-CD inclusion of the coordinated bridging ligand yields a semirotaxane, which may be rapidly recomplexed by $[Fe(CN)_5OH_2]^{3-}$. The rate constants for this self-assembly process are dependant on the lability of the iron–nitrogen bond. We have recently reported the results of kinetic and spectroscopic investigations on similar α- and β-CD [2]rotaxanes containing shorter, conjugated neutral bis(4′-pyridyl) bridging ligands (24).

In this paper we report the results of kinetic and spectroscopic studies on the formation of α- and β-cyclodextrin [2]rotaxanes of the type $[(NC)_5Fe\{\mathbf{Ln}\cdot CD\}Fe(CN)_5]^{6-}$ in basic solution, where the neutral **Ln** bridging ligands are *N*,*N*′-bis(4-pyridinylmethylene)-1,2-ethanediimine (**L2**), -1,4-butanediimine (**L4**), and –1,6-hexanediimine (**L6**).

n = 1 **L2**
n = 2 **L4**
n = 3 **L6**

The **L2** ligand has recently been employed as a bridging ligand in the construction of a number of one-, two-, and three-dimensional coordination polymers of transition metals (25–28) and as a component in photochromic co-crystals with 1,2-diaryl-1,2-ethanediols (29). The structure of **L2** has been determined by X-ray crystallography (26).

The end group precursor, $[Fe(CN)_5OH_2]^{3-}$, is generated in basic solution by the aquation of the $[Fe(CN)_5(SO_3)]^{5-}$ ion, instead of the $[Fe(CN)_5NH_3]^{3-}$ ion, which is normally employed in acidic or neutral solutions. The stability constants for the [2]pseudorotaxanes, {**Ln**·CD}, have been determined by means of ^{1}H NMR spectroscopic titrations. We report the results of kinetic and spectroscopic studies on the ligand substitution reactions involving α- and β-cyclodextrin inclusion complexes of the neutral diimine ligands **Ln** in basic solution. In addition, the kinetics and mechanism of the self-assembly of $[(NC)_5Fe\{\mathbf{Ln}\cdot CD\}Fe(CN)_5]^{6-}$ rotaxanes from the corresponding iron dimer complex have been studied using ^{1}H NMR spectroscopic techniques.

Experimental

Materials

The α- and β-cyclodextrins (Aldrich) were dried at 80 °C under reduced pressure for at least 12 h prior to use. The 4-pyridinecarboxaldehyde, 1,2-diaminoethane, 1,4-diaminobutane, and 1,6-diaminohexane (Aldrich) were used as received. Sodium pentacyano(sulphito)ferrate(II) hydrate ($Na_5[Fe(CN)_5SO_3]\cdot 3H_2O$) was prepared by a literature method (30). The $[Fe(CN)_5OH_2]^{3-}$ ion was generated in basic solution by the rapid aquation of the sulphite salt ($t_{1/2} \approx$ 1 min, I = 0.05 mol/L (31)). The sulphite salt is relatively stable at concentrations up to 10^{-3} mol/L without dimerization and oxidation (32).

Syntheses of *N*,*N*′-bis(4′-pyridinylmethylene)-α,ω-alkanediimines (L2, L4, and L6)

4-Pyridinecarboxaldehyde (1 mL, 1.136 g, 10.32 mmol) and 5.2 mmol of the appropriate α,ω-diaminoalkane were dissolved in 1 and 2 mL of methanol, respectively. The two methanolic solutions were mixed rapidly and stirred at room temperature for approximately 30 min. The methanol was then removed under vacuum to yield a pale yellow semi-solid. The reaction product was then recrystallized from ether:methanol (2:1) to give white crystals.

Physical measurement

The kinetics of the ligand substitution reactions of the substituted pentacyanoferrate(II) complexes ($[Fe(CN)_5L]^{3-}$) were determined spectrophotometrically by stopped-flow (Applied Photophysics SX-17MV) or conventional (Hewlett-Packard 8452A) mixing techniques. The formation reactions were carried out under pseudo-first-order conditions of excess entering ligand concentrations over the concentrations of freshly prepared $[Fe(CN)_5OH_2]^{3-}$ ion solutions (λ_{max} = 440 nm, ε = 660 M^{-1} cm^{-1} (35)). The dissociations of the substituted $[Fe(CN)_5\mathbf{Ln}]^{3-}$ complexes involved the use of 0.10 mol/L DMSO to scavenge the dissociated metal center. Plots of $\ln(A_t - A_\infty)$ or $\ln(A_\infty - A_t)$ against time were linear for at least three half-lives, with six to eight replicate experiments performed for the stopped-flow measurements and

one experiment for the ligand dissociation reactions (the first-order rate constants are available in the Supplementary material).[2] The reaction temperature was maintained to within 0.1 °C over the range 20.0–32.5 °C by means of external circulating water baths. The ionic strength was kept at 0.05 mol/L by using sodium chloride.

The ^{1}H NMR spectra were recorded on Bruker AC-200 and AM-400 instruments in D_2O or DMSO-d_6, utilizing the residual solvent proton signal as the reference. The cyclodextrin inclusion stability constants for the ligands in this study were determined by ^{1}H NMR titrations of the ligands with α- or β-cyclodextrins, as described previously (36, 37). The mass spectrometry measurements were obtained on a VG Quattro quadrupole mass spectrometer, with an atmospheric pressure electrospray source. Samples, as solutions in 1:1 mixture of methanol and distilled water with 0.010 mol/L α-cyclodextrin, were introduced into the source at a flow rate of 5 mL min^{-1}. Elemental analyses were performed by Canadian Microanalytical Services, Delta, British Columbia.

The stability constants for the α- and β-cyclodextrin pseudorotaxanes of the **L2**, **L4**, and **L6** ligands were calculated from ligand substitution kinetic data and ^{1}H NMR chemical shift titrations by the application of nonlinear least-squares and Simplex optimization programs to the equations for a 1:1 guest–host model as described previously (36, 37).

Results and discussion

[2]Pseudorotaxane complexes

While the neutral *N,N′*-bis(4′-pyridylmethylene)-α,ω-alkanediimine ligands, **L2**, **L4**, and **L6** prepared in this study are easily hydrolysed in the acid and neutral aqueous solution, they are relatively stable in basic solution (pH > 12). The stabilities of α- and β-cyclodextrin in the basic solution permit an investigation of their inclusion interactions with the ligands in this medium. The additions of α- or β-CD to aqueous solutions of the neutral ligands result in the formation of [2]pseudorotaxane complexes (eq. [1]).

$$[1] \qquad \mathbf{Ln} + \mathrm{CD} \underset{}{\overset{K_L}{\rightleftharpoons}} \{\mathbf{Ln}\cdot\mathrm{CD}\}$$

The formations of the [2]pseudorotaxane complexes {**Ln**·CD} result in downfield chemical shifts for the threaded ligand proton resonances with respect to their positions for the free ligand. The observed chemical shift changes ($\Delta\delta_{obs}$) are proportional to the fraction of the ligand that is included in the CD cavity (eq. [2]).

$$[2] \qquad \Delta\delta_{obs} = \frac{\Delta\delta_{lim}[\mathbf{Ln}\cdot\mathrm{CD}]}{[\mathbf{Ln}]_T}$$

Using a global fit of the changes in the chemical shifts ($\Delta\delta_{obs}$) of the aromatic and aliphatic protons, the stability constants (K_L) for **L2**, **L4**, and **L6** with α- and β-CD, were determined at 25 °C at I = 0.05 mol/L (NaCl), and are presented in Table 1, along with the values of $\Delta\delta_{lim}$. The values of $\Delta\delta_{lim}$ for the included ligands are greater with α-CD than with β-CD as a result of the tighter fit of the ligand in the smaller α-CD cavity.

The stability constants K_L for the formation of cyclodextrin inclusion complexes of diimine neutral ligands increase with an increase in the methylene chain length n. This trend has already been observed previously in our laboratory (20–23) for other ligands with *N*-heterocyclic end groups ($R(CH_2)_nR^{2+}$, n = 8–12). With a shorter polymethylene chain linking the end group, the hydrophilic 4-pyridyl group is inserted further into the hydrophobic cyclodextrin interior, resulting in a destabilization of the pseudorotaxane. The cyclodextrin stability constant determined for {**L6**·α-CD} (730 ± 38 M^{-1}) is similar to the values measured previously for related ligands ($R(CH_2)_{10}R^{2+}$) with similar chain lengths; 1400 ± 130 M^{-1} for $\{pyz(CH_2)_{10}pyz\cdot\alpha\text{-CD}\}^{2+}$ (22), 1500 ± 100 M^{-1} for $\{bpy(CH_2)_{10}bpy\cdot\alpha\text{-CD}\}^{2+}$ (21), 1300 M^{-1} for $\{pyr(CH_2)_{10}pyr\cdot\alpha\text{-CD}\}^{2+}$ (38), 610 ± 130 M^{-1} for $\{3CNpyr(CH_2)_{10}3CNpyr\cdot\alpha\text{-CD}\}^{2+}$, and 900 ± 230 M^{-1} for $\{4CNpyr(CH_2)_{10}4CNpyr\cdot\alpha\text{-CD}\}^{2+}$ (23). From the present and previous studies (39), it has been concluded that the stability constants are dependent more on the length of polymethylene chain than on the size and charge of the end groups. Due to the poorer aqueous solubility of the present neutral ligands with more than six methylene groups in the chain, data are limited in this study to two-, four-, and six-methylene chain ligands.

[a]Kinetic measurements at 25.0 °C, I = 0.05 mol/L (NaCl). The α and β symbols refer to limiting parameters measured for α-CD and β-CD, respectively.

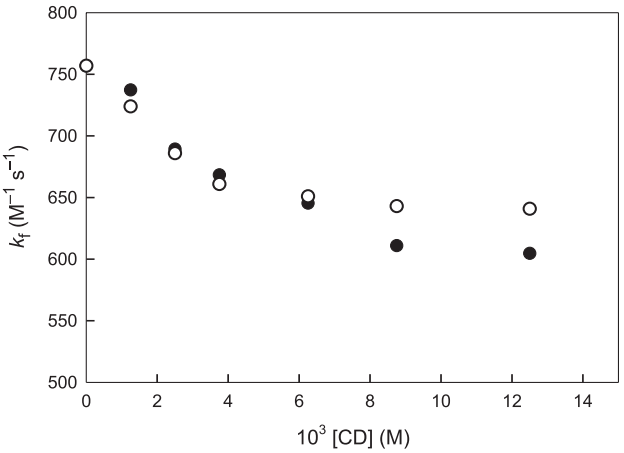
The presence of the [2]pseudorotaxanes of the **Ln** ligands with α-CD ({**Ln**·α-CD}$^{2+}$) was also detected by electrospray mass spectroscopy (ES-MS). In the ES-MS spectra, signals were observed at m/z = 1266.9 for {**L6**·α-CD+H}$^+$ (expected at m/z = 1267.2) and 1288.9 for {**L6**·α-CD+Na}$^+$. A signal observed at m/z = 1088.9 was assigned to the {$NH_2(CH_2)_6NH_2$·α-CD} fragment. Similar molecular ions and fragments were observed in the ES-MS spectra of the [2]pseudorotaxanes with the other **Ln** ligands.

Cyclodextrin semirotaxane and rotaxane complexes

The ligand substitution reactions between the $[Fe(CN)_5OH_2]^{3-}$ ion and the neutral ligands (**Ln**) result in the rapid formation of $[Fe(CN)_5(\mathbf{Ln})]^{3-}$ complexes, which exhibit metal-to-ligand charge transfer (MLCT) bands in the 460–480 nm range. The addition of 1 equiv. of $[Fe(CN)_5OH_2]^{3-}$ ion to a solution containing the cyclodextrin-included ligands produces a semirotaxane species (eq. [3]). The visible spectra of the semirotaxanes exhibit a bathochromic shift in the MLCT bands (Table 2), as observed previously for pentacyanoferrate(II) complexes containing several neutral 4-substituted pyridine ligands (24, 37). The addition of one or more further equivalents of the $[Fe(CN)_5OH_2]^{3-}$ ion yields the corresponding rotaxane complex, $[(NC)_5Fe\{\mathbf{Ln}\cdot CD\}Fe(CN)_5]^{6-}$ (eq. [4]).

$$[3]\quad [Fe(CN)_5OH_2]^{3-} + \{\mathbf{Ln}\cdot CD\} \underset{k_d^{CD}}{\overset{k_f^{CD}}{\rightleftharpoons}} [Fe(CN)_5\{\mathbf{Ln}\cdot CD\}]^{3-} + H_2O$$

$$[4]\quad [Fe(CN)_5\{\mathbf{Ln}\cdot CD\}]^{3-} + [Fe(CN)_5OH_2]^{3-} \rightleftharpoons [(NC)_5Fe\{\mathbf{Ln}\cdot CD\}Fe(CN)_5]^{6-}$$



Ligand substitution kinetics

In this study, the labile $[Fe(CN)_5OH_2]^{3-}$ ion was generated in basic solution by the aquation of the $[Fe(CN)_5SO_3]^{5-}$ ion (31, 40) rather than the $[Fe(CN)_5NH_3]^{3-}$ ion more commonly employed in neutral solutions. The ligand substitution reactions of the $[Fe(CN)_5OH_2]^{3-}$ ion with the neutral ligands in basic solution (eq. [5]) may be monitored by following the appearance of the MLCT bands of the $[Fe(CN)_5(\mathbf{Ln})]^{3-}$ products (Table 2) and measured by using stopped-flow

$$[5]\quad [Fe(CN)_5OH_2]^{3-} + \mathbf{Ln} \underset{k_d^0}{\overset{k_f^0}{\rightleftharpoons}} [Fe(CN)_5\mathbf{Ln}]^{3-} + H_2O$$

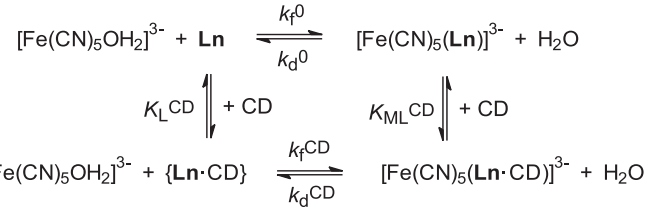
Fig. 1. Dependences of k_f on[α-CD] (●) and [β-CD] (o) for the reaction of the $[Fe(CN)_5OH_2]^{3-}$ ion with the **L4** ligand at 25.0 °C, I = 0.05 mol/L (NaCl).

techniques. The reactions were carried out under pseudo-first-order conditions of excess entering ligand concentration. The observed pseudo-first-order rate constants display a first-order dependence on [**Ln**], and the second-order rate constants (k_f^0) determined at 25.0 °C and an ionic strength of 0.05 mol/L (NaCl), are presented in Table 2. The formation rate constants (771 ± 7 M^{-1} s^{-1} for **L2**, 757 ± 11 M^{-1} s^{-1} for **L4**, and 721 ± 29 M^{-1} s^{-1} for **L6**) are of similar magnitude as the literature (24, 37, 40) values for other neutral bis(4-pyridyl) ligands and significantly less than those of the singly and doubly positive charged bis(4-pyridyl) ligands (21–23, 36, 40–42), as discussed in the following. The rate constants for the formation of $[Fe(CN)_5(\mathbf{Ln})]^{3-}$ also decrease with an increase in the methylene chain length. Upon inclusion of the ligand by α- or β-CD (Scheme 1), the rate constant for the substitution reaction is observed to decrease (Fig. 1), reaching a limiting value of k_f^{CD} at high α- or β-CD concentrations.



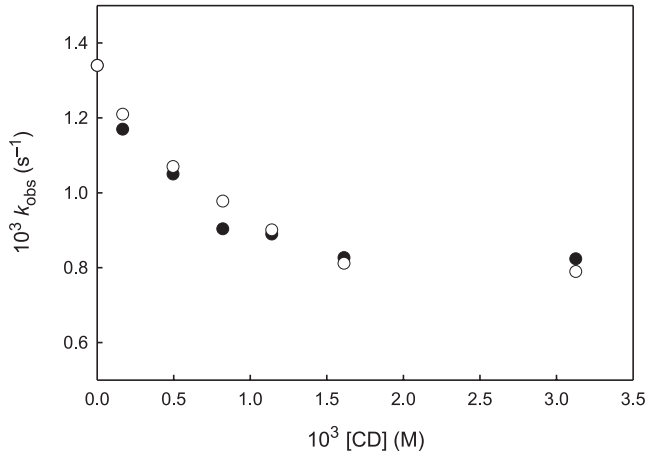
The second-order rate constants (k_f^{CD}) for the reactions of the included ligands and the inclusion stability constants (K_L) were obtained from nonlinear least-squares fits of the experimental rate constants (k_f^{obs}) to eq. [6].

$$[6] \qquad k_f^{obs} = \frac{k_f^0 + k_f^{CD} K_L^{CD} [CD]}{1 + K_L^{CD} [CD]}$$

The values of k_f^0, k_f^{CD}, and K_L at 25 °C and the corresponding activation parameters are presented in Table 2.

The ligand substitution reactions of the $[Fe(CN)_5OH_2]^{3-}$ are commonly accepted to proceed by an ion pair dissociative (D_{IP}) mechanism (40) in which the rate-determining step involves the dissociation of the aqua ligand from the metal center within a $[Fe(CN)_5OH_2//L]^{(3-n)-}$ ion-pair complex. The observed rate constants (k_f) are therefore dependent on the magnitude of the ion-pair stability, which increases with the charge on the entering ligand. The decrease in the formation rate constants results from an increase in the methylene chain length from two to six carbons, as the donor nitrogens are placed further apart and the efficiency of the precusor ion pair $[Fe(CN)_5OH_2//L]^{3-}$ leading to substitution decreases. In the presence of excess cyclodextrin, the rate constants for the formation of semirotaxanes were reduced to approximately 75% of the corresponding value of free ligand. The decrease also results from a decrease in the proportion of "effective" ion pairs that lead to substitution by placing the donor atom of the ligand in close proximity to the site of the leaving aqua ligand. Upon inclusion of the ligand within the cyclodextrin cavity, the neutral ligand is less accessible to form an ion pair with the $[Fe(CN)_5OH_2]^{3-}$ ions. In addition, the included ligand is much larger than the free ligand, such that its donor nitrogen atom is accessible on a smaller portion of the surface of the cyclodextrin-ligand host–guest complex. The larger β-CD host allows for deeper insertion and therefore the limiting rate constants in the presence of high [β-CD] are generally somewhat lower relative to those measured at high [α-CD]. These diminutions are small compared with the decreases reported previously for the $[bpy(CH_2)_{10}bpy]^{2+}$ (21) and $[4CNpyr(CH_2)_{10}4CNpyr]^{2+}$ (23) ligands in the presence of α-CD, for example. With positively charged ligands the charges are "separated" by the cyclodextrin cavity, resulting in a reduction of the effective charge. The enthalpies of activation associated with k_f^0 and k_f^{CD} are the same within the experimental errors, which are attributed to the same rate-determining step by loss of the aqua ligand. There is reasonable agreement between the stability constants for cyclodextrin guest–host complexes {**Ln**·CD} determined from NMR chemical shift titrations (Table 1) and from the ligand substitution kinetic data (Table 2). Similar differences, resulting from the use of these different techniques, have been observed previously for other substituted pentacyanoferrate(II) complexes with cyclodextrins (36, 37).

Scheme 1.



The kinetics of the dissociation of the ligands **Ln** from the $[Fe(CN)_5(\mathbf{Ln})]^{3-}$ complexes have been investigated. The reaction may be followed by the addition of an excess of dimethyl sulfoxide (0.10 mol/L) to trap the $[Fe(CN)_5]^{3-}$ intermediate and form a very inert (k_{-DMSO} = 7.5 × 10^{-5} s^{-1} at 25.0 °C (I = 1.0 mol/L ($LiClO_4$) (43)), colorless (λ_{max} = 352 nm) $[Fe(CN)_5DMSO]^{3-}$ product Limiting first-order rate constants (k_d^0) are observed at 0.10 mol/L DMSO. The addition of either α- or β-CD, which forms a semirotaxane complex ($[Fe(CN)_5(\mathbf{Ln}\cdot CD)]^{3-}$), resulted in a decrease in the rate constant for dissociation of included coordinated **Ln** ligand (Fig. 2). The observed first-order dissociation rate constants (k_d^{obs}) may be expressed in terms of the specific rate constants k_d^0 and k_d^{CD} and the cyclodextrin inclusion stability constants (eq. [7]).

$$[7] \qquad k_d^{obs} = \frac{k_d^0 + k_d^{CD} K_{ML}^{CD} [CD]}{1 + K_{ML}^{CD} [CD]}$$

The limiting rate constants for the included complexes k_d^{CD} and the inclusion stability constants were determined by the nonlinear least-squares fit of the experimental rate constants

© 2005 NRC Canada

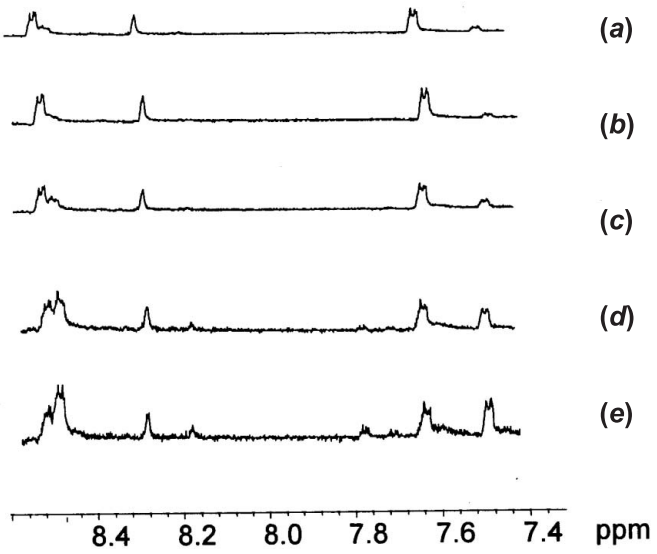


Fig. 2. Dependences of k_d on [α-CD] (●) and [β-CD] (o) for the reaction of the $[Fe(CN)_5\mathbf{L6}]^{3-}$ ion with DMSO (0.10 mol/L) at 25.0 °C, I = 0.05 mol/L (NaCl).

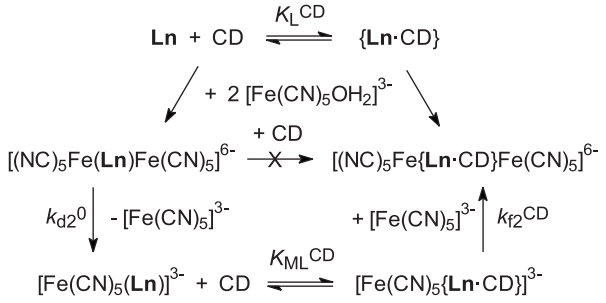

k_d^{obs} to eq. [7]. The dissociation rate constants and activation parameters for the $[Fe(CN)_5(\mathbf{Ln})]^{3-}$ complexes and the corresponding semirotaxanes $[Fe(CN)_5\{\mathbf{Ln}\cdot CD\}]^{3-}$ species are presented in Table 2.

The ligand dissociation reactions of substituted pentacyanoferrate(II) complexes procede by a dissociative (D) mechanism (40), with the rate constant for loss of the L^{n+} from $[Fe(CN)_5L]^{(3-n)-}$ being independent of the nature of the entering ligand, and reaching a limiting value at high entering ligand (such as DMSO) concentrations. The diminution of rate constant decreases with the length of the polymethylene chain, with decreases of 58% (ethane), 51% (butane), and 39% (hexane) from the nonincluded ligand rate constants (Table 2). The magnitudes of the decreases in the ligand dissociation rate constants are comparable to the trends observed for other neutral (24, 36) and cationic (21–23, 36) ligands and are attributed, in part, to a stabilization of the ground state through greater π-back-bonding from the metal to the CD-included, 4′-substituted pyridine ring.

Fig. 3. ^{1}H NMR spectra of the aromatic pyridine protons as a function of time for the self-assembly of the $[(NC)_5Fe\{\mathbf{L2}\cdot\alpha\text{-}CD\}Fe(CN)_5]^{6-}$ rotaxane upon addition of α-CD (5×10^{-2} mol/L) to the $[(NC)_5Fe\{\mathbf{L2}\cdot\alpha\text{-}CD\}Fe(CN)_5]^{6-}$ dimer (5×10^{-3} mol/L) in 8 mmol/L NaOD (I = 0.05 mol/L (NaCl)) at: (*a*) 1 min, (*b*) 5 min, (*c*) 9 min, (*d*) 30 min, and (*e*) 45 min.

Scheme 2.

Rotaxane self-assembly

The addition of an excess of α-cyclodextrin to solutions of the dimer complexes resulted in a slow formation of the corresponding [2]rotaxane. The kinetics of this process may be monitored by ^{1}H NMR spectroscopy. The symmetry-related proton resonances of the bridging ligand of the dimer are separated into pairs of peaks as rotaxane is formed, as indicated in Fig. 3 for the complex containing the **L2** ligand. The direct inclusion of the dimer by threading through the α-CD cavity (5.5 Å diameter) is prevented by the bulky $[Fe(CN)_5]^{3-}$ units (9.0 Å diameter). The self-assembly of [2]rotaxanes has been shown to proceed by two possible routes (20–24), depending on the order of addition of the three components (Scheme 2).

The first route, resulting from the addition of the labile aquapentacyanoferrate(II) ion to the corresponding preassembled [2]pseudorotaxane species (eqs. [1], [3], and [4]), is very rapid. A second, slower route involves the addition of cyclodextrin to the dimeric $[(NC)_5Fe(\mathbf{Ln})Fe(CN)_5]^{6-}$ species. This pathway involves the rate-determining dissociation of a pentacyanoferrate(II) ion from the bridging ligand, followed by the threading of the cyclodextrin by the free end of the coordinated ligand, and the rapid recomplexation by an aquapentacyanoferrate(II) ion (Scheme 2). The extent of the rotaxane formation is determined by the stability constant of the semirotaxane species (K_{ML}) and the kinetics of approach to equilibrium is given by $\ln[([L]_0\text{-}[L\cdot CD]_e)/([L\cdot CD]_t\text{-}[L\cdot CD]_e)] = kt$, where $[L]_0$ is the initial dimer concentration, and $[LCD]_t$ and $[LCD]_e$ are the concentrations of the rotaxane at time t and at equilibrium, respectively. The first-order rate constants determined for the self-assembly process at 25 °C, using [α-CD] = 5×10^{-2} mol/L, are $(1.82 \pm 0.28) \times 10^{-3}$ s^{-1}, $(1.77 \pm 0.21) \times 10^{-3}$ s^{-1}, and $(1.45 \pm 0.16) \times 10^{-3}$ s^{-1} for **L2**, **L4**, and **L6**, respectively. The rate constants for this process are very similar in magnitude to values (k_d^0) determined for the ligand dissociation reactions of iron complexes (Table 2). The self-assembly by the latter route may be related to the lability of the iron–nitrogen bond. More rapid self-assembly processes were observed for the pentacyanoferrate(II) complexes with greater lability of the iron–nitrogen bond in the complexes containing the 4-cyanopyridine head groups ($k = (3.8 \pm 0.1) \times 10^{-2}$ s^{-1} (23)),

© 2005 NRC Canada

while with the more inert bond to the pyrazinium (pyz) nitrogen, in a threading ligand such as $pyz(CH_2)_{10}pyz^{2+}$ (k = $(2.6 \pm 0.1) \times 10^{-4}$ s^{-1} (22)), results in much slower self-assembly of the rotaxane.

Stereoselective synthesis and stereochemistry of *r*-2-alkoxycarbonyl-*c*-3-*o*-substituted phenyl-1,4-thiazane 1,1-dioxides

N. Bhavani, S. Perumal, and R. Banureka

Abstract: *r*-2-Alkoxycarbonyl-*c*-3-aryl-1,4-thiazane 1,1-dioxides were obtained as the stereoselective product, when the aldehyde used was *o*-substituted benzaldehyde while the *p*-substituted benzaldehydes gave a trans product. The relative configuration of the adjacent alkoxycarbonyl and aryl groups was assigned from the vicinal coupling constant, ^3J = 10.6 Hz in the trans isomer and 3.2 Hz in the cis isomer, and from the multiplicity pattern, i.e., a doublet for the H-2 proton of the trans isomer and a triplet for the H-2 proton of the cis isomer. The unusual, large long-range coupling (^4J = 2.8 Hz) because of the "W" arrangement between H-2e and H-6e across the ring type was very useful for confirming the cis configuration and chair conformation of the isomer. The various ^{1}H and ^{13}C NMR assignments were made with the help of ^{1}H–^{1}H COSY, ^{1}H–^{13}C COSY, HMBC, and NOESY spectral analyses.

Key words: ^{1}H and ^{13}C NMR, ^{1}H–^{1}H COSY, ^{1}H–^{13}C COSY, HMBC, NOESY, stereoselectivity, 1,4-thiazane.

Résumé : Les 1,1-dioxydes de *r*-2-alkoxycarbonyl-*c*-3-aryl-1,4-thiazane sont obtenus comme produit stéréosélectif lorsque l'aldéhyde utilisé est un benzaldéhyde ortho substitué alors que les benzaldéhydes substitués en para conduisent au produit trans. Les configurations relatives des groupes alkoxycarbonyle et aryle adjacents ont été attribuées sur la base de la constante de couplage vicinale, ^3J = 10,6 Hz dans l'isomère trans et 3,2 Hz dans l'isomère cis, et du patron de multiplicité, c'est-à-dire la présence d'un doublet pour le proton H-2 de l'isomère trans et d'un triplet pour le proton H-2 de l'isomère cis. La constante de couplage à longue distance relativement importante (^4J = 2,8 Hz) causée par l'arrangement en « W » des protons H-2e et H-6e à travers ce type de cycle a été très utile pour confirmer la configuration cis et la conformation chaise de l'isomère. Les diverses attributions des spectres RMN du ^{1}H et du ^{13}C ont été faites sur la base d'analyses spectrales ^{1}H–^{1}H COSY, ^{1}H–^{13}C COSY, HMBC et NEOSY.

Mots clés : ^{1}H et ^{13}C RMN, ^{1}H–^{1}H COSY, ^{1}H–^{13}C COSY, HMBC, NEOSY, stéréosélectivité, 1,4-thiazane.

[Traduit par la Rédaction]

Introduction

Stereochemistry is an intrinsic universal feature of organic compounds and influences virtually all pharmacodynamic, pharmacokinetic, and biotransformation processes (1). Drug molecules having the proper absolute configuration only react with the receptor sites in the human body (2). Hence, the stereoselectivity (3) gains importance in organic synthesis. Thiazanes are widely used in new drug development (4, 5). Thiazane derivatives stimulate calcium uptake (6) used as antitumour, antiviral (7), bactericidal, parasiticidal (8), antituberculotic (9), and cardiovascular (10) agents, and they are also used as local anesthetics (11).

So far 3,5-disubstituted (12), 2,3,5-trisubstituted (13, 14), and 2,3,5,6-tetrasubstituted (15, 16) 1,4-thiazanes have been reported. Eliel and co-workers (17) reported the synthesis of *cis*-2,3-diphenyl-1,4-thiazane 1,1-dioxide from optically active starting material, and there too after several (more than 10 steps) tedious procedures. There has been no report on the synthesis of 2,3-disubstituted-1,4-thiazane 1,1-dioxides where the two substituents are different and in less stable cis configuration. Here, we report an one-pot synthesis of *cis*-2-alkoxycarbonyl-3-aryl-1,4-thiazane 1,1-dioxides, where the position of a substituent in the aryl ring controls the stereochemistry of the product.

For a 2,3-disubstituted 1,4-thiazane (in the rigid chair form), two configurational isomers, cis and trans, are possible. Generally, the thermal reaction will lead to the thermodynamically more stable trans isomer with the preferred diequatorial orientation of the substituents. The cis isomer with one axial substituent and one equatorial substitutent will be the less stable, kinetic-controlled product. In the present work, the trans isomer was obtained with benzaldehyde and *p*-substituted benzaldehydes, but the cis isomer was the product with *o*-substituted benzaldehydes.

Results and discussion

Synthesis of 2-alkoxycarbonyl-3-aryl-1,4-thiazane 1,1-dioxides (Scheme 1) has been carried out by the condensation of dialkyl ethane – 1,2-disulphonylacetate (18) with 1 mol of araldehyde and ammonium acetate. Formation of a six-

membered 1,4-thiazane ring was confirmed by microanalysis, IR, and mass spectra. Their stereochemistry was studied through NMR spectra.

The ^{1}H NMR chemical shift values with multiplicity patterns and coupling constants, along with their assignments are given in Table 1.

The diaxial coupling constant (10.6 Hz) between the H-2 and H-3 protons for the compounds (**1**–**3**) gives evidence for the trans (17) configuration with the preferred diequatorial orientation of the two substituents for the *p*-substituted phenyl compounds.

Stereochemistry of *o*-substituted phenyl compounds (6 and 7)

The H-2 and H-3 protons do not appear as two simple doublets with diaxial coupling constants. From the small coupling (17) constant (Table 1) between H-2 and H-3 protons, it is inferred that there is a change in configuration from *e*, *e* to *a*, *e*. For the cis configuration of the substituents with an *a*, *e* conformation, there are two possibilities, i.e., aryl group equatorial and ethoxycarbonyl group axial or aryl group axial and ethoxycarbonyl group equatorial. The benzylic proton signal appears as a doublet ($^3J_{a,e}$ = 3.2 Hz) so it has only one coupling partner. But the triplet (Spectrum 1) for the H-2 proton indicates that it has one more coupling partner, and that should be necessarily a long-range coupling partner (19). Long-range coupling is possible only with a "W" arrangement (20), and hence, the H-2 proton must be equatorial and ester group axial; consequently, the aryl group should be equatorial. In the ^{1}H–^{1}H COSY (21) spectrum (Spectrum 2), there is a cross peak (A) between the H-2e triplet and the doublet of the quartet signal at 2.96 ppm (i.e., H-6e), and this is an added evidence for the long-range coupling. The large cross peak (B) is due to the coupling be-

signals, 155.41 and 165.67 ppm, the former is assigned to the methoxy group bearing the ipso carbon (C-2′) since it gives multiple bond correlations with aromatic protons and methoxy methyl protons, and the latter is assigned to the carbonyl carbon since it gives multiple bond correlations with H-3a, H-2e, and ester methylene protons.

The orientation of the NH proton, whether axial or equatorial, is derived only from the NOE (21) spectrum (Spectrum 4). The NH proton gives a NOE with the H-6′ proton (A) and a strong NOE with the H-5a proton (B); the latter excludes the axial orientation of the NH proton and there is no NOE cross peak between the NH proton and the methoxy methyl protons. The various NOE cross peaks confirm the equatorial orientation of the NH proton and the perpendicular orientation of the *o*-methoxyphenyl ring to the plane of the thiazane ring (Fig. 2). The absence of NOE between the NH and ethoxycarbonyl methyl and methylene protons (which are relatively in the 1,3-diaxial position, if N-H is axial) excludes the possibility of an equilibrium between axial NH and equatorial NH.

Thus, the axial orientation of the ester group at the C-2 position, the equatorial and perpendicular orientation of the

o-substituted phenyl group at the C-3 position, and the chair conformation of the thiazane ring are derived from NMR spectra and confirmed by single crystal X-ray diffraction study. The ORTEP diagram is given in Fig. 3.

Conclusion

o-Substituted benzaldehydes give *r*-2a-alkoxycarbonyl-*c*-3-*o*-substituted phenyl-1,4-thiazane 1,1-dioxides when treated with dialkyl ethane – 1,2–disulphonylacetate and ammonium acetate as the stereoselective cis product. On the other hand, benzaldehyde and *p*-substituted benzaldehydes

© 2005 NRC Canada

give stereoselectively the trans product. The cis configuration with the axial ethoxycarbonyl group and equatorial aryl group is a consequence of the steric hindrance between the *o*-substituent in the phenyl ring and the ethoxycarbonyl group if it were in an equatorial orientation.

Experimental

Melting points are uncorrected. Microanalytical data were obtained from IISc, Bangalore-12, India. IR spectra were recorded on a JASCO-IR-700 IR spectrophotometer as potassium bromide discs of the sample. Mass spectra were obtained from RSIC, IIT, Chennai, India.

NMR spectra were recorded at 27 °C on a Bruker AMX 400 instrument operating at 400 MHz at a concentration of 20 mg/mL in $CDCl_3$ for ^1H NMR and 100 MHz at a concentration of 40 mg/mL in $CDCl_3$ for ^{13}C NMR, and chemical shifts were referenced internally to TMS in all cases.

The experimental parameters for the ^1H–^1H COSY spectra were: number of scans 16, number of data points 1 K, relaxation delay 1 s, acquisition time 0.1348 s, and spectral width 3817 Hz. The ^1H–^{13}C COSY spectra were obtained using the following parameters: number of scans 64, number of data points 2 K, acquisition time 0.666 s, relaxation delay 1 s, and spectral width 9981 Hz in F_1 and 15 576 Hz in F_2.

Crystallogrpahic data (22)

Compound **6** forms monoclinic crystals, a = 25.706 Å (5), b = 9.7180 Å (19), c = 12.245 Å (2), β = 93.44(3)°, Z = 8, space group $C2/c$. The structure was solved from 3132 observed reflections (Mo Kα radiation), and refined to R = 0.093 and R_w = 0.100.

Compounds

r-2e-Ethoxycarbonyl-*t*-3-phenyl-1,4-thiazane 1,1-dioxide (1)

A mixture of diethyl ethane – 1,2-disulphonylacetate (0.05 mol) (18), benzaldehyde (0.05 mol), and ammonium acetate (0.06 mol) in ethanol (100 mL) was heated under reflux for 6 h. The excess of solvent was removed by distillation and the mixture was kept overnight. The separated solid was filtered, washed with water, dried and recrystallized from ethanol. Yield: 55%; mp 164 to 165 °C. IR (cm^{-1}): 3400 (NH), 1722 (C=O), 1292 (asy. SO_2), 1126 (sym. SO_2). ^1H NMR (ppm): 1.00 (3H, t, CH_3), 1.88 (1H, br.s, NH), 3.19 (2H, m, H-6a, H-6e), 3.47 (2H, m, H-5a, H-5e), 4.01 (2H, q, CH_2), 4.06 (1H, d, $^3J_{a,a}$ = 10.6 Hz, H-2a), 4.46 (1H, d, $^3J_{a,a}$ = 10.6 Hz, H-3a), 7.32–7.38 (5H, m, aromatic). ^{13}C NMR (ppm): 13.69 (CH_3), 43.71 (C-5), 52.89 (C-6), 62.20 (CH_2), 62.78 (C-3), 72.65 (C-2), 127.71–128.92 (aromatic carbon), and 138.05 (ipso carbon). MS (*m*/*z*): 283, 238, 211, 196, 191, 172, 146, 133, 131, 130, 119, 118, 105, 104. Anal. calcd. for $C_{13}H_{17}NO_4S$: C 55.12, H 6.01, N 4.94; found: C 55.45, H 6.10, N 4.81.

r-2e-Ethoxycarbonyl-*t*-3-*p*-tolyl-l,4-thiazane 1,1-dioxide (2)

r-2e-Ethoxycarbonyl-*t*-3-*p*-tolyl-l,4-thiazane 1,1-dioxide (**2**) was obtained following the procedure of compound **1**. Yield: 50%; mp 145 to 146 °C. IR (cm^{-1}): 3420 (NH), 1724 (C=0), 1290 (asy. SO_2), 1125 (sym. SO_2). ^1H NMR (ppm): 0.99 (3H, t, CH_3), 2.05 (1H, br.s, NH), 2.29 (3H, s, tolyl), 3.12 (2H, m, H-6a, H-6e), 3.40 (2H, m, H-5a, H-5e), 3.99 (2H, q, CH_2), 4.04 (1H, d, $^3J_{a,a}$ = 10.6 Hz, H-2a), 4.38 (1H, d, $^3J_{a,a}$ = 10.6 Hz, H-3a), 7.10 (2H, d, aromatic), 7.23 (2H, d, aromatic). ^{13}C NMR (ppm): 13.66 (CH_3), 21.03 (tolyl), 43.62 (C-5), 52.77 (C-6), 62.08 (CH_2), 62.42 (C-3), 72.58 (C-2), 125.49–138.62 (aromatic), 161.71 (C=O). Anal. calcd. for $C_{14}H_{19}NO_4S$: C 56.56, H 6.40, N 4.71; found: C 56.43, H 6.46, N 4.63.

r-2e-Methoxycarbonyl-*t*-3-phenyl-1,4-thiazane 1,1-dioxide (3)

r-2e-Methoxycarbonyl-*t*-3-phenyl-1,4-thiazane 1,1-dioxide (**3**) was obtained following the procedure of compound **1**. Yield: 45%; mp 144–146 °C. IR (cm^{-1}), 3425 (NH), 1715 (C=0), 1295 (asy. SO_2), 1130 (sym. SO_2). ^1H NMR (ppm): 2.05 (1H, s, NH), 3.22 (2H, m, H-6a, H-6e), 3.48 (2H, m, H-5a, H-5e), 3.59 (3H, s, CH_3), 4.09 (1H, d, $^3J_{a,a}$ = 10.6 Hz, H-2a), 4.48 (1H, d, $^3J_{a,a}$ = 10.6 Hz, H-3a), 7.31 (5H, m, aromatic). ^{13}C NMR (ppm): 43.58 (C-5), 52.73 (C-6), 52.92 (CH_3), 62.67 (C-3), 72.44 (C-2), 127.48–128.83 (aromatic), 138.07 (ipso), 162.28 (C=O). Anal. calcd. for $C_{12}H_{15}NO_4S$: C 53.53, H 5.58, N 5.20; found: C 53.38, H 5.62, N 5.14.

r-2e-Ethoxycarbonyl-*t*-3-(*p*-methoxyphenyl)-1,4–thiazane 1,1-dioxide (4)

Diethylethane-1,2-disulphonyl acetate (0.05 mol), *p*-methoxybenzaldehyde (0.05 mol), and ammonium acetate (0.06 mol) in ethanol (100 mL) was refluxed for 15 h. The excess solvent was removed by distillation and the residue was poured into water. It solidified after 15 days. The solid was filtered, washed with water, then with ether, dried, and recrystallized from an ethanol–acetone mixture. Yield: 25%; mp 165–167 °C. IR (cm^{-1}): 3450 (NH), 1735 (C=O), 1290 (asy. SO_2), 1115 (sym. SO_2). Anal. calcd. for $C_{14}H_{19}NO_5S$: C 53.67, H 6.07, N 4.47; found: C 53.60, H 6.03, N 4.38. Very low solubility in $CDCl_3$.

r-2e-Ethoxycarbonyl-*t*-3-(*p*-chlorophenyl)-1,4-thiazane 1,1-dioxide (5)

r-2e-Ethoxycarbonyl-*t*-3-(*p*-chlorophenyl)-1,4-thiazane 1,1-dioxide (**5**) was obtained following the procedure of compound **4**. Yield: 30%; mp 178–180 °C. IR (cm^{-1}): 3420 (NH), 1687 (C=O), 1290 (asy. SO_2), 1120 (sym. SO_2). Anal. calcd. for $C_{13}H_{16}NO_4SCl$: C 49.21, H 5.05, N 4.42; found: C 49.24, H 5.02, N 4.38. Very low solubility in $CDCl_3$.

r-2a-Ethoxycarbonyl-*c*-3-(*o*-methoxyphenyl)-1,4-thiazane 1,1-dioxide (6)

r-2a-Ethoxycarbonyl-*c*-3-(*o*-methoxyphenyl)-1,4-thiazane 1,1-dioxide (**6**) was obtained following the procedure of compound **4**; reaction time 20 h. Yield: 20%; mp 143–145 °C. IR (cm^{-1}): 3475 (NH), 1740 (C=O), 1295 (asy. SO_2), 1114 (sym. SO_2). ^1H NMR (ppm): 0.86 (3H, s, CH_3), 2.39 (1H, br.s, NH), 2.96 (1H, dt, J = 13.4, 2.2 Hz, H-6e), 3.42 (1H, td, J = 14.1, 12.5, 2.2 Hz, H-5a), 3.56 (1H, td, J = 13.4, 12.5, 2.2 Hz, H-6a), 3.68 (1H, m, J = 14.1, 2.2 Hz, H-5e), 3.87 (3H, s, methoxy), 3.90 (2H, Dq, CH_2), 4.32 (1H, t, J = 3.2, 2.8 Hz, H-2e), 4.91 (1H, d, J = 3.2 Hz, H-3a), 7.07 (4H, m, aromatic). ^{13}C NMR (ppm): 13.44 (CH_3), 43.90 (C-

A novel enamination of β-dicarbonyl compounds catalyzed by $Bi(TFA)_3$ immobilized on molten TBAB

Mohammad M. Khodaei, Ahmad R. Khosropour, and Mehdi Kookhazadeh

Abstract: Enamination of a wide variety of primary amines was successfully carried out in the presence of catalytic amounts of bismuth(III) trifluoroacetate immobilized on molten tetrabutylammonium bromide as "green" media under mild conditions. This new system of the catalyst is recyclable and reusable. Generally, the results of the reaction in tetrabutylammonium bromide is better than the previously obtained results in water because of their yields and reaction times.

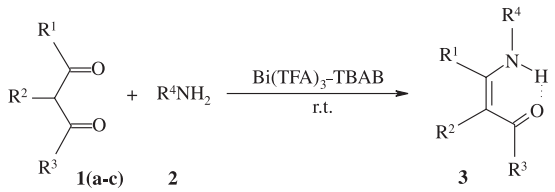
Key words: amine, bismuth compounds, β-dicarbonyl compounds, enamination, ionic liquid.

Résumé : On a procédé avec succès à une évaluation d'une grande variété d'amines primaires, en présence de quantités catalytiques de trifluoroacétate de bismuth(III) immobilisé sur de bromure de tétrabutylammonium fondu comme milieu « vert », dans des conditions douces. Ce nouveau système de catalyseur est recyclable et réutilisable. En général, les résultats de la réaction dans le bromure de tétrabutylammonium sont meilleurs que ceux obtenus antérieurement dans l'eau en raison de leurs rendements et de leurs temps de réaction.

Mots clés : amine, composés du bismuth, composés β-dicarbonylés, énamination, liquide ionique.

[Traduit par la Rédaction]

Introduction



The increasing attention during the last decades for environmental protection has influenced both modern academic and industrial groups to develop chemical processes with maximum yield under minimum amounts of harmful reagents. Therefore, much attention has been devoted to the use of alternative reaction media (1, 2). Besides the use of water or supercritical fluids, organic reaction in ionic liquids (ILs) as new reaction media, are aimed toward green chemistry (3). The use of these liquids in place of conventional organic solvents can lead to significant improvements in the rates and yields of reactions. In addition, they possess a number of interesting properties, especially their lack of vapor pressure, a widely accessible temperature range with lack of flammability, and ease of recycling that facilitates product recovery and may reduce environmental emissions (4–8). Also, ILs often contain poorly coordinating anions and thus form a new class of polar, noncoordinating solvents (9). Consequently, ionic liquids have been used in several catalytic reactions involving many different catalysts. Several catalysts have been immobilized in ionic liquids and successfully recycled as a result of the involatile nature of these media. Some reactions that have been investigated in these catalytic media are the use of palladium catalysts for Suzuki (10), Stille (11), and Heck coupling reactions (12, 13), a chromium catalyst for asymmetric epoxide openings (14), a ruthenium catalyst for asymmetric alkenes hydrogenations (15), and etc. (16–19). Recently, molten tetrabutylammonium bromide (TBAB) as an ionic liquid for immobilization of some catalysts has been used successfully (20–25).

Results and discussion

As part of our program aimed at developing new selective and environmentally friendly methodologies for the preparation of fine chemicals (26–27), we were interested in investigating another method (28–31) for the enamination reaction.

Very recently, we have reported that $Bi(TFA)_3$, as an efficient and water-tolerant Lewis acid, catalyzes the enamination of β-dicarbonyl compounds in aqueous media (32). Herein, we would like to report another modified procedure on the enamination reaction of various primary amines with β-dicarbonyl compounds in the presence of catalytic amounts of $Bi(TFA)_3$ immobilized on molten TBAB as inexpensive ionic liquid at room temperature (Scheme 1).

This condensation reaction with a wide range of aromatic and aliphatic primary amines and β-dicarbonyl compounds proceeded effectively in these conditions. The results are summarized in Table 1. The reaction is performed at ambient temperature with very short reaction times and does not require the use of an inert atmosphere (16).

In all cases, in comparison to the reaction under aqueous media, the reactions were very rapid and in excellent yields.

24	**1d**	$HOCH_2CH_2$		10	96

[a]All products were identified by comparison of their physical and spectral data with those of authentic samples (17).
[b]Isolated yields.

For example, the yield from the enamination of 1-butyl amine with acetyl acetone in the presence of $Bi(TFA)_3$ under aqueous media was only 63% for 3 h while, the reaction yield and rate were improved significantly using 50 mol % of molten TBAB instead of water (entry 1, Table 1). It was also observed that these reactions could not be performed in the absence of the Lewis acid.

This method was successfully applied to enamination of diketones (entries 1–11, Table 1), linear (entries 12–19, Table 1), and cyclic β-ketoesters (entries 20–24, Table 1). The regiochemistry observed from these β-dicarbonyls is similar to that in aqueous media, which was limited to preferential amines' attack at the acetyl position and no by-product was observed.

Interestingly, when $Bi(TFA)_3$ was added to the molten TBAB, the mixture did not result in solidification after cooling to room temperature and remained a liquid paste in such a way that the magnetic bar stirred well.

Another advantage of this method for the transformation is recyclability of this catalyst. Since $Bi(TFA)_3$–TBAB was weakly soluble in Et_2O, it was separated by washing with Et_2O and dried at 60 °C under reduced pressure and reused in five runs without any loss of activity.

In conclusion, $Bi(TFA)_3$–TBAB is a new, highly efficient, and reusable catalyst for the enamination of 1,3-dicarbonyl compounds. Mild reaction conditions, short reaction times, excellent yields, and high chemoselectivity are noteworthy advantages of this procedure. Moreover, stability and low toxicity of the Lewis acid and the ionic liquid are the other merits of this method.

Experimental

General experimental procedure

To a solution of the amine (1 mmol) and β-dicarbonyl compound (1 mmol) in molten TBAB (0.5 mmol), $Bi(TFA)_3$ (0.05 mmol) was added and the reaction mixture stirred at room temperature for the appropriate time according to Table 1. After completion of the reaction as indicated by GLC or TLC, the mixture was washed with Et_2O (3 × 10 mL). Crude products were purified by preparative chromatography on silica gel using *n*-heptane–AcOEt (10:1) as the eluent. The β-enaminones were thus prepared in 60%–99% yields.

Efficient one-pot transformation of aminoarenes to haloarenes using halodimethylisulfonium halides generated in situ

Woonphil Baik, Wanqiang Luan, Hyun Joo Lee, Cheol Hun Yoon, Sangho Koo, and Byeong Hyo Kim

Abstract: Halodimethylsulfonium halide **1**, which is readily formed in situ from hydrohaloic acid and DMSO, is a good nucleophilic halide. This activated nucleophilic halide rapidly converts aryldiazonium salt prepared in situ by the same hydrohaloic acid and nitrite ion to aryl chlorides, bromides, or iodides in good yield. The combined action of nitrite ion and hydrohaloic acid in DMSO is required for the direct transformation of aromatic amines, which results in the production of aryl halides within 1 h. Substituted compounds with electron-donating or -withdrawing groups or sterically hindered aromatic amines are also smoothly transformed to the corresponding aromatic halides. The only observed by-product is the deaminated arene (usually <7%). The isolated aryldiazonium salts can also be converted to the corresponding aryl halides using **1**. The present method offers a facile, one-step procedure for transforming aminoarenes to haloarenes and lacks the environmental pollutants that usually accompany the Sandmeyer reaction using copper halides.

Key words: aminoarenes, haloarenes, halodimethylsulfonium halide, halogenation, amination.

Résumé : Les halogénures d'halogénodiméthylsulfonium (**1**) qui se forment facilement à partir des acides hydrohaloïques et du DMSO sont de bons halogénures nucléophiles. Sous l'action de ce type d'halogénure nucléophile, les sels d'aryldiazonium préparés in situ à l'aide du même acide hydrohaloïque et de l'ion nitrite peuvent facilement être transformés en chlorures, bromures ou iodures d'aryles, avec de bons rendements. L'action combinée de l'ion nitrite et d'un acide hydrohaloïque dans le DMSO est requise pour la transformation directe des amines aromatiques qui conduit à la formation d'halogénures d'aryles en moins d'une heure. Les composés substitués par des groupes électrodonneurs ou électroattracteurs ainsi que les amines stériquement empêchées sont aussi transformées facilement en halogénures d'aryles correspondants. Le seul produit secondaire observé est l'arène désaminé (généralement moins de 7 %). Sous l'action des produits **1**, les sels d'aryldiazonium isolés peuvent aussi être transformés en halogénures d'aryles correspondants. Cette méthode est présentée comme une procédure facile, en une étape, qui permet de transformer des aminoarènes en halogénoarènes et qui n'est pas entachée des polluants environnementaux qui accompagnent généralement la réaction de Sandmeyer qui utilise des halogénures de cuivre.

Mots clés : aminoarènes, halogénoarènes, halogénure d'halogénodiméthylsulfonium, halogénation, amination.

[Traduit par la Rédaction]

Introduction

Aromatic halides are versatile reagents that can be converted to a wide variety of materials. Representative processes for preparing aromatic halides include: (*i*) direct aromatic halogenation (1), wherein the hydrogen atom is replaced by a halogen atom, and (*ii*) the Sandmeyer reaction (2, 3), which involves the substitution of an amino group by a halogen atom via a diazonium salt. Since aromatic amines are generally more economical to produce, most methods for preparing highly substituted aromatic halides have centered around improving the Sandmeyer reaction. The Sandmeyer reaction is a two-step process: diazotization followed by halogenation (3). The typical Sandmeyer reaction is generally carried out in the presence of more than one equimolar amount of cuprous halide (3*b*–3*d*), and the discharge of excess copper salt can cause environmental pollution. In addition, since the stability and formation of the diazonium salt are the important factors in the Sandmeyer reaction, special conditions such as a low reaction temperature and filtration are necessary (2, 3). Considering the wide range of potential applications for aromatic halides, the development of a simple method that requires a low manufacturing cost while minimizing environmental pollution is required. Some modi-

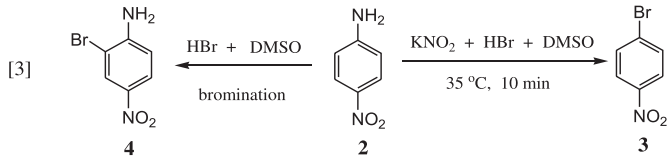
[a]Reactions were performed by adding 10.0 mmol of *p*-nitroaniline and the indicated amount of HBr to KNO_2 in 50 mL of solvent.
[b]Yields were determined by GLC analysis by comparison to dodecane as an internal standard.
[c]The deaminated product, nitrobenzene.
[d]The aryldiazonium salt was formed.
[e]Other solvents (THF, HMPA, hexane, and benzene) were also examined, but none gave the desired product.

fied Sandmeyer reactions (4) that involve a diazonium salt have been developed for the purpose of simplicity. Unlike the sodium nitrite and acidic conditions needed for the preparation of diazonium salt, alkyl nitrite is a useful in situ diazotizing agent for the one-step preparation of aromatic halides (4*a*–4*d*). This method also uses anhyd. $CuCl_2$ (4*a*–4*b*) or $CuBr_2$ (4*a*–4*b*) and I_2 with CH_2I_2 for iodination (4*d*). Iodination suffers in this case in that it is difficult to separate the product from excess diiodomethane. A similar direct replacement of the aromatic amino group by iodine or bromine through reactions with gaseous nitrogen dioxide, but without an added metal activator, has been reported (4*h*, 4*k*). Although there are specific advantages to each of these methods, none of the modified variations has received wide application. To simplify the reaction and minimize the environmental problems and manufacturing cost, several factors should be considered: (*i*) the development of in situ diazotization for a single-step reaction, and (*ii*) the development of an activated halogen nucleophile that can replace CuX_2, I_2, CH_2I_2, etc.

Bromodimethylsulfonium bromide **1b** has been used as a bromide nucleophile in the substitution of hydrogen atom(s) of aromatic compounds (5–7). As shown in eqs. [1] and [2], when HBr is added with DMSO as the solvent, bromodimethylsulfonium bromide **1b** is formed instantly, and replacement of a hydrogen atom of the benzene ring by bromide occurs simultaneously (5).



Despite the synthetic utility of **1b** in the bromination of arenes, it has not been investigated as an activated halogen nucleophile in the replacement of a diazonium group. An aromatic amine would be converted to a diazonium salt by the addition of nitrite salt and hydrohaloic acid, while at the same time an activated halide nucleophile **1** (X = Cl (**1a**), X = Br (**1b**), X = I (**1c**)) would be prepared readily in situ from the same hydrohaloic acid and DMSO. Thus, the transformation of an amine group to a halogen group in aromatic compounds may occur in a single-step process via concurrent diazotization–displacement using the combination of NO_2^-–HX–DMSO. Therefore, we sought to use **1** in the halogenation of the diazonium salt that is prepared in situ using the same halohydric acid and nitrite ion.

Results and discussion

Bromination and (or) chlorination

Preliminary studies on the bromination of *p*-nitroaniline were carried out using KNO_2 and 48% aq. HBr[2] in DMSO. *p*-Nitroaniline **2** with KNO_2 (4 equiv.) and HBr (4 equiv.) in DMSO at 35 °C afforded *p*-bromonitrobenzene **3** in 86% yield within 10 min along with a 7% yield of nitrobenzene (Table 1 and eq. [3]). None of the brominated product, 2-bromo-4-nitroaniline **4**, was observed. However, when *p*-nitroaniline was reacted with a mixture of HBr and DMSO in the absence of KNO_2, 2-bromo-4-nitroaniline **4** was observed in 26% yield, as reported by Chauhan and co-workers (6). The transformation to *p*-bromonitrobenzene was not observed without the nitrite ion. With stoichiometric amounts of HBr and KNO_2 in DMSO, 35% of *p*-bromonitrobenzene and 40% of the starting material were observed, but even after 24 h the brominated product was only formed in a trace amount (~2%). Presumably, the diazonium salt that is instantly formed by the action of KNO_2 and HBr prevents the bromination of *p*-nitroaniline.

The molar ratio of HBr to aromatic amine for this reaction should be from about 3:1 to about 5:1; preferably, about 4:1. A higher molar ratio of HBr will lead to the formation of brominated product as a by-product. For example, with 7 equiv. of HBr and 4 equiv. of KNO_2 in DMSO, *p*-bromoaniline was transformed to 76% *p*-dibromobenzene and 15%

[2]Due to safety and handling considerations, aqueous hydrohaloic acid or hydrohaloic acid in glacial acetic acid solution is preferred. It is generally available commercially and contains about 48%–57% by weight H_2O solution or acetic acid.

[a]Reactions were performed by adding 10.0 mmol of the aniline and 40.0 mmol of 48% aq. HBr (or 37% aq. HCl) in 25 mL of DMSO to 40.0 mmol of KNO_2 in 25 mL of DMSO. The reaction temperature was 35 °C.

[b]Yields were generally determined by GLC analysis by comparison to an internal standard. Isolated yields after column chromatography or recrystallization are given in parentheses.

tribromobenzene. Thus, the use of excess HBr results in dibromobenzene, which is further brominated to give the tribromobenzene. The molar ratio of nitrite to aromatic amine should be about 3:1 to 5:1. The use of low molar ratios may cause a drop in product yields. To investigate the role of DMSO in the transformation of *p*-nitroaniline to *p*-bromonitrobenzene, other solvents were studied. However, none of the other solvents (H_2O, DMF, THF, HMPA, hexane, benzene, etc.) gave the desired product under the same conditions. The formation of the diazonium salt was observed in H_2O, and the reaction was very sluggish in DMF. No further reaction was seen in the absence of DMSO. Thus, DMSO has two roles; first, it reacts with HBr to form bromodimethylsulfonium bromide **1b**, and second, it readily dissolves nitrite ion. In fact, the reaction is too fast to observe the formation of the diazonium salt. To prove that the reaction proceeds via aryldiazonium salt under our conditions, isolated diazonium salt that was prepared by the general method (8) using sodium nitrite and HCl was treated with a premixed solution of HBr and DMSO as shown in eq. [4]. As expected, *p*-bromonitrobenzene was produced in 52% yield. According to this two-step protocol (diazotization–replacement), the activated bromodimethylsulfonium bromide **1b** directly converted the diazonium salt to provide the aryl bromide compound.

[4] 

The present method is characterized by the simultaneous in-situ formation of the activated bromide **1b** and aryldiazonium salt of the same HBr at room temperature and the smooth one-pot transformation of aminoarenes to monohaloarenes without further halogenated by-products.

The reaction is carried out by dissolving KNO_2 in DMSO and then adding *p*-nitroaniline and HBr to the resulting mixture at ambient temperature. The order in which the nitrite ion, hydrobromic acid, and an aromatic amine are added is not critical to the reaction.

The general applicability of this procedure for several other aminoarenes was then investigated, and the results are presented in Table 2. As can be seen, clean transformation occurs in good to excellent yields. The products were checked for purity by GLC and ^1H NMR. All of the products were also checked by GC–MSD to ensure the absence of any brominated by-products.

Reactions of sterically hindered aminobenzenes took place in reasonable yields within 1 h. Furthermore, anilines, even those with electron-withdrawing substituents, such as an aldehyde, ketone, nitro group, or carboxylic group, also showed good reactivity. For example, with 2,4-dinitroaniline

[b]Yields were generally determined by GLC analysis by comparison to an internal standard.

or 2,6-dimethylaniline, transformation took place to predominantly produce 1-bromo-2,4-dinitrobenzene or 1-bromo-2,6-dimethylbenzene, respectively. Furthermore, bromination or side-chain bromination was not observed, which suggests a highly effective transformation that is fully controlled by electronic and steric factors. However, in most cases, deaminated product was observed in trace (~7%) yields, and this was not affected by the amount of either HX or KNO_2. Conventional diazotization of electron-deficient anilines such as dinitroanilines is usually carried out using concentrated sulfuric acid as the reaction medium (4*c*, 8). Thus, the present method is especially attractive for anilines bearing electron-withdrawing groups. In addition, the present method was effective for preparing highly halogen-substituted benzenes. For example, 2,4-difluoroaniline reacts with KNO_2–HBr–DMSO to give 1-bromo-2,4-difluorobenzene in 87% yield within 30 min. For electron-rich anilines, the yields were also modest to high. However, conversion of aromatic diamines to the corresponding dibromo or monobromo products was unsatisfactory.

Having demonstrated the superiority of the aminoarenes, we then turned our attention to the evaluation of heterocyclic amine compounds. Reactions with aminopyridines also showed good transformations to their corresponding bromopyridines without any noticeable side reactions (Table 2, entries 22~25). Typically, during the reactions with aminopyridines, such as 5-aminoisoquinoline, 1-aminoisoquinoline, 2-amino-3-nitropyridine, or aminoquinoline, complete conversion was observed even though the pyridinium salt was formed by the action of HBr. We believe that the positively charged nitrogens of the pyridinium salt and the diazonium salt exert some electronic and inductive effects to enhance the electrophilicity of the carbon atom of the ring.

We successfully performed this transformation on a semi-preparatory scale (1000 g)[3] and a microscale (<0.1 g). In any case, this one-pot procedure is superior to the classical or modified Sandmeyer reactions in terms of yield, convenience, cost, and reaction time. In addition, the ease with which the product can be purified due to the use of the water-miscible solvent DMSO and aq. HX allows a large-scale preparation in an efficient one-pot reaction.

The versatility of halodimethylsulfonium halide, especially chlorodimethylsulfonium chloride **1a**, is also demonstrated in Table 2. Upon treatment of 37% aq. HCl with KNO_2 in DMSO, the amino group is transformed to give a chlorinated arene. The yields were relatively low compared to the bromination, indicating that the pK_a values of HX may affect the stabilities of both the halodimethylsulfonium halide and the diazonium salt.

In an attempt to increase the product yield for some aminoarenes and aminopyridines, we examined the effect of a copper halide. The typical conversion of arenediazonium ions to aryl halides requires a quantitative amount of Cu(II) halide (Sandmeyer reaction). We observed that the addition of 0.2 equiv. of CuBr (or CuCl) to the reaction mixture under our conditions increased the yield and reduced the reaction time (Table 3).

Iodination

Since some reactions, such as the Ullmann (9, 10), Suzuki (11), and Heck reactions (12), are facile for iodoarenes, a simple and reliable preparation method is still under investigation. Attractive methods have been proposed by several groups (4*d*–4*j*), such as using "isoamyl nitrite" as the diazotizing agent and "diiodomethane" as both a solvent and halogen source (4*d*). However, it can be difficult to separate the product from excess diiodomethane and the use of sterically hindered anilines is problematic. To evaluate the sequence using iododimethylsulfonium iodide **1c**[4] prepared in situ by HI and DMSO, the conversion of anilines to iodobenzenes was also investigated. Most of the conversions to iodobenzenes were successful under these conditions. Furthermore, the yields were excellent with a very short reaction time and in most cases by-products were not observed. We were surprised by the high transformation efficiency of sterically hindered and electron-withdrawing group substi-

[3]A high-speed mechanical stirrer with a multiblade paddle was adequate for dissolving KNO_2 for the preparatory-scale reaction.
[4]It is likely that the mechanism of the formation of halodimethylsulfonium halides (**1c**) iododimethylsullfonium iodide, involves reversible formation of a sulfur dichloride (R_2SCl_2) intermediate. See ref. 5*b*. Bromodimethylsulfonium iodide prepared from HBr, DMSO, and I^- via the formation of bromodimethylsulfonium bromide was treated followed by the replacement of bromide with a more nucleophilic iodide, as shown in eq. [6].

[a]**1c**: Reactions were performed by adding 10.0 mmol of the aniline and 40.0 mmol of 57% aq. HI in 25 mL of DMSO to 40.0 mmol of KNO_2 in 25 mL of DMSO. **1c′**: 48% aq. HBr and KI were used instead of HI. The reaction temperature was 35 °C.
[b]Yields were generally determined by GLC analysis by comparison to an internal standard. Isolated yields after column chromatography or recrystallization are given in parentheses.
[c]CuI (0.1 equiv.) was added.

tuted anilines in Table 4 (entries 3–6), where 1-iodo-2,6-dinitrobenzene and 1-iodo-2,6-dimethylbenzene were formed in respective yields of 89% and 87% with a very short reaction time. The reported yield of 1-iodo-2,6-dinitrobenzene for the route with isoamyl nitrite in diiodomethane is only 36% at 105 °C (6). The present method is highly attractive for the preparation of aryl iodides because of the simple one-pot conversion and high yields.

Similar to the formation of bromodimethylsulfonium bromide **1b** from HBr and DMSO, iododimethylsulfonium iodide **1c** is prepared by HI and DMSO (eq. [5]). To confirm the halogen source of halodimethylsulfonium halide, bromodimethylsulfonium iodide **1c′**, prepared from HBr, DMSO, and KI via the formation of bromodimethylsulfonium bromide **1b**, was examined (eq. [6]). As shown in Table 4 (entries 9–11), similar results were obtained using HBr–KI–KNO_2–DMSO, which indicates that bromodimethylsulfonium iodide **1c′** also acts as an excellent halogen source for the replacement of aryldiazonium salt.

[5] $CH_3SOCH_3 \xrightarrow[H_2O]{2HI} [CH_3SCH_3]^+ I^-$ **1c**

[6] $CH_3SOCH_3 \xrightarrow[H_2O]{2\,HBr} [CH_3SCH_3]^+ Br^- \xrightarrow{I^-} [CH_3SCH_3]^+ I^-$ **1c′**

Fluorination

In addition to our study of the direct transformation of aryldiazonium salt to fluoroarenes, some halodimethylsulfonium fluorides were also investigated. Similar reaction protocols were used with various fluoride sources, however, the conversion of aminoarenes to fluoroarenes was not successful even in the presence of CuF. Presumably, the weak nucleophilicity and low acidity of HF may not lead to the formation of halodimethylsulfonium fluoride.

Conclusions

We have described an efficient protocol for the transformation of aminoarenes to iodo-, bromo-, or chloroarenes using in-situ-generated halodimethylsulfonium halides. The present method offers several advantages: (*i*) the amino group in an aromatic compound can be transformed to a halide in reasonable to high yields regardless of a substituent effect; (*ii*) the process is simple and consists of a single step; (*iii*) the reaction time is very short (generally 10~60 min), and the reaction temperature is mild (e.g., at 35 °C); (*iv*) the cost of the hardware is very low; and (*v*) the reaction can minimize environmental pollution.

Experimental section

General

All reagents were used without further purification. Mass spectra were obtained at a 70 eV via GC–MSD coupling. ^1H NMR spectra were recorded on a 300 MHz spectrometer in $CDCl_3$ solution. GLC analyses were performed using a capillary column (25 m × 0.2 mm i.d.). Melting points were determined on a Mel-Temp II apparatus and were uncorrected. All known products were identical in all respects (mp, IR, MS, and NMR) to those previously reported.

General procedure for microscale production — Use of bromodimethylsulfonium bromide prepared by HBr and DMSO

A solution of 48% aq. HBr (2.49 mL, 20.0 mmol) dissolved in DMSO (25 mL) was added dropwise to a solution of aminoarene (5 mmol) in a mixture of 25 mL of DMSO and KNO_2 (1.70 g, 20.0 mmol) at 35 °C with stirring. The added mixture was stirred at 35 °C for the time given in Table 2 and then transferred to a solution of K_2CO_3 (5 g) in 100 mL of ice water. The reaction mixture was then taken up in ether, and the ethereal extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent under reduced pressure gave the crude product. The crude product was further purified by column chromatography (or recrystallization) to give the product, the mp, and spectral data (^{1}H NMR and GC–MS) all of which were in full agreement with those of an authentic sample.

General procedure for preparative-scale production

A mixture of 2.5 L of DMSO and KNO_2 (85.1 g, 1.0 mol) was vigorously stirred at 60 °C to rapidly dissolve KNO_2, and aminoarene (0.25 mol) was then added.[3] The resulting solution was then cooled to room temperature. Aqueous HBr solution (48%, 124.5 mL, 1.0 mol) diluted with 2.0 L of DMSO was added dropwise at a rate of 20 mL/min, and the mixture was then warmed to 35 °C. The DMSO solution of HBr added to the reaction mixture can be carried off through a long condenser tube. After the usual workup, the crude product was purified by recrystallization.

Preparation of 4-bromoanisole

A mixture of 4-methoxyaniline (0.25 mol, 30.75 g), KNO_2 (85.1 g, 1.0 mol), HBr solution (48%, 124.5 mL, 1.0 mol), and 4.5 L of DMSO was stirred at 60 °C for 2 h. The product was recovered by the standard procedure, yielding 37.87 g of pure 4-bromoanisole (81%).

General procedure for microscale production — Use of iododimethylsulfonium iodide prepared by HI and DMSO

Aminoarene (5.0 mmol) was added to a solution of KNO_2 (1.70 g, 20.0 mmol) in DMSO (25 mL) at 35 °C. Aqueous HI (57%, 2.64 mL, 20 mmol) in DMSO (25 mL) was added, and the reaction mixture was stirred for the time given in Table 4. After the reaction was completed, the cooled reaction mixture was neutralized with 10% aq. Na_2CO_3 and extracted with methylene chloride (3 × 10 mL). The combined methylene chloride extracts were washed with brine and dried over magnesium sulfate. The solvent was removed in vacuo and the residue was chromatographed to give the product, the mp, and spectral data (^{1}H NMR and GC–MS) all of which were in full agreement with those of an authentic sample.

General procedure for microscale production — Use of bromodimethylsulfonium iodide prepared by HBr, KI, and DMSO

To a solution of aminoarene (5.0 mmol) in a mixture of 25 mL of DMSO and KNO_2 (1.70 g, 20 mmol) was added dropwise a solution of 47% HBr (2.49 mL, 20 mmol) and KI (4.15 g, 25 mmol) dissolved in DMSO (25 mL) at 35 °C. When the addition was complete, the mixture was further stirred at 35 °C for an additional 10 min and then transferred to a solution containing K_2CO_3 (5 g) in 100 mL ice water. The reaction mixture was then taken up in ether, and the ethereal extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent under reduced pressure gave the crude product.

Dew points of quaternary ethane + carbon dioxide + water + methanol mixtures — Measurement and modelling

C. Jarne, S.T. Blanco, S. Avila, C. Berro, S. Otín, and I. Velasco

Abstract: Dew points have been measured for eight ethane + carbon dioxide + water + methanol mixtures at pressures from 0.11 to 2.17 MPa and temperatures from 249.0 to 288.7 K. The results are analysed in terms of a predictive excess-function equation of state (EF-EOS) method based on the zeroth approximation of Guggenheim's reticular model. This method can be used to adequately predict the dew points of the mixtures in the temperature and pressure ranges used in the present study. In fact, the model reproduces the experimental dew point temperature data with ≤3.1 K average absolute deviation.

Key words: dew point, equation of state, excess function.

Résumé : On a mesuré les points de rosée de huit mélanges d'éthane + dioxyde de carbone + eau + méthanol, à des pressions allant de 0,11 à 2,17 MPa et à des températures allant de 249,0 à 288,7 K. On a analysé les résultats en termes d'une méthode basée sur une équation d'état de fonction d'excès permettant de faire des prédictions basées sur l'approximation zéro du modèle réticulaire de Guggenheim. On peut utilizer cette méthode pour prédire adéquatement les points de rosée de mélanges dans les plages de température et de pression utilizées dans la présente étude. En fait, le modèle permet de reproduire les données expérimentales de points de rosée avec une déviation absolue moyenne de moins de 3,1 K.

Mots clés : point de rosée, équation d'état, fonction d'excès.

[Traduit par la Rédaction]

Introduction

To investigate the influence of carbon dioxide, water, methanol and heavy hydrocarbons on the vapour–liquid equilbrium (VLE) of natural gas within the usual pressure and temperature conditions of natural gas transported by pipeline, we have previously studied the following systems: carbon dioxide + water and carbon dioxide + water + methanol (1), methane + carbon dioxide + water (2), ethane + carbon dioxide + water (2) and methane + carbon dioxide + water + methanol (3). Dew point data for the quaternary ethane + carbon dioxide + water + methanol system, which are not available in the literature, are reported in the present work. In addition, we have developed a theoretical model for dew point prediction.

A water + methanol dew point generation device was built and tested in previous studies (4, 5). The results for eight ethane + carbon dioxide + water + methanol mixtures at pressures from 0.11 to 2.17 MPa and temperatures from 249.0 to 288.7 K are presented here. The experimental results obtained for the quaternary mixtures are analysed in terms of a predictive excess-function equation of state (EF-EOS) method based on the zero-order approximation of Guggenheim's reticular model, which reproduces the experimental dew point temperature data with an average absolute deviation (AAD) less than or equal to 3.1 K.

Experimental procedure

The experimental method used in this work is based on the generation of gases saturated with water and methanol by condensation of these components in a temperature-controlled condenser with continuous gas flow at specified pressures.

A schematic diagram of the experimental apparatus is shown in Fig. 1. The gas supply bottles that contain ethane + carbon dioxide mixtures (Table 1) were prepared by weight by Abello-Linde (6). After controlled expansion (RV1), the gas from the ethane + carbon dioxide bottle was saturated with water and methanol vapour by flowing the gas through a saturator containing a liquid mixture of water and methanol at laboratory temperature (TI1). The temperature of con-

Component	Gas 1 (%)	Gas 2 (%)
Ethane	55±1	5±1
Carbon dioxide	45±1	95±1

densation of water and methanol was then achieved in a stainless-steel condenser, which was located in a thermostatic bath set at the desired temperature of condensation (TI2). This temperature (TI2) is lower than the temperature in the saturator (TI1). The values for the water and methanol contents in the gas phase of the generated VLE are obtained at the outlet of the condenser using the Karl Fischer titration (7) for water content and by gas chromatographic analysis for methanol content.

The dew point values for the ethane + carbon dioxide + water + methanol mixtures were measured by means of a chilled mirror instrument. The input pressure (PI6) of the gas in the chilled-mirror instrument was set using a regulator valve (RV2). When the apparatus reached a stable dew point temperature (TI6), both the pressure and temperature were recorded.

The following instrumentation is used in the experimental apparatus: a Mitsubishi CA 06 Karl Fischer titrator, coupled with an Elster wet gasmeter Type Gr. 00, E51 to measure the water content (0.2% accuracy); a HP 5890 gas chromatograph fitted with a Haysep Q column and a thermal conductivity detector to measure the methanol content; a MBW dew point instrument (model DP3-D-HP-K2) to measure the dew point temperatures. The cooling of the mirror as achieved by a cascaded-element Peltier cooling unit and the dew-point mirror temperature was opto-electronically controlled; a pressure transmitter to measure the dew point pressures (max error of 0.1%).

Prior to the study of ethane + carbon dioxide + water + methanol mixtures, the precision of the dew point measurements was determined as described previously (4, 5).

Results

We calculated the dew-point curves for gas 1 and gas 2 (Table 1) using the Peng–Robinson equation of state (8). The experimental dew points for the quaternary systems range from 0.11 to 2.17 MPa at temperatures from 249.0 to 288.7 K to avoid the presence of liquid ethane and carbon dioxide in the apparatus.

The water and methanol mol fractions and the dew point temperatures and pressures for the quaternary systems are collected in Table 2.

As shown in Table 2 for ethane + carbon dioxide + water + methanol mixtures with the same ethane and carbon dioxide contents and similar water mol fractions (such as gas 1 + 0.00048 water mol fraction + 0.0033 methanol mol fraction and gas 1 + 0.00040 water mol fraction + 0.0086 methanol mol fraction), increasing the methanol mol fraction in the mixture leads to an increase of the dew point temperature at a given pressure.

For the quaternary mixtures with the same ethane and carbon dioxide contents and similar methanol mol fractions (such as gas 1 + 0.00029 water mol fraction + 0.0049 methanol mol fraction and gas 1 + 0.00083 water mol fraction + 0.0053 methanol mol fraction), increasing the water content also increases the dew point temperature at a given pressure.

On the other hand, the dew point curve of gas 2 is on the right hand side of that of gas 1 in the pressure–temperature diagram. However, if we consider the mixtures gas 1 + 0.00040 water mol fraction + 0.0086 methanol mol fraction and gas 2 + 0.00044 water mol fraction + 0.0083 methanol mol fraction, we observe that, for a given pressure, the values of the dew temperatures are practically the same for the

two quaternary mixtures. Therefore, it seems that the values of dew temperature and pressure for the quaternary mixtures are more sensitive to the water and methanol content than to the ethane and carbon dioxide content. Similar results were found for methane + carbon dioxide + water + methanol mixtures in an earlier work (3).

In a previous study (2), the dew points of ethane + carbon dioxide + water mixtures were studied. When comparing the results from the present work for ethane + carbon dioxide + water + methanol with the results of the previous study (2) for mixtures with the same ethane, carbon dioxide, and water content, we found that the presence of methanol in the mixtures leads to a displacement of the dew point curves to higher values of dew point temperature and pressure. This is observed for gas 1 + 0.00083 water mol fraction + 0.0053 methanol mol fraction (Table 2), gas 1 + 0.00082 water mol fraction (2), gas 2 + 0.00086 water mol fraction + 0.0056 methanol mol fraction (Table 2) and gas 2 + 0.00091 water mol fraction (2). At a given pressure, the difference between the dew temperature values of the mixture with methanol and without methanol are up to 7 K.

Discussion

As mentioned earlier, this work is part of a program of research investigating the influence of carbon dioxide, water, methanol, and heavy compounds of natural gases on the VLE of natural gas. Therefore, the ranges of dew temperature and pressure are studied within the typical ranges for natural gas transmission through pipelines, which means temperatures from 249 to 288 K and pressures up to 10 MPa. Although classical models such as UNIQUAC (9), DISQUAC (10), or modified UNIFAC (11) allow the prediction of vapour–liquid equilibria at low pressures for systems that contain polar compounds, they are not suitable for the present work. Instead, we use in this work the EF-EOS model, which is based on the zeroth-order approximation of Guggenheim's quasi-reticular model. In the EF-EOS model, which is an extension of the development originally presented by Vidal (12), the connection between excess functions and equations of state is established by equating excess

© 2005 NRC Canada

functions derived from Guggenheim's quasi-lattice theory to expressions derived from equations of state (13).

A comparison between experimental and calculated dew point temperatures was carried out. The values of dew temperature for the system investigated were calculated by means of the EF-EOS method (13) using the experimental values of pressure and composition obtained in the present work.

The EF-EOS model has been chosen because it can be used to adequately predict the dew points of all the mixtures of present interest in the temperature and pressure ranges. The model satisfies two important conditions: (1) the Helmholtz energies of the pure components are calculated by an equation of state; (2) the excess functions are defined at a constant packing fraction described by v^0/v, where v^0 is the molar close-packed volume and v the molar volume. It is assumed that it is possible to define a "co-volume" b proportional to v^0, which allows the evaluation of the packing fraction η by the ratio $\eta = b/v$. The packing fraction for the pure components and for the mixture is assumed to be the same, which means that the lattice on which the pure components are placed undergoes no distortion during the mixing process.

Regarding the EOS used in the EF-EOS model, given that the thermodynamic properties of carbon dioxide, such as saturation density, are often represented by cubic equations of state with poor accuracy, we have used for this component the more accurate IUPAC equation of state (14).

For ethane, water, and methanol, the translated Peng–Robinson cubic equation of state is used (13, 15). The name for this equation is due to the use of a translated molar volume $\bar{v}$ called the pseudo-molar volume (16) instead of the molar volume as for the Peng–Robinson cubic equation of state.

$$[1] \qquad P = \frac{RT}{\bar{v} - \bar{b}} - \frac{a(T)}{\bar{v}(\bar{v} + \gamma\bar{b})}$$

where P and T are the system pressure and temperature, R is the gas constant, $\bar{b}$ is the pseudo-co-volume, and γ is a constant. For ethane, the equations proposed by Rauzy (15) are used to calculate a, and for $\bar{b}$, the equations proposed by Péneloux et al. (13) and Rauzy (15) are used.

For water and methanol, the attractive parameter a is calculated using the equations taken from Carrier et al. (16) and Carrier (17). For the pseudo co-volume $\bar{b}$, the equations used are those of Péneloux et al. (13) and Rauzy (15).

The excess function of the EF-EOS model is the residual excess Helmholtz energy ($A^{\mathrm{E}}_{\mathrm{res}}$), which contributes to the molar Helmholtz energy (A) of the mixtures as follows

$$[2] \qquad A = A^{\mathrm{id}} - RT\ln(1-\eta) - \sum_{i=1}^{p} \frac{x_i}{b_i}\psi_i(\eta) + A^{\mathrm{E}}_{\mathrm{res}}$$

where A^{id} is the ideal mixture molar Helmholtz energy, b_i is the molar co-volume for the component i, $\psi_i(\eta)$ is a function of the packing fraction, and x_i is the molar fraction for component i in the mixture. The residual excess Helmholtz energy ($A^{\mathrm{E}}_{\mathrm{res}}$) is a function in which composition x and packing fraction η are separated variables

Table 3. Values for E^0_{ij} and r used in this work (eq. [6]).

Binary	E^0_{ij} (J cm^{-3})	r
CO_2 + CH_3OH	673.15	–1.319
H_2O + CH_3OH	253.20	–3.068

$$[3] \qquad A^{\mathrm{E}}_{\mathrm{res}}(T, x, \eta) = E(T, x)\int_0^{\eta} (Q'(\eta)/\eta)\mathrm{d}\eta$$

where $Q'(\eta)$ is a function of the packing fraction.

For the first factor on the right-hand side of eq. [3], different equations are used depending on the binary interaction that is present in the mixture. For binary interactions between carbon dioxide and water, carbon dioxide and methanol, carbon dioxide and ethane, and water and methanol (18), we used

$$[4] \qquad E(T, x) = \frac{1}{2}\sum_{i=1}^{p}\sum_{j=1}^{p} \frac{q_i q_j x_i x_j}{q_{\mathrm{m}}} E_{ij}(T)$$

where the subscripts i and j refer to the components i and j of the mixture with p components, q_i is the molecular surface of the component i, q_{m} is the mean molecular surface, and E_{ij} is the interaction energy between components i and j. E_{ij} is calculated using the following equation for binary interactions between carbon dioxide and water (18)

$$[5] \qquad E_{ij} = \alpha - \beta T\ln(T) + \lambda T$$

where α = 5018.172 J cm^{-3}, β = 13.645 J cm^{-3} K^{-1}, and λ = 102.580 J cm^{-3} K^{-1} are adjusted parameters taken from Rauzy and Péneloux (1986) (18).

E_{ij} is calculated for binary interactions between carbon dioxide and methanol, and between water and methanol (18) using

$$[6] \qquad E_{ij} = E^0_{ij}\left[\frac{T^0}{T}\right]^r$$

E^0_{ij} is the interaction energy at the reference temperature T^0 and r is an adjusted parameter taken from Rauzy and Péneloux (18) and listed in Table 3.

E_{ij} is calculated for binary interactions between carbon dioxide and ethane by means of a group contribution method as follows (19)

$$[7] \qquad E_{ij} = -\frac{1}{2}\sum_{k=1}^{N}\sum_{l=1}^{N} (\alpha_{ik} - \alpha_{jk})(\alpha_{il} - \alpha_{jl})A_{kl}(T)$$

where the subscripts k and l refer to the groups k and l of the components of the mixture with N groups, α_{ik} is the surface area fraction of group k in molecule i, and A_{kl} is the group interaction parameter between groups k and l taken from ref. 19.

The binary interactions between ethane and water and between ethane and methanol (20) were calculated using

[a]This work.

$$[8] \quad E(T,x) = \frac{1}{2q_m}\left[\sum_{i=1}^{p} q_i x_i \left(\sum_{j=1}^{p} q_j x_j K_{ij}\right) + \sum_{i=1}^{p} q_i x_i \left(\sum_{j=1}^{p} q_j^{1/3} x_j L_{ji}^{1/3}\right)\right]$$

where K_{ij}, L_{ij} are binary interaction parameters calculated using the following equations

$$[9] \quad K_{ij} = \frac{E_{ij}^1 + E_{ij}^2}{2}$$

$$[10] \quad L_{ij} = E_{ij}^2 - E_{ij}^1$$

$$[11] \quad L_{ij} = -L_{ji}$$

E_{ij}^1 the interchange energy between components i and j in a binary mixture where the mol fraction of j tends to zero, while E_{ij}^2 is the interchange energy in a binary mixture of i and j where the mol fraction of i tends to zero. E_{ij}^1 and E_{ij}^2 are calculated using a group contribution method as follows (20)

$$[12] \quad E_{ij}^1 = -\frac{1}{2}\sum_{k=1}^{N}\sum_{l=1}^{N}(\alpha_{ik} - \alpha_{jk})(\alpha_{il} - \alpha_{jl})A_{kl}^1(T)$$

with

$$[13] \quad A_{kl}^1 = {}_1A_{kl}^0\left(\frac{T^0}{T}\right)^{{}_1B_{kl}^0}$$

$$[14] \quad E_{ij}^2 = -\frac{1}{2}\sum_{k=1}^{N}\sum_{l=1}^{N}(\alpha_{ik} - \alpha_{jk})(\alpha_{il} - \alpha_{jl})A_{kl}^2(T)$$

$$[15] \quad A_{kl}^2 = {}_2A_{kl}^0\left(\frac{T^0}{T}\right)^{{}_2B_{kl}^0}$$

Superscripts 1 and 2 for A_{kl}^1 and A_{kl}^2 have the same meaning as previously explained for E_{ij}^1 and E_{ij}^2 and ${}_1A_{kl}^0$, ${}_1B_{kl}^0$ and ${}_2A_{kl}^0$, ${}_2B_{kl}^0$ are group interaction parameters at the reference temperature T^0. The values for these parameters are presented in Table 4. The parameters for interchange energies between ethane + water were taken from previous studies (20, 21). In the present work, these parameters for the interchange energy between ethane and methanol are calculated using previously reported vapour–liquid equilibrium data for ethane + methanol mixtures (22–24).

Conclusions

The measured dew point curves and calculated values using the EF-EOS method are presented in Figs. 2–5. Values of AAD are calculated using eq. [16] and listed for each dew point curve in Table 5.

$$[16] \quad \text{AAD} = \frac{1}{N}\sum_{n=1}^{N}\left|T_n^{exp} - T_n^{calc}\right|$$

where N is the number of measured dew points that constitute an experimental dew point curve and T is the dew temperature.

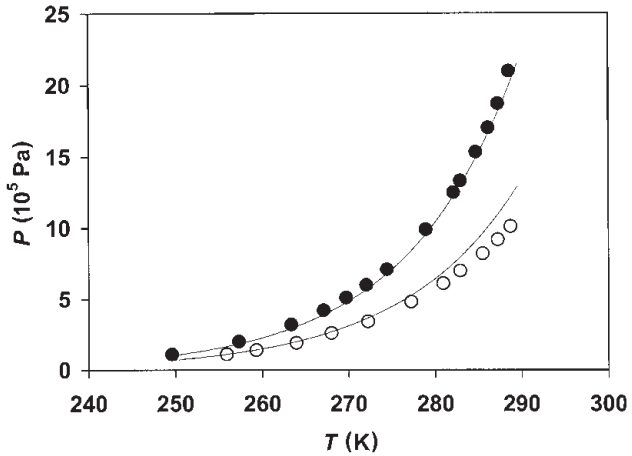

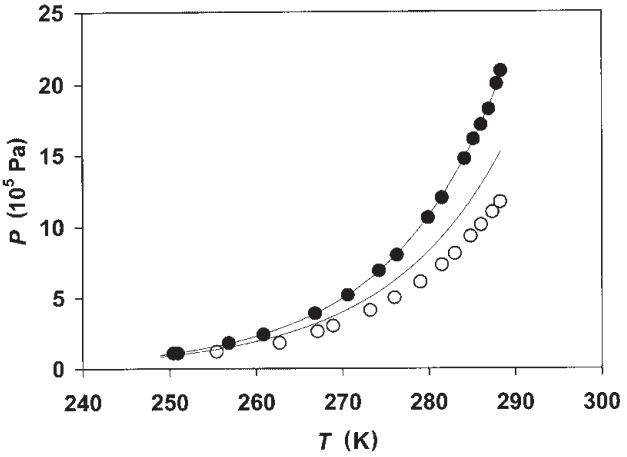

Fig. 5. Comparison of measured dew points (symbols) and calculated values using the EF-EOS method (curves) for {Gas 2 + $\bar{x}_{water}$ + $\bar{x}_{methanol}$} systems: $\bar{x}_{water}$ = 0.000 57, $\bar{x}_{methanol}$ = 0.0034 (●); $\bar{x}_{water}$ = 0.000 86, $\bar{x}_{methanol}$ = 0.0056 (○).

The AAD values for the studied quaternary systems are ≤3.1 K. No influence of temperature and pressure is found for the values of the deviations. The good agreement with the predictions obtained in this paper using the EF-EOS method validates this model for the prediction of dew points of the investigated ethane + carbon dioxide + water + methanol mixtures in our work.

Because the EF-EOS model uses a group contribution model, the availability of binary experimental data corresponding to every binary interaction in the mixture is not necessary. In view of this feature and the good results obtained with this model in this work and previous studies (1–3, 25), the EF-EOS model could be used to predict reliable dew points for hydrocarbons, water and water + methanol in real natural gases, even though binary experimental data for all components of the so-called C_6 + fraction are not available.

Substituent effects of the cycloaddition reaction of 7-substituted 5*H*-benzocycloheptenes with singlet oxygen and the chemistry of the benzocycloheptene endoperoxides

Murat Güney, Zeynep Çelik Ceylan, Arif Daştan, and Metin Balci

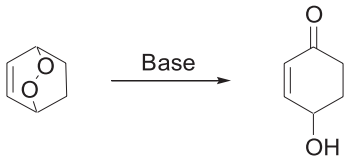
Abstract: The cycloaddition reaction of 7-substituted 5*H*-benzocycloheptenes with singlet oxygen and the chemistry of the obtained endoperoxides were investigated. Reaction of carboethoxy-substituted endoperoxide with NEt_3 gave a mixture of products; hydroxyketone, diketone, and carboethoxy-substituted keto–enol tautomers, whereas the reaction of methyl-substituted endoperoxide only formed a diketone under the same reaction conditions. Thermolysis, thiourea, and CoTPP reactions of the endoperoxides were also studied. The reaction mechanism and electronic effect of substituents were discussed.

Key words: benzocycloheptene, photooxygenation, endoperoxides, rearrangement, CoTPP.

Résumé : On a étudié la réaction de cycloaddition de 5*H*-benzocycloheptènes substitués en position 7 avec de l'oxygène singulet et la chimie des endoperoxydes obtenus. Alors que la réaction du NEt_3 avec de l'endoperoxyde substitué par un groupe méthyle conduit uniquement à la formation d'une dicétone, la réaction dans les mêmes conditions de l'endoperoxyde substitué par un groupe carboéthoxy fournit des mélanges de produits, tels des hydroxycétone, dicétone et tautomères céto–énoliques substitués par un groupe carboéthoxy. On a aussi étudié la thermolyse des endoperoxydes et leurs réactions avec la thiourée et le CoTPP. On discute du mécanisme réactionnel et de l'effet électronique des substituants.

Mots clés : benzocycloheptène, photooxygénation, endoperoxydes, réarrangement, CoTPP.

[Traduit par la Rédaction]



Introduction

Bicyclic endoperoxides serve as key substances in a variety of chemical and biological transformations (1). They can be readily synthesized by the photooxygenation of the appropriate dienes (1). The peroxide linkage is highly susceptible to reductive cleavage as well as to acid- and base-catalyzed rearrangements. The base-catalyzed decomposition of unsaturated bicyclic endoperoxides is a general type of elimination reaction (1, 2). The application of this reaction to bicyclic endoperoxides results in the formation of hydroxyenones (Scheme 1) (3).

The reaction of unsaturated bicyclic endoperoxides derived from cycloheptatriene and its derivatives with bases should open up an entry to the synthesis of tropone and tropolone derivatives. For example, cycloheptatriene endoperoxide gives tropone upon treatment with a base such as triethylamine (4). In earlier research, we applied the triethylamine-catalyzed reaction of the endoperoxide **3** derived from benzocycloheptene, to the synthesis of benzotropone and benzotropolone derivatives. Instead of the expected hydroxy-ketone **4**, the saturated 1,4-diketone **5** was isolated as the sole product in an almost quantitative yield (5). This rearrangement, the transformation of **3** into **5**, is an unusual reaction observed in the chemistry of bicyclic endoperoxides (Scheme 2).

To shed some light onto the generality of this reaction and to study the applicability (6) of the bicyclic endoperoxides derived from benzocycloheptene to the synthesis of benzotropone derivatives, we have synthesized two derivatives **10** and **13** containing electron-withdrawing and electron-donating substituents. In this paper, we report on the synthesis of these compounds and their photooxygenation reactions and transformations.

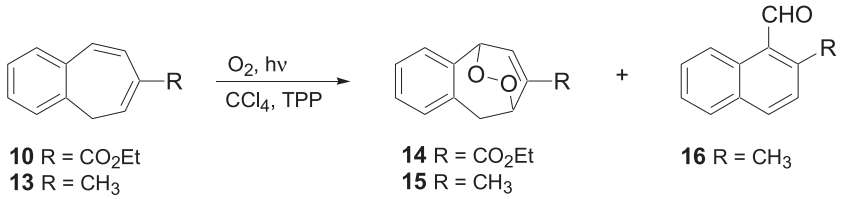
Results and discussion

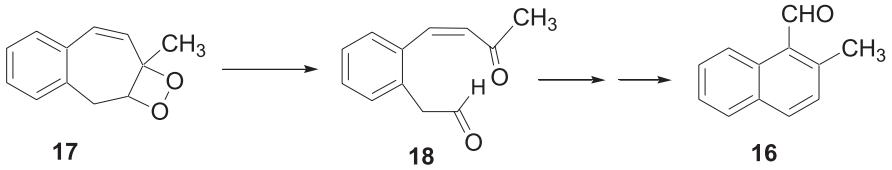
The starting materials **10** and **13** were synthesized starting from dihydronaphthalene **6**. The addition of carbenes to an aromatic compound is an important method for the construction of seven-membered rings (7). However, the yields are usually not good and the reactions are without selectivity. Therefore, the Rh(II)-catalyzed cyclopropanation of the dihydronaphthalene **6** was performed with ethyl diazoacetate to give **7** (8). Bromination of **7** with NBS followed by Zn elimination produced the benzocycloheptatriene derivative **9** (9). The base-catalyzed isomerization of **9** with triethylamine afforded the conjugated isomer **10** in a 94% yield. For the synthesis of methyl derivative **13**, dibromocarbene was added to **6** to afford **11**. The ring expansion with quinoline followed by HBr elimination of **11** produced the vinyl bromide **12** (9) in a high yield. The halogen-metal exchange of the bromine atoms in **12** with *n*-BuLi followed by quenching with CH_3I furnished the target compound, methylbenzocycloheptene **13** (10) (Scheme 3).

The photooxygenation of benzocycloheptene derivatives **10** and **13** was carried out by the bubbling of oxygen in carbon tetrachloride while irradiating with a 500 W lamp in the presence of tetraphenylporphine as a sensitizer. ^{1}H NMR monitoring indicated complete consumption of **13** after 24 h, but ester **10** only after 9 days (Scheme 4).



In contrast to the parent hydrocarbon,[3] the ester derivative **10** formed the endoperoxide **14** as the sole compound in 94% yield. On the other hand, the photooxygenation of **13** formed a mixture consisting of the expected bicyclic endoperoxide **15** and naphthalene derivative **16**. Formation of naphthaldehyde **16** from **13** may be explained by the [2 + 2]-cycloaddition of singlet oxygen to the electron-rich double bond. The formed dioxetane can easily undergo a ring cleavage reaction to give the dicarbonyl compound **18**, which in turn can undergo intramolecular Aldol-type condensation reactions (11) to form naphthaldehyde **16** (Scheme 5).

In the case of ester **10**, a [2 + 2]-cycloaddition product was not observed, which was probably due to the electron-withdrawing effect of the ester group, which decreases the electron density at the double bond. The deactivation effect



[3] See ref. 5. The parent compound forms four products: a [2 + 4]-cycloaddition product, a dialdehyde formed by the cleavage of the initially formed dioxetane, naphthalene, and naphthaldehyde.

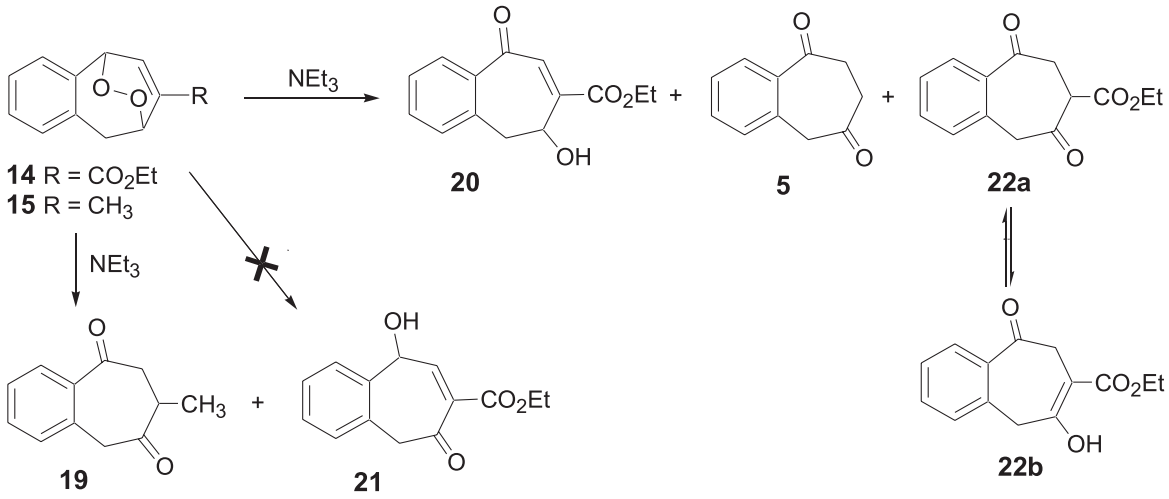

Scheme 4.

Scheme 5.

Scheme 6.

of the ester group was also reflected in the reaction time of **10**, which was converted in 9 days to endoperoxide **14**.

NEt_3-catalyzed reaction of the endoperoxides 14 and 15

The NEt_3-catalyzed reaction of endoperoxide **15** gave only diketone **19** in 90% yield, whereas the reaction of **14** under the same reaction conditions resulted in the formation of three products: hydroxy ketone **20** (37%), diketone **5** (18%), and **22a/22b** (45%) (Scheme 6).

The formation of diketones during the NEt_3-catalyzed reaction of the bicyclic endoperoxide was observed before (5). Contrary to diketone **19**, diketoester **22a** was in equilibrium with its enol form **22b** because of the conjugation of the enol double bond with the ester carbonyl group. Both isomers were observed by NMR spectroscopy in a ratio of 64:36. The signal at δ 12.49 ppm showed the hydroxyl proton of the enol form, which was exchanged upon treatment with D_2O. The singlets at 3.91 and 3.73 ppm were assigned to the methylene protons of the enol form. In the keto form, these methylenic protons appear as AB systems. It is noteworthy that the compound prefers to crystallize in enol form, which allowed us to observe the enol structure **22b** spectroscopically. When the crystalline enol **22b** was dissolved in $CDCl_3$ and the NMR spectrum measured immediately only the enol was observed, and on standing the equilibrium mixture was formed after 2 h. The product **20** was an expected, rearranged product. Methyl derivative **15** did not form any trace of the corresponding hydroxyenone. According to the mechanism of base-catalyzed endoperoxide rearrangement (12), the first step of the reaction includes an abstraction of the α-proton to give a carbanion intermediate. In the second step, the electron pair of the carbanion causes heterolytic cleavage of the peroxide linkage. Finally, in the last step, the formed alkoxide anion captures a proton to form the expected rearranged product **20** (Scheme 7).

The isolated hydroxyketone **20** was treated under the same reaction conditions with NEt_3, to see whether **20** will be converted into **22a/22b** or not. It was shown that ketone **20** was stable. Therefore, it may be assumed that hydroxyketone **20** was not an intermediate. To observe the nature of the intermediate, the reaction of endoperoxide **15** (5*c*) with NEt_3 was monitored by ^1H NMR spectroscopy. After 25 h, we observed a new AB system at 3.92 and 3.68 ppm with a coupling constant of J_{AB} = 14.0 Hz. This coupling constant indicated the formation of a ring-contracted product **28** as we have observed previously (5). We assume that the primarily formed alkoxide **26** attacks the carbonyl group and forms a cyclic ether **28**, which can then rearrange rapidly

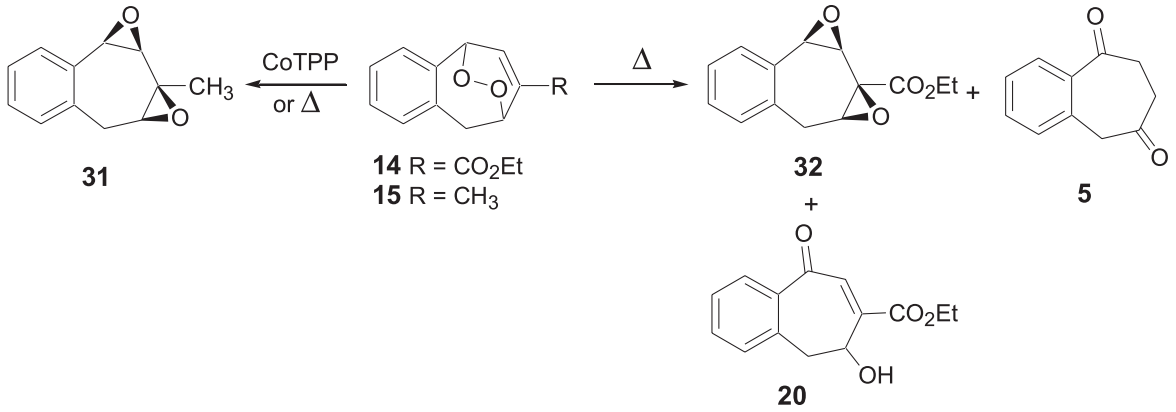
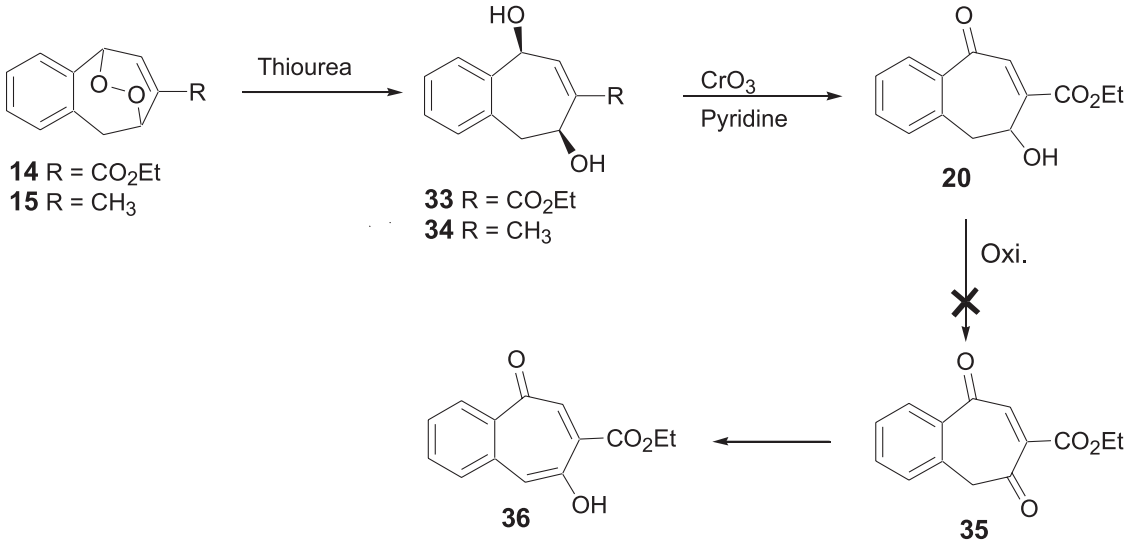
Compounds	 **19**	 **37**	 **38**
Relative energies in kcal/mol	0.0	8.23	9.56



into the dienol **30** by removal of the bridgehead proton. Tautomerization of **30** forms diketone **19**. A hydroxyenone having the structure of **20** was not formed in the case of the methyl derivative **15**. This difference in the reactivity of these bicyclic endoperoxides **14** and **15** upon treatment with NEt_3 may tentatively be attributed to electronic interaction between the alkoxide and neighboring ethyl carboxylate group, which probably partially hinders the formation of cyclic ether **27**. The interesting feature of this reaction was the formation of diketone **5** from **14** where the ester group was removed from the molecule. The formation mechanism of the product **5** is not clear. However, we assume that the neighbouring hydroxyl groups support the decarboxylation reaction. Heating of **22a** up to 109 °C also resulted in the formation of **5**. Therefore, we assume that diketone **5** is a secondary product.

Since both endoperoxides **14** and **15** formed different products by way of a NEt_3 reaction, we evaluated the relative stability of the possible isomers. To do this we carried out AM1 calculations. Our computational investigation of these isomers indicated that the formed diketones **19** and **22a** are thermodynamically more stable isomers, by from 8 to 14 kcal/mol, compared with the isomeric hydroxyketones **20**, **21**, **37**, and **38** (Fig. 1).



Since bicyclic endoperoxides have a large synthetic potential from the point of view of the mechanistic and synthetic

Scheme 8.

Scheme 9.

aspect (5, 6), we were interested in the further transformation of these bicyclic endoperoxides. For the conversion of the endoperoxides into synthetically useful intermediates we studied their thermolysis and tetraphenylporphine (Co-TPP)-catalyzed (13) reactions. It is well-established that unsaturated bicyclic endoperoxides undergo thermal homolytic cleavage of the weak oxygen–oxygen bond followed by the addition of the formed oxygen radicals to the adjacent double bond to give bis(epoxides) with a syn configuration.

Thermolysis or the CoTPP-catalyzed reaction of endoperoxide **15** gave bis(epoxide) **31** (in 45% yield) as expected, whereas the reaction of the endoperoxide **14** with CoTPP produced a complex mixture. On the other hand, the thermal decomposition of endoperoxide **14** resulted in the formation of bis(epoxide) **32** (51%), hydroxy ketone **20** (7%), and diketone **5** (5%), respectively (Scheme 8).

Thiourea reduction of bicyclic endoperoxides provides convenient and efficient access to 2-ene-1,4-diols with a syn configuration. In previous studies, we showed that the reaction of endoperoxides derived from cycloheptatriene derivatives with thiourea formed tropone and tropolone derivatives (6). We, therefore, turned our attention to the thiourea reaction of the endoperoxides **14** and **15**. When the reduction of endoperoxides **14** and **15** with thiourea in methanol was carried out, the diols **33/34** were formed as the sole products. The oxidation of diol **33** gave the hydroxyenone **20**. All of the efforts to oxidize the second hydroxyl group in **33** failed. No other benzotroponoid compounds such as **35** and **36** were observed. This resistance against the oxidation reagent can be attributed to the strong electrostatic interaction between the hydroxyl group and the ester carbonyl group (Scheme 9).

In summary, the results of the present work demonstrate that the photooxygenation of benzocycloheptene derivatives **10** and **13** mainly provided [2 + 4]-cycloaddition products. In the case of **13**, 2-methyl-naphthalene-1-carbaldehyde **16** was isolated as the side product. The fact that the isomer **10** did not form any trace of a naphthalene derivative can be attributed to the effect of the ester group, which decreases the electron density in the seven-membered ring. The base-

© 2005 NRC Canada

catalyzed reaction of the endoperoxide **15** resulted in the formation of the rearranged diketone **19**. This transformation is unusual in the chemistry of the bicyclic endoperoxides. On the other hand, the endoperoxide **14** also gave a diketone **22a** in only a 45% yield besides the normally expected hydroxy ketone **20** and unusual diketone **5**. These results show that an electron-withdrawing substituent attached to the double bond decreases the ratio of the diketone **22a** compared to the methyl-substituted endoperoxide **15**. Furthermore, the formation of the diketone **5** where the ester group is removed from the molecule is also unusual in peroxide chemistry and is observed here for the first time. Thiourea reduction of **14** and **15** provided the ene-2,4-diol derivatives **33** and **34**, which could not be converted into benzotropone derivatives.

Experimental

General

The melting points are uncorrected. IR spectra were obtained from a solution in 0.1 mm cells or KBr pellets on a regular instrument. The ^{1}H and ^{13}C NMR spectra were recorded on 400 (100) and 200 (50) MHz spectrometers. Apparent splitting is given in all of the cases. Column chromatography was performed on silica gel (60-mesh, Merck). TLC was carried out on Merck 0.2 mm silica gel 60 F_{254} analytical aluminum plates. All substances reported in this paper were in racemic form.

Synthesis of ethyl 7*H*-benzo[*a*]cycloheptene-7-carboxylate (9)

Synthesis of 8 (14)

Dibromide **8** was synthesized according to the procedure (8) for methyl ester analogies in a 30% overall yield starting from dihydronaphthalene **6**.

A solution of **8** (2.0 g, 5.35 mmol) in THF (10 mL) and 0.1 mL glacial AcOH was stirred with powdered Zn (0.86 g, 13.17 mmol) for 20 min at rt and 2 h at 45 ± 5 °C. The solution was filtered, the solvent was removed under vacuum, and the oily residue was dissolved in ether (60 mL). The ether solution was washed with satd. NH_4Cl (2 × 60 mL) and dried over $MgSO_4$. Removal of the solvent under vacuum gave crude **9** (0.95 g, 83%), which was recrystallized from *n*-hexane to give **9** (7), but it melted at below room temperature. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.41–7.29 (AA′BB′ system, 4H, H_{aryl}), 6.70 (dd, A part of AB system, $J_{5,6} = J_{8,9} = 10.0$ Hz, $J_{5,7} = J_{7,9} = 1.7$ Hz, 2H, H_5 and H_9), 6.05 (dd, B part of AB system, $J_{5,6} = J_{8,9} = 10.0$ Hz, $J_{6,7} = J_{7,8} = 5.2$ Hz, 2H, H_6 and H_8), 4.26 (q, $J = 7.2$ Hz, 2H, OCH_2), 3.19 (tt, $J_{6,7} = J_{7,8} = 5.2$ Hz, $J_{5,7} = J_{7,9} = 1.7$ Hz, 1H, H_7), 1.30 (t, $J = 7.2$ Hz, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 174.8, 138.4, 132.3, 131.6, 129.1, 128.5, 63.2, 45.1, 16.2. Anal. calcd. for $C_{14}H_{14}O_2$: C 78.48, H 6.59; found: C 78.71, H 6.53.

Ethyl 5*H*-benzo[*a*]cycloheptene-7-carboxylate (10)

A solution of **9** (1.1 g, 5.1 mmol) and triethylamine (74 mg, 0.73 mmol) in 5 mL of CCl_4 was refluxed for 16 h. After removing the solvent and triethyl amine, the residue was filtered on a short silica gel column (10 g) eluting with *n*-hexane to give 1.01 g (93%) of **10** as a colorless wax. ^{1}H NMR (200 MHz $CDCl_3$) δ: 7.37–7.19 (m, 5H, H_{aryl} and H_9), 6.99 (d, B part of AB system, $J_{8,9} = 11.7$ Hz, 1H, H_8), 6.97 (t, $J_{5,6} = 7.4$ Hz, 1H, H_6), 4.22 (q, $J = 7.2$ Hz, 2H, OCH_2), 3.16 (d, $J_{5,6} = 7.4$ Hz, 2H, H_5), 1.30 (t, $J = 7.2$ Hz, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 168.3, 138.2, 137.8, 137.2, 136.3, 131.9, 131.1, 130.0, 129.7, 128.2, 127.9, 62.8, 36.2, 16.3. Anal. calcd. for $C_{14}H_{14}O_2$: C 78.48, H 6.59; found: C 78.67, H 6.48.

Synthesis of 7-methyl-5*H*-benzo[*a*]cycloheptene (13)

To a magnetically stirred solution of monobromide **12** (10) (3.0 g, 13.6 mmol) in tetrahydrofuran (150 mL) was added dropwise 6.8 mL of BuLi (2 mol/L, hexane, 13.6 mmol) under N_2 at –78 °C by a syringe. The reaction mixture was stirred for 3 h at the given temperature, then CH_3I (1.1 mL, 2.32 g, 13.6 mmol) was added. The reaction mixture was stirred for an additional 1 h at –78 °C, and then the temperature was increased to 0 °C. Tetrahydrofuran was removed at a reduced pressure and water (50 mL) was added to the residue. The resulting mixture was extracted with *n*-hexane (3 × 100 mL). The combined extracts were washed with water and dried ($MgSO_4$). Removal of the solvent and chromatography of the residue on a silica gel (100 g) column, with *n*-hexane as eluant, gave **13** (9) as a colorless liquid (1.5 g, 70%). ^{1}H NMR (200 MHz $CDCl_3$) δ: 7.40–7.15 (m, 4H, H_{aryl}), 7.05 (d, A part of AB system, $J_{8,9} = 11.6$ Hz, 1H, H_9), 6.45 (d, B part of AB system, $J_{8,9} = 11.6$ Hz, 1H, H_8), 5.62 (t, 1H, H_6), 3.02 (d, 2H, H_5), 1.90 (bs, 3H, CH_3).

Photooxygenation of ethyl 5*H*-benzo[*a*]cycloheptene-7-carboxylate (10)

The ester **10** (0.34 g, 1.59 mmol) and tetraphenylporphrine (10 mg) were dissolved in 20 mL of CCl_4. The solution was put in a 100 mL round-bottomed (Pyrex glass) flask equipped with a cooling jacket and was then irradiated with a projection lamp (500 W) while a slow stream of dry oxygen was passed through the solution at room temperature. To keep the reaction temperature constant, water was circulated through the cooling jacket. After 9 days, the solvent was evaporated at low temperature (20 °C). Chromatography of the residue on a silica gel (50 g) column, with *n*-hexane – ethyl acetate (97:3) as the eluant, gave **14**. After recrystallization of the residue from CH_2Cl_2–*n*-hexane (1/2) the endoperoxide **14** was obtained as colorless crystals (367 mg, 94%, mp 82 °C).

Ethyl 10,11-dioxatricyclo[7.2.2.0^{2,7}]trideca-2,4,6,12-tetraene-13-carboxylate (14)

IR (KBr, cm^{-1}): 3069, 2976, 2907, 1723, 1484, 1453, 1392, 1353, 1269, 1215, 1107, 1069, 1023, 961. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.64 (dd, $J_{1,12} = 7.4$ Hz, $J_{9,12} = 1.5$ Hz, 1H, H_{12}), 7.33–7.13 (m, 4H, H_{aryl}), 5.53 (m, 1H, H_9), 5.42 (dd, $J_{1,12} = 7.4$ Hz, $J_{1,9} = 1.5$ Hz, 1H, H_1), 4.25 (q, $J = 7.1$ Hz, 2H, OCH_2), 3.71 (dd, A part of AB system, $J_{8,8'} = 18.3$ Hz, $J_{8,9} = 3.9$ Hz, 1H, H_8), 3.19 (dd, B part of AB system, $J_{8',8} = 18.3$ Hz, $J_{8',9} = 3.0$ Hz, 1H, $H_{8'}$), 1.30 (t, $J = 7.1$ Hz, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 165.4, 141.7, 139.8, 137.7, 133.1, 132.6, 130.8, 129.1, 128.0, 81.0, 77.0, 63.1, 39.3, 16.1. EI-MS (70 eV) *m/z* (%): 246 (M^+, 1), 228 (4), 201 (28), 172/171 (60), 116/115 (100), 103 (26), 91

(60), 89 (32), 65 (33). Anal. calcd. for $C_{14}H_{14}O_4$: C 68.28, H 5.73; found: C 67.93, H 5.66.

Photooxygenation of 7-methyl-*5H*-benzocycloheptene (13)

The reaction was carried out according to the above mentioned procedure by using 3.0 g (19.2 mmol) of **13** and TPP (10 mg) in 400 mL of carbon tetrachloride. After 24 h, the solvent was evaporated and the residue was chromatographed on silica gel (80 g) eluting with hexane. The first fraction was TPP and the second fraction was identified as 2-methyl-naphthalene-1-carbaldehyde (6%) (15). The third fraction was identified as 13-methyl-10,11-dioxatricyclo[7.2.2.$0^{2,7}$]trideca-2,4,6,12-tetraene (**15**) as a pale yellow wax (1.2 g, 36%). IR (KBr, cm^{-1}) 2910, 1490, 1450, 1410, 1330, 1230, 1190, 1000, 920, 840, 760. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.30–7.05 (m, 4H, H_{aryl}), 6.43 (bd, $J_{1,12}$ = 7.4 Hz, 1H, H_{12}), 5.21 (dd, $J_{1,12}$ = 7.4 Hz, $J_{1,9}$ = 1.5 Hz, H_1), 4.77 (m, 1H, H_9), 3.61 (dd, A part of AB system, $J_{8,8'}$ = 18.2 Hz, $J_{8,9}$ = 4.3 Hz, 1H, H_8), 3.18 (dd, B part of AB system, $J_{8',8}$ = 18.2 Hz, $J_{8',9}$ = 2.7 Hz, 1H, $H_{8'}$), 1.92 (d, $J_{12,methyl}$ = 1.7 Hz, 3H, methyl). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 140.5, 136.3, 136.1, 131.4, 128.5, 127.2, 126.6, 126.3, 80.7, 80.4, 37.1, 20.3. Anal. calcd. for $C_{12}H_{12}O_2$: C 76.27, H 6.43; found: C 75.91, H 6.61.

Reaction of the endoperoxide 14 with NEt_3

Freshly distilled triethylamine (1 mL) in 3 mL of CH_2Cl_2 was added dropwise to a solution of the endoperoxide **14** (1.0 g, 4.10 mmol) in 50 mL of CH_2Cl_2 at 0 °C during 15 min. The mixture was then stirred at 0 °C for 2 h and at room temperature for 20 h and the solvent evaporated. The residue was submitted to column chromatography (silica gel, 50 g) eluting with *n*-hexane – ethyl acetate (9:1). The first fraction (450 mg, 45%) was identified as keto–enol equilibrium tautomers **22a/22b**. It was recrystallized from CH_2Cl_2–*n*-hexane (4:1) (mp 76 to 77 °C). The rapidly measured NMR spectrum of the crystals showed only the enol form **22b**; however, at standing at room temperature for 2 h, equilibrium between the tautomers **22a/22b** was established consisting of 64% enol **22b** and 36% ketone **22a**.

Ethyl 8-hydroxy-5-oxo-6,9-dihydro-5H-benzo[a]cycloheptene-7-carboxylate (22b)

^{1}H NMR (400 MHz, $CDCl_3$) δ: 12.49 (bs, 1H, OH), 8.14 (dd, $J_{3,4}$ = 7.7 Hz, $J_{2,4}$ = 1.5 Hz, 1H, H_{4aryl}), 7.49–7.28 (m, 3H, H_{aryl}), 4.23 (q, *J* = 7.1 Hz, 2H, OCH_2), 3.92 (s, 2H, H_6), 3.74 (s, 2H, H_9), 1.33 (t, *J* = 7.1 Hz, 3H, CH_3).

Ethyl 5,8-Dioxo-6,7,8,9-tetrahydro-5H-benzocycloheptene-7-carboxylate (22a)

IR (KBr, cm^{-1}): 2976, 1684, 1661, 1461, 1415, 1361, 1338, 1269, 1192, 1100, 1061. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.94 (dd, $J_{3,4}$ = 7.7 Hz, J_{24} = 1.5 Hz, 1H, H_{4aryl}), 7.54–7.24 (m, 3H, H_{aryl}), 4.15 (d, A part of ABX system, $J_{9,9'}$ = 15.2 Hz, 1H, H_9), 4.06 (m, 2H, OCH_2), 3.97 (d, B part of ABX system, $J_{9,9'}$ = 15.2 Hz, 1H, $H_{9'}$), 3.70 (dd, J_{67} = 9.5 Hz, $J_{6'7}$ = 2.9 Hz, 1H, H_7), 3.45 (dd, A part of AB system, $J_{6,6'}$ = 18.0 Hz, $J_{6,7}$ = 9.5 Hz, 1H, H_6), 3.19 (dd, B part of AB system, $J_{66'}$ = 18.0 Hz, $J_{6',7}$ = 2.9 Hz, $H_{6'}$), 1.12 (t, *J* = 7.2 Hz, 1H, CH_3).^{13}C NMR for the mixture **22a/22b** (50 MHz, $CDCl_3$) δ: 202.6, 200.2, 195.5, 178.6, 173.4, 169.9, 140.1, 138.4, 137.1, 135.6, 134.8, 134.7, 134.6, 132.7, 132.5, 132.1, 131.9, 130.2, 129.7, 63.8, 63.0, 54.4, 51.1, 43.8, 43.2, 42.3, 16.1, 15.8. Anal. calcd. for $C_{14}H_{14}O_4$: C 68.28, H 5.73; found: C 67.88, H 5.67.

The second fraction was 6,7-dihydro-9*H*-benzocycloheptene-5,8-dione (**5**) (4) as a colorless wax (127 mg, 18%). IR (NaCl, film, cm^{-1}): 3072, 2972, 2914, 1722, 1684, 1603, 1483, 1452, 1418, 1379, 1325, 1287, 1240, 1094. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 8.01 (dd, $J_{3,4}$ = 7.6 Hz, $J_{2,4}$ = 1.4, 1H, H_{4aryl}), 7.98–7.20 (m, 3H, H_{aryl}), 4.01 (s, 2H, H_9), 3.08 (AA′ part of AA′BB′ system, 2H, H_6), 2.68 (BB′ part of AA′BB′ system, 2H, H_7). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 208.1, 201.9, 138.05, 135.8, 135.5, 132.6, 132.0, 130.0, 52.2, 41.0, 37.4.

The last fraction was identified as ethyl 6-hydroxy-9-oxo-6,9-dihydro-5*H*-benzocycloheptene-7-carboxylate (**20**) as a colorless wax (370 mg, 37%). IR (KBr, cm^{-1}): 3446, 2984, 2900, 1715, 1623, 1584, 1446, 1423, 1400, 1369, 1246, 1123, 1076, 1023, 930. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.66 (bd, $J_{1,2}$ = 7.6 Hz, 1H, H_{1aryl}), 7.51–7.28 (m, 3H, H_{aryl}), 7.12 (s, 1H, H_8), 4.92 (t, $J_{5,6}$ = $J_{5',6}$ = 5.2 Hz, 1H, H_6), 4.32 (q, *J* = 7.2 Hz, 2H, OCH_2), 3.33 (d, $J_{5,6}$ = $J_{5',6}$ = 5.2 Hz, 2H, H_5, $H_{5'}$), 1.35 (t, *J* = 7.2 Hz, 3H, CH_3). ^{13}C NMR (APT, 50 MHz, $CDCl_3$) δ: 195.2, 169.6, 146.0, 141.1, 138.5(–), 136.9, 134.7(–), 132.9(–), 131.2(–), 129.4(–), 68.1(–), 64.1, 42.4, 16.0(–). EI-MS (70 eV) *m/z* (%): 246 (M^+, 1), 217 (7), 201 (100), 172/171 (47), 144 (43), 132 (53), 116/115 (83), 90/89 (40), 65 (18). Anal. calcd. for $C_{14}H_{14}O_4$: C 68.28, H 5.73; found: C 68.78, H 5.67.

Reaction of the endoperoxide 15 with NEt_3

The reaction was carried out according to the above procedure by using 100 mg (532 mmol) of **15** and NEt_3 (2 to 3 drops) in 50 mL of chloroform. After 5 days, the solvent was removed and the residue was chromatographed on silica gel (50 g) eluting with *n*-hexane–$CHCl_3$ (1:1). 7-Methyl-6,7-dihydro-9*H*-benzocycloheptene-5,8-dione (**19**) was obtained as the sole product. Colorless crystals from *n*-hexane–$CHCl_3$ (1:1) mp 216–218 °C (90 mg, 90%). IR (KBr, cm^{-1}): 2970, 2910, 1730, 1690, 1590, 1440, 1370, 1270, 1160, 1050, 1030, 950, 920. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.99 (dd, $J_{3,4}$ = 7.6 Hz, $J_{2,4}$ = 1.6 Hz, 1H, H_{4aryl}), 7.54–7.20 (m, 3H, H_{aryl}), 4.15 (d, A part of AB system, $J_{9,9'}$ = 14.6 Hz, 1H, H_9), 3.90 (d, B part of AB system, $J_{9,9'}$ = 14.6 Hz, 1H, $H_{9'}$), 3.13–3.03 (m, 2H, H_6 and $H_{6'}$), 2.78 (m, 1H, H_7), 1.18 (d, $J_{7,methyl}$ = 7.0 Hz, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 209.1, 200.5, 136.2, 134.5, 134.2, 131.4, 130.6, 129.6, 51.4, 47.4, 40.3, 16.7. Anal. calcd. for $C_{12}H_{12}O_2$: C 76.57, H 6.43; found: C 76.71, H 6.57.

Thermolysis of 22a/22b

In a sealed tube, the keto–enol tautomers **22a/22b** (100 mg, 0.41 mmol) in toluene (3 mL) were heated to 109 °C for 3 days. After removing the solvent, the ^{1}H NMR spectrum of the residue showed the formation of the diketone **5** in 55% yield.

Thermolysis of endoperoxide 14

Endoperoxide **14** (990 mg, 4.02 mmol) was dissolved in toluene (10 mL) and heated to 173 °C for 24 h in a sealed

© 2005 NRC Canada

tube. After evaporation of the solvent, the residue was crystallized from CH_2Cl_2–*n*-hexane to give bis(epoxide) **32** (500 mg, 51%). The NMR spectrum of the filtrate showed that diketone **5** (5%) and hydroxy ketone **20** (7%) were also formed.

