Chemoselective thioacetalization with odorless 2-(1,3-dithian-2-ylidene)-3-oxobutanoic acid as a 1,3-propanedithiol equivalent

Haifeng Yu, Dewen Dong, Yan Ouyang, and Qun Liu

Abstract: Odorless 2-(1,3-dithian-2-ylidene)-3-oxobutanoic acid (**1c**) was prepared and investigated in the thioacetalization of carbonyl compounds as a 1,3-propanedithiol equivalent. The results showed that the thioacetalization of various carbonyl compounds **2** with **1c** proceeded smoothly and afforded the corresponding dithioacetals **3** in high yields (up to 99%) in the presence of acetyl chloride at room or reflux temperatures. Moreover, the thioacetalization exhibited high chemoselectivity between aldehydes and ketones.

Key words: chemoselectivity, 2-(1,3-dithian-2-ylidene)-3-oxobutanoic acid, α-oxo ketene dithioacetal, 1,3-propanedithiol equivalent, thioacetalization.

Résumé : On a préparé l'acide inodore 2-(1,3-dithian-2-ylidène)-3-oxoburanoîque (**1c**) et on a évalué son utilité comme équivalent du propane-1,3-dithiol dans la thioacétalisation de composés carbonyles. Les résultats ont montré que la thioacétalisation des divers composés **2** à l'aide de **1c** en présence de chlorure d'acétyle, à la température ambiante, s'effectue sans problème et conduit aux dithioacétals **3** avec des rendements élevés (99 %). De plus, la thiacétalisation présente une chimiosélectivité élevée entre les aldéhydes et les cétones.

Mots clés : chimiosélectivité, acide 2-(1,3-dithian-2-ylidène)-3-oxoburanoîque, dithioacétal d'α-oxocétène, équivalent du propane-1,3-dithiol, thioacétalisation.

[Traduit par la Rédaction]

Introduction

Thioacetals play very important roles in organic synthesis since they are widely used as protecting groups for carbonyl compounds and applied as umpolung reagents in a diverse array of organic transformations (1, 2).

To date, there are many approaches developed for the synthesis of thioacetals from carbonyl compounds or *O*,*O*-acetals with thiols employing various acid catalysts such as protic acids, Lewis acids, and solid acids (3, 4). Unfortunately, the conventional methods suffer from the use of volatile, foul-smelling, low molecular weight thiols that can lead to serious safety and environment problems. To resolve these drawbacks, some attempts have been made to develop odorless substitutes for these obnoxious thiols. As a result, a range of odorless or faint smell thiols have been prepared by increasing the alkyl chain length of thiol or introducing a trialkylsilyl group into the benzene ring of benzyl mercaptan and benzenethiol (5). Alternatively, incorporation of 1,3-propanedithiol functions within linear or cross-linked copolymeric reagents have been realized and applied in organic synthetic chemistry (6). However, the multistep process of preparation, the high cost of catalysts, and the toxicity of some precursors limit the further utilization of such thiol reagents or their equivalents. From the green chemistry point of view, the development of practically odorless and less volatile substitutes for such thiols is still of great importance and necessity.

Recently, we developed a novel thioacetalization with nonthiolic odorless cyclic ketene dithioacetals, e.g., 2-(2-chloro-1-(1-chloroethenyl)-2-propenylidene)-1,3-dithiane (**1a**) and 3-(1,3-dithian-2-ylidene)pentane-2,4-dione (**1b**) (Fig. 1), as 1,3-propanedithiol equivalents (7). We demonstrated that the reaction of carbonyl compounds with **1a** is an acid-assisted, self-catalyzed thioacetalization running through the formation of the intermediate **1b** (7*a*). The thioacetalization of **1b**, achieved under mild acidic conditions with high chemoselectivity (7*b*), encouraged us to believe that a wide range of cyclic ketene dithioacetals might be used as dithiol equivalents. There are many reports, including some review articles, regarding synthesis and application of α-oxo ketene dithioacetals (8). The decomposition reaction of α-oxo ketene dithioacetals had a different course depending on the reagent structure (9). For example, 2-(1,3-dithian-2-ylidene)-3-oxobutanoic acid (**1c**) undergoes iododecarboxylation rather than iododeacylation after treatment with iodine in

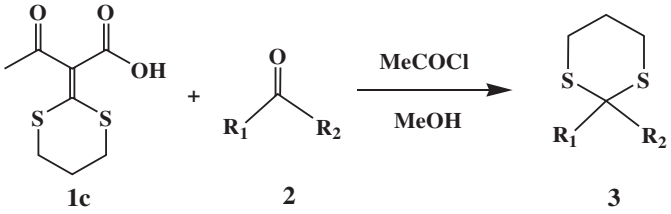
EtOH–H_2O, affording the same intermediate obtainable with **1b** (9*a*). With the aim of obtaining efficient and practical reagents for general application, we investigated the thioacetalization reaction of a range of selected carbonyl compounds **2** with **1c**.

Results and discussion

According to the literature, we prepared ethyl 2-(1,3-dithian-2-ylidene)-3-oxobutanoate (10) from ethyl 3-oxobutanoate, carbon disulfide, 1,3-dibromopropane, and K_2CO_3 in nearly quantitative yield (99%), then we converted it into the 2-(1,3-dithian-2-ylidene)-3-oxobutanoic acid (**1c**) via a hydrolysis process (9*a*, 11). It is worth noting that **1c** is an odorless solid, stable under ambient atmosphere, which is associated with some advantages such as a simple synthetic procedure, mild conditions, high yield, and commercial starting materials without a foul smell.



Since our previous experience has revealed that it is a convenient way to achieve the thioacetalization of a range of aldehydes and ketones in the presence of a mixture of acetyl chloride and methanol (7*b*), in the present work the same mixture was adopted for studying the thioacetalization of various carbonyl compounds **2** with **1c** (Scheme 1).

The thioacetalization of piperonal (**2a**) with **1c**, initially carried out under reflux, showed that the reaction was completed within 30 min affording the corresponding dithioacetal **3a** in 89.3% yield. Significantly, this reaction proceeded much faster in comparison to the reaction reported in our previous work (7). So, we repeated the reaction at room temperature. To our delight, **2a** was transformed into **3a** in 92.7% yield within 2 h. It is worth mentioning that only a very faint smell of thiol was perceived during both the reaction and work-up process, in agreement with practically no release of 1,3-propanedithiol.

We next investigated the thioacetalization of aromatic, aliphatic, and heterocyclic aldehydes and ketones (**2a**–**2w**) with **1c** in the presence of acetyl chloride in methanol at both room and reflux temperatures. With a constant feed molar ratio of acetyl chloride : **1c** : **2** of 3:2:2, all the reactions proceeded smoothly under mild acidic conditions. Table 1 summarizes some reaction data. The results confirm the general value of **1c** as a key reagent for the thioacetalization reaction.

A range of aromatic and aliphatic aldehydes and aliphatic ketones (**2a**–**2p**) were rapidly converted into their corresponding dithioacetals (**3a**–**3p**) in very high yields at both room and reflux temperatures. The reflux condition allowed a shorter reaction time, nevertheless, some thermosensitive substrates could benefit from the use of room temperature. In the cases of entries 23 and 24 in Table 1, the yield was increased by 25% when the reaction of thermo- and acid-sensitive furan-2-carbaldehyde (**2l**) proceeded at room temperature rather than at reflux. Generally, it is difficult to cleanly realize the thioacetalization of **2l** with the use of conventional acid catalysts (12). Several research groups reported high-yield thioacetalizations of **2l** by using thionyl chloride treated silica gel (12), trimethylsilyl chloride (13), and lithium tetrafluoroborate (14) as the catalyst, respectively. Our thioacetalization of **2l** can be considered a useful alternative procedure.

Scheme 1. Thioacetalization of carbonyl compounds **2** with **1c**.

In contrast with **2a**–**2p**, the aromatic ketones **2q**–**2u** could not be thioacetalized at room temperature, but they gave their corresponding dithioacetals in high yields after prolonged reflux. The aromatic sterically hindered benzophenone (Table 1, entry 37) was the slowest to react with an excess of **1c** (feed molar ratio of acetyl chloride : **1c** : **2** = 3:4:2).

To exploit the differences in the thioacetalization rate of aldehydes and aliphatic ketones and aromatic ketones, for the selective protections we carried out some competitive reactions under the above reaction conditions (Table 1, entries 38 and 39). The reaction of **2b**–**2q**–**1c** with a 1:1:1 molar ratio performed at reflux temperature (Table 1, entry 38) afforded the thioacetal **3b** in 92.4% yield, while the ketone **2q** was almost completely recovered (97.2%), **3q** not even being detectable. Similar results were obtained in the case of **2p**–**2q**–**1c** with a 1:1:1 molar ratio (Table 1, entry 39), where **2p** was converted into thioacetal **3p** in 91.2% yield, while **2q** remained intact. The reported thioacetalization procedure thus showed a high chemoselectivity, providing selective protection of an aromatic aldehyde or an aliphatic ketone in the presence of an aromatic ketone.

The mechanism of the thioacetalization reaction was investigated with the help of a supporting reaction. The mixture of **1c** (1.0 mmol), **2a** (1.0 mmol), and acetyl chloride (1.5 mmol) in methanol (10 mL) was stirred at room temperature and interrupted after 50 min by neutralizing with 10% aq. $NaHCO_3$. With this procedure, decarboxylated product 1-(1,3-dithian-2-ylidene)propan-2-one (**4**) and dithioacetal **3a** were obtained in 79.3% and 14.6% yields, respectively, while unreacted **2a** (81.3%) was recovered. Compound **4** was also obtained in our previous work and assumed to be an intermediate (7*a*, 7*b*). These results indicate that **1c** undergoes decarboxylation much more easily than deacylation under the acidic conditions applied. The novelty of the reagent **1c** is in the fact that the thioacetalization of aldehydes and aliphatic ketones could proceed at room temperature with high yields. On the basis of the previously mentioned experimental results together with our previous work (7), a mechanism for the thioacetalization reaction of various carbonyl compounds with **1c** in methanol is proposed in

[d]Recovery of the intact compound **2q**.

Scheme 2. The reaction process starts with the generation of HCl from the esterification between acetyl chloride and methanol, which catalyzes the decarboxylation of **1c** to give **4**. Through the addition of a proton to the carbon–carbon double bond, **4** is converted into the carbocation **5**, stablized by the electron-donating effect of two sulfur atoms, then into **6** or **7** with H_2O or methanol, respectively, and finally by cleavage of the ring into **8**, which reacts with the carbonyl compound **2** to give the corresponding dithioacetal **3**. An indirect evidence of the formation of **8** is the production of the dithiane **9** (7*b*), obtained in the present work most likely from the inter- or intra-molecular transformation of **8**.

Scheme 2. Proposed mechanism for the thioacetalization of carbonyl compounds **2** with **1c**.

In summary, odorless 2-(1,3-dithian-2-ylidene)-3-oxobutanoic acid (**1c**) has been investigated as a 1,3-propanedithiol equivalent in thioacetalization. In the presence of **1c**, a wide range of carbonyl compounds, aldehydes, and ketones have been converted into the corresponding dithioacetals **3** in high yields. The thioacetalization reaction is characterized by a simple procedure, mild conditions, high yields, and high chemoselectivity towards aldehydes and aliphatic ketones with respect to aromatic ketones.

Experimental

All reagents were purchased from commercial sources. The products were purified by column chromatography over silica gel. ^{1}H NMR spectra were recorded at 25 °C on a Varian INOVA500 (500 MHz) spectrometer in $CDCl_3$ and with TMS as the internal standard. IR spectra (KBr) were recorded on a Magna-560 FT IR spectrophotometer. Elemental analyses were measured on a PE-2400 analyzer (PerkinElmer).

General procedure for thioacetalization of aldehydes and ketones 2 with 1c

Preparation of **3a** as a typical procedure: the mixture of **1c** (218 mg, 1 mmol), **2a** (150 mg, 1 mmol), and CH_3COCl (0.11 mL, 1.5 mmol) in MeOH (10 mL) was stirred under reflux. As monitored by TLC, compound **1c** was consumed within 10 min; whereas aldehyde **2a** disappeared after 25 min. The reaction mixture, allowed to cool to room temperature, was neutralized with 10% aq. $NaHCO_3$ and extracted with diethyl ether (3 × 10 mL). The combined organic extracts were dried over anhydr. $MgSO_4$, filtered, and concentrated under reduced pressure to yield the crude product. The purification by silica gel chromatography (eluent: petroleum ether – EtOAC, 75:1) gave the dithioacetal **3a** in 89.3% yield.

Ionic liquid promoted simple and efficient synthesis of β-enamino esters and β-enaminones from 1,3-dicarbonyl compounds — One-pot, three-component reaction for the synthesis of substituted pyridines

Ganesan Karthikeyan and Paramasivan T. Perumal

Abstract: A facile enamination of 1,3-dicarbonyl compounds with amines has been developed that affords good to excellent yields of β-enamino esters and β-enaminones using Brønsted acidic ionic liquid 1-methylimidazolium trifluoroacetate ([Hmim]$^+$Tfa$^-$) at room temperature. This methodology has been extended for the synthesis of substituted pyridines in excellent yield by a one-pot, three-component reaction of 1,3-dicarbonyl compounds, ammonium acetate, and alkynone in the presence of [Hmim]$^+$Tfa$^-$.

Key words: ionic liquid, β-enaminones, β-enamino esters, 1,3-dicarbonyl compounds, amines, pyridines.

Résumé : Opérant à la température ambiante et utilizant le trifluoroacétate de 1-méthylimidazolinum, [Hmim]$^+$Tfa$^-$, un liquide ionique agissant comme acide de Brønsted, on a mis au point une méthode facile d'énamination des composés 1,3-dicarbonyles par les amines qui fournit des rendements allant de bons à excellents en β-énaminoesters et β-énaminones. Cette méthode a été étendue à la synthèse de pyridines substituées réalisée avec d'excellents rendements par une réaction monotope à trois composants formés de composés 1,3-dicarbonyles, d'acétate d'ammonium et d'alkynone, en présence de [Hmim]$^+$Tfa$^-$.

Mots clés : liquide ionique, β-énaminones, β-énaminoesters, composés 1,3-dicarbonyles, amines, pyridines.

[Traduit par la Rédaction]

β-Enamino esters and β-enaminones are important precursors for the synthesis of biologically active compounds such as amino acids (1), γ-aminols (1*d*), peptides (2), and heterocyclic compounds (3).

The most common route for the synthesis of these compounds involves the direct condensation of β-dicarbonyl compounds with amines at reflux in benzene–toluene with azeotropic removal of water (4). Recently, K_{10}clay/ultrasound (5*a*), silica-supported microwave irradiaton (5*b*), $NaAuCl_4$ (5*c*), $Bi(TFA)_3$ (5*d*), and $Zn(ClO_4)_2{\cdot}6H_2O$ (5*e*) have been used for the condensation of 1,3-dicarbonyl compounds with amines. However, these methods have not been entirely satisfactory owing to such drawbacks as low yields, long reaction time, nonreusable catalyst, and use of hazardous solvents such as benzene and chlorinated solvents.

Several improved methods have been reported for the Bohlmann–Rahtz pyridine synthesis (6) from β-enaminones. Recently Bagley and co-workers (7) have reported one-pot, three-component reactions for the synthesis of pyridines in toluene at reflux temperature by generating the enaminone from the corresponding β-ketoesters for in situ heteroannulation in the Bohlmann–Rahtz reaction. In these studies we set out to test similar methodology using an ionic liquid for the mild preparation of enaminones and their in situ heteroannulation reaction for the Bohlmann–Rahtz pyridine synthesis.

Room-temperature ionic liquids (RTILs) consisting of imidazolium cations have gained popularity as an alternative to conventional organic solvents (8). They are highly polar yet noncoordinating and dissolve a wide range of organic and organometallic compounds. Ionic liquids were shown to enhance reaction rates in a range of reactions (9), including acid-catalysed processes (10). Chloroaluminate ionic liquids have been reported as both solvents and Lewis acid catalysts for Diels–Alder reactions and the Friedel–Crafts reaction. However, chloroaluminate ionic liquids are sensitive to water, and lead to undesired side reactions due to the release of HCl. Several Brønsted acidic ILs are synthesized and used as catalysts and solvents for esterification and pinacol–benzopinacol rearrangement (11).

In continuation of our research interest in the application (12) of RTILs in organic synthesis, we report a facile, high-yielding protocol for the condensation of 1,3-dicarbonyl compounds with amines using 1-methylimidazolium tri-

fluoroacetate ([Hmim]$^+$Tfa$^-$) at room temperature. The ionic liquids were prepared according to the procedures reported in the literature (13).

In our initial search for optimal reaction conditions, we explored the condensation of benzoyl acetone with aniline in [Hmim]$^+$Tfa$^-$, [Hmim]$^+$Tsa$^-$, and a neat solution. The results are summarized in Table 1.

Encouraged by these results, several β-diketones were condensed with amines giving the β-enaminones in excellent yields at room temperature. The results are summarized in Table 2.

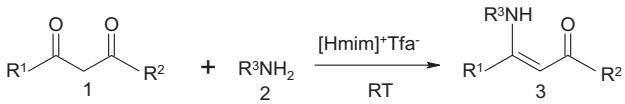
Anilines and aliphatic amines reacted efficiently to produce the corresponding β-enaminones in excellent yields. Although an earlier report (10*d*) shows that anilines with strong electron-withdrawing groups, such as 4-nitro aniline, are unreactive, we have shown that they produce the corresponding β-enaminone in good yield (Table 2, entry 6). The stereochemistry of the compounds is Z because of the intramolecular H-bonding. The (Z)-s-cis configuration shown for β-enaminones and β-enamino esters was confirmed from their ^{1}H NMR. The characteristic signals of the vinylic proton (δ 4.5–5.1 ppm) and NH signals (δ 8.3–11.3 ppm) corroborate the proposed structure.

In the case of 1,2-diaminoethane, 2 equiv. of the 1,3-dicarbonyl compound were used giving bisenaminones in 80% yield (Table 2, entry 7). In the case of aryl alkyl dicarbonyl compounds, we observed the regioselective amination of the aliphatic carbonyl group. In addition, when the 1,1,1-trifluoro-pentan-2,4-dione (**1b**) reacted with benzylamine (Table 2, entry 8) only enaminones derived from the regioselective amination of the less reactive carbonyl-bound methyl group were observed.

The scope and generality of this method was also expanded for the condensation of β-ketoesters with amines to produce β-enamino esters. The results are summarized in Table 3.

Several β-ketoesters were subjected to condensation with amines to get the β-enamino esters in excellent yields at room temperature. Due to steric hindrance, the condensation of ethyl benzoyl acetate with benzylamine requires 60 °C heating to produce the corresponding β-enamino esters in 75% yield.

Finally, the reusability of ionic liquid was studied and we found that the ionic liquid could be reused at least four times without significant loss of activity (Table 4).



Next, we extended this methodology for a one-pot, three-component reaction of 1,3-dicarbonyl compounds, ammonium acetate, and alkynone in [Hmim]$^+$Tfa$^-$ to synthesize various substituted pyridines. The results are summarized in Table 5.

Ethyl acetoacetate reacts with ammonium acetate and 4-phenyl-3-butyn-2-one in the presence of [Hmim]$^+$Tfa$^-$ at room temperature to give ethyl 2,6-dimethyl-4-phenylpyridine-3-carboxylate in 80% yield. When methyl acetoacetate or acetyl acetone was reacted with 4-(trimethylsilyl)but-3-yn-2-one, the corresponding protodesilylated pyridines **6b** and **6d** were obtained in 90% and 92% yield.

Conclusion

In summary, this paper describes a novel and efficient protocol for the synthesis of β-enamino esters and β-enaminones from 1,3-dicarbonyl compounds and amines. The advantage of this methodology lies in its operational simplicity and relatively shorter reaction time. This method also avoids the use of hazardous solvents such as benzene and azeotropic distillation conditions. The ionic liquid used can be recycled up to four times without an appreciable fall in yield, indicating that this protocol will be useful for the synthesis of natural products involving the intermediacy of β-enamino esters and β-enaminones. The one-pot, three-component reaction for the synthesis of substituted pyridines was achieved without using hazardous solvents, such as toluene or dichloromethane, at room temperature in excellent yields.

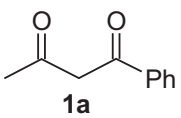
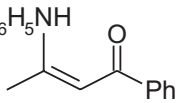
Experimental

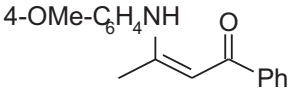
IR spectra were recorded as solids in KBr pellets on a PerkinElmer FT IR spectrometer. ^{1}H NMR spectra were recorded on a 500 MHz Joel spectrometer using TMS as the internal standard. ^{13}C NMR spectra were recorded on a 125 MHz spectrometer in $CDCl_3$, and chemical shifts are given in δ relative to the solvent peak. Mass spectra were recorded on a Joel DX-303 mass spectrometer. Analytical TLC was performed on precoated sheets of silica gel G of 0.25 mm thickness containing PF 254 indicator (Merck, Darmstadt). Column chromatography was performed with silica gel (60–120 mesh, S.d Fine, Boisar).

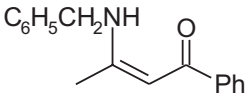
Typical experimental procedure for the preparation of β-enaminones 3a–3k and β-enamino esters 5a–5e

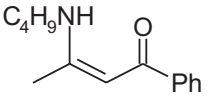
To a solution of 1,3-dicarbonyl compounds (1 mmol) in [Hmim]$^+$Tfa$^-$ (1 mL) was added amines (1.5 mmol). The reaction mixture was stirred at room temperature for the appropriate time (Tables 1 and 2). After completion of the reaction as indicated by TLC, the reaction mixture was diluted with distilled water (20 mL) and extracted with diethyl ether (3 × 15 mL). The combined organic layer was dried over anhydr. Na_2SO_4, filtered, and concentrated under reduced pressure. The crude product was purified by filtration on a short silica gel column pretreated with Et_3N.

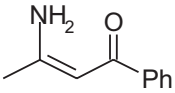


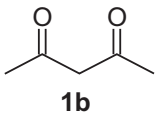


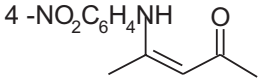


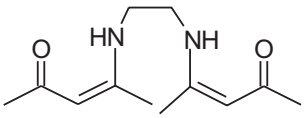


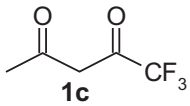


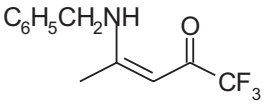


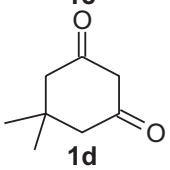


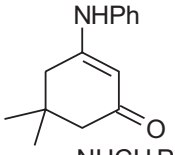


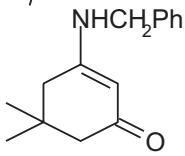












The aqueous layer was extracted with ether to remove residual reactants. Then the aqueous layer was collected and concentrated under reduced pressure at 70 °C to recover the IL, and was recycled.

The mechanism of 1,3-dipolar cycloaddition reactions of cyclopropanes and nitrones — A theoretical study

D. Wanapun, K.A. Van Gorp, N.J. Mosey, M.A. Kerr, and T.K. Woo

Abstract: The 1,3-dipolar cycloaddition reaction of cyclopropanes and nitrones to give tetrahydro-1,2-oxazine has been studied with density functional theory calculations at the B3LYP/6-31+G(d,p) level of theory. Realistic substituents were modelled including those at the 2-, 3-, 4-, and 6-positions of the final oxazine ring product. The strained σ bond of the cyclopropane was found to play the role of an alkene in a conventional [3+2] dipolar cycloaddition. Two distinct, but similar, reaction mechanisms were found — an asymmetric concerted pathway and a stepwise zwitterionic pathway. The reaction barriers of the two pathways were nearly identical, differing by less than ~1 kcal/mol, no matter what the substituents were. The effect of a Lewis acid catalyst was examined and found to have a very large effect on the calculated barriers through coordination to the carbonyl oxygen atoms of the diester substituents on the cyclopropane. The reaction barrier was found to decrease by as much as ~19 kcal/mol when using a BF_3 molecule as a model for the Lewis acid catalyst. Solvent effects and the nature of the regiospecificity of the reaction were also examined. Trends in the calculated barriers for the reaction were in good agreement with available trends in the reaction rates measured experimentally.

Key words: 1,3-dipolar cycloaddition, cyclopropane, nitrone, tetrahydro-1,2-oxazines, ab initio quantum chemistry, mechanism.

Résumé : Faisant appel à des calculs de la théorie de la densité fonctionnelle au niveau B3LYP/6-31+G(d,p), on a étudié la réaction d'addition 1,3-dipolaire des cyclopropanes et des nitrones qui conduit à la formation de tétrahydro-1,2-oxazines. On a effectué des études modèles réalistiques de substituants, y compris ceux dans les positions 2, 3, 4 et 6 du cycle oxazine du produit final. On a trouvé que les liaisons σ tendues du cyclopropane jouent le rôle d'un alcène dans une cycloaddition dipolaire [3+2] conventionnelle. On a trouvé deux mécanismes distincts, mais similaires, soit une voie asymétrique concertée et une voie zwitterionique par étape. Les barrières à la réaction pour les deux voies sont presque identiques, ne différant que par moins qu'une kcal/mol, quelle que soit la nature du substituant. On a examiné l'effet catalytique d'un acide de Lewis et on a trouvé un effet très important sur les barrières calculées en raison d'une coordination des atomes d'oxygène du carbonyle des substituants esters sur le cyclopropane. On a trouvé que la barrière diminue par une valeur allant jusqu'à environ 19 kcal/mol lorsqu'on a utilisé une molécule de BF_3 comme modèle d'un catalyseur acide de Lewis. On a aussi étudié les effets de solvant et la nature de la régiospécificité de la réaction. Les tendances dans les barrières calculées pour la réaction sont en bon accord avec les tendances disponibles dans les vitesses de réactions qui ont été mesurées expérimentalement.

Mots clés : cycloaddition 1,3-dipolaire, cyclopropane, nitrone, tétrahydro-1,2-oxazines, chimie quantique ab initio, mécanisme.

[Traduit par la Rédaction]

Introduction

The tetrahydro-1,2-oxazine heterocycle forms the central feature of several natural products possessing antitumor and antibiotic properties, such as FR900482 (1–3) and FR66979 (4), shown in Fig. 1. These natural products have received great interest from the synthetic community for their potential as therapeutic drugs. The tetrahydro-1,2-oxazine heterocycle has also been used recently in the synthesis of a pyrrolidine ring in a synthetically challenging fused 6/5/5/5 ring system that forms the tetracyclic core of nakadomarin A (5). However, the preparations of the heterocyclic core are not abundant (6), making alternative methods for the synthesis of the tetrahydro-1,2-oxazine ring desirable. Recently, a new and flexible synthesis of the 1,2-oxazine ring has been developed involving the reaction of nitrones with

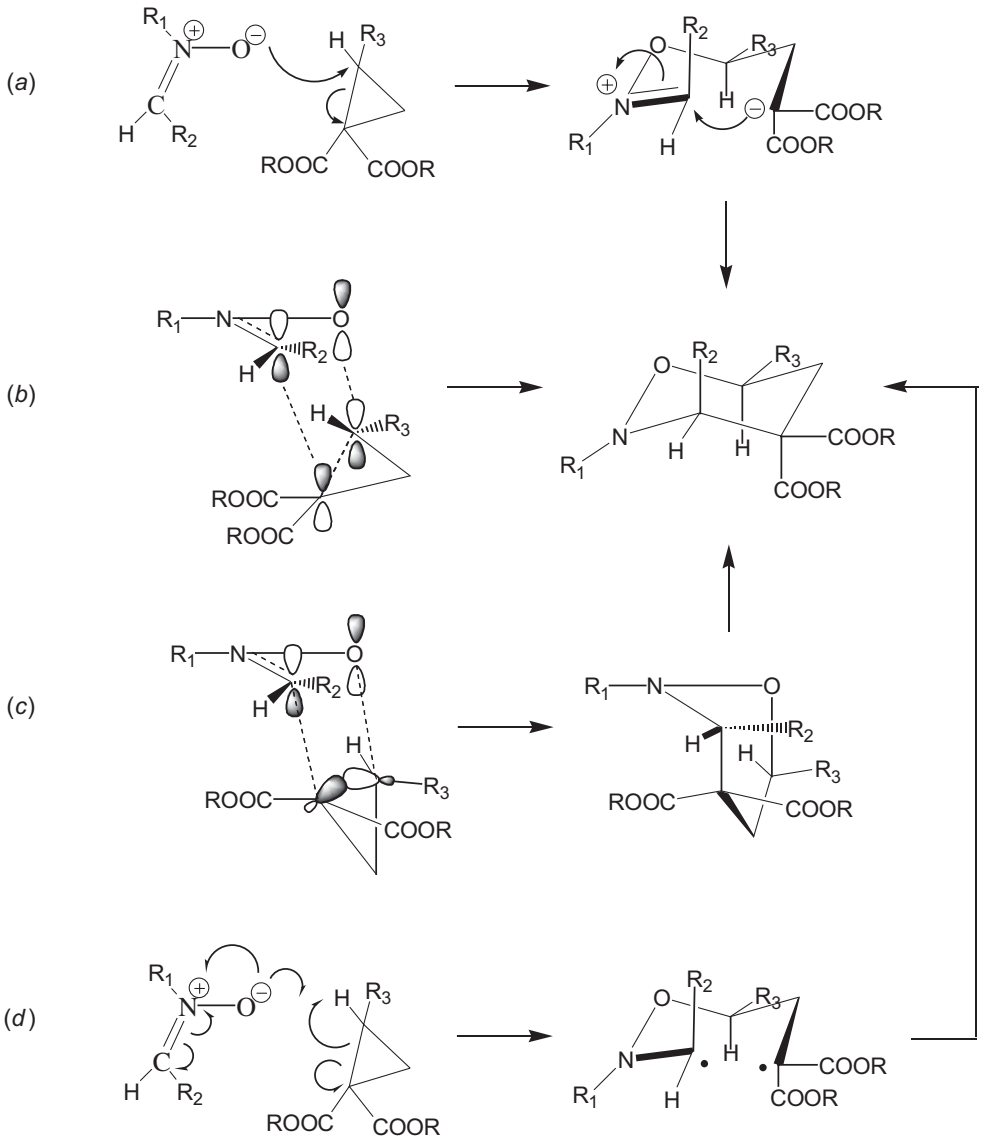
Scheme 1.



cyclopropane rings that bear electron-withdrawing ester substituents (5, 7–10). This reaction, which is shown in Scheme 1, was the first report of a cycloaddition reaction between a nitrone and a cyclopropane. The synthetic utility of the reaction is evident with the formidable tetrahydro-1,2-oxazine heterocycle being prepared in excellent yields under relatively mild conditions and with virtually complete diastereoselectivity. More recently, an effective three-component, one-pot protocol has been developed where the nitrone is generated in situ allowing for a diversity-oriented synthesis of tetrahydro-1,2-oxazines (8). It was found that electron-withdrawing groups (EWGs) are required on the cyclopropane for the reaction to proceed and, to date, 1,1-cyclopropanediesters have been utilized almost exclusively. Additionally, the presence of electron-donating groups, such as phenyl or vinyl, vicinal (R3 in Scheme 1) to the diester moiety on the cyclopropane enhances the activity of the reaction. The reaction also requires the presence of a Lewis acid catalyst, the best of which, in terms of activity and yield, was found to be $Yb(OTf)_3$. The reaction is regiospecific, with the sole regioisomer being that with the oxygen atom lying distal to the diester moiety in the product 1,2-oxazine ring.

1,3-Dipolar cycloadditions are amongst the most important synthetic reactions for generating heterocycles (11–14). The predictability of cycloaddition reactions based on steric and electronic considerations in the transition-state structure allows for the selective synthesis of complex heterocyclic structures (15). Consequently, a detailed understanding of the mechanism of the reaction will improve the predictability and the synthetic utility of the reaction. Three distinct reaction mechanisms were proposed originally (7) and are depicted in Schemes 2*a*–2*c*. The first pathway, labeled "*a*" in Scheme 2, involves the stepwise formation of the products through the initial formation of the C—O bond to yield a zwitterionic intermediate with a negative charge on the carbon atom bearing the ester groups and the positive charge on the nitrogen followed by formation of the C—C bond to yield the products. The second pathway, labeled "*b*", involves concerted bond formation through a chairlike conformation to form the products in a single step. This pathway is analogous to that of the reaction of nitrones with alkenes. The third pathway also involves concerted bond formation between the nitrone and cyclopropane ring; however, this time the strained σ bond of the cyclopropane ring is involved and the transition-state species is in a half-chair geometry. Another possible pathway, not mentioned by the initial work of Young and Kerr (7), for 1,3-dipolar cycloadditions is a stepwise mechanism involving a diradical intermediate (Scheme 2*d*) that was proposed by Firestone in the 1970s (16). To date, however, no convincing experimental evidence has been reported that supports the diradical mechanism (17), and it is now a general consensus that 1,3-dipolar cycloadditions do not react through a diradical pathway (18). A recent computational study of the reaction of a nitrone with ethene further supports this picture (17).

As mentioned in the preceding paragraph, the reaction of nitrones with substituted cyclopropanes can be described as a 1,3-dipolar cycloaddition. In general, this class of reactions provides an efficient means of forming heterocyclic components of larger systems, such as that of FR-900482 previously described. 1,3-Dipolar cycloadditions have also been well-studied through computational and theoretical means (19–22), including those of nitrones with alkenes (23–30). Such previous work is relevant to the current study since it has been proposed that the strained bonds in the

Scheme 2.

cyclopropane rings exhibit substantial π character (31). Although the specific details of these studies will not be discussed here, it is important to consider several general observations that have been reported in these studies that can be applied to this system. In general, density functional theory (DFT) has been employed as a relatively accurate, cost-effective method for the study of these systems (24). From a mechanistic point of view most ab initio calculations favour or assume a concerted pathway for the addition of nitrones to alkenes (21). Although the regio- and stereochemistry of the products of the reaction of nitrones with alkenes is quite complicated and dependent upon substituent effects, it has been found that the origins of the regio- and stereo-selectivity can often be adequately described by frontier molecular orbital (FMO) theory (32–34). In cases where such analysis is inadequate, more sophisticated models have been used that take into account secondary orbital interactions (21) and closed-shell repulsions (35) between the two reactant species, or alternative reactivity concepts based on hard and soft acid–base principles such as local and global hardness (25).

In this work we apply quantum chemistry to examine the mechanism of the 1,3-dipolar cycloaddition reaction between nitrones and cyclopropanes. The goal is to provide a detailed mechanistic account of the reaction that will hopefully provide key information that will assist in future experimental efforts to optimize the reaction. Specifically, the effect of the diester substitution and the R3 substitution on the reactant cyclopropane on the reaction has been probed. Up to two BF_3 molecules have been used to study the role of the Lewis acid catalyst that is required for the reaction to be observed. Using a continuum solvation model, solvent effects on the reaction have been examined. Finally, we have examined the nature of the regiospecificity of the reaction. The computational methods used throughout this study are introduced in the next section. This section is followed by a discussion of the results of the calculations that have been performed and finishes with conclusions.

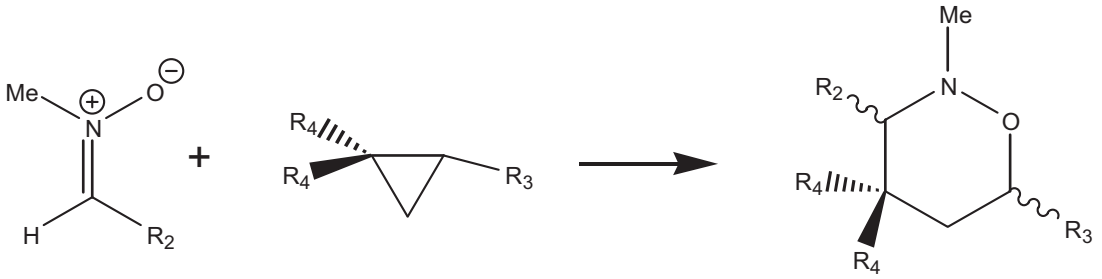
Methods

Computational details

All energies and geometry optimizations of the stationary points (reactants, products, transition states, and intermediates) were performed using Kohn–Sham DFT (36, 37) at the B3LYP level of theory (38, 39) using the Jaguar 5.0 program (40) unless otherwise stated. The results from a basis set study using the 6-31G(d,p), B3LYP/6-31+G(d,p), 6-31++G(d,p), and 6-311++G(d,p) basis sets are summarized in Table 1 for the reaction of a nitrone with both an unsubstituted and substituted cyclopropane. The data in Table 1 reveals that the relative energies of the transition states, intermediates, and products converge with the 6-31+G(d,p) basis set, and using a larger basis set, results in minimal changes in these properties. Thus, the 6-31+G(d,p) basis set was used for this study as it provided the best balance of accuracy and computational efficiency. To search for the biradical pathway, a procedure similar to that in our previous work on diradical dimetallenes (41) was followed where unrestricted DFT was employed with mixing of the HOMO and LUMO in the initial guess of the wave function to generate open shell electronic structures.

Due to the conformational flexibility of the substituents on some of the cyclopropanes studied, a comprehensive conformer search was carried out on the reactants, intermediates, and products using the following protocol. First, a conformational search was performed at the semiempirical PM3 (42) level of theory using the default Monte Carlo based conformational search engine of the Spartan 2002 molecular modeling package (43). The three lowest energy and distinct structures obtained at the PM3 level were then optimized at the B3LYP/6-31+G(d,p) level. The structures and energies reported here are the lowest energy structures resulting from this procedure. Frequency calculations were performed on all stationary points to confirm that minimum energy structures had no imaginary frequencies and that transition states had only one imaginary frequency. All of the energies include unscaled zero point energy corrections. Intrinsic reaction coordinate (IRC) calculations were performed for the reactions involving cyclopropane, 1,1-cyclopropane-dimethylester, and 2-methyl-1,1-cyclopropane-dimethylester using the GAUSSIAN 98 program (44). For other reactions, it is reasonable to assume that the transition states located correspond to analogous pathways as those found in the aforementioned IRC calculations based on the comparison of geometries, relative energies, and bond orders of the stationary points.