Ethyl 5R(S),6R(S),7S(R),8S(R)-diepoxy-6,7,8,9-tetrahydro-5H-benzocycloheptene-7-carboxylate (32)

IR (KBr, cm^{-1}): 3000, 2938, 1753, 1461, 1438, 1376, 1292, 1184, 1123, 1076, 1038, 992, 930, 915. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.47–7.11 (m, 4H, H_{aryl}), 4.17 (d, A part of AB system, $J_{5,6}$ = 4.1 Hz, 1H, H_5), 4.15 (m, 2H, OCH_2), 4.08 (d, B part of AB system, $J_{5,6}$ = 4.1 Hz, 1H, H_6), 3.72 (dd, A part of ABX system, $J_{9,9'}$ = 13.6 Hz, $J_{8,9}$ = 7.3 Hz, 1H, H_9), 3.46 (dd, $J_{8,9}$ = 7.3 Hz, $J_{8,9'}$ = 6.6 Hz, 1H, H_8), 3.01 (dd, B part of ABX system, $J_{9',9}$ = 13.6 Hz, $J_{8,9'}$ = 6.6 Hz, 1H, $H_{9'}$), 1.25 (t, J = 7.1 Hz, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 170.8, 136.7, 134.1, 133.1, 132.6, 130.1, 129.2, 63.9, 61.6, 58.0, 57.0, 54.1, 34.6, 15.9. EI-MS (70 eV) *m/z* (%): 246 (M^+, 1), 228 (4), 201 (30), 172/171 (37), 144/145 (34), 115 (100), 103 (26), 91 (36), 77 (32), 65 (33). CoTPP-catalyzed reaction of 15

Cobalt-*meso*-tetraphenylporphyrin (CoTPP, 5 mg) was added in portions to a magnetically stirred solution of endoperoxide **15** (100 mg, 532 mmol) in 5 mL of $CHCl_3$ at –10 °C. The mixture was then stirred for 2 h and the solvent evaporated. ^{1}H NMR spectral analysis of the reaction mixture indicated the formation of compounds **31** and the residue was submitted to column chromatography (silica gel, 50 g) eluting with $CHCl_3$–*n*-hexane (3:2) and gave 5*R*(*S*),6*R*(*S*),7*S*(*R*),8*S*(*R*)-diepoxy-7-methyl-6,7,8,9-tetrahydro-5*H*-benzocycloheptene (**31**) as colorless crystals (45 mg, 45%) from CH_2Cl_2–*n*-hexane (1:3), mp 85 to 86 °C. IR (KBr, cm^{-1}): 2940, 1490, 1430, 1370, 1210, 1190, 1090, 1030, 990, 910, 880, 840, 790, 750. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.41–7.11 (m, 4H, H_{aryl}), 4.08 (d, A part of AB system, $J_{5,6}$ = 4.0 Hz, 1H, H_5), 3.65 (dd, $J_{9,9'}$ = 12.8 Hz, $J_{8,9}$ = 6.2 Hz, 1H, H_9), 3.55 (d, B part of AB system, $J_{5,6}$ = 4.0 Hz, 1H, H_6), 3.06–2.87 (m, 2H, $H_{9'}$ and H_8), 1.37 (s, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 136.7, 132.7, 131.4, 131.0, 129.1, 127.4, 60.3, 58.3, 56.2, 56.1, 33.4, 21.4. Anal. calcd. for $C_{12}H_{12}O_2$: C 76.57, H 6.43; found: C 76.64, H 6.54.

Thermolysis of endoperoxide 15

The reaction was carried out according to the above procedure by using 50 mg (266 mmol) of **23** in 5 mL of toluene at 190–210 °C. After 1 h, the solvent was removed and the residue was chromatographed on silica gel (50 g) eluting with *n*-hexane–$CHCl_3$ (1:1). The bis(epoxide) **31** was obtained as the sole product (13 mg, 27%).

The reaction of endoperoxide 14 with thiourea

The endoperoxide **14** (350 mg, 1.42 mmol) was dissolved in 12 mL of CH_3OH. A solution of thiourea (114 mg, 1.5 mmol) in 5 mL of methanol was then added dropwise in 10 min. After stirring of the solution at room temperature for 3.5 h, the residue was filtered through silica gel (5 g) eluting with ethyl acetate – *n*-hexane (1:1) to give ethyl 6*S*(*R*),9*S*(*R*)-6,9-dihydroxy-6,9-dihydro-5*H*-benzo[*a*]cycloheptene-7-carboxylate (**33**) (335 mg, 95%), mp 63 to 64 °C from $CHCl_3$. IR (KBr, cm^{-1}): 3502, 3378, 3131, 2993, 2900, 2800, 1697, 1465, 1380, 1265, 1041, 879. ^{1}H NMR (200 MHz, CD_3OD) δ: 7.53 (d, $J_{1,2}$ = 6.9 Hz, 1H, H_{1aryl}), 7.30–7.21 (m, 3H, H_{aryl}), 7.10 (m, 1H, H_8), 5.69 (m, 1H, H_9), 4.84 (m, 1H, H_6), 4.19 (q, J = 7.1 Hz, 2H, OCH_2), 3.27 (bd, A part of AB system, $J_{5,5'}$ = 14.3 Hz, 1H, H_5), 3.01 (dd, B part of AB system, $J_{5',5}$ = 14.3 Hz, $J_{5',6}$ = 4.4 Hz, 1H, $H_{5'}$), 1.28 (t, J = 7.1 Hz, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 170.8, 149.8, 146.7, 136.2, 135.4, 134.1, 129.6, 129.4, 125.5, 70.9, 67.0, 63.9, 41.5, 16.4. Anal. calcd. for $C_{14}H_{16}O_4$: C 67.73, H 6.50; found: C 68.09, H 6.44.

The reaction of endoperoxide 15 with thiourea

The reaction was carried out according to the above procedure by using 140 mg (745 mmol) of **15** in 10 mL of CH_3OH at –10 °C. After 24 h, the solvent was removed and the residue was chromatographed on silica gel (5 g) eluting with *n*-hexane–$CHCl_3$ (1:1). (5*S(R)*,8*S*(*R*))-7-methyl-8,9-dihydro-5*H*-benzo[*a*]cycloheptene-5,8-diol (**34**) was obtained as a pale yellow wax (90 mg, 64%). IR (KBr, cm^{-1}): 3580, 2900, 2840, 1640, 1590, 1370, 1120, 1060, 1000, 900, 870. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.56–715 (m, 4H, H_{aryl}), 5.68 (m, 1H, H_6), 5.58 (m, 1H, H_5), 4.14 (m, 1H, H_8), 3.25 (bd, A part of AB system, $J_{9,9'}$ = 14.6 Hz, 1H, H_9), 3.05 (dd, A part of AB system, $J_{9,9'}$ = 14.6 Hz, $J_{8,9'}$ = 4.5 Hz, 1H, $H_{9'}$), 1.80 (bs, 3H, CH_3). Anal. calcd. for $C_{12}H_{14}O_2$: C 75.76, H 7.42; found: C 76.21, H 7.37.

Oxidation of 33 with CrO_3

To a magnetically stirred solution of CrO_3 (360 mg, 3.6 mmol) in 16 mL of CH_2Cl_2 and pyridine (284 mg, 3.6 mmol) cooled to 0 ± 5 °C was added dropwise a solution of diol **33** (297 mg, 1.20 mmol) in 4 mL methylene chloride during 5 min. This solution was stirred for 2 h at 0 ± 5 °C and for an additional 22 h at room temperature. The solvent was removed by rotoevaporation. Methylene chloride (100 mL) was added to the residue, and then filtered to remove the precipitated material. The organic layer was washed with 1 mol/L (20 mL) HCl solution, water, and then dried over $MgSO_4$. After removal of the solvent, the residue was filtered through a short silica gel column eluting with *n*-hexane–EtOAc (85:15) to give hydroxy ketone **20** (206 mg, 70%).

Investigation of the density dependence of the shear relaxation time of dense fluids

Mehrdad Bamdad, Saman Alavi, Bijan Najafi, and Ezat Keshavarzi

Abstract: The shear relaxation time, a key quantity in the theory of viscosity, is calculated for the Lennard–Jones fluid and fluid krypton. The shear relaxation time is initially calculated by the Zwanzig–Mountain method, which defines this quantity as the ratio of the shear viscosity coefficient to the infinite shear modulus. The shear modulus is calculated from highly accurate radial distribution functions obtained from molecular dynamics simulations of the Lennard–Jones potential and a realistic potential for krypton. This calculation shows that the density dependence of the shear relaxation time isotherms of the Lennard–Jones fluid and Kr pass through a minimum. The minimum in the shear relaxation times is also obtained from calculations using the different approach originally proposed by van der Gulik. In this approach, the relaxation time is determined as the ratio of shear viscosity coefficient to the thermal pressure. The density of the minimum of the shear relaxation time is about twice the critical density and is equal to the common density, which was previously reported for supercritical gases where the viscosity of the gas becomes independent of temperature. It is shown that this common point occurs in both gas and liquid phases. At densities lower than this common density, even in the liquid state, the viscosity increases with increasing temperature.

Key words: dense fluids, radial distribution function, shear modulus, shear relaxation time, shear viscosity.

Résumé : Le temps de relaxation de cisaillement, une quantité clé dans la théorie de la viscosité, a été calculé pour le fluide de Lennard–Jones et pour le krypton solide. Le temps de relaxation de cisaillement a été initialement calculé par la méthode de Zwanzig–Mountain qui définit cette quantité comme le rapport du coefficient de viscosité de cisaillement au module de cisaillement infini. Le module de cisaillement est calculé à partir de fonctions de distribution radiale très précises obtenues à partir de simulations dynamiques moléculaires du potentiel de Lennard–Jones et d'un potentiel réaliste pour le krypton. Ce calcul permet de montrer que la dépendance entre la densité et les isothermes du temps de relaxation de cisaillement du fluide de Lennard–Jones et du krypton passe par un minimum. On a aussi calculé le minimum du temps de relaxation de cisaillement en utilisant les différentes approches proposées originalement par van der Gulik. Dans cette approche, le temps de relaxation est déterminé comme le rapport du coefficient de viscosité de cisaillement et de la pression thermique. La densité du minimum du temps de relaxation de cisaillement est égale à environ deux fois la densité critique et elle est égale à la densité commune qui a été rapportée antérieurement pour les gaz supercritiques où la viscosité du gaz devient indépendante de la température. Il est démontré que ce point commun se retrouve dans les phases tant gazeuses que liquides. À des densités inférieures à cette densité commune, même à l'état liquide, la viscosité augmente avec une augmentation de la température.

Mots clés : fluides denses, fonction de distribution radiale, module de cisaillement, temps de relaxation associé au cisaillement, viscosité de cisaillement.

1. Introduction

The flow of linear momentum, thermal energy, or mass in a fluid can result from local fluctuations inside an equilibrium system or from external driving forces in nonequilibrium systems. In nonequilibrium states of a fluid, the velocity distribution differs from the Maxwell distribution. Internal collisions reestablish a new Maxwell distribution in the system, and the timescale for reestablishing a new equilibrium state is determined by the relaxation time (τ) of the system (1).

The notion that viscosity and elasticity are two different aspects of the same phenomenon and that ordinary liquids behave elasticity at short enough times was first suggested by Maxwell and put on a firm molecular footing in 1965 by Zwanzig and Mountain (2). By starting with the Green–Kubo time-correlation expression for the frequency-dependent shear viscosity they derived that

$$[1] \qquad \eta_0 = \tau G_\infty$$

where η_0 is the zero-frequency shear viscosity and G_∞ the infinite-frequency shear modulus.

Zwanzig and Mountain (2) derived the formula relating the infinite-frequency shear modulus to the radial distribu-

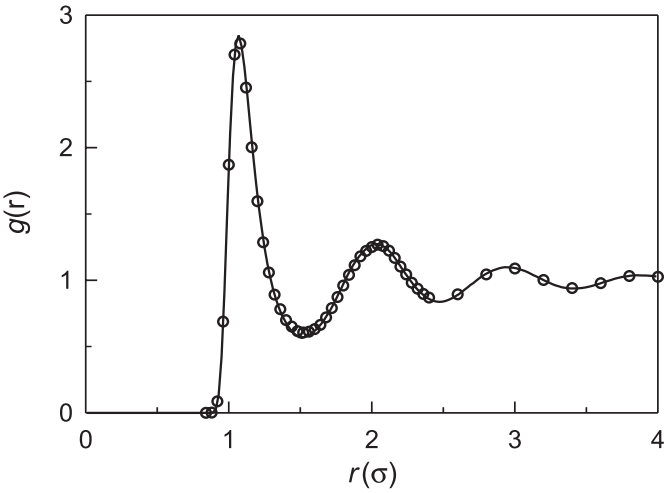
tion function (RDF) for fluids interacting with a spherically symmetric potential

$$[2] \qquad G_\infty = \rho kT + \frac{2\pi}{15}\rho^2 \int_0^\infty g(r)\frac{\mathrm{d}}{\mathrm{d}r}\left[r^4 \frac{\mathrm{d}\phi(r)}{\mathrm{d}r}\right]\mathrm{d}r$$

where $g(r)$, $\phi(r)$, k, T, and ρ are the radial distribution function, intermolecular pair potential, Boltzmann constant, absolute temperature, and density, respectively. Zwanzig and Mountain (2, 3) calculated relaxation times for monatomic fluids using the Lennard–Jones potential. For more general classes of fluids, this approach requires a proper selection of intermolecular potential and mathematical form for the radial distribution function.

Van der Gulik (4–6) showed that the viscosity coefficient of a dense fluid is directly proportional to the thermal pressure, i.e., the sum of the external and internal pressure. By using the classical ideas of Maxwell regarding the equivalence of elasticity and viscosity and the modern basis given by Zwanzig and Mountain, van der Gulik interpreted the Maxwell relaxation time as the slope of the linear viscosity–pressure curve. In this approach, the relaxation time is the time in which a perturbation to the Maxwellian distribution decreases to $1/e$ of its original magnitude, and is related to the average collision interval. This approach can yield precise relaxation times since the method is based on the accurate viscosity and thermal pressure values and does not depend on the form of the intermolecular potential.



This paper is organized as follows. In section 2, molecular dynamics simulations of highly accurate radial distribution functions (RDF) for the Lennard–Jones fluid and krypton using a realistic potential are described. These functions are used to study the density dependence of the shear relaxation time in the Zwanzig–Mountain approach (section 3). The density dependence of the shear relaxation time will also be studied using the van der Gulik scheme for Lennard–Jones fluids and some real fluids (section 4). Both approaches show that the shear relaxation times for Lennard–Jones (LJ) fluids and real fluids pass through a minimum at a specific reduced density and this minimum is related to the intersection point observed in viscosity–density isotherms (7) at which the temperature variation of viscosity is reversed (section 5).

2. The radial distribution function of LJ fluids and krypton

To obtain the shear modulus for the LJ potential, the integral in eq. [2] is evaluated numerically using the RDF of LJ fluids. Although a number of analytical functions are available for the calculation of the RDF for the LJ fluids (8), they are based on fitting the simulated values of Verlet (9) over a limited density and temperature range. In this work, the RDF at each density and temperature is obtained by a standard molecular dynamics simulation.

The RDF is calculated (10, 11) from the spatial distributions of atoms in a system with 864 particles enclosed in a cube of side L with periodic boundary conditions interacting through a two-body LJ potential

Fig. 1. The agreement between the Verlet (9) RDF (open circles) for the LJ fluid with those calculated in the present work (solid line) at $T^* = kT/\varepsilon = 1.095$ and $\rho^* = \rho\sigma^3 = 0.88$.

$$[3] \qquad \phi(r) = 4\varepsilon\left(\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right)$$

A cutoff of at $r_v = 2.5\sigma$ is used for the potential. The simulation was run for a total of 50 000 time steps and the step size for the velocity – Verlet integrator was set to $\Delta t^* = 0.001$. The RDF calculated for the LJ fluids is compared to the accurate Verlet RDF (9) in Fig. 1 for a sample temperature and density, and the agreement between the points indicates the accuracy of the simulations. The RDFs required at each density and temperature are determined in a similar manner without introducing uncertainties involved in the construction of a correlation function.

Similar calculations were performed for krypton using the highly accurate krypton HFD-B2 potential (12). This potential (E_{int}) is based on partitioning the interaction energy of Kr into uncorrelated (ΔE_{SCF}, Hartree–Fock) and correlated (ΔE_{corr}) parts. The parameters in the HFD-B2 potential are adjusted by fitting to precise spectroscopic and transport properties of krypton. The form of this potential is

$$[4] \qquad E_{int} = A\exp(-\alpha R + \beta R^2) - [C_6F^{-6} + C_8R^{-8} + C_{10}R^{-10}]F(R)$$

with

$$[5] \qquad F(R) = \exp[-(DR_mR^{-1} - 1)^2] \qquad R < DR_m$$

$$= 1 \qquad R \geq DR_m$$

where A, α, β, C_6, C_8, C_{10}, and D are adjustable parameters and R_m is the interatomic separation at the minimum of the potential. The molecular dynamics simulations for this potential were run for a total of 50 000 time steps with a step size of $\Delta t^* = 0.001$. The RDFs calculated for Kr with this potential show good agreement with available RDF data for this gas.

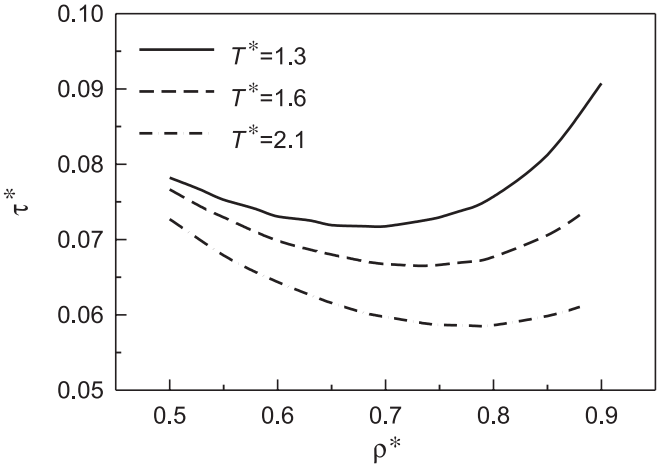
3. The relaxation time from the Zwanzig–Mountain approach

There are several semiemperical and analytical expressions for the viscosity of LJ fluids (13), but there is little data and no unique formula for predicting the shear relaxation time. In this section, the RDF for the LJ and accurate krypton potentials are used to calculate G_∞, which along with the viscosity, is used to determine the density dependence of the shear relaxation time of the fluids.

In the first approach, the Mountain–Zwanzig (3) relation (eq. [1]) is used along with the analytical expression for reduced shear viscosity of (supercritical) LJ fluids given by Rowley and Painter (13) to determine the shear relaxation time. The reduced viscosity is defined as $\eta^* = \eta\sigma^2/\sqrt{m\varepsilon}$, where m is molecular weight. The reduced shear modulus ($G_\infty^* = G_\infty\sigma^3/\varepsilon$) for the LJ fluid is obtained from the numerical solution of eq. [2] and is tabulated for several reduced temperatures and densities in Table 1. In Fig. 2, the reduced shear relaxation time ($\tau^* = \eta^*/G_\infty^*$) of a LJ fluid is plotted as a function of the reduced density for three isotherms. The relaxation time goes through a minimum at $\rho^* = 0.69$ for the $T^* = 1.3$ isotherm ($\rho^* = \rho\sigma^3$ and $T^* = kT/\varepsilon$). This minimum shifts to $\rho^* = 0.78$ for $T^* = 2.1$. The reduced relaxation times and densities at different temperatures are given in Table 2. The presence of the minima is discussed in section 5.

Argon, krypton, nitrogen, and carbon dioxide can be considered as examples of LJ fluids and the viscosities of these fluids from the NIST Standard Reference Database (14) along with eq. [2] can be used to predict their infinite-limit shear modulus and then shear relaxation time. The best values of ε and σ for these fluids (7, 12) are given in Table 3. As shown in Fig. 3, the use of experimental viscosities for LJ fluids gives shear relaxation time isotherms, which also show a minima at certain densities (Table 2).

To obtain the relaxation time for a fluid described with a realistic potential, the RDF of krypton is determined from a molecular dynamics simulation using a highly accurate HFD-B2 potential (12). The integral in eq. [2] is evaluated numerically using this RDF. Viscosities from the NIST Standard Reference Database (14) are used to determine the shear relaxation time for krypton. The values of the reduced infinite shear modulus for this potential are given in Table 1. The shear relaxation time of Kr calculated at $T^* = 1.6$ is plotted vs. density and compared to the similar curve for the LJ potential in Fig. 4. The location of the minimum of the krypton potential is at $\rho^* = 0.65$ compared to $\rho^* = 0.70$ for the LJ potential. The value of the relaxation time for the krypton potential at the minimum is also ~10% lower than the LJ potential.



4. Relaxation time from the thermal pressure approach

In the second approach, the relaxation time is calculated from an expression recently proposed by van der Gulik (6) who derived the relaxation time as the ratio of the shear viscosity to thermal pressure

Table 1. The reduced shear modulus ($G_\infty^* = G_\infty\sigma^3/\varepsilon$) from the numerical solution of eq. [2] for LJ and krypton potentials.

	LJ			Krypton		
ρ^*	T^*			T^*		
	1.3	1.6	2.1	1.3	1.6	2.1

Fig. 2. The reduced relaxation time of the LJ fluid vs. reduced density for three reduced isotherms using the Zwanzig–Mountain method with the viscosity values of Rowley and Painter (13).

$$[6] \qquad \tau = \frac{\eta}{p_{th}}$$

where $p_{th} = T(\partial p/\partial T)_\rho$ is the thermal pressure. The thermal pressure can be calculated directly from eq. [7], which covers the entire fluid range

$$[7] \qquad \left(\frac{\partial p}{\partial T}\right)_\rho = R\rho\left[1 + \sum_{i=1}^{6}\left(a_i + \frac{b_i}{T_r} + \frac{c_i}{T_r^2}\right)\rho_r^i\right]$$

where a_i, b_i, and c_i are the adjustable parameters, and $T_r = T/T_C$ and $\rho_r = \rho/\rho_C$ are the reduced temperature and density, respectively, T_C and ρ_C are the critical temperature and density, and R is the gas constant.[2]

In the zero-density limit, the thermal pressure equals the external pressure (p) and the result of eq. [6] is in agreement with the Maxwell relation for ideal gases ($\eta = p\tau$). This implies that viscosity exists because the velocity distribution in a nonequilibrium system cannot adjust instantaneously to an equilibrium distribution. The importance of this formula lies in the fact that it can be generalized to all fluids in the form $\eta = G\tau$, where G is the shear modulus, which for ideal gases equals the pressure p. At low densities, the external pressure is related to the average number of collisions between gas

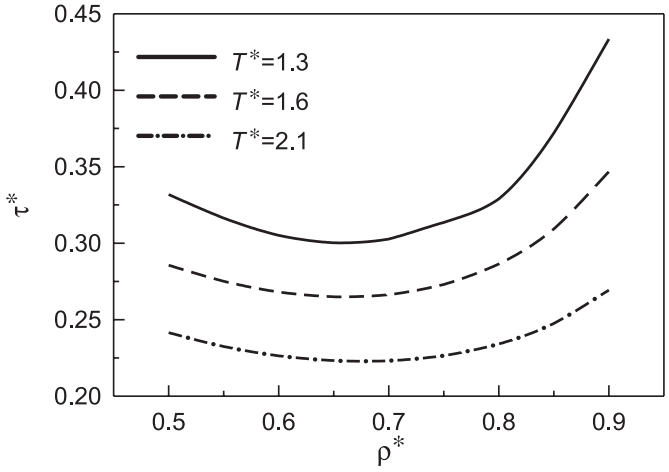
Table 3. Intermolecular parameters used in the Zwanzig–Mountain approach.

Fluid	σ (nm)	ε/*k* (K)
Ar	0.3350	143.23
Kr	0.3571	201.30
N_2	0.3728	85.229
CO_2	0.3800	233.03

Note: Parameters for Kr are from ref. 12 and the other parameters from ref. 7.

Fig. 4. The reduced relaxation time of krypton as a function of the reduced density for $T^* = 1.6$ isotherm for the LJ potential (solid line) and the krypton HFD-2B potential (dashed line).



particles and the container wall. At high densities, the intermolecular forces change the number and intensity of molecule–wall collisions, and as a result, the effective pressure that the particles exert is not equal to the external pressure, but rather to the thermal (or kinetic) pressure (15). This result is plausible since the shear viscosity of dense fluids is related to the exchange of momentum between molecular layers via collisions. The viscosity coefficient is thus determined by the number of collisions per unit volume per unit time and by the efficiency of the exchange of momentum during collisions (5).

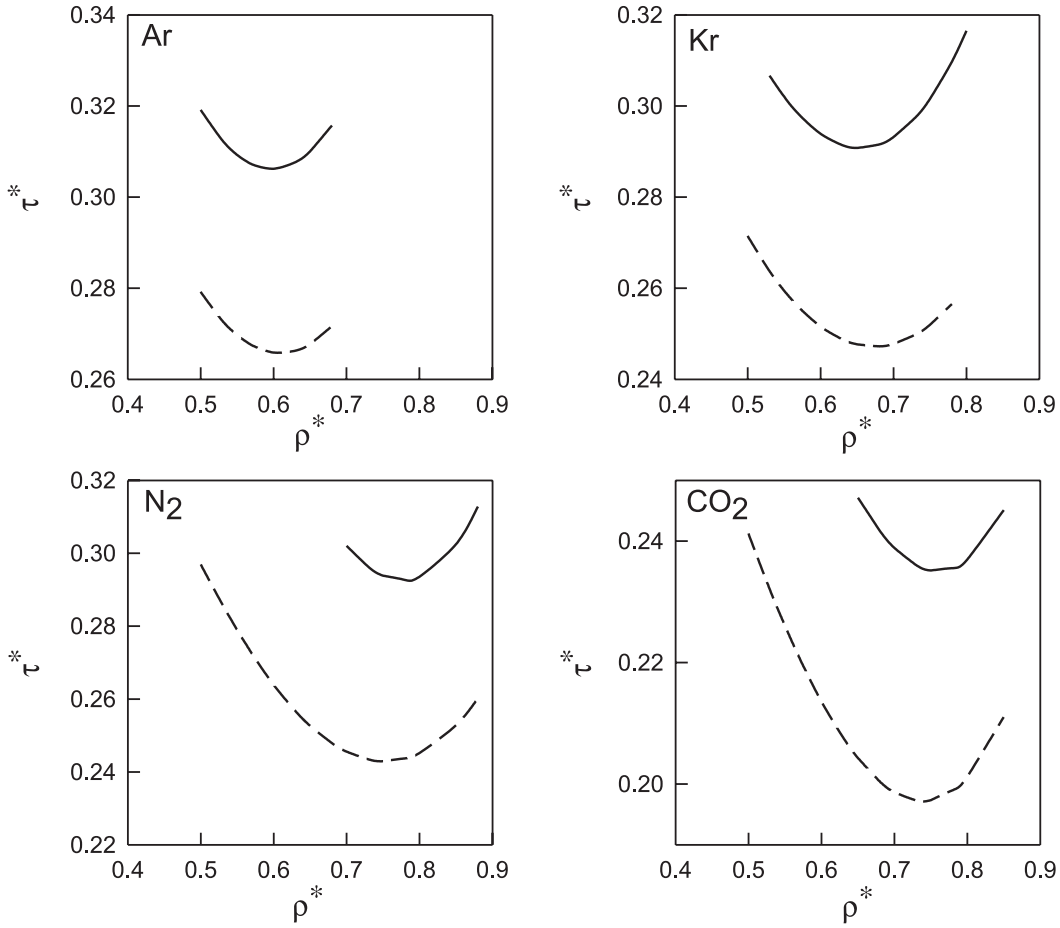
To obtain the shear relaxation time of LJ potentials, we use the analytical expression for reduced shear viscosity of LJ (supercritical) fluids given by Rowley and Painter (13), and the thermal pressure of the LJ fluids is calculated using an equation of state for LJ fluids (16). The reduced relaxation time ($\tau^* = \eta^*/p^*_{th}$, where $p^*_{th} = p_{th}\sigma^3/\varepsilon$) is plotted vs. reduced density for three isotherms in Fig. 5. The reduced relaxation times and densities for the different isotherms are given in Table 2. The density of the minimum increases from about $\rho^* = 0.66$ to $\rho^* = 0.68$ as we go from $T^* = 1.3$ to $T^* = 2.1$.

The density dependence of the reduced shear relaxation times of argon, krypton, nitrogen, and carbon dioxide using eq. [6] for $T^* = 1.3$ and $T^* = 1.6$ are shown in Fig. 6, and the locations of the minima are given in Table 2. The viscosities from the NIST Standard Reference Database (14) are used. These results show that the shear relaxation times for different isotherms of real fluids pass through a minimum at a reduced density, which is about twice the critical density.

Fig. 5. The reduced relaxation time of LJ fluid vs. reduced density for three reduced isotherms using the thermal pressure approach with the viscosity values of Rowley and Painter (13).

The relaxation time at the minima occur at densities that are very close to those calculated in section 3 and shown in Fig. 3.

5. Conclusion



Although relaxation time is a key parameter for transport phenomena, data for this quantity in the literature are very rare. In this study, the shear relaxation time for LJ and real fluids are calculated using the Zwanzig and Mountain (2, 3) and van der Gulik (4–6) approaches. Although these methods use very different data to calculate the shear relaxation time, they predict similar trends for the density and temperature dependence of the relaxation times.

As Figs. 2 (based on the Zwanzig–Mountain method) and 5 (based on the van der Gulik method) show, the shear relaxation time – density isotherms of LJ fluids have minima at densities located at $\rho^* \approx 0.7$. This minimum density is about twice the critical density of LJ fluids and real fluids such as argon, krypton, nitrogen, and carbon dioxide. The minimum density is very close to the common density point (ρ_{com}), which was previously reported for the viscosity of supercritical gases (7). This common density point was determined by Najafi et al. (7) and Michels et al. (17) based on the experimental viscosity data of argon. They showed for supercritical isotherms at densities lower than ρ_{com}, $(\partial\eta/\partial T)_\rho > 0$ as is the normal case for gases and at densities higher than ρ_{com}, $(\partial\eta/\partial T)_\rho < 0$ as is normal for liquids. This is shown in Fig. 7 for the LJ fluid and argon. The change in the temperature dependence of viscosity is observed in the supercritical region and is therefore not due to the gas–liquid phase transition. The density minima of the relaxation time and the common-viscosity density point are in the same general region of the phase diagram. The values of the density at the common point for the different fluids studied in this work are given in Table 2.

Recently, Meier et al. (18) performed extensive molecular dynamic simulations for the viscosity of LJ fluids and some of their observations overlap with those discussed in this work. Based on the time-correlation function approach, they

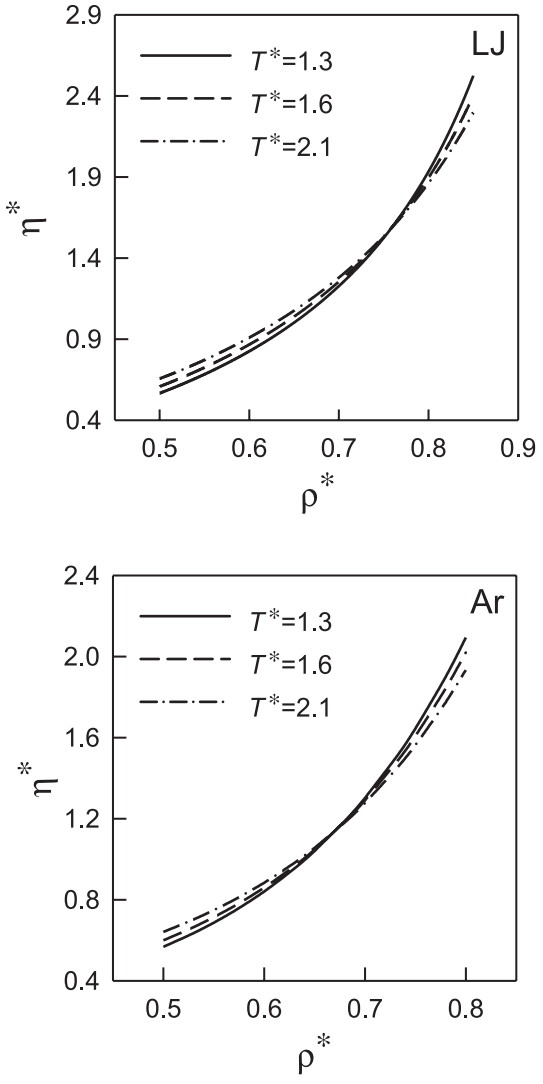
Fig. 6. The density dependence of the reduced relaxation time of Ar, Kr, N_2, and CO_2 for $T^* = 1.3$ (solid line) and $T^* = 1.6$ (dashed line) using the thermal pressure method, and experimental viscosities from the NIST database (14).

calculated the temperature and density dependence of the three different contributions to the viscosity

$$[8] \qquad \eta(\rho,T) = \eta_{KK}(\rho,T) + \eta_{KP}(\rho,T) + \eta_{PP}(\rho,T)$$

where η_{KK}, η_{KP}, and η_{PP} represent kinetic–kinetic, kinetic–potential, and potential–potential contributions, respectively. In the zero-density limit, the sole contributor is the kinetic–kinetic term, which is the Chapman–Enskog viscosity. They showed that the density isotherms of η_{KK} and η_{PP} vary monotonically for densities greater than the critical density. However, the density isotherms of η_{KP} have a maximum in the range of $0.6 < \rho^* < 0.75$, which is approximately 2–2.5 times the critical density of the LJ fluid ($\rho_c^* \approx 0.3$). The maximum of the η_{KP} isotherms shifts to higher densities as the temperature increases in a manner similar to the increase in the minimum of the shear relaxation time. This behaviour of η_{KP} causes the viscosity–density isotherms to intersect in the $0.75 < \rho^* < 0.80$ density range.



The existence of the minimum in the shear relaxation time can be further clarified by studying the density dependence of $(\partial G_\infty/\partial\rho)_T$ or $(\partial p_{th}/\partial\rho)_T$ and $(\partial\eta/\partial\rho)_T$ for a typical a LJ isotherm in Fig. 8. Although both $(\partial G_\infty/\partial\rho)_T$ and $(\partial p_{th}/\partial\rho)_T$ increase monotonically with density, $(\partial\eta/\partial\rho)_T$ decreases slowly at first, but then increases very rapidly after $\rho^* \approx 0.6$. This contrast in the behavior of viscosity at densities higher than the common point density can be attributed to the collisional transfer mechanism, which becomes dominant and yields higher viscosities than the kinetic transfer mechanism, which is dominant at low densities. By noting that the shear relaxation time is the ratio of the viscosity to the shear modulus or thermal pressure, the origin of the minimum in the relaxation time at the common point density will be evident.

The origin of the relaxation time minimum can be investigated from the molecular view point. For supercritical isotherms at lower densities, as the density is increased, the relaxation time decreases. This behaviour is expected since at low densities the viscosity is density-independent. At the same time, with increasing density, the number of molecular momentum carriers increases and so the relaxation time must decrease. The viscosity arises from the transport of momentum between the fluid layers during laminar flow. By increasing the correlation between layers, the relaxation time required for a system to eliminate any velocity gradients decreases. Momentum transfer in a fluid can occur by mass carriers (represented by the η_{KK} contributions) and by the effect of intermolecular forces (represented by the η_{PP} and η_{KP} contributions). The former mechanism predominates at low, and the latter at high densities (15).

In the intermediate density range ($\rho^* < 0.70$), the role of attractive forces becomes more important than in dilute fluids, as is evident from the molecular dynamics calculations.

© 2005 NRC Canada

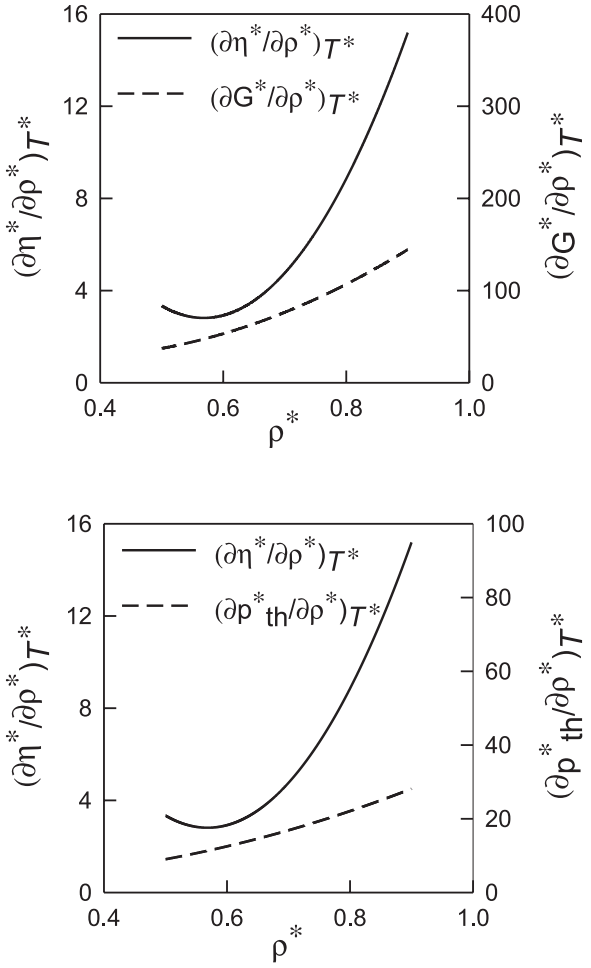


Fig. 7. Intersection of the reduced viscosity–density isotherms of the LJ fluid (top) and argon (bottom).

Molecular dynamics calculations show the viscosity of a square-well fluid increases with a greater slope as a function of density as the attractive well depth becomes larger (19). Although in molecular dynamics simulations temperature and well depth are not separable, for small changes of ε/kT it is possible to assume the well depth has been varied for an isotherm. An intersection point at about twice the critical density for isotherms of viscosity vs. density is found in molecular dynamics simulations of square-well fluids (20). In this intermediate density range, attraction between adjacent fluid layers becomes the dominant contributor to viscosity and causes a decrease in the relaxation time. For $\rho^* > 0.70$, the fluid becomes more compressed and the repulsive contribution of the intermolecular potential becomes dominant and cancels the effects of attractive forces. Consequently, the relaxation time increases for $\rho^* > 0.70$. Weeks et al. (21) pointed out that for LJ liquids, repulsive forces are dominant for densities higher than $\rho^* = 0.65$, which is twice the critical density in real fluids.

In addition to the gas phase, the density of the minima in the shear relaxation time isotherms are observable in the liquid phase, as shown for subcritical isotherms of *liquid* argon in Fig. 9. The density at which the viscosity isotherms for liquid argon intersect is also given in Fig. 9. This figure shows that for $\rho/\rho_c < 2.23$, the viscosity of liquid argon increases with increasing temperature, which is a behaviour usually associated with the gas phase. Although the increase of the viscosity with temperature is small, it is nonetheless measurable. This increase in viscosity with increasing temperature is observed in the experimental viscosity of liquid carbon dioxide (5) and liquid methane (22). Molecular dynamics simulations of Meier et al. (18) for the LJ fluid show that at densities lower than $\rho^* \approx 0.75$, the viscosity increases with temperature, while for densities higher than $\rho^* \approx 0.75$ in the liquid region in the range, the viscosity decreases with temperature.

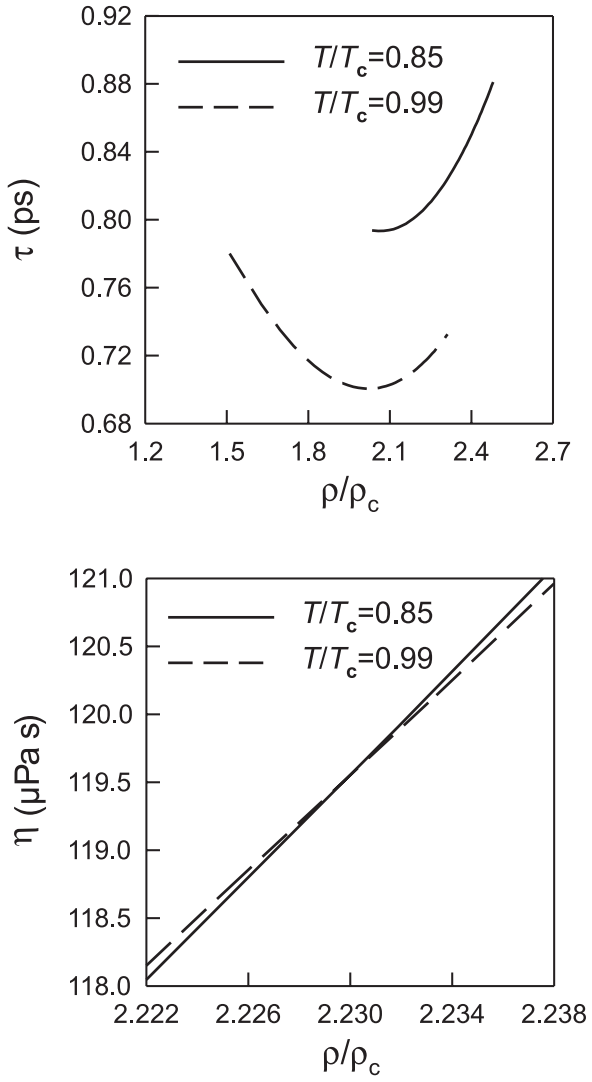

Fig. 8. Slope of reduced viscosity (left vertical axes) and G^*_∞ or p^*_{th} (right vertical axes) with respect to density vs. reduced density for the LJ fluid at $T^* = 1.6$.

The reason why most texts (23, 24) state that the viscosity of liquids decreases with increasing temperature is that viscosity data for liquids are normally measured at liquid densities greater than twice that of the critical density ($\rho/\rho_c > 2.23$ for the case of argon). Our results emphasize that the trend of increasing viscosity with increasing temperature depends only on the density of the fluid, regardless of its gas or liquid state. A similar behavior is observed for the metal-to-nonmetal transition where metallic or nonmetallic behavior

Fig. 9. Relaxation time (top) and viscosity (bottom) vs. reduced density, where ρ_C and T_C are the critical density and temperature, respectively, for liquid argon. Experimental data for Ar are obtained from the NIST database (14).

depends only on the density and not on the physical state of the fluid metal (25).

As a final note, it is necessary to emphasize that eq. [2] is derived for two-body potentials (2). At high densities, three and further many-body terms yield contributions to the macroscopic properties that can cause the difference between the relaxation times obtained by the Zwanzig–Mountain and thermal pressure approaches. These many body terms are not taken into account in the present simulations and might yield some contribution to the magnitude of the shear modulus. However, since the density minima obtained from the two approaches are close, the effect of many body forces on the density of the minimum of the relaxation time will not be large.

Oxidation of 1-(4′-substituted phenyl)-2-(4-methylphenyl)diazene — Benzylic substitution vs. C–azo bond breaking

Alexandru C. Razus, Carmen Nitu, Claudia Pavel, Crinu-Anghel Ciuculescu, Valentin Cimpeanu, Corneliu Stanciu, and Philip P. Power

Abstract: The low oxidation potential of 1-phenyl-2-(4-methylphenyl)diazene 4′-substituted with a dimethylamino or methoxy group (**10** and **11**) allows the easy single electron transfer with radical cation generation in the presence of $FeCl_3$. At the same time, the stabilizing effect of the positive charge exerted by 4-dimethylaminophenyl > 4-methoxy groups on the intermediate carbocation favors the hydrogen atom elimination in comparison with proton loss. Whereas benzylic substitution towards di- and triarylmethane derivatives takes place starting from diazene **11**, the oxidation of diazene **10** leads mainly to products of C–azo breaking. This difference is well-supported by the idea that the electron, in the first step of oxidation, is extracted from the azo and (or) from the amino nitrogen atom.

Key words: diazenes, oxidation, single electron transfer, benzylic substitution, C–azo bond breaking.

Résumé : Le faible potentiel d'oxydation des 1-phényl-2-(4-méthylphényl)diazènes substitués en position 4′ par des groupes diméthylamino (**10**) ou méthoxy (**11**) permet, en présence de $FeCl_3$ le transfert facile d'un seul électron avec la formation d'un cation radical. En même temps, l'effet stabilisant de la charge positive des groupes 4-diméthylamino-phényle > 4-méthoxy sur le carbocation intermédiaire favorise l'élimination de l'atome d'hydrogène par rapport à une perte de proton. Alors que la substitution benzylique vers les dérivés di- et triarylméthanes se fait à partir du diazène **11**, l'oxydation du diazène **10** conduit principalement à des produits résultant d'une rupture de la liaison C–azo. Cette différence est bien expliquée par l'idée que l'électron, dans la première étape de l'oxydation, est extrait de l'atome d'azote de l'azo et (ou) amino.

Mots clés : diazènes, oxydation, transfert d'un seul électron, substitution benzylique, rupture d'une liaison C–azo.

Introduction

In a previous paper (1), we investigated the oxidation of *para*-methyl substituted (*E*)-1-azulen-1-yl-2-phenyldiazene (**1**), with iron(III) chloride (Scheme 1). The reaction was performed in benzene, with good conversion of the starting diazene (between 60% and 80%) to afford products that are mono- and diphenyl-substituted at the methyl group. As shown in the scheme, the di- and triphenylmethane derivatives, the corresponding carbinols, and compounds resulting from hydroxyl oxidation or intramolecular water elimination were also generated. When chlorinated diazene **1**(Cl) was oxidized, 3,3′-dichloro-1,1′-biazulene was also separated from the reaction mixture.

The proposed oxidation mechanism shown in Scheme 2 (1) is based on an initial single electron transfer (SET), **1** → $\mathbf{1}^{+\cdot}$, and on the efficient stabilization of the positive charge on a tropylium ion moiety both in the radical cation $\mathbf{1}^{+\cdot}$ (the most favoured resonance structure is represented) and in the subsequent cation **8**.

We now extend these results on the azulenic diazenes to compounds having the azulenic moiety replaced by other groups, which lower the oxidation potential and stabilize the positive charge, such as 4-dimethylamino- and 4-methoxyphenyl groups (compounds **10** (2) and **11** (3), respectively).

Oxidation of diazenes 10 and 11

The previously used reaction conditions (1) were maintained: the ratio of diazene : ferric chloride = 1:4 in benzene (1 mmol diazene in 25 mL benzene), without atmospheric protection. Because of the lower reactivity of the starting compounds and the rather high number of formed products, a longer reaction time was necessary. The reaction was monitored by TLC and when no changes in the compound ratio were detected, the reaction mixture was worked-up, and the products were separated by liquid chromatography on alumina. Not all of the compounds could be separated and individually characterized. Some products were identified by the careful analysis of GC–MS and NMR spectra of the eluted chromatographic fractions. Along with the main products, the reaction mixtures also contained other unidentified deriv-

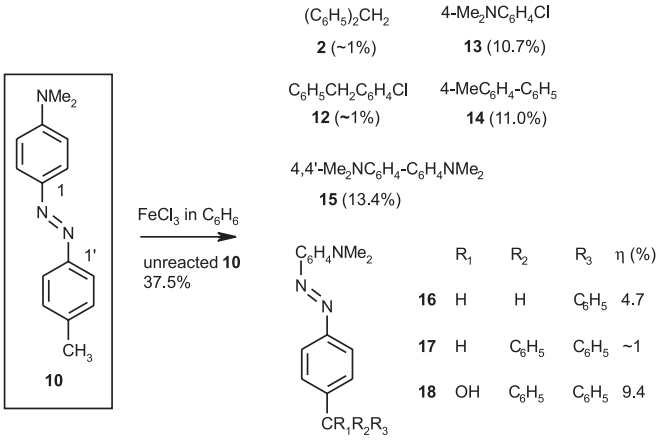
Scheme 1.

Scheme 2.



atives in very small amounts (under 1%) as well as a small quantity of a complex tar mixture.[2]

The reaction of diazene 10

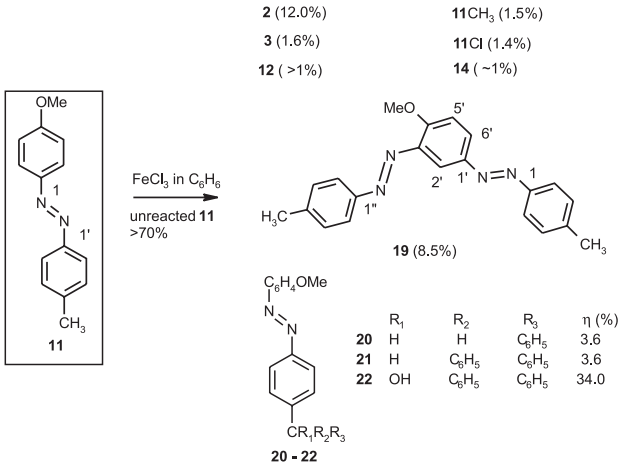
The reaction mixture was stirred for 1 week and after work-up, six fractions were chromatographically separated. The main products obtained and their yields are given in Scheme 3. In this case, a significant amount of tar product was not eluted, but remained on the column.

The GC–MS of fraction 1 indicated the presence of three compounds in the molar ratio of 10:1:1.[3] The first two components had the same M^+ (molecular ion) (*m/z*): 168 ($C_{13}H_{12}^{+\cdot}$). For the last compound, the fragments 202/204 in abundances of 40%/12% indicated the presence of one chlorine atom in the molecule ($C_{13}H_{11}Cl^{+\cdot}$). The first compound with an M^+ of 168 had the same mass spectral features as 4-methyl-substituted biphenyl **14** (4), whereas the mass spectrum of the second compound resembled that of diphenylmethane **2**. In the ^{1}H NMR spectrum of fraction 1, the singlet at δ 3.92 ppm, near the methylene protons of **2** (δ 3.96 ppm) (5), supported the presence of the second compound that also possessed a methylene group. On the basis of chemical shifts and integrations in the ^{1}H NMR spectrum, the diphenylmethane type of structure was attributed to the

Scheme 3.

halogenated compound **12**. Unfortunately, the chlorine position in the molecule could not be accurately assigned, however, the para position seems to be a plausible assumption. The MS of the single compound contained in fraction 2 displayed the characteristic peak of a monochlorinated derivative, M^+ 155/157 (76%/25%). The structure of this compound (**13**) (6) was ascertained on the basis of the AB group signal at δ 7.16 and 6.63 ppm (J = 9.1 Hz) for 1,4-disubstituted benzene as well as on the singlet peak corresponding to six methyl protons at 2.86 ppm. Fraction 3 consisted of the unreacted diazene **10**. The GC–MS of fraction 4 showed the presence of two compounds (**16** and **17**) with M^+ at 315 and 391, in a molar ratio of 6:1 (5), with very similar retention times on the chromatographic column. In the ^{1}H NMR spectrum of this fraction, the singlets at δ 4.03 and 5.60 ppm proved the presence of diaryl- and triarylmethane protons, respectively (other signals characteristic to the proposed structures (**16** and **17**) were also present). The dimeric compound **15** (4, 5, 7) was isolated from fraction 5, whereas fraction 6 contained the carbinol **18** (8).

The reaction of diazene 11



The reaction mixture was maintained at reflux for 48 h and after work-up, seven fractions were separated chromatographically. The results are described in Scheme 4.

Lower yields of the products were obtained in this case because of the very low reactivity of **11**, even under severe reaction conditions. For this reason, the separation and identification of the products from this diazene were more difficult in comparison to those of **10**. The GC–MS of fraction 1 was consistent with the presence of compounds **2**, **12** (in traces), and **14**, products also obtained from the oxidation of **10**, together with triphenylmethane (**3**) (4), in a molar ratio **2**:**3**:**14** of 12:1.6:1. The GC–MS of fraction 2 showed the presence of two compounds in a molar ratio of 1.1:1 with M^+ at (*m/z*) 241 and 260/262 (36%/84%) corresponding to the methylated and monochlorinated starting diazenes (**11**(CH_3) and **11**(Cl)), respectively. Unfortunately, the position of substitution could not be established. Fraction 3 was the starting material (**11**). The diaryl- and triarylmethanic compounds (**21** and **22**) (8) were present in an equimolar ra-

[2] The search for eventually formed products soluble in aqueous solution at work-up (as, for instance, phenols) was unsuccessful.
[3] The ratio between the integral of singlets in the ^{1}H NMR spectrum is in accord with the ratio from the GC–MS.

Scheme 4.

tio in fraction 4 as can be concluded from both MS (M^+ 302 and 378) and ^{1}H NMR spectra (δ 4.06 and 5.62 ppm for methylene and methyne protons). The value of M^+ = 344 for compound **19**, eluted in fraction 5, corresponded to the structure of starting diazene **11** substituted by the 4-methylphenylazo group. In the ^{1}H NMR spectrum of **19**, two phenyl moieties were present, both with para positions substituted by N=N and CH_3 (the AB group signal at δ 7.28–7.34 ppm corresponding to 4H, and at δ 7.81 and 7.87 ppm each accounting for 2H). The two singlets very closely placed (at δ 2.43 and 2.44 ppm each making for 3H) and the singlet at δ 4.11 ppm accounting for 3H corresponded to two benzylic and one methoxy methyl groups, respectively. The chemical shifts and the coupling values for other signals of **19** are consistent with methoxybenzene 2,4-di-substituted by 4-methylphenylazo groups. Unfortunately, the elemental analysis of compound **19** failed because of the presence of a very small amount of an unidentified compound, present in fraction 5, which could not be eliminated by chromatography. Fraction 6 contained some unidentified compounds in traces (as shown by GC–MS), and in fraction 7, the carbinol **22** (8) was separated and characterized.

Discussion

The experimental and spectroscopic data described previously support the following conclusions.

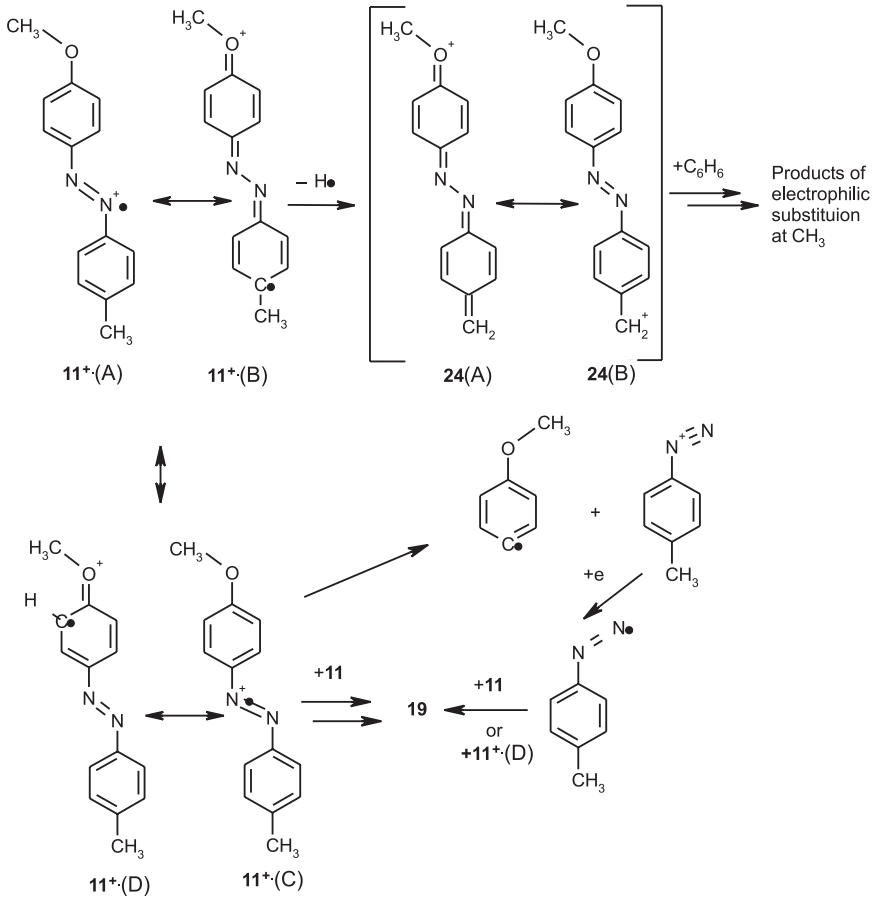
The increase in the amount of unreacted diazenes along the series **1**(CH_3) = **1**(Cl) > **10** > **11** (Schemes 1, 3, and 4) reflects the decrease in their reactivity. This trend follows their oxidation potentials (9).[4] The high oxidation potential of the diazenes that have no activating groups, for example 1-(4-methylphenyl)-2-phenyldiazene, prevents the reaction (90% of starting material remains unreacted after 2 weeks and an amount of tar is formed).

The most unexpected difference among the reactivities of the diazenes is the nature and ratio of the oxidation products. The products obtained can be classified by: (*a*) compounds formed by C–azo bond breaking, and (*b*) benzylic substituted compounds (in some cases the substitution was followed by C–azo bond breaking as for **2**, **3**, and **12**).

For the oxidation of the diazene **10**, the major products **13** and **15** belong to group (*a*) and preserve 4-dimethylaminophenyl moiety. A moderate amount of compound **14** with a 4-tolyl moiety is also formed. When diazene **11** was reacted, such products were not generated except for a small amount of compound **14**, which formed in only 1% yield.

The products of benzylic substitution, i.e., **3**, **12**, and **20**–**22**, were obtained by the oxidation of diazene **11** in about 46% yield. In contrast, for the diazene **10,** the compounds of the type (*b*), **2**, **12**, and **16**–**20**, result only in 17% yield.

In the reaction mixture of diazene **11**, the interesting bisdiazene **19** and a very small amount of compounds **11**(CH_3) and **11**(Cl) were also present. However, the assignment of the structures of the last two products as methyl- or chlorine-substituted starting diazene **11** was based only on their mass spectra.



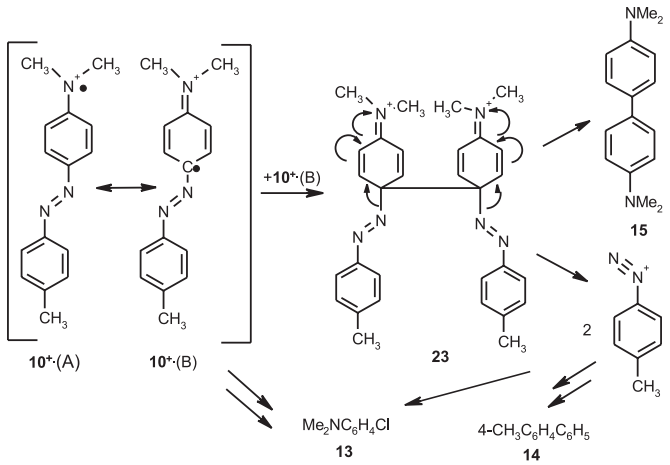
Accordingly, the benzylic substitution without C–azo bond breaking represents the major oxidation route for the diazenes **1** and **11** (Schemes 1 and 4). The main compounds formed in the reaction mixture of **10** were, however, generated by C–azo breaking followed by subsequent stabilization of the fragments **13**–**15** (Scheme 3). Another feature of the reactivity of diazene **10** is the higher amount of the product conserving the 4-dimethylaminophenyl moiety in comparison with those with a 4-tolyl group. This illustrates the difference between the two types of C–azo bond breaking in **10**, which involves the =N-dimethylaminophenyl and =N-tolyl moieties.

As for all oxidations with $FeCl_3$ that we studied, the first reaction step consists of a SET with radical cation generation. Based on the results of EPR and theoretical investigations of the diphenyldiazene radical cation, Rhodes and coworkers (10) suggested the structure [–:N=$N^{+\bullet}$– ↔ –$^{+\bullet}$N=N:–] for the azo group, with the possibility of spin delocalization on the phenyl ring. A good electron donor group, such as the methoxy at one of the phenyl moieties, as in compound **11** or azulene, as in the diazene **1**, enhances the spin delocalization. Some resonance structures for the radical cation **11**$^{+\bullet}$ are presented in Scheme 5.[5] If the structure **11**$^{+\bullet}$ (B) is the most favoured (11), the intermediates formed during the most important oxidation route, namely benzylic substitution, would resemble those for the azulenic diazene **1** (Scheme 2). The presence of a significant amount of bisdiazene **19** in the oxidation mixture of **11** can be considered a surprising result. Thus, the electrophilic substitution of diazene **11** by the diazonium cation, formed in a homolytic breaking of the C–azo bond (12),[6] is prevented by the presence of the deactivating azo double bond (in spite of the existence of the electron donor methoxy substituent).[7]

[4] The overall yield of all products is almost the same for each of the oxidized diazenes.
[5] Other structures could also be written as, for instance, a structure with one electron transferred from the oxygen atom; however, the obtained products seem to infringe on this possibility.
[6] The similar C–azo breaking in structure **11**$^{+\bullet}$ (A), if it takes place, leads to the formation of a low reactive diazonium salt. Possibly, at the work-up of the reaction mixture, the small amount of stabilization products formed from diazonium salts was lost.
[7] The coupling at the anisole succeeds only with very reactive diazonium salts.

© 2005 NRC Canada

Scheme 5.



The radicalic route for generation of **19** seems to be more realistic. Thus, the attack of the nitrogen spin of the radical cation $\mathbf{11}^{+\cdot}$ (C) on the *ortho*-CH_3O position in **11** gives a new radical cation. The subsequent proton elimination and anisyl radical cleavage results in the formation of compound **19**. An alternative route that can be also considered starts from the above-mentioned diazonium salt. The diazonium radical obtained by reduction of this salt with $FeCl_2$, present in the medium, substitutes the radical cation $\mathbf{11}^{+\cdot}$ (D) or, more probably, the compound **11**. Incertitude remains, however, in connection with the aryl diazonium radical lifetime. Some results obtained in the thermic decomposition of such intermediates (13) indicate a rate constant for loss of nitrogen between 10^7 and 10^9 s^{-1}; therefore, it is difficult to imagine another faster reaction even if the reaction is diffusion controlled (14).

At the oxidation of diazene **10**, the di- and triarylmethane derivatives originate in a radical cation similar to $\mathbf{11}^{+\cdot}$. However, it is difficult to say whether this intermediate is formed, namely, by single electron transfer from the azo nitrogen (Scheme 5) or from the amino nitrogen (Scheme 6) or by both ways.

One further question remains to be answered: what is the reaction route by which diazene **10** can generate significant amounts of the products **13** and **15**, which have the 4-dimethylaminophenyl moiety, but no azo bond? The best fit to the experimental data involves, as the first reaction step, the SET from the amino nitrogen atom. This interpretation is

Scheme 6.

supported by the reported structure of the radical cation that was obtained by the anodic oxidation of dimethylaniline (15). This intermediate possesses both the charge and the spin at the nitrogen atom with the possibility of spin delocalization to the para position followed by spin coupling. In contrast with our chemical oxidation, the electrochemical oxidation of **10** did not allow the separation of products and only formation of a thin film was reported (16). The key intermediate for the generation of the product **15** seems to be the radical cation $\mathbf{10}^{+\cdot}$ with a charge distribution depicted by

© 2005 NRC Canada

structure (B) (Scheme 6). The dimerization of $\mathbf{10}^{+\cdot}$ (B) by spin-spin coupling to **23** and the diazonium salt elimination gives the biphenyl **15** (the same reaction route explains the presence of the azulene dimer coupled at the 1,1′ positions during the oxidation of **1**(Cl)). The generation of **15** from the free 4-dimethylaminophenyl radical can be excluded because no products of cross coupling were found in the reaction mixture. The chlorine (atom or anion) attack on $\mathbf{10}^{+\cdot}$ (B) provides the compound **13**. It seems possible that the 4-methylbiphenyl **14** is a result of the radical arylation of benzene (17). The 4-tolyl radical is formed by the reduction of the diazonium salt obtained at the decomposition of **23** and the subsequent nitrogen elimination.

Conclusion

In conclusion, the low oxidation potentials of the diazenes **10** and **11**, as well as of **1**, result in an easy single electron transfer with radical cation generation. At the same time, the stabilizing effects exerted by the azulene > 4-dimethylaminophenyl > 4-methoxyphenyl groups on the carbocations favour hydrogen atom elimination over proton loss (1). Therefore, the superacidic behaviour of the radical cation intermediates proposed earlier (18) must be carefully considered. Factors such as the type of substituent or the polarity of reaction medium can favour either the homolytic or the heterolytic breaking of the C—H bond. The differences in the nature and the product ratios for diazenes oxidation are complex. Whereas di- and triarylmethane derivatives are the major products starting from **1** and **11**, diazene **10** leads mainly to products of C–azo breaking. This difference can be satisfactorily explained by the different position from which the electron is lost in the first step of the oxidation process to generate the radical cation intermediate.

Experimental

^{1}H and ^{13}CNMR: Bruker Avance DRX4 (^{1}H: 400 MHz, ^{13}C: 100.62 MHz) and Varian Gemini 300BB (^{1}H: 300 MHz, ^{13}C: 75.47 MHz) spectrometers; chemical shifts (δ) are expressed in ppm, and *J* values are given in Hz; TMS was used as internal standard in $CDCl_3$ as solvent; in a few cases the signals were assigned on the basis of COSY and HETCOR experiments. IR: Beckmann IR 5A. Mass spectra were recorded on a JEOL JMS-DX303 spectrometer coupled to a Shimadzu GC-14B gas chromatograph with a DB-1 capillary column and a C-R6A integrator. Column chromatography: basic alumina (activity BII-III (Merck)). Dichloromethane (DCM) was distilled over CaH_2 and ethyl acetate was distilled over Na_2CO_3. The numbering of the positions in the compounds is reported in Schemes 3 and 4.

Starting diazenes

N,*N*-Dimethyl-*N*-{4-[(*E*)-(4′-methylphenyl)diazenyl]phenyl}amine (**10**) was obtained as described in literature (2).

(*E*)-1-(4-Methoxyphenyl)-2-(4-methylphenyl)diazene (**11**) was obtained by coupling of the 4-tolyldiazonium salt with phenol (18) and reacting the diazene with diazomethane. Compound **11** shows the ^{1}H NMR spectrum as described (18): δ_H ($CDCl_3$): 2.42 (3H, s, CH_3), 3.89 (3H, s, OCH_3), 7.00 (2H, d, J = 9.2 Hz, 3-, 5-H), 7.29 (2H, d, J = 8.1 Hz, 3′-, 5′-H), 7.79 (2H, d, J = 8.3 Hz, 2′-, 6′-H), 7.90 (2H, d, J = 9.2 Hz, 2-, 6-H). ^{13}C NMR ($CDCl_3$) δ_C: 21.44 (CH_3), 55.54 (OCH_3), 114.15 (C-3, -5), 122.52 (C-2′, -6′), 124.55 (C-2, -6), 129.67 (C-3′, -5′), 140.79 (C-4′), 147.03 (C-1), 150.81 (C-1′), 161.80 (C-4).

Oxidation with ferric chloride — General procedure

In a round-bottomed flask to a magnetically stirred solution of diazene **10** or **11** in benzene (1 mmol diazene for 25 cm^3), anhydrous ferric chloride was added at room temperature (the oxidation of diazene **11** occurred at reflux of the solvent) without air protection (ratio between $FeCl_3$ and diazene is 4:1). From time to time the separated viscous oily product was mechanically removed from the flask wall for a better contact between the reactants. The reaction was monitored by TLC (homogenous samples were collected, washed with a saturated sodium bicarbonate solution, and dried), and it was stopped when the spot of the starting compound vanished or maintained a stationary intensity (the reaction time will be indicated for each diazene). The reaction mixture was quenched with a saturated sodium bicarbonate solution and the major amount of the benzene was evaporated in vacuum. The suspension was extracted three times with 200 cm^3 DCM, the organic extracts were washed once with water, dried (Na_2SO_4), and the solvent was evaporated in vacuum. The residue was fractionated by column chromatography under conditions described in the following. To establish the ratio between the compounds in the eluted fractions, GC–MS and ^{1}H NMR signal integrals were considered and the product yields were calculated towards the reacted diazene. For some of the obtained compounds, mass spectra and (or) ^{1}H NMR spectra, available in the spectra libraries, were used for identification.

Reaction of 10

After 7 days at room temperature, the reaction mixture was worked-up and from 1.5 mmol of **10**, an amount of 367 mg of the rough product was separated on an alumina column (d = 3 cm; l = 13 cm) in six fractions, the first five with *n*-pentane:DCM (4:1), the last one with ethyl acetate. Fraction 1: (the ratio between the compounds was calculated on the basis of GC–MS and ^{1}H NMR spectra of the fraction) 4-methyl-1,1′-biphenyl (**14**, 17 mg, 0.102 mmol, 11%), benzylbenzene (**2**, ~2 mg, 0.010 mmol, ~1%), 1-benzyl-chlorobenzene (**12**, ~2 mg, 0.010 mmol, ~1%). Fraction 2: *N*-(4-chlorophenyl)-*N*,*N*-dimethylamine (**13**, 16 mg, 0.100 mmol, 10.7%). Fraction 3: unreacted **10** (135 mg, 0.564 mmol, conversion 62.4%). Fraction 4: 17 mg, *N*,*N*-dimethyl-*N*-{4-[(*E*)-(4-(phenylmethyl)phenyl)diazenyl]phenyl}amine (**16**) and *N*,*N*-dimethyl-*N*-{4-[(*E*)-(4-(diphenylmethyl)phenyl)diazenyl]phenyl}amine (**17**) with a molar ratio (determined by GC–MS and ^{1}H NMR) of 5.8:1 (4.7% and ~1%, respectively). Fraction 5: *N*,*N*,*N*′,*N*′-tetrametyl-1,1′-biphenyl-4,4′-diamine (**15**, 15 mg, 0.063 mmol, 13.4%). Fraction 6: *N*,*N*-dimethyl-*N*-{4-[(*E*)-(4-(diphenylhydroximethyl)phenyl)diazenyl]phenyl}amine (**18**, 36 mg, 0.088 mmol, 9.4%).

Spectra of resultant fractions or compounds

Mixture of **16** and **17** in fraction 4: yellow powder. ^{1}H NMR ($CDCl_3$) δ_H: 3.07 (40.8H, s, $N(CH_3)_2$), 4.03 (11.6H, s,

CH_2), 5.60 (1H, s, C*H*), 6.75 (13.6H, d, *J* = 9.3 Hz, 3-, 5-H), 7.12–7.31 (52.6H, m, 3′-, 5′-H, and phenyl protons), 7.77 (13.6H, d, *J* = 9.2 Hz, 2-, 6-H), 7.86 (13.6H, d, *J* = 9.2 Hz, 2-, 6-H). GC–MS, *m*/*z* (70 eV): 317 (M(**16**)$^+$ + 2, 2%), 316 (M^+ + 1, 13), 315 (M^+, 71), 165 (13), 157 (15), 152 (18), 148 (10), 121 (6), 120 (100), 118 (8), 105 (15), 104 (20), 91 (23), 77 (22); 392 (M(**17**)$^+$ + 1, 16%), 391 (M^+, 68), 167 (17), 165 (55), 120 (100), 105 (18), 104 (20), 91 (19), 77 (26).

Because only the melting point, elemental analysis, and ^{1}H NMR spectrum for compound **18** were reported in the literature (8) without the proton assignments, we now report the complete characterization of this compound: yellow crystals with mp 210 °C (lit. value (8) mp 209 °C). ν_{max} (CH_2Cl_2) cm^{-1}: 3580 weak (OH). ^{1}H NMR ($CDCl_3$) δ_H: 3.07 (6H, s, N(CH_3)$_2$), 6.74 (2H, d, *J* = 9.3 Hz, 3-, 5-H), 7.30–7.32 (10H, m, phenyl protons), 7.39 (2H, d, *J* = 8.7 Hz, 3′-, 5′-H), 7.76 (2H, d, *J* = 8.7 Hz, 2-, 6-H), 7.86 (2H, d, *J* = 9.2 Hz, 2′-, 6′-H). ^{13}C NMR ($CDCl_3$) δ_C: 40.23 (N(CH_3)$_2$), 81.91 (*C*-OH), 111.43 (t), 121.59 (t), 124.94 (t), 127.29 (t), 127.89 (t), 127.94 (t), 128.55 (t), 143.67 (q), 146.66 (q), 147.86 (q), 152.21 (q), 152.38 (q). GC–MS *m*/*z* (70 eV): 409 (M^+ + 2, 1%), 408 (M^+ + 1, 5), 407 (M^+, 15), 121 (13), 120 (69), 105 (34), 95 (15), 93 (17), 91 (11), 81 (46), 77 (23), 69 (100), 67 (11).

Reaction of 11

After 2 days at reflux, the reaction mixture was worked-up and from 3.54 mmol of **11**, an amount of 826 mg of the rough product was separated on an alumina column (*d* = 4 cm, *l* = 15 cm) in seven fractions, the first two with *n*-pentane:DCM (4:1), the next fractions with increasing ratios of ethyl acetate : *n*-pentane from 1:10 to pure ester for the last fraction. Fraction 1: (the molar ratio between the compounds resulted from the GC–MS and ^{1}H NMR spectra of the fraction) compound **2** (4 mg, 0.022 mmol, 2%), compound **14** (~2 mg, 0.012 mmol, ~1%), benzhydrylbenzene (**3**, 4 mg, 0.018 mmol, 1.6%), and in traces, chlorinated compound **12**. Fraction 2: (the ratio between the compounds resulted from the GC–MS of the fraction): **11**(CH_3) (4 mg, 0.017 mmol, 1.5%) and **11**(Cl) (4 mg, 0.016 mmol, 1.4%). Fraction 3: unreacted **11** (558 mg, 2.46 mmol, conversion 30%). Fraction 4: (the molar ratio was determined by GC–MS and ^{1}H NMR): (*E*)-1-(4-methoxyphenyl)-2-(4-(phenylmethyl)phenyl)diazene (**20**, 12 mg, 0.038 mmol, 3.6%), (*E*)-1-(4-methoxyphenyl)-2-(4-(diphenylmethyl)phenyl)diazene (**21**, 14 mg, 0.038 mmol, 3.6%). Fraction 5: (*E*)-1-{2-methoxy-5-[(*E*)-(4-methylphenyl)diazenyl]phenyl}-2-(4-methylphenyl)diazene (**19**, 16 mg, 0.046 mmol, 8.5%), and traces from an unknown product. Fraction 6: a mixture of unidentified products (28 mg). Fraction 7: (*E*)-1-(4-methoxyphenyl)-2-(4-(hydroxydiphenylmethyl)phenyl)diazene (**22**, 144 mg, 0.36 mmol, 34%).

Spectra of resultant fractions or compounds

Compound **11**(Cl) *m*/*z* (70 eV): 262/260 (M^+, 36%/84%), 261 (83), 153 (17), 135 (96), 125 (93), 107 (91), 92 (90), 77 (100), 63 (91).

Compound **11**(CH_3) *m*/*z* (70 eV): 241 (M^+ + 1, 14%), 240 (M^+, 80), 149 (47%), 122 (20), 121 (99), 119 (17), 92 (30), 91 (100), 77 (57), 65 (97).

Compound **19**: ^{1}H NMR ($CDCl_3$) δ_H: 2.43 and 2.44 (two singlets, 3H + 3H, two CH_3), 4.11 (3H, s, OCH_3), 7.21 (1H, d, *J* = 8.9 Hz, 5′-H), 7.28–7.34 (4H, m, 2-, 2″-H), 7.81 (2H, d, *J* = 8.2 Hz, 3- or 3″-H), 7.87 (2H, d, *J* = 8.2 Hz, 3″- or 3-H), 8.05 (1H, dd, *J* = 8.8 and 2.4 Hz, 6′-H), 8.22 (1H, d, *J* = 2.4 Hz, 2′-H). GC–MS *m*/*z* (70 eV): 344 (M^+, 1.5%), 255 (2), 119 (45), 91 (100), 76 (16), 65 (65).

Mixture of **20** and **21** (8) in fraction 4: yellow powder. ^{1}H NMR ($CDCl_3$) δ_H: 3.87 (6H, s, OCH_3), 4.06 (2H, s, CH_2), 5.61 (1H, s, C*H*), 7.00 (4H, d, *J* = 8.9 Hz, 3-, 5-H), 7.05–7.40 (19H, m, 3′-, 5′-H, and phenyl protons), 7.80 (4H, d, *J* = 8.3 Hz, 2′-, 6′-H), 7.85 (4H, d, *J* = 9.2 Hz, 2-, 6-H). GC–MS *m*/*z* (70 eV): 302 (M(**20**)$^+$, 71%), 239 (1), 228 (3), 215 (6), 180 (6), 168 (9), 165 (100), 163 (19), 152 (66), 139 (25), 135 (44), 115 (37), 107 (77), 91 (92), 89 (45), 77 (99), 63 (99); 378 (M(**21**)$^+$, 15%), 334 (2), 310 (1), 189 (3), 162 (5), 134 (20), 106 (12), 104 (20), 91 (100), 90 (22), 77 (10), 65 (60).

Because only the melting point, elemental analysis, and ^{1}H NMR spectrum were reported for compound **22** (8), without the proton position assignments, the compound was now completely characterized by us: yellow crystals with mp 181 to 182 °C (lit. value (8) mp 182 °C). ν_{max} (CH_2Cl_2) cm^{-1}: 3590 weak (OH). ^{1}H NMR ($CDCl_3$) δ_H: 3.87 (3H, s, OCH_3), 6.99 (2H, d, *J* = 8.9 Hz, 3-, 5-H), 7.29–7.31 (10H, m, phenyl protons), 7.43 (2H, d, *J* = 8.6 Hz, 3′-, 5′-H), 7.80 (2H, d, *J* = 8.3 Hz, 2′-, 6′-H), 7.90 (2H, d, *J* = 9.2 Hz, 2-, 6-H). GC–MS *m*/*z* (70 eV): 396 (M^+ + 2, 2%), 395 (M^+ + 1, 11), 394 (M^+, 42), 318 (2), 317 (10), 289 (10), 259 (5), 242 (4), 241 (22), 239 (13), 183 (8), 135 (47), 107 (100), 105 (55), 92 (22), 77 (52).

Synthesis of some heterocyclic systems of anticipated biological activities via 6-aryl-4-pyrazol-1-yl-pyridazin-3-one

A.S.A. Youssef, M.I. Marzouk, H.M.F. Madkour, A.M.A. El-Soll, and M.A. El-Hashash

Abstract: 6-Aryl-4-pyrazol-1-yl-pyridazin-3-one (**1**) reacted with a PCl_5–$POCl_3$ mixture to give the 3-chloropyridazine derivative **3**. Reaction of **3** with 2-hydroxybenzoylhydrazide and semicarbazide hydrochloride afforded **4** and **5**. Reaction of **1** with ethyl chloroacetate gave **8**. Reaction of **8** with hydrazine hydrate yielded the hydrazide **9**. The hydrazide **9** condensed with the acetylenic ketones and esters **10a**–**10d** and acetylacetone to give the adducts **11a**, **11b**, **12**, **13**, and **14**. Reacting **1** with formaldehyde and piperidine, morpholine, or piperazine, 3-bromopropanoic acid, acetic anhydride, *p*-toluenesulphonyl chloride, succinyl chloride, oxalyl chloride, ethanolamine, or ethyl chloroacetate gave the adducts **15**–**22**. The structures of all newly synthesized compounds were evidenced from their spectral and microanalytical data.

Key words: 6-aryl-4-pyrazol-1-yl-pyridazinone derivative, 6-aryl-3-chloropyridazine derivative, 3,6-diaryl-1,2,4-triazino[4,3-*b*]pyridazine derivative, 6-aryl-3-ethoxycarbonylmethoxypyridazine derivative, 6-aryl-3-(ω-benzoylacetophenone)hydrazinocarbonylmethoxypyridazine.

Résumé : La 6-aryl-4-pyrazol-1-yl-pyridazin-3-one (**1**) réagit avec un mélange de PCl_5–$POCl_3$ pour conduire à la formation du dérivé 3-chloropyridazine **3**. La réaction de **3** avec le 2-hydroxybenzoylhydrazide et le chlorhydrate de semicarbazide conduit aux dérivés **4** et **5**. La réaction de **1** avec le chloroacétate d'éthyle conduit à **8**. La réaction de **8** avec l'hydrate d'hydrazine permet d'obtenir l'hydrazide **9**. L'hydrazide **9** se condense avec les cétones acétyléniques, les esters **10a**–**10d** et l'acétylacétone pour fournir les produits **11a**, **11b**, **12**, **13** et **14**. La réaction de **1** avec le formaldéhyde et la pipéridine, la morpholine ou la pipérazine, l'acide 3-bromopropanoïque, l'anhydride acétique, le chlorure de *p*-toluènesulfonyle, le chlorure de succinyle, le chlorure d'oxalyle, éthanolamine ou le chloroacétate d'éthyle conduit aux adduits **15**–**22**. Les structures de tous les composés nouvellement synthétisés ont été caractérisés par leurs données microanalytiques et spectroscopiques.

Mots clés : dérivé de la 6-aryl-4-pyrazol-1-yl-pyridazinone, dérivé de la 6-aryl-3-chloropyridazine, dérivé de la 3,6-diaryl-1,2,4-triazino[4,3-*b*]pyridazine, dérivé de la 6-aryl-3-éthoxycarbonylméthoxypyridazine, 6-aryl-3-(ω-benzoylacétophénone)hydrazinocarbonylméthoxypyridazine.

[Traduit par la Rédaction]

Introduction

In a recent previous publication (1) we reported the reaction of β-aroylacrylic acid with some nitrogen nucleophiles and active methylene reagents and the utility of some of the reaction products in heterocyclic synthesis. A large number of pyridazin-3-ones were reported to exhibit insecticidal (2–6), allergenic (7), antihypertensive (8–12), analgesic (13, 14), anti-inflammatory, and bactericidal (15, 16) activities. This prompted us to study the behaviour of 6-(4-chloro-3-methyl) phenyl-4-(3,5-dimethyl-pyrazol-1-yl)-4,5-dihydropyridazin-3-one toward various reagents, hoping to get new compounds of anticipated biological activities.

Results and discussion

It has been reported (17, 18) that the reaction of 6-(4-chloro-3-methyl)phenyl-4-(3,5-dimethylpyrazol-1-yl)-**1a** or 6-(4-chloro-3-methyl) phenyl-4-(5-isopropyl-2-methyl)phenyl-**1b**-2,3,4,5-tetrahydropyridazin-3-one with a phosphorous pentachloride – phosphorous oxychloride mixture yielded 4,6-diaryl-3-chloro-4,5-dihydropyridazine derivatives **2a** and **2b**, respectively. In the present investigation, similar treatment of **1a** with the same reagent afforded 6-aryl-3-chloropyridazine derivative **3**. The previous reports suggested structure **2** for the products where there was a lack of spectroscopic data.

b, Ar = 5-*i*-Pr-2-$CH_3C_6H_3$

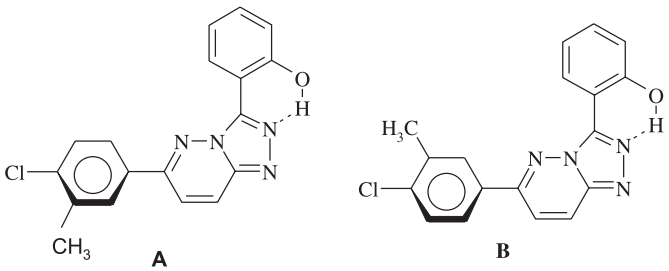
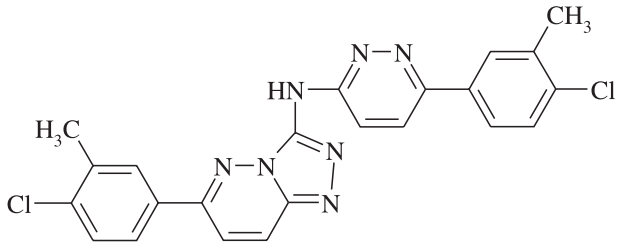
(3)



The ^{1}H NMR spectrum of compound **3** shows the aromatic proton resonances and doesn't exhibit the signals of the ABX pattern of the CH_2-CH- group as well as the signals of the methyl protons of the dimethylpyrazole ring. This infers the absence of these moieties. It discloses AB quartet signals owing to the two protons H_a and H_b of the pyridazine ring. The appearance of extra signals correlated with methyl and the aromatic protons is good evidence for the existence of **3** in the two conformations **A** and **B**, as a result of the limited rotation of the aryl group around the pyridazine ring as shown. The same phenomenon was observed for strucrures **4**, **5**, **8**, **9**, **14**, and **22**. The structure of **3** gets further support from mass spectroscopy. Thus, its EI-MS exhibits a molecular ion peak.

A (3) B

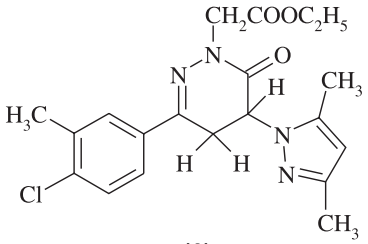
The formation of **3** has been rationalized in terms of the route mentioned in Scheme 1.



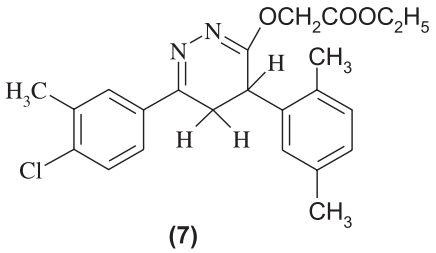
Treating an equimolar amount of 6-aryl-3-chloropyridazine derivative **3** with 2-hydroxybenzoylhydrazide in pyridine gave 3-(2-hydroxy) phenyl-6-aryl-1,2,4-triazolo[4,3-*b*]pyridazine derivative **4**. The structure of compound **4** is substantiated from its microanalytical and spectral data. The ^{1}H NMR spectrum of **4** is in accord with the proposed structure. The higher δ value of the OH proton is in accord with the existence of **4** as its chelated form as shown. Further support for the assigned structure of **4** was gained from EI-MS that revealed the molecular ion peak.

A B

(4)



Reacting **3** with semicarbazide hydrochloride in the presence of triethylamine as a base afforded 3-[6-(4-chloro-3-methyl)phenylpyridazin-3-yl]amino-6-(4-chloro-3-methyl)-phenyl-1,2,4-triazolo[4,3-*b*]pyridazine (**5**).



(5)

The structure of compound **5** is evidenced from its microanalytical and spectral data. The ^{1}H NMR spectrum exhibits exchangeable NH as well as two well-separated singlets consistent with protons of two methyl groups. The

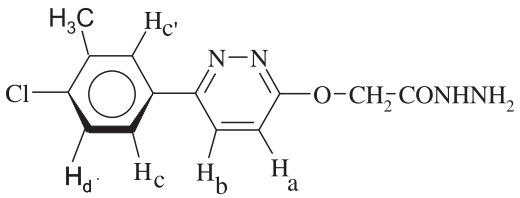
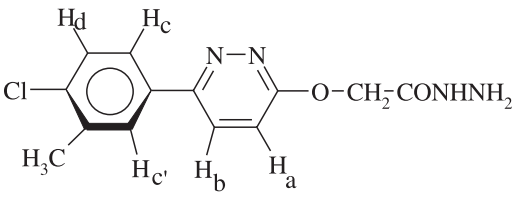


Scheme 2.

complexity of signals in the aromatic region suggests the existence of more than two diastereomers. The EI-MS spectrum of **5** doesn't show the molecular ion peak, but instead shows the ($M^{+\cdot}$ – Cl) peak. The formation of **5** is outlined in Scheme 2.



It has been reported (17, 19) that 4,6-diaryl pyridazinone derivatives **1a** and **1c** reacted with ethyl chloroacetate in the presence of potassium carbonate in dry acetone to give the adducts **6** (17) and **7** (19), respectively. In the present work, treatment of **1a** with ethyl chloroacetate in dioxane instead of dry acetone yielded the adduct **8** as a mixture of two conformers **8A** and **8B**. Although compounds **6–8** have the same melting point, the conflict in structure is probably due to the lack in the spectroscopic evidence used by previous authors (17, 19) in the assignment of structures.

The structure of compound **8** is evidenced from its microanalytical and spectral data. Thus, its IR spectrum shows absorptions correlated with the $\nu_{C=O}$ (ester). The ^{1}H NMR spectrum shows absorption signals correlated with the OCH_2 and $COOCH_2CH_3$ protons. Moreover, the structure of **8** gets further support from its EI-MS as it shows the molecular ion peak and some of the abundant peaks. On the other hand, the treatment of **8** with hydrazine hydrate afforded the hydrazides **9**.

A

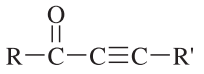
(9)

B

© 2005 NRC Canada

The structure of compound **9** is established from its microanalytical and spectral data. Thus, its IR spectrum shows absorptions characteristic for ν_{NH} and $\nu_{C=O}$ (amide). The ^{1}H NMR spectrum supports the proposed structure as it is devoid of any signals corresponding to the protons of the ethyl group, but instead to signals correlated with the hydrazino group. The suggested structure gets further support from the EI-MS as it shows the correct molecular ion peak beside some of the abundant peaks.

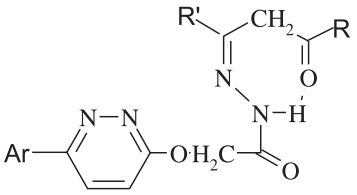
The reaction of hydrazide **9** with acetylenic ketones and ester **10a**–**10d** in refluxing dioxane afforded the adducts **11a**, **11b**, **12**, and **13**, respectively. The structures of compounds **11a**, **11b**, **12**, and **13** are deduced from their microanalytical and spectral data. Thus, their IR spectra reveal characteristic bands for ν_{NH} and $\nu_{C=O}$. The lower absorption values for the C=O and NH groups in **11** and **13** are in good agreement with the existence of compounds **11** and **13** in their chelated forms as shown. Further support for the suggested structure of compounds **11a** and **11b** was gained from their ^{1}H NMR spectra, which revealed two ABqs representing AB systems, one owing to the methylene protons of the CH_2COR group and the other owing to the OCH_2CO protons (20–22). The fact that these methylene protons behave as AB systems can be attributed either to the large anisotropic effect of the C=N or C=O groups and the nitrogen lone pair or to the restriction of rotation at the aroyl group by the weak hydrogen bonding between the NH and carbonyl group. The ^{1}H NMR spectra of **12** and **13** are in good agreement with the proposed structures.



Furthermore, the electron impact mass spectra of compounds **11a** and **11b** don't show the molecular ion peaks, instead they show the ($M^{+\cdot}$ – $ArCOCH_2C(Ar')$=N·NH) peak beside some of the abundant peaks. On the other hand, the EI-MS spectra of compounds **12** and **13** show molecular ion peaks beside some of the abundant peaks.

The formation of **11** and **13** seems to proceed by Michael addition of the hydrazide **9** at the β-carbon of the acetylenic compounds **10**. Similarly, compound **12** is formed, followed by ring closure.

On the other hand, the reaction of the hydrazide **9** with acetylacetone in boiling methanol yielded the adduct **14**. The structure of **14** is evidenced by microanalytical, ^{1}H NMR, and mass spectral data. Thus, its IR spectrum shows bands characteristic for $\nu_{C=O}$, $\nu_{C=N}$, and (or) $\nu_{C=C}$. Moreover, the assigned structure of compound **14** gets further support from the ^{1}H NMR spectrum.



Inspection of the ^{1}H NMR spectrum revealed the existence of two closely spaced singlets for the methyl protons attached at position 5 in the pyrazole ring, probably because the rate of rotation of the pyrazole ring around the hindered "partial double bond" is slow (23). This allows the existence of this methyl group in two different conformations (**A** and **B**) under different magnetic environments as shown in the following. Furthermore, the mass spectrum of **14** shows the molecular ion peak in addition to some abundant peaks. Compound **14** is formed through condensation of the hydrazide **9** with one of the two carbonyl groups of acetylacetone followed by ring closure.

Treatment of pyridazinone derivative **1a** with piperidine or morpholine and an excess of 40% formaldehyde solution in refluxing dioxane afforded 6-aryl-2-piperidin-1-yl-methyl-

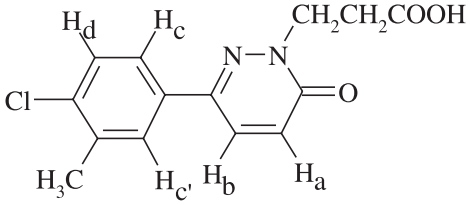
15a or 6-aryl-2-morpholin-4-yl-methyl-**15b**-4-(3,5-dimethyl pyrazol-1-yl)-2,3,4,5-tetrahydropyridazin-3-one. However, similar treatment of **1a** with piperazine yielded a mixture of the two isomeric compounds (**3**-hydroxymethoxy-6-arylpyridazine derivative **16** and 2-hydroxymethyl-6-aryl-2,3-dihydropyridazin-3-one derivative **17**, respectively).

The structures of compounds **15**–**17** are evidenced from their microanalytical and spectral data. Thus, their IR spectra show absorptions characteristic for $\nu_{C=O}$, $\nu_{C=N}$, and (or) $\nu_{C=C}$ in addition to ν_{OH} for structures **16** and **17**. The lower absorption values for the OH and C=O groups for compounds **16** and **17** are in good agreement with their existence in the chelated forms shown. The ^{1}H NMR spectra of compounds **15a** and **15b** disclosed ABX patterns consistent with -CH_X-CH_AH_B-CO moieties in which each of these coupled protons appears as a doublet of doublet with a geminal coupling constant $J \approx 16.8$ Hz and a vicinal coupling constant of ≈13 or 7 Hz. In addition, they show two central peaks of ABq corresponding to the -CH_2-N group. Analysis of the observed ^{1}H NMR spectrum of the mixture containing **16** and **17** inferred that they exist in deuterated dimethylsulphoxide in a ratio of 2:1, respectively. Moreover, the structures of compounds **15a** and **15b** and the mixture containing **16** and **17** get further support from the EI-MS spectra, where the spectra of compounds **15b** and the mixture of **16** and **17** show molecular ion peaks, whereas that of compound **15a** doesn't show the molecular ion peak, but does show a peak corresponding to [$M^{+\cdot}$ – dimethylpyrazole].

The reaction of equimolar amounts of **1a** and 3-bromopropanoic acid in refluxing dioxane and in the presence of potassium carbonate as a base gave a mixture of the two isomeric products 6-aryl-2-(2-carboxy) ethylpyridazinone derivative **18** and 6-aryl-3-(2-carboxyl)ethoxy pyridazine derivative **19**.

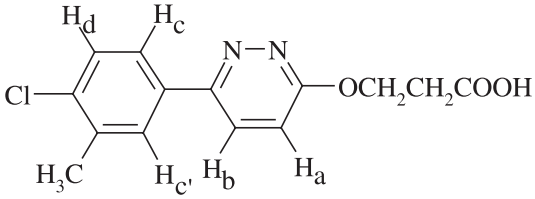
(20)

(21)



The structures of compounds **18** and **19** are substantiated from microanalytical and spectral data. Thus, the IR spectrum shows absorptions characteristic for $\nu_{OH(br.)}$, $\nu_{C=O}$ (acid), and $\nu_{C=O}$ (amide). Analysis of the ^{1}H NMR spectrum inferred that compounds **18** and **19** exist in deuterated dimethylsulphoxide as a mixture in a ratio of 1:1.2. Existence of compounds **18** and **19** as a mixture has been evidenced from the location of two triplet signals consistent with the protons of the NCH_2 and OCH_2 groups for structures **18** and **19**, respectively. The EI-MS spectrum of compounds **18** and **19** doesn't show the molecular ion peak, but does show a peak at *m*/*e* 220, which corresponds to the [$M^{+\cdot}$ – CH_2=CHCOOH] peak beside some of the abundant peaks.

Treatment of **1a** with acetic anhydride yielded a mixture of equimolar amounts of 2-acetyl-6-aryl-2,3-dihydropyridazin-3-one derivative **20** and 3-acetoxy-6-arylpyridazine derivative **21**.



The structures of compounds **20** and **21** are deduced from microanalytical and spectral data. The IR spectrum shows absorptions characteristic for $\nu_{C=O}$, $\nu_{C=N}$, and (or) $\nu_{C=C}$. Moreover, the ^{1}H NMR spectrum supports the structures of **20** and **21** as it shows two closely spaced singlets at δ 2.75 and 2.78 correlated with the methyl protons of the $NCOCH_3$ and $OCOCH_3$ groups, respectively. The EI-MS spectrum of the mixture doesn't show the molecular ion peak, but instead the [$M^{+\cdot}$ – CH_2=C=O] peak as a base peak.

It has been reported (17) that 6-aryl-4-pyrazolylpyridazinone derivative **1a** reacted with benzenesulphonyl chloride in refluxing acetone and in the presence of potassium carbonate as a base to give the *N*-benzenesulphonyl derivative **23**. However, in the present work, treatment of equimolar amounts of **1** with *p*-toluenesulphonyl chloride, succinyl

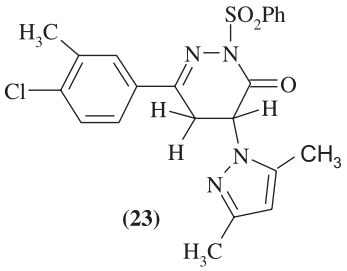
(18)



(19)

chloride, oxalyl chloride, or ethanolamine in refluxing pyridine or with ethyl chloroacetate in boiling dimethylformamide afforded 6-aryl-2,3-dihydro pyridazin-3-one (**22**) as a mixture of two conformations **22A** and **22B**. Compounds **22** and **23** have identical melting points although they have different structures, as there is a lack in the spectroscopic evidence used by previous authors (17) in their assignment of structure **23**.

(22)

(23)

The structure of compound **22** is deduced spectroscopically and chemically. Its IR spectrum shows ν_{NH} and $\nu_{C=O}$. The ^{1}H NMR spectrum is in good agreement with the proposed structure considering the existence of the conformations **22A** and **22B**. Further support for the proposed structure was gained from the EI-MS spectrum as it shows the molecular ion peak beside some of the abundant peaks. A chemical proof for the structure of compound **22** was given by comparison (mp, mixed mp, and TLC) with an authentic sample prepared by treating **1a** with hydrazine hydrate in boiling ethanol. Also, by refluxing compound **1a** with pyridine to give compound **22**. This supports the role of pyridine as a base in the removal of the dimethylpyrazolyl group.

The formation of compounds **16** and **17** (mixture), **18** and **19** (mixture), **20** and **21** (mixture), and **22** upon treating **1** with piperazine–HCHO, 3-bromopropanoic acid – K_2CO_3, acetic anhydride, *p*-toluenesulponyl chloride – pyridine, succinyl chloride – pyridine, oxalyl chloride – pyridine, ethanolamine – pyridine, or ethyl chloroacetate – DMF can be explained on the basis of an acid- or base-catalysed removal of the dimethylpyrazolyl moiety, as in case of **22**, followed by nucleophilic attacks of the lactam–lactim tautomer to the reagents used in the other cases.

Experimental

All melting points are uncorrected. The IR spectra were recorded on FT IR Mattson (infinity series) spectrometers as KBr discs. The ^{1}H NMR spectra were measured on a Varian Gemini 200 MHz instrument with chemical shifts (δ) expressed in ppm downfield from TMS. Mass spectra were recorded on a Shimadzu GC-MS-QP 1000 Ex instrument operating at 70 eV. TLC was run using TLC aluminum sheets silica gel F_{254} (Merck). Note: All attempts to separate all of the isomeric mixtures mentioned, including column chromatography, failed possibly because of isomerization taking place during separation.

Reaction of 1a with the PCl_5–$POCl_3$ mixture — Formation of 3

A mixture of **1a** (5 mmol), PCl_5 (5 mmol), and $POCl_3$ (10 mL) was gently heated for 3 h, cooled, poured into crushed ice, and the precipitated solid was filtered and recrystallized from benzene to give **3**.

6-(4-Chloro-3-methyl) phenyl-3-chloropyridazine (3)

Yield: 60%; white crystals, mp 175 to 176 °C, lit. value (17, 18) mp 176 °C. IR (cm^{-1}): 3078 (CH_{aryl}), 2924, 2854 (CH_{alkyl}), 1672, 1600 (C=N and (or) C=C), 821 (C-Cl). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.439, 2.461 (two singlets, $2CH_3$), 7.37, 7.481 (two doublets, H_d, J_o = 8.2 Hz), 7.559 (d, H_a, J_{ab} = 9.2 Hz), 7.764 (dd, $H_{c'}$, J_o = 8.2 Hz, J_m = 2.2 Hz), 7.806 (d, H_b, J_{ab} = 9.0 Hz), 7.95, 8.041 (two doublets, Hc, J_m = 2.2 Hz). EI-MS *m*/*z*: 238 ($M^{+\cdot}$, 56), 210 ($M^{+\cdot} - N_2$, 23), 150 (4-Cl-3$CH_3C_6H_3C{\equiv}CH$, base), 115 (89), 90 (6), 89 (29), 64 (10), 63 (44). Reaction of 1a with ethyl chloroacetate — Formation of 8

A solution of **1a** (5 mmol) in dry dioxane (20 mL) was heated with ethyl chloroacetate (5 mmol) for 24 h in the presence of potassium carbonate (3 g). The reaction mixture was concentrated, cooled then poured into ice-cold water. The precipitated solid was filtered off, dried, and then recrystallized from petroleum ether 80–100 °C.

6-(4-Chloro-3-methyl)phenyl-3-ethoxycarbonylmethoxypyridazine (8)

Yield: 70%; pale yellow crystals, mp 100 °C, lit. value (17, 19) mp 96 °C, 89 °C. IR (cm^{-1}): 3071 (CH_{aryl}), 2987, 2911 (CH_{alkyl}), 1749 (C=O), 1672, 1596 (C=N and (or) C=C). ^1H NMR (200 MHz, $CDCl_3$) δ: 1.292 (t, 3, CH_3CH_2O, J = 7.2 Hz), 2.403, 2.421 (two singlets, $2CH_3$), 4.255 (q, 2, CH_3CH_2O, J = 7.2 Hz), 4.956 (s, 2, OCH_2CO), 7.041, 7.646 (two doublets, H_a, J_{ab} = 9.8 Hz), 7.292, 7.399 (two doublets, H_d, J_o = 8.4 Hz), 7.551, 7.501 (two doublet doublets, H_c, J_o = 8.6 Hz, J_m = 1.8 Hz), 7.557, 7.771 (two doublets, $H_{c'}$, J_m = 1.8 Hz), 7.676, 7.682 (two doublets, H_b, J_{ba} = 9.6 Hz). EI-MS *m/z*: 308 ($M^{+\cdot}$ + 2, 20), 306 ($M^{+\cdot}$, 55), 263 ($M^{+\cdot}$ + 2-OC_2H_5, 9), 261 ($M^{+\cdot}$ – OC_2H_5, 4), 233 ($M^{+\cdot}$ + 2-$COOC_2H_5$, base), 231 ($M^{+\cdot}$ – $COOC_2H_5$, 41), 205 (19), 198 (13), 170 (17), 163 (51), 128 (23), 115 (15), 89 (17), 63 (73). Anal. calcd. for $C_{15}H_{15}N_2O_3Cl$ (%): C 58.73, H 4.93, N 9.13, Cl 11.56; found: C 58.81, H 5.00, N 9.22, Cl 11.63.

Reaction of 8 with hydrazine hydrate

A solution of **8** (3 mmol) in ethanol (20 mL) was refluxed with hydrazine hydrate (5 mmol) for 4 h. The reaction mixture was cooled. The precipitated solid was filtered off and recrystallized from methanol.

6-(4-Chloro-3-methyl) phenyl-3-hydrazinocarbonylmethoxypyridazine (9)

Yield: 82%; white crystals, mp 210–212 °C. IR (cm^{-1}): 3409, 3306, 3205 (NH), 3055 (CH_{aryl}), 2953, 2921, 2853 (CH_{alkyl}), 1667 (C=O), 1589, 1533 (C=N and (or) C=C). ^1H NMR (200 MHz, DMSO-d_6) δ: 2.393, 2.413 (two singlets, $2CH_3$), 4.306 (br.s, 2, NH_2 exchangeable), 4.742 (s, 2, OCH_2), 7.078, 7.090 (two doublets, H_a, J_{ab} = 9.78 Hz), 7.491, 7.541 (two doublets, H_d, J_o = 8.4 Hz), 7.732, 7.774 (two doublet doublets, H_c, J_o = 8.52 Hz, J_m = 1.86 Hz), 7.885, 7.929 (two doublets, $H_{c'}$, J_m = 1.82 Hz), 8.086, 8.110 (two doublets, H_b, J_{ba} = 9.8 Hz), 9.316 (br.s, 1, NH exchangeable). EI-MS *m/z*: 292 ($M^{+\cdot}$, 5), 263 ($M^{+\cdot}$ + 2-$NHNH_2$, 59), 261 ($M^{+\cdot}$ – $NHNH_2$, 17), 235 ($M^{+\cdot}$ + 2-$CONHNH_2$, 29), 231 ($M^{+\cdot}$ – $CONHNH_2$, base), 205 (12), 198 (13), 170 (15), 163 (21), 151 (10), 89 (15), 63 (20). Anal. calcd. for $C_{13}H_{13}N_4O_2Cl$ (%): C 53.34, H 4.48, N 19.14, Cl 12.11; found: C 53.46, H 4.52, N 19.24, Cl 12.35.

Reactions of 9 with acetylenic ketones, esters 10a–10d, and with acetylacetone

General procedure

A mixture of **9** (3 mmol) and **10a**–**10d** (3 mmol) in dioxane (15 mL) or acetylacetone (3 mmol) in methanol (20 mL) was refluxed for 10 h. The reaction mixture was concentrated, left to stand at room temperature. The solid formed was recrystallized from a suitable solvent to give **11a**, **11b**, **12**, **13**, and **14**.

6-(4-Chloro-3-methyl)phenyl-3-[ω-(4-chlorobenzoyl)acetophenone]hydrazonocarbonylmethoxypyridazine (11a)

Yield: 62%; white crystals, mp 198–200 °C (from methanol). IR (cm^{-1}): 3391 (NH), 3039 (CH_{aryl}), 2954, 2906, 2843 (CH_{alkyl}), 1662 (C=O). ^1H NMR (200 MHz, $CDCl_3$) δ: 2.421 (s, 3, CH_3), 3.371, 3.752 (ABq, 2, CH_2CO, J = 18.5 Hz), 4.848 (br.s, 1, NH), 5.355, 5.688 (ABq, 2, OCH_2CO, J = 16.4 Hz), 7.005–7.756 (m, 14, Ar-H). Efficient, microwave-assisted intramolecular 1,3-dipolar cycloadditions of oximes and *N*-methylnitrones derived from *o*-alkenylmethoxy-acetophenones

Surinderjit Singh, M.P.S. Ishar, Gajendra Singh, and Rajinder Singh

Abstract: Contrary to literature reports, the *o*-allyloxy- and crotyloxy-acetophenone-oximes (**2a**, **2b**) are transformed to nitrones, which undergo regio- and stereoselective intramolecular 1,3-dipolar cycloadditions, both on microwave heating under solvent free conditions and refluxing in toluene, to afford novel cycloadducts (**5a**, **5b**); the oxazepine-*N*-oxide (**3a**) reported to be formed in 98% yield was obtained only as a minor product (~10%). However, *o*-cinnamyloxy-acetophenone-oxime (**2c**) under similar conditions undergoes intramolecular *N*-alkylation to afford nitrone (**3c**). The reactions carried out under microwave irradiation are cleaner, require shorter reaction times, and have higher yields. Corresponding intramolecular 1,3-dipolar cycloadditions of *N*-methylnitrones (**B**), generated in situ from *o*-alkenylmethoxy-acetophenones (**1a**–**1c**) and *N*-methylhydroxylamine under solvent-free microwave irradiation conditions, are completely regio- and stereoselective, require much shorter reaction times, and afford adducts (**4a**–**4c**) in higher yields, as compared with their thermal counterparts.

Key words: cycloadditions, nitrones, oximes, *o*-alkenylmethoxy-acetophenones, microwave, isoxazolidines.

Résumé : Contrairement à ce qui a déjà été rapporté dans la littérature, les oximes des *o*-allyloxy- et crotyloxy-acétophénones (**2a**, **2b**) se transforment en nitrones qui subissent des cycloadditions 1,3-dipolaires intramoléculaires régio- et stéréosélectives aussi bien par chauffage micro-onde dans des conditions n'impliquant pas de solvant que par reflux dans du toluène pour conduit à la formation de nouveaux cycloadduits (**5a**, **5b**); il avait été rapporté que cette réaction conduisant à la formation du *N*-oxyde de l'oxazépine (**3a**) se formait avec un rendement de 98 %; toutefois au cours de la présente étude, il ne forme qu'un produit mineur obtenu qu'avec environ 10 % de rendement. Toutefois, dans les mêmes conditions, l'oxime de la *o*-cinnamyloxy-acétophénone (**2c**) subit une *N*-alkylation intramoléculaire qui conduit à la formation de la nitrone **3c**. Les réactions effectuées dans des conditions d'irradiation micro-onde sont plus propres, demandent moins de temps et conduisent à de meilleurs rendements. Dans des conditions d'irradiation micro-onde sans solvant, les cycloadditions 1,3-dipolaires intramoléculaires correspondantes des *N*-méthylnitrones (**B**) générées in situ conduisent à des formations complètement régio- et stéréosélectives de *o*-alcénylméthoxy-acétophénones (**1a**–**1c**) et de *N*-méthylhydroxylamine; ces réactions nécessitent des temps de réaction plus courts et conduisent à la formation des produits **4a**–**4c** avec des rendements plus élevés que ceux obtenus dans les réactions thermiques équivalentes.

Mots clés : cycloadditions, nitrones, oximes, *o*-alcénylméthoxy-acétophénones, micro-onde, isoxazolidines.

[Traduit par la Rédaction]

Introduction

Considerable interest is centered on nitrone cycloadditions (1), including the nitrones derived from 1,2-*H* shifts in oximes (2), for generating biologically active molecules or precursors and scaffolds for the same (1–3). However, there are only few examples wherein oxime–nitrone transformation and intramolecular cycloadditions of keto-oximes have been investigated (4). Recently, it has been reported that oximation of *o*-allyloxy-acetophenone and -benzophenone (**1**) affords *E*-oximes (**2**), which are quantitatively converted to dipoles (**3**, Scheme 1) on refluxing in xylene for 14 h (5).

On the other hand, reaction of **1a** (R = CH_3, R^1 = H) with *N*-methylhydroxylamine hydrochloride in the presence of NaOH in aqueous ethanol, under reflux for 36 h, has been reported to furnish cycloadduct **4** (78% yield) derived from intramolecular 1,3-dipolar cycloaddition of an in-situ-generated nitrone (6) (Scheme 1). The same adduct has also been obtained in 49% yield by reaction of *o*-allyloxyphenylacetylene with *N*-methylhydroxylamine in a sealed tube at 110 °C for 46 h (6). Recently, microwave-assisted organic transformations, particularly under solvent free conditions, have emerged as an important component of the modern nonconventional green organic synthetic methodologies,

Scheme 2.

whose effectiveness has also been demonstrated for intramolecular cycloadditions (7). As a part of our ongoing investigations on 1,3-dipolar cycloadditions (8), and with the aim of developing scaffolds for some peptidomimetics, we have investigated the intramolecular 1,3-dipolar cycloaddition of *N*-methylnitrones and nitrones generated from oximes, derived from *o*-allyloxy-, -crotyloxy-, -cinnamyloxy-acetophenones (**1a**–**1c**). The reactions have been carried out under microwave-assisted, solvent-free conditions and the results compared with those of the reactions carried out under conventional (toluene–ethanol reflux) conditions.

Results and discussion

Oximes (**2a**–**2c**) were obtained in high yields (93%–95%) by refluxing corresponding ketones **1a**–**1c** (9) and hydroxylamine hydrochloride in dry ethanol as crystalline solids and characterized spectroscopically. Although oxime **2a** has been reported previously (5) and assigned a geometry –*E*, its melting point has not been reported; the spectroscopic data determined for **2a** is comparable with the data reported in the literature (5). Oximes **2a**–**2c** were adsorbed on silica gel and exposed to microwave heating (500 W, 75 °C) and products **5a**–**5b** and **3a** and **3c** (Scheme 2) were separated by column chromatography over silica gel.

The products were characterized by rigorous spectroscopic (IR, ^{1}H and ^{13}C NMR including COSY, hetero-COSY, and NOESY 2D NMR measurements, and mass spectra) and microanalytical data, and comparison of the data with the data reported for related systems (2, 3, 5). The assigned mode and regiochemistry of the addition in the case of **5a** and **5b** is based on the chemical shift of the C9b-methyl group, which indicated that it is no longer attached to an unsaturated carbon in the product and chemical shift of C3-H(s), which indicated the proximity of C3 to the oxygen; C3-H(s) resonances were easily identified from their multiplicity. The stereochemical disposition between the C9b-methyl group and C3a-H, i.e., the cis arrangement is based on spatial proximity established by the NOESY spectrum. Compound **3a** has been identified from its NMR spectral data (5). The assigned structure of compound **3c** is based, inter alia, on the observation of a 3H singlet (methyl)

Table 2. Reaction conditions, reaction times, and % yields of the products.

Serial No.	Compound	Ethanol reflux Temp (°C)	Time (min)	Yield (%)	Microwave irradiation Temp (°C)[a]	Time (min)	Yield (%)
1	**4a**	78 to 79	720	82	75	15	96
2	**4b**	78 to 79	720	84	75	15	97
3	**4c**	78 to 79	720	80	75	15	95

[a]The final temperature was measured at the end of microwave irradiation by introducing a glass thermometer into the reaction mixture.

at δ 2.54 indicating that the methyl group is attached to an unsaturated carbon and the presence of an intense band in its IR spectrum at 1218 cm^{-1}, which is characteristic of the nitrone functionality (10). The alternative structure **6** for this compound was ruled out by ^1H multiplicities and connectivities as well as ^{13}C NMR assignments established by rigorous 2D NMR measurements. For instance, two 1H double doublets at δ 3.50 (^2J = 13.8 Hz and ^3J = 4.9 Hz) and δ 2.87 (^2J = 13.8 Hz and ^3J = 8.2 Hz) have been attributed to benzylic-Hs in **3c**, and such a pattern is not anticipated for C3-Hs in **6**; the hetero-COSY – 2D NMR spectrum revealed the corresponding benzylic-C resonance at δ 32.90.

As the formation of **5a** and **b** was contrary to the reported production (5) of only oxazepine-*N*-oxides (**3**) (5), in the thermal transformations of related oximes, thermal reactions of **2a**–**2c** were reinvestigated by refluxing dry toluene solutions and the products were similarly isolated by column chromatographic separation of the reaction concentrates. The results of thermal and corresponding microwave-assisted transformations are summarized in Table 1 and clearly indicate that similar results are obtained under both sets of conditions as far as the nature of the major products is concerned. However, the reactions carried out under microwave irradiation are attended with higher yields of the cycloadducts (**5a** and **5b**) as well as nitrones (**3c**) with much shortened reaction times.

For reactions of *N*-methylnitrones derived from ketones **1a**–**1c** under microwave heating, the ketones **1a**–**1c** were mixed with *N*-methylhydroxylamine hydrochloride and sodium bicarbonate, adsorbed on silica gel, and exposed to microwave radiation; products were isolated and purified by column chromatography. For corresponding thermal reactions, equimolar solutions of **1a**–**1c** and *N*-methylhydroxylamine hydrochloride in anhydrous ethanol were refluxed and products **4a**–**4c**) were similarly isolated by column chromatography. The results are summarized in Scheme 3 and Table 2.

Compound **4a** could be easily identified from the comparison of its spectroscopic data with the data reported in the literature (6); the assigned structures and stereochemistry in the case of **4b** and **4c** are again based on rigorous spectroscopic analysis, particularly, the NMR spectral data, and comparison of the same with that of the related systems (2, 3*k*, 6).

Thus, contrary to the reported (5) thermal transformation of oxime **2a** and corresponding *o*-allyloxybenzophenone oxime, leading, quantitatively, to bicyclic nitrones such as **3a**, and the recorded observation (5) that the formation of these bicyclic nitrones is related to the preferred *E* geometry of these oximes, the present investigations reveal that intramolecular 1,3-dipolar cycloaddition is the preferred mode of transformation of oximes **2a** and **2b**, both under thermal and

© 2005 NRC Canada

microwave irradiation conditions. Though, the precise reasons for the differential behavior of the oximes under comparable conditions, leading to **3a** and **3c** in the present investigations, are not very clear, in general, the exo-trig processes leading to seven-membered rings are favored (11). Mechanistically, as far as the regiochemistry of addition is concerned, i.e., the preferential formation of annelated products **5a**, **5b**, and **4a**–**4c**) vis-à-vis the bridged products, molecular modeling (MOPAC) studies on both *E* and *Z* forms of the involved nitrones revealed that the obtained regiochemistry as well as stereochemistry of addition are a consequence of the only feasible, less-cumbersome approach for intramolecular cycloadditions of these nitrones.

Conclusions

The present report thus describes regio- and stereoselective microwave-assisted intramolecular 1,3-dipolar cycloadditions of nitrones derived from *o*-allyloxy- and -crotyloxy-acetophenone oximes and *N*-methylnitrones derived from *o*-allyloxy-, -crotyloxy-, and -cinnamyloxy-acetophenones. A comparison with their thermal counterparts reveals that the reactions carried out under microwave irradiation conditions are cleaner, attended with higher yields, along with a drastic reduction in the reaction times. The obtained cycloadducts will be utilized, after opening of the isoxazolidine moiety, for synthesis of some peptidomimetics.

Experimental

Instrumentation and general procedures

Bruker AC-200FT (200 MHz) and JEOL AL-300FT (300 MHz) spectrometers were used to record ^{1}H and ^{13}C NMR spectra. IR spectra were recorded on a Shimadzu DR-2001 FT-IR spectrophotometer in $CHCl_3$ solution or as KBr pellets. Mass spectra, EI and ESI methods were recorded on Shimadzu GC–MS QP-2000A and Bruker Daltonics Esquire 300 mass spectrometers, respectively. Elemental analyses were carried out on a PerkinElmer 240C elemental analyzer and are reported in % atomic abundance. All melting points are uncorrected and were measured in open glass capillaries. Thin layer chromatography (TLC) was carried out on silica gel G-coated (Loba Chemie, containing 13% $CaSO_4$ as a binder) (1 mm thick layer) glass plates.

General procedure for preparation of oximes

Solutions of ketones **1a**–**1c** (200 mg, (9)) and hydroxylamine hydrochloride (1.0 molar equiv.) in dry ethanol were refluxed for 15–18 h. After the completion of the reaction (TLC, $CHCl_3$ solvent), the solvent was removed under reduced pressure. The residue was taken up in chloroform (20 mL) and washed successively with aqueous bicarbonate and water. After drying over anhydr. Na_2SO_4, the solutions were concentrated to one-fifth of their volume and triturated with hexane when colorless solids separated out.

MS (ESI) *m*/*z*: 290 (M + Na)$^+$.

General procedure for the transformations of oximes under microwave irradiation

Oximes **2a**–**2c** (200 mg) were dissolved in chloroform (10 mL) and to the solution was added silica gel (G, 3.0 g) and the solvent was removed under vacuum. The obtained powder was exposed to microwave irradiation (500 W) for 15 min (five cycles, 3 min each); the exposure time optimization is based on TLC ($CHCl_3$ solvent) monitoring. The adsorbed material was then extracted with ethyl acetate (25 mL) and dried over anhydr. Na_2SO_4. The solvent was then distilled off under reduced pressure. The products were isolated by column chromatographic separation over silica gel (60–120 mesh, 30 g). The column was packed in hexane and hexane – ethyl acetate gradients were used for elution.

(3aS,9bR)-9b-Methyl-1,3a,4,9b-tetrahydro-3H-chromeno[4,3-c]isoxazole (5a)

Elution of the column initially with hexane – ethyl acetate (9:1) afforded **1a** (14 mg, 7%) and unreacted oxime **2a** (30 mg, 15%) with hexane – ethyl acetate (7:1). Further elution with hexane – ethyl acetate (3:1) afforded cycloadduct **5a** (116 mg, 58%) as a yellow oil. R_f 0.37 ($CHCl_3$). IR ($CHCl_3$, cm^{-1}): 3260, 1585, 1510, 1482, 1430, 1290. ^{1}H

MS (ESI) m/z: 290 (M + Na)$^+$. Anal. calcd. for $C_{17}H_{17}NO_2$: C 76.48, H 7.29, N 6.94; found: C 76.38, H 6.41, N 5.24.

General procedure for thermal transformations of oximes

Oximes **2a**–**2c** (200 mg) were refluxed in dry toluene (50 mL) for 72 h. After the completion of the reaction (TLC, $CHCl_3$ solvent), the solvent was removed under reduced pressure and the products were isolated by similar column chromatographic separations of the concentrate. From the reaction of **2a** were obtained **1a** (84 mg, 42%), **2a** (30 mg, 15%), and **5a** (66 mg, 33%), eluted with hexane – ethyl acetate 9:1, 7:1, and 3:1, respectively.

From the reaction of **2b** were obtained **1b** (80 mg, 40%), **2b** (32 mg, 16%), and **5b** (70 mg, 35%), eluted, respectively, with hexane – ethyl acetate 9:1, 7:1, and 3:1.

From the reaction of **3c** were isolated **1c** (86 mg, 43%), **2c** (28 mg, 14%) and **3c** (68 mg, 34%), eluted with hexane – ethyl acetate 9:1, 7:1, and 1:1, respectively.

General procedure for the reactions of ketones 1a–1c with *N*-methylhydroxylamine hydrochloride under microwave irradiation

Ketones **1a**–**1c** (200 mg) were mixed with *N*-methylhydroxylamine hydrochloride (equimolar) and sodium bicarbonate (1.0 g), and adsorbed on silica gel (G, 3.0 g) as described earlier. The reaction mixture was exposed to microwave radiation (500 W) for 15 min (five cycles, 3 min each); exposure time optimization is based on TLC ($CHCl_3$ solvent) monitoring. The adsorbed material was then extracted with ethyl acetate (25 mL), and dried over anhydr. Na_2SO_4. The solvent was then distilled off under reduced pressure. The products were isolated by column chromatographic separation over silica gel (60–120 mesh, 30 g). The column was packed in hexane and hexane – ethyl acetate gradients were used for elution.

*(3S,3aS,9bR)-1,3,9b-Trimethyl-1,3a,4,9b-tetrahydro-3*H*-chromeno[4,3-*c*]isoxazole (4b)*

Elution with hexane – ethyl acetate (3:1) afforded cycloadduct **4b** (223 mg, 97%) as a colorless oil. R_f 0.35 ($CHCl_3$). IR ($CHCl_3$, cm^{-1}): 1610, 1575, 1490, 1430, 1290, 1245, 1235. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.35 (d, 1H, J = 7.5 Hz, arom.-H), 7.16 (unresolved dd, 1H, $J \sim 7.5$ Hz, arom.-H), 6.96 (unresolved dd, 1H, $J \sim 7.5$ Hz, arom.-H), 6.82 (d, 1H, J = 8.1 Hz, arom.-H), 4.27–4.09 (m, 3H, C3-H and C4-Hs), 2.89 (s, 3H, *N*-CH_3), 2.27–2.19 (m, 1H, C3a-H), 1.51 (s, 3H, C9b-CH_3), 1.42 (d, 3H, J = 6.3 Hz, C3-CH_3). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 154.59 (C5a), 128.29 (CH), 128.09 (CH), 126.1 (quat.), 121.16 (CH), 117.03 (CH), 74.89 (C3), 65.0 (C4), 63.64 (C9b), 39.29 (*N*-CH_3), 54.04 (C3a), 20.33 (C3-CH_3 and C9b-CH_3, hetero-COSY). MS (EI) m/z: 220 (M^+ + 1, 6), 219 (M^+, 40). Anal. calcd. for $C_{13}H_{17}NO_2$: C 71.21, H 7.81, N 6.39; found: C 71.34, H 7.70, N 6.21.

Review on green chemistry — Suzuki cross coupling in aqueous media

Robert Franzén and Youjun Xu

Abstract: The Suzuki cross-coupling reaction is a very efficient, reliable, and environmentally friendly method for the introduction of novel carbon–carbon bonds into molecules. This review summarizes recent advances in the use of the reaction in aqueous media with a focus on different types of ligands and the ligandless protocols currently in use. Several synthetic targets for the reaction have been mentioned. The work summarizes recent results from studies on asymmetric Suzuki reactions performed in organic – aqueous mixed solvents.

Key words: Suzuki reaction, green chemistry, metal-catalyzed cross-coupling reactions, aqueous synthesis media.

Résumé : La réaction de couplage croisé de Suzuki est une méthode très efficace, fiable et environnementalement correcte pour l'introduction de nouvelles liaisons carbone–carbone dans des molécules. Cette revue résume les progrès récents réalisés dans l'utilisation de la réaction en milieu aqueux, en se concentrant sur les divers types de ligands et les protocoles sans ligands actuellement en usage. Plusieurs cibles de synthèse pour cette réaction sont mentionnées. Le travail résume les résultats récents obtenus à partir d'études sur les réactions de Suzuki asymétriques effectuées dans des solvants mixtes organique – aqueux.

Mots clés : réaction de Suzuki, chimie verte, réactions de couplage croisé catalysées par les métaux, milieu de synthèse aqueux.

[Traduit par la Rédaction]

Introduction

The chemical industry is a major contributor to environmental pollution, largely because of the use of hazardous solvents. These solvents released or disposed by the chemical industry include methanol, toluene, xylene, methyl ethyl ketone, and methylene chloride (1). With sharpened regulatory pressure focusing on organic solvents, the search for alternatives is of increasing importance. In this respect, organic transformations in aqueous media (2), have received much attention because water is easily available, economical, and harmless to the environment. The cross-coupling reaction of alkenyl and aryl halides with organoborane derivatives in the presence of a palladium catalyst and a base, known as the Suzuki reaction, has often been carried out in an organic–aqueous mixed solvent. Although Davidson and Triggs (3) discovered in 1968 that arylboronic acids reacted with palladium(II) acetate to give corresponding biaryls, and Garves (4) in 1970 that arylsulfinic acids could be coupled to biaryls using Pd(II) in aqueous solvents, it was not until 1979 when biaryls could efficiently be prepared by a palladium-catalyzed reaction. Miyaura and Suzuki (5) reported that cross-coupling reactions between alkenylboranes and organic halides were efficiently catalyzed by a catalytic amount of tetrakis(triphenylphoshine) palladium ($Pd(PPh_3)_4$) in the presence of a suitable base. Starting from these observations, the reaction has developed to become one of the most utilized methods for the introduction of novel carbon–carbon bonds in solution (6) and on solid phase (7). This current paper summarizes recent developments in Suzuki-type, palladium-catalyzed coupling reactions in water. This short review summarizes the advantages of using the Suzuki protocol instead of other similar cross-coupling reactions in aqueous media, several structurally different ligands that promote the reaction in water, recent results from ligandless Suzuki protocols, and target molecules mainly produced by the method. The paper ends with a few examples for the utilization of the reaction in an asymmetric manner.

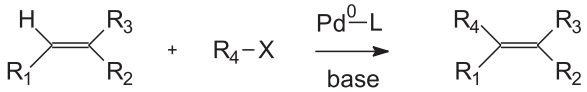

Fig. 1. Selected palladium-catalyzed cross-coupling reactions.

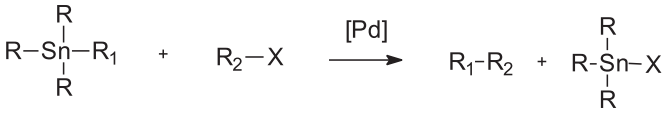
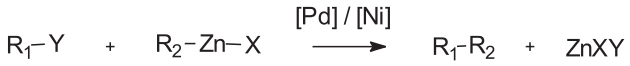
Suzuki coupling: Pd-catalyzed cross coupling of organic halides or perfluorinated sulfonates with organoboron derivatives.

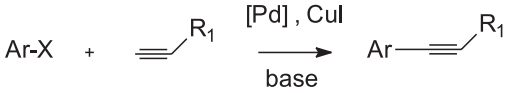
X = I, Br, Cl, OSO_2
BY_2 = $B(OR_2)$, 9-BBN, $B(alkyl)_2$
R_1 or R_2 = various aromatic or alifatic hydrocarbons



Heck reaction: Pd-catalyzed coupling of an alkyl, aryl, or vinyl entity to an alkene



Kumada coupling: Ni- or Pd-catalyzed substitution of aryl halides with Grignard reagents

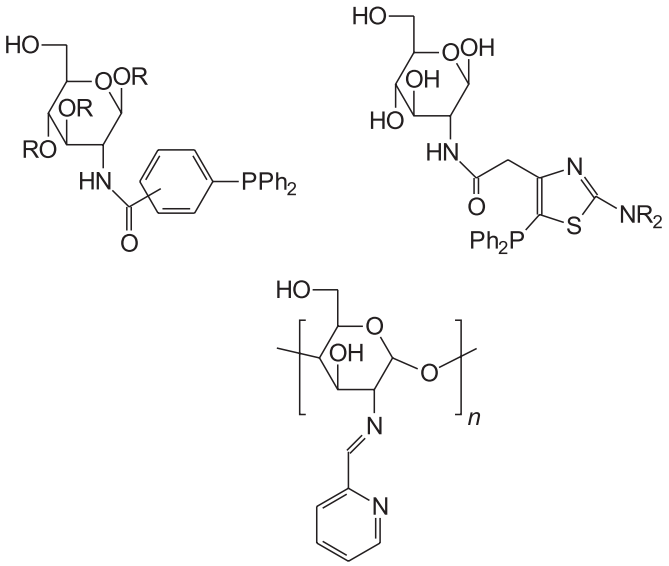


Stille coupling: Pd-catalyzed reaction of organostannanes with halides, acetates, or perfluorinated sulfonates lacking a sp^3-hybridized β-hydrogen

Negishi coupling : Ni- or Pd-catalyzed coupling of a alkenyl, aryl, allylic, or benzylic halide with alkyl- or arylzinc reagents

Sonogashira coupling: Cu(I) mediated and Pd-driven alkyne coupling to aromatic halides in the presence of a base

Suzuki cross coupling vs. other palladium-catalyzed reactions



In the Suzuki reaction (5, 6), the Heck reaction (8), the Kumada reaction (9), the Stille reaction (10), the Negishi reaction (11), and the Sonogashira reaction (12), palladium is known to be particularly effective in activating sp^2-carbon–halogen bonds even in aqueous media (13) (Fig. 1). All reaction types have drawbacks that limit the use in synthesis. Suzuki cross coupling has, on the other hand, less limitations than the other reactions mentioned. In the Heck reaction, for example, where an aryl or vinyl halide and an alkene are converted to a more highly substituted alkene under Pd catalysis, the intermolecular reaction often proceeds well when the alkene is electrophilic. With nucleophilic substituents, the reaction gives less satisfactory results. The Kumada coupling is very sensitive to air and the presence of radical inhibitors, and this has limited the use of the reaction in aqueous media. In the Stille reaction, stannates are used as substrates, and many of these are environmentally hazardous. There is no toxicity issue involved in organoborane reagents. For a large-scale setting, a Suzuki coupling is an attractive choice. The organoborane reagents are usually more easy to prepare in the laboratory, and the workup procedures are more simple than using other cross-coupling methods (14–17).

Ligands

The vast majority of ligands applied in modern synthesis possess low water solubility. Many strategies have been used to enhance the solubility of metal–ligand complexes in water of which three are mostly utilized (18). The catalytic reaction is performed in the presence of micelle-forming surfactants, solubilizing functionalities are added to the ligand, i.e., ionic groups to poorly soluble ligands and easily accessible, water-soluble sources from nature are utilized as ligands. These include, for example, carbohydrates and the

© 2005 NRC Canada

Fig. 2. Ligand alternatives from nature suitable for Suzuki cross coupling.

biopolymer chitosan suitable for the Suzuki reaction (19) (Fig. 2). Ligands based on monosaccharides usually have only moderate solubility in water and often require incorporation of extra hydrophilic groups to improve the ligand property. Also, a co-solvent or a surfactant is sometimes needed for optimum efficiency. Dissaccharide ligands have the advantage of higher aqueous solubility, but the synthesis of these is usually tedious. Chitosan, on the other hand (20–23), has proven to be a very promising material for organic synthesis and catalysis. For example, Suzuki and Heck reactions have successfully been completed using metal–chitosan complexes as catalysts in aqueous solutions (24). The complexes have offered both economically and environmentally more favourable conditions for many reactions. Catalysts for the Suzuki reaction heterogenized through covalent attachment to organic or inorganic supports have also been synthesized (25). The supports have included organic polymers (7, 26), silica (27), and layered clays (28).

Ligandless Suzuki cross coupling

From an environmental point of view, development of a new catalytic system without the use of stabilizing phosphine ligands in aqueous media under mild conditions has attracted much attention. The reaction with ligandless catalysts such as Pd/C in water has, for example, very recently been investigated (16, 29) (Fig.3). Compared to air-sensitive and expensive homogenous palladium catalysts, palladium charcoal can safely be handled and removed from the reaction mixture by simple filtration. The recovered palladium charcoal can be purified and reused as palladium metal. These features are also of great advantage in industrial processes. Other palladium catalysts useful for the ligandless Suzuki reaction in water include $Pd(OAc)_2$ and $PdCl_2$ (30, 31).

Targets for the Suzuki cross coupling

The synthesis of biaryl compounds, reviewed by Stanforth (32), is of importance for numerous agrochemical and pharmaceutical applications (Fig. 4). The classic Ullmann methology (33) is well-known in this context. Owing, on the other hand, to the versatile chemistry of palladium compounds in carbon–carbon bond-forming reactions, several palladium-catalyzed prosesses have been proposed as eco-friendly replacement for this stoichiometric protocol. Essentially based on the Pd(II)–Pd(0) redox cycle, these processes require in situ regeneration of the active palladium catalyst, which can be achieved, for example, during the Suzuki reaction by various reagents, e.g., 2-propanol, hydrogen gas, or aqueous alkali salts. In the synthesis of heterocyclic compounds, the aqueous Suzuki reaction has found many applications (34). A few examples include the structural modifications and preparations of pyrroles (35), indoles (36), pyridines (37), quinoxalines (38), benzofurans (39),

pyrimidyl thiazoles (40*a*), pyridyl pyrimidines (40*b*), and imidazoles (41) (Fig. 5). The Suzuki reaction of boronic acids in water and a variety of heteroaryl halides has been conducted to prepare 5-substitued heteroaryl pyrimidines, which can be hydrolyzed to 5-substituted uracils as potential antiviral agents (42*a*). Using a palladium(0) complex having a monosulfated phosphine as a ligand, Casalnuovo and Calabrese (42*b*) performed an alkylation of biomolecules in an aqueous medium. The reaction could tolerate a broad range of functional groups, including those present in unprotected nucleotides and amino acids. In the preparation of purines on solid phase, Pd catalyses have also successfully been utilized (43). In the synthesis of polymeric materials (Fig. 6), the Suzuki reaction has found applications in water. A hydrocarbon nonmetallic conducting polymer with a rigid rod of benzene rings was synthesized recently in water (44). Another example is the synthesis of phenyl–pyrrole mixed

polymers (45) using a method where originally β-octasubstituted tetramethylporphyrins were crafted by various arylboronic acids (46). In the total synthesis of complex molecules, such as aporphinoids (47), oximidine II (48), (+)-phomactin (49), gymnocin-A (50), quaterpyridine nemertelline (51), and ristocetin aglycon (52), an organic solvent – aqueous mixed Suzuki reaction has successfully been used as a key step (Fig. 7). These mentioned molecules are only a few very recent examples. The Suzuki cross coupling has, since its discovery, been used for a large group of different natural products (53).

Catalytic asymmetric Suzuki cross coupling

The asymmetric Suzuki cross-coupling reaction has successfully been accomplished in both organic solvents and inorganic–aqueous mixed solvents. For the preparation of C_2-symmetric biaryls, a modified Suzuki cross-coupling method of haloarenes was designed in 1996 by Keay and co-workers (54) (Fig. 8). The catalytic asymmetric version of the reaction for the synthesis of axially chiral biaryl compounds was later developed by the Buchwald group (55) (Fig. 9). The first, asymmetric Suzuki cross coupling performed in an organic–aqueous mixed solvent resulting in binaphthalene derivatives in up to 63% ee, was described by Cammidge and Crepy (56) (Fig. 10). In DME, the reaction gave up to 85% ee. Following these discoveries, other reports on the asymmetric synthesis for chiral binaphhyls or biaryls have been reported, for example, by Castanet et al. (57) in the study on chirality reverseal depending on the palladium – chiral phosphine ratio in the reaction of sterically hindered arylboronic acids. The reaction was performed in DME–water or toluene–EtOH–water. An atropo-enantioselective Suzuki cross coupling towards an axially chiral antimitotic biaryl has very recently been prepared by Herrbach et al. (58) in dioxane–water. Chiral atropisomeric binaphthalenes have also been synthesized in water–DME and a mixture of water–EtOH–toluene.

Concluding remarks

Suzuki cross coupling as a method for carbon–carbon bond formation has been a highly useful and versatile method needed for the development of modern drug discovery and in the synthesis of many natural products and polymers. Although the method has found many applications in synthesizing hitherto different molecules, there is still much work on the development towards an efficient catalyst applicable for structurally different substrates. The work on developing a catalyst working entirely in water has resulted in

© 2005 NRC Canada

a few remarkable discoveries. However, during the next few years, it is anticipated that new and more efficient catalysts will be discovered, giving even more excellent results in aqueous media.

RAPID COMMUNICATION / COMMUNICATION RAPIDE

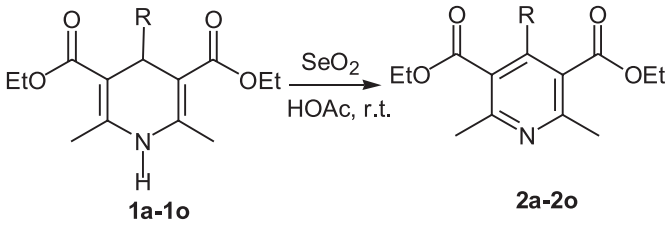
Aromatization of 1,4-dihydropyridines with selenium dioxide

Xiao-hua Cai, Hai-jun Yang, and Guo-lin Zhang

Abstract: 1,4-Dihydropyridines were aromatized to corresponding pyridines using stoichiometric selenium dioxide at ambient temperature in a yield of 87%~98%.

Key words: 1,4-dihydropyridines, aromatization, oxidation, pyridine derivatives, selenium dioxide.

Résumé : Les 1,4-dihydropyridines sont aromatisés en pyridines correspondantes avec des rendements allant de 87 %~98 % par traitement avec une quantité stoechiométrique de dioxyde de sélénium, à la température ambiante.



Mots clés : 1,4-dihydropyridines, aromatisation, oxydation, dérivés de la pyridine, dioxyde de sélénium.

[Traduit par la Rédaction]

Introduction

1,4-Dihydropyridines are calcium antagonists (1), antitubercular agents (2), and neuropeptide Y Y1 receptor antagonists (3). They possess neuroprotective (4), platet anti-aggregration (5), and antidiabetic (6) activities. Aromatization of 1,4-dihydropyridines has received considerable attention owing to the fact that 1,4-dihydropyridine-based calcium channel blockers are oxidatively converted to pyridine derivatives by the action of cytochrome P-450 in the liver (7). In addition, the corresponding pyridine derivatives show antihypoxic and antiischemic activites (8). 1,4-Dihydropyridines can easily be synthesized by Hantzsch condensation of aldehydes, β-keto esters, and ammonia or ammonium acetate (7*b*, 9). 1,4-Dihydropyridines have been aromatized to pyridines by various reagents such as $KMnO_4$ (10), HNO_3 (11), DDQ (12), $NaNO_2$ (13), $Zr(NO_3)_4$ (14), $Cu(NO_3)$ (15), $Bi(NO_3)\cdot 5H_2O$ (16), $Mn(OAc)_3$ (17), $(NH_4)_4Ce(NO_3)_6$ (18), urea nitrate and $K_2S_2O_8$–Co^{2+} (19), Pd/C (20), Pt(II) complex – *h*ν (21), GSNO (22), and O_2 – activated carbon (23). Despite these intensive efforts, most of the reported oxidation procedures require long reaction time, utilize strong oxidants in large excess, and afford products with only modest yields. In particular, the aromatization reaction with these reagents leads to dealkylation of the 4-position or formation of side products (11, 24). Therefore, the development of more effective methods for aromatization of 1,4-dihydropyridines is still necessary.

Scheme 1.

Selenium dioxide was widely used for the oxidation of a methylene group activated allyically or benzylically, or by an adjacent carbonyl group (25). Here, we wish to describe a simple and efficient precodure for the aromatization of 1,4-dihydropyridines with selenium dioxide at room temperature (Scheme 1).

Our initial attempts to aromatize 1,4-dihydropyridines (**1a**) as a test case in EtOH, CH_3CN, or THF at ambient or thermal conditions led to corresponding pyridine **2a** in very low yield (<40%). But the aromatization of **1a** in acetic acid occurred smoothly to give the expected pyridine at room temperature in 96% yield. The success of this reaction prompted us to examine the aromatization of some 4-alkyl, aryl, and alkenyl 1,4-dihydropyridines under the same conditions. All reactions proceeded efficiently within 20~60 min to provide the corresponding pyridines in good yields (87%~98%, Table 1). With respect to the yields of the products, a 1:1 mol ratio of 1,4-dihydropyridines and selenium dioxide in HOAc was optimal. The salient features for this procedure are milder reaction conditions, shorter reaction

time, higher yield, avoidance of dealkylation or debenzylation at C-4, and stoichiometric oxidants used. Moreover, this is a simple procedure for the separation of the products.

Conclusion

An efficient and simple procedure for the aromatization of 1,4-dihydropyridines to correponding pyridine derivatives with stoichiometric selenium dioxide was developed.

Experimental

In a typical procedure, a mixture of **1a** (165 mg, 0.5 mmol), selenium dioxide (66 mg, 0.5 mmol), and HOAc (4 mL) was stirred at room temperature for 30 min. After completion monitored by TLC, the reaction mixture was quenched with a satd. aqueous $NaHCO_3$ solution and the red solid selenium was filtered off. The filtrate was extracted with Et_2O. The organic layer was washed with water, dried over anhydr. $MgSO_4$, and concentrated to give the pure product **2a** (156 mg, 96%), mp 63–65 °C (lit. value (14) mp 62 to 63 °C). Under similar conditions, various substituted 1,4-dihydropyridines were converted to corresponding pyridines (Table 1).

Bert Allen and the first complex of dinitrogen[1]

G.J. Leigh

Abstract: A personal account is given of the effect that the report of the first dinitrogen complex by Allen and Senoff in 1965 had on people who were working in this area of nitrogen fixation.

Key words: history, ruthenium, dinitrogen, ammonia, complex, serendipity.

Résumé : Un témoignage personnel est offert sur les effets de la caractérisation du premier complexe diazote par Allen et Senoff en 1965 sur les intervenants du domaine de la fixation de l'azote.

Mots clés : historique, ruthénium, diazote, ammoniac, complexe, sérendipité.

[Traduit par la Rédaction]

The 1960s saw the birth of an enormous effort to uncover the mystery of biological nitrogen fixation. The hopes that this might enable mankind to develop radically new ways of maintaining soil fertility have, alas, yet to be fulfilled (1). In biological terms, the isolation of cell-free extracts of nitrogenase in 1960 (2) for the first time enabled us to study the structure and function of the enzyme. Parallel developments in chemistry were rather later, but it had long been known (3) that molybdenum (or, in its absence, vanadium, though this metal was long overlooked) seemed to be necessary to sustain biological nitrogen fixation, and the obvious inference was that dinitrogen complexes were somehow involved. Although dinitrogen complexes had long been expected, simply on the basis that dinitrogen and carbon monoxide are isoelectronic, and that a multitude of metal carbonyls were known, none had been found. Indeed, Orgel (4) had suggested a side-on structure for them, analogous to the binding of acetylenes to metals.

The discovery of the first dinitrogen complex by Allen and Senoff (5) was apparently accidental. Bert was trying to repeat a literature preparation of $[Ru(NH_3)_6]^{2+}$ from $RuCl_3 \cdot 3H_2O$ and $N_2H_4 \cdot H_2O$. The vigorous reaction of these two materials generates lots of N_2 and NH_3, as well as causing the reduction of the ruthenium(III) to ruthenium(II) (6). If ammonium chloride is added to the reaction mixture, then $[Ru(NH_3)_6]Cl_2$ can indeed be isolated, but in its absence $[Ru(NH_3)_5(N_2)]^{2+}$ is formed (5). Bert was undertaking an IR study of ruthenium(II) poly(ammine) complexes, and the use of IR spectroscopy gave him information that was not really available to the original investigators of this reaction, who had to rely on analysis and magnetic properties alone to characterize their materials. In fact, the dinitrogen complex may even have been prepared by those who originally prepared $[Ru(NH_3)_6]^{2+}$, but they could not have recognised it. Bert must have seen immediately the strong band at ca. 2130 cm^{-1}, which he assigned correctly to $\nu(N{\equiv}N)$. He formulated the compound $[Ru(NH_3)_5(N_2)]^{2+}$ though he did not then note that the strong IR band meant that the dinitrogen must have been bound end-on to the ruthenium. As dinitrogen complexes go, this ruthenium complex is actually not a very interesting compound, but its discovery and announcement (once the reluctant referees of *Chemical Communications* had been convinced that Bert's claim was a reasonable one) had tremendous implications. Some of these are outlined in the following.

First, it established that metal complexes of dinitrogen could indeed be isolable materials. I myself repeated the preparation described in *Chemical Communications* within a couple of hours of receiving the paper. Other claims for further dinitrogen complexes soon followed. It confirmed that we were probably on the right track in trying to model the function of the enzyme using metal complexes, even though the dinitrogen in this particular ruthenium complex turned out not to be reducible to ammonia.

Secondly, it became evident that $[Ru(NH_3)_5(N_2)]^{2+}$could be formed not just from hydrazine, but also from dinitrogen gas in aqueous media, such as from the reduction under N_2 of $[Ru(NH_3)_5Cl]^{2+}$ by zinc in dilute sulphuric or from the reduction of a solution of ruthenium trichloride by zinc amalgam in aqueous tetrahydrofuran (7). In fact, dinitrogen can displace the ligand water from $[Ru(NH_3)_5(H_2O)]^{2+}$. At the time (8, 9), this observation was a considerable surprise.

$$[Ru(NH_3)_5(H_2O)]^{2+} + N_2 \rightarrow [Ru(NH_3)_5(N_2)]^{2+} + H_2O$$

Almost at the same time, experiments with cobalt complexes (10) showed that, in favourable circumstances, dinitrogen could also displace the ligand ammonia. Thus, Bert's compound gave us the first indication of the ligand properties of dinitrogen. This was not the end of the story, because it was soon discovered by Taube and co-workers (8) and others (11) that the bound dinitrogen could also act as a donor to further metal ions, and this was the first suggestion that the bound dinitrogen was polarized in the sense Ru-

 doi: 10.1139/V05-056 © 2005 NRC Canada

$N^+\equiv N^-$. This direction of polarization was confirmed by an ESCA study of rhenium–dinitrogen complexes (12).

$$[Ru(NH_3)_5(H_2O)]^{2+} + [Ru(NH_3)_5(N_2)]^{2+} \rightarrow [Ru(NH_3)_5(\mu\text{-}N_2)Ru(NH_3)_5]^{4+} + H_2O$$

There are now numerous examples of dinitrogen bridging between metal ions. Later workers (13) showed that this polarization of dinitrogen in complexes such as those of molybdenum and tungsten could lead to the protonation of coordinated N_2.

Thirdly, initial reports (5, 14) claimed that by addition of sodium borohydride the dinitrogen in $[Ru(NH_3)_5(N_2)]^{2+}$ was convertible to ammonia. Bearing in mind that the compound itself contains a lot of ammonia, and also that it was formed from hydrazine, well-known to be reducible to ammonia, this claim needed to be treated with some caution. Subsequently, my colleagues in the Unit of Nitrogen Fixation prepared samples of $[Ru(NH_3)_5(^{15}N_2)]^{2+}$, as well as dinitrogen compounds of iridium and cobalt. In all three cases, the dinitrogen ligands were unequivocally obtained from $^{15}N_2$ (15) rather than from hydrazine or ammonia. Treatment of these labelled dinitrogen complexes with acid or with reducing agents caused general decomposition in all three cases, but in no case was $^{15}NH_3$ obtained. This brought to the attention of the community that extreme care needs to be taken in assessing claims both of dinitrogen fixation and of dinitrogen reduction, and that positive results from isotopic labelling were a requirement for definitive proof. Considering that some dinitrogen complexes are formed with very slow dinitrogen uptake (over hours or even days), and that scavenging of impurities such as nitrogen oxides from the dinitrogen gas stream was always possible, the same consideration must apply to the formation of dinitrogen complexes as well as to dinitrogen reduction.

In summary, the compound first identified by Bert Allen and his student Caesar Senoff was the first dinitrogen complex, and although its chemistry is not very exciting in terms of the dinitrogen reactivity it facilitates, its formation and the circumstances of its formation demonstrated that dinitrogen complexes are indeed feasible models for the interaction of metal centres in nitrogenases with N_2. It shed the first light on the remarkable ligating properties of dinitrogen. It stimulated the discovery of the large number of dinitrogen complexes known today, and it allowed the uncovering of the completely new range of dinitrogen activity that is still being developed 40 years later.

Ligand-assisted reduction of Co(II) to Co(I) and subsequent coordination of dinitrogen[1]

Jennifer Scott, Sandro Gambarotta, and Ilia Korobkov

Abstract: Reaction of the bis-aminopyridine dianion {[2,6-[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)]$_2$(C$_5$H$_3$N)]Li(THF)}{Li(THF)$_4$} with $CoCl_2(THF)_{1.5}$ under Ar afforded the dinuclear complex {[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)](C$_5$H$_3$N)[2,6-(*i*-Pr)$_2$PhN=C(CH$_2$)]}$_2$[Co(μ-Cl)Li(THF)$_3$]$_2$·4(THF) (**1**) in which the ligand is coupled to a second identical unit at a terminal methylene carbon. In turn, the C—C bond formation caused reduction of the Co(II) center to the monovalent state. The same reaction performed under a nitrogen atmosphere afforded the double dinitrogen complex {[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)](C$_5$H$_3$N)[2,6-(*i*-Pr)$_2$PhN=C(CH$_2$)]}$_2$[Co(N$_2$)]$_2$·2(toluene) (**2**).

Key words: low-valent Co, diiminopyridinato, dinitrogen fixation.

Résumé : La réaction du dianion bis-aminopyridine {[2,6-[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)]$_2$(C$_5$H$_3$N)]Li(THF)}{Li(THF)$_4$} avec le $CoCl_2(THF)_{1,5}$, sous atmosphère d'argon, conduit à la formation du complexe dinucléaire {[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)](C$_5$H$_3$N)[2,6-(*i*-Pr)$_2$PhN=C(CH$_2$)]}$_2$[Co(μ-Cl)Li(THF)$_3$]$_2$·4(THF) (**1**) dans lequel le ligand est couplé à une deuxième unité identique au niveau d'un carbone méthylénique terminal. Par ailleurs, la formation d'une liaison C—C provoque une réduction du Co(II) vers l'état monovalent. La même réaction réalisée sous atmosphère d'azote conduit au complexe double de diazote {[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)](C$_5$H$_3$N)[2,6-(*i*-Pr)$_2$PhN=C(CH$_2$)]}$_2$[Co(N$_2$)]$_2$·2(toluène) (**2**).

Mots clés : cobalt de basse valence, diiminopyridinato, fixation de diazote.

[Traduit par la Rédaction]

Introduction

The catalytic transformation of dinitrogen into ammonia is the driving force behind the flourish of interest towards coordination of dinitrogen by transition metal complexes. However, despite the amount of research dedicated to this topic in the last 40 years, this coveted catalytic transformation has been documented in only a handful of cases and has remained limited to the occurrence of a few turnovers (1). A significant step in this direction was recently achieved by Yandulov and Schrock (2) with the cobaltocene-promoted reduction of the molybdenum-coordinated dinitrogen complex [HIPTN$_3$N]MoN$_2$, {[HIPTN$_3$N]$^{3-}$ = [{3,5-(2,4,6-*i*-Pr$_3$C$_6$H$_2$)$_2$C$_6$H$_3$NCH$_2$CH$_2$}$_3$N]$^{3-}$}. Chirik and co-workers (3) have also reported an exciting development in the dinitrogen chemistry of zirconium by observing the formation of ammonia after the addition of H_2 to a zirconocene dinitrogen dimer. On the same line, albeit not catalytic, is the formation of a metal-bound NH_2 unit from N_2 cleavage, as obtained during the reduction of a tetra-aryloxide actinide system (4).

The possibility of performing cleavage of coordinated dinitrogen into the corresponding nitride moieties has fueled research towards the use of strongly reducing, low-valent, early metal systems (2–5). However, a metal whose redox potential is sufficiently reducing to transfer several electrons to a coordinated dinitrogen molecule might not necessarily have the chance to perform efficient catalytic transformations. Accordingly, the versatile nitrogenase enzyme initially forms a dinitrogen complex, possibly *weakly* bound, which receives electrons from the pyruvate electron pool via multiple association–dissociation rounds between the Fe-protein and the Fe-Mo protein (6, 7). This is possibly suggesting the puzzling idea that a system capable of performing *weak* reduction of dinitrogen (e.g., labile coordination instead of multi-electron reduction) might actually be the starting point for the search for catalytic transformations. The premise of employing a labile dinitrogen complex as a prelude to a multi-metallic cooperative interaction is somewhat substantiated by recent observations in Sm-dipyrrolide chemistry (8).

Dinitrogen chemistry involving late transition metals is substantially less developed when compared with low-valent early metals and *f*-block elements. The large volume and variety of transformations involving early metal dinitrogen systems, including partial reduction followed by elemental modifications or incorporation into the ligand system, has made early metal complexes the most popular targets for these studies and several recent reviews have detailed the latest developments in this area (9). On the other hand, late metal complexes have a definite inclination towards labile coordination of dinitrogen and, interestingly, Fe is the protagonist of the unique performances of the nitrogenase enzyme. Recent encouraging observations in this direction

have been made by Holland and co-workers (10) with the reduction of dinitrogen coordinated to an Fe(*nacnac*) system. The reduction formed a new complex in which the dinitrogen unit undergoes only a relatively minor elongation of the N—N bond, thus suggesting that, similar to the case of a tetranuclear Sm dinitrogen complex (8*a*), electron density is mainly stored on the metal rather than in the N_2 unit. We believe that this may be particularly significant because if the strengthening of the Fe—N bond as a result of the reduction is minute, an increased reactivity of the coordinated N_2 unit could be found.

Dinitrogen complexes of cobalt are scarce (11–24). In addition, the few reported complexes all appear to be rather similar, the main differences arising from the skeleton of the supporting phosphine ligand and the oxidation state of the Co center, which varies from –1 to +1. In some cases, the coordination of dinitrogen is assisted by another metal center (13–18, 21, 22). An alternative to the main phosphine theme is provided by a cobalt complex of the bis-iminopyridine ligand system (24). A Co(II) derivative was specifically prepared for ethylene polymerization purposes. However, activation of the catalyst caused the reduction of the metal to the monovalent state, which, while cationized by a Lewis acid, performed dinitrogen coordination. Furthermore, the behavior of the bis-iminopyridine ligand is truly unique. Not only has it shown much promise as a supporting ligand for catalytic olefin polymerization (25, 26), but it has also displayed a desirable ability to store electrons in the large, delocalized π system (27). In addition, it may engage in a number of metal-promoted transformations (28–31). The fact that this ligand system can stabilize a NdI_2 moiety via internal redox (31) raises questions about the possibility of its use for electron storage towards promoting catalytic dinitrogen activation.

Recent work in our lab has demonstrated that the bis-imino pyridinato ligand can be further transformed into the corresponding dianion via deprotonation of the two methyl groups attached to the imine function (31). The electron-accepting ability is still very strong in the dianionic version of this ligand. Therefore, as part of an ongoing program, we have now probed the reactivity of the dianionic {[2,6-[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)]$_2$(C$_5$H$_3$N)]Li(THF)}{Li(THF)$_4$} with divalent cobalt with the hope of preparing a new family of labile, yet reactive, dinitrogen complexes. In this paper, we describe the preparation of a double dinitrogen complex supported by a ligand system capable of holding a substantial amount of negative charge.

Experimental section

All operations were performed either under an argon atmosphere using standard Schlenk techniques or in a dry box filled with purified nitrogen. The THF complex of $CoCl_2$ was prepared according to the standard procedure and 2,6-[2,6-(*i*-Pr)$_2$PhN-C(CH$_3$)]$_2$(C$_5$H$_3$N) (32), LiCH$_2$Si(CH$_3$)$_3$ (33), and {[2,6-[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)]$_2$(C$_5$H$_3$N)]Li(THF)}{Li(THF)$_4$} (31) were prepared following published procedures. IR spectra were recorded on a Mattson 9000 and Nicolet 750-Magna FT-IR instrument from Nujol mulls prepared in a dry box. Samples for magnetic susceptibility measurements were weighed inside a dry box equipped with an analytical balance and sealed into calibrated tubes, and the measurements were carried out at room temperature with a Gouy balance (Johnson Matthey). Elemental analyses were performed on a PerkinElmer 2400 CHN analyzer. Data for X-ray crystal structure determinations were obtained with a Bruker diffractometer equipped with a Smart CCD area detector. NMR spectra were recorded on a Bruker AMX-500 spectrometer.

Preparation of {[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)](C$_5$H$_3$N)[2,6-(*i*-Pr)$_2$PhN=C(CH$_2$)]}$_2$[Co(μ-Cl)Li(THF)$_3$]$_2$·(THF)$_4$ (1)

A solution of {[2,6-[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)]$_2$(C$_5$H$_3$N)]Li(THF)}{Li(THF)$_4$} (1.25 g, 1.5 mmol) in THF was added to a stirred suspension of $CoCl_2(THF)_{1.5}$ (0.35 g, 1.5 mmol) in THF. The solution instantly became dark burgundy. The reaction was allowed to stir for 5 min and centrifuged to remove small amounts of insoluble material. The solvent was evaporated in vacuo until a small volume, and the resulting solution was allowed to stand at room temperature for 24 h upon which large, dark-burgundy crystals of **1** were isolated (0.92 g, 0.48 mmol, 65%). IR (Nujol mull, cm^{-1}) ν: 3058 (w), 2895 (s), 1640 (m), 1565 (vs), 1517 (m), 1466 (vs), 1399 (m), 1378 (m), 1323 (w), 1304 (m), 1260 (s), 1200 (w), 1174 (s), 1160 (w), 1099 (vs), 1048 (vs), 1026 (vs), 1003 (vs), 936 (m), 913 (s), 892 (m), 801 (vs), 778 (m), 764 (m), 748 (m), 726 (s), 694 (m). Anal. calcd. for $C_{106}H_{164}N_6Cl_2Li_2O_{10}Co_2$: C 67.54, H 8.77, N 4.46; found: C 67.78, H 9.01, N 4.55.

Preparation of {[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)](C$_5$H$_3$N)[2,6-(*i*-Pr)$_2$PhN=C(CH$_2$)]}$_2$[Co(N$_2$)]$_2$·2(toluene) (2)

A solution of {[2,6-[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)]$_2$(C$_5$H$_3$N)]Li(THF)}{Li(THF)$_4$} (1.25 g, 1.5 mmol) in toluene was added to a stirred suspension of $CoCl_2(THF)_{1.5}$ (0.35 g, 1.5 mmol) in toluene under an argon atmosphere. The solution instantly became dark-burgundy red. The mixture was stirred overnight and centrifuged to remove small amounts of insoluble residue. The solution was then exposed to nitrogen gas causing an extreme deepening of the colour with standing overnight. The black-coloured solution was evaporated in vacuo down to a small volume. Small dark brown crystals of **2** were obtained after allowing the solution to stand at room temperature for 48 h (0.59 g, 0.45 mmol, 60%). IR (Nujol mull, cm^{-1}) ν: 3057 (w), 2895 (s), 2153 (vs), 1598 (w), 1583 (m), 1548 (m), 1533 (m), 1494 (m), 1464 (vs), 1418 (w), 1372 (vs), 1323 (s), 1250 (s), 1203 (w), 1176 (s), 1142 (w), 1098 (m), 1073 (m), 1057 (m), 1038 (m), 1006 (s), 935 (m), 915 (m), 894 (w), 869 (w), 800 (s), 780 (vs), 762 (m), 747 (s), 729 (vs), 694 (m). ^{1}H NMR (500 MHz, C$_6$D$_6$, 25 °C) δ: 0.917 (d, 12H, (C*H*$_3$)$_2$CH), 1.21 (m, 24H, (C*H*$_3$)$_2$CH), 1.42 (d, 12H, (C*H*$_3$)$_2$CH), 2.47 (quint, 4H, (CH$_3$)$_2$C*H*), 3.16 (quint, 4H, (CH$_3$)$_2$C*H*), 3.53 (br s, 4H, N=C-C*H*$_2$-C*H*$_2$-C=N), 4.01 (s, 2H, NC=C*H*$_2$), 4.67 (s, 2H, NC=C*H*$_2$), 6.74 (d, 4H, *m*-C$_6$*H*$_3$-*i*-Pr$_2$), 6.88 (d, 4H, *m*-C$_6$*H*$_3$-*i*-Pr$_2$), 7.01 (t, 2H, *p*-C$_6$*H*$_3$-*i*-Pr$_2$), 7.10 (t, 2H, *p*-C$_6$*H*$_3$-*i*-Pr$_2$), 7.30 (t, 2H, *p*-C$_5$*H*$_3$N), 7.41 (d, 2H, *m*-C$_5$*H*$_3$N), 8.26 (d, 2H, *m*-C$_5$*H*$_3$N). Anal. calcd for $C_{80}H_{98}Co_2N_{10}$: C 72.93, H 7.50, N 10.63; found: C 72.71, H 7.83, N 10.88.

fracted weakly and the results presented are the best of several trials. The crystals were mounted on thin glass fibers using paraffin oil and cooled to the data collection temperature. Data were collected on a Bruker AXS SMART 1K CCD diffractometer. To obtain acceptable redundancy data, compounds **1** and **2** were collected with the sequence of 0.3° ω scans at 0°, 120°, and 240° in φ. Initial unit cell parameters were determined from 50 data frames collected at the different sections of the Ewald sphere. Semi-empirical absorption corrections based on equivalent reflections were applied. Systematic absences in the diffraction data set and unit-cell parameters were consistent with monoclinic, $P2_1/n$ for **1** and triclinic, $P\bar{1}$ for **2**. Solutions in the centrosymmetric space groups yielded chemically reasonable and computationally stable results of refinement. The structures were solved by direct methods, completed with difference Fourier syntheses and refined with full-matrix least-squares procedures based on F^2. The compound molecule was located in the inversion center in the structure of **1**. Two molecules of THF with full occupancy not located on any symmetry operators were found in the lattice of **1**. Two molecules of toluene with a full occupancy not located on any symmetry operators were found in the asymmetric unit of **2**. All non-hydrogen atoms, except those of the THF solvent molecules in **1**, were refined with anisotropic displacement coefficients. THF solvent molecules in the structure of **1** were refined isotropically. All hydrogen atoms were treated as idealized contributions. All scattering factors are contained in several versions of the SHELXTL program library with the latest version used being v.6.12 (34). Crystallographic data and relevant bond distances and angles are reported in Tables 1 and 2.[3]

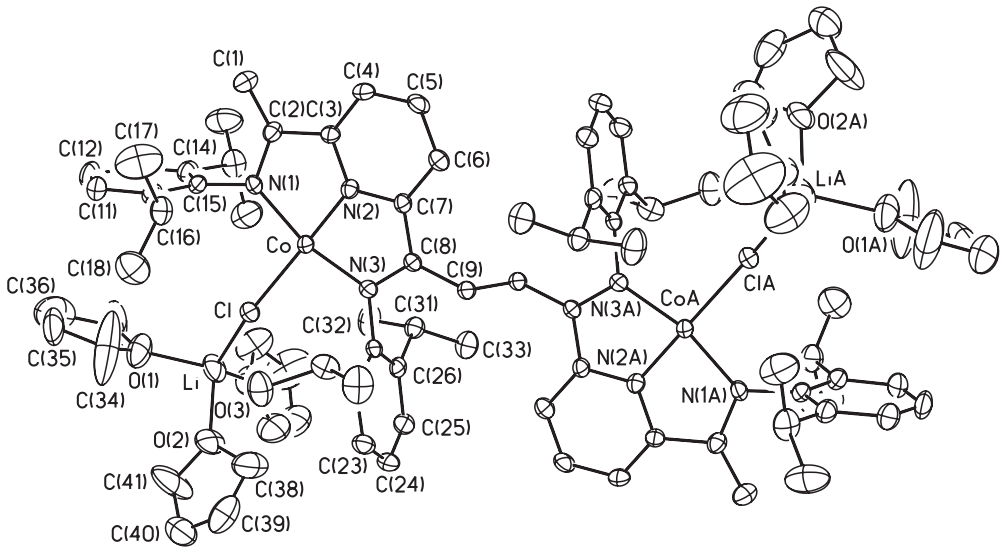
Results and discussion



The reaction of $CoCl_2(THF)_{1.5}$ with the dilithium salt of the bis-aminopyridine dianion {[2,6-[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)]$_2$(C$_5$H$_3$N)]Li(THF)}{Li(THF)$_4$} was carried out under an Ar atmosphere affording a dark-burgundy solution from which very dark red crystals of the dimeric {[2,6-(*i*-Pr)$_2$PhN-C=(CH$_2$)](C$_5$H$_3$N)[2,6-(*i*-Pr)$_2$PhN=C(CH$_2$)]}$_2$[Co(μ-Cl)Li-(THF)$_3$]$_2$·4(THF) (**1**) were isolated in 65% yield.

The formula and connectivity of **1** were elucidated by an X-ray crystal structure. The molecule consists of a symmetry-generated dimer (Fig. 1) where the metal is surrounded by the ligand system (Co-N(1) = 1.902(5) Å, Co-N(2) = 1.816(5) Å, Co-N(3) = 1.882(5) Å) and one chlorine atom (Co-Cl = 2.2677(19) Å) in a lightly folded square-planar arrangement (N(1)-Co-N(2) = 83.0(2)°, N(2)-Co-N(3) = 82.1(2)°, N(1)-Co-N(3) = 165.1(2)°, N(1)-Co-Cl = 96.76(16)°, N(3)-Co-Cl = 98.05(17)°, N(2)-Co-Cl = 177.29(17)°). The chlorine atom bridges one Li cation solvated by three molecules of THF (Cl-Li = 2.397(14) Å). Of the two -ene functions originally present in the dilithium salt, only one remained intact after the reaction, exhibiting a short C—C bond distance (C(1)-C(2) = 1.359(9) Å) as expected for a C—C double bond. The other -ene function was reduced to a single bond (C(8)-C(9) = 1.498(9) Å). The terminal C atom of this function now forms a C—C single bond with an identical C atom of a second unit (C(9)-C(9A) = 1.554(13) Å), thereby assembling the dinuclear structure. Consequently, the adjacent C-N distance was shortened to a length exhibiting substantial double bond character (N(3)-C(8) = 1.359(8) Å). The

Scheme 1.

slightly large values of the final convergence parameters are due to the disorder encountered in the THF molecules, which could not be properly modeled.

The chemical connectivity, as summarized in Scheme 1, doubtlessly assigns the monovalent state to the two Co atoms. Accordingly, complex **1**, which is extremely air-sensitive and turns brown immediately upon exposure to air, is diamagnetic in the solid state as expected for a d^8 species in a square-planar field. Unfortunately, the very low solubility of **1** in most common deuterated solvents prevented the recording of informative NMR spectra. The coupling of the ligand at the expense of a C=C double bond as observed during the formation of **1** has two precedents in the chemistry of Mn(II) (28) and Ln(III) (Ln = Nd, La) (31). However, in both cases, the coupling required the presence of a strong reducing agent. By contrast, the coupling affording complex **1** occurred via *spontaneous reduction* to Co(I). In other words, the electron necessary for the reduction is supplied by the C=C double bond undergoing a radical type of coupling. This is particularly striking considering that Co(I) has a very strong reducing power and is usually regarded as far more reactive than the divalent congener.

We have observed that the preparation of **1** in toluene and under a dinitrogen atmosphere afforded a much deeper colour and precipitation of a dark-coloured microcrystalline solid. Its solid state IR showed the presence of a sharp and intense band at 2153 cm^{-1}, possibly diagnosing the presence of weakly bound dinitrogen. The recrystallization of this new compound was unsuccessful, and thus, crystals of sufficient quality could only be obtained from the reaction mixture. The X-ray crystal structure revealed this new species to be a double dinitrogen complex formulated as $\{[2,6\text{-}(i\text{-}Pr)_2PhN\text{-}C{=}(CH_2)](C_5H_3N)[2,6\text{-}(i\text{-}Pr)_2PhN{=}C(CH_2)]\}_2\text{-}[Co(N_2)]_2\cdot 2(\text{toluene})$ (**2**).

The basic structure of complex **2** (Fig. 2) is very similar to that of **1** where each cobalt center is connected to one moiety of the binucleating ligand (Co-N(1) = 1.850(4) Å, Co-N(2) = 1.821(4) Å, Co-N(3) = 1.856(4) Å). The dinuclear structure is realized through the coupling of one methylene unit with that of a second identical entity. The bond dis-

$[CoLN_2][MeB(C_6F_5)_3]$	Not given	1.112(6)	24

Note: Tp′ = hydridotris(3-*tert*-butyl-5-methylpyrazolyl)borate and L = 2,6-[CMe=N(2,6-C_6H_3-*i*-Pr_2)]$_2C_5H_3N$.
[a]No structure reported to date.

tances and angles are comparable to those found for complex **1**. The geometry around the cobalt is once again distorted square-planar (N(1)-Co-N(2) = 82.95(17)°, N(2)-Co-N(3) = 82.00(18)°, N(1)-Co-N(3) = 164.95(18)°, N(1)-Co-N(4) = 96.88(18)°, N(3)-Co-N(4) = 98.14(18)°, N(2)-Co-N(4) = 177.6(2)°), the only difference being that the pendant Cl-Li(THF)$_3$ unit has been replaced by a terminally bound N_2 unit (Co-N(4) = 1.808(5) Å).

The ^{1}H NMR spectrum of **1** showed the terminal =CH_2 groups as two rather broad singlets at 4.67 and 4.01 ppm coupled to the same resonance at 72.53 ppm of the ^{13}C NMR spectrum. Two sets of *i*-Pr groups are present, while the CH_2CH_2 bridge between the two units gives a broad resonance at 3.53 ppm.

The N-N distance of the coordinated N_2 unit of **2** (N(4)-N(5) = 1.095(6) Å) suggests very little if no activation of the N—N triple bond. This is in good agreement with the stretching frequency of the coordinated dinitrogen, which displays an unusually high value (ν = 2153 cm^{-1}). The result of a search on existing cobalt dinitrogen complexes is summarized in Table 3. Of the 18 complexes listed, nine contain cobalt in the formal monovalent state. All of these species display stretching frequencies substantially lower than that of **2**, thus indicating the lowest level of activation among all

© 2005 NRC Canada

the Co–N_2 complexes reported to date. As mentioned above, the majority of these species are phosphine derivatives, and the only closely related compound is the cationic bis-iminopyridinato complex (24). However, the ligand is formally neutral in this complex, and it is the Lewis acidity of a Co(I) cationic complex that is regarded as the driving force for the labile coordination of dinitrogen. Unfortunately, no IR data were reported for this complex. Its N-N distance (N-N = 1.112(6) Å) is slightly longer than that observed for **2**. From these observations, it is conceivable to expect that the coordination of N_2 in **2** might be especially labile. In sharp contrast with these expectations, the dinitrogen moiety could *not* be expelled from the complex even in boiling toluene or THF. Nevertheless, ethylene polymerization was observed upon activation with MAO, which demonstrates that the dinitrogen unit must be labile to free at least one coordination site necessary for the ensuing polymerization.

In summary, in this preliminary study aimed at assessing the reactivity of labile N_2 complexes, we have prepared a Co(I) dimer from the reaction of Co(II) with a dianionic tridentate bis-aminopyridine ligand system via coupling of the ligand and subsequent reduction of the metal center. In the absence of THF, the Co(I) species coordinates dinitrogen and shows the weakest perturbation of a N—N multiple bond among the existing Co–N_2 complexes. Nevertheless, the coordination of the N_2 unit appears to be robust.

Acknowledgments

This work was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC). We are grateful to Dr. G.P.A. Yap for solving the crystal structure of **1**.

The importance of cyclopentadienyl substituent effects in group 4 metallocene dinitrogen chemistry[1]

Jaime A. Pool and Paul J. Chirik

Abstract: This article highlights some of our recent efforts and presents new data on the importance of cyclopentadienyl substituent effects on group 4 metallocene dinitrogen chemistry. Reactions such as the coordination of N_2 to an isolated titanium sandwich complex, alkali-metal reductions of zirconocene dihalide complexes, alkane reductive elimination reactions, and the hydrogenation of zirconium dinitrogen complexes are all extremely sensitive to the groups present on the cyclopentadienyl rings. These results are promising for the future of N_2 fixation, as the reactivity of a specific metallocene can be dramatically altered by subtle manipulations in ligand substituents.

Key words: cyclopentadienyl, zirconium, dinitrogen, ammonia, sandwich.

Résumé : Ce travail met en relief des travaux récents de notre équipe et présente de nouvelles données sur l'importance des effets des substituants du cyclopentadiényle sur la chimie du diazote des métallocènes du groupe 4. Les réactions, telle la coordination du N_2 sur un complexe sandwich isolé, les réductions par les métaux alcalins des complexes dihalogénés du zirconocène, les réactions d'éliminations réductrices d'alcane et l'hydrogénation des complexes de diazote du zirconium sont toutes extrêmement sensibles aux groupes présents sur les cycles cyclopentadiényles. Ces résultats sont remplis de promesses pour la fixation future du N_2 puisque la réactivité spécifique d'un métallocène spécifique peut être dramatiquement altérée par des manipulations subtiles des ligands substituants.

Mots clés : cyclopentadiényle, zirconium, diazote, ammoniac, sandwich.

[Traduit par la Rédaction]

Introduction

The isolation and characterization of the first homogeneous transition metal dinitrogen complex, $[(H_3N)_5Ru(N_2)]^{2+}$, by Allen and Senoff (1) spawned a new era in nitrogen fixation. As demonstrated by Shepherd and Taube (2), synthetic chemists were presented with the unprecedented opportunity to rationally assemble and investigate the metal–N_2 linkage (3, 4), and, more significantly, determine its proclivity to participate in functionalization reactions. One pervasive theme common to all subsequent work on well-defined transition metal dinitrogen compounds is the ability to tune metal–ligand combinations and explore structure–reactivity relationships. This prospect paved the way for Chatt et al.'s pioneering work (5), highlighted by the fixation of N_2 to ammonia by successive proton and electron transfers with zerovalent group 6 dinitrogen compounds. Recently, this cycle has been extended to include iron complexes (6), systems where ruthenium dihydrogen complexes serve as the H-atom source (7), and molybdenum compounds that are catalytically competent (8, 9).

In addition to studies with group 6 and 8 compounds, there has been a long-standing interest in early transition metal complexes for nitrogen fixation. Not long after Allen and Senoff's report (1), Vol'pin and Shur (10) described ammonia production from N_2 by protonation of a $(\eta^5\text{-}C_5H_5)_2TiCl_2$–alkyllithium mixture. Subsequently, van Tamelen (11) and Brintzinger (12) independently explored the mechanism of this reaction, leading to the pioneering synthesis by the latter's research group of the first well-defined titanium dinitrogen compound, $[(\eta^5\text{-}C_5Me_5)_2Ti]_2(\mu_2, \eta^1, \eta^1\text{-}N_2)$ (13). This molecule, as well as its zirconium congener, $[(\eta^5\text{-}C_5Me_5)_2Zr(\eta^1\text{-}N_2)]_2(\mu_2, \eta^1, \eta^1\text{-}N_2)$, can be protonated with mineral acids to yield hydrazine (14). Since these seminal discoveries, group 4 transition metal dinitrogen chemistry has experienced remarkable growth and numerous successes (15). A few recent highlights include the synthesis by Mori and co-workers (16) of *N*-heterocycles and natural products from N_2 using modified Vol'pin chemistry and Fryzuk and co-workers' (17, 18) side-on bound dinitrogen complex that undergoes partial hydrogenation and reacts with both silanes and terminal alkynes.

Inspired by these advances, we initiated a program in July 2001 aimed at incorporating atmospheric N_2 into value-added nitrogen-containing products using well-defined group 4 transition metal dinitrogen compounds. Specifically, we hoped to gain an understanding of how dinitrogen is acti-

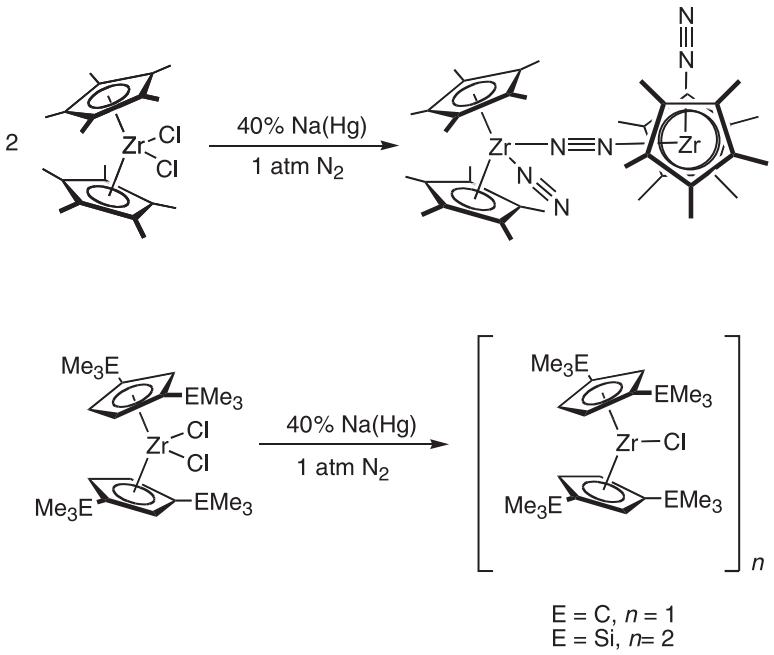
Fig. 1. Effect of cyclopentadienyl ligand substitution on N_2 coordination to titanium sandwich complexes. T_{max} refers to the maximum temperature at which N_2 coordination is observed. Temperature values are ±2 °C.

vated by low-valent metal centers, elucidate the factors that govern its hapticity (e.g., "side-on" vs. "end-on"), and translate these findings onto reactions that transform and liberate a functionalized nitrogen fragment from the metal center. Here, we recount some of our previous results as well as present new data that underscore the importance of cyclopentadienyl substituent effects in group 4 metallocene dinitrogen chemistry. Particularly striking is how seemingly modest changes in substitution, such as the replacement of a methyl group with a hydrogen atom or a *tert*-butyl with an isopropyl group, can completely alter the course of N_2 activation and functionalization.

Results and discussion

Activation of N_2 by low-valent group 4 metallocenes



Our illustration of the importance of cyclopentadienyl substituent effects on N_2 activation begins with one of the simplest reactions imaginable for dinitrogen reduction — the coordination of N_2 to a preformed, low-valent titanium(II) sandwich compound (Fig. 1). Previous reports from the literature hinted at subtle, yet interesting substituent effects. The transiently generated titanium(II) sandwiches, $(\eta^5\text{-}C_5Me_5)_2Ti$ (13), $(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2Ti$ (19), and presumably $(\eta^5\text{-}C_5Me_4H)_2Ti$ (20), react rapidly with N_2 to afford end-on bound, bridged, dimeric dinitrogen complexes. In contrast, Lawless and co-workers (21) have isolated and crystallographically characterized $(\eta^5\text{-}C_5Me_4SiMe_2\text{-}t\text{-}Bu)_2Ti$, which is unreactive toward N_2 at ambient temperature and pressure. Mach and co-workers (22) have since independently prepared a family of silyl-substituted titanocenes that are reported to resist N_2 coordination up to pressures of 50 atm (1 atm = 101.325 kPa).

Intrigued by these reactivity differences, we sought to understand the steric and electronic properties of cyclopentadienyl ligands that govern N_2 activation by the titanium sandwiches. In an attempt to separate steric and electronic contributions, two new titanium(II) complexes, $(\eta^5\text{-}C_5Me_4R)_2Ti$ (R = $CHMe_2$, CMe_3), were prepared. The presence of 10 alkyl substituents on the ligand framework served to simulate the electronic environment of N_2-reactive $(\eta^5\text{-}C_5Me_5)_2Ti$ while large isopropyl or *tert*-butyl groups mimicked the steric disposition of reportedly N_2-inert $(\eta^5\text{-}C_5Me_4SiMe_3)_2Ti$ (22). The magnetic and NMR spectroscopic data collected at 23 °C, in addition to elemental analyses, were consistent with isolation of the sandwich complexes, $(\eta^5\text{-}C_5Me_4CHMe_2)_2Ti$ and $(\eta^5\text{-}C_5Me_4CMe_3)_2Ti$ (23).

Attempts to grow X-ray quality crystals of $(\eta^5\text{-}C_5Me_4CHMe_2)_2Ti$ by cooling a concentrated pentane solution to –35 °C in an N_2 atmosphere produced a spectacular color change from red to intense blue. Warming the solutions back to room temperature resulted in vigorous evolution of gas and regeneration of the diagnostic red color of the sandwich compound. A combination of in situ React-IR spectroscopy, Toepler pump analysis, and X-ray diffraction were used to identify the blue compound as the monomeric titanocene bis-dinitrogen complex, $(\eta^5\text{-}C_5Me_4CHMe_2)_2Ti(N_2)_2$ (23). Further investigation of other titanium sandwiches such

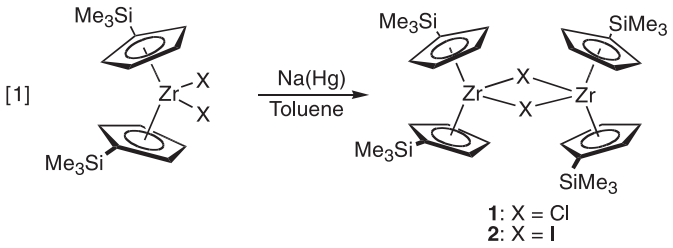
Fig. 2. Cyclopentadienyl substituent effects on the outcome of alkali-metal reduction of zirconocene dichloride complexes (1 atm = 101.325 kPa).



as $(\eta^5\text{-}C_5Me_4CMe_3)_2Ti$ and $(\eta^5\text{-}C_5Me_4SiMe_3)_2Ti$ by in situ React-IR studies established reversible dinitrogen coordination for these molecules as well, although N_2 loss is observed at much lower temperatures (Fig. 1). While N_2 and CO are isoelectronic, these molecules are the first examples of bent metallocene dinitrogen complexes with a bonding motif frequently encountered with more familiar titanocene dicarbonyl complexes.

Importantly, these studies have demonstrated the effect that cyclopentadienyl substitution can have on the coordination of dinitrogen to a low-valent transition metal center. Changing two methyl groups on the ligand array to isopropyl, *tert*-butyl, or silyl substituents blocks formation of dimeric dinitrogen compounds and thus allows reversible dinitrogen coordination.

For zirconium, the situation is more complicated. Isolation of a bona fide bis-cyclopentadienyl zirconium sandwich complex, $[(CpR_n)_2Zr]$, has not been achieved, most likely owing to the increased thermodynamic potential for the second-row metal to attain its highest oxidation state. Typically, access to zirconium dinitrogen compounds proceeds by reduction of the appropriate Zr(IV) dihalide complex with an alkali metal or its equivalent (e.g., KC_8). Again, significant cyclopentadienyl substituent effects are operative in these reactions. Whereas $(\eta^5\text{-}C_5Me_5)_2ZrCl_2$ undergoes smooth reduction with 40% sodium amalgam in the presence of N_2 to yield $[(\eta^5\text{-}C_5Me_5)_2Zr(\eta^1\text{-}N_2)]_2(\mu_2, \eta^1, \eta^1\text{-}N_2)$ (14), related zirconocenes such as $(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(EMe_3)_2)_2ZrCl_2$ (E = C (24), Si (25)) only undergo a one-electron reduction to produce the corresponding Zr(III) monochloride under similar conditions (Fig. 2).

These results prompted further investigation into the reduction of various substituted zirconocene dihalide complexes. Reduction of $(\eta^5\text{-}C_5H_4SiMe_3)_2ZrCl_2$ with 0.5% sodium amalgam in toluene under 1 atm of N_2 (1 atm = 101.325 kPa) afforded deep-purple, diamagnetic crystals identified as the zirconium(III) monochloride dimer, $[(\eta^5\text{-}C_5H_4SiMe_3)_2Zr(\mu_2\text{-}Cl)]_2$ (**1**) (eq. [1]). Stronger reducing agents such as KC_8, CsC_8, and sodium potassium alloy also yielded **1**. The ^1H NMR spectrum of **1** in benzene-d_6 is consistent with a C_{2v} symmetric compound. The cyclopentadienyl resonances, observed at 5.31 and 5.44 ppm, are relatively upfield-shifted as compared to the analogous resonances of the starting dichloride complex, which appear at 6.09 and 6.69 ppm.

Cooling a concentrated pentane solution of **1** afforded purple blocks suitable for X-ray diffraction. The solid-state structure, presented in Fig. 3, establishes a dimeric molecule possessing a planar Zr_2Cl_2 core where the $[SiMe_3]$ substituents are oriented away from the metallocene wedge in a *cisoid* arrangement. The Zr–Zr distance of 3.512(12) Å is shorter than the values of 3.86 and 3.94 Å reported for the two molecules in the unit cell of paramagnetic $[(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2Zr(\mu_2\text{-}Cl)]_2$ (25), but is significantly longer than the value of 2.96 Å for the sum of the covalent radii for zirconium. The presence of only one $[SiMe_3]$ on the cyclopentadienyl ring affords a more open metallocene compared to $[(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2Zr(\mu_2\text{-}Cl)]_2$ and, as a result, a much shorter Zr–Zr distance is observed.

Reduction of the corresponding zirconocene diiodide complex, $(\eta^5\text{-}C_5H_4SiMe_3)_2ZrI_2$, with the range of reductants described above again resulted in one-electron reduction to

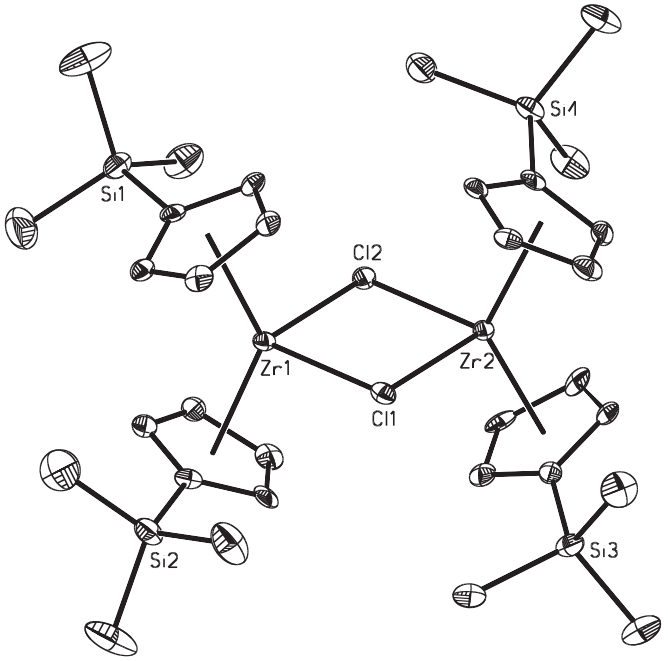

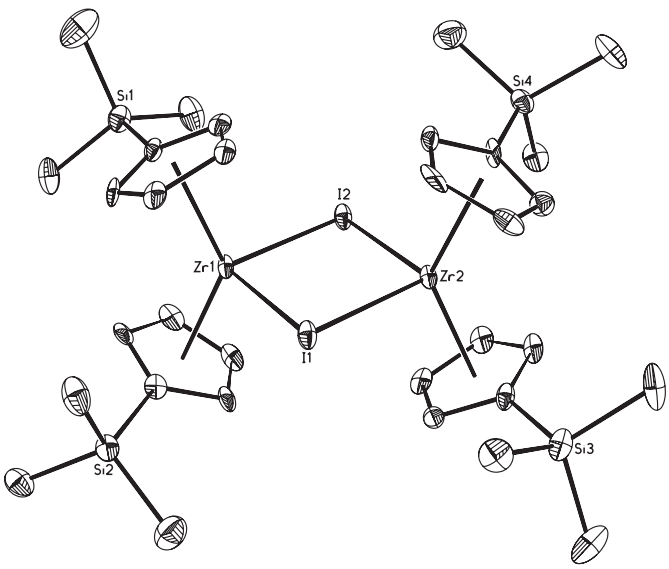

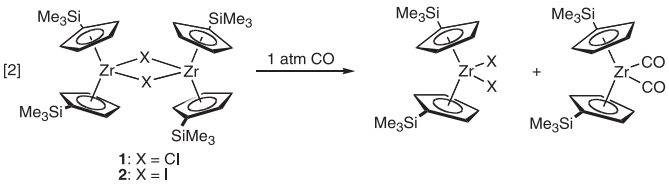

Fig. 4. Molecular structure of **2** at 30% probability ellipsoids. Hydrogen atoms are omitted for clarity.

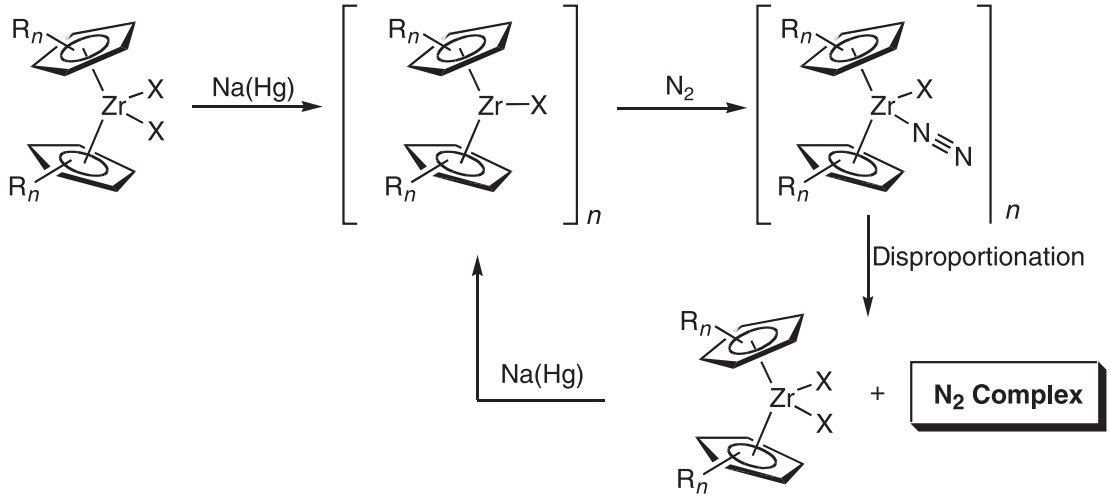
the zirconium(III) monoiodide complex, $[(\eta^5\text{-}C_5H_4SiMe_3)_2Zr(\mu_2\text{-}I)]_2$ (**2**) (eq. [1]). As with **1**, **2** is diamagnetic and has been characterized by NMR spectroscopy, elemental analysis, and X-ray diffraction (Fig. 4). As expected with the larger iodide ligands, the Zr–Zr distance has expanded to 3.6855(8) Å and the I(1)-Zr(1)-I(2) angle has opened to 101.870(19)° as compared to 93.24(8)° for **1**. Similar chemistry is also observed for the reduction of $(\eta^5\text{-}C_5H_4SiMe_2\text{-}t\text{-}Bu)_2ZrCl_2$ (26), where only one-electron reduction to the diamagnetic Zr(III) monohalide dimer results (27).

Dimeric, diamagnetic Zr(III) monohalide complexes have been prepared previously by Gambarotta and co-workers (28, 29). Independent computational studies by DeKock et al. (30) and Bénard and Rohmer (31) have established that a partial Zr–Zr bonding interaction accounts for the observed spin pairing. However, the metal–metal interaction can be attenuated, and therefore the spin state of the molecule altered, by both the bridging ligand and cyclopentadienyl substituents. Relatively unhindered cyclopentadienyl ligands such as those found in **1** and **2** allow close contact (3.512–3.685 Å) of the two zirconium centers, allowing a metal–metal interaction and spin pairing. Interestingly, in the case of the larger iodide ligands present in **2**, the I-Zr-I angle opens to allow electronic communication between the two zirconium centers. Introduction of an additional [$SiMe_3$] substituent as in the case of $[(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2Zr(\mu_2\text{-}Cl)]_2$ limits the contact of the metal centers, and the compound is paramagnetic (25).

The inability to reduce the silylated zirconocenes to zirconium(II) dinitrogen compounds with potent reducing agents such as CsC_8 and NaK suggested that a kinetic rather than a thermodynamic barrier inhibited the desired two-electron reduction. Considering that an array of formally zirconium(II) dicarbonyl complexes can be prepared by straightforward reduction of the dihalide complexes with activated Mg and CO (32), the affinity of the zirconium for the incoming ligand appears to influence the outcome of the reduction. Addition of 1 atm of CO (1 atm = 101.325 kPa) to both **1** and **2** induced disproportionation into the known zirconocene dicarbonyl, $(\eta^5\text{-}C_5H_4SiMe_3)_2Zr(CO)_2$ (33), and the dihalide complex, $(\eta^5\text{-}C_5H_4SiMe_3)_2ZrX_2$ (eq. [2]). Similar reactivity has also been observed by Gambarotta and co-workers with the unsubstituted zirconium cyclopentadienyl compounds (29).



A mechanism that accounts for these observations is presented in Fig. 5. Following the initial reduction to Zr(III), an exogenous ligand coordinates (N_2 is shown in this case) and forms the intermediate dinitrogen complex, $(CpR_n)_2ZrX(N_2)$, which then disproportionates into the Zr(IV) dihalide and the Zr(II) dinitrogen complex. The resulting zirconocene dihalide is then recycled back to Zr(III) by the reducing agent and the process continues. Lappert and co-workers (34) have obtained EPR evidence for a monomeric, side-on bound Zr(III) dinitrogen compound, $Cp_2Zr(CH_2SiMe_3)(\eta^2\text{-}N_2)$, providing experimental support for such an intermediate. Thus, the ability of the Zr(III) compound to bind dinitrogen, not the strength of the reducing agent, appears to dictate whether a two-electron reduction occurs.

This model, in conjunction with the known steric and electronic properties of zirconocene complexes (32), accounts

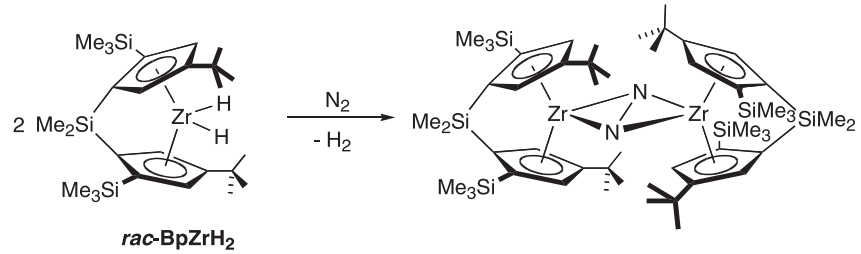
Fig. 5. Proposed mechanism for the synthesis of zirconocene dinitrogen complexes by alkali-metal reduction.

for the observed reduction chemistry. Zirconocenes with sterically demanding, electron-donating ligands such as (η^5-C_5Me_5) or (η^5-C_5Me_4H) inhibit dimerization of the Zr(III) intermediate and stabilize the Zr–N_2 interaction through π-backbonding. In contrast, zirconocenes with single silyl substituents are prone to form robust halide-bridged dimers and have less electron density for back donation. These effects should be considered when exploring zirconocene complexes for dinitrogen activation.



The limitations of the alkali-metal reduction reactions, in particular with cyclopentadienyl ligands containing electron-withdrawing substituents, demonstrated the need for alternative methods for the synthesis of zirconocene dinitrogen complexes. Alkane or dihydrogen reductive elimination from the appropriate Zr(IV) precursor could also achieve the desired two-electron reduction. Importantly, ground-state considerations (vide infra) also suggest that reductive elimination will be favored for electron-poor zirconocenes and would therefore complement reduction by alkali metals in terms of the class of metallocenes that could be targeted.

Inspiration for this aspect of the chemistry derived from several sources. Teuben and co-workers (20) had reported the synthesis of an end-on bound titanocene dinitrogen complex upon loss of dihydrogen from the corresponding titanium(III) monohydride. Fryzuk et al. (35) also had described a similar reaction with a dinuclear tantalum tetrahydride to yield an unusual dinitrogen complex with a N_2 ligand that can be classified as being both side-on and end-on. This molecule has since exhibited rich reaction chemistry (36).

Another major inspiration stems from a serendipitous discovery made by one of us (PJC) while working with John Bercaw at Caltech. We were studying rates of olefin insertion and β-hydrogen elimination with zirconocene dihydrides and alkyl hydrides to gain an understanding of molecular weight control in metallocene-catalyzed olefin polymerization. Having worked with a number of model complexes, we became interested in extending our studies to isospecific *ansa*-zirconocenes. A stock solution of *rac*-$BpZrH_2$ (Bp = $Me_2Si(C_5H_2$-2-$SiMe_3$-4-$CMe_3)_2$) in toluene was prepared for kinetic studies and placed in the drybox freezer and essentially forgotten. About a year later during one of John's famous group cleanups, the vial (clearly labeled of course!) was found, and we discovered that beautiful pleochroic crystals had formed. X-ray diffraction established a side-on bound, modestly activated N_2 ligand (37). Subsequent NMR experiments demonstrated that loss of H_2 and coordination of dinitrogen took place over the course of hours at ambient temperature (eq. [3]).

In July 2001 at Cornell, we began a systematic investigation of the rate of alkane reductive elimination as a function of cyclopentadienyl ligand. Zirconocene isobutyl hydrides were chosen because these molecules could be conveniently prepared by addition of 2 equiv. of *tert*-butyllithium to the corresponding dichloride complex (38). Using this methodology, a series of "mixed-ring" zirconocene isobutyl hydrides, (η^5-C_5Me_5)(CpR_n)$Zr(CH_2CHMe_2)H$, were prepared. Their relative rates of reductive elimination were measured and the products formed from alkane loss identified. In each case, loss of isobutane afforded a single diastereomer of a cyclometalated zirconium hydride rather than the desired dinitrogen complex. Importantly, however, it was established that the rate of alkane reductive elimination increased with incorporation of [$SiMe_3$] substituents, an effect ascribed to both steric and electronic destabilization of the Zr(IV) alkyl

[3]

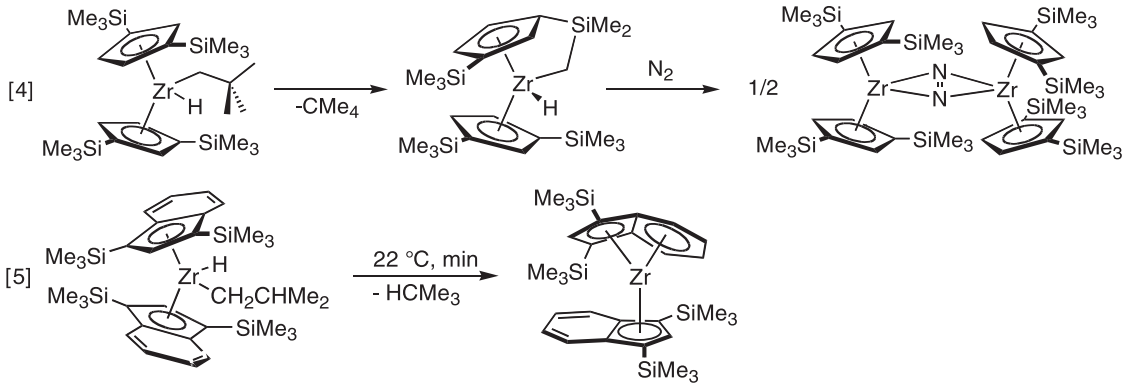
hydride ground state (39). Subsequent experiments with the $(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)Zr(R)H$ (R = alkyl) family of complexes demonstrated increased rates of elimination with increasing size of the alkyl group, a phenomenon also attributed to ground-state destabilization (40).

These results led to the design and synthesis of the purely silyl-substituted zirconocene neopentyl hydride, $(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2Zr(CH_2CMe_3)H$, which undergoes facile loss of neopentane at ambient temperature to afford the corresponding cyclometalated zirconocene hydride. Exposure of this molecule to a blanket of N_2 at –35 °C afforded crystals of the dinitrogen complex $[(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2Zr]_2(\mu_2, \eta^2, \eta^2\text{-}N_2)$ (eq. [4]). X-ray diffraction revealed a side-on bound N_2 ligand with an elongated N—N bond of 1.47 Å. Thus, alkane reductive elimination provides a unique synthetic pathway to a dinitrogen complex that cannot be accessed by alkali-metal reduction. Unfortunately, the yield of the dinitrogen complex is low owing to the propensity of the cyclometalated zirconocene hydride to participate in numerous side reactions. However, preliminary reactivity studies with $[(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2Zr]_2(\mu_2, \eta^2, \eta^2\text{-}N_2)$ are encouraging as reaction with ethyl chloroformate yields diethylazodicarboxylate, a useful precursor for the synthesis of amino acids and other organic molecules.

Low-valent bis-indenyl zirconium chemistry



Because incorporation of $[SiMe_3]$ groups into the cyclopentadienyl ligand array afforded N_2-reactive cyclometalated hydride complexes, we have also explored similar reactions with the corresponding silylated indenyl complexes. The indenyl anion, the benzo-substituted version of the cyclopentadienyl ligand, has enjoyed considerable success as a supporting ligand in metallocene-catalyzed olefin polymerization (41), although investigations into the chemistry of low-valent species have been limited. Moreover, replacement of the cyclopentadienyl anion with an indenyl ligand often results in enhanced or even unique reactivity. This behavior, when applied to associative substitution reactions, has been termed the "indenyl effect" (42).

Treatment of the silylated bis-indenyl zirconocene dichloride, $(\eta^5\text{-}C_9H_5\text{-}1,3\text{-}(SiMe_3)_2)_2ZrCl_2$, with 2 equiv. of isobutyllithium allows observation of the transient bis-indenyl zirconocene isobutyl hydride, which undergoes rapid reductive elimination of isobutane to yield a unique bis-indenyl zirconium sandwich (43). Recent crystallographic studies have established an unprecedented η^9 bonding interaction of one of the indenyl rings, where the planarity of the carbocycle is compromised to engage in bonding with the zirconium (eq. [5]) (44). These molecules have proven to be isolable sources of Zr(II), participating in numerous coupling and ligand addition reactions, although N_2 activation has not been observed. Thus, the chemistry of low-valent zirconium cyclopentadienyl and indenyl-substituted complexes is distinctly different, again highlighting the sensitivity to "ancillary" ligand environment.

End-on vs. side-on coordination and the hydrogenation of N_2

The elongated N—N bond in $[(\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2Zr]_2(\mu_2, \eta^2, \eta^2\text{-}N_2)$ and the reaction of this complex with electrophiles prompted further investigation into the origins of side-on coordination of the dinitrogen ligand. Particularly, we were interested in elucidating the effect of cyclopentadienyl substituents on N_2 hapticity and exploring reactivity differences between the side-on and end-on coordination modes. Based on the observed end-on coordination in $[(\eta^5\text{-}C_5Me_5)_2Zr(\eta^1\text{-}N_2)]_2(\mu_2, \eta^1, \eta^1\text{-}N_2)$, we hypothesized that side-on coordination was in fact electronically favored and should be observed in the absence of overriding steric effects. To test this assertion, we decided to systematically investigate the hapticity of the N_2 ligand as methyl groups were removed from the pentamethylcyclopentadienyl ligand. Ideally, the methyl substitution would maintain sufficient electron density and steric protection to promote complete reduction to the zirconium(II) dinitrogen complex yet allow close contact of the metal centers for η^2-coordination of the bridging N_2 ligand (Fig. 6).

The bis-tetramethyl zirconocene dichloride, $(\eta^5\text{-}C_5Me_4H)_2ZrCl_2$ (45), was first explored owing to the commercial availability of the ligand and the relative ease of synthesis of homoleptic zirconocene dichloride compounds. Reduction of the Zr(IV) dihalide with 0.5% sodium amalgam under N_2 afforded a green solid. Diagnostic reactions with CO and I_2 afforded the zirconocene dicarbonyl and diiodide complexes, respectively, suggesting that the product was indeed a dinitrogen complex. Not long after the initial synthesis, beautiful single crystals were obtained for a diffraction experiment. The solid-state structure confirmed our formulation of the molecule's identity, but revealed that the N_2 had changed hapticity to side-on as compared to end-on in the case of permethylzirconocene (eq. [6]) (46). Another important feature of the solid-state structure was the peculiar arrangement of the cyclopentadienyl ligands in the dimer. The two metallocene wedges are canted with respect to each

[6] 

other, forming a dihedral angle of 65.3°. This angle is significantly distorted from the electronically preferred coplanar arrangement observed in less-substituted dinitrogen complexes (39).

Having isolated and crystallographically characterized a new, side-on bound N_2 complex, we were anxious to explore its reactivity. Given the long-standing interest in the synthesis of ammonia from its elements, we first studied hydrogenation. Based on literature precedent, we anticipated that this nitrogen complex would behave like most others — addition of H_2 would induce loss of free N_2 with concomitant formation of the zirconocene dihydride. Addition of 1 atm of H_2 (1 atm = 101.325 kPa) to $[(\eta^5\text{-}C_5Me_4H)_2Zr]_2(\mu_2, \eta^2, \eta^2\text{-}N_2)$ in benzene-d_6 immediately bleached the intense purple solution and resulted in a sparingly soluble white solid. Much to our surprise (and delight!), we isolated not the expected dihydride complex but rather the zirconocene hydrazido compound, $[(\eta^5\text{-}C_5Me_4H)_2ZrH]_2(\mu_2, \eta^2, \eta^2\text{-}N_2H_2)$, arising from hydrogenation of the N_2 ligand (Fig. 7). IR and NMR experiments in conjunction with isotopic labeling studies quickly established the molecule's identity, but a crystal structure was essential. The zirconocene hydrazido complex was sparingly soluble in both aromatic and aliphatic hydrocarbons, making crystallization difficult. Fortunately, slow diffusion of hydrogen into a concentrated benzene-d_6 solution of the dinitrogen complex afforded a very large single crystal that yielded high-quality diffraction data.

Having hydrogenated atmospheric nitrogen to a hydrazido ligand, we next explored the possibility of fixation to ammonia. Mild thermolysis of $[(\eta^5\text{-}C_5Me_4H)_2ZrH]_2(\mu_2, \eta^2, \eta^2\text{-}N_2H_2)$ resulted in loss of H_2 along with N_2 scission, forming the zirconocene amido, nitrido complex, $[(\eta^5\text{-}C_5Me_4H)_2Zr]_2\text{-}(\mu_2\text{-}N)(\mu_2\text{-}NH_2)$ (eq. [7]). Protonolysis of this molecule with mineral acids does indeed yield free ammonia. Although this was an interesting result, N_2 fixation where H_2 was the sole hydrogen source was desired. Warming heptane solutions of

[7] 

© 2005 NRC Canada

$[(\eta^5\text{-}C_5Me_4H)_2ZrH]_2(\mu_2, \eta^2, \eta^2\text{-}N_2H_2)$ to 85 °C under 1 atm of H_2 (1 atm = 101.325 kPa) yielded small quantities of free ammonia, the zirconocene dihydride, and several Zr(IV) products arising from the reaction of the two.

The remarkable hydrogenation activity observed with $[(\eta^5\text{-}C_5Me_4H)_2Zr]_2(\mu_2, \eta^2, \eta^2\text{-}N_2)$ prompted us to investigate the reduction of $(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_5Me_4H)ZrCl_2$. Reaction of the zirconocene dichloride or diiodide with KC_8 afforded a purple solution from which the end-on dinitrogen complex, $[(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_5Me_4H)Zr(\eta^1\text{-}N_2)_2](\mu_2,\eta^1,\eta^1\text{-}N_2)$, was isolated. Exposure to 1 atm of H_2 (1 atm = 101.325 kPa) resulted in loss of N_2 and formation of the zirconocene dihydride (47). The reactions of zirconocene dinitrogen complexes again emphasize the sensitivity of the observed chemistry to cyclopentadienyl substituent effects. Replacing a single methyl group by a hydrogen atom completely alters the course of N_2 fixation. In the more substituted cases, trivial N_2 loss is observed whereas in the less-hindered example, ammonia synthesis can be achieved under mild conditions in solution.

Recent work in our laboratory has focused on the origin of the unprecedented reactivity of $[(\eta^5\text{-}C_5Me_4H)_2Zr]_2(\mu_2, \eta^2, \eta^2\text{-}N_2)$. Both computational and isotopic labeling studies (47) are consistent with the "twist" of the dimer as the origin of N_2 hydrogenation. Canting of the zirconium centers permits increased π back donation to the π^* molecular orbital of the side-on bound N_2 ligand, imparting significant Zr=N character and allowing facile 1,2-addition of H_2 across the zirconium–nitrogen bond (48, 49). Thus, both side-on coordination of N_2 and twisting of the zirconium dimer appear to be essential ingredients for nitrogen fixation.

Conclusions and future outlook

Over the past 3 years, our laboratory has observed the profound consequences that cyclopentadienyl ligand manipulations have on the activation, hapticity, and reactivity of dinitrogen with group 4 metallocenes. For titanium sandwich complexes, introduction of large substituents into $[C_5Me_4R]^-$ ligands allowed observation of monomeric, bis-dinitrogen complexes that are isoelectronic and isostructural to titanocene di-carbonyl complexes. In zirconium chemistry, access to the desired Zr(II) dinitrogen complex can be controlled by manipulation of the electronic properties of the cyclopentadienyl substituents. For electron-deficient metallocenes, reductive elimination is facile, whereas for electron-rich compounds, alkali-metal reduction is the preferred synthetic route. Significantly, either alkali-metal reduction or reductive elimination with the corresponding bis-indenyl zirconocene complexes affords unusual zirconium sandwich compounds in which one of the ligands is engaged in η^9 bonding.

Investigation into the substituent effects on the hapticity of dinitrogen allowed observation of the first hydrogenation of N_2 to ammonia in solution under relatively mild conditions. The $[C_5Me_4H]^-$ ligand supports a side-on bound zirconocene dinitrogen complex in which two metallocene wedges are twisted with respect to one another. This distortion from the electronically preferred planar geometry imparts zirconium-imido character to the N_2 ligand, resulting in facile 1,2-addition of H_2 at ambient temperature. Because such subtle changes in ligand structure produce such significant consequences, the prospects for stoichiometric and possibly even catalytic nitrogen functionalization reactions are promising.

Experimental

General considerations

All air- and moisture-sensitive manipulations were carried out using standard vacuum line, Schlenk, or cannula techniques or in an M. Braun inert-atmosphere drybox containing an atmosphere of purified nitrogen. The M. Braun drybox was equipped with a cold well designed for freezing samples in liquid nitrogen. All glassware was predried in an oven at 150 °C. Solvents for air- and moisture-sensitive manipulations were initially dried and deoxygenated using literature procedures (50). Deuterated solvents for NMR spectroscopy were distilled from sodium metal under an atmosphere of argon and stored over 4 Å molecular sieves. Argon and hydrogen gas were purchased from Airgas Incorporated and passed through a column containing manganese oxide on vermiculite and 4 Å molecular sieves before admission to the high-vacuum line.

^1H and ^{13}C NMR spectra were recorded on a Varian Inova 400 spectrometer operating at 399.860 MHz (^1H) and 100.511 MHz (^{13}C). All chemical shifts are reported relative to $SiMe_4$ using ^1H (residual) or ^{13}C NMR chemical shifts of the solvent as a secondary standard. Elemental analyses were performed by Robertson Microlit Laboratories, Inc. (Madison, N.J.).

Single crystals suitable for X-ray diffraction were coated with polyisobutylene oil in a drybox and were quickly transferred to the goniometer head of a Siemens SMART CCD area detector system equipped with a molybdenum X-ray tube (λ = 0.710 73 Å). Preliminary data revealed the crystal system. A hemisphere routine was used for data collection and determination of lattice constants. The space group was identified and the data were processed using the Bruker SAINT program and corrected for absorption using SADABS. The structures were solved using direct methods (SHELXS) completed by subsequent Fourier synthesis and refined by full-matrix least-squares procedures. The crystallographic data for complexes **1** and **2** are provided in the supplementary data.[4]

Preparation of $[(\eta^5\text{-}C_5H_4SiMe_3)_2Zr(\mu_2\text{-}Cl)]_2$

A 250 mL round-bottomed flask was charged with 0.901 g (2.06 mmol) of $(\eta^5\text{-}C_5H_4SiMe_3)_2ZrCl_2$ (51) and approximately 100 mL of toluene. In a separate flask, 5 equiv.

of 0.5% (by weight) Na(Hg) was prepared. The solution of the zirconocene dichloride was added to the amalgam and the reaction mixture was stirred for 4 days. The resulting purple solution was separated from the amalgam by pipette and filtered through Celite. The solvent was removed in vacuo, and the purple oil was triturated with pentane to yield a purple solid. Recrystallization from pentane at –35 °C afforded 0.553 g (67% yield) of $[(\eta^5\text{-}C_5H_4SiMe_3)_2ZrCl]_2$. ^{1}H NMR (benzene-$d_6$) δ: 0.40 (s, 36H, Si$Me_3$), 5.31 (s, 8H, Cp), 5.44 (s, 8H, Cp). ^{13}C NMR (benzene-d_6) δ: 1.29 (SiMe_3), 104.10, 107.31, 113.12 (Cp). Anal. calcd. for $C_{32}H_{52}Si_4Zr_2Cl_2$: C 47.89, H 6.53; found: C 48.20, H 6.31.

Preparation of $(\eta^5\text{-}C_5H_4SiMe_3)_2ZrI_2$

A 100 mL round-bottomed flask was charged with 1.445 g (3.32 mmol) of $(\eta^5\text{-}C_5H_4SiMe_3)_2ZrCl_2$ and approximately 50 mL of CH_2Cl_2. A CH_2Cl_2 solution containing 1.552 g (3.959 mmol) of BI_3 was prepared and added to the metallocene solution with stirring. The reaction mixture was stirred for 2 days, after which time the solvent was removed in vacuo. The resulting yellow solid was extracted into pentane and the yellow solution filtered through Celite. The pentane was removed in vacuo, leaving 0.586 g (29%) of a yellow solid identified as $(\eta^5\text{-}C_5H_4SiMe_3)_2ZrI_2$. ^{1}H NMR (benzene-$d_6$) δ: 0.29 (s, 18H, Si$Me_3$), 6.07 (d, 4H, Cp), 6.68 (d, 4H, Cp). ^{13}C NMR (benzene-d_6) δ: 0.57 (SiMe_3), 115.95, 123.74, 125.40 (Cp).

Preparation of $[(\eta^5\text{-}C_5H_4SiMe_3)_2Zr(\mu_2\text{-}I)]_2$

This molecule was prepared in a similar manner to $[(\eta^5\text{-}C_5H_4SiMe_3)_2ZrCl]_2$ with 0.143 g (0.234 mmol) of $(\eta^5\text{-}C_5H_4SiMe_3)_2ZrI_2$ yielding 0.087 g (77% yield) of deep-purple crystals identified as $[(\eta^5\text{-}C_5H_4SiMe_3)_2ZrI]_2$. ^{1}H NMR (benzene-$d_6$) δ: 0.41 (s, 36H, Si$Me_3$), 5.21 (d, 8H, Cp), 5.36 (d, 8H, Cp). ^{13}C NMR (benzene-d_6) δ: 1.14 (SiMe_3), 102.04, 103.44, 113.64 (Cp). Anal. calcd. for $C_{32}H_{52}Si_4Zr_2I_2$: C 39.00, H 5.32; found: C 38.90, H 4.93.

Low-coordinate iron complexes as synthetic models of nitrogenase[1]

Patrick L. Holland

Abstract: Three-coordinate iron sites are potentially important intermediates in the reduction of dinitrogen by the enzyme nitrogenase, but synthetic work to outline the behavior of three-coordinate iron complexes is in its infancy. Recent work shows that bulky diketiminate ligands give a general route to three-coordinate iron complexes with a variety of third ligands. The low coordination number leads to exciting new reactions in which N—N bonds are weakened or broken. Such complexes show great promise for evaluating the ability of low-coordinate iron to perform bond cleavage reactions akin to the individual steps of the nitrogenase system.

Key words: nitrogenase, three-coordinate iron, diketiminate, N–N cleavage.

Résumé : Les sites de fer tricoordiné sont potentiellement d'importants intermédiaires dans la réduction du diazote par l'enzyme nitrogénase, mais le travail de synthèse pour ébaucher le comportement des complexes de fer tricoordiné n'en est qu'à ses débuts. Des travaux récents montrent que des ligands dicétiminates volumineux permettent de tracer une route générale conduisant à des complexes de fer tricoordiné avec une variété de troisièmes ligands. Le faible nombre de coordination conduit à d'excitantes nouvelles réactions dans lesquelles les liaisons N—N sont affaiblies ou rompues. De tels complexes offrent de grandes possibilités pour évaluer l'habilité du fer à faible coordination à provoquer des réactions de bris de liaisons ressemblant aux étapes individuelles du système de la nitrogénase.

Mots clés : nitrogénase, fer tricoordiné, dicétiminate, clivage N–N.

[Traduit par la Rédaction]

Introduction — Nitrogenase and synthetic models

The discovery of facile reactions through which N_2 may be transformed into more useful nitrogen-containing molecules is a chemical challenge that has occupied chemists for more than a century. The greatest success in this quest happened roughly a century ago, when Haber and Bosch developed the high-temperature iron-based hydrogenation of N_2 that is performed on a staggering scale today (1). When Haber was awarded the Nobel Prize, he recognized in his address an attractive route for learning how to reduce N_2 more easily: "Nitrogen bacteria teach us that Nature, with her sophisticated forms of the chemistry of living matter, still understands and utilizes methods which we do not as yet know how to imitate" (2). Inorganic chemists still believe that mimicking the biological fixation of nitrogen is an important goal, but have not yet been able to elucidate the "methods" of which Haber spoke.

One guide in this effort is the study of the *nitrogenase* enzymes, which have been reviewed (3, 4). Particular attention has fallen on iron–molybdenum nitrogenase, because it is the most active nitrogenase and because it has been crystallographically characterized to high resolution (5). The site at which N_2 is bound and reduced to ammonia (the limiting stoichiometry is shown in eq. [1]) is the *iron–molybdenum cofactor* or *FeMoco*.

$$[1] \qquad N_2 + 8H^+ + 8e^- + 16\text{MgATP} \rightarrow 2NH_3 + H_2 + 16\text{MgADP} + 16\text{phosphate}$$

Figure 1 shows the isolated form of the cluster (5). X represents a hypervalent light atom, most likely nitrogen (6–10), which is coordinated to the six central iron atoms of the cluster. These six iron atoms have a geometry that is intermediate ($\tau = 0.46$) between trigonal pyramidal ($\tau = 1$) and tetrahedral ($\tau = 0$) (11). The oxidation states of the metals are thought to be $Fe_4^{2+}Fe_3^{3+}Mo^{4+}$ in this isolated form (10), but unfortunately this picture is not strictly relevant to the reaction with N_2 because the cluster must be reduced by several electrons before substrates bind. The reduced, activated form is unstable, reducing protons to hydrogen in the absence of substrate. Therefore, the active form of the cofactor is frustratingly obscured from crystallographic view, and chemists can only speculate as to its topology, geometry, and modes of reactivity.

The *synthetic modeling approach* has been a valuable strategy for many outstanding issues in bioinorganic chemistry (12). Synthetic inorganic compounds that have structural, spectroscopic, and (or) functional similarity to the enzyme active site are studied in detail and profitably compared with data for the enzymatic system. In the case of nitrogenase, this quest has involved synthesis and characterization of iron–sulfur and iron–molybdenum–sulfur clusters, and the

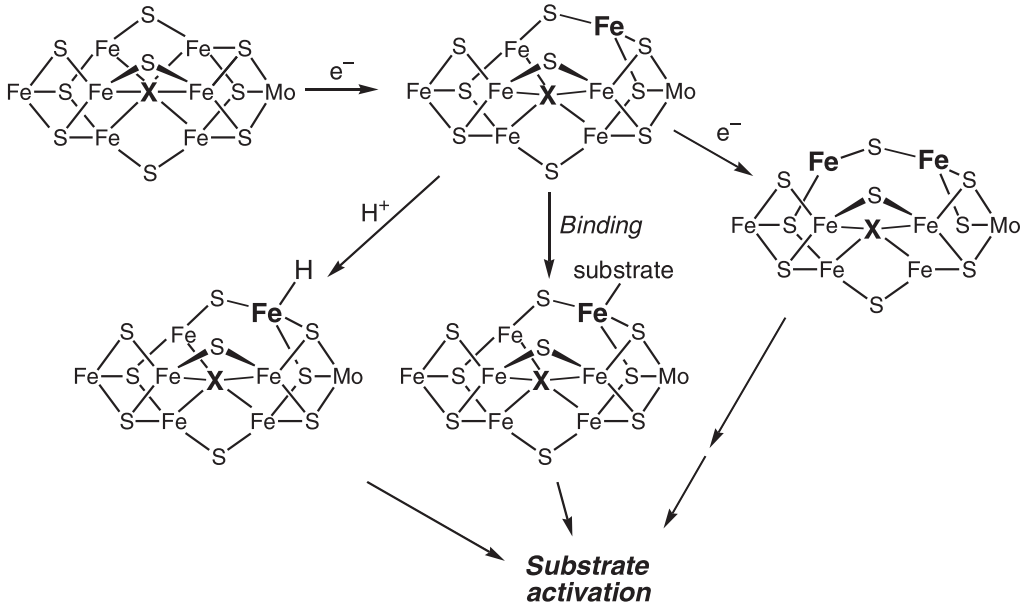

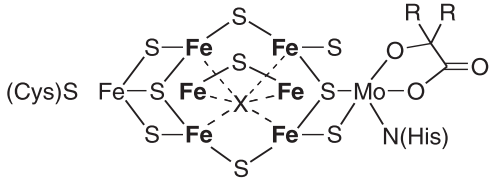

Fig. 1. The isolated form of the iron–molybdenum cofactor of nitrogenase. X represents a light atom that is thought to be C, N, or O.

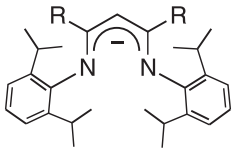
binding and reduction of N_2 by metals. An important step along this road came with the synthesis of metal–N_2 complexes, as first reported by Allen and Senoff (13). As the known chemistry of N_2 has grown, increasing effort has been devoted to the study of molybdenum and iron compounds as synthetic models that teach us about the geometric and chemical capabilities of these metals.

In the synthetic literature, most modeling efforts have focused on molybdenum, with especially important contributions from the research groups of Chatt (14), Cummins (15), and Schrock (16), who have each completely broken the N—N bond of N_2. Despite the feasibility of molybdenum for N_2 reduction, recent work shows several pieces of evidence that N_2 binding may occur instead at iron in the enzyme! (*a*) There are nitrogenases that contain no molybdenum and have only somewhat lower activity (17). (*b*) The selectivity of the iron–molybdenum enzyme changes drastically with mutations near the *iron* sites of the FeMoco (18). (*c*) The six iron atoms at the center of the cluster have unusual, low-coordinate geometries. In view of these findings, there is an urgent need to explore the nitrogenase-relevant chemistry of iron complexes to gain the level of insight that has been accomplished for molybdenum.

The relevance of three-coordinate iron



Scheme 1 shows the framework for a nitrogenase mechanism that guides our experiments on low-coordinate iron compounds. Reduction of metal–sulfur clusters is known to place electrons into orbitals that have metal–ligand antibonding character (19). Therefore, one expects weakening and (or) breaking of cluster bonds upon FeMoco reduction. Bonds to the hypervalent X atom are presumably weak, and breaking an Fe—X bond generates a three-coordinate, unsaturated, and highly reactive iron center. This iron atom may directly bind N_2, or be protonated to form a low-coordinate iron hydride (with electrons coming from the cluster). This process may be repeated without reducing the coordination number of X to an unstable level. The binding of substrates would then occur at the belt of the FeMoco, as implicated by ingenious studies on nitrogenase mutants (18, 20).

Despite the fact that three-coordinate iron is unprecedented in biological compounds, this deduction is persuasive for a number of reasons. First, a highly coordinatively unsaturated, low-valent iron atom could conceivably coordinate the weak donor N_2. Second, the role of X would be explained as a hemilabile ligand (21) that coordinates and saturates iron in the inactive form but releases it for activity in the reduced form. This role of X is consistent with several lines of evidence that indicate that X is *not* from turnover N_2 (namely, ENDOR/ESEEM studies do not show a signal after turnover with $^{15}N_2$ (22, 23), and nitrogenase mutants that are incapable of turning over N_2 are spectroscopically identical to the wild-type enzyme (18)). Finally, the research of Wolczanski and of Cummins has shown that three-coordinate transition-metal complexes have extensive bond-breaking ability (24), suggesting that exploration of analogous iron complexes could yield important clues about N—N bond breaking by the FeMoco.

A number of computational studies (using density functional theory (DFT)) have given a picture of potential N_2 binding modes and intermediates. However, only one reported study has taken the essential step of determining the energetic cost of the barriers between the intermediates (25). The mechanism with catalytically relevant activation barriers

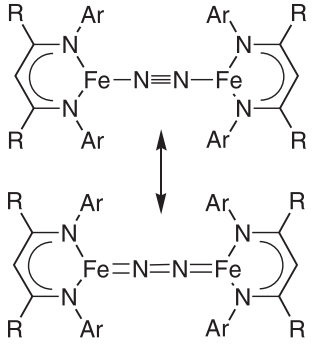
has N_2 bound between two iron atoms that have lost some bonds to X and to the bridging sulfide. Although the synthetic compounds described below do not have perfect topological congruence with the theoretical models, it is heartening that calculations are consistent with Scheme 1 in that bond breaking within the cofactor is important in the process of binding nitrogen.



Synthesis and spectroscopy of three-coordinate iron(II) complexes

To test the ideas outlined in Scheme 1, it is necessary to study low-coordinate iron compounds, and there are few in the literature. The following research builds on the discovery that bulky β-diketiminate ligands (Fig. 2) are useful bidentate ligands that stabilize three-coordinate compounds, even with copper(II) where three-coordination previously had been unprecedented (26). In initial work, we demonstrated that coordination of β-diketiminate ligands to iron(II), cobalt(II), and nickel(II) gives three-coordinate halide complexes, which are sometimes in equilibrium with four-coordinate dimers or lithium halide adducts (27, 28). Substitution of the halide ligand leads to complexes in which the third ligand coordinates through C, N, O, S, Cl, and H, giving great variety in electronic and steric properties of the three-coordinate iron(II) complexes (29).

In collaborative work with Eckard Münck and his research group, the electronic structure of these compounds was elaborated (30). The three-coordinate iron(II) compounds are invariably high-spin (S = 2), with four half-filled d orbitals and one filled d orbital. This filled orbital is the d_{z^2} orbital, using an axis system where z is perpendicular to the coordination plane of iron. Interestingly, there is substantial unquenched orbital angular momentum, arising from mixing between the d_{z^2} orbital and another low-lying d orbital (mediated by spin-orbit coupling). This unusual electronic structure leads to large negative zero-field splitting, which was quantified using Mössbauer and EPR spectroscopies. Interestingly, DFT calculations separated the Mössbauer quadrupole splitting into components attributable to specific ligands, which helped to understand the Mössbauer parameters for the FeMoco. More recently, the Münck group has used these parameters to show that the bonding between iron and X in the FeMoco is ionic and relatively weak (10). That is, X does not greatly perturb the electronic structure of the iron atoms to which it is attached.

The possession of well-characterized three-coordinate iron(II) complexes with one differentiated site allowed us to experimentally ask certain questions about the potential roles of low-coordinate iron in the FeMoco. The remainder of this review will consist of three specific questions, along with the results of initial studies that have started to answer these questions.

Fig. 3. Diiron complex with weakened N_2 ligands (N–N distances are 1.18–1.19 Å). The lower resonance structure suggests the weakening of N_2 through backbonding from the iron d orbitals into the π* orbital of N_2. Ar = 2,6-diisopropylphenyl. R = *tert*-butyl.

Does low coordination number enable iron to interact strongly with N_2 and to weaken the N—N triple bond?

Prior to the year 2001, all known complexes in which N_2 was coordinated only by iron had the metal in a coordination number of five or greater. In these iron(0) and iron(II) compounds, the N—N bond lengths were 1.13 Å or less, and N–N stretching frequencies were greater than 1900 cm^{-1}, corresponding to a nearly unperturbed N—N triple bond. Hence, iron–nitrogen complexes were categorized as "unactivated", based on the numerous precedents from iron in five- or six-coordinate geometries (31).

The bulky diketiminate ligands lead to iron–N_2 complexes that have a coordination number of only three (Fig. 3). These were synthesized by reduction of the iron chloride complexes under an atmosphere of N_2 (32). The crystal structures of the formally iron(I) and iron(0) complexes show that the N—N bonds are stretched to lengths of 1.18–1.24 Å, distances that are characteristic of N—N double bonds. Confirming the weakening of the bonds, resonance Raman spectra show N–N stretching bands below 1800 cm^{-1}. DFT calculations indicate that the molecules have high-lying filled orbitals with substantial Fe–N π-bonding character; these same orbitals have antibonding π interactions between the two nitrogen atoms. Therefore, there is backbonding of iron d orbitals into the π* orbital of the bridging N_2 ligand, weakening the N—N bond by shifting charge from Fe to N_2.

To confirm that the weakening of the bonds is attributable to the low coordination number, we performed comparative calculations on the five-coordinate and three-coordinate diiron–dinitrogen models illustrated in Fig. 4. The former model closely resembles literature N_2 complexes of iron(0) (33), and the latter is a modification in which the coordination number forcibly has been changed from five to three. Interestingly, despite retention of the π-withdrawing CO ligands in the three-coordinate model, the optimized N–N distance is quite long (1.173 Å), and similar to that in the diketiminate compound. The stretching of N_2 upon reducing the coordination number of iron from five to three supports a

Scheme 2.

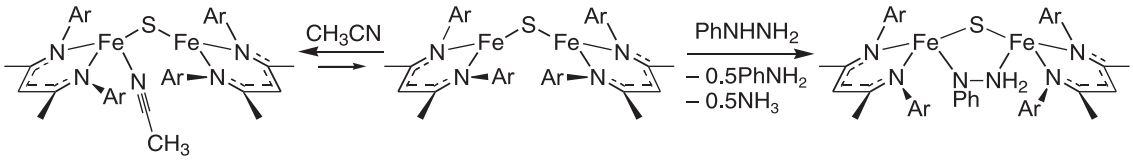

Fig. 4. A theoretical test of the effect of coordination number on iron–N_2 bonding. According to DFT calculations, removal of the two axial ligands shortens the Fe—N bonds and stretches the N—N bond, demonstrating the link between coordination number and N_2 weakening.

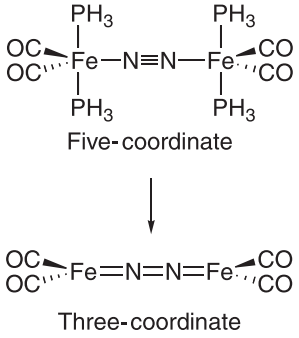

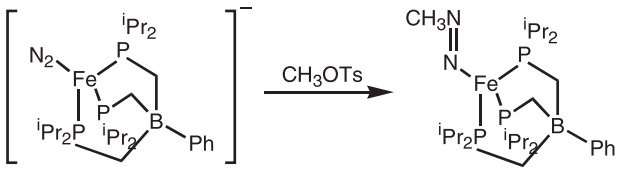

Fig. 5. A four-coordinate iron-dinitrogen complex that has a weakened N—N bond and reacts with electrophiles at the N_2 ligand.

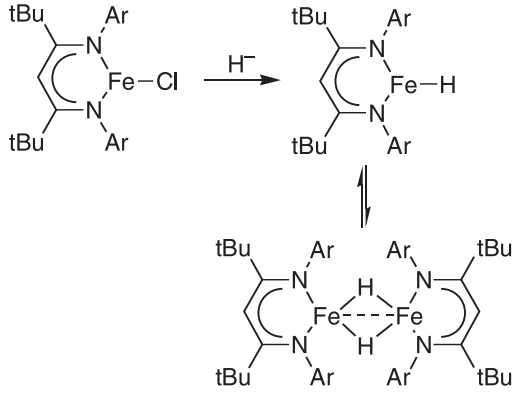
fundamental connection between coordination number and the ability to weaken the N—N bond of coordinated N_2.

Does this anomalous ability to weaken N_2 extend to four-coordinate iron? An affirmative answer to this question comes from recent work from Betley and Peters (34) in which tris(phosphino)borate ligands stabilize tetrahedral iron complexes. Notably, the four-coordinate iron–dinitrogen complexes have weakened and stretched N—N bonds. In the example shown in Fig. 5, the weakening from iron(0) was demonstrated with the N-N stretching frequency of 1884 cm^{-1}. Therefore, the principle that low coordination number engenders anomalous N_2-weakening ability appears to be general to three- and four-coordination, and the strength of the N—N bond is perhaps more sensitive to the coordination number than to the oxidation state. Further studies will use this weakening to enable reactions at the N_2 unit; for example, the Fe–N_2 complex in Fig. 5 reacts with methyl tosylate to give a methyldiazenido complex.

Do sulfide-bridged diiron complexes react with nitrogenase-relevant compounds?

One potential reduced form of the FeMoco has a pair of iron atoms that have been "freed" from the central X ligand (Scheme 1). The juxtaposition of two coordinatively unsaturated sites in one complex is a good recipe for activating N_2 toward reactivity, based on the work of Fryzuk et al. (35). Because diketiminates differentiate one coordination site, it was possible to access a complex in which two three-coordinate iron atoms are bridged by sulfide. When one of the N_2 complexes was treated with elemental sulfur, we isolated a bridging sulfidodiiron(II) complex in high yield. Scheme 2 shows this compound and some of its reactivity (11). Variable-field Mössbauer spectroscopy experiments demonstrate that in the compound, the two iron(II) ions are high-spin but magnetically coupled.

The X-ray crystal structure of the sulfido complex shows that the Fe_2S core is bent at sulfur (Fe-S-Fe = 102°), but the angle at sulfur is not as acute as its analogue in the FeMoco (Fe-S-Fe ~ 71°). This difference may be due to the absence of the X bridge in the model compound, or to steric interactions between the large diketiminate ligands. However, the steric clash is not sufficient to keep the iron centers from coordinating additional weak ligands like acetonitrile, ammonia, and alkylhydrazines. For example, the 1:1 adduct with acetonitrile is shown at the left of Scheme 2.



The sulfido compound undergoes a very interesting reaction with phenylhydrazine, giving the mixed-valence iron(II)–iron(III) complex at the right side of Scheme 2. In this product, the hydrazine is converted into a hydrazido ligand concurrent with oxidation of iron. The oxidizing agent in the reaction is phenylhydrazine itself, which is reduced to aniline and ammonia! Titration experiments showed that 1.5 equiv. of the hydrazine react, and the ammonia was distilled out of the reaction to verify the reaction stoichiometry shown in Scheme 2. We liken the cleavage of N—N bonds by this diiron compound to the rupture of N—N single bonds that must take place during the catalytic cycle of nitrogenase. More generally, the reaction indicates that the Fe_2S core is a substantial reducing agent and a reactive functionality.

Are iron hydrides reactive enough to be considered as potential FeMoco intermediates?

Thorough studies on the time course of H_2 production upon rapid acidification of the FeMoco during nitrogenase turnover strongly implied that several protonations of the enzyme occur prior to N_2 binding (36). There are many potential sites on the FeMoco that could be protonated, including the metal centers: protonation of a metal formally oxidizes the metal by two units and reduces H^+ to H^-. The possibility of hydride species as nitrogenase intermediates is persuasive to organometallic chemists, because nitrogenase reduces organic substrates in a manner that is reminiscent of the reac-

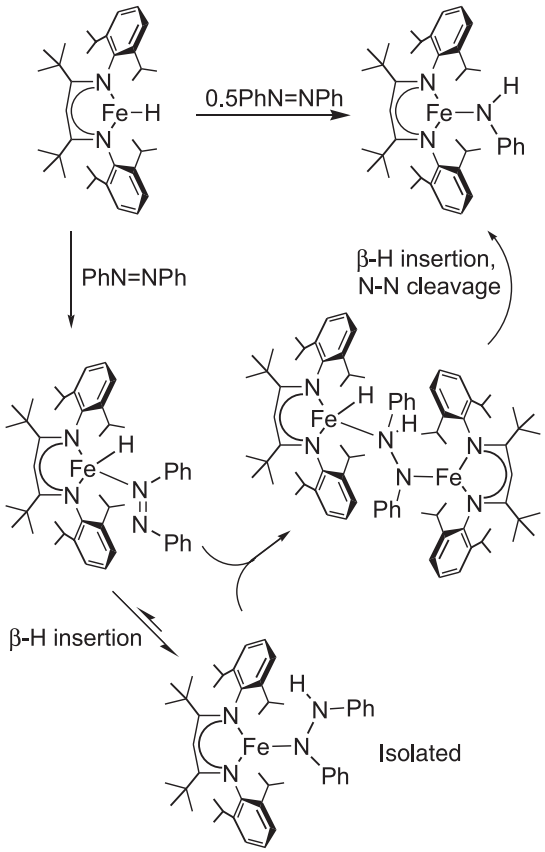
Fig. 6. Synthesis of a low-coordinate iron(II) hydride complex. Ar = 2,6-diisopropylphenyl. The iron–iron distance in the dimer is only 2.62 Å.



tions of metal-hydride species (37). However, *all* iron-hydride complexes in the literature had a coordination number of five or higher, and a low-spin electronic configuration (38). The surprising stability of high-spin, three-coordinate alkyliron(II) complexes (39, 40) suggested that it would be possible to make the first low-coordinate, high-spin iron hydride. This compound would allow evaluation of a high-spin iron-hydride functionality toward nitrogenase-relevant substrates.

The transformation shown in Fig. 6 leads to the isolation of a stable hydride complex, as long as the BEt_3 by-product is promptly removed (41). This synthetic strategy can be used to generate gram quantities of the hydride complex shown. Surprisingly, hydride (the smallest possible ligand!) bridges the two metals. The short bridge holds the two iron atoms very close together, and the Fe–Fe distance is nearly identical to the 2.63 Å Fe–Fe distance between pairs of iron atoms in the FeMoco.

In solution, the hydride dimer is in equilibrium with a three-coordinate monomer. The monomeric hydridoiron(II) complex was characterized by its high-temperature UV–vis and ^{1}H NMR spectra and magnetism, which are very similar to three-coordinate alkyl analogues (40). Because the position of ^{1}H NMR resonances in paramagnetic compounds is very sensitive to the electronic structure at the metal, the similarity of the NMR spectra is good evidence that the monomeric hydride has the same trigonal-planar geometry seen in the crystal structures of the alkyl complexes (40). Another interesting feature is the ^{1}H NMR spectrum of the dimer, which consists of a multitude of peaks for analytically pure material. We believe that the complicated ^{1}H NMR spectrum results from hindered C—C bond rotations in the ligand. Consistent with decreased flexibility, the dimeric hydride is much less soluble in alkanes than the other diketiminate–iron complexes.

In an amazing transformation, reaction of the hydride complex with 0.5 molar equiv. of diphenyldiazene ("azobenzene") quantitatively gives a phenylamido complex. This reaction, shown in Scheme 3, represents the first example of complete N—N double bond cleavage by an iron-hydride complex. Other examples of N—N double bond cleavage by synthetic compounds occur with four-electron oxidation of the metal and formation of two imido ligands. In contrast,

Scheme 3.

the reaction in Scheme 3 results in no overall change in oxidation state at the metal: the reducing equivalents formally come from oxidation of the hydride ligands. In our view, the possibility of hydride as a reducing agent for biological bond cleavage is persuasive because drastic changes in oxidation state at the metal would not be required to accomplish the necessary reduction chemistry.

We have isolated and crystallographically characterized the hydrazido intermediate shown in Scheme 3. Isolated samples of this compound independently convert to a mixture of the amido complex and 0.5 equiv. of diazene, with a reaction rate that is first-order in iron concentration. Ongoing mechanistic experiments suggest the mechanism shown in Scheme 3, but confirmation of this mechanism requires further study.

Summary and implications

The biological reduction of N_2 is a stunning transformation for which the mechanism is quite unclear. By conceptually breaking down the cofactor into monoiron and diiron units, and by hypothesizing that low coordination is the key feature that engenders high reactivity by the FeMoco, we have been able to identify specific questions that can be answered by small, well-characterized iron complexes. In contrast to the established chemistry of five- and six-coordinate iron complexes that show "normal" organometallic reductions and little N_2 weakening, three- and four-coordinate iron complexes are more active. It is not yet clear whether the major determinant of this higher reactivity is the high-

© 2005 NRC Canada

spin electronic configuration or the low coordination number. Thus, the conventional wisdom that iron is not reactive enough to be responsible for nitrogenase activity needs to be reconsidered in light of these studies.

Acknowledgments

I thank the Rochester Department of Chemistry, the National Science Foundation, the National Institutes of Health, and the Alfred P. Sloan Foundation for financial support of the work described. Thanks are due to the faculty and staff at Rochester for assistance, to Dennis Dean for thoughtful comments, and to Jonas Peters and his group for insightful discussions. Most of all, I thank the students, collaborators, and co-workers who are responsible for these research accomplishments: Jeremy Smith, Nathan Eckert, and Javier Vela at the University of Rochester, Hanspeter Andres, Sebastian Stoian, Emile Bominaar, and Eckard Münck at Carnegie Mellon University, Kenton Rodgers and Gudrun Lukat-Rodgers at North Dakota State University, and Karl Pittard and Thomas Cundari at the University of North Texas.

Portability of the RNNMo(3+) core — Application to the synthesis of dinitrogen-derived trialkoxymolybdenum organodiazenido complexes[1]

John-Paul F. Cherry, Paula L. Diaconescu, and Christopher C. Cummins

Abstract: An alcoholysis strategy has been employed in the synthesis of new oligo- or polymeric trialkoxymolybdenum diazenido complexes $[R^1NNMo(O\text{-}1\text{-}Ad)_3]_x$ (R^1 = Me or C(O)OMe) as well as their mononuclear THF solvates $R^1NNMo(O\text{-}1\text{-}Ad)_3(THF)$. Dinitrogen-derived diazenido precursor complexes $R^1NNMo(N[R]Ar)_3$ (R = *i*-Pr, Ar = 3,5-$C_6H_3Me_2$) react smoothly with 3 equiv. 1-adamantanol to liberate 3 equiv. HN(R)Ar without disruption of the diazenidomolybdenum(3+) core. X-ray structural investigations were carried out for diazenido complex $MeNNMo(O\text{-}1\text{-}Ad)_3(THF)$ and for the corresponding cationic dimethyldiazenido complex $[Me_2NNMo(O\text{-}1\text{-}Ad)_3(THF)]^+$, obtained as its triflate salt. The latter cation was found upon cobaltocene reduction to undergo N—N bond cleavage, producing nitride $NMo(O\text{-}1\text{-}Ad)_3$ (synthesized independently) and dimethylamine.

Key words: molybdenum, dinitrogen, bond cleavage, hydrazido, diazenido.

Résumé : On a utilisé une stratégie d'alcoolyse dans la synthèse de nouveaux complexes oligo- et polymériques du diazénido trialkoxymolybdène $[R^1NNMo(O\text{-}1\text{-}Ad)_3]_x$ (R^1 = Me ou C(O)OMe) et celle de leurs complexes monomoléculaires monosolvatés par le THF $R^1NNMo(O\text{-}1\text{-}Ad)_3(THF)$. Les complexes précurseurs diazénido dérivés du diazote $R^1NNMo(N[R]Ar)_3$ (R = *i*-Pr, Ar = 3,5-$C_6H_3Me_2$) réagissent sans problème avec trois équivalents d'adamant-1-ol pour libérer trois équivalents de HN(R)Ar sans disruption du noyau diazénidomolybdène(3+). On a examiné les structures du complexe diazénido $MeNNMo(O\text{-}1\text{-}Ad)_3(THF)$ et du complexe diméthyldiazénido cationique correspondant $[Me_2NNMo(O\text{-}1\text{-}Ad)_3(THF)]^+$ isolé sous la forme de triflate. On a trouvé que la réduction de ce dernier cation par le cobaltocène conduit à un clivage de la liaison N—N qui conduit à la formation du nitrure $NMo(O\text{-}1\text{-}Ad)_3$ (qui a été synthétisé par une voie indépendante) et de la diméthylamine.

Mots clés : molybdène, diazote, clivage d'une liaison, hydrazido, diazénido.

[Traduit par la Rédaction]

Introduction

Amide (NR_2^{1-}) ligands (1) and tripodal variants incorporating them have become established supporting ligands for the dinitrogen chemistry of metals from groups 4, 5, and 6 (2–16). In contrast, while early metal alkoxides and (or) aryloxides are abundant and their chemistry is well-established (17), the combination of alkoxide supporting ligands and dinitrogen activation–functionalization remains rare. A prime example of dinitrogen binding, activation, and cleavage to nitride by an early metal aryloxy system is provided by the niobium-calix[4]arene system reported by Floriani and co-workers (18). Furthermore, N_2 splitting in combination with intermetal N-atom transfer has been reported in a system that produces $^{15}NMo(O\text{-}t\text{-}Bu)_3$ from $^{15}N_2$ (19).

Since a common mode of reactivity for coordinated dinitrogen is that involving treatment with simple electrophiles (e.g., H^+, Me^+ synthons) and conversion to diazenido (NNH^{1-} or $NNMe^{1-}$) units (20–24), and since such conversions are essentially absent from the known chemistry of early-metal alkoxides, we sought an alternative synthetic entry to trialkoxymolybdenum(IV) diazenido systems. Dinitrogen-derived diazenido, hydrazido, and related ligands have interested theoreticians for at least a quarter century (25).

We have shown recently that certain Mo-ligand multiply bonded functional groups are "portable" in the sense that they can be retained while exchanging all the supporting ligands. Accordingly, the monomeric terminal phosphide (P^{3-}) complex $PMo(O\text{-}1\text{-}MeCy)_3$ was synthesized by treatment of $PMo(N[i\text{-}Pr]Ar)_3$ with 3 equiv. of 1-methyl cyclohexanol (26). In addition, a variety of Schrock-type alkyne metathesis catalysts $R^1CMo(OR^2)_3$ could be synthesized by an analogous alcoholysis protocol, involving treatment of precursor $R^1CMo(N[i\text{-}Pr]Ar)_3$ with 3 equiv. of the desired alcohol or phenol, R^2OH (27, 28). The latter two examples reveal the "portability" of the MoP and MoC triple bond functional groups, attributable to their compatibility with the required protic reaction conditions in concert with the protolytic sen-

Scheme 1.

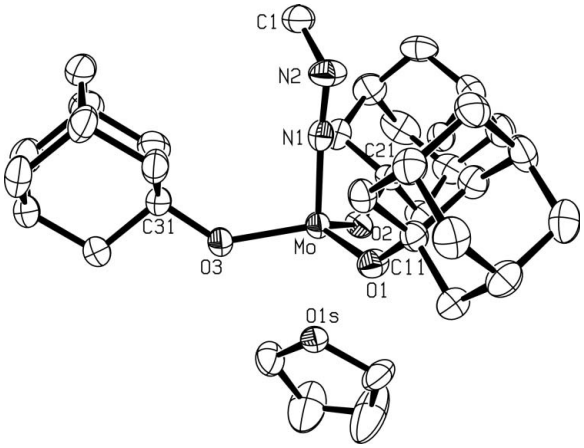
sitivity of the molybdenum–amide bonds. In the present work, we show that the same approach lends itself to the synthesis of a diazenido trialkoxymolybdenum(IV) system.

Results and discussion

Prepared by treatment of the corresponding anionic dinitrogen complex (29) (sodium salt) with, respectively, methyl tosylate (MeOTs) and methyl chloroformate are the diazenido complexes $R^1NNMo(N[i\text{-}Pr]Ar)_3$ **1a** ($R^1 = CH_3$, synthesis and structure reported previously) (29) and **1b** (R^1 = C(O)OMe). Gram quantities of **1a** could be obtained as red blocks in 58% isolated yield, as crystallized from ether (23). In contrast, **1b** was recovered in 94% yield as an analytically pure dark oil that dissolves in benzene to give a yellow solution.

The choice of MeOTs as the CH_3^+ source in the synthesis of **1a** was not random (29). A mild and non-oxidizing methylating agent is required to avoid both over-methylation and 1e oxidation of the anionic dinitrogen complex to its labile neutral counterpart (7). Furthermore, we had shown previously that sodium amalgam reduction of three-coordinate $Mo(N[t\text{-}Bu]Ar)_3$ in the presence of MeOTs under N_2 constituted a one-pot synthesis of $MeNNMo(N[t\text{-}Bu]Ar)_3$ (7). Structural precedent for molecules containing the [N=N C(O)OMe](1–) ligand, as found in **1b**, is extant (30).

Adamantanolysis of **1a** (Scheme 1) was accomplished by treating with 3 equiv. of 1-AdOH in THF at –25 °C, followed by warming to 25 °C and stirring for 4 h (Scheme 1). Solvent removal in vacuo, followed by suspension in pentane of the resulting orange solid, and subsequent collection by filtration, gave $MeNNMo(OAd)_3(THF)$ (**2a**·THF) in 81% isolated yield. The filtrate was shown to contain, essentially exclusively, pure HN(*i*-Pr)Ar. A band at 1544 cm^{-1} in the IR spectrum of **2a**·THF is assigned to ν_{NN}, and this diamagnetic derivative exhibits ^1H and ^{13}C NMR spectra consistent with a single 1-adamantyl environment.



The specific choice of adamantanol in this work derives from a combined consideration of steric bulk and solubility properties. The steric protection afforded by adamantoxide in complexes such as **2a**·THF is often sufficient to favor a mononuclear formulation, but in addition, such complexes have sufficiently low solubility in saturated hydrocarbon media for efficient separation from the nonvolatile HN(*i*-Pr)Ar aniline liberated in the alcoholysis reaction. In the latter respect, adamantoxy is superior to, for example, *tert*-butoxy.

Adamantanolysis of **1a** was also possible in the absence of THF, under more forcing conditions (toluene, 92 °C, 39 h). In this case, the orange product precipitated from the brown reaction mixture while still hot. The product obtained in this manner (**2a**, 30% yield) was only sparingly soluble in benzene, toluene, or chloroform, but dissolved quantitatively in THF to provide solvate **2a**·THF. The properties of solvent-free **2a** are reminiscent of those reported for nitrosyl $ONW(O\text{-}t\text{-}Bu)_3$ (31), and both compounds are presumably polymeric in the solid state, though the nature of the bridging interactions is not known in either case. For **2a**, it may be surmised that the nucleophilic β-N atom of the diazenido ligand serves to provide the bridging contact, leading to infinite polymer formation. If so, then by analogy, the nitrosyl oxygen in $ONW(O\text{-}t\text{-}Bu)_3$ may behave similarly. Such structural features (i.e., topologically linear bridging N=NR or NO) are of interest given the paucity of data concerning such interactions (32), and their potential relevance to oxygen-atom or nitrene-group transfer reactions (33).

The molecular structure of **2a**·THF (Fig. 1) was determined via single-crystal X-ray diffraction. The overall molecular conformation is quite reminiscent of that observed for nitrosyl $ONW(O\text{-}t\text{-}Bu)_3(py)$ (31), with local threefold axial symmetry in the trialkoxymetal core, an apical metal–ligand multiple bond, and a solvent adduct trans thereto. The

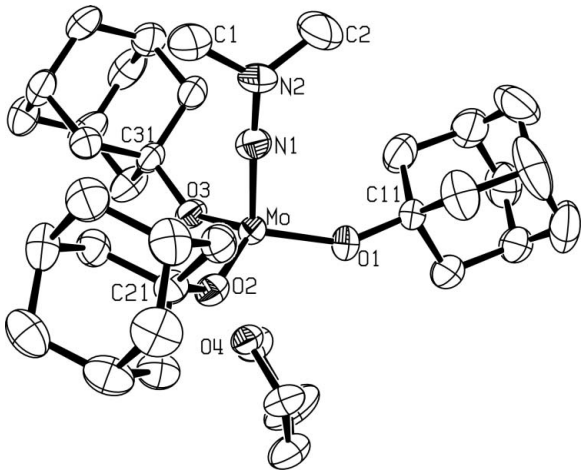
Fig. 1. Thermal ellipsoid representation at 50% probability of **2a**·THF. Selected interatomic distances (Å) and angles (°): Mo-N1, 1.773(3); N1-N2, 1.250(4); Mo-O2, 1.902(2); Mo-O1s, 2.300(2); Mo-N1-N2, 171.8(3); N1-N2-C1, 118.7(3).



key structural parameters for the diazenidomolybdenum core in **2a**·THF (see caption to Fig. 1) are essentially unperturbed relative to those reported previously for **1a** (26), indicating that the exchange of alkoxide for anilide ligation, along with the inclusion of a trans solvent molecule, alters little the apical metal–ligand multiple bonding. The bond angles in the diazenido core reveal *sp* and sp^2 hybridization at, respectively, N1 and N2, as is typical of this functional group. The Mo-N1 distance is elongated by only ca. 0.1 Å relative to values typical of terminal MoN triple bonds (6), such that the resonance structure used to represent **2a**·THF in Scheme 1 is not by itself a complete description of the Mo—N bonding.

While **1b** was obtained only as a dark oil, its conversion to a solid derivative was accomplished via room-temperature adamantanolysis. Product **2b** was obtained accordingly as a yellow powder in 62% yield. The low solubility of **2b** in toluene suggests that like **2a**, the complex is polymeric in the solid phase. While in **2a** the β-N atom is likely to provide a bridging contact, in the case of **2b**, the carbonyl oxygen atom in the carboxylmethyl residue may alternatively serve this function. Carboethoxydiazenido molybdenum 3+ systems have been obtained from $O_2Mo(dtc)_2$ (dtc = *N*,*N*-dimethyldithiocarbamate) by treatment with the corresponding hydrazine, or by ethylchloroformate derivitization of dinitrogen complexes $(N_2)_2Mo(dppe)_2$ (dppe = 1,2-diphenylphosphinoethane) (34).

Nucleophilicity of the β-N in **2a**·THF was demonstrated by reaction of the complex with methyl triflate. The triflate salt [**3**]OTf was thereby produced as an orange powder in 82% isolated yield. Dimethylhydrazido complexes related to [**3**]OTf include the triaryloxy system $Me_2NNV(dipp)_3$ (dipp = 2,6-diisopropylphenoxy) studied with reference to vanadium-containing nitrogenase (35). The latter system displayed a short metal–nitrogen interatomic distance: V-N = 1.653(3) Å, an elongated N—N bond: N-N = 1.311(4) Å, and near linearity at the α-N atom: V-N-N = 175.8(3)° (35). While the structure of unsolvated [**3**]OTf is unknown, solvate [**3**·THF]OTf was obtained straightforwardly and its structure determined crystallographically (Fig. 2). Structural parameters for the dimethylhydrazido ligand in [**3**·THF]OTf are very similar to those seen for the aforementioned triaryloxy vanadium system. Accordingly, the methylation event leading to [**3**]OTf may be viewed as a redox event, the metal undergoing a formal oxidation state change from 4+ to 6+ concomitantly. The bonding between metal and α-N is then accurately described as for a metal imido complex (25). On the other hand, donation of the dimethylamino lone pair of electrons into the metal-α-N π* system leads to its observed planarity and suggests the alternative formulation, as drawn in Scheme 1 for the line drawings of [**3**]OTf and [**3**·THF]OTf. A related, structurally characterized molybdenum dimethylhydrazido complex cation was obtained by methyl triflate treatment of a trimethylsilyldiazenido complex (36).[3]

Fig. 2. Thermal ellipsoid representation at 50% probability of [**3a**·THF][OTf] (disordered triflate anion omitted for clarity). Selected interatomic distances (Å) and angles (°): Mo-N1, 1.745(3); N1-N2, 1.296(5); Mo-O2, 1.860(3); Mo-O4, 2.297(3); Mo-N1-N2, 177.2(3); N1-N2-C2, 119.5(4); N1-N2-C2, 120.0(4); C2-N2-C1, 118.2(4).