The natural bond orbital (NBO) analysis (45) was performed with the NBO program that is distributed with Jaguar 5.0. The use of Kohn–Sham orbitals, both virtual and occupied, for qualitative chemical analysis in molecular orbital arguments has been previously shown to be suitable (46, 47). Solvent effects on the relative energetics of the various reaction pathways were taken into account through the polarizable continuum model of Friesner and co-workers (48) as implemented in the Jaguar 5.0 package. The default values of Jaguar were used for the solvent dielectric constants and probe radii. Frequency calculations with the continuum solvation model performed on both minima and transition states revealed that the structures had many more low frequency (<40 cm^{-1}) vibrational modes compared with their gas-phase counterparts. Additionally, the structures often possessed several superfluous imaginary vibrational frequencies that could not be eliminated after many optimization attempts with adjusted convergence parameters. The small vibrational modes have a large impact on the calculated vibrational free energy term that can result in large errors when comparing relative free energies of species. Although a cut-off frequency can be applied, one must ensure all compared species have the same number and nature of frequencies removed or again, large errors can ensue when comparing energies. For these reasons, we have opted to report the relative free energies of solvation that do not include any vibrational, rotational, and translational thermal or entropic corrections. The relative free energies of solvation reported, however, do include the zero point vibrational energy corrections, which are not significantly effected by the low vibrational modes, such that these values can be most directly compared with the ΔE values reported for the gas phase.

Model systems

The typical approach to the development of model systems for use in a computational study is to decrease the size of the system as much as possible through the removal of all substituents that are not absolutely necessary to achieve the goals of the study. As such, a completely hydrogen substi-

tuted nitrone was used initially as a model reactant. However, reactions of this nitrone with the 1,1-cyclopropanedicarboxylic acid reactant lead to proton transfer between the nitrone and the carboxylic acid groups, which is also observed in experiment (8). Replacing the hydrogen bonded to the nitrogen of the nitrone with a methyl group prevented the proton transfer and was also a more realistic model. This model, shown in Scheme 3, is referred to as methyl nitrone **N1** and was used in all calculations performed in this study.

Results and discussion

The discussion section begins with a minimally substituted model system, where the reactant cyclopropane is unsubstituted. Substituent effects are examined in the following two sections. More specifically, the role of the diester moiety on the cyclopropane is studied, followed by the nature of the R3 substitution on the cyclopropane. Solvent effects are briefly discussed in the next section, followed by a more detailed examination of the role of the Lewis acid catalyst. The last section details the nature of the regiospecificity that was experimentally observed.

Throughout this discussion an unconventional naming scheme has been employed to reflect both the nature of the pathway and the reactant species involved. Although it is common practice to simply identify species with a numerical digit, it is hoped that the nomenclature system used here will ease in the identification of the species that is being discussed. The reactant nitrones and cyclopropanes are labeled **N*x*** and **C*x***, respectively, with *x* representing the specific nitrone or cyclopropane (see Scheme 3). The names of the other stationary points have three parts to them. The nature of the pathway is expressed in the first part of the name for the transition states and intermediates — either **CN** for a concerted pathway or **SW** for a stepwise pathway. The second part of the name is a numeric digit (*n*) used to identify the unique combination of R2 and R3 substituents. These are shown in the product labels "**P*n***" in Scheme 3. For example, the concerted reaction that gives rise to the product **P4**, goes through a concerted transition state **CN4**‡, where the superscript double dagger denotes a transition-state structure. For the stepwise pathways a third portion of the name exists that consists of an alphabetical character that corresponds to the position of the stationary point beyond the reactants towards the products. For example, **SW2-A**‡ refers to first transition state for the stepwise reaction of methyl nitrone to dimethyl 1,1-cyclopropanedicarboxylate. The label "**A**" refers to the fact that this transition state is the first stationary point following the reactants. **SW2-B** refers to the intermediate for the stepwise pathway. The intermediate is the second stationary point along the reaction coordinate past the reactants and, hence, "**B**". Additions to this naming scheme for the calculations that model the solvent, the Lewis acid, and regiochemistry will be introduced in the respective sections ahead.

Reaction of methyl nitrone with unsubstituted cyclopropane

We began our study by investigating the reaction of **N1** with the unsubstituted cyclopropane ring **C1**. The goal here is to examine the intrinsic reactivity of these two species in the absence of any substituents for later comparison with more realistic models. Attempts were made to locate intermediates and transition states corresponding to all four of the proposed mechanisms depicted in Scheme 2, including the diradical pathway. However, the only pathway that was found is one that is consistent with a concerted addition through a half-chair geometry (reaction c in Scheme 2). The transition-state structure (**CN1**‡) is shown in Fig. 2*a*, and the relative energies for this reaction pathway are detailed in Table 2. The electronic barrier for the reaction is 60.4 kcal/mol, while the estimated free energy barrier at 298 K and 1 atm is 71.0 kcal/mol (1 atm = 10.325 kPa). The large reaction barriers are consistent with the fact that the reaction involving unsubstituted reactants is not observed.

Examination of the geometry of the transition-state structure reveals that **CN1**‡ can be characterized as a half-chair

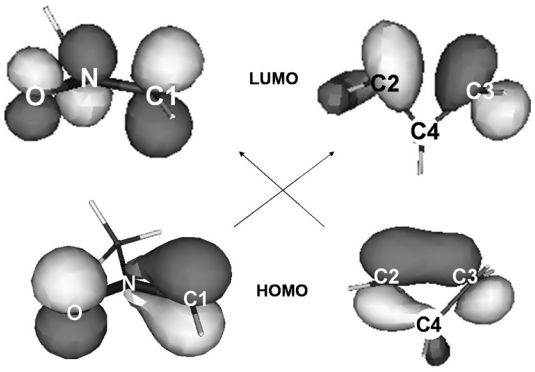
	Energies		Wiberg bond orders			
Species	ΔE	ΔG^a	C1—C2	C2—C3	C3—O	C1—N
N1 + C1	0.00	0.00	0.00	1.00	0.00	1.55
CN1‡	60.37	71.00	0.53	0.48	0.30	1.27
P1	–30.13	–18.24	1.01	0.01	0.91	0.98



Note: Energies are relative to **N1 + C1**.
[a]Gas-phase relative free energy at 298 K and 1 atm.

conformation. For example, the C4-C3-C2-O dihedral angle in **CN1**‡ of 182° is very close to the value of 180° found in an ideal half-chair geometry. The C4-C3-C2-C1 dihedral angle of 160.0° and the N-O-C1-C4 dihedral angle of 132.3° are close enough to the ideal values of 180.0° and 125.3°, respectively, to be classified as half-chair geometries.

It is possible to further characterize this transition state through an examination of the bond orders and lengths at stationary points along the reaction path. Relevant Wiberg bond orders are listed in Table 2 along side the relative energies. The C1—C2 and O—C3 bond orders in the transition state (**CN1**‡) have values of 0.53 and 0.30, respectively, which indicates that these bonds are both partially formed. Also, the C2—C3 bond order (0.48) shows evidence of dissociation, and the C1—N bond order (1.27) illustrates that the double bond is being decreased to a single bond. The bond lengths for the C1—C2 and O—C3 bonds, which are shown in Fig. 2*a*, are typical for partially formed bonds of this nature. The initial C2—C3 bond length was found to increase from a value of 1.51 Å in the reactant to a value of 2.05 Å in the transition state, which is indicative of bond dissociation. The C1—N transition-state bond length of 1.35 Å is larger than the reactant value of 1.31 Å, signifying that the bond is converting to a single bond. The bond order and bond length results complement each other and indicate that the process is in fact a synchronous concerted mechanism.

Fig. 3. Frontier molecular orbitals of the two reactant species fragments in their respective geometries in transition state **CN1**‡. For nitrone, ε_{LUMO} = –0.083969 and ε_{HOMO} = –0.235387 au. For cyclopropane, ε_{LUMO} = –0.047419 and ε_{HOMO} = –0.220461 au. All isosurfaces are plotted at a value of 0.07 au.

Further characterization of the pathway can be obtained through examination of the FMO interactions (15, 34). Isosurface plots of the frontier molecular orbitals of the two reactant species in their respective transition-state geometries are shown in Fig. 3 along with their respective orbital energies. It is possible to identify the HOMO of the cyclopropane as a strained σ bond between the C2 and C3 atoms, while the LUMO of this fragment is its antibonding counterpart. The HOMO of the nitrone fragment is a nonbonding orbital with a nodal plane approximately centered on the nitrogen atom, while the LUMO consists of π-antibonding interactions along the C1—N and N—O bonds. Drawing the analogy between the strained σ-bonding frontier orbitals of cyclopropane to the π-bonding orbitals of an alkene, it is apparent that the frontier molecular orbitals of the reactants have the proper symmetry to take part in a classic, concerted 1,3-dipolar cycloaddition reaction. The energy difference between the LUMO of the nitrone and the HOMO of the cyclopropane is 0.14 au, while the energy difference between the LUMO of the cyclopropane and the HOMO of the nitrone is 0.19 au. Thus, on the basis of a smaller HOMO–LUMO difference, the dominant orbital interaction involves the LUMO of the nitrone and the HOMO of the cyclopropane. Since the LUMO of the nitrone is clearly polarized toward the C atom, one would expect the formation of the C1—C2 bond to lead the reaction. This is consistent with the slightly larger C1—C2 bond order of 0.53 as compared with the C3—O bond order of 0.30 in the transition state (**CN1**‡).

The reaction of **N1** with the unsubstituted cyclopropane ring **C1** occurs via a concerted mechanism. Moreover, analysis of the geometry, bond orders, and frontier molecular orbitals of the transition state (**CN1**‡) reveals that the reaction can be further characterized as a classic [3+2] synchronous concerted cycloaddition.

Reaction of methyl nitrone with 1,1-cyclopropanedimethyl ester

Experimentally, the cycloaddition reaction requires EWGs on the cyclopropane to proceed under normal reaction conditions, and to date 1,1-cyclopropanediesters have been used almost exclusively (7). In this section the reaction of **N1** with 1,1-cyclopropanedimethyl ester (**C2**) to yield the product (**P2**) will be examined. Two pathways were found — a concerted mechanism and a stepwise mechanism. An intrinsic reaction coordinate calculation starting from each transition-state structure verified that these structures connect the reactants to the products and that the two pathways are in fact distinct. In what follows, the concerted pathway will be examined in detail, followed by an examination of the stepwise pathway.

Concerted pathway

The first pathway is a concerted process as it involves progression over a single transition-state structure (**CN2**‡), shown in Fig. 2*b*, linking the reactants to the products. Energetics and bond orders of the stationary points involved in the concerted pathway and the stepwise pathway are detailed in Table 3. The concerted pathway has a gas-phase free energy barrier of 59.3 kcal/mol at 298 K and 1 atm, which is significantly less than the barrier for the reaction of **N1** with the unsubstituted cyclopropane, which possessed a free energy barrier of 71.0 kcal/mol.

Analysis of the geometric details of this transition state indicate that the two reactant species have the correct relative orientations to be characterized as an approximate half-chair conformation with the C4-C3-C2-O (148.1°), C4-C3-C2-C1 (160.8°), and N-O-C1-C4 (152.3°) dihedral angles all slightly deviated from the ideal values of 180.0°, 180.0°, and 125.3°, respectively. However, the C1—C2 and O—C3 bond distances are not indicative of a synchronous concerted process where both bonds form simultaneously. The C1—C2 bond length of 3.10 Å in the transition state is too large for significant bond formation, while the O—C3 bond length of 2.14 Å is approximately 15% shorter than that observed in the synchronous concerted transition-state structure (**CN1**‡). Thus, the O—C3 bond is preferentially forming over the C1—C2 bond, and the transition-state structure is suggestive of an asynchronous concerted process. Calculated bond orders also support this picture, with the C1—C2 bond order in the transition state being negligible at 0.05, with the O—C3 bond order being 0.33. The double bond character of the C1—N bond does not significantly change in the transition state, which differs from that of the unsubstituted transition state (**CN1**‡).

A FMO analysis of the reaction is also consistent with an asynchronous bond formation. The HOMO and LUMO of each of the two reactant fragments in their respective transition-state geometries are shown in Fig. 4 along with the energies of these orbitals. The effect of ester groups is to lower the LUMO level of the cyclopropane and to polarize the LUMO away from C2 towards the C3 atom. Conversely, the HOMO of the cyclopropane is polarized in the opposite direction. Favourable overlap appears to be possible for both HOMO–LUMO pairs between the two species and the formation of the O—C3 and C1—C2 bonds is sterically unimpeded. The orbital energies demonstrate that the HOMO(nitrone)–LUMO(cyclopropane) gap has a value of only 0.087 au; whereas the HOMO(cyclopropane)–LUMO(nitrone) is significantly larger with a value of 0.186 au. As a result, donation from the HOMO of the nitrone to the LUMO of the cyclopropane, both orbitals of which are polarized toward the oxygen atom and C3, is

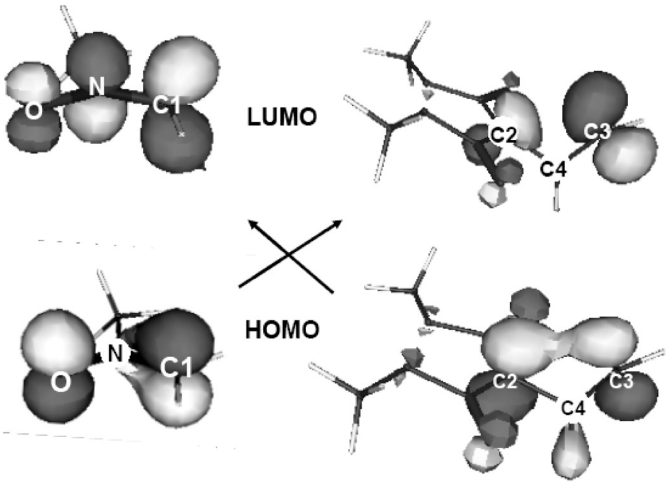
[a]Gas-phase relative free energy at 298 K and 1 atm.



favoured. This is consistent with the observed asynchronous pathway in which the O—C3 bond forms first.

Stepwise pathway

The second pathway for the addition of **N1** to 1,1-cyclopropanedimethylethyl (**C2**) occurs in a stepwise fashion. Geometric details of the transition states and the intermediate for the stepwise pathway are shown in Figs. 2*c*–2*e*, while the bond orders and relative energetics are listed in Table 3. As shown in Fig. 5, the stepwise pathway involves the progression of the reactants over an initial transition state (**SW2-A**‡) to form an intermediate (**SW2-B**), which then proceeds over a second transition state (**SW2-C**‡), to form the product (**P2**).

Examination of the first transition state (**SW2-A**‡) shows that the geometry around the C2, C3, and O atoms is similar to the transition state **CN2**‡ located for the asynchronous concerted pathway. The only exception to this is the C1—C2 distance, which is slightly longer at 3.24 Å compared with 3.10 Å in **CN2**‡. Analysis of the bond orders at this transition state indicates partial formation of the C3—O bond (0.36), as well as initial dissociation of the C2—C3 bond (0.27). The C1—C2 bond order has a value of 0.06, confirming that there is no significant bonding interaction between these two atoms. These bond orders are remarkably similar to the bond orders found in the asynchronous concerted transition state (**CN2**‡). Similarly, the electronic and free energy barriers associated with this transition state of $\Delta E^{\ddagger}$ = 47.0 and $\Delta G^{\ddagger}$ = 59.5 kcal/mol, respectively, are almost identical to the **CN2**‡ barriers of $\Delta E^{\ddagger}$ = 47.0 and $\Delta G^{\ddagger}$ = 59.3 kcal/mol.

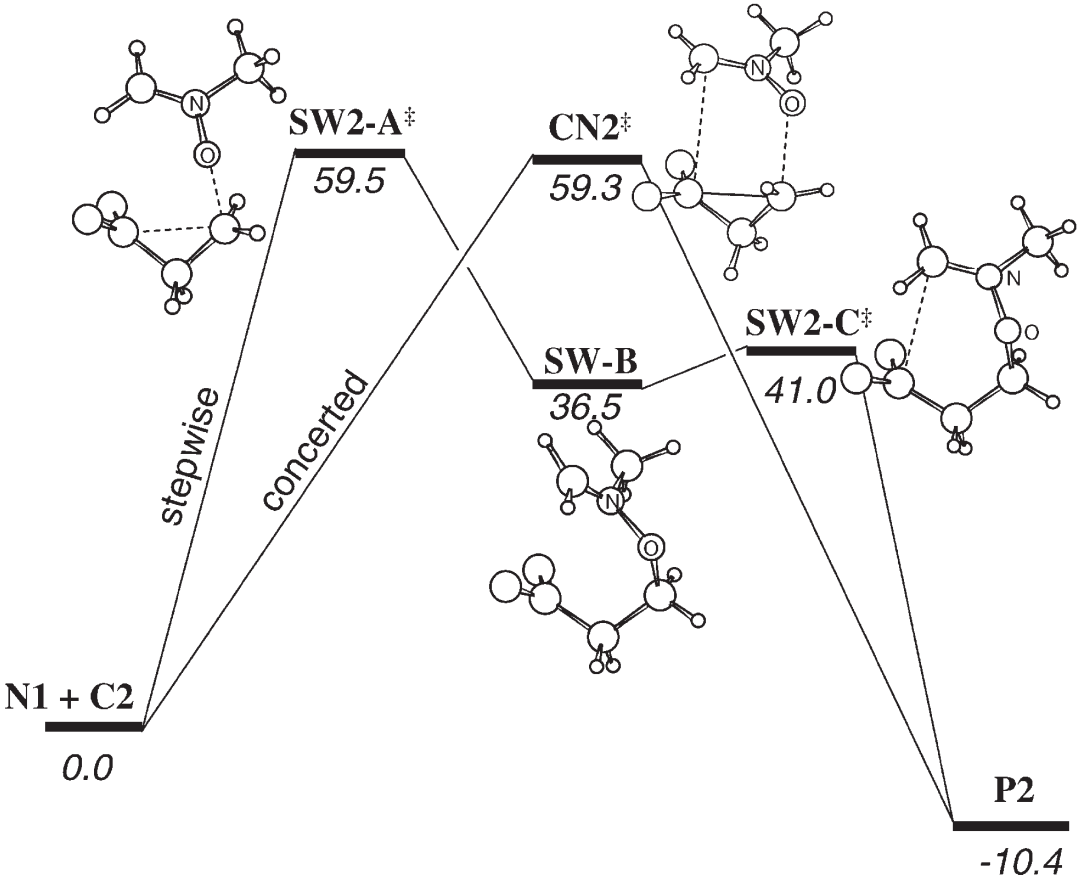


Fig. 4. Frontier molecular orbitals of the two reactant species fragments in their respective geometries in transition state **CN2**‡. For nitrone, ε_{LUMO} = –0.047957 and ε_{HOMO} = –0.234643 au. For cyclopropane, ε_{LUMO} = –0.147346 and ε_{HOMO} = –0.233880 au. All isosurfaces are plotted at a value of 0.07 au.

Once the system passes over the transition state it proceeds to a stable minimum energy structure (**SW2-B**) that is 36.5 kcal/mol higher in energy than the separated reactants. This intermediate can be described as a zwitterionic

© 2005 NRC Canada

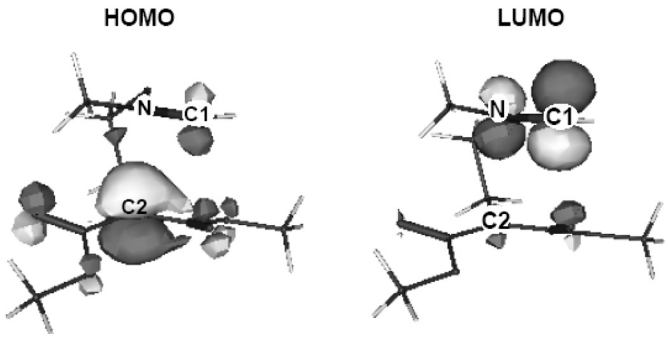

Fig. 5. Reaction profile comparing the concerted and stepwise reaction pathways for the reaction of **N1** with **C2**. Numbers in italics represent the gas-phase free energy at 298 K and 1 atm relative to the free nitrone and cyclopropane.

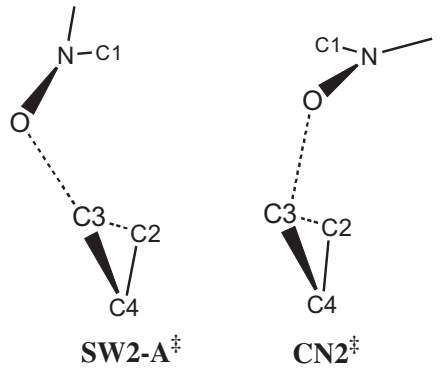
imminium species as depicted in rxn. *a* of Scheme 2. As shown by the bond distances and the calculated bond orders, the O—C3 bond has fully formed, the C2—C3 σ bond of the reactant cyclopropane has completely dissociated, while the C1=N double bond remains unchanged from that of the original nitrone fragment. The HOMO and LUMO orbitals of **SW2-B** visualized in Fig. 6 are consistent with the characterization of this intermediate as zwitterionic. The isosurface plot of the HOMO reveals a lone pair orbital that is localized on C2; whereas the LUMO can be described as a π* orbital between the C1 and N atoms.

To form the product (**P2**), the intermediate proceeds over a second transition state (**SW2-C**‡) that only lies 4.5 kcal/mol higher in free energy than the preceding intermediate. Interestingly, the C1—C2 and C1—N bond orders in the transition state remain unchanged from those in the intermediate, suggesting that the origin of this barrier does not directly involve the formation of the C1—C2 bond and breakage of the C1=N double bond. Following the IRC trajectory from the intermediate **SW2-B** to the transition state **SW2-C**‡ suggests that the barrier is associated with rotation about the N—O bond. The reduction of the C1-N-O-C3 dihedral angle from 136° in **SW2-B** to 102° in **SW2-C**‡ facilitates reduction of the C1—C2 bond distance from 3.52 to 2.92 Å. Only in the later stages of the IRC trajectory from the transition state (**SW2-C**‡) to the product does the C1—C2 bond order increase and the C1—N bond order decrease.

Fig. 6. Isosurface plots of the HOMO and LUMO molecular orbitals of the stepwise zwitterionic intermediate, **SW2-B**. All isosurfaces are plotted at a value of 0.07 au.



Comparison of the pathways

Several similarities exist between the concerted and stepwise reaction pathways, most notably the remarkable similarity in the energetic barrier and bond orders of the concerted transition state (**CN2**‡) and the first stepwise transition state (**SW2-A**‡). Bond orders of the transition states (**CN2**‡ and **SW2-A**‡), which show that the only bond in the process of breaking is the C2—C3 bond, one can conclude that the origin of the barrier for both pathways is the dissociation of the C2—C3 bond of the cyclopropane moiety. The foremost geometric difference between the two transition

© 2005 NRC Canada

Fig. 7. Comparison of the structures of the transition states for the stepwise zwitterionic and asynchronous concerted pathways that highlights their foremost differences.

SW2-A‡ **CN2**‡

states is the orientation of the nitrone moiety relative to the plane of the cyclopropane ring as depicted in Fig. 7. The C2-C4-C3-O dihedral angle can be used to quantify this difference in the two transition states. In **CN2**‡ this dihedral angle is –40°; whereas it is +37° in **SW2-A**‡. In the stepwise pathway, the nitrone moiety is twisted such that a weak intermediate forms instead of the C1—C2 bond forming directly as in the concerted pathway. Thus, although the two pathways are distinct, one can characterize the difference as only conformational in nature.

Substitution at the R3 position of the cyclopropane

Kerr and Young (7) have investigated the presence of phenyl, styryl, and vinyl substituents vicinal to the diester moiety on the cyclopropane or, in the labeling convention of this work, substitution at the R3 position of Scheme 3. Only qualitative reaction times were recorded in their experiments, but it was found that these substitutions at the R3 position resulted in greatly reduced reaction times. We have computationally examined the effect of replacing R3 = H with R3 = Me, vinyl, and phenyl. Relative energetics for the reactions of **N1** with these substituted dimethyl 1,1-cyclopropanedicarboxylates — **C3** (R3 = Me), **C4** (R3 = vinyl), and **C5** (R3 = phenyl) — are detailed in Table 3. In all cases, both concerted and stepwise reaction pathways were found. Although an IRC calculation was only performed for the reaction of **N1** with **C3** (R3 = Me), we are reasonably certain that all of the pathways located are consistent with the asynchronous concerted and stepwise pathways described in the previous section through comparison of the geometries, relative energies, and bond orders of the stationary points.

Addition of the R3 substituent resulted in a significant decrease in the free energy barriers for each of the substituents studied. The phenyl substitution had the strongest effect, followed in sequence by the vinyl and methyl substitutions. More specifically, for the concerted pathway, the free energy barrier was lowered by 10.1, 7.4, and 6.1 kcal/mol for the R3 = Ph, vinyl, and Me substitutions, respectively, compared with the reaction involving **C2**. These computed values are consistent with the experimental results that the phenyl substitution resulted in a lower reaction time than the vinyl substitution (7). Substitution at the R3 position is expected to stabilize the carbocationic character of the C3 atom in the transition states as the C2—C3 bond of the cyclopropane breaks. The trends in the C2—C3 bond orders for both the concerted and first stepwise transition states are in agreement with this picture. For example, for **CN2**‡ with R3 = H, the C2—C3 bond order is 0.27. Upon substitution with R3 = Me, vinyl, and phenyl this is reduced to 0.17, 0.12, and 0.09, respectively. This trend in the C2—C3 bond orders matches that of the reaction barriers for the concerted reaction. A similar trend is observed for the bond orders involving the first stepwise transition states. It is worth noting that regardless of the substituent at the R3 position, the energetic barriers for the concerted and stepwise reaction pathways are remarkably close — each within 2 kcal/mol of one another. This provides further evidence of the similarity between the asynchronous concerted and the stepwise zwitterionic cycloaddition pathways, in the sense that they are influenced equally by the substituents. Similarily, it is notable that the free energy barrier of the second transition state (**SWn-C**‡) is in all cases 5 kcal/mol or less, suggesting that the intermediate **SWn-B** is very short lived and would not be isolatable.

Solvent effects

Experimentally, the reactions were often performed in dichloromethane or, when heating was required, 1,2-dichloroethane was used as a solvent. Toluene was also a suitable solvent and was used when the nitrone was formed in situ from hydroxylamines and aldehydes (8). More polar solvents were found to be less suitable. We have employed a continuum solvation model (48) to examine solvation effects on the quantum mechanical potential energy surface. The reaction of **N1** with **C2** was examined in a low polarity solvent (1,2-dichloroethane, $\varepsilon \sim 10$), and a more polar solvent (methanol, $\varepsilon \sim 33$). In both solvents, the concerted and stepwise reaction pathways were found with stationary points that are similar in structure to those in the gas phase. Important geometric parameters for the concerted and first stepwise transition-state structures are shown in Figs. 2*b* and 2*c*, respectively, with the values for dichloroethane shown in parenthesis and the values for methanol shown in square brackets. In these structures, the solvation model results in a modest elongation (<6%) of all the bonds that are being formed or broken. Relative free energies of solvation of the pathways in both solvents are summarized in Table 4, with species solvated in methanol suffixed with the label **(M)** and those solvated in dichloroethane suffixed with **(D)**. As mentioned in the computational details section, the relative free energies of solvation reported here do not include any vibrational, rotational, or translation free energy corrections and are best compared to the reported internal energies (ΔE) for the gas-phase reactions.

One might expect that a polar solvent would favour the zwitterionic pathway more than the concerted pathway because of the greater charge separation in the former. The calculated results are in agreement with this picture. In the gas phase, the barrier difference between zwitterionic and concerted pathways is only 0.02 kcal/mol in favour of the zwitterionic pathway. In 1,2-dichloroethane this preference increases to 1.7 kcal/mol and in methanol it increases to 2.9 kcal/mol. In all cases, the solvent model modestly increases the barriers compared with the gas phase. This can be attributed to the favourable free energy of solvation of the reactant nitrone, which can be characterized as zwitterionic.

Fig. 8. Transition-state structure **SW2-A‡** with model Lewis catalyst (BF_3) coordinated on site *i* (left) and *ii* (right).

The thermodynamics of the overall reaction are more strongly affected by the solvent model than the reaction barriers. In the gas phase, the overall reaction energy is ΔE = –24.2 kcal/mol, which compares with ΔE = –15.3 kcal/mol in dichloroethane and ΔE = –14.1 kcal/mol in methanol. The decrease in reaction energy as the solvent polarity increases can be attributed to the fact that the reactant nitrone is zwitterionic and has a more polarizable π system; whereas the oxazine product is not zwitterionic and lacks a π system.

Lewis acid catalysis

Experimentally, the reaction of nitrones with cyclopropane diesters has only been observed in the presence of a Lewis acid catalyst. It was proposed that the Lewis acid induces polarization of the C2—C3 bond by coordinating to the carbonyl oxygen of the ester group on the cyclopropane ring (7). The most often used and effective Lewis acid is ytterbium triflate ($Yb(OTf)_3$). Here we explore the influence of a Lewis acid on the reaction using a much smaller and computationally tractable model Lewis acid, trifluoroborane (BF_3). The BF_3 molecule was assumed to coordinate to the diester moiety and coordination at numerous sites was tested, followed by a Monte Carlo conformational search of these coordination motifs.

The naming scheme used so far must now be expanded upon to incorporate the addition of a Lewis acid catalyst. Coordination of a single BF_3 molecule was found to occur in one of two distinct sites, which will be referred to as site "*i*" and site "*ii*". The two sites are shown in Fig. 8 for a stepwise transition state to be discussed ahead. An additional descriptor **(BF_3-i)** will be added to the structure name to denote coordination to site *i*, while **(BF_3-ii)** will be used to denote coordination at site *ii*. For example, the transition state **CN2‡** with the Lewis acid bound to site *i* becomes **CN2(BF_3-i)‡** and the stepwise intermediate **SW2-B** with the Lewis acid bound to site *ii* becomes **SW2-B(BF_3-ii)**. It should be noted that for **C2** the two coordination sites are actually identical. Thus, one molecule of BF_3 coordinated to **C2** will be referred to as **C2(BF_3)**. The effect of two molecules of BF_3 acting simultaneously was also studied, and is identified by descriptor **($2BF_3$)**.

Coordination of a single BF_3 molecule to **C2** results in a significant decrease in the reaction barriers, as one would expect. Kerr and Young (7) have suggested that the coordi-

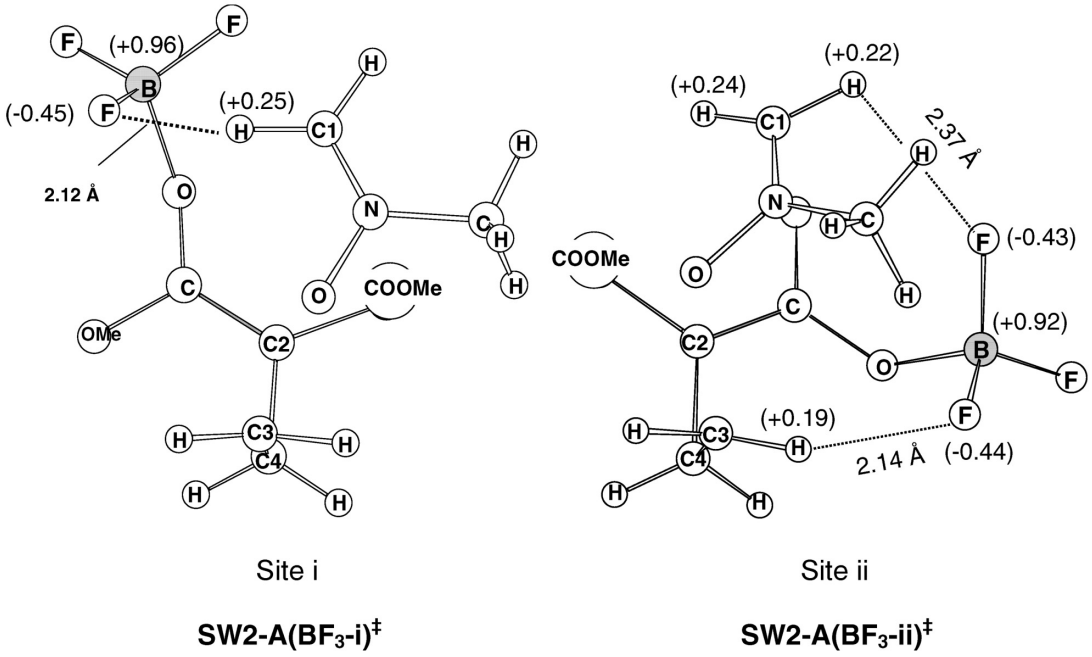
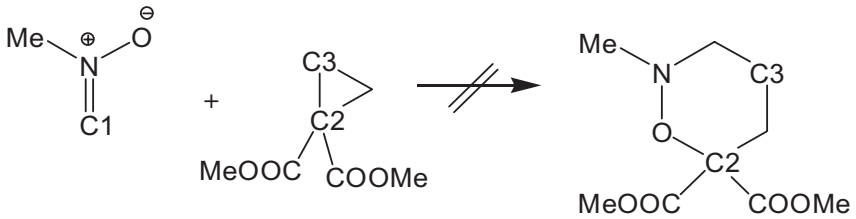
Note: Energies are relative to the free **N1 + C2** with coordinated BF_3 molecule(s).
[a]Gas-phase relative free energy at 298 K and 1 atm.

nation of the Lewis acid to the carbonyl groups of the ester substituents would further enhance the electron-withdrawing nature of the substituents as to further polarize the C2—C3. Calculated ESP charges on the C2 and C3 atoms in the free cyclopropane indeed show an observable charge polarization in the C2—C3 bond. The uncoordinated **C2** molecule is calculated to have ESP charges on the C2 and C3 atoms of –0.58 and –0.21 *e*, respectively; whereas upon coordination of the BF_3 molecule the charges become –0.72 and –0.13 *e*, indicating a stronger polarization of the C2—C3 bond.



The calculated energetics of the reaction with the model Lewis acid (BF_3) are given in Table 5 relative to the free nitrone and cyclopropane–BF_3 complex. Both the concerted and the stepwise pathways were successfully located. The presence of the BF_3 promotes the transition state of the concerted pathway to be more asynchronous. This is supported by the geometrical parameters of the transition state (**CN2(BF_3-i)‡**), where the C1—C2 and O—C3 bond distances are 3.45 and 2.25 Å, respectively. The transition-state structures of the stepwise pathways (**SW2-A(BF_3-i)‡** and **SW2-A(BF_3-ii)‡**) are depicted in Fig. 8. The addition of a single BF_3 molecule results in a significant (11.8 (site *i*) and 14.0 (site *ii*) kcal/mol) decrease in the energetic barrier for the concerted pathway compared with the equivalent reaction without the coordinated Lewis acid. For the stepwise pathway, the decrease in the first barriers are 10.4 (site *i*) and 15.2 (site *ii*) kcal/mol. Thus, for the stepwise pathway, the site *ii* pathway is markedly more favourable than the site *i* pathway by 4.8 kcal/mol. A steric preference for the site *i* pathway, which one might expect, was not present. Rather, the preference appears to be due to the formation of what may be characterized as weak hydrogen bonds involving the fluorine atoms of the BF_3 moiety. For the site *ii* coordination two such hydrogen bonds are formed as compared with the site *i* coordination of the BF_3 molecule. These stabilizing interactions are highlighted in Fig. 9 for the transition states **SW2-A(BF_3-i)‡** and **SW2-A(BF_3-ii)‡**. The H—F bond distances are long for hydrogen bonds (>2.1 Å) and consequently, labeling these interactions as hydrogen bonds may be debatable. Nevertheless, the calculated ESP charges (also shown in Fig. 9) suggest that these "bonds" minimally involve a favourable electrostatic interaction between the atoms. Although the hydrogen bonding is interesting, it and the site *ii* coordination preference are not likely to be a general feature of other Lewis acids. On the other hand, the coordination observed here does suggest that the Lewis acid has a very strong influence on the reaction and such interactions may be important in steering the reaction, particularly the relative stereochemistry of the R2 and R3 groups in the product.

Coordination of a second BF_3 molecule to the ester substituents of the cyclopropane further decreases the calculated cycloaddition barriers. The relevant energetics are tabulated in Table 5. With two BF_3 molecules coordinated, the concerted free energy barrier is 39.8 kcal/mol, and the first stepwise barrier is 39.7 kcal/mol. This compares with an energetic barrier of 59.3 kcal/mol for both the concerted and stepwise pathways without any coordinated Lewis acid. This is a substantial ~20 kcal/mol decrease. Compared to the site *ii* coordination of a single BF_3 molecule, addition of a second BF_3 molecule modestly lowers the barriers by approximately 5 kcal/mol. Although reaction conditions that have been reported are not such that it is likely that two Lewis acid molecules would be coordinated to a single cyclopropane, the two BF_3 molecules used here do model the likely scenario that a single Lewis acid, such as $Yb(OTf)_3$ or MgI_2, binds to the ester groups in a bidentate manner.



It should be noted that in some previous theoretical studies (49, 50) of nitrone cycloadditions with alkenes, it has been suggested that in the reaction the addition of a Lewis acid catalyst changes the mechanism from a classic cycloaddition to a stepwise reaction that is more akin to a Michael addition followed by cyclization. In those studies, the stepwise mechanisms are similar to the stepwise path-

Scheme 4.

ways located in the present case. Thus, one could similarly classify the stepwise pathways found in this study as Michael additions followed by cyclization. On the other hand, both stepwise and concerted pathways were found, with or without the Lewis acid catalyst. Additionally, with or without the catalyst, the intermediate in the stepwise pathways is transient, with the barrier to form the products being very small (<5 kcal/mol). To be consistent with the current literature on the reaction, the term cycloaddition has been chosen for this work.

Regioselectivity of the cycloaddition

The cycloaddition reaction of nitrones to 1,1-cyclopropanediesters is found to be regiospecific with the oxygen atom of the reacting nitrone always lying distal to the diester substituent in the product as shown in Scheme 1 (7). An example of the cycloaddition reaction leading to the regioisomer that is not observed is shown in Scheme 4. The regiochemistry of the reaction was explained (7) by considering that significant charge separation occurs within the substituted cyclopropane ring due to the electron-withdrawing effect of the ester groups. The carbon atom bearing the ester substituents becomes negative while the carbon bearing the R3 substituent undergoes an increase in positive charge and, hence, becomes a preferred site for attack by the negatively charged oxygen of the nitrone.

To investigate the nature of the regiochemistry, the reaction of **N1** with **C2** to give the unobserved regioisomer (**(U)P2**) has been examined (Scheme 4). For lack of better words, we will refer to this as the "incorrect" pathway. Only a stepwise reaction pathway could be located for the formation of the unobserved regioproduct (**(U)P2**) that involves an initial transition state (**(U)SW2-A**‡), zwitterionic intermediate (**(U)SW2-B**), and second transition state (**(U)SW2-C**‡). The most striking feature of **(U)SW2-A**‡ (not shown) is that the oxygen atom of the nitrone is not involved in the initial attack on the cyclopropane. Rather, the carbon atom of the nitrone initially attacks cyclopropane as can be seen by examining the calculated bond orders of **(U)SW2-A**‡ in Table 6. This contrasts the concerted and stepwise pathways leading to the correct regioisomer, where the oxygen of the nitrone initially attacks the cyclopropane.

The calculated energetics suggest that the observed regioisomer is favoured both kinetically and thermodynamically. Relative energies of important stationary points along the reaction pathway are given in Table 6 for the incorrect

[b]For the unobserved pathway, the O—C2 and C3—C1 bonds form, but these are not applicable for the observed pathway in which the O—C3 and C1—C2 bonds form instead.

pathway. These values can be compared with Table 3, which shows the equivalent data for the "correct" regioisomer. Again the first transition state is rate-determining, and the calculated free energy barrier is found to be 63.2 kcal/mol. This compares with the 59.3 and 59.5 kcal/mol barriers for the correct concerted and stepwise pathways, respectively. In other words, the calculated barrier for the correct regioisomer is only favoured by about 3 kcal/mol. Thermodynamically, the observed product (**P2**) is found to be 5.4 kcal/mol more stable than the unobserved product ((**U**)**P2**) on the gas-phase B3LYP/6-31+G(d,p) free energy surface at 298 K and 1 atm.

The calculated kinetic preference for the observed regioisomer is perhaps surprisingly small with a barrier difference of only 3 kcal/mol. Thus, the affect of more realistic reactant models on the calculated thermodynamic and kinetic preference for the correct regioisomer has been examined. It is interesting that the carbon atom, not the oxygen atom, of the nitrone leads the initial attack of the δ+ C3 atom in the cyclopropane in the incorrect pathway. As it turns out, the ESP charges on the C1 and O atoms of the nitrone N1 are nearly identical, at –0.54 and –0.55 *e*, respectively. Therefore, from an electrostatic perspective, both centers have similar potential to act as nucleophiles. It is therefore notable that the model nitrone (**N1**) is unsubstituted at the R2 position (i.e., R2 = H); whereas all nitrones experimentally described were substituted at this position. Thus, the stepwise reaction pathway was studied using the nitrone **N2** with R2 = Me for both the observed and unobserved regioisomer pathways. It was found that the transition state for the incorrect regioisomer is 10.5 kcal/mol higher in free energy than the transition state for the correct pathway. Examination of the ESP charges of the substituted **N2** reveals that the charges on the C1 and O atoms are –0.11 and –0.53 *e*, respectively. Therefore, Me substitution at the R2 position makes the C1 atom significantly less negative and therefore less effective than the oxygen center of the nitrone to interact with a positively charged C3 center. Similarly, from a FMO perspective, methyl substitution has the effect of polarizing the HOMO of the nitrone away from the C1 atom (15). Surprisingly, the product (**P6**) of the observed pathway is 3.1 kcal/mol higher in energy than its regioisomer ((**U**)**P6**). This result is opposite to that of the reaction between **N1** and **C2**, where the correct pathway gives a more thermodynamically stable product. It also contradicts the experimental results, which show that the reaction is regiospecific. Analysis of the geometries of the two products shows there is a steric interaction between the R2 = Me substituent and the diester groups in **P6**; whereas in (**U**)**P6**, this steric interaction is relieved because the C1 atom lies vicinal to the diester groups. We note that this steric relief is only available when the R3 substituent is hydrogen and that the majority of experimental results have utilized a electron-donating group in the R3 position. Nevertheless, these results suggest that with some substitution patterns, the thermodynamic product may indeed be the oxazine ring with the oxygen atom lying adjacent to the diester groups.

The influence of a Lewis acid on the regiochemistry has been examined. The reaction of **N1** and **C2** with a single BF_3 molecule coordinated to it, as previously described, has been calculated. As previously described the coordination of a model Lewis acid results in a large ~14 kcal/mol decrease in the free energy barrier for the correct pathway. On the other hand, addition of a coordinated BF_3 molecule only decreases the barrier for the unobserved regioisomer by 3.3 kcal/mol. Thus, without the Lewis acid, the difference in the free energy barrier for the observed and unobserved reactions is only 3 kcal/mol; whereas the difference is more than 17 kcal/mol with the Lewis acid. As a result, the coordination of a Lewis acid to the cyclopropane results in a stronger kinetic preference for the observed regioisomer.

Conclusions

The mechanism of the 1,3-dipolar cycloaddition of nitrones with cyclopropane has been examined with quantum chemical DFT calculations. With realistic substituents, two very similar, but distinct reaction pathways were found. The first can be characterized as an asynchronous concerted mechanism involving a transition state that has an approximate half-chair conformation and where the oxygen atom of the nitrone leads the attack on the cyclopropane. The second is a stepwise mechanism involving a zwitterionic imminium intermediate, again with the oxygen atom of the nitrone

© 2005 NRC Canada

leading the attack of the cyclopropane. The intermediate is short lived as the barrier to form the product from this intermediate is very small in all cases. For both pathways, the origin of the barrier is the breaking of the C—C σ bond of the cyclopropane. Substituents that promote this process will provide an enhancement of the reaction rates. Substituent effects were examined and the influence on the calculated barriers matches the available experimental data on the observed reaction rates.

The influence of a Lewis acid catalyst on the reaction was also examined, using a small model for the catalyst (BF_3) that was coordinated to a carbonyl oxygen of the ester groups in the cyclopropane. The effect of the Lewis acid on the calculated barriers was found to be dramatic as one might expect, since experimentally the reaction is not observed without the catalyst. For example, the barriers were found to decrease by as much as 20 kcal/mol with coordination of two BF_3 molecules. This provides additional evidence that the Lewis acid's role during the reaction is indeed to further polarize the C—C bond of the cyclopropane via coordination to the ester substituents.

Solvation effects were briefly examined with a polarizable continuum model. Two solvents were used: 1,2-dichloroethane and methanol. In both solvents the reaction barriers were slightly increased; whereas the overall exothermicity of the reaction was significantly decreased. Both effects were more prominent in the more polar solvent.

The nature of the regiochemistry was also examined. Experimentally, it was found that the oxygen atom of the reacting nitrone exclusively ends up lying distal to the diester substituent in the product oxazine ring. The calculations show that there is both a kinetic and thermodynamic preference for the observed regioisomer. This preference was found to be significantly enhanced in the presence of a Lewis acid and with substitution at the R2 position of the reactant nitrone.

The 1,3-dipolar cycloaddition reactions of nitrones and cyclopropanes represents a new and important synthetic route for generating tetrahydro-1,2-oxazine rings that have been difficult to synthesize in the past. The computational study presented here provides a detailed account of the mechanism for this reaction and provides the basis for future work on optimizing the reaction.[3] Of particular interest is the relative stereochemistry of the R2 and R3 substituents in the product tetrahydrooxazine ring. In almost all cases the reaction is highly diastereoselective with the major product containing the R2 and R3 substituents in a cis relationship in the oxazine ring. However, recently it was found that by using MgI_2 as the Lewis acid catalyst an observable amount of the trans isomer could be isolated (9). The synthetic utility of the cycloaddition reaction would be greatly expanded if one could control the stereochemistry of the reaction. A computational study in this direction is currently underway.

Synthesis and structural characterization of zinc complexes of the imido–amido phosphate anions $OP[(NHR)_{3-x}(NR)]^{x-}$ (R = Me, *t*-Bu; *x* = 1–3) and $EP[(NH\text{-}t\text{-}Bu)_2(N\text{-}t\text{-}Bu)]^-$ (E = S, $NSiMe_3$)

Andrea F. Armstrong, Tristram Chivers, Mark Krahn, and Masood Parvez

Abstract: The reaction of $OP(NH\text{-}t\text{-}Bu)_3$ with 1 equiv. of $ZnMe_2$ generates the dimeric eight-membered ring $\{MeZn[(\mu\text{-}NH\text{-}t\text{-}Bu)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)(\mu\text{-}O)]\}_2$ (**5**) and the cubane $\{[MeZn]_3[OP(N\text{-}t\text{-}Bu)_3][OP(NH\text{-}t\text{-}Bu)_3]\}$ (**6**), which contains the first known trisimidophosphate trianion. A related complex $\{Zn[ZnMe]_2[OP(N\text{-}t\text{-}Bu)(NH\text{-}t\text{-}Bu)_2][OP(N\text{-}t\text{-}Bu)_3]\}$(**7**) is obtained by the reaction of $OP(NH\text{-}t\text{-}Bu)_3$ with $ZnMe_2$ in a 2:3 molar ratio. The treatment of $OP(NHMe)_3$ with 1 equiv. of $ZnMe_2$ produces the oxide-templated cluster $\{Zn_4(\mu_4\text{-}O)[OP(NMe)(NHMe)_2]_4[OP(NMe)_2(NHMe)]\}_2$ (**8**). Each half of this centrosymmetric dimer contains a tetrahedral arrangement of four 4-coordinate Zn^{2+} ions surrounding the central $\mu_4\text{-}O^{2-}$ anion. The reaction of $SP(NH\text{-}t\text{-}Bu)_3$ with $ZnMe_2$ in a 1:1 molar ratio generates the dimer $\{MeZn(\mu\text{-}S)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)_2\}_2$ (**10**), which has a ladder-type structure. When a 2:1 molar ratio of the same reagents is employed, the bis(*N*,*S*)-chelated complex $\{Zn[(\mu\text{-}S)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)_2]_2\}$ (**11**) is obtained. The monomeric *N*,*N′*-chelated complex $\{MeZn[(\mu\text{-}N\text{-}t\text{-}Bu)(\mu\text{-}NSiMe_3)P(NH\text{-}t\text{-}Bu)_2]\}$ (**12**) results from the reaction of $Me_3SiNP(NH\text{-}t\text{-}Bu)_3$ with 1 equiv. of dimethylzinc. All new compounds have been characterized by multinuclear (^1H, ^{13}C, and ^{31}P) NMR spectroscopy and, in the case of **5**, **6**, **7**, **8**, and **10**, by X-ray structural determinations.

Key words: zinc, phosphate, imido ligands, sulfur.

Résumé : La réaction du $OP(NH\text{-}t\text{-}Bu)_3$ avec un équivalent de $ZnMe_2$ conduit à la formation du cycle dimère à huit chaînons $\{MeZn[(\mu\text{-}NH\text{-}t\text{-}Bu)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)(\mu\text{-}O)]\}_2$ (**5**) et du cubane $\{[MeZn]_3[OP(N\text{-}t\text{-}Bu)_3][OP(NH\text{-}t\text{-}Bu)_3]\}$ (**6**) qui contient le premier trisimidophosphate connu. Le complexe apparenté $\{Zn[ZnMe]_2[OP(N\text{-}t\text{-}Bu)(NH\text{-}t\text{-}Bu)_2][OP(N\text{-}t\text{-}Bu)_3]\}$ (**7**) est obtenu lors de la réaction du $OP(NH\text{-}t\text{-}Bu)_3$ avec du $ZnMe_2$ dans un rapport de 2 : 3. Le traitement du $OP(NHMe)_3$ avec un équivalent de $ZnMe_2$ conduit à la formation de l'agrégat avec gabarit d'oxyde $\{Zn_4(\mu_4\text{-}O)[OP(NMe)(NMe)_2]_4[OP(NMe)_2(NHMe)]\}_2$ (**8**). Chacune des moitiés de ce dimère centrosymétrique comprend un arrangement tétraédrique de quatre ions Zn^{2+} tétracoordinés qui entourent l'anion $\mu_4\text{-}O^{2-}$ central. La réaction du $SP(NH\text{-}t\text{-}Bu)_3$ avec du $ZnMe_2$ dans un rapport molaire de 1 : 1 génère la formation du dimère $\{MeZn(\mu\text{-}S)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)_2\}_2$ (**10**) dont la structure est en échelle. Quand on utilize un rapport 2 : 1 des même réactifs, on obtient le complexe bis-*N,S*-chélaté $\{Zn[(\mu\text{-}S)(\mu\text{-}N\text{-}t\text{-}Bu)P(\mu\text{-}NH\text{-}t\text{-}Bu)_2]_2\}$ (**11**). Le complexe *N,N′*-chélaté monomère $\{MeZn[(\mu\text{-}N\text{-}t\text{-}Bu)(\mu\text{-}NSiMe_3)P(NH\text{-}t\text{-}Bu)_2]\}$ (**12**) résulte de la réaction du $Me_3SiNP(NH\text{-}t\text{-}Bu)_3$ avec un équivalent de diméthylzinc. Tous les nouveaux composés ont été caractérisés par spectroscopie RMN (^1H, ^{13}C et ^{31}P) et dans les cas des composés **5**, **6**, **7**, **8** et **10**, par diffraction des rayons X.

Mots clés : zinc, phosphate, ligands imido, soufre.

Introduction

The preparation and structural characterization of imido analogues of common phosphorus oxoanions is an active area of main group chemistry (1, 2). The imido group $[NH]^{2-}$ is formally isoelectronic with the oxo $[O]^{2-}$ substituent;[2] partial or complete replacement of the oxygen atoms in an oxoanion such as orthophosphate $[PO_4]^{3-}$ by NH ligands generates a series of polyimido anions that are isoelectronic with phosphate. The introduction of an alkyl or aryl substituent on nitrogen is expected to result in polyimido anions whose metal complexes will exhibit significantly different structures and chemical properties compared with those of $[PE_4]^{3-}$ (E = O, NH). In addition, one or more of the oxo substituents in a polyimido phosphate can be replaced by a heavier chalcogen, such as sulfur, to create

[2]The original definition of "isoelectronic" (isosteric) compounds restricts the term to species having the *same number of atoms* and the same number of electrons (I. Langmuir. J. Am. Chem. Soc. **41**, 1543 (1919)). Thus, according to this definition, N^{3-} is isoelectronic with O^{2-}. However, nitrides are compositionally different to oxides as a result of the different charges on the anions.

ligands with different coordinating properties as a result of the presence of both hard (N) and soft (S) binding sites.

In recent years, we have thoroughly investigated the reactivities of the triamidophosphates $OP(NH\text{-}t\text{-}Bu)_3$ (**1a**) (3, 4), $SP(NHR)_3$ (**2**, R = alkyl, aryl) (4, 5), and $Me_3SiNP(NH\text{-}t\text{-}Bu)_3$ (**3**) (3, 6) toward alkyllithium reagents. The mono- and di-lithium salts $\{Li[(\mu\text{-}N\text{-}t\text{-}Bu)(\mu\text{-}O)P(NH\text{-}t\text{-}Bu)_2]\}_3\cdot THF$ (**4**) and the double cubane $\{Li_2[OP(NH\text{-}t\text{-}Bu)(N\text{-}t\text{-}Bu)_2]\}_2\cdot 4THF$, isoelectronic with $[H_2PO_4]^-$ and $[HPO_4]^{2-}$, respectively, are readily obtained by treatment of **1a** with *n*-BuLi. However, complete deprotonation of **1a** to give the trianion $[OP(N\text{-}t\text{-}Bu)_3]^{3-}$ could not be achieved (3, 4). The mono- and di-anions $[OP(N\text{-}t\text{-}Bu)_x(NH\text{-}t\text{-}Bu)_{3-x}]^{x-}$ (x = 1 or 2) are also produced from the reactions of **1a** with $AlMe_3$ or $LiAlH_4$ (7).

Similar reactivity was observed for the thiophosphates $SP(NHR)_3$ (**2a** (R = *t*-Bu), **2b** (R = *i*-Pr)) (4, 5). The mono- and di-lithium salts of **2b** ($\{Li[(\mu\text{-}N\text{-}i\text{-}Pr)(\mu\text{-}S)P(NH\text{-}i\text{-}Pr)_2]\}_2\cdot 2THF$) and $\{[Li(TMEDA)]_2[SP(NH\text{-}i\text{-}Pr)(N\text{-}i\text{-}Pr)_2]\}_2$ have been isolated and characterized, as has a mixed monolithium–dilithium derivative of **2a**; attempts to generate $[SP(N\text{-}i\text{-}Pr)_3]^{3-}$ resulted in sulfur extrusion. Trilithiation can be achieved, however, by replacement of the alkyl substituents by more electron-withdrawing *para*-tolyl groups; in this case, the trisimidothiophosphate $\{Li_3[SP(N\text{-}p\text{-}tol)_3]\}$ is readily obtained (4).

In sharp contrast to the somewhat limited reactivities of the chalcogen systems **1a** and **2** toward *n*-BuLi, both symmetrical and unsymmetrical tetraimidophosphates, $\{Li_3[P(NPh)_4]\}$ (8) and $\{Li_3[P(NR)_3(NSiMe_3)]\}$ (3) (R = *t*-Bu, Cy), respectively, are readily prepared by the reaction of the corresponding iminophosphorane $(RNH)_3PNR$ with 3 equiv. of *n*-butyllithium.

Zinc phosphates are the second-largest family of the well-known metal phosphate open-framework materials and have applications as both catalysts and molecular sieves. These materials are generally prepared under hydro- or solvothermal conditions; the three-dimensional structures of the products are highly dependent upon reaction conditions such as temperature and time, and the presence and shape of a templating agent (9–11). Consequently, it is of interest to explore the possibility of preparing a series of zinc imidophosphates. While the steric bulk of the imido groups is expected to hinder aggregation resulting in the formation of much smaller oligomers than the extended networks that are characteristic of metal-phosphate complexes (12), it remains to be seen whether these systems will exhibit similar dependencies on reaction conditions as do the zinc phosphates. In addition, it is germane to examine the modes of coordination of these multidentate ligands for comparison with their behaviour in the lithium derivatives (3–6). In an attempt to shed light upon these and other points, we have investigated the reactions of the triamidophosphates $OP(NHR)_3$ (R = Me, *t*-Bu), $SP(NH\text{-}t\text{-}Bu)_3$, and $Me_3SiNP(NH\text{-}t\text{-}Bu)_3$ towards dimethylzinc.

Experimental

Reagents and general procedures

All experiments were carried out under an argon atmosphere using standard Schlenk techniques. Toluene, *n*-hexane, and diethyl ether were dried over Na/benzophenone, distilled, and stored over molecular sieves prior to use. Dimethylzinc (1.0 and 2.0 mol/L solutions in toluene) was used as received from Aldrich. $Me_3SiNP(NH\text{-}t\text{-}Bu)_3$ (3), $OP(NHR)_3$ (R = Me, *t*-Bu) (4), and $SP(NH\text{-}t\text{-}Bu)_3$ (5) were prepared according to the literature procedures.

Instrumentation

^1H, ^7Li, ^{13}C, and ^{31}P NMR spectra were collected on a Bruker DRX-400 spectrometer with chemical shifts reported relative to Me_4Si in $CDCl_3$ (^1H and ^{13}C), LiCl in D_2O (^7Li), and 85% H_3PO_4 in D_2O (^{31}P). All spectra were collected at 22 °C, with the exception of compound **10** (spectra recorded at –30 °C). Infrared spectra were recorded as Nujol mulls on KBr plates using a Nicolet Nexus 470 FT IR spectrometer in the range 4000–400 cm^{-1}. Mass spectra were recorded on a Bruker Esquire 3000 ESI ion trap mass spectrometer. Elemental analyses were provided by the Analytical Services Laboratory, Department of Chemistry, University of Calgary.

Preparation of $\{MeZn[(\mu\text{-}NH\text{-}t\text{-}Bu)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)(\mu\text{-}O)]\}_2$ (5) and $\{[MeZn]_3[OP(N\text{-}t\text{-}Bu)_3][OP(NH\text{-}t\text{-}Bu)_3]\}$ (6)

A solution of $ZnMe_2$ (0.70 mL, 2.0 mol/L, 1.40 mmol) in toluene was added to a slurry of $OP(NH\text{-}t\text{-}Bu)_3$ (0.366 g, 1.39 mmol) in toluene (20 mL) at 22 °C, resulting in a clear solution after 10 min. The reaction mixture was heated at 60 °C for 4 h; the solvent was then removed under vacuum to give a white powder (0.417 g). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 46.8, 28.6, 24.3 (minor), 13.2 (minor), 11.3, 10.2, 9.3 (br), 8.1 (s).

Recrystallization of the product (72 mg) from toluene yielded colourless crystals of **5** (35 mg, 0.051 mmol, 21% based on $ZnMe_2$). $^{13}C\{^1H\}$ NMR (solid state, 12 kHz) δ: 53.03 (s, N*C*Me_3), 52.28 (s, μ-HN*C*Me_3), 49.79 (s, HN*C*Me_3), 34.52 (s, N*C*Me_3), 32.05 (s, μ-HN*C*Me_3), 31.44 (s, HN*C*Me_3), –11.63 (s, MeZn). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 9.3 (br), 8.1 (s). $^{31}P\{^1H\}$ NMR (solid state, 5 kHz) δ: 7.4 (s). Anal. calcd. for $C_{38}H_{64}N_6O_2P_2Zn_2$: C 45.73, H 9.45, N 12.31; found: C 45.53, H 9.68, N 12.36.

Recrystallization of the product (51 mg) from Et_2O yielded colourless crystals of **6** (14 mg, 0.018 mmol, 32% based on $ZnMe_2$). ^1H NMR (C_6D_6) δ: 2.30 (br, 3H, N*H*), 1.38 (s, 9H, NC*Me*$_3$), 1.33 (s, 27H, NHC*Me*$_3$), 1.09 (s, 18H, NC*Me*$_3$), –0.12 (s, 9H, $MeZn^+$). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 46.8, 10.2. Anal. calcd. for $C_{27}H_{66}N_6O_2P_2Zn_2$: C 42.39, H 8.70, N 10.99; found: C 42.02, H 8.93, N 11.21.

Preparation of $\{Zn[MeZn]_2[OP(N\text{-}t\text{-}Bu)(NH\text{-}t\text{-}Bu)_2][OP(N\text{-}t\text{-}Bu)_3]\}$ (7)

A solution of $ZnMe_2$ (5.34 mL, 1.0 mol/L, 5.34 mmol) in toluene was added dropwise to a solution of $OP(NH\text{-}t\text{-}Bu)_3$ (0.937 g, 3.56 mmol) in toluene (25 mL) at 22 °C. The toluene solution was refluxed at 113 °C for 18 h yielding a clear, colourless solution. The volume was reduced to 10 mL and after 1 day at 22 °C, colourless crystals of **7** had formed (0.601 g, 0.802 mmol, 45%). IR (cm^{-1}): 3279 (ν(N-H)). ^1H NMR (C_6D_6) δ: 2.05 (br s, N*H*), 1.75–1.18 (numerous resonances, NC*Me*$_3$), 0.29 (s, Zn*CH*$_3$). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 22.0 (s), 14.6 (s), 13.1 (s) (1:1:1), and additional minor reso-

nances; solid state (10 kHz) δ: 22.0 (s), 13.5 (s). MS (ESI^+): 549 ($M^+ - 199$).

Preparation of $\{Zn_4(\mu_4\text{-}O)[OP(NMe)(NHMe)_2]_4[OP(NMe)_2(NHMe)]\}_2$ (8)

A solution of $ZnMe_2$ (1.18 mL, 1.0 mol/L, 1.18 mmol) in toluene was added dropwise to a solution of $OP(NHMe)_3$ (0.162 g, 1.18 mmol) in toluene (25 mL) at 22 °C. The toluene solution was heated at reflux for 24 h. The volume of the solution was reduced to one-half and the concentrate was placed in the freezer. After 7 days at –15 °C, colourless crystals of **8**·C_7H_8 were recovered (0.144 g, 0.0718 mmol, 49% based on $ZnMe_2$). IR (cm^{-1}): 3323 (ν(N-H)). ^1H NMR (C_6D_6) δ: 2.25 (s, NH*Me*), 2.22 (s, NH*Me*), 2.20 (s, NH*Me*), 2.16 (s, NH*Me*) (1:1:1:1), 1.36 (br s, N*Me*). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 37.9 (s), 28.2 (s) (relative intensities ~1:3), and additional minor resonances; solid state (13 kHz) δ: 38.7 (s), 27.6 (s). Anal. calcd. for $C_{37}H_{116}N_{30}O_{12}P_{10}Zn_8$: C 22.15, H 5.83, N 20.94; found: C 22.02, H 6.05, N 19.96.

Preparation of $[MeZn(\mu\text{-}S)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)_2]_2$ (10)

A solution of $ZnMe_2$ (0.83 mL, 2.0 mol/L, 1.66 mmol) in toluene was added slowly to a slurry of $SP(NH\text{-}t\text{-}Bu)_3$ (0.461 g, 1.65 mmol) in toluene (20 mL) at 22 °C. The clear solution was stirred for 18 h; the solvent was then removed under vacuum to give **10** as a white powder (0.468 g, 0.652 mmol, 79%). ^1H NMR (C_6D_6) δ: 2.15 (br, N*H*), 1.48 (s, 9H, N), 1.31 (d, $^4J(^1H\text{-}^{31}P)$ = 6.8 Hz, 18H, NHC*Me*$_3$), –0.1 (s, 3H, *Me*Zn^+). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: 53.90 (d, *C*Me_3, $^2J(^{13}C\text{-}^{31}P)$ = 44.4 Hz), 51.63 (d, *C*Me_3, $^2J(^{13}C\text{-}^{31}P)$ = 19.3 Hz), 33.40 (d, C*Me*$_3$, $^3J(^{13}C\text{-}^{31}P)$ = 27.7 Hz), 30.41 (d, C*Me*$_3$, $^3J(^{13}C\text{-}^{31}P)$ = 136.5 Hz). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 39.3 (s). Anal. calcd. for $C_{26}H_{62}N_6P_2S_2Zn_2$: C 43.68, H 9.03, N 11.76; found: C 44.33, H 9.28, N 11.87.

Preparation of $\{Zn[(\mu\text{-}S)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)_2]_2\}$ (11)

A solution of $ZnMe_2$ (0.58 mL, 2.0 mol/L, 1.16 mmol) in toluene was added slowly to a slurry of $SP(NH\text{-}t\text{-}Bu)_3$ (0.648 g, 2.32 mmol) in toluene (20 mL) at 22°C. The resulting clear solution was stirred for 18 h; the solvent was then removed under vacuum to give **11** as an analytically pure white powder (0.710 g, 1.14 mmol, 98%). ^1H NMR (C_6D_6) δ: 2.12 (br, 2H, N*H*), 1.44 (s, 9H), 1.32 (s, 18H, C*Me*$_3$). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: 54.06 (d, *C*Me_3, $^2J(^{13}C\text{-}^{31}P)$ = 43.5 Hz), 51.82 (d, *C*Me_3, $^2J(^{13}C\text{-}^{31}P)$ = 9.9 Hz), 34.18 (d, C*Me*$_3$, $^3J(^{13}C\text{-}^{31}P)$ = 38.7 Hz), 31.67 (d, C*Me*$_3$, $^3J(^{13}C\text{-}^{31}P)$ = 17.1 Hz). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 42.0 (s). Anal. calcd. for $C_{24}H_{58}N_6P_2S_2Zn$: C 46.33, H 9.40, N 13.51; found: C 45.30, H 10.64, N 13.48.

Preparation of $\{MeZn[(\mu\text{-}N\text{-}t\text{-}Bu)(\mu\text{-}NSiMe_3)P(NH\text{-}t\text{-}Bu)_2]\}$ (12)

A solution of $ZnMe_2$ (0.53 mL, 2.0 mol/L, 1.06 mmol) in toluene was added slowly to a pale yellow solution of $Me_3SiNP(NH\text{-}t\text{-}Bu)_3$ (0.357 g, 1.07 mmol) in hexane (20 mL) at 22 °C, resulting in an opaque yellow mixture. After 3 h, the solvent was removed under vacuum to give **12** as a yellow paste (0.400 g, 0.966 mmol, 91%). Washing with organic solvents did not improve the physical appearance of this highly soluble paste, which was shown to be pure **12** on the basis of spectroscopic and analytical data. ^1H NMR (C_6D_6) δ: 1.75 (br, N*H*), 1.22 (s, 27H, C*Me*$_3$), 0.27 (s, 9H, Si*Me*$_3$), –0.24 (s, 3H, *Me*Zn). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: 51.14 (d, *C*Me_3, $^2J(^{13}C\text{-}^{31}P)$ = 8.9 Hz), 50.41 (d, *C*Me_3, $^2J(^{13}C\text{-}^{31}P)$ = 11.9 Hz), 34.06 (d, C*Me*$_3$, $^3J(^{13}C\text{-}^{31}P)$ = 34.2 Hz), 32.42 (d, C*Me*$_3$, $^3J(^{13}C\text{-}^{31}P)$ = 15.5 Hz), 4.61 (d, Si*Me*$_3$, $^3J(^{13}C\text{-}^{31}P)$ = 12.5 Hz), –15.0 (s, Zn*Me*). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 9.1 (s). Anal. calcd. for $C_{16}H_{41}N_4PSiZn$: C 46.42, H 9.98, N 13.53; found: C 46.50, H 10.05, N 13.86.

X-ray analyses

Colourless crystals of **5**, **6**, **7**, **8**·C_7H_8, and **10** were coated with Paratone 8277 oil and mounted on a glass fibre. All measurements were made on a Nonius Kappa CCD diffractometer using graphite-monochromated molybdenum–K_α radiation. Crystallographic data are summarized in Table 1. The structures were solved by direct methods (13) and refined by full-matrix least-squares methods with SHELXL-97 (14). Hydrogen atoms were included at geometrically idealized positions and were not refined; the non-hydrogen atoms were refined anisotropically. Thermal ellipsoid plots were created using Diamond version 2.1 (15). Additional data are available in the Supporting information.[3]

Results and discussion

Reactions of $OP(NHR)_3$ with $ZnMe_2$ — Formation and structures of $\{MeZn[(\mu\text{-}NH\text{-}t\text{-}Bu)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)O]\}_2$ (5), $\{[MeZn]_3[OP(N\text{-}t\text{-}Bu)_3][OP(NH\text{-}t\text{-}Bu)_3]\}$ (6), and $\{Zn[ZnMe]_2[OP(N\text{-}t\text{-}Bu)(NH\text{-}t\text{-}Bu)_2][OP(N\text{-}t\text{-}Bu)_3]\}$ (7)

Initial attempts to conduct a thorough investigation of the reactivity of $ZnMe_2$ towards $OP(NHR)_3$ (**1a** (R = *t*-Bu), **1b** (R = Me), **1c** (R = Ad)) were confounded by the subtle dependence of these reactions upon both temperature and time. A mixture of products was observed by ^{31}P NMR spectroscopy in all cases. Both the number and relative intensities of the resonances observed were strongly influenced by minor changes in the reaction conditions so that reproducible results were difficult to obtain, except for the reaction of **1a** with 1 equiv. of dimethylzinc at 60 °C. The solid-state ^{31}P NMR spectrum of the white powder produced in this reaction contains a single broad signal centred at 7 ppm. In solution at 22 °C, eight ^{31}P NMR resonances of various intensities and linewidths were observed, suggesting the presence of multiple products. A variable-temperature NMR experiment showed that the linewidths, relative intensities, and indeed the number of resonances present are dependent upon temperature, indicating that this system is highly dynamic in solution and suggesting that different modes of ag-

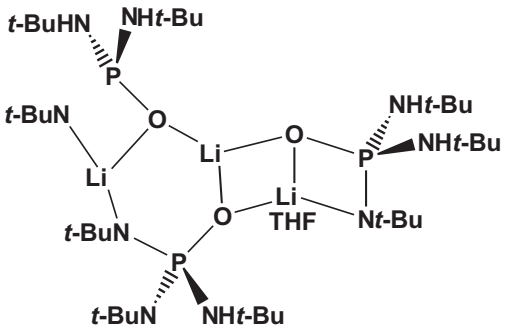
[b] $R_w = \{[\Sigma w(F_o^2 - F_c^2)^2]/[\Sigma w(F_o^2)^2]\}^{1/2}$ for all reflections.

gregation can occur for these products, even in the noncoordinating solvent d_8-toluene.

Recrystallization of the white powder from toluene resulted in the isolation of colourless crystals, which were characterized by X-ray crystallography and multinuclear NMR spectroscopy; crystal data are compiled in Table 1. An X-ray structure, depicted in Fig. 1, showed the crystals to consist of the monoanion [OP(N-*t*-Bu)(NH-*t*-Bu)$_2$]$^-$ with a methylzinc counterion. The complex {MeZn[(μ-NH-*t*-Bu)(μ-N-*t*-Bu)P(NH-*t*-Bu)(μ-O)]}$_2$ (**5**) exists as a centrosymmetric dimer. Each of the methylzinc cations is chelated by a *t*-BuNH and a *t*-BuN group of one monoanion, with a Zn—O bond serving to both link the zinc atom to the second monoanion and to complete the tetrahedral coordination sphere of the Zn atom. The second *t*-BuNH group on each phosphorus centre is not coordinated to either of the methylzinc cations.

Selected bond lengths and bond angles for **5** are summarized in Table 2. Three different P—N bond lengths and two distinct Zn—N distances are observed: the Zn(1)—N(1) bond length (1.980(9) Å) is substantially shorter than the Zn(1)—N(2) distance (2.430(8) Å), reflecting the greater strength of the zinc–imido linkage. Similarly, the P(1)—N(1) bond distance (1.590(8) Å) is considerably shorter than the P(1)—N(2) single-bond distance of 1.705(8) Å. The fact that N(3) is not coordinated to an electropositive zinc centre results in a shorter, stronger P—N bond (P(1)—N(3) 1.627(9) Å) than that observed for the coordinated N(2) atom. The Zn—O distances in **5** are slightly longer than those typically observed in zinc phosphates, with an average value of 2.001(7) Å, cf., mean values of 1.936(4) Å in the histidine complex [Zn(HPO$_4$)·(C$_6$H$_9$N$_3$O$_2$)] (9) and 1.933(2) Å in the aminobenzene-templated system [Zn(HPO$_3$)$_2$·C$_6$N$_2$H$_{10}$] (11). As expected, the bond angle at the sp^2 nitrogen atom (∠P(1)-N(1)-Zn(1), 102.5(5)°) is larger than the corresponding angle involving the sp^3 amido nitrogen atom (∠P(1)-N(2)-Zn(1), 83.1(3)°), though both angles markedly deviate from ideal values, presumably owing to steric repulsions among the three *tert*-butyl groups attached to the nitrogen atoms.

Fig. 1. Thermal ellipsoid plot of **5** (30% probability ellipsoids). Only α-carbon atoms of the *t*-Bu groups are shown.



The structure of **5** is a sharp contrast to the trimeric structure adopted by the lithium salt {Li[(μ-N-*t*-Bu)(μ-O)P(NH-*t*-Bu)$_2$]}$_3$·THF (**4**) (4), which contains the same monoanion. The Li$^+$ cations in **4** are coordinated only by the oxo- and N-*t*-Bu ligands, while the NH-*t*-Bu groups are exocyclic. Whereas **5** is centrosymmetric, the trimer **4** displays C_1 symmetry, due in part to the presence of a molecule of THF coordinated to one Li$^+$ cation. Some of these structural differences can be attributed to the high polarity of Li-E (E = N or O) units and their consequent propensity for aggregation to form ladder-type motifs.

The solid-state ^{31}P and ^{13}C NMR data for **5** were consistent with the X-ray structure; a major ^{31}P resonance is observed at 7.4 ppm, and three distinct ^{13}C signals for the

inequivalent C*Me*$_3$ groups occur at 34.52, 32.05, and 31.44 ppm. In C_6D_6 solution, however, the ^{31}P NMR spectrum consists of a sharp singlet at 8.1 ppm and a broader resonance at 9.3 ppm, possibly owing to an equilibrium between the dimer **5** and the corresponding monomer {[MeZn][(N-*t*-Bu)P(O)(NH-*t*-Bu)$_2$]}. A variable-temperature NMR experiment showed that, at low temperature (–50 °C), the 8.1 ppm species is predominant, while the intensity of the resonance at 9.3 ppm increases at higher temperatures, consistent with the proposed monomer–dimer equilibrium. The apparently facile dissociation of **5** into the corresponding monomer is somewhat surprising in light of its relatively strong Zn—O linkages (vide supra). Interestingly, the solid-state ^{31}P NMR spectrum of **5** also displays a minor resonance at 9.8 ppm, which may be attributable to the presence of a small amount of the monomer.