There has long been interest in the conversion of dinitrogen-derived hydrazido systems to amines, and it has been shown that treatment of cationic hydrazido complexes with $LiAlH_4$ can effect the conversion (37). Although not a clean transformation, it has been shown that [{ArN_3N}$MoNNMe_2$]OTf upon reduction with Na–Hg in THF undergoes N—N bond cleavage producing nitride [ArN_3N]MoN together with dimethylamine and other products (38), implying that neutral dimethylhydrazido complex [ArN_3N]$MoNNMe_2$ lacks sufficient stability for isolation. Presumably, fragmentation of the latter neutral system leads to nitride along with the [NMe_2] radical, the latter being

capable of hydrogen atom abstraction from THF solvent to produce dimethylamine. Sodium amalgam reduction of dimethylhydrazido $[Me_2NNMo(N[t\text{-}Bu]Ar)_3][OTf]$ likewise gave rise to dimethylamine and the corresponding nitrido complex, $NMo(N[t\text{-}Bu]Ar)_3$ (7). Similarly, in the present work we find (Scheme 1) that cobaltocene reduction of [**3**]OTf produced cobaltocenium triflate, nitride $NMo(O\text{-}1\text{-}Ad)_3$, and dimethylamine, as determined spectroscopically. Nitride $NMo(O\text{-}1\text{-}Ad)_3$ was prepared independently using the method described by Chisholm and co-workers (39) for the synthesis of $NMo(O\text{-}t\text{-}Bu)_3$, for determination of the NMR spectroscopic characteristics of the former. The existence of neutral molybdenum(V) dimethylhydrazido complexes has been probed for electrochemically (38), and such systems remain interesting as putative reactive intermediates in this manifold of amine-producing N—N bond cleavage reactions.

Concluding remarks

Diazenido complexes synthesized from N_2 in the context of a simple supporting platform, namely the $Mo(N[R]Ar)_3$ (R = *i*-Pr, Ar = 3,5-$C_6H_3Me_2$) fragment, have been shown to be amenable to replacement of the full complement of ancillary ligands. Accordingly, trialkoxymolybdenum-supported diazenido systems have become available for study, expanding the scope of systems combining the chemistry of N_2 or N_2-derived ligands with an O-donor supporting framework. This approach, harnessing the portability of the diazenidomolybdenum(3+) core, provides an opportunity to study this functional group's behavior in a variety of contexts.

Experimental

General considerations

All operations were performed in a drybox under an atmosphere of purified nitrogen. Anhydrous ether, toluene, benzene, pentane, and hexane were purified according to the procedure of Grubbs and co-workers (40). Deuterated solvents were degassed and dried over molecular sieves (4 Å) and transferred under vacuum into a storage vessel. Molecular sieves (4 Å) and Celite® were activated in vacuo overnight at a temperature above 180 °C. Other chemicals were purified and dried by standard procedures or were used as received. IR spectra were recorded on a Bio-Rad 135 Series FT IR spectrometer. ^{1}H and ^{13}C NMR spectra were recorded on a Varian VXR-500, Varian Mercury-300, Varian XL-300, or Varian Unity-300 spectrometer. ^{1}H and ^{13}C NMR chemical shifts are reported with reference to solvent resonances. Dinitrogen complex $[Na(THF)][N_2Mo(N[i\text{-}Pr]Ar)_3]$ and compound **1a** were prepared as previously reported (29, 41).

Synthesis of $(Ar[i\text{-}Pr]N)_3MoN_2C(O)OMe$ (1b) (41)

To a solution of $[Na(THF)][N_2Mo(N[i\text{-}Pr]Ar)_3]$ (151 mg, 0.214 mmol) in ether (8 mL) was added a solution of methyl chloroformate (18 µL, 0.235 mmol) at –25 °C. The mixture was allowed to warm to room temperature and was stirred for a total of 3 h. The resultant mixture was filtered through a pad of Celite® on a sintered glass frit. The solvent was removed from the filtrate in vacuo to give **1b** as a dark brown oil (135 mg, 94% yield). FT IR (C_6D_6, KBr, cm^{-1}): ν_{NN} 1654, ν_{CO} 1212. ^{1}H NMR (C_6D_6, 25 °C) δ: 6.46 (3H, para), 6.32 (6H, ortho), 4.81 (3H, methine), 3.62 (3H, $N_2C(O)OCH_3$), 1.93 (18H, Ar-CH_3). ^{13}C NMR (C_6D_6, 25 °C) δ: 165.1 ($N_2C(O)OCH_3$), 148.0 (ipso), 138.8 (meta), 127.5 (ortho), 125.2 (para), 64.4 ($CH(CH_3)_2$), 52.6 ($N_2C(O)OCH_3$), 25.4 ($CH(CH_3)_2$), 21.7 (aryl-CH_3). Anal. calcd. for $C_{35}H_{51}N_5O_2Mo$: C 62.77, H 7.68, N 10.46; found: C 62.55, H 7.79, N 10.41.

Synthesis of $(AdO)_3Mo(N_2Me)(THF)$ (2a·THF) (41)

A solution of 1-adamantanol (667 mg, 4.38 mmol) in THF (4 mL) was added to a solution of **1a** (884 mg, 1.41 mmol) in THF (8 mL) at –25 °C. The mixture was then stirred for 4.5 h at room temperature after which the solvent was removed in vacuo. The resultant orange powder was suspended in pentane and stirred for 20 min. This gave a suspension that was chilled to –25 °C, and from which orange powder was collected by filtration and washed with cold pentane. The filtrate was subjected twice to the same concentration–suspension–cooling–washing procedure to maximize the yield. The combined orange precipitate was dried in vacuo to yield **2a** (759 mg, 81% yield). FT IR (THF, KBr, cm^{-1}): ν_{NN} 1544. ^{1}H NMR (THF-d_8, 25 °C) δ: 3.75 (3H, N_2CH_3), 3.60 (4H, THF), 2.13 (9H, C*H*), 1.92 (18H, CH_2), 1.76 (4H, THF), 1.66 (18H, CH_2). ^{13}C NMR (THF-d_8, 25 °C) δ: 78.8 ($OC(CH_2\text{-})_3$), 68.4 (THF), 47.6 ($CH\text{-}CH_2$), 43.8 (N_2CH_3), 37.5 ($C(CH_2\text{-})_3$), 32.7 ($CH\text{-}CH_2$), 26.5 (THF). Anal. calcd. for $C_{35}H_{56}N_2O_4Mo$: C 63.24, H 8.49, N 4.22; found: C 63.16, H 8.4, N 4.16.

Synthesis of $(AdO)_3Mo(N_2Me)$ (2a) (41)

$(Ar[i\text{-}Pr]N)_3MoN_2Me$ (**1a**, 328 mg, 0.524 mmol), 1-adamantanol (239 mg, 1.57 mmol), and toluene (12 mL) were installed in a flask equipped with a Teflon stopcock. The reaction mixture was stirred for 39 h at 92 °C. Then, the mixture was cooled to –25 °C, and the resulting orange precipitate was filtered off and washed with cooled toluene to give **2a** as an orange powder (92 mg, 30% yield). ^{1}H NMR ($CDCl_3$, 25 °C) δ: 3.77 (3H, $NNCH_3$), 2.10 (9H, C*H*), 1.88 (18H, CH_2), 1.56 (18H, CH_2). Anal. calcd. for $C_{31}H_{48}N_2O_3Mo$: C 62.82, H 8.16, N 4.73; found: C 62.58, H 8.25, N 4.67.

Synthesis of $(AdO)_3MoNNC(O)OMe$ (2b) (41)

A toluene (4 mL) solution of $(Ar[i\text{-}Pr]N)_3MoN_2C(O)OMe$ (**1b**, 190 mg, 0.284 mmol) was added to 1-adamantanol (134 mg, 0.879 mmol). The mixture was stirred for 12 h, producing a yellow solution with a yellow precipitate. The yellow precipitate was filtered off, washed with cold toluene, and dried in vacuo to give **2b** as a yellow powder (113 mg, 62% yield). FT IR (C_6D_6, KBr, cm^{-1}) ν: 2915, 2852, 1113, 1086, 1061. ^{1}H NMR ($CDCl_3$, 25 °C) δ: 3.70 (3H, $N_2C(O)OCH_3$), 2.32 (9H, C*H*), 2.10 (18H, CH_2), 1.65/1.62 (18H, CH_2). ^{13}C NMR ($CDCl_3$, 25 °C) δ: 163.9 ($N_2C(O)OCH_3$), 86.8 ($C(CH_2\text{-})_3$), 52.9 ($CH\text{-}CH_2$), 45.4 ($N_2C(O)OCH_3$), 36.2 ($C(CH_2\text{-})_3$), 31.9 ($CH\text{-}CH_2$). Anal. calcd. for $C_{32}H_{48}N_2O_5Mo$: C 60.37, H 7.60, N 4.40; found: C 60.84, H 7.71, N 4.48.

Synthesis of $[(AdO)_3Mo(NNMe_2)][OTf]$ ([3][Otf]) (41)

Methyl triflate (258 µL, 2.28 mmol) was added to a toluene (8 mL) suspension of $(AdO)_3MoN_2Me(THF)$ (**2a**·THF, 759 mg, 1.14 mmol) at –25 °C. The mixture was stirred for

© 2005 NRC Canada

3 h at room temperature. The resultant purple-red mixture was filtered through Celite® and the solvent was removed from the filtrate in vacuo. The crude red solid thereby obtained was suspended in ether–pentane 1:1 and cooled to –25 °C. An orange precipitate of [**3**][OTf] was collected by filtration and dried in vacuo (709 mg, 82%). FT IR (C_6D_6, KBr, cm^{-1}) ν: 2915, 2852, 1113, 1086, 1061. ^1H NMR (C_6D_6, 25 °C) δ: 3.34 (6H, NN(CH_3)$_2$), 2.11 (9H, C*H*), 2.06 (18H, CH_2), 1.52/1.49 (18H, CH_2). ^{13}C NMR (C_6D_6, 25 °C) δ: 86.6 (*C*(CH$_2$-)$_3$), 45.8 (*C*H-CH$_2$), 45.3 (NN(*C*H$_3$)$_2$), 36.6 (C(*C*H$_2$-)$_3$), 32.0 (*C*H-CH$_2$). Anal. calcd. for $C_{33}H_{51}N_2O_6F_3SMo$: C 52.37, H 6.79, N 3.70; found: C 52.48, H 6.74, N 3.78.

Synthesis of [(AdO)$_3$Mo(NNMe$_2$)(THF)][OTf] ([3·THF][OTf]) (41)

The complex [(AdO)$_3$Mo(NNMe$_2$)(THF)][OTf] ([**3**·THF][OTf]) was obtained simply by dissolving [**3**]OTf in THF. Unlike **2a**·THF, the THF ligand in [**3**·THF][OTf] can be removed by simply dissolving the complex in toluene and removing the solvent. A single crystal suitable for X-ray structure analysis was obtained by recrystallization from toluene–THF. ^1H NMR (C_6D_6, 25 °C) δ: 3.76 (4H, THF), 3.46 (6H, NN(CH_3)$_2$), 2.12 (9H, C*H*), 2.00 (18H, CH_2), 1.57/1.54 (18H, CH_2), 1.48 (4H, THF).

Independent synthesis of (AdO)$_3$MoN (41)

Sodium azide (801 mg, 12.3 mmol) was added to a THF (50 mL) suspension of $MoCl_4(THF)_2$ (3.92 g, 10.3 mmol) at room temperature, and the mixture was stirred for 1 h. Then, Li(OAd) (4.74 g, 30.0 mmol) was added, and the mixture was stirred for 4 h at room temperature. The resulting mixture was filtered through Celite®, and the solvent was removed from the filtrate to give a dark, red-brown solid. The solid was stirred in boiling toluene (125 mL) and filtered through a pad of Celite® on a sintered glass frit, and the solid collected on the frit was washed with toluene. The filtrate was condensed and allowed to stand at room temperature for 36 h. The white precipitate was collected by filtration, washed with pentane, and dried in vacuo. The resulting powder was further suspended in cold toluene (25 mL), collected by filtration, and dried in vacuo to give (AdO)$_3$MoN as a white powder (0.98 g, 17% yield). FT IR (pyridine-d_5, KBr, cm^{-1}) ν: 2938, 2893, 2851, 1453, 1104, 1077, 940, 745. ^1H NMR (pyridine-d_5, 25 °C) δ: 2.24 (18H, CH_2), 2.17 (9H, C*H*), 1.63/1.61 (18H, CH_2). ^{13}C NMR (pyridine-d_5, 25 °C) δ: 78.1 (*C*(CH$_2$-)$_3$), 46.1 (*C*H-CH$_2$), 36.9 (C(*C*H$_2$-)$_3$), 32.0 (CH-*C*H$_2$). Anal. calcd. for $C_{30}H_{45}NO_3Mo$: C 63.93, H 8.05, N 2.49; found: C 64.06, H 8.12, N 2.58.

Mesoporous tantalum oxide photocatalysts for Schrauzer-type conversion of dinitrogen to ammonia[1]

Chaoyang Yue, Michel L. Trudeau, and David Antonelli

Abstract: Mesoporous tantalum oxide, Fe^{3+}-doped mesoporous tantalum oxide, and bis(toluene) titanium reduced mesoporous tantalum oxide were used for the first time as Schrauzer-type photocatalysts for the conversion of dinitrogen to ammonia. The materials were characterized by XRD, TEM, XPS, and nitrogen absorption before and after catalytic runs. The results showed low to moderate activities depending on the composition. In contrast to previously studied Ti catalysts, Fe doping and heat pretreatment were not prerequisites for photocatalytic activity, but did improve the turnover rates by up to a factor of two. The optimal Fe loading for the tantalum oxides was found to be 1 wt% and the optimal heating condition at 300 °C for 3 h. Increased surface area and heat treatment were also found to improve activities. Contrary to our expectations, reduction of the mesostructure with bis(toluene) titanium had little effect on the catalytic activity. In spite of the dramatically higher surface areas of the mesoporous tantalum oxides as compared with bulk titanias used previously in this process, the overall catalytic activities were still less than those obtained in the Schrauzer system. This suggests that the increase in diffusion and surface area offered by the mesoporous structure is offset by the smaller crystalline domain sizes in the walls of the structure, leading to poor electron-hole separation and a reduction in catalytic efficiency.

Key words: mesoporous, Schrauzer, ammonia, photocatalysis, tantalum oxide.

Résumé : On a utilisé pour la première fois de l'oxyde de tantale mésoporeux, de l'oxyde de tantale mésoporeux dopé au Fe^{3+} et de l'oxyde de tantale mésoporeux réduit par du bis(toluène)titane comme photocatalyseurs de type Schrauzer pour la conversion du diazote en ammoniac. Les matériaux ont été caractérisés par XRD, TEM, XPS et adsorption d'azote avant et après les réactions catalytiques. Les résultats démontrent la présence d'activités allant de faibles à modérées suivant la composition. Par opposition aux catalyseurs de titane étudiés antérieurement, le dopage au Fe et le prétraitement à la chaleur ne sont pas des prérequis pour l'activité catalytique, mais ils améliorent les vitesses d'échange par des facteurs pouvant atteindre deux. On a trouvé que les additions optimales de Fe aux oxydes de tantale sont de 1 % en poids et que les conditions de chauffage sont de 300 °C pendant 3 h. On a aussi observé qu'une augmentation de l'aire de la surface et le traitement par la chaleur améliorent les activités. Contrairement à ce qui avait été prévu, la réduction de la mésostructure à l'aide de bis(toluène)titane n'a que peu d'effet sur l'activité catalytique. Malgré une augmentation dramatique des aires de la surface des oxydes de tantale mésoporeux en comparaison aux titanes en masse utilisés antérieurement dans ce procédé, les activités catalytiques globales étaient inférieures à celles obtenues dans le système Schrauzer. Cette observation suggère que l'augmentation de la diffusion et de l'aire de la surface offerte par la structure mésoporeuse sont contrebalancées par des tailles plus faibles du domaine cristallin dans les parois de la structure qui conduisent à une séparation plus mauvaise des trous électroniques et à une réduction de l'efficacité catalytique.

Mots clés : mésoporeux, Schrauzer, ammoniac, photocatalyse, oxyde de tantale.

[Traduit par la Rédaction]

Introduction

In the past decade, a variety of photocatalytic systems using semiconducting transition metal oxides have been developed for oxidative degeneration of organic chemicals (1, 2), fixation of carbon dioxide (3, 4), evolution of H_2 from water (5, 6), and reduction of metal ions (7). Coupling the controlled pore size and high surface areas of mesoporous materials with the photocatalytic properties of many oxides would represent an important advance in terms of reaction

rates and overall efficiency because of better diffusion rates and a greater number of reactive surface sites per mol of catalyst. One of the more unusual photocatalytic processes is the conversion of dinitrogen and water over a metal-doped titanium oxide catalyst (8–10). This process uses water as the reductant with high-energy UV light as the driving force and contrasts to other methods of dinitrogen activation, which are the subject of much current interest (11–16). Initial work by Schrauzer demonstrated that electron-hole separation on Fe-doped titania led to highly reactive sites on the surface, which could trap and reduce dinitrogen. Oxidation of water by the hole provided a source of protons and electrons to complete the cycle and make the process catalytic. The doping of the metal oxide was found to be a necessary step for high activity for reasons that are still not clear, but may be related to the creation of a permanent space-charge region in the material. Further work by Hoshino demonstrated that activities of n-doped titania could be increased by incorporation of a conducting polymer on the surface, creating a p–n junction, which aided in the electron-hole separation, and thus increased the efficiency (10). The rates quoted for these reactions are on the order of mmol/h/g of catalyst. While modest, these rates could be improved by increasing the surface area and a judicious choice of dopant. Recent work in our group demonstrated that mesoporous Ti and Nb oxides when treated with bis(toluene) niobium or bis(toluene) titanium gave materials that readily cleaved dinitrogen under ambient conditions, leading to the formation of surface ammonia in 1% to 2% levels in the presence of low levels of moisture (17, 18). Since these materials are based on oxides that normally display photocatalytic activity in the bulk phase, it appears that the development of a related mesoporous transition-metal-oxide-based photocatalytic process for nitrogen fixation may indeed be feasible. However, to date there have been numerous difficulties in exploiting the surface area of mesoporous titanium in photocatalytic processes. In 1998, Stone and Davis (19) studied the photocatalytic activity of phosphated titania based mesoporous molecular sieves. The well-known oxidative dehydrogenation of 2-propanol to acetone was used as a probe to measure the photocatalytic activity of the materials. The lower photocatalytic activity of mesoporous titania compared to the anatase phase was attributed to the amorphous nature of the walls of these materials and the presence of phosphorous in the case of the titania materials: the low degree of crystalline wall and the high surface concentration of defects lead to surface electron-hole recombination, and (or) the poisoning of catalytic surface sites by the phosphorus remaining from the templates. Since high surface area phosphate-free mesoporous titania are now readily available, the presence of phosphorous in these materials should no longer hinder applications (20), however it appears that the low crystallinity of the walls of the structure may be the tallest hurdle to overcome before the development of functional mesoporous titanium oxide photocatalysts can be realized (21).

Although mesoporous Ti oxide has been disappointing as a photocatalyst, Takahara, Domen, and co-workers (22) reported more promising activity for mesoporous Ta oxide in the photocatalytic decomposition of water. When as-synthesized tantalum oxide, prepared by the method of Antonelli and Ying (23), was used as a photocatalyst, H_2 evolved in a rate of 50 μmol/h. In contrast, a sample calcined at 600 K after template removal by acid treatment and solvent extraction showed higher photocatalytic activity and released both H_2 and O_2 in a stoichiometric ratio, even though a brief induction period was observed. The initial H_2 evolution was attributed to the decomposition reaction of the remaining surfactants and the stoichiometric evolution of H_2 and O_2 started after complete consumption of the surfactant template. A NiO-loaded sample showed higher photocatalytic activity and shorter induction time than those samples without NiO since NiO can act as co-catalyst in the water decomposition reaction. The optimal NiO loading level for the overall water decomposition was found to be 4.0 wt%. The NiO loaded samples showed an important trend in increasing photocatalytic activity. Thus, mesoporous Ta_2O_5 showed better photocatalytic activity than the bulk amorphous and crystallized samples because of its higher surface area. These high activities as compared to those reported above for titania and niobia were explained by the different band gaps of the respective materials. The authors suggest that mesoporous Ta oxide functions as an efficient photocatalyst in this case (22) because the very thin walls of the structure ensure that virtually all electron-hole pairs generated are close enough to the surface to allow rapid migration and reaction with water.

Recent work in our group has shown that mesoporous Ta oxide, when treated with bis(toluene) titanium, converts dinitrogen to ammonia on the surface (24). This is important because it demonstrates that the Ti-reduced surface of the Ta oxide mesostructure can split dinitrogen, the first part of the Schrauzer process, and this reduced species can react with ambient moisture to form ammonia. Further, the activity of mesoporous Ta oxide as a photocatalyst in water splitting, suggests it may also be useful in the Schrauzer process. The use of a Ta oxide surface is also of special interest owing to recent work by Fryzuk and co-workers (25) demonstrating that organometallic Ta hydrides are capable of coordinating and partially reducing dinitrogen. In this paper, we focus on the photocatalytic behavior of pure mesoporous tantalum oxide, Fe^{3+}-doped tantalum oxide, and semiconducting bis(toluene) titanium reduced mesoporous tantalum oxide. Fe was used in this system because both Schrauzer and Guth (8) and Palmisano et al. (9) showed that Fe was the best dopant for the photocatalysis in the case of titanium oxide and also because Fe species are important as active centers in the commercial Haber process. Furthermore, X-ray studies on biological nitrogen fixation have suggested that a seven-Fe cluster in Fe–Mo nitrogenase is the site of N_2 reduction.

Experimental section

Chemicals and catalysts preparation

All chemicals, except tantalum ethoxides from Alfa Aesar, were obtained from Aldrich. Mesoporous tantalum oxides were synthesized following the ligand-assisted templating method introduced by Antonelli and Ying (23). Fe^{3+}-doped catalysts were prepared by aqueous impregnation of iron nitrate nonahydrates with mesoporous tantalum oxide for 4 h with stirring and dried in oven at 110 °C overnight, then cal-

© 2005 NRC Canada

cined in a furnace at 300 °C for 3 to 4 h. Bis(toluene) titanium reduced catalysts were prepared by stirring 0.5 g of the mesoporous solid with 0.5 g of bis(toluene) titanium in 50 mL of toluene. The mesoporous solid immediately turns from a light faun color to a deep blue-black. After 1 day of additional stirring to ensure complete absorption of the organometallic, the reduced material was collected by suction filtration under nitrogen and washed several times with toluene. The resulting black material was dried in vacuo at 10^{-3} torr (1 torr = 133.322 4 Pa) on a Schlenk line until all condensable volatile had been removed.

Apparatus and procedure for photocatalysis

All experiments were conducted in a U-shaped Pyrex reactor with a sintered glass frit as the fixed bed. A 450 W UV photochemical lamp was set up parallel to the reactor at a distance of about 8 cm. The photocatalytic reactions were initialized by feeding N_2 (ultrahigh purity), bubbled through deionized water at a constant flow rate of 60 cm^3/min, into the reaction tube. NH_3 produced from the reaction was absorbed by a 60 mL 0.01 N HCl aqueous solution, which was replaced every hour and kept for subsequent quantitative determination by the indophenol blue method (9). This method detects both NH_4^+ and NH_3 forms of N and the detection limit was reported to be about 10 μg NH_3-N/L, and Beer's law was obeyed up to about 1200 μg NH_3-N/L. After a 3 h run, samples were flushed again by pure helium to measure the adsorbed NH_3 on the powder surface. However, complete release of trapped NH_3 may require heating at 573 K or higher for several hours. Comparison experiments were also conducted under the same operation conditions, but using inert helium instead of the mixture of N_2 + H_2O as the feeding gas. These experiments are important for the $Fe(NO_3)_3$-doped catalysts to eliminate trace amounts of ammonia formed by heat treatment of the surface nitrate.

Characterization

Nitrogen adsorption and desorption data were collected on a Micromeritics ASAP 2010. X-ray diffraction (XRD) patterns (Cu Kα) were recorded on a Siemens D500δ-2δ diffractometer. All X-ray photoelectron spectroscopy (XPS) peaks were referenced to the carbon C–(C, H) peak at 284.8 eV, and the data were obtained using a Physical Electronics PHI-5500 using charge neutralization. Transmission electron microscopy (TEM) pictures were obtained by using a H9000 HR-TEM operated at 300 kV. The powder was deposited on a SiO_2-coated Cu grid.

Results and discussion

Pure mesoporous tantalum oxide

The X-ray diffraction patterns for a sample of mesoporous tantalum oxide, and that of the material treated in an oven at 300 °C for 3 h are shown in Fig. 1. The intense (100) reflection at d = 2.7 nm without resolved (110) and (200) reflections, is consistent with a wormhole structure rather than a highly ordered hexagonal structure. Apart from a slight broadening and diminishing in intensity, the XRD pattern of the calcined material shows little difference from that of the starting material, demonstrating that the initial mesostructure is largely retained after heat treatment. Figure 2 shows the

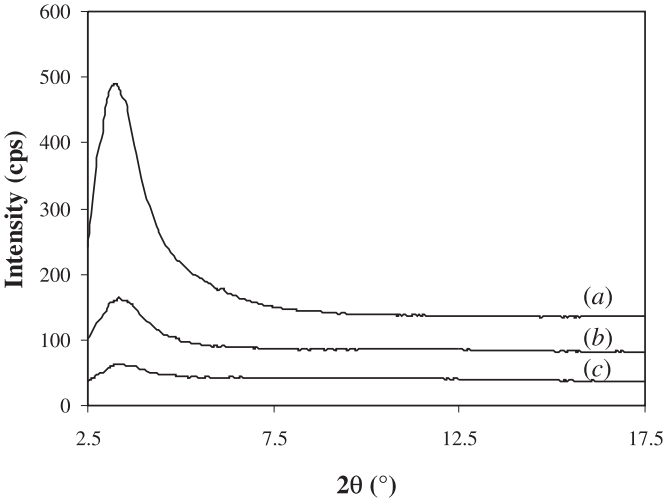

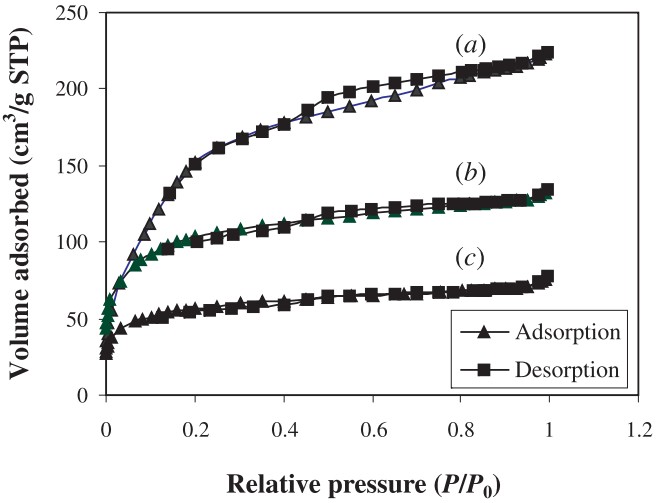

Fig. 2. Nitrogen adsorption–desorption isotherms for (*a*) mesoporous Ta oxide (S1); (*b*) mesoporous Ta oxide after calcination at 300 °C for 3 h (S7); and (*c*) 1% Fe^{3+}-doped mesoporous Ta oxide after calcination at 300 °C for 3 h (S8).

nitrogen adsorption and desorption isotherms of these materials. Heat treatment results in a decrease in specific BET surface area from 624 m^2/g to 366 m^2/g, and a corresponding decrease in the cumulative Horvan–Kawazoe (HK) pore volume from 0.304 cm^3/g to 0.103 cm^3/g, with the pore size remaining at 23 Å. Unlike MCM-41, which has a sharp pore-size distribution and a typical type IV isotherm, these materials possess a broader pore-size distribution and an isotherm somewhere between that of type I and IV because of the pore size, which is on the cusp between the microporous and mesoporous regimes. TEM was used to directly image mesoscopic order, particle morphology, as well as pore size and wall thickness of this material. Figure 3 clearly shows spherical particles with a wormhole pore structure consistent with XRD pattern; the measured pore size is about 25 Å, in good agreement with the results from nitrogen adsorption;

the wall is roughly 15 Å, differing slightly from the calculated value of 8 Å on the basis of *d* spacing and HK pore size assuming a perfectly hexagonal unit cell.

Photocatalytic activities of pure Ta oxide (S1) and Ta oxide after heat treatment (S2, S7) are listed in Table 1. Pure tantalum oxide without any treatment only shows low activity of 0.263 μmol/g/h and thermal treatment at 300 °C for 3 h (S7) improves the activity to 0.683 μmol/g/h. Prolonged heating time decreases the activity again to 0.47 μmol/g/h (S2). To examine the oxidation states of surface Ta and possible N species in these materials, XPS measurements were carried out. Figure 4 shows the Ta $4f_{5/2,\ 7/2}$ region for pure mesoporous Ta oxide before and after the photocatalytic reaction. The emissions at 26.6 eV and 28.5 eV are characteristic of Ta (V) and demonstrate that there has been little or no change in the oxidation state of the Ta over the course of the reaction. The N 1*s* region of this spectrum before and after the photocatalytic run are also similar (Fig. 5), showing a single peak at 405 eV for the Ta $4p_{3/2}$ emission. The expected N 1*s* emission for ammonia or other nitrogen species (396–403 eV) are not seen either because the Ta emission is too large and obscures the N emission, or because the quantities of N on the surface after the reaction are too small to be detected by XPS.

© 2005 NRC Canada

The improved activity on heat treatment is not unexpected because it increases local crystallization of materials, which often leads to more efficient migration of electrons and holes through the lattice to the surface. In Schrauzer and Guth's work (8), conversion from the anatase phase to the rutile modification by heat treatment at 1000 °C was a prerequisite for the high activity. In contrast, mesoporous tantalum oxide is considerably photoactive without heat treatment, as Domen and co-workers reported (22), most probably because of the small wall thickness, which enables the excited electron to migrate to the surface. While heat treatment in the case of the mesoporous Ta oxides initially improves the activity, prolonged calcination causes a diminution of the active surface in addition to an increasing loss of surface metal hydroxide groups, both contributing to a decrease of photocatalytic activity. In the case of very high surface mesoporous materials, this problem becomes even more prominent because of the apparent incompatibility of the presence of the mesostructure and the crystallinity of the walls. All mesoporous materials reported so far have either amorphous wall structures or disconnected nanocrystalline grains embedded in the walls. Crystallization of the walls to bulk oxides occurs upon exhaustive thermal treatment, resulting in a collapse of the mesostructure. Thus, high surface area and porosity is normally offset by crystallinity. In light of these observations, the difference of activity between S2 and S7 likely results from their different surface areas.

Fe^{3+}-doped mesoporous tantalum oxides

To get higher activities, we prepared a series of Fe^{3+}-doped Ta oxides with different loading levels. The XRD pattern and the N_2 adsorption and desorption isotherm of the 1 wt% Fe^{3+}-doped sample are also shown in Figs. 1 and 2, respectively. Surprisingly, the BET surface area of this sample decreased by more than two-thirds, i.e., from the original 624 m^2/g to 199 m^2/g, although the HK pore size remains unchanged. After carefully examining each step of preparation, we found the loss in surface area originates mainly from the aqueous impregnation of $Fe(NO_3)_3$. This phenomena is not uncommon as (26, 27) the Davis group reported that Ru/MCM-41, when impregnated with $CsNO_3$ in aqueous solution, experiences a loss of surface area to 623 m^2/g from 1058 m^2/g and a loss of total pore volume to 0.417 cm^3/g from 1.015 cm^3/g. This effect is likely related to the surface tension of water confined in the nanopores. Liquid water has a much higher surface tension (72.75×10^{-3} N m^{-1} at 20 °C) than organic solvents (23.7 0^{-3} N m^{-1} for acetone, at 20 °C).

XPS spectra of Fe^{3+}-doped tantalum oxides for Ta 4*f* and N 1*s* regions are quite similar to those of pure mesoporous tantalum oxides, except that the two peaks of Ta $4f_{5/2,\ 7/2}$ show slight broadening and are relatively weaker in intensity, which can be attributed to a broader distribution of Ta sites in the walls of the material. The Fe 2*p* region in all materials could not be resolved due to the very low content of this element.

The activities of all Fe^{3+}-doped catalysts from the experiments are listed in Table 1. Clearly, the highest activities appear on the 1 wt% Fe^{3+}-doped samples, S5 and S8. Although the underlying reason for this Fe-induced enhancement of activity is not completely clear, it may be related to a modification of the band-gap region and (or) formation of a permanent space charge region in the walls. Fe has always been one of the best choices for the photocatalytic conversion of dinitrogen to ammonia (9). For example, Palmisano et al. (9) demonstrated that the pure TiO_2, with band-gap energy in the near-UV, is not active under visible light, but doping with Fe extends the light absorbed by TiO_2 to the visible region. An optimal doping is achieved when a space charge region exists with an electric force more than 0.2 eV, whose thickness is more or less equal to the light penetration depth, which ensures all the generated electron-hole pairs are efficiently separated. Tantalum oxides possess a band-gap energy of 4.0 eV and absorb in the near-UV without doping, so that the modification of the bang-gap region should not be necessary. In fact, pure tantalum oxide (S7) demonstrates moderate photocatalytic activity, while the activity of the 0.3% Fe^{3+}-doped sample (S3) is actually lower than that of pure tantalum oxide (S2, S7). However, this surprising observation can be rationalized when considering the additional and offsetting effect of the loss of surface area resulting from aqueous impregnation.

The nearly identical activities of S5 and S8 are also of some interest. From the standpoint of surface area alone, S8 should have higher activity than S5. After careful examination of the experimental data presented in Figs. 6 and 7, it becomes evident that S5 has more preadsorbed NH_3 than S8 although they have theoretically the same wt% of $Fe(NO_3)_3$-doping content. This suggests that more catalytically active Fe is present in S5 than in S8, possibly because of the longer calcination time. Since we cannot identify the exact phase(s) of Fe(III) from XRD and XPS because of the low level of Fe, it is not possible at this stage to establish any structure–property relationships that might elucidate the nature of the active Fe centers. The higher content of more active Fe in S5 counteracts the disadvantage of lower surface area, bringing the two samples to the same level of activity.

Mesoporous Ta oxide reduced with bis (toluene) titanium

To improve the activities of these catalysts by improving electron-hole separation on the surface of the Ta oxide mesostructure, we pursued methods of improving surface conductivity in these otherwise insulating structures. The development of a stoichiometric process for fixing dinitrogen on the surface of a mesoporous oxide reduced with a bis(toluene) metal species (17, 18) was an extension of previous work in which organometallic sandwich compounds were used as reducing agents to make low-dimensional molecular conductors in the pores of the mesostructure (28–32). The introduction of the organometallic into the pores was similar to a classical redox intercalation reaction in which an electron donor reduces the walls of the inorganic host to create a material with periodic charge regions consisting of a anionic metal oxide phase and a cationic dopant intercalate phase. In the case of bis(toluene) titanium and mesoporous Ta oxide, the organometallic acts as a reductant, but does not retain its structural integrity on loss of electrons, instead losing the toluene ligands to essentially deposit Ti atoms on the surface of the mesostructure while also reducing the mesostructure. XPS studies show that there are several Ta and Ti environments in this material, including a low-valent Ti species that

reacts almost spontaneously with dinitrogen to create surface nitride (24). Charge balancing of this highly reduced mesoporous system requires that the electron-depleted, low-valent coat have a cationic charge and the partially reduced higher valent coat have a negative charge. This morphology should create a depletion zone between the two layers similar to that between a p–n junction, which may be useful in promoting electron-hole separation in a photocatalytic process involving dinitrogen, since coating of n-doped titania with a p-doped conducting polymer creates a p–n junction with a depletion region that improves the thermodynamics of nitrogen reduction by water (10). By analogy, the bis(toluene)-Ti-reduced mesoporous Ta oxide may thus show very high activity towards dinitrogen in photocatalysis. These reduced materials are metallic or semiconductors depending on the degree of reduction, while other reduced mesoporous oxides are insulators. The highly conducting nature has been attributed to the low-valent coat on the surface, and implies that the surface states are continuous in nature. This may provide a further advantage in photocatalysis, as surface defects and localized electron traps have been indicated as reasons why amorphous oxides usually have poor electron-hole separation properties (19). Thus, the modification of mesoporous Ta oxide with bis(toluene) titanium to create a metallic oxide coat on the surface of the material may represent a strategy of overcoming electron localization leading to electron-hole pair recombination, since electrons tend to drift towards metallic regions on the surfaces of photocatalysts, and these reduced mesoporous oxides must have a more continuous band structure with fewer surface defects to display such high conductivities.

Surprisingly, our catalytic runs with the bis(toluene)-Ti-reduced mesoporous Ta oxide catalyst did not give better results than pure tantalum oxide (see Table 1, S7 vs. S9). The most likely explanation for this is that although bis (toluene) titanium increases the surface conductivity and creates sites capable of splitting dinitrogen, this surface coat is very air sensitive and possibly degrades as O_2 is formed over the course of the reaction. For this reason, it may be more effective to coat the inner surface of the material with a more robust semiconducting polymer to create an internal p–n junction capable of effecting superior electron-hole separation without degrading during the catalytic process. Since uniformly coating the inside mesoporous materials without clogging the pores is not trivial, requiring careful selection of catalyst dopants on the inner surface and control of polymer substrate concentrations, this strategy represents the body of an independent study.

Conclusion

For the first time, we have studied the photocatalytic conversion of dinitrogen to ammonia over a mesoporous Ta-oxide-based catalyst. All catalysts studied showed low to moderate activity and the 1 wt% Fe-doped catalysts show comparable molar activities to Schrauzer's initial results. Higher surface area, heat treatment, and Fe content were found to increase the activities, however, the latter two factors have an adverse effect on the first, i.e., surface area, such that optimization is hindered. Treatment of the material with bis(toluene) Ti had little effect on the photocatalytic activity, most likely because of the oxygen sensitivity of this material.

Functionalization and cleavage of coordinated dinitrogen via hydroboration using primary and secondary boranes[1]

Bruce A. MacKay, Samuel A. Johnson, Brian O. Patrick, and Michael D. Fryzuk

Abstract: The reaction of the side-on, end-on ditantalum dinitrogen complex $([NPN]Ta)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}N_2)(\mu\text{-}H)_2$ (where NPN = $PhP(CH_2SiMe_2NPh)_2$) with a variety of secondary and primary boranes is reported. With 9-BBN, hydroboration of the Ta_2N_2 unit occurs via B-H addition, which in turn triggers a cascade of reactions that result in N—N bond cleavage, ancillary ligand rearrangement involving silicon group migration, and finally elimination of benzene from the N-Ph group and a B-H moiety to generate the imide–nitride derivative. In the presence of excess 9-BBN, the Lewis acid – base adduct of the imide–nitride ($[NP\mu\text{–}N]Ta(=NBC_8H_{14})(\mu\text{-}NB(H)C_8H_{14})Ta[NPN]$) is formed. A similar set of reactions is observed for dicyclohexylborane (Cy_2BH), which hydroborates the dinitrogen complex to generate $[NPN]Ta(H)(\mu\text{-}\eta^1\text{:}\eta^2\text{-}NNBCy_2)(\mu\text{-}H)_2Ta[NPN]$, followed by loss of H_2 and silicon group migration to yield the imide–nitride $[NP\mu\text{–}N]Ta(=NBCy_2)(\mu\text{-}N)(Ta[NPN]$. With thexyl borane ($H_2BCMe_2CHMe_2$), a similar sequence of reactions is suggested starting with hydroboration to generate $[NPN]Ta(H)(\mu\text{-}\eta^1\text{:}\eta^2\text{-}NNB(H)C_6H_{13})(\mu\text{-}H)_2Ta[NPN]$, followed by loss of H_2 and ancillary ligand rearrangement. When bis(pentafluorophenyl)borane ($HB(C_6F_5)_2$) is used, no hydroboration of coordinated N_2 is observed, rather simple adduct formation to give $([NPN]Ta)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}NN\text{-}B(H)(C_6F_5)_2)(\mu\text{-}H)_2$ occurs.

Key words: dinitrogen, tantalum, hydroboration, N—N bond cleavage.

Résumé : On rapporte les résultats de la réaction du complexe de diazote ditantale $([NPN]Ta)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}N_2)(\mu\text{-}H)_2$ (dans lequel NPN = $PhP(CH_2SiMe_2NPh)_2$) avec une variété de boranes secondaires et primaires. Avec le 9-BBN, l'hydroboration de l'unité Ta_2N_2 se produit par une addition B-H, qui provoque à son tour une cascade de réactions conduisant à une rupture de la liaison N—N, un réarrangement du ligand impliquant une migration du groupe du silicium et finalement l'élimination du benzène du groupe N-Ph et une portion B-H pour générer la formation du dérivé imide–nitrure ($[NP\mu\text{–}N]Ta(=NBC_8H_{14})(\mu\text{-}NB(H)C_8H_{14})Ta[NPN]$). On observe un ensemble de réactions semblables avec le dicyclohexylborane (Cy_2BH) qui provoque une hydroboration du complexe de diazote pour générer le $[NPN]Ta(H)(\mu\text{-}\eta^1\text{:}\eta^2\text{-}NNBCy_2)(\mu\text{-}H)_2Ta[NPN]$, suivie d'une perte de H_2 et de la migration du groupe du silicium pour conduire à la formation de l'imide nitrure $[NP\mu\text{–}N]Ta(=NBCy_2)(\mu\text{-}N)Ta[NPN]$. Avec le thésylborane ($H_2BCMe_2CHMe_2$), la réaction suivrait un cours semblable qui débuterait avec une hydroboration pour générer le $[NPN]Ta(H)(\mu\text{-}\eta^1\text{:}\eta^2\text{-}NNB(H)C_6H_{13})\text{-}(\mu\text{-}H)_2Ta[NPN]$, suivie d'une perte de H_2 et d'un réarrangement de ligand. Avec le bis(pentafluorophényl)borane ($HB(C_6F_5)_2$), on n'observe pas l'hydroboration du N_2 coordiné, uniquement la formation d'un adduit simple qui génère le $([NPN]Ta)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}NN\text{-}B(H)(C_6F_5)_2)(\mu\text{-}H)_2$.

Mots clés : diazote, tantale, hydroboration, scission de la liaison N—N.

[Traduit par la Rédaction]

Introduction

The activation of small molecules by metal complexes is a mature area of inorganic chemistry. Nevertheless, molecular nitrogen, one of the most abundant small molecules in the biosphere, continues to frustrate inorganic chemists because of its intrinsic lack of reactivity (1–5). Under extreme conditions, N_2 will react with H_2 over an activated iron surface to generate ammonia; this energy-intensive catalytic transformation, known as the Haber–Bosch process, supplies the global need for NH_3-derived fertilizers (6). While discovery of a homogeneous version of the Haber–Bosch process is the goal of a number of groups around the world (7, 8), another worthwhile goal is to develop a process that converts molecular nitrogen to high-value organonitrogen materials, such as amines, substituted hydrazines, and *N*-heterocycles (9–15).

A key challenge in devising any homogeneous catalytic cycle involving molecular nitrogen is coordination of N_2 to the metal centre. Because dinitrogen is intrinsically unreactive, formation of N_2 complexes is not straightforward.

Scheme 1.

Scheme 2.

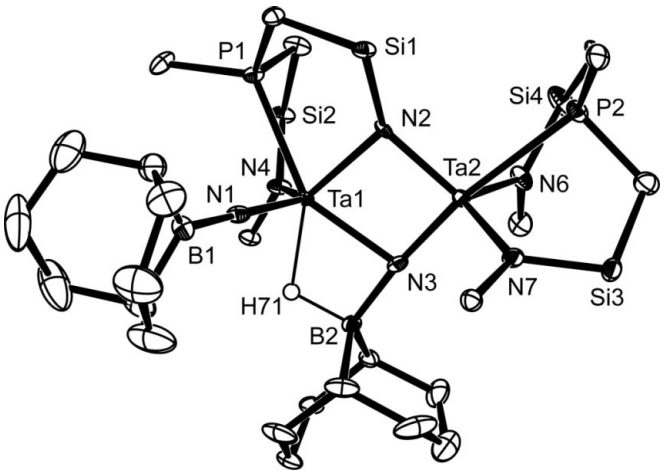
Since the first report of a dinitrogen complex in 1965 (16), many N_2 derivatives have been synthesized (17–20). The most common method of synthesis generally requires strongly reducing conditions, which unfortunately is incompatible with many functionalization protocols. Recently, we reported (21) a facile method for the formation of a ditantalum dinitrogen complex that involves reaction of N_2 with the ditantalum tetrahydride **1** (Scheme 1). This reaction proceeds smoothly to generate the side-on, end-on dinitrogen complex **2** without the necessity of added reducing agents. It occurred to us that multiple additions of some simple hydride reagent (E-H) across the Ta_2N_2 core of **2** could regenerate the starting tetrahydride **1** and produce a functionalized hydrazine moiety (N_2E_4). Since addition of N_2 to **1** reforms the dinitrogen complex **2**, this could result in a catalytic sequence.

To test this hypothesis, we have examined the reaction of **2** with a number of simple hydride reagents, and preliminary communications have already been published (22, 23). In the case where E-H is 9-borabicyclo[3.3.1]nonane (9-BBN), one E-H addition occurs cleanly; however, a catalytic cycle was precluded because of an ancillary ligand dominated rearrangement. Nevertheless, this work did allow the discovery of a new type of N—N bond cleavage process that results from functionalization of coordinated N_2. In this paper, we report the full details of the reaction of the dinitrogen complex **2** with some primary and secondary boranes.

Results and discussion

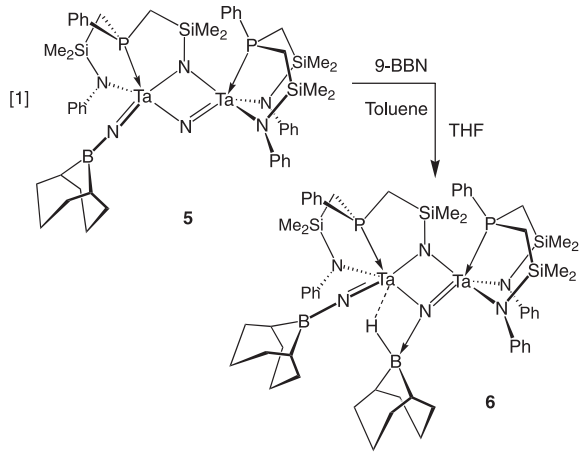
As summarized in Scheme 2, our initial attempt at E-H addition to **2** using 9-BBN resulted in the first example of a hydroborated dinitrogen complex (**3**). It was found that addition product **3** is thermally unstable and undergoes H_2 elimination and N—N bond cleavage, presumably via the unobserved intermediate **A**, followed by silicon migration from the ancillary ligand to the bridging nitride to generate **4**. We presume that the final step is elimination of benzene via the B—H bond and the phenyl of the Ta=N-Ph unit to generate the final imide-nitride **5**. Postulation of this proposed scheme was facilitated by the X-ray crystal structures of intermediates **3** and **4**, and final product **5**, along with detailed labeling experiments (22).

Attempted second hydroboration — Synthesis and characterization of [NPN]Ta(H)(μ-N_2-B(C_6H_{11})$_2$)(μ-H)$_2$Ta[NPN] (6)



Having established that hydroboration of **2** with 9-BBN leads to N—N bond cleavage and the formation of reactive nitrides, we examined multiple additions of 9-BBN to further test the catalytic plan shown in Scheme 1. Addition of 2 or more equiv. of 9-BBN to **2** resulted in a complicated mixture of products as observed by ^{31}P NMR spectroscopy. Although none of the products were immediately identifiable, there did seem to be a major product present; unfortunately, it could not be separated from the other materials present. Fortuitously, addition of 1 equiv. of 9-BBN to imide–nitride **5** resulted in the clean formation of this same major product unencumbered by impurities. This new complex **6** has two resonances (1:1 integration) in its ^{31}P NMR spectrum that are distinct from those of **5**, and the ^{1}H NMR spectrum does not feature resonances indicative of tantalum hydrides. To determine its identity, crystals of **6** were obtained from a cooled THF solution and subjected to X-ray diffraction analysis.

The solid-state molecular structure of **6** (Fig. 1) shows that a simple Lewis acid – base reaction between the bridging nitride in **5** and the B atom of 9-BBN has taken place. This second equiv. of 9-BBN occupies a position roughly equal to that of the single 9-BBN fragment in intermediate **4** (Scheme 2). The N3—B2 bond length of 1.516(5) Å suggests a N—B single bond (24). The borylimido group is deflected towards the phosphine donor Pl by the presence of the second equiv. of 9-BBN. Other than this, complex **6** is very similar in structure to **5**.



In solution, the presence of the boron hydride is implied by a broad ^{1}H NMR resonance integrating to one proton at δ 4.32 ppm. In the solid state, hydrogen atom H71 was re-

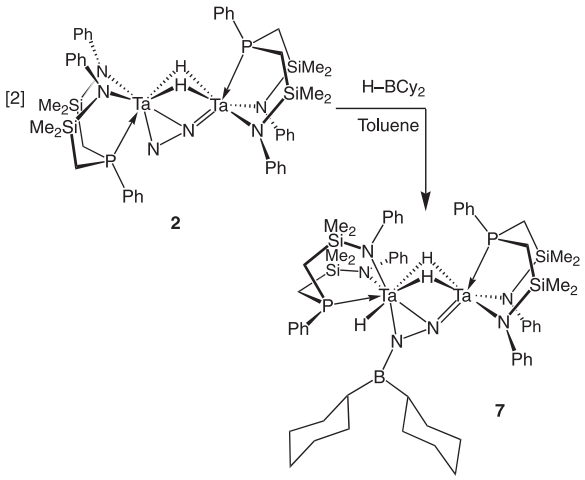
Selected bond lengths (Å), bond angles (°), and torsion angles (°): Ta1—N1 1.824(3), N1—B1 1.404(5), Ta1—N2 2.175(3), N2—Ta2 1.947(3), Ta2—N3 1.854(3), N3—Ta1 2.156(3), N3—B2 1.516(5), N2—Si1 1.738(3), Ta1—N4 2.126(3), Ta1—P1 2.5825(10), Ta2—N5 2.091(3), Ta2—N6 2.048(3), Ta2—P2 2.7737(10); Ta1-N2-Ta2 93.87(11), N2-Ta2-N3 91.05(12), Ta2-N3-Ta1 97.23(13), N3-Ta1-N2 77.58(11), Ta1-N1-B1 179.3(3), Ta1-N3-B2 88.6(3), N1-Ta1-P1 86.99(10), N1-Ta1-N4 123.12(13), Ta1-N2-Si1 139.05(16), N3-Ta2-N5 101.25(13), N3-Ta2-N6 103.04(12), N3-Ta2-P2 171.01(9), Ta1-N2-Ta2-N3 3.87(11), Ta1-Ta2-N2-Si1 6.9(6), N1-Ta1-N2-Ta2 –117.54(13), P1-Ta1-Ta2-P2 13.46(4), Ta2-N2-Ta1-N4 98.92(14).

fined isotropically, and thus its position as shown in Fig. 1 is likely based on the structures obtained for **4** as well as the position and coordination geometry of B2. This reaction is shown in eq. [1]. Significantly, the intramolecular reaction to give **5** from **3** proceeds whether additional hydroboration

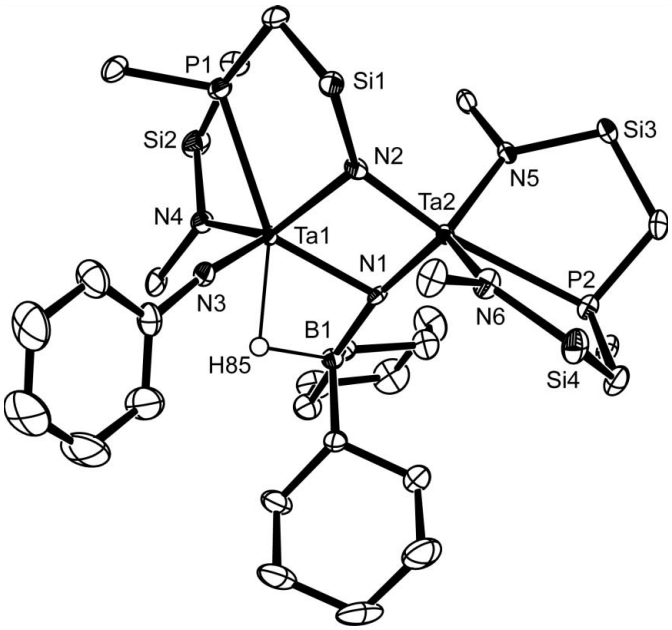


reagent is present or not; as mentioned above, the 2:1 reaction between 9-BBN and **2** also gives mostly **6** when this reaction is monitored by ^{31}P NMR spectroscopy, indicating that 9-BBN is not competent to intercept the nascent nitrido intermediate postulated in the transformation of **4** to **5**, either by hydroboration or simple Lewis acid adduct formation. This precludes hydroboration as the appropriate E-H addition to completely satisfy the proposal of Scheme 1.

A homologous series of complexes prepared with dicyclohexylborane (Cy_2BH) and thexyl borane ($H_2BCMe_2CHMe_2$)

We wondered about the generality of the cascade of reactions shown in Scheme 2. The ability to cleave coordinated N_2 and to generate a new N—B bond was incentive to examine whether or not other borane reagents would engage in similar outcomes or in fact open up new reaction pathways. Given the ready availability of different organoborane reagents, this seemed worthwhile.

The reaction of 1 equiv. of dicyclohexylborane (Cy_2BH) with **2** in toluene gives [NPN]Ta(H)(μ-η^1:η^2-NNBCy_2)(μ-H)$_2$Ta[NPN] (**7**) in 93% yield after stirring for 12 h (eq. [2]).



Identification of **7** was facilitated by the similarity of its ^{1}H and ^{31}P NMR spectra to those of the initial 9-BBN adduct (**3**). Thus, the ^{1}H NMR spectrum of **7** indicates C_1 solution symmetry (eight silyl methyl resonances and two separate one-proton resonances associated with bridging hydrides are present), and a new resonance at δ 16.04 ppm implies the existence of a new terminal hydride, as was found for **3**. The solid-state molecular structure of **7** was not established.

Does **7** decompose in the same manner as **3** (Scheme 2)? Toluene or THF solutions of **7** show conversion to [NPμ-N]Ta(=NPh)(μ-NB(H)Cy_2)Ta[NPN] (**8**) in similar yield and on a time scale comparable to the decomposition of **3** into **4**. Therefore, hydroboration and N—N bond cleavage are both possible using Cy_2BH interchangeably with 9-BBN. The solid-state molecular structure of **8** has been determined and it is shown in Fig. 2. The relative orientations of the phenylimido ligand and H85 are similar to **4**. The fact that N—N bond scission and silyl group migration from an [NPN] ligand amide to the new dinitrogen-derived nitrido ligand have occurred in an exactly analogous fashion is evident. Bond lengths and angles are comparable to those of **4**, except that the [NPN] ancillary ligand bound to Ta2 of complex **8** is rotated by 70° about the Ta-Ta axis as compared to its position in **4**.

Like its 9-BBN analogue **4**, **8** is observed via NMR spectroscopy to eliminate benzene in d^8-THF solution, and at the

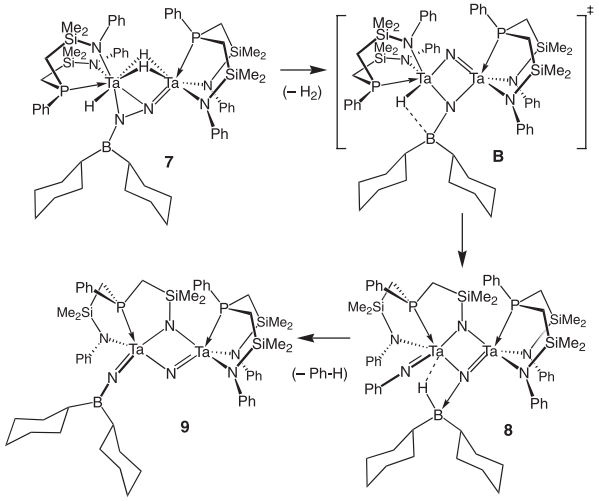

Fig. 2. ORTEP drawing (spheroids at 50% probability) of **8** ([NPμ-N]Ta(=NPh)(μ-NB(H)Cy_2)Ta[NPN]). Silyl methyl and phenyl ring carbons other than ipso omitted for clarity. H85 was located in the electron difference map and refined isotropically. Selected bond lengths (Å), bond angles (°), and torsion angles (°): Ta1—N1 2.142(3), Ta1—N2 2.191(3), Ta1—N3 1.788(3), Ta1—N4 2.146(3), Ta1—P1 2.6370(11), N1—B1 1.532(7), B1—H1 1.59(6), Ta1—H1 1.90(8), N2—Si1 1.738(3), N1—N2 2.675(3), Ta2—N5 2.070(3), Ta2—N6 2.066(3), Ta2—P2 2.7897(10); N1-Ta1-N2 76.31(12), Ta1-N2-Ta2 94.88(12), N2-Ta2-N1 90.40(13), Ta2-N1-Ta1 98.41(13), Ta1-N1-B1 89.8(2), N1-B1-H1 90.2(6), N1-Ta1-N3 117.17(13), N1-Ta1-N4 114.08(11), N1-Ta1-P1 136.84(8), N1-Ta2-N5 114.35(12), N1-Ta2-N6 117.00(13), N1-Ta2-P2 99.46(9), Ta1-N2-Ta2-N1 0.25(11), P1-Ta1-Ta2-P2 –143.96(4), N1-Ta1-N2-Si1 –176.8(2), N2-Ta1-N1-B1 –169.8(2).

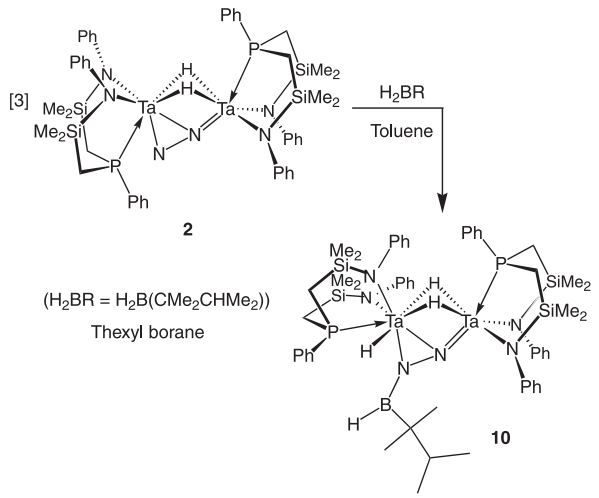
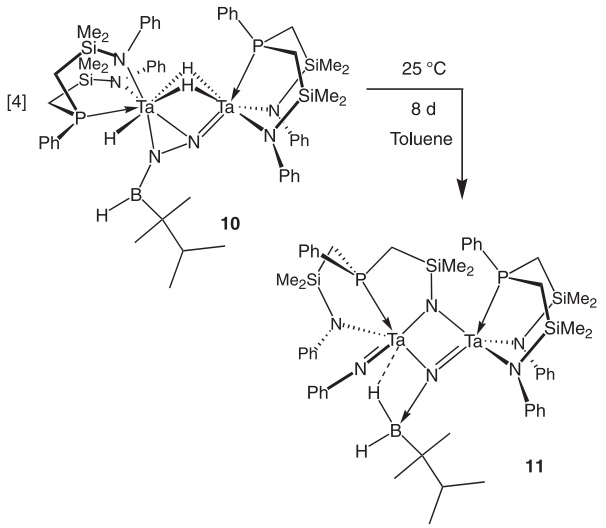


same time, ^{31}P NMR resonances of a new species (**9**) arise. Identification of this complex as ([NPμ–N]Ta(=NBCy_2)(μ-N)Ta[NPN] was made by ^{1}H and ^{31}P NMR spectroscopy in analogy to that already shown in Scheme 2. This new imide–nitride **9** forms cleanly from **8** in an overall yield of 83% as measured by ^{31}P NMR spectroscopy against an internal reference. This is an improvement over the conversion of **4** to **5**, in which many other ^{31}P NMR-active side-products were detected. Although the change from 9-BBN to dicyclohexylborane does not significantly attenuate hydroboration of **1** or N—N bond cleavage, it did increase the yield of **9** vs. the yield of **5**. In Scheme 3, this chemistry is summarized starting with hydroboration adduct **7**; loss of H_2 triggers N—N bond cleavage, presumably through an unobserved intermediate such as **B**, which then undergoes silicon migration from the ancillary [NPN] ligand to generate **8** and finally **9** via loss of benzene. Presumably, addition of another equivalent of dicyclohexylborane to **9** would produce an adduct similar to **6** in eq. [1]; however, this was not pursued.

Since hydroboration of **2** and N—N bond cleavage occurred for the secondary boranes 9-BBN and Cy_2BH, it was of interest to examine the course of the reactions with a primary borane. The presence of another boron hydride for intramolecular reactions after an initial hydroboration suggested the possibility of different post-hydroboration reaction paths including another potential opportunity to form N—H bonds. The 1:1 reaction between **2** and thexyl borane ($H_2BCMe_2CHMe_2$) proceeds to completion over 12 h as shown in eq. [3] to give [NPN]Ta(H)(μ-η^1:η^2-NNB(H)C_6H_{13})(μ-H)$_2$Ta[NPN] (**10**) in 92% yield.

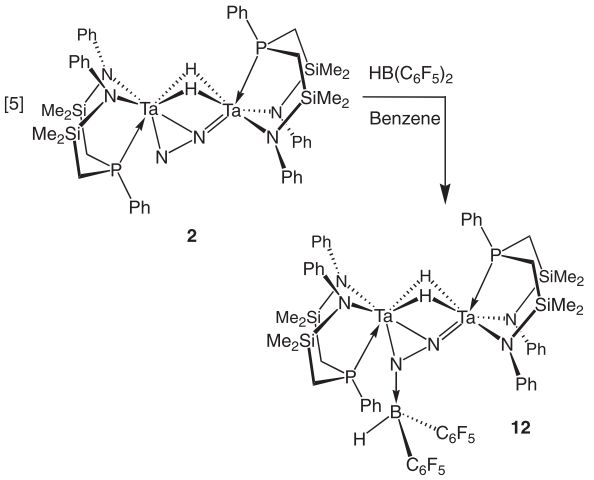
Scheme 3.



Although crystals suitable for X-ray diffraction were not isolated, the ^{1}H NMR spectrum of **10** shows the expected C_1 symmetry and the new resonance characteristic of a terminal hydride at δ 15.52 ppm, analogous to that already observed for **3** and **7**. The remaining boron hydride is evident as a broad singlet at δ 4.42 ppm that integrates to one proton.

As for complexes **3** and **7**, solutions of **10** are thermally unstable. The rearranged product (**11**) has no resonances suggestive of bridging or terminal hydride ligands in its ^{1}H NMR spectrum, and the ^{31}P NMR resonances of **11** do not unequivocally make it a sister complex to **4** or **8**. The ^{1}H NMR spectrum is indicative of C_1 symmetry, and the resonances can be assigned as [NPμ-N]Ta(=NPh)(μ-N$B(H)_2C_6H_{13}$)Ta[NPN], as shown in eq. [4].

© 2005 NRC Canada



Satisfactory elemental analysis was obtained for this formulation, but the solid-state molecular structure of **11** has not been established. The only indication that **11** might be other than that suggested is that it does not degrade via elimination of benzene to a congener of **5** or **9**. Instead it can be observed by ^{31}P NMR spectroscopy to convert into a number of different products over a week. None of these were spectrally related to **5** or **9**. Hydroboration of **2** with thexyl borane may lead to new rearrangements for **8** that were not observed with secondary boranes, but characterization of the resulting complexes has not been possible. It is likely that the additional B-H functionality coupled with the already documented propensity for ancillary ligand rearrangements in this system renders this combination too reactive. With group 6 dinitrogen complexes, the reaction with thexyl borane results in a totally different and distinct outcome than described herein (25) (Table 1).

Synthesis of ([NPN]Ta)$_2$(μ-η^1:η^2-NN-B(H)(C$_6$F$_5$)$_2$)(μ-H)$_2$ (12)

Although the dinitrogen unit of **2** can be derivatized by hydroboration, it is not clear how to remove the functionalized dinitrogen moiety or the dinitrogen-derived atoms in the descendant complexes from the bimetallic core, because the Ta–N interactions remain quite strong. It was postulated that a more Lewis acidic borane might react in a similar manner to 9-BBN, but would remove additional electron density from the dinitrogen moiety, and thus greatly weaken the Ta—N bonds. A straightforward synthesis of the strongly Lewis acidic secondary borane HB(C$_6$F$_5$)$_2$ has recently been reported (26, 27), and so the reactivity of this borane with **2** was investigated.

The reaction of HB(C$_6$F$_5$)$_2$ with complex **2** occurs immediately; however, the colour of the solution changes from the red-brown of **2** to a dark yellow-brown colour, rather than to an orange colour as observed for the B-H addition adducts **3**, **7**, and **10**. Two new resonances are observed in the ^{31}P NMR spectrum at δ 10.0 and δ 22.8 with a J_{PP} value of 25.1 Hz. A broad peak at δ 4.7 in the ^{1}H NMR spectrum integrates to a single proton. The location and broadness of this resonance identifies it as a hydrogen atom bound to boron. A similar peak is observed in the ^{1}H NMR spectrum of the starting borane HB(C$_6$F$_5$)$_2$. The ^{15}N NMR spectrum of the ^{15}N$_2$-enriched complex ***^{15}N$_2$*-12**, which was prepared by the reaction of ***^{15}N$_2$*-2** with HB(C$_6$F$_5$)$_2$, contains two resonances, at δ –46.9 and δ 24.0. The resonance at δ –46.9 is a doublet of doublets, with a $^2J_{NP}$ value of 25.9 Hz and a $^1J_{NN}$ value of 15.3 Hz. As for ***^{15}N$_2$*-2**, the chemical shift of this resonance and the large coupling to ^{31}P indicates that this is the end-on nitrogen. The chemical shift of the second ^{15}N resonance (δ = 24.0) is much closer to that observed in the B(C$_6$F$_5$)$_3$ adduct of ***^{15}N$_2$*-2** (δ 2.4) than to ***^{15}N$_2$*-3** (δ –114.8), where a tantalum hydride bond is formed. This reaction product is, therefore, not related to complexes **3**, **7**, and **10**, which are the products of B-H addition. Rather, this spectral information indicates that **12** is more closely related to the Lewis acid – base adducts of **2** with B(C$_6$F$_5$)$_3$, GaMe$_3$, and AlMe$_3$, (28) and can be assigned as [NPN]Ta(μ-η^1:η^2-NN-B(H)(C$_6$F$_5$)$_2$)(μ-H)$_2$Ta[NPN]. As for these complexes and parent complex **2**, the solution symmetry of **12** is C_s as evidenced by the four unique silyl methyl resonances in its ^{1}H NMR spectrum. The formation of complex **12** is illustrated in eq. [5].

This assignment was confirmed by X-ray crystallography. An ORTEP drawing of the solid-state molecular structure of **12** is shown in Fig. 3. Hydrides were not located in the diffraction experiment, but the Ta$_2$N$_2$ core bonding and the relative disposition of the ancillary [NPN] ligands is reminiscent of parent complex **2** and of its Lewis acid adducts.

Upon hydroboration, the N—N bond was elongated from 1.319(4) Å in **2** to 1.411(15) Å in **3**. The same bond in **12** is only marginally elongated as compared to the starting dinitrogen complex and the other metric parameters of the Ta$_2$N$_2$ core are similar. Therefore, derivatizaton of the coordinated N$_2$ unit of **2** with strongly Lewis acidic boranes does not affect core bonding. Like **2** and its Lewis adducts, **12** is a stable molecule as compared to **3**, **7**, and **10**, and it shows no propensity to undergo the reductive elimination and N—N bond scission common to these complexes. It seems that addition of the H—B bond across the exposed Ta=N bond of **2** is a precondition for these processes. The theoretically predicted reversal of the polarity of this bond in HB(C$_6$F$_5$)$_2$ vs. dialkylboranes may preclude this reaction, implying that E—H bond polarity is a important consideration in selecting

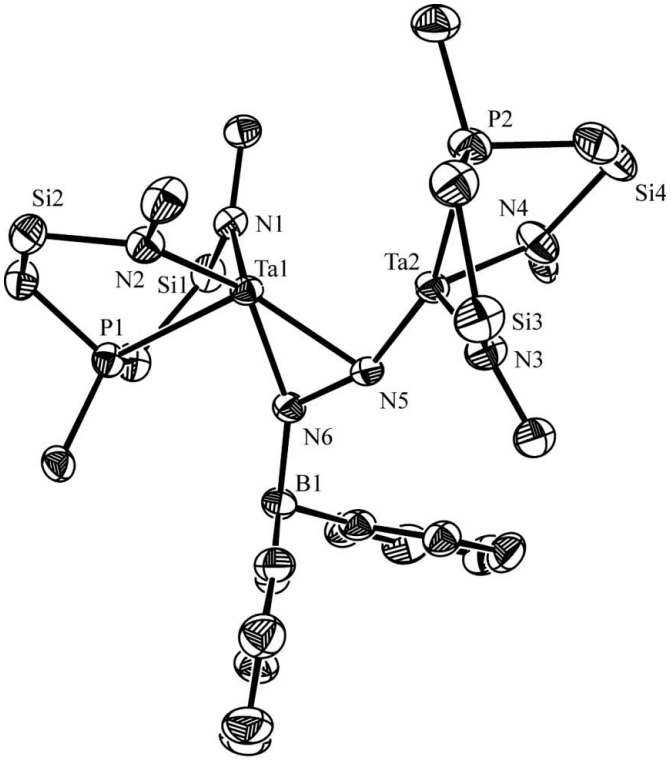
reagents for any scheme bent on using **2** for catalytic functionalization of N_2.

Summary

The initial study of the hydroboration of a dinuclear tantalum dinitrogen complex with 9-BBN has been extended to other monoalkyl- and dialkylboranes. In all cases, the N_2 complexes, derivatized by H—B bond addition across the exposed Ta=N bond, spontaneously undergo reductive elimination of two bridging hydrides as H_2 coupled to N—N bond cleavage without loss of the new B—N bond. This cascade of reactions is only somewhat attenuated by different substituents on the hydroboration reagent. Subsequent addition reactions across new Ta=N moieties do not occur, but the additional equivalents of hydroboration reagent can be incorporated into the complex as alkylborohydride adducts. Bis(pentafluorophenyl)borane $HB(C_6F_5)_2$ fails to react with the starting dinitrogen complex **2** in the same manner as the alkylboranes; instead, a stable adduct is formed, likely a result of the enhanced Lewis acidity of the boron centre owing to the presence of the perfluorophenyl substituents. This is summarized in Scheme 4.

Experimental section



General considerations

Unless otherwise stated, all manipulations were performed under an atmosphere of dry oxygen-free dinitrogen by means of standard Schlenk or glovebox techniques (Vacuum Atmospheres HE-553-2 glovebox equipped with a MO-40-2H purification system and a –60 °C freezer). Anhydrous hexanes and toluene were purchased from Aldrich, sparged with dinitrogen, and passed through columns containing activated alumina and Ridox catalyst before use. Anhydrous diethylether was stored over sieves and distilled from so-

dium benzophenone ketyl under argon. Pentane was stored over sieves and distilled from sodium benzophenone ketyl solublized by tetraglyme under dry dinitrogen prior to storage over a potassium mirror. Tetrahydrofuran was heated at reflux over CaH_2 prior to distillation from sodium benzophenone ketyl under argon. Nitrogen gas was dried and deoxygenated by passage through a column containing activated molecular sieves and MnO.

Deuterated benzene was dried by heating at reflux with sodium–potassium alloy in a sealed vessel under partial pressure, then trap-to-trap distilled, and freeze–pump–thaw degassed three times. Deuterated tetrahydrofuran and toluene were dried by refluxing with molten potassium metal in a sealed vessel under vacuum, then trap-to-trap-distilled, and freeze–pump–thaw degassed three times. Unless otherwise stated, ^{1}H, ^{31}P, ^{1}H{^{31}P}, ^{13}C, ^{11}B, ^{15}N, ^{29}Si-DEPT, and two-dimensional NMR spectra were recorded on either a Bruker AMX-500 instrument (5 mm BBI probe) operating at 500.1 MHz for ^{1}H or a Bruker AVA-400 instrument (5 mm BBI probe) operating at 400.1 MHz for ^{1}H. ^{1}H NMR spectra were referenced to residual proton in deuterated solvent as follows: C_4D_7HO (δ 3.58 ppm), C_6D_5H (δ 7.15 ppm), and

Scheme 4.

C_7D_7H (δ 2.09 ppm). ^{31}P NMR spectra were referenced to external $P(OMe)_3$ (δ 141.0 ppm with respect to 85% H_3PO_4 at δ 0.0 ppm) or internal $P(OMe)_3$ flame-sealed inside a 1 mm × 25 mm glass capillary tube if required, ^{13}C NMR spectra to $^{13}CC_5D_6$ (δ 128.4 ppm) and $^{13}CD_2Cl_2$ (δ 54.0 ppm), ^{11}B spectra to neat $BF_3{\cdot}Et_2O$ (δ 0.0 ppm), ^{15}N spectra to external nitromethane at 0.0 ppm, and ^{29}Si to Me_4Si 50% in $CDCl_3$ (δ 0.0 ppm). Elemental analyses were performed by Mr. P. Borda and Mr. M. Lakha, of The University of British Columbia Department of Chemistry.

The syntheses of complexes **1**, **2** (21), **3**, **4**, and **5** (22), dicyclohexylborane (29), thexyl borane (30), and $HB(C_6F_5)_2$ (27) were performed as described in the literature.

[NPμ-N]Ta(=N-BC$_8$H$_{14}$)(μ-NB(H)C$_8$H$_{14}$)Ta[NPN] (6)

To a stirred 15 mL toluene solution of **5** (298 mg, 0.229 mmol) was added dropwise 0.25 mL (1.1 equiv.) of 1.0 mol/L 9-BBN solution in THF. The resulting mixture was stirred overnight and the ^{31}P NMR spectrum of a small portion indicated that the reaction had proceeded to consume all of complex **5**, giving exclusively resonances of **6**. After evaporation of solvent and precipitation from pentane, 241 mg (0.169 mmol, 74% yield) of **6** was recovered on a frit. ^{1}H NMR (C_6D_6, 300 K, 400 MHz) δ: –0.69, –0.21, 0.05, 0.13, 0.25, 0.34, 0.43, (s, 3H each) SiCH_3; 0.84, 0.97 (d, 1H each) PCH_2, complicated overlapping multipets from 0.70 to 2.26 (total 39H), B-C_8H_{14} and PCH_2 (solvent was contaminated with a small amount of hexanes) 4.32 (b, 1H), B-*H*; 6.73, 6.79, 6.81, 6.85, 6.93, 7.07, 7.09, 7.20 (s, d, t, some peaks obscured by solvent) C_6H_5-N and C_6H_5-P; (7.51 (d, 2H, J_{HH} = 6.95 Hz), 7.94 (d, 2H, J_{HH} = 7.05 Hz), *o*-C_6H_5-P. ^{31}P NMR (C_6D_6, 300 K, 161.9 MHz) δ: –12.52 (b), 27.26 (s). Anal. calcd. for $C_{58}H_{86}B_2N_6P_2Si_4Ta_2$: C 48.88, H 6.08, N 5.90; found: C 49.12, H 6.23, N 5.81.

[NPN]Ta(H)(μ-η^1:η^2-NNBCy$_2$)(μ-H)$_2$Ta[NPN](7)

Toluene (25 mL) was added to an intimate mixture of dry **2** (0.412 g, 0.327 mmol) and white solid dicyclohexylborane (58.2 mg, 1 equiv.) in a glove box. The resulting mixture was stirred vigorously overnight, the solvent was evaporated, and the residues were triturated under hexanes, giving 0.438 mg (0.305 mmol, 93.2% yield) of **7**. ^{1}H NMR (500.1 MHz, C_6D_6, 300 K) δ: –0.37, –0.22, –0.17, –0.05, –0.10, –0.01, 0.09, 0.14 (s, 24H total), SiCH_3; 0.28, 0.40, 0.64, 0.73, 0.77, 0.86, 1.09, 1.15 to 1.34 (broad), 1.47, 1.59,

and 1.77 (broad overlapping resonances), cyclohexyl and PCH_2; 6.61, 6.66, 6.73, 6.82, 6.88, 6.96, 7.13 to 7.26 (overlapping), 7.29, 7.38, and 7.70 (overlapping doublets, triplets, 20H total, some resonances obscured by solvent) P-C$_6H_5$ and N-C$_6H_5$; 8.14 (d, J_{PH} = 6.38 Hz), 8.24 (d, J_{PH} = 6.82 Hz), *o*-P-C$_6H_5$; 10.70 and 11.51 (d, 1H each, J_{HH} = 10.0 Hz) μ-H; 16.04 (d, J_{PH} = 14.6 Hz), Ta-*H*. ^{13}C NMR was not recorded. ^{31}P NMR (202.5 MHz, C$_6$D$_6$, 300 K) δ: 7.98 (d, J_{PP} = 10.2 Hz), 20.0 (d, J_{PP} = 10.2 Hz). Anal. calcd. for $C_{60}H_{87}BN_6P_2Si_4Ta_2$: C 50.07, H 6.09, N 5.84; found: C 50.35, H 6.34, N 5.48.

Decomposition of 7 to [NPμ-N]Ta(=NPh)(μ-NB(H)Cy$_2$)Ta[NPN] (8)

A capped THF solution of 396 mg (0.275 mmol) **7** was left in a glove box at ambient temperature for 3 weeks and then cooled in a –60 °C freezer, giving crystals of **8**. Yield 0.186 g, 0.129 mmol, 47%. ^{1}H NMR (400.1 MHz, C$_7$D$_8$, 300 K) δ: –1.13, –0.90, –0.09, –0.15, –0.36, 0.18, 0.34 (s, 24H total), SiCH_3; 0.50, 1.16 (d, 1H each) PCH_2; –0.01, 0.68, 0.87, 1.06, 1.33, 1.45, 1.48 (broad overlapping multiplets, total 26H) B-C$_6H_{11}$ and PCH_2; 4.09 (b, FWHM 32 Hz, 1H) B*H*; 6.28, 6.30, 6.34, 6.40, 6.50, 6.74, 6.83, 6.94, 7.00, 7.11, 7.18 (overlapping doublets, triplets, 20H total, some resonances obscured by solvent) P-C$_6H_5$ and N-C$_6H_5$; 7.84 (d, J_{PH} = 6.59 Hz), 7.49 (d, J_{PH} = 7.06 Hz), (10H total) *o*-P-C$_6H_5$. ^{13}C NMR (100.6 MHz, C$_7$D$_8$, 300 K) δ: –1.77, –0.80, –0.64, 0.30, 2.67, 2.75, 3.30, 5.39, Si*C*H$_3$; 32.85 (b), B-C_{ipso} of cyclohexyl; 11.14, 15.45, 18.19, 25.93, 26.05, *C*H$_2$ of cyclohexyl; 20.99, 25.32, 26.05, 26.41, 27.16, 29.99, 30.49, 31.58, P-*C*H$_2$; 118.27, 119.03, 120.98, 122.79, 123.16, 123.29, 125.70, 126.98, 127.15, 127.51, 127.74, 128.56, 133.56, 135.84 (some resonances obscured by solvent), P-*C*$_6$H$_5$ and N-*C*$_6$H$_5$; 127.62, 131.96, *o*-P-*C*$_6$H$_5$; 151.24, 158.19, ipso-P-*C*$_6$H$_5$. ^{31}P NMR (161.9 MHz, C$_7$D$_8$, 300 K) δ: –2.30 (d, J_{PP} = 3.1 Hz), 28.30 (d, J_{PP} = 3.1 Hz). Anal. calcd. for $C_{60}H_{85}BN_6P_2Si_4Ta_2$: C 50.14, H 5.96, N 5.85; found: C 50.28, H 6.13, N 5.46.

Decomposition of 8 to [NPμ-N]Ta(=NBCy$_2$)(μ-N)Ta[NPN] (9)

A d^8-THF solution of **8** suitable for NMR spectroscopy in a Wilmad NMR tube capped with a plastic stopper and sealed with ParaFilm laboratory film and bearing a sealed capillary containing internal standard was left in a glove box for 3 weeks. Spectra were acquired intermittently. After this time, the ^{31}P and ^{1}H NMR spectra were exclusively that of **8**, and the integration with respect to internal standard allowed evaluation of 83% yield. The total integration of other ^{31}P NMR active resonances was 6%. ^{1}H NMR (400.1 MHz, C$_7$D$_8$, 300 K) δ: –1.10, –0.88, –0.34, –0.13, –0.02, 0.18, 0.20, 0.33 (s, 3H each), SiCH_3; 0.49, 0.75, 0.89, 1.17, 1.21, 1.31, 1.55 (d, 1H each), P-CH_2; 0.6–1.6 (complicated overlapping multiplets, 22H total), B-(C$_6H_{11}$)$_2$; 3.81 (b, FWHM 28 Hz, 1H) B-*H*; 6.27, 6.34, 6.51, 6.57, 6.63, 6.67, 6.77, 6.83, 6.86, 6.95, 6.99, 7.03, 7.11, 7.16, 7.42, 7.57 (d, t, overlapping, 26H total) P-*C*$_6$H$_5$ and N-*C*$_6$H$_5$; 7.47, 7.83 (d, 2H each), *o*-P-*C*$_6$H$_5$. ^{31}P NMR (161.9 MHz, C$_7$D$_8$, 300 K) δ: 0.76 (d, J_{PP} = 5.94 Hz), 17.41 (d, J_{PP} = 5.94 Hz). Elemental analysis was not obtained.

[NPN]Ta(H)(μ-η^1:η^2-NNB(H)C$_6$H$_{13}$)(μ-H)$_2$Ta[NPN] (10)

To a stirred toluene solution of **1** (0.336 g, 0.266 mmol) was added 0.54 mL (0.27 mmol, 1.02 equiv.) of freshly prepared thexyl borane (0.5 mol/L in THF). After stirring overnight the solvents were evaporated, leaving an orange residue that was triturated under hexanes and recovered on a frit, giving 0.332 g (0.244 mmol, 91.8% yield) of solid pale orange **10**. ^{1}H NMR (400 MHz, C$_6$D$_6$, 300 K) δ: –0.32, –0.14, –0.05, 0.11, 0.17, 0.19, 0.25, 0.34 (s, 3H each), SiCH_3; 1.21, 1.41, 1.45, 1.59, 1.61, 1.67, 1.78, 1.81 (d, 1H each) PCH_2; 0.82, 0.89 (d, 3H each) 1.11, 1.23 (s, 3H each), B-C(CH_3)$_2$CH(CH_3)$_2$; 1.64 (m, ^{1}H) B-C(CH$_3$)$_2$C*H*(CH$_3$)$_2$; 4.42 (b, ^{1}H) B-*H*; 5.96, 6.07, 6.22, 6.28, 6.35, 6.66, 6.91, 6.94, 7.01, 7.12, 7.20, 7.22, 7.25 (d, t, total 26H), P-C$_6H_5$ and N-C$_6H_5$; 7.71, 7.92 (d, 2H each) *o*-P-C$_6H_5$; 10.2, 11.6 (d, ^{1}H each) Taμ*H*; 15.52 (s, ^{1}H) Ta*H*. ^{31}P NMR (161.9 MHz, C$_6$H$_6$, 300 K) δ: 8.73 (d, J_{PP} = 15.3 Hz), 24.16 (d, J_{PP} = 15.3 Hz). Anal. calcd. for $C_{54}H_{79}BN_6P_2Si_4Ta_2$: C 47.72, H 5.86, N 6.18; found: C 47.32, H 6.26, N 6.12.

[NPμ-N]Ta(=NPh)(μ-NB(H)$_2$C$_6$H$_{13}$)Ta[NPN] (11)

A 15 mL toluene solution of 0.328 g (0.241 mmol) **11** was allowed to stand in a glove box at ambient temperature for 8 days. The ^{31}P NMR spectrum of a portion of this solution showed no remaining **10**, and solvent was evaporated. Solid **11** (134 mg, 41% yield) was recovered on a frit after trituration under hexanes. ^{1}H NMR (400 MHz, C$_4$D$_8$O, 300 K) δ: –0.48, –0.43, –0.08, –0.02, 0.08, 0.11, 0.27, 0.34 (s, 3 H each, 24H total), SiCH_3; 0.55, 0.78, 1.20, 1.30, 1.57, 1.81, 2.22, 2.36 (d, 1H each), PCH_2; 0.73, 0.81, 1.40, 1.57 (s, 3H each), B-C(CH_3)$_2$CH(CH_3)$_2$; 3.58, 4.32 (b, 1H each), B-*H*; 6.76, 6.80, 6.96, 7.02, 7.05, 7.06, 7.09, 7.12, 7.14, 7.16, 7.19, 7.30, 7.33 (d, t, 1 and 2H each, 26H total) P-C$_6H_5$ and N-C$_6H_5$; 7.61, 8.02 (d, 2H each) P-C$_6H_5$. ^{31}P NMR (161.9 MHz, C$_4$D$_8$O, 300 K) δ: –6.68 (b), 18.55 (s). Anal. calcd. for $C_{54}H_{77}BN_6P_2Si_4Ta_2$: C 47.79, H 5.72, N 6.19; found: C 47.42, H 6.10, N 6.38.

([NPN]Ta)$_2$(μ-η^1:η^2-NNB(H)(C$_6$F$_5$)$_2$)(μ-H)$_2$ (12)

To a solution of **2** (0.7589 g, 0.6017 mmol) in 10 mL of C$_6$H$_6$ was added solid HB(C$_6$F$_5$)$_2$ (0.2081 g, 0.6017 mmol, 1.0 equiv.). The solution was allowed to stir for 3 h, and the product was then allowed to crystallize by slow evaporation. The solid was collected and dried, to yield ([(NPN]$_2$TaH)$_2$N$_2$(HB(C$_6$F$_5$)$_2$) as a brown solid (0.943 g, 97%). ^{1}H NMR (500 MHz, C$_7$D$_8$, 350 K) δ: –0.28, –0.07, –0.03, 0.03 (s, 24H total, SiCH_3), 0.61, 1.45, 1.68, 2.03 (AMX, 8H total, CH_2 ring), 4.7 (br, $W_{1/2}$ = 250 Hz, 1H, B*H*), 6.77, 6.87, 6.94, 6.98, 7.06, and 7.20 (overlapping m, 26 H, NPh and PPh), 7.02 and 7.57 (m, 4H total, PPh *o*-*H*), 11.56 (dd, $^2J_{HP}$ = 20.9 Hz, $^2J_{HP}$ = 17.3 Hz, 2H, Ta*H*). ^{1}H NMR (500 MHz, C$_7$D$_8$, 245 K) δ: –0.26, –0.26, –0.24, –0.17, 0.00, 0.09, 0.11, 0.41 (s, 24H total, SiCH_3), 0.63, 1.05, 1.20, 1.28, 1.36, 1.39, 1.67, 2.73 (AMX, 8H total, CH_2 ring), 4.7 (br, 1H, B*H*), 5.80, 6.16, 6.51, 6.75, 6.85 (m, 1H each, NPh or PPh) 6.91–7.37 (overlapping m, 18 H, NPh and PPh), 7.49 (m, 2H, PPh-*o*-*H*), 7.53 (m, 2H, PPh or NPh), 7.88 (m, 2H, PPh-*o*-*H*), 11.00 (br m, $^2J_{HH}$ = 14.2 Hz, 1H, Ta*H*), 11.67 (ddd, $^2J_{HH}$ = 14.2 Hz, $^2J_{HP}$ = 14.7 Hz, $^2J_{HP}$ = 31.9 Hz, 1H, Ta*H*). ^{31}P NMR (C$_7$D$_8$, 299 K) δ: 10.0 (d, $^2J_{PP}$ = 25.1, [NPN] ligand), 22.8 (d, $^2J_{PP}$ = 25.1, [NPN]

Synthesis and structure of a (NacNac)rhodium terminal dinitrogen complex[1]

Jason D. Masuda and Douglas W. Stephan

Abstract: Reaction of the ligand salt $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Li(Et_2O)$ with $[Rh(COE)(\mu\text{-}Cl)]_2$ proceeds to give the brown crystalline product $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Rh(N_2)(COE)$ (**1**) in 38% yield. X-ray crystallographic study of **1** confirmed the formulation and revealed that the terminally bound dinitrogen molecule exhibits a Rh—N distance of 1.943(4) Å and an N—N distance of 1.091(6) Å. Comparison to other Rh–N_2 complexes shows that the N—N distances reflect a complex admixture of the trans influence and the net electron density at the metal center.

Key words: rhodium, dinitrogen, diimine, structure.

Résumé : La réaction du sel ligand $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Li(Et_2O)$ avec le $[Rh(COE)(\mu\text{-}Cl)]_2$ conduit à la formation d'un produit cristallin de couleur brune, le $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Rh(N_2)(CEO)$ (**1**), avec un rendement de 38 %. Une étude du composé **1** par diffraction des rayons X a permis de confirmer sa formule et a révélé que, pour la molécule de diazote liée en position terminale, la distance Rh—N est égale à 1,943(4) Å et la distance N—N est égale à 1,091(6) Å. Une comparaison avec d'autres complexes Rh–N_2 montre que les distances N—N sont un reflet d'un mélange complexe de l'influence trans et d'une densité électronique nette au niveau du centre métallique.

Mots clés : rhodium, diazote, diimine, structure.

[Traduit par la Rédaction]

Introduction

The 40th anniversary of the discovery of dinitrogen complexes is being commemorated with this issue of the *Canadian Journal of Chemistry*. During the time since the initial discovery of a Ru–N_2 complex by Allen and Senoff (1), a variety of other metals have been shown to interact with N_2 in either a terminal or bridging fashion. Moreover, the reactivity of such species, have led to significant breakthroughs in the understanding of N_2 chemistry. This work has been reviewed (2–6). In continuing studies towards N_2 reduction, metals capable of both N_2 and H_2 activation have been targeted. While Rh complexes have a well-known ability to react with hydrogen, few Rh–N_2 complexes are known. Several examples of bridging bimetallic species have been described including $[Me_2C_6H(CH_2P\text{-}i\text{-}Pr_2)_2Rh]_2(\mu\text{-}N_2)$ (7), $[Me_2C_6H(CH_2P\text{-}t\text{-}Bu_2)(CH_2NEt_2)Rh]_2(\mu\text{-}N_2)$ (8), $[MeC_6H_2(CH_2P\text{-}t\text{-}Bu_2)_2ORh]_2(\mu\text{-}N_2)$ (9), $[(i\text{-}Pr_3P)_2RhH]_2(\mu\text{-}N_2)$ (10), and $[CH_2(P\text{-}t\text{-}Bu_2)_2RhCH_2\text{-}t\text{-}Bu]_2(\mu\text{-}N_2)$ (11) (Scheme 1). In addition, terminally bound N_2 complexes that have been characterized include $(Ph\text{-}t\text{-}Bu_2P)_2RhH(N_2)$ (12), $(i\text{-}Pr_3P)_2RhCl(N_2)$ (13), and $MeCH(CH_2CH_2P\text{-}t\text{-}Bu_2)_2Rh(N_2)$ (14). In these complexes, the presence of strong σ-donor ligands (phosphine, alkyl, aryl) is thought to strengthen the Rh to N_2 interaction via π backbonding (Scheme 2).

In this manuscript, we report the synthesis and X-ray structural study of the terminal N_2–Rh complex, $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Rh(N_2)(COE)$ (COE = cyclooctene), containing a bulky diimine ligand (NacNac). In a very recent communication, Chirik and co-workers (15) reported the analogous Ir complex.

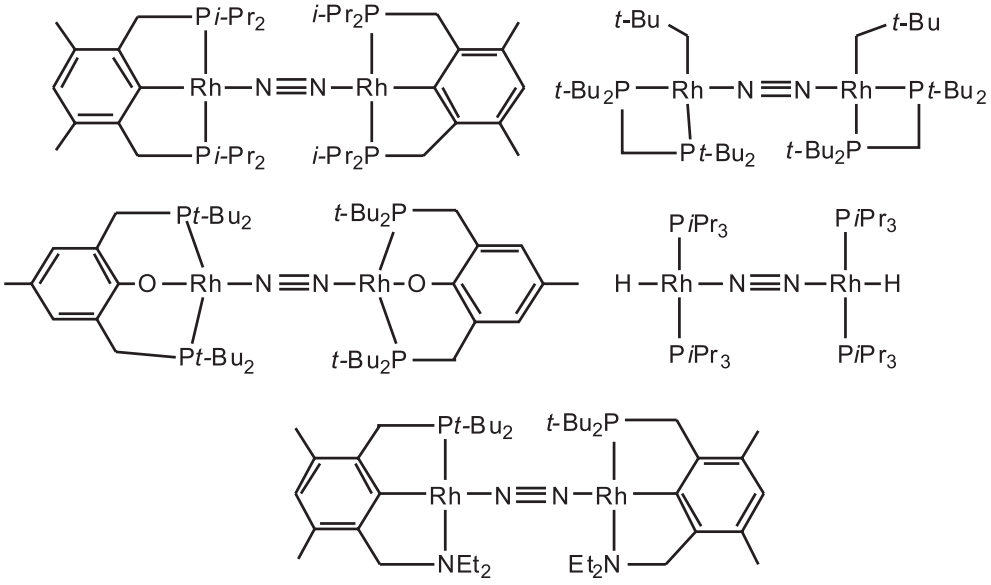
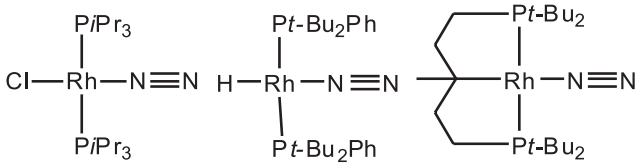
Experimental

General data



All preparations were done under an atmosphere of dry, O_2-free N_2 in a Vacuum Atmospheres inert atmosphere glovebox. Solvents were purified employing a Grubbs' type solvent purification system manufactured by Innovative Technology. Deuterated solvents were purified using the appropriate techniques. All organic reagents were purified by conventional methods. ^1H and ^{13}C NMR spectra were recorded on Bruker Avance-300 and -500 spectrometers. Trace amounts of protonated solvents were used as references and chemical shifts are reported relative to $SiMe_4$. Combustion analyses were done in house employing a PerkinElmer CHN analyzer. $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Li(Et_2O)$ was prepared following the literature procedure (16). $[Rh(COE)_2(\mu\text{-}Cl)]_2$ was purchased from the Strem Chemical Co.

Synthesis of $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Rh(N_2)(COE)$ (1)



To a solution of $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Li(Et_2O)$ (0.500 g, 1.00 mmol) in 10 mL Et_2O was added $[Rh(COE)_2(\mu\text{-}Cl)]_2$ (0.249 g, 0.50 mmol). The mixture was allowed to stir overnight whereupon the solution became dark brown-black. The mixture was filtered through Celite® and solvent was removed to give a dark semisolid. This material was dissolved

in pentane (5 mL) and again filtered through Celite®. Cooling the pentane solution to –35 °C gave 263 mg of a dark brown crystalline solid after work-up. Yield: 38%. IR (KBr pellet, cm^{-1}): 2175 (ν_{NN}), 1535 (ν_{NC}). ^1H NMR (0 °C): 6.98–7.13 (m, 6H, *m*, *p*-Ar, C_7D_7H), 5.12 (s, 1H, CH), 3.73 (br sept, 2H, CH, $J_{H\text{-}H}$ = 7 Hz), 3.46 (br sept, 2H, CH, $J_{H\text{-}H}$ = 7 Hz), 3.27 (br d, 2H, HC=CH, $J_{H\text{-}H}$ = 10 Hz), 1.59 (6H, Me), 1.58 (d, 6H, *i*-Pr, $J_{H\text{-}H}$ = 7 Hz), 1.47 (d, 6H, *i*-Pr, $J_{H\text{-}H}$ = 7 Hz), 1.41 (br m, 4H, CH_2), 1.20 (d, 6H, *i*-Pr, $J_{H\text{-}H}$ = 7 Hz), 1.14–1.29 (m, 8H, CH_2), 1.02 (d, 6H, *i*-Pr, $J_{H\text{-}H}$ = 7 Hz). ^{13}C NMR (25 °C, partial): 157.8, 152.0, 143.1, 142.7, 141.6, 130.3, 127.8–129.0 (m, obscured by toluene-d_8) 126.2, 125.4, 123.9, 123.7, 123.3, 97.3 (C-H, 74.9, (broad s, H-C=C-H), 30.7, 29.5, 28.9, 28.1, 26.5, 25.8, 25.0, 24.7, 24.4, 23.6. Anal. calcd. for $C_{37}H_{55}N_4Rh$: C 67.46, H 8.42, N 8.50; found: C 67.46, H 8.49, N 8.30.

X-ray data collection and reduction

Crystals were manipulated and mounted in capillaries in a glovebox, thus maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer. The data were collected in a hemisphere of data in 1448 frames with 10 s exposure times. The observed extinctions were consistent with the space groups in each case. The data sets were collected (4.5° < 2θ < 45–50.0°). The intensities of reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and XPREP processing packages. An empirical absorption correction based on redundant data was applied to each data set. Subsequent solution and refinement was performed using the SHELXTL solution package.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (17, 18). The heavy atom positions were determined using direct-methods employing the SHELXTL direct-methods routine. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on *F*, minimizing the function $\omega (F_o - F_c)^2$ where the weight ω is defined as $4F_o^2/2\sigma(F_o^2)$, and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of each refinement, all non-hydrogen atoms were assigned anisotropic temperature factors in the absence of disorder or insufficient data. In the latter cases, atoms were treated isotropically. C-H atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. H atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the C atom to which they are bonded. The H-atom contributions were calculated, but not refined. The locations of the largest peaks in the final difference Fourier map calculation as well as the magnitude of the residual electron densities in each case were of no chemical significance. Additional details are provided in the supplementary data.[3]

Results and discussion

Reaction of the ligand salt $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Li(Et_2O)$ with $[Rh(COE)(\mu\text{-}Cl)]_2$ proceeds with stirring overnight to give a dark brown-black solution. Work-up of this reaction afforded the dark brown crystalline product **1** in 38% yield. The NMR data were consistent with a disymmetric environment about Rh as two sets of resonances attributable to the isopropyl groups on the aryl rings of the ligand. NMR data were also consistent with the presence of a COE ring bound to Rh. The nature of the fourth ligand on Rh was unclear although IR spectrometry revealed an absorption at 2175 cm^{-1}. This compares with the absorption at 2126 cm^{-1} observed for the Ir analog of **1** suggesting the possibility of coordinated N_2. The higher N–N stretching frequency further suggests a shorter N—N bond distance in **1**. All of these data are consistent with the formulation of **1** as $CH[C(Me)(N\text{-}i\text{-}Pr_2C_6H_3)]_2Rh(N_2)(COE)$ (Scheme 3).

X-ray crystallographic study of **1** confirmed the formulation and revealed the pseudo-square-planar coordination geometry about Rh (Table 1). The coordination sphere is comprised of the two nitrogen atoms of the diimine ligand, a side-bound olefinic fragment of COE, and a terminally bound dinitrogen molecule. The metal-bound nitrogen of the N_2 fragment forms angles of 179.04(16)° and 88.93(15)° with the N atoms of the diimine ligand consistent with the pseudo-square-planar coordination geometry (Fig. 1).

Fig. 1. ORTEP drawing of **1**; 30% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Distances (Å) and angles (°): Rh(1)—N(1) 2.076(3), Rh(1)—N(2) 2.074(3), Rh(1)—N(3) 1.943(4), Rh(1)—C(30) 2.167(5), Rh(1)—C(37) 2.179(5), N(1)—C(1) 1.320(6), N(2)—C(4) 1.332(6), N(3)—N(4) 1.091(6), C(37)—C(30) 1.382(6), N(3)-Rh(1)-N(2) 179.04(16), N(3)-Rh(1)-N(1) 88.93(15), N(2)-Rh(1)-N(1) 90.11(13), N(3)-Rh(1)-C(30) 87.94(17), N(2)-Rh(1)-C(30) 92.99(15), N(1)-Rh(1)-C(30) 161.49(16), N(3)-Rh(1)-C(37) 86.29(17), N(2)-Rh(1)-C(37) 94.59(15), N(1)-Rh(1)-C(37) 160.58(16), C(30)-Rh(1)-C(37) 37.08(17), N(4)-N(3)-Rh(1) 179.6(6).

The diimine ligand is N-bound to Rh with Rh—N distances of 2.076(3) and 2.074(3) Å. The "bite-angle" (N-Rh-N) for the diimine ligand is 90.11(13)°. These compare with the Rh—N distance and bite angle of 1.955(2) Å and 91.3(1)° observed in the three coordinate Rh–olefin complex $CH[C(Me)(NMe_2C_6H_3)]_2Rh(COE)$ (19). The imine C—N bond distances are typical at 1.320(6) and 1.332(6) Å, respectively.

The olefinic fragment of a COE ligand is π bound to Rh with Rh—C distances of 2.167(5) and 2.179(5) Å, and a corresponding C—C distance of 1.382(6) Å. In comparison, the coordinated olefinic C—C bond distance of $CH[C(Me)(N\text{-}Me_2C_6H_3)]_2Rh(COE)$ (19) gives rise to Rh—C distances of 2.072(5) and 2.066(6) Å, with a C—C distance of 1.398(7) Å. The longer Rh—C distances in **1** are consistent with the lesser Lewis acidity of the Rh center as a result of its four-coordinate nature.

The terminally bound dinitrogen molecule exhibits a Rh—N distance of 1.943(4) Å. This is shorter than the Rh—N bond distance in $(Ph\text{-}t\text{-}Bu_2P)_2RhH(N_2)$ (1.970(4) Å) (12) and yet much longer than that in $(i\text{-}Pr_3P)_2RhCl(N_2)$ (1.885(4) Å) (13) (Table 2). The Rh-N-N angle is essentially linear with an angle of 179.6(6)° and the N—N distance is 1.091(6) Å. In general, the N—N distance in **1** is shorter than those observed for the bridging $Rh_2(\mu\text{-}N_2)$ complexes, consistent with interaction with only one metal center. The N—N distance in **1** is also longer than the N—N distances seen in $(i\text{-}Pr_3P)_2RhCl(N_2)$, $MeCH(CH_2CH_2P\text{-}t\text{-}Bu_2)_2Rh(N_2)$, and the Ir

Note: n/a = not available.

analog of **1**. While the Rh—N distance in the terminal-N_2 complexes correlates the expected trend based on the trans influence of the ligand opposite dinitrogen, there is no direct correlation between the Rh—N and the N—N distances in the compiled list of Rh–N_2 complexes (Table 2). The N—N distance appears to reflect a complex mixture of the trans influence and the net electron density at the metal center. It is these features together that impact on the π donation to N_2, and thus the resulting N—N bond length.

Synthesis and structure of a terminal dinitrogen complex of nickel[1]

Rory Waterman and Gregory L. Hillhouse

Abstract: Reaction of petroleum ether solutions of $[(dtbpe)Ni]_2(\eta^2,\mu\text{-}C_6H_6)$ (**1**, dtbpe = 1,2-bis(di-*tert*-butylphosphino)ethane) with triphenylphosphine under a dinitrogen atmosphere gives the Ni(0) dinitrogen adduct $(dtbpe)Ni(N_2)(PPh_3)$ (**2**), which can be isolated as dark red crystals in 87% yield. The X-ray crystal structure of **2** reveals pseudotetrahedral geometry about Ni and a terminal dinitrogen ligand with Ni—N(1) = 1.830(2) Å, N(1)—N(2) = 1.112(2) Å, and Ni-N(1)-N(2) = 177.5(2)°.

Key words: dinitrogen, nickel, X-ray.

Résumé : La réaction du $[(dtbpe)Ni]_2(\eta^2,\mu\text{-}C_6H_6)$ (**1**, dtbpe = 1,2-bis(di-*tert*-butylphosphino)éthane) en solution dans l'éther de pétrole avec de la triphénylphosphine, sous une atmosphère de diazote, conduit à la formation de l'adduit Ni(0) diazote $(dtbpe)Ni(N_2)(PPh_3)$ (**2**) que l'on peut isoler sous la forme de cristaux rouges avec un rendement de 87 %. Une étude du composé **2** par diffraction des rayons X révèle une géométrie pseudotétraédrique autour du Ni et la présence d'un ligand diazote terminal avec des distances Ni—N(1) = 1,830(2) Å, N(1)—N(2) = 1,112(2) Å et un angle Ni-N(1)-N(2) = 177,5(2)°.

Mots clés : diazote, nickel, rayons X.

[Traduit par la Rédaction]

Introduction

The 1965 report from University of Toronto chemistry professor Bert Allen and his graduate student Caesar Senoff of the isolation of stable dinitrogen complex salts of the formulation $[(NH_3)_5Ru(N_2)^{2+}][X^-]_2$ from the reaction of ruthenium trichloride with hydrazine hydrate in aqueous solution rocked the scientific community (1, 2). The crystallographic determination of the solid-state structure of the Allen and Senoff complex definitively corroborated the proposed binding mode of the N_2 ligand as end-on bound to Ru in an approximately linear fashion (3). In the intervening 40 years since that landmark discovery, nearly every transition metal has been reported to utilize dinitrogen as a ligand, and many binding modes, including bridging and side-bound, have been observed for N_2 ligands (4). Because the dinitrogen ligand is often quite labile, N_2 complexes can serve as useful starting materials for a variety of synthetic purposes. Over the years much research effort has focused on designing systems containing ligated N_2 in which coordination to a metal sufficiently activates the N—N triple bond that it can be subsequently functionalized (or "fixed"), such as in processes that cleave the N—N triple bond (5) or model enzymatic systems that perform catalytic N_2 reduction (6).

Only a few examples of isolated nickel complexes possessing a dinitrogen ligand have appeared in the literature. Most Ni–N_2 species have been dimeric or polynuclear (7–9). The dinitrogen-bridged complex $[(PCy_3)_2Ni]_2(\mu\text{-}N_2)$ has been reported and structurally characterized (9), and an unusual side-bound N_2 complex, $[(C_6H_5Li)_6Ni_2(N_2)(Et_2O)_2]_2$, has been reported (7). Surprisingly, no structural data exist for simple end-on N_2 complexes of nickel, even though this is by far its most common coordination mode. Herein we report the preparation and structural characterization of the first example of an isolable nickel complex containing a terminal, end-on bound N_2 ligand.

Experimental

General considerations

Unless otherwise stated, all operations were performed in a M. Braun Lab Master dry box under an atmosphere of purified nitrogen. Petroleum ether was dried by passage through activated alumina and Q-5 columns. C_6D_6 was purchased form Cambridge Isotope Laboratory (CIL), degassed, and dried over CaH_2 or activated 4 Å molecular sieves. Celite®, alumina, and 4 Å molecular sieves were activated under vacuum overnight at a temperature above 180 °C. Anhydrous solvents such as benzene and diethylether were purchased from Acros or Fischer, stirred over sodium metal, and filtered through activated alumina. $[(dtbpe)Ni]_2(\eta^2,\mu\text{-}C_6H_6)$ (**1**, dtbpe = 1,2-bis(di-*tert*-butylphosphino)ethane) was

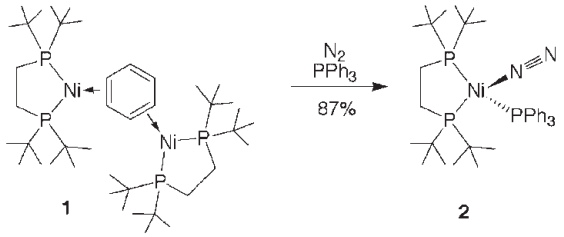
prepared according to the literature procedure (10). All other chemicals were used as received. IR data (Fluorolube S-20 mulls, CaF_2 plates) were measured with a Nicolet 670 FT-IR instrument. Elemental analyses were performed by Desert Analytics (Tucson, Arizona). ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on Bruker 500 and 400 MHz NMR spectrometers. ^1H and ^{13}C NMR data are reported with reference to solvent resonances (residual C_6D_5H in C_6D_6, 7.16 ppm; C_6D_6, 128.0 ppm). ^{31}P NMR spectra are reported with respect to external 85% H_3PO_4 (0 ppm).

Preparation of (dtbpe)Ni(N_2)(PPh_3) (2)

In a nitrogen-filled, inert-atmosphere glovebox, a 25 mL round-bottomed flask was charged with 72 mg (0.087 mmol) of [(dtbpe)Ni]$_2$(η^2,μ-C_6H_6) (**1**) and 45 mg (0.174 mmol) of PPh_3 followed by 14 mL of petroleum ether. The solution immediately became blood red in color and was filtered after stirring for 90 min. The volume of the solution was reduced to ca. 5 mL, and upon cooling to –35 °C, dark red crystals were deposited, which were collected by filtration and dried to give **2** (100 mg, 0.149 mmol, 87% yield). IR (Fluorolube mull, CaF_2, cm^{-1}): 3050–2850 (vs br), 2072 (ν_{NN}, vs), 1585 (m), 1479 (s), 1434 (s), 1392 (m), 1360 (m). ^1H NMR (22 °C, 500 MHz, C_6D_6) δ: 7.94 (t, C_6H_5, 6H), 7.15 (d, C_6H_5, 6H), 7.07 (t, C_6H_5, 3H), 1.55 (m, CH_2, 4H), 1.17 (mult, CH_3, 36H). ^{13}C NMR (22 °C, 125.8 MHz, C_6D_6) δ: 133.8 (d, J_{PC} = 14.5 Hz, C_6H_5), 129.8 (s, C_6H_5), 127.9 (s, C_6H_5), 127.7 (s, C_6H_5), 34.6 (m, J_{PC} = 4.4 Hz, $C(CH_3)_3$), 30.7 (br t, J_{PC} = 3.6 Hz, CH_3), 23.4 (m, CH_2). ^{31}P NMR (22 °C, 202.4 MHz, C_6D_6) δ: 73.5 (d, J_{PP} = 95.7 Hz, PtBu$_2$), 28.7 (t, J_{PP} = 95.7 Hz, PPh$_3$). Anal. calcd for $C_{36}H_{55}N_2NiP_3$: C 64.78, H 8.31, N 4.20; found: C 65.11, H 8.28, N 3.31.



Crystallographic data collection, structure solution, and refinement

A dark red block of **2** was selected under a stereomicroscope while immersed in mineral oil to avoid possible reaction with air. The crystal was removed from the oil using a tapered fiber that also served to hold the crystal for data collection, and mounted and centered on a Bruker SMART APEX system in a nitrogen cold stream. Rotation and still images showed diffractions to be sharp, while frames separated in reciprocal space were obtained and provided an orientation matrix and initial cell parameters. Final cell parameters were obtained from the full data set. A "hemisphere" data set was obtained, which samples approximately 1.2 hemispheres of reciprocal space to a resolution of 0.84 Å using 0.3° steps in ω using 10 s integration times for each frame. The space group was determined as *P*-1 based on systematic absences and intensity statistics. Direct methods were used to locate non-hydrogen atoms from the electron difference map. All heavy atoms were converted to and refined anisotropically. Hydrogen atoms were refined isotropically and fixed at calculated positions. A semiempirical absorption correction was applied from ψ-scans. All software and sources of scattering factors are contained in the SHELXTL (version 5.1) program library (G. Sheldrick, Bruker Analytical X-ray Systems, Madison, Wisconsin). Details of the data set and the refinement are given in Table 1. Table 2 lists selected metrical parameters of the structure of **2**.[4]

Results and discussion

Reaction of petroleum ether solutions of the benzene complex [(dtbpe)Ni]$_2$(η^2,μ-C_6H_6) (**1**) with PPh_3 under a nitrogen atmosphere gives a dark red solution from which the dinitrogen complex (dtbpe)Ni(N_2)(PPh_3) (**2**) can be isolated as analytically pure dark red crystals in 87% yield (eq. [1]).

[1]

Even in the presence of excess PPh_3, only **2** is formed and no tetrakisphosphine species is observed. Characterization of **2** followed from its NMR (^1H, ^{13}C, and ^{31}P) and IR spectra, and a single crystal X-ray diffraction study. The ^{31}P NMR spectrum of **2** exhibits a single resonance for the dtbpe ligand (δ 73.5, doublet) and a single resonance for the PPh_3 ligand (δ 28.7, triplet) with $^2J_{PP}$ = 95.7 Hz for both, indicating pseudotetrahedral geometry about nickel. The solid-state IR spectrum of **2** shows a strong ν_{NN} at 2072 cm^{-1}.

Single crystals of **2** were grown by slowly cooling concentrated hexane solutions of the complex. A perspective view of the molecular structure of **2** is shown in Fig. 1 with select metrical parameters given in Table 2. The complex features a pseudotetrahedral nickel center with a terminal N_2 ligand with a short N—N bond of 1.112(2) Å. The nitrogen ligand is approximately linear with Ni-N(1)-N(2) = 177.5(2)° and Ni—N(1) = 1.830(2) Å. These values can be compared with those found in the structure of the bridged dinitrogen complex [(PCy_3)$_2$Ni]$_2$(μ-N_2) (9) which exhibits Ni—N bond lengths of 1.77 and 1.79 Å, and N—N = 1.12 Å (standard errors were not given in the report).

Complex **2** is, to the best of our knowledge, the only example of an *isolated* nickel complex with a terminal N_2 ligand. It is noteworthy that a family of nickel(II) complexes of the formula L_2NiX_2 (X = Cl or Br; L = PEt_3, PEt_2Ph, or P-*n*-Bu_3) can be reduced in the presence of phosphine to generate $L_3Ni(N_2)$ species that have not been isolated, but lose N_2 to give tetrakisphosphine nickel(0) complexes L_4Ni upon precipitation (11). Solution IR, ^{31}P NMR, and electronic spectra for these $L_3Ni(N_2)$ complexes led to their formulation as pseudotetrahedral at Ni with terminal N_2 ligands

meric $(PCy_3)_2Ni(N_2)$ that results from dissociation of the dimer in toluene (9). In the light of these previous reports, the stability of **2** is undoubtedly the result of the steric bulk of the dtbpe ligand, which prevents expulsion of N_2 and coordination of a second PPh_3 ligand to give the hypothetical $(dtbpe)Ni(PPh_3)_2$. Finally, an unusual "Ni(I)" complex, $(PEt_3)_2Ni(H)(N_2)$, has been formulated on the basis of UV–vis and IR data (12), but the absence of magnetic susceptibility or ^1H NMR information and the similarity of the IR and UV–vis spectra to $(PEt_3)_3Ni(N_2)$ (vide supra) casts doubts on the identity of this compound (11*a*).

Synthesis and characterization of cationic iron complexes supported by the neutral ligands $NP^{i\text{-}Pr}_3$, $NArP^{i\text{-}Pr}_3$, and $NS^{t\text{-}Bu}_3$[1]

Cora E. MacBeth, Seth B. Harkins, and Jonas C. Peters

Abstract: This paper compares the local geometries, spin states, and redox properties of a series of iron complexes supported by neutral, tetradentate NP_3 (tris(phosphine)amine) and NS_3 (tris(thioether)amine) ligands. Our consideration of an Fe-mediated N_2 fixation scheme similar to that proposed by Chatt for molybdenum motivates our interest in systems of these types. This report specifically describes the synthesis and characterization of cationic Fe(II) chloride complexes supported by the neutral ligands $NP^{i\text{-}Pr}_3$ ($NP^{i\text{-}Pr}_3$ = $[N(CH_2CH_2P\text{-}i\text{-}Pr_2)_3]$), $NArP^{i\text{-}Pr}_3$ ($NArP^{i\text{-}Pr}_3$ = [N(2-diisopropylphosphine-4-methylphenyl)$_3$]), and $NS^{t\text{-}Bu}_3$ ($NS^{t\text{-}Bu}_3$ = $[N(CH_2CH_2S\text{-}t\text{-}Bu)_3]$). The solid-state structures, electrochemistry, and magnetic properties of these complexes are reported. Whereas the $NP^{i\text{-}Pr}_3$ and $NArP^{i\text{-}Pr}_3$ ligands provide pseudotetrahedral $S = 2$ ferrous cations $[Fe(NP^{i\text{-}Pr}_3)Cl]PF_6$ (**1**[PF_6]) and $[Fe(NArP^{i\text{-}Pr}_3)Cl]BPh_4$ (**2**[BPh_4]) featuring a long Fe—N bond distance, the $NS^{t\text{-}Bu}_3$ ligand gives rise to a trigonal bipyramidal structure with a $S = 1$ ground state and a much shorter Fe–N interaction. The complexes **1**[BPh_4] and **2**[BPh_4] can be reduced under CO to give rise to the five-coordinate Fe(I) monocarbonyls $[Fe(NP^{i\text{-}Pr}_3)CO]BPh_4$ (**4**[BPh_4]) and $[Fe(NArP^{i\text{-}Pr}_3)CO]BPh_4$ (**5**[BPh_4]). The solid-state structures and electrochemistry of **4**[BPh_4] and **5**[BPh_4] are described, as is the EPR spectrum of **4**[BPh_4]. The synthesis and characterization of the hydride–dinitrogen complex $[Fe(NP^{i\text{-}Pr}_3)(N_2)(H)]PF_6$ (**6**[PF_6]) has also been accomplished and its properties are also reported.

Key words: nitrogenase, iron, polydentate phosphines, thioether ligands, N_2 chemistry, nitrogen, Fe(I).

Résumé : Dans ce travail, on compare les géométries locales, états de spin et propriétés redox d'une série de complexes de fer supportés par les ligands neutres et tridentates NP_3 (tris(phosphine)amine) et NS_3 (tris(thioéther)amine). Notre considération d'un schéma de fixation du N_2 catalysé par le Fe semblable à celui proposé par Chatt pour le molybdène motive notre intérêt dans les systèmes de ce type. Dans ce travail, on décrit spécifiquement la synthèse et la caractérisation de complexes cationiques du chlorure de Fe(II) supportés par les ligands neutres $NP^{i\text{-}Pr}_3$ ($NP^{i\text{-}Pr}_3$ = $[N(CH_2CH_2P\text{-}i\text{-}Pr_2)_3]$), $NArP^{i\text{-}Pr}_3$ ($NArP^{i\text{-}Pr}_3$ = [N(2-diisopropylphosphine-4-méthylphényl)$_3$]) et $NS^{t\text{-}Bu}_3$ ($NS^{t\text{-}Bu}_3$ = $[N(CH_2CH_2S\text{-}t\text{-}Bu)_3]$), y compris les structures à l'état solide, l'électrochimie et les propriétés magnétiques de ces complexes. Alors que les ligands $NP^{i\text{-}Pr}_3$ et $NArP^{i\text{-}Pr}_3$ conduisent à des cations ferreux pseudotétraédriques $S = 2$ $[Fe(NP^{i\text{-}Pr}_3)Cl]PF_6$ (**1**[PF_6]) et $[Fe(NArP^{i\text{-}Pr}_3)Cl]BPh_4$ (**2**[BPh_4]) comportant une longue liaison Fe—N, le ligand $NS^{t\text{-}Bu}_3$ conduit à la formation d'un complexe de structure bipyramidale trigonale avec un état fondamental $S = 1$ et une interaction Fe–N beaucoup plus courte. Les complexes **1**[BPh_4] et **2**[BPh_4] peuvent être réduits sous l'influence du CO pour conduire à des complexes monocarbonylés et pentacoordinés du Fe(I), $[Fe(NP^{i\text{-}Pr}_3)CO]BPh_4$ (**4**[BPh_4]) et $[Fe(NArP^{i\text{-}Pr}_3)CO]BPh_4$ **5**[BPh_4]. On décrit aussi les structures solides et l'électrochimie des complexes **4**[BPh_4] et **5**[BPh_4] ainsi que le spectre RPE du composé **4**[BPh_4]. On a aussi réalisé la synthèse et la caractérisation du complexe hydrure–diazote $[Fe(NP^{i\text{-}Pr}_3)(N_2)(H)]PF_6$ (**6**[PF_6]) et on rapporte ses propriétés.

Mots clés : nitrogénase, fer, phosphines polydentates, ligands thioéther, chimie du N_2, azote, Fe(I).

[Traduit par la Rédaction]

Introduction

The site(s) of substrate binding and reactivity (e.g., N_2, HC≡CH, H^+, CO) at the inorganic cofactors of nitrogenase enzymes is a fascinating and complicated issue (1). Because crystallographic data is presently available only for the FeMo-nitrogenase (FeMo-N_2ase) enzyme (2), the biochemical (3), theoretical (4), and synthetic (1, 5), model communities have focused the bulk of their attention on understanding its mode of mechanistic action. The presence of a single molybdenum center in the FeMo-cofactor (2, 3*a*), in addition to a wealth of structurally diverse functional

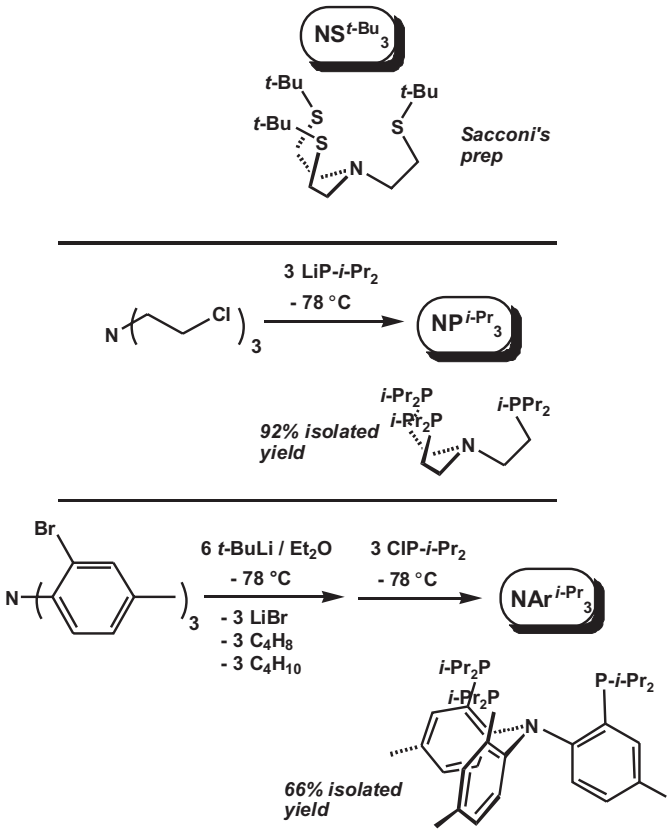
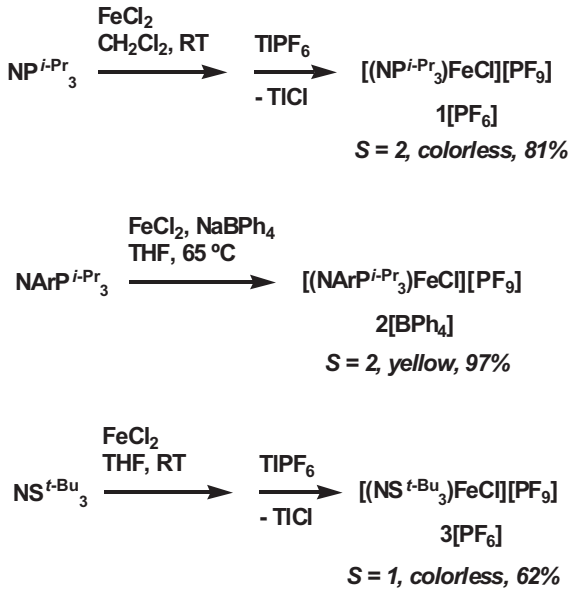
Scheme 1.

model systems (6), has reinforced the suggestion that a single molybdenum site may be responsible for mediating N_2 uptake and reduction in FeMo-N_2ase. Particularly attractive is a scheme akin to that originally put forward by Chatt et al. (7) and later modified by Pickett (8) in which a vacant Mo^{III} site, perhaps generated via homocitrate dechelation under electron loading conditions, binds N_2 to mediate its successive reduction to NH_3 by the successive transfer of protons and electrons. Such a scenario is schematically outlined in the top portion of Scheme 1. Significant in this regard is the recent work of Yandulov and Schrock (9), who have demonstrated that such a cycle can be accomplished in a small molecule synthetic system. They have shown that certain triamidoamine-supported molybdenum complexes are capable of catalytically shuttling among various oxidation states ($Mo^{III}/Mo^{IV}/Mo^{V}/Mo^{VI}$) as nitrogen is taken up and reduced to ammonia.



These successes not withstanding, it needs to be emphasized that iron is the only metal *known* to be ubiquitous to all nitrogenase enzymes (10) (also true of hydrogenase enzymes), and biochemical and spectroscopic data (11) are available to suggest that the iron sites of the FeMo-cofactor play a critical, albeit ill-defined, role in facilitating N_2 reduction, and myriad proposals have been put forth stressing an Fe-mediated N_2 fixation scheme. Problematic is that the inorganic dinitrogen chemistry of iron is far less well-developed than that for molybdenum, and therefore evaluating the chemical feasibility of such schemes is at present difficult. Most of the Fe-mediated scenarios being considered in the literature invoke multiple iron centers during N_2 uptake–reduction (5). This is due to the presence of multiple iron centers in the cofactor, and perhaps more importantly, to the implicit assumption that a single iron site cannot support the various N_x intermediates, oxidation states, and multi-electron transformations that would need to be invoked *en route* to NH_3 production from N_2 (bottom of Scheme 1, steps A–G), in sharp contrast to the case of redox-rich molybdenum.

Inorganic coordination chemistry can play a key role with respect to expanding our understanding of the N_2 chemistry available to iron, and in testing the validity of the assumptions mentioned above. The recent structural assignment of a central light atom in the MoFe-cofactor core (2) suggests that, if one or more iron atoms in the central section of the cofactor provides an initial site for N_2 uptake (3*a*), then coordinatively unsaturated iron centers provide plausible starting points for inorganic iron model chemistry (12). At the bottom of Scheme 1 we sketch a N_2 reduction scenario that mirrors that of the molybdenum postulate, but in this case invokes a hemi-labile role for the central light atom that exposes a low-valent iron site for N_2 uptake under electron loading conditions. Such a scenario would set the stage for the further reduction of N_2 to ammonia, perhaps via a Chatt-type cycle based upon iron (steps A–G). Fe–N_x model complexes will help to evaluate the chemical feasibility of this mechanistic scheme. Depending on the degree to which the Fe–X linkage is broken during the cycle, four- and (or) five-coordinate complexes may be considered as the most appropriate starting points.



In this context, our own group has recently developed four-coordinate iron, phosphine-supported systems of the generic type $L_3Fe–N_x$ (13). These pseudotetrahedral platforms exhibit: (*i*) an unprecedented degree of redox flexibility for mononuclear iron systems; (*ii*) a fascinating propensity to populate low-spin, ground-state configurations for pseudotetrahedral Fe^{2+}, Fe^{3+}, and Fe^{4+} species; and (*iii*) a capacity to accommodate strongly π-basic (e.g., N^{3-}, NR^{2-}), π-acidic (e.g., N_2), and intermediate type (e.g., N_2R^-, NR_2^-) ligands

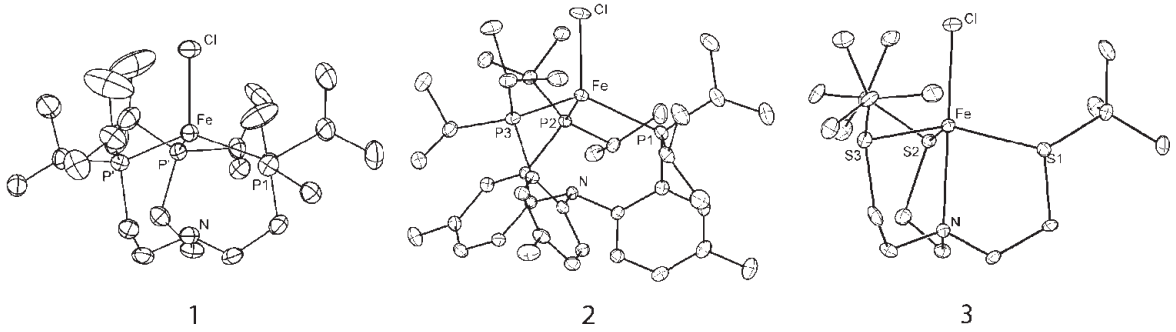
Scheme 2.

Scheme 3.

at a single coordination site. An obvious question that emerges is whether five-coordinate iron scaffolds will display similar properties.

In the present paper, we compare the local geometries, spin states, and redox properties of a series of iron complexes supported by neutral, tetradentate NP_3 (tris(phosphine)amine) and NS_3 (tris(thioether)amine) ligands (14). Two new NP_3-type ligands are introduced, $NP^{i\text{-Pr}}_3$ ($NP^{i\text{-Pr}}_3$ = $N(CH_2CH_2P\text{-}i\text{-}Pr_2)_3$) and $NArP^{i\text{-Pr}}_3$ ($NArP^{i\text{-Pr}}_3$ = N(2-diisopropylphosphine-4-methylphenyl)$_3$) are described, and we establish the nature of their ferrous "$(NP_3)Fe^{II}$–X" ions. For comparison, we also describe a structurally related "$(NS^{t\text{-Bu}}_3)Fe^{II}$–X" system ($NS^{t\text{-Bu}}_3$ = (e.g., $N(CH_2CH_2S\text{-}t\text{-}Bu)_3$)) (14). It is established that the $NP^{i\text{-Pr}}_3$ and $NArP^{i\text{-Pr}}_3$ scaffolds support unusual monovalent, trigonal bipyramidal monocarbonyl derivatives. Additionally, it is demonstrated that the $NP^{i\text{-Pr}}_3$ ligand supports N_2 coordination to iron.

Results and discussion



Five-coordinate iron complexes supported by neutral, tetradentate NP_3 (15, 16) and PP_3 (17) ligands are well-known, dating back to the early pioneering efforts of Sacconi and co-workers (14, 15). Despite the general utility of these types of polydentate phosphines, little attention has been paid to derivatives with sterically encumbering phosphine substituents. To begin to explore such systems we have targeted the preparation of the isopropyl-substituted systems $NP^{i\text{-Pr}}_3$ and $NArP^{i\text{-Pr}}_3$ (Scheme 2). Isopropyl-substituted $NP^{i\text{-Pr}}_3$ can be prepared by a straightforward modification of the literature procedure for NP^{Ph}_3 (NP^{Ph}_3 = $N(CH_2CH_2PPh_2)_3$) (14). Accordingly, the addition of 3 equiv. of lithium diisopropylphosphide to an ethereal solution of tris(2-chloroethyl)amine at low temperature affords $NArP^{i\text{-Pr}}_3$ in excellent isolated yield (92%) following work-up. Preparation of $NArP^{i\text{-Pr}}_3$ requires a combination of a suitable carbanion nucleophile and chlorophosphine electrophile. We find that the addition of chlorodiisopropylphosphine to an ethereal solution of $[2\text{-Li-4-Me-}C_6H_3]_3N$, generated in situ by the addition of *tert*-butyllithium to tris(*o*-bromo-*p*-tolyl)amine, affords crystalline $NArP^{i\text{-Pr}}_3$ in good yield (66%) after work-up.

As shown in Scheme 3, cationic Fe(II)–chloride complexes of these NP_3-type ligands can be prepared by reacting the neutral phosphine ligands with $FeCl_2$ in the presence of a halide abstraction reagent ($TlPF_6$ or $NaBPh_4$) in either CH_2Cl_2 or THF, providing colorless $[Fe(NP^{i\text{-Pr}}_3)Cl]PF_6$ (**1**[PF_6]) and yellow $[Fe(NArP^{i\text{-Pr}}_3)Cl]BPh_4$ (**2**[BPh_4]). For structural and magnetic comparison, we also prepared the colorless complex $[Fe(NS^{t\text{-Bu}}_3)Cl]PF_6$ (**3**[PF_6]) by the addition of $FeCl_2$ to a THF solution of $NS^{t\text{-Bu}}_3$ followed by chloride abstraction with $TlPF_6$. The isolated yield of **3**[PF_6] is fairly good (62%), although not in comparison to the high yields obtained for **1**[PF_6] and **2**[BPh_4]. Somewhat surprising is that the iron chemistry of Sacconi's $NS^{t\text{-Bu}}_3$ ligand has not been previously described, though its coordination to the first row transition metals Co (18), Ni (19), and Cu (20) has been known for some time. Given the sulfur-rich environment of the central iron sites of the MoFe-cofactor, and the possible presence of an interstitial N atom, $NS^{t\text{-Bu}}_3$ and related ligands provide an interesting structural starting point for functional iron model studies.

X-ray diffraction analyses of single crystals of **1**[PF_6], **2**[BPh_4], and **3**[PF_6] (Fig. 1) establishes that each complex is monomeric. NP_3-supported **1**[PF_6] and **2**[BPh_4] are best described as tetrahedral complexes and are structurally quite similar to the ferrous cation of NP^{Ph}_3 (15*b*). Accordingly, **1**[PF_6] features an elongated Fe-N distance of 2.801(3) Å

Fig. 1. Displacement ellipsoid (50%) representation of **1**[PF_6], **2**[BPh_4], and **3**[PF_6]. Hydrogen atoms and counteranions have been removed for clarity. Selected bond lengths (Å) and angles (°) for **1**[PF_6]: Fe—Cl 2.262(2), Fe—P1 2.455(1), Fe—N 2.801(3), N-Fe-Cl 180.00(11), P1-Fe-P′ 112.10(2), P1-Fe-Cl 106.70(2). For **2**[BPh_4]: Fe—Cl 2.253(2), Fe—P1 2.467(2), Fe—P2 2.485(2), Fe—P3 2.481(2), Fe—N 2.701(2), P1-Fe-C1 103.83(6), P2-Fe-Cl 115.89(5), P3-Fe-Cl 105.64(4), Fe-N 2.701(2). For **3**[PF_6]: Fe—Cl 2.298(1), Fe—S1 2.447(1), Fe—S2 2.453(1), Fe—S3 2.407(1), Fe—N 2.378(3), N-Fe-Cl 178.32(8), S1-Fe-Cl 101.38(4), S2-Fe-Cl 97.54(4), S3-Fe-Cl 100.11(4).

1 2 3

(2.701(2) Å for **2**[BPh_4]) (21). The iron centers in **1**[PF_6] and **2**[BPh_4] lie above the P_3 plane, projected into the hemisphere opposite the apical N atom. Both systems are high spin (S = 2), expected for conventional pseudotetrahedral iron(II) systems.

It is interesting that the local geometry of sulfur-supported **3**[PF_6] is better described as trigonal bipyramidal. It displays a much shorter Fe–N interaction (2.378(3) Å), which in turn places the Fe center closer to the plane created by its three sulfur donor atoms. The trigonal bipyramidal geometry of **3**[PF_6] gives rise to an average S-Fe-Cl bond angle of 99.7°. For comparison, the average P-Fe-Cl angles of **1**[PF_6] and **2**[BPh_4] are 106.7° and 108.5°, respectively, closer to that expected for an idealized tetrahedral geometry (109.5°). The fact that complex **3**[PF_6] adopts a higher coordination number is perhaps reflective of the decreased electron-releasing character of sulfur relative to phosphorus, resulting in a more electron-deficient iron center that draws the additional N-atom donor inward. The spin state of **3**[PF_6] (S = 1) also reflects the change in coordination number. Two unpaired electrons are expected for an σ-only *d*-orbital splitting scheme under a trigonal bipyramidal ligand field.

Electrochemical characterization of **1**[PF_6] and **2**[BPh_4] shows that each system supports a reversible $Fe^{II/I}$ redox process (–1.65 V for **1**[PF_6] and –1.51 V for **2**[BPh_4]; internally referenced to Cp_2Fe in THF). Only **1**[PF_6] affords a reversible $Fe^{III/II}$ couple (0.54 V). Cationic **2**[BPh_4] is irreversibly oxidized at above ca. 0.5 V. For comparison, we note that NS_3-supported **3**[PF_6] does not feature any well-defined redox processes in the potential window scanned, although problematic adsorption of the complex to the glassy carbon electrode cannot be discounted. Electrochemical data for **1**[PF_6] and **2**[BPh_4] suggests that Fe(I) species should be accessible, at least for the phosphine-supported complexes. While the neutral iron(I) chloride complexes of $NP^{i\text{-}Pr}{}_3$ and $NArP^{i\text{-}Pr}{}_3$ have proven synthetically elusive, formal replacement of the chloride by CO leads to well-defined cationic iron(I) species. Thus, tetraphenylborate salts of $\mathbf{1}^+$ and $\mathbf{2}^+$ can be reduced by Na/Hg amalgam in THF under a blanket of CO to provide deep red, crystalline material. Thorough analysis establishes the products to be the cationic, monocarbonyl derivatives [$Fe(NP^{i\text{-}Pr}{}_3)CO$]$BPh_4$ (**4**[BPh_4]) and [$Fe(NArP^{i\text{-}Pr}{}_3)CO$]$BPh_4$ (**5**[BPh_4]), each of which is isolated in high yield (>85%). Attempts to prepare the related iron(I) $NS^{t\text{-}Bu}{}_3Fe(CO)^+$ species by similar strategies have not been successful.

Structurally characterized, Fe(I) monocarbonyl complexes are rare. To our knowledge, Parkin and co-workers (22) have reported the only crystallographically characterized example of such a species, which is pseudotetrahedral, using an anionic substituted tris(pyrazolyl)borate ligand auxiliary. Recently, we have reported the structural characterization of an iron(I) dicarbonyl complex, which is approximately square pyramidal, supported by an anionic tris(phosphino)borate ligand (13*a*). The solid-state structures of **4**[BPh_4] and **5**[BPh_4] were obtained for comparison and are shown in Fig. 2. Each cationic complex is rigorously trigonal bipyramidal. The Fe—N bond distances observed for **4**[BPh_4] (2.150(2) Å) and **5**[BPh_4] (2.164(2) Å) are dramatically contracted (>0.6 Å) compared with their Fe(II)–chloride precursors. Each carbonyl derivative also displays an unusually short Fe—C bond length (1.680(4) Å for **4**[BPh_4], 1.709(2) Å for **5**[BPh_4]) because of the presence of very strong π backbonding from the iron(I) centers into the π* orbitals of the coordinated CO ligand. The strength of this interaction is also reflected by the observation of very low ν(CO) stretching frequencies (1881 cm^{-1} for **4**[BPh_4], 1880 cm^{-1} for **5**[BPh_4]; THF/KBr). For comparison, Parkin's four-coordinate iron(I) monocarbonyl [$PhTp^{t\text{-}Bu}$]Fe(CO) exhibits a longer Fe—C bond length of 1.789(3) Å, and a ν(CO) value of 1907 cm^{-1} (22). Despite their cationic nature, the π-backbonding ability of **4**[BPh_4] and **5**[BPh_4] is appreciably stronger than in Parkin's tetrahedral derivative, presumably resulting from the presence of a fifth donor group.

The cyclic voltammetry of complexes **4**[BPh_4] and **5**[BPh_4] was also studied. As shown in Fig. 3, both species exhibit two fully reversible redox processes that we assign as $Fe^{I/0}$ (–1.6 V for **4**[BPh_4] and **5**[BPh_4]) and $Fe^{II/I}$ (–0.3 V for **4**[BPh_4], –0.2 V for **5**[BPh_4]) redox events. Bianchini et al. (23) have explored the cyclic voltammetry of a related iron system, [$(PP_3)Fe(C{\equiv}CPh)$]BPh_4, which shows a reversible $Fe^{II/I}$ process but an irreversible $Fe^{I/0}$ event. The neutral π-acidic CO ligand of $\mathbf{4}^+$ and $\mathbf{5}^+$ is better able to stabilize the zero-valent state of iron than the anionic phenylacetylide ligand of [$(PP_3)Fe(C{\equiv}CPh)$]BPh_4.

Because complexes **4**[BPh_4] and **5**[BPh_4] represent rather

Fig. 2. Displacement ellipsoids (50%) of **4**[BPh_4], **5**[BPh_4], and **6**[PF_6]. Hydrogen atoms and counteranions have been removed for clarity. Selected bond lengths (Å) and angles(°) for **4**[BPh_4]: Fe—C 1.680(4), Fe—N 2.150(2), Fe—P1 2.2939(8), Fe—P2 2.2379(8), Fe—P3 2.2851(8), C-Fe-N 177.43(11). For **5**[BPh_4]: Fe—C 1.709(3), Fe—N 2.164(2), Fe—P1 2.3091(7), Fe—P2 2.2936(7), Fe—P3 2.2722(7), C-Fe-N 177.6(1). For **6**[PF_6]: Fe—N2 1.804(3), Fe—N1 2.142(3), Fe—H 1.53(4), Fe—P1 2.245(1), Fe—P2 2.250(1), Fe—P3 2.286(1), N1-Fe-N2 176.4(1).

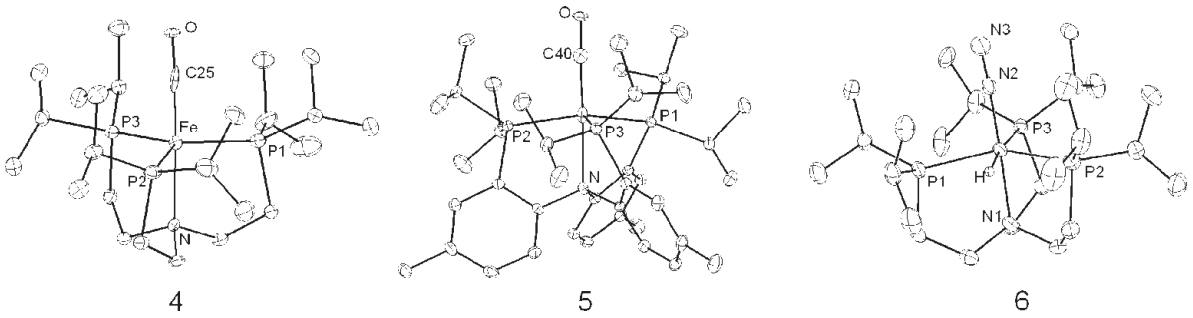

Fig. 3. Cyclic voltammograms of **5**[BPh_4] and **4**[BPh_4] recorded at 100 mV/s in THF vs. $Ag/AgNO_3$.

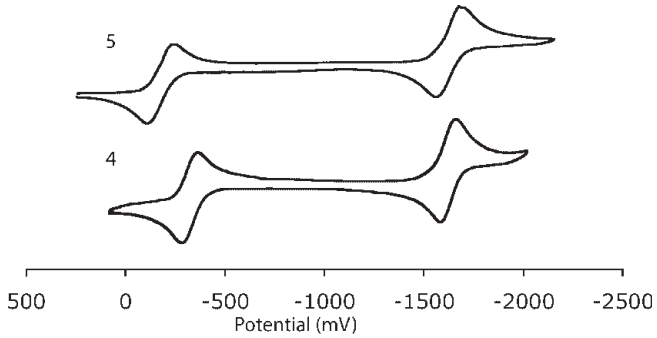

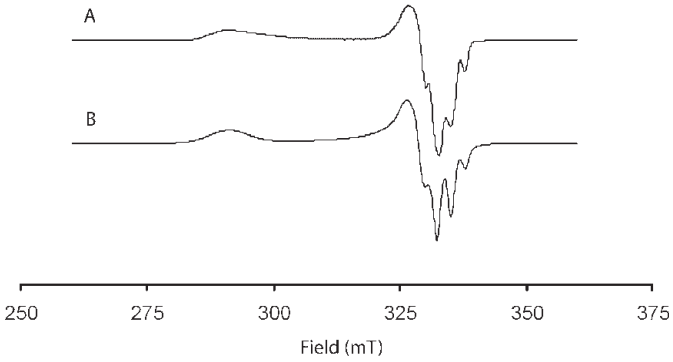

Fig. 4. EPR spectrum of **4**[BPh_4] (5.4 K, ν = 9.475 GHz) recorded in a frozen glass of 1-methyltetrahydrofuran. (A) Experimental spectrum, (B) simulated spectrum: g_1 = 2.302, $a_{1(P)}$ = 30 G; g_2 = 2.0365, $a_{2(P)}$ = 15 G; g_3 = 2.0075, $a_{3(P)}$ = 28 G.

unusual examples of mononuclear iron(I) carbonyls it was prudent to undertake their magnetic characterization. Solution moments for **4**[BPh_4] and **5**[BPh_4] (24, d_8-THF) were measured to be 2.05 μ_B and 1.96 μ_B, respectively, implying a doublet ground state for each species. We also collected a glassy 1-methyltetrahydrofuran EPR spectrum of **4**[BPh_4] at 5.4 K (Fig. 4A). The observed signal, which is rhombic with three components at g_1 = 2.3020, g_2 = 2.0365, and g_3 = 2.0075, shows well-resolved superhyperfine coupling to the phosphorus nuclei of the ligand (3 × P, I_p = 1/2). The spectrum can be satisfactorily simulated as an S = 1/2 spin system by inclusion of the superhyperfine interactions (Fig. 4B). The three-component, rhombic signal observed is qualitatively comparable to that reported by Bianchini et al. (23) for the iron(I) derivative (PP_3)Fe(C≡CPh). However, Bianchini notes the absence of superhyperfine interactions between the unpaired electron and the phosphorous nuclei of PP_3 as a result of a spin-spin exchange narrowing processes occurring at sufficiently fast rates. The presence of resolvable superhyperfine interactions in the spectrum of **4**[BPh_4] likely benefits from the acquisition of the spectrum in the glassy phase.

The reduction of the cationic complexes **1**, **2**, and **3** under dinitrogen is a topic of ongoing study. For the present contribution, we note that N_2 uptake can be achieved by the ($NP^{i\text{-}Pr}_3$)Fe system by slight modification of the route used for the original preparation of [(NP^{Ph}_3)Fe(H)(N_2)][BPh_4] (NP^{Ph}_3 = $N(CH_2CH_2PPh_2)_3$) (15*a*, 16). Addition of a THF solution of Li[BEt_3H] to **1**[PF_6] under N_2 generates yellow, diamagnetic [Fe($NP^{i\text{-}Pr}_3$)(N_2)(H)]PF_6 (**6**[PF_6]) in good yield. Complex **6**[PF_6] has been thoroughly characterized and its X-ray crystal structure is shown in Fig. 2. The spectroscopic and structural data for **6**[PF_6] compare favorably with those reported for [(NP^{Ph}_3)Fe(H)(N_2)][BPh_4] (16). The ν(N_2) vibration is observed at only slightly lower energy for **6**[PF_6] (2087 vs. 2090 cm^{-1} in THF/KBr), and the Fe—N_{N2} bond distances are indistinguishable (1.81(1) Å). The ν(Fe-H) vibration for **6**[PF_6], which has been confirmed by preparation of a deuterated sample, is shifted to a much lower frequency than for [(NP^{Ph}_3)Fe(H)(N_2)][BPh_4] (1865 vs. 1913 cm^{-1}), likely reflecting the presence of an isopropyl-substituted rather than a phenyl-substituted phosphine donor trans to the hydride.

In conclusion, we have attempted to motivate renewed interest in the small molecule coordination chemistry of five-coordinate iron systems supported by ligands that allow access to low-valent states. Understanding potential reactivity patterns for local iron sites of the cofactor of nitrogenase provides one such impetus. In this regard, we have expanded the versatile NP_3 ligand set popularized by Sacconi and co-workers (15) to include the bulkier, more electron-releasing $NArP^{i\text{-}Pr}_3$ and $NP^{i\text{-}Pr}_3$ derivatives that feature isopropyl-substituted phosphine donors. The iron coordination chemistry of these new generation polyphosphine ligands is well-defined, and iron(I) carbonyl and iron(II)

dinitrogen adducts have been described. A key feature of these tetradentate ligands concerns the flexibility of the ligand. The apical Fe–N donor interaction reacts to the nature of the ligand in the fifth binding site: it contracts for π-acidic CO (Fe(I) relative to chloride (Fe(II)). The related but less electron-releasing $NS^{t\text{-}Bu}_3$ ligand supports a well-defined, cationic $(NS_3)Fe^{II}$–Cl species whose local geometry and donor ligands are interesting given the local geometry of the central iron sites of the MoFe-cofactor of nitrogenase. A difference in spin state is observed when comparing the $(NS^{t\text{-}Bu}_3)Fe^{II}$–Cl complex **3**[$PF_6$] ($S = 1$) and its $(NP_3)Fe^{II}$–Cl analogues ($S = 2$). This difference results from a severe contraction of the apical Fe–N linkage to lend a trigonal bipyramidal rather than a tetrahedral geometry for the divalent iron center in **3**[PF_6]. Future work will examine the installation of nitrogenous donor ligands in the fifth binding site of these scaffolds.[3]

Experimental section

All manipulations were carried out using standard Schlenk or glovebox techniques under a nitrogen atmosphere. All solvents were deoxygenated and dried by sparging with N_2 gas and passage through an activated alumina column. Non-halogenated solvents were tested with a standard purple solution of sodium benzophenone ketyl in tetrahydrofuran to ensure dioxygen and water removal. Deuterated solvents were purchased from Cambridge Isotopes Laboratories, Inc. and were degassed and stored over activated 3 Å molecular sieves prior to use. All other reagents and solvents were purchased from commercial vendors and used without further purification unless otherwise noted. $NS^{t\text{-}Bu}_3$ (14), LiP-*i*-Pr_2 (25), and $N(CH_2CH_2Cl)_3$ (26) were prepared according to literature procedures. *CAUTION: $N(CH_2CH_2Cl)_3$ (a mustard agent) and thallium reagents are toxic and should be handled with extreme care.*

Elemental analyses were performed by Desert Analytics, Tucson, Arizona. A Varian Mercury-300 spectrometer was used to record ^1H and ^{31}P NMR spectra at room temperature. ^1H and ^{13}C NMR chemical shifts were referenced to residual solvent. ^{31}P NMR are reported relative to an external standard of 85% H_3PO_4 (0 ppm). Abbreviations for reported signal multiplicites are as follows: singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), broad (br). IR spectra were recorded on a Bio-Rad Excalibur FTS 3000 spectrometer controlled by Win-IR Pro software using a KBr solution cell. MS data were obtained by injection of a hydrocarbon solution onto a Hewlett-Packard 1100MSD mass spectrometer (ES^+) or an Agilent 5973 mass selective detector (EI). UV–vis measurements were recorded on a Varian Cary 50 Bio spectrophotometer controlled by Cary WinUV Software. All measurements were recorded using a quartz cell fitted with a Teflon® cap.

Room temperature solution magnetic susceptibilities were determined using the method of Evans (24). Electrochemical measurements were recorded in a glovebox under a dinitrogen atmosphere using a BAS CV 100 W (Bioanalytical Systems Inc., West Lafayette, Indiana). A glassy carbon working electrode, a platinum wire auxiliary electrode, and a $Ag/AgNO_3$ nonaqueous reference electrode were used in all studies. All measurements were carried out in THF solutions of electrolyte (0.32 mol/L tetra-*n*-butylammonium hexafluorophosphate) and analyte. All electrochemical measurements are referenced to Fc/Fc^+ as an internal standard.

X-band EPR measurements were recorded using a Bruker EMX spectrometer (controlled by Bruker Win EPR software version 3.0) equipped with a rectangular cavity working in the TE_{102} mode. Low-temperature measurements were conducted with an Oxford continuous-flow helium cryostat. Accurate frequency values were recorded from a frequency counter on the microwave bridge. Solution spectra were acquired in 1-methyltetrahydrofuran. Samples were prepared in a glovebox under dinitrogen in a quartz EPR tube equipped with a ground glass joint.

Crystallographic data for complexes **1**–**6** appear in Tables 1 and 2. X-ray diffraction studies were carried out at the Beckman Institute Crystallographic Facility on a Bruker Smart 1000 CCD diffractometer. Crystals were mounted on a glass fiber with Paratone-N oil. Crystallographic data were collected on a Bruker P4 diffractometer (0.710 73 Å MoKα) with a CCD area detector. Data were collected using the Bruker SMART program, collecting scans at five settings. Data reduction was performed using Bruker SAINT v6.2. Structure solution and structure refinement were performed using SHELXS-97 (Sheldrick, 1990) and SHELXL-97 (Sheldrick, 1997).

Refinement of F^2 against all reflections

The weighted *R* factor (*wR*) and goodness of fit (S) are based on F^2, conventional *R* factors (*R*) are based on *F*, with *F* set to zero for negative F^2. The threshold expression of $F^2 > 2\sigma(F^2)$ is used only for calculating *R* factors(gt), etc., and is not relevant to the choice of reflections for refinement. *R* factors based on F^2 are statistically about twice as large as those based on *F*, and *R* factors based on *all* data will be even larger.

All esds (except the esd in the dihedral angle between two l.s. planes) are estimated using the full covariance matrix. The cell esds are taken into account individually in the estimation of esds in distances, angles, and torsion angles; correlations between esds in cell parameters are only used when they are defined by crystal symmetry. An approximate (isotropic) treatment of cell esds is used for estimating esds involving l.

Synthesis of $NP^{i\text{-}Pr}_3$

In a 100 mL flask, tris(2-chloroethyl)amine (1.72 g, 8.41 mmol) was dissolved in THF (100 mL) and cooled to –78 °C, while stirring, for 30 min. Diisopropyllithiophosphine (3.34 g, 26.9 mmol) was dissolved in THF (50 mL)

and added dropwise to the stirring, cold solution of tris(2-chloroethyl)amine over the course of 30 min. After addition of the diisopropyllithiophosphine was complete, the reaction was slowly warmed to room temperature and stirred for 3 h. All volatiles were removed in vacuo to yield a pale yellow oil and white precipitate. The reaction mixture was then stirred in diethylether (30 mL) for 20 min. The resulting mixture was then filtered through a 60 mL, medium porosity, scintered glass frit that was layered with 1 inch (1 inch = 25.4 mm) of Celite® and 1 inch (1 inch = 25.4 mm) of silica gel. The white solids collected on the frit where then washed with two 20 mL portions of petroleum ether. All volatiles

© 2005 NRC Canada

were removed from the filtrate to yield $NP^{i\text{-}Pr}_3$ as a very viscous, pale yellow oil (3.48 g, 92%). ^{1}H NMR (300 MHz, C_6D_6): 2.87 (dt, 5.4 Hz, 6H), 1.5–1.75 (m, 12H) 1.05 (m, 36H). ^{13}C NMR (75 MHz, C_6D_6): 53.2 (d, 29.5 Hz), 24.1 (d, 14.3 Hz), 20.6 (t, 16.6 Hz), 19.4 (d, 9.7 Hz). ^{31}P NMR (121.4 MHz, C_6D_6): 0.78 (br s). FAB-MS (*m*/*z*): 450.3526 ($NP^{i\text{-}Pr}_3$ + H^+).

Synthesis of $NArP^{i\text{-}Pr}_3$

In a 100 mL flask, tris(2-bromo-*p*-tolyl)amine (3.0 g, 5.73 mmol) was dissolved in ether (50 mL) and cooled to –78 °C. Solid *t*-BuLi (2.2 g, 34.4 mmol) was added portionwise over 15 min. The reaction was warmed to room temperature after 30 min. Following 3 h of stirring, the reaction mixture was yellow in color with LiBr precipitate. The reaction vessel was cooled to –78 °C and chlorodiisopropylphosphine (2.8 g, 18.0 mmol) was added over 5 min. The mixture was stirred at ambient temperature for 18 h at which time it was filtered through a plug of silica gel and the solvent removed in vacuo. The resulting tacky solid was dissolved in CH_2Cl_2 (50 mL), filtered through Celite®, and dried to a solid. Trituration of the filtrate in methanol (150 mL) afforded an analytically pure fine white solid, which was collected on a fritted glass funnel and dried thoroughly under reduced pressure (2.4 g, 66%). ^{1}H NMR (300 MHz, $CDCl_3$): 7.25 (s), 7.16 (br s), 6.95 (s), 6.93 (s), 6.87 (dd, 2.0 Hz, 8.0H), 6.48 (dd, 4.0 Hz, 8.0H), 2.54 (m), 2.30 (s), 2.28 (s), 1.51 (d sept, 2.0 Hz, 7.0H), 1.21 (q, 7.5 Hz, 14.5H), 1.13 (dd, 7.0 Hz, 10.0H), 1.00 (br s), 0.91 (dd, 7.5 Hz, 10.0H), 0.825 (br s), 0.41 (7.5 Hz, 14H). ^{13}C NMR (126 MHz, $CDCl_3$): 155.1 (m), 154.5 (m), 135.0 (m), 134.7 (s), 133.9 (br s), 131.9 (s), 129.9 (br s), 129.3 (s), 127.7 (s), 23.9 (m), 23.4 (m), 21.9 (m), 21.1 (s), 21.0 (s), 19.2 (m). ^{31}P NMR (121 MHz, $CDCl_3$): –2.87 (br m), –11.28 (s). Synthesis of $[Fe(NP^{i\text{-}Pr}_3)Cl]PF_6$ (1[PF_6])

Solid $FeCl_2$ (0.335 g, 2.65 mmol) was added to a stirring solution of $NP^{i\text{-}Pr}_3$ (1.19 g, 2.56 mmol) dissolved in CH_2Cl_2 (2.0 mL). The slurry was stirred for 10 min and $TlPF_6$ was added dropwise as a THF (4.0 mL) solution over 15 min. A white precipitate began to form immediately. The reaction was stirred for 4 h and then filtered through Celite®. The pad of Celite® was washed with two portions of CH_2Cl_2 (5.0 mL). All volatiles were then removed in vacuo to yield a white solid. The white solid was extracted into CH_2Cl_2 (5.0 mL) and again filtered through a pad of Celite®. The colorless solution was then layered with Et_2O and stored at –35 °C for 2 days to afford colorless crystals of the desired product (1.48 g, 81.3%). μ_{eff} (CD_2Cl_2, 298 K): 5.04 μ_B. ^{1}H NMR (300 MHz, CD_2Cl_2): 27.5 (b), 3.2 (b), –8.5 (b). ^{31}P NMR (121.4 MHz, CD_2Cl_2): –141.5 (septet, 711 Hz, PF_6). Anal calcd. for $C_{24}H_{54}ClF_6FeNP_4$: C 42.03, H 7.94, N 2.04; found: C 42.13, H 8.00, N 2.05.

Synthesis of $[Fe(NP^{i\text{-}Pr}_3)Cl]BPh_4$ (1[BPh_4])

The tetraphenylborate salt was synthesized in a similar maner as **1**, with the following exceptions: sodium tetraphenylborate was used in place of $TlPF_6$, and methanol was used in place of THF.

Synthesis of $[Fe(NArP^{i\text{-}Pr}_3)Cl]BPh_4$ (2[BPh_4])

A 50 mL reaction vessel was charged with $NArP^{i\text{-}Pr}_3$ (1.0 g, 1.57 mmol), $FeCl_2$ (0.20 g, 1.57 mmol), sodium tetraphenylborate (0.540 g, 1.57 mmol), and THF (25 mL) and sealed with a Teflon® stopper. The reaction was heated at 65 °C for 12 h, cooled, and the solvent was removed in vacuo. The resultant yellow solids were washed with petroleum ether (2 × 20 mL) and dried under reduced pressure. The product was extracted into CH_2Cl_2, filtered through a plug of Celite® and layered petroleum ether, which afforded analytically pure yellow crystals upon standing (1.60 g, 97%). Crystals suitable for X-ray diffraction were obtained by layering an CH_2Cl_2 solution with diethylether. μ_{eff} (acetone-d_6, 298 K): 5.3 μ_B. ^{1}H NMR (300 MHz, CD_2Cl_2): 140.9 (br s), 30.2 (br s), 19.4 (br s), 15.3 (s), 15.0 (s), 9.76 (s), 7.32 (s), 7.03 (t, 7.8 Hz), 6.87 (m), 5.03 (s), –3.05 (br s), –16.1 (br s), –20.7 (br s). Anal. calcd. for $C_{63}H_{80}BClFeNP_3$: C 72.32, H 7.71, N 1.34; found: C 72.08, H 7.53, N 1.46.

Synthesis of $[Fe(NS^{t\text{-}Bu}_3)Cl]PF_6$ (3[PF_6])

$NS^{t\text{-}Bu}_3$ (0.133 g, 0.364 mmol) was stirred in 5.0 mL of THF and solid $FeCl_2$ (0.0457 g, 0.364 mmol) was added. A THF solution (4.0 mL) of $TlPF_6$ (0.127 g, 0.364 mmol) was added to the reaction dropwise over 20 min. A white precipitate began to form immediately. The reaction mixture was stirred for 3 h, concentrated to dryness, dissolved in CH_2Cl_2 (3.0 mL), and filtered through a pad of Celite®. Layering the resulting colorless filtrate with Et_2O produced colorless crystals (0.136 g, 62%) of the desired product. ^{1}H NMR (300 MHz, d_8 -THF): 20.5 (b), 10.9 (b), 2.6 (b). ^{31}P NMR (121.4 MHz, THF-d_8): –143.5 (septet, 711 Hz, PF_6). Anal. calcd. for $C_{18}H_{39}ClF_6FeNP$: C 35.91, H 6.16, N 2.33; found: C 35.23, H 6.16, N 2.46.

Synthesis of $[Fe(NP^{i\text{-}Pr}_3)(CO)]BPh_4$ (4[BPh_4])

A 0.23 weight% amalgam was prepared in a 25.0 mL Shlenk flask by dissolving solid Na (5.1 mg, 0.22 mmol) in mercury (2.21 g). The flask was then charged with $[Fe(NP^{i\text{-}Pr}_3)Cl]BPh_4$ (0.190 g, 0.221 mmol) dissolved in THF (5.0 mL) and a stir bar. The headspace of the flask was quickly evacuated and refilled three times with 1 atm of CO(g) (1 atm = 101.325 kPa). After the third cycle, the flask was sealed under 1 atm of CO(g) (1 atm = 101.325 kPa) and stirring commenced. The reaction mixture changed immediately from colorless to bright yellow. The reaction mixture was stirred for 12 h over which the color changed again from golden yellow to dark red. All volatiles were removed in vacuo and the resulting red-brown solid was extracted into THF (3.0 mL) and filtered through a pad of Celite® to remove insoluble material. The resulting red solution was layered with Et_2O and stored at –35 °C overnight. The next day, large red crystals of the product were isolated on a medium porosity frit and dried. IR (THF, KBr, cm^{-1}) ν(CO): 1881. μ_{eff} (THF-d_8, 298 K): 2.15 μ_B. ^{1}H NMR (THF-d_8): 19.1 (b), 7.65 (b), 7.2 (b), 7.0 (b), 3.6 (b), –0.47 (b). Anal. calcd. for $C_{49}H_{75}BFeNOP_4$: C 68.94, H 8.86, N 1.64; found: C 68.96, H 8.62, N 1.66.

Synthesis of $[Fe(NArP^{i\text{-}Pr}_3)(CO)]BPh_4$ (5[BPh_4])

In a 50 mL Schlenk flask, $[(NArP^{i\text{-}Pr}_3)FeCl][BPh_4]$ (60 mg, 0.057 mmol) was dissolved in THF (50 mL) and so-

© 2005 NRC Canada

dium metal (1.3 mg, 0.057 mmol) amalgamated in mercury (1.84 g, 9.17 mmol) was added. The solution was sparged with CO(g) for 10 min and then stirred vigorously for 18 h during which time the solution became green in color. The solvent was removed under reduced pressure, and the resultant green solids were extracted with THF (5 mL) and then filtered. The green filtrate was layered with petroleum ether (15 mL) and the desired product precipitated as analytically pure red crystals (49 mg, 83%). μ_{eff} (THF-d_8, 298 K): 2.1 μ_B. IR (THF, KBr, cm^{-1}) ν(CO): 1880. Anal. calcd. for $C_{63}H_{80}BFeNOP_3$: C 73.99, H 7.76, N 1.35; found: C 73.76, H 7.70, N 1.47.

Synthesis of $[Fe(NP^{i\text{-}Pr}{}_3)(N_2)(H)]PF_6$ (6[PF_6])

Solid **1**[PF_6] (0.222 g, 0.324 mmol) was dissolved in THF (10 mL) and cooled to –78 °C. To this solution a solution of $Li(HBEt_3)$ (1.0 mol/L in ether) (356 μL, 0.356 mmol) was added dropwise via syringe. The reaction mixture changed slowly from colorless to pale yellow over 1 h. The reaction mixture was warmed to room temperature and filtered through a pad of Celite®. The yellow filtrate was dried in vacuo to yield a yellow-brown solid. The solid was extracted into THF (4.0 mL) and filtered through a pad of Celite®. The filtrate was layered with Et_2O (4.0 mL) and stored at –35 °C for 3 days to afford light yellow crystals of the desired product (0.142 g, 66%). IR (THF, KBr, cm^{-1}): ν(N_2) 2090, ν(FeH) 1865. ^{1}H NMR (300 MHz, THF-d_8): –8.77 (dt, J_{PH} = 74.1 Hz (cis), J_{PH} = 38.1 Hz (trans)), 1.4–1.6 (m, 36H), 1.8 (t, 2H), 1.94 (m, 4H), 1.98 (m, 2H), 2.15–2.25 (m, 4H), 2.32 (m, 2H), 2.48 (m, 2H) 2.70 (m, 2H). ^{31}P NMR (121.4 MHz, THF-d_8): 67.6 (d, 2P J_{pp}= 41.4 Hz), 62.2 (t, 1P), –141.5 (septet, 1P, J_{FP} = 711 Hz, PF_6). Anal. calcd. for $C_{24}H_{55}F_6FeN_3P_4$: C 42.43, H 8.16, N 6.18; found: C 42.82, H 8.16, N 5.72.

Synthesis of $[Fe(NP^{i\text{-}Pr}{}_3)(N_2)(D)]PF_6$

$Fe(NP^{i\text{-}Pr}{}_3)(N_2)(D)]PF_6$ was prepared by following the synthetic protocol outlined for **6**[PF_6] and using $Li(DBEt_3)$ in place of $Li(HBEt_3)$. The IR (THF, KBr) for this complex exhibits a ν(FeD) = 1341 cm^{-1}.

Synthesis of tungsten complexes that contain hexaisopropylterphenyl-substituted triamidoamine ligands, and reactions relevant to the reduction of dinitrogen to ammonia

Dmitry V. Yandulov and Richard R. Schrock

Abstract: [$HIPTN_3N$]WCl (**W**Cl) can be synthesized readily by adding H_3[$HIPTN_3N$] to WCl_4(DME) followed by $LiN(SiMe_3)_2$ ([$HIPTN_3N$]$^{3-}$ = [(HIPTNCH$_2$CH$_2$)$_3$N]$^{3-}$ where HIPT = 3,5-(2,4,6-*i*-Pr$_3$C$_6$H$_2$)$_2$C$_6$H$_3$ = HexaIsoPropylTerphenyl). Reduction of **W**Cl with KC_8 in benzene under N_2 yields **W**N=NK. **W**N=NK is readily oxidized in THF by $ZnCl_2$ to yield zinc metal and **W**N_2. Reduction of **W**N_2 to [**W**N_2]$^-$ is reversible at –2.27 V vs. $FeCp_2^{+/0}$ in 0.1 mol/L [Bu_4N][BAr$'_4$]/PhF electrolyte (Ar′ = 3,5-(CF$_3$)$_2$C$_6$H$_3$), while oxidation of **W**N_2 to [**W**N_2]$^+$ is also reversible at –0.66 V. Protonation of **W**N=NK by [Et_3NH][OTf] in benzene yields **W**N=NH essentially quantitatively. Protonation of **W**N=NH at N_β with [H(OEt)$_2$][BAr$'_4$] in ether affords [**W**=NNH_2][BAr$'_4$] quantitatively. Electrochemical reduction of [**W**=NNH_2][BAr$'_4$] in 0.1 mol/L [Bu_4N][BAr$'_4$]/PhF is irreversible at scan rates of up to 1 V/s. Addition of NaBAr$'_4$ and NH_3 to **W**Cl in PhF yields [**W**(NH_3)][BAr$'_4$]. Electrochemical reduction of [**W**(NH_3)][BAr$'_4$] in 0.1 mol/L [Bu_4N]-[BAr$'_4$]/PhF is irreversible at –2.06 V vs. $FeCp_2^{+/0}$ at a scan rate of 0.5 V/s. Treatment of [**W**(NH_3)][BAr$'_4$] with triethylamine and [$FeCp_2$][PF_6] in C_6D_6, followed by $LiN(SiMe_3)_2$, yielded **W**≡N. Treatment of [**W**(NH_3)][BAr$'_4$] with $LiBHEt_3$ (1 mol/L in THF) results in formation of **W**H, which is converted to **W**H_3 upon exposure to an atmosphere of H_2. Attempts to prepare **W**N=NH by treating **W**N_2 with [2,6-LutH][BAr$'_4$] and $CoCp_2$ yielded only [**W**=NNH_2][BAr$'_4$]. [**W**=NNH_2][BAr$'_4$] is reduced to **W**=NNH_2 by $CoCp_2^*$, but this species disproportionates to yield **W**N=NH, **W**≡N, and ammonia. Reduction of [**W**(NH_3)][BAr$'_4$] with $CoCp_2^*$ does not yield any observable **W**(NH_3). Attempted catalytic reduction of dinitrogen using **W**N_2 as the catalyst under conditions identical or similar to those employed for catalytic reduction of dinitrogen by **Mo**N_2 and related Mo complexes failed. Single crystal X-ray studies were carried out on **W**-N=NK, **W**N_2, **W**-N=NH, [**W**=NNH_2][BAr$'_4$], and [**W**(NH_3)][BAr$'_4$].

Key words: dinitrogen, reduction, tungsten, ammonia.

Résumé : Le complexe [$HIPTN_3N$]WCl (**W**Cl) peut facilement être synthétisé par l'addition de H_3[$HIPTN_3N$] à du WCl_4(DME), suivie d'une additon de $LiN(SiMe_3)_2$ ([$HIPTN_3N$]$^{3-}$ = [(HIPTNCH$_2$CH$_2$)$_3$N]$^{3-}$ dans lequel HIPT = 3,5-(2,4,6-*i*-Pr$_3$C$_6$H$_2$)$_2$C$_6$H$_3$ = HexaIsoPropylTerphényle). La réduction de **W**Cl par du KC_8, dans du benzène, sous atmosphère d'azote, conduit à la formation de **W**N=NK. Sous l'action du $ZnCl_2$ dans du THF, le **W**N=NK s'oxyde facilement pour conduire à la formation de zinc métallique et de **W**N_2. Dans un électrolyte à 0,1 mol/L de [Bu_4N][BAr$'_4$]/PhF (Ar′ = 3,5-(CF$_3$)$_2$C$_6$H$_3$), la réduction du **W**N_2 en [**W**N_2]$^-$ est réversible à –2,27 V vs. $FeCp_2^{+/0}$ alors que l'oxydation du [**W**N_2] en [**W**N_2]$^+$ est aussi réversible à –0,66 V. La protonation du **W**N=NK par le [Et_3NH][OTf], dans le benzène, conduit à la formation de **W**N=NH, avec un rendement pratiquement quantitatif. La protonation du **W**N=NH au niveau du N_β avec du [H(OEt)$_2$][BAr$'_4$], dans l'éther, conduit à la formation de [**W**=NNH_2][BAr$'_4$] avec un rendement quantitatif. La réduction électrochimique du [**W**=NNH_2][BAr$'_4$] dans du [Bu_4N][BAr$'_4$]/PhF à 0,1 mol/L est irréversible à des vitesses de balayage allant jusqu'à 1 V/s. L'addition de NaBAr$'_4$ et de NH_3 au **W**Cl dans du PhF conduit à la formation de [**W**(NH_3)][BAr$'_4$]. La réduction électrochimique du [**W**(NH_3)][BAr$'_4$] dans du [Bu_4N][BAr$'_4$]/PhF à 0,1 mol/L est irréversible à –2,06 V vs. $FeCp_2^{+/0}$, à une vitesse de balayage de 0,5 V/s. Le traitement du [**W**(NH_3)][BAr$'_4$] par de la triéthylamine et du [$FeCp_2$][PF_6] dans du C_6D_6, suivi de $LiN(SiMe_3)_2$ conduit à la formation de **W**≡N. Le traitement de [**W**(NH_3)][BAr$'_4$] par du $LiBHEt_3$ (1 mol/L dans du THF) conduit à la formation de **W**H qui peut être transformé en **W**H_3 par exposition à un atmosphère de H_2. Des essais en vue de préparer le **W**N=NH par traitement du **W**N_2 avec du [2,6-LutH][BAr$'_4$] et du $CoCp_2$ ne fournissent que du [**W**=NNH_2][BAr$'_4$]. Sous l'influence du $CoCp_2^*$, le [**W**=NNH_2]-[BAr$'_4$] est réduit en **W**=NNH_2, mais cette espèce subit une réaction de dismutation conduisant à la formation de **W**N=NH, de **W**≡N et d'ammoniac. La réduction du [**W**(NH_3)][BAr$'_4$] par le $CoCp_2^*$ ne fournit aucune trace de **W**(NH_3). Des essais en vue d'effectuer la réduction du diazote en utilisant du **W**N_2 comme catalyseur, dans des

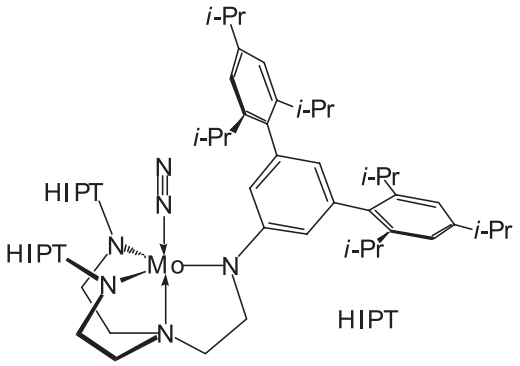
conditions identiques ou semblables à celles utilisées pour la réduction catalytique du diazote par le **Mo**N_2 et les complexes apparentés du molybdène n'ont pas donné les résultats escomptés. Des études de diffraction des rayons X sur un cristal unique ont été effectuées sur le **W**-N=NK, le **W**N_2, le **W**-N=NH, le [**W**=NNH_2][BAr'_4] et le [**W**(NH_3)][BAr'_4].

Mots clés : diazote, réduction, tungstène, ammoniac.

[Traduit par la Rédaction]



Introduction

Discovery of the first dinitrogen complex of a transition metal, $[Ru(NH_3)_5(N_2)]^{2+}$, in 1965 (1) provided support for the proposal that dinitrogen might be reduced to ammonia at a molybdenum center in nitrogenase (only the FeMo nitrogenase was known at the time (2–4)). As more and more types of transition-metal-catalyzed reactions were discovered in the following decades, scientists became optimistic that catalysts would be discovered for the reduction of dinitrogen to ammonia, or for the combination of dinitrogen with elements other than hydrogen (5–16). Unfortunately, although hundreds of man years have been directed toward this goal in the last 40 years, and although hundreds of dinitrogen complexes of all transition metals in groups 4 through 10 (if we include those detected at low temperature in matrices) are now known, progress has been relatively slow.

Chatt, a pioneer, along with Hidai, in dinitrogen chemistry involving W(0) and Mo(0) phosphine complexes (5–7, 12, 14) believed that dinitrogen could be reduced to ammonia at a single metal center through end-on binding of dinitrogen, and was the first to show that up to 2 equiv. of ammonia per metal could be formed from M(0) dinitrogen complexes (M = Mo or W) upon addition of protons, the six electrons being provided by the metal (5). If dinitrogen could be reduced to ammonia catalytically through the addition of six external protons and six external electrons, and if a distinct intermediate were formed upon addition of each proton and electron, then 12 intermediates could be imagined, or a total of 14 if one includes a dinitrogen complex and a complex that contains no nitrogen or nitrogen-derived ligand. Although examples of almost all of the proposed intermediates for reduction of dinitrogen at a single Mo or W center in a "Chatt cycle" have been isolated, the ligand environment (L_x) of the metal has varied from compound to compound, and no catalytic reaction to give ammonia was ever achieved (see, however, the synthesis of silylamines catalytically (17)). Significant progress has been made toward utilizing atmospheric dinitrogen to make organic molecules (6, 7, 18–26). One catalytic reduction is known in which dinitrogen is reduced to a mixture of hydrazine (largely) and ammonia (9, 27, 28). This system requires molybdenum, is catalytic with respect to molybdenum, produces >90% hydrazine, and takes place in methanol in the presence of $Mg(OH)_2$ and a strong reducing agent (e.g., Na amalgam). Unfortunately, few details concerning the mechanism of this intriguing reaction have been established. In this context, it should be noted that ammonia can be formed from hydrazine via disproportionation (to dinitrogen and ammonia) in the presence of transition metals. In fact, $[Ru(NH_3)_5(N_2)]^{2+}$ was first prepared by treating Ru salts with hydrazine (1).

We have been interested in dinitrogen chemistry of early metals in relatively high oxidation states for more than two decades (29). Approximately 4 years ago, we began to explore the chemistry of Mo complexes that contain a triamidoamine ($[(ArNCH_2CH_2)_3N]^{3-}$ = $[ArN_3N]^{3-}$, Ar = aryl) ligand (30, 31). To prevent formation of what we believe to be relatively stable and unreactive bimetallic [ArN_3N]Mo-N=N-Mo[ArN_3N] complexes, maximize steric protection of a metal coordination site in a monometallic species, and provide increased solubility in nonpolar solvents, we synthesized species that contain a $[HIPTN_3N]^{3-}$ ligand, where HIPT = 3,5-(2,4,6-*i*-$Pr_3C_6H_2)_2C_6H_3$ (HexaIsoPropylTerphenyl, see Fig. 1) (32, 33). Starting with **Mo**Cl (**Mo** = [$HIPTN_3N$]Mo), we showed that we could isolate and characterize many intermediates in a hypothetical Chatt-like reduction of dinitrogen, all of which contain the same $[HIPTN_3N]^{3-}$ supporting ligand (Fig. 2). These intermediates include paramagnetic **Mo**(N_2) (**1**), diamagnetic [**Mo**(N_2)]$^-$ (**2**), diamagnetic **Mo**-N=N-H (**3**), diamagnetic {**Mo**=N-NH_2}{BAr'_4} (**4**; Ar′ = 3,5-$(CF_3)_2C_6H_3$), diamagnetic Mo≡N (**7**), diamagnetic {**Mo**=NH}{BAr'_4} (**8**), paramagnetic {**Mo**(NH_3)}{BAr'_4} (**12**), and paramagnetic **Mo**(NH_3) (**13**). Extensive ^{15}N labeling studies, NMR studies, and X-ray studies (of **1**, **2** (as two different Mg derivatives), **7**, and **12** (33), and **3**, **4**, **8**, and **13** (34)) all reveal a trigonal pocket in which N_2 or its reduced products are protected to a dramatic degree by three 3,5-(2,4,6-*i*-$Pr_3C_6H_2)_2C_6H_3$ (HIPT) rings clustered around it. Compounds **5**, **6**, **10**, and **14** (Fig. 2) have not yet been observed. The oxidation state of the metal varies between Mo(III) and Mo(VI) in the species as they are drawn in Fig. 2. No other unambiguous example of one of these complexes (**3**) is known, presumably either because in other systems bimolecular processes that involve H radical or proton transfer result in facile decomposition, or the synthetic methods are incompatible with the ligands that are present. Steric protection of the nitrogen entities within the pocket provided by the bulky HIPT groups are believed to be an important reason why several of the most unusual species can be prepared.

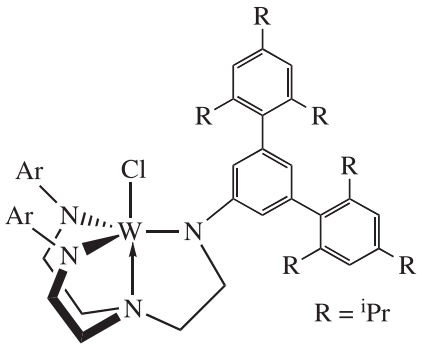
Fig. 2. Proposed intermediates in the reduction of dinitrogen at a [HIPTN$_3$N]Mo (**Mo**) center through the step-wise addition of protons and electrons.

We then showed that it is possible in fact to reduce dinitrogen catalytically in heptane using {2,6-lutidinium}{BAr$'_4$} as the proton source and decamethylchromocene as the electron source (35). The results of 16 runs using four different Mo derivatives (**1**, **3**, **7**, or **12**) revealed that ~8 equiv. of ammonia are formed with an efficiency of 63%–66% based on reducing equivalents available. A run employing **Mo**(^{15}N^{15}NH) under ^{15}N$_2$ yielded entirely ^{15}N-labeled ammonia. We assume at this stage that any equivalents of reducing agent that are not consumed in making ammonia are consumed to form hydrogen, and we now know that no hydrazine is formed.[3] The fact that compounds that contain hexamethylterphenyl or hexa-*tert*-butylterphenyl variations of the [HIPTN$_3$N]$^{3-}$ ligand are relatively inefficient catalysts for catalytic reduction of dinitrogen to ammonia (37) suggests that the catalytic reaction is extremely finely balanced and that perhaps most or all of the intermediates shown in Fig. 2 are actually involved. All are likely to be equilibria with exception of the actual N—N bond cleavage reaction (**Mo**=N-NH$_3^+$ + e → **Mo**≡N + NH$_3$).

It has been known for some time that certain bacteria grown in the presence of tungsten will produce a "FeW nitrogenase", but that enzyme will not reduce dinitrogen to ammonia (2, 3, 38). Therefore, we became interested in preparing some tungsten analogs of the [HIPTN$_3$N]Mo species shown in Fig. 2, exploring conversion of one to another, and testing at least one of them for catalytic dinitrogen reduction activity. We report this work here.

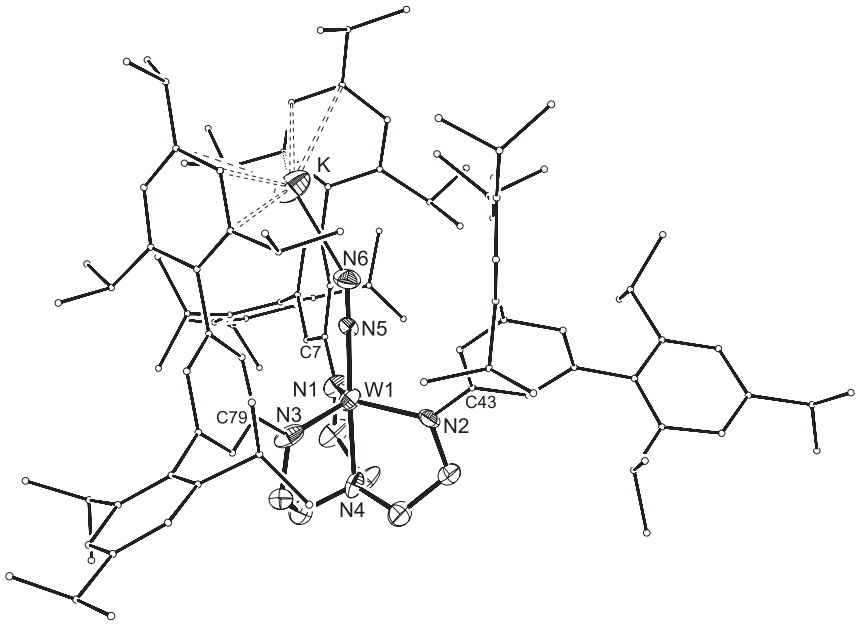


Results

Synthesis of WCl and diazenido species

The starting material for this chemistry ([HIPTN$_3$N]WCl (**W**Cl)) can be readily synthesized by a two-step method analogous to that used to prepare [HIPTN$_3$N]MoCl (33) as shown in eq. [1]. The ^{1}H NMR spectrum of high-spin **W**Cl (d^2) contains sharper resonances than does the spectrum of **Mo**Cl; this difference, and the pattern of relative shifts of the corresponding resonances between Mo and W complexes is very similar to that observed previously for a series of related [ArN$_3$N]MCl (M = Mo, W) (30, 39, 40) and [Me$_3$SiN$_3$N]MCl (41–43) complexes. Like **Mo**Cl, **W**Cl is exceedingly air- and moisture sensitive, so the utmost care is required to ensure that solvents are pure, dry, and free of oxygen.

Reduction of **Mo**Cl with magnesium in THF under an atmosphere of dinitrogen led to salts that contain the [**Mo**(N$_2$)]$^-$ anion (33). However, attempts to prepare [**W**(N$_2$)]$^-$ salts in this manner were not successful; **W**Cl was slowly converted into a complex mixture of unidentified products. Reduction of **W**Cl is markedly accelerated when potassium graphite (KC$_8$) is employed as the reductant in THF or DME, but a complex mixture of products is still formed. However, when **W**Cl is treated with KC$_8$ in benzene under dinitrogen, clean and nearly quantitative conversion of **W**Cl to diamagnetic **W**-N=NK takes place over a period of 1 to 2 days at room temperature (eq. [2]). No intermediates could be detected by ^{1}H NMR when this reaction was performed in C$_6$D$_6$. Deep red **W**-N=NK was isolated in good yield and was fully characterized. Since **W**-N=NK can be dissolved in THF without decomposition (vide infra), failure of the reductions in THF and DME must be attributed to a some side reaction or reactions prior to binding of dinitrogen to the metal, presumably at the W(III) stage. **W**N=NK is readily soluble in aliphatic



[1] WCl$_4$(DME) —(1. H$_3$[HIPTN$_3$N], C$_6$H$_6$, 2 h; 2. 3.1 LiN(SiMe$_3$)$_2$, 2 h)→ **W**Cl

solvents and can be recrystallized without change from pentane.

The structure of **W**-N=NK, as determined through a single crystal X-ray study, is shown in Fig. 3 (see also Table 1 for crystal data and Table 2 for selected M—N and N—N bond distances and angles in W and Mo analogs, along with selected IR and NMR data. A full set of X-ray data is available as supporting information.[4] The potassium ion is 2.536(7) Å from N6, the β nitrogen in the unsubstituted diazenido ligand, and is supported through six interactions with aryl carbon atoms in two Trip (2,4,6-*i*-$Pr_3C_6H_2$) aromatic rings of two HIPT substituents. The potassium ion resides 3.229 and 3.301 Å from the ring centroids, and all K···H contacts are >2.92 Å. Interaction between the potassium and the aromatic rings is not symmetric, with K···C distances spanning a range of 0.52 Å for each ring. The presence of the potassium ion has no noticeable effect on the C—C bond distances in the two aryl rings with which it interacts. Understandably, the orientations of the three HIPT groups are significantly different, with one HIPT group in contact with K being rotated by only 10° out of the plane of the amide nitrogen (N1), while the other two HIPT groups are rotated by an average of 28.3° outside of the plane of the amide nitrogen to which they are attached. "Encapsulation" of the K ion between two aryl rings accounts for the high solubility of **W**-N=NK in aliphatic solvents (binding of sodium or potassium ions to aryl rings in high oxidation state amido complexes has considerable precedent in the literature (44–47)). The N—N (1.220(8) Å) and W—N (1.849(7) Å) bond distances are consistent with a considerably greater degree of reduction of the N_2 unit in **W**-N=NK relative to that in **Mo**-N=NMgBr$(THF)_3$ (1.156(8) and 1.863(7) Å, respectively) (33). Greater backbonding from the tungsten center in **W**-N=NK (vs. the molybdenum center in **Mo**-N=NMgCl$(THF)_3$ (33)) is also evident from the relative values for ν_{NN} in the two species (1745 cm^{-1} (W) and 1812 cm^{-1} (Mo), respectively, in benzene). The W-N_α-N_β angle is essentially linear (177.3(6)°), as expected.

[b]Anion = BAr$'_4^-$.

Doubly labeled **W**-^{15}N=^{15}NK reveals sharp doublet resonances for ^{15}N$_\alpha$ (at 357 ppm) and ^{15}N$_\beta$ (at 350 ppm) in the ^{15}N NMR spectrum in C_6D_6 at room temperature. The ^{15}N$_\alpha$ and ^{15}N$_\beta$ resonances in **W**-^{15}N=^{15}NK are relatively close together, yet fall well within the range typical for compounds of this general type (48, 49). The ^{1}H NMR spectrum of **W**-N=NK in C_6D_6 at room temperature features slightly broadened resonances, yet is otherwise consistent with a C_{3v}-symmetric structure. Apparently the interactions between the potassium ion and the aryl rings are weak enough so that intramolecular ligand fluxionality in **W**-N=NK, including rotation of the HIPT rings around the N—C$_{ipso}$ bonds, is not hindered significantly at room temperature.

Treatment of a C_6D_6 solution of **W**-N=NK with Bu$_4$NCl results in a rapid color change from maroon-red to dark green. Both IR and ^{1}H NMR spectra of the green solution show complete conversion of **W**-N=NK to a single diamagnetic product with a ν_{NN} frequency shifted to higher energy

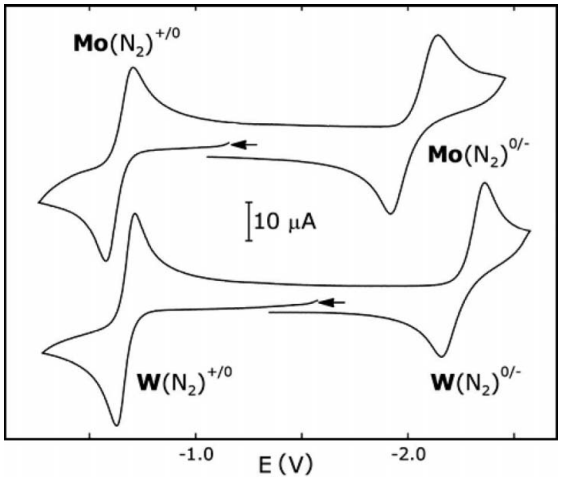
Fig. 4. Thermal ellipsoid drawing of $\mathbf{W}N_2$ (50% probability level, hydrogen atoms omitted).



by 56 cm^{-1} from what it is in **W**-N=NK. These observations are analogous to those made for related **Mo** diazenides (33) and indicate formation of a species in which there is essentially no interaction between the cation and the β nitrogen, i.e., formation of $[\mathbf{W}\text{-}N{=}N]^-$. However, all attempts to crystallize [**W**-N=N][Bu_4N] (e.g., by precipitation with pentane) have failed. This compound appears to decompose to yield two major pentane-soluble diamagnetic tungsten complexes and Bu_3N. We speculate that part of the decomposition consists of a reaction between $[\mathbf{W}N_2]^-$ and Bu_4N^+ to yield **W**-N=NBu and Bu_3N. In contrast, [**Mo**-N=N][Bu_4N] can be isolated and is stable at room temperature (33). A greater nucleophilicity of $[\mathbf{W}N_2]^-$ compared to $[\mathbf{Mo}N_2]^-$ at N_β would be consistent with the observed greater degree of backbonding from tungsten to the N_2 unit and would not be surprising.

Synthesis of a terminal dinitrogen complex of W(III)

Like various $\{\mathbf{Mo}\text{-}N{=}N\}^-$ salts (33), **W**N=NK is readily oxidized in THF by $ZnCl_2$ to yield zinc metal and the neutral dinitrogen complex, $\mathbf{W}N_2$, essentially quantitatively. The $\mathbf{W}N_2$ complex was isolated as an orange solid in 53% yield starting from **W**Cl and has been fully characterized. The ^1H NMR spectrum of $\mathbf{W}N_2$ in C_6D_6 resembles that of the low-spin d^3 $\mathbf{Mo}N_2$ analog (33), although the ligand backbone resonances of the **W** complex are broader and shifted with respect to those for $\mathbf{Mo}N_2$ (at 35, –11, and –23 ppm for $\mathbf{W}N_2$ and at 23 (NCH_2), –5 (4,6-*H*), and –34 (NCH_2) ppm in $\mathbf{Mo}N_2$). $\mathbf{W}N_2$ is the only known terminal dinitrogen complex of tungsten in which a triamido/amine ligand is present and the only one of W(III) to our knowledge.

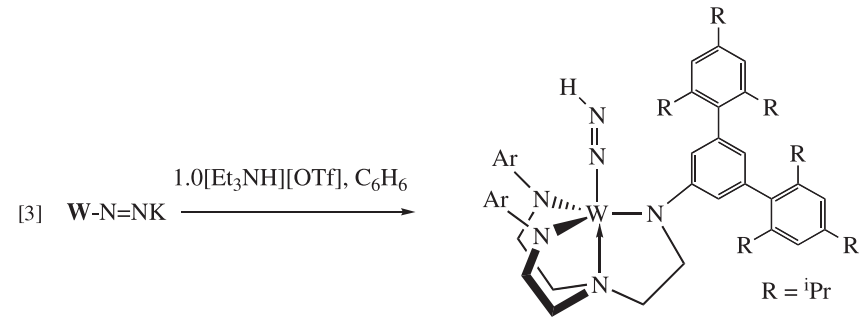
A single crystal X-ray study of $\mathbf{W}N_2$ (Fig. 4) shows it to have a structure analogous to that of $\mathbf{Mo}N_2$ (33) with an N—N bond distance of 1.132(8) Å (cf. 1.098 Å in free N_2 and 1.061(7) Å in $\mathbf{Mo}N_2$). The observed "shorter" N—N bond length in $\mathbf{Mo}N_2$ than in free dinitrogen is believed to be a consequence of a slight "libration" of the bound dinitrogen about the center of the N—N bond, which would make the N—N bond appear slightly shorter than it actually is (34). The actual N—N bond distance in $\mathbf{W}N_2$ therefore actually also could be somewhat longer than what is observed, although one might expect the degree of this type of libration of a bound dinitrogen to decrease as backbonding to dinitrogen increases. There is clearly a greater degree of backbonding to N_2 in $\mathbf{W}N_2$ than in $\mathbf{Mo}N_2$ also according to ν(N-N) frequencies, i.e., the value for ν(N-N) is nearly 100 cm^{-1} lower in $\mathbf{W}N_2$ (1888 cm^{-1}) than in $\mathbf{Mo}N_2$ (1990 cm^{-1}). All other structural details are normal for $[HIPTN_3N]^{3-}$ complexes (see supporting information).[4]

Fig. 5. Electrochemical behavior of $\mathbf{M}N_2$ (**M** = **Mo** or **W**) in 0.1 mol/L [Bu_4N][BAr'_4]/PhF, recorded at a glassy carbon electrode (3 mm diam.) at a scan rate of 500 mV/s. The potential scale is referenced to $FeCp_2^{+/0}$.

Electrochemical reduction of $\mathbf{W}N_2$ to $[\mathbf{W}N_2]^-$ is reversible and takes place at –2.27 V vs. $FeCp_2^{+/0}$ in 0.1 mol/L [Bu_4N][BAr'_4]/PhF electrolyte (Fig. 5) (the advantages of $[Bu_4N]^+$ salts of relatively unreactive and weakly coordinating anions as electrolytes in polar, but relatively unreactive solvents such as fluorobenzene, were demonstrated more than 10 years ago (50), and have been explored more systematically by Geiger and co-workers in the last several years (51–55)). The $\mathbf{W}N_2^{0/-}$ potential is 260 mV more negative than the corresponding $E^{\circ\prime}(\mathbf{Mo}N_2^{0/-})$ value (34), consistent with tungsten being more difficult to reduce than

© 2005 NRC Canada

molybdenum, as expected. The tungsten dinitrogen complex also undergoes a reversible electrochemical oxidation, but at the *same* potential as the molybdenum dinitrogen complex (–0.66 V, Fig. 5). The similarity in the $\mathbf{M}N_2^{+/0}$ potentials for Mo and W can be ascribed to an effective "leveling" of the HOMO energies in the two $\mathbf{M}N_2$ complexes as a consequence of increased π donation from the metal to N_2 in $\mathbf{W}N_2$ ($\Delta\nu$(N-N) = 102 cm^{-1}, vide supra). However, the HOMO energies in $[\mathbf{Mo}N_2]^-$ and $[\mathbf{W}N_2]^-$ are not approximately the same, and $[\mathbf{W}N_2]^-$ therefore remains a stronger one-electron reductant than $[\mathbf{Mo}N_2]^-$ by 260 mV under the conditions described.

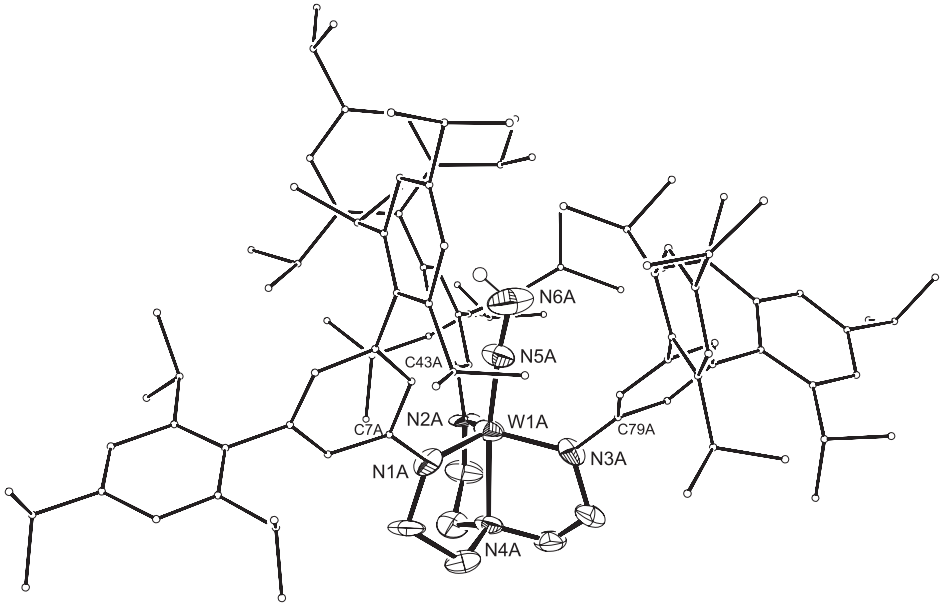


Synthesis of WN=NH and $[W{=}NNH_2][BAr'_4]$

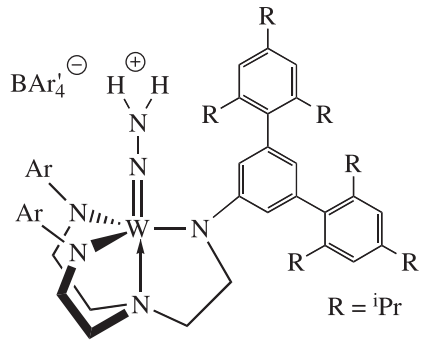
Protonation of **W**N=NK by [Et_3NH][OTf] in benzene is virtually instantaneous and yields **W**N=NH essentially quantitatively (eq. [3]). Diamagnetic **W**N=NH was isolated in 55% yield starting from **W**Cl and has been fully characterized. The N=N*H* resonance appears at 8.43 ppm in the ^{1}H NMR spectrum in C_6D_6, flanked by ^{183}W satellites with $^3J(^{183}W\text{-}H)$ = 17.4 Hz. The IR spectrum in C_6D_6 exhibits a ν(N-N) absorption at 1542 cm^{-1}, a frequency 45 cm^{-1} lower than the corresponding value in **Mo**N=NH (34). The ^{1}H NMR spectrum of doubly labeled **W**-^{15}N=^{15}NH features a doublet of doublets for the ^{15}N=^{15}N*H* resonance ($^1J(^{15}N_\beta\text{-}H)$ = 53.1 Hz, $^2J(^{15}N_\alpha\text{-}H)$ = 6.7 Hz) and two doublets of doublets at 394 ($^{15}N_\alpha$) and 229 ($^{15}N_\beta$) ppm ($^1J(^{15}N\text{-}^{15}N)$ = 15.4 Hz) in the ^{15}N NMR spectrum. These NMR data are similar to those observed for **Mo**N=NH (Table 2). Unlike **Mo**N=NH, however, **W**N=NH is quite stable thermally, suffering only minor decomposition after a solution in C_6D_6 had been heated to 65 °C for 11 days. In contrast, **Mo**N=NH decays in C_6D_6 with a half-life of ~7 h at 61 °C, forming predominantly **Mo**H, when prepared via a method analogous to that shown in eq. [3]. This decomposition was shown to be promoted by traces of acid (33) that are believed to remain after the Mo reaction analogous to that shown in eq. [3].

The X-ray crystal structure of **W**N=NH is shown in Fig. 6. Owing to the presence of two independent molecules in the unit cell and the difficulty of obtaining adequately sized crystals of this compound, the quality of this structure is mediocre (*R*1 = 10%). However, it was possible to refine all non-hydrogen atoms anisotropically. The critical geometrical parameters of the two crystallographically independent molecules are statistically indistinguishable (within 3σ). The average W—N_α (1.732(9) Å) and N_α—N_β (1.286(11) Å) distances are shorter and longer, respectively, than those in **Mo**N=NH (1.810(7) and 1.25(1) Å, Table 2), consistent with a greater degree of backbonding from tungsten into the N=NH group. A greater degree of backbonding from W is also evident from a lower value for ν(N-N) in **W**N=NH (1542 cm^{-1}) than in **Mo**N=NH (1587 cm^{-1}). Each molecule of **W**N=NH is noticeably asymmetric within the $[HIPTN_3N]^{3-}$ ligand. One W—N(amide) distance is slightly shorter than the other two in each molecule, and the HIPT group attached to that amido nitrogen is rotated out of its plane by an average of 68° in the direction *opposite* to the average turn of 28° found for the other two HIPT groups in each molecule. As a result, the three HIPT groups in each molecule do not form a pseudo three-fold symmetric propeller arrangement around the apical pocket similar to what is found in 13 other [HIPTN_3N]Mo and [HIPTN_3N]W derivatives. The hydrazide ligand is bent at both W (N5-W-N4 = 173.1(4)°) and N5 (W-N5-N6 = 173.6(9)°) in the same direction, primarily toward the unique N(amide) (N3A in the molecule shown in Fig. 6). The diazenide hydrogen was not located, but was added and refined in the position shown. It should be noted that N_α-N_β-R angles in diazenido compounds vary, e.g., from 132° in [$(Me_3SiNCH_2CH_2)_2NCH_2CH_2NMe_2$)]-Mo($CH_3$)($N_2$TMS) to 170° in {[$(Me_3SiNCH_2CH_2)_2$N-$CH_2CH_2NMe_2$]Mo-N=N$SiMe_3$}OTf (56). Therefore, we cannot say with any degree of certainty exactly where H_β is located. To our knowledge, **Mo**N=NH (33, 34) and **W**N=NH are the only structurally characterized examples of parent diazenide complexes of any metal.

Protonation of **W**N=NH at N_β with [H$(OEt)_2$][BAr'_4] in ether affords the hydrazido(2–) species $[\mathbf{W}{=}NNH_2][BAr'_4]$ essentially quantitatively (eq. [4]). This W(VI) species can be isolated in good yield as a pale-yellow solid and has been fully characterized. The NNH_2^+ resonance appears at 5.96 ppm in the ^{1}H NMR spectrum in C_6D_6, flanked by barely resolved ^{183}W satellites ($^1J(^{183}W\text{-}H)$ = 6 Hz). Labeled $[\mathbf{W}{=}{}^{15}N^{15}NH_2][BAr'_4]$ features a doublet of doublets for the $^{15}N^{15}NH_2^+$ resonance in the ^{1}H NMR spectrum ($^1J(^{15}N_\beta\text{-}H)$ = 83.6 Hz, $^2J(^{15}N_\alpha\text{-}H)$ = 1.8 Hz) and a doublet at 344 ($^{15}N_\alpha\text{-}^{15}N_\beta H_2^+$) and a triplet of doublets at 131 ppm ($^{15}N_\alpha\text{-}^{15}N_\beta H_2^+$, $J(^{15}N\text{-}^{15}N)$ = 10.1 Hz) in the ^{15}N NMR spectrum. While the spectra of $[\mathbf{W}{=}NNH_2][BAr'_4]$ are generally similar to those of $[\mathbf{Mo}{=}NNH_2][BAr'_4]$, ^{15}N NMR data for $[\mathbf{W}{=}NNH_2][BAr'_4]$ reveal a reduction of $^1J(^{15}N_\beta\text{-}H)$ to 83.6 Hz in $[\mathbf{W}{=}NNH_2][BAr'_4]$ from 90.5 Hz in $[\mathbf{Mo}{=}NNH_2]$-$[BAr'_4]$ (34), consistent with an increased *p* character in the bonding at N_β as a consequence of a greater degree of backbonding to the NNH_2 unit in $[\mathbf{W}{=}NNH_2][BAr'_4]$.



The structure of $[\mathbf{W}{=}NNH_2][BAr'_4]$ (Fig. 7) is similar to other {[HIPTN_3N]M}[BAr'_4] (M = Mo, W) derivatives that have been characterized in an X-ray study. The N_α—N_β distance (1.315(5) Å) is essentially identical to that in



W-N=NH, 55%

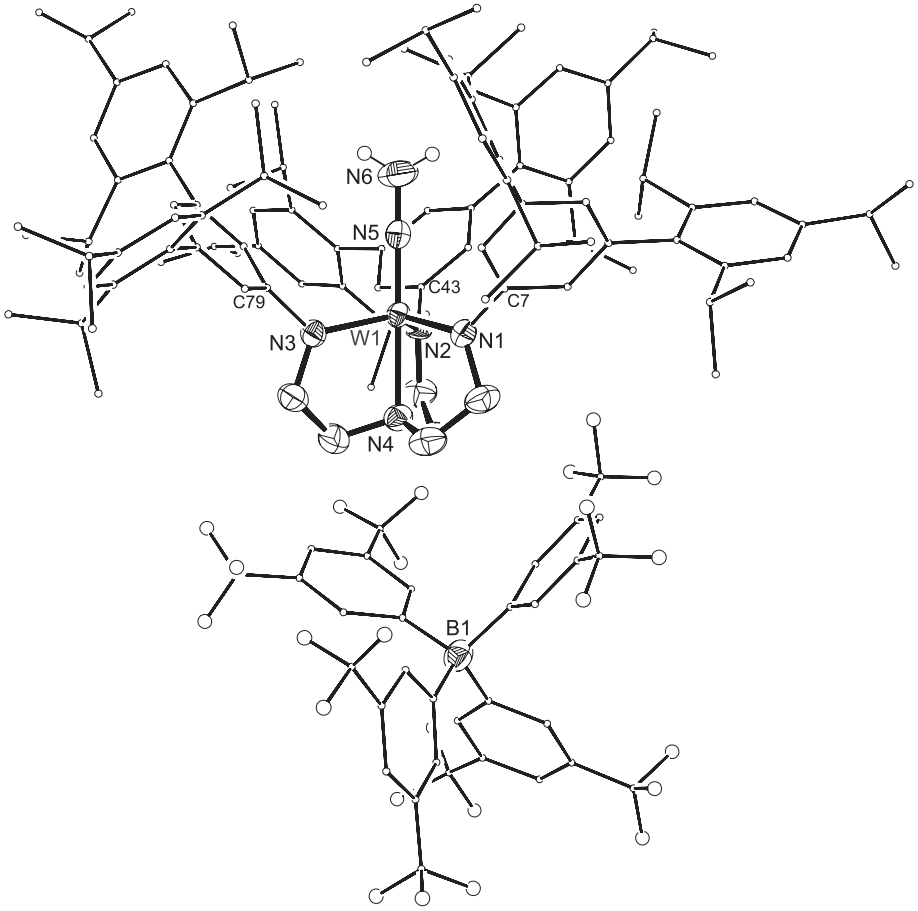
Fig. 6. Thermal ellipsoid drawing of **W**-N=NH (50% probability level, selected hydrogen atoms omitted).

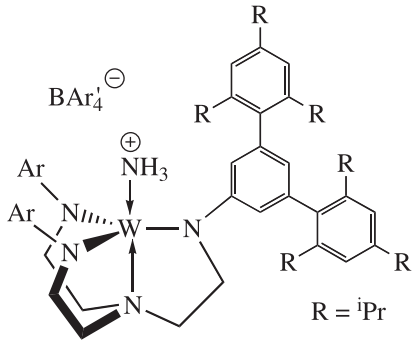
[4] **W**-N=NH —1.05[H(OEt$_2$)$_2$][BAr$'_4$], Et$_2$O, -35 °C to RT, 1 h→ [**W**=NNH$_2$][BAr$'_4$], 72%

[**Mo**=NNH$_2$][BAr$'_4$] (1.310(5) Å). Since the N$_\alpha$—N$_\beta$ distance in [**W**=NNH$_2$][BAr$'_4$] is similar to that in **W**N=NH (1.29(1) Å), the amount of N$_\alpha$—N$_\beta$ double bond character must be significant, as one would expect in a M-N-N π system of this type. The NNH$_2^+$ hydrogens were not located, but were refined in calculated positions. Regardless of the particular orientation chosen for their representation, their presence in the model had a slight, but constant, effect on the refined N—N distance.



Electrochemical reduction of [**W**=NNH$_2$][BAr$'_4$] in 0.1 mol/L [Bu$_4$N][BAr$'_4$]/PhF at a glassy carbon electrode is irreversible at scan rates of up to 1 V/s and takes place at I_{pc} = –2.2 V vs. FeCp$_2^{+/0}$ (100 mV/s scan rate). The **Mo** analog, [**Mo**=NNH$_2$][BAr$'_4$], undergoes a quasi-reversible reduction at –1.56 V under the same conditions (34), which allows us to estimate the difference between the **Mo**=NNH$_2^{+/0}$ and **W**=NNH$_2^{+/0}$ couples as being 400–500 mV. The magnitude of this difference is considerably greater than that found for [**M**N$_2$]$^{0/-}$ (260 mV) and [**M**N$_2$]$^{+/0}$ (0 mV) potentials (M = Mo or W, vide supra). Apparently π donation of electron density from M into the [NNH$_2$]$^{2-}$ system does not differ substantially for Mo and W, and the **M**=NNH$_2^{+/0}$ potential difference therefore better reflects the difference in the HOMO energy that results from substitution of W for Mo alone. Consistent with this hypothesis, a large difference between Mo and W is also found for the **M**(NH$_3$)$^{+/0}$ potentials (vide infra).

Synthesis of [W(NH$_3$)][BAr$'_4$], its structure, and reactivity



When **W**Cl is treated with NaBAr$'_4$ and NH$_3$ in PhF [**W**(NH$_3$)][BAr$'_4$] is formed nearly quantitatively (eq. [5]). This reactivity mirrors that established for **Mo**Cl (33), except that fluorobenzene had to be used as a solvent because **W**Cl was found to be incompatible with dichloromethane. The ammonia adduct was isolated in good yield and fully characterized. Its ^{1}H NMR spectrum in C$_6$D$_6$ features a pattern of paramagnetically shifted and broadened resonances characteristic of a high-spin d^2 **W** environment in complexes of this general type. The resonances in **W**(NH$_3$)$^+$ are paramagnetically shifted to a greater extent than those of **W**Cl, a phenomenon that was also observed for **Mo**(NH$_3$)$^+$ vs. **Mo**Cl.

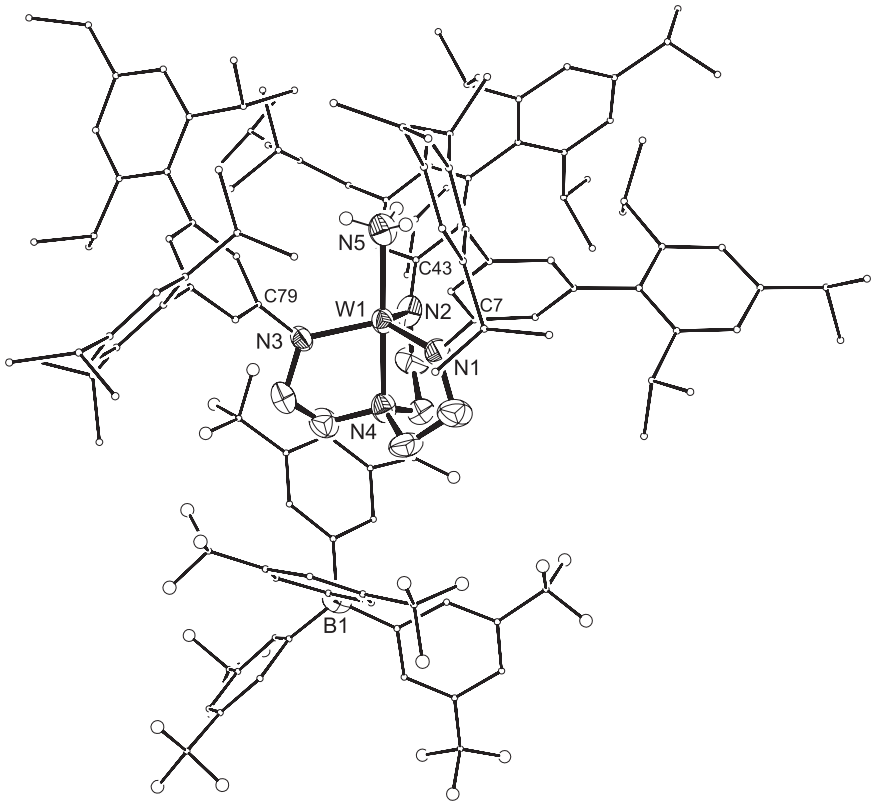
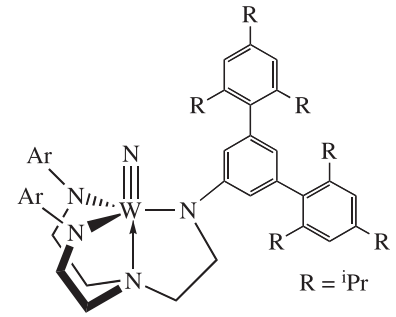
Fig. 7. Thermal ellipsoid drawing of [**W**=NNH_2][BAr'_4] (50% probability level, selected hydrogen atoms omitted).

[5] **W**Cl —(2.2$NaBAr'_4$, 4NH_3; PhF, 2 h)→ [**W**(NH_3)][BAr'_4], 87%



The X-ray crystal structure of [**W**(NH_3)][BAr'_4] (Fig. 8) is essentially identical to that of [**Mo**(NH_3)][BAr'_4] (33). The M—N(ammonia) distances are 2.210(4) Å in [**W**(NH_3)][BAr'_4] vs. 2.24(1) Å in [**Mo**(NH_3)][BAr'_4] (Table 2). The ammonia protons were not located, but are shown in calculated positions.

Electrochemical reduction of [**W**(NH_3)][BAr'_4] in 0.1 mol/L [Bu_4N][BAr'_4]/PhF at a glassy carbon electrode reveals an irreversible wave at a scan rate of 0.5 V/s (Fig. 9). The couple appears to become more reversible at faster scan rates (1 and 2 V/s) at –2.06 V vs. $FeCp_2^{+/0}$, although it cannot be called reversible even at 2 V/s. In contrast, one-electron reduction of [**Mo**(NH_3)][BAr'_4] is fully reversible both in PhF (0.1 mol/L [Bu_4N][BAr'_4]) at a glassy carbon electrode and THF (0.4 mol/L [Bu_4N][PF_6]) at a platinum disk at all scan rates and takes place at $E^{o\prime}$(**Mo**(NH_3)$^{+/0}$) = –1.63 V vs. $FeCp_2^{+/0}$ in PhF (0.1 mol/L [Bu_4N][BAr'_4]). The difference in **M**(NH_3)$^{+/0}$ potentials (M = Mo or W) is thus ~430 mV, similar to the difference between the **Mo**=$NNH_2^{+/0}$ and **W**=$NNH_2^{+/0}$ potentials (vide supra). Chemical reductions of both [**W**=NNH_2][BAr'_4] and [**W**(NH_3)][BAr'_4] are described below.



Deprotonation of [**W**(NH_3)]$^+$ with $LiN(SiMe_3)_2$/4TMEDA in C_6D_6 yields a single paramagnetic product, which we pre-

Fig. 8. Thermal ellipsoid drawing of [**W**(NH$_3$)][BAr$'_4$] (50% probability level, selected hydrogen atoms omitted).

[6] [**W**(NH$_3$)][BAr$'_4$] → (1) 2.2[Cp$_2$Fe][PF$_6$], 4Et$_3$N; (2) 3LiN(SiMe$_3$)$_2$, C$_6$D$_6$ → **W**≡N

sume to be (at least initially) **W**(NH$_2$). However, attempts to isolate the product in analytically pure crystalline form so far have failed. Treatment of [**W**(NH$_3$)][BAr$'_4$] with triethylamine and [FeCp$_2$][PF$_6$] in C$_6$D$_6$, followed by LiN(SiMe$_3$)$_2$ yielded **W**≡N essentially quantitatively (eq. [6]). The nitride can be prepared more conveniently via salt metathesis of **W**Cl with 3 equiv. of NaN$_3$ in a mixture of C$_6$H$_6$ and MeCN over a period of 16 h at room temperature (eq. [7]), the method utilized originally in the synthesis of [Me$_3$SiN$_3$N]W≡N (42). The IR spectra of **W**≡N and **Mo**≡N in C$_6$D$_6$ are virtually identical in the 1200–900 cm^{-1} region, with the exception of an absorption at 1012 cm^{-1} in the **Mo**≡N spectrum (ν(Mo-N)) and at 1024 cm^{-1} in the **W**≡N spectrum. Therefore, we assign the 1024 cm^{-1} absorption to the ν(W-N) stretch. As in [Me$_3$SiN$_3$N]M≡N complexes, ν(M-N) is slightly higher for **W**≡N than it is in **Mo**≡N. The ^{15}N NMR spectrum of **W**≡^{15}N shows a resonance for the nitride at 827 ppm (vs. 898 ppm in **Mo**≡^{15}N).

[7] **W**Cl → (3NaN$_3$, C$_6$H$_6$: MeCN, 16 h, RT, 58%) → **W**≡N

Treatment of a C$_6$D$_6$ solution of [**W**(NH$_3$)][BAr$'_4$] with LiBHEt$_3$ (1 mol/L in THF) results in a color change to brown and formation of a largely one paramagnetic species, which is tentatively assigned as the monohydride complex, **W**H, on the basis of reactivity similar to that exhibited by **Mo**H (33). However, a small amount of a diamagnetic product is present initially, which becomes the sole observable species when the reaction mixture is exposed to an atmosphere of H$_2$ for ~10 min (eq. [8]); this diamagnetic species (**W**H$_3$) can be isolated in 42% yield. This compound was identified on the basis of the similarity of its NMR and IR spectra with those of the crystallographically characterized

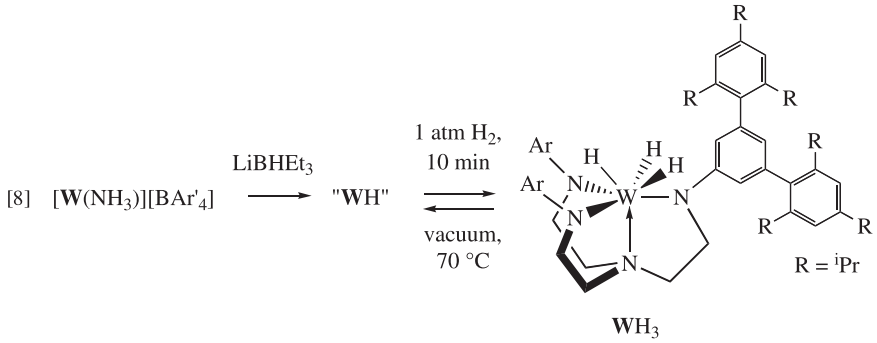

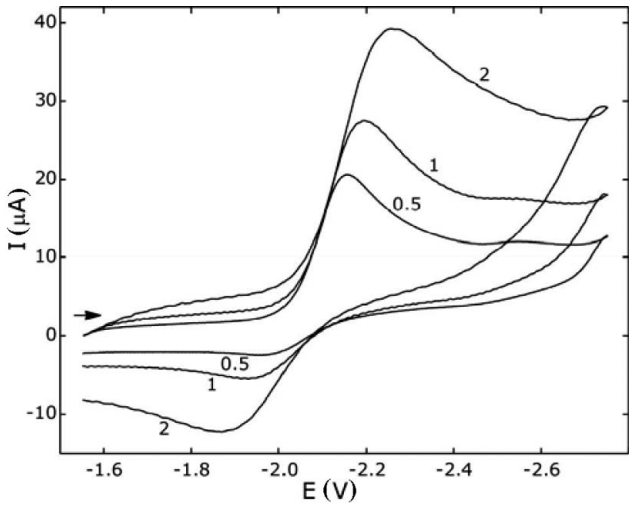

Fig. 9. Electrochemical behavior of $[\mathbf{W}(NH_3)][BAr'_4]$ in 0.1 mol/L $[Bu_4N][BAr'_4]$/PhF, recorded at a glassy carbon electrode (3 mm diam.) at the scan rates shown in V/s. The potential scale is referenced to $FeCp_2^{+/0}$.

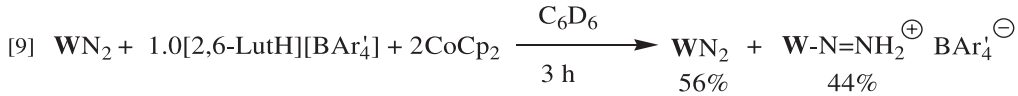
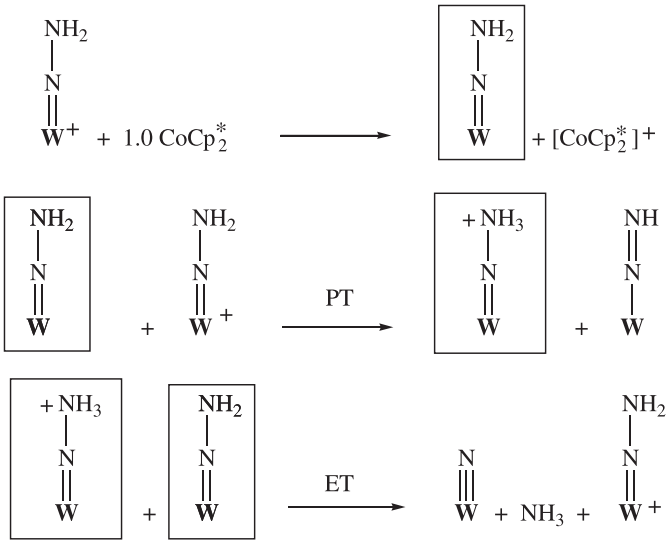


complex, $[Me_3SiN_3N]WH_3$ (57). Like $[Me_3SiN_3N]WH_3$, $\mathbf{W}H_3$ features a low-field resonance of intensity three in its ^1H NMR spectrum in C_6D_6 at 11.99 ppm with $^1J(^{183}W\text{-}H)$ = 24 Hz (cf. 10.01 ppm and 23 Hz in $[Me_3SiN_3N]WH_3$), in addition to characteristic ligand resonances. The IR spectrum of $\mathbf{W}H_3$ in C_6D_6 shows two broad absorptions at 1958 and 1966 cm^{-1} consistent with ν(W-H) stretching modes (cf. 1903 and 1887 cm^{-1} in $[Me_3SiN_3N]WH_3$ in Nujol). However, unlike $[Me_3SiN_3N]WH_3$, $\mathbf{W}H_3$ can be induced to lose H_2, by exposure to a high vacuum at 70 °C to yield a mixture that contains a considerable amount of **W**H after a few hours. This difference in behavior can be attributed to less electron donation by the $[HIPTN_3N]^{3-}$ ligand compared to the $[Me_3SiN_3N]^{3-}$ ligand. It should be noted that what is proposed to be $[HIPTN_3N]MoH_3$ cannot be isolated since it readily loses dihydrogen to form $[HIPTN_3N]MoH$ at room temperature (34).

Reduction of dinitrogen on W with protons and electrons



Treatment of $\mathbf{W}N_2$ with 1 equiv. of $[2,6\text{-LutH}][BAr'_4]$ (2,6-Lut = 2,6-lutidine) and 2 equiv. of $CoCp_2$ in C_6D_6 results in a subtle color change, formation of a yellow precipitate of $[CoCp_2][BAr'_4]$, complete consumption of the acid, and conversion of approximately half of the starting $\mathbf{W}N_2$ to $[\mathbf{W}{=}NNH_2][BAr'_4]$ in 3 h at 22 °C (eq. [9]). This mixture remains unchanged over a period of 24 h. **W**N=NH is converted quantitatively into $[\mathbf{W}{=}NNH_2][BAr'_4]$ upon reaction with 1 equiv. of $[2,6\text{-LutH}][BAr'_4]$ in C_6D_6. Therefore, we propose that **W**N=NH is formed in the reduction of $\mathbf{W}N_2$ in the presence of $[2,6\text{-LutH}][BAr'_4]$ and that **W**N=NH then consumes a proton relatively irreversibly to give $[\mathbf{W}{=}NNH_2][BAr'_4]$, thereby limiting consumption of $\mathbf{W}N_2$ when 1 equiv. of acid is present to ~50%. In contrast, the analogous reaction between $\mathbf{Mo}N_2$ and $[2,6\text{-LutH}][BAr'_4]$ and $CoCp_2$ rapidly yields **Mo**N=NH quantitatively (34). $[\mathbf{Mo}{=}NNH_2][BAr'_4]$ is considerably more acidic than $[\mathbf{W}{=}NNH_2][BAr'_4]$, as judged from the fact that treatment of **Mo**N=NH with 1 equiv. of $[2,6\text{-LutH}][BAr'_4]$ in C_6D_6 gives an equilibrium mixture of **Mo**N=NH and $[\mathbf{Mo}{=}NNH_2][BAr'_4]$ (44:56); therefore, conversion of $\mathbf{Mo}N_2$ to **Mo**N=NH can be complete when $\mathbf{Mo}N_2$ is treated with only 1 equiv. of $[2,6\text{-LutH}][BAr'_4]$ and $CoCp_2$. The most important point is that a one-electron reduction–protonation of $\mathbf{W}N_2$ to yield **W**N=NH is feasible, although this process appears to be slower than conversion of $\mathbf{Mo}N_2$ to **Mo**N=NH under analogous conditions.

Isolated $[\mathbf{W}{=}NNH_2][BAr'_4]$ reacts rapidly with 2 equiv. of $CoCp_2^*$ ($E^{\circ\prime}$ = –2.01 V vs. $FeCp_2^{+/0}$ in PhF) in C_6D_6, as indicated by the formation of a yellow precipitate of $[CoCp_2^*][BAr'_4]$. However, instead of the expected one-electron reduced (W(V)) product ($\mathbf{W}{=}NNH_2$), a proton NMR spectrum of the reaction mixture recorded 20 min after mixing $[\mathbf{W}{=}NNH_2][BAr'_4]$ and $CoCp_2^*$ revealed that only **W**N=NH and **W**≡N were present in a 52:48 ratio. After 17 h, the ratio of **W**N=NH to **W**≡N had not changed, but a well-resolved triplet for free ammonia could be observed. This ammonia was collected by vacuum transfer and shown (using the indophenol analytical method) to amount to 0.43 equiv. of the original $[\mathbf{W}{=}NNH_2][BAr'_4]$. Therefore, one-electron reduction of $[\mathbf{W}{=}NNH_2][BAr'_4]$ predominantly results in the net reaction shown in eq. [10]. In fact, this reaction was used to prepare $\mathbf{W}{\equiv}{}^{15}N$ from $[\mathbf{W}{=}{}^{15}N^{15}NH_2][BAr'_4]$. This stoichiometry is consistent with the disproportionation of the initial reduction product, $\mathbf{W}{=}NNH_2$, a W(V) species, into a W(IV) and a W(VI) species, **W**N=NH and **W**≡N, respectively. A plausible sequence of elementary electron- and

© 2005 NRC Canada

Scheme 1. A proposed sequence of reactions that yields the net process shown in eq. [10]. Unobservable intermediates are shown in boxes. The counterion ($BAr'_4{}^-$) is excluded for clarity. PT = proton transfer, ET = electron transfer.

proton-transfer steps that comprises the overall process is proposed in Scheme 1.

[10] $[\mathbf{W}{=}N\text{-}NH_2]BAr'_4 + 1.0CoCp^*_2 \xrightarrow{C_6D_6} 0.5\mathbf{W}\text{-}N{=}NH + 0.5\mathbf{W}{\equiv}N + 0.5\,NH_3 + [CoCp^*_2]BAr'_4$

Initial one-electron reduction of $\mathbf{W}{=}NNH_2^+$ yields as yet unobserved $\mathbf{W}{=}NNH_2$, possibly in a rapid equilibrium. A small amount of $\mathbf{W}{=}NNH_2^+$ then protonates $\mathbf{W}{=}NNH_2$ to yield the proposed hydrazidium(2–) species ($\mathbf{W}{=}NNH_3^+$), while $\mathbf{W}{=}NNH_2^+$ is transformed into **W**N=NH. The hydrazidium(2–) species ($\mathbf{W}{=}NNH_3^+$) then oxidizes $\mathbf{W}{=}NNH_2$ to regenerate $\mathbf{W}{=}NNH_2^+$, and in the process is reduced to form $\mathbf{W}{\equiv}N$ and ammonia. Essentially, the disproportionation of $\mathbf{W}{=}NNH_2$ is catalyzed by $\mathbf{W}{=}NNH_2^+$.

It is possible that the disproportionation shown in Scheme 1 requires some time to proceed to completion and that the initial "**W**(V) = NNH_2" exists in a fast electron-transfer equilibrium with $\mathbf{W}{=}NNH_2^+$ and (or) $CoCp^{*+}_2$, which causes extensive broadening and (or) complete disappearance of the resonances for $\mathbf{W}{=}NNH_2^+$ and $CoCp^{*+}_2$ in the ^{1}H NMR spectrum. A similar situation was encountered in the reversible reduction of{[$HTBTN_3N$]Mo(NH_3)}[BAr'_4] with $CrCp^*_2$ in C_6D_6 (37). However, irreversibility of the electrochemical reduction of $[\mathbf{W}{=}NNH_2][BAr'_4]$ suggests that the sequence of reactions following the initial electron transfer takes place rapidly at 22 °C. We are puzzled by the apparently fast rate of net proton transfer in the absence of conspicuous proton-transfer mediators. However, we note that small amounts of the free ligand, H_3[$HIPTN_3N$], are typically formed in a decomposition reaction, and could easily mediate the proton-transfer step. The actual mechanism of the proton-transfer step remains to be clarified.

Reduction of $[\mathbf{Mo}{=}NNH_2][BAr'_4]$ at room temperature proceeds in a manner closely analogous to that shown in eq. [10] and (it is proposed) Scheme 1 (34). One of the reasons to investigate the chemistry of $[\mathbf{W}{=}NNH_2][BAr'_4]$ was the possibility that $\mathbf{W}{=}NNH_2$ would be more stable than $\mathbf{Mo}{=}NNH_2$ and that $\mathbf{W}{=}NNH_2$, therefore, could at least be observed. Instead, however, we find that $\mathbf{W}{=}NNH_2$ is even less stable than $\mathbf{Mo}{=}NNH_2$. In each case, the high propensity of $\mathbf{M}{=}NNH_2$ to disproportionate can be attributed to a combination of a high Brønsted basicity of N_β in combination with strong reducing properties. We attribute the strong reducing properties to the presence of one of the five electrons in the M-N_α-N_β π system in a π orbital that has a node at N_α; four electrons are in the two perpendicular lowest energy bonding molecular orbitals. This combination of properties makes $\mathbf{M}{=}NNH_2$ susceptible to *both* protonation by its own oxidized form *and* oxidation by its own protonated form, at least in a thermodynamic sense. If both steps are kinetically feasible, then disproportionation proceeds readily, perhaps in part because of the fact that the step in which ammonia is formed (N—N bond cleavage) is almost certainly irreversible. It is important to note that disproportionation of $\mathbf{M}{=}NNH_2$ intermediates has no adverse consequences for overall reduction of dinitrogen to ammonia, since it merely leads to species that are themselves susceptible to further reactions that lead to the formation of ammonia. Disproportionations of d^1 species and related intermolecular proton or electron transfer reactions are likely to complicate the mechanism of ammonia formation depicted in Fig. 2, when all species are in solution.

Attempted conversion of $W(NH_3)^+$ to WN_2, and catalytic reduction of N_2

The results discussed in the previous section show that it is possible to reduce $\mathbf{W}N_2$ to yield ammonia and $\mathbf{W}{\equiv}N$ in the presence of acid and reductant. Since reduction of $\mathbf{Mo}{\equiv}N$ to $\mathbf{Mo}(NH_3)^+$ is a relatively easy transformation in the **Mo** dinitrogen reduction cycle (35), while reduction of $\mathbf{Mo}(NH_3)^+$ to $\mathbf{Mo}(NH_3)$ and transformation of $\mathbf{Mo}(NH_3)$ into $\mathbf{Mo}N_2$ can be observed (34), we examined the feasibility of converting $\mathbf{W}(NH_3)^+$ into $\mathbf{W}N_2$.

Reduction of $[\mathbf{W}(NH_3)][BAr'_4]$ with 2 equiv. of $CoCp^*_2$ in C_6D_6 proceeds to some extent, as judged by the rapid formation of a yellow precipitate of $[CoCp^*_2][BAr'_4]$. However, the ^{1}H NMR spectrum of the resulting solution is unusually featureless, i.e., few resonances beyond isopropyl methyl resonances and some aryl resonances can be observed. Since the ^{1}H NMR spectrum of $\mathbf{Mo}(NH_3)$ is similar to that of other d^3 Mo complexes in this general family, we expected $\mathbf{W}(NH_3)$ to be observable and to have a very similar spectrum to that of $\mathbf{Mo}(NH_3)$.

The mixture of $[\mathbf{W}(NH_3)][BAr'_4]$ and $\mathbf{W}(NH_3)$ remained unchanged for days and also did not change after being exposed to 800 psi (1 psi = 6.894 757 kPa) of N_2 for 48 h. Thermolysis at 60 °C for a day resulted only in minor decomposition and formation of $\mathbf{W}{\equiv}N$ and $\mathbf{W}H_3$. Treatment of $\mathbf{W}N_2$ with ~4 equiv. of NH_3 in C_6D_6 under argon also resulted in no change after 15 days, again in sharp contrast to the behavior in the analogous molybdenum system where an equilibrium between $\mathbf{Mo}(NH_3)$ into $\mathbf{Mo}N_2$ is readily established in a closed system over a period of several hours. Although it has not been possible to transform $\mathbf{W}(NH_3)$ into $\mathbf{W}N_2$, $\mathbf{W}(NH_3)$ appears to be relatively stable, at least as

[a]Single runs of all experiments were carried out with 5.84 μmol of $\mathbf{W}N_2$, 36 equiv. of the reductant, and 48 equiv. of the acid, under conditions otherwise identical to those previously described (35, 37).
[b]V vs. $FeCp_2^{+/0}$ in 0.4 mol/L [Bu_4N][PF_6].
[c]V vs. $FeCp_2^{+/0}$ in 0.1 mol/L [Bu_4N][BAr'_4].
[d]The maximum possible is 12 equiv. of ammonia (36 electrons available).

generated by reduction of [$\mathbf{W}(NH_3)$][BAr'_4] with $CoCp^*_2$. However, this conclusion is difficult to reconcile with a limited degree of reversibility of the electrochemical reduction of [$\mathbf{W}(NH_3)$][BAr'_4] ([Bu_4N][BAr'_4]/PhF) (Fig. 9). Therefore, the exact nature of the putative "$\mathbf{W}(NH_3)$" remains obscure, and we cannot exclude the possibility that some reaction involving oxidation of W(III) (e.g., intramolecular NH addition) is facile. In any case, it seems likely that $\mathbf{W}(NH_3)$ is not strictly analogous to well-behaved $\mathbf{Mo}(NH_3)$ (34).

Treatment of the mixture containing partly reduced $\mathbf{W}(NH_3)^+$ in C_6D_6 with [Et_3NH][BAr'_4] produced a new paramagnetic species that gave rise to considerable quantities of both $\mathbf{W}(NH_3)^+$ and $\mathbf{W}H_3$ after several days, but no $\mathbf{W}N_2$ or products of its reduction. The net reaction of $\mathbf{W}(NH_3)^+$ with a reductant and an acid thus results primarily in reduction of protons (presumably) and formation (ultimately) of $\mathbf{W}H_3$ (eq. [11]), but dinitrogen is not bound or reduced.

$$[11]\quad [\mathbf{W}(NH_3)][BAr'_4] + 4CoCp^*_2 + 3[Et_3NH][BAr'_4] \longrightarrow \mathbf{W}H_3 + NH_3 + 4[CoCp^*_2][BAr'_4] + 3Et_3N$$

In view of the previous observations, it is perhaps not surprising that attempted catalytic reduction of dinitrogen using $\mathbf{W}N_2$ as the catalyst under conditions identical or similar to those employed for catalytic reduction of dinitrogen by Mo complexes (35) failed (Table 3). This can be attributed chiefly to the inability to convert $\mathbf{W}(NH_3)^+$ into $\mathbf{W}N_2$ to any significant extent on the timescale of a typical catalytic experiment (6 h), as was independently established in the experiments previously described. Ammonia is formed, but less than 2 equiv., i.e., at most 1.51 equiv. with $CoCp^*_2$ as the reductant and [2,6-LutH][BAr'_4] as the acid. Therefore, while it is possible to cleave the N—N bond and form the first equivalent of ammonia, and to form some $\mathbf{W}NH_x^{y+}$ species that yield additional ammonia upon workup, dinitrogen is not bound and reduced further under the conditions employed.

Conclusions

We have been able to synthesize a number of [$HIPTN_3N$]W complexes analogous to the [$HIPTN_3N$]Mo species that are proposed intermediates in the catalytic reduction of dinitrogen to ammonia (35), among them the first terminal dinitrogen complex of W(III) ($\mathbf{W}N_2$), the second structurally characterized example of a parent diazenide of any metal ($\mathbf{W}$N=NH), and three other tungsten derivatives containing dinitrogen at various stages of reduction ($\mathbf{W}N{=}NH_2^+$, $\mathbf{W}{\equiv}N$, and $\mathbf{W}(NH_3)^+$). As expected, tungsten variants of known molybdenum complexes are characterized by greater nucleophilicities (at N_β) and lower reduction potentials. Interestingly, however, the differences between Mo and W potentials are considerably less pronounced for complexes that contain a dinitrogen ligand, e.g., 260 mV for $\mathbf{M}N_2^{0/-}$ and 0 mV for $\mathbf{M}N_2^{+/0}$. Structural and spectroscopic data (Table 2) signify the more electron-rich nature of all other tungsten derivatives without exception. We had hoped to observe and possibly isolate W variants of several proposed Mo species that are either exceedingly difficult to isolate, and in some cases even observe in situ. However, many of the W complexes, e.g., [$\mathbf{W}N_2$][Bu_4N] and $\mathbf{W}(NH_3)$, were in fact less stable than the analogous Mo complexes. Also $\mathbf{W}{=}NNH_2$ disproportionates into a mixture of $\mathbf{W}$N=NH, $\mathbf{W}{\equiv}$N, and ammonia much faster than does $\mathbf{Mo}{=}NNH_2$. Although dinitrogen in $\mathbf{W}N_2$ could be reduced to ammonia with acid and reductant combinations similar to those used in the catalytic reduction of dinitrogen with [$HIPTN_3N$]Mo species, catalytic turnover could not be achieved as a consequence of (inter alia) major difficulties in converting $\mathbf{W}(NH_3)^+$ into $\mathbf{W}N_2$. Complications of this magnitude in a system where Mo analogs are intermediates in the catalytic reduction of dinitrogen to ammonia would appear to doom tungsten as a plausible site for dinitrogen reduction. *If* MoFe and WFe nitrogenases are structurally analogous, and *if* dinitrogen is reduced at Mo in the MoFe nitrogenase, then one can imagine why reduction of dinitrogen by the WFe nitrogenase might fail.

Experimental section

General

All air- and moisture-sensitive compounds were manipulated using standard Schlenk and glovebox techniques under an atmosphere of nitrogen in flame- and oven-dried glassware (including NMR tubes). Ether, pentane, and toluene were purged with nitrogen, passed through activated alumina columns (58), and freeze–pump–thaw degassed three times. THF, DME, 1,4-dioxane, and benzene were distilled from dark purple Na–benzophenone ketyl solutions. Dichloromethane and acetonitrile were distilled from CaH_2, while fluorobenzene was distilled from P_2O_5 under N_2. All dried and deoxygenated solvents were stored over molecular sieves in a nitrogen-filled glovebox. Small quantities of hydrocarbon and ether solvents, as well as all such deuterated NMR solvents, were purified a second time by vacuum transfer from dark-purple solutions and (or) suspensions of Na–benzophenone ketyl (or CaH_2 for CH_2Cl_2, PhF, and

© 2005 NRC Canada

CD_2Cl_2), degassed, and stored in gas-tight solvent bulbs inside a glovebox. Molecular sieves (3 Å) and Celite® were activated in vacuo at 230 °C for several days. Cobaltocene (sublimed), $CrCp^*_2$ (sublimed), $[CoCp^*_2][PF_6]$ (Strem), $(Me_3Si)_2NLi$ (sublimed), anhydr. $ZnCl_2$, $LiBHEt_3$ (1 mol/L THF), and NaN_3 (Aldrich) were used as received, unless indicated otherwise. WCl_4(DME) (59), $H_3[HIPTN_3N]$ (33), $NaBAr'_4$ (60), $[H(OEt_2)_2][BAr'_4]$ (60), and [2,6-LutH][BAr'_4] (35) were prepared according to the published procedures or slight modifications thereof. Potassium graphite (KC_8) was prepared by stirring potassium metal, freshly cut in a nitrogen-filled glovebox, and graphite in 1:8 stoichiometry with a glass-coated stirbar under 700 torr (1 torr = 133.322 Pa) of Ar at 140 °C for an hour. $CoCp^*_2$ was prepared from $[CoCp^*_2][PF_6]$ and a slight excess of KC_8 in THF over 4 h and sublimed. $[Et_3NH][BAr'_4]$ was prepared from Et_3NHCl and 1.05 equiv. of $NaBAr'_4$ in CH_2Cl_2. All metal complexes were stored in the dark, under N_2 at –35 °C. ^1H, ^{19}F, and ^{15}N NMR spectra were recorded on a Varian Mercury 300 (^1H 300 MHz, ^{19}F 282 MHz), Varian Unity 300 (^1H 300 MHz) or a Varian Inova 500 (^1H 500 MHz, ^{15}N 50.7 MHz) spectrometers and referenced to the residual protio solvent peaks (^1H) or external neat PhF (^{19}F, –113.15 ppm relative to $CFCl_3$) and neat MeCN (^{15}N, +245.5 ppm relative to neat NH_3 at 303 K (61)). Attempted catalytic dinitrogen reduction runs and analyses of ammonia by the indophenol method (62–65) utilized procedures, equipment, and reagents described previously (35, 37). IR spectra were recorded on a Nicolet Avatar 360 FT-IR spectrometer in 0.2 mm KBr solution cells; frequencies are given in cm^{-1}. Elemental analyses were performed by H. Kolbe Mikroanalytisches Laboratorium, Mülheim an der Ruhr, Germany.

Electrochemistry

Electrochemical measurements were carried out using a BAS CV-50W potentiostat, 0.1 mol/L $[Bu_4N][BAr'_4]$ in PhF electrolyte, and a standard three-electrode cell assembly with glassy carbon (3.0 mm diam.) disk working electrode, platinum wire auxiliary electrode, and a AgCl-coated silver wire reference electrode. All measurements were referenced internally with $FeCp_2$, $CoCp_2$, or **Mo**N_2 (35), as appropriate. Compensation of internal solution resistance was used to lower the peak separation of reversible couples to 100–200 mV using the standard routines available with the BAS CV-50W potentiostat and accompanying software. An explanation of the technique can be found on the web at http://www.epsilon-web.net/Ec/manual/Setup/ir_comp.html.

[$HIPTN_3N$]WCl

A mixture of WCl_4(DME) (3.897 g, 9.37 mmol) and $H_3[HIPTN_3N]$ (14.93 g, 9.40 mmol) was stirred vigorously in benzene (100 mL) for 2 h to give a dark red-brown homogeneous solution. Solid $(Me_3Si)_2NLi$ (4.868 g, 29.1 mmol) was added in portions over a period of 10 min. The solution was stirred for an additional 2 h and taken to dryness in vacuo. The residue was dried at 70 °C overnight and extracted with benzene. The extracts were filtered through Celite®, and the filtrates were concentrated and centrifuged in portions to remove residual LiCl. The resulting homogeneous solution was then taken to dryness in vacuo and the residue was heated at 85 °C for several hours. Trituration of the residue with pentane (60 mL) afforded a dark orange microcrystalline solid, which was collected by filtration on a glass frit after standing the mixture at –35 °C overnight, washed with cold pentane, and dried in vacuo at 85 °C for several hours. Yield: 11.28 g (6.25 mmol, 67%). ^1H NMR (C_6D_6, 20 °C) δ: 18.81 (s, 6H, 4′,6′-*H*), 7.49 (s, 12H, 3,5,3″,5″-*H*), 3.47 (br s, 12H, 2,6,2″,6″-C*H*Me_2), 3.18 (sept, J_{HH} = 6.6 Hz, 6H, 4,4″-C*H*Me_2), 2.98 (s, 3H, 2′-*H*), 1.58 (d, J_{HH} = 6.6 Hz, 36H, 4,4″-CH(CH_3)$_2$), 1.34 (s, 36H, 2,6,2″,6″-CH(CH_3)$_2$), 0.83 (br s, 36H, 2,6,2″,6″-CH(CH_3)$_2$), –27.06 (s, 6H, NCH_2), –50.1 (br s, 6H, NCH_2). Anal. calcd. for $C_{114}H_{159}ClN_4W$ (%): C 75.87, H 8.88, N 3.10, Cl 1.96; found: C 75.97, H 8.78, N 2.97, Cl 2.10.

[$HIPTN_3N$]WN=NK

A mixture of **W**Cl (500 mg, 0.277 mmol) and KC_8 (93.6 mg, 0.692 mmol) was stirred in benzene (6 mL) under 1 atm of N_2 (1 atm = 101.325 kPa) with a glass-coated magnetic stirbar for 42 h. The resulting dark maroon-red mixture was taken to dryness in vacuo and the solid residue was extracted with pentane. The pentane extracts were filtered through Celite® and concentrated to 5 mL; a black-red crystalline solid formed within in minutes. The mixture was kept at –35 °C for several days and the product was then collected on a frit, washed with cold pentane, and dried in vacuo at 35 °C for 2 h. Yield: 310 mg (0.169 mmol, 61%). IR (C_6D_6): 1745 ($\nu_{N\text{-}N}$). IR (pentane): 1747 ($\nu_{N\text{-}N}$). ^1H NMR (C_6D_6, 20 °C) δ: 7.54 (br s, 6H, 4′,6′-*H*), 7.16 (s, 12H, 3,5,3″,5″-*H*), 6.61 (s, 3H, 2′-*H*), 3.75 (br s, 6H, NCH_2), 3.42 (sept, J_{HH} = 6.8 Hz, 12H, 2,6,2″,6″-C*H*Me_2), 2.84 (br sept, J_{HH} = 6 Hz, 6H, 4,4″-C*H*Me_2), 1.93 (br s, 6H, NCH_2), 1.26 (d, J_{HH} = 6.5 Hz, 36H, 4,4″-CH(CH_3)$_2$), 1.24 (d, J_{HH} = 6.0 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$), 1.2 (br sh, 36H, 2,6,2″,6″-CH(CH_3)$_2$). Anal. calcd. for $C_{114}H_{159}KN_6W$ (%): C 74.56, H 8.73, N 4.58; found: C 74.43, H 8.59, N 4.45.

X-ray quality crystals were obtained from a supersaturated heptane solution at room temperature.

[$HIPTN_3N$]W^{15}N=^{15}NK

A mixture of **W**Cl (500 mg, 0.277 mmol) and KC_8 (93.6 mg, 0.692 mmol) in benzene (6 mL), prepared under regular N_2 in a 25 mL flask fitted with a Teflon® valve, was freeze–pump–thaw degassed five times, pressurized to 1 atm (1 atm = 101.325 kPa) with $^{15}N_2$ purified with solid Na–Ph_2CO and stirred with a glass-coated magnetic stirbar for 50 h. A work-up procedure analogous to that used in the preparation of the unlabeled complex yielded 285 mg (0.155 mmol, 56%) of a black-red solid, identified by spectroscopic data as the labeled compound enriched with ^{15}N at the N_α and N_β diazenido sites to the extent of only 92% as a consequence of some initial reaction under $^{14}N_2$ to yield [$HIPTN_3N$]W^{14}N=^{14}NK. IR (C_6D_6): 1745 ($\nu_{14N\text{–}14N}$), 1688 ($\nu_{15N\text{–}15N}$). ^{15}N NMR (C_6D_6, 20 °C) δ: 356.6 (d, $J(^{15}N_\alpha\text{-}^{15}N_\beta)$ = 11.2 Hz, $^{15}N_\alpha$), 349.5 (d, $J(^{15}N_\alpha\text{-}^{15}N_\beta)$ = 11.2 Hz, $^{15}N_\beta$).

[$HIPTN_3N$]WN_2

A mixture of **W**Cl (500 mg, 0.277 mmol) and KC_8 (93.6 mg, 0.692 mmol) was stirred in benzene (6 mL) under 1 atm of N_2 (1 atm = 101.325 kPa) with a glass-coated mag-

© 2005 NRC Canada

netic stirbar for 42 h. The resulting mixture was filtered through Celite® and brought to dryness in vacuo. Solid $ZnCl_2$ (30.2 mg, 0.222 mmol) and THF (6 mL) were added to the residue. After stirring the solution for a few minutes, a dark orange-red solution and a precipitate of Zn metal formed. The mixture was taken to dryness in vacuo and heated to 75 °C for 2 h. The solid residue was extracted with pentane and the pentane extracts were filtered through Celite®. The extracts were taken to dryness in vacuo. Addition of Me_4Si (7 mL) to the solid residue led to the formation of a microcrystalline orange solid after 1 h. The mixture was kept at –35 °C for several days and the solid product was collected on a frit, washed with cold Me_4Si, and dried in vacuo at 75 °C for 2 h. Yield: 265 mg (0.147 mmol, 53%). IR (C_6D_6): 1888 ($\nu_{N\text{-}N}$). ^{1}H NMR (C_6D_6, 20 °C) δ: 35.2 (br s, 6H, NCH_2), 6.79 (s, 12H, 3,5,3″,5″-*H*), 2.83 (s, 6H, 4,4″-C*H*Me_2), 2.58 (br s, 36H, 2,6,2″,6″-CH(CH_3)$_2$), 1.29 (s, 36H, 4,4″-CH(CH_3)$_2$), 0.66 (s, 36H, 2,6,2″,6″-CH(CH_3)$_2$), –0.25 (s, 2H, 2′-*H*), –0.95 (s, 12H, 2,6,2″,6″-C*H*Me_2), –11.1 (br s, 6H, 4′,6′-*H*), –22.5 (br s, 6H, NCH_2). Anal. calcd. for $C_{114}H_{159}N_6W$ (%): C 76.18, H 8.92, N 4.68; found: C 75.93, H 9.08, N 4.57.

X-ray quality crystals were obtained from a supersaturated heptane solution at room temperature.

[HIPTN$_3$N]W(^{15}N$_2$)

A mixture of **W**^{15}N=^{15}NK (10 mg) and $ZnCl_2$ (0.6 mg, 0.8 equiv.) in THF (0.6 mL) was stirred for 10 min. The mixture was filtered through Celite® and the filtrate was taken to dryness in vacuo. The solid residue was dissolved in C_6D_6 for spectroscopic analysis. IR (C_6D_6): 1888 ($\nu_{14N\text{–}14N}$), 1826 ($\nu_{15N\text{–}15N}$).

[HIPTN$_3$N]WN=NH

A mixture of **W**Cl (500 mg, 0.277 mmol) and KC_8 (93.6 mg, 0.692 mmol) was stirred in benzene (6 mL) with a glass-coated magnetic stirbar for 42 h under 1 atm of N_2 (1 atm = 101.325 kPa). The resulting dark maroon-red mixture was treated with solid [Et_3NH][OTf] (69.6 mg, 0.277 mmol), stirred for 30 min, and taken to dryness in vacuo. The solid residue was extracted with pentane and the pentane extracts were filtered through Celite®. Upon concentration of this solution to ~5 mL, the product precipitated as a cotton-like solid. Repeated warming and cooling of the mixture to –35 °C induced crystallization of the product in the form of a microcrystalline solid sufficiently dense to allow isolation by filtration. The resulting beige solid was washed with cold pentane and dried in vacuo at 60 °C. Yield: 273 mg (0.152 mmol, 55%). IR (C_6D_6): 1542 ($\nu_{N\text{-}NH}$). ^{1}H NMR (C_6D_6, 20 °C) δ: 8.43 (s, 1H, J(^{183}W-H) = 17.4 Hz, N=N*H*), 7.30 (br d, 6H, 4′,6′-*H*), 7.20 (s, 12H, 3,5,3″,5″-*H*), 6.64 (br t, 3H, 2′-*H*), 3.68 (br t, 6H, NCH_2), 3.14 (sept, J_{HH} = 6.6 Hz, 12H, 2,6,2″,6″-C*H*Me_2), 2.93 (sept, J_{HH} = 6.9 Hz, 6H, 4,4″-C*H*Me_2), 1.88 (br t, 6H, NCH_2), 1.37 (d, J_{HH} = 6.6 Hz, 36H, 4,4″-CH(CH_3)$_2$), 1.24 (d, J_{HH} = 6.6 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$), 1.14 (d, J_{HH} = 6.6 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$). Anal. calcd. for $C_{114}H_{160}N_6W$ (%): C 76.14, H 8.97, N 4.67; found: C 76.00, H 8.96, N 4.55.

X-ray quality crystals were obtained from a supersaturated heptane solution at room temperature.

[HIPTN$_3$N]W^{15}N=^{15}NH

W^{15}N=^{15}NK (40 mg) was treated with [Et_3NH][OTf] (1.05 equiv.) in C_6D_6 in an NMR tube to yield the title compound, 92% ^{15}N-enriched, essentially quantitatively. The solution was taken to dryness in vacuo and the residue was dissolved in C_6D_6 for spectroscopic analysis. IR (C_6D_6): 1499 ($\nu_{^{15}N-^{15}NH}$). ^{1}H NMR (C_6D_6, 20 °C) δ: 8.42 (s, 0.08H, ^{14}N$_\alpha$=^{14}N$_\beta$*H*), 8.41 (dd, ^1J(^{15}N$_\beta$-H) = 53.1 Hz, ^2J(^{15}N$_\alpha$-H) = 6.7 Hz, J(^{183}W-H) = 17.1 Hz, 0.92H, ^{15}N$_\alpha$=^{15}N$_\beta$*H*) (other resonances are identical to those measured for the unlabeled sample). ^{15}N NMR (C_6D_6, 20 °C) δ: 393.5 (dd, J(^{15}N$_\alpha$-^{15}N$_\beta$) = 15.8 Hz, ^2J(^{15}N$_\alpha$-H) = 6.5 Hz, $^{15}N_\alpha$=^{15}N$_\beta$H), 229.3 (dd, ^1J(^{15}N$_\beta$-H) = 53.9 Hz, J(^{15}N$_\alpha$-^{15}N$_\beta$) = 14.9 Hz, ^{15}N$_\alpha$=$^{15}N_\beta$H).