When the product of the reaction of OP(NH-*t*-Bu)$_3$ with 1 equiv. of $ZnMe_2$ at 60 °C was recrystallized from diethyl ether rather than toluene, colourless crystals of a different product were obtained. An X-ray structure (Fig. 2) identified this compound as {[MeZn]$_3$[OP(N-*t*-Bu)$_3$][OP(NH-*t*-Bu)$_3$]}

Fig. 2. Thermal ellipsoid plot of **6** (30% probability ellipsoids). Only α-carbon atoms of the *t*-Bu groups are shown.

(**6**), which is comprised of the trianion [OP(N-*t*-Bu)$_3$]$^{3-}$ and three MeZn$^+$ counterions, with a neutral molecule of **1a** coordinated to two of the zinc centres. The formation of this previously unobserved trianion was somewhat unexpected given the lack of success encountered in attempts to generate [OP(N-*t*-Bu)$_3$]$^{3-}$ using organolithium reagents (4). In addition, the presence of unreacted OP(NH-*t*-Bu)$_3$ concomitant with the formation of this trianion is rather surprising; the generation of a mixture of mono- and di-anions would seem more probable.

In the solid state, **6** exists as a distorted PN_3Zn_3O cube, with the phosphorus and nitrogen atoms of the [OP(N-*t*-Bu)$_3$]$^{3-}$ trianion contributing four of the vertices, while the remaining positions are occupied by the three zinc cations and the oxygen atom O(2) of the neutral OP(NH-*t*-Bu)$_3$ molecule. While O(2) is coordinated to two of the methylzinc cations, the =P(NH-*t*-Bu)$_3$ fragment is pendant from the cube. Selected bond lengths and bond angles for **6** are given in Table 3. The oxo ligand of the trianion is exo to the cluster, with a P(1)—O(1) bond distance of 1.475(2) Å, cf., 1.474(3) Å in **1a** (4). In contrast, the P(2)—O(2) bond length is significantly longer (1.519(2) Å) because of coordination of this oxygen atom to two zinc atoms. The increase in this P=O distance has little effect on the P—N bond lengths in the neutral fragment; the average P(2)—N distance is 1.631(3) Å, cf., 1.637(3) Å in **1a** (4). The mean P—N bond length in the trianion is significantly longer (1.689(3) Å), since the nitrogen atoms in this moiety are four-coordinate.

Two of the zinc centres are four-coordinate, with two Zn—N bonds, one Zn—O linkage, and a methyl substituent, while the third zinc cation exhibits only a weak Zn—O contact (2.648(2) Å) and is thus considered three-coordinate. The zinc–oxygen distances for the two four-coordinate zinc atoms are Zn(1)—O(2) = 2.333(2) Å and Zn(2)—O(2) = 2.314(2) Å. These Zn—O distances are substantially longer than the mean values of 1.980(4) Å found in zinc-di(oxo)cyclodiphosph(V)azane systems (16), or the distances reported for the polymeric di(*tert*-butyl)phosphates {Zn[O$_2$P-(O-*t*-Bu)$_2$]$_2$[H$_2$N(CH$_2$)$_6$NH$_2$]}$_n$ and {Zn[O$_2$P(O-*t*-Bu)$_2$]$_2$}$_n$ (range: 1.914(8)–1.929(6) Å) (17). tance for the three-coordinate zinc cation Zn(3) is 2.040(2) Å, cf., 2.073(2) Å for the four-coordinate zinc centres. The mean ∠N-P-N bond angle is 98.9(1)° while the ∠N-Zn-N and ∠N-Zn-O bond angles range from 76.54(9)° to 89.62(9)°.

A ^{31}P NMR spectrum of **6** in C_6D_6 solution displayed two sharp singlets at 46.8 and 10.2 ppm, which are assigned to the $[OP(N\text{-}t\text{-}Bu)_3]^{3-}$ trianion and the neutral $OP(NH\text{-}t\text{-}Bu)_3$ ligand, respectively. Three resonances are observed in the ^{1}H NMR spectrum with relative intensities of 3:1:2, attributed to the three NH-*t*-Bu groups of the coordinated molecule of **1a** (27H) and the inequivalent N-*t*-Bu ligands of the trianion (9H and 18H), while a single broad resonance at –0.12 ppm is assigned to the methylzinc cations. These NMR data are consistent with the solid-state structure of **6**.

When the reaction of **1a** with dimethylzinc was carried out in a 2:3 molar ratio in boiling toluene, the ^{31}P NMR spectrum of the resulting white powder indicated the formation of a mixture of products. However, recrystallization from toluene produced a single compound identified as $\{Zn[ZnMe]_2[OP(N\text{-}t\text{-}Bu)(NH)_2][OP(N\text{-}t\text{-}Bu)_3]\}$ (**7**) by X-ray crystallography. Although the structure could not be satisfactorily refined (R_1 = 0.12) because of poor diffraction of the crystals and disorder of the *tert*-butyl substituents, the atom connectivities of **7** were established. Complex **7** is closely related to **6** in that its primary structural feature is a PN_3Zn_3O cube; however, in place of the neutral $OP(NH\text{-}t\text{-}Bu)_3$ ligand of **6**, complex **7** contains a monoanion $[OP(N\text{-}t\text{-}Bu)(NH\text{-}t\text{-}Bu)_2]^-$ that is *N*,*O* chelated to a Zn^{2+} dication. The oxo substituent of this monoanion is coordinated to all three zinc centres, all of which are four-coordinate: the Zn^{2+} dication is also coordinated to nitrogen donors, while the other zinc atoms are also bound to two nitrogen atoms and a methyl substituent.

7

The solid-state ^{31}P NMR spectrum of **7** consists of two singlets at 22.0 and 13.5 ppm, consistent with the X-ray structure. In C_6D_6 solution, the ^{31}P NMR spectrum exhibits three major resonances at 22.0, 14.6, and 13.1 ppm, suggesting that more than one mode of aggregation occurs in solution; consistently, the solution ^{1}H NMR spectrum of **7** contains numerous resonances in the N-*t*-Bu region.

The contrasting structures of **5**, **6**, and **7** suggest that there are two different pathways possible for the reaction of dimethylzinc with $OP(NH\text{-}t\text{-}Bu)_3$. Complex **6** is clearly a precursor of **7**; in a separate experiment, it was shown by ^{31}P NMR spectroscopy that crystalline **6** can, in fact, be converted to **7** by thermal elimination of methane under reduced pressure (Scheme 1). At the same time, **5** is clearly not a precursor of **6**, despite the fact that the first step in the formation of both **5** and **6** is likely the monodeprotonation of $OP(NH\text{-}t\text{-}Bu)_3$. In the case of **6**, the second step of the reaction results in the double deprotonation of one of the ligands.

The different coordination modes of the two ligands within both **6** and **7** are also noteworthy. The oxo unit of one ligand (the trianion) remains exo to the cubane, while the other oxygen atom plays an integral role in cluster formation, as it is coordinated to either two or three zinc centres in **6** and **7**, respectively. Additionally, two distinct modes of coordination for the $[OP(N\text{-}t\text{-}Bu)(NH\text{-}t\text{-}Bu)_2]^-$ monoanion are observed in these complexes, with *N*,*O* chelation displayed in **7**, whereas *N*,*N*′ chelation prevails in **5**; similar *N*,*N*′ coordination also occurs for the trianionic ligands in **6** and **7**, but in those two instances the oxo substituent remains noncoordinated.

Formation and X-ray structure of $\{Zn_4(\mu_4\text{-}O)[OP(NMe)(NHMe)_2]_4[OP(NMe)_2(NHMe)]\}_2$ (8)

Following the successful generation of the trisimidophosphate trianion $[OP(N\text{-}t\text{-}Bu)_3]^{3-}$ utilizing dimethylzinc, similar reactions with tris(methylamido)phosphate $OP(NHMe)_3$ (**1b**) were investigated to determine the effect of the replacement of the bulky *tert*-butyl groups of **1a** with the much smaller NMe units on the size of the zinc imidophosphate clusters formed. The reaction of dimethylzinc with **1b** in a

1:1 ratio in boiling toluene led to the isolation of colourless crystals of the oxide-templated complex $\{Zn_4(\mu_4\text{-}O)[OP(NMe)(NHMe)_2]_4[OP(NMe_2)(NHMe)]\}_2$ (**8**) in 49% yield.

An X-ray structure of **8** revealed that this complex is a centrosymmetric dimer, which crystallizes with a molecule of toluene in its lattice. A thermal ellipsoid plot is shown in Fig. 3, while the framework of the cluster is pictorially represented in Fig. 4. Each monomeric unit consists of four Zn^{2+} ions, four $[OP(NMe)(NHMe)_2]^-$ monoanions, one $[OP(NMe_2)(NHMe)]^{2-}$ dianion, and one oxide ligand; in each half of the cluster there is a tetrahedral core of four 4-coordinate Zn^{2+} ions that surround a central $\mu_4\text{-}O^{2-}$ anion. The four monoanions bridge four edges of the Zn_4 tetrahedron. The two halves of the molecule are joined together by the two $[OP(NMe_2)(NHMe)]^{2-}$ dianions, while the NHMe

Fig. 4. Structural framework of **8**. All methyl groups and noncoordinated NHMe groups are omitted for clarity.

© 2005 NRC Canada

group of each dianion does not participate in cluster bonding. Three of the four Zn^{2+} ions (Zn(1), Zn(2), and Zn(4)) interact with the two dianions and thus participate in linking together the two halves of the dimer. As a result of these linkages, there are numerous six-, eight-, ten-, and twelve-membered rings in the structure. The Zn and O atoms reside near the centre of the cluster, while the methyl groups of the phosphate anions point away from the central core.

The X-ray structure described in the preceding section is expected to give rise to five resonances in the ^{31}P NMR spectrum of **8**. However, a solution ^{31}P NMR spectrum in d_6-benzene revealed two dominant resonances at 37.9 and 28.2 ppm in an approximately 1:4 ratio, while the solid-state spectrum exhibited only two singlets centred at 38.7 and 27.6 ppm. These observations are tentatively attributed to the similar chemical environments experienced by the four crystallographically inequivalent $[OP(NMe)(NHMe)_2]^-$ monoanions, which result in the appearance of only one resonance for those four phosphorus atoms, along with a second resonance attributed to the $[OP(NMe)_2(NHMe)_2]^{2-}$ dianion. The solution ^1H NMR spectrum of **8** exhibits four singlets of equal intensities at 2.25, 2.22, 2.20, and 2.16 ppm, assigned to the four different environments of the NHMe groups, while a single broad resonance centred at 1.36 ppm is observed for the indistinguishable NMe substituents. While no NH resonance could be detected in the ^1H NMR spectrum, the NHMe fragments were clearly identified by a sharp N-H stretch (3323 cm^{-1}) in the IR spectrum of **8**.

The formation of the much larger cluster **8**, as compared with complexes **5**, **6**, and **7**, is a direct consequence of the decrease in steric bulk of the NR groups, which allows for more extensive aggregation. Roesky and co-workers (18, 19) have reported the synthesis of a zinc complex of *tert*-butylphosphonic acid, $[Zn_2(THF)_2(EtZn)_6Zn_4(\mu_4\text{-}O)(t\text{-}BuPO_3)_8]$ (**9**), with a structure similar to that of **8**: complex **9** contains a central $Zn_4(\mu_4\text{-}O)$ core, with the *tert*-butylphosphonate ligands radiating outwards from the centre of the dodecanuclear cluster. Selected bond lengths and bond angles for **8** are summarized in Table 4. The phosphorus–μ_2-O bond lengths range from 1.498(3) to 1.532(2) Å (cf., 1.499(5)–1.527(5) Å in **9**). The zinc–μ_4-O distance is also similar to those of **9** (1.957(2)–2.026(2) Å in **8**; 1.948(4)–2.073(4) Å in **9**); however, the Zn—μ_2-O distances are significantly longer in **8** than those in **9** (1.964(2)–2.055(1) Å vs. 1.891(5)–1.990(5) Å, respectively).

The origin of the μ_4-oxygen atom of **8** remains uncertain. It has been suggested that the presence of oxide in **9** results from the dehydration of *tert*-butylphosphonic acid induced by diethylzinc (19). However, this explanation is clearly not applicable to the reaction of $ZnMe_2$ with $OP(NHMe)_3$. Possible sources of the oxide ligand in the current case include (*a*) P=O bond cleavage during the course of the reaction, (*b*) the contamination of the reagent **1b** by water, or (*c*) the presence of "adventitious" water during the recrystallization process, as suggested for related systems (17, 20). As ^{31}P NMR studies of the reaction mixtures gave no evidence for P=O bond cleavage, and the IR spectrum of **1b** showed that it was anhydrous, the most probable source of the oxide unit is the introduction of moisture during the recrystallization process.

[a] $-x + 1/2, -y + 1/2, -z$.

Fig. 5. Thermal ellipsoid plot of **10** (30% probability ellipsoids). Only hydrogen atoms bonded to nitrogen atoms are shown.

Preparation and characterization of [MeZn(μ-S)(μ-N-*t*-Bu)P(NH-*t*-Bu)$_2$]$_2$ (10) and {Zn[(μ-S)(μ-N-*t*-Bu)P(NH-*t*-Bu)$_2$]$_2$} (11)

The reaction of SP(NH-*t*-Bu)$_3$ with 1 equiv. of dimethylzinc produces {MeZn(μ-S)(μ-N-*t*-Bu)P(NH-*t*-Bu)$_2$}$_2$ (**10**) in 78% yield. An X-ray structure (Fig. 5) revealed that in the solid state, **10** exists as a centrosymmetric dimer in which each ligand is *N*,*S* chelated to a MeZn$^+$ cation, with Zn—S bonds linking the two halves together into a step-shaped ladder motif. Each zinc atom is thus four-coordinate, with two Zn—S linkages, one Zn—C bond, and a Zn-N-*t*-Bu unit. Selected bond lengths and bond angles for **10** are given in Table 5. As expected, the mean P—N distances involving the pendant NH-*t*-Bu groups (1.650(2) Å) are longer than the P-N(*t*-Bu) linkage (1.592(2) Å). The substantial difference between the Zn(1)—N(1) (2.007(2) Å) and Zn(1)—S(1) (2.5849(9) Å) bond lengths, combined with the tetrahedral geometries of the phosphorus and zinc atoms, gives the four-membered PNSZn rings a distorted diamondoid shape. The Zn_2S_2 ring is closer to square-shaped, with bond angles of 97.10(3)° and 82.90(3)° at the zinc and sulfur centres, respectively. Two distinct Zn—S distances are observed with the shorter bond (2.4627(9) Å) linking the two monomeric units and contributing to the distortion of the ring.

The dimeric laddering arrangement exhibited by **10** has been observed for other complexes of imidophosphate monoanions. The lithium derivatives {Li[(μ-N-*t*-Bu)(μ-NSiMe$_3$)P(NH-*t*-Bu)$_2$]}$_2$ (6) and {Li[(μ-N-*i*-Pr)(μ-S)P(NH-*i*-Pr)$_2$]}$_2$·2THF (5) both display this connectivity. The latter thiophosphate complex and **13** both exist in the trans conformation to minimize steric repulsions between the bulky *tert*-butyl substituents. The different mode of coordination of the heteroleptic imidophosphate ligand to zinc in **10** compared with that in **5** may be attributed, in part, to the greater affinity of zinc for the softer sulfur centre, resulting in *N*,*S* chelation, while *N*,*N*′ coordination is observed for the *O*-containing ligand in **5**. This, in turn, results in significantly different modes of oligomerization for these two dimers. It should be noted that the first transition-metal complexes of the monoanion [SP(N-*t*-Bu)(NH-*t*-Bu)$_2$]$^-$ have been reported recently (21); interestingly, both *N*,*S* and *N*,*N*′ chelation were observed in a single Ni(II) complex.

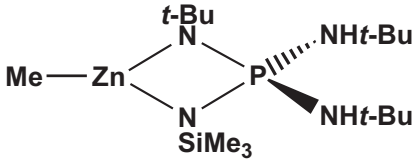
[a]Symmetry transformations used to generate equivalent atoms: $-x + 1, -y + 1, -z$.

The ^{31}P NMR spectrum of **10** in C_6D_6 at 22 °C exhibits resonances at 41.1 and 39.6 ppm in an approximately 1:3 ratio, rather than the expected single peak; multiple resonances are observed in the ^{1}H NMR spectrum. Variable-temperature ^{31}P NMR spectra were recorded at temperatures ranging from –30 to +40 °C. At higher temperatures, the minor signal at 41.1 ppm was observed to increase in intensity, while at lower temperatures this resonance became less intense and was not observed below –15 °C. This suggests that an equilibrium exists between the dimer **10** and the corresponding monomer. The ^{1}H and ^{13}C NMR spectra of **10** at –30 °C showed the expected resonances for two inequivalent *tert*-butyl environments in a 2:1 ratio, as well as a singlet assigned to the two equivalent $MeZn^+$ cations. Thus the low-temperature NMR spectra are consistent with the presence of a single species consistent with the solid-state structure of **10**.

When the reaction of $SP(NH\text{-}t\text{-}Bu)_3$ with dimethylzinc was carried out in a 2:1 molar ratio, a white powder was recovered and characterized by multinuclear NMR spectroscopy and CHN analysis. The ^{31}P NMR spectrum of this product contained a singlet at 42.0 ppm, while the ^{1}H and ^{13}C NMR spectra revealed two *tert*-butyl resonances with relative intensities of 1:2. No resonance for a $MeZn^+$ cation was observed. These NMR data are consistent with the formation of $\{Zn[(\mu\text{-}S)(\mu\text{-}N\text{-}t\text{-}Bu)P(NH\text{-}t\text{-}Bu)_2]_2\}$ (**11**) in which a Zn^{2+} cation is *N*,*S* chelated by two monoanions. A peak at *m*/*z* 607 ($M - Me^+$) is observed in the ESI mass spectrum of **11**.



In contrast to the diverse reaction pathways and complex product mixtures in the reactions of $OP(NHR)_3$ with $ZnMe_2$, only monodeprotonation is observed in the corresponding reaction of $SP(NH\text{-}t\text{-}Bu)_3$. The lower reactivity of **2a** toward $ZnMe_2$ is unexpected, as previous studies have shown this thiophosphate to be much more reactive toward alkyllithium reagents than is the oxo analogue **1a** (3–5).

11

Preparation and characterization of {MeZn[(μ-N-*t*-Bu)-(μ-NSiMe$_3$)P(NH-*t*-Bu)$_2$]} (12)

The reaction of $(t\text{-}BuNH)_3PNSiMe_3$ with 1 equiv. of dimethylzinc generates $\{MeZn[(\mu\text{-}N\text{-}t\text{-}Bu)(\mu\text{-}NSiMe_3)P(NH\text{-}t\text{-}Bu)_2]\}$ (**12**) as a yellow oil, which has been characterized by multinuclear NMR spectroscopy and CHN analysis. The ^{1}H NMR spectrum of **12** exhibits only three resonances with relative intensities of 9:3:1 assigned to the *t*-Bu groups, the $SiMe_3$ substituent, and the $MeZn^+$ cation, respectively. Although the signals from the μ-N-*t*-Bu and NH-*t*-Bu groups are not resolved in the ^{1}H NMR spectrum, the ^{13}C NMR spectrum shows two distinct sets of *t*-Bu resonances in an approximately 1:2 ratio. A singlet is observed at 9.1 ppm in the ^{31}P NMR spectrum. Thus, the NMR data indicate a *N*,*N*′-chelated structure for **12**.

12

The reaction of **3** with $ZnMe_2$ in a 2:1 molar ratio produces a 1:1 mixture of **12** and unreacted **3**, indicating that dimethylzinc in only sufficiently basic to effect monodeprotonation of **3**. This result was somewhat surprising, given that **3** can be triply deprotonated by reactions with *n*-BuLi at room temperature; conversely, the trisamidophosphate **1a** can only be dilithiated regardless of reaction conditions, whereas reactions with dimethylzinc lead to the formation of triply deprotonated species such as **6** and **7**.

Conclusions

The reactivity of the triamidophosphates $EP(NHR)_3$ (E = O, S, $NSiMe_3$; R = alkyl) toward dimethylzinc markedly decreases on moving from oxygen to the heavier chalcogen sulfur. The higher basicity of the oxo ligand results in a tendency for coordination to numerous metal centres. Both the oxygen and sulfur systems display temperature-dependent solution dynamics. A further decrease in reactivity is observed when the chalcogen atom is replaced by an $NSiMe_3$ group; the only product observed is the monomer $\{[MeZn][(\mu\text{-}N\text{-}t\text{-}Bu)(\mu\text{-}NSiMe_3)P(NH\text{-}t\text{-}Bu)_2]\}$, presumably because the steric bulk of the alkylimido groups impedes aggregation. Curiously, the reactivities of these triamidophosphates towards *n*-butyllithium decrease in the reverse order; threefold deprotonation of $OP(NHR)_3$ occurs only in reactions with dimethylzinc. The reactions of other organometallic reagents such as $MgBu_2$ with these triamidophosphates is worthy of investigation for comparison with the results observed for *n*-BuLi and $ZnMe_2$.

Enhancing image quality of scanning electrochemical microscopy by improved probe fabrication and displacement

Renkang Zhu and Zhifeng Ding

Abstract: Scanning electrochemical microscopy (SECM) is a powerful tool for its wide applications in determining charge transfer kinetics, imaging chemical reactions and topography, as well as fabricating microstructures at various interfaces and (or) surfaces. Imaging applications, in particular, rely on the natures of SECM probes and the scanning systems to move them in the vicinity of interfaces. While progress has been made in new approaches to tip fabrication, there are few reports on the improvement of the tip positioning system to enhance SECM image quality. We have recently built an advanced SECM setup using a closed-loop scanning system and improved probe fabrication and characterization procedures. Here we will describe this development, as well as the application of these techniques to greatly improve the quality of SECM images. Video micrograph, cyclic voltammograms, and SECM approach curves (current vs. tip–substrate distance) were chosen to characterize probe quality and to determine the ratio of electrode diameter to glass sheath diameter. The SECM setup has a resolution and repeatability of 20 nm in three dimensions (*x*, *y*, and *z*) and can locate and relocate areas of interest precisely after a coarse image. Interdigitated electrode arrays of platinum and gold were first imaged. Image resolution revealed by sharpness of Pt band edges was enhanced by using a 2 μm diameter electrode. Pt or Au band height was found to be around 80–200 nm by fitting the approach curves to the theoretical ones. Imaging conditions such as delay time for a large step size between two succeeding data points were optimized. To test its thermal and temporal stability, the system was then used to image letters, which were printed on a transparency with font bold Courier New and font size 2. Minor drifts were found during the image process up to the experimental length of 8 h and 45 min. Letter thickness was found to be 1.0–1.2 μm. A silicon substrate with an array of square pits spaced apart on 10 μm centers was finally imaged. Good quality images were obtained at various tip–substrate distances even though the squares were just as small, if not smaller, than the tip. The samples were also imaged by AFM for comparison.

Key words: scanning electrochemical microscopy, atomic force microscopy, microelectrode fabrication, closed-loop imaging, probe approach curve.

Résumé : La microscopie électrochimique à balayage (MECB) est un puissant outil avec de nombreuses applications dans la détermination de la cinétique de transfert de charge, dans l'imagerie et la topographie des réactions chimiques ainsi que dans la fabrication de microstructures à diverses interfaces et (ou) surfaces. En particulier, les applications en imagerie reposent sur la nature de sondes de MECB et de systèmes de balayage pour les amener dans les environs des interfaces. Même si des progrès ont été réalisés dans de nouvelles approches pour fabriquer des électrodes pointus (pointes), il y a eu peu de publications sur les améliorations des systèmes de positionnement des pointes afin d'améliorer la qualité des images de MECB. On a récemment construit un ensemble élaboré de MECB qui utilise un système de balayage à circuit fermé, des méthodes améliorées de fabrication des sondes et de méthode de caractérisation. Dans ce travail, on décrit les développements mentionnés dessus ainsi que l'application de ces techniques afin d'améliorer considérablement les images de MECB. Afin de caractériser la qualité des sondes et pour déterminer le rapport du diamètre de l'électrode par rapport au diamètre de la gaine de verre, on a choisi un micrographe vidéo, des voltampérogrammes et les courbes d'approche de la MECB (courant en fonction de la distance entre la pointe et le substrat). La résolution et la répétabilité de l'arrangement de MECB est de 20 nm dans les trois dimensions *x*, *y* et *z* et il est possible de localiser et de relocaliser les zones d'intérêt avec précision à partir d'une image grossière. Dans un premier temps, on a déterminé des images d'arrangements d'électrodes d'or et de platine interdigitées. La résolution de l'image mise en évidence par la netteté des arêtes de la bande du platine a été améliorée en utilisant une électrode de 2 μm de diamètre. En ajustant les courbes d'approche aux courbes théoriques, on a trouvé que la hauteur des bandes du platine ou de l'or est d'environ 80 à 200 nm. On a optimisé les conditions d'obtention des images, par exemple, pour le temps d'attente pour une montée importante entre deux points successifs de données. Afin d'évaluer la stabilité thermique et temporelle du système, on l'a ensuite utilisé pour produire des images de lettres qui avaient été imprimées

sur une diapositive avec police Courrier New en gras et une taille de 2. On a observé des déplacements mineurs lors de l'obtention de l'image, jusqu'à 8 h et 45 min. On a trouvé que l'épaisseur de la lettre était de 1,0 à 1,2 μm. Enfin, on a obtenu l'image d'un substrat de silicium comportant un arrangement de puits carrés éparpillés sur des centres de 10 μm. On a obtenu des images de bonne qualité à des distances variables entre la pointe et le substrat, même si les carrés étaient de la même taille que la pointe, si non plus gros. Pour fins de comparaison, on a aussi obtenu des images par AFM.

Mots clés : microscopie électrochimique à balayage, microscopie de forces atomiques, fabrication de microélectrodes, imagerie en circuit fermé, courbe d'approche de la sonde.

[Traduit par la Rédaction]

Introduction

In recent years, scanning electrochemical microscopy (SECM) (1–3) has shown great applications in the area of chemical and biochemical kinetics (4–16), chemical activity imaging (17–34), and micrometer scale structuring (32, 35–43) at liquid–liquid, liquid–solid, and liquid–membrane interfaces. The most significant advantage offered by SECM is its capability of probing chemical information of interfacial electron and ion transfer processes at the interfaces. Consequently, there is great interest in the development and application of SECM, as over 600 publications have appeared to date. While SECM is a powerful tool for these studies, two challenges remain: speed and resolution. These link to the nature of the available SECM probes (also named as tips, ultramicroelectrodes (UME)) and the techniques used to displace them in the vicinity of the interfaces (3).

The SECM probe is usually a platinum disk insulated by a glass sheath. A constant potential is applied to the electrode to quickly drive an electrochemical reaction of one redox species (the mediator) in a bulk solution. The measured current has to be constant (steady-state current), which is determined by hemispherical diffusion of the reactant at a fixed concentration to the electrode with a diameter of less than 25 μm. When the tip is brought down toward a substrate, this constant current is perturbed by the substrate at close proximity through either blockage of the diffusion (on an insulator, negative feedback) or dominant regeneration of the reacted species from the tip (on a conductor, positive feedback) (3). To better detect the feedback, the probe should get closer to the substrate. The edge of the glass sheath has to be machined down to a small size (sharpened to a tip) to avoid touching a tilted substrate. A small ratio of the outermost glass diameter to Pt disk diameter (RG) is very critical. On the other hand, the disk diameter and then the global tip diameter (outermost diameter), determine the resolution of SECM directly as the feedback reflects the perturbation from a substrate domain as small as the electrode. The reduction of the electrode size, however, further increases the workload and the difficulty in making the electrode. A lot of efforts are therefore needed to fabricate submicron or nanometer scale tips, aiming at high-resolution SECM (36, 44–47). For instance, it is very time-consuming and difficult to prepare a 2 μm diameter electrode with a small RG. We present here our improved procedure to make 2 μm diameter UMEs. The condition for sealing Pt wires was optimized and the workload to sharpen an UME was reduced by pulling the glass tubing. The rate for breaking the glass sheath and accidentally cutting the Pt disk was decreased to a minimum by employing a used computer hard disk drive.

It is possible to map out the surface topography and (or) chemical reactions by monitoring the current perturbation when the tip is rastered above a plane close to the substrate. It is obvious that the quality of SECM images is determined by how accurately the tip is positioned and the current is measured.

In fact, tip displacement in SECM is mostly driven by a piezoelectric device where the move is a function of the applied voltage to piezoelements (48). In some reports, the tip was displaced by a stepper motor (34, 49). While piezoelectric tube or disc scanners are widely applied in other scanning probe microscopy (SPM), an inchworm motor stage for three orthogonal dimensions is typically used in SECM due to its long traveling range (more than 25 mm), rigid stiffness, high stability, and minor creep, an effect of relaxation to a steady state after a fast movement. However, an inchworm scanning system suffers from two other common problems as those of other SPM techniques do: nonlinearity and hysteresis. Nonlinearity is a variation of the travel distance with the same increment of applied voltage. For instance, an image of a circular object will look like an oval if the linearity in the x direction is different from that in the y direction. The case will become much worse if each move is nonlinear to the voltage. Hysteresis is the deviation between curves of extension-voltage and retraction-voltage, i.e., the traveling distance is direction dependent. Both factors deform the images. In most SPM techniques, hysteresis and nonlinearity are compensated for by a scan in a single direction and a calibration array for a specific scanning system generated with a well-characterized sample. It is more difficult to calibrate an inchworm motor in this way because more parameters, such as direction, speed, step size, etc., should be considered (48).

Note that the operation of the inchworm scanning system as previously depicted employs an open-loop mode, where a voltage is applied to command a move without measuring the real travel that occurred. The controller in the system is only a voltage generator. Encoder-counting circuitry in the controller and a linear encoder integrated in the inchworm motor constitute a closed-loop operation, where the system applies a voltage to the motor, measures the actual motion, and eventually adjusts the position. Closed-loop operation gives the additional features of setting a zero point, stepping, moving to a targeted position, maintaining the position, as well as relocating the original position. The resolution of the system is the same as that of the encoder. We report here a

© 2005 NRC Canada

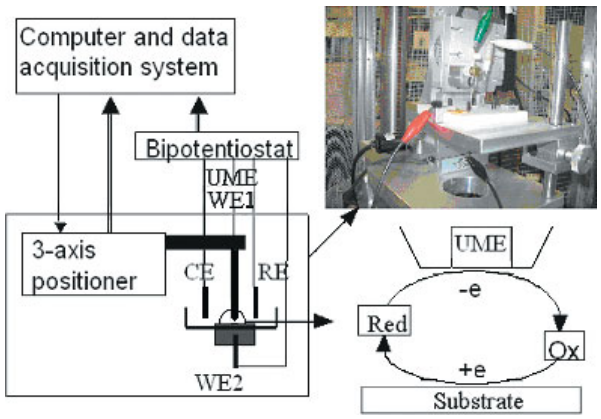
new SECM facility built with a closed-loop scanning system, which allows for bidirectional repeatability of ±20 nm linearly and easy programming through graphic user interfaces (GUI). Nonlinearity and hysteresis are minimized with the instrument. The scanning system not only receives motor control instructions from a computer, but also sends back the information on position and motor status. Other instrumentation details will be described in the Experimental section. Several samples were imaged with the setup to show how the system enhanced the SECM image quality. They included platinum and gold interdigitated electrode arrays (IDEAs) with alternative 20 μm digit width and interdigit space, printed letters in bold font New Courier and font size 2, and a platinum-coated silicon substrate with an array of square pits spaced apart on 10 μm centers. The IDEAs and the platinum-coated silicon substrate were also imaged for comparison, using a commercial atomic force microscope (AFM).

It is worth noting that SECM instrumentation was well-documented in a review by Wipf in the SECM monograph (48). However, the incorporation of a closed-loop scanning system into the SECM technique remains scarce. Only recently has the closed-loop system been introduced to the *z* direction by Denuault and co-workers (50). We believe that the new instrument, with added advantages, will benefit SECM research and its applications to various fields.

Experimental section

Chemicals

Electrolyte solutions consisted of 0.9 mmol/L ferrocenemethanol (Fc, 97%, Aldrich, Mississauga, Ontario) as the mediator and 0.1 mol/L sodium perchlorate hydrate (99.99%, Aldrich) as the supporting electrolyte. Concentrated nitric acid (Caledon Laboratories Ltd., Georgetown, Ontario) was diluted to 1:1 (*v*/*v*) with water. Distilled water (Milli-Q, Millipore, Bedford, Massachusetts, 18.2 MΩ resistivity) was used to prepare all aqueous solutions.



Samples

Pt- or Au-coated IDEAs were purchased from ABTECH Scientific, Inc. (Richmond, Virginia). A 100 nm thick layer of metals was sputtered on the Schott D263 borosilicate glass substrate metallized with 100 Å Ti in a monolithic configuration. Each IDEA electrode had 25 digital pairs with a 20 μm digit width, a 20 μm interdigit space, and a digit length of 3 mm. Letters, "SECM", "CHEM", and "UWO" were printed on a transparency (3M, London, Ontario) in bold font Courier New and in font size 2 with an HP 2200 Laser jet printer (HP, Mississauga, Ontario). A platinum-coated silicon substrate with an array of square pits spaced apart on 10 μm centers is the calibration reference from Digital Instruments (Santa Barbara, California).

Electrode fabrication

Platinum UMEs of 25 μm diameter were prepared by sealing nominal diameter Pt wire (Goodfellow Metals, Cambridge, UK) into glass capillary (o.d.: 2 mm; i.d.: 1 mm; length: 10 cm, Sutter instrument) as described elsewhere (36). We have modified the preparation procedure as described in the following. One end of the glass capillary was pulled by a heating coil puller (PP-83, Narishige, Japan) and was sealed by a Bunsen lamp. A corn shape inside the pulled capillary favourably fitted the inserted Pt wire to keep it straight. The thinner glass wall at the pulled end not only enhanced the quality of sealing the glass onto the Pt wire but also reduced the workload of sharpening the glass sheath.

Fig. 1. An illustrative scheme of the home-built SECM instrument. The inset is the zoom-in assembly of the electrochemical cell and the SECM probe mounted on the positioning system.

To prepare 2.0 μm diameter Pt tip UMEs, 2 μm diameter Pt wire (Goodfellows Metals, Cambridge, UK), known as Wollaston wire, was loaded into a similar pulled capillary but with an open-end. The support silver coating on the wire was etched out by briefly dipping the assembly in 1:1 (*v*/*v*) water – nitric acid. Exposed Pt wire was sealed in the glass capillary after washing out the residue acid with copious water and drying the inside by vacuum pumping and heating simultaneously.

All the tip surfaces were polished in succession by polishing pads (Buehler Ltd., Bluff, Ilinois) coated with alumina having diameters of 3.0, 0.3, and 0.05 μm, respectively. The glass sheath was sharpened by 3.0 and 0.05 μm diameter diamond pads. The RG is 6–8 for the 2 μm diameter Pt UME and 4 for the 25 μm diameter Pt UME. A used hard drive disk was used as polishing wheel, which was spun at high speed and had minor planer vibration.

The quality of these probes was monitored by cyclic voltammetry in the electrolyte solution, video micrography (TE-300, Nikon, Japan), as well as the SECM approach curves. In the cyclic voltammetry experiments, an electrochemical analyzer (CH 832A, CH Instruments, Austin, Texas) was used. A three-electrode system was employed, where the UME in question was the working electrode, a Pt wire 0.75 mm in diameter was used as the counter electrode, and a saturated Ag/AgCl (CH Instruments) electrode was the reference electrode.

Custom-built SECM instrument

The custom-built SECM instrument is schematically shown in Fig. 1. Indeed, the instrument is composed of three major parts: the electrochemical system, the positioning system, and the active data acquisition system. In general practice, a potential was applied to the SECM probe and a current was measured by the electrochemical system. The positioning and data acquisition systems were used to dis-

© 2005 NRC Canada

place the probe and record the current and position data simultaneously. The electrochemical and positioning systems were built together in a Faraday cage to isolate external electrical noise. At this time, our SECM setup can be operated in approach curve and constant-height imaging modes. In the approach curve experiments, UME current was monitored when the probe was brought closer to the specimen. In constant-height imaging mode, the current was recorded vs. lateral coordinates when the electrode was scanned in a plane at a fixed height in the vicinity of the substrates. Details on SECM instrumentation have been previously described (48). Here we outline some important aspects in our microscope.

Electrochemical system

A 3 mL cell circular in cross section was machined on a 4 cm × 4 cm Teflon block with a thickness of 0.8 cm. Substrates were mounted at the bottom opening of the cell and exposed a 5 mm diameter area. The cell block was clamped onto a very stable supporter, where the horizontal plane of the sample was adjusted to minimize the substrate tilt. Unless otherwise stated, three-electrode configuration was utilized, as described in the CV experiments. All electrochemical measurements were performed on an electrochemical analyzer (CH 832A, CH Instruments), which combined a bipotentiostat with an internal waveform generator. Note that it is possible for us to apply another potential with the instrument to the substrate for future SECM study as shown in the inset of Fig. 1.