{[HIPTN$_3$N]W=NNH$_2$}[BAr′$_4$]

An ether (4 mL) solution of **W**N=NH (100 mg, 55.6 μmol) was stirred and treated with solid [H(OEt$_2$)$_2$][BAr′$_4$] (59.1 mg, 58.4 μmol) at –35 °C. The solution was stirred for 1 h while being allowed to warm up to room temperature, and then taken to dryness in vacuo. The resulting solid was extracted with pentane and the pentane extracts were filtered through Celite® and concentrated to ~3 mL. Seeding this solution with a minute amount of {[HIPTN$_3$N]Mo=NNH$_2$}[BAr′$_4$] (33) led to a gradual formation of pale yellow microcrystals over a period of ~1 h. The mixture stood at –35 °C for several days and the product was isolated by filtration, washed with cold pentane, and dried in vacuo at 60 °C. Yield: 106 mg (39.8 μmol, 72%). ^{1}H NMR (C_6D_6, 20 °C) δ: 8.36 (br s, 8H, C_6H_3-3,5-(CF_3)$_2$-2,6-*H*), 7.66 (br s, 4H, C_6H_3-3,5-(CF_3)$_2$-4-*H*), 7.13 (s, 12H, 3,5,3″,5″-*H*), 6.79 (br d, 6H, 4′,6′-*H*), 6.62 (br t, 3H, 2′-*H*), 5.96 (s, 2H, J(^{183}W-H) ~ 6 Hz, N-NH_2), 3.78 (br t, 6H, NCH_2), 2.88 (sept, J_{HH} = 6.9 Hz, 6H, 4,4″-C*H*Me_2), 2.67 (sept, J_{HH} = 6.8 Hz, 12H, 2,6,2″,6″-C*H*Me_2), 2.32 (br t, 6H, NCH_2), 1.33 (d, J_{HH} = 6.6 Hz, 36H, 4,4″-CH(CH_3)$_2$), 1.11 (d, J_{HH} = 6.8 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$), 0.98 (d, J_{HH} = 6.8 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$). ^{19}F NMR (C_6D_6, 20 °C) δ: –62.4 (s, CF_3). Anal. calcd. for $C_{146}H_{173}BF_{24}N_6W$ (%): C 65.86, H 6.55, N 3.16; found: C 65.74, H 6.46, N 3.08.

X-ray quality crystals were obtained from a supersaturated heptane solution at room temperature.

{[HIPTN$_3$N]W=^{15}N^{15}NH$_2$}[BAr′$_4$]

W^{15}N=^{15}NH, generated in situ as described above, was treated with 1 equiv. of [H(OEt$_2$)$_2$][BAr′$_4$] in C_6D_6 in an NMR tube to yield the title compound, 92% ^{15}N-enriched, essentially quantitatively. ^{1}H NMR (C_6D_6, 20 °C) δ: 5.99 (s, 0.08 H, ^{14}N$_\alpha$-^{14}N$_\beta H_2$), 5.99 (dd, ^1J(^{15}N$_\beta$-H) = 83.6 Hz, ^2J(^{15}N$_\alpha$-H) = 1.8 Hz, 0.92 H, ^{15}N$_\alpha$-^{15}N$_\beta H_2$) (other resonances are identical to those measured for the unlabeled sample). ^{15}N NMR (C_6D_6, 20 °C) δ: 343.8 (d, J(^{15}N$_\alpha$-^{15}N$_\beta$) = 10.2 Hz, 1N, $^{15}N_\alpha$-^{15}N$_\beta H_2$), 131.1 (td, ^1J(^{15}N$_\beta$-H) = 83.8 Hz, J(^{15}N$_\alpha$-^{15}N$_\beta$) = 9.9 Hz, 1N, ^{15}N$_\alpha$-$^{15}N_\beta H_2$).

[HIPTN$_3$N]W≡N

A mixture of **W**Cl (500 mg, 0.277 mmol) and NaN_3 (54.0 mg, 0.831 mmol) in a mixture of benzene and acetonitrile (4:6 mL) was stirred vigorously for 16 h. The mixture became lighter in color and was taken to dryness in vacuo. The solid residue was dried at 80 °C in vacuo and ex-

© 2005 NRC Canada

tracted with benzene. The benzene extracts were filtered through Celite® and the filtrates were taken to dryness in vacuo. Addition of pentane (3 mL) led to the precipitation of a pale beige solid after 1 h at room temperature. The mixture was allowed to stand at –35 °C for several days, and the product was then isolated by filtration, washed with cold pentane, and dried at 70 °C in vacuo. Yield: 286 mg (0.160 mmol, 58%). IR (C_6D_6): 1024 ($\nu_{Mo\text{-}N}$). ^{1}H NMR (C_6D_6, 20 °C) δ: 8.01 (br s, 6H, 4′,6′-*H*), 7.21 (s, 12H, 3,5,3″,5″-*H*), 6.59 (s, 3H, 2′-*H*), 3.66 (br t, 6H, NCH_2), 3.10 (sept, J_{HH} = 6.6 Hz, 12H, 2,6,2″,6″-C*H*Me$_2$), 2.93 (sept, J_{HH} = 6.8 Hz, 6H, 4,4″-C*H*Me$_2$), 1.66 (br t, 6H, NCH_2), 1.37 (d, J_{HH} = 6.9 Hz, 36H, 4,4″-CH(CH_3)$_2$), 1.24 (d, J_{HH} = 6.6 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$), 1.10 (br d, J_{HH} = 6.3 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$). Anal. calcd. for $C_{114}H_{159}N_5W$ (%): C 76.78, H 8.99, N 3.93; found: C 76.57, H 9.01, N 3.94.

[HIPTN$_3$N]W≡^{15}N

[**W**=^{15}N^{15}NH$_2$][BAr′$_4$], generated in situ as described above, was treated with 2 equiv. of $CoCp_2^*$ in C_6D_6 in an NMR tube to yield a mixture consisting predominantly of **W**^{15}N=^{15}NH and the title compound. ^{15}N NMR (C_6D_6, 20 °C) δ: 827.0 (s, W≡^{15}*N*), 393.5 (dd, W$^{15}N_\alpha$=^{15}N$_\beta$H), 229.3 (dd, W^{15}N$_\alpha$=$^{15}N_\beta$H).

{[HIPTN$_3$N]W(NH$_3$)}[BAr′$_4$]

Ammonia (57 mL, 360 torr (1 torr = 133.322 Pa), ~1.11 mmol) was vacuum transferred from a bronze-colored Na solution to a frozen mixture of **W**Cl (500 mg, 0.277 mmol) and NaBAr′$_4$ (540.2 mg, 0.610 mmol) in fluorobenzene (10 mL). The mixture was thawed and stirred at room temperature for 2 h, at which time ^{1}H NMR analysis of an aliquot taken from the reaction mixture showed complete consumption of **W**Cl. The mixture was taken to dryness in vacuo, and the solid residue was dried at 60 °C and extracted with pentane. The pentane extracts were filtered through Celite® and the filtrate was concentrated to 3 mL. This solution was seeded with a minute quantity of crystalline {[HIPTN$_3$N]Mo(NH$_3$)}[BAr′$_4$], which led to rapid formation of a bright yellow microcrystalline solid. The mixture was left standing at –35 °C for several days and the product was then isolated by filtration, washed with cold pentane, and dried in vacuo at 60 °C, turning light orange. Yield: 642 mg (242 mmol, 87%). ^{1}H NMR (C_6D_6, 20 °C) δ: 18.66 (s, 6H, 8.27, 4′,6′-*H*), 7.41 (s, 12H, 3,5,3″,5″-*H*), 7.34 (s, 8H, C$_6H_3$-3,5-(CF$_3$)$_2$-2,6-*H*), 7.21 (s, 4H, C$_6H_3$-3,5-(CF$_3$)$_2$-4-*H*), 3.15 (sept, J_{HH} = 6.9 Hz, 6H, 4,4″-C*H*Me$_2$), 2.7 (v br s, 12H, 2,6,2″,6″-C*H*Me$_2$), 1.54 (d, J_{HH} = 6.6 Hz, 36H, 4,4″-CH(CH_3)$_2$), 1.01 (br s, 36H, 2,6,2″,6″-CH(CH_3)$_2$), 0.6 (v br s, 36H, 2,6,2″,6″-CH(CH_3)$_2$), –0.20 (s, 3H, 2′-*H*), –28.79 (s, 6H, NCH_2), –63.7 (br s, 6H, NCH_2). Anal. calcd. $C_{146}H_{174}BF_{24}N_5W$ (%): C 66.16, H 6.62, N 2.64; found: C 65.97, H 6.68, N 2.52.

X-ray quality crystals were obtained from a supersaturated heptane solution at room temperature.

[HIPTN$_3$N]WH$_3$

A benzene (5 mL) solution of [**W**(NH$_3$)][BAr′$_4$] (700 mg, 0.264 mmol) was treated with LiBHEt$_3$ (1 mol/L THF, 264 μL, 0.264 mmol) at room temperature. The resulting brown-red mixture was stirred for 30 min, freeze–pump–thaw degassed, and exposed to 1 atm of H_2 (1 atm = 101.325 kPa), which caused some lightening in color. The mixture was stirred for 1 h and brought to dryness in vacuo. The resulting solid was dried at 80 °C and extracted with benzene. The benzene extracts were filtered through Celite® and the filtrate was taken to dryness. Addition of pentane (4 mL) to the residue led to a gradual formation of a light brown solid. The mixture was left standing at –35 °C for several days and the product was then isolated by filtration, washed with cold pentane, and dried in vacuo at 70 °C. As was explained in the text, **W**H$_3$ loses hydrogen in the solid state at elevated temperatures under vacuum, forming an observable quantity of a paramagnetic compound tentatively assigned as the monohydride **W**H. Thus, solid **W**H$_3$ isolated as described previously was stored under an atmosphere of H_2 overnight, which nearly eliminated the **W**H impurity. Yield: 208 mg (0.117 mmol, 44%). IR (C_6D_6): 1966, 1958 (both broad, $\nu_{W\text{-}H}$). ^{1}H NMR (C_6D_6, 20 °C) δ: 11.99 (s, 3H, J(^{183}W-H) = 24 Hz, W(*H*)$_3$), 7.66 (s, 6H, 4′,6′-*H*), 7.21 (s, 12H, 3,5,3″,5″-*H*), 6.54 (s, 3H, 2′-*H*), 3.65 (s, 6H, NCH_2), 3.10 (sept, J_{HH} = 6.8 Hz, 12H, 2,6,2″,6″-C*H*Me$_2$), 2.93 (sept, J_{HH} = 6.9 Hz, 6H, 4,4″-C*H*Me$_2$), 2.01 (s, 6H, NCH_2), 1.37 (d, J_{HH} = 6.9 Hz, 36H, 4,4″-CH(CH_3)$_2$), 1.24 (d, J_{HH} = 6.9 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$), 1.12 (d, J_{HH} = 6.6 Hz, 36H, 2,6,2″,6″-CH(CH_3)$_2$). Anal. calcd. for $C_{114}H_{162}N_4W$ (%): C 77.25, H 9.21, N 3.16; found: C 77.08, H 9.28, N 3.06.

Research inspired by the chemistry of nitrogenase — Novel metal complexes and their reactivity toward dinitrogen, nitriles, and alkynes[1]

Masanobu Hidai and Yasushi Mizobe

Abstract: Summarized here are our continuous studies of the last three decades concerning syntheses of new types of complexes learned from nitrogenase and their reactivites toward dinitrogen, nitriles, and alkynes. For Mo and W dinitrogen complexes with tertiary phosphine coligands, a variety of their intriguing reactivities have been demonstrated, and novel transformations of the N_2 ligands into numerous nitrogen-containing ligands and compounds have been developed. The C≡N bond cleavage of certain nitriles also proceeds on the Mo site surrounded by tertiary phosphines. Stimulated by the sophisticated structure of the active site of nitrogenase, multinuclear metal–sulfur complexes have been synthesized in rational ways. New types of stoichiometric and catalytic reactions of alkynes have been found by using the thiolato-bridged diruthenium complexes and some cubane-type sulfido clusters containing a noble metal.

Key words: nitrogen fixation, molybdenum and tungsten dinitrogen complexes, ruthenium thiolato complexes, metal sulfido clusters, nitriles, alkynes.

Résumé : Dans ce travail, on présente un résumé des études qui se poursuivent dans notre laboratoire et qui ont été réalisées depuis au moins trente ans sur des synthèses de nouveaux types de complexes basées sur la façon de faire de la nitrogénase et sur leurs réactivités vis-à-vis du diazote, des nitriles et des alcynes. Pour les complexes du diazote avec le molybdène et le tungstène comportant des coligands de nature phosphine tertiaire, on a mis en évidence une variété de réactivités intrigantes et on a développé de nouvelles transformations de ligands N_2 en de nombreux ligands et composés contenant de l'azote. Le clivage de la liaison C≡N de certains nitriles procède au niveau d'atomes de molybdène entourés de phosphines tertiaires. Stimulés par la structure sophistiquée du site actif de la nitrogénase, on a synthétisé de façons rationnelles des complexes sulfurés de métaux polynucléaires. On a aussi découvert de nouveaux types de réactions stoechiométriques et catalytiques des alcynes en faisant appel à des complexes de diruthénium comportant des ponts thiolato et quelques agrégats sulfido de type cubane contenant des métaux nobles.

Mots clés : fixation de l'azote, complexes de diazote avec le molybdène et le tungstène, complexes thiolato du ruthénium, agrégats sulfido métalliques, nitriles, alcynes.

Introduction

Dinitrogen and carbon monoxide are isoelectronic and both molecules have a triple bond. However, their reactivities are quite different. The Haber–Bosch process developed in the early 20th century requires drastic reaction conditions to form ammonia from dinitrogen and dihydrogen. Thus, about 40 years ago, dinitrogen was recognized to be chemically inert. In contrast, a variety of metal carbonyl complexes were known at that time and carbon monoxide was widely used as a carbon source for organic synthesis under relatively mild conditions, as typically found in hydroformylation. Nobody believed that a dinitrogen complex, in which dinitrogen is bound to a transition meal, is readily isolated as a stable compound. Therefore, the discovery of the first dinitrogen complex $[Ru(NH_3)_5(N_2)]X_2$ (X = Br, I, BF_4, PF_6) by Allen and Senoff in 1965 (1) was a great surprise to chemists. This finding, together with the observation by Vol'pin in 1964 that ammonia was formed after hydrolysis of the mixture of a Ti complex and a reducing agent under dinitrogen (2), had spurred chemists to have a dream that dinitrogen is converted into ammonia under mild conditions as observed in biological nitrogen fixation. In 1967, Yamamoto et al. (3) succeeded in synthesis of the cobalt dinitrogen complex $[CoH(N_2)(PPh_3)_3]$ from dinitrogen itself. However, those dinitrogen complexes did not show the favorable reactivity of the coordinated N_2: i.e., treatment of the complexes with acids resulted in release of N_2 gas. At that time, molybde-

num was believed to be a key metal in biological nitrogen fixation. Fortunately, we succeeded in the preparation of the first molybdenum dinitrogen complex *trans*-$[Mo(N_2)_2(dppe)_2]$ (**1a**, dppe = $Ph_2PCH_2CH_2PPh_2$) in 1969 (4). Later, Chatt et al. (5) prepared a series of molybdenum and tungsten dinitrogen complexes of the type $[M(N_2)_2(L)_4]$ (M = Mo, W, L = tertiary phosphine). Typical dinitrogen complexes are shown in Fig. 1. Noteworthy is that these molybdenum and tungsten dinitrogen complexes are outstanding in the reactivity of the coordinated N_2, as compared with other dinitrogen complexes containing almost all transition metals prepared later. The N—H and N—C bond formation of the coordinated N_2 is readily achieved to form ammonia, hydrazine, and organo-nitrogen compounds. The first part of this review focuses on our long-standing studies on the chemistry of molybdenum and tungsten dinitrogen complexes. Readers should refer to comprehensive reviews to fully understand the chemistry of dinitrogen complexes (6).

In the middle 1980s, we embarked on our second approach toward activation of dinitrogen as well as nitriles and alkynes by learning more precisely from biological nitrogen fixation. Biological nitrogen fixation proceeds under mild conditions with the aid of nitrogenase (7). In 1978, the active site of nitrogenase was believed to be a molybdenum–iron–sulfur cluster, the structure of which was proposed mainly on the basis of EXAFS studies of nitrogenase as shown in Fig. 2 (8). The single-crystal X-ray analysis of nitrogenase has very recently revealed the $MoFe_7S_9$ cluster structure with an interstitial light atom, probably nitrogen, in the FeMo cofactor of the MoFe protein (9), which is directly involved in reduction of dinitrogen. It is to be noted that the molybdenum and iron atoms are coordinated by sulfur atoms, which is in sharp contrast to the above molybdenum and tungsten dinitrogen complexes with phosphine ligands. Extensive studies by Holm, Coucouvanis, and other groups (10) have been directed toward synthesis of iron–molybdenum–sulfur clusters with a similar structure to the active site of nitrogenase. However, our studies have intentionally been directed to synthesis of noble metal–sulfur clusters and development of their unique reactivities towards small molecules including not only dinitrogen, but also nitriles and alkynes. We are aware that the natural enzyme "nitrogenase" does not use noble metals to build the active site, but we are able to employ noble metals to prepare analogous metal–sulfur clusters, which might exhibit unique catalysis for transformation of dinitrogen as well as other small molecules. The second part of this review summarizes our studies of the chemistry of noble metal–sulfur clusters (11).

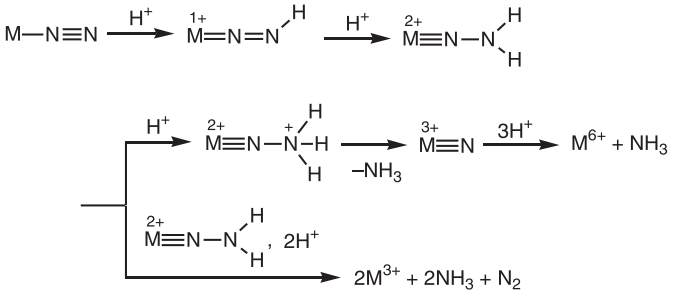
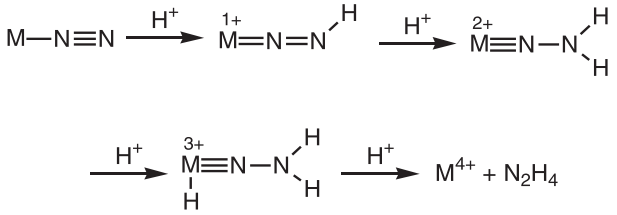
Chemistry of molybdenum and tungsten dinitrogen complexes with phosphine ligands



N—H bond formation

Although the first molybdenum dinitrogen complex *trans*-$[Mo(N_2)_2(dppe)_2]$(**1a**) was prepared by our group, well-defined protonation of the coordinated N_2 in dinitrogen complexes of the type $[M(N_2)_2(L)_4]$ (M = Mo, W, L = tertiary phosphine) was discovered by Chatt et al. (13) for the reactions of *trans*-$[M(N_2)_2(dppe)_2]$ with HX (M = Mo (**1a**): X = Br; M = W (**1b**): X = Cl, Br), affording the hydrazido(2–) complexes *trans*-$[MX(NNH_2)(dppe)_2]X$ (12), just after their novel finding of the N—C bond formation by treatment of **1b** with RCOCl or RCOCl–HCl to give *trans*-$[WCl(NNCOR)(dppe)_2]$ or *trans*-$[WCl(NNHCOR)(dppe)_2]Cl$, respectively (vide infra). Single-crystal X-ray analysis of hydrazido(2–) complexes has been undertaken for *trans*-$[WCl(NNH_2)(dppe)_2][BPh_4]$ (14), and also for *trans*-$[MoF(NNH_2)(dppe)_2][BF_4]$ obtained by our group from the reaction of **1a** with aq. HBF_4 in THF (15). These crystallographic studies disclosed the linear M–N–N linkage, the trigonal planar geometry around the terminal N atom, and the N—N bond order greater than unity, as the common structural features of the hydrazido(2–) ligand derived from the coordinated N_2.



Although the reactions of **1** with protic acids stop at the hydrazido(2–) stage except for those under quite drastic conditions, subsequent extensive studies mainly done by Chatt and co-workers (16) on the reactions of complexes of the type $[M(N_2)_2(L)_4]$ have clarified the pathway to convert one N_2 ligand in *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ (**2b**) almost quantitatively into ammonia under ambient conditions. Thus, **2b** re-

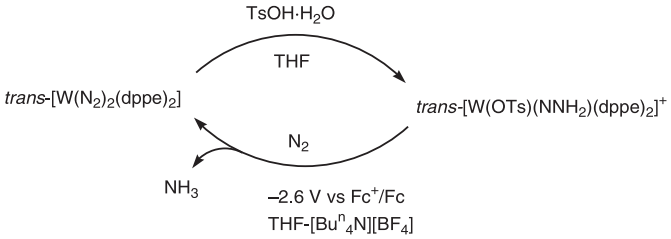
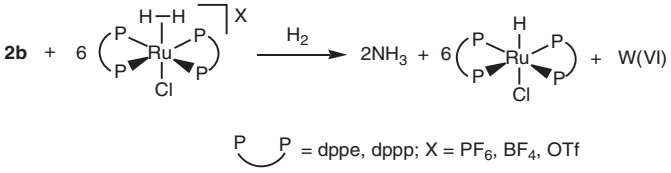
Scheme 2.



acts with sulfuric acid in MeOH at room temperature to give ammonia (ca. 1.9 mol/W atom) together with uncharacterized W(VI) species. Sequence of the N_2 reduction is shown in Scheme 1, which involves the dianenido (WNNH), hydrazido(2–) ($WNNH_2$), hydrazidium ($WNNH_3^+$), and nitrido (WN) intermediates formed by the stepwise protonation of the N_2 ligand coupled with the electron transfer from the central metal to the nitrogenous ligands. Ammonia formation from the Mo analogue *cis*-$[Mo(N_2)_2(PMe_2Ph)_4]$ (**2a**) proceeds less effectively (ca. 0.65 mol/Mo atom), since the disproportionation of the hydrazido(2–) intermediates predominates over the formation of the hydrazidium intermediate owing to the weaker electron-donating ability of Mo than W (Scheme 1). Not only the central metal, but also the nature of the acid and solvent remarkably affects the yields of the nitrogen hydrides from **2**. For example, we observed the preferential formation of hydrazine from both **2a** and **2b** upon treatment with HCl gas in ethereal solvents like $MeOCH_2CH_2OMe$ (17). The mechanism operating in this system involves the hydrido-hydrazido(2–) species as the other isolable intermediate after the hydrazido(2–) stage (Scheme 2).

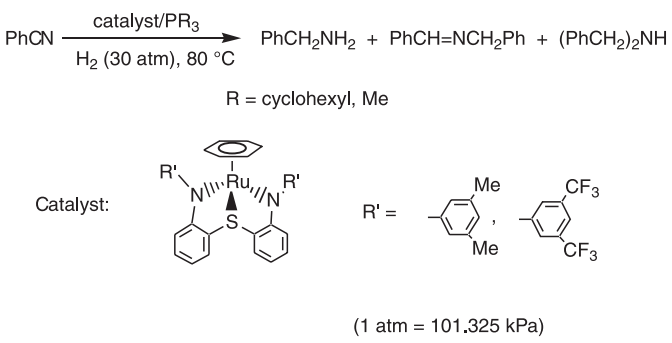


Important advances in the reduction of the coordinated N_2 in **1** and **2** have then been achieved by employment of electroreductive conditions or by application of bimetallic systems. Thus, Pickett and co-workers (18) found that the controlled-potential electrolysis of the hydrazido(2–) complex *trans*-$[W(OTs)(NNH_2)(dppe)_2]^+$ (TsO = *p*-$MeC_6H_4SO_3$) in THF produced ammonia (0.21 mol/W atom) with concomitant regeneration of the parent N_2 complex **1b** in high yield. By repeating the cycle of protonation and electro-reduction shown in Scheme 3 three times, the yield of ammonia reached 0.73 mol/W atom.

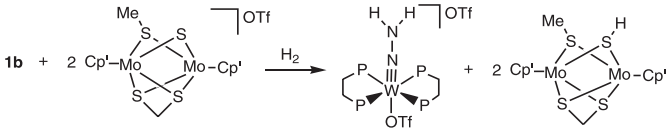
We and other groups (19) have independently found that treatment of **2b** with a series of metal hydrides in MeOH gives ammonia in low to moderate yields after base distillation of the reaction mixtures. The metal hydrides employed include the "acidic" metal hydrides such as $H_2Fe(CO)_4$, $HCo(CO)_4$, and $HFeCo_3(CO)_{12}$, as well as the "hydridic"

Scheme 3.

Scheme 4.



metal hydride $[Cp_2ZrHCl]$ (Cp = η^5-C_5H_5). Reactions of **1** with the acidic hydridometal carbonyls in ROH afforded the hydrazido(2–) complexes *trans*-$[M(OR)(NNH_2)(dppe)_2]X$ (X = $Co(CO)_4$, $FeCo_3(CO)_{12}$) (19*b*), suggesting that this reaction course forming ammonia also involves the hydrazido(2–) complexes as the intermediate. As for the protonation of the N_2 ligand in **1** and **2** by using bimetallic systems, several intriguing reactions have more recently been developed by our group (20).



The η^2-H_2 complexes are now variously known, and in certain complexes the η^2-H_2 ligand is quite acidic to undergo the heterolytic cleavage by a base. Morris and co-workers (21) reported the reaction of **1b** with 2 equiv. of $[CpRu(dtpfe)H_2][BF_4]$ (dtpfe = $(p\text{-}CF_3C_6H_4)_2PCH_2CH_2P(C_6H_4CF_3\text{-}p)_2$), which exists as a slowly interconverting mixture of the dihydrogen and dihydrido species in solution, to form *trans*-$[WF(NNH_2)(dppe)_2][BF_4]$ and [CpRu(dtpfe)H], although $[CpRu(dtpfe)H_2][BF_4]$ is not available directly from gaseous H_2. Recently, we have found that when **2b** is treated with 10 equiv. of dihydrogen complexes *trans*-$[RuCl(\eta^2\text{-}H_2)(\mathbf{P_2})_2]X$ ($\mathbf{P_2}$ = dppe, dppp; dppp = $Ph_2PCH_2CH_2CH_2PPh_2$; X = PF_6, BF_4, TfO; TfO = CF_3SO_3), which are derived from $[RuCl(\mathbf{P_2})_2]X$ and H_2 gas, ammonia is obtained in the yields of 0.45–0.79 mol/W atom after the reactions at 55 °C under H_2 (Scheme 4) (22). Analogous treatment of **1b** with *trans*-$[RuCl(\eta^2\text{-}H_2)(dppp)_2]X$ (X = PF_6, BF_4) afforded the hydrazido(2–) complexes *trans*-$[WF(NNH_2)(dppe)_2]X$ as expected. Isolation of *trans*-$[M(OTf)(NNH_2)(PMe_2Ph)_4][OTf]$ from the reaction of **2b** with *trans*-$[RuCl(\eta^2\text{-}H_2)(dppe)_2][OTf]$ at room temperature more straightforwardly confirmed the presence of the hydrazido(2–) complexes as the intermediates for the formation of ammonia shown in Scheme 4. In these reactions, the N—H bond formation presumably occurs via the direct attack of the basic terminal N atom in **2b** and **1b** on the η^2-H_2 ligand, leading to the heterolytic cleavage of the H—H bond to give the N–H protons and the Ru–H hydrides. Since the N_2 ligand in Mo complexes **1a** and **1b** behaves as a weaker base, the N—H bond forming reactions did not take place upon treatment with these Ru η^2-H_2 complexes. This result is reminiscent of the reactions of **2** with MeOH, EtOH, and water at 50 °C, in which ammonia is obtained only from the W complex **2b** and not from the Mo

Scheme 5.

Scheme 6.

Scheme 7.

complex **2a** (23). Replacement of the above Ru η^2-H_2 complexes by less acidic *trans*-[RuH(η^2-H_2)(**P_2**)$_2$]X (X = BF_4, TfO) resulted in a dramatic decrease in the yields of ammonia.

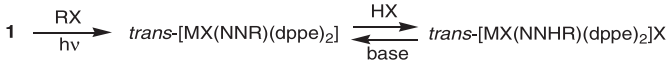
Although the above reaction of the coordinated N_2 and the coordinated H_2 forming ammonia is of great interest, electrons for the reduction of the coordinated N_2 are supplied from the metal, and hence the reaction is no more than stoichiometric. Our extensive study has led to the finding that Ru bis(diarylamido)-thioether complexes are effective in the presence of an alkylphosphine for catalytic hydrogenation of benzonitrile to give benzylamine and benzylidenebenzylamine at 80 °C. The reaction was presumed to proceed through the heterolytic cleavage of H_2 on the Ru—N bond. Dinitrogen was also bound to the metal center, however, no ammonia was observed from the reaction of N_2 and H_2 (Scheme 5) (24).

It is to be noted that catalytic conversion of N_2 into ammonia by using a well-defined N_2 complex has very recently been achieved for the first time by Schrock and co-workers (25): a Mo dinitrogen complex having a triamidoamine ligand is treated with 2,6-lutidinium salt as the proton source and decamethylchromocene as the reductant to produce ammonia (ca. 4 mol/Mo atom).

When **2b** is treated under H_2 with 10 equiv. of sulfur-bridged dimolybdenum complex [(CpMo)$_2$(μ-S_2CH_2)(μ-S)(μ-SH)][OTf], which is known to mediate the reductive cleavage of the C≡N bond in nitriles by H_2 gas (26), ammonia is obtained in the yield of 0.38 mol/W atom (27). The reaction of **1b** with 2 equiv. of the related dimolybdenum complex [(Cp′Mo)$_2$(μ-S_2CH_2)(μ-S)(μ-SMe)][OTf] (Cp′ = η^5-C_5H_4Me) under H_2, which has been reported to split H_2 heterolytically in the presence of base such as pyridine (28), results in the formation of the hydrazido(2–) complex *trans*-[W(OTf)(NNH_2)(dppe)$_2$][OTf] together with [(Cp′Mo)$_2$(μ-S_2CH_2)(μ-SH)(μ-SMe)] (Scheme 6) (27). Although the detailed mechanism is yet unknown, the NH protons are apparently supplied through the heterolytic cleavage of H_2.

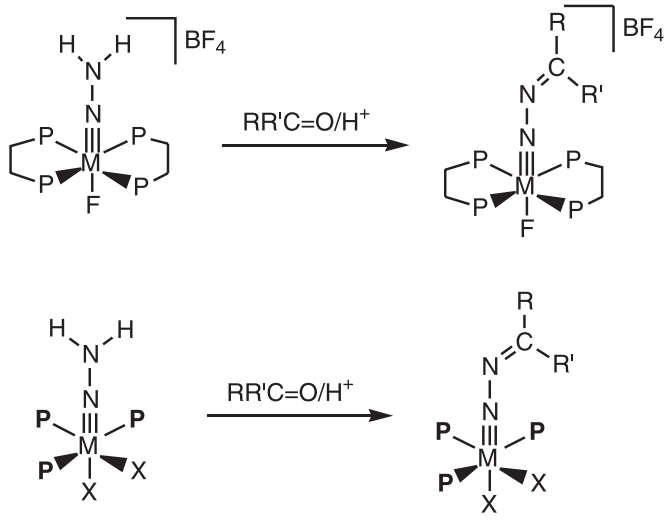
Protonation of the coordinated N_2 has also been attempted by using hydrosulfido complexes as the proton source. This has led to the finding that the μ-hydrosulfido complexes [(Cp*Ir)$_3$(μ-SH)$_3$]Cl (Cp* = η^5-C_5Me_5) and [{Fe[PhP(CH_2CH_2PPh_2)$_2$]}$_2$(μ-SH)$_3$][BF_4] react with **2b** to yield 0.78 and 0.38 mol ammonia per W atom, respectively (29). Dance (30) has proposed that the mechanism for the N_2 reduction in the FeMo-cofactor of nitrogenase involves the μ-SH intermediate generated by the protonation of the μ-sulfides of the $MoFe_7S_9$ core, whose protons are then transferred to the adjacent N_2 molecule bonded to the Fe_4 face. The reactivities of the μ-SH complexes toward **2b** observed here are therefore quite interesting because of their relevance to the biological N_2-reducing system. It is to be noted that the reactions of both H_2S and PhSH with **2b** result in the loss of all N_2 ligands as N_2 gas.

N—C bond formation



Extensive studies on the protonation of the N_2 ligand in **1** and **2** have demonstrated many reaction systems that transform molecular nitrogen into ammonia, and less commonly hydrazine, under mild conditions. In some cases, the mechanisms have been clarified in a well-defined manner. These results, which are of great importance in their own right, provide much information for gaining insight into biological nitrogen fixation. However, as far as the ammonia synthesis is concerned, it is highly improbable that the homogeneous system surpassing the modern Haber-Bosch process will be realized practically in the near future. On the other hand, direct conversion of molecular N_2 into nitrogen-containing organic compounds might be of more industrial significance than the ammonia synthesis. Development of the N—C bond forming reactions on the N_2 ligand is therefore quite interesting.

As already described, acyl- and aroyldiazenido complexes *trans*-[WCl(NNCOR)(dppe)$_2$] and their hydrazido(2–) derivatives *trans*-[WCl(NNHCOR)(dppe)$_2$]Cl have first been obtained through the C—N bond formation of the coordinated N_2 (13) (Scheme 7). The structure of the diazenido complex was clarified in detail for *trans*-[MoCl(NNCOPh)(dppe)$_2$] derived from the reaction of *trans*-[Mo(N_2)(NCR)(dppe)$_2$] with PhCOCl (31).

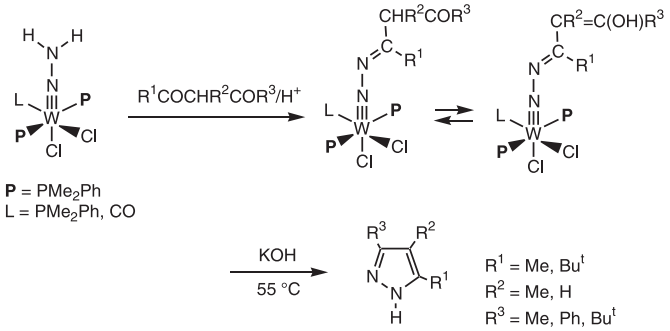


These reactions of **1** with acyl and aroyl chlorides involving the nucleophilic attack of the coordinated N_2 on the carbonyl C atoms as the principal step have further been extended by Chatt, George, and co-workers (32) to those with alkyl halides RX, yielding the corresponding alkyldiazenido complexes *trans*-[MX(NNR)(dppe)$_2$], although the latter reactions proceed via the reaction of the terminal N atom of the N_2 ligand with the alkyl radical generated through the homolysis of RX in the coordination sphere of Mo or W under irradiation with a W lamp. Interconversion between these diazenido complexes and their alkylhydrazido(2–) derivatives *trans*-[MX(NNHR) (dppe)$_2$]X readily proceeds through protonation and deprotonation (Scheme 8). Dialkylhydrazido(2–) complexes *trans*-[MBr(NNMe_2)(dppe)$_2$]Br and

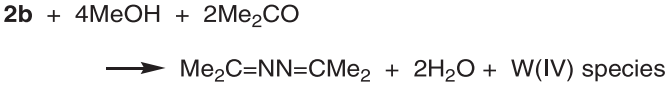
© 2005 NRC Canada

Scheme 8.

Scheme 9.

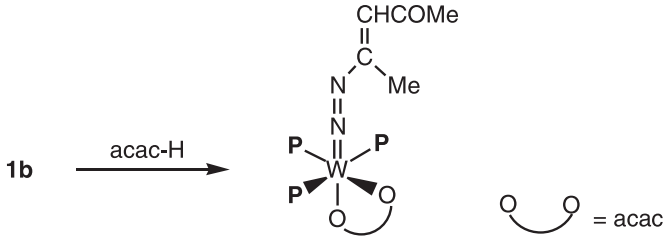


trans-[MBr(NN(CH$_2$)$_{n-1}$CH$_2$)(dppe)2]Br can be obtained directly, when complexes **1** were treated with MeBr or Br(CH$_2$)$_n$Br (n = 3–5) (33). For *trans*-[MoBr(NN(CH$_2$)$_4$CH$_2$)(dppe)$_2$]Br, the cyclic system producing H$_2$NN(CH$_2$)$_4$CH$_2$ from N_2 has been attained by coupling with the electrolysis of the dialkylhydrazido(2–) complex under N_2 to regenerate **1a** (34). Unfortunately, the N—C bond formation using alkyl halides is not applicable to the monophosphine complexes **2** under these conditions because of the loss of all N_2 ligands as N_2 gas.



As for the more convenient and general methods to form the N—C bonds from the N_2 ligand in complexes **1** and **2**, we have demonstrated the condensation reactions of hydrazido(2–) complexes with aldehydes and ketones to give a variety of diazoalkane complexes. Thus, hydrazido(2–) complexes *trans*-[MF(NNH$_2$)(dppe)$_2$][BF$_4$] and *cis*,*mer*-[MX$_2$(NNH$_2$)(PMe$_2$Ph)$_3$] (X = Br, Cl) both react with various aldehydes and ketones RR′C=O to afford *trans*-[MF(NN=CRR′)(dppe)$_2$][BF$_4$] (35) and *cis*,*mer*-[MX$_2$(NN=CRR′)(PMe$_2$Ph)$_3$] (36) (Scheme 9). Addition of a catalytic amount of acid enhances these condensation reactions remarkably, especially for those with ketones. Treatment of *cis*,*mer*-[WBr$_2$(NN=CMe$_2$)(PMe$_2$Ph)$_3$] with HBr gives a mixture of N_2H_4 and acetone azine (Me$_2$C=NN=CMe$_2$), while that with LiAlH$_4$ yields a mixture of *i*-Pr-NH$_2$ and NH$_3$ (36*a*).

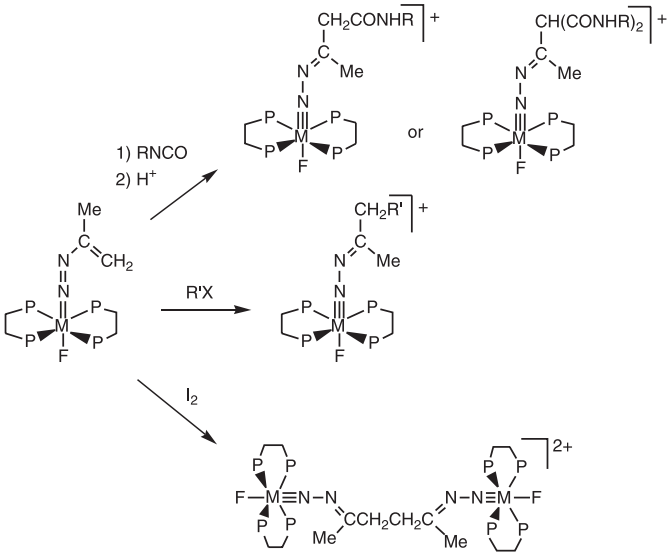
From the reactions of these hydrazido(2–) complexes and *cis*,*trans*-[WCl$_2$(NNH$_2$)(PMe$_2$Ph)$_2$(CO)] (37) with 1,3-diketones R^{1}COCHR^{2}COR^3, diazoalkane complexes *trans*-[MF{NN=CMe(CH$_2$COMe)}](dppe)$_2$]BF$_4$ (35) and *cis*,*mer*- or *cis*,*trans*-[MX$_2$\{NN=CR^1(CHR^{2}COR^3)\}(PMe$_2$Ph)$_2$(L)] (M = Mo: L = PMe$_2$Ph; M = W: L = PMe$_2$Ph, CO) were prepared analogously. From the latter complexes *cis*,*mer*- or *cis*,*trans*-[WCl$_2$\{NN=CR^1(CHR^{2}COR^3)\}(PMe$_2$Ph)$_2$(L)], pyrazoles were obtained by reaction with KOH in EtOH (38) (Scheme 10).



Scheme 10.

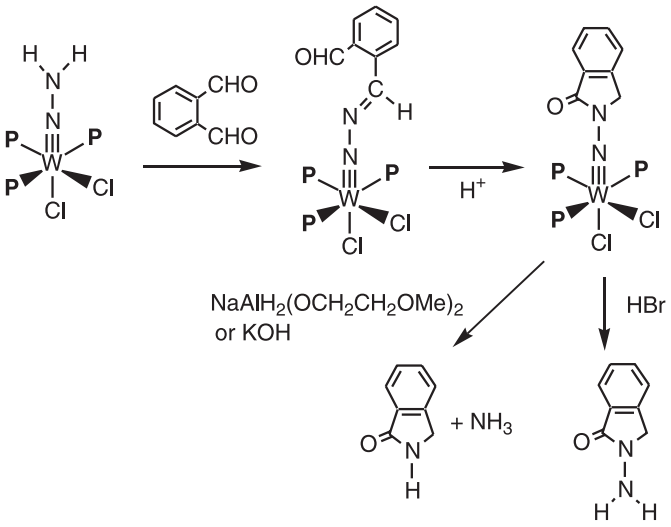
Scheme 11.

Scheme 12.



Treatment of *cis*,*mer*- or *cis*,*trans*-[WCl$_2$(NNH$_2$)(PMe$_2$Ph)$_2$(L)] with 1,3,5-triketones resulted in the formation of either the mononuclear complexes with diazoalkane (e.g., NN=CMeCH=C(OH)CH=C(OH)Ph) ligand or the dinuclear complexes with bridging bis(diazo)alkane (e.g., NN=CPh-CH$_2$COCH$_2$CPh=NN) ligand (39).

It is noteworthy that the reaction of the N_2 complex **2b** with a mixture of MeOH–acetone at 50 °C gives acetone azine directly (Scheme 11), which presumably proceeds through the formation of the hydrazido(2–) intermediate and the subsequent condensation with acetone forming a diazoalkane species (23). The yield of the azine increases significantly by addition of KOH to the reaction mixture. On the other hand, an alkenyldiazenido complex *mer*-[W(acac)\{NN-CMe(=CHCOMe)\}(PMe$_2$Ph)$_3$] (acac = acetylacetonante) was isolated from the reaction of **2b** with acetylacetone in MeOH (Scheme 12). The related diazenido complexes *trans*-[MF\{NNCMe(=CHCOMe)\}(dppe)$_2$] were derived by deprotonation from the diazoalkane complexes *trans*-[MF\{NN=CMe-(CH$_2$COMe)\}](dppe)$_2$][BF$_4$] by the use of NaOMe (40).



Diazenido complexes *trans*-[MF\{NNCMe(=CH$_2$)\}](dppe)$_2$] have been prepared similarly from *trans*-[MF(NN=CMe$_2$-(dppe)$_2$][BF$_4$] and LDA or NaN(SiMe$_3$)$_2$, which are converted to a series of new mononuclear diazoalkane complexes with NN=CMe(CH$_2$CONHR) and NN=CMe(CH$_2$R) ligands as well as dinuclear complexes with μ-bis(diazo)alkane ligand NN=CMeCH$_2$CH$_2$CMe=NN by treatment with RNCO/H$^+$, RX, and I$_2$, respectively (41) (Scheme 13). From the cationic diazoalkane complex *mer*-[WCl(NN=CMe$_2$)(PMe$_2$Ph)$_3$(CO)]$^+$, the μ-alkyldiazenido complex [{*trans*,*trans*-WCl(PMe$_2$Ph)$_2$(CO)$_2$}$_2$(μ-NNCMe$_2$CMe$_2$NN)] was isolated by reduction with Mg under CO (42).

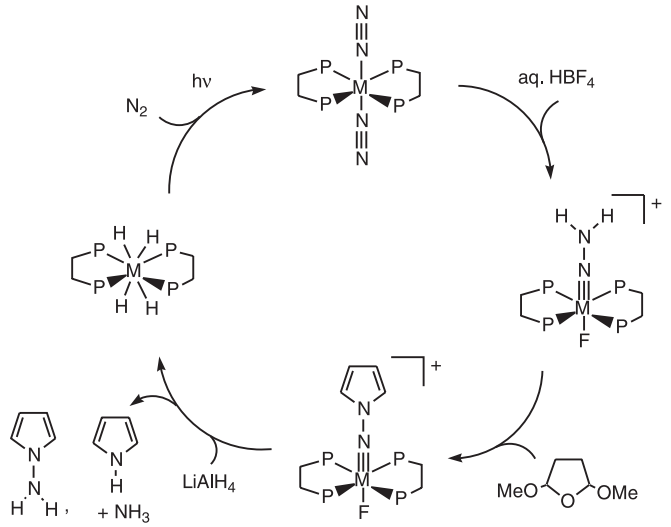
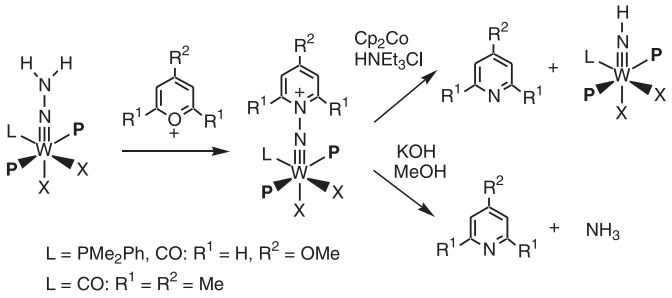


Scheme 13.

Scheme 14.

Scheme 15.



Condensation reactions of the hydrazido(2–) complexes as the versatile methods for the N—C bond formation have further been studied, aiming at the syntheses of *N*-heterocyclic ligands and compounds. Treatment of *cis*,*mer*-[$WCl_2(NNH_2)(PMe_2Ph)_3$] with phthalaldehyde at room temperature in the presence of a catalytic amount of aq. HCl gives (phthalimidin-2-yl)imido complex *cis*,*mer*-[$WCl_2(NNCH_2C_6H_4CO)(PMe_2Ph)_3$] via the condensation of the hydrazido(2–) ligand with one formyl group of the aldehyde to give a diazoalkane complex, followed by the cyclization forming the phthalimidine ring (43). In the absence of the acid, the reaction stops at the intermediate diazoalkane stage, which is converted into the (phthalimidin-2-yl)imido complex by addition of the acid. In the case of *trans*-[$WF(NNH_2)(dppe)_2]^+$, the reaction catalyzed by the acid gives the diazoalkane complex at room temperature, which can be transformed into the corresponding (phthalimidin-2-yl)imido complex by heating the reaction mixture in the presence of $AlCl_3$. Reaction of *cis*,*mer*-[$WCl_2(NNCH_2C_6H_4CO)(PMe_2Ph)_3$] with HBr gives 2-aminophthalimidine, while that with $NaAlH_2(OCH_2CH_2OMe)_2$ or KOH affords a mixture of phthalimidine and NH_3 (Scheme 14).

A cyclic acetal of succinaldehyde, i.e., 2,5-dimethoxytetrahydrofuran, also reacts with the hydrazido(2–) complexes *trans*-[$MX(NNH_2)(dppe)_2]^+$ (X = F, Cl) and *cis*,*mer*-[$WX_2(NNH_2)(PMe_2Ph)_3$] (X = Cl, Br) to give the condensation products *trans*-[$MX(NNCH{=}CHCH{=}CH)(dppe)_2]^+$ and *cis*,*mer*-[$WX_2(NNCH{=}CHCHC{=}CH)(PMe_2Ph)_3$], respectively (44). Interestingly, electrophilic substitution reactions at the pyrrole ring in the former dppe complexes occur selectively at the β position because of the steric effect of the dppe ligands giving *trans*-[$MX(NNCH{=}C(E)CH{=}CH)(dppe)_2]^+$ (E = Br, CN, COR). Complexes *trans*-[$MX(NNCH{=}CHCH{=}CH)(dppe)_2]^+$ are reduced by $LiAlH_4$, yielding pyrrole and *N*-aminopyrrole together with [$MH_4(dppe)_2$]. These hydrido complexes are known to be converted to the parent N_2 complexes **1** under certain conditions, so that the cycle forming pyrrole and *N*-aminopyrrole from N_2 has been accomplished (Scheme 15). In the degradation of the PMe_2Ph complex *cis*,*trans*-[$WX_2(NNCH{=}CHCHC{=}CH)(PMe_2Ph)_2(L)$], it has turned out that the reaction conditions and the nature of L (L = PMe_2Ph, CN-*t*-Bu, CO, PhC≡CH, PhCHO, Br) significantly affect the yield of the products: either pyrrole and ammonia or aminopyrrole (45). For example, treatment of *cis*,*trans*-[$WBr_2(NNCH{=}CHCHC{=}CH)(PMe_2Ph)_2$(CN-*t*-Bu)] with $LiAlH_4$ followed by methanolysis gives pyrrole and ammonia quantitatively, whereas the reactions of the CO, PhC≡CH, and PhCHO complexes with KOH in alcohol produce aminopyrrole selectively.

Reactions of hydrazido(2–) complexes *cis*,*mer*- or *cis*,*trans*-[$WX_2(NNH_2)(PMe_2Ph)_2(L)$] (L = PMe_2Ph, CO, C_2H_4) with pyrylium cations result in the formation of (1-pyridinio)imido complexes such as [$WX_2(NNC_5H_4OMe)(PMe_2Ph)_2(L)]^+$ and [$WX_2(NNC_5H_2Me_3)(PMe_2Ph)_2(L)]^+$, which

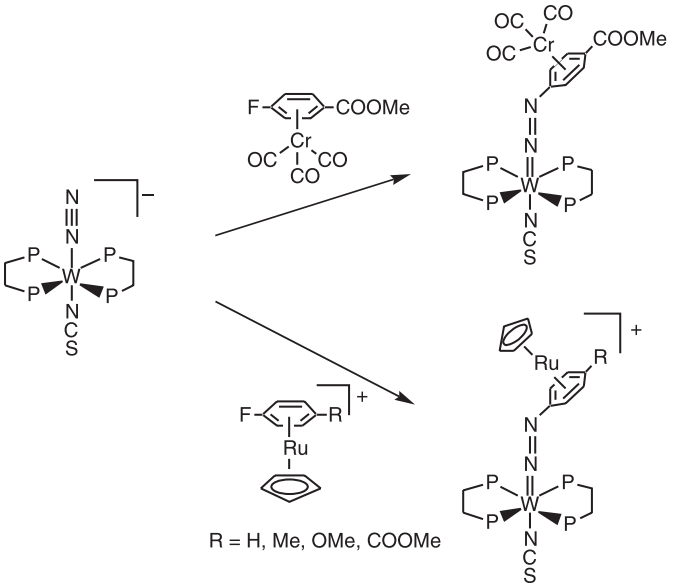
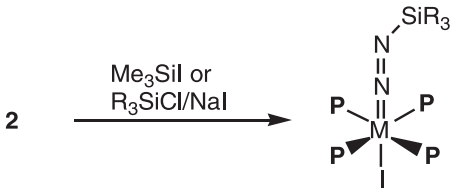
Scheme 16.



liberate pyridines by treatment with $CoCp_2$/$HNEt_3Cl$ in THF or KOH in MeOH (46) (Scheme 16).



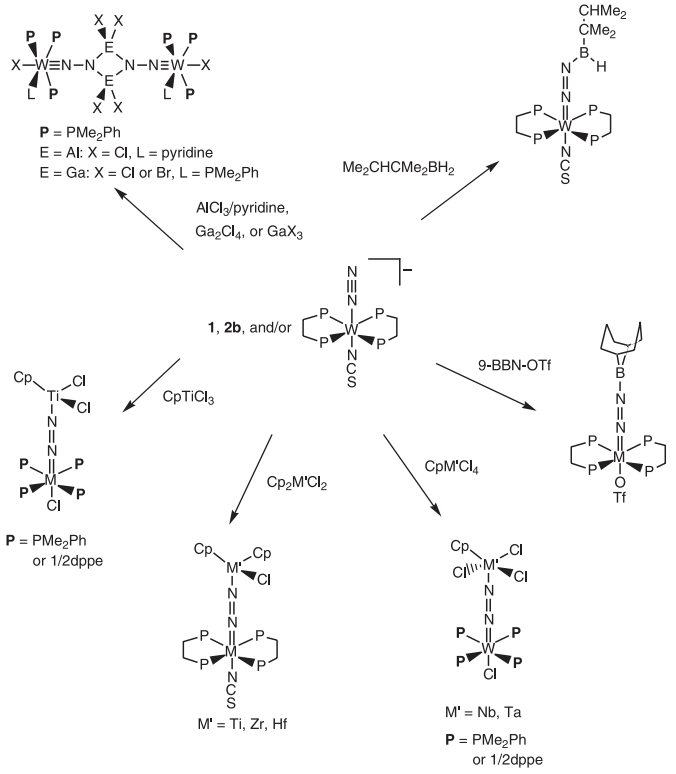
As summarized above, the Mo and W hydrazido(2–) complexes are quite potential compounds that readily condense with numerous carbonyl compounds and related oxygen-containing organic compounds. The hydrazido(2–) ligands also react as the nucleophiles with organic acid halides and heteroallenes to give the substitution products and addition products. These include, for example, a diacylated complex *trans*-[WF(NNCOCH$_2$CH$_2$CO)(dppe)$_2$][BF4] from *trans*-[WF(NNH$_2$)(dppe)$_2$][BF$_4$] and succinyl chloride (47), and *cis*,*mer*-[WCl$_2$(NNHCOCHPh$_2$)(PMe$_2$Ph)$_3$] from *cis*,*mer*-[WCl$_2$(NNH$_2$)(PMe$_2$Ph)$_3$] and diphenylketene (48), respectively.

Finally, arylation of the coordinated N_2 is shown. Alkylation of the N_2 ligand in **1** is the well-demonstrated reaction applicable to a series of alkyl halides and dihalides (vide supra). However, arylation of the coordinated N_2 by aryl halides is hardly accessible except for the pathway via the reaction of the highly activated aryl fluoride 2,4-$(O_2N)_2C_6H_3F$ with the diazenido complexes [WX(NNH)(dppe)$_2$] (X = F, Br, CF_3COO) generated in situ from the corresponding hydrazido(2–) complexes with bases (49). We have found that the anionic N_2 complex [W(NCS)(N$_2$)(dppe)$_2$]$^-$ reacts with π-fluoroarene complexes such as [(*p*-FC$_6$H$_4$CO-OMe)Cr(CO)$_3$] and [(*p*-FC$_6$H$_4$R)RuCp]$^+$ (R = H, Me, OMe, COOMe) to give the bimetallic complexes with bridging aryldiazenido ligands (50) (Scheme 17), where by activating both the N_2 ligand and the fluoroarenes, arylation of the coordinated N_2 has been attained.

Scheme 17.

Scheme 18.

Scheme 19.



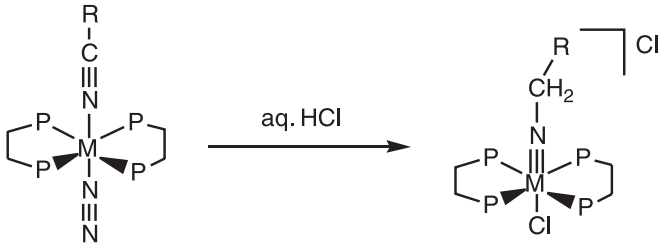
Formation of the N—heteroatom bond

The terminal N atom having the nucleophilic character of the N_2 ligand in **1** and **2** reacts with electrophilic heteroatom centers in addition to protons and electron-deficient C atoms. Thus, by treatment with Me_3SiI in benzene at 50 °C under dry conditions, **1** and **2** give the silyldiazenido complexes [MI(NNSiMe$_3$)(dppe)$_2$] and *trans*-[MI(NNSiMe$_3$)(PMe$_2$Ph)$_4$]. In the presence of adventitious moisture, silylhydrazido(2–) complexes [MI(NNHSiMe$_3$)(dppe)$_2$]I and *cis*,*mer*-[MI$_2$(NNHSiMe$_3$)(PMe$_2$Ph)$_3$] are obtained in addition to the diazenido complexes (51). Although Me_3SiCl does not react with **1** and **2** under these conditions, it has turned out that treatment of **2b** with a mixture of Me_3SiCl–NaI gives *trans*-[MI(NNSiMe$_3$)(PMe$_2$Ph)$_4$]. Following this procedure, synthesis of a variety of silyldiazenido complexes becomes available by the use of numerous silyl chlorides obtained commercially (52) (Scheme 18). From the reaction of **2b** with ClSiMe$_2$CH$_2$CH$_2$SiMe$_2$Cl–NaI followed by treatment with certain π-acceptor molecules L, disilylated complexes *cis*,*trans*-[WI(NNSiMe$_2$CH$_2$CH$_2$SiMe$_2$)(PMe$_2$Ph)$_2$(L)] (L = CO, alkene, isonitrile, nitrile) were isolated (53). Germylation also proceeds similarly at the N_2 ligand in **2b** upon reacting with R_3GeCl–NaI (52). Bimetallic silylation systems were also explored, which resulted in the finding that the silylcobalt complex [Ph$_2$MeSiCo(CO)$_4$] prepared from Ph$_2$MeSiH and [Co$_2$(CO)$_8$] reacts with **1** and **2** to give silyldiazenido complexes *trans*-[{MI(NNSiPh$_2$Me)(**P**)$_4$}(μ-OC)Co(CO)$_3$] (**P** = PMe$_2$Ph, 1/2dppe) (54).

Reduction of *trans*-[MI(NNSiMe$_3$)(PMe$_2$Ph)$_4$] with Na under N_2 in THF has been revealed to give N_1 products including NH_3, HN(SiMe$_3$)$_2$, $NaNH_2$, $NaNHSiMe_3$, and NaN(SiMe$_3$)$_2$, accompanied by the regeneration of the parent N_2 complexes **2** (55). Detailed study on this and related reactions has led to the development of the novel catalytic system converting molecular N_2 into silylamines. Thus, when Me_3SiCl is treated with an equimolar amount of Na dispersion in THF under N_2 at 30 °C in the presence of **2a**, N(SiMe$_3$)$_3$ was obtained in the yield of 24 mol/Mo atom to-

© 2005 NRC Canada

Scheme 20.



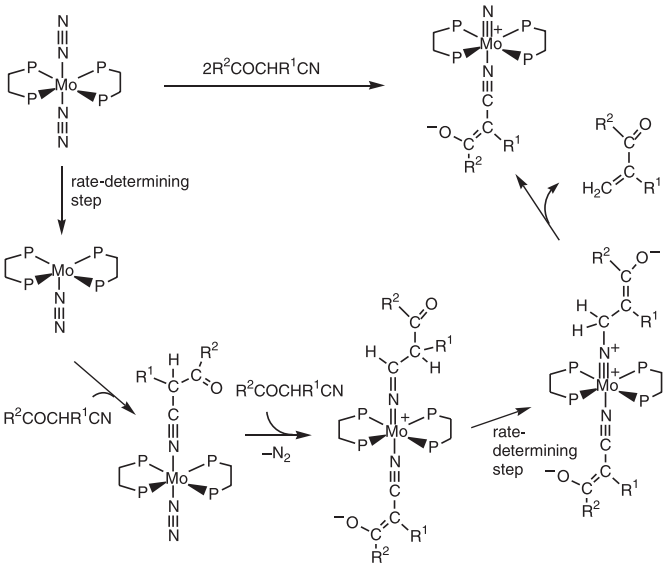
gether with a small amount of $HN(SiMe_3)_2$ after 15 h (Scheme 19) (55*a*). A major by-product is $Me_3SiSiMe_3$. For the N_2 complexes **1** and **2**, the catalytic activities decrease in the order **2a** > **1a** > **2b**, **1b**. The reactions in which molecular N_2 is converted catalytically into nitrogenous compounds under mild conditions are quite rare and those using well-defined N_2 complexes as a catalyst or catalyst precursor are still limited to only two systems: one is the present system and the other is the reaction of a Mo dinitrogen complex having a triamidoamine ligand (vide supra) (25).

With respect to the Group 13 elements, reactions of **1** and **2** with AlR_3 (R = Me, Et) forming Lewis acid – base adducts containing the $MNNAlR_3$ moieties were known for some time (56). In contrast, treatment of **2b** with $AlCl_3$–pyridine and $GaCl_3$ gives the ditungsten complexes having the $ClWNN(ECl_2)_2NNWCl$ array (E = Al (57), Ga (58)) (Scheme 20). As for boron compounds, by treating the anionic W complex $[W(NCS)(N_2)(dppe)_2]^-$ with 1,1,2-trimethylpropylborane and 9-borabicyclo[3.3.1]nonane, or by reacting **1** with 9-borabicyclo[3.3.1]nonyl triflate, novel borylation of coordinated N_2 was successful (59) (Scheme 20). The boryldiazenido complexes obtained were fully characterized, which demonstrated the bent N–N–B linkages for the complexes with the NCS anion, and the essentially linear N–N–B linkages for the triflate complexes.

Lewis acidic compounds containing Group 4 and Group 5 metals such as $CpTiCl_3$, Cp_2MCl_2 (M = Ti, Zr, Hf), and $CpMCl_4$ (M = Nb, Ta) also react with the coordinated N_2 in **1**, **2b**, and (or) $[W(NCS)(N_2)(dppe)_2]^-$ to form dinuclear complexes containing an essentially linear XWNNM array (60) (Scheme 20). Interestingly, heterobimetallic dinitrogen complexes $[Cp'TiCl_2(\mu\text{-}N_2)WCl(L)_4]$ (Cp′ = Cp, Cp*, etc.; L = 1/2dppe, 1/2depe, PMe_2Ph) obtained from similar reactions exhibit high catalytic activity for olefin polymerization when combined with modified methylaluminoxane, in which the W dinitrogen fragment acts as a novel metallodinitrogen ligand to the catalytically active Ti center (61).

Scheme 21.

Reactions of coordinated nitriles — C≡N bond cleavage



When nitrile–dinitrogen complexes *trans*-$[M(N_2)(NCR)(dppe)_2]$ (M = Mo (62), W (63)), which are readily derived from **1** and RCN, are treated with aq. HCl in THF, imido complexes *trans*-$[MCl(NCH_2R)(dppe)_2]Cl$ (R = Me, aryl) are obtained (Scheme 21). Reactions with aq. HBF_4 proceed in a similar manner to give *trans*-$[MF(NCH_2R)(dppe)_2]BF_4$ (64). The nitriles bound to the $M(dppe)_2$ site are susceptible to the attack by protons because of the strong π back donation from the electron-rich M centers. It is to be noted, however, that the protonation of *trans*-$[M(N_2)(NC\text{-}n\text{-}Pr)(dppe)_2]$ with HCl or H_2SO_4 has been reported to occur at the N_2 ligand to give the hydrazido(2–) complexes *trans*-$[M(NNH_2)(NC\text{-}n\text{-}Pr)(dppe)_2]^{2+}$ (63), and the reactions of *trans*-$[Mo(N_2)(NCR)(dppe)_2]$ with PhCOCl afford *trans*-$[MoCl(NNCOPh)(dppe)_2]$ (vide supra) (31, 62).

It is quite interesting that in the reactions of **1a** with 2 equiv. of β-ketonitriles R^2COCHR^1CN, unique C≡N bond cleavage takes place under mild conditions, yielding the complexes with nitrido- and nitrile-enolato ligands *trans*-$[Mo(N)(NCCR^1COR^2)(dppe)_2]$ (65). This reaction is initiated by the dissociation of one N_2 ligand as the first rate-determining step. The vacant site is occupied by one β-ketonitrile, which undergoes rapid protonation at the cyano C atom by the second β-ketonitrile, yielding the alkylideneamido (or azavinylidene) complex with the nitrile-enolato ligand *trans*-$[Mo(N{=}CHCHR^1COR^2)(NCCR^1COR^2)(dppe)_2]$. Migration of the β-proton in the alkylideneamido ligand to the α-C atom leading to the imido ligand constitutes the second rate-determining step in this reaction, which is followed by the rapid elimination of vinylketone $CH_2{=}CR^1COR^2$ to give the final product (Scheme 22). The mechanism of the present C≡N bond cleavage is quite rare, which is in sharp contrast with the precedented metathesis-type mechanism demonstrated for the reactions promoted by, e.g., $[W(C\text{-}t\text{-}Bu)(OC_6H_3\text{-}i\text{-}Pr_2\text{-}2,6)_3]$ and $[W_2(OR)_6]$ (R = *t*-Bu, CMe_2CF_3) (66).

As observed in the reactions of **1a** with β-ketonitriles, the N_2 complexes **1** can serve as good precursors to generate in situ the highly reactive, coordinatively unsaturated species "Mo(dppe)(N_2)" and "Mo(dppe)$_2$", which can activate not only nitriles but also a number of other small molecules including dihydrogen, isocyanide, alkynes, alkenes, etc. Such

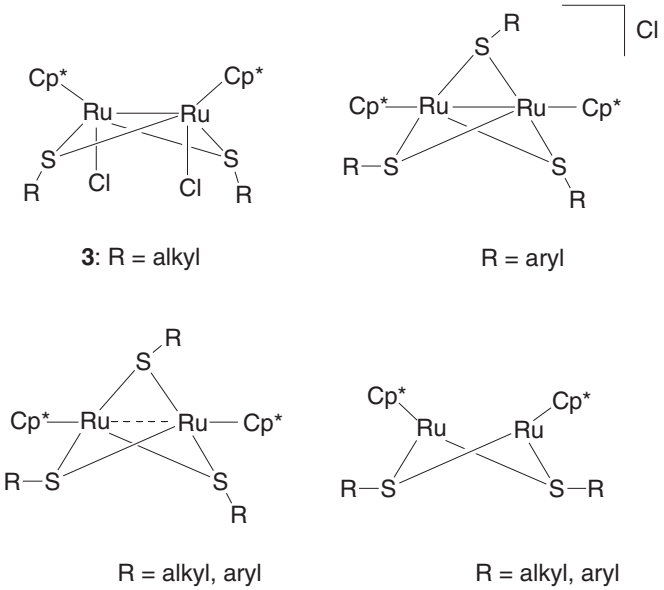
Scheme 22.

remarkable reactivities characteristic of **1** have recently been reviewed by the authors elsewhere (67).

Chemistry of noble metal–sulfur cluster complexes



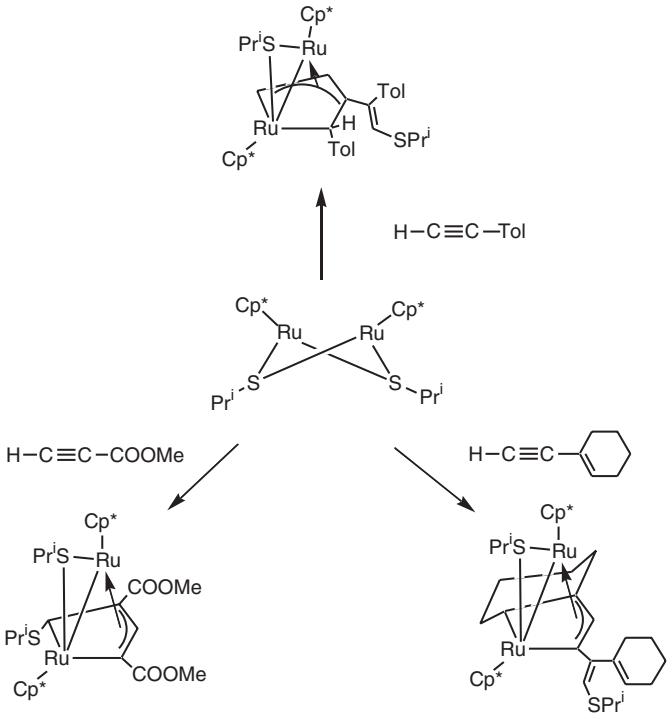
As summarized above, the zero-valent Mo and W dinitrogen complexes with phosphine co-ligands **1** and **2** display numerous outstanding reactivities, which include those relating intimately to the function of nitrogenase. However, this natural enzyme consists of the multimetallic site with a sulfur environment to activate dinitrogen and so-called "alternative substrates" such as N_2H_4, acetylene, nitrile, etc. Recent studies have further revealed that a modified MoFe protein reduces, under turnover conditions, alkynes larger than acetylene, including propargyl alcohol (68). Hence, our studies have been done to synthesize the multimetallic complexes with sulfur ligands and to clarify their reactivities toward these small molecules. It is to be noted that fully characterized N_2 complexes with sulfur ligands are quite limited, which include the thioether (69), thiolato (70), and dithiocarbamato (71) complexes, and either the N_2 complexes with the sulfide ligands or those with sulfur-bridged multimetallic cores are yet unknown.

Diruthenium complexes with bridging thiolato ligands

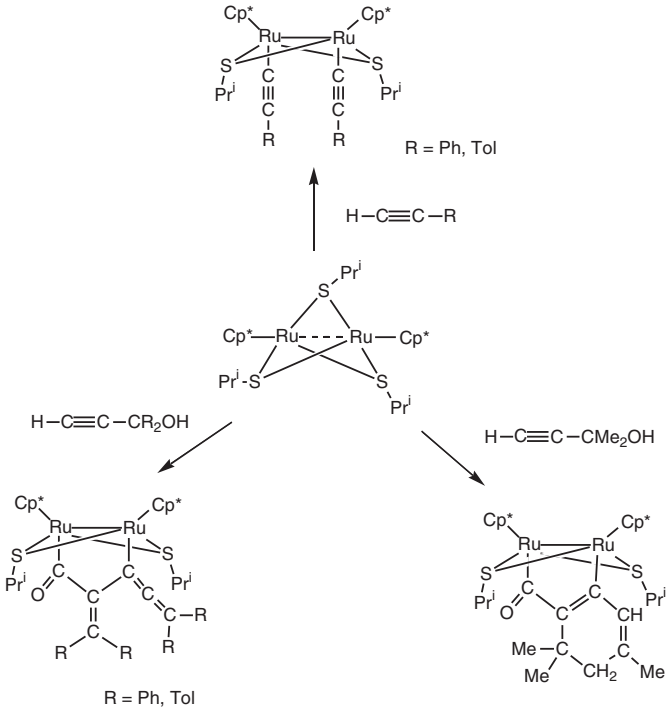
Our studies on the polynuclear metal–sulfur compounds started about 20 years ago from synthesis of a new series of thiolato-bridged diruthenium complexes. Although the chemistry of transition metal – thiolato complexes was already the subject of much interest, this was almost limited to the compounds containing the biologically important metals. With respect to the Group 8 metals, extensive studies had been carried out on the Fe thiolato complexes, however, studies on the corresponding Ru complexes were developed only poorly at that time.

By treating the Ru(III) complex $[(Cp^*RuCl)_2(\mu\text{-}Cl)_2]$ (72) with certain thiolato sources, we isolated four types of diruthenium complexes with bridging thiolato ligands; i.e.,

Fig. 3. Structures of thiolato-bridged diruthenium complexes.



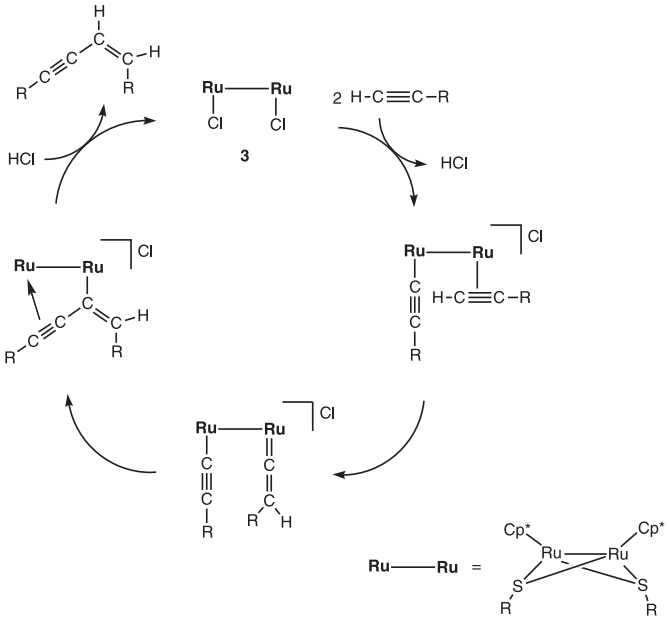
Ru(III)–Ru(III) complexes $[(Cp^*RuCl)_2(\mu\text{-}SR)_2]$ (**3**) and $[(Cp^*Ru)_2(\mu\text{-}SR)_3]Cl$ (73), paramagnetic Ru(III)–Ru(II) complexes $[(Cp^*Ru)_2(\mu\text{-}SR)_3]$, and Ru(II)–Ru(II) complexes $[(Cp^*Ru)_2(\mu\text{-}SR)_2]$ (74) (Fig. 3). The latter Ru(II)–Ru(II) complexes were prepared more readily (75) via the Ru(II) complexes $[(Cp^*Ru)_2(\mu\text{-}OMe)_2]$ (76) or $[(Cp^*Ru)_4(\mu_3\text{-}Cl)_4]$ (77) derived from $[(Cp^*RuCl)_2(\mu\text{-}Cl)_2]$. Studies on the reactivities toward small molecules were first done intensively for Ru(II)–Ru(II) and Ru(II)–Ru(III) complexes $[(Cp^*Ru)_2(\mu\text{-}S\text{-}i\text{-}Pr)_n]$ (n = 2, 3), which disclosed that these are quite versatile complexes that display various novel reactivities as already summarized elsewhere (11*e*). It is noteworthy that the reactions at the diruthenium site including coordination of neutral π-acceptor molecules such as CO and *t*-BuNC, dinuclear oxidative addition of H_2 and alkyl halides, and incorporation of two or three terminal alkyne molecules proceed with retention of the dinuclear core owing to the strong bridging ability of the thiolato ligand. Among these interesting reactions, those of alkynes with $[(Cp^*Ru)_2(\mu\text{-}S\text{-}i\text{-}Pr)_n]$ (n = 2, 3) are especially unique, which may be exemplified by the preparation of various dinuclear ruthenacyclopentenyl complexes from $[(Cp^*Ru)_2(\mu\text{-}S\text{-}i\text{-}Pr)_2]$ with a series of terminal alkynes (78) (Scheme 23) as well as the formations of bis(alkynyl) complexes (79) and diruthenacyclopentanone or diruthenacyclopentenone complexes (80) from $[(Cp^*Ru)_2(\mu\text{-}S\text{-}i\text{-}Pr)_3]$ with monoarylacetylenes and propargyl alcohols (Scheme 24), respectively. Extension of these studies on the reactions of Ru(II)–Ru(II) and Ru(II)–Ru(III) complexes with alkynes to those of Ru(III)–Ru(III) complexes **3** and the cationic complexes $[(Cp^*RuCl)(\mu\text{-}SR)_2\{Cp^*Ru(H_2O)\}][OTf]$ (**4**) derived from **3** through the anion metathesis has led more recently to the finding of new catalytic reactions promoted at their thiolato-bridged diruthenium sites.



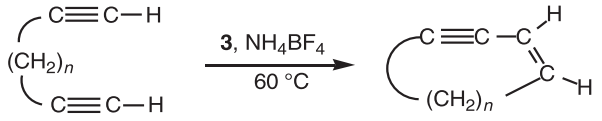
In the presence of NH_4BF_4 at 60 °C, complexes **3** (R = Me, Et, *n*-Pr) catalyze the head-to-head dimerization of various terminal alkynes into (*Z*)-en-ynes (81). It is noteworthy that aliphatic alkynes having chloro, hydroxy, and ester groups at the ω-positions are also converted to the corre-

© 2005 NRC Canada

Scheme 23.



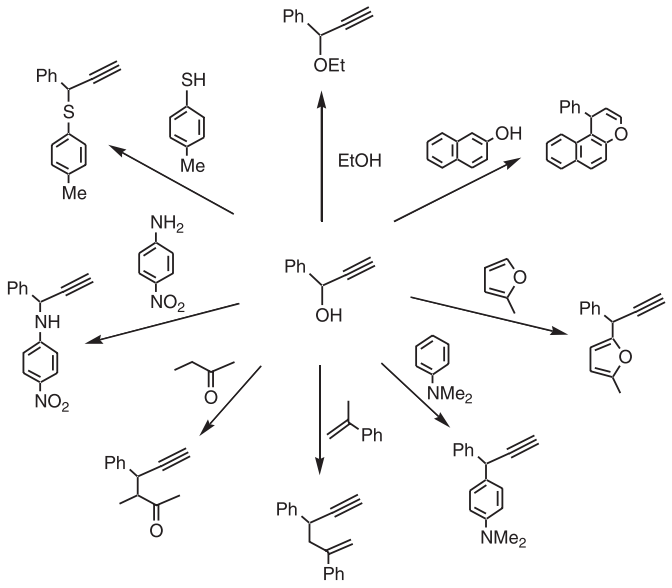
Scheme 24.



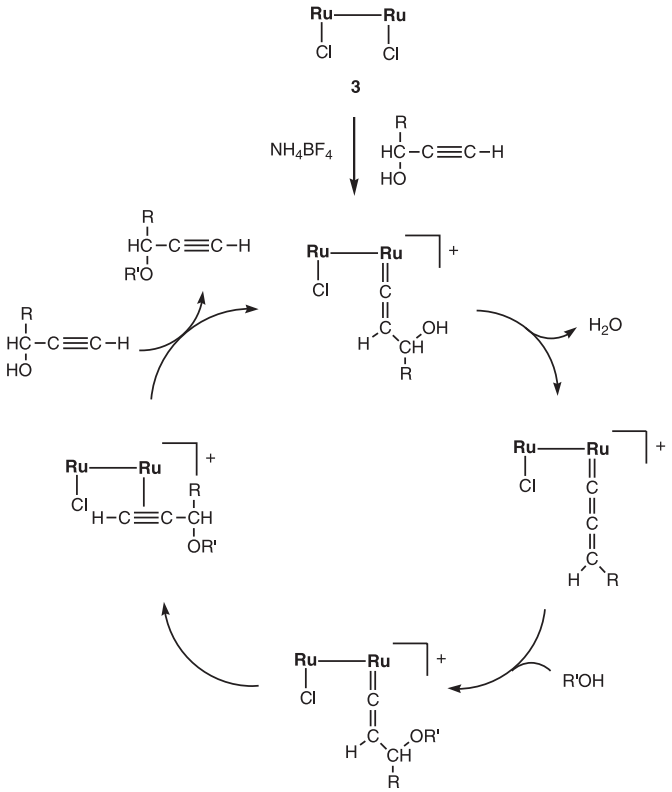
sponding (*Z*)-en-ynes in moderate to high yields. The mechanism involving the alkynyl-alkyne, alkynyl-vinylidene, and butenynyl intermediates was proposed (Scheme 25) on the basis of the isolation of vinylidene complexes [(Cp*Ru-Cl)(μ-S-*i*-Pr)$_2${Cp*Ru(=C=CHR)}][OTf] (R = H, COOMe, COMe) from the reaction of **4** (R = *i*-Pr) with HC≡CR (82)

Scheme 25.

Scheme 26.



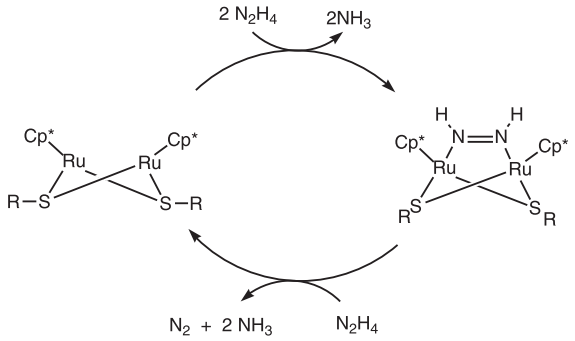
and the butenynyl complex [{Cp*Ru(C(=CHFc)C≡CFc)}(μ-S-*i*-Pr)$_2$(Cp*Ru)][OTf] (Fc = ferrocenyl) from **4** (R = *i*-Pr) and HC≡CFc (83). The latter butenynyl complex has turned out to catalyze the regio- and stereoselective dimerization of FcC≡CH to *Z*-FcCH=CHC≡CFc. This catalysis was later applied to the intramolecular reactions of α,ω-diynes HC≡C(CH$_2$)$_n$C≡CH (*n* = 6, 8, 10, 12), leading to a new method for synthesizing *endo*-macrocyclic (*Z*)-1-en-3-ynes (84) (Scheme 26).



Noteworthy is that complexes **3** display the catalytic activity for the propargylic substitution reactions of propargylic alcohols HC≡CCHROH with a number of nucleophiles, which include not only heteroatom-centered nucleophiles such as alcohols, amines, and thiols (85), but also carbon-centered nucleophiles such as simple ketones (86), alkenes (87), phenols (88), and aromatic compounds (89) (Scheme 27). The above reactions proceed catalytically with complete regioselectivities, which are in sharp contrast to the Nicholas reaction effective for the propargylic substitution, but requiring a stoichiometric amount of Co_2CO_8 (90). It is also to be emphasized that conventional mononuclear ruthenium complexes are not effective for these propargylation reactions and the diruthenium core is essential for this catalysis. In Scheme 28, the mechanism proposed for the catalytic reaction of a propargylic alcohol with alcohol R′OH is shown as a typical example. Thus, the reaction is initiated by the formation of a vinylidene complex from **3** and the propargylic alcohol, which is then transformed into an allenylidene complex via dehydration. Nucleophilic attack of the alcohol on the γ-carbon atom in the allenylidene ligand gives another vinylidene complex,

© 2005 NRC Canada

Scheme 27.



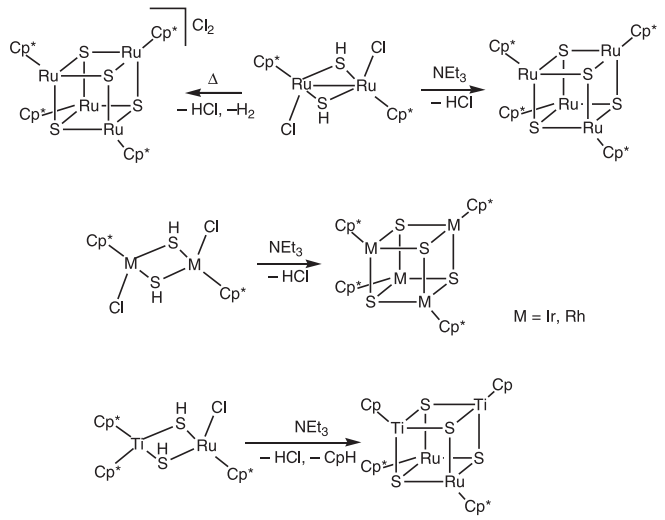
Scheme 28.

which subsequently isomerizes to a π-propargylic ether complex. The ether is liberated from the metal by reaction with excess of the propargylic alcohol to regenerate the initial vinylidene species. Formation of an allenylidene complex from the reaction of **3** with a propargylic alcohol was demonstrated by reacting **3** (R = Me) with $HC{\equiv}CC(Tol)_2OH$ in the presence of NH_4BF_4 at room temperature, whereby the isolated allenylidene complex $[\{Cp^*Ru(=C=C=CTol_2)\}(\mu\text{-}SMe)_2(Cp^*RuCl)][BF_4]$ liberated the ether $HC{\equiv}CC(Tol)_2OEt$ by treatment with EtOH at 60 °C.

Scheme 29.

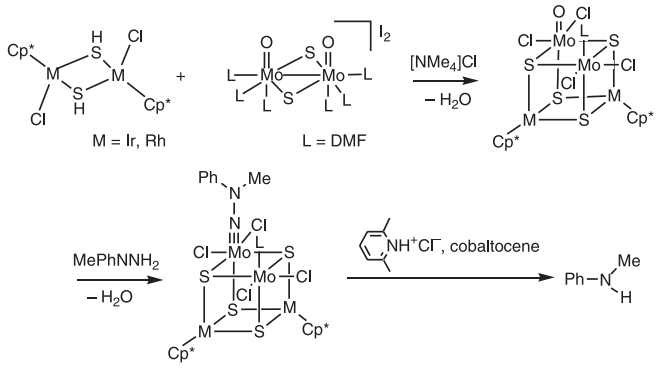
The propargylation of ketones with propargylic alcohols has further been extended to convenient direct synthesis of tri- and tetra-substituted furans and pyrroles by employing a combination of two catalysts **3** and $PtCl_2$ (91). Quite interestingly, when the cationic diruthenium complex **4** (R = Me) was employed as catalyst, propargylation of aromatic compounds proceeds by using propargylic alcohols bearing not only a terminal acetylene group, but also an internal acetylene group (92), although elucidation of the reaction mechanism requires further investigation. Complex **4** also works effectively as a catalyst for the propargylic substitution reactions of various propargylic alcohols with thiols (93).

As the reaction that is relevant more closely to nitrogen fixation, disproportionation of hydrazine has been demonstrated to proceed at the thiolato-bridged diruthenium site. Thus, the Ru(II)–Ru(II) complex $[(Cp^*Ru)_2(\mu\text{-}S\text{-}i\text{-}Pr)_2]$ catalyzes the transformation of hydrazine into ammonia and dinitrogen, a balance equation of which is shown as $3N_2H_4 \rightarrow 4NH_3 + N_2$. Spectroscopic data of the reaction mixture suggested the presence of the μ-diazene complex as the intermediate (Scheme 29) (94).



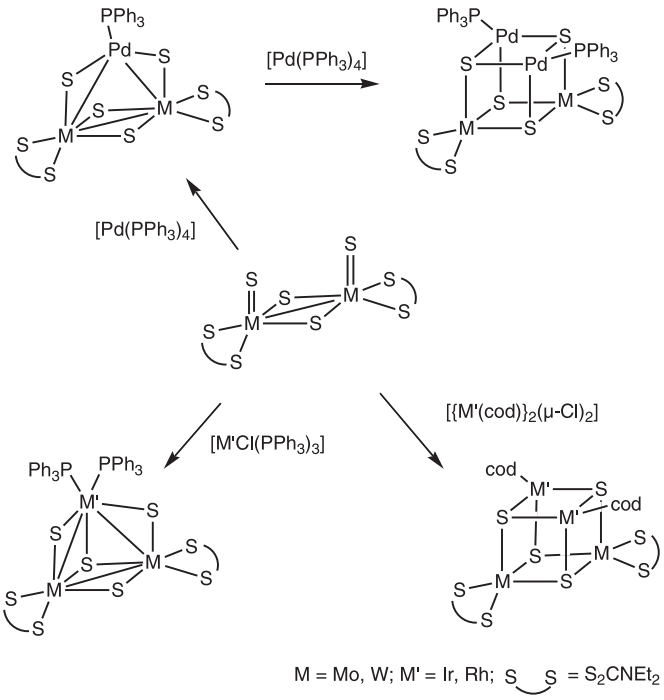
Chemistry of metal–sulfur cubane-type complexes

Metal–sulfur cubane-type M_4S_4 clusters have long been attracting much attention since the Fe_4S_4 core was demonstrated as the active site of bacterial ferredoxin in the early 1970s. Several years later, the mixed-metal, cubane-type $MoFe_3S_4$ core was proposed as a model of the metal–sulfur active site of the FeMo-cofactor (vide supra). In this context, cubane-type $MoFe_3S_4$ clusters had been prepared intensively as the model compounds of the nitrogenase active site (10). To be noted is that the cores of these clusters were prepared by the self-assembly methods in solution. Although subsequent studies on their reactivities have made some success in the cluster-catalyzed nitrogenase model reactions, e.g., reduction of N_2 into ammonia in a protic media under electrolytic conditions (95) and catalytic conversion of hydrazine into ammonia in the presence of certain proton and electron sources (96), development of intriguing reactivities of these clusters toward small molecules has been only poorly realized.



We have long been interested in synthesis and reactivities of noble metal-containing sulfur clusters and much effort has

© 2005 NRC Canada



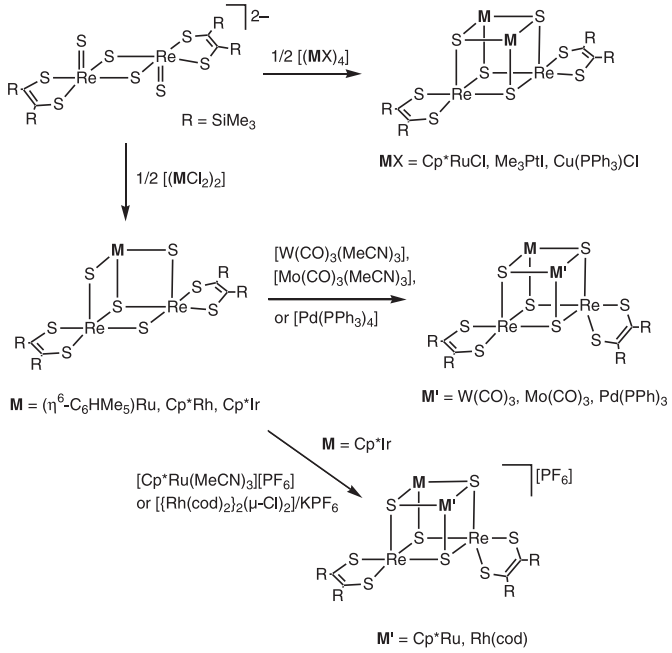
Scheme 30.

Scheme 31.

Scheme 32.

been devoted to the exploration of the *reliable* synthetic routes to prepare the sulfido clusters of this type with the desired atom composition in high yields (11*b*). These studies in this laboratory have resulted in the finding of several versatile methods to construct the cubane-type, metal–sulfido cores as summarized below.

A series of hydrosulfido-bridged dinuclear complexes with homometallic $M(\mu\text{-}SH)_2M$ (M = Ru (97), Ir, Rh (98)) and heterometallic $Ti(\mu\text{-}SH)_2Ru$ cores (99) have proved to be excellent precursors to prepare the homo- and heterometallic cubane-type clusters (Scheme 30). Thermal reaction of $[(Cp^*RuCl)_2(\mu\text{-}SH)_2]$ gives the cationic cluster $[(Cp^*Ru)_4(\mu_3\text{-}S)_4]Cl_2$ via the dimerization accompanied by dehydrogenation and dehydrochlorination (97), while treatment of $[(Cp^*MCl)_2(\mu\text{-}SH)_2]$ or $[(Cp_2Ti)(Cp^*RuCl)(\mu_2\text{-}SH)_2]$ with NEt_3 affords the neutral clusters $[(Cp^*M)_4(\mu_3\text{-}S)_4]$ (M = Ru, Ir, Rh) (100) or $[(CpTi)_2(Cp^*Ru)_2(\mu_3\text{-}S)_4]$ (99) through the dimerization with concomitant loss of HCl or HCl–CpH, respectively. By mixing $[(Cp^*RuCl)_2(\mu\text{-}SH)_2]$ and $[(Cp_2Ti)(Cp^*RuCl)(\mu_2\text{-}SH)_2]$ in the presence of NEt_3, the crossed condensation product $[(CpTi)(Cp^*Ru)_3(\mu_3\text{-}S)_4]$ is formed selectively (101).

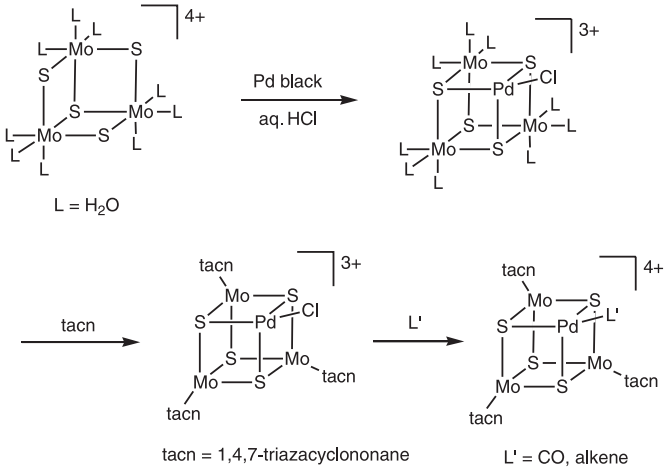


Condensation of the hydrosulfido-bridged complexes $[(Cp^*MCl)_2(\mu\text{-}SH)_2]$ (M = Ir, Rh) with the sulfido-bridged dimolybdenum oxo complex $[\{MoO(DMF)_3\}_2(\mu\text{-}S)_2]I_2$ in the presence of excess $[NMe_4]Cl$ gives the mixed-metal, cubane-type clusters with an oxo group on one Mo atom $[(MoOCl_2)\{MoCl_2(DMF)\}(Cp^*M)_2(\mu_3\text{-}S)_4]$ via dehydration. Further reaction of this Mo_2Ir_2 cluster with $MePhNNH_2$ affords the hydrazido(2–) cluster $[\{Mo(NNMePh)Cl_2\}\{MoCl_2(DMF)\}(Cp^*Ir)_2(\mu_3\text{-}S)_4]$, for which reductive cleavage of the N—N bond proceeds to form *N*-methylaniline by treatment with a lutidinium chloride – cobaltocene mixture (Scheme 31). Catalytic formation of *N*-methylaniline occurs when $MePhNNH_2$ is reacted with lutidinium chloride – cobaltocene in the presence of the oxo clusters $[(MoOCl_2)\{MoCl_2(DMF)\}(Cp^*M)_2(\mu_3\text{-}S)_4]$ (102). This reaction provides a rare example of catalytic reactions promoted by metal–sulfido clusters (103).

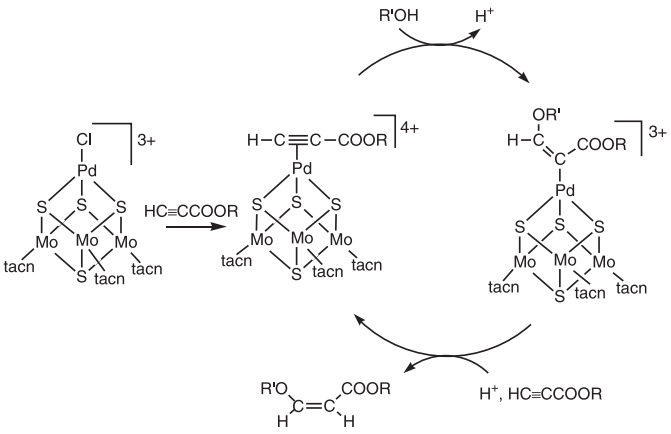
Sulfido-bridged dinuclear complexes $[\{MS(dtc)\}_2(\mu\text{-}S)_2]$ (M = Mo, W; dtc = diethyldithiocarbamate) also serve as good precursors to afford mixed-metal, cubane-type clusters by incorporating two metal fragments into their $MS(\mu\text{-}S)_2MS$ cores. Cubane-type clusters derived from this method are $[\{Pd(PPh_3)\}_2\{MS(dtc)\}_2(\mu_3\text{-}S)_4]$ (104) and $[\{M'(cod)\}_2\{MS(dtc)\}_2(\mu_3\text{-}S)_4]$ (M′ = Rh, Ir) (105). The trinuclear clusters $[\{Pd(PPh_3)\}\{MS(dtc)\}_2(\mu_3\text{-}S)(\mu_2\text{-}S)_3]$ as an intermediate are isolable from the reaction of $[\{MS(dtc)\}_2(\mu\text{-}S)_2]$ with an equimolar amount of $[Pd(PPh_3)_4]$. Although the formation of trinuclear clusters was not observed for the reaction of $[\{MS(dtc)\}_2(\mu\text{-}S)_2]$ with $[\{M'(cod)\}_2(\mu\text{-}Cl)_2]$ to give $[\{M'(cod)\}_2\{MS(dtc)\}_2(\mu_3\text{-}S)_4]$ (M′ = Rh, Ir), the incomplete cubane-type clusters $[\{M'(PPh_3)_2\}\{MS(dtc)\}_2(\mu_3\text{-}S)(\mu_2\text{-}S)_3(\mu_2\text{-}Cl)]$ (M′ = Rh, Ir) were obtained as the sole products from the reactions of $[\{MS(dtc)\}_2(\mu\text{-}S)_2]$ with $[M'Cl(PPh_3)_3]$ (Scheme 32).

Employment of the Re dithiolene complex $[PPh_4]_2[\{ReS(L)\}_2(\mu\text{-}S)_2]$ (L = $S_2C_2(SiMe_3)_2$) (106) as the alternative $MS(\mu\text{-}S)_2MS$ source gives rise to a new series of bimetallic cubane-type and incomplete cubane-type clusters.

© 2005 NRC Canada

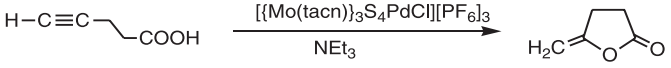


Scheme 33.



It is noteworthy that from the incomplete cubane-type clusters $[(Cp^*M)\{Re(L)_2\}(\mu_3\text{-}S)(\mu_2\text{-}S)_3]$ (M = Ir, Rh) and $[\{(\eta^6\text{-}C_6HMe_5)Ru\}\{Re(L)_2\}(\mu_3\text{-}S)(\mu_2\text{-}S)_3]$ obtained here, novel trimetallic cubane-type clusters containing $MM'Re_2(\mu_3\text{-}S)_4$ cores (M = Ir, Rh: M′ = W, Mo, Ru, Rh, Pd; M = Ru: M′ = W, Pd) could be prepared (Scheme 33). This contrasts sharply with the previous observation that such trimetallic cubane-type clusters were not available from the trinuclear PdM_2, RhM_2, and IrM_2 clusters derived from $[\{MS(dtc)\}_2(\mu\text{-}S)_2]$ (M = Mo, W) shown above.

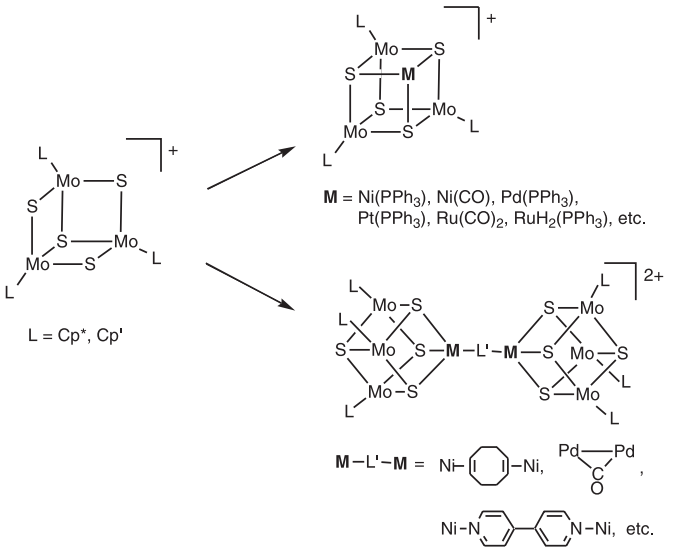
Incorporation of a metal fragment into the void of the incomplete cubane-type $M_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3$ core had earlier proved to be a versatile method to prepare bimetallic cubane-type $M_3M'(\mu_3\text{-}S)_4$ cores. Thus, Shibahara (107) reported the syntheses of a series of $Mo_3M'(\mu_3\text{-}S)_4$ clusters by the reaction of zero-valent M′ with an incomplete cubane-type Mo aqua cluster $[Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3(H_2O)_9]^{4+}$ in acidic solutions. We attempted for the first time the reactions of this aqua cluster $[\{Mo(H_2O)_3\}_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3]^{4+}$ with noble metals and succeeded in the isolation of $Mo_3Pd(\mu_3\text{-}S)_4$ clusters $[\{Mo(H_2O)_3\}_3(PdCl)(\mu_3\text{-}S)_4]^{3+}$ and $[\{Mo(H_2O)_3\}_6(\mu_3\text{-}S)_6Pd_2(\mu_4\text{-}S)_2]^{8+}$ (108). A $Mo_3Pt(\mu_3\text{-}S)_4$ cluster was also available, which was isolated as the crystallographically characterizable cluster $[\{Mo(dppe)Cl\}_3(PtCl)(\mu_3\text{-}S)_4]$ (109). Related aqua clusters containing $Mo_3M'(\mu_3\text{-}S)_4$ and $W_3M'(\mu_3\text{-}S)_4$ cores with various M′ including noble metals were also synthesized later by Sykes and co-workers (110). The Mo_3Pd clusters have an unique tetrahedral Pd site and coordination of alkenes and CO occurs on the Pd site in $[\{Mo(tacn)\}_3(PdCl)(\mu_3\text{-}S)_4]^{3+}$ (tacn = 1,4,7-triazacyclononane) (Scheme 34). More interestingly, it has turned out that this cluster catalyzes the stereoselective addtion of alcohols and carboxylic acids to electron-deficient alkynes such as methyl propiolate (108, 111). A plausible mechanism for the addition of an alcohol to alkyl propiolate is shown in Scheme 35, where the coordinated tacn ligands on thee Mo atoms are omitted for clarity. The reaction is initiated by coordination



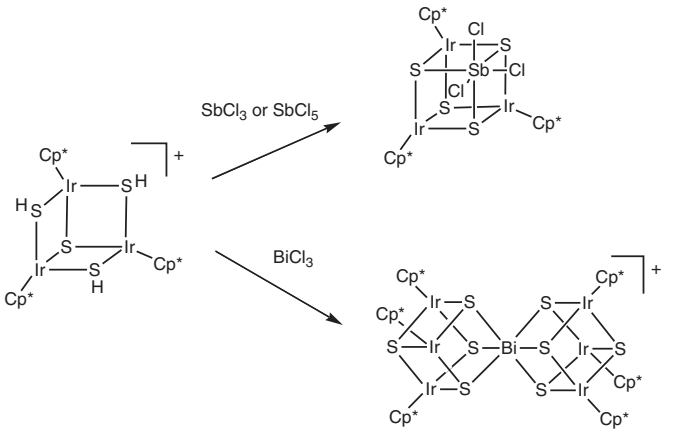
Scheme 34.

Scheme 35.

Scheme 36.



of the alkyne to the unique Pd atom, which is followed by nucleophilic attack of the alcohol to the activated alkyne to form a vinylpalladium intermediate. Liberation of the trans addition product from the metal occurs by protonolysis, and the cubane-type core is retained during the catalysis. This type of reaction was further extended to the intramolecular cyclization of alkynoic acids to afford enol lactones. The lactonization of 4-pentynoic acid catalyzed by this cluster proceeds very efficiently and the turnover reaches 100 000 after 19 h (112) (Scheme 36). Such catalytic activities were not observed for conventional mononuclear Pd complexes. These reactions are noteworthy since reactions efficiently catalyzed by well-defined metal–sulfido clusters are still rare.

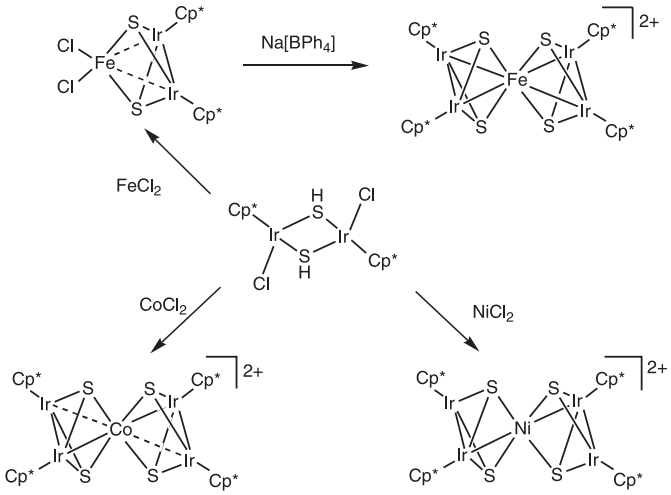


Incomplete cubane-type Mo clusters with cyclopentadienyl ligands $[(Cp^*Mo)_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3]^+$ (113) and $[(Cp'Mo)_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3]^+$ (Cp′ = $\eta^5\text{-}C_5MeH_4$) (114) have also been prepared recently, which incorporate various transition metal fragments to form cubane-type organometallic clusters (113, 115) (Scheme 37). Coordination of the alkyne

© 2005 NRC Canada

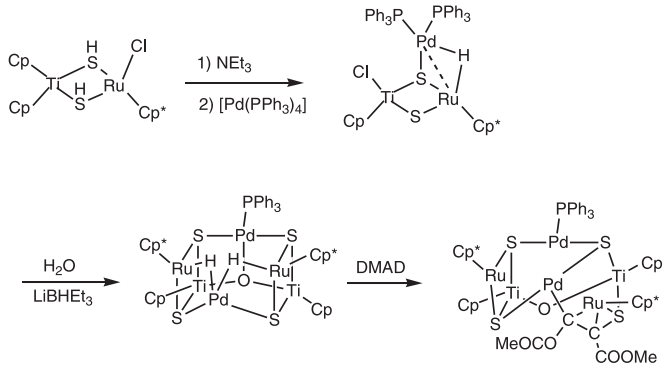
Scheme 37.

Scheme 38.



MeOCOC≡CCOOMe (DMAD) to the nickel site embedded in the Mo_3S_4 aggregate has been demonstrated by isolation of $[(Cp^*Mo)_3\{Ni(\eta^2\text{-DMAD})\}(\mu_3\text{-}S)_4][PF_6]$, whereas treatment of 4-pentynoic acid with a small amount of $(Cp^*Mo)_3Ni(\mu_3\text{-}S)_4$ clusters gives rise to the catalytic formation of an enol lactone as shown in Scheme 36 (115*a*).

Another new versatile precursor having an incomplete cubane-type core is the Ir sulfido – hydrosulfido cluster $[(Cp^*Ir)_3(\mu_3\text{-}S)(\mu_2\text{-}SH)_3]Cl$ (116). It is noteworthy that in contrast to the $Mo_3S_4^{4+}$ core containing relatively electron-deficient d^2 Mo(IV) centers described above, this Ir cluster has more electron-rich d^6 Ir(III) centers. This difference is reflected in the reactivities of these clusters: incorporation of the formal M(0) species including Sb(0) and Bi(0) occurs in the case of the $Mo_3S_4^{4+}$ clusters, whereas $[(Cp^*Ir)_3(\mu_3\text{-}S)(\mu_2\text{-}SH)_3]Cl$ does react with $SbCl_5$ and MCl_3 (M = Sb, Bi) to give a single cubane-type cluster $[(Cp^*Ir)_3(SbCl_3)(\mu_3\text{-}S)_4]$ and a corner-shared double cubane-type cluster $[\{(Cp^*Ir)_3(\mu_3\text{-}S)_4\}_2Bi]Cl$ containing high valent Sb(V) and Bi(V) centers (Scheme 38) (117).



Penta- and hexanuclear sulfido complexes

Pentanuclear bow-tie clusters $[\{(Cp^*Ir)_2(\mu_3\text{-}S)_2\}_2M]^{2+}$ are

Scheme 39.

Scheme 40.

derived from the reaction of the hydrosulfido-bridged diiridium complex $[(Cp^*IrCl)_2(\mu\text{-}SH)_2]$ with MCl_2 (M = Fe, Co, Ni). In the reaction with $FeCl_2$, a trinuclear cluster $[(Cp^*Ir)_2(\mu_3\text{-}S)_2(FeCl_2)]$ is produced initially, which is then transformed into the pentanuclear cluster by treatment with $NaBPh_4$ (Scheme 39) (118).

As a metal–sulfido cluster with higher nuclearity, a novel hexanuclear trimetallic cluster $[(CpTi)_2(Cp^*Ru)_2Pd_2(PPh_3)\text{-}(\mu_3\text{-}S)_4(\mu_3\text{-}O)(\mu_2\text{-}H)_2]$ is formed from the reaction of the trinuclear cluster $[(CpTiCl)(Cp^*Ru)\{Pd(PPh_3)_2\}(\mu_3\text{-}S)(\mu_2\text{-}S)(\mu_2\text{-}H)]$ with water and $LiBHEt_3$. The latter trinuclear cluster is derived from the hydrosulfido-bridged complex $[(Cp_2Ti)(Cp^*RuCl)(\mu_2\text{-}SH)_2]$ and $[Pd(PPh_3)_4]$ in the presence of NEt_3 (Scheme 40) (119). Incorporation of the alkyne DMAD into the hexanuclear cluster core takes place to afford a new cluster depicted in Scheme 40 through the insertion of the alkyne into a Pd—S bond with concurrent loss of two hydrides.

Conclusion

We have summarized here our two approaches toward activation of dinitrogen, nitriles, and alkynes by using novel complexes learned from nitrogenase. During the last three decades, various types of reactions of those small molecules by employment of molybdenum and tungsten complexes have been developed, revealing that dinitrogen is not a chemically

© 2005 NRC Canada

inert molecule if it is bound to a transition metal surrounded by appropriate ligands. On the other hand, stimulated by the active site of nitrogenase, a variety of metal–sulfur clusters containing noble metals ranging from dinuclear to hexanuclear cores have been prepared in rational ways, and their structures and reactivities toward small molecules have been extensively investigated. This has led to the finding of the unique catalysis of dinuclear and tetranuclear cubane-type metal–sulfur complexes. Further studies from both approaches may lead to the development of new types of catalytic reactions of small molecules, which are not attainable by conventional mononuclear complexes, and hopefully to the development of a new generation of chemical nitrogen fixation that efficiently transforms dinitrogen into nitrogen hydrides and organo-nitrogen compounds under mild conditions.

Early developments in lanthanide-based dinitrogen reduction chemistry[1]

William J. Evans and David S. Lee

Abstract: Although the first crystallographically characterized lanthanide dinitrogen complex was reported in 1988 with samarium, it is only in recent years that this field has expanded to include fully characterized examples for the entire series of lanthanides. The development of lanthanide dinitrogen chemistry has been aided by a series of unexpected results that present some good lessons in the development of science. This review presents a chronological account of the lanthanide dinitrogen chemistry discovered in our laboratory through the summer of 2004.

Key words: lanthanides, dinitrogen, reduction, alkali metal, nitrogen fixation, diazenido.

Résumé : Même si un premier complexe de diazote et d'un lanthanide a été caractérisé en 1988 avec le samarium, ce n'est que dans les années récentes que ce domaine a connu une expansion au cours de laquelle des exemples de complexes de chacun des membres de la série des lanthanides ont finalement été complètement caractérisés. Le développement de la chimie des complexes du diazote et des lanthanides a été aidé par une série de résultats inattendus qui présentent de bonnes leçons dans le développement de la science. Cette revue présente un exposé chronologique de la chimie des complexes de diazote et de lanthanides telle que développée dans notre laboratoire jusqu'au milieu de l'été 2004.

Mots clés : lanthanides, diazote, réduction, métal alcalin, fixation du diazote, diazénido.

[Traduit par la Rédaction]

Initial discovery

Just as Allen and Senoff's discovery of the first transition metal complex of dinitrogen (1) resulted from trying to rationalize data that did not quite match that expected, lanthanide dinitrogen chemistry in our laboratory was initiated by pursuing an experimental irregularity. While investigating the chemistry of the bent metallocene, $(C_5Me_5)_2Sm$ (**1**) (2), graduate student Tamara Ulibarri noticed that the C_6D_6 ^1H NMR spectra of samples of this compound occasionally contained an extra resonance at –0.6 ppm. This was observed in addition to the usual broad resonance of pure $(C_5Me_5)_2Sm$ in the 1 to 2 ppm region, a peak that varied depending on the concentration of this paramagnetic compound (3). Although the highly reactive $(C_5Me_5)_2Sm$ was freshly prepared each time by the same procedure, this small "impurity" peak was only occasionally present in the spectrum.

This intermittent extra resonance could easily have been ignored as an artifact. However, Tamara noticed that it was present only in samples prepared in the nitrogen-containing glovebox and not in samples prepared on the high vacuum line. Once she made this correlation, a sample prepared under nitrogen was cooled and the –0.6 resonance was observed to grow at the expense of the $(C_5Me_5)_2Sm$ signal. Subsequent crystallization of the sample gave a mixture of green and red crystals. Separation of the red crystals by hand from the green $(C_5Me_5)_2Sm$ and subsequent X-ray analysis revealed the structure of the first crystallographically characterized *f* element dinitrogen complex, $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**2**) shown in Fig. 1 (4).

The unusual $Sm_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ structure

Isolation of a dinitrogen complex of a lanthanide was most unexpected considering the traditional view of lanthanide bonding (5). The limited radial extension of the 4*f* orbitals gave these metal ions primarily ionic chemistry in which hard donor atom anions were the preferred ligands. In fact, for many years it was even believed that only oxygen donor ligands were hard enough for the lanthanides: nitrogen donor ligands were thought to be incapable of forming stable complexes with lanthanides (6, 7). This misconception was formed because much of the early chemistry was done in aqueous solution in which water was the predominant ligand. It was subsequently found that a variety of harder nitrogen ligands like $(NR_2)^-$, pyridine, nitriles, etc., would bind the trivalent ions (8). However, reactions with a neutral, soft ligand like dinitrogen seemed unlikely for these hard metal ions.

$[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ was unusual not only because it was the first dinitrogen complex of an *f* element, but also because it was the first dinitrogen complex *of any metal* in which the metals and N_2 were coplanar (structure **I** in Fig. 2). A variety of bimetallic dinitrogen complexes had been identified in 1988 when **2** was discovered (9), but they

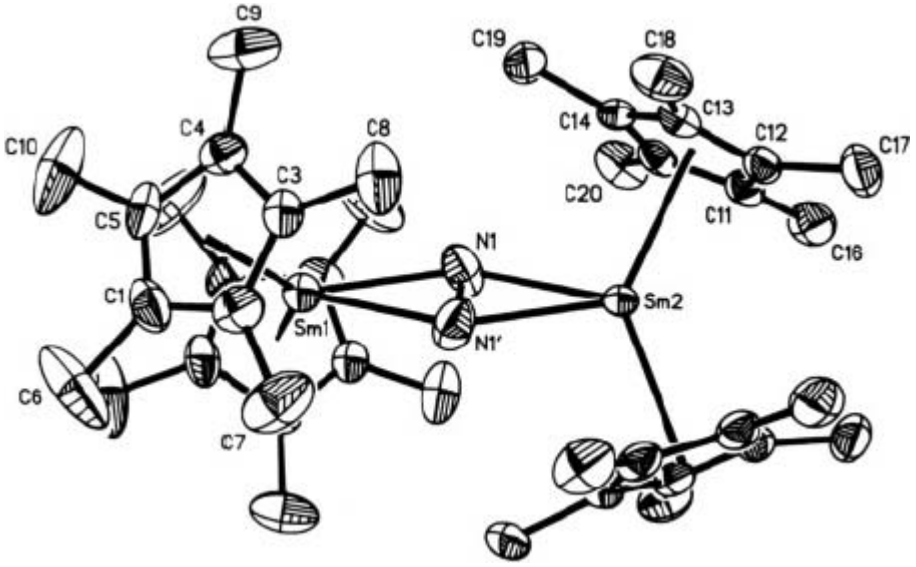
Fig. 1. Thermal ellipsoid plot of $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**2**).



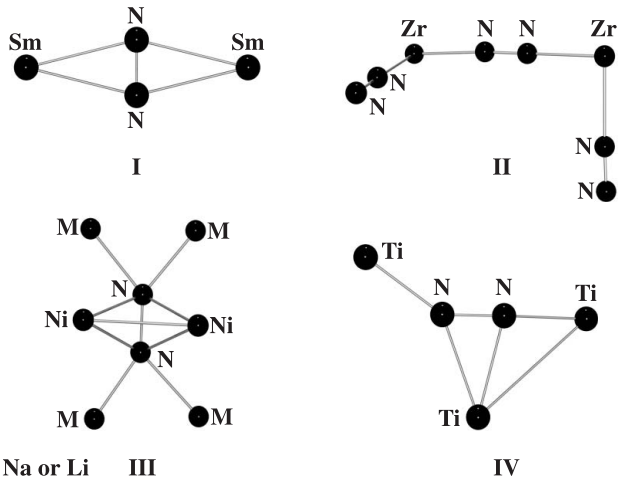


Fig. 2. Metal dinitrogen core structures: (**I**) found in $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**2**) (4); (**II–IV**) other M_XN_2 arrangements known at that time (9–14).

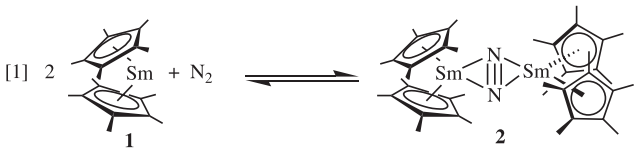

typically displayed end-on coordination of N_2, as in $[(C_5Me_5)_2Zr(\eta^1\text{-}N_2)]_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}N_2)$ (10), whose core structure is shown as **II** in Fig. 2. The closest dinitrogen examples to the coplanar $M_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ binding in **2** at that time in the literature were the tetrahedral M_2N_2 components of $[(PhLi)_6Ni_6N_2(OEt_2)_2]_2$ (11, 12) and $[Ph_5Ni_2N_2Na_3Li_6(OEt)_4(OEt_2)_3]_2$ (13) (structure **III**), and the triply bridging M_3N_2 unit in $(C_{10}H_8)(C_5H_5)_5(C_5H_4)Ti_4(\mu_3\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (14) (structure **IV**, Fig. 2).

As is often the case with discoveries, the unusual structure found in **2** was also being observed at about the same time in another system in another laboratory. The Fryzuk group, investigating the $[(i\text{-}Pr_2PCH_2SiMe_2)_2N]^{1-}$ ligand system, independently found a structure of this type in the complex $\{[(i\text{-}Pr_2PCH_2SiMe_2)_2N]ClZr\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$. This was published (15) shortly after $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ was revealed.

The isolation of $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ is all the more remarkable because of its unusual structural features and chemical behavior. $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ is clearly a trivalent complex on the basis of its metrical parameters in the solid state and its ^{13}C NMR characteristics in solution. Hence, the Sm-C(C_5Me_5) distances are clearly in the trivalent range, which is distinct from that of divalent complexes (16). Likewise, the ^{13}C NMR shift pattern is characteristic of Sm^{3+} (ring carbons at 112 ppm, methyl carbons at 27 ppm) and is distinct from that of the more paramagnetic Sm^{2+} complexes, which have ring carbons around –100 ppm and methyl carbons around +100 ppm (4, 17).

Since the Sm^{3+} centers in $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ indicate that dinitrogen was reduced to $(N_2)^{2-}$, an N—N bond distance of around 1.25 Å would be expected. However, the N—N distance in **2** (1.088(12) Å) was equivalent to that in free dinitrogen (1.0975 Å). In contrast, the N—N distance in the Fryzuk analog, $\{[(i\text{-}Pr_2PCH_2SiMe_2)_2N]ClZr\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (1.548(7) Å), was among the longest of those observed for activated dinitrogen.

The short distance in $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ could be connected with the fact that the structure of **2** was determined at room temperature, but it could also be associated with the unusual equilibrium shown in eq. [1]. Complex **2** exists in equilibrium with $(C_5Me_5)_2Sm$ (eq. [1]). This is a

strange situation since it involves a reversible Sm^{3+} to Sm^{2+} interconversion. Since Sm^{2+} is a strong reducing agent (18–20) (Table 1), once Sm^{3+} complexes are formed, they generally do not revert to Sm^{2+} (21, 22).

Hiatus

For the next 12 years, no dinitrogen complexes were dis-

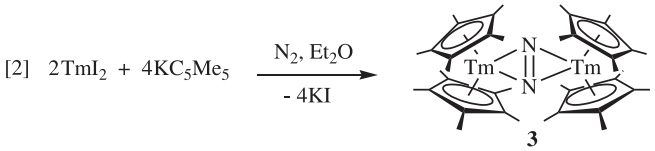
covered in our laboratory. This appeared to be a testament to the special properties of $(C_5Me_5)_2Sm$ (19, 20). Apparently, the analogous Eu and Yb metallocenes (23, 24) were not reducing enough to make the analogous isolable complexes (25), and Eu, Yb, and Sm were the only lanthanides that had molecular divalent complexes at that time. None of the other molecular Sm^{2+} complexes known at the time, such as $SmI_2(THF)_5$ (26, 27), $Sm[N(SiMe_3)_2]_2(THF)_2$ (28), $[C_5H_3(SiMe_3)_2]_2Sm(THF)$ (29), and $[(C_5Me_5)SmI(THF)]_2$ (30) appeared to be strong enough reductants to reduce N_2.

However, samarium dinitrogen chemistry did continue to advance. In 1994, Gambarrotta and co-workers began investigating the chemistry of Sm^{2+} in the coordination environments of tetrapyrrole tetraanion and dipyrrole dianion ligands. Tetrametallic $(N_2)^{4-}$ complexes were obtained from dinitrogen (31–36) as well as one $Sm_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ complex with an apparently short 1.08(3) Å N—N distance like that found in **2**. In some cases, these complexes were made from Sm^{2+} precursors and in others they were obtained from Sm^{3+} precursors and Li or Na in reactions that presumably made Sm^{2+} intermediates. In 1998, Floriani and co-workers (37) published a report on tetrapyrrole tetraanion Nd and Pr dinitrogen complexes prepared in the presence of Na. Interestingly, all of these polypyrrole lanthanide dinitrogen complexes also displayed the $Ln_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ coplanar arrangement found in $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$.

A new approach to lanthanide dinitrogen chemistry based on Tm^{2+}, Dy^{2+}, and Nd^{2+}

Significant expansion of dinitrogen chemistry in our laboratory resulted from the crystallographic identification of three new divalent molecular lanthanide diiodides, $TmI_2(DME)_3$ (38), $DyI_2(DME)_3$ (39), and $NdI_2(THF)_5$ (40). For many years it was expected that the only lanthanide ions that would form isolable, soluble, divalent, molecular species were Eu^{2+}, Yb^{2+}, and Sm^{2+}. As shown in Table 1, these three ions are the least reducing of the entire series (18). The next most reducing ions (Tm^{2+}, Dy^{2+}, and Nd^{2+}) were known in solid-

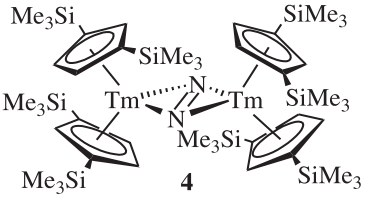
Fig. 3. Structures of the first molecular complexes of Tm^{2+}, Dy^{2+}, and Nd^{2+}, $TmI_2(DME)_3$ (38), $DyI_2(DME)_3$ (39), and $NdI_2(THF)_5$ (40).



state materials obtained from Ln and I_2 in sealed tantalum vessels at high temperature (41), but attempts to isolate fully characterizable molecular species from these ions were unsuccessful. Transient, intensely colored solutions were reported to contain these ions, but their lifetimes were typically short (42–44). It was generally believed that these ions were too reactive to isolate and utilize in solution.

This belief was overturned in 1997, when the first crystallographic data on a stable, soluble, molecular Tm^{2+} complex were obtained (Fig. 3) (38). The existence of $TmI_2(DME)_3$ clearly showed that molecular divalent lanthanide chemistry was not limited only to Eu, Yb, and Sm.

On the basis of the rich chemistry previously observed for Sm^{2+} (19, 20), much was anticipated from the new divalent ion (Tm^{2+}). However, initial attempts to obtain chemistry from Tm^{2+} were not particularly productive (45–48). It readily formed Tm^{3+} products, but without generating any significantly new inorganic or organometallic reduction products. Attempts to utilize Tm^{2+} in situ in organic reaction chemistry as a replacement for SmI_2–HMPA suggested that in situ chemistry might be the best way to pursue this highly reactive divalent chemistry (49).



The reappearance of lanthanide dinitrogen chemistry in our laboratory came during the exploration of this in situ Tm^{2+} chemistry. In a reaction designed to mimic in situ the organometallic reduction chemistry of $(C_5Me_5)_2Sm$ (19, 20), TmI_2 was combined with 2 equiv. of KC_5Me_5. However, before a substrate could be added to this mixture, a reaction occurred. The product that was isolated from this reaction was $[(C_5Me_5)_2Tm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**3**), a complex analogous to the first lanthanide dinitrogen complex, $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**2**). This result (eq. [2]) (50) showed that the supposedly inert atmosphere of dinitrogen provided the substrate for this in situ Tm^{2+} reaction!

This discovery advanced both divalent lanthanide chemistry and lanthanide dinitrogen chemistry. It revealed a new route to lanthanide-based reduction of dinitrogen and it showed one reason why the previous attempts to isolate molecular Ln^{2+} complexes might have failed.

Further studies of in situ TmI_2–cyclopentadienide chemistry showed that eq. [2] was not limited to $(C_5Me_5)^{1-}$ ligands. Dinitrogen complexes of $[C_5H_3(SiMe_3)_2]^{1-}$ (51) and even the mono-substituted $[C_5H_4(SiMe_3)]^{1-}$ ligand (52) could be isolated: $\{[C_5H_3(SiMe_3)_2]_2Tm\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**4**) (eq. [3]), and

$\{[C_5H_4(SiMe_3)]_2Tm\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**5**) (eq. [4]) (50). With the smaller, monosubstituted, cyclopentadienyl ligand in complex **5**, the thulium ions were solvated with THF, but the internal structure of the complex still maintained the formerly unusual $M_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ arrangement.

While the Tm^{2+} chemistry was being developed, new syntheses of divalent Dy^{2+} and Nd^{2+} compounds were reported (53), and crystallographic confirmation of the existence of these molecular divalent complexes of Dy^{2+} (39) and Nd^{2+} (40) was also obtained (Fig. 3). These advances allowed the dinitrogen reduction chemistry of these two elements to be studied. On the basis of the Tm^{2+} chemistry above, it was no surprise that DyI_2–$KC_5H_3(SiMe_3)_2$ would extend lanthanide dinitrogen chemistry to Dy (54). Again, a $M_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ structure was observed in the product, $\{[C_5H_3(SiMe_3)_2]_2Dy\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**6**) (eq. [5]).

Attempts to make analogous cyclopentadienyl neodymium dinitrogen complexes were unsuccessful. This seemed reasonable considering the high reactivity of Nd^{2+} (Table 1). For example, the TmI_2–$2KC_5Me_5$ combination had been found to be reactive enough to decompose Et_2O (in the absence of N_2) (50). However, more reactive NdI_2 would decompose THF at room temperature without any added ligand (55). It appeared that the combination of this more reducing Nd^{2+} ion and the electron-donating cyclopentadienyl ligand might be "too reactive" for dinitrogen reduction. This suggested that other ligands should be tried with Nd^{2+}.

To determine if the divalent ions of Tm^{2+}, Dy^{2+}, and Nd^{2+} could reduce dinitrogen without the aid of cyclopentadienyl ligands, in situ reactions of other "Ln^*Z_2" combinations were examined (Ln^* = Tm, Dy, Nd; $(Z)^{1-}$ = monoanion). The first two $(Z)^{1-}$ ligands studied were the amide and aryloxide ligands most commonly used in lanthanide chemistry, $[N(SiMe_3)_2]^{1-}$ (56) and $[OC_6H_3\text{-}t\text{-}Bu_2\text{-}2,6]^{1-}$ (57, 58). As shown in eqs. [6] and [7], in situ reactions of Ln^*I_2 with $KN(SiMe_3)_2$ and $KOC_6H_3\text{-}t\text{-}Bu_2\text{-}2,6$ generated two new series of lanthanide dinitrogen complexes, the amides, $\{[(Me_3Si)_2N]_2(THF)Ln^*\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**7**), and the aryloxides exemplified by $[(2,6\text{-}t\text{-}Bu_2C_6H_3O)_2(THF)_2Nd]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**8**) (59). The $[N(SiMe_3)_2]^{1-}$ lanthanide dinitrogen complexes (**7**) were

© 2005 NRC Canada

analogous to the $[C_5H_4(SiMe_3)]^{1-}$ thulium complex (**5**) above, and contained one THF of solvation per metal. With NdI_2 and $[OC_6H_3$-*t*-Bu_2-2,6$]^{1-}$, the isolated product (**8**) contained *two* THF molecules of solvation per metal center.

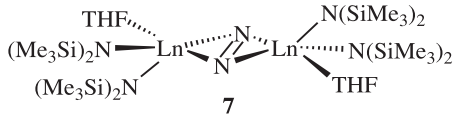
Preponderance of the $Ln_2(\mu$-η^2:η^2-$N_2)$ structure

As shown in eqs. [6] and [7], despite the variation in metals, ligands, and degree of THF solvation, the new amide and aryloxide lanthanide dinitrogen complexes retained the formerly rare $M_2(\mu$-η^2:η^2-$N_2)$ structure first reported for $[(C_5Me_5)_2Sm]_2(\mu$-η^2:η^2-$N_2)$. Hence, the coplanar arrangement of two metals and dinitrogen that originally was unusual, subsequently became the structure found in all of the lanthanide cyclopentadienyl, amide, aryloxide, and polypyrrole polyanion dinitrogen complexes isolated. Although this structure originally could have been attributed to some constraints in the coordination environment enforced by the ancillary ligands, e.g., the four $(C_5Me_5)^{1-}$ ligands in $[(C_5Me_5)_2Sm]_2(\mu$-η^2:η^2-$N_2)$ (60) or the cyclic tetrapyrrole tetraanions (31–37), this was not possible with the new THF-solvated dinitrogen complexes with these simple monodentate amides and aryloxides. The fact that this $M_2(\mu$-η^2:η^2-$N_2)$ structure formed with both mono- and polydentate ligands and in unsolvated, mono-solvated, and di-solvated complexes, suggested that this was in fact the preferred structure for a Ln_2N_2 unit regardless of the ancillary ligands.