Positioning system

Our positioning system was a FREEDOM^{TM} 1500-3 nano robot system purchased from EXFO Burleigh Products Group Inc. (Canada), which consisted of an EXFO 8200 controller and three Burleigh TSE-820 linear stages for the displacement in *x*, *y*, and *z* directions. The positioning speed could be adjusted to as high as 1.5 mm/s. The 8200 controller generates desired motion waveforms and supplies power to drive the motors and to control the encoders simultaneously. The 8200 can not only receive motor control instructions from a system controller (typically a personal computer), but also send position and motor status information. The controller allowed us to move an absolute target value, set a motor speed and a step size, and read the current motor position. Each TSE-820 linear stage was based on a 25 mm travel, 75 mm × 75 mm footprint, crossed roller bearing stage driven by a compact inchworm motor integrated with a 20 nm resolution encoder. The integral encoder was connected with a Heidenhain model EXE-650B electronic box that converts the analog signals into digital signals that are compatible with the controller. The *z* axis supported by a vertical bracket was also equipped with an adjustable spring-loaded counterbalance (TS-CB, Burleigh) to minimize gravity loads resting directly on the inchworm motor. The SECM probe was held in a groove by a screw and a Teflon Lucite washer on a custom-built holder mounted on the *z*-axis stage as shown in the inset of Fig. 1.

Active data acquisition system

This part consisted of a computer loaded with home-made virtual instruments (VIs) programmed in LabVIEW (Version 7, National Instruments, Austin, Texas), a general purpose interface bus (GPIB) board (PCI-GPIB, National Instruments) to communicate with the 8200 controller, and a 16 bit DAQ card (PCI-6052E, National Instruments) with a connection board (BNC-2090, National Instruments) to record current output from the electrochemical workstation. All SECM experiments were driven and automated by the custom-built LabVIEW VIs. In our LabVIEW VI programming, various controller implementations written in C++ language were called from the C++ library into a thin front end GUI, a Microsoft technology named Active X interface that accelerated the operation speed. Programming was very straightforward. After the input of parameters such as scan range, pixel and delay between action steps, the SECM VIs generated a loop consisting of iterations to move an absolute distance in one direction at a time (only call the C++ interface for target positioning), and then to measure the electrochemical current and record the positions simultaneously. The data were displayed in situ. For instance, approach curves were obtained by plotting the current vs. the displacement in the *z* direction. Images were acquired by plotting the current vs. lateral motion. A spreadsheet file was saved after each experiment for further analysis.

SECM experiments

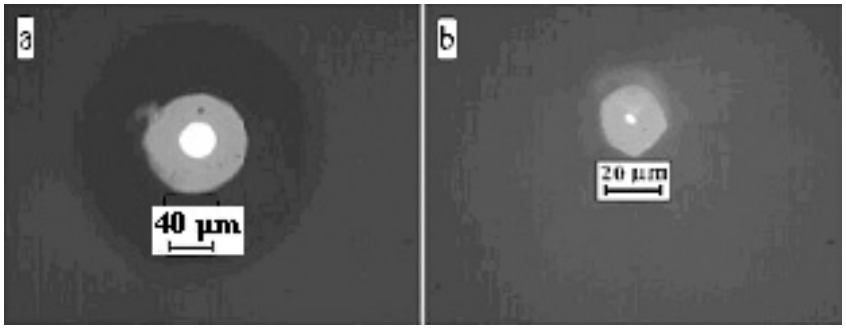
The redox potential value, determined by CV in the bulk electrolyte solution, to oxidize the mediator, ferrocenemethanol, was held at 0.35 V vs. Ag/AgCl. The biased SECM probe was slowly brought (at a speed of 1 μm/s) to a specimen, until a normalized positive feedback current of 2 or a normalized negative feedback current of 0.3 was achieved. The distance between this engaged tip and the substrate was adjusted by withdrawing or pushing an absolute distance. Images were obtained by scanning the tip laterally above the substrate. Interesting spots (small areas) in images were zoomed in by relocating the tip and rescanning the substrate in closed loops. All experiments were conducted in air under an ambient temperature of 20 ± 2 °C.

Data analysis

Theoretical approach curves were obtained based on previous studies (4, 51, 52) and our simulation using FluxExpert software at the Swiss Federal Institute of Technology in Lausanne (EPFL). The height of the gold bands on the IDEAs was extracted from the approach curves by differentiating the distances corresponding to the normalized current (positive feedback) above the band and that above the glass (negative feedback). Similarly, the heights of the printed letters were obtained by reading the distance differences corresponding to the appropriate normalized currents on the negative feedback approach curve.

AFM image

AFM images were carried out in air on Alpha-SNOM (WiTec, Ulm, Germany), using a contact mode. The AFM probes had a spring constant of 2.8 N/m.



Results and discussion

Characterization of SECM probes (UMEs)

Video micrographs, cyclic voltammograms, and SECM

© 2005 NRC Canada

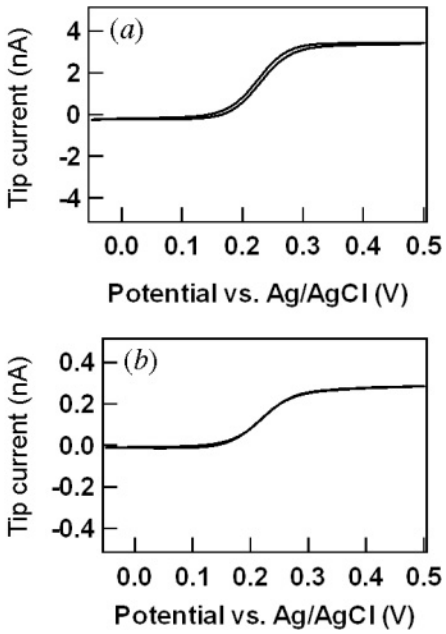
Fig. 2. Typical video micrographs of (*a*) a 25 μm diameter electrode with a RG value of about 3 and (*b*) a 2 μm ultramicroelectrode with a RG value of 8.

approach curves were used to characterize the prepared UMEs, which were finely polished and sharpened.

Video micrographs

Figure 2 illustrates representative micrographs of the two types of microelectrodes (25 and 2 μm in diameter) monitored after intensive polishing and sharpening. RG, the ratio of the glass sheath radius to the Pt disk radius, was determined via a high-magnification optical microscope. RG values for the 25 μm microelectrodes used in the experiments of this report can easily go to 3 to 4 with our modified fabrication procedure (Fig. 2*a*). It is known that the smaller the RG, the greater the feedback the SECM probe will give (3). This is because the reduced glass sheath will decrease the case where the electrode edge touches a substrate, especially a tilted one. The touching, in fact, compromises the expected feedback response from the probe. The prepared 2 μm diameter electrode showed a quasi-disk shape (Fig. 2*b*). In the following, these UMEs are defined as 2 μm "effective diameter" probes, assuming that there is no large difference between the oval shape and the disk shape in very small sizes. The RG for these electrodes can reach 6–8. The micrographs of both electrodes show a very smooth surface. There was little shade at the edge of the Pt disk, showing a good sealing of the glass sheath surround the disk.

Cyclic voltammograms



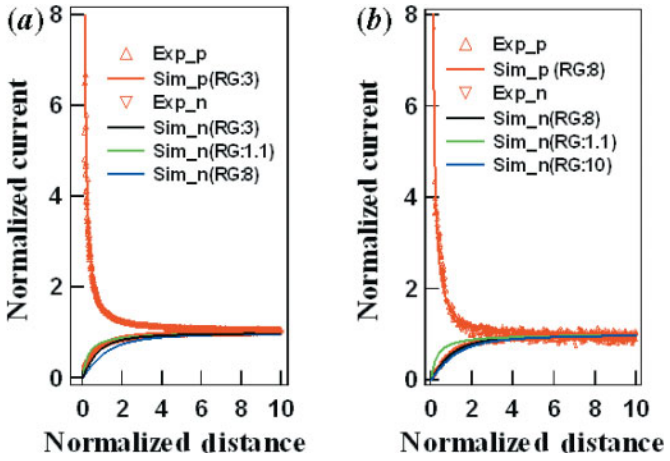
Cyclic voltammetry of a 0.9 mmol/L ferrocenemethanol solution containing 0.1 mol/L TEAP as the supporting electrolyte was carried out on each of the electrodes to test their electrochemical behavior. The electrochemical active group, ferrocene (Fc), in ferrocenemethanol is oxidized to ferrocenium (Fc^+) when the applied potential at the electrode is scanned in a positive direction.

$$[1] \qquad Fc - e^- \rightarrow Fc^+$$

The redox couple (Fc^+/Fc) has a fast electron transfer rate at an UME and shows a steady-state voltammogram (Fig. 3) because of its hemispherical diffusion to the electrode (53). The size of the 25 μm UME was confirmed by calculating its radius (*a*) from the measured steady-state current or diffusion-limiting current on the voltammogram (Fig. 3*a*) via eq. [2],

$$[2] \qquad a = \frac{i_{T,\infty}}{4nFDc^0}$$

Fig. 3. Representative cyclic voltammograms recorded at (*a*) a 25 μm diameter UME and (*b*) a 2 μm diameter UME. The solution in the electrochemical cell contained 0.9 mmol/L ferrocenemethanol and 0.1 mol/L KCl. The scan rate was 10 mV/s.



where $i_{T,\infty}$ is the steady-state limiting current of the UME far from a substrate (several UME diameters), n is the number of electrons transferred in eq. [1], F is the Faraday constant, D and c^0 are the diffusion coefficient and concentration of ferrocenemethanol, respectively. The diffusion coefficient here was taken as 7.8×10^{-6} cm^2/s from a previous report (54). The electrochemically determined result of $a = 13$ μm agrees well with that measured on the micrographs. From the voltammogram of the 2 μm diameter UME shown in Fig. 3*b*, the effective radius was 1.0 μm, a result calculated from eq. [2]. Both voltammograms show a flat steady-state current. The forward and backward current–potential curves almost overlapped, indicating a very small capacitive current and therefore a good electric isolation on the sides of UME disks (44).

Approach curves

UMEs were further checked by recording SECM approach curves of the UMEs toward a conductor or an insulator substrate (Fig. 4). In fact, an UME was biased with a potential at 0.35 V in the same solution as in Fig. 3, and the

© 2005 NRC Canada

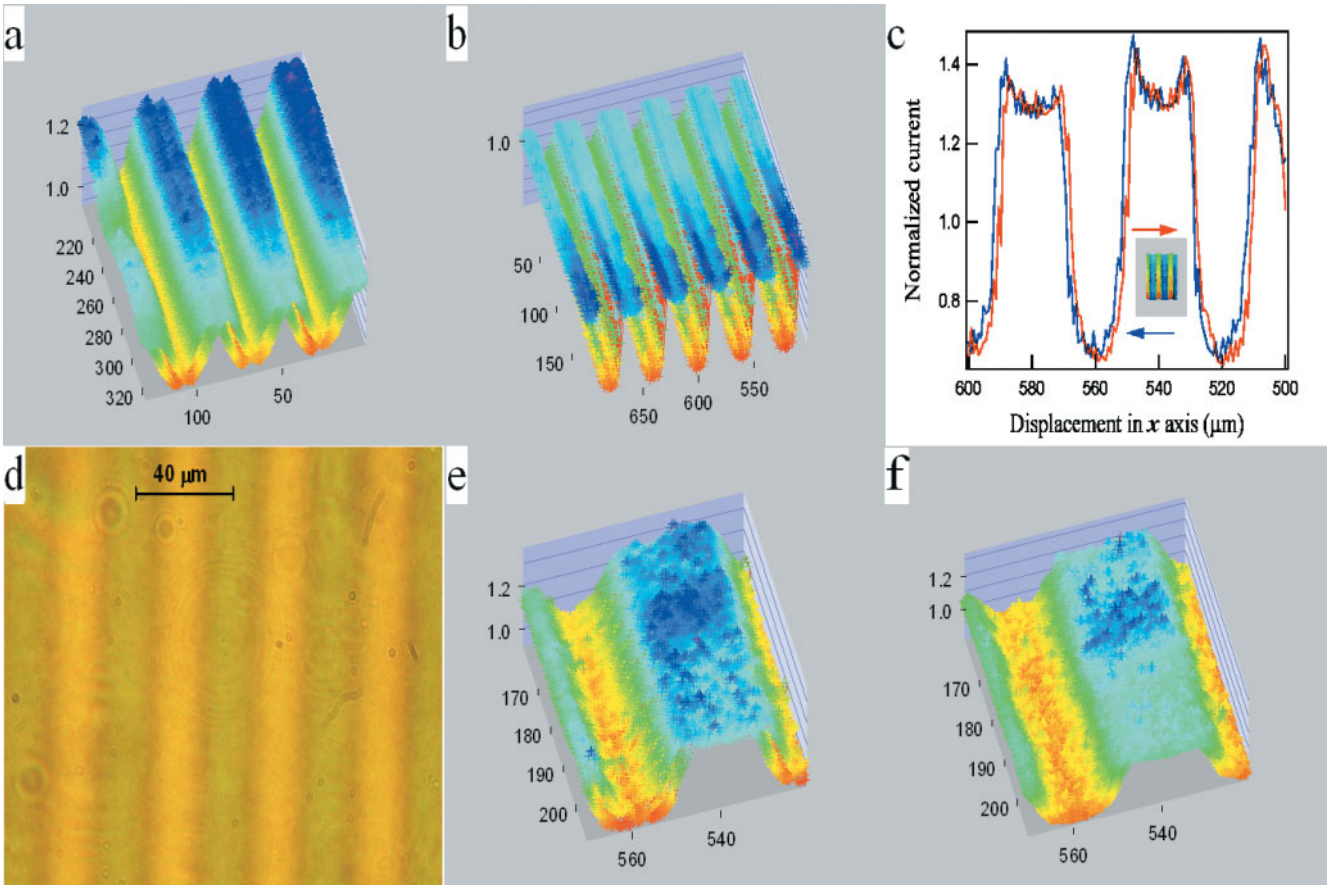
Fig. 4. Respective approach curves toward a 2 mm diameter Pt disk electrode and a glass microscope slide for a (*a*) 25 μm diameter UME with RG = 3 and (*b*) a 2 μm diameter UME with RG = 8. The electrochemical cell is the same as described in Fig. 3. The applied potential at the UMEs was 0.35 V and the approach speed was 1 μm/s. The current shown here was normalized by the infinite tip current ($i_{T,\infty}$) when the UME was far away from the substrate, whereas the distance was normalized by the electrode radius. Simulated negative approach curves with RG values of 4, 8, and 10 for both substrates are plotted for comparison.

diffusion-limiting current was monitored vs. the distance between the electrode and the substrate while it was driven toward the substrates by a *z*-inchworm motor. Figure 4*a* illustrates two expected approach curves for a 25 μm diameter SECM tip: (*i*) the steady-state current decreased when the SECM tip moved toward a glass slide (negative feedback) because the insulator blocked the diffusion of ferrocenemethanol to the tip and the reaction shown in eq. [1] slowed down; (*ii*) the diffusion-limiting current increased when the UME approached a 25 μm diameter Pt disk electrode (positive feedback) because the reaction below at the Pt substrate regenerated the ferrocenemethanol to the tip and most importantly, the electrochemical reaction was faster than the normal diffusion.

[3] $Fc^+ + e^- \rightarrow Fc$ (fast)

The detail of this reaction governed by the Nernst equation at open circuit has been described elsewhere (24, 55). Note that the substrate also blocked the diffusion. However, the fast regeneration of Fc (eq. [3]) dominated. Normalized current ($i_T/i_{T,\infty}$) of 8 and 0.1 at both SECM tips was attained for positive and negative feedback, respectively, as shown in Fig. 4. Relative small RG in the probe fabrication avoided contacting the tip glass sheath with substrates eventually tilted and enabled the UMEs to get closer to the substrate. Shao and Mirkin (51) and Amphlett and Denuault (52) have demonstrated that RG affects SECM approach curves for insulating substrates more obviously than those for conductive substrates. RG values estimated from video micrographs were therefore confirmed by fitting experimental approach curves with theoretical ones generated by solving the diffusion problems with different RG values in this system based on previous publications (51, 52) and the simulation using FluxExpert software. While the experimental approach curves are practically coincident with theoretical ones for RG = 10, 8, and 4 in positive feedback mode (with Pt substrates), the curves for the negative feedback differentiate from simulated ones with different RG values as illustrated in Fig. 4. An extracted RG value of 3 agrees well with that estimated from video micrographs. Similar responses were observed from a 2 μm diameter SECM tip as shown in Fig. 4*b*. A RG value of 8 was determined from the theoretical curves for negative feedback.

Imaging Pt and Au IDEAs



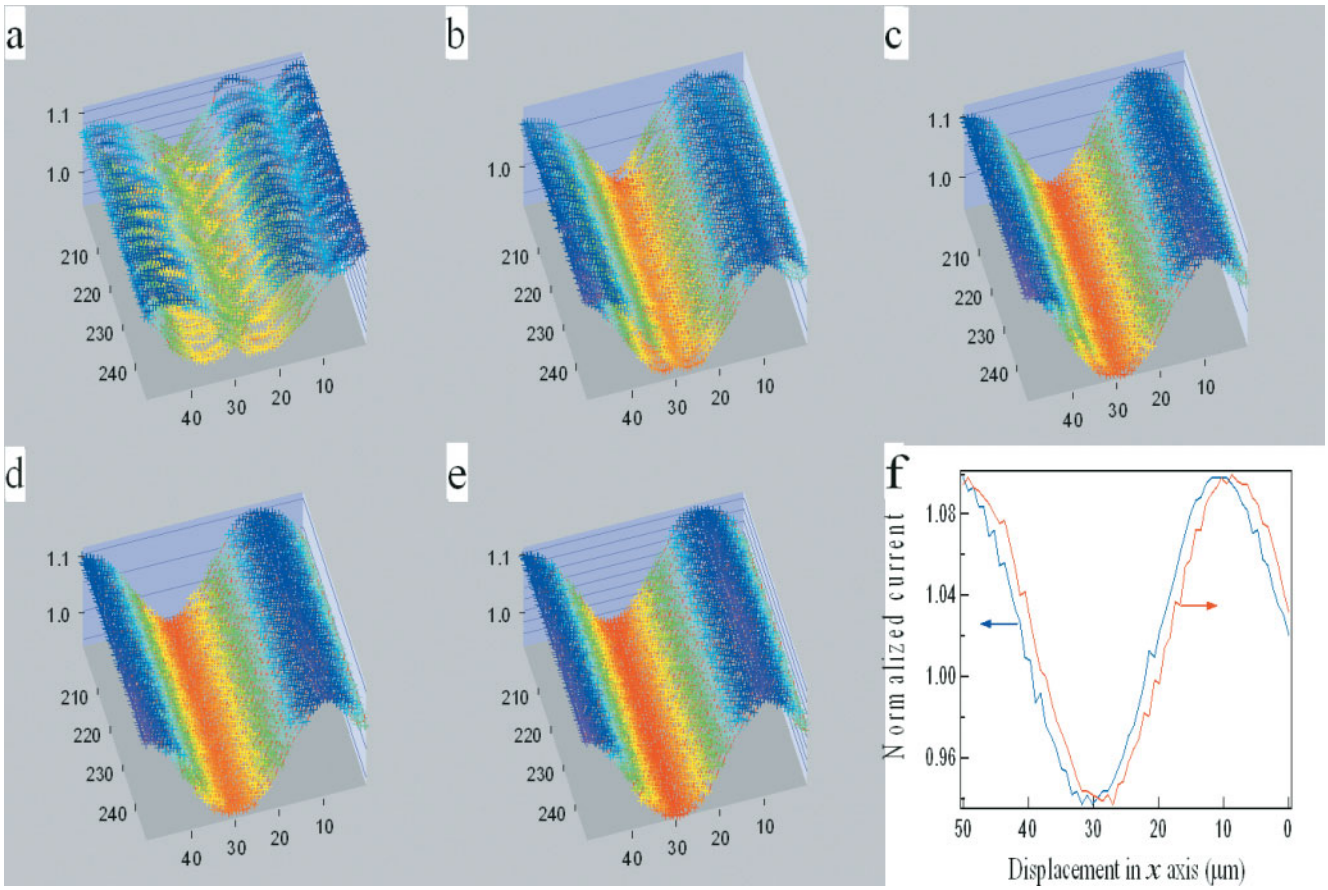
Well-characterized UMEs were first used to image Pt and Au IDEAs consisting of 25 digital pairs with 20 μm digit width, 20 μm interdigit space, and a digit length of 2985 μm. 0.35 V was applied to a UME tip immersed in a solution containing 0.9 mmol/L ferrocenemethanol and 0.1 mol/L KCl.

Tip size effect

A 25 μm UME tip was driven slowly toward a Pt array until a normalized current of 4 was achieved. The tip was withdrawn 6.0 μm before starting to image. This avoided a potential crash of the electrode against the substrate because of the tilt surface. Notice that the tip-to-substrate distance cannot be calculated by reading the distances from the approach curves as shown in Fig. 4*a* because the tip diameter is larger than the Pt bandwidth. The UME was then rastered in the *x*,*y* plane above the IDEA by the closed-loop inchworm positioner system, and the tip current was recorded to obtain SECM images (Fig. 5*a*). Data acquisition followed a zigzag scan pattern, i.e., the image was composed of alternative forward and backward line scans in the *x* direction. It took only 11 min to obtain this 130 μm × 130 μm (with 256 × 256 pixels) image because of this time-saving dual direction scanning. The step size was then 510 nm. The *x*,*y* position coordinate data recorded by the closed-loop system was examined. Real step size was found to be 510 and 490 nm alternatively. Note that the anodic current for ferrocenemethanol was monitored in Fig. 5. Normalized current would be more than 1 if the UME tip was above a Pt band. In contrast, the current would be less than 1 when it was positioned above a glass spacer. As shown by its cross section, the resolution can be evaluated by examining the sharpness of the rise and fall of the tip current when the probe was crossing the edges from a glass spacer to a Pt band or vice versa. The resolution shown in Fig. 5*a* is quite low because of the large size of the electrode. Quantitative analysis was therefore difficult to do in this case. However, the image clearly shows the alternative structure of the Pt bands and their glass spacers. The sharp contrast and the repeatability of the image match those of a micrograph magnified at 400 times (Fig. 5*d*). Images obtained by using this closed-loop system show a good quality. When the UME size was reduced to 2 μm in diameter, sharper rises and falls of the normalized current than those obtained with the 25 μm UME were observed at the Pt band edges as shown in Fig. 5*b*, indicating a higher resolution. The starting tip-to-substrate distance was set at 2.78 μm. It is evident that SECM resolution is dependent on the tip size. Further analysis of the resolution can be carried out by examining the cross section of the image (Fig. 5*c*). It is interesting to note

© 2005 NRC Canada

Fig. 5. Surface plots of tip current recorded at (*a*) a 25 μm diameter UME and (*b*) a 2 μm diameter UME during an image scan of a Pt IDEA in the area of 130 μm × 130 μm and 200 μm × 200 μm, respectively. Graph (*c*) shows two line scans in a length of 50 μm, from left to right (red) and from right to left (blue). In fact, the lines were extracted from an image that magnified a small area of 100 μm × 100 μm in image (*b*) as shown in the inset. An optical micrograph at a magnification of 400 times is shown in graph (*d*). Figures (*e*) and (*f*) illustrate step-size effect on SECM images of an area of 50 μm × 50 μm obtained on a 2 μm UME, with pixels 128 × 128 and 256 × 256, respectively. The UME tips were biased at 0.35 V and the IDEA was at open circuit. The tip-to-substrate distance (*d*) for (*a*) was set by first approaching the tip to a Pt band on the IDEA until the normalized current of 4 was reached and then withdrawing an extra distance of 6 μm. For graphs (*b*), (*c*), (*e*), and (*f*), the *d* was set at 2.78, 2.78, 3.30, and 2.92 μm, respectively. Inchworm speed for all three axes was set at 1000 μm/s. The solution was 0.90 mmol/L ferrocenemethanol and 0.1 mol/L KCl. The current shown here was normalized by the infinite tip current ($i_{T,\infty}$) when the UME was far away from the substrate, whereas the distance was normalized by the electrode radius. The scale of the *x*,*y* position was in μm units.



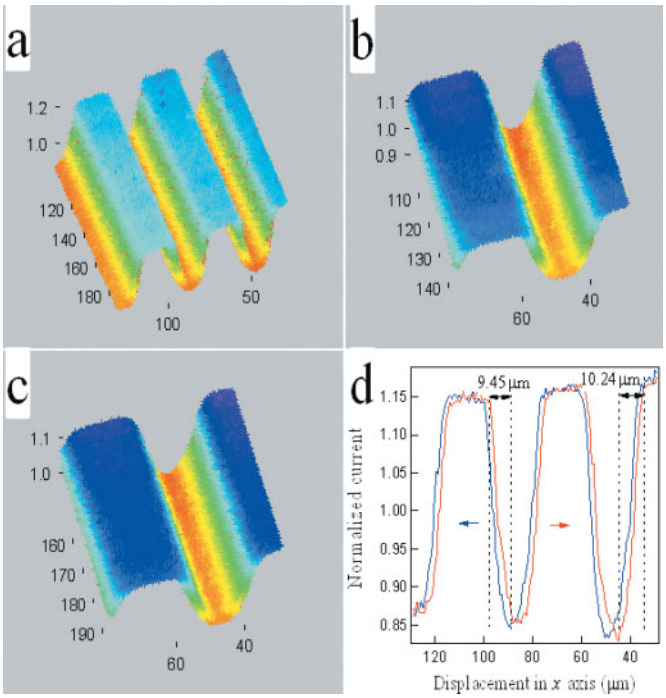
that the line scans tell us more detail about the band structures. For instance, the feedback current above the two edges of the Pt bands is higher than that above the center of the bands. This higher current corresponds to a shorter tip-to-substrate distance, i.e., the edges are thicker than the center. This can be well-understood by looking closely at the approach curve for the positive feedback. Interesting areas were zoomed in to show details as illustrated in the inset of Fig. 5*c*. In addition, a fine step size for imaging is helpful to enhance the image quality. For example, a sharper current rise and fall were observed in imaging an area of 50 μm × 50 μm with 256 × 256 pixels (equivalent to a step size of 195 nm) than in imaging the same area but with of 128 × 128 pixels (step size of 390 nm), as illustrated in Figs. 5*e* and 5*f*.

Overcoming hysteresis

Looking closer at the surface plot shown in Fig. 5*a*, the cross section reveals a double alternative wave, a systematic deviation between forward and backward scans in the *x* direction at the imaging conditions previously indicated. The hysteresis was worse especially when a large step size was taken (Fig. 6*a*). It is unlikely that this hysteresis came from natural behaviors of a closed-loop positioning system at a resolution of 20 nm because the tip position was measured by the capacitive sensor and was forced to adjust until the programmed targets were attained. Imaging conditions with a 25 μm diameter electrode, such as scan range, inchworm speed, as well as delay time (dt) between two succeeding data points on the scan line etc., were further adjusted and optimized with the home-made LabVIEW VIs. In fact, a 50 μm × 50 μm area of the Pt IDEA was located to image each time when one condition was changed. With the help of the closed-loop system, the UME tip was easily relocated to the original point by simply setting the coordinates of this point as the target position. The image quality was then inspected through SECM surface plots. For instance, the dt optimizing process is demonstrated in Fig. 6, where the tip-

© 2005 NRC Canada

Fig. 6. SECM images demonstrating optimization processes for delay time (dt), an interval taken between the two succeeding data points. (*a*) dt = 0 ms (data acquisition rate depended on the CPU dedicated to the LabVIEW VI; (*b*) dt = 20 ms; (*c*) dt = 40 ms; (*d*) dt = 50 ms; and (*e*) dt = 60 ms. (*f*) Forward and reverse line scans extracted from image (*e*) are shown. The UME diameter was 25 μm. An exact 50 μm × 50 μm area of the Pt IDEA was located and relocated again and again via the closed-loop system to keep other imaging conditions identical. The starting tip-to-substrate distance was set in the same way as in Fig. 5*a*. Pixels were at 64 × 64, equivalent to a step size of 780 nm. The electrochemical parameters were the same as described in Fig. 5.



to-substrate distance was set as in Fig. 5*a*. When the dt was set at 0, the forward and backward scans deviated almost 10 μm (Fig. 6*a*), and the SECM image showed much wider Pt bands and their glass spacers, almost twice larger than the real ones. Note that the data acquiring speed at this dt totally depended on the computer processing unit (CPU) dedicated to the system in which the software and the hardware, including an inchworm motor, its capacitive sensor, and its controller as well, should have recorded the current after finishing several cycles of moving, judging, and adjusting the tip position to reach a target position. Real dt was probably within 1 ms at dt = 0 and was too short for the system to fulfill the task. The hysteresis became worse if the travel distance between the two succeeding data points is longer. In addition, the diffusion-limiting current might not reach a steady state immediately after positioning the tip. This explains that current signal, shown in Fig. 6*a*, was a little noisy. Delay time was then set to 20, 40, 50, and 60 ms, respectively, and the same area was imaged again and again (Figs. 6*b*–6*e*). The longer the dt, the less the hysteresis. The deviation became small and constant if the dt was larger than 50 ms. The remaining hysteresis was caused by the asymmetry of the glass sheath around the Pt disk. For instance, in the case of this experiment, the Pt disk located on the right slightly from the central axis of the global electrode. Positive feedback from the Pt bands was monitored earlier in forward scan (the direction of the red arrow, left to right) than that in the reverse scan (the direction of the blue arrow, right to left) as illustrated by the cross sections in Fig. 6*f*, which were extracted from the image in Fig. 6*d*. We will come back to this point later in examining the SECM images of a gold IDEA. Effects on the image quality such as scan range and inchworm speed were also investigated. It turned out that the dt was mostly related to the hysteresis previously observed.

A gold IDEA with the same structure as the platinum one was also imaged by a 2 μm diameter probe (Fig. 7). When the probe was approaching the IDEA this time, a negative feedback was observed as shown in Fig. S1 in the Supporting information[2] of this report. The negative feedback

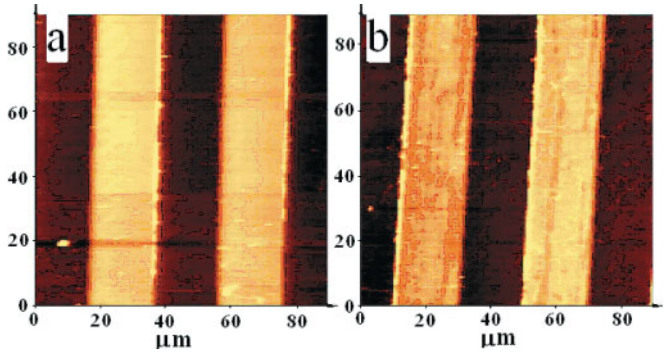

Fig. 7. SECM images of a gold IDEA acquired by a 2 μm UME. Image (*a*) shows an area of 100 μm × 100 μm covering 2.5 Au bands. Images (*b*) and (*c*) demonstrate 1.5 Au bands in an area of 50 μm × 50 μm. Graph (*d*) shows a forward (red) and a reverse (blue) line scan of image (*a*). All images were conducted with 128 × 128 pixels. The starting tip-to-substrate distance was set at 2.82 μm. Other imaging conditions are the same as in Fig. 5.

indicated that the electrode approached to an interdigit. The tip-to-substrate distance was set at 2.82 μm, and the probe was scanned in the constant-height mode to obtain images. Two and a half Au bands imaged in an area of 100 μm × 100 μm were well-resolved in Fig. 7*a*. The digit and interdigit width was measured and both were found to be 20 μm, which agreed well with their specification from the manufacturer. Two parts of the one and a half bands on the right in Fig. 7*a* were rescanned (magnified) in an area of 50 μm × 50 μm, as shown in Figs. 7*b* and 7*c*. These again demonstrated the quality of the SECM images using the closed-loop positioning system.

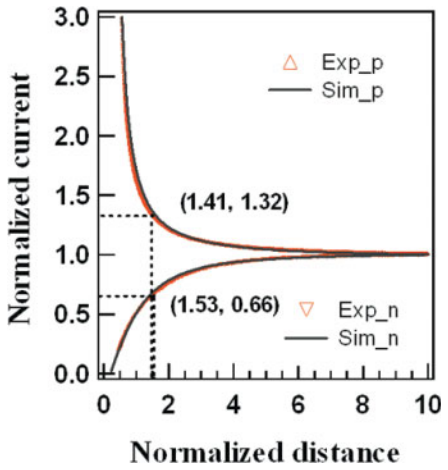
Lee et al. (18) investigated a gold IDEA with combined SECM and scanning optical microscopy in a constant-distance feedback mode. They showed that a topographic image of Au band edges is affected by the substrate tilt. We extracted both the forward and backward scan lines, which are shown in Fig. 7*d*. A similar phenomenon was observed both in forward and backward scans: the upward (from the glass to the Au band) edge width (10.24 μm) is larger than that of the downward (from the Au band to the glass) (9.45 μm) because of the substrate tilt. In addition, slight hysteresis because of the asymmetry of the glass sheath around the Pt disk was also observed. In the case of Fig. 7*d*, the disk is located further to the right. The positive feedback from the Au bands responded earlier in forward scans than in the backward scans. This was also observed in the SECM

Fig. 8. Topographical AFM images of (*a*) the Pt IDEA and (*b*) the Au IDEA.

images of the previous Pt IDEA scanned by a 25 μm diameter electrode, as shown in Fig. 6*f*.

Figure 8 shows topographical images for the Pt and Au IDEAs for a comparison with the previous SECM images. The AFM images correlate well with those from SECM. This demonstrates the enhanced quality of images on our SECM setup.

Measuring Pt and Au band height



Two average tip currents (1.32 and 0.66) were measured when the tip was above the center of a Pt digit and above the center of an interdigit (Fig. 5*c*). The distance from the tip to the digit (1.41 μm) and the distance from the tip to the interdigit (1.53 μm), corresponding to the two currents, respectively, were read from the approach curves for positive feedback (above the conductor) and negative feedback (above the insulator). The Pt band height is then the difference of the two distances (120 nm), which agrees with the 100 nm indicated in the specification from the manufacturer and that from AFM measurements. This measuring procedure is outlined in Fig. 9. As described in the Tip size effect section, higher currents at the band edges were observed (Fig. 5*c*), and therefore larger heights were expected. The height at the edges of the Pt bands was found to be 130–270 nm in the same measuring manner. Similarly, the cross section extracted from the image in Fig. 7*a* is shown in Fig. 7*d*. The Au bands look flatter than the Pt ones. However, the band thickness was determined to be around 200 nm.

High-resolution images of printed letters

To further demonstrate the advantages of the closed-loop scan system, such as high repeatability, high resolution, and low hysteresis, some letters printed on a transparency and in very small font size were imaged. The sample was fixed in the electrochemical cell described in the Experimental section, which contained a solution of 0.90 mmol/L ferrocenemethanol and 0.10 mol/L KCl. A 2 μm diameter UME biased at a potential of 0.35 V was first brought to the transparency body to attain a normalized current of 0.5, corresponding to a tip-to-substrate distance of 1.0 μm. Both the transparency substrate and the printed letters were found to behave like an insulator because a negative feedback was observed everywhere. The tip-to-substrate distance was set at 1.5 μm by withdrawing the tip an extra distance of 0.5 μm. At this fixed height, the tip was rastered above the letters to

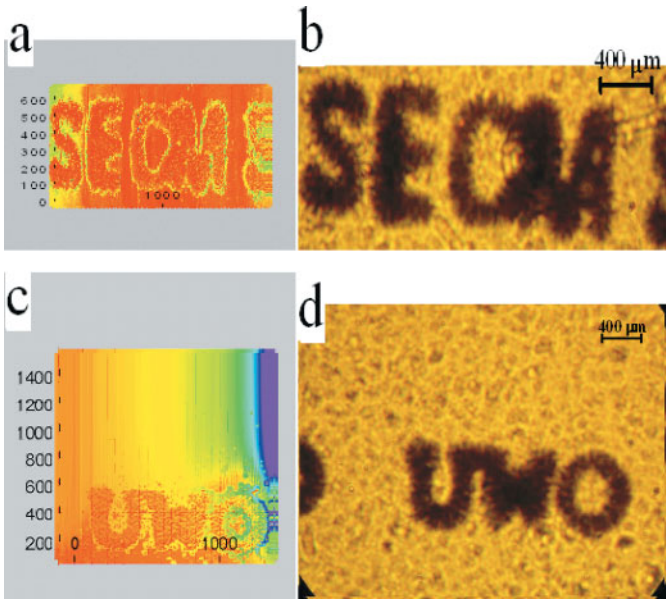

Fig. 9. Respective approach curves toward (*a*) a Pt digit and (*b*) an interdigit with a 2 μm diameter UME for RG = 8. The electrochemical cell is the same as described in Fig. 5. The applied potential at the UMEs was 0.35 V and the approach speed was 1 μm/s. Simulated approach curves are also plotted.

obtain images (Fig. 10). A large area was first scanned to find the letters. The UME was then relocated to a desired position and rastered over desired letters. Figure 10*a* shows a SECM image of the letters SECM printed with bold font Courier New and in font size 2. An area as large as 700 μm × 2000 μm was imaged with a step size of 5 μm. Knowing that the tip to substrate was fixed relative to the transparency substrate and the printed letters protruded out of the substrate plane, a more negative feedback above the letters was expected because the letters with a shorter distance blocked more redox species diffusing to the UME. This can be further demonstrated by the current profile of a line across the image. From the theoretical approach curve for negative feedback on an insulator, a height of 1.2 μm for the letters can be estimated by differentiating the distances of tip-to-letter and tip-to-transparency, corresponding to the tip currents above the letter and above the transparency, respectively. The image quality in terms of contrast, sharpness, etc. is even better than that of an optical micrograph at a magnification of 400× (Fig. 10*b*). No deformation was observed due to the closed-loop control.