Although the $M_2(\mu$-η^2:η^2-$N_2)$ structure may have appeared to be unusual on the basis of transition metal chemistry, which initially had many more η^1 end-on bound dinitrogen complexes, it is actually a quite reasonable structure for the more ionic lanthanides. Bradley et al. (61, 62) discovered bimetallic lanthanide complexes of the $(O_2)^{2-}$ ligand in 1974 that had a $Ln_2(\mu$-η^2:η^2-$O_2)$ structure analogous to the $Ln_2(\mu$-η^2:η^2-$N_2)$ arrangement and similar structures have subsequently been identified (63). Calculations on the electrostatic stabilization of that $Ln_2(\mu$-η^2:η^2-$O_2)$ peroxide vs. a $Ln_2(\mu$-η^1:η^1-$O_2)$ arrangement, i.e., Ln-O-O-Ln, indicated that the μ-η^2:η^2-option was quite favored (62). The same argument could apply to $(N_2)^{2-}$ complexes of the lanthanides if the bonding is largely electrostatic.

In contrast to the predominance of the $M_2(\mu$-η^2:η^2-$N_2)$ structure in lanthanide dinitrogen chemistry, this arrangement still tends to be rare in transition metal chemistry. The structures of $\{[(Me_3Si)_2N]Cl(TMEDA)Ti\}_2(\mu$-$\eta^1$:$\eta^1$-$N_2)$ vs. $\{[(Me_3Si)_2N]_2Ti\}_2(\mu$-$\eta^2$:$\eta^2$-$N_2)_2$ were early examples of how changes in the ligand set can affect the preference for $M_2(\mu$-η^2:η^2-$N_2)$ bonding in transition metal complexes (64). The recent example of the $M_2(\mu$-η^2:η^2-$N_2)$ structure in $[(C_5Me_4H)_2Zr]_2(\mu$-η^2:η^2-$N_2)$ (65), in contrast to the end-on bonding in $[(C_5Me_5)_2Zr(\eta^1$-$N_2)]_2(\mu$-η^1:η^1-$N_2)$ (10), indicates that only small changes in the ancillary ligands can affect the stability of the $M_2(\mu$-η^2:η^2-$N_2)$ structure in transition metal chemistry. Examples of the $M_2(\mu$-η^2:η^2-$N_2)$ geometry have also been found with actinide metals, which often display chemistry intermediate between the lanthanides and transition metals. These include $[\{N(CH_2CH_2NSi$-*t*-$BuMe_2)_3\}U]_2(\mu$-η^2:η^2-$N_2)$ (66) and $[(C_5Me_5)(C_8H_4\{Si$-*i*-Pr_3-1,4$\}_2)U]_2(\mu$-η^2:η^2-$N_2)$ (67).

Paramagnetism in lanthanide dinitrogen complexes



Although the advent of molecular complexes of the divalent ions of Tm^{2+}, Dy^{2+}, and Nd^{2+} expanded lanthanide dinitrogen chemistry to a wider range of metals, further studies of the reactivity of these reduced dinitrogen complexes remained challenging because of their paramagnetism. In the $(N_2)^{2-}$ complexes (**3**–**7**), the Tm^{3+} and Dy^{3+} ions have magnetic moments of 6.9 and 9.9 μ_B, respectively, and the compounds do not give observable NMR spectra. The Nd^{3+} complex (**8**) with a magnetic moment of 3.5 μ_B, gave observable spectra, but the broad resonances were still not very definitive. No ^{15}N NMR data were obtained on any of these species.

A new approach based on LnZ_3–K reactivity — The $Ln[N(SiMe_3)_2]_3$–K reduction system

If the presumed divalent "$Ln[N(SiMe_3)_2]_2$" intermediates thought to be responsible for the formation of the dinitrogen complexes in the syntheses from LnI_2 and $KN(SiMe_3)_2$ (eq. [6]) could be generated in situ from the readily accessible $Ln[N(SiMe_3)_2]_3$ complexes (56) and potassium (68), the synthesis of **7** would be improved since it did not depend on the highly reactive Ln^{*2+} ions. Accordingly, $Tm[N(SiMe_3)_2]_3$ was prepared (56) and treated with K under nitrogen. As shown in eq. [8], this "LnZ_3/K" approach (where Z is a monoanionic ligand that allows this chemistry) to dinitrogen reduction was successful and generated $\{[(Me_3Si)_2N]_2$-$(THF)Tm\}_2(\mu$-η^2:η^2-$N_2)$ (**7-Tm**).

This was a significant synthetic breakthrough, since it meant that **7-Tm** could be obtained from $Tm[N(SiMe_3)_2]_3$ rather than TmI_2. $Tm[N(SiMe_3)_2]_3$ is readily available from $LnCl_3$ and $KN(SiMe_3)_2$ by literature methods dating back to 1973 (56). Since $Tm[N(SiMe_3)_2]_3$ is much less reactive than TmI_2, this made the experimental procedure to make the **7-Tm** complex less demanding. Since Tm has a –2.3 V (vs. NHE) calculated Ln^{3+}/Ln^{2+} reduction potential (Table 1, (18)), and K has a –2.9 V reduction potential, eq. [8] was reasonable on the basis of redox potentials.

Although eq. [8] was successful with thulium, no evidence of a highly colored, divalent intermediate consistent with "$Tm[N(SiMe_3)_2]_2$" was observed. Similar results were obtained with the $Dy[N(SiMe_3)_2]_3$–K reaction (eq. [8], Ln = Dy). $\{[(Me_3Si)_2N]_2(THF)Dy\}_2(\mu$-$\eta^2$:$\eta^2$-$N_2)$ (**7-Dy**) could be synthesized by this method, but the intense color expected from "$Dy[N(SiMe_3)_2]_2$" generated via a –2.5 V Dy^{3+}/Dy^{2+} reduction by K was not visible. Although it was possible that the divalent intermediates reacted so fast that they were not seen, we decided to examine eq. [8] with a lanthanide for which no molecular divalent complex had been crystallographically characterized. Using Ho, which has a –2.9 V

[8] $2Ln[N(SiMe_3)_2]_3 + 2K \xrightarrow[-\,2KN(SiMe_3)_2]{N_2,\ THF}$ 

7

© 2005 NRC Canada

Ln^{3+}/Ln^{2+} reduction potential, eq. [8] was similarly successful and the first holmium dinitrogen complex was isolated ($\{[(Me_3Si)_2N]_2(THF)Ho\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$, **7-Ho**).

Encouraged by these results, eq. [8] was examined with Y and Lu, for which no molecular divalent chemistry has previously been reported. These were important elements, because their trivalent complexes are diamagnetic. If eq. [8] was successful with these metals, this would produce the first diamagnetic $\{[(Me_3Si)_2N]_2(THF)Ln\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ complexes (68). Much to our delight, the $Ln[N(SiMe_3)_2]_3$–K reactions were also successful with yttrium and lutetium and produced **7-Y** and **7-Lu**. Subsequent studies showed that $\{[(Me_3Si)_2N]_2(THF)Ln\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ compounds could also be obtained in this way with Gd, Tb, and, Er, metals with Ln^{3+}/Ln^{2+} reduction potentials of –3.9, –3.7, and –3.1 V (vs. NHE), respectively. These reactions were all the more remarkable in that they could be accomplished with Na (–2.7 V) as well as K (69).

The success of eq. [8] not only with Tm and Dy, but also with Nd, Gd, Tb, Ho, Y, Er, and Lu suggested several mechanistic possibilities that are still under investigation at this time. If eq. [8] proceeds through divalent $Ln[N(SiMe_3)_2]_2$ intermediates, these reactions represent the first examples of molecular Gd^{2+}, Tb^{2+}, Er^{2+}, Ho^{2+}, Y^{2+}, and Lu^{2+} chemistry. Alternatively, if the trivalent $Ln[N(SiMe_3)_2]_3$ complexes were activating dinitrogen for reduction by potassium in THF, e.g., by formation of a "$(N_2)Ln[N(SiMe_3)_2]_3$" complex, which would allow alkali metal reduction to occur, this would be the first evidence of dinitrogen complexation to a trivalent lanthanide. Although this type of dinitrogen activation is common with transition metals (70, 71), and is known for actinides (72), formation of a dinitrogen complex of a trivalent lanthanide in the presence of a much larger concentration of a more polar, harder Lewis base, namely THF, is not precedented in lanthanide chemistry. An additional possibility involves activation of dinitrogen by the alkali metal reductant with subsequent electron transfer in the presence of $Ln[N(SiMe_3)_2]_3$. If this option is operating, it must occur with Na as well as K and potassium graphite.

Regardless of the mechanism, the LnZ_3 – alkali metal reduction system when applied to dinitrogen as a substrate using $[N(SiMe_3)_2]^{1-}$ as the $(Z)^{1-}$ ligand generates a series of isomorphous $\{[(Me_3Si)_2N]_2(THF)Ln\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ complexes (**7**) for Nd, Gd–Tm, Y, and Lu without the need for divalent reagents. Interestingly, this reaction did not give isolable crystalline complexes for the larger metals in the series, La, Ce, and Pr. Since these metals have Ln^{3+}/Ln^{2+} reduction potentials of –3.1, –3.2, and –2.7 V (vs. NHE), respectively, and since reactions with Gd (–3.9 V) and Tb (–3.7 V) were successful, it seems that reduction potential was not the determining factor here.

^{15}N NMR spectroscopy — The first diamagnetic data

The ability to extend reductive lanthanide dinitrogen chemistry to Y and Lu using the LnZ_3–K approach provided the opportunity for the first time to use NMR spectroscopy to study diamagnetic lanthanide dinitrogen complexes. Obtaining ^{15}N NMR data on $\{[(Me_3Si)_2N]_2(THF)Ln\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (Ln = Y, Lu) was not easy, however (68). To insure the validity of the measurement only crystalline samples were examined and the yields of X-ray quality crystals whose identity could be verified by unit cell determination were small. Ultimately, the ^{15}N NMR shifts were obtained and found to be 513 and 557 ppm (vs. $MeNO_2$) for the **7-Y** and **7-Lu** analogs, respectively. These are compared with other complexes in Table 2.

Table 2. ^{15}N NMR shifts for some selected dinitrogen complexes.

Compound	^{15}N NMR shift referenced to $MeNO_2$
$[(C_5Me_5)_2(THF)La]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$	569
$\{[(Me_3Si)_2N]_2(THF)Lu\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$	557
$\{[(Me_3Si)_2N]_2(THF)La\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$	516
$\{[(Me_3Si)_2N]_2(THF)Y\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$	513
$[(C_5Me_4H)_2(THF)La]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$	495
$[(C_5Me_4H)_2Zr]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (65)	240
$[(C_5Me_5)_2Zr(\eta^1\text{-}N_2)]_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}N_2)$ (10)	183 (Bridging)
	85 (Terminal)
$\{[(i\text{-}Pr_2PCH_2SiMe_2)_2N]ZrCl\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (15)	82

Detection of a $La_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ complex

Once an estimate of the ^{15}N NMR shifts of diamagnetic Ln_2N_2 complexes was in hand, it was possible to look for the success of eq. [8] with Ln = La via ^{15}N NMR spectroscopy. Although the $La[N(SiMe_3)_2]_3$–K reaction did not give a crystalline **7-La** product, it was possible that the reaction occurred, but **7-La** just did not crystallize well under these conditions (69). When the $La[N(SiMe_3)_2]_3$–K reaction was conducted under $^{15}N_2$, a signal at 516 ppm was observed, which suggested that this LnZ_3–K reaction also succeeded with the largest metal in the lanthanide series (Table 2). This suggested that the LnZ_3–K–N_2 reaction was indeed general for the lanthanides, but that for the larger metals, the products did not readily crystallize. Since the radial size of the lanthanides changes by 0.18 Å from La to Lu (73), it is rare that the size of a given ligand set is ideal for crystallizing isomorphous examples for all the metals.

The $Ln(C_5Me_4H)_3$–K system

If the only factor that prevented identification of N_2 reduction via $Ln[N(SiMe_3)_2]_3$–K with the larger metals, La–Pr, involved the crystallizability of the $\{[(Me_3Si)_2N]_2(THF)Ln\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ products, then a change in the ligand environment could lead to success with these other metals. Accordingly, a new $(Z)^{1-}$ was sought for the LnZ_3–K–N_2 reaction (eq. [9]). It was further desirable to examine the LnZ_3–K reaction with other $(Z)^{1-}$ ligands to determine if the success of this approach to dinitrogen reduction in eq. [8] was involved with the fact that $(Z)^{1-}$ was specifically $[N(SiMe_3)_2]^{1-}$.

$$[9]\quad 2LnZ_3 + 2K \xrightarrow[THF]{N_2} [Z_2(THF)_XLn]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2) + 2KZ$$

© 2005 NRC Canada

A key factor in choosing $(Z)^{1-}$ was that LnZ_3 could be easily synthesized for all the lanthanides from readily available precursors, preferably the chloride, $LnCl_3$ (74), or from the elemental metal (75, 76). A $(Z)^{1-}$ ligand that met this requirement was $(C_5Me_4H)^{1-}$ (eq. [10]) (77, 78).

[10] $LnCl_3 + 3KC_5Me_4H \xrightarrow[-3KCl]{THF} (C_5Me_4H)_3Ln$

Hence, the $Ln(C_5Me_4H)_3$–K dinitrogen reduction reaction was examined. The Ln = La case was of particular interest since crystallographic evidence had not yet been obtained on this diamagnetic system. As shown in eq. [11], $(C_5Me_4H)_3La$ and $(C_5Me_4H)_3Nd$ in the presence of K and dinitrogen generate the new lanthanide dinitrogen complexes $[(C_5Me_4H)_2(THF)Ln]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**9**) (79). Each has the $Ln_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ internal structure previously observed with other lanthanide complexes. The overall structure was similar to that of the $\{[(Me_3Si)_2N]_2(THF)Ln\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ complexes (**7**), except that C_5Me_4H groups had replaced the $[N(SiMe_3)_2]^{1-}$ ligands. This result demonstrated that with the proper ligand set, La_2N_2 complexes analogous to those of the other metals could be isolated in crystalline form. The ^{15}N NMR shift of this lanthanum complex was in the same region as the other diamagnetic lanthanides (495 ppm, Table 2).

The extension of the LnZ_3–K reaction to the organometallic $(C_5Me_4H)_3Ln$ starting materials showed that this reaction was not limited to $(Z)^{1-} = [N(SiMe_3)_2]^{1-}$. It provided another advance in that the yield of the reduced dinitrogen products was high. In contrast, the $Ln[N(SiMe_3)_2]_3$–K–N_2 reactions did not give yields that exceeded 50%, a factor that hindered subsequent reactivity studies of the $(N_2)^{2-}$ moiety. In addition, purification of the $\{[(Me_3Si)_2N]_2(THF)Ln\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ products was achieved only through crystallization as this was the primary means of separating the product (**7**) from the soluble $KN(SiMe_3)_2$ by-product of eq. [8]. The organometallic LnZ_3–K–N_2 system was superior in that the unwanted KZ by-product, in this case, KC_5Me_4H would precipitate from solution. Formation of an insoluble KZ by-product may prove to be useful in obtaining high yields in eq. [9] and may be an important point to consider in future applications of the LnZ_3–K reduction system.

LnZ_3–K reduction with heteroleptic precursors (LnZ_2Z'–K)

Since $(C_5Me_5)^{1-}$ is such a heavily investigated ligand with the lanthanides and since the first lanthanide dinitrogen complex (**2**) was obtained with $(C_5Me_5)^{1-}$ ligands (4), it was desirable to investigate the LnZ_3–K–N_2 reaction with Z = $(C_5Me_5)^{1-}$. However, the $(C_5Me_5)_3Ln$ complexes are not viable starting materials for a LnZ_3–K reaction. They are not known for all the lanthanides and in addition, they are not stable to the THF solvent typically used for eq. [9] (80). Specifically, $(C_5Me_5)_3Ln$ complexes ring-open THF to make $(C_5Me_5)_2Ln[O(CH_2)_4C_5Me_5]$ (80).

Since the LnZ_3–K reaction (eq. [9]) sacrifices one $(Z)^{1-}$ ligand per lanthanide in the reduction process, it is not necessary to have a homoleptic precursor composed of three identical $(Z)^{1-}$ ligands. In fact, a LnZ_2Z' precursor in which KZ′ is insoluble could be superior to LnZ_3 as a starting material. Accordingly, we examined the precursors to the $(C_5Me_5)_3Ln$ complexes, the $[(C_5Me_5)_2Ln][(\mu\text{-}Ph)_2BPh_2]$ salts, as starting materials for the LnZ_3–K reduction with the expectation that elimination of $KBPh_4$ would be favorable. These lanthanide tetraphenylborate salts are readily prepared from $LnCl_3$ for all of the lanthanides (81, 82).

As shown in eq. [12], $[(C_5Me_5)_2La][(\mu\text{-}Ph)_2BPh_2]$ can function as a precursor for a LnZ_3–K reduction of N_2 (79). $[(C_5Me_5)_2(THF)La]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**10**) was isolated from this reaction and characterized by X-ray crystallography and ^{15}N NMR spectroscopy (Table 2). Hence, eq. [12] was the first example of the successful use of a heteroleptic LnZ_2Z' precursor in the LnZ_3–K reduction system. It also provided the first good crystallographic data on a $(C_5Me_5)^{1-}$ lanthanide dinitrogen complex since the isolation of $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$. Interestingly, the lanthanum complex is isolated as a THF solvate, whereas the samarium complex is not.

LnZ_3–K overview

The preliminary results obtained to date on the LnZ_3–K reduction reaction (eq. [9]) suggest it is a general method to make reduced dinitrogen complexes of all the lanthanides. The range of Z ligands that is possible in these reactions has barely been explored, and it has been shown to be possible to use LnZ_2Z' precursors as well. This LnZ_3–K reduction system allows, for the first time, high-yield syntheses of diamagnetic Ln_2N_2 complexes. This should be very helpful in

[11] $2\ (C_5Me_4H)_2Ln + 2KC_8 \xrightarrow[-2KC_5Me_4H,\ -graphite]{THF,\ N_2} [(C_5Me_4H)_2(THF)Ln]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ **9**

Ln = La and Nd

[12] $2\ (C_5Me_5)_2La[(\mu\text{-}Ph)_2BPh_2] + 2KC_8 \xrightarrow[-2KBPh_4,\ -graphite]{THF,\ N_2} [(C_5Me_5)_2(THF)La]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ **10**

allowing the dinitrogen chemistry of the lanthanides to be fully explored. Certainly, the low yield and paramagnetism and the need to work only with crystallized samples inhibited earlier development.

More generally, the LnZ_3–K reduction system brings reductive, divalent-like chemistry to all the lanthanides. This should allow size optimization of this reductive chemistry (80) and selective choice of the metals with the most favorable spectroscopic and magnetic properties. The LnZ_3–K reduction system also should be applicable to substrates other than dinitrogen.

Retrospective

With the helpful advantage of hindsight, it is interesting to consider alternative routes by which lanthanide dinitrogen chemistry could have been developed. For example, if it had been suspected that the divalent lanthanide ions Tm^{2+}, Dy^{2+}, and Nd^{2+} would reduce dinitrogen, the preliminary investigations of these ions might have been done differently. It is likely that the short lifetimes observed for at least Tm^{2+} and Dy^{2+} in the early spectroscopic studies reviewed in 1984 (44) could have been prolonged by using Ar instead of N_2 as an inert atmosphere. Lanthanide dinitrogen complexes could have been discovered at that time and by using Ar, the molecular divalent chemistry of these ions could have been developed starting in the 1980s instead of in 1997 (38). Since the more reactive Nd^{2+} even attacks THF at room temperature, more than an Ar atmosphere might have been needed to identify dinitrogen complexes with that divalent ion.

Likewise, if, in the 1970s, potassium had been used in any reaction in the presence of the $Ln[N(SiMe_3)_2]_3$ complexes (56) under N_2, the series of $\{[(Me_3Si)_2N]_2(THF)Ln\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ compounds might have been discovered. The $(O_2)^{2-}$ complex of similar structure, $\{[(Me_3Si)_2N]_2(PPh_3\text{-}O)La\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)$, was identified in 1974 (61).

The recent results also raise questions about the intermediacy of divalent states of the polypyrrole polyanion chemistry reported for Sm, Pr, and Nd (33, 37). These dinitrogen reduction reactions, which used Li and Na, were assumed to involve divalent intermediates, but they could also have been forerunners of the LnZ_3–K chemistry that we now know is available for the entire lanthanide series. Related to these possibilities, we recently became aware of Russian papers from the 1980s in which Vol'pin, Bochkarev, and co-workers reported that ammonia was generated from hydrolysis of combinations of lanthanide complexes and excess sodium naphthalenide under dinitrogen (83, 84). Interestingly, of all the metals examined in those studies, the use of divalent Yb^{2+} starting materials gave the most ammonia, about 0.25 NH_3/Yb. This is one of the lanthanides for which no dinitrogen complex is known, nor expected to be very stable on the basis of spectroscopic data and calculations (25). It is possible that with slightly different starting materials, these sodium naphthalenide reactions could also have led to crystallographically characterizable lanthanide dinitrogen complexes via a LnZ_3–K reaction before the 1988 discovery of **2**.

Hence, hints of $(N_2)^{2-}$ complexes of the lanthanides, which have now been fully defined in many examples by X-ray crystallography and ^{15}N NMR spectroscopy, were in the literature many years earlier. This is probably the case for many discoveries. The challenge is to identify and follow up on these early clues. In the case of the chemistry described here, it was the strange extra peak in the ^1H NMR spectrum of $(C_5Me_5)_2Sm$, the decision to do in situ chemistry with the reactive new Ln^{*2+} ions, and the absence of the appropriate color in the $Ln[N(SiMe_3)_2]_3$–K–N_2 reaction that provided us with key suggestions.

Conclusion

Lanthanide dinitrogen chemistry has grown enormously since the discovery of $[(C_5Me_5)_2Sm]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ in 1988. Although the first example depended on the special reductive chemistry of Sm^{2+} and many of the subsequent examples resulted from the reactive divalent Tm^{2+} and Dy^{2+} ions, the discovery of the LnZ_3–K reduction system opened this chemistry to all the metals in the lanthanide series. Trivalent lanthanide complexes of the reduced dinitrogen $(N_2)^{2-}$ moiety have now been crystallographically characterized for all of the lanthanides in the series except the one radioactive member, Pm, the two most easily reduced elements, Eu and Yb, and Ce, which has not yet yielded to crystallization. These $(N_2)^{2-}$ compounds are available with a variety of simple ligands common in lanthanide chemistry, including cyclopentadienyls, amides, and aryloxides. Further diversity is likely to be possible via the LnZ_3–K and LnZ_2Z'–K reduction routes. More importantly, with the advent of high-yield routes to diamagnetic complexes, the stage is set for the first time for development of the chemical reactivity of these $(N_2)^{2-}$ ligands.

Bonding, activation, and protonation of dinitrogen on a molybdenum pentaphosphine complex — Comparison to *trans*-bis(dinitrogen) and -nitrile – dinitrogen complexes with tetraphosphine coordination[1]

Gerald C. Stephan, Gerhard Peters, Nicolai Lehnert, Carsten M. Habeck, Christian Näther, and F. Tuczek

Abstract: The molybdenum-N_2 pentaphosphine complex [$Mo(N_2)$(dpepp)(dppm)] (**1**) containing a bi- and a tridentate phosphine ligand (dpepp = $PhP(CH_2CH_2PPh_2)_2$, dppm = $Ph_2PCH_2PPh_2$) has been prepared and characterized. By protonation of **1** with triflic acid the NNH_2 complex [$Mo(NNH_2)$(dpepp)(dppm)]$(CF_3SO_3)_2$ (**2**) is formed without loss of the pentaphosphine coordination. The electronic properties of **1** and **2** and their ^{15}N and (or) ^2H counterparts are investigated by NMR, IR, and Raman spectroscopy coupled to DFT frequency and NMR shift calculations. Force constants are evaluated from experimental frequencies and isotope shifts by the quantum chemistry based normal coordinate analysis procedure (QCB-NCA). The results for the N_2 complex **1** are compared with those obtained earlier for bis(dinitrogen) and *trans*-nitrile dinitrogen systems. Importantly, the N_2 in the pentaphosphine complex is more strongly activated compared to corresponding bis(dinitrogen) compounds and more weakly activated compared to *trans*-nitrile N_2 systems. The activation of the NNH_2 ligand in complex **2** is similar to *trans*-nitrile systems and weaker compared to corresponding NNH_2 complexes with coordinated anions like [$MoF(NNH_2)(dppe)_2$](BF_4). These results are discussed based on the relative donor–acceptor properties of the respective trans ligands, demonstrating the influence of σ donation and π acceptance on the activation of N_2 in transition metal complexes.

Key words: nitrogen fixation, phosphine complexes, NMR shifts, DFT calculations, normal coordinate analysis.

Résumé : On a préparé et caractérisé le complexe pentaphosphine de molybdène-N_2 [$Mo(N_2)$(dpepp)(dppm)] (**1**) qui contient un ligand phosphine bidentate et un tridentate (dpepp = $PhP(CH_2CH_2PPh_2)_2$; dppm = $Ph_2PCH_2PPh_2$). Par protonation du complexe **1** avec l'acide triflique, le complexe NNH_2 [$Mo(NNH_2)$(dpepp)(dppm)]$(CF_3SO_3)_2$ (**2**) se forme sans perte de la coordination pentaphosphine. Les propriétés électroniques des composés **1** et **2** et de leurs contreparties ^{15}N et (ou) ^2H ont été étudiées par spectroscopie RMN, infrarouge et Raman couplées à des calculs de fréquences et de déplacements en RMN par la théorie de la densité fonctionnelle. Les constantes de force ont été évaluées à partir des fréquences expérimentales et les déplacements isotopiques par la chimie quantique en se basant sur une méthode d'analyse de coordonnées normales (QBC-NCA). Les résultats pour le complexe de N_2 (**1**) ont été comparés à ceux obtenus antérieurement avec les systèmes bis(diazote) et diazote nitrile *trans*. Le plus important est que, par comparaison avec les composés bis(diazote) correspondants, l'activation du complexe N_2 avec la pentaphosphine est plus forte alors que celle des systèmes nitriles *trans*. L'activation du ligand NNH_2 dans le complexe **2** est semblable à celle des systèmes nitriles *trans* et plus faible par comparaison aux complexes correspondants avec des anions coordinés comme le [$MoF(NNH_2)(dppe)_2$](BF_4). Une discussion de ces résultats sur la base des propriétés donneur–accepteur relatives des ligands trans respectifs permet de démontrer l'influence des caractères σ donneur et π accepteur sur l'activation du N_2 dans les complexes de métaux de transition.

Mots clés : fixation de l'azote, complexes de phosphines, déplacements chimiques en RMN, calculs de la théorie de la densité fonctionnelle, analyse de coordonnées normales.

Introduction

Since the discovery of the first dinitrogen complex, synthetic nitrogen fixation in analogy to the biological process has presented a continuing challenge (1). Today, two systems exist that mediate the full conversion of N_2 to ammonia in a step-wise and well-defined manner. The first one of these is based on molybdenum or tungsten dinitrogen complexes with mono- or diphosphine coligands that can be protonated to give the corresponding NNH, NNH_2, and NNH_3 complexes (2). We have studied these systems with the help of spectroscopy coupled to DFT calculations (3). If monophosphine ligands are employed, protonation of the bis(dinitrogen) complex leads to formation of ammonia and a Mo(VI)/W(VI) species. Protonation of the corresponding Mo(0)/W(0) N_2 complexes with diphosphine ligands (dppe = $Et_2PCH_2CH_2PEt_2$ or depe = $Ph_2PCH_2CH_2PPh_2$) stops at the NNH_2 or NNH_3 stage (2). The N—N bond can be cleaved after two-electron reduction of the NNH_2 complex, generating the first molecule of NH_3 and a nitrido or imido complex (4). Protonation and reduction of these species produces a second molecule of ammonia and regenerates the Mo(0)/W(0) complex, which is able to bind N_2 (5). Importantly, a catalytic conversion of N_2 to ammonia has been reported for this system, achieving three cycles (6). More recently, a second system, able to fix dinitrogen, has been developed, which is based on a sterically shielded Mo(III) triamidoamine complex. For the conversion of complex-bound N_2 to NH_3, analogous intermediates have been evidenced and characterized, respectively, as for the classic Mo/W diphos compounds. Catalytic production of NH_3 from N_2 has been evidenced for this system as well, achieving six cycles with an efficiency of 65%. This represents a considerable improvement over the Mo/W diphos systems and a major breaktrough in the field of synthetic nitrogen fixation (7).

As compared to the novel Mo(triamidoamine) system that provides a sterically shielded site for the reduction and protonation of N_2, the Mo/W diphos complexes suffer from three disadvantages: (*i*) two molecules of N_2 are bound at the zero valent stage, one of which is replaced upon conversion to the NNH_2 stage by the conjugate base of the acid employed for protonation or the solvent. This already limits the maximum efficiency of the overall process to 50% with respect to the substrate, N_2; (*ii*) the different intermediates of the Mo/W diphos system along the pathway from N_2 to NH_3 react with each other. This in particular relates to Mo/W(IV) NNH_2 complexes, which are fairly acidic and protonate their two-electron reduced counterparts according to the simplified equation (co-ligands omitted).

$$[1] \quad Mo(IV)(NNH_2)^{2+} + Mo(II)(NNH_2) \rightarrow Mo(0)(N_2) + Mo(IV)(NH)^{2+} + NH_3$$

Analogous reactions are possible between Mo(IV) imido complexes and their two-electron reduced derivatives, and accordingly, between Mo(IV) and Mo(II) NNH_2 and NH species, respectively (5). It is obvious that these cross reactions further decrease the overall efficiency of the transition-metal-mediated conversion of N_2 to ammonia based on Mo/W diphos complexes. Efforts have been presented to overcome these problems by attachment of Mo/W dinitrogen complexes with phosphine co-ligands to polymers or electrodes (8).

The third and perhaps most serious disadvantage of the Mo/W mono- and diphosphine systems appears to be the fact that the phosphine ligation becomes labile at the Mo/W(IV) stage (3*c*). This leads to irreversible replacement of these ligands by Lewis-basic species present in solution, i.e., the conjugate bases of the acids employed for protonation or solvent molecules. Regeneration of zero valent tetraphosphine species capable of binding N_2 then is not possible any more, and the catalytic circle is interrupted. In an effort to increase the thermodynamic and kinetic stability of the phosphine ligation in Mo or W dinitrogen complexes, we have recently synthesized the tetraphosphine ligand prP_4 ($Ph_2P(CH_2)_2PPh(CH_2)_3PPh(CH_2)_2PPh_2$) and investigated the stereochemistry and coordination properties of this ligand based on $Fe(NCS)_2$ complexes (9). The synthesis and characterization of a corresponding Mo/W(0) complex is currently under investigation.

One step further along this line would correspond to binding of N_2 on a Mo(0)/W(0) complex with a pentaphosphine ligand. This would also solve the first one of the above-mentioned problems as only formation of mono-dinitrogen complexes is possible. While a linear pentaphosphine ligand is known (10), we have chosen to first investigate the properties of a ligand sphere with five phosphine donors based on a complex containing a combination of a bidentate and a tridentate ligand. Such a compound, $Mo(N_2)$(dpepp)(dppm) (**1**), has been synthesized and investigated by George et al. (11) (dpepp = $PhP(CH_2CH_2PPh_2)_2$, dppm = $Ph_2PCH_2PPh_2$). In the present paper, the electronic structure and the spectroscopic properties of this complex are determined. Moreover, the complex is protonated to generate the NNH_2 complex $[Mo(NNH_2)(dpepp)(dppm)](CF_3SO_3)_2$ (**2**). ^{15}N and ^{31}P NMR spectroscopic data of **1** and **2** are presented. IR and Raman data of **1** and **2** are evaluated with the QCB-NCA procedure, which has been developed to analyze the vibrational structure of large molecules (12). DFT calculations are performed for the model systems $[Mo(N_2)(PH_3)_5]$ (**Ia**), $[Mo(N_2)(P3)(dpm)]$ (**Ib**), $[Mo(NNH_2)(PH_3)_5]^{2+}$ (**IIa**), and $[Mo(NNH_2)(P3)(dpm)]^{2+}$ (**IIb**) of compounds **1** and **2**, respectively, (dpm = $H_2PCH_2CH_2PH_2$, P3 = $HP(CH_2CH_2PH_2)_2$). Based on spectroscopic and quantum chemical data, the activation of N_2 in complex **1** is compared to that present in the bis(dinitrogen) complex $[Mo(N_2)_2(dppe)_2]$ (**3**) and the dinitrogen complex with a *trans*-nitrile ligand $[Mo(N_2)(NCCH_3)(dppe)_2]$ (**4**) (dppe = $Ph_2PCH_2CH_2PPh_2$) (3*c*, 13). The general implications of these results are discussed.

Experimental

Synthesis, isotopic substitution, and sample preparation

All reactions were performed under an inert gas atmosphere using Schlenk techniques. The solvents were dried and freshly destilled under argon. All other reagents were used without further purification. The phosphine ligands were obtained from Strem Chemicals, CF_3SO_3D from Sigma-Aldrich, and $^{15}N_2$ from Deutero GmbH. All sample manipulations for vibrational and NMR spectroscopy were performed in a glovebox.

© 2005 NRC Canada

The dinitrogen complex [Mo(N_2)(dpepp)(dppm)] was prepared following the literature procedure with slight variations (see the following) (11). The ^{15}N isotopomer [Mo($^{15}N_2$)(dpepp)(dppm)] was synthesized using $^{15}N_2$ (98%). The NNH_2 complex [Mo(NNH_2)(dpepp)(dppm)](CF_3SO_3)$_2$ was obtained by protonation of the dinitrogen complex with triflic acid. The preparation of the protonated, ^{15}N-labeled complex [Mo($^{15}N^{15}NH_2$)(dpepp)(dppm)](CF_3SO_3)$_2$ was carried out from the ^{15}N-substituted dinitrogen complex. The deuterated complex [Mo(NND_2)(dpepp)(dppm)](CF_3SO_3)$_2$ was prepared using CF_3SO_3D. [$MoCl_3$(dpepp)] was prepared following a published method (14).

*[Mo(N_2)(dpepp)(dppm)] (**1**^{14})*

In a 100 mL Schlenk flask, a suspension of 820 mg (1.07 mmol) [$MoCl_3$(dpepp)] and 455 mg (1.2 mmol) dppm in 30 mL THF was added to sodium amalgam (250 mg Na, 30 g Hg). The mixture was stirred for 3 h at 0 °C and 18 h at ambient temperature under N_2. The red solution was decanted, filtered, and reduced to 8 mL in vacuum. Upon adding 10 mL of methanol, an orange precipitate formed. The product was filtered off, washed (3 × 4 mL) with methanol, and dried in vacuo for 6 h. Yield: 583 mg (0.56 mmol, 51%). Anal. calcd. for $C_{59}H_{55}MoN_2P_5$: C 67.9, H 5.3, N 2.7; found: C 67.3, H 5.4, N 2.5.

*[Mo($^{15}N_2$)(dpepp)(dppm)] (**1**^{15})*

The synthesis was performed analogous to **1**^{14} with 433 mg (1.2 mmol) dppm and 753 mg (1.02 mmol) [$MoCl_3$(dpepp)]. Instead of using a continuous N_2 flow, the flask was filled with $^{15}N_2$. Yield: 551 mg (0.53 mmol, 52%). Anal. calcd. for $C_{59}H_{55}Mo^{15}N_2P_5$: C 67.8, H 5.3, N 2.9; found: C 67.3, H 5.7, N 2.3.

*[Mo(NNH_2)(dpepp)(dppm)](CF_3SO_3)$_2$ (**2**^{14})*

In a 25 mL Schlenk flask, 0.05 mL (0.57 mmol) triflic acid was added to a solution of 300 mg (0.29 mmol) [Mo(N_2)(dpepp)(dppm)] in 8 mL THF at –78 °C. While the solution was stirred for 10 min, the colour changed from orange to green. Leaving the solution for 2 h at –78 °C led to the formation of a dark green solid. The product was filtered and dried in vacuo. The solution was cooled overnight to produce more of the product. Overall yield was 264 mg (0.2 mmol, 70%).

*[Mo($^{15}N^{15}NH_2$)(dpepp)(dppm)](CF_3SO_3)$_2$ (**2**^{15})*

The synthesis was performed analogous to **2**^{14} with 240 mg (0.23 mmol) [Mo(N_2)(dpepp)(dppm)] and 0.04 mL (0.46 mmol) triflic acid. Yield: 180 mg (0.13 mmol, 58%).

*[Mo(NND_2)(dpepp)(dppm)](CF_3SO_3)$_2$ (**2**^{D})*

The synthesis was performed analogous to **2**^{14} with 270 mg (0.27 mmol) [Mo(N_2)(dpepp)(dppm)] and 0.05 mL (0.57 mmol) deuterated triflic acid CF_3SO_3D. Yield: 110 mg (0.08 mmol, 30%).

Spectroscopy

IR spectroscopy

Mid-IR and far-IR spectra were obtained from KBr or PE pellets using a Bruker IFS v66/S FT-IR spectrometer.

Raman spectroscopy

Raman spectra were obtained on a Bruker IFS 66/CS NIR FT-Raman spectrometer at 294 K. The setup involves a 350 mW Nd-YAG laser with an excitation wavelength of 1064 nm. The samples were pressed into the groove of a holder that can be sealed with a glass plate to ensure inert gas conditions.

NMR spectroscopy

NMR spectra were recorded on a Bruker Avance 400 pulse Fourier transform spectrometer operating at a ^1H frequency of 400.13 MHz (^{31}P NMR 161.98 MHz, ^{15}N NMR 40.55 MHz, ^{19}F NMR 376.50 MHz) using a 5 mm inverse triple-resonance probe head. References as substitutive standards: H_3PO_4 85% pure, $\delta(^{31}P)$ 0 ppm; CH_3NO_2 neat, $\delta(^{15}N)$ 0 ppm; $CFCl_3/CDCl_3$, $\delta(^{19}F)$ 0 ppm. Samples of **1**^{14} and **1**^{15} were measured in THF-d^8 at 300 K. Samples of **2**^{14}, **2**^{15}, and **2**^{D} were measured in CD_2Cl_2 at 243 K. Because of the instability of the NNH_2 compound, sample preparation was performed at 263 K. Spin simulations were performed using the WinDNMR Calculation V.7.1.6 software package by Hans J. Reich.

DFT calculations

Spin-restricted DFT calculations were performed for the model systems [Mo(N_2)(PH_3)$_5$] (**Ia**), [Mo(N_2)(P3)(dpm)] (**Ib**), [Mo(NNH_2)(PH_3)$_5$]$^{2+}$ (**IIa**), and [Mo(NNH_2)(P3)(dpm)]$^{2+}$ (**IIb**) of compounds **1** and **2**, respectively, using Becke's three parameter hybrid functional with the correlation functional of Lee, Young, and Parr (B3LYP) (15). The LANL2DZ basis set was used for the calculations. It applies Dunning–Huzinaga full-double ξ basis functions (16) on the first row and Los Alamos effective core potentials plus DZ functions on all other atoms (17). Charges were analysed using the natural bond orbital (NBO) formalism (natural population analysis, NPA) (18). For the calculation of magnetic shielding tensors, the gauge invariant shielding atomic orbitals (GIAO) method was used. The calculations are based on the models **Ia**, **IIa**, [Mo(N_2)$_2$(PH_3)$_4$] (**III**), [Mo(N_2)($NCCH_3$)(PH_3)$_4$] (**IV**), and [MoF(NNH_2)(PH_3)$_4$]$^+$ (**V**), respectively (3, 13). All computational procedures were used as implemented in the GAUSSIAN 03 package (19). Wave functions were plotted with GaussView03 (20).

Normal coordinate analysis

Normal coordinate calculations were performed using the QCPE computer program by Peterson and McIntosh (21). It involves solutions of the secular equation **GFL** = Λ**L** by the diagonalisation procedure of Miyazawa. The calculations were based on a general valence force field, and the force constants were refined using the nonlinear optimization of the simplex algorithm according to Nelder and Mead (22). Normal coordinate analysis was based on the QCB-NCA procedure, which involves generation of an initial force field by DFT methods (3). For this purpose, models **Ib** and **IIb** of compounds **1** and **2**, respectively, were used. In the QCB-NCA procedure, the frequencies of the optimized models **Ib** and **IIb** were determined. No negative frequencies were found. The *f* matrix that derived from these calculations had its force constants in cartesian coordinates. These cartesian coordinates were transformed to internal coordinates using

the program REDONG (23). The resulting *f* matrix in internal coordinates was put into FFIT, a fit program for force constants. In the last step, only the force constants of interest were fitted to the experimental frequencies. In contrast to QCA-NCA where only the large force constants were retained in the fitting procedure (3), no force constants were deleted in the QCB-NCA.

X-ray structure analysis

Intensity data were collected using a STOE image plate diffraction system with Mo Kα radiation. The structure was solved using direct methods using SHELXS-97 (24). Refinement was done against F^2 using SHELXS-97. Three of the phenyl rings of the ligands were disordered and were refined using a split model. All non-hydrogen atoms were refined with anisotropic displacement parameters except the carbon atoms of one disordered phenyl ring. The hydrogen atoms were placed in ideal positions and were refined isotropically using the riding model. Selected crystallographic data are presented in Table 1. Bond lengths and angles of the Mo-NN unit are presented in Table 2.[3]

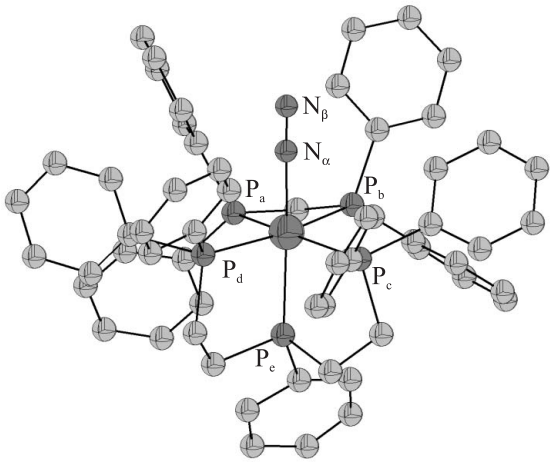
Results and analysis

Crystal structure determination of [Mo(N$_2$)(dpepp)(dppm)] (1)

The crystal structure of [Mo(N$_2$)(dpepp)(dppm)] (Fig. 1) represents the first structural characterization of a molybdenum(0) dinitrogen complex having a P_5 ligand set. The compound crystallizes in the triclinic space group *P*-1 with $Z = 6$ and three crystallographically independent complexes in the asymmetric unit. Bond lengths and angles in all three independent complexes are comparable. In each of the complexes, the molybdenum atoms are coordinated by five phosphorus atoms of one dpepp and one dppm ligand and one nitrogen atom of the dinitrogen molecule within distorted octahedra. The two phosphorus atoms of the dppm ligand and the two terminal phosphorus atoms of the dpepp ligand form the basal plane of the octahedra, whereas the nitrogen atom and the central phosphourus atom of the dpepp ligand are located in the axial positions. The dinitrogen molecule is located nearly above the center of the basal plane and is oriented almost perpendicular to this plane. The Mo—P bond lengths to the dppm ligand are significantly longer than those to the dpepp ligand. The Mo—P bond lengths to the central phosphorus atom of the dpepp ligand, which is located in the axial position trans to the dinitrogen molecule, are shorter than those to the terminal phosphorus atoms.

NMR spectroscopy

NMR spectroscopy of [Mo(N$_2$)(dpepp)(dppm)] (1^{14}, 1^{15})



^{31}P NMR spectra and spin simulation

Complex **1^{14}** has an AMM′XX′-type ^{31}P NMR spectrum. Chemical shifts and signal multiplicities agree with the data reported by George et al. (11). For a better understanding of the coupling scheme, a spin simulation with the program WinDNMR was performed. In the simulation of this five-spin system, the chemical shifts of the signals and all known coupling constants were fixed. The unknown constants were varied until optimal agreement between the simulated and measured spectrum was achieved (Fig. 2).

The central phosphorus atom of the dpepp ligand P_e is in the trans position to the dinitrogen ligand (Fig. 3), which can be inferred from the absence of a large $^2J_{PP,trans}$ coupling. The signal of P_e (1, δ 89.5 ppm) has a triplet structure by coupling with P_a and P_b deriving from the dppm ligand ($^2J_{PP,cis}$ = –13.9 Hz). The coupling constant to the other phosphine donors P_c and P_d is below 1 Hz and therefore not resolved. The small value is due to the combination of a negative $^2J_{pp}$ cis coupling constant transmitted by the metal center and a positive $^3J_{PP}$ coupling constant mediated by the alkyl bridge with $^2J_{PP} \approx -^3J_{PP}$ (25). The signals of P_c and P_d (2, δ 66.4 ppm) show a large trans coupling ($^2J_{PP,trans}$ = 106.0 Hz) and a smaller cis coupling ($^2J_{PP,cis}$ = –23.1 Hz) with P_a and P_b. The simulation reveals an additional coupling constant, $^2J_{Pc,Pd}$ = –15 Hz. Another group of signals (2, δ 9.8 ppm) is assigned to the phosphorus atoms of dppm, P_a, and P_b. All coupling constants are listed in Table 3.

The ^{31}P NMR spectrum of the ^{15}N-containing complex **1^{15}** exhibits no changes in the signals of P_a, P_b, P_c, and P_d because the $^2J_{PN,cis}$ coupling constant is smaller than the line width. The signal of P_e in **1^{15}** is a quartet. This structure is caused by the $^2J_{NP,trans}$ coupling, which accidentally has the same value as the $^2J_{PP,cis}$ coupling to P_a, P_b (14 Hz) and by the fact that $^2J_{PP,cis}$ to P_c, $P_d \approx 0$.

Fig. 1. Crystal structure of [Mo(N$_2$)(dpepp)(dppm)] (**1**). Split phenyl rings and hydrogen atoms are not shown for clarity.

^{15}N NMR spectra and GIAO calculations

The ^{15}N NMR spectrum of complex **1^{15}** shows a doublet (δ –15.7 ppm) for the terminal nitrogen atom N_β ($^1J_{NN}$ = 5.7 Hz) whereas the coordinated nitrogen N_α (δ –30.5 ppm) exhibits a broad multiplet caused by $^2J_{cis/trans}$ couplings to the phosphorus atoms. Especially, N_β exhibits a remarkable low-field shift compared to bis(dinitrogen) complexes like [Mo(N$_2$)$_2$(dppe)$_2$] (**3**, δ(N_α) –43.1 ppm, δ(N_β) –42.8 ppm) (26) and even compared to *trans*-nitrile dinitrogen complexes like [Mo(N$_2$)(NCMe)(dppe)$_2$] (**4**, δ(N_α) –31.2 ppm, δ(N_β) –34.0 ppm) (27). These experimental results are supported by DFT GIAO calculations of the ^{15}N NMR shifts. The calculations were performed for models **Ia**, **III**, and **IV** of compounds **1**, **3**, and **4**, respectively, (cf. the Electronic structure section); the results are collected in Table 4.

The calculated chemical shifts of **Ia** referenced to nitromethane (–136 ppm) are δ 9.6 ppm for N_α and δ 3.9 ppm for N_β (expt. values –15.7 and –30.5 ppm, respectively; Table 4). ^{15}N shifts calculated for **III** and **IV** show a comparable discrepancy to the experimental data, but the *relative* magnetic shieldings Δδ of the different models exhibit good agreement to the experimentally observed trend (Table 5). Specifically, N_α of **Ia** is 12.5 ppm (expt. 12.6 ppm) low-field shifted compared to the bis(dinitrogen) complex **III** and 2.1 ppm (expt. 0.8 ppm) low-field shifted compared to the *trans*-nitrile dinitrogen complex **IV**. The terminal nitrogen atom N_β of **Ia** shows a calculated low-field shift of 24.0 ppm (expt. 27.2 ppm) compared to **III** and a calculated low-field shift of 11.3 ppm (expt. 18.3 ppm) compared to **IV**.

Magnetic shieldings consist of a paramagnetic and a diamagnetic term (25), and the calculations show that the differences among the magnetic shieldings of **Ia**, **III**, and **IV** are entirely caused by the paramagnetic term, which depends on $\sigma \rightarrow \pi$ and $\pi \rightarrow \sigma$ calculations (27, 28). For complex bound ligands like N_2, the $d_{xz/yz}(\pi) \rightarrow d_{z2}(\sigma)$ ligand field transitions of the central atom are important in this respect. The $d_{xz/yz}$ and d_{z2} orbitals are admixed with N_α/N_β π and σ atomic orbitals, respectively. The value of the paramagnetic term on

a particular nitrogen atom is then determined by the energy of the ligand field transition and by the contribution of the nitrogen atomic orbitals to the $d_{xz/yz}$ and d_{z2} molecular orbitals involved in this transition, i.e., the lower the energy of the LF transition and the higher the contribution of N_α or N_β to the respective σ/π molecular orbitals, the higher the paramagnetic shift. The unusual low-field shift of the ^{15}N NMR resonances of **1** is explained in the framework of this concept in the Discussion.

*NMR spectroscopy of $[Mo(NNH_2)(dpepp)(dppm)](CF_3SO_3)_2$ (**2**[14], **2**[15], **2**[D])*

^{31}P NMR spectra

The ^{31}P NMR spectra of **2**[14], **2**[15], and **2**[D] are identical. They exhibit three broad signals (P_c, P_d, δ 54.5 ppm; P_e, δ 48.6 ppm; P_a, P_b δ –2.9 ppm). The signals of P_c, P_d and P_a, P_b are split by the strong $^2J_{PP,trans}$ coupling; the weaker $^2J_{PP,cis}$ and $^2J_{PN,trans}$ couplings are not resolved.

Table 3. Simulated coupling constants (J_{PP}) of **1**[14].

Coupling constant	Value (Hz)
J_{P_a,P_b}	0
J_{P_a,P_c}	–23.1
J_{P_a,P_d}	106.0
J_{P_a,P_e}	–13.9
J_{P_b,P_c}	106.0
J_{P_b,P_d}	–23.1
J_{P_b,P_e}	–13.9

J_{P_c,P_e}	0.8
J_{P_d,P_e}	0.8

^{19}F NMR spectra

^{19}F NMR spectroscopy exhibits one sharp singlet at –79.5 ppm caused by the $CF_3SO_3^-$ counterion. There are no indications for a coordination of the counterion at the complex.

^{15}N NMR spectra and GIAO calculations

The protonated nitrogen N_β in complex **2**[15] shows a sharp signal at –216.1 ppm; in an INEPT experiment, this signal exhibits a triplet structure ($^1J_{NH}$ = 93.8 Hz). The coordinated nitrogen N_α gives a weak signal at –22.4 ppm and no signal

Chemical shielding	**III** → **I** (ppm)	**IV** → **I** (ppm)
$\Delta\delta(N_\alpha)$ calcd.	+12.5	+2.1
$\Delta\delta(N_\alpha)$ expt.	+12.6	+0.8
$\Delta\delta(N_\beta)$ calcd.	+24.0	+11.3
$\Delta\delta(N_\beta)$ expt.	+27.2	+18.3

in the INEPT spectrum. The signals of $\mathbf{2^{15}}$ are low-field shifted compared to the corresponding *trans*-fluoro NNH_2 complex $[MoF(NNH_2)(dppe)_2](BF_4)$ (**5**, $\delta(N_\alpha)$ –79.9 ppm, $\delta(N_\beta)$ –240.5 ppm) (29). These results can again be reproduced by GIAO calculations based on models **IIa** and **V** of compounds **2** and **5**, respectively (Table 4). Again, the absolute values of the calculated magnetic shielding are too low compared to the experimental data, but the *relative* shifts show good agreement to the observed trend. Specifically, the magnetic shielding of N_α in $\mathbf{2^{15}}$ is calculated to be 62.1 ppm lower than in **V** (expt. 57.5 ppm). The N_β of $\mathbf{2^{15}}$ shows a calculated low-field shift of 24.7 ppm with respect to **5**, which exactly reproduces the measured value. As for the dinitrogen complexes, the variations in magnetic shielding are dominated by the paramagnetic term.

^1H NMR spectra

The hydrazido protons of complex $\mathbf{2^{14}}$ give rise to a singlet at 9.9 ppm. In the ^{15}N compound $\mathbf{2^{15}}$, the signal appears as a doublet (10.1 ppm, $^1J_{HN}$ = 93.9 Hz) because of coupling with ^{15}N. In the deuterated complex $\mathbf{2^D}$, only a very weak signal at 9.9 ppm can be observed, which is caused by $[Mo(NNHD)(dpepp)(dppm)](CF_3SO_3)_2$).

Vibrational spectra and normal coordinate analysis

Vibrational spectra of [Mo(N$_2$)(dpepp)(dppm)] (1^{14}, 1^{15})

The FT-Raman spectra of $\mathbf{1^{14}}$ (Fig. 4) exhibits two peaks at 2003/1984 and 454 cm^{-1}, which shift in the spectra of the ^{15}N compound $\mathbf{1^{15}}$. The split peak at 2003/1984 shifts about 66 cm^{-1} to 1935/1918 cm^{-1} and is assigned to the N-N stretch ν(NN). The peak at 454 cm^{-1} is assigned to the Mo-N stretching vibration ν(MoN) and shifts by about 5 cm^{-1} to 449 cm^{-1} in the spectrum of $\mathbf{1^{15}}$. Other intense signals in the Raman spectra at 526, 1000, 1028, 1096, and 1585 cm^{-1} remain unshifted in the ^{15}N compound. These vibrations are due to the phenyl residues of the dpepp and dppm ligands: the peak at 1585 cm^{-1} belongs to the C=C stretch; the peaks at 1093 and 1028 cm^{-1}correspond to plane bending vibrations δ(CC) and δ(CH) and the signal at 526 cm^{-1} is either an out-of-plane bend γ(CC) or a P-phenyl stretch (30).

IR spectra of the complexes $\mathbf{1^{14}}$ and $\mathbf{1^{15}}$ are given in Fig. 5. The N-N stretching vibration exhibits an intense band at 1979 cm^{-1} that shifts by 65 cm^{-1} to 1914 cm^{-1} in the ^{15}N compound. In the far-IR region, two other isotope-sensitive signals are found. The two bands at 505 and 497 cm^{-1}, which are part of a broad feature, show a slight shift to 503 and 493 cm^{-1}, respectively, and are assigned to the linear bending vibrations δ(MoNN). The Mo-N stretching vibration gives a weak signal in the far-IRspectra of $\mathbf{1^{14}}$ and $\mathbf{1^{15}}$ (453 and 448 cm^{-1}, respectively). The intense bands at 1584, 1571, 1480, and 1432 cm^{-1} are assigned to four C=C stretching modes of the phenyl residues (30, 3).

DFT frequency calculation of [Mo(N$_2$)(dpepp)(dppm)] (1^{14}, 1^{15})

Besides isotopic substitution, spectral analysis was assisted by a DFT frequency calculation based on the optimized model complex of **1**, $[Mo(N_2)(P3)(dpm)]$ (**Ib**). For the N-N stretching ν(NN), a frequency of 1973 cm^{-1} was obtained. The corresponding model containing ^{15}N $\mathbf{Ib^{15}}$ gives a frequency of 1908 cm^{-1}. The Mo-N stretching frequencies are calculated to 433 cm^{-1} ($\mathbf{Ib^{14}}$) and 428 cm^{-1} ($\mathbf{Ib^{15}}$). The calculated linear bending vibrations δ(MoNN) ($\mathbf{Ib^{14}}$ 521/502 cm^{-1}, $\mathbf{Ib^{15}}$ 489/474 cm^{-1}) show a stronger splitting as well as a stronger isotope shift than the experiment. For the ν(NN) vibration, **Ib** seems to be a good model, but for the ν(MoN) and δ(MoNN) vibrations, interactions with the hydrogen-substituted ligands are possibly influencing the predicted frequencies.

Quantum chemistry based normal coordinate analysis (QCB-NCA) of [Mo(N$_2$)(dpepp)(dppm)] (1a, 1b)

To analyze the vibrational properties of the dinitrogen complex **1**, a QCB-NCA has been applied that uses the full *f* matrix generated from the GAUSSIAN frequency calculation. This procedure is useful for the treatment of large molecules with low symmetry like **Ib**. Besides the force constants of the Mo-N-N unit (f_{NN}, f_{MoN}, f_{MoNN}), some off-

diagonal elements were also included in the fit. The resulting *f* matrix is shown in the supplemental material (Table D5).[3] The resulting frequencies are collected in Table 6. Comparison between the experimental frequencies and the results from QCB-NCA shows overall good agreement. The calculated force constants for the Mo-N-N unit of **1** are f_{NN} = 16.3 mdyn/Å for the N—N bond, f_{MoN} = 2.8 mdyn/Å for the Mo—N bond, and f_{MoNN} = 0.44/0.43 mdynÅ for the bending coordinates. Compared to the corresponding bis(dinitrogen) complex [Mo(N_2)$_2$(dppe)$_2$] (**3**, f_{NN} = 17.22 mdyn/Å, f_{MoN} = 2.04 mdyn/Å) (3), the N—N bond is weaker and the Mo—N bond is stronger.

Vibrational spectra of [Mo(NNH_2)(dpepp)(dppm)](CF_3SO_3)$_2$ (2^{14}, 2^{15}, 2^{D})

The mid-IR spectrum of **2^{14}** (Fig. 6) shows a band at 3244 cm^{-1}, which can be attributed to the N-H stretching vibration. Because the signal is very broad and overlaps with C-H bands, the small shift to lower energy in **2^{15}** cannot be resolved. However, this feature shows a strong shift in the corresponding deuterium compound **2^{D}**. In this case, the broad band has a maximum at 2239 cm^{-1} and a shoulder at 2323 cm^{-1}, possibly indicating the presence of two N-D vibrations (symmetric and antisymmetric). In the mid-IR region below 1500 cm^{-1}, another isotope sensitive signal can be found. Specifically, the peak at 1377 cm^{-1} in the spectra of the ^{15}N compound **2^{15}** is missing in the spectra of **2^{14}** and **2^{D}**. Instead, the deuterium compound **2^{D}** shows a weak, broad band around 1383 cm^{-1}. In the IR spectra of **2^{14}**, the peak is partly masked by the ligand signal, causing a shoulder at 1417 cm^{-1}. All of these features are assigned to the N-N stretch. In addition to ligand signals at 1486, 1436,

$\nu(MoN)$	606	596	592	607	596	591	622	607	599

1030, and 1001 cm^{-1}, very intense bands appear at 1250 and 1094 cm^{-1}; these can be assigned to the symmetric and antisymmetric S=O modes of the $CF_3SO_3^-$ counterions. The signals of the linear bending vibrations δ(MoNN) are not observed in the far-IR spectra because of a very intense band around 500 cm^{-1}. The far-IR spectrum of **2** does not contain any isotope-sensitive bands, and therefore is not shown.

Raman spectra of the NNH_2 complexes **2^{14}**, **2^{15}**, and **2^{D}** (Fig. 7) show one isotope-sensitive peak, which shifts from 606 cm^{-1} in the ^{14}N compound to 596 cm^{-1} in the ^{15}N and 592 cm^{-1} in the deuterium compound, respectively. These signals can be identified as Mo-N stretching vibrations. In the IR spectra, no signals are observed at the corresponding frequencies.

DFT frequency calculations of $[Mo(NNH_2)(dpepp)(dppm)](CF_3SO_3)_2$ (2^{14}, 2^{15}, 2^{D})

The DFT calculations indicate a splitting of the N-H vibration into an antisymmetric component at higher energy and a symmetric component at lower energy (Table 7). The same applies to the deuterated model. In all cases, the absolute values of the ν_{as} and ν_s vibrations are calculated too high. This is attributed to the absence of anharmonic terms in the calculation. The calculated frequency of the N-N stretching vibration is 1483 cm^{-1}, considerably higher than observed experimentally (~1417 cm^{-1}). Better agreement with the measured values is achieved for the Mo-N stretching vibrations (**IIb^{14}** 622 cm^{-1}, **IIb^{15}** 607 cm^{-1}, **IIb^{D}** 599 cm^{-1}). The relative magnitude of isotopic shifts ($\Delta\nu(^{15}N) < \Delta\nu(D)$) is in agreement with the experimental (Table 7).

QCB-NCA of $[Mo(NNH_2)(dpepp)(dppm)](CF_3SO_3)_2$ (2^{14}, 2^{15}, 2^{D})

The QCB-NCA of the NNH_2 complex **2** was performed in analogy to the QCB-NCA of the dinitrogen complex **1**. Based on the DFT treatment of model **IIb**, an *f* matrix in internal coordinates was generated using the program REDONG. The force constants of the Mo-NNH_2 unit were fitted to the experimental vibrational frequencies. Moreover, some off-diagonal force constants that correspond to interac-

© 2005 NRC Canada

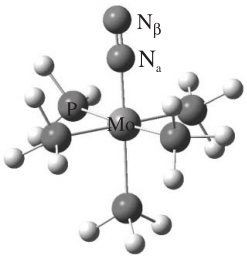
tions between NN, MoN, and NH vibrations were included in the fitting process. The corresponding *f* matrix is shown in the supplemental material (Table D7).[3] The obtained frequencies are collected and compared to the experimental data in Table 7. Taking into account the limited spectroscopic information, especially for the NH and NN vibrations, good agreement between the QCB-NCA and the measured spectra was achieved. The calculated force constants are 7.65 mdyn/Å for the N—N bond and 5.94 mdyn/Å for the Mo—N bond. The NH force constants both have a value of 5.60 mdyn/Å.

Electronic structure

Model systems for [Mo(N$_2$)(dpepp)(dppm)]

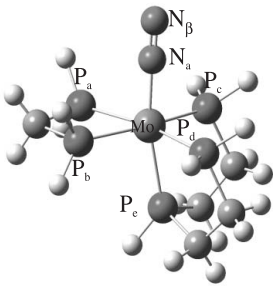
DFT calculations of [Mo(N$_2$)(dpepp)(dppm)] (**1**) have been performed based on two different models. For the determination of the molecular orbital scheme and the NMR shift calculations, model [Mo(N$_2$)(PH$_3$)$_5$] (**Ia**) (Fig. 8) has been used. For the frequency calculations (vide supra) a more sophisticated model, [Mo(N$_2$)(P3)(dpm)] (**Ib**), (Fig. 8) has been employed. In this model, the phenyl residues are substituted by hydrogen atoms, but all alkyl bridges of the dppm and dpepp ligands, respectively, are included.

Optimized geometry of Ia and Ib



The optimized structures of **Ia** and **Ib** are shown in Fig. 8. The parameters of the MoNN unit are similar in both models: $\Delta_{\mathbf{Ia}}$(NN) = 1.17 Å, $\Delta_{\mathbf{Ib}}$(NN) = 1.17 Å, $\Delta_{\mathbf{Ia}}$(MoN) = 1.99 Å, $\Delta_{\mathbf{Ib}}$(NN) = 2.00 Å. In **Ib**, the dppm ligand has a P-Mo-P bite angle of 70.2°. Moreover, owing to the presence of the dpepp ligand, the N-Mo-P$_{trans}$ unit is bent; the corresponding angle is 168.3°. Cartesian coordinates of the optimzed structures of **Ia** and **Ib** are given in the supplemental material.[3]

Electronic structure of Ia



The molecular orbital scheme of **Ia** is shown in Fig. 9. For comparison, the MO schemes of the bis(dinitrogen) model complex [Mo(N$_2$)$_2$(PH$_3$)$_4$] (**III**) and the *trans*-nitrile dinitrogen model complex [Mo(N$_2$)(NCCH$_3$)(PH$_3$)$_4$] (**IV**) are given. Models **III** and **IV** have been studied earlier (3, 30). Countour plots of some relevant orbitals are displayed in Fig. 10.

The MO scheme of **Ia** is very similar to that of **III** and **IV**. The three highest occupied orbitals <32>, <33>, <34> are bonding combinations of d_{xz}, d_{yz}, and d_{xy} with the π_x* and π_y* orbitals of N$_2$. In contrast to **III** and **IV**, the d_{xy} orbital is mixed with the d_{yz} orbital in **Ia**, and thus becomes part of metal-N backdonation. This is caused by a reduction of the symmetry (**III** has C_{2v} symmetry, whereas **Ia** has C_s symmetry). Moreover, the contribution of N$_\beta$ to the backbonding orbitals is noticeably larger in **Ia** (Table 8) than in **III** (Table 9). Even compared to the strongest activated model complex **IV** (Table 9), the N$_\beta$ of **Ia** seems to have a slightly larger component in the backbonding orbitals. This is of relevance with respect to the magnitude of the ^{15}N NMR shift (vide infra). The Mo-N$_2$ σ-bonding interaction is represented by orbital <27>, a combination of σ(NN) with the d_{z2} orbital and a strong contribution of the four in-plane phosphine donors. <29> is the bonding combination of p_σ(P$_{trans}$) and d_{z2}, which is antibonding to p_σ(NN).

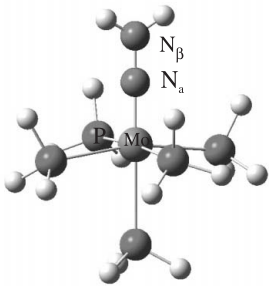


Fig. 8. Optimized structures of models **Ia**, **Ib**, **IIa**, and **IIb**.

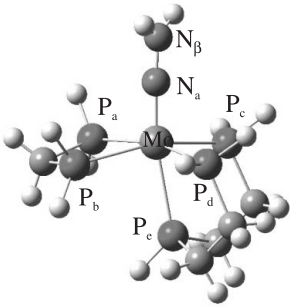

[Mo(N$_2$)(PH$_3$)$_5$] **Ia**

[Mo(N$_2$)(P3)(dpm)] **Ib**

[Mo(NNH$_2$)(PH$_3$)$_5$]$^{2+}$ **IIa**

[Mo(NNH$_2$)(P3)(dpm)]$^{2+}$ **IIb**

NPA charges of the three model complexes **Ia**, **III**, and **IV** are collected in Table 10. Importantly, the *trans*-nitrile model **IV** exhibits the highest charge (–0.21) on the N$_2$ unit, followed by **Ia** with a total charge of –0.17. The bis(dinitrogen) system **III** has the lowest total charge of –0.13. Based on these values, the activation of N$_2$ increases in the sequence **III** < **I** < **IV**. More detailed insight into the electronic-structural origin of this trend is provided by the partition of the atomic charges into atomic orbitals ($2s$, $3s$, $2p_x$, $2p_y$, $2p_z$, $3p_x$, $3p_y$, $3p_z$), which is given in

Table 11. $\Sigma\sigma$ corresponds to the summed contribution of σ-type atomic orbitals $2s$, $3s$, $2p_z$, $3p_z$ to the total NPA charge, and $\Sigma\pi$ corresponds to the summed contributions of the π-type atomic orbitals $2p_x$, $2p_y$, $3p_x$, $3p_y$. σ Donation from N_2 to the metal can be inferred from the value of $\Delta\sigma = 3 - \Sigma\sigma$ and π acceptance of N_2 from the metal is evident from $\Delta\pi = 2 - \Sigma\pi$. Strictly speaking, $\Delta\pi$ has two contributions: in the N_2 π-bonding orbitals π_x and π_y, a polarization of the dinitrogen unit occurs such that N_α gets negatively and N_β positively charged (Table 8). π backbonding almost exclusively transfers electron density to N_β, such that this atom gets negatively charged as well.

As evidenced from Table 11, both σ donation and π acceptance are largest in the *trans*-nitrile system **IV**, effectively leading to the highest activated N_2 ligand (vide supra). This can be explained by the fact that a high degree of σ donation leads to an elongation of the N—N bond, which acts to enhance the degree of π backbonding, overcompensating the effect of σ donation. The N_2 ligand of the pentaphosphine complex **Ia**, on the other hand, exhibits a significantly smaller degree of σ donation because of the presence of a strong donor in the trans position; therefore, π acceptance is not as large as in **IV**, and a lower activation of N_2 as compared to the *trans*-nitrile complex **IV** results. The activation of N_2 in **Ia**, on the other hand, is larger than in the bis(dinitrogen) complex **III**, as one backbonding ligand (N_2) has been exchanged by a σ-donor ligand (phosphine). In agreement with this description, $\Delta\pi$ values of N_α and N_β are more negative in **Ia** than in **III**. Based on the higher backbonding, N_2 is also slightly more σ donating in **Ia** as compared to **III**, but in sum the N_2 ligand in **Ia** is more strongly activated than in the bis(dinitrogen) complex **III**.

Model systems for $[Mo(NNH_2)(dpepp)(dppm)](CF_3SO_3)_2$

In analogy to the N_2 complex, two different models have been used for the NNH_2 complex. The molecular orbital scheme and the magnetic shielding calculation are based on $[Mo(NNH_2)(PH_3)_5]^{2+}$ (**IIa**) (Fig. 8). For the calculation of

the vibrational properties, the more realistic model $[Mo(NNH_2)(P3)(dpm)]^{2+}$ (**IIb**) (Fig. 8) was used, which included the alkyl bridges.

Optimized geometry of IIa and IIb

The bond distances of the NNH_2 unit are very similar in both models. Compared to the N_2 complex in **IIa**, the N—N bond is lengthened to 1.31 Å (**IIb**, 1.32 Å) by protonation. Simultaneously, the Mo—N bond is shortened to 1.77 Å (**IIa**) (**IIb**, 1.78 Å). In both models, the N—H bond distance is calculated to 1.02 Å. The geometric structure of the ligand framework in **IIb** is similar to that found for **Ib**. Cartesian coordinates of the optimized structures of **IIa** and **IIb** are collected in the supplemental material.[3]

Electronic structure of IIa

Figure 11 shows the molecular orbital scheme of **IIa**. For comparison, the MO schemes of the *trans*-fluoro NNH_2 model complex $[MoF(NNH_2)(PH_3)_4]^+$ (**V**) (3) and the *trans*-nitrile NNH_2 model complex $[Mo(NNH_2)(NCCH_3)(PH_3)_4]^{2+}$(**VI**) are given (9).

The MO scheme of **IIa** basically corresponds to those of **V** and **VI.** In all model systems, the nonbonding d_{xy} orbital is the HOMO. Below the HOMO are the bonding combinations of d_{xz} with π_v* (π* orbital perpendicular to the NNH_2 plane) <33> and d_{yz} with π_h* (π* orbital in the NNH_2 plane) <29>, respectively. The protonation of the dinitrogen model complex **Ia** causes a shortening of the Mo—N bond, which is accompanied by an enlargement of the N—N distance. This causes a decrease of the π_v* in energy, thus increasing the contribution of π_v* to the bonding combination d_{xz}–π_v* to 52% (Table 12). As a consequence, the backbonding interaction to d_{xz} orbital is strengthened. The bonding combination of π_h* with d_{yz} has 62% N_2 and 22% Mo character, and therefore a preponderance of π_h*. This represents an inverted bonding situation compared to the N_2 system, which is accounted for by the π_h*–d_{yz} labeling. The π_h* orbitals of the NNH_2 ligand in model systems **IIa**, **V**, and **VI** have the properties of a *p* donor at N_α (Table 13, Fig. 12). Therefore, the NNH_2 ligand receives electrons via π_v* and donates electron density via π_h*. In summary, the charge of the NNH_2 unit is not "2–", but slightly positive (**IIa**, +0.20) or negative (**V**, –0.03 from NPA, Table 14), respectively (3*b*). In contrast to the d_{xz}–π_v* and π_h*–d_{yz} orbitals of **V**, which have considerable contributions of the fluoride and phosphine ligands, the d_{xz}–π_v* and π_h*–d_{yz} orbitals of $[Mo(NNH_2)(PH_3)_5]^{2+}$ have almost no contributions besides the metal and the dinitrogen. LUMO <35> and <36> are the antibonding combinations of the NNH_2 π orbitals with the d_{xz} and d_{yz} orbitals, respectively.

Discussion

In the preceding sections, the structural, spectroscopic, and electronic properties of a molybdenum dinitrogen complex with a pentaphosphine coordination and its NNH_2 derivative were studied. The pentaphosphine coordination was achieved by combination of a tridentate (dpepp) and a bidentate (dppm) ligand. In this constitution, the complex exists in only one isomeric form and the pentaphosphine coordination sphere is stable towards protonation with triflic acid. Besides the investigated protonated compound **2**, only one more NNH_2 complex with five-coordinated phosphines is known; i.e., the complex with dimethylphosphinomethane (dmpm) instead of dppm (6). On this complex George et al. (11) demonstrated that only triflic acid forms the corresponding NNH_2 system, whereas protonation with other acids like HCl or HBr leads to different hydrido complexes under a loss of dinitrogen.

In the vibrational data of **1**[14] and **1**[15], all vibrations of the MoNN unit were identified, i.e., the NN stretch (1979 cm^{-1}), the MoN stretch (453 cm^{-1}), and the two bending vibrations (505/497 cm^{-1}). Especially for the NN stretch, good agreement between calculated frequencies and observed values was achieved (**IIb**, 1973 cm^{-1}). Based on the vibrational data and the DFT calculations of model **IIb**, a QCB-NCA was performed. The force constants of the N—N and Mo—N bonds, which are correlated with the activation of N_2 (1), were calculated as f_{NN} = 16.3 mdyn/Å and f_{MoN} = 2.8 mdyn/Å, respectively (free N_2 = 22.42 mdyn/Å). Therefore, the vibra-

tional spectra show a *stronger* activation of N_2 in the molybdenum pentaphosphine complex than in (bis)dinitrogen complexes like $[Mo(N_2)_2(dppe)_2]$ (f_{NN} = 17.2 dyn/Å and f_{MoN} = 2.0 mdyn/Å). Force constants for *trans*-nitrile dinitrogen systems are only known for W complexes that are more strongly activated by the metal center, and therefore, not directly comparable to **1** ($[W(N_2)(NCEt)(dppe)_2]$: f_{NN} = 14.95 mdyn/Å and f_{WN} = 3.15 mdyn/Å) (13). However, $[Mo(N_2)(NCCH_3)(dppe)_2]$ has an N-N stretching frequency of 1906 cm^{-1} (13); therefore, in *trans*-nitrile molybdenum dinitrogen systems the NN force constant should be smaller as compared with pentaphosphine complexes, corresponding to a higher activation of N_2. This is in agreement with the calculation (see the following). Interestingly, $[Mo(N_2)(dpepp)(dmpm)]$ exhibits an N-N stretching frequency of 1966 cm^{-1} (11), reflecting a stronger activation of N_2 by alkylphosphine as compared with the phenylphosphine ligands. This has been already known for bis(dinitrogen) complexes with diphosphine co-ligands (3).

The results of the DFT calculations on $[Mo(N_2)(PH_3)_5]$ (**Ia**) were compared with the parallel treatments of the bis(dinitrogen) and *trans*-nitrile dinitrogen model systems

III and **IV**, respectively. Based on the calculated charges, the activation of N_2 follows the sequence **III** < **I** < **IV**. Specifically, the mono-dinitrogen complexes **Ia** and **IV** exhibit a stronger activation of the N_2 unit compared to **III** because of the absence of a second strong π acceptor (NPA charges of the N_2 unit: **Ia** (–0.17), **IV** (–0.21), **III** (–0.13)). The *trans*-nitrile system **IV** has the highest activated N_2 because of the fact that the nitrile is a weak σ donor and π acceptor (13). Therefore, σ donation of the coordinated N_2 to the metal is high, as evidenced from the large Δσ value in the NPA charge analysis. As a consequence, the energy of the π* orbitals is lowered and π backbonding is enforced. Strong backbonding overcompensates the stronger σ donation, and thus causes the high activation of the N_2 in the *trans*-nitrile system **IV**. This synergetic effect is missing in the pentaphosphine complex $[Mo(N_2)(PH_3)_5]$ (**Ia**) where because of the strongly σ-donating phosphine group in the *trans*-position, N_2 is a weaker σ donor than in **IV**. Therefore, the energy of the π* orbitals is not lowered as much as in **IV**, and no increase of backbonding occurs.

Another remarkable result is the low-field shift of the terminal nitrogen atom N_β in **1**. In fact, with a chemical shift of –16.7 ppm, N_β exhibits one of the largest low-field shifts recorded for end-on coordinated dinitrogen (23). Based on

© 2005 NRC Canada

DFT GIAO calculations, it can be shown that the origin of this unusual shift is the paramagnetic term. In analogy to observations on ^{31}P NMR shifts in ruthenium carbonyl phosphine complexes (31), the paramagnetic term to the ^{15}N NMR shift in mono-dinitrogen complexes appears to increase with the nitrogen contribution in the backbonding orbitals, going parallel to the activation of N_2. Besides the relatively high activation of N_2, there is an additional effect that increases the paramagnetic shift on N_β in **1**: The d_{xy} orbital <32>, which is nonbonding in the bis(dinitrogen) and *trans* nitrile complexes **III** and **IV**, respectively, is also involved in a backbonding interaction with N_2 and gets a N_β contribution. As a consequence, *all* $t_{2g} \rightarrow d_{z2}$ ligand-field transitions contribute to the paramagnetic shift of N_β in **I**, in contrast to **III** and **IV**.

The results of the vibrational and NMR spectroscopy confirm the structure of the NNH_2 complex with pentaphosphine coordination. Based on vibrational spectroscopy and DFT calculations, a QCB-NCA could be accomplished. The resulting force constants (f_{NN} = 7.65 mdyn/Å, f_{MoN} = 5.94 mdyn/Å) reflect the decrease of the N—N bond strength and the increase of the Mo—N bond strength caused by the protonation. They are similar to other molybdenum NNH_2 complexes like $[MoCl(NNH_2)(depe)_2]Cl$ (f_{NN} = 7.16 mdyn/Å, f_{MoN} = 5.52 mdyn/Å) (3). Unfortunately, no vibrational data for molybdenum-dppe NNH_2 complexes with coordinated counterions (Cl^-, F^-) or *trans*-nitrile ligands exist, which precludes a spectroscopic comparison of **2** to related NNH_2 systems in analogy to that performed for the N_2 complexes **1**, **3**, and **4**. However, DFT calculations of the model complex $[Mo(NNH_2)(PH_3)_5]^{2+}$ (**IIa**) show a NPA charge of +0.20 on the NNH_2 group while the corresponding *trans*-fluoro model **V** has a corresponding charge of –0.03. This reflects a lower activation of the NNH_2 ligand in **IIa** towards further protonation, which is due to weaker charge donation of a neutral phosphine group as compared to the anionic fluoride ligand in the *trans* position to the NNH_2 group of **V**.

The measured ^{15}N NMR data of $\mathbf{2^{15}}$ exhibit a considerable low-field shift compared with the *trans*-fluoro systems, i.e., the signal of the protonated nitrogen N_β in $\mathbf{2^{15}}$ is shifted by 24.7 ppm and the signal of the coordinated nitrogen N_α by 57.5 ppm. By employing GIAO shielding tensor calculations, it could be shown that these shifts are caused by the paramagnetic term. This result is explained by the fact that the Mo-NNH_2 metal–ligand π-bonding orbitals have considerable F and P parts in model $[MoF(NNH_2)(PH_3)_4]^+$ (**V**) of the fluoro system. In contrast, the corresponding orbitals of $\mathbf{2^{15}}$ are not admixed by the co-ligands and almost exclusively consist of Mo and N contributions. Therefore, they cause a greater paramagnetic shift of the nitrogen atoms than the corresponding orbitals of the *trans*-fluoro complex.

Remarkably, the pentaphosphine ligation of **1** is stable against exchange reactions induced by treatment with acid, in analogy to the $[Mo(N_2)(dpepp)(dmpm)]$ complex prepared by George et al. (11). An even higher stability could be achieved by using just one ligand with five phosphine donors. King and Cloyd (10) have synthesized linear and branched pentaphosphines with ethylene bridges. However, these ligands may be too small to accommodate Mo(0) or W(0) centers owing to a P-Mo-P angle of about 80° for ethyl-bridged phosphines. Possibly, the introduction of propylene bridges would offer a better ligand system for this purpose.

In summary, an octahedral mono-dinitrogen complex containing five phosphine groups and its NNH_2 counterpart was described and characterized. Based on the results of NMR, IR, and Raman spectroscopy coupled to DFT calculations, the dinitrogen complex was shown to exhibit a stronger activation compared to bis(dinitrogen) and a weaker activation compared to *trans*-nitrile N_2 complexes. The spectroscopic and theoretical investigations of the analogous hydrazido system with pentaphosphine ligation suggest a relatively low activation of the NNH_2 ligand towards further protonation, comparable to that present in *trans*-nitrile NNH_2 systems.

FOREWORD / AVANT-PROPOS

This issue of the *Canadian Journal of Chemistry* commemorates the 40th anniversary of a landmark Canadian discovery by A.D. Allen and C.V. Senoff at the University of Toronto in the mid-60s. In 1965, a paper appeared in *Chemical Communications*, entitled "Nitrogenopentaammineruthenium(II) Complexes" that detailed the serendipitous formation of the $[Ru(NH_3)_5N_2]^{2+}$ complex cation, *the first dinitrogen complex*, from the reaction of $RuCl_3$ with hydrazine hydrate. Instead of ending up as a curiosity and relegated to secondary literature reviews of esoteric inorganic complexes, this report sparked an intense effort in the coordination chemistry and reactivity of molecular nitrogen that continues to this day.

Research into nitrogen fixation is a topic with great historical perspective and continues even today on three fronts. The first front stems from the early work by Haber on ammonia synthesis, and is concerned with efforts to further improve the efficiency of the heterogeneous reaction of N_2 and H_2 over activated metal surfaces to produce NH_3. Another active front involves understanding the biological fixation of nitrogen by certain enzymes. The third front involves homogeneous activation and functionalization of molecular nitrogen by metal complexes, an area that overlaps with the previous two fronts from a modeling point of view, but also is concerned with expanding the known reactivity patterns of the simple N_2 molecule.

In this issue, an international slate of authors who are active in the area of dinitrogen chemical research were contacted to submit an article, either original or a minireview of their work. Authors from Japan, Germany, the United States, and Canada have submitted 13 articles that provide retrospective and updates of current research in this important area. It is interesting that four of the principal authors were not even born in 1965, a testament to the importance of this long-standing problem in chemistry. A number of the other authors clearly indicate how important this complex was to this area of research.

In the following pages, the original article from 1965 is reproduced (by permission of The Royal Society of Chemistry). In addition, a brief historical perspective is given by G.J. Leigh on A.D. (Bert) Allen and this discovery. The goal of this commemorative issue is to provide a forum for recent work in dinitrogen coordination chemistry and celebrate an important Canadian milestone. I want to personally thank all of the contributors for their enthusiasm and support of this project.

Michael D. Fryzuk
Vancouver, 2005

Ce numéro de la *Revue canadienne de chimie* souligne le 40^{e} anniversaire d'une découverte historique canadienne au milieu des années 60 par A.D. Allen et C.V. Senoff de l'Université de Toronto. En effet, en 1965, on note la parution d'un article dans *Chemical Communications* intitulé « Nitrogenopentaammineruthenium(II) Complexes » dans lequel les auteurs exposent en détail la formation fortuite du cation du complexe $[Ru(NH_3)_5N_2]^{2+}$, *le premier complexe diazoté*, à partir de la réaction du $RuCl_3$ avec de l'hydrate d'hydrazine. Plutôt que d'être considéré comme une simple trouvaille inusitée et d'être relégué aux rapports de synthèses secondaires sur les complexes inorganiques ésotériques, ce rapport a profondément dynamisé la chimie de coordination et la réactivité de l'azote moléculaire et cet intérêt est toujours aussi manifeste aujourd'hui.

L'étude de la fixation de l'azote est un domaine de grande perspective historique qui repose, encore de nos jours, sur trois composantes. La première est le fruit des travaux initiaux de Haber sur la synthèse de l'ammoniac visant à améliorer l'efficacité de la réaction hétérogène de l'azote (N_2) et de l'hydrogène (H_2) sur des surfaces métalliques activées menant à la production de l'ammoniac (NH_3). La deuxième composante consiste à approfondir les connaissances sur les mécanismes de la fixation biologique de l'azote par certains enzymes. La troisième composante porte sur la fonctionnalisation et l'activation homogène de l'azote moléculaire par des complexes métalliques, un domaine de recherche qui chevauche les deux premières composantes sur le plan de la modélisation, mais qui vise également le développement des modes réactionnels de l'azote comme simple molécule.

Pour réaliser ce numéro commémoratif, un éventail international d'auteurs oeuvrant dans le domaine de la chimie du diazote ont été invités à soumettre un article original ou une minisynthèse sur leurs travaux. Des auteurs du Japon, de l'Allemagne, des États-Unis et du Canada ont soumis 13 articles qui présentent un historique des travaux réalisés dans le domaine en plus de faire le point sur la recherche actuelle. Par ailleurs, il est intéressant de noter que quatre des principaux auteurs qui ont contribué à ce numéro n'étaient même pas nés en 1965, ce qui témoigne de l'importance de ce problème de longue date en chimie. De plus, plusieurs autres auteurs ont clairement indiqué à quel point ce complexe est important pour ce domaine de recherche.

On y retrouve notamment l'article original de 1965 (reproduit avec l'autorisation de la Royal Society of Chemistry). De plus, G.J. Leigh présente un bref historique sur A.D. (Bert) Allen et cette découverte. Ce numéro commémoratif a pour but d'offrir un forum pour les travaux récents menés dans le domaine de la chimie de la coordination du diazote et de souligner cet important jalon canadien. Je tiens à remercier personnellement toutes les personnes qui ont contribué leur enthousiasme et leur appui à ce projet.

Nitrogenopentammineruthenium(II) Complexes

By A. D. Allen and C. V. Senoff

(*Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Canada*)

Vol'pin and Shur have recently explored the possibility of fixing molecular nitrogen under mild conditions.[1–3] We now report that from aqueous solutions of ruthenium trichloride (free from nitric oxide) and hydrazine hydrate at 25° it is possible to isolate complexes which appear to be of the type $[Ru(NH_3)_5N_2]X_2$ where X = Br^-, I^-, BF_4^-, and PF_6^-. These salts are the first reported compounds in which N_2 is co-ordinated to a transition metal. The iodide salt is diamagnetic and has the following analysis: N, 20·52; H, 3·96; NH_3, 17·84; I, 54·05%. (Calc. for $H_{15}N_7I_2Ru$: N, 20·94; H, 3·21; NH_3, 18·16; I^-, 54·27%). The complexes are only moderately stable towards air

and decompose fairly rapidly in water. The conductance of solutions of the di-iodide salt in dimethyl sulphoxide is exactly the same as solutions of the reference compound $[Ru^{III}(NH_3)_5I]I_2$ over the concentration range measured (1—10 × 10^{-5} M).

The infrared spectra of these compounds contain a strong, sharp, band between 2170—2115 $cm.^{-1}$ (see Table) which is assigned to the N_2 stretch. Upon co-ordination to the metal the N_2 stretching mode has undergone a shift to lower frequency of about 200 $cm.^{-1}$ from that observed for molecular nitrogen (2331 $cm.^{-1}$).[4] It is not possible at present to ascertain whether co-ordination occurs through the lone pair of electrons on one of the nitrogen atoms or through the π-electron system of the molecule, but the crystal structure of these compounds is being investigated.

If the iodide salt is treated with 20% aqueous $NaBH_4$ solution and 40% NaOH solution the amount of ammonia evolved corresponds to 24%, compared with 18% found on normal treatment with alkali, indicating that nearly all of the co-ordinated nitrogen is converted into ammonia by the action of the borohydride ion.[1–3]

When the fluoborate salt is treated with 95% sulphuric acid under high vacuum the non-condensable gas (77° K) that is liberated was shown to be nitrogen by mass spectrometry. A maximum of about 40% of the theoretical amount of nitrogen has been obtained in this way, and it is thought that the remaining nitrogen may have been converted into ammonia or oxidized by the acid. The complexes, $[Ru(NH_3)_6](BF_4)_2$, $[Ru(NH_3)_6]Cl_3$, and $FeCl_2,2N_2H_4$ were treated with sulphuric acid in a similar manner. No nitrogen was evolved, indicating that the source of the nitrogen is not hydrazine or ammonia.

We have considered the possibility that the complex contains a co-ordinated di-imide molecule, *i.e.*, $[Ru^{II}(NH_3)_5.NH{=}NH]^{2+}$. Evidence against this is (a) that the $\nu_{N=N}$ frequency should be at about 1400 $cm.^{-1}$,[5] (b) that the n.m.r. spectrum in dimethyl sulphoxide contains no bands other than those attributed to the ammonia hydrogens, and (c) that the gas liberated on treatment with sulphuric acid contains no hydrogen.

Because of the lability of the N_2 ligand these complexes are ideal starting materials for the preparation of a number of ruthenium(II) and ruthenium(III) complexes. Mild treatment with the hydrohalic acids leads to the formation of the corresponding halogenopentammineruthenium(III) salts. The following ruthenium(II) complexes have also been prepared by the reaction of the nitrogenopentammine complexes with the appropriate ligand: $[Ru(NH_3)_6]X_2$, $[Ru(NH_3)_4py_2]X_2$, $[Ru(NH_3)_2py_4]X_2$, $[Ru(NH_3)_5DMSO]X_2$ where X = I^-, BF_4^-, PF_6^-, and DMSO = dimethyl sulphoxide.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2004 Fred Beamish Award Lecture — Analytical – materials chemistry on old CDs — Beyond self-assembly

Cassie Ho, Dinah M. Soolaman, and Hua-Zhong Yu

Abstract: This review describes a variety of new chemistry that has been established in our research laboratory and by other scientists worldwide related to optical compact disc (CD) technology. In particular, we have discovered that gold substrates from CD-Rs can be used to prepare high-quality, self-assembled monolayers (SAMs) after removing the protective polymer films with concentrated nitric acid. It was proven that these substrates are feasible for electrochemical, spectroscopic, and surface wetting studies. We have also demonstrated that CD-R gold films are ideal micropatterned conductive substrates for the "customized" fabrication of material microstructures. In addition, we have been working on the micropatterning of DNA probes on CD-R substrates, and exploring the possibility of using the CD-R writing/reading system for biochip fabrication and gene analysis.

Key words: compact disc-recordable (CD-R), self-assembled monolayers (SAMs), electrochemical analysis, material micro- and (or) nanostructures, biomedical diagnosis.

Résumé : Cette revue décrit plusieurs aspects d'une nouvelle chimie développée dans notre laboratoire ainsi que par d'autres chimistes à travers le monde en relation avec la technologie du disque compact optique (CD). En particulier, on a découvert que des substrats d'or obtenus à partir de CD-R peuvent être utilisés pour préparer des monocouches autoassemblées de haute qualité après avoir enlevé les films de polymères protecteurs à l'aide d'acide nitrique concentré. Il a été prouvé que ces substrats peuvent être réalisés pour des études électrochimiques, spectroscopiques et de mouillage de surface. On a aussi démontré que les films d'or de CD-R sont les substrats conducteurs à micromotifs idéaux pour la fabrication de matériaux à microstructures « personnalisées ». De plus, des travaux ont aussi été effectués sur le micromodelage de sondes d'ADN sur des substrats CD-R et dans le domaine de l'exploration des possibilités d'utiliser un système d'écriture/lecture d'un CD-R dans la fabrication d'une biopuce et de l'analyse des gènes.

Mots clés : disque compact enregistrable (CD-R), monocouches autoassemblées, analyse électrochimique, matériaux à micro- et (ou) nanostructures, diagnostic biomédical.

[Traduit par la Rédaction]

Introduction

Compact discs are the most commonly used optical information storage media because of their versatility and ease of use (1). The structures of the compact disc read-only memory (CD-ROM) and the compact disc-recordable (CD-R) differ significantly; while the CD-ROM contains pits and plateaus that represent binary data, the CD-R uses organic dyes that decompose when it is "burnt" and the alternating "burnt – not burnt" pattern is then used to represent data.

Received 2 September 2004. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 22 April 2005.

[1]Corresponding author (e-mail: hzyu@sfu.ca).

The structure of a CD-ROM consists of three layers: (1) a polycarbonate (PC) layer that forms the support for the entire structure, (2) a reflective layer that is usually made from sputtered aluminium, silver or gold, and (3) a protective layer of lacquer that protects the reflective layer from everyday wear. The properties of the polycarbonate often differ slightly among manufacturers (1*a*). The PC substrate is normally created via injection moulding from a master pattern and good flow properties are essential for easy moulding (2). A pattern of pits and plateaus that represents the binary data is stamped onto the PC. Then, a thin reflective layer that is used to reflect the CD reading laser back into the reading head is sputtered over top. Finally, a protective lacquer layer is spin-coated on top of it all.

The CD reader uses polarized light to read the data (Fig. 1). The laser beam is circularly polarized in the polarizing prism; it then goes through the quarter-wave plate to be polarized in one direction. After it is reflected from the CD,

 doi: 10.1139/V05-006 © 2005 NRC Canada

Fig. 1. Schematic illustration of the construction of a compact disc-recordable (CD-R) and the optical reading/writing system. Reprinted from ref. 1*b*. Reproduced by permission of The Royal Society of Chemistry.

the light will go back through the quarter-wave plate and be polarized in the other direction. The prism will direct the light to the sensors (3). When the incident light hits the PC, it will be refracted (n = 1.55) and the laser spot will be focused even further into a smaller spot (2). The wavelength of the light in the PC will be 1.55 times shorter than in the air (λ = 780 nm in air, $\lambda \approx$ 500 nm in the PC). The depth of the pits in the PC layer is designed to be $\lambda/4$, so that when the light is reflected back it will have travelled $\lambda/2$. This causes destructive interference and no light travels back into the reading head. In this manner, the pattern on the CD represents binary data.

CD-Rs contain four layers that are sandwiched together on top of a polycarbonate substrate (Fig. 1). Unlike CD-ROMs, the PC substrate does not contain any pits or plateaus, but rather contains many racks that spiral around the entire PC; these tracks are used to position the reading and writing laser. They impart a "mountain-and-valley" topography to all the other layers in the disc (3). The distance between each valley is approximately 1.3 μm.

The most commonly used dyes in CD-R medias are derivatives of cyanine and phthalocyanine, although azo-based dyes are also used (1*a*). During the recording process, the CD writer focuses an IR laser beam on the dye layer. The dye layer absorbs the laser light and darkens, blocking the reflective layer from the visible laser light used by regular CD drives and (or) players. The actual darkening process has not been very well understood; some dye formulations seem to change colour chemically and become opaque, while others absorb enough IR laser light and they deform from the heat, literally "burning" a dark spot into the dye layer.

Over top of the dye layer is a reflective layer made of silver, gold, or aluminium that is more common today. This layer is very thin (ca. 50–100 nm) and serves to reflect the reading laser back through the polarizing prism into the CD reading head (1*b*). A protective lacquer film goes on top of the reflective layer to protect it from being scratched or damaged during everyday use. Depending on the brand, there might also be another layer over top that allows the CD-R to be labelled.

Aside from being a popular information storage media, CD-Rs have proven to be very versatile in modern chemical research. Extended from our short report published in *Chemical Communications* as a Focus Article (1*b*), this review provides a comprehensive summary of the recent developments in the use of compact disc technology in a (bio-)chemical laboratory setting. Herein, we will focus on the work carried out in our laboratory during the past few years, while brief descriptions of related research work from other laboratories worldwide will be included in corresponding sections.

Surface chemistry on CD-Rs — Self-assembly and beyond

The surface chemistry of materials plays an important role in determining their behaviour in different chemical and biological environments. The surface property of the reflective gold layer in a CD-R was characterized with wetting measurements, electrochemistry, and a scanning tunnelling microscope (STM). It was found to be a suitable substrate for the formation of self-assembled monolayers (SAMs) (4).

Self-assembly is one of the most remarkable and ubiquitous events in chemical and biological processes. It has been employed by chemists to prepare highly organized monolayers on solid substrates. For the past two decades, the use of SAMs to modify the surface characteristics of solid materials has been very popular. An extensive review of SAMs was written by Ulman (5) more than 10 years ago and many more applications of SAMs have been proposed since that time. For example, alkanethiolate SAMs on gold electrodes have been used as model systems to study the kinetics of long-range electron transfer (6, 7). In the field of nanofabrication, SAMs can be used to protect nanoparticles to avoid coalescence; more details can be found in Murray's recent review on monolayer-protected nanocrystals (8). As well, SAMs of thiol-terminated oligonucleotides have potential applications in gene analysis; several recent reviews on advances in electrochemical DNA sensors are available (9–11).

One of the key issues in preparing high quality SAMs is the choice and pretreatment of substrates. In 2001, we reported the formation of high quality SAMs on gold substrates from CD-Rs (4). These SAMs were compared with those formed on commercially available gold slides purchased from Evaporated Metal Films (EMF), Inc. (Ithaca, New York) using FT IR, contact angle measurements, electrochemical measurements, and STM.

The preparation of the CD-R gold substrates is very simple: gold CD-Rs (Kodak CD-R Gold Ultima) are cut into pieces using a pair of regular scissors and stripped of their protective layer via immersion in concd. HNO_3 for 3–5 min. After the protective layer is peeled off, the CD pieces can be

© 2005 NRC Canada

used to prepare SAMs by submersing them in a dilute solution of organothiols in absolute ethanol for 18–24 h (Fig. 2).

The SAMs formed on two different gold substrates were initially characterized by contact angle measurements. As expected, gold substrates modified with 1-octadecanethiolate SAMs were found to be more hydrophobic than the bare ones in both cases. The comparisons between the bare gold substrates were more complicated because of their time-dependent nature. However, the equilibrated contact angles of both substrates agree within experimental uncertainties. The contact angles of the bare CD-R gold substrate was found to be 60 ± 2° and the EMF gold substrate was found to be 62 ± 2°; the SAM-modified CD-R gold substrate, on the other hand, was found to be 100 ± 3° and the EMF gold substrate was found to be 100 ± 2°. From these wetting studies, we can conclude that the CD-R gold substrates are comparable to the commercial EMF samples and that the SAMs formed on these two substrates show similar quality. This certainly confirms that CD-R gold substrates can be used in place of commercial gold substrates in wetting property studies.

The results from the wetting studies are rather macroscopic because the resolution of the contact angle is limited by the size of the water drops that were around 2–4 mm in diameter, depending on the hydrophobicity of the surface. Electrochemical measurements were carried out using cyclic voltammetry (CV) because this technique has been shown to be sensitive to the quality and thickness of monolayers on gold (12). The CV scans of both the bare gold substrates and the SAM-modified substrates were done with a 1.0 mmol/L solution of $Fe(CN)_6^{3-}$ acting as the electroactive species in a 1.0 mol/L KCl electrolyte (Fig. 3). The scans of the bare gold surfaces were of the same shape and so were the scans of the modified surfaces. The current in the scans of the modified surfaces is lower and mostly capacitive; it is also independent of scan rate, indicating that the reduction of $Fe(CN)_6^{3-}$ is kinetically limited, which is the result of the decreased interfacial electron transfer rate as electrons have to tunnel through the monolayer to reach the electrode. Both decreases in current from the monolayer on CD-R and EMF substrates are in the same order of magnitude, indicating that the packing and coverage of both monolayers are approximately the same.

As a further confirmation of the integrity of SAMs on CD-R gold substrates, infrared spectroscopy (IR) was carried out. All the assigned peaks in their IR spectra agreed with each other within experimental uncertainties, while their intensities differed only slightly (Fig. 4). The band at 2964 cm^{-1} is assigned to the CH_3 asymmetric in-plane CH stretching mode (ν_a), while the bands at 2937 and 2877 cm^{-1} are assigned to the CH_3 symmetric CH stretching mode (ν_s), which is split due to Fermi resonance interactions with the lower frequency asymmetric CH_3 deformation. The bands at 2917 and 2850 cm^{-1} are assigned to the $\nu_a(CH_2)$ and $\nu_s(CH_2)$ modes, respectively. These two modes were generally chosen for structural interpretation because of the minimal overlap of their bands with those of other modes. For example, the absorbance band of $\nu_a(CH_2)$ at 2917 cm^{-1} indicates a crystalline structure in the alkyl chains of the SAMs on both substrates. We can conclude from the IR data that the packing and orientation of the alkyl chains in the monolayers were comparable on the CD-R and the commercial substrate.

Fig. 2. Fig. 3. Cyclic voltammgrams for (A) bare gold from CD-Rs, (B) bare gold from EMF, (C) $CH_3(CH_2)_{17}S$-Au(CD-Rs), and (D) $CH_3(CH_2)_{17}S$-Au(EMF) in 1.0 mmol/L $K_3Fe(CN)_6$ and 0.1 mol/L KCl. The scanning rate is 50 mV/s. Reprinted in part with permission from ref. 4. Copyright 2001 American Chemical Society.

STM images provided a close look at the surface morphology of the substrates. Both CD-R and EMF gold substrates showed a polycrystalline structure, i.e., a "rolling hills" topography in their respective STM images (Fig. 5). However, the CD-R substrates show a more uniform grain size with diameters of 20–40 nm and a more even peak-to-valley height of around 3 to 4 nm. The EMF substrates were not as uniform and the peak-to-valley height was significantly higher. Neither one of the bare gold substrates is atomically flat; this means they are suitable only for microscale studies.

Based on the above studies, it can be clearly seen that gold substrates prepared from CD-Rs are suitable for self-assembly. The resulting monolayers are comparable to those formed from commercial gold substrates and give very reproducible results. The best advantage of using a CD-R substrate is that it does not require the use of highly corrosive and dangerous "piranha" (H_2O_2:H_2SO_4, 1:3) solution, which will explode when in contact with organic materials. CD-R substrates are also considerably less expensive when compared with commercial gold substrates, because each CD will produce many smaller pieces that can be used in individual studies.

We have extended the application of gold CD-R substrates to other surface chemistry studies. In our study of the evapo-

ration of water microdroplets (13), mixed SAMs of *n*-decanethiol and 11-mercaptoundecanol on both CD-R and EMF gold substrates were used as the model surfaces. The property of the SAMs, and in turn, the property of the surface, could be tuned with the relative concentrations of each component in the SAM. The evaporation of liquid droplets from a solid surface is a commonplace phenomenon and has been the subject of continuous investigation for quite some time. Picknett and Bexon (14) proposed that there are two modes of evaporation of liquid droplets on solid surfaces and they are: (1) the constant contact angle mode, where the area changes while the contact angle remains constant, and (2) the constant area mode, where the contact angle changes while the area remains constant. However, up to 30 years of experimental observations have yet to validate the theory.

Despite the difference in their initial contact angle, it was found in our study that for all the SAMs, regardless of their composition, the evaporation begins in the constant area mode and reaches an equilibrium contact angle that was approximately 10° less than the initial contact angle. At the point where this equilibrium contact angle is reached, the evaporation mode switches to the constant contact angle mode, whereby the area begins to shrink. It is believed that the change in the contact mode is due to the equilibration of the different interfacial forces acting on the droplet and not because of surface orientation reorganization. Although the SAMs have a different ratio of *n*-decanethiol to 11-mercaptoundecanol, nevertheless, they all exhibited the identical behaviour. In addition, no significant differences were found between the CD-R and commercial gold substrates.

CD-R gold substrates were also utilized in the study of surface reaction kinetics. For example, we studied the formation process of titanium(IV) dioxide on functionalized gold surfaces (15). Titanium dioxide (TiO_2) is a widely used photocatalyst and semiconducting material that has many potential applications. Due to their higher surface areas and enhanced activity, research into nanocrystalline TiO_2 particles and TiO_2 thin films has been very active during the past decade. It has been shown that hydrolysis and condensation of titanium(IV) alkoxides can yield thermally stable, nanocrystalline thin films (16). In our studies, the gold surface was first modified with dithiolreitol (DTT) and then it was immersed into a solution of titanium(IV) alkoxide to immobilize the titanium complex. The surface was then examined with contact angle measurements and it was found that as time passes, the water contact angle decreases. This change is believed to be caused by the hydrolysis of the titanium(IV) alkoxides on the surface to form more hydrophilic titanium dioxide. These experiments were completed on both CD-R and EMF gold substrates with equal success; this again demonstrates the versatility of the CD-R gold substrates.

Electrochemical analysis using CDtrodes

Once the protective layer is removed from the gold CD-Rs, the revealed reflective layer is suitable for use as an electrode for electrochemical analysis. Such electrodes were named CDtrodes and can be produced via a similar procedure as depicted in Fig. 2. This field of research has been pioneered by Angnes and his colleagues during the past 5 years (17–20). They have shown that the performance of

© 2005 NRC Canada

these CDtrodes are very reproducible and are comparable to commercial gold electrodes (Fig. 6). Thin-layer flow cells using CDtrodes were designed to analyse both organic (e.g., dipyrone (18)) and inorganic analytes (e.g., copper (19) and mercury (20)). Independently, De Strycker and co-workers (21) used CDtrode flow cells to analyze the cerium content during polymerization reactions. The detection limit of the CDtrode flow cells was shown to be similar to that of atomic absorption spectroscopy (19). With little to no loss in performance, the advantage of using CDtrodes over commercial electrodes is obvious as the low-cost electrodes allows for "single-use" cells that are convenient and, unlike commercial electrodes, do not require stringent cleaning before use.

A spectroelectrochemical cell that allows simultaneous detection using UV–vis spectroscopy and flow injection analysis was constructed by Daniel and Gutz (22) using two gold CDtrodes inside a cuvette (Fig. 7). The CDtrodes were glued with epoxy onto two acrylic plates for stability and served as both the working and auxiliary electrode in the cell. A 200 μm silicon rubber spacer was placed between the two electrodes to provide space for the light to pass through the cell (22). Using these cells, the electrochemical and UV–vis spectroscopic analyses can be conducted simultaneously.

Tailored electrode arrays have also been constructed from the reflective layer of a gold CD-R using heat transferred masks and wet etching techniques (23). This innovative method uses a laser printout as a positive mask for the electrode. After the desired electrode pattern is printed out onto wax paper, it is then transferred onto the gold surface via thermal pressing. The toner, but not the wax paper, sticks to the gold and prevents the aqueous etching solution from taking away the gold underneath. The minimum size of the electrodes was determined mainly by the resolution of the printer and the size of the toner particles. These custom-designed electrodes were then used to create microfluidic cells that showed very good reproducibility during amperometric analysis.

Aside from gold CD-Rs, similar CDtrodes have also been made using silver CD-Rs (24). These silver electrodes were used for quantification of chloride and cyanide in flow injection analysis and for lead analysis in voltammetry. The reproducibility of these silver CDtrodes was found to be quite good, and the detection limit was fairly low (i.e., 0.2, 50, and 200 μg/L for Pb^{2+}, Cl^-, and CN^-, respectively). This further demonstrates that the use of reflective layers from CD-Rs as an inexpensive source for noble metal electrodes is very attractive owing to its ideal performance in the electrochemical analysis.

Micro-fabrication with CD-Rs

Micro- and nano-fabrication has many potential applications in advanced technologies, such as miniaturized electronic and biomedical devices. The use of the unique CD-R substrates with their prepatterned grooves to create inorganic material microstructures is described in the following.

To explore the applications of CD-R substrates in microfabrication, we used controlled electrochemical deposition to create zirconia thin films on top of the mountain-and-valley structure of these substrates as shown in Fig. 8*a* (25). This research stems from the fact that zirconia thin films have potential applications as photocatalysts and oxygen sensors, and that electrochemical deposition is a common method of preparing oxide thin films (26, 27). We investigated the zir-

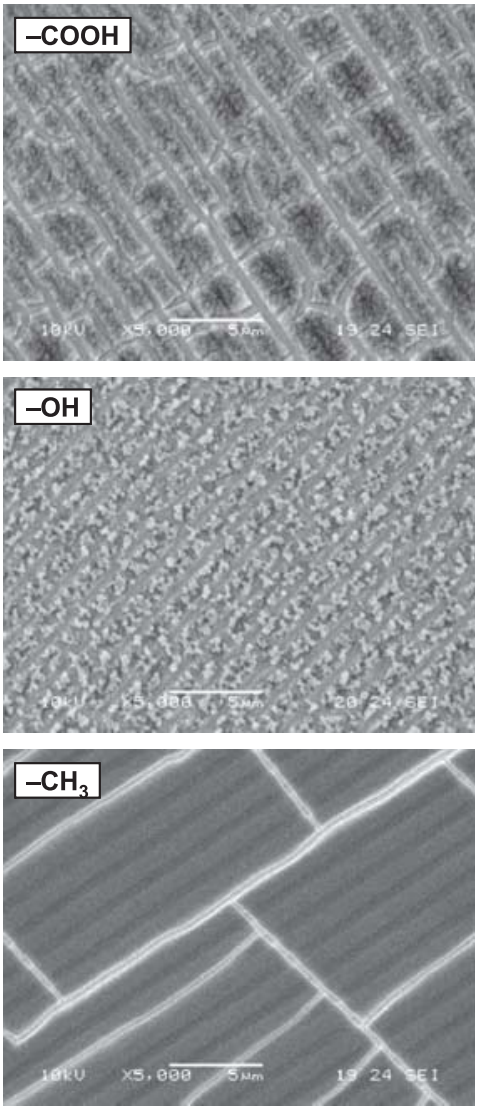
conia electrodeposition on bare gold CD-R surfaces and those modified with ω-terminated SAMs.

Cyclic voltammetry was used to deposit the zirconia thin film onto the gold substrate in an aqueous electrolyte of 5.0 mmol/L $ZrOCl_2 \cdot 8H_2O$ and 0.1 mol/L KCl. A zirconium thin film was formed on all of the surfaces after 10 cycles between –1.1 and +0.7 V (vs. Ag/AgCl). After each cycle, the cathodic current at the electrode would drop because of the buildup of zirconia on the surface, giving a greater resistance. It is believed that the $ZrOCl_2$ in the electrolyte coordinates to the surface and is hydrolyzed by the cathodically generated hydroxyl ions.

The SEM images show that the growth of zirconia thin films is dependent on the electrochemical conditions. Higher scan rates gave even more uniform surfaces that had pronounced growth on the mountains compared with the valleys (Fig. 9). For example, at a scan rate of 50 mV/s, the zirconia film was uniform on the mountains while the formation in the valleys was significantly less. The sample cycled at 20 mV/s, on the other hand, had zirconia particle formation

Fig. 9. SEM images of zirconium thin film formed on Au-$S(CH_2)_{11}OH$. Samples were prepared by cyclic voltammetry at different scan rates in 5.0 mmol/L $ZrOCl_2$ and 0.1 mol/L aqueous KCl solution. The accelerating voltage of the electron beam used was 10 kV and the magnification setting used for imaging was ×5000. Reprinted in part with permission from ref. 25. Copyright 2002 American Chemical Society.



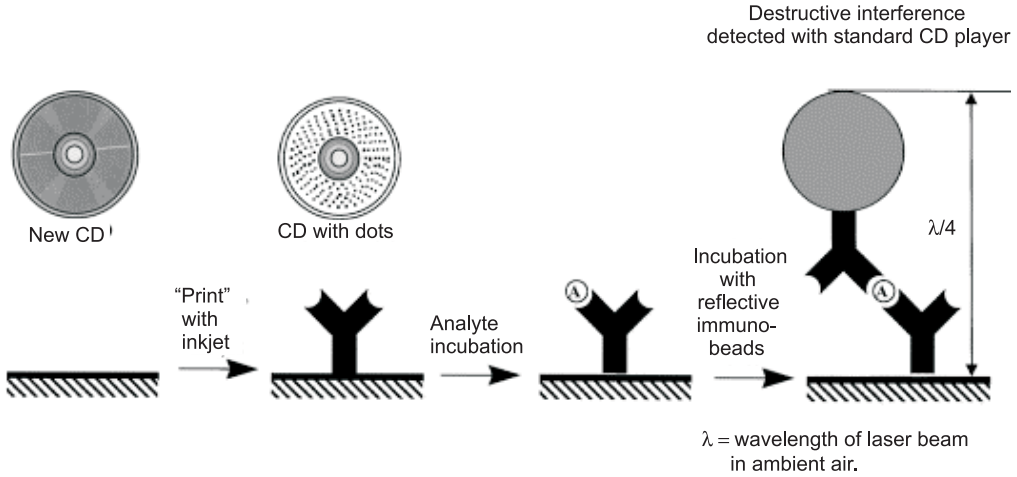
very much confined to the mountains In addition, the particles were only a few hundred nanometres in size and oriented along the mountains to give microscale strips of zirconia particles. At a lower scan rate (e.g., 10 mV/s), the film showed a larger, more amorphous growth with nucleation appearing on top of or starting from smaller particles without any confinement to the mountains It is believed that the two main factors contributing to these unique structures are: (1) the charge builds up on the corners and edges of the ridged substrate, and (2) the impeded diffusion of the electrolyte to the valleys; both of these factors favour the growth of zirconia on the mountains over the valleys. On flat gold substrates, however, the zirconia thin films had a characteristic racked-mud appearance that signifies an amorphous film (28).

© 2005 NRC Canada

The zirconia thin films formed on the CD-R substrate modified with differently functionalized SAMs (i.e., with different terminal groups, such as -COOH, -OH, and -CH_3) showed different types of growth (Fig. 10). The thin film formed on top of the Au-S$(CH_2)_{10}$COOH SAM showed some preferential growth along the mountains, but not as distinctive as the Au-S$(CH_2)_{11}$OH sample. The Au-S$(CH_2)_{11}CH_3$ sample, on the other hand, showed almost no preferences, but formed an almost uniform thin film that cracked along the valleys of the CD-R substrate as a result of the dehydration of the films. Because the interactions between the terminating groups and the $ZrOCl_2$ in solution are important to the formation of the films, we believe that the different SAMs contributed differently to the film formation. For the CH_3-terminated SAMs, the uniformly hydrophobic surface did not favour the selective nucleation and growth of the zirconia. In the case of the carboxyl-terminated SAM, the surface charge, which is sensitive to the local pH, will help the formation of the films. The preliminary X-ray diffraction studies showed all these zirconium thin films to be amorphous, despite the different substrates and scan rates. While the simple patterns on the CD-R substrate do not allow for fabrication of more complex structures, it is suitable for studies in selective crystal growth and template-directed deposition of inorganic thin films.

Aside from the metal reflective layer, the polycarbonate base of the CD-R has also been found useful in micro- and (or) nanostructural fabrications. For example, the microscale "track-and-trail" structure of the polycarbonate base was used as the pattern and mould to form microstructures on glass and plastic substrates (29). A soft-lithographic method for synthesis and transfer of materials to and from polymers (STOMP) was developed by Batteas and co-workers (30) to create nanostructures in gold film on mica by using "naked" PC substrates as stamps. The reflective layer and the dye layer were first removed via vigorous rinsing with ultrapure water and sonication with a 1:4 methanol–water mixture. The polycarbonate base was then pressed onto the gold and, while still pressed together, both the stamp and the gold were submerged into an etching solution. The resulting fine gold wires (ca. 200–500 nm wide) will be embedded in the stamp. If two PC stamps with embedded gold wires are compressed together, 3-D crosshatched structures can be created.

Fig. 10. SEM images of zirconium thin film formed on differently functionalized CD-R gold substrates (i.e., Au-S$(CH_2)_{11}CH_3$, Au-S$(CH_2)_{10}$COOH, and Au-S$(CH_2)_{11}$OH). All samples were prepared and imaged under experimental conditions otherwise identical to those in Fig. 9. Reprinted in part with permission from ref. 25. Copyright 2002 American Chemical Society.



Biomedical diagnosis with CDs

Plastic disks having the same shape as conventional CDs have been found to be useful in the design of microfluidic platforms. Microfluidic devices based on these circular plastic disks have been pioneered and reviewed by Madou et al. (31). In one of their designs, multiple sets of interconnected fluid reservoirs on a polycarbonate disk were created by a computer numerically controlled (CNC) machine and were used to perform an enzyme-linked immunosorbent assay (ELISA) for rat IgG from a hybridoma cell culture (32). Each step of the assay was controlled by the rotation speed of the disk; the centrifugal and capillary forces were used to control the flow sequence of the solutions through the microchannels. Detection was carried out using a fluorescence microscope at the end of the sequence. The results of the microfluidic disks are similar to that of a microtiter plate within the same detection range; however, it only consumed one-tenth of the same reagents as a microtiter plate. This would lower the cost of each assay by reducing the amount of expensive antigens and antibodies needed. Although these developments are significant, it should be noted that these devices are not based on conventional CDs and are thus not covered in detail in this review.

The detection of a DNA hybridization event is done mostly through the use of fluorescence labels that are either directly incorporated into the target and (or) probe DNA strand or via a second labelling step in most assays; however, fluorescence detection on DNA microarrays created on regular CDs may not be ideal because of the autofluorescense of the polycarbonate substrate. The search for alter-

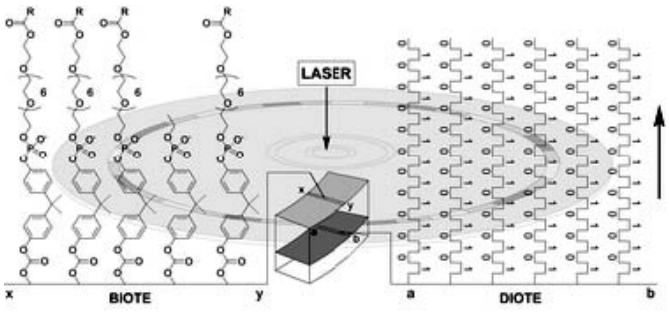
Fig. 11. Concept of reflective immunobead-based sandwich assay on CD. Light reflected from the reflective surface of the disc would be detected. However, light reflected from the reflective beads would cause destructive interference and would not be detected. The difference in height between the top of the bead and the reflective disc layer would be equal to one-quarter of the wavelength of the laser beam used (λ/4). This system would allow the use of standard CD ROM drives for analysis of the disc without any modifications. Reprinted from Anal. Chim. Acta, Vol. 411. H. Kido, A. Maquieira, and B.D. Hammock. Disc-based immunoassay microarrays pp. 1–11. Copyright (2000), with permission from Elsevier.

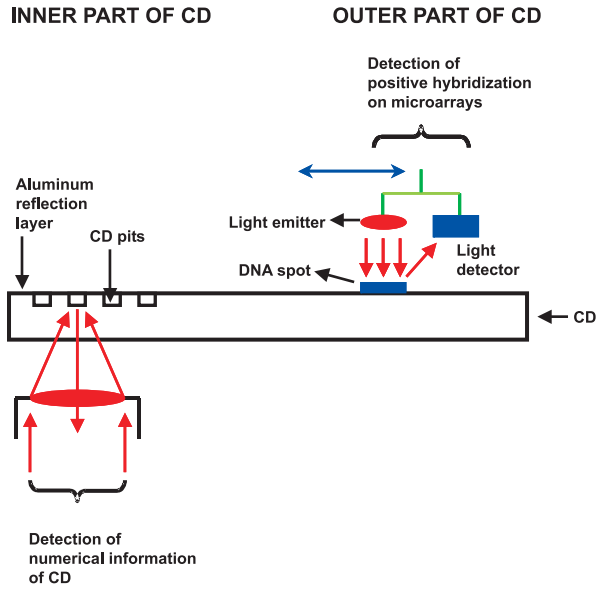


native methods of detection on CD-based microarrays has produced several other options as described in the following.

An innovative concept of detecting biological molecules on CDs by disrupting the laser beam in a conventional CD reader was proposed by Hammock and co-workers (33). As shown in Fig. 11, arrays of protein or DNA probes can be deposited onto the polycarbonate of the CD by hand, using a pipette, or it can be "printed" onto the CD using an inkjet printer using modified ink. The target proteins would be modified with a reflective substance, such as a gold or silver particles and when the two bind, the reflective particle would be immobilized to the surface. Ideally, the distance between the top of the reflective particle and the CD reflective surface would be λ/4, where λ is the wavelength of the reading laser. This would cause the same destructive interference that occurs when the reading laser hits a pit in the CD-ROM. This method of detection would allow the use of conventional CD readers to conduct the analysis of the microarrays. However, up to date, no experimental work based on this idea followed from that laboratory.

In the work of La Clair and Burkart (34), a similar method of CD-reading laser disruption is employed in the detection of large protein molecules. Numerical data were first written onto specific regions on a CD-R (DIOTE); these regions were then later modified with phosphodiesterated ligands (BIOTE) (Fig. 12). These biological ligands were chosen for their activity with streptavidin and concanavalin A, and were deposited onto the polycarbonate layer via inkjet printing Once the BIOTE–DIOTE construct was complete, the CD-R was read on a standard CD reader on a computer and the digital information was obtained and analyzed. This data should contain a certain amount of errors caused by the introduction of the ligands in the path of the optical laser and these errors will form the baseline for subsequent error analysis. After this, the regions containing the ligands, including nonbinding ligands to serve as blanks, were incubated with solutions of streptavidin in PBS buffer or concanavalin A in

Fig. 12. Pictorial representation of the BIOTE layer containing biological ligands and the DIOTE layers containing digital binary data on the sectors of a CD-R; details explained in the text. Reprinted from ref. 34. Reproduced by permission of The Royal Society of Chemistry.



acetate buffer and then washed in deionized water. The data from the CD-R was read again to obtain the higher error rate that is generated by the even larger molecules (streptavidin and concanavalin A) now bound to the surface. By comparing the second set of error rates to the blank, it was possible to determine the binding efficiency of the protein molecules to the respective ligands. It was also possible to determine the concentration of streptavidin by the level of errors that were generated.

Besides the method of disrupting the CD-reading laser, there are also other protocols of detecting DNA hybridization and protein interactions. Remacle and co-workers (35) designed a colorimetric detection protocol to recognize the hybridization of DNA. Their DNA microarray platform contains both numerical and genomic information on a single CD (Bio-CD) (35). As shown in Fig. 13, there are two sections in these specially manufactured Bio-CDs: (1) the inner section of the disk is similar to a conventional CD and contains numerical data used to identify the DNA probes and to control the Bio-CD reader, and (2) the outer section is a

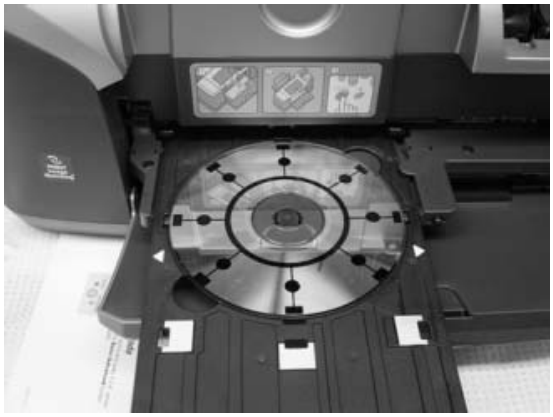
Fig. 13. Schematic representation of a reading system for colorimetric CD detection composed of two laser-based devices. The first one is a classic laser CD reader reading the numeric information registered in the inner phase of the CD, and the second one is a photodiode head detecting the laser light diffraction in the presence of positive hybridization onto the microarray of the CD. Adapted from ref. 35, copyright 2002 by Eaton Publishing Co., used with permission.



polycarbonate substrate that contains the genomic information in several sets of DNA probes. It is similar to the Hammock concept (33) in that a reflective entity is attached to the target to allow for laser detection, but dissimilar in that a separate diode is used to collect the information on the microarray. The target DNA (the *fem A* gene of various *Staphylococci*) was first modified with biotin so that after hybridization with the DNA probe on the polycarbonate substrate the biotin will stand up from the polycarbonate surface (36). The microarray is then incubated with a solution of streptavidin – colloidal gold conjugate. After washing with a Silver Blue solution that contained silver nitrate and hydroquinone (37), a silver layer will be plated on the surface of the gold particles. When the Bio-CD is read with the doubled-sided Bio-CD reader, the silver-coated gold particles reflect the laser into a photodiode detector and show up as bright spots. A computer program will then analyze and quantify the data collected by the photodiode. It should be noted that a specially designed CD reader/writer is required to utilize their Bio-CDs.

We find the idea of directly using conventional CD/CD-R technology for biosensing applications most appealing, and thus it is our current research goal. We have been attempting to immobilize DNA directly onto the CD polycarbonate surface via either chemical or photochemical routes. Inspired by the Hammock concept (33), we have been working on the data error comparison method to monitor DNA hybridization on CDs.

We are also working on electrochemical methods of detecting DNA hybridization for a potentially more sensitive and cost effective gene analysis (38, 39). We have created electrode microarrays on a gold CD-R using soft lithography

Fig. 14. Demonstration of printing electrode-patterns on a gold CD-R with an Epson PhotoStylus R300 printer.

and inkjet technology. Soft lithographic techniques, such as microcontact printing, do not require expensive laser equipment such as those of conventional photolithography. It uses self-assembly and replica moulding to fabricate micro- and nanostructures; a comprehensive review has been written on this subject by Xia and Whitesides (40). In place of the microcontact printing used by Kumar and Whitesides (41) to stamp patterns onto their gold substrates, we use inkjet printing technology to print masks of hydrophobic ink with our electrode patterns onto the gold CD-R substrates (Fig. 14). After forming the electrode array on the polycarbonate substrate by etching away the gold, we can modify the surface of each electrode with different DNA probes. In principle, by employing a large array of electrodes, simultaneous detection and quantification of many different strands of DNA is feasible.

Conclusions

Rather than being discarded or used as coasters for hot drinks, old CD-Rs are very useful in modern research. CD-R gold substrates can be used to prepare high-quality, self-assembled monolayers (SAMs) after removing the protective polymer films with concentrated nitric acid. These substrates are comparable to other commercial gold substrates in terms of the quality of the monolayers formed, and are well suited for surface wetting, electrochemical, and spectroscopic studies. CD-R polycarbonate bases are also ideal micropatterned substrates for the fabrication of material microstructures and miniaturized devices. The potential applications of micropatterned DNA probes on CDs used in combination with conventional CD technology for biomedical and gene analysis are very appealing.

Synthesis and evaluation of 7-hydroxyindan-1-one-derived chiral auxiliaries

Arun A. Narine and Peter D. Wilson

Abstract: A series of novel chiral acetals were prepared from 7-hydroxyindan-1-one and a variety of substituted chiral nonracemic C_2-symmetric 1,2-ethanediols (R = Me, Ph, CH_2OMe, CH_2OBn, CH_2O(1-Np), and *i*-Pr). These acetals were evaluated as chiral auxiliaries for use in asymmetric synthesis. A high degree of stereochemical induction was observed in the diethylaluminum chloride-promoted Diels–Alder reaction of an acrylate derivative (R = *i*-Pr) with cyclopentadiene (91:9 dr). This demonstrated that these acetals could serve as effective chiral directors in asymmetric substrate-directed reactions.

Key words: 7-hydroxyindan-1-one, chiral nonracemic C_2-symmetric 1,2-diols, acetals, chiral auxiliaries, Diels–Alder reaction.

Résumé : On a préparé une série de nouveaux acétals chiraux à partir de la 7-hydroxyindan-1-one et une variété d'éthane-1,2-diols substitués, de symétrie C_2, non racémiques et chiraux (R = Me, Ph, CH_2OMe, CH_2OBn, CH_2O(1-Np) et *i*-Pr). On a évalué ces acétals comme auxiliaires chiraux dans des synthèses asymétriques. On a observé un degré élevé d'induction stéréochimique dans la réaction de Diels–Alder, catalysée par le chlorure de diéthylaluminium, d'un acrylate (R = *i*-Pr) avec le cyclopentadiène (91 : 9 dr). Ce résultat démontre que ces acétals peuvent servir de directeurs chiraux efficaces dans des réactions asymétriques dirigées par le substrat.

Mots clés : 7-hydroxyindan-1-one, 1,2-diols de symétrie C_2 non racémiques et chiraux, acétals, auxiliaires chiraux, réaction de Diels–Alder.