The letters UWO, printed in bold font Courier New and font size 2, were imaged in addition. The same imaging procedure was followed. In fact, a very high-resolution image (1024 × 1024 pixels) for an area of 1500 μm × 1500 μm was acquired ambitiously (Fig. 10*c*). It took about 8 h and 44 min to finish this image. A clear picture of the letters was obtained and the image quality matched to that of a video micrograph (Fig. 10*d*). Capacitive sensors integrated in the three inchworm motors measured the traveling distance precisely and lead the system to attain the target movement in each step. Thermal and temporal drafts were minor according to the sharpness of letter edges shown in Fig. 10*c*. This proved again that the present closed-loop scanning system has a superior repeatability, high resolution, very low hysteresis, and high stability as well. The letter height was estimated to be 1.0 μm from the approach curve. While high quality SECM images can be obtained by the closed-loop scanning system, the effect caused by tilted substrates is still

Fig. 10. (*a*) SECM image of the letters SECM printed in bold font Courier New and font size 2 on a transparency, with a step size of 5.00 μm. (*b*) Optical micrograph corresponding to letters in (*a*). (*c*) SECM image of the letters UWO printed in bold font Courier New and font size 2 on a transparency, with a step size of 1.46 μm. (*d*) Optical micrograph corresponding to the letters in (*c*). The UME size was 2 μm in diameter. The tip was engaged by approaching the transparency body unitl the normalized current of 0.50 was attained. A distance of 1.0 μm was withdrawn before starting to image. The tip-to-substrate distance was determined to be 1.5 μm. Other imaging conditions are the same as in Fig. 5.

observed, especially when a large area was imaged. This is because a so-called constant-height mode was employed. The regular variation of the tip-to-substrate distance because of the tilt can be easily distinguished with original sample topography and should be accounted for during the examination of SECM images. The letters CHEM printed in the same size and font were then imaged individually. Less tilt effect was observed as demonstrated in Fig. 11.

Imaging a sample with small topography structures

Finally, SECM was used to image a platinum-coated silicon substrate with an array of square pits spaced apart on 10 μm centers. A 2 μm diameter UME poised at a potential of 0.35 V was brought to the sample immersed in a solution containing 0.90 mmol/L ferrocenemethanol as the mediator and 0.1 mol/L KCl as the supporting electrolyte. A slight positive feedback approach curve was obtained, showing that reaction expressed by eq. [3] became much slower than that on a Pt band electrode. An effective reaction constant (0.1 cm/s) can be extrapolated by fitting the approach curve with theoretical curves obtained by Mirkin and Bard and coworkers (4, 56). This is possibly because the Pt coating is very thin and the sample does not behave as a conductor. The tip-to-substrate position was set by approaching the tip to the silicon specimen until a normalized current of 1.5 was reached and then withdrawing an extra distance. Images of various areas on the specimen in different sizes are demon-

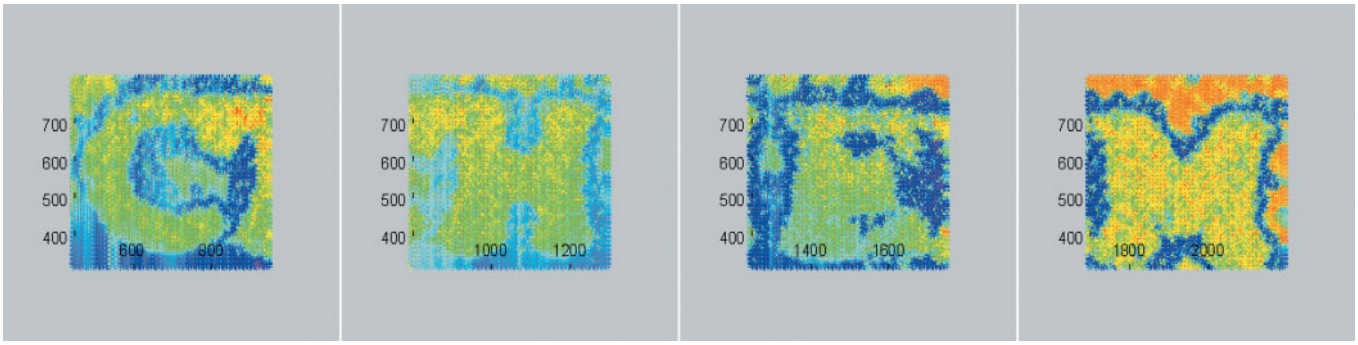
Fig. 11. SECM image of the letters CHEM printed in bold font New Courier and font size 2 on a transparency, with a step size of 3.90 μm. The letters (*a*) C, (*b*) H, (*c*) E, and (*d*) M were imaged individually to minimize the effect of the substrate tilt. The UME size was 2 μm in diameter. The tip was engaged by approaching the transparency body until the normalized current of 0.50 was attained. A distance of 1.9 μm was withdrawn before starting to image. The starting tip-to-substrate distance was determined to be 2.4 μm from the approach curve. Other imaging conditions are the same as in Fig. 5.



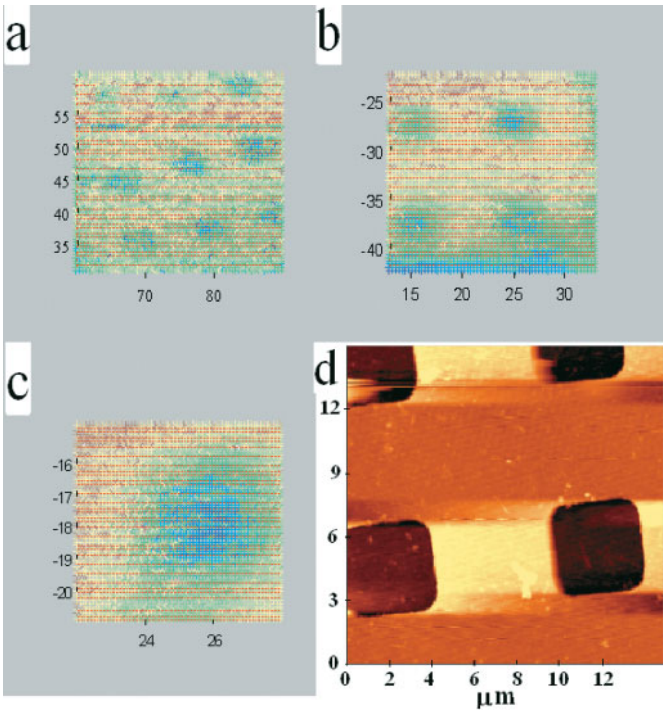


Fig. 12. The silicon structures of a DI calibration reference imaged by a 2 μm diameter UME to demonstrate (*a*) an area of 30 μm × 30 μm, (*b*) an area of 20 μm × 20 μm, (*c*) and a single square. Pixels were at 64 × 64. The tip was brought to the silicon body until the normalized current of 1.5 was attained. A distance of 1.50, 1.36, and 0.86 μm was withdrawn before starting to image in (*a*), (*b*), and (*c*), respectively. Other imaging conditions are the same as in Fig. 5. An AFM image is shown in (*d*).

strated in Fig. 12. Clear square structures were observed. In fact, a less positive feedback was observed when the tip moved from the substrate body to a square because the tip–substrate distance above a square was larger than that above the body and less ferrocene molecules regenerated at the substrate could be detected. The edge-to-edge distance of two neighboring squares, equivalent to center-to-center distance, was determined to be 10 μm from Figs. 12*a* and 12*b*, which agrees very well with the specification from the manufacturer. The squares on the substrate were estimated to be 4 μm × 4 μm from the SECM images. It was a challenge to map them with a 2 μm diameter UME, whose size is barely smaller than that of the squares. A typical AFM image of the calibration reference is shown in Fig. 12*d*, which agree well with our SECM images.

Note that the shape of the SECM tip is probably related to the observed lateral size when the probe size is close to that of the squares on the substrate. The size of the squares is expected to be affected. This phenomenon is common in scanning probe microscopy such as atomic force microscopy. The shape of the tip and sample in the SECM experiments is what might be seen in the final images. That is why the observed squares were somehow deformed. However, these considerations are not well-described in previous reports and are not completely understood.

Conclusions

This work improves the fabrication of ultramicroelectrodes of various sizes, especially of 2 μm diameter electrodes. Application of a pulled glass tubing optimized the sealing of glass around the Pt disk and reduced the workload for sharpening the electrode to a small RG. Normalized currents of 8 and 0.1 for positive and negative feedback, respectively, can be easily attained with SECM probes having a RG value of 3–8. Video micrographs, cyclic voltammetry, and SECM approach curves were complementary to each other and were routinely used for characterization of the prepared electrodes. Electrochemical behavior and RG values can be verified in this manner.

Open-loop imaging procedures in conventional SECM instruments are problematic in obtaining an authentic image, especially when a large area is mapped and (or) a fast scan rate is used. Frequent trivial calibration is essential to correct any image deformation that occurs. The case is even worse when both forward and reverse scans are used for imaging purposes. Images lack integrity because of the alternative deviation of scans in two directions. The present work illustrates that a closed-loop system can be used to correct for these nonlinearity and hysteresis effects.

© 2005 NRC Canada

An advanced scanning electrochemical microscope has been built, for the first time, using a closed-loop scanning system. This new generation of SECM system consists of a bipotentiostat capable of measuring a current as small as 1 pA, a scanning stage of three inchworm motors integrated with a capacitive sensor, an Active-X controller, and an active data acquisition system for experimental control, fast data acquisition of the data, and in situ display and analysis of the data. SECM approach curves and images can be carried out with user-friendly, home-built LabVIEW VIs in which parameters such as scan range and step size (pixels) can be adjusted. The strategy for moving the probe in each step is to stand in a closed-loop of positioning, sensing and adjusting until attaining a target distance. The scanning system has a superior repeatability of 20 nm as well as a high resolution of 20 nm in the whole scan range of 25 mm × 25 mm × 25 mm. This new instrument opens a wide avenue for SECM image studies on reactions at various substrates, without requiring a calibration of the scanning system. The microscope provides real information on three-dimensional displacement of the probe and avoids artifacts on the size and shape of chemically active spots.

In the case of Pt and Au IDEAs, SECM images clearly showed the alternative Pt bands and glass spacers. Image quality can match that of an optical micrograph. In addition, reduction of tip size from 25 μm in diameter to 2 μm leads to a higher resolution image. It is noted that enough time delay to fulfill the closed-loop in each scan step is necessary to obtain an optimal image. Information on detained band structures was revealed. Pt band height was found to be 80–120 nm, deducting from tip – Pt band and tip – glass spacer distances the corresponding normalized current in the approach curves, and band height for Au was measured to be 200 nm. Another advantage of the present SECM is the capability to locate, relocate, and zoom into the area of interest.

In the case of printed letters on a transparency in font Courier New and font size 2, responses of the negative feedback on an insulator were obtained above both letters and the transparency substrate. More negative feedback was observed when a 2 μm diameter UME was displaced from the transparency substrate to the letters in a constant-height image mode. This is because letters have a certain height (1.0 μm) and therefore provide more of a block to the diffusion of ferrocene molecules diffusing to the tip. In addition, the SECM setup was used exhaustively for imaging letters as long as 8 h and 40 min. No much thermal and temporal draft was observed.

For the silicon substrate with an array of square pits spaced apart on 10 μm centers, it was fortuitous that a 2 μm diameter UME, only a little smaller than the the squares in a size 4 μm × 4 μm, was able to map the array. In fact, small positive feedback was observed due to a slow electrochemical reaction when a 2 μm diameter electrode was brought to the substrate immersed in a solution of 0.9 mmol/L ferrocenemethanol as the mediator. By properly relocating the original position of the probe and adjusting the imaging parameters, a single square, though it looked like a hole, was imaged. Tip shape plays an important role in imaging. A smaller probe is needed to obtain the real structure information.

We are confident that SECM image quality is enhanced by improving UME fabrication and introducing a closed-loop scanning system. More operation modes can be added on, such as constant-distance mode, constant-current mode, etc. It is anticipated that instrumentation of this kind will further broaden the applicability and the reliability of SECM for the study of the various (bio)chemical processes at interfaces and (or) surfaces.

Acknowledgments

We appreciate the financial support for this research from the Natural Sciences and Engineering Research Council of Canada (NSERC, New Discovery and Equipment Grants), Canada Foundation for Innovation (CFI), Ontario Innovation Trust (OIT), the Premier's Research Excellence Award (PREA), and the University of Western Ontario (Academic Development Fund (ADF) and the Start-up Fund). ZFD is grateful to the Swiss Federal Institute of Technology in Lausanne (EPFL) for a visiting professorship in Professor Hubert Girault's group during the summer of 2003. We thank Dr. Bernie Quinn for her constructive discussions and suggestions on the fabrication of ultramicroelectrodes. Technical assistance from John Vanstone, Sherrie McPhee, Mary Lou Hart, and Marty Scheiring is gratefully acknowledged. We are in debt to Drs. David Shoesmith, Peter Norton, Mark Workentin, and Milan Kovar for their kind help and fruitful discussions. Thanks are owed to Dr. Jacques Josserand at EPFL for his expertise on using FluxExpert software to fit approach curves.

A new method for evaluation of the mobility of silica-grafted alkyl chains by suspension-state ^{1}H NMR

Mahnaz Derakhshan, Hamid R. Ansarian, M. Mizanur Rahman, Toshihiko Sakurai, Makoto Takafuji, and Hirotaka Ihara

Abstract: Although molecular mobility is usually probed by measurement of the T_1 relaxation time, it is not the case for methylene groups of grafted acyl chains because each methylene group has a different mobility and hence, a different T_1 relaxation time depending on the distance from the junction between organic molecule and nonorganic particle. Therefore, we devised a very simple method that can semiquantitatively determine the extent of mobility in the grafted acyl chains. Silica-supported poly(octadecylacrylate) (Sil-ODA$_n$), polymeric octadecylsilyl silica (polymeric ODS), and monomeric octadecylsilyl silica (monomeric ODS) were studied by comparing the intensity of NMR peaks from grafted molecules with the same amount of nongrafted molecules. In the case of Sil-ODA$_n$, with a gradual increase in temperature, the intensity of the proton signals (^{1}H NMR) of the octadecyl moieties (mainly methylene groups) rose dramatically. This dramatic rise was at the same temperature as that of an endothermic peak detectable in its DSC thermogram, indicating a relatively complete solid to liquid phase transition. Sil-ODA$_n$, as the stationary phase in RP-HPLC, showed analogous temperature dependencies of the separation factor between naphthacene and triphenylene (as a simple indicator of shape selectivity). Using this method we determined the liquid phase percentage (LPP) in Sil-ODA$_n$, polymeric ODS, and monomeric ODS at various temperatures. We suggest LPP as a semiquantitative index of mobility for grafted organic layers.

Key words: comb-shaped polymer, nanocomposite, alkyl chain mobility, NMR, liquid chromatography.

Résumé : Même si la mobilité moléculaire est généralement étudiée par une mesure du temps de relaxation T_1, cette méthode ne peut s'appliquer aux groupes méthylènes liés à des chaînes acyles en raison du fait que chaque groupe méthylène présente une mobilité et, en conséquence, un temps de relaxation T_1 différent suivant la distance entre la jonction entre la molécule organique et la particule non organique. On a donc mis au point une méthode très simple qui permet de déterminer semi-quantitativement le degré de mobilité des chaînes acyles greffées. On a étudié du poly(acrylate d'octadécyle) supporté sur de la silice (Sil-ODA$_n$), de l'octadécylsilylsilice polymère (ODS polymère) et de l'octadécylsilylsilice monomère (ODS monomère) en comparant l'intensité des pics de RMN de molécules greffées avec ceux obtenus avec la même quantité de molécules non greffées. Dans le cas du (Sil-ODA$_n$), en RMN du ^{1}H, l'intensité des signaux des protons des portions octadécyles, qui sont composées principalement de groupes méthylènes, augmente d'une façon dramatique avec une augmentation graduelle de la température. Cette augmentation dramatique se produit à la même température qu'un pic endothermique décelé dans son thermogramme de calorimétrie à balayage différentiel, ce qui indique qu'il se produit une transition relativement complète de la phase solide à la phase liquide. Si on utilise le Sil-ODA$_n$ comme phase stationnaire en chromatographie liquide à haute performance « RP », on observe le même type de dépendance entre la température et le facteur de séparation entre le naphtacène et le triphénylène, utilisé comme simple indicateur de la forme de la sélectivité. Utilisant cette méthode, on a déterminé le pourcentage de phase liquide (PPL) dans le Sil-ODA$_n$, l'ODS polymère et l'ODS monomère, à diverses températures. On suggère un indice semi-quantitatif de la mobilité des phases organiques greffées.

Mots clés : polymère en forme de peigne, nanocomposite, mobilité d'une chaîne alkyle, RMN, chromatographie liquide.

Fig. 1. The structures of the silica-supported stationary phases discussed in this paper: silica-supported polyoctadecylacrylate (Sil-ODA$_n$), polymeric octadecylsilyl silica (polymeric ODS), and monomeric octadecylsilyl silica (monomeric ODS).

Introduction

Much effort has gone into the characterization of various kinds of grafted polymers on nonorganic compounds to disclose mechanisms of their function. Perhaps the most popular one is the characterization of various stationary phases applicable in reverse-phase high performance chromatography (RP-HPLC) (1–10). Identifying the structure–function relationship of these silica-supported organic materials, as well as other organic–inorganic hybrid materials, enhances our knowledge of their underlying mechanisms of function, and enables scientists to make and use such products more effectively.

Monomeric octadecylsilyl silica (monomeric ODS) and polymeric octadecylsilyl silica (polymeric ODS) are two popular stationary phases for RP-HPLC. Polymeric ODS has the benefit of higher immobilization compared with monomeric ODS, but its potential to self-assemble is still perturbed because of the short rigid covalent bonds of Si-O-Si either between the alkylsilane and silica surface or between two alkylsilanes (cross-polymerization). Silica-supported poly(octadecylacrylate) (Sil-ODA$_n$) differs from conventionally modified silicas because octadecyl moieties are not directly bonded to the silica surface, so they can form an ordered structure. In this study we have tried to evaluate and compare the mobility of octadecyl chains among these three stationary phases at different temperatures. Previously we studied poly(octadecylacrylate) (ODA$_n$) grafted on porous silica particles, which proved advantageous for use as a stationary phase for geometrical detection with a strong temperature dependency (11–15). This prominent temperature dependency in the separation behaviour of grafted ODA$_n$ was coincident with an endothermic peak detectable by DSC. This unique behaviour of Sil-ODA$_n$, poly(octadecyacrylate) grafted on silica, was supposed to be due to a dramatic increase in the mobility of the grafted polymer. Suspension-state ^{1}H NMR was performed at different temperatures to identify the mobility of the alkyl chains of Sil-ODA$_n$, polymeric ODS, and monomeric ODS. Our efforts, as discussed in this paper, eventually led us to a simple method for determining the mobility of grafted organic molecules on the surface of nonorganic particles. We hope this study will be useful for providing more effective methods in the characterization of polymers grafted on nonorganic materials by NMR spectroscopy. The chemical composition of the stationary phases mentioned are shown in Fig. 1.

Experimental

Sample preparation

Reagents

Silica particles (120-S5, diameter 5 μm, pore size 120 Å, specific surface area 300 m^2 g^{-1}) were purhased from YMC (Kyoto, Japan), and all other materials were from Sigma-Aldrich (Tokyo, Japan) or Fluka Chemica-Biochemica (Tokyo, Japan).

Synthesis of Sil-ODA$_{25}$

Sil-ODA$_n$ was prepared by radical telomerization of octadecyl acrylate (ODA) with 3-mercaptopropyltrimethoxysilane (MPS), followed by immobilization onto sil-

© 2005 NRC Canada

ica, mostly according to our previously reported method (15). The preparation procedure was as follows: ODA and MPS (30:1 molar ratio) were dissolved in ethanol and azobisisobutyronitrile (20 mol% for the mercapto group) was added to the ethanol solution at 80 °C. The mixture was stirred for 6 h at 80 °C under an atmosphere of N_2 gas. The resulting white precipitate was gathered by filtration, washed successfully with methanol and acetone, and dried in vacuo.

The structure and polymerization degree was determined by NMR spectroscopy. ^{1}H NMR shifts of ODA_n were as follows: δ 0.8 ppm ($SiCH_2$), δ 1.9 ppm ($CHCO$), δ 3.6 ppm ($SiOCH_3$), and δ 4 ppm ($C(=O)OCH_2$). The average degree of polymerization was determined to be 25 by the proton ratio at 3.6 and 4.0 ppm.

Then ODA_{25} was readily immobilized onto porous silica by mixing in toluene at reflux temperature for 24 h. YMC 120-S5 was used as the porous silica. The white powder was gathered after filtration and several consecutive washings with toluene and chloroform. After vacuum drying the amount of carbon and hydrogen were determined to be 18.3% and 3.2% by elemental analysis. Successive washing with chloroform (as a good solvent for ODA_{25}) showed no significant change in the elemental analysis results. Coverage of Sil-ODA_{25} by octadecyl moieties was calculated to be 3 μmol m^{-2} and 726 μmol g^{-1}.

Synthesis of polymeric ODS

The same silica particles (YMC 120-S5) were mixed with octadecyltrichlorosilane at reflux temperature in toluene for 24 h. There was no effort made for a controlled inclusion of water in the reaction. The white powder was gathered after washing with chloroform and toluene several times. After vacuum drying the amount of carbon and hydrogen were determined to be 23.3% and 4.3% according to elemental analysis. Successive washing with chloroform showed no significant change in the elemental analysis results. Coverage of polymeric ODS by octadecyl moieties was calculated to be 4.9 μmol m^{-2} and 1078 μmol g^{-1}.

Synthesis of monomeric ODS

YMC 120-S5 particles were mixed with dimethyloctadecylchlorosilane at reflux temperature in toluene for 24 h. The white powder was gathered after filtration and frequently washed with chloroform and toluene. After vacuum drying the amount of carbon and hydrogen was determined to be 13.8% and 2.7% based on elemental analysis. Successive washing with chloroform showed no significant change in the elemental analysis results. Coverage of monomeric ODS by octadecyl moieties was calculated to be 2.5 μmol m^{-2} and 638 μmol g^{-1}.

NMR spectroscopy

All NMR spectra were measured by a Varian ^{UNITY}INOVA AS400 at a static magnetic field of 9.4 T using a GHX Varian AS400 nanoprobe for suspension-state ^{1}H NMR. All NMR parameters mentioned in this paper are compatible with the terminology of the Varian ^{UNITY}INOVA. A spin rate of 2000–3500 Hz for suspension-state ^{1}H NMR was used.

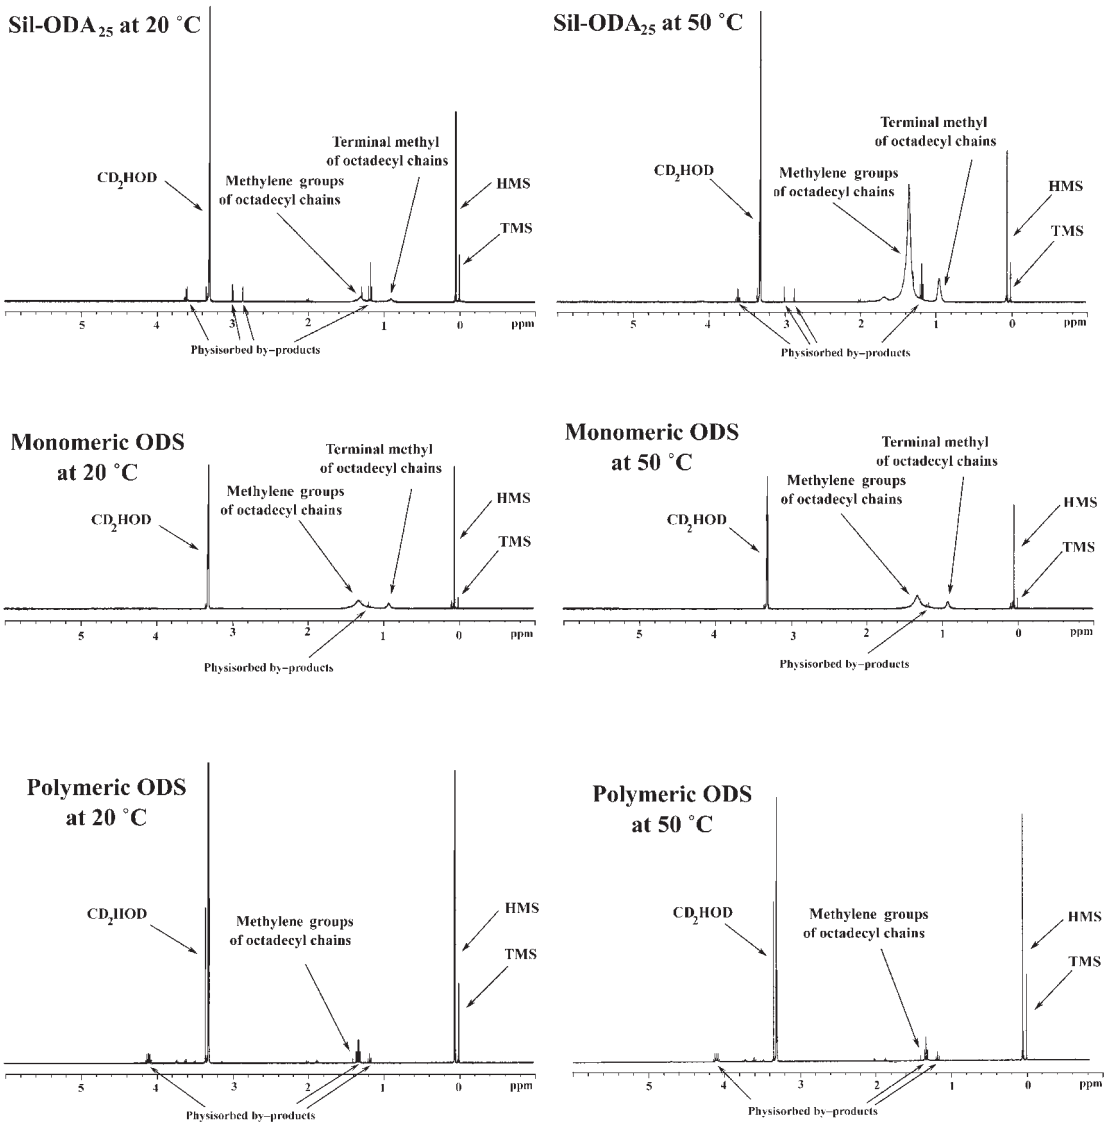
Suspension-state ^{1}H NMR

Three suspensions were made by adding 10 mg of each of Sil-ODA_{25}, polymeric ODS, and monomeric ODS to 100 μL of methanol-*d* (CD_3OD) including 0.03% tetramethylsilane (TMS) and 0.05% hexamethyldisilane (HMS). Hexamethyldisilane was added as a reference for signal intensity, but the protons of CD_3OD proved better for this purpose. All samples were prepared at the same time using one single ampoule of CD_3OD. Forty microliters of each suspension was transferred to the nanotube for measurement. Suspension-state ^{1}H NMR spectra were measured at the temperatures: 20, 25, 30, 35, 40, 45, and 50 °C using the GHX Varian AS400 nanoprobe. The parameters used for measurement were delay time = 10 s, pulse width = 30°, number of transients = 32, and spectral width = 6000 Hz. For assigning peaks, after determining the 90° pulse width, DQCOSY (correlation spectroscopy) was performed and the chemical shifts of the terminal methyl and methylene of the octadecyl groups were determined. Shimming was adjusted for each temperature using a standard semiautomatic method. Delay time was chosen to be long enough to avoid saturation in order to have reliable NMR intensities for the quantitative measurements. Baseline correction was performed on all spectra before measuring the under-peak areas.

Solution-state ^{1}H NMR

A solution was made of 1 mg of octadecyl acrylate in 100 μL of hot methanol-*d*. Forty microliters of the solution was transferred to a nanotube for measurement. The amount of 1 mg was chosen in a way that represented the approximate amount of alkyl chains relative to their correspondent grafted samples in suspension-state ^{1}H NMR because the NMR intensity of methylene groups in the nongrafted solution state was meant to be compared with the grafted suspension state. The NMR measurements were performed at 50 °C. The same parameters used in suspension-state ^{1}H NMR were used for these measurements.

Chromatography



The polymeric ODS column (Shodex C18P 4E) was purchased from Shodex (Tokyo, Japan). The monomeric ODS (Inersil) was purchased from G.L. Sciences (Tokyo, Japan). Sil-ODA_n was packed into stainless steel columns (4.6 mm i.d. × 250 mm) using a hexanol–chloroform (1:1) mixture. Methanol–water (9:1) was used as the mobile phase at a flow rate of 1 mL min^{-1}. The chromatograph included a Gulliver 980 PU pump, a JASCO photodiode array detector (UVIDEC-100-IV), and a NESLAB column Jacket (Newington, New Hampshire). Five microliters of the sample dissolved in methanol were injected through a Reodyne model 7125 injector. Indicators of shape selectivity, naphthacene and triphenylene, were purchased from Sigma-Aldrich (Schnelldorf, Germany). The separation factor ($\alpha_{naphthacene-triphenylene}$) was defined as the ratio of the retention factor of naphthacene to the retention factor of triphenylene. The retention factors (k') were determined by the equation $(t_e - t_0)/t_0$, where t_e and t_0 are the retention times of the sample and the void volume mark, respectively.

Differential scanning calorimetery

DSC was performed using a heating rate of 1 °C min^{-1} with Seiko I and E SSC-580 and DSC-10 instruments.

Results and discussion

Surface coverage

The molar amount of octadecyl moieties per 1 g of silica (R, μmol g^{-1}) can be calculated as follows

$$[1] \qquad R = 10^6(P_C/100)/12n$$

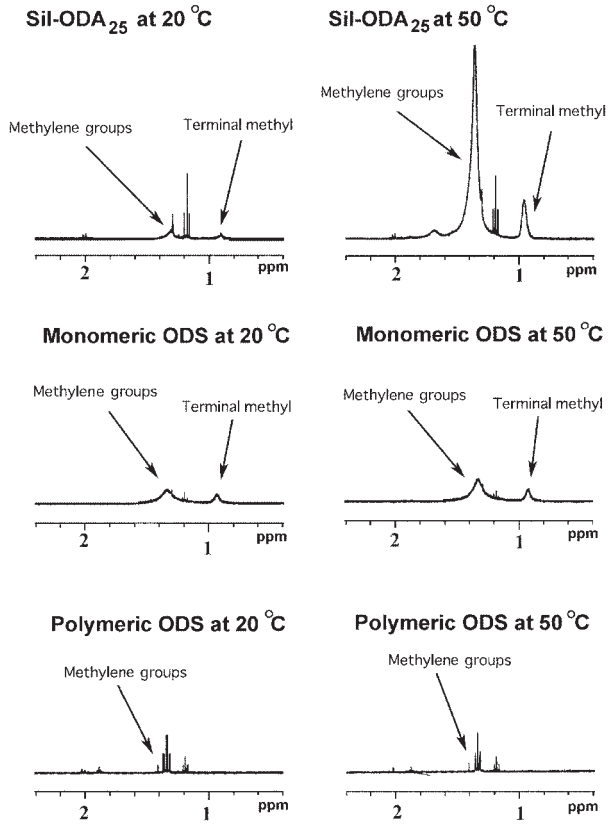
where P_C is the percentage of the carbon element according to elemental analysis, and n is the corresponding number of carbon atoms per one octadecyl moiety, which in polymeric and monomeric ODS is 18, and in Sil-ODA$_{25}$ is equal to 21 (Fig. 1).

On the other hand, because the molecular mass of a grafted octadecyl moiety is 253 Da, the weight % of the grafted phase (P_w) in each case can be calculated as follows

$$[2] \qquad P_w = (253 \times 10^{-4})R(n/18)$$

Furthermore, surface coverage (N, μmol m^{-2}) can be calculated as follows

$$[3] \qquad N = R/\{S[(100 - P_w)/100]\} = 10^6P_C/[12nS(100 - P_w)]$$



where S is the surface area per 1 g of nonmodified silica.

^{1}H NMR spectroscopy

Although molecular mobility is usually probed by the measurement of the T_1 relaxation time, this was not the case for our study because the NMR peaks of several methylene groups (with different mobilities and hence, different T_1 relaxation times) were superimposed. There are three methods for the measurement of T_1: inversion recovery, progressive saturation, and saturation recovery. Here we provide a detailed discussion about how the peculiarity of relaxation in grafted alkyl chains makes the inversion recovery method unreliable. Our reasoning undermines the very assumption that the relaxation of grafted alkyl chains has an averaged relaxation time constant. Therefore, the reliability of other methods that are based on that assumption will be spontaneously ruled out.

© 2005 NRC Canada

Fig. 2 (*concluded*). (*b*) Intensity of the NMR peaks of methylene groups in the case of Sil-ODA$_{25}$ increases dramatically as temperature rises. However, monomeric ODS shows only a slight increase as temperature rises, and polymeric ODS shows almost no increase.

In a common inversion recovery experiment, the magnetization vector is inverted with a 180° pulse, then the magnetization vector ($\mathbf{M}_z$) begins to relax exponentially during a given period of time:

$$[4] \qquad \mathbf{M}_z = \mathbf{M}_0\ (1 - 2e^{-t/T_1})$$

Finally, a monitoring 90° pulse is used to measure the correspondent peak height. The peak height (H) as a function of the given delaying time is supposed to behave exponentially with the same exponential time as T_1.

$$[5] \qquad H = H_{max}(1 - 2e^{-t/T_1})$$

In the process of measuring T_1, a software program solves eq. [5] by matching the array of measurements to the most fitting exponential curve. But if an actual NMR peak is the result of several NMR peaks, each with a distinct exponential time (like that of methylene groups in the case of grafted alkyl chains), the equation of peak height will be:

$$[6] \qquad H = H_a + H_b + H_c + \cdots + H_n$$
$$H = H_{max-a}(1 - 2e^{-t/T_{1a}}) + H_{max-b}\ (1 - 2e^{-t/T_{1b}})$$
$$+ H_{max-c}(1 - 2e^{-t/T_{1c}}) + \cdots + H_{max-n}(1 - 2e^{-t/T_{1n}})$$

The important point is that the sum of two or several exponential functions does not remain exponential. Therefore, the NMR peak height of the methylene groups as a function of delaying time, in the case of grafted polymers, no longer behaves exponentially. In other words, the relaxation function cannot be expressed by an averaged T_1.

$$[7] \qquad H_{max-a}(1 - 2e^{-t/T_{1a}}) + H_{max-b}(1 - 2e^{-t/T_{1b}})$$
$$+ H_{max-c}(1 - 2e^{-t/T_{1c}}) + \cdots \neq H_{max}(1 - 2e^{-t/T_{1avg}})$$

Therefore, we turned to a rather new, but very simple approach that determines the percentage of octadecyl moieties with liquid-type mobility in each case. The form of the motionally averaged Hamiltonian depends very strongly on the type and the timescale of the molecular motion and hence, on the phase of matter (16). In suspension-state NMR, only those molecules or parts of molecules with very fast rotational motions are detectable. Motion most be in a range that can average out dipolar coupling and chemical shift anisotropy until the related NMR peaks become narrow enough to be detected. Those molecules or those parts of molecules that have a low mobility scale will give such a broad peak (because of the dipolar coupling and the chemical shift anisotropy contribution) that they cannot be detected.

The suspension-state ^{1}H NMR spectra were obtained for Sil-ODA$_{25}$, polymeric ODS, and monomeric ODS at variable temperatures from 20 to 50 °C. Neither half-height width (line width) of the methylene groups nor the spin–spin relaxation time (T_2) showed any significant change with temperature. Figure 2*a* shows the ^{1}H NMR spectra of the three samples at 20 and 50 °C. As shown in Fig. 2*b*, the intensity of the NMR peaks representing the terminal methyl and methylene groups of the octadecyl moieties increases significantly in Sil-ODA$_{25}$. If there was any transition from the liquid crystalline phase to the isotropic phase, a fixed intensity with a declining line width (or an increasing T_2) would be expected.

For the monomeric ODS, the intensity of the NMR peaks representing the terminal methyl and methylene groups increased slightly, but for the polymeric ODS only the peaks of the methylene groups were detectable when a very high vertical scale was used for graphical presentation.

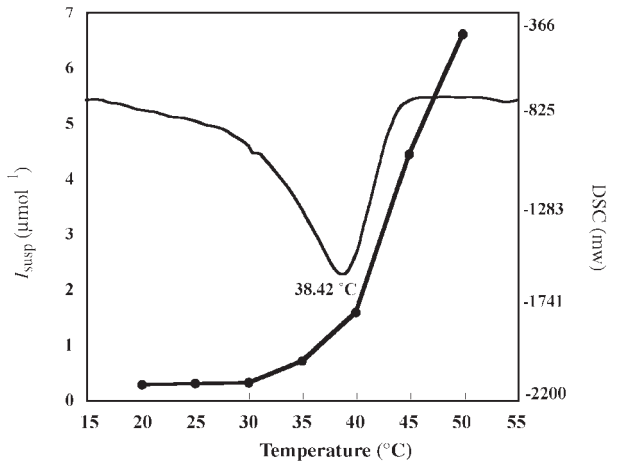
As all the three samples were washed carefully with toluene and chloroform, the small sharp peaks detected in the ^{1}H NMR spectra should be regarded as those of the physisorbed by-products of the grafting reactions. Interestingly, the amount of physisorbed by-products of polymeric ODS or Sil-ODA$_{25}$ was higher than that of monomeric ODS, a fact that indicates the presence of more closed spaces in the nano-architecture of polymeric ODS and Sil-ODA$_{25}$. As shown in Fig. 3, the intensity of the NMR signals from the methylene groups of Sil-ODA$_{25}$ increases distinctly around an endothermic peak in DSC. Peak-top temperature was measured to be 38.4 °C for Sil-ODA$_{25}$ in the presence of methanol. To make suspension-state NMR intensities comparable with the solution state in different samples and at different temperatures, they were weighted according to the following formula (justification will be discussed in the next section):

$$[8] \qquad I_{susp} = (I_m/I_D)/(4 \times 10^{-3}R) = 250[I_m/(I_D R)]$$

I_{susp} (μmol^{-1}) is the calculated normalized intensity (the relative intensity of the suspension-state ^{1}H NMR signal per

© 2005 NRC Canada

Fig. 3. Normalized relative ^{1}H NMR–NMR intensities of the methylene groups of Sil-ODA$_{25}$ increase distinctly around 38 °C, which is just around the peak-top temperature of its DSC thermogram.