[Traduit par la Rédaction]

Introduction

The development and evaluation of new chiral auxiliaries, ligands, and catalysts for use in asymmetric synthesis is a central focus of modern synthetic organic chemistry. To date, a variety of chiral acetals have been designed and employed as chiral directors in a broad range of asymmetric reactions (1, 2). We have designed a series of novel cyclic acetals (**1**) as a general class of conformationally constrained chiral auxiliaries, ligands, and catalysts for use in asymmetric synthesis (Fig. 1). These acetals should be readily accessible from the parent ketones (**2**) (such as functionalized indan-1-one (n = 1) and tetral-1-one (n = 2) derivatives as well as their heterocyclic analogues) and a series of chiral nonracemic C_2-symmetric 1,2-diols (**3**) via experimentally simple acid-catalyzed condensation reactions.

The atom or substituent X is the attachment or binding site of the chiral auxiliary, ligand, or catalyst. The substituent Y can be varied to alter the electronic properties of this system and could also serve as an attachment site to a polymeric support. Thus, the structure of these chiral directors could be optimized using automated synthesis or used to prepare polymer-supported reagents. Similarly, the substituents of the cyclic acetal moiety could be varied to alter the electronic and steric environment of the chiral auxiliary, ligand, or catalyst. The use of chiral nonracemic C_2-symmetric 1,2-diols **3** to prepare these acetals ensures that only a single diastereoisomer is produced in these condensation reactions (3). Of note, the two planes of the acetal moiety are positioned in an approximately orthogonal manner that results in one of the diastereotopic faces of these molecules being effectively blocked by one of the substituents of the cyclic acetal.

In this paper, the synthesis of a series of 7-hydroxyindan-1-one-derived chiral auxiliaries (**4**) is described (Fig. 2) (4). These structurally rigid chiral auxiliaries were synthesized in a modular and convergent manner from readily available 7-hydroxyindan-1-one (**5**) and a series of chiral nonracemic C_2-symmetric 1,2-diols (**3**). In addition, these chiral auxiliaries were evaluated by undertaking a study of the Lewis acid-promoted Diels–Alder reactions of the corresponding acrylate derivatives **6** (5).

Results and discussion

7-Hydroxyindan-1-one (**5**) was prepared on a multi-gram scale by a known three-step, two-pot, procedure (Scheme 1) (6, 7). This involved conversion of 3-chloropropanoic acid to

Scheme 1. Synthesis of 7-hydroxyindan-1-one-derived chiral auxiliaries **4a** (R = Me) and **4b** (R = Ph). Reagents and conditions: (*a*) 3-chloropropanoic acid, PCl_3, ~115 °C, 3 h; then phenol, toluene, reflux, 3 h; $AlCl_3$, 90–180 °C, ~6 h (ref. 6); (*b*) AcCl, pyridine, CH_2Cl_2, 0 °C to room temperature, 19 h, 89%; (*c*) 1,2-diols **3a** (R = Me) and **3b** (R = Ph), *p*-TsOH, benzene, reflux, 16–40 h, 90% **8a** (R = Me), 83% **8b** (R = Ph); (*d*) LiOH, THF–H_2O (3:1), room temperature, 16–40 h, 84% **4a** (R = Me), 90% **4b** (R = Ph). The compound used in this study was the enantiomer of that indicated in the reaction scheme (*).

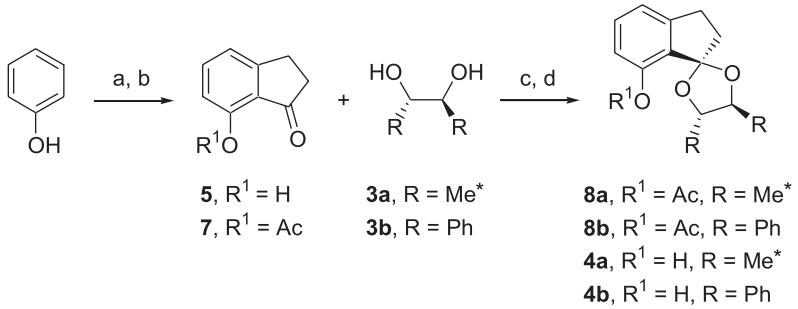

Fig. 1. Novel chiral acetals **1** as auxiliaries, ligands, and catalysts for asymmetric synthesis.

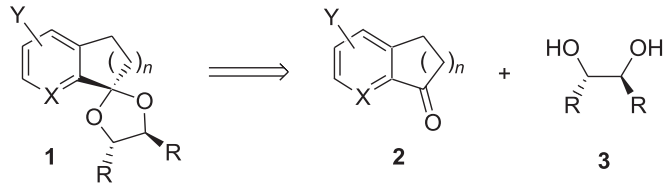

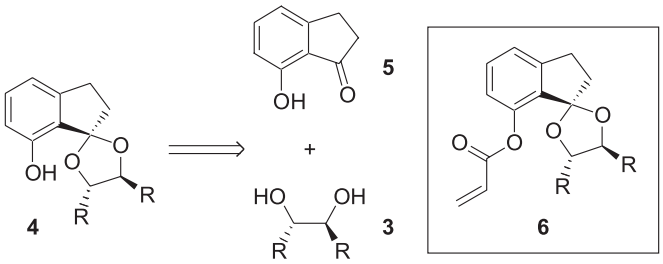

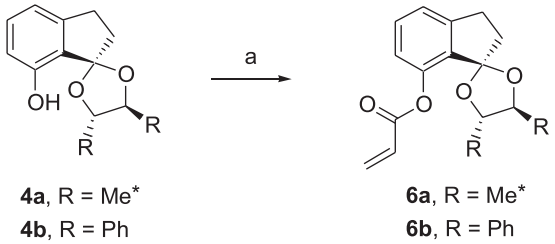

Fig. 2. 7-Hydroxyindan-1-one-derived chiral auxiliaries **4**.

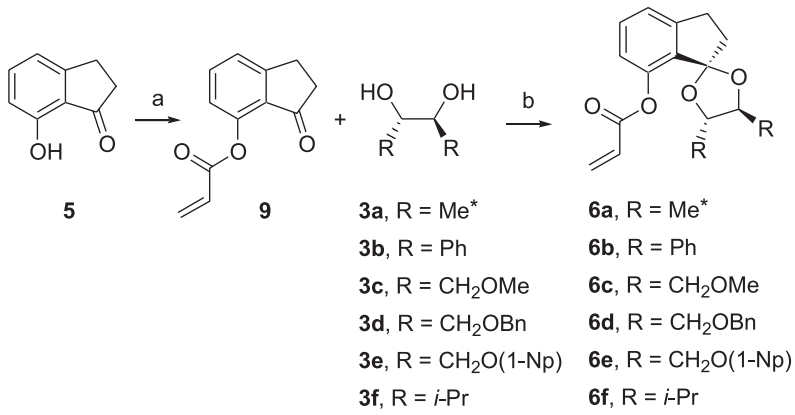
the corresponding acid chloride, on heating with phosphorous trichloride, which in turn was reacted with phenol to afford phenyl 3-chloropropanoate. This ester was purified by distillation and then reacted with aluminum trichloride. Following the addition of aqueous hydrochloric acid, 7-hydroxyindan-1-one (**5**) was isolated directly from the reaction mixture by steam distillation and purified by recrystallization.

It was found that 7-hydroxyindan-1-one (**5**) could not be condensed directly with a series of chiral nonracemic 1,2-diols **3** or with 1,2-ethanediol (8). Various reaction conditions and acid catalysts were screened, without success, to effect this key acetal formation reaction. We consider that this finding is due to the acid-catalyzed enolization of the ketone moiety. This results in a decrease in the reactivity of the carbonyl centre of 7-hydroxyindan-1-one (**5**) towards nucleophilic attack by the diol. To solve this problem, the phenol moiety of 7-hydroxyindan-1-one (**5**) was protected as an acetate using acetyl chloride and pyridine as reagents (8). Condensation of the acetate **7** with commercially available (2*R*,3*R*)-2,3-butanediol **3a** (R = Me) and (1*S*,2*S*)-1,2-diphenyl-1,2-ethanediol **3b** (stilbenediol, R = Ph), using *para*-toluenesulfonic acid (*p*-TsOH) as a catalyst, afforded the acetals **8a** (R = Me) and **8b** (R = Ph) in good yield (9). These acetals were then converted efficiently to the target chiral auxiliaries **4a** (R = Me) and **4b** (R = Ph) on hydrolysis of the acetate moieties with lithium hydroxide.[2]

Scheme 2. Synthesis of Diels–Alder reaction substrates, acrylates **6a** (R = Me) and **6b** (R = Ph). Reagents and conditions: (*a*) acryloyl chloride, Et_3N, benzene, 0 °C to room temperature, 2–2.5 h, 88% **6a** (R = Me), 86% **6b** (R = Ph). The compound used in this study was the enantiomer of that indicated in the reaction scheme (*).



The 7-hydroxyindan-1-one-derived chiral auxiliaries **4a** (R = Me) and **4b** (R = Ph) were then reacted with acryloyl chloride and triethylamine (Scheme 2). This afforded the required Diels–Alder reaction substrates **6a** (R = Me) and **6b** (R = Ph) in 88% and 86% yields, respectively.

To prepare a more extensive series of Diels–Alder reaction substrates and to determine the effect of the chiral acetal substituents in subsequent substrate-directed reactions, a more direct route was developed (Scheme 3). In this instance, 7-hydroxyindan-1-one (**5**) was converted to the ketoester **9** on reaction with acryloyl chloride and triethylamine in good yield. Condensation of the ketoester **9** with (2*R*,3*R*)-

[2] The chiral auxiliaries **4a** (R = Me) and **4b** (R = Ph) are stable compounds and can be stored in a capped vial at 4 °C for several months without any sign of decomposition.

Scheme 3. Direct synthesis of Diels–Alder reaction substrates, acrylates **6a**–**6f** (R = Me, Ph, CH_2OMe, CH_2OBn, CH_2O(1-Np), and *i*-Pr). Reagents and conditions: (*a*) acryloyl chloride, Et_3N, CH_2Cl_2, 0 °C to room temperature, 12 h, 93%; (*b*) 1,2-diols **3a**–**3f** (R = Me, Ph, CH_2OMe, CH_2OBn, CH_2O(1-Np), and *i*-Pr), *p*-TsOH or PPTS, benzene, reflux, 4 h–4 days, 93% **6a** (R = Me), 93% **6b** (R = Ph), 82% **6c** (R = CH_2OMe), 80% **6d** (R = CH_2OBn), 56% **6e** (R = CH_2O(1-Np)), 80% **6f** (R = *i*-Pr). The compound used in this study was the enantiomer of that indicated in the reaction scheme (*).

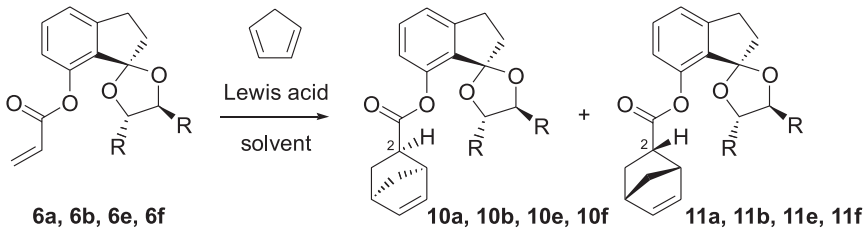
2,3-butanediol **3a** (R = Me) and (1*S*,2*S*)-1,2-diphenyl-1,2-ethanediol **3b** (R = Ph) afforded the acrylates **6a** (R = Me) and **6b** (R = Ph), which were prepared earlier by the less direct route, again in good yield.[3,4] In addition, the ketoester **9** was condensed with (2*S*,3*S*)-1,4-dimethoxy-2,3-butanediol **3c** (R = CH_2OMe) (10), (2*S*,3*S*)-1,4-dibenzyloxy-2,3-butanediol **3d** (R = CH_2OBn) (11), (2*S*,3*S*)-1,4-bis(1-naphthoxymethyl)-2,3-butanediol **3e** (R = CH_2O(1-Np)) (12), and (1*S*,2*S*)-1,2-diisopropyl-1,2-ethanediol **3f** (R = *i*-Pr) (13). These chiral nonracemic 1,2-diols were all prepared from (2*R*,3*R*)-(+)-diethyltartrate based on literature procedures. The condensation reactions afforded the acrylates **6c**–**6f** (R = CH_2OMe, CH_2OBn, CH_2O(1-Np), and *i*-Pr) in 56%–93% yield.

The Diels–Alder reactions of all of the acrylates **6** with cyclopentadiene were performed in the presence of either diethylaluminum chloride or titanium tetrachloride in dichloromethane or toluene (Table 1). For the (2*R*,3*R*)-acrylate **6a** (R = Me), the diethylaluminum chloride-promoted cycloaddition reaction afforded the desired products **10a** and **11a** (R = Me) in good yield and was moderately diastereoselective (63:37 dr in dichloromethane and 64:36 dr in toluene). Thus, the outcome of this reaction was found to be independent of the reaction solvent employed (Table 1, entries 1 and 2). Repeating these reactions using titanium tetrachloride as the Lewis acid resulted in cleavage of the acetal moiety. The Diels–Alder reaction of the (1*S*,2*S*)-acrylate **6b** (R = Ph) with cyclopentadiene, using diethylaluminum chloride as the Lewis acid in dichloromethane, afforded the desired products **10b** and **11b** (R = Ph) in good yield and again was moderately diastereoselective (74:26 dr, Table 1, entry 3). However, a significant improvement in the diastereoselectivity of the reaction was observed when this reaction was performed in toluene (83:17 dr, Table 1, entry 4). When titanium tetrachloride (0.75 equiv.) was used to effect this cycloaddition reaction in dichloromethane, the adducts **10b** and **11b** (R = Ph) were isolated in this instance (26:74 dr, Table 1, entry 5).[5] Of note, it is of interest that the stereochemical outcome of the reaction was reversed with this dibasic Lewis acid. However, no reaction was observed when the reaction was repeated in toluene (14).[6] For the (2*S*,3*S*)-acrylate **6e** (R = CH_2O(1-Np)), the diethylaluminum chloride-promoted cycloaddition reaction afforded the desired products **10e** and **11e** (R = CH_2O(1-Np)) in good yield, but was only moderately diastereoselective (68:32 dr, Table 1, entry 6).[7] However, the diethylaluminum chloride-promoted Diels–Alder reaction of the (1*S*,2*S*)-acrylate **6f** (R = *i*-Pr) in toluene finally proved to be highly stereoselective (91:9 dr, Table 1, entry 7).

The absolute stereochemistry of the major diastereoisomers of the reaction products from all of the Diels–Alder reactions was determined unequivocally. This was achieved

[3] In the case of the formation of acrylate **6b** (R = Ph) from ketoester **9** and diol **3b** (R = Ph), a mixture of *p*-TsOH and PPTS was employed as the catalyst for this condensation reaction.

[4] Of note, the acrylates **6a** (R = Me) and **6b** (R = Ph) are highly crystalline compounds, as compared to the acetates **8a** (R = Me) and **8b** (R = Ph), which facilitates their purification. They can also be hydrolyzed with lithium hydroxide at room temperature to prepare the 7-hydroxyindan-1-one-derived chiral auxiliaries **4a** (R = Me) and **4b** (R = Ph) in 97% and 73% yield (18 and 40 h, respectively). The acrylate **6b** (R = Ph) can be converted more efficiently to the auxiliary **4b** (R = Ph) using lithium aluminum hydride in 82% yield.



[5] The use of titanium tetrachloride (1.5 equiv.) in this reaction resulted in the decomposition of the starting material.

[6] A variety of other Lewis acids were screened to effect the Diels–Alder reaction of acrylate **6b** (R = Ph) and cyclopentadiene. Zinc chloride, tin tetrachloride, bis(cyclopentadienyl)titanium dichloride ($(C_5H_5)_2TiCl_2$), boron trifluoride diethyl etherate, and titanium tetraisopropoxide afforded the Diels–Alder adducts **10b** and **11b** (R = Ph) in ~20%, 50%, 65%, 80%, and 90% combined yields, respectively. However, these reactions afforded ~1:1 mixtures of adducts **10b** and **11b** (R = Ph). The use of boron trichloride (1.5 equiv.) resulted in the decomposition of the starting material.

[7] The Lewis acid-promoted Diels–Alder reactions of acrylates **6c** (R = CH_2OMe) and **6d** (R = CH_2OBn) were not diastereoselective (54:46 and 55:45 dr, respectively).

[a]The reactions were performed at –78 °C with excess cyclopentadiene and 1.5 equiv. of the Lewis acid for 10–60 min unless stated otherwise.
[b]Combined yields of the Diels–Alder adducts (**10** and **11**) after purification by flash chromatography.
[c]Determined by ^{1}H NMR spectroscopy (400 or 600 MHz) of the crude reaction mixtures. In all cases, the endo:exo stereoselectivity was greater than 98:2.
[d]Refers to the stereochemical configuration at C-2 of the major norbornene Diels–Alder adduct.
[e]The compound used in this study was the enantiomer of that indicated in the reaction scheme.
[f]0.75 equiv. of the Lewis acid was employed and the reaction mixture was allowed to warm to room temperature overnight.

by the facile and efficient removal of the chiral auxiliary and comparison of the specific rotation of the resultant norbornene Diels–Alder adducts to literature values (see Supplementary material)[8] (15). These reactions were either performed by hydrolysis with lithium hydroxide, transesterification with sodium methoxide, or reduction with lithium aluminum hydride. Of note, the chiral auxiliaries **4a**, **4b**, **4e**, and **4f** were recovered in good yield (78%, 87%, 60%, and 79%, respectively, on hydrolysis with lithium hydroxide) for use in subsequent asymmetric transformations.

The stereochemical outcome of the diethylaluminum chloride-promoted Diels–Alder reaction of the acrylate derivates **6** can be rationalized in terms of the transition state shown below (Fig. 3, TS-**12**) (16). Here, cyclopentadiene attacks from the top face of the complex. This is due to the steric influence of one of the substituents of the chiral acetal moiety that projects directly over the bottom face of the complex. In the case of the titanium tetrachloride-promoted Diels–Alder reaction, we suggest that the acrylate moiety is rotated and coordinated to the more accessible acetal oxygen (TS-**13**). Attack of cyclopentadiene, again from the top face of the complex, would result in the observed reversal in the stereochemical outcome of the reaction.

Fig. 3. Transition states for the Lewis acid-promoted Diels–Alder reactions (TS-**12** and TS-**13**).

Conclusions

A series of acrylate derivatives **6a**–**6f** (R = Me, Ph, CH_2OMe, CH_2OBn, CH_2O(1-Np), and *i*-Pr) of the 7-hydroxyindan-1-one-derived chiral auxiliaries **4** were prepared. A high degree of stereochemical induction was observed in a diethylaluminum chloride-promoted Diels–Alder reaction of the acrylate derivative **6f** (R = *i*-Pr) with cyclopentadiene (91:9 dr). This demonstrated that these designed chiral acetals could serve as effective chiral directors in asymmetric processes. Current studies involve the synthesis of additional derivatives of these chiral auxiliaries for use in other asymmetric substrate-directed reactions. Studies are also focused on the elaboration of the 7-hydroxyindan-1-one-derived acetals **4**, by regioselective functionalization at C-6, to prepare a variety of chiral ligands for use in catalytic asymmetric synthesis. In addition, the preparation and evaluation of related chiral pyridine, *N*,*N*-dialkylaminopyridine,

[8]Detailed experimental procedures and complete product characterization data for all of the additional compounds synthesized as well as ^{1}H and ^{13}C NMR spectra for compounds **4a**, **4b**, **6b**, and **6f**. In addition, the experimental procedures for the stereochemical proof of the major Diels–Alder adducts **10b** and **10f** are provided. and bipyridine catalysts and ligands is being actively pursued. Moreover, we have recently completed an efficient and modular synthesis of a series of chiral nonracemic *P*,*N*-ligands based on the design concept described in this paper (17). These ligands were evaluated in palladium(II)-catalyzed asymmetric allylic substitution reactions. A *P*,*N*-ligand derived from (1*S*,2*S*)-1,2-diphenyl-1,2-ethanediol **3b** (R = Ph) was found to be highly stereoselective (up to 90% ee).

Experimental section

For general experimental details refer to the Supplementary material.[8]

7-Acetoxyindan-1-one (7) (18)

To a stirred solution of 7-hydroxyindan-1-one (**5**) (101 mg, 0.682 mmol) in dichloromethane (3 mL) at 0 °C were added pyridine (164 μL, 2.03 mmol) and acetyl chloride (96 μL, 1.4 mmol). The reaction mixture was stirred at 0 °C for 1 h and then at room temperature for 18 h. The resultant mixture was poured into a saturated aqueous solution of ammonium chloride (25 mL) and was extracted with dichloromethane (3 × 10 mL). The combined organic extracts were then dried over anhydrous magnesium sulfate, filtered and concentrated to afford a yellow oil. Purification by flash chromatography using hexanes–ether (2:1) as the eluant afforded the title compound **7** (115 mg, 89%) as a white crystalline solid; mp 75–77 °C (hexanes–ether), lit. value (18) mp 78 to 79 °C (ether). IR (ef) cm^{-1}: 1770, 1710, 1610, 1472, 1368, 1245, 1187, 1013. ^1H NMR (400 MHz, $CDCl_3$) δ: 2.40 (3H, s, C*H*$_3$), 2.67 (2H, m, ArC*H*$_2$), 3.14 (2H, m, C*H*$_2$CO), 6.97 (1H, ddd, *J* = 7.9, 1.5, 0.9 Hz, Ar*H*), 7.34 (1H, ddd, *J* = 7.6, 1.5, 0.9 Hz, Ar*H*), 7.58 (1H, m, Ar*H*). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 20.9, 25.6, 36.7, 120.6, 124.5, 128.7, 135.9, 147.7, 157.0, 169.3, 203.8. MS (C.I.) *m*/*z*: 191 (M + H), 149. Anal. calcd. for $C_{11}H_{10}O_3$: C 69.46, H 5.30; found: C 69.30, H 5.35.

7-Acetoxyindan-1-one (*S*,*S*)-stilbenediol acetal (8b) — Representative procedure for the preparation of acetal 8a

A stirred solution of the acetate **7** (196 mg, 1.03 mmol), diol **3b** (258 mg, 1.20 mmol), and *para*-toluenesulfonic acid monohydrate (20 mg, 0.10 mmol) in benzene (2 mL) was heated at reflux for 40 h with azeotropic removal of water. After allowing the reaction mixture to cool to room temperature, potassium carbonate (0.1 g) was added and the mixture was stirred for 10 min. Direct purification of the reaction mixture by flash chromatography using hexanes–ether (4:1) as the eluant afforded the title compound **8b** (332 mg, 83%) as a colourless gum. $[\alpha]_D^{20}$ –158 (*c* 1.70, chloroform). IR (ef) cm^{-1}: 1746, 1616, 1590, 1473, 1403, 1307, 1225, 1153, 1114, 1084. ^1H NMR (400 MHz, C_6D_6) δ: 1.82 (3H, s, C*H*$_3$), 2.28–2.44 (2H, m, ArCH$_2$C*H*$_2$), 2.63 (1H, ddd, *J* = 15.9, 8.5, 2.1 Hz, ArC*H*H), 2.72–2.83 (1H, m, ArCH*H*), 4.80 (1H, d, *J* = 8.5 Hz, PhC*H*), 5.17 (1H, d, *J* = 8.5 Hz, PhC*H*), 6.82 (1H, dd, *J* = 5.5, 2.7 Hz, Ar*H*), 7.09–7.12 (3H, m, Ar*H*), 7.13–7.19 (5H, m, Ar*H*), 7.34 (2H, m, Ar*H*), 7.40 (2H, m, Ar*H*). ^{13}C NMR (101 MHz, C_6D_6) δ: 20.9, 28.6, 39.2, 85.9, 87.0, 118.4, 121.9, 122.8, 127.0, 127.2, 128.6, 128.7, 128.8, 130.9, 133.3, 136.8, 137.9, 147.0, 148.1, 168.1. MS (MALDI-TOF) *m*/*z*: 409 (M + Na). Anal. calcd. for $C_{25}H_{22}O_4$: C 70.06, H 6.61; found: C 70.30, H 6.52.

7-Hydroxyindan-1-one (*S*,*S*)-stilbenediol acetal (4b) — Representative procedure for the preparation of chiral auxiliary 4a

To a solution of the acetate **8b** (91 mg, 0.24 mmol) in tetrahydrofuran (6 mL) and water (2 mL) was added lithium hydroxide monohydrate (50 mg, 1.2 mmol). The resultant opaque solution was stirred at room temperature for 40 h and then diluted with a saturated aqueous solution of ammonium chloride (25 mL) and extracted with dichloromethane (3 × 10 mL). The combined organic extracts were dried over anhydrous magnesium sulfate, filtered and concentrated to afford a pale orange oil. Purification by flash chromatography using hexanes–ether (4:1) as the eluant afforded the title compound **4b** (74 mg, 90%) as a white solid; mp 50–52 °C (hexanes–ether). $[\alpha]_D^{20}$ –100 (*c* 3.16, chloroform). ^1H NMR (400 MHz, C_6D_6) δ: 2.25 (1H, ddd, *J* = 12.8, 7.6, 3.7 Hz, ArCH$_2$C*H*H), 2.30–2.39 (1H, m, ArCH$_2$CH*H*), 2.67 (1H, ddd, *J* = 15.9, 8.2, 4.0 Hz, ArC*H*H), 2.71–2.80 (1H, m, ArCH*H*), 4.85 (1H, d, *J* = 8.2 Hz, C*H*Ph), 5.02 (1H, d, *J* = 8.5 Hz, CHPh), 6.58 (1H, s, O*H*), 6.68 (1H, d, *J* = 7.6 Hz, Ar*H*), 6.82 (1H, d, *J* = 8.2 Hz, Ar*H*), 7.01–7.19 (9H, m, Ar*H*), 7.26–7.30 (2H, m, Ar*H*). ^{13}C NMR (101 MHz, C_6D_6) δ: 28.9, 38.9, 85.9, 86.1, 114.7, 117.3, 119.6, 125.9, 126.7, 127.2, 128.3, 128.7, 128.8, 128.9, 132.1, 136.5, 138.3, 146.0, 154.7. IR (ef) cm^{-1}: 3446, 1619, 1598, 1469, 1317, 1166, 1123, 1047, 936, 745. MS (CI) *m*/*z*: 345 (M + H), 238. Anal. calcd. for $C_{23}H_{20}O_3$: C 80.21, H 5.85; found: C 80.02, H 5.97.

7-Acryloyloxyindan-1-one (*S*,*S*)-stilbenediol acetal (6b) from the chiral auxiliary 4b — Representative procedure for the preparation of Diels–Alder substrate 6a from the chiral auxiliary 4a

To a stirred solution of the chiral auxiliary phenol **4b** (80 mg, 0.23 mmol), in benzene (3 mL) at 0 °C was added triethylamine (39 μL, 0.28 mmol) and acryloyl chloride (23 μL, 0.28 mmol). After 2 h, the reaction mixture was allowed to warm to room temperature over 30 min. The resultant mixture was diluted with a saturated aqueous solution of ammonium chloride (25 mL) and extracted with dichloromethane (2 × 15 mL). The combined organic extracts were washed with brine (10 mL), dried over anhydrous magnesium sulfate, filtered and concentrated to afford a colourless gum. Purification by flash chromatography using hexanes–ether (5:1) as the eluant afforded the title compound **6b** (79 mg, 86%) as a white solid. An analytical sample of the product, as large colourless crystals, was prepared by recrystallization from hexanes–ether by slow evaporation; mp 82 to 83 °C (hexanes–ether). $[\alpha]_D^{20}$ –197 (*c* 1.98, chloroform). IR (ef) cm^{-1}: 1746, 1473, 1403, 1316, 1224, 1146, 1048, 751. ^1H NMR (400 MHz, C_6D_6) δ: 2.29–2.45 (2H, m, ArCH$_2$C*H*$_2$), 2.57 (1H, ddd, *J* = 15.6, 8.2, 1.8 Hz, ArC*H*H), 2.78 (1H, m, ArCH*H*), 4.80 (1H, d, *J* = 8.5 Hz, C*H*Ph), 5.14 (1H, d, *J* = 8.5 Hz, C*H*Ph), 5.18 (1H, dd, *J* = 10.4, 0.9 Hz, CH=C*H*H), 6.11 (1H, dd, *J* = 17.4, 10.4 Hz, C*H*=CH$_2$), 6.34 (1H, dd, *J* = 17.4, 1.1 Hz, CH=CH*H*), 6.82 (1H, d, *J* = 7.0 Hz, Ar*H*), 7.01–7.20 (10H, m, Ar*H*), 7.28 (2H, d, *J* =

7-Acryloyloxyindan-1-one (9)

To a stirred solution of 7-hydroxyindan-1-one (**5**) (1.00 g, 6.75 mmol) and triethylamine (1.0 mL, 7.2 mmol) in dichloromethane (15 mL) at 0 °C was added acryloyl chloride (0.60 mL, 7.4 mmol) over 5 min. The reaction mixture was then allowed to warm slowly to room temperature over 12 h. The resultant mixture was diluted with ether (50 mL) and washed with saturated aqueous solutions of ammonium chloride (2 × 10 mL) and sodium bicarbonate (2 × 10 mL), brine (10 mL), and water (10 mL). The organic layer was then dried over anhydrous magnesium sulfate, filtered and concentrated to afford a white solid. Purification by flash chromatography using hexanes–ether (3:2) as the eluant afforded the title compound **9** (1.27 g, 93%) as a white crystalline solid. An analytical sample of the product, as large colourless crystals, was prepared by recrystallization from hexanes–ether by slow evaporation; mp 83 to 84 °C (hexanes–ether). IR (ef) cm^{-1}: 1737, 1699, 1607, 1150. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.67 (2H, m, ArCH_2), 3.14 (2H, m, CH_2C=O), 6.06 (1H, dd, *J* = 10.4, 1.2 Hz, CH=C*H*H), 6.40 (1H, dd, *J* = 17.4, 10.4 Hz, C*H*=CH$_2$), 6.65 (1H, dd, *J* = 17.1, 1.2 Hz, CH=CH*H*), 7.03 (1H, d, *J* = 7.9 Hz, Ar*H*), 7.35 (1H, d, *J* = 7.6, Ar*H*), 7.59 (1H, m, Ar*H*). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 25.7, 36.8, 120.7, 124.5, 127.6, 128.8, 133.1, 135.9, 147.6, 157.0, 164.2, 203.6. MS (CI) *m*/*z*: 203 (M + H), 149. Anal. calcd. for $C_{12}H_{10}O_3$: C 71.28, H 4.98; found: C 71.26, H 4.95.

7-Acryloyloxyindan-1-one (3*S*,4*S*)-2,5-dimethyl-3,4-hexanediol acetal (6f) from the ketoester 9 — Representative procedure for the preparation of the Diels–Alder substrates 6a–6e from the ketoester 9

A stirred solution of the ketoester **9** (132 mg, 0.653 mmol), diol **3f** (16) (109 mg, 0.745 mmol), and *para*-toluenesulfonic acid monohydrate (7 mg, 0.04 mmol) in benzene (6 mL) was heated at reflux for 20 h with azeotropic removal of water. The reaction mixture was then allowed to cool to room temperature and potassium carbonate (0.2 g) was added. After 30 min, the resultant mixture was filtered and concentrated to afford a light brown oil (231 mg). Purification by flash chromatography using hexanes–ether (8:1) as the eluant afforded the title compound **6f** (173 mg, 80%) as a white crystalline solid; mp 83 to 84 °C (hexanes–ether). $[\alpha]_D^{20}$ –76 (*c* 0.78, tetrahydrofuran). IR (ef) cm^{-1}: 1750, 1617, 1591, 1471, 1403, 1316, 1254, 1232, 1225, 1153, 1048, 985, 799, 755. ^{1}H NMR (400 MHz, C_6D_6) δ: 0.94 (3H, d, *J* = 7.0 Hz, CH_3CH), 0.95 (3H, d, *J* = 6.7 Hz, CH_3CH), 1.01 (3H, d, *J* = 6.7 Hz, CH_3CH), 1.04 (3H, d, *J* = 6.7 Hz, CH_3CH), 1.60–1.69 (1H, m, C*H*CH$_3$), 1.76–1.86 (1H, m, C*H*CH$_3$), 2.08 (2H, dd, *J* = 5.5, 5.2 Hz, ArCH$_2$CH_2), 2.47 (1H, dt, *J* = 15.9, 5.5 Hz, ArC*H*H), 2.66–2.76 (1H, m, ArCH*H*), 3.56 (1H, dd, *J* = 8.2, 4.9 Hz, C*H*O), 3.79 (1H, dd, *J* = 8.2, 4.6 Hz, C*H*O), 5.36 (1H, dd, *J* = 10.4, 1.5 Hz, CH=C*H*H), 6.21 (1H, dd, *J* = 17.4, 10.1 Hz, C*H*=CHH), 6.46 (1H, dd, *J* = 17.4, 1.5 Hz, CH=CH*H*), 6.74 (1H, d, *J* = 7.6 Hz, Ar*H*), 6.91 (1H, d, *J* = 8.2 Hz, Ar*H*), 6.97–7.02 (1H, m, Ar*H*). ^{13}C NMR (101 MHz, C_6D_6) δ: 17.4, 17.7, 20.1, 20.4, 28.6, 30.5, 31.0, 39.3, 83.5, 84.4, 116.7, 121.8, 122.8, 128.8, 130.6, 131.5, 134.1, 146.8, 148.0, 163.8. MS (CI) *m*/*z:* 331 (M + H), 203, 183. Anal. calcd. for $C_{20}H_{26}O_4$: C 72.70, H 7.93; found: C 72.41, H 7.99.

7-((1*R*,2*R*,4*R*)-Bicyclo[2.2.1]hept-5-ene-2-carboxyl)indan-1-one (3*S*,4*S*)-2,5-dimethyl-3,4,-hexanediol acetal (10f) using diethylaluminum chloride as the Lewis acid and toluene as the solvent — Representative procedure for the Lewis acid-promoted Diels–Alder reactions

To a stirred solution of the acrylate **6f** (85 mg, 0.26 mmol) in toluene (7 mL) at –78 °C was added diethylaluminum chloride (1.0 mol/L in hexanes, 0.39 mL, 0.39 mmol) over 1 min. Cyclopentadiene (1.0 mL, 12 mmol) was added to the resultant solution. After 1 h, the reaction mixture was poured into a saturated aqueous solution of sodium bicarbonate (25 mL). The resultant mixture was extracted with dichloromethane (2 × 25 mL) and the combined organic extracts were washed with brine (10 mL), dried over anhydrous magnesium sulfate, filtered and concentrated to afford a pale yellow gum (112 mg). Purification by flash chromatography using hexanes–ether (10:1) as the eluant afforded an inseparable mixture of the title compound **10f** and a trace amount of the diastereoisomer **11f** (73 mg, 71%) as a colourless oil, which solidified on standing. As determined by analysis of the ^{1}H NMR (600 MHz) spectrum of the crude reaction product, the diastereoisomeric ratio of the products was 91:9 (**10f**:**11f**) and the endo:exo ratio of the major product **10f** was >98:2; mp 81 to 82 °C (hexanes–ether). $[\alpha]_D^{20}$ –39 (*c* 0.86, tetrahydrofuran). IR (ef) cm^{-1}: 1763, 1616, 1591, 1472, 1316, 1234, 1176, 1164, 1147, 1130, 1106, 1041, 755, 711. ^{1}H NMR (600 MHz, C_6D_6) (major diastereoisomer **10f**) δ: 0.97 (3H, d, *J* = 7.0 Hz, CH_3CH), 1.00 (3H, d, *J* = 7.0 Hz, CH_3CH), 1.03 (3H, d, *J* = 6.7 Hz, CH_3CH), 1.08 (1H, m, C*H*H-bridge), 1.12 (3H, d, *J* = 6.7 Hz, CH_3CH), 1.40 (1H, dq, *J* = 8.2, 1.8 Hz, CH*H*-bridge), 1.62–1.72 (1H, m, C*H*CH$_3$), 1.73–1.83 (2H, m, CH$_2$C*H*C=O), 1.83–1.95 (1H, m, C*H*CH$_3$), 1.99–2.12 (2H, m, ArCH$_2$CH_2), 2.46 (1H, ddd, *J* = 15.9, 7.9, 2.4 Hz, ArC*H*H), 2.67 (1H, broad s, C*H*-bridgehead), 2.69–2.79 (1H, m, ArCH*H*), 3.23–3.29 (1H, m, C*H*C=O), 3.41 (1H, broad s, C*H*-bridgehead), 3.60 (1H, dd, *J* = 7.9, 4.6 Hz, C*H*O), 3.90 (1H, dd, *J* = 7.9, 5.2 Hz, C*H*O), 6.13 (1H, dd, *J* = 5.6, 2.9 Hz, C*H*=CH), 6.17 (1H, dd, *J* = 5.7, 2.7 Hz, C*H*=CH), 6.75 (1H, dd, *J* = 7.5, 0.7 Hz, Ar*H*), 6.88 (1H, d, *J* = 7.9 Hz, Ar*H*), 7.02 (1H, m, Ar*H*). ^{13}C NMR (101 MHz, C_6D_6) (major diastereoisomer **10f**) δ: 17.5, 17.7, 20.2, 20.4, 28.6, 29.6, 30.7, 31.3, 39.3, 43.2, 43.9, 46.5, 50.1, 83.4, 84.6, 116.9, 122.0, 122.5, 130.4, 132.3, 133.8, 138.2, 146.7, 148.4, 172.1. 8. Wipf and co-workers have also reported that a derivative of an 8-hydroxytetral-1-one could not be condensed with 1,2-ethanediol. However, on protection of the phenol moiety as an acetate the desired reaction proceeded smoothly on using pyridinium *para*-toluenesulfonate (PPTS) as an acid catalyst, see: P. Wipf, J.K. Jung, S. Rodríguez, and J.S. Lazo. Tetrahedron, **57**, 283 (2001). The lack of reactivity of the carbonyl functional group of 7-hydroxyindan-1-one (**5**) could also be explained if it behaves as a vinylogous acid. Of note, the carbonyl stretch for 7-hydroxyindan-1-one (**5**) is at 1676 cm^{-1} and the carbonyl stretch for the acetate **7** is at 1710 cm^{-1}. This indicates that there is intramolecular hydrogen bonding in 7-hydroxyindan-1-one (**5**), but no significant enolization. Similarly, the hydroxyl stretch for 7-hydroxyindan-1-one (**5**), at 3364 cm^{-1}, is sharp.

13. The noncommercially available chiral nonracemic diol **3f** was prepared by Mr. M.P.A. Lyle from L-diethyl tartrate according to literature procedures, see: (*a*) X. Wang, S.D. Erickson, T. Iimori, and W.C. Still. J. Am. Chem. Soc. **114**, 4128 (1992); (*b*) D.S. Matteson, E.C. Beedle, and A.A. Kandil. J. Org. Chem. **52**, 5034 (1987).
14. In preliminary studies using the acrylate **6b** (R = Ph) and diethylaluminum chloride as the Lewis acid (~1 mol/L, hexanes, Aldrich) in which a small amount of white precipitate had been deposited in the reagent bottle, diastereoselectivities of 92:8 and combined yields of 85%–90% were consistently achieved when these reactions were performed in toluene. In the case of the acrylate **6e** (R = CH_2O(1-Np)), the diastereoselectivity of the reaction was 87:13 (74% yield). In efforts to duplicate these initial findings, experiments were performed using freshly prepared diethylaluminum chloride solutions (1.5 equiv.) in which aliquots of water (0.25–1.5 equiv.) were added. However, in these instances only slight increases in the diastereoselectivities of the reactions were observed (up to 86:14) for acrylate **6b** (R = Ph). Also, there was no significant change in the reaction yields. Methylalumoxane afforded adducts **10b** and **11b** (R = Ph) as a 68:32 mixture of diastereoisomers in 90% yield, see: M. Akakura and H. Yamamoto. Synlett, 277 (1997). The use of trimethylaluminum as a less active Lewis acid with acrylate **6b** (R = Ph) afforded the expected product in only ~25% yield (58:42 dr, endo:exo = 82:18). A more active Lewis acid, methylaluminum dichloride, also afforded the expected products (82:18 dr). In this case, it was not possible to determine the yield of the reaction because of co-eluting decomposition products. No reaction of this acrylate with cyclopentadiene was observed when aluminum trichloride was employed as the Lewis acid.

Thermodynamic properties of water in the water-poor region of binary water + alcohol mixtures

Karin Liltorp, Peter Westh, and Yoshikata Koga

Abstract: In our previous thermodynamic studies, we suggested that alcohol molecules in water-poor water + alcohol mixtures exist as alcohol clusters in a form similar to the pure alcohols. Here, we use calorimetry and densitometry to investigate how H_2O interacts with alcohol clusters in water-poor binary aqueous mixtures of 12 different alcohols. The composition dependence of the measured excess partial molar enthalpy and volume of water (H_W^E and V_W^E), along with entropy data calculated from H_W^E and literature data for excess chemical potentials, showed that in water-poor solutions of small alcohols such as methanol, ethanol, and 1-propanol, mutual water–water interactions are endothermic, but entropically favorable. Conversely, in long-chain solvents such as 1-octanol and 1-decanol, the interaction is exothermic and entropically unfavorable. We suggest that these observations reflect water–alcohol hydrogen bonding in short-chain solvents and water clustering with more hydrogen bonding than in pure water or "dewetting" in mixtures of the longer alcohols, respectively. The composition dependence of H_W^E was also used to locate anomalies that specify the boundary between the mixing schemes characterizing the intermediate and the water-poor regions of alcohol + water mixtures.

Key words: aqueous alkane-mono-ols, excess partial molar enthalpy, entropy and volume, mixing schemes.

Résumé : Dans des études thermodynamiques antérieures réalisées dans ces laboratoires, il a été suggéré que les molécules d'alcool dans des mélanges eau + alcool pauvres en eau existent sous la forme d'agrégats d'alcool semblable à celle qu'on retrouve dans les alcools purs. Dans ce travail, on fait appel à la calorimétrie et à la densitométrie pour étudier la façon dont H_2O interagit avec les agrégats d'alcool dans des mélanges aqueux binaires pauvres en alcool de douze alcools différents. La relation qui existe entre la composition et l'enthalpie molaire partielle en excès et le volume d'eau (H_W^E et V_W^E) ainsi que les données d'entropie calculées à partir des valeurs de H_W^E obtenues à partir de la littérature et les données de la littérature relatives aux potentiels chimiques en excès ont montré que dans des solutions pauvres en eau de petites molécules d'alcool, telles le méthanol, l'éthanol et le propan-1-ol, les interactions sont endothermiques, mais favorables d'un point de vue entropique. Par ailleurs, dans des solvants à longue chaîne, tels l'octan-1-ol et le décan-1-ol, l'interaction est exothermique mais défavorisée d'un point de vue entropique. Il est suggéré que ces observations sont un reflet respectivement des liaisons hydrogènes eau–alcool dans les solvants à courte chaîne et de l'agrégation de l'eau avec plus de liaison hydrogène que dans l'eau pure ou d'une « déshydratation » dans les mélanges impliquant des alcools à plus longues chaînes. On a aussi utilisé la relation de dépendance entre la composition et le H_W^E pour localiser les anomalies qui déterminent la frontière entre les schémas de mélange et qui caractérisent les régions intermédiaires et les pauvres en eau des mélanges eau + alcool.

Mots clés : alcane-monoalcools aqueux, enthalpie molaire partielle en excès, entropie et volume, schémas de mélange.

[Traduit par la Rédaction]

Introduction

Aqueous mixtures of small alcohols have been extensively studied, and they continue to be one of the most important model systems for the fundamental elucidation of the hydrophobic effect, and thus for the understanding of biomolecular self-assembly. The vast majority of these studies address dilute (water-rich) alcohol solutions in which the drive towards expelling hydrophobic solutes is large, and hence the characteristics of hydrophobicity are readily studied. However, an increasing amount of biochemical information suggests that water-poor model systems might also be important. Thus, the living cell is "crowded" with macromolecules and solutes (1, 2) to the extent where most water is surface associated, and thus has properties that are likely to be different from those of bulk water or dilute solutions. Another interesting aspect comes from recent research that has questioned the conventional wisdom of the so-called "bound" water. It has been shown that water at biopolymer interfaces may be characterized by high mobility and (or) high entropy (3–7), in obvious conflict with the properties expected for a bound molecule. To account for these and similar observations it has been speculated that water is a "plasticizer" (8, 9) or "lubricant" (10), which promotes fast

dynamics, and hence the function of biopolymers and biomolecular aggregates. Such effects are to be understood in terms of direct (or "contact") interactions of water and the biomolecules, and they are not readily elucidated by water-rich model systems, in which strong solute-induced changes in mutual water interactions, sometimes denoted "iceberg formation" (11), dominate solution properties. Such cooperative changes in water–water hydrogen bonding will vanish at low water concentration, and the thermodynamic properties in this composition range might consequently more clearly provide information on direct interactions of water and organic nonelectrolytes.

We have previously used aqueous solutions of alkane-mono-ols (AL) as model systems in an attempt to elucidate molecular interactions in aqueous mixtures. As summarized in review articles (12–14), we have found that there are three distinctive composition regions in each of which the mixing scheme is qualitatively different from the other regions. Starting from the water-rich side, we named them Mixing scheme I, II, and III, respectively. Details of each mixing scheme were discussed earlier (11–17). In the water-poor region in particular, AL molecules form clusters with structures and properties similar to the pure alcohol. Water molecules, on the other hand, interact with the AL clusters in a manner depending on the identity of the alcohol. These conclusions were deduced from the excess partial molar quantities of the alcohols, H^E_{AL}, S^E_{AL}, and V^E_{AL}, and the composition derivatives of these quantities

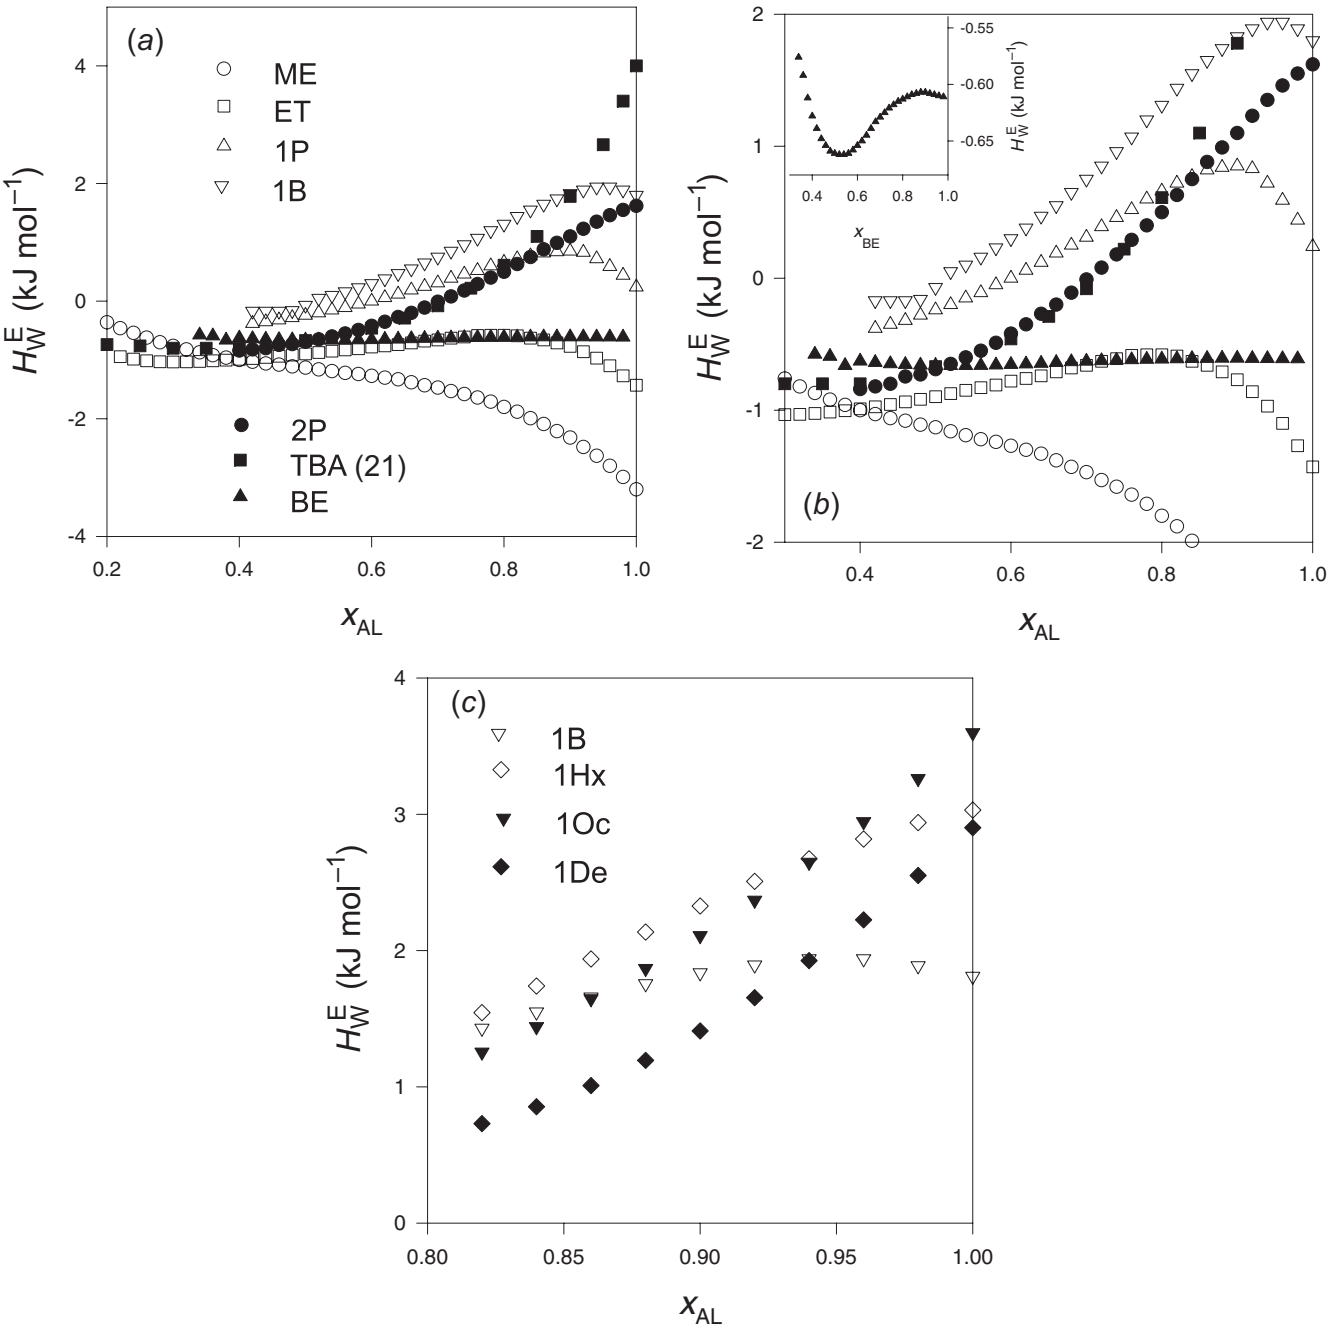
$$[1] \qquad F^E_{AL-AL} \equiv N\left(\frac{\partial F^E_{AL}}{\partial n_{AL}}\right) = (1 - x_{AL})\left(\frac{\partial F^E_{AL}}{\partial x_{AL}}\right) \qquad (F = H, S, \text{ or } V)$$

The H^E_{AL-AL} function, for example, reflects the effect of incoming AL on the enthalpic situation of an existing AL in solution. Hence, H^E_{AL-AL} signifies the enthalpy change generated by mutual AL interactions. A positive sign for H^E_{AL-AL}, which has been generally found for dilute aqueous solutions, shows that AL–AL interactions act to increase H^E_{AL}, i.e., that mutual AL interactions are endothermic in the sense that they are energetically less favorable than the mixed AL–water interaction. Analysis of H^E_{AL-AL} data was the key information that led to the details of the mixing scheme in the water-rich region. In particular, some anomalous behaviors of H^E_{AL-AL} and of the analogous functions for excess entropy and volume were instrumental in locating the boundary between Mixing schemes I and II. In the water-poor region, however, the absolute values of H^E_{AL} and other excess partial molar functions of AL and their composition derivatives were found to be almost zero, which indicated that AL molecules exist as clusters purely consisting of AL molecules as in their pure state (11–18). Because the values of the excess partial molar quantities of AL are nearly zero and constant, the resulting values of H^E_{AL-AL} and its entropy and volume analogues in the water-poor region are therefore almost zero, and possible anomalies are rather difficult to identify. In contrast, the excess partial molar enthalpy of water (H^E_W) together with other partial molar quantities of water are expected to be sizable in this range, which of course contains thermodynamic information as to how water molecules interact with AL clusters. It follows that measurements of H^E_W and subsequent analysis with respect to the function,

$$[2] \qquad H^E_{W-W} \equiv N\left(\frac{\partial H^E_W}{\partial n_W}\right) = (1 - x_W)\left(\frac{\partial H^E_W}{\partial x_W}\right)$$

which is analogous to the AL–AL interaction function in eq. [1], could identify anomalies more conspicuously, and consequently shed some light on the mixing schemes in the water-poor composition range.

In the light of this, we have conducted a series of this type of measurements in the water-poor region and a number of parallel investigations on the volumetric behavior of the same systems. Here, we report these results and discuss the mode of interactions of water molecules with AL clusters, and the mixing scheme boundaries in the water-poor composition region.



Experimental

The alcohols used as solvents were methanol (ME, 99.9%, Fluka), ethanol (ET, 99.8%, Fluka), 1-propanol (1P, 99.8%, Fluka), 2-propanol (2P, 99.5%, Sigma, St. Louis, Missouri), 1-butanol (1B, 99.9%, Merck, Darmstadt, Germany), 1-pentanol (1Pe, 8.5%, Merck), 1-hexanol (1Hx, 99%, Fluka), 1-octanol (1Oc, 99.5%, Fluka), 1-decanol (1De, 99.5%, Fluka), 2-butoxyethanol (i.e., ethylene glycol monobutyl ether) (BE, 99.5%, Sigma), and glycerol (Gly, 99.5%, Merck). A spot check by an analytical gas chromatograph equipped with mass spectroscopy, indicated the purity quoted by the supplier were correct. Due care was exercised in handling all the alcohol samples so as not to contaminate them with moisture. Water was freshly prepared using MilliQ equipment (Millipore, Bedford, Mass.). For ethanol–water, the calorimetric data were retrieved on a home-made instrument similar to the LKB Bromma 8700 (18). The uncertainty of this data is ±30 J mol^{-1}. All other calorimetric measurements were conducted on a TAM 2277 isothermal calorimeter (Thermometric, Järfälla, Sweden), equipped with a nW amplifier module. Type 2250 titration modules (Thermometric) with a 1 mL stainless steel cell and a gold stirrer were used. The cell initially contained pure alcohol quantified by weight, which was subsequently titrated with 1 µL aliquots of water. The experimental scatter upon repeated injections of water ranged from ±5 J mol^{-1} for the smaller water miscible alcohols to about ±50 J mol^{-1} for the most hydrophobic solvents. All calorimetric measurements were made at 25.0 °C. For the large alcohols (1Pe, 1Hx, 1Oc, and 1De), the measurements were limited to the composition region, $x_{AL} > 0.8$, since near the phase separation, the rate of dissolution becomes too slow for the determination of H^E_W within the stated uncertainty.

The densities of the alcohol–water mixtures were determined in a DMA 602 vibrating tube measuring cell (Anton Parr, Graz, Austria). The measuring cell was built into a set-up allowing automated cycles of "titrate–mix–measure" (19). In the present work, samples of pure alcohol (about 7 mL) were weighed in the instrument mixing cell and titrated with a number of 10 µL aliquots of pure water. For the most hydrophobic alcohols, this method showed increased scatter, probably because of incomplete mixing. Thus, for

these systems, parallel trials were made in which samples were prepared manually by weight and stirred for 24–48 h prior to density measurements. As discussed in the following, this method of mixing seems satisfactory. The experimental temperature was 25.000 ± 0.005 °C. The equipment was calibrated against air and pure water, and the experimental repeatability was $\pm 5 \times 10^{-6}$ g cm^{-3}.

Results

Calorimetry

Measured values of H_W^E dissolved in ME, ET, 1P, 2P, 1B, 1Hx, 1Oc, 1De, BE, and Gly are listed in Table A1.[2] Based on these data and the literature values of the excess chemical potential of water (μ_W^E) (16, 20), the excess partial molar en-

tropy of water × temperature (TS^E_W) can be calculated using $TS^E_W = H^E_W - \mu^E_W$. We used values of H^E_W and μ^E_W read off smooth curves at a mol fraction interval of 0.02. The resulting TS^E_W data are listed in Table A2[2], together with the smooth values of H^E_W and μ^E_W. Data from the calorimetric measurements are plotted in Fig. 1 together with those for *tert*-butanol (TBA) determined earlier (21). The derived TS^E_W values are plotted as a function of x_{AL} in Fig. 2. It is clear from Figs. 1 and 2 that the values of H^E_W and TS^E_W have some modest dependence on x_{AL} in this water-rich region, though certainly not as much as H^E_{AL} and TS^E_{AL} in the water-rich end.

For some of the systems, where data for both H^E_W and H^E_{AL} are available in an extended concentration range, the consistency of the measurements can be tested against the Gibbs–Duhem relation

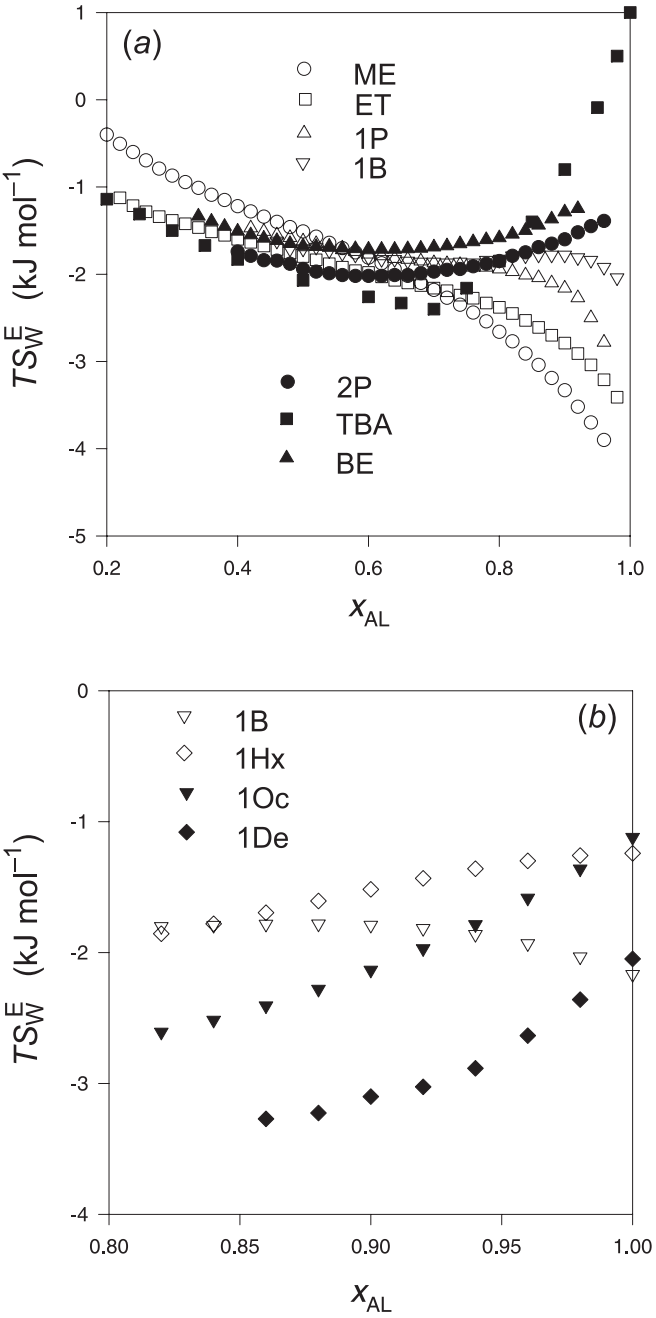
$$[3] \qquad x_{AL}\delta H^E_{AL} + x_W H^E_W = 0$$

From the previous H^E_{AL} data (17, 22), the Gibbs–Duhem sums (left hand side of eq. [3]) were calculated at increments of $\delta x_{AL} = 0.02$ for ME, ET, 1P, 2P, and BE. The resulting sums are within ±0.003 kJ mol^{-1} with a few sporadic exceptions of ±0.01 kJ mol^{-1}. Considering the experimental uncertainties, we conclude that the Gibbs–Duhem consistency is satisfactory.

The quality of the present measurements was further tested by calculating the excess (integral) molar enthalpy (H^E_m)

$$[4] \qquad H^E_m = x_{AL}H^E_{AL} + x_W H^E_W$$

from H^E_W measured here and previously published values of H^E_{AL} for ME, ET, 1P, 2P, and BE (17, 22). The calculated H^E_m values were compared with previously published data (17, 22–31) and it was found that the current results fell within the scatter of the literature values. We point out that this analysis only serves to check the reliability of the current methodology. The H^E_W needed for the present discussion cannot be derived with sufficient precision from the literature data on H^E_m (32). The values of H^E_W and TS^E_W at infinite dilution ($x_{AL} \to 1$) are listed in Table 1 for comparison together with the available literature data for H^E_{AL} and TS^E_{AL} for $x_{AL} \to 0$.



Density measurements

The measured density data for the water-poor solutions of ME, ET, 1P, 1B, 1Pe, 1Hx, 1Oc, 1De, and BE are listed in Table A3.[2] Figure 3 shows the representative data illustrated as the excess molar volumes of the mixtures (V^E_m) plotted against the mol fraction of the alcohol (x_{AL}). The excess volumes are calculated as:

$$[5] \qquad V^E_m = V_m - x_{AL}V^*_{AL} - x_W V^*_W$$

where V_m is the measured molar volume and the asterisk signifies pure liquid (water or alcohol). For small alcohols, the match with the literature data (33–38) is acceptable within the respective uncertainties. In the subsequent analysis, we use the literature data since the latter cover wider composition ranges. For 1Hx, 1Oc, and 1De, however, the existing data (39) for V^E_m are scattered by about 10-fold of our data shown in Fig. 3. For these alcohols, therefore, we used our data for further analysis.

Fig. 2. Excess partial molar entropy of water × the temperature (TS^E_W) at 25 °C calculated from the literature μ^E_W values and the H^E_W values measured in this work. (*a*) For shorter alcohols; (*b*) For longer alcohols.

The excess molar volume reflects changes in "free volume" (or molecular packing) when a mixture is made from its constituents in their standard (pure) state. The results in Fig. 3 confirm earlier observations (40) that the dissolution of water in small alcohols is accompanied with increased packing ($V^E_m < 0$), and that this negative volume change tapers off as the chain length of the solvent increases. For ME, ET, 1P, and 1B, V^E_m is a weakly concave function. However,

Fig. 3. Measured (this work) excess molar volume of aqueous alcohols (V^E_m) at 25 °C.

for alcohols larger than BE, V^E_m becomes small and is practically linear in the mol fraction. To further analyze this volumetric behavior, we calculated the excess partial molar volume of AL ($V^E_{AL} = V^E_m + (1 - x_{AL})(dV^E_m/dx_{AL})$), and that of water ($V^E_W = V^E_m - x_{AL}(dV^E_m/dx_{AL})$). The slope ($dV^E_m/dx_{AL}$) was determined from the smooth curves.

The results are shown in Fig. 4 for V^E_{AL} and in Fig. 5 for V^E_W. It is clear that V^E_{AL} is generally very small in this region. Earlier, we suggested from the H^E_{AL} and S^E_{AL} data (11–18) that alcohols form clusters in a form similar to pure AL in the water-poor region. The fact that the V^E_{AL} values are close to zero (Fig. 4*b*) is consistent with this cluster formation, particularly so for large alcohols (Fig. 4*b*). Figure 5*a* provides a general overview of V^E_W based primarily on literature data (34–38), while Fig. 5*b* shows a close-up of the most water-poor range in solutions of 1B, 1Hx, 1Oc, or 1De. Table 1 lists the respective V^E_{AL} and V^E_W data at their respective infinite dilutions. It appears that the limiting value of V^E_W for small alcohols (ME, ET, 1P, and 2P) is about –3 to –4 cm^3 mol^{-1}. In other words, water is about 20% more densely packed in small alcoholic solvents than in pure water (V^*_W = 18.07 cm^3 mol^{-1}). If H_2O was considered to be a van der Waals liquid, its molar volume would be about 12 cm^3 mol^{-1}, assuming that a water molecule is a sphere of radius 1.5 Å

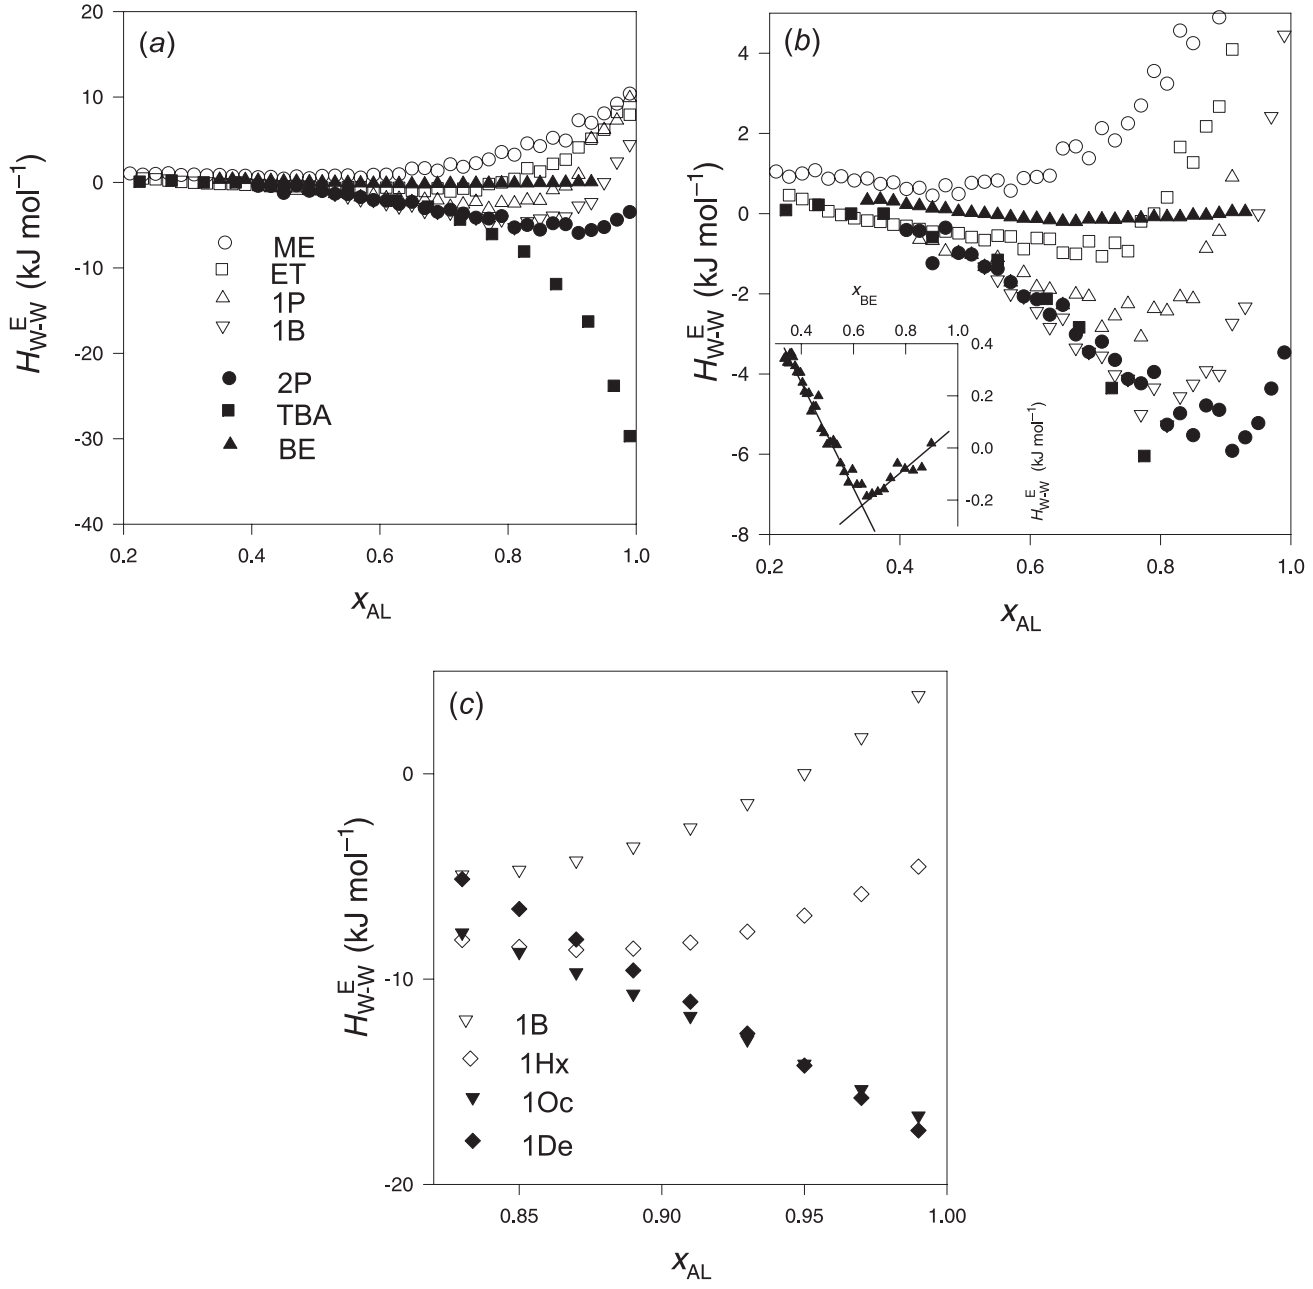
using the van der Waals radii of H and O atoms (41), and assuming close packing. For water dissolved in longer alcohols, on the other hand, V^{E}_{W} gradually becomes less negative, and for the most hydrophobic solvents it is practically zero. This suggests that the packing density of water in hydrophobic alcohols deviates only a percent or so from the pure state.



Discussion

Mixing scheme boundaries

As pointed out elsewhere (12–14) and in references quoted therein, comparative analysis of the higher order derivatives of the excess Gibbs energy is a powerful technique for detecting subtleties of molecular interactions in solutions. In particular, we have found that classification of the observed thermodynamic behavior according to the specific mixing schemes, reflecting characteristic modes of interactions, or "solution structures" is most helpful in singling out important general effects in aqueous solutions. In most aqueous alcohol solutions, changes in mixing schemes have been identified from the composition dependence of the AL–AL interaction (H^{E}_{AL-AL}), eq. [1], and its entropy and volume analogues. The same is true for aqueous nonelectrolytes in

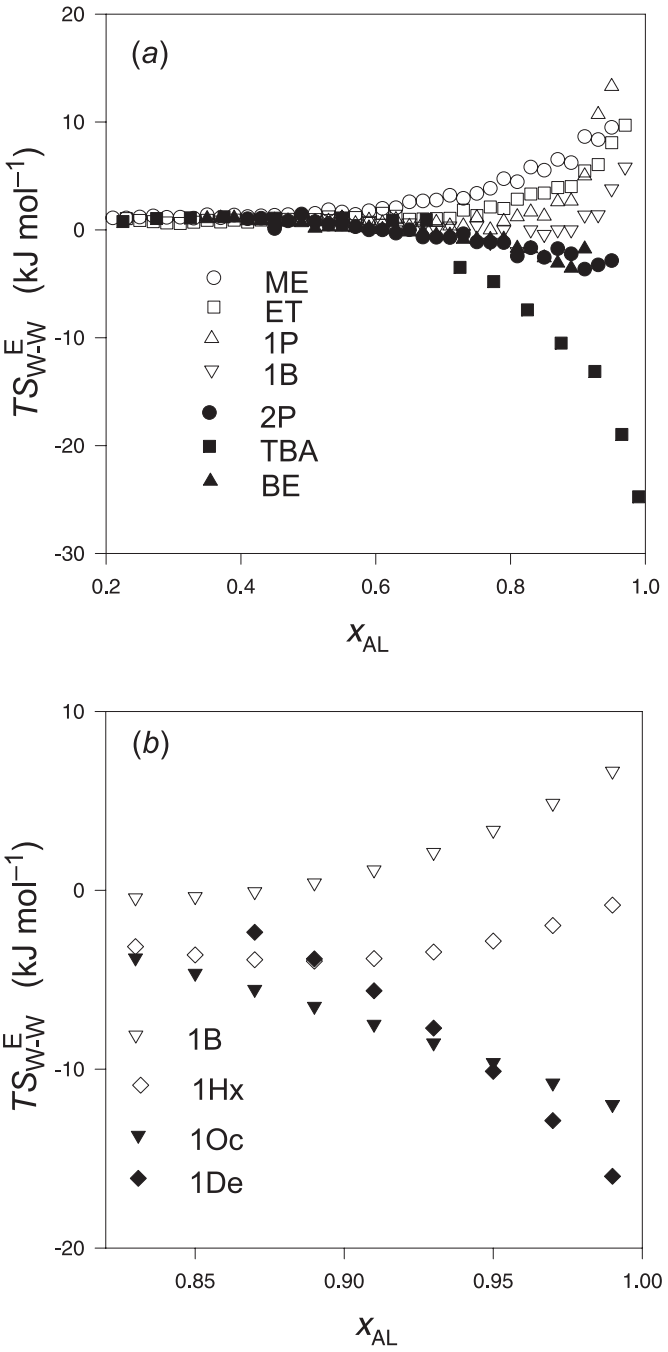
Fig. 6. (*a*) H_2O–H_2O interaction in terms of enthalpy (H^E_{W-W}) at 25 °C. (*b*) Expanded version of panel (*a*). (*c*) The same for larger alcohols. The inset in (*b*) is further expanded for BE.



general (12–14). However, the data of H^E_{AL} and H^E_{AL-AL} are also inevitably small in their absolute values in the water-poor composition range, and it follows that H^E_W (measured in this work) and other partial molar quantities of water are potentially more sensitive parameters to identify changes in mixing schemes. Hence, the data in Figs. 1 and 2 have been used to reappraise previous discussions of mixing scheme boundaries in aqueous alcohols.

For this purpose, we calculated H^E_{W-W} using a smooth curve in Fig. 1 and the approximation ($\partial H^E_W/\partial x_W \approx \delta H^E_W/\delta x_W$) with $\delta x_W = 0.02$. The results are plotted in Fig. 6 and the data for the analogous entropy interaction function is given in Fig. 7. For ME, ET, 1P, 1B, and BE, H^E_{W-W} starts with a positive value, but decreases on increasing x_W, and reaches a minimum and starts to increase (Fig. 6). This minimum is the inflection point of the H^E_W vs. x_{AL} curve in Fig. 1, which corresponds to the boundary between Mixing schemes II and III. Best estimates for the location of this boundary are listed in Table 2. In general, the minimum in H^E_{AL-AL} is rather broad and it is difficult to pinpoint its location. However, the current method is much more reliable than identifying an anomaly from the H^E_{AL-AL} function, since the absolute values of the latter are close to zero (17). For 2P, although the value of H^E_{W-W} starts negative at $x_{AL} = 1$ ($x_W = 0$), it decreases as x_W increases to the minimum, and then increases just as for the other *n*-alkanols. For TBA, H^E_{W-W} in Fig. 6 in-

© 2005 NRC Canada

creases smoothly to the maximum at about x_{TBA} = 0.05, which is the boundary between Mixing schemes I and II. Thus, there seems to be no sign of Mixing scheme III in terms of H^E_{W-W} for TBA. In Fig. 7, however, TS^E_{W-W} shows a sharp bend at about x_{TBA} = 0.62, which was argued to be the transition point between Mixing schemes II and III (42). This sharp bend in TS^E_{W-W} comes from a sharp bend at about x_{TBA} = 0.6 in μ^E_W obtained from the vapor pressure data (42). At x_{TBA} = 0.6, the TBA–H_2O system has an azeotrope, at which the data analysis used in the original paper (42) becomes difficult. A method of circumventing difficulties associated with azeotropy was subsequently developed (16), and its application to TBA–H_2O is warranted. Until such reexamination, we postpone any conclusion in this regard.

Table 2. Loci of the boundary in x_{AL} between Mixing schemes II and III for aqueous alcohols at 25 °C.

AL	From H^E_{W-W} (this work)	From H^E_{AL-AL} (ref. 15)
ME	0.47	0.54
ET	0.68	0.38
1P	0.74	0.30
2P	0.88	0.19
1B	0.80	
TBA	?	0.62[a]
BE	0.63	0.43

[a]The value of 0.38 quoted in ref. 15 is the value of x_W, not that of x_{AL}.

Interactions of water in the water-poor region

As discussed in the Introduction, there is some interest in the interrelationships of solvent hydrophobicity and the properties of water at high dilution (i.e., for $x_{AL} \rightarrow 1$). One straightforward approach to this is a comparison of the data for excess partial molar enthalpy, entropy, and volume of water at infinite dilution compiled in Table 1. Several interesting features can be identified from these data. Comparing, for example, the series of 1-alkanols, reveals that the H^E_W increases gradually with the alkyl chain length of the solvent, from –3 kJ mol^{-1} for ME to about +3 kJ mol^{-1} for 1Hx, 1Oc, and 1De. This course may seem intuitive for highly polar water molecules, which must (*a*) break away from mutual interactions, and (*b*) disperse into increasingly nonpolar environments, with limited capacity for establishing favorable interactions. While of some relevance, this picture turns out to be an oversimplification as discussed in more detail in the following. The competing thermodynamic effect of each of the two processes (*a*) and (*b*) must be an order of magnitude larger than the net result of a few kJ mol^{-1}. For example, the enthalpy of vaporization for alcohols is known to be about 50 kJ mol^{-1}. Hence, subtle differences for each alcohol in the energetics of each step (*a*) and (*b*) may result in a sizable difference in the net result. Thus, comparison among alcohols at the H^E_W or TS^E_W level must be exercised with caution. The relative changes in these quantities within the same alcohol, on the other hand, may be safer parameters to discuss the detailed molecular interactions. In the following, we use the relative changes in these quantities on changing the mol fraction, i.e., H^E_{W-W}, eq. [2], and TS^E_{W-W} extensively.

Another interesting trend to note in Table 1 is that V^E_W increases from large negative values in small solvents (ME, ET, 1P, and 2P) and levels off at a value near zero for more hydrophobic solvents such as 1Hx, 1Oc, and 1De.

To assess the characteristic properties of water more specifically in a predominantly nonpolar environment, we now focus on four of the more hydrophobic solvents, 1B, 1Hx, 1Oc, and 1De. Volumetric properties of dilute solutions of water in these solvents are presented in Figs. 4*b* and 5*b*. The calorimetric data for these systems is illustrated in Fig. 1*c*. Figure 2*b* shows TS^E_W calculated from the literature data for the excess chemical potential (16, 20). Based on the data in

© 2005 NRC Canada

Figs. 1*c* and 2*b*, the enthalpy and entropy interaction functions (H^E_{W-W} and TS^E_{W-W}) were calculated (eq. [2]) and are plotted in Figs. 6*c* and 7*b*. The results show that in 1B, H^E_{W-W} is positive at the highest x_{AL} values, but changes sign around x_{AL} = 0.95. This behavior resembles that of water dissolved in smaller alcohols (see Figs. 6*a* and 7*a*), and suggests that at very low water concentrations, mutual water interactions are less favorable in terms of enthalpy than water–alcohol interactions. Upon addition of more water, this picture changes H^E_{W-W} (becomes more negative) and water–water interactions become more enthalpically favorable. For water in 1Hx, H^E_{W-W} is slightly negative even at x_{AL} = 1, and for still longer alcohols, H^E_{W-W} attains sizable negative values in the most water-poor samples. This signifies that the first water molecules, on entering the alcohol, exhibit mutual interactions that are strongly enthalpically favored over water–alcohol contacts. The composition dependence of TS^E_{W-W} shown in Fig. 7 follows a very similar pattern, taking into account the opposite sign for the stability criterion. Thus, for water–1B, TS^E_{W-W} is positive in very water-poor samples, but changes sign around x_{AL} = 0.88. In other words, mutual water interactions are entropically favored over water–alcohol contacts for $x_{AL} > 0.88$. For the higher alcohols shown in Fig. 7*b*, TS^E_{W-W} remains negative over the investigated composition range, suggesting that water–water interactions bring about a decrease in entropy, i.e., that they are entropically unfavorable.

These observations may be rationalized in terms of a balance or a competition between strong alcohol–water interactions predominantly in mixtures of small alcohols and, on the one hand, the formation of water clusters more organized than in pure water predominantly in large alcohols. Thus, we suggest that the formation of water clusters around the alcohol -OH groups even in very water-poor mixtures becomes increasingly important as the solvent alkyl chain becomes longer (and the average distance between -OH groups increases). In 1Oc and 1De, this sequestering of water is associated with strong negative TS^E_{W-W} and H^E_{W-W} values (Figs. 6 and 7), which reflect ordering of water into more organized clusters with favorable enthalpic, but entropically unfavorable water–water interactions. In smaller alcohol solvents with a higher density of -OH groups, positive TS^E_{W-W} and H^E_{W-W} values probably reflect polar interactions of the alcohol hydroxyl group and a single molecule of water. This conclusion is supported by the volume data. In general, the volume behaviour of AL + water in the water-poor range is governed by a balance between a volume increase of organized clusters and a decrease by the direct interaction of a single molecule of water with AL clusters. For the larger alcohols (1Hx, 1Oc, 1-De), the remarkable composition independence of V^E_W (Figs. 4 and 5) suggests that the former effect is much larger. We point out that this organized clustering may be closely related to the so-called "dewetting" near large hydrophobic surfaces (43).

The suggestion that putative organized water clusters form primarily around the large alcohol -OH group is supported by data on the solubility of water in nonpolar solvents. Water is rather soluble in long-chain 1-alkanols and interestingly, the solubility becomes independent of the size of the alkyl group for solvents larger than 1-heptanol. Hence, the mol fraction of water at saturation remains at about 0.25 (x_{AL} = 0.75) for C8, C9, C10, C11, and C12 1-alkanols (44). For comparison, the solubility of water in normal alkanes, such as hexane, is almost three orders of magnitude smaller (45). The solubility data stress the importance of the -OH group and to reconcile this with the present observations, we suggest that the properties of water-poor aqueous solutions of long-chain 1-alkane-mono-ols are governed by the formation of (short-lived) organized clusters around the alcohol hydroxyl group. A similar conclusion was recently reached by Segatin and Klofutar (39).

Conclusions

We suggest that in the water-poor region of water + alcohol mixtures, alcohol molecules form clusters, presumably with -OH groups pointing outwards. Water molecules, on the other hand, interact with the -OH groups of alcohol clusters predominantly as single molecules for small alcohols. The H_2O–H_2O interaction is enthalpically repulsive and entropically favorable for small alcohols. As the alkyl group becomes larger, this interaction weakens to almost zero for BE. For even larger alcohols such as 1De, water molecules tend to cluster together in a more organized manner than in pure H_2O around the -OH groups of AL clusters.

In the Introduction we argued that information on the direct interaction of water and nonpolar molecules may be relevant for a number of biochemically important processes. Examples include the permeation of water through bilayer membranes and the roles of water bound to amphiphilic surfaces of biomolecules. We suggest here that some fundamental information on this may be derived from studies of water-poor aqueous alcohols. The present work concludes that even in 1-decanol, whose accessible surface area is dominated by the nonpolar alkyl chain, the properties of water around the hydroxyl group may be governed by the formation of clusters with more hydrogen bonds than in pure water. This behavior of water at low concentrations may be highly relevant for the understanding of some of its roles in biochemistry and indeed for the general elucidation of ubiquitous "hydrophobic interactions" among biomolecules. However, since clustering will reduce water – alkyl chain contacts, it may very well disqualify long-chain alkanols as model compounds for studies of "contact interactions" between water and hydrophobic interfaces, if the concept of contact interactions is important at all.

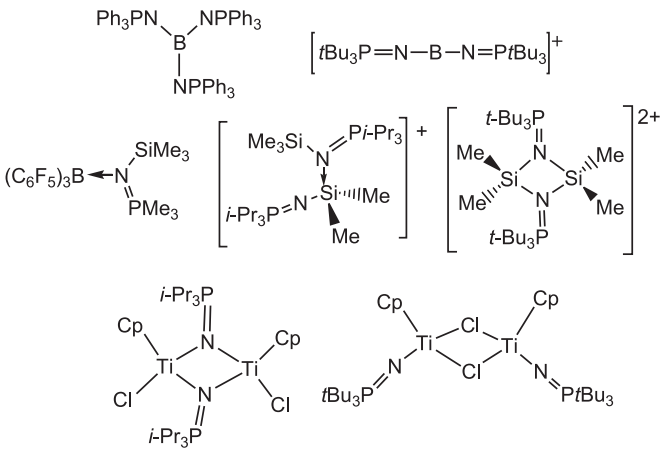
Homoleptic magnesium bis-phosphinimide derivatives

Emily Hollink, Pingrong Wei, and Douglas W. Stephan

Abstract: The homoleptic Mg-phosphinimide complexes $Mg_2(\mu\text{-NP-}t\text{-Bu}_3)_2(\text{NP-}t\text{-Bu}_3)_2$ (**1**) and $Mg_3(\mu\text{-NP-}i\text{-Pr}_3)_4(\text{NP-}i\text{-Pr}_3)_2$ (**2**) were obtained from the reaction of 2 equiv. of the phosphinimines $HNPR_3$ (R = *t*-Bu, *i*-Pr) with $MgBu_2$. Spectroscopic and crystallographic studies confirmed the dimeric and trimeric structures of compounds **1** and **2**, respectively.

Key words: magnesium, phosphinimides, homoleptic, crystal stuctures.



Résumé : On a obtenu les complexes homoleptiques Mg-phosphinimides $Mg_2(\mu\text{-NP-}t\text{-Bu}_3)_2(\text{NP-}t\text{-Bu}_3)_2$ (**1**) et $Mg_3(\mu\text{-NP-}i\text{-Pr}_3)_4(\text{NP-}i\text{-Pr}_3)_2$ (**2**) par réaction de 2 équiv. des phosphinimides $HNPR_3$ (R = *t*-Bu, *i*-Pr) avec du $MgBu_2$. Les études spectroscopiques et cristallographiques ont permis de confirmer la nature dimère et trimère des structures des composés **1** et **2**, respectivement.

Mots clés : magnésium, phosphinimides, homoleptique, structures cristallines.

[Traduit par la Rédaction]

Introduction

Main group derivatives of phosphinimine and phosphinimide ligands have been investigated and a large number of species have been structurally characterized. Much of the early work was reviewed by Dehnicke and Weller (1). In more recent studies of such species, we have prepared cationic silicon, germanium, tin, aluminum, and boron derivatives (2–4). Marked structural changes for phosphinimide derivatives as a result of steric effects have been previously seen for both main group and transition metal derivatives. For example, in the reactions of the phosphinimines with $B(C_6F_5)_3$, simple adducts, mono and dicationic species such as $Me_3PN(SiMe_3)\cdot B(C_6F_5)_3$, $[R_3PNSiMe_2(N(PR_3)SiMe_3)][MeB(C_6F_5)_3]$ (R = *i*-Pr, Ph), and $[((\mu\text{-}t\text{-}Bu_3PN)SiMe_2)_2][MeB(C_6F_5)_3]_2$ were characterized (2). In a similar sense, steric effects played a role in the formation of the linear cationic B species $[(t\text{-}Bu_3PN)_2B]^+X^-$, regardless of the ligand to boron stoichiometry used in the reaction (3). This stands in contrast to the species $B(NPPh_3)_3$, where the sterically less demanding phosphinimide accommodates a trigonal planar geometry at boron (5). One example of such steric effects in transition metal – phosphinimide complexes is represented by the contrasting structures of the Ti(III) species $[CpTi(\text{NP-}t\text{-}Bu_3)(\mu\text{-Cl})]_2$ and $[CpTiCl(\mu\text{-NP-}i\text{-}Pr_3)]_2$ (6). In this note, we probe the related steric effects for Mg-phosphinimide species. Herein, we report the first homoleptic Mg-phosphinimide complexes, $Mg_2(\mu\text{-NP-}t\text{-}Bu_3)_2(\text{NP-}t\text{-}Bu_3)_2$ and $Mg_3(\mu\text{-NP-}i\text{-}Pr_3)_4(\text{NP-}i\text{-}Pr_3)_2$ to be characterized. Preliminary examinations of the reactivity of these species are also reported.

Experimental section

All syntheses were performed employing an atmosphere of dry, oxygen-free nitrogen in a Vacuum Atmospheres inert atmosphere glovebox using oven-dried (140 °C) glassware unless otherwise stated. ^{1}H NMR data were acquired on a Bruker Avance 500 MHz spectrometer, while ^{13}C and ^{31}P NMR data were obtained from a Bruker Avance 300 MHz spectrometer. ^{1}H and ^{13}C NMR chemical shifts are listed relative to $SiMe_4$ in ppm, and were referenced to the residual solvent peak. ^{31}P NMR data were referenced using 85% H_3PO_4 as an external standard. All NMR spectra were recorded in C_6D_6. The University of Windsor Analytical Services (PerkinElmer 2400 series II Instrument) performed the combustion analyses.

Synthesis of $Mg_2(\mu\text{-NP-}t\text{-Bu}_3)_2(\text{NP-}t\text{-Bu}_3)_2$ (1) and $Mg_3(\mu\text{-NP-}i\text{-Pr}_3)_4(\text{NP-}i\text{-Pr}_3)_2$ (2)

These compounds were prepared employing similar procedures and thus only one is detailed. To a solution of Mg-*n*-Bu_2 (2.40 mL, 2.4 mmol; 1.0 mol/L in hexanes) in toluene (40 mL) was added a clear, colorless solution of HNP-*t*-Bu_3 (1.04 g, 4.8 mmol) in toluene (40 mL). After stirring at 25 °C for 10 h, all volatiles were removed in vacuo, affording a white solid (980 mg, 89%). Colorless crystals suitable for X-ray diffraction were grown from pentanes at –35 °C. **1**: ^{1}H NMR: 1.49 (d, 54H, $^3J_{P\text{-}H}$ = 11 Hz, *t*-Bu), 1.42 (d, 54H, $^3J_{P\text{-}H}$ = 12 Hz, *t*-Bu). ^{13}C NMR: 40.8 (d, $^1J_{P\text{-}C}$ = 46 Hz), 40.1 (d, $^1J_{P\text{-}C}$ = 52 Hz), 31.1, 30.9. ^{31}P NMR: 43.2 (s, 2P, μ-NP), 25.2 (s, 2P, σ-NP). Anal. calcd. for $C_{48}H_{108}Mg_2N_4P_4$: C 63.08, H 11.91, N 6.13; found: C 63.12, H 12.28, N 6.16. **2**: White solid (1.23 g, 87%). ^{1}H NMR: 2.25 (m, 12H, CH), 1.85 (m, 6H, CH), 1.32 (dd, 72H, $^3J_{P\text{-}H}$ = 12 Hz, $^3J_{H\text{-}H}$ = 7 Hz, Me), 1.27 (dd, 36H, $^3J_{P\text{-}H}$ = 12 Hz, $^3J_{H\text{-}H}$ = 7 Hz, Me). ^{13}C NMR: 28.8 (d, $^1J_{P\text{-}C}$ = 57 Hz), 26.1 (d, $^1J_{P\text{-}C}$ = 64 Hz), 18.8, 18.2. ^{31}P NMR: 27.6 (s, 4P, μ-NP), 7.9 (s, 2P, σ-NP). Anal. calcd. for $C_{54}H_{126}Mg_3N_6P_6$: C 57.99, H 11.36, N 7.51; found: C 57.85, H 11.67, N 7.26.

X-ray data collection and reduction

Crystals were manipulated and mounted in capillaries in a glovebox, thus maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer. The data were collected in a hemisphere of data in 1448 frames with 10 s exposure times. The observed extinctions were consistent with the space groups in each case. The data sets were collected ($4.5° < 2\theta < 45°$–$50.0°$). The intensities of reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and XPREP processing packages. An empirical absorption correction based on redundant data was applied to each data set. Subsequent solution and refinement was performed using the SHELXTL solution package.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (7). The heavy atom positions were determined using direct methods employing the SHELXTL direct-methods routine. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on *F*. In the final cycles of each refinement, all non-hydrogen atoms were assigned anisotropic temperature factors in the absence of disorder or insufficient data. In the latter cases, atoms were treated isotropically. C-H atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. H-atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the C atom to which they are bonded. The H-atom contributions were calculated, but not refined. The locations of the largest peaks in the final difference Fourier map calculation as well as the magnitude of the residual electron densities in each case were of no chemical significance. Additional details are provided in the supplementary data[2] and in Table 1.

Results and discussion

The reaction of 2 equiv. of the phosphinimine HNP-*t*-Bu_3 with $MgBu_2$ resulted in the formation of the product **1** in 87% yield (Scheme 1). This species is extremely soluble in pentanes (ca. 1 g in 2 mL), but can be isolated from a saturated solution as colorless crystals at –35 °C. NMR characterization of **1** revealed two sets of resonances attributable to *tert*-butyl groups in the ^{1}H and ^{13}C NMR spectra, as well as two equal-intense signals in the ^{31}P NMR spectrum at 43.2 and 25.2 ppm. This is suggestive of a dimeric structure, in which two Mg centers are coordinated to both terminal and bridging phosphinimide units. The formulation of **1** as $Mg_2(\mu\text{-NP-}t\text{-Bu}_3)_2(\text{NP-}t\text{-Bu}_3)_2$ was confirmed by a crystallographic study (Fig. 1). As indicated by the spectroscopic data, two phosphinimide ligands bridge the two Mg centers with Mg—N distances in the range from 2.043(5) to 2.101(6) Å, giving rise to a Mg–Mg separation of 2.773(3) Å. Terminal phosphinimide ligands complete the coordination sphere of both Mg atoms. The terminal Mg—N distances of 1.922(6) and 1.902(6) Å are much shorter than the bridging Mg—N distances, as expected. The geometries about the Mg atoms

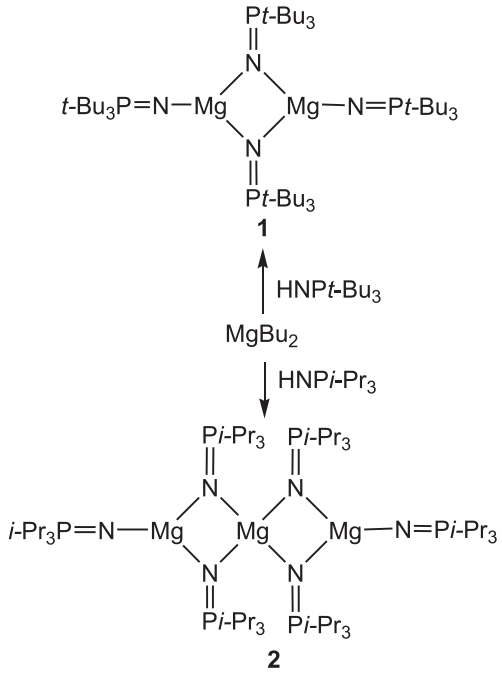

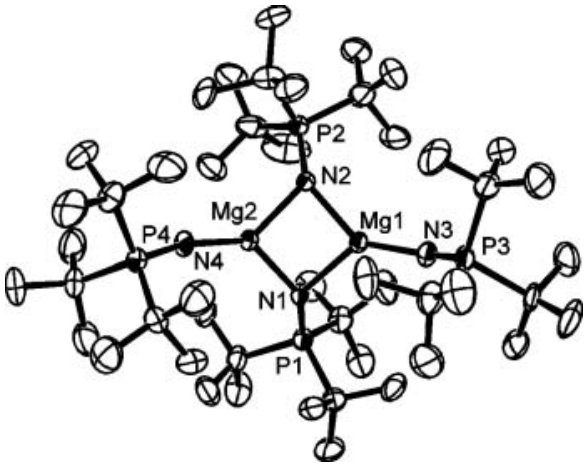

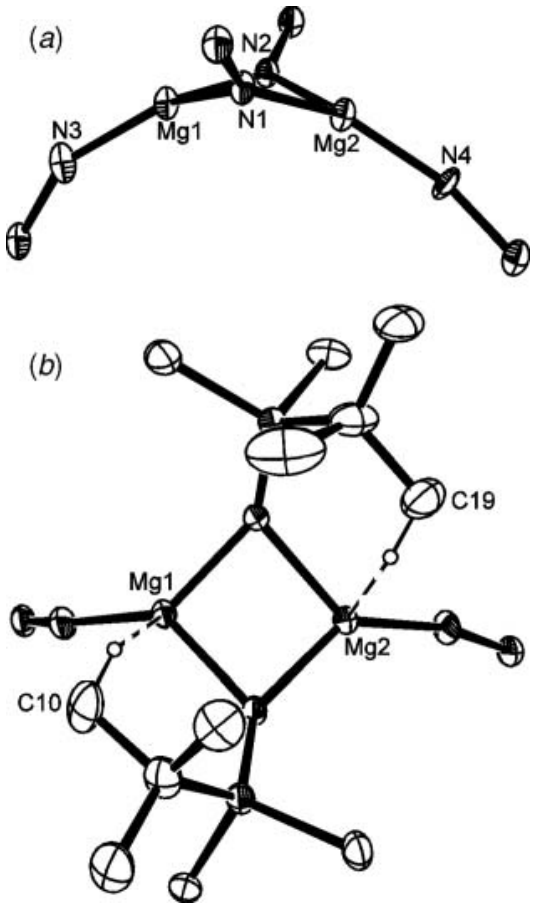

Fig. 1. ORTEP drawing of one of the two molecules of **1** in the asymmetric unit, hydrogen atoms omitted. Distances (Å): Mg(1)—N(3) 1.922(6), Mg(1)—N(2) 2.043(5), Mg(1)—N(1) 2.101(6), Mg(1)—Mg(2) 2.773(3), Mg(2)—N(4) 1.902(6), Mg(2)—N(1) 2.050(5), Mg(2)—N(2) 2.089(6), N(1)—P(1) 1.541(5), N(2)—P(2) 1.545(5), N(3)—P(3) 1.541(6), N(4)—P(4) 1.543(5). Angles (°): N(3)-Mg(1)-N(2) 134.2(3), N(3)-Mg(1)-N(1) 131.6(3), N(2)-Mg(1)-N(1) 90.4(2), N(4)-Mg(2)-N(1) 134.9(3), N(4)-Mg(2)-N(2) 132.0(3), N(1)-Mg(2)-N(2) 90.5(2), Mg(2)-N(1)-Mg(1) 83.8(2), Mg(1)-N(2)-Mg(2) 84.3(2), P(1)-N(1)-Mg(2) 144.0(3), P(1)-N(1)-Mg(1) 130.1(3), P(2)-N(2)-Mg(1) 143.4(3), P(2)-N(2)-Mg(2) 128.6(3), P(3)-N(3)-Mg(1) 150.3(4), P(4)-N(4)-Mg(2) 164.5(4).

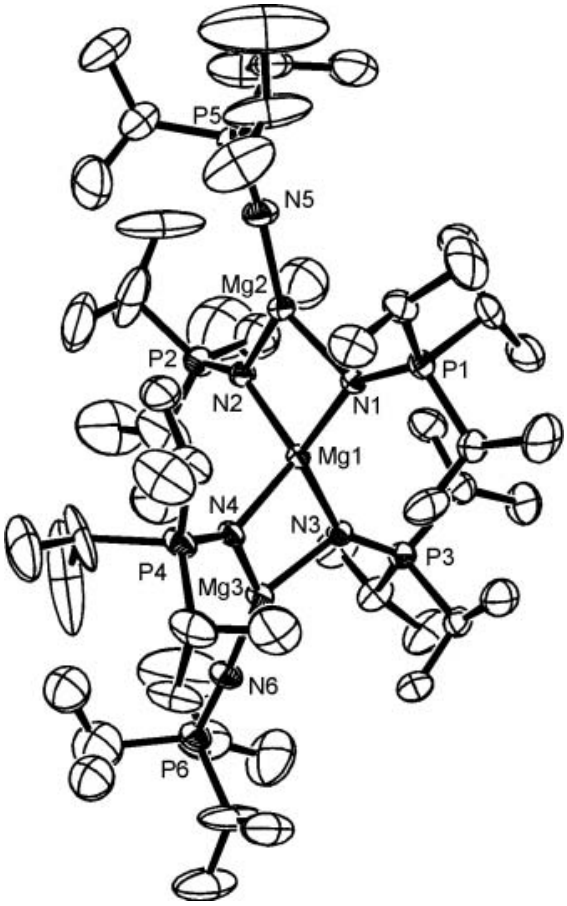
are planar and three coordinate. The N-Mg-N angles in the Mg_2N_2 core are 90.4(2)°, while the N-Mg-N angles between the bridging and terminal phosphinimides are much larger, varying from 131.6(3)° to 134.9(3)°. The angles at N within these cores are 83.8(2)° and 84.3(2)°. Of the four P-N-Mg

Fig. 2. ORTEP drawings of: (*a*) the heavy atom core of **1**; (*b*) agostic C-H-Mg interactions in **1**.



angles with this core, two are similar at 144.0(3)° and 143.4(3)°, while the others are 130.1(3)° and 128.6(3)°. This structural formulation of **1** is similar to the related three-coordinate Mg species $Mg_2(\mu\text{-}NBn_2)_2(NBn_2)_2$ (8), although the Mg_2N_4 core geometries are markedly different. In the amido derivative, the Mg_2N_4 core is planar, while in contrast, the core in **1** exhibits a significant distortion. The average angle between the N-Mg-N planes of the Mg_2N_2 core is 36.2°, while the angle between the terminal N(3)-P(3) and N(4)-P(4) vectors is 77.5° (Fig. 2*a*). These distortions are a consequence of the sterically demanding phosphinimide ligands. Interestingly, the Lewis acidic, three-coordinate Mg centers also give rise to close interactions in the solid state with H atoms of a *tert*-butyl group at distances from 2.298 to 2.487 Å (Fig. 2*b*). Similar intramolecular agostic interactions have been described for $Mg_2(\mu\text{-}t\text{-}Bu)_2(t\text{-}Bu)_2$ (9), while related intermolecular agostic interactions were observed for $Mg(CH(SiMe_3)_2)_2$ (10). The phosphinimide ligands exhibit consistent P—N bond lengths, averaging 1.543(5) Å. The terminal P-N-Mg angles vary significantly as demonstrated by a P(3)-N(3)-Mg(1) angle of 150.3(4)° and a P(4)-N(4)-Mg(2) angle of 164.5(4)°. This variation is a further reflection of the steric crowding in this molecule.

The analogous reaction of the less bulky phosphinimine HNP-*i*-Pr_3 with $MgBu_2$ proceeded in a similar manner to afford the highly soluble species **2** in 89% yield (Scheme 1). The ^1H and ^{13}C NMR data revealed two sets of resonances

Angles (°): N(3)-Mg(1)-N(4) 87.94(17), N(3)-Mg(1)-N(1) 127.69(18), N(4)-Mg(1)-N(1) 122.57(19), N(3)-Mg(1)-N(2) 120.46(19), N(4)-Mg(1)-N(2) 112.07(18), N(1)-Mg(1)-N(2) 88.59(17), N(5)-Mg(2)-N(2) 136.6(2), N(5)-Mg(2)-N(1) 130.4(2), N(2)-Mg(2)-N(1) 92.80(18), N(6)-Mg(3)-N(4) 137.4(2), N(6)-Mg(3)-N(3) 130.4(2), N(4)-Mg(3)-N(3) 91.97(18), Mg(2)-N(1)-Mg(1) 87.96(17), Mg(2)-N(2)-Mg(1) 88.65(18), Mg(3)-N(3)-Mg(1) 88.42(17), Mg(3)-N(4)-Mg(1) 88.63(18), P(1)-N(1)-Mg(2) 124.5(2), P(1)-N(1)-Mg(1) 147.3(2), P(2)-N(2)-Mg(2) 131.9(3), P(2)-N(2)-Mg(1) 139.1(3), P(3)-N(3)-Mg(3) 124.8(2), P(3)-N(3)-Mg(1) 145.9(3), P(4)-N(4)-Mg(3) 134.6(3), P(4)-N(4)-Mg(1) 136.7(3), P(5)-N(5)-Mg(2) 174.9(4), P(6)-N(6)-Mg(3) 175.0(4).

for isopropyl groups, as well as two distinct resonances in the ^{31}P NMR spectrum at 27.6 and 7.9 ppm. However, in contrast to **1**, the ratio of these resonances was 2:1, with the downfield resonances being the more abundant. This suggested a 2:1 ratio of bridging to terminal phosphinimide ligands. Based on this information, **2** was formulated to be $Mg_3(\mu\text{-NP-}i\text{-Pr}_3)_4(\text{NP-}i\text{-Pr}_3)_2$. Despite some degree of disorder in the peripheral isopropyl groups, a crystallographic study of **2** confirmed the trimetallic nature of **2**, in which two pairs of phosphinimide ligands link two Mg centers to a central four-coordinate pseudo-tetrahedral Mg (Fig. 3). Terminal phosphinimide ligands complete the coordination sphere of terminal, tri-coordinate Mg centers. Similar to **1**, the average terminal Mg—N distances in **2** of 1.916(5) Å are significantly shorter than the bridging Mg—N distances that range from 2.082(4) to 2.110(5) Å. The resulting Mg–Mg separations of 2.868(3) and 2.880(3) Å in **2** are slightly longer than that seen in **1**. The angles about the central Mg atom are significantly distorted from pseudo-tetrahedral with the chelate N-Mg-N angles within the Mg_2N_2 units being 87.94(17)° and 88.59(17)°. The corresponding N-Mg-N angles at the three-coordinate Mg centers are 92.80(18)° and 91.97(18)°, while the N(bridging)-Mg-N(terminal) angles range from 130.4(2)° to 137.4(2)°. The Mg-N-Mg angles for the bridging phosphinimides are slightly larger than those in **1**, ranging from 87.96(17)° to 88.65(18)°. This is attributed to steric interactions among the four bridging phosphinimide ligands. The remaining N-Mg-N angles range from 112.07(18)° to 127.69(18)°. The P—N distances in **2** fall in the range of those in **1**, however, the terminal P-N-Mg angles are closer to linearity at 174.9(4)° and 175.0(4)°. The trimeric nature of **2** in comparison to the dimeric nature of **1** is attributed to the diminished steric demands of *i*-Pr vs. *t*-Bu substitutents on the phosphinimide ligand. Agostic Mg···H interactions analogous to those seen in **1** were not seen for **2**.

Preliminary examination of the reactivity of **1** revealed that reaction of $Ti(N\text{-}t\text{-Bu})Cl_2(t\text{-BuPy})_3$ (11) with **1** gave a mixture of products. In contrast, reaction of $CpZr(N\text{-}t\text{-Bu}_3)Cl_2$ with **1** proceeded cleanly to transfer a phosphinimide ligand from the Mg reagent to Zr, yielding the known species $CpZr(N\text{-}t\text{-Bu}_3)_2Cl$ in 85% yield (12). These results suggest that Mg-bis-phosphinimide derivatives may be highly soluble, effective ligand transfer reagents in our continuing studies of the chemistry of phosphinimide compounds.

Construction and application of a single-molecule fluorescence microscope

Sangram Bagh and Matthew F. Paige

Abstract: In this paper, we describe the construction, optimization, and testing of an epifluorescence microscope that has single-molecule (SM) resolution and sensitivity. The microscope makes use of a novel new type of wide-area charge-coupled device (CCD) photodetector with on-chip multiplier gain. Sensitivity and spatial resolution of the instrument are demonstrated by imaging individual Rhodamine 6G (R6G) molecules and characterizing their basic photophysical behaviour under a variety of imaging conditions. A simple, general method for calibrating the photodetector (correlating CCD counts with incident photons) using a highly attenuated laser beam is presented, and the performance of the photodetector is compared with that of other detectors commonly used in SM fluorescence imaging applications. We also demonstrate the versatility of the microscope system by characterizing the SM photophysical behaviour of several other fluorescent molecules, including bodipy-FL and the enhanced green fluorescent protein (EGFP).

Key words: single molecule, fluorescence, microscopy, CCD camera, calibration, photobleaching.

Résumé : Dans ce travail, on a construit, optimisé et vérifié d'un microscope à épifluorescence à résolution et sensibilité d'une seule molécule (SM). Le microscope fait appel à nouveau type de photodétecteur avec un dispositif à couplage de charge (« CCD ») à grand angle et un multiplicateur du gain sur la puce. On a démontré la sensibilité et la résolution spatiale de l'instrument en faisant l'image des molécules individuelles de Rhodamine 6G (R6G) et en caractérisant leur comportement photophysique dans diverses conditions. On présente une méthode générale et simple de calibrer le photodétecteur (qui relie le comptage du CCD avec les photons incidents) qui fait appel à un faisceau laser fortement atténué et on a comparé la performance du photodétecteur avec celle d'autres détecteurs régulièrement utilisés dans des applications d'imagerie de fluorescence SM. On démontre aussi la versatilité de ce système de microscope en caractérisant le comportement photophysique SM de plusieurs autres molécules fluorescentes, y compris le bodipy-FL et la protéine de fluorescent à vert exalté (« EGFP »).

Mots clés : molécule unique, fluorescence, microscopie, caméra à CCD, calibration, photolessivage.

Introduction

Single-molecule (SM) fluorescence spectroscopy is a rapidly growing field of research in which the fluorescence emission of individual, isolated molecules is directly measured. The principal motivation for carrying out SM experiments is that one can directly observe the behaviour of molecules in the absence of ensemble averaging. In standard, "bulk" chemical assays, the behaviour of individual molecules is blurred out through averaging; it has been shown on numerous occasions, however, that many chemical systems are heterogeneous when probed at the SM level, and that these hidden heterogeneities can play an important role in dictating the overall properties of the system (1–3). Studies of individual molecules have been extended beyond simple proof-of-principle experiments, and are now being used in a wide range of disciplines, including investigations of biological systems, polymers, and inorganic materials, to name a few (2, 4–7).

Fluorescence microscopy has become one of the primary tools used by researchers in the field of SM fluorescence spectroscopy, as the technique can provide both high sensitivity and good (diffraction-limited) spatial resolution. A number of different experimental methods for carrying out SM fluorescence microscopy have been demonstrated, including epifluorescence, wide-field total-internal reflection (TIR), confocal, and near-field scanning optical microscopies (3, 8, 9). There are a number of common criteria that these microscopy methods must meet to achieve SM detection; these include optimization of fluorescence collection efficiency, reduction of unwanted background signal, and the use of extremely sensitive, low-noise photodetectors. Optimal collection efficiency is achieved through careful alignment of the microscope, selection of suitable emission filters to attenuate residual excitation and scattered light, and by use of colour-corrected, oil-immersion microscope objectives with high numerical apertures (typically NA = 1.4) to maximize the number of collected photons. Background signals are typically minimized through a combination of careful sample preparation that makes use of only the highest purity solvents and buffers, and again through careful selec-

tion of emission filters to maximize rejection of excitation and scattered light.

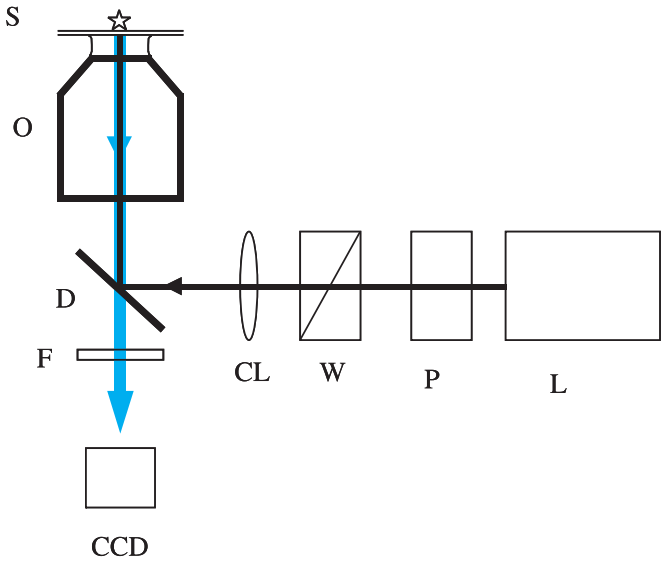
Perhaps the most important component of a fluorescence microscope system with SM imaging capabilities is the photodetector. The primary requirements for photodetectors in SM experiments are both high-sensitivity, preferably over the visible region of the spectrum where fluorophores commonly used for biological fluorescent labeling purposes emit, and a high data acquisition rate. The latter is important for detecting rapid photophysical events and processes, and also because most fluorophores undergo rapid, irreversible photobleaching and the photodetector should ideally acquire many data points before photobleaching takes place. There are a number of photodetectors currently available that meet these requirements. Photomultiplier tubes (PMTs), for example, were used in some of the earliest SM fluorescence detection measurements (for a recent review, see ref. 8). However, PMTs typically suffer from low quantum efficiencies (photoelectrons generated per incident photon) in the visible region of the spectrum and require the use of sophisticated electronics to operate in single-photon counting mode, which is often desirable for SM experiments. Researchers in SM fluorescence microscopy more often make use of silicon-based photon-counting modules (avalanche photodiodes (APDs)) for scanned techniques such as confocal and near-field, and high-sensitivity charge-coupled device (CCD) cameras for wide-field illumination approaches such as epifluorescence or wide-field TIR. Both types of devices have high quantum efficiencies over the visible to near-IR regions of the spectrum. Also, both types of devices often have substantial gain, which is vital for overcoming the detector read-noise that can be a limiting factor in low-light level experiments.

CCD cameras have proven to be particularly useful for SM fluorescence microscopy experiments. They are parallel devices; that is, the entire sample illumination area can be imaged onto the CCD chip, allowing many individual molecules to be imaged simultaneously. This allows large data sets to be accumulated in just a few experiments. Modern CCD detectors also have a sufficiently rapid data acquisition rate (fastest acquisition time per single whole chip frame is typically ~30 ms) for SM measurements. The most sensitive of commercial CCD cameras often make use of image intensification, typically through the application of a known voltage to a multichannel plate (MCP) between the detector's photocathode and phosphor screen, to enhance signal levels. While offering superb sensitivity and good data acquisition rates, intensified CCD cameras are both expensive and prone to light-induced damage; a sudden jump in light levels while operating the image intensifier can cause severe damage to the detector chip.

Recently, a new type of CCD camera capable of ultrasensitive imaging without the use of an image intensifier has become commercially available. This new class of cameras, now available from several different manufacturers, makes use of a process termed on-chip multiplication gain to overcome detector read-noise at low light levels. In the on-chip multiplication process, a serial register of pixels is placed between the detector chip and the camera preamplifier. When electrons are transferred from the detector chip through the serial register, they are accelerated by an applied potential. This leads to the generation of secondary electrons through an impact-ionization process. The degree of amplification (gain) can be controlled by adjusting the magnitude of the potential applied to the serial register. With the use of multiplier gain and thermoelectric cooling of electronic elements, photodetector read-noise and dark current can be overcome and ultra-low light levels can be detected (10). Cameras with on-chip multiplier gain are significantly less expensive than conventional intensified CCD cameras, and since amplification takes place after the signal has reached the photodetector chip, the camera is relatively insensitive to damage caused by sudden increases in signal intensity. This new class of camera has tremendous potential in SM imaging applications, and their full capabilities in this regard should be explored.

In this paper, we describe our recent efforts at constructing and testing an epifluorescence microscope with SM sensitivity, which makes use of a CCD camera with on-chip multiplication gain for a photodetector. We demonstrate that our system has sufficient sensitivity and spatial resolution for imaging individual molecules of several different fluorophores, including Rhodamine 6G (R6G), enhanced green fluorescent protein (EGFP), and bodipy-FL, a fluorophore that has never before been characterized at the SM level. Basic photophysical measurements, including characterizing signal-to-noise ratios, generation of histograms of photobleaching rates, and characterization of photobleaching dynamics ("blinking") have been carried out for all of these fluorophores and are compared with data available from the literature. In addition, we present a simple, approximate procedure for calibrating the CCD photodetector such that the detector counts can be directly converted into numbers of photons, and discuss the overall potential of this class of camera for SM fluorescence imaging applications.

Materials and methods



Microscope setup

The epifluorescence microscope used in these experiments is based on a commercial Nikon TE2000 inverted optical microscope (Nikon, Canada). A schematic diagram of the instrument is shown in Fig. 1. Briefly, a collimated, linearly polarized output beam from a tunable argon-ion laser (Melles Griot, Carlsbad, California, USA) was passed through neutral density filters to adjust laser power and a quarter waveplate to generate circularly polarized light. The beam was then focused onto the back focal plane of a 60×, 1.4NA oil-immersion objective lens (PlanApo, Nikon, Canada) by means of a 500 mm focal length lens. Excitation light was reflected onto the sample by a dichroic beamsplitter (for 488 nm excitation, a DRLP 500 nm, Omega Optical, Brattleboro, Vermont, USA; for 514 nm, a DRLP 540 nm).

After excitation, fluorescence emission from the sample was filtered through two long-pass emission filters (500AELP, Omega Optical, Brattleboro, Vermont, USA) to remove residual excitation light and directed onto a wide-area, front-illuminated CCD photodetector (Cascade 512F, Photometrics, Tucson, Arizona, USA). Unless stated otherwise, the CCD was operated at a fixed multiplication gain of 2907 arbitrary units for imaging. Operation of the CCD photodetector and data analysis was carried out through the soft-

L (tunable Ar^+ laser), P (Glan–Thomson polarizing prism), W (quarter waveplate), CL (focusing lens (f = 500 mm)), D (dichroic beamsplitter), O (microscope objective (NA = 1.4, 60×)), S (sample and coverglass), F (longpass emission filter(s)), CCD (CCD photodetector). The lens focuses the excitation light onto the back focal plane of the microscope objective, resulting in an approximately 10 μm diameter excitation spot. The resulting fluorescence is collected back through the objective, passed through the dichroic and emission filters, and finally directed onto the CCD photodetector.

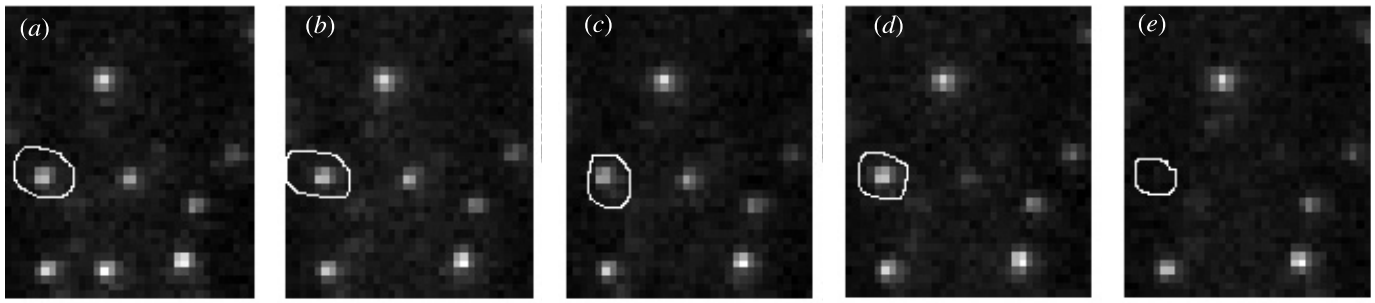
ware package MetaMorph (Universal Imaging, Downington, Pennsylvania, USA), which allows both static and time-resolved (time-lapse) imaging.

Sample preparation

Samples were prepared from very dilute dye solutions (~10^{-10} mol/L) in water, phosphate buffer, or methanol. Dyes used in these experiments included R6G (Sigma-Aldrich, Canada), bodipy-FL (Molecular Probes, Eugene, Oregon, USA), and EGFP (a kind gift from Professor H. Iwai, University of Saskatchewan). Aliquots of dye solution were deposited directly onto microscope coverglass (No. 1 thickness, borosilicate float glass, VWR, Canada) and the solvent allowed to evaporate, or were deposited by spin-casting. Coverglass was precleaned by first thoroughly rinsing with methanol and then repeatedly passing through the flame of a propane torch. Control samples of coverglass cleaned in this way showed no fluorescent impurities when imaged under conditions typically used for single-molecule measurements. For some samples, the dye-treated coverglass was also coated with a thin film of polymethylmethacrylate (PMMA; Polysciences, Warrington, Pennsylvania, USA), deposited by spin-casting a 5% *w*/*v* ethyl acetate solution of the polymer onto the coverglass. Samples of EGFP were prepared by diluting stock EGFP in phosphate buffer (pH 7.0), and mixing the sample in a 2% *w*/*v* agarose gel, prepared from the same buffer, at approximately 37 °C. A 5 μL aliquot of molten agarose was sandwiched between two clean pieces of coverglass and allowed to cool before imaging in the microscope.

Results and discussion

Initial characterization and testing of the microscope



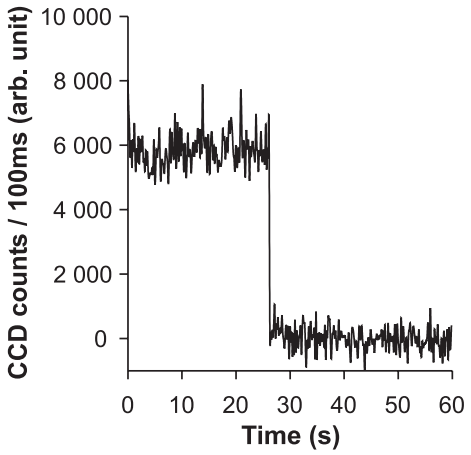
The SM fluorescence microscope was constructed as described in the Materials and methods section. Overall efficiency of the optical system in terms of light transmission in the microscope was determined by measuring the initial laser power entering the epi-illumination port and comparing this value to the laser power at different points in the optical train. Relative to this initial value, ~60% of the incident light is reflected off of the dichroic beamsplitter into the microscope objective and ~50% of the incident light is projected through the objective onto the sample plane. Losses are likely caused by reflection, scattering, and partial blocking of the excitation beam by optical elements that are not readily accessible in a commercial microscope. Based on experimentally measured light losses, the known values for numerical aperture of the objective lens and the transmission efficiency of the emission filters, we estimate the overall fluorescence collection efficiency of our microscope to be ~3% to 4%. This compares well with collection efficiency values reported by other researchers in this discipline (e.g., ref. 11).

After basic construction of the microscope system was complete, we tested its ability to detect individual molecules of R6G that had been immobilized in a PMMA matrix. When these samples (preparation described previously) were placed in the microscope and illuminated with an intensity of ~0.5–6.0 kW/cm^2, we observed images consisting of multiple (~5–10, depending on preparation conditions), well-dispersed spots on a dark background. In these experiments, illumination intensity is reported as the total laser power at the microscope objective, divided by the illumination area at the sample plane. A typical image of a sample prepared and imaged in this manner is shown in Fig. 2*a*. The fluorescent spots had diameters of approximately 300 nm, as determined by calibrating the CCD pixel size against a standard United States Air Force (USAF) test target. The sizes of the fluorescent spots are in reasonable agreement with the diffraction-limited size (~λ/2) that is anticipated when measuring individual molecules. When imaged under constant illumination conditions, the bright spots showed abrupt (single-step) photobleaching behaviour. That is, the emission intensity of a spot dropped down to the background level of the experiment during the time course of a single 100 ms integration period. This is shown in Figs. 2*a*–2*d*, in which a series of consecutive images is displayed. One particular spot has been circled to highlight the single-step photobleaching event. Single-step photobleaching, when observed in conjunction with low concentration levels and diffraction-limited size, is a well-known signature of single-molecule fluorescence experiments (1, 12), indicating that the fluorescent spots we observe are individual R6G molecules.

A simple and useful approach to data analysis in SM fluorescence experiments is to generate plots of fluorescence emission intensity of an individual molecule as a function of illumination time. These plots can provide basic "analytical" information about a fluorophore and detection system (i.e., signal-to-noise ratio, background signal intensity) that is

© 2005 NRC Canada

Fig. 2. Consecutive CCD images (*a*–*e*) of individual R6G molecules immobilized in a PMMA matrix. One molecule is circled for reference. The single step photobleaching of a bright spot in frame (*e*) is a characteristic signature of a single molecule (image size is approximately 5.0 μm × 5.7 μm, integration time = 100 ms per frame, excitation intensity = 0.6 kW/cm^2, excitation wavelength = 514 nm).



useful for optimizing the apparatus and sample preparation, and can also provide fundamental insight into the basic photophysical behaviour of the fluorophore. A typical plot showing fluorescence emission intensity vs. time for an individual molecule of R6G in PMMA is shown in Fig. 3. We operationally define the signal-to-noise (SNR) ratio as the mean signal (corrected for background and detector offset) measured with a 100 ms integration period for the entire duration of the molecule's on-time, divided by the standard deviation of the same signal. For R6G, we measured SNRs of around 11. This compares well with other SNRs for typical, good laser dyes found in the literature (e.g., ref. 9). It is worth noting that not every molecule in a SM measurement will have the same SNR. One primary reason for this is a distribution of effective absorption cross-sections for molecules resulting from the different orientation of molecules along the *z* axis when excitation light is circularly polarized in the *x*–*y* plane (see for example, ref. 13).

In general, we found that for R6G in PMMA, photobleaching takes place in a single-step after which the vast majority (>95%) of molecules remain in a permanently nonemissive state. Occasionally, we observed a molecule that displays blinking — that is, the fluorophore undergoes multiple transitions between an emissive and nonemissive state, but this was rare. Samples that were not coated with PMMA show a considerably larger fraction of molecules that undergo blinking, and the molecules photobleach much more rapidly than those coated with polymer (data not shown). This observation is in good agreement with numerous other studies, which suggest that blinking is connected to environmental factors such as interactions with glass surface sites and photochemical reactions with atmospheric oxygen (8, 14–16).

Another useful approach to analyzing single-molecule properties in chemical systems is to generate frequency histograms of fluorescence "on-times", the time required for a molecule to undergo irreversible photobleaching. This can provide insight into the presence of inhomogeneities in the chemical system, as well as more complex photophysical phenomena. For example, simple, homogeneous systems in which all molecules are subjected to identical local environmental conditions have fluorescence on-times that follow simple Poisson-type statistics, a consequence of selecting a small, random number of sample molecules from a large overall population. That is, the frequency of fluorescence

Fig. 3. A plot showing fluorescence emission intensity as a function of integration time for a single R6G molecule immobilized in a PMMA matrix (excitation intensity = 0.6 kW/cm^2, excitation wavelength = 514 nm). The intensity is shown in CCD counts/100 ms (arb. unit) after subtracting the mean background signal.

on-times can be expected to show a simple, single-exponential decrease (17). However, if there are several different sub-populations of molecules in the system, for instance a small subset of molecules bound to defects on a surface or molecules located in a region of the sample that has a different chemical composition, then one would observe significantly more complicated (typically multi-exponential) histograms. We show a histogram of fluorescence on-times for our test system of R6G in PMMA in Fig. 4, along with a simple, single-exponential fit. As seen in Fig. 4, the system shows an excellent fit to a single-exponential function, which is the expected result for the measurement of fluorescence on-time for a simple fluorophore like R6G in a uniform polymer matrix. These measurements are in reasonable agreement with those collected by a number of researchers (for example, refs. 15 and 18). We take these results, in combination with those described in the preceding paragraphs, as evidence that our microscope system (and most notably the photodetector) is sufficiently sensitive to detect individual molecules and can produce SM data that is consistent with the literature.

Fig. 4. The histogram and single exponential fit of on-time distribution for R6G in PMMA coating. The fitting function is $N = A_0 \exp(-t/\tau_{ON})$ where N = number of molecules at time t, τ_{ON} = photobleaching time constant, and A_0 = amplitude. The corresponding photobleaching time constant is $\tau_{ON} = 2.00$ s. The excitation intensity used was 0.6 kW/cm^2.