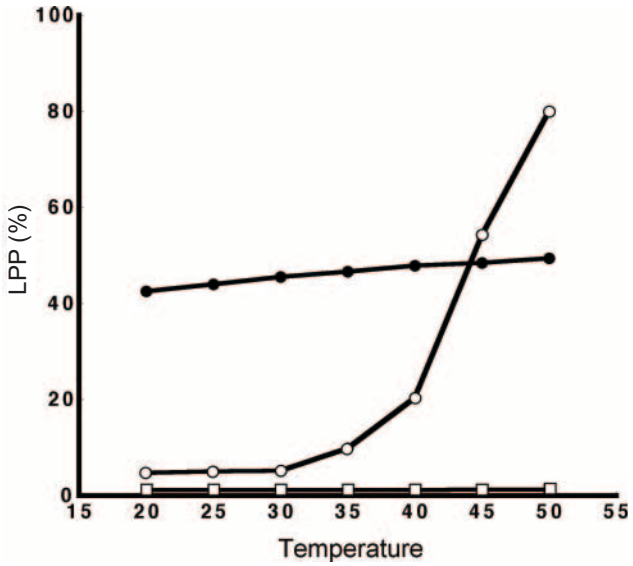


Fig. 4. Temperature dependencies of the liquid phase percentages (LPP) of the methylene groups of Sil-ODA$_n$ (○), monomeric ODS (●), and polymeric ODS (□).

1 μmol of grafted octadecyl moieties) shown in Fig. 4, I_m is the under-peak area of the methylene peak, I_D is the intensity of a few protons belonging to methanol-*d*, and *R* is the amount of grafted octadecyl moiety per 1 g of modified silica.

The intensity of the signals can be affected by time to time instrumental conditions, namely tuning of the observation channel. Considering the fact that instrumental conditions affect the intensities of I_m and I_D equally, and using one single ampoule of methanol-*d* for all measurements, the value of I_m/I_D can be assumed to be independent from instrumental conditions. At this stage, the value of I_m/I_D represents all octadecyl moieties with liquid-type mobility. Finally, dividing this value with $4 \times 10^{-3}R$ will give us a normalized value for comparison among different experiments.

Table 1. Summarized characterizations of Sil-ODA$_{25}$, monomeric ODS, and polymeric ODS.

Stationary phase	Temperature (°C)	I_{susp}	I_{sol}	LPP
Sil-ODA$_{25}$	20	0.37	7.84	4.76
Sil-ODA$_{25}$	50	6.28	7.84	80.04
Monomeric ODS	20	3.34	7.84	42.07
Monomeric ODS	50	3.88	7.84	49.43
Polymeric ODS	20	0.09	7.84	1.14
Polymeric ODS	50	0.09	7.84	1.23

The term 4×10^{-3} is included because the NMR signal of only 4 mg of the modified silica was measured in each suspension-state ^{1}H NMR spectroscopy.

On the other hand, normalized NMR intensities of octadecyl chains in the solution state (I_{sol}, μmol^{-1}), in order to be comparable with the suspension state, were calculated according to the following formula:

$$[9] \quad I_{sol} = (I_m/I_D)/[(0.4 \times 10^{-3}/\mathrm{MW}) \times 10^6] = (I_m \times \mathrm{MW})/(400 \times I_D)$$

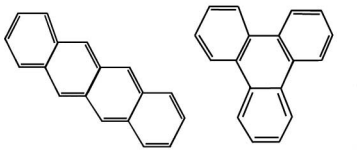
Again the value of I_m/I_D can be assumed to be independent from instrumental conditions. At this stage, the value of I_m/I_D represents all octadecyl moieties. Finally, dividing this value with 0.4×10^3 MW will give us a normalized value for comparison among different experiments. MW is the molecular weight of each monomer and the term 0.4×10^3 is included because the NMR signal of only 0.4 mg of each monomer was measured in each solution-state ^{1}H NMR spectroscopy. The term 10^6 is included because I_{sol} is meant to be the normalized NMR intensity per 1 μmol of each monomer.

Determination of the liquid phase percentage (LPP)

By comparing the standardized NMR intensities of the methylene groups per 1 μmol of grafted odtadecyl chains (I_{susp}) and the standardized NMR intensities of the methylene groups per 1 μmol of nongrafted octadecyl chains (I_{sol}), we can determine the percentage of octadecyl chains with liquid scale mobility, the liquid phase percentage (LPP), at each temperature (Table 1) according to the following simple formula:

$$[10] \quad \mathrm{LPP} = (I_{susp}/I_{sol})100$$

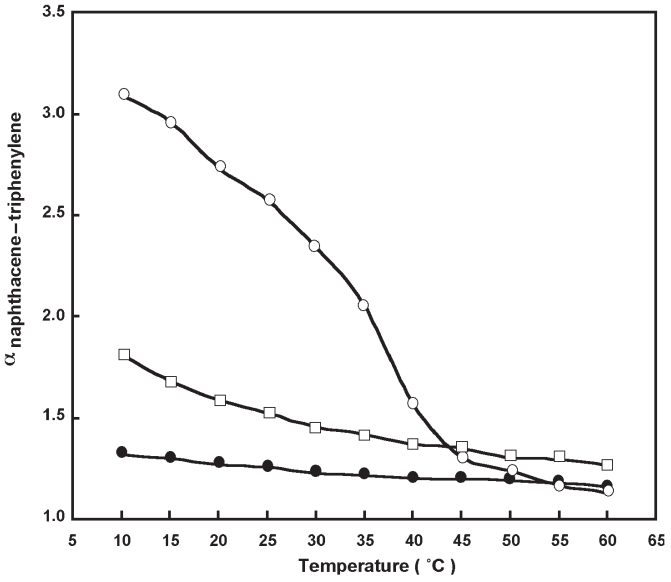
The temperature dependency of LPP is shown in Fig. 4.



Chromatography

We used $\alpha_{\text{naphthacene–triphenylene}}$ as a quantitative index of the ability to detect the linearity of compounds. As shown in Fig. 5, naphthacene and triphenylene have equal molecular weights, but naphthacene is apparently more linear than triphenylene (its length to breadth ratio is higher than that of triphenylene), so $\alpha_{\text{naphthacene–triphenylene}}$ can be regarded as a quantitative index of shape selectivity. Figure 6 shows the temperature dependencies of $\alpha_{\text{naphthacene–triphenylene}}$ in the three stationary phases.

Although comparing separation factors between two stationary phases based on their LPP is not reliable (because mobility is not the only factor that affects performance of a stationary phase), it has been shown that the shape selectiv-



© 2005 NRC Canada

Fig. 5. The structures of napthacene and triphenylene. Naphthacene and triphenylene have similar molecular weights but different shapes, therefore the separation factor ($\alpha_{naphthacene-triphenylene}$) can show the ability of each stationary phase to detect molecular shapes.

Naphthacene Triphenylene

Fig. 6. Temperature dependencies of $\alpha_{naphthacene-triphenylene}$ in Sil-ODA$_n$ (○), monomeric ODS (●), and polymeric ODS (□). The shape selectivity of Sil-ODA$_n$ is highest at low temperatures, but decreases dramatically as the temperature increases from 20 to 50 °C.

ity of silica-grafted alkyl chains in each stationary phase is considerably correlated with their mobility as the temperature changes. As shown in Figs. 4 and 6, a dramatic increase in mobility of the alkyl chains in Sil-ODA$_{25}$ is coincident with a dramatic decrease of its molecular shape selectivity, but in ODS a gradual increase in mobility is concomitant with a gradual decrease in shape selectivity.

Conclusion

These comparative methods, based on suspension-state ^{1}H NMR, can be used for categorizing the scale of mobility (liquid scale or solid scale) of the polymers grafted on silica or any other supporting particles. This phase characterization is important for a better understanding of the function of organic layers grafted onto nonorganic particles.

Triazene derivatives of (1,*x*)-diazacycloalkanes. Part V.[1] Synthesis and characterization of 4-ethyl-3-({6-ethyl-3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-aryl-1-diazenyl)hexahydropyrimidines from the reaction of diazonium salts with mixtures of formaldehyde and 1,3-diaminopentane

Reid Tingley, M. Brad Peori, Ryan Church, and Keith Vaughan

Abstract: A new series of bistriazenes has been synthesized from a general reaction of diazonium salts with a mixture of 1,3-diaminopentane (DYTEK® EP diamine) and formaldehyde, which affords the 4-ethyl-3-({6-ethyl-3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-aryl-1-diazenyl]hexahydropyrimidines (**1**). Each of the molecules of type **1** is built up of two equivalent 3-(aryldiazenyl)-6-ethylhexahydro-1-pyrimidinyl groups attached to a central methylene group. The importance of this study is in part due to the fact that the formaldehyde–1,3-diaminopentane system has not previously been investigated. All new compounds have been characterized by IR and NMR spectroscopy, with elemental analysis for selected compounds; one example from the series has been unequivocally characterized by X-ray crystallography. Although analysis of the NMR spectra is made somewhat difficult because of broadness and coalescence of signals due to the rotational dynamics of the N—N single bonds, it is possible to fully assign the proton spectra of all compounds and to detect 94% of all carbon signals. The fine structure within the proton spectra illustrate the diastereotopic nature of the methylene group protons because of the presence of a stereocenter in each hexahydropyrimidine ring. The general conclusion of this study is that alkanediamines with three carbon atoms in the spacer link between the nitrogen atoms give rise to the linear bicyclic molecules of type **1**, **2**, and **3**, in contrast to the case of ethylenediamine (spacer link has two carbon atoms), which affords molecules of type **7** that exemplify the bridged bicyclic bistriazene structure. The new compounds of series **1** represent an extension of a broad ranging study of the synthesis of new bistriazene derivatives of (1,*x*)-diazacycloalkanes.

Key words: triazene, diazonium coupling, hexahydropyrimidine, diaminopentane, diazacycloalkanes, stereocenter, diastereotopic protons.

Résumé : On a effectué la synthèse d'une nouvelle série de bistriazènes par le biais d'une réaction générale des sels de diazonium avec un mélange de 1,3-diaminopentane (DYTEK® EP diamine) et de formaldéhyde qui conduit à la formation de 4-éthyl-3-({6-éthyl-3-[2-aryldiazén-1-yl]hexahydropyrimidin-1-yl}méthyl)-1-[2-aryldiazén-1-yl]hexahydropyrimidines (**1**). Chacune des molécules du type **1** correspond à l'addition de deux équivalents de groupes 3-(aryldiazényl)-6-éthylhexahydropyrimidin-1-yle à un groupe méthylène central. L'importance de cette étude réside en partie dans le fait que le système formaldéhyde–1,3-diaminopentane n'avait pas été étudié antérieurement. Tous les nouveaux composés ont été caractérisés par spectroscopies IR et RMN et par analyse élémentaire de composés choisis; un exemple de la série a été caractérisé sans équivoque par diffraction des rayons X. Même si l'analyse des spectres RMN est rendue assez difficile en raison de la largeur et de la coalescence des bandes provoquée par la dynamique rotationnelle des liaisons simples N—N, il a été possible de faire une attribution complète des spectres du proton de tous les composés et de détecter 94 % des signaux dus au carbone. La structure fine observée dans les spectres du proton illustre la nature diastéréotopique des protons du groupe méthylène qui découle de la présence d'un centre stéréogène dans chacun des cycles hexahydropyrimidines. La conclusion générale de cette étude est que les alcanediamines comportant trois atomes de carbone comme lien qui sépare les atomes d'azote conduisent à des molécules bicycliques linéaires des types **1**, **2** ou **3**, en opposition avec ce qui a été observé dans le cas de l'éthylènediamine (lien comportant deux atomes

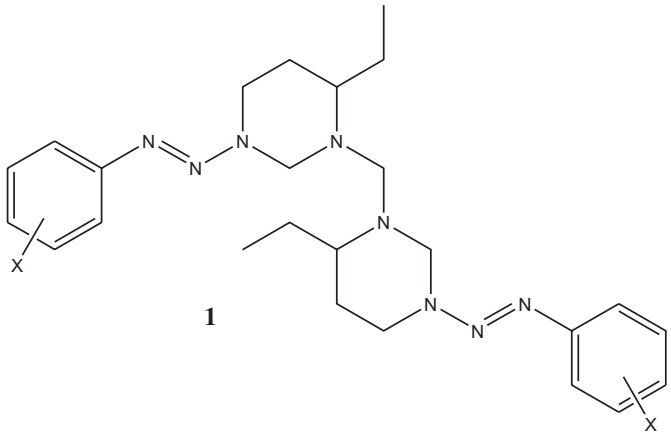
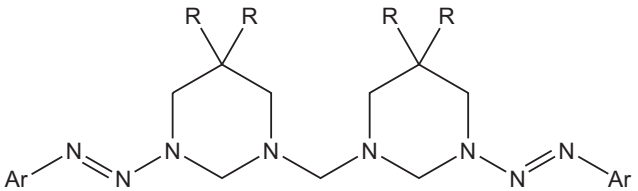
[Traduit par la Rédaction]



Introduction

A triazene is any molecule containing three contiguous nitrogen atoms with one N=N double bond, i.e., N=N-N. Triazenes have been studied extensively as versatile tools for organic synthesis (1), as multifunctional linkers in the solid-phase synthesis of heterocyclic libraries (2), as antitumour agents (3), specifically recently in the treatment of brain tumours (4), and in natural product synthesis (5). The term "bistriazene" has been coined to describe any molecule that contains two triazene units in the same molecule, with a link or spacer in between the triazene moieties. A typical example of a bistriazene is the bis[aryldiazenyl]ethylenediamine ($ArN{=}N\text{-}N(Me)CH_2CH_2N(Me)\text{-}N{=}NAr$) available from diazonium coupling with *N*,*N*′-dimethylethylenediamine (6). Recent progress in the synthesis of bistriazenes has been reviewed (7).

This paper reports the synthesis and characterization of a series of 4-ethyl-3-({6-ethyl-3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-aryl-1-diazenyl]hexahydropyrimidines (**1a**–**1m**), which have been obtained by the reaction of a series of diazonium salts with a mixture of 1,3-diaminopentane (DYTEK® EP diamine) and formaldehyde. This work complements a recent study (8) of the synthesis of the bistriazene series **2** and **3**, which were synthesized in a similar manner from 1,3-propanediamines. The molecular scaffold of the new series (**1**) has been established unequivocally by the solution of an X-ray structure of the *p*-bromo derivative (**1g**) (9).



Fundamental to the appreciation of the importance of this new work is to consider the previous work dealing with the reaction of alkanediamines with formaldehyde. Krassig (10) conducted extensive work on these condensation reactions, but Evans (11) was the first to find spectroscopic evidence for the formation of hexahydropyrimidine (**4**) from 1,3-diaminopropane and formaldehyde. However, isolation of compound **4** in a free state was hindered by its apparent proclivity to form oligomers (10, 11). Later studies demonstrated that the unlikely end-product of the reaction of 1,3-diaminopropane with formaldehyde is in fact 1-formyl-3-methylhexahydropyrimidine (**5**) (12). The most comprehensive work in this field is the study by Dale and Sigvartsen (13), who investigated the reactions of ethylenediamine, 1,3-diaminopropane, 1,4-diaminobutane, and 1,5-diaminopentane with formaldehyde and identified novel heterocycles as products in all cases. However, none of the previous studies have included the reaction of 1,3-diaminopentane (**6**) with formaldehyde, which gives the present work a certain degree of importance in the study of new heterocycles.

One focus of research in this laboratory is the synthesis of novel bistriazenes from the reaction of diazonium salts with mixtures of formaldehyde and alkanediamines. Previously, we found that such reaction with ethylenediamine affords the bridged bicyclic bistriazene (**7**) (14); this structure was clearly established by X-ray crystallography (15). When this study was extended to the cyclohexanediamine–formaldehyde system, the products were found to be of a linear bicyclic structure (**8**), which has also been established by X-ray analysis (16). Clearly, there is a crossover in molecular architecture going from ethylenediamine to cyclohexanediamine, and our recent studies have shown that this crossover also occurs when going from ethylenediamine to propanediamine, as evident from the formation of the linear bicyclic compounds in series **2** and **3** (8). This trend is continued in the present study, which reports the synthesis of the linear bicyclic bistriazene series (**1a**–**1m**) from the reaction of a series of diazonium salts with mixtures of 1,3-diaminopentane and formaldehyde.

Experimental

All reagents were reagent grade materials purchased from the Aldrich Chemical Co. Ltd. (Oakville, Ontario), and were used without further purification. DYTEK® EP diamine is the Aldrich trade name for 1,3-diaminopentane. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Infrared spectra were obtained using Nujol mulls, unless otherwise stated, on a PerkinElmer 299 spectrophotometer or with a Brucker Vector 22 spectrometer. ^{1}H and ^{13}C NMR spectra were obtained using either the Anasazi Instruments 60 MHz EFT spectrometer at Saint Mary's University, or the Bruker 250 MHz spectrophotometer at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University in Halifax, Nova Scotia. Chemical shifts were recorded in $CDCl_3$ or d_6-DMSO solutions at 20 °C and are relative to TMS as the internal standard. Elemental analysis was carried out at the Canadian Microanalytical Laboratory, Delta, British Columbia.

4-Ethyl-3-({6-ethyl-3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-aryl-1-diazenyl]hexahydropyrimidines (1)

General procedure

The appropriate arylamine (0.010 mol) was dissolved in 3 mol/L hydrochloric acid (20 mL) with heating if necessary to obtain a clear solution, and this solution was cooled in an ice–salt bath. The arylamine hydrochloride solution was diazotized at 0–5 °C with a solution of sodium nitrite (0.011 mol) in water and the resulting mixture was stirred in the cold for 0.5 h after which any insoluble impurities were removed by vacuum filtration. The mixture was brought to pH 7 using a saturated solution of sodium bicarbonate at which point 37% aqueous formaldehyde solution (5 mL) was added. An appropriate amount of 1,3-diaminopentane (0.010 mol) was slowly added to the solution, which was allowed to stir in the cold for a further 0.5 h. Occasionally, a slight precipitate was evident during the period of the addition, but it was not removed. The mixture was then adjusted to alkaline pH with additional saturated sodium bicarbonate solution, whereupon the product precipitated out of solution. Solid precipitates were isolated by vacuum filtration and purified by recrystallization from an appropriate solvent (see Tables 1 and 2). Oils were recovered by extraction into dichloromethane (3 × 20 mL aliquots), dried over anhydr. $MgSO_4$, and rotoevaporated under vacuum. This procedure afforded the following products.

*4-Ethyl-3-({6-ethyl-3-[2-(*p*-cyanophenyl)-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-(*p*-cyanophenyl)-1-diazenyl]-hexahydropyrimidine (**1a**)*

Yield: 95%; off-white needles, mp 144–147 °C (hexanes – ethyl acetate). IR ν_{max} (cm^{-1}): 2222 (CN), 843 (OOP). Anal. calcd. for $C_{27}H_{34}N_{10}$ (%): C 65.1, H 6.8, N 28.1; found: C 65.2, H 6.9, N 28.3.

*4-Ethyl-3-({6-ethyl-3-[2-(*p*-nitrophenyl)-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-(*p*-nitrophenyl)-1-diazenyl]hexahydropyrimidine (**1b**)*

Yield: 80%; red oil. IR ν_{max} (cm^{-1}): 1529, 1353 (NO_2), 854 (OOP).

*4-Ethyl-3-({6-ethyl-3-[2-(*p*-methoxycarbonylphenyl)-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-(*p*-methoxycarbonylphenyl)-1-diazenyl]hexahydropyrimidine (**1c**)*

Yield: 15%; amorphous, mp 105–108 °C (hexanes – ethyl acetate). IR ν_{max} (cm^{-1}): 1709 (C=O), 866 (OOP).

*4-Ethyl-3-({6-ethyl-3-[2-(*p*-ethoxycarbonylphenyl)-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-(*p*-ethoxycarbonylphenyl)-1-diazenyl]hexahydropyrimidine (**1d**)*

Yield: 95%; golden yellow prisms, mp 120–123 °C (hexanes – ethyl acetate). IR ν_{max} (cm^{-1}): 1707 (C=O), 861 (OOP). Anal. calcd. for $C_{31}H_{44}N_8O_4$ (%): C 62.8, H 7.4, N 18.9; found: C 62.7, H 7.0, N 18.5.

*4-Ethyl-3-({6-ethyl-3-[2-(*p*-acetylphenyl)-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-(*p*-acetylphenyl)-1-diazenyl]-hexahydropyrimidine (**1e**)*

Yield: 62%; brown prisms, mp 144–147 °C (ethyl acetate). IR ν_{max} (cm^{-1}): 1732 (C=O), 845 (OOP). Anal. calcd. for $C_{29}H_{40}N_8O_2$ (%): C 65.4, H 7.5, N 21.05; found: C 65.7, H 7.4, N 21.1.

*4-Ethyl-3-({6-ethyl-3-[2-(*p*-carboxamidophenyl)-1-diazenyl]hexahydro-1-pyrimidinyl}-methyl)-1-[2-(*p*-carboxamidophenyl)-1-diazenyl]hexahydropyrimidine (**1f**)*

Yield: 95%; off-white small prisms, mp 91–94 °C (hexanes – ethyl acetate – toluene). IR ν_{max} (cm^{-1}): 3174, 3341 (NH), 1645 (C=O), 856 (OOP). Anal. calcd. for $C_{27}H_{38}N_{10}O_2$ (%): C 60.7, H 7.1, N 26.2; found: C 60.8, H 7.2, N 26.7.

*4-Ethyl-3-({6-ethyl-3-[2-(*p*-bromophenyl)-1-diazenyl]-hexahydro-1-pyrimidinyl}methyl)-1-[2-(*p*-bromophenyl)-1-diazenyl]hexahydropyrimidine (**1g**)*

Yield: 88%; pale beige prisms, mp 100–102 °C (hexanes – ethyl acetate). IR ν_{max} (cm^{-1}): 827 (OOP). Anal. calcd. for $C_{25}H_{34}N_8Br_2$ (%): C 49.5, H 5.6, N 18.5; found: C 49.3, H 5.7, N 18.2.

^{1}H NMR spectroscopic data for compounds **1a**–**1m** are shown in Table 1; Table 2 is a list of the ^{13}C NMR spectroscopic data for these compounds. Proton and carbon labels relevant to these tables are shown in Fig. 1.

Results and discussion

The reaction of 1,3-diaminopentane (DYTEK® EP diamine, **6**) with arene diazonium salts in the presence of formaldehyde results in the formation of a series of 4-ethyl-3-({6-ethyl-3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinyl}methyl)-1-[2-aryl-1-diazenyl]hexahydropyrimidines (**1a**–**1m**) in moderate to excellent yields (20%–100%). These products represent a novel series of new bistriazenes and also represent new derivatives of the hexahydropyrimidine heterocyclic system. Also, the dimeric character of these molecules is novel because of the bis(hexahydropyrimidinyl)methane structure. The bistriazene series **1** is a new extension of our broad-ranging study of triazene derivatives of (1,*x*)-diazacycloalkanes; previously, we reported the synthesis of new aryldiazenylpiperazines (17), bis(aryldiazenyl)piperazines (18), aryldiazenylhomopiperazines (19), bis(aryldiazenyl)-homopiperazines (19), and a series of aryldiazenylhexahydropyrimidines (8).

The structure of the new compounds of series **1** has been established by a variety of spectroscopic methods, but a crucial piece of evidence providing unequivocal corroboration is the X-ray crystal structure of one compound in the series, that of compound **1g**, the *p*-bromo derivative. An ORTEP perspective diagram of **1g** is shown in Fig. 2; full details of the X-ray structure of **1g** have been published (9). Compound **1g** crystallizes in two polymorphic forms; both polymorphs display crystallographic disorder within the hexahydropyrimidine rings. Another feature evident in the ORTEP diagram (Fig. 2) is the chirality of the two stereocentres; C9 has the R configuration whereas C14 has the S configuration. Thus, it is clear that the molecule of **1g** is the meso compound, and we can infer that all the compounds of series **1** have this configuration.

The structure of other members of series **1** can be deduced by spectroscopic correlation, as well as elemental analysis. The IR spectra of the compounds of series **1** are consistent with the presence of the functional group (X) in the aryl moiety, and the out-of-plane bending vibrations in the region 750–850 cm^{-1} confirm the ortho- or para-substitution. The ^1H NMR spectral data of the compounds of series **1** are shown in Table 1 and are consistent with the proposed structures. However, many of the signals are broadened and not fully resolved for several possible reasons. For example, the protons of the methylene groups H_f, H_g, and H_j (see Fig. 1 for proton and carbon labels) are overlapping in a broad multiplet in the range 1.4–2.0 ppm. Also, the proton signals of the methylene groups H_h and H_i are consistently broadened, possibly owing to the rotational dynamics of the N—N bond in the triazene moieties; it is well-known that the restricted rotation around the N—N bond in the triazene causes broadening of signals in the NMR spectrum (20). Nevertheless, some of the spectra of these triazenes show remarkable fine structure, which can be interpreted to support the assigned structures. A good example is the spectrum of the *p*-tolyl-derivative (**1i**), which shows some evidence for the existence of two rotamers in $CDCl_3$ solution. Also, many of the complex features of the proton spectrum of **1i** (and others in the series) indicate the presence of sets of diastereotopic protons (e.g., H_c and H_d) arising from the presence of the stereocentre at C5.

Thus, the signal from the terminal methyl groups (H_k) in **1i** is clearly a doublet of triplets integrating for 6H; the triplet splitting arises from coupling to the adjacent methylene protons (H_j), but the doubling of the triplets is interpreted as arising from two different rotamers of the molecule. A set of multiplets in the range 1.39–1.89 ppm, integrating for 8H, is assigned to the overlapping methylene protons H_f, H_g, and H_j. At 2.75 ppm, a multiplet for 2H is assigned to the two equivalent methine protons (H_e), which couple to the neighbouring hydrogens H_f, H_g, and H_j. Multiple signals at 3.77–3.80 and 3.94 ppm are assigned to the diastereotopic methylene protons H_h and H_i; the multiplicity, when resolved, is eight lines (doublets of doublets of doublets) owing to the combination of geminal coupling and vicinal coupling to protons H_f and H_g. The signals of the diastereotopic protons (H_c and H_d) each appear as a doublet of doublets at 4.665 and 4.835 ppm, owing to the combination of geminal coupling and long range coupling to H_e. The signal from the single central methylene group (H_a and H_b) is complex, showing five lines, which appear to consist of a doublet of doublets plus a singlet in the middle. This is interpreted as arising from a combination of geminal coupling of the

diastereotopic protons H_a and H_b and rotational isomerism of the triazene. The singlet + doublet of doublets set is also clearly seen in the spectra of compounds **1a**, **1d**, **1e**, and **1g**.

Further characterization of the triazenes of series **1** by ^{13}C NMR spectroscopy was complicated by the rotational dynamics of the triazene moiety. The carbon signals are broadened to the extent that they are often not detected at normal concentrations. However, by making very concentrated solutions of the compounds in $CDCl_3$, the ^{13}C NMR spectra were recorded with the in-house SMU 60MHz Anasazi spectrometer set for 512 scans per spectrum. In this way, it was possible to detect most of the carbon signals from all of the compounds in series **1a**–**1m**; the results are presented in Table 2. The success of detecting the various carbon atoms largely depends on the proximity of the carbon atom to the triazene group within the molecule; the carbon atoms closest to the triazene are most affected by the rotational dynamics. Thus, the extreme methyl carbon (C7; see Fig. 1)is readily observed at ca. 11 ppm in all compounds, as is the methylene carbon C6 at ca. 26 ppm. The carbon signal of C4 is observed in most compounds at ca. 43 ppm, but is shifted to 31.5 ppm in compound **1j**, which has an electron-releasing group in the aryl ring. The electron-withdrawing effect of the N atom attached to C5 causes this signal to shift downfield to ca. 59 ppm, but this signal shows signs of doubling because of the presence of more than one rotational isomer. Carbons C2 and C3, which are directly attached to the triazene moiety, are the most elusive signals to observe as broad, weak signals at variable frequency, C2 at 65–72 ppm and C3 at 61–64 ppm. The bridging methylene

© 2005 NRC Canada

carbon C1 is observed as a weak signal in the range 72–79 ppm.

In the previous part of this study (8*a*), the bistriazenes of types **2** and **3** were characterized, but it was observed that there is a wide range of stability of the compounds of series **2** and **3**. This range of stability is also evident in the new compounds of series **1**. Several of the compounds, notably **1b**, **1c**, **1j**, and **1l**, started to decompose within a short time of being isolated, so that characterization of these products was restricted to immediate IR and NMR spectroscopic analysis. The low yields of some products, particularly **1c** and **1i**, may be partially attributable to the instability of the compounds. Several of the more stable products displayed a limited shelf life when stored for a couple of years; samples that were fine powders when fresh are now glass, such as **1e** and **1h**. Others like **1a**, **1d**, **1f**, and **1g** show little if any sign of decay. Compounds **1e** and **1h** are somewhat fickle in this regard; crude samples that were stored for over 2 years show definite signs of decomposition, whereas purified samples of the same compounds show no sign of decomposition. It is possible that the stability of these bis[{6-ethyl-}3-(aryldiazenyl)hexahydropyrimidin-1-yl]methanes is prolonged in the crystalline state compared with the amorphous state, but we have not undertaken a systematic study of this question.

An important issue regarding the synthesis of compounds of series **1** is the question of the manner of their formation. Central to this question is the previously reported work relating to the reaction of 1,3-diaminopropanes and formaldehyde, which was reviewed in the Introduction to this paper. Several groups have studied the reaction of alkanediamines with formaldehyde, but surprisingly there has been no previous work on the reaction of formaldehyde with 1,3-pentanediamine. However, it seems likely that the initial reaction of these molecules will produce the 4-ethylhexahydropyrimidine (**9**) (eq. [1]).

[1] **6** + CH_2O $\xrightarrow{-H_2O}$ **9**

Further condensation–dimerization of **9** with formaldehyde could theoretically lead to any of the three dimeric isomers 6-ethyl-1-[(6-ethylhexahydro-1-pyrimidinyl)methyl]hexahydropyrimidine (**10**), 4-ethyl-1-[(6-ethylhexahydro-1-pyrimidinyl)methyl]hexahydropyrimidine (**11**), or 4-ethyl-1-[(4-ethylhexahydro-1-pyrimidinyl)methyl]hexahydropyrimidine (**12**), which differ in the location of the ethyl groups relative to the bridging methylene group (C1) (eq. [2]).

The observed product **1** is readily formed by diazonium coupling to the preferred isomer (**10**) (eq. [3]).

Effectively, the diazonium coupling reaction serves as a tool for trapping otherwise unstable amines from solution; it could also mean in this case that the dimer (**10**) is more reactive than either of the isomers (**11** or **12**). The X-ray structure evidence (9) of the *p*-bromo derivative (**1g**) is the unequivocal evidence for the structure and by inference is evidence for the mechanism of formation of **1** via **10**. An alternative pathway for formation of **1** would involve diazonium coupling with the monomeric perhydropyrimidine (9), followed by condensation. However, such a pathway would likely lead to mixtures of products that we have not observed. Although intermediate **10** should exist as a mixture of diastereomers, it would appear that only the meso form is involved in the formation of the meso form of product **1**.

Oligomers of hexahydropyrimidine, analogous to the proposed intermediate (**10**), are reported to be thermally unstable (13). Although the mechanism of decomposition is unclear, there may be a connection between this previous work and the observation in the present work that the bistriazenes of type **1** are not universally stable. The instability of compounds of type **1** is also evident from attempts to record their mass spectra under electron ionization conditions; no molecular ions were observed under EI, thus inhibiting our ability to obtain accurate mass measurement of their molecular ions.

Conclusion

It appears from our on-going studies that the interaction of a diazonium salt with a mixture of formaldehyde and an alkanediamine ($NH_2(CH_2)nNH_2$) gives rise to two distinct types of oligomer. Bistriazenes of types **7** (14) and **13** (21) are examples of the bridged bicyclic bistriazene, whereas the compounds of series **2** and **3** (8) exemplify the linear bicyclic bistriazene. The new compounds of series **1**, reported here, clearly belong to the linear bicyclic class, providing further evidence that there is a crossover in the molecular architecture going from ethylenediamine (two-carbon spacer) to propanediamine (three-carbon spacer). This type of crossover was also observed in the transition from ethylenediamine to cyclohexanediamine in structure **8** (16).

This paper is part V in a series that describes the synthesis of a variety of triazenes and bistriazenes that fit the general classification of 1-aryldiazenyl-(1,*x*)-diazacycloalkanes described by the general structure **14**, where *m* = 1 or 2 and *n* = 2–5. The new compounds of series **1** fit to the general structure **14**, where *m* = 1 and *n* = 3. Previously, we reported new triazenes derived from piperazine (17, 18) (*m* = *n* = 2) and homopiperazine (19) (*m* = 2, *n* = 3). It is worth pointing out that the hexahydropyrimidine rings in **1**, **2**, and **3** represent the isomeric heterocycle to the piperazine ring system, and that the compounds of series **1** are isomeric with those of series **3**.

13

14

In future papers in this series, we will report more examples of the linear bicyclic bistriazene derived from other diamines, such as 1,4-diaminobutane, 1,5-diaminopentane, and 2-methyl-1,2-diaminopropane. Evidently, the linear bicyclic bistriazene reported here in the new compounds of series **1** appears to be the normal type of molecular architecture in this field of chemistry.

Effective and regioselective iodination of arenes using iron(III) nitrate in the presence of tungstophosphoric acid

Mohammad Jafarzadeh, Kamal Amani, and Farzad Nikpour

Abstract: An easy, cheap, and effective method for iodination of various aromatic compounds takes place with molecular iodine and iron nitrate nonahydrate as the oxidant in the presence of a catalytic amount of tungstophosphoric acid in dichloromethane, with good yield and high regioselectivity under very mild conditions.

Key words: iodination, arenes, iodine, iron(III) nitrate, tungstophosphoric acid.

Résumé : On a mis au point une méthode facile, peu coûteuse et efficace de procéder à l'iodation de divers composés aromatiques; elle fait appel à de l'iode moléculaire et du nonahydrate du nitrate de fer qui agit comme agent oxydant en présence de quantités catalytiques d'acide tungstophosphorique dans le dichlorométhane et elle donne de bons rendements et une régiosélectivité élevée dans des conditions très douces.

Mots clés : iodation, arènes, iode, nitrate de fer(III), acide tungstophosphorique.

[Traduit par la Rédaction]

Introduction

Heteropoly acids (HPAs) and their salts are useful acid and oxidation catalysts for various reactions and there are already many practical applications (1–3). One of the most interesting aspects may be the fact that they can be used in various kinds of reaction media or fields. Furthermore, they can be active solid acid catalysts and can provide unique reaction fields such as a pseudoliquid that is a "catalytically active solid solvent". HPA catalysts will find more green and sustainable applications in the future (4). Solid HPAs possess purely Brønsted acidity and are stronger than the usual mineral acids such as H_2SO_4, HCl, HNO_3, $HClO_4$, CF_3SO_3H, etc. (5, 6), and than conventional solid acids such as SiO_2–Al_2O_3, H_3PO_4–SiO_2, HX, HY, and H-ZSM-5 zeolites, Amberlyst-15, and Nafion-H (7). Among HPAs, polytungstic acids are the most widely used catalysts because of their high acid strengths, thermal stabilities, and low reducibility. Tungstophosphoric acid ($H_3PW_{12}O_{40}$) is a inexpensive, reusable, heterogeneous, and easily available catalyst (8, 9).

Iodoaromatic compounds are useful synthetic reagents for fine organic synthesis. They are valuable, versatile synthetic intermediates and have found wide applications in medicine and biochemistry (10, 11). The direct iodination of arenes with molecular iodine under mild conditions requires an oxidizing agent to activate the low reactivity of iodine. The oxidants such as oleum (12*a*), $Pb(OAc)_4$ (12*b*), diiodine pentoxide (12*c*), CrO_3 (12*d*), sodium perborate (12*e*), hydrogen peroxide (12*e*), $KMnO_4$ (12*f*), MnO_2 (12*f*), tetrabutylammonium disulfate (12*g*), sodium periodate (12*h*), sodium iodate (12*h*), ceric ammonium nitrate(CAN) (12*i*), F-TEDA-BF_4(1-fluoro-4-chloromethyl-1,4-diazoniabicyclo[2.2.2]-octane bis(tetrafluoroborate)) (12*j*, 12*k*), urea–H_2O_2 (12*l*), etc., were reported. Recently, silica-supported $Bi(NO_3)_3{\cdot}5H_2O$ and $Fe(NO_3)_3{\cdot}9H_2O$ (silfen) were used as mild oxidizing agents for the iodination of active arenes (12*m*, 12*n*). However, most of the described reactions in the literature require one or some of the following conditions: an excess of the reagent or strong oxidizing agent, hazardous toxic solvents such as acetonitrile at elevated temperature, the use of expensive catalysts that need to be prepared prior to use, corrosive mineral acids, expensive Lewis acids, the use of corrosive and moisture-sensitive iodine monochloride, iodine vapor irritant in solvent free conditions and mostly waste remains.

Here, we describe an improved, simple, and eco-friendly method for regioselective iodination of arenes with iodine and iron(III) nitrate nonahydrate as the oxidant in the presence of a catalytic amount of tungstophosphoric acid at room temperature with good yields (Scheme 1).

Results and discussion

Effect of catalyst

Iron(III) nitrate nonahydrate, an abundant, inexpensive, nontoxic, and commercially available reagent can be used as an oxidant in the presence of a catalytic amount of dehy-

R' = OCH_3, CH_3, NO_2, Br, H

drated heteropoly acids. Primarily, iodination of anisole, as a model compound, was performed in the presence of several HPAs and some other solid acids in dichloromethane at room temperature for 8 h (GC results are presented in Table 1). The result shows that in the absence of the catalyst, the reaction proceeds with low yield, but in the presence of HPAs, this conversion proceeded efficiently under similar reaction conditions. In this reaction, anisole was converted to *p*-iodoanisole in good yield and excellent regioselectivity (100%) without the formation of diiodinated derivatives. To show that tungstophoric acid is more effective than other HPAs and solid acids, we chose $H_3PW_{12}O_{40}$, which is a very efficient and environmentally friendly catalyst (6), for further iodination studies.

Heterogeneous acid-catalyzed systems

Heteropoly acids and solid acids are not dissolved in dichloromethane, thus the iodination reaction takes place in heterogeneous conditions. The acid catalysis of heteropoly compounds in the solid state is classified into "surface-type" and "bulk-type" catalysis. Catalytic reactions involving polar molecules (here, anisole) occur not only at the surface, but also in the bulk solid HPAs. This shows good parallelism between catalytic activity (bulk-type) and acidity (surface-type) (13). Under bulk-type conditions, all of the acid sites are available to the reactant and therefore high catalytic activity could be expected. Cs and NH_4 salts (scarcely soluble in polar solvents) usually show only surface-type catalysis. However, solid HPAs containing a cation of low ionic radii to charge ratio (H^+) readily absorb small polar molecules and tend to exhibit pseudoliquid behaviour (bulk-type), and are soluble in polar solvents. The diffusion of reactant molecules in the solid is faster than the reaction; the solid bulk forms a pseudoliquid phase in which the catalytic reaction can proceed (14). Therefore, the heteropoly salts containing Cs, NH_4, and Fe (Table 1, entries 6–9) showed less catalytic activity than HPAs containing W and Mo (Table 1, entries 3–5).

On the other hand, although Keggin-type HPAs ($H_3PM_{12}O_{40}$, M = W, Mo) are much stronger acids than the Dawson-type HPAs ($H_6P_2Mo_{18}O_{62}$) (6), but Dawson-type heteropoly acids, because of their amorphous shape (ellipsoidal shape of the polyanion), show higher catalytic acivity than Keggin-type HPAs, and this is because of their crystalline shape (spherical shape) (14). Consequently, we can see a low selectivity in the iodination of anisole in the presence of $H_6P_2Mo_{18}O_{62}$. The formation of the resulting by-product is due to the amorphous shape and high catalytic activity in Dawson-type HPAs (Table 1, entry 10). Also, solid acids show only surface-type activity, so their catalytic activities are less than those of $H_3PM_{12}O_{40}$ (M = W, Mo) (Table 1, entries 11–13). One of the most desirable properties for a catalyst is the ease of its recovery. We have found that $H_3PW_{12}O_{40}$ can be easily recovered and recycled simply by filtering (by diethyl ether) and drying (Table 1, entry 14). The recovery had only slightly decreased their catalytic activity (because of the reduction of tungsten atoms) without structural degradation.

[e]One gram of solid acid was used.
[f]Catalyst: after recovery and reuse.

Effect of oxidant

We also investigated other metal nitrates for the iodination of anisole under similar reaction conditions in dichloromethane at room temperature for 8 h (GC results are presented in Table 2). The results revealed that in the absence of the oxidant (Table 2, entry 1), and also with an excess of the catalyst (tungstophosphoric acid) (Table 2, entry 2), the iodination reaction did not proceed after 8 h. Therefore, we have concluded that in the presence of oxidant, most of the metal nitrates were effective oxidants for this reaction, but iron(III) and bismuth(III) nitrates gave better results. These results were expected regarding their reduction potential.

Effect of solvent

The iodination of anisole was also conducted in different solvents at room temperature for 8 h (GC results are presented in Table 3). The results show that in the absence of solvent (Table 3, entry 1) the iodination reaction proceeds with low yield after 1 h at room temperature. The iodination

[b]Catalyst: 0.5 mmol.

reaction also proceeds with the use of microwave irradiation (using a common household microwave oven) under solvent-free conditions for 2 min with the power set at 200 W (Table 3, entry 2). The microwave-assisted method has been accepted as a method for dramatically reducing reaction time, and for increasing isolated yields of products compared with the conventional method, but unfortunately this technique is not a selective tool. The results (Table 3, entries 3–6) show that the efficiency and the yield of the reaction in chlorinated solvents is much more than other solvents at room temperature. We chose dichloromethane for further studies.

On the other hand, HPAs do not dissolve in nonpolar solvents (chlorinated solvents), thus the iodination reaction takes place in a heterogeneous system. HPAs have very high solubility in polar solvents such as water, lower alcohols, ketones, ethers, esters, etc. They absorb a large amount of polar solvents not only on the surface, but also in the bulk of crystalline HPA, forming heteropoly acid solvates (14). Consequently, a homogeneous system exists. Therefore, the iodination reaction in ethyl acetate and MeOH takes place in homogeneous conditions (Table 3, entries 11 and 12). The formation of a by-product can result from high catalytic activity in homogeneous conditions. For relatively polar solvents, we can expect heterogeneous bulk-type (pseudoliquid) catalysis conditions (Table 3, entries 7–10).

According to the results obtained from effects of catalyst, metal nitrate, and solvent, our method is suitable for the iodination of arenes. The aromatic compounds were converted to the corresponding monoiodoaromatic compounds at room temperature in good yields with excellent regioselectivities for 8–24 h. The results of this study are shown in Table 4.

The iodination occurred at a less sterically hindered position. As anticipated, *o*-iodination occurred only when the para position was occupied. In the present method, the formation of a nitro derivative was not observed in spite of increasing reaction time. Our investigation showed that the electron-releasing substituents increased the rate of reaction and yield; however, the electron-attracting groups decreased the rate of reaction and yield of iodination. Aromatic compounds, such as acetanilide, aniline, and phenol, were converted to the corresponding monoiodoproducts in good

yields (Table 4, entries 6–9). Xylenes and toluene were converted to iodo derivatives in relatively good yields (Table 4, entries 10–12), but activated naphthalenes were converted to diiodinated derivatives (Table 4, entries 13 and 14). Finally, this method is only suitable and effective for activated aromatic compounds.

Conclusion

The present method is very simple, cheap, effective, and selective for iodination of electron-rich aromatic compounds, which when carried out under mild conditions and ambient temperature by tungstophosphoric acid, is an effective, readily available, recoverable, reusable, and low-cost catalyst.

Experimental

Chemicals were purchased from Fluka and Merck. Organic solvents were purified and dried by the procedures extracted from *Vogel's textbook of practical organic chemistry* (5th ed. John Wiley and Sons, New York. 1991). $H_3PW_{12}O_{40}$, $H_3PMo_{12}O_{40}$, $Cs_{2.5}H_{0.5}PMo_{12}O_{40}$, and $(NH_4)_2HPW_{12}O_{40}$ were purchased from Merck and were purified by extraction with Et_2O from aqueous solutions of the acids, and dried and dehydrated by evacuating at 150–300 °C for 1 to 2 h. These HPAs can be prepared according to the known procedures (15). Some solid HPAs and their salts, such as $Cs_{2.5}H_{0.5}PW_{12}O_{40}$, $Fe_{0.85}H_{0.45}PMo_{12}O_{40}$, and $H_6P_2Mo_{18}O_{62}$, were prepared according to the reported methods (16) in our laboratory.

General reaction procedure

To iodine (0.6 mmol, 0.152 g) in dichloromethane (1 mL), iron nitrate (0.4 mmol, 0.161 g) and then $H_3PW_{12}O_{40}$ (0.1 mmol, 0.288 g) were added. After 10 min, arene (1 mmol) was added and the reaction mixture was stirred at room temperature for 8–24 h. The completion of the reaction

was monitored by TLC and GC. After the usual work-up of the reaction mixture with Na_2SO_3 (25 mL, 5%), the crude product was extracted with CH_2Cl_2 (3 × 25 mL). The organic phase was dried over $MgSO_4$ and filtered, the crude product was purified by column chromatography on silica gel (petroleum ether – ethyl acetate, 5:1). All products are well-known in the literature. The products were identified by the comparison of their mp and IR data with those reported for the authentic samples in the literature.

Acknowledgments

The authors are thankful to Dr. Roushan Khoshnavazi and Fariba Maleki for useful discussions and their encouragement. We are also thankful to the Kurdistan University Research Council for the partial support of this work.

Thermodynamics of organic mixtures containing amines. IV. Systems with aniline

Juan Antonio González, Ismael Mozo, Isaías García de la Fuente, and José Carlos Cobos

Abstract: Binary mixtures of aniline with benzene, toluene, alkane, alkanol, or *N*,*N*-dialkylamide have been investigated in the framework of the DISQUAC model. The reported interaction parameters change regularly with the molecular structure of the mixture components. The model consistently describes a set of thermodynamic properties including liquid–liquid equilibria, vapor–liquid equilibria, and molar excess enthalpies. The two latter properties for ternary systems are well-represented by DISQUAC using binary parameters only (i.e., neglecting ternary interactions). A comparison of DISQUAC results and those obtained from the UNIFAC (Dortmund version) and ERAS models is also shown. The experimental molar excess enthalpies for binary and ternary mixtures are better described by DISQUAC than by UNIFAC. ERAS fails when representing molar excess enthalpies of those binary systems including methanol or ethanol. This may be due to the existence of strong dipolar interactions among aniline molecules as well as to effects related to the equation of state term, evaluated comparing molar excess enthalpies, and molar excess internal energies at constant volume. The study of the aniline systems in terms of the concentration–concentration structure factor also underlines the importance of dipolar interactions in solutions with alkanes or alcohols, which may be due to the high polarizability of the aniline molecule.

Key words: thermodynamics, mixtures, aniline, dipolar interactions, structural effects.

Résumé : Étude de mélanges binaires d'aniline en présence de benzène, de toluène, d'alcane, d'alcanol et de *N*,*N*-dialkylamide dans le contexte du modèle DISQUAC. Les paramètres d'interaction qui ont été rapportés varient régulièrement en fonction de la structure moléculaire des composés des mélanges. Le modèle décrit d'une façon consistante un ensemble de propriétés thermodynamiques, y compris les équilibres liquide–liquide, les équilibres vapeur–liquide et les enthalpies molaires en excès. Pour les systèmes ternaires, ces deux dernières propriétés sont bien représentées par le modèle DISQUAC en n'utilisant que des paramètres binaires, c'est-à-dire en négligeant les interactions ternaires. On présente aussi une comparaison des résultats obtenus avec le modèle DISQUAC et de ceux obtenus avec les modèles UNIFAC (version Dortmund) et ERAS. Les enthalpies molaires en excès des mélanges binaires ou ternaires sont mieux représentées par DISQUAC que par UNIFAC. Le modèle ERAS n'arrive pas à représenter les enthalpies molaires en excès de ces systèmes binaires, y compris le méthanol ou l'éthanol. Ce résultat peut être dû à l'existence de fortes interactions dipolaires entre les molécules d'aniline ainsi qu'aux effets reliés aux termes de l'équation d'état, qui est évalué en comparant les enthalpies molaires en excès, et les énergies internes molaires en excès à volume constant. L'étude des systèmes de l'aniline en termes de facteur de structure concentration-concentration met aussi en évidence l'importance des interactions dipolaires en solutions dans des alcanes ou des alcools qui peuvent être dus à la grande polarisabilité de la molécule d'aniline.

Mots clés : thermodynamique, mélanges, aniline, interactions dipolaires, effets de structure.

[Traduit par la Rédaction]

Introduction

Amines are a very interesting class of compounds. Primary and secondary linear amines are weakly self-associated (1–5). Solutions of tertiary amines with aliphatic hydrocarbons, and particularly with homomorphic alkanes, are nearly ideal (6). Therefore, different effects can be studied through mixtures including amines. Such investigations may contribute to the development of chemical theories of solutions, and are also useful to obtain information on the interactions between amines and other molecules characterized by different functional groups, for example, in biological systems.

Mixtures containing aniline show very interesting features. Except in dilute regions, aniline does not mix with alkanes at 298.15 K (7). Systems with 1-alkanols are characterized by quite large positive deviations from Raoult's law. For example, at equimolar composition and 298.15 K, the molar excess enthalpy (H^E) of the aniline + 1-propanol system is 783 J mol^{-1} (8). Primary or secondary linear amines or tertiary amine + 1-alkanol mixtures behave quite differently. At the

same conditions as above, H^E(hexylamine + 1-propanol) = –2561 J mol^{-1} (9), H^E(dipropylamine + 1-butanol) = –2432 J mol^{-1} (10), and H^E(triethylamine + 1-propanol) = –1413 J mol^{-1} (11). Therefore, these mixtures show rather large negative deviations from Raoult's law (12, 13). All this makes the study of systems with aniline very interesting, which have been investigated using different models. For example, the aniline + toluene mixture has been treated in terms of the Mecke–Kempter theory (14). The UNIQUAC association solution model (15) has been applied to correlate and (or) predict thermodynamic properties of this class of binary–ternary mixtures (16–18). For technical applications, in the framework of the UNIFAC model (Dortmund version) (19, 20), interaction parameters for contacts between the aniline group and other different groups are available.

As a continuation of our studies on mixtures containing amines (12, 13, 21–23), the first purpose of this article is to extend the purely physical model DISQUAC (24), based on the rigid lattice model developed by Guggenheim (25), to mixtures containing aniline. The solvents considered are: benzene, toluene, alkanes, alkanols, dimethylformamide (DMF), and dimethylacetamide (DMA). In previous studies, we showed that DISQUAC rather accurately represents thermodynamic properties, such as vapour–liquid equilibria (VLE), molar excess Gibbs energies (G^E), H^E, or molar excess heat capacity at constant pressure (C_P^E), of any class of system, independently of its deviation from Raoult's law (12, 13, 26–30). For mixtures with large positive deviations from this law (28–30), DISQUAC also properly describes liquid–liquid equilibria (LLE). From a practical point of view, the model provides reliable predictions on VLE and H^E for ternary systems (31–33), improving UNIFAC predictions (32, 33). Our second purpose is to gain insight into the interactions and structural effects present in solutions with aniline. As in terms of DISQUAC, the excess molar volume (V^E) is assumed to be zero, here we also apply, to some selected systems, the so-called ERAS model (34). As it is known, ERAS combines the real association solution model (35, 36) with a physical term, Flory's equation of state (37), and simultaneously provides information on H^E and V^E. Amine + alkane (4, 22) systems and 1-alkanol + primary or secondary linear amines, or + triethylamine (4, 9, 12, 13, 38–42) mixtures have been successfully characterized using ERAS. To complete our study, we also analysed the experimental database and investigated the mixture structure in terms of the concentration–concentration structure factor ($S_{CC}(0)$) (43). We have shown elsewhere (44, 45) that DISQUAC is a reliable tool to describe this important property.

THEORY

DISQUAC

In the framework of DISQUAC, mixtures of aniline with an organic solvent are regarded as possessing the following four types of surface: (*i*) type n, NH_2 in aniline; (*ii*) type p, C_6H_5 in aniline or toluene; (*iii*) type a, aliphatic (CH_3, CH_2, CH in *n*-alkanes, toluene, methylcyclohexane, alkanols, or *N*,*N*-dialkylamides); (*iv*) type s (s = b, C_6H_6 in benzene; s = c, *c*-CH_2 or *c*-CH in cycloalkanes; s = h, OH in alkanols; s = m, N-CO in *N*,*N*-dialkylamides).

Assessment of geometrical parameters

When DISQUAC is applied, the total molecular volumes (r_i), surfaces (q_i), and the molecular surface fractions (α_i) of the compounds present in the mixture are calculated additively on the basis of the group volumes (R_G) and surfaces (Q_G) recommended by Bondi (46). As volume and surface units, the volume R_{CH_4} and surface Q_{CH_4} of methane are taken arbitrarily (47). For the NH_2 group, r_{NH_2} = 0.61565 and q_{NH_2} = 0.6000. For the CH group, r_{CH} = 0.39603 and q_{CH} = 0.19655. The geometrical parameters for the remaining groups referred to in this work are given elsewhere (47–50).

General equations

The main features of DISQUAC are: (*i*) the partition function is factorized into two terms, in such a way that the excess functions are calculated as the sum of two contributions: a dispersive (DIS) term that represents the contribution from the dispersive forces and a quasichemical (QUAC) term that arises from the anisotropy of the field forces created by the solution molecules. Thus,

$$[1] \qquad G^E = G^{E,COMB} + G^{E,DIS} + G^{E,QUAC}$$

$$[2] \qquad H^E = H^{E,DIS} + H^{E,QUAC}$$

(*ii*) The interaction parameters are assumed to be dependent on the molecular structure. (*iii*) The value $z = 4$ for the coordination number is used for all the polar contacts. This represents one of the most important shortcomings of the model, and is partially removed via the hypothesis of considering structure dependent interaction parameters. In eq. [1], the combinatorial term ($G^{E,COMB}$) is represented by the Flory–Huggins equation (47, 48).

The temperature dependence of the interaction parameters has been expressed in terms of the DIS and QUAC interchange coefficients (49) ($C_{st,l}^{DIS}$ and $C_{st,l}^{QUAC}$), where s ≠ t = a, b, c, h, m, n, p, and l = 1 (Gibbs energy, $C_{st,1}^{DIS/QUAC} = g_{st}^{DIS/QUAC}(T_o)/RT_o$); l = 2 (enthalpy, $C_{st,2}^{DIS/QUAC} = h_{st}^{DIS/QUAC}(T_o)/RT_o$); l = 3 (heat capacity, $C_{st,3}^{DIS/QUAC} = c_{pst}^{DIS/QUAC}(T_o)/R$). T_o = 298.15 K is the scaling temperature and R is the gas constant.

Modified UNIFAC (Dortmund version)

Modified UNIFAC (19) differs from the original UNIFAC (51) by the combinatorial term and the temperature dependence of the interaction parameters.

The equations to calculate G^E and H^E are obtained from the fundamental equation for the activity coefficient (γ_i) of component i:

$$[3] \qquad \ln\gamma_i = \ln\gamma_i^{COMB} + \ln\gamma_i^{RES}$$

where $\ln\gamma_i^{COMB}$ is the combinatorial term and $\ln\gamma_i^{RES}$ is the residual term. The equations are given elsewhere (12).

Assessment of geometrical and interaction parameters

In modified UNIFAC, a new main group $ACNH_2$, different to that of linear primary or secondary amines, is defined for the representation of the thermodynamic properties of aniline + organic solvent mixtures. In this model, the geo-

[a]Estimated value.

metrical parameters, the relative van der Waals volumes, and the relative van der Waals surfaces are not calculated from molecular parameters as in the original UNIFAC, but fitted together with the interaction parameters to the experimental values of the thermodynamic properties considered. The geometrical and interaction parameters were taken from the literature and used without modifications (19, 20).

ERAS

The excess functions are split into two additive terms, which arise from hydrogen-bonding effects (the so-called chemical contribution, X^E_{chem}) and nonpolar van der Waals' interactions including free volume effects (the so-called physical interactions, X^E_{phys}). The excess functions are written as:

$$[4] \qquad X^E = X^E_{phys} + X^E_{chem}$$

where $X^E = H^E$, V^E, or G^E. The resulting expressions for these functions are given elsewhere (12).

Moreover, it is assumed that only consecutive linear association occurs, which is described by a chemical equilibrium constant (K_A) independent of the chain length (m) of the associated species, according to the equation

$$[5] \qquad A_m + A \xleftrightarrow{K_A} A_{m+1}$$

with m ranging from 1 to ∞. The cross-association between two self-associated species, A_m and B_n, is represented by

$$[6] \qquad A_m + B_n \xleftrightarrow{K_{AB}} A_mB_n$$

The association constants (K_{AB}) of eq. [6] are also assumed to be independent of the chain length. Equations [5] and [6] are characterized by Δh^*_i, the enthalpy for the reactions that corresponds to the hydrogen-bonding energy, and by the volume change (Δv^*_i) related to the formation of the linear chains.

X^E_{phys} is derived from Flory's equation of state (37), which is assumed to be valid not only for pure components but also for the mixture (9, 38).

Estimation of the model parameters

DISQUAC interaction parameters

The general procedure applied in the estimation of the interaction parameters has been explained in detail elsewhere (28). Some remarks are given in the following.

Aniline + benzene system

This mixture is characterized by the contacts (b,n), (p,n), and (b,p). The (b,p) contact is represented by DIS parameters only, which are neglected in view of the low values of the excess functions of the benzene + toluene system (e.g., at equimolar composition and 298.15 K; H^E = 68 J mol^{-1} (52)). On the other hand, and for the sake of simplicity, we assumed that the (b,n) and (p,n) contacts are represented by the same interaction parameters, i.e., only the $C^{DIS/QUAC}_{bn,l}$ coefficients must be determined (Table 1). In our previous work on sulfolane (28), alkanol (53), dimethylsulfoxide (54), and amides (44, 45, 50) + benzene or + toluene, we have already shown that for solute (characteristic group X) + benzene or + toluene mixtures ($C^{QUAC}_{bx,l} = C^{QUAC}_{px,l}$), while the DIS parameters are quite close.

Aniline + n-*alkane or + cyclohexane systems*

The mixtures with *n*-alkanes are built by three contacts: (a,p), (p,n), and (a,n). The (a,p) contacts are represented by DIS parameters only. Here, the values used are: $C^{DIS}_{ap,1}$ = 0.332 and $C^{DIS}_{ap,2}$ = 0.57 (53). As $C^{DIS/QUAC}_{bn,l} = C^{DIS/QUAC}_{pn,l}$ and these parameters are known (see the previous section), only the interchange coefficients for the (a,n) contacts must be fitted. This is somewhat difficult because these systems show miscibility gaps (7). DISQUAC is a mean field theory and LLE calculations are developed under the basic and wrong assumption that G^E is an analytical function close to the critical point. The instability of a system is given by $(\partial^2 G^M/\partial x_1^2)_{P,T}$ ($G^M = G^E + G^{ideal}$) and represented by the critical exponent $\gamma > 1$ in the critical exponents theory (55). According to this theory, mean field models (γ = 1) provide LLE curves that are too high at the upper critical solution temperature (UCST) and too low at the lower critical solution temperature (LCST) (55). Thus, one must keep the

$C_{an,l}^{DIS/QUAC}$ coefficients between certain limits to provide not very high calculated UCSTs. The same occurs, e.g., for sulfolane (28), alkoxyethanol (29), crown ether (30), or amide (44, 45, 50) + alkane mixtures. Final parameters are collected in Table 1.

The aniline + cyclohexane system is characterized by the following contacts: (c,p), (p,n), and (c,n). For the (c,p) contacts the values used for the interchange coefficients are $C_{cp,1}^{DIS} = 0.332$ and $C_{cp,2}^{DIS} = 0.65$ (31). The interaction parameters for the (p,n) contacts are known, so only those for the (c,n) contacts must be fitted (Table 1). Calculations were carried out assuming that $C_{an,l}^{QUAC} = C_{cn,l}^{QUAC}$. This general rule is valid for many other solutions, such as sulfolane (28), alkoxyethanol (29), amide (44, 45, 50), linear oxaalkane (56), linear alkanone (57), linear organic carbonate (58), alkanoic acid anhydride (59), chloroalkane (60), linear carboxylic acid (61), alkanol (62–67), + *n*-alkane, or + cyclohexane mixtures. On the other hand, as the aniline + cyclohexane also shows a miscibility gap, similar considerations to those previoiusly stated are still valid.

Aniline + alkanol or + N,N-*dialkylamide systems*

Solutions with alkanols are built by five types of contacts: (a,h), (a,n), (a,p), (p,h), and (h,n). The $C_{ah,l}^{DIS/QUAC}$ and $C_{ph,l}^{DIS/QUAC}$ (l = 1–3) coefficients, different for contacts involving the OH group in 1-alkanols or 2-alkanols, have been previously determined from data on VLE, LLE, SLE (solid–liquid equilibria), H^E, and C_P^E for 1-alkanol or 2-alkanol + *n*-alkane or + toluene systems (13, 49, 53, 62–64). Therefore, only the interaction parameters for the (h,n) contacts must be fitted (Table 1).

Mixtures including amides are also formed by five contacts: (a,m), (a,n), (a,p), (p,m), and (m,n). The $C_{am,l}^{DIS/QUAC}$ and $C_{pm,l}^{DIS/QUAC}$ (l = 1, 2) coefficients have been determined in a previous study from thermodynamic properties of *N*,*N*-dialkylamide + *n*-alkane or + toluene systems (50). The $C_{mm,l}^{DIS/QUAC}$ values (l = 1–3) fitted in this work for the (m,n) contacts are listed in Table 1.

Adjustment of ERAS parameters

For pure compounds, the reduction parameters of volume and pressure (V_i^* and P_i^*, i = A, B) are collected in Table 2. The parameters adjustable to H^E and (or) V^E data are K_i, Δh_i^*, and Δv_i^* (values for aniline or 1-alkanols) and K_{AB}, Δh_{AB}^*, Δv_{AB}^*, and X_{AB} (binary parameters for aniline + *n*-alkane or for 1-alkanol + aniline systems). X_{AB} is the energetic interaction parameter characterizing the difference of dispersive intermolecular interactions between molecules A and B in the solution and in the pure components, and is the only adjustable parameter of the physical part of H^E and V^E (4, 9, 38).

The determination of K_i, Δh_i^*, and Δv_i^* for aniline is somewhat difficult because only a few H^E data at very high T are available (68). Our parameters are listed in Table 2. These H^E data were also used to determine the binary X_{AB} parameters of such systems (Table 3).

K_i, Δh_i^*, and Δv_i^* for 1-alkanols are known from H^E and V^E data for the corresponding mixtures with alkanes (Table 2). The remaining parameters K_{AB}, Δh_{AB}^*, Δv_{AB}^*, and X_{AB} for 1-alkanol + aniline systems (Table 3) were adjusted using the available data in the literature for H^E (8, 69–72) and V^E (73–75) for such solutions.

Results

DISQUAC results

These results are compared with experimental data for LLE, VLE G^E and H^E in Tables 4–8 and in Figs. 1–6. DISQUAC is useful for describing the thermodynamic properties of the studied mixtures. Here, we show three severe tests of the model: (*i*) LLE curves are calculated using the same parameters as for VLE and H^E. It should be considered as a success that immiscibility is predicted in the right temperature and composition region (Table 4, Fig. 1). As usual, the calculated curves for LLE and H^E are not as flat as the experimental curves close to the UCST (Figs. 1 and 4; refs. 29, 30, 44, 45, 50, 58, 59, 62, 63). (*ii*) DISQUAC correctly predicts H^E for ternary systems involving aniline. As in other applications (32, 33), deviations between experimental data and calculated values for ternary mixtures and for the constituent binaries are of the same order (Tables 6 and 8), which suggests that ternary interactions can be neglected when calculating H^E of these ternary systems. Their mean deviation, defined as

[a]Treated as n-alkane (58).

$$\mathrm{Mdev}(H^E) = \sum \frac{\mathrm{dev}(H^E)}{N_S}$$

where N_S is the number of systems and dev(H^E) is given in the footnote of Table 8, is 0.061 (N_S = 6), in agreement with the value 0.058 calculated for the 163 mixtures previously studied (32, 33). The UNIQUAC association solution model using only binary parameters improves results for the ternary mixtures considered here. For example, the mean absolute deviation (in J mol^{-1}) is 11, 15, and 24.5 for methanol + aniline + benzene (18), 1-propanol + aniline + benzene (8), and for 2-butanol + aniline + benzene (76) systems, respectively. DISQUAC provides, in the same order, 14, 43, and 91 J mol^{-1}. A part of the observed differences between the results from the DISQUAC and UNIQUAC association solution models may be due to in this one the binary parameters are obtained from a direct fitting to H^E of the constituent binaries. The few VLE ternary data available in the literature are also well-represented by DISQUAC (Table 7). The mean deviation in pressure is ≈1.6%. For the other 39 systems examined in a previous study, this deviation was 2.2%. (*iii*) DISQUAC can be applied to those mixtures showing large positive deviations from Raoult's law (aniline + alkane), or to those mixtures showing large negative deviations from this law (aniline + DMF). It is remarkable that for systems containing alcohols or amides, the QUAC interchange coefficients are usually constant along each homologous series. This behaviour has been also found when investigating other solutions in terms of DISQUAC (12, 13, 26, 29, 30, 44, 45, 49, 50, 62, 64–66). The different values of $C^{QUAC}_{hn,l}$ (l = 1, 2) for aniline + methanol or + ethanol may be ascribed to the different character (higher dielectric constant, stronger self-association) of these alcohols when compared to the longer ones. A similar trend has been found when developing the DISQUAC treatment of alkanol + aromatic compound (53), 1-alkanol + CCl_4 (77), + linear primary or secondary amine (12), + triethylamine (13), or + amide (44, 45, 50), or the study of 1-alkanol + aromatic compound or + CCl_4 using Barker's theory (78, 79).

Comparison between DISQUAC and UNIFAC results

UNIFAC provides similar results to those from the DISQUAC model for VLE of binary and ternary mixtures (Tables 5 and 7). However, H^E is poorly represented in terms of UNIFAC (Tables 6 and 8). The same occurs for the temperature dependence of the thermodynamic properties. For example, UNIFAC predicts UCST = 363 K for the aniline + n-heptane system (experimental value (7), 343.11 K; DISQUAC result, 346.5 K). At 298.15 K, for the aniline(1) + toluene(2) mixture, UNIFAC yields for the excess heat capacity at constant pressure, $C^E_P(x_1 = 0.5) = 2.7$ J mol^{-1} K^{-1}. This value is rather high, as this system is characterized by $C^E_P \approx 0$ (14). DISQUAC provides $C^E_P(x_1 = 0.5) = -1$ J mol^{-1} K^{-1} and positive values at high mole fractions of aniline in agreement with the experimental data (14). The Mecke–Kempter model gives $C^E_P(x_1 = 0.329) = -0.63$ J mol^{-1} K^{-1}, this value calculated assuming that aniline is a moderately associated liquid (14).

ERAS results

Results for H^E from the ERAS model for some aniline mixtures are collected in Table 6. At 298.15 K and equimolar composition, ERAS gives V^E(aniline + 1-propanol) = –0.53 cm^3 mol^{-1} and V^E(aniline + 1-butanol) = –0.39 cm^3 mol^{-1}. The experimental values are –0.515 (73) and –0.365 cm^3 mol^{-1} (74), respectively.

The ERAS parameters of pure aniline (K_A and Δh^*_{AB}) are in good agreement with the values determined (24.2 (at 323.15 K) and –15.4 kJ mol^{-1}, respectively) in the frame-

work of the UNIQUAC association solution model (see, e.g., 8, 16, 18, 76). In terms of the Mecke–Kempter model the self-association enthalpy of aniline is –8.4 kJ mol^{-1} (14). The ERAS parameters derived in this work are supported by the predicted enthalpy of vaporization (51.7 kJ mol^{-1}), which is close to the experimental value (55.8 kJ mol^{-1} (80)).

Regarding the ERAS parameters for the studied mixtures, we note: (*i*) The large X_{AB} values for the systems with *n*-alkane remark the importance of the physical interactions in these solutions. It should be kept in mind that, typically, the X_{AB} values are in the range between 2 and 20 J cm^{-3} (9). (*ii*) From the comparison of the K_{AB} and Δh^*_{AB} values with those for other 1-alkanol + linear amine mixtures (Table 3), it is possible to conclude that interactions between dissimilar molecules are much weaker in aniline systems. (*iii*) In contrast, Δv^*_{AB} is lower for solutions involving aniline (Table 3), which suggests that structural effects are more important in this class of mixtures (see the following).

We note that H^E is better represented by DISQUAC for mixtures with methanol or ethanol (Table 6). In addition, ERAS yields for the aniline + methanol system a G^E curve skewed to low mol fractions of the alcohol, while the experimental one is rather symmetrical. Therefore, it is possible to conclude that ERAS overestimates the self-association of the alcohol in systems containing methanol or ethanol.

Discussion

The inmiscibility of aniline with alkanes at room temperature (7) is characteristic of systems where strong polar inter-

actions between like molecules exist, and is found, e.g., in sulfolane (28), alkoxyethanol (29), 1-methyl pyrrolidin-2-one (44), dimethylformamide (50), or dimethylsulfoxide (54) + alkane mixtures. Such interactions may be roughly evaluated in terms of $\Delta\Delta_{vap}H_m$, (27, 56, 81), the difference between the standard enthalpy of vaporization ($\Delta_{vap}H_m$, (data taken from refs. 80 and 82) of a given component with a characteristic group X and that of the homomorphic alkane. Therefore, $\Delta\Delta_{vap}H_m$(aniline) = 18.2 > $\Delta\Delta_{vap}H_m$(cyclohexylamine) = 10.36 > $\Delta\Delta_{vap}H_m$(hexylamine) = 8.52 > $\Delta\Delta_{vap}H_m$(dipropylamine) = 3.46 > $\Delta\Delta_{vap}H_m$(triethylamine) = –1.77 (all values in kJ mol^{-1}). The large $\Delta\Delta_{vap}H_m$ value for aniline suggests that the high polarizability of the aromatic ring of this amine enhances the interactions between aniline mole-

Fig. 7. Excess molar volumes (V^E) at 298.15 K for aniline(1) + 1-alkanol(2) mixtures. Experimental results: 1-propanol (73) (■); 1-butanol (74) (●). ERAS calculations (solid lines), including results for the system with methanol.

cules. Therefore, the strength of the interactions among amine molecules decreases in the sequence: aniline > cyclohexylamine > hexylamine > dipropylamine > triethylamine. This may explain some of the features previously mentioned, or that at equimolar composition and 298.15 K, H^E(hexylamine + n-C_7) = 1064 J mol^{-1} (83) > H^E(dipropylamine + n-C_7) = 454 J mol^{-1} (84).

For linear primary or secondary amines + 1-alkanol mixtures, V^E is large and negative. At 298.15 K and equimolar composition, V^E(hexylamine + 1-propanol) = –1.147 cm^3 mol^{-1} (42) and V^E(dipropylamine + 1-propanol) = –1.550 cm^3 mol^{-1} (39). This has been interpreted in terms of strong interactions between dissimilar molecules, which is supported by large and negative H^E values (see Table A1 of the Appendix), as well as by solid–liquid equilibria measurements (85, 86). However, taking into account the rather large positive H^E of aniline + 1-alkanol (≠methanol, ethanol) systems, the corresponding negative V^E values suggest that important structural effects exist in these solutions. So, the V^E curve for aniline + 1-propanol is very skewed towards high mole fractions of the alcohol (Fig. 7), the smaller compound, indicating that free volume effects exist.

To evaluate the importance of the equation of state term, it is interesting to calculate the excess internal energy at constant volume U_V^E, for some aniline + 1-alkanol systems. Neglecting terms in higher order in V^E (55, 87), U_V^E is displayed as

$$[7] \qquad U_V^E = H^E - \frac{\alpha_P V^E}{\kappa_T}$$

where α_P and κ_T are the isobaric thermal expansion coefficient and the isothermal compressibility factor of the mixture, respectively. Due to the lack of experimental data, these quantities were calculated as (88, 89)

$$[8] \qquad M = \phi_1 M_1 + \phi_2 M_2$$

In this equation, M is the value of α_P or κ_T for the mixture, M_i is the value of these magnitudes for the pure compound i (i = 1, 2) and

$$\phi_i = \frac{x_i V_i}{x_1 V_1 + x_2 V_2}$$

The results are: U_v^E(aniline + 1-propanol) = 985 J mol^{-1} and U_v^E(aniline + 1-butanol) = 1158 J mol^{-1}. Using V^E = –0.81 cm^3 mol^{-1}, the value calculated from the ERAS model, U_v^E(aniline + methanol) = 160 J mol^{-1}. Therefore, the poor results obtained from ERAS for these mixtures may be ascribed, at least in part, to effects related to the equation of state term that are not properly described by the model. In contrast, 1-alkanol + primary or secondary linear amine mixtures are much better represented by ERAS because thermodynamic properties of these solutions are mainly determined by strong interactions between dissimilar molecules (see Table A1 of the Appendix) (42).

The concentration–concentration structure factor ($S_{CC}(0)$) (43), is defined as

$$[9] \qquad S_{CC}(0) = \frac{RT}{\left(\frac{\partial^2 G^M}{\partial x_1^2}\right)_{P,T}} = \frac{x_1 x_2}{D}$$

with

$$[10] \qquad D = \frac{x_1 x_2}{RT}\left(\frac{\partial^2 G^M}{\partial x_1^2}\right)_{P,T} = 1 + \frac{x_1 x_2}{RT}\left(\frac{\partial^2 G^E}{\partial x_1^2}\right)_{P,T}$$

D is a function closely related to thermodynamic stability (55, 90). For ideal mixtures, $G^{E,id} = 0$, $D^{id} = 1$, and $S_{CC}(0) = x_1 x_2$. As stability conditions require, $S_{CC}(0) > 0$, and if the system is close to phase separation, $S_{CC}(0)$ must be large and positive (∞, when the mixture presents a miscibility gap). In contrast, if compound formation between components appears, $S_{CC}(0)$ must be very low (0, in the limit). So, if $S_{CC}(0) > x_1 x_2$, i.e., $D < 1$, the dominant trend in the system is the separation of the components (homocoordination), and the mixture is less stable than the ideal. If $0 < S_{CC}(0) < x_1 x_2 = S_{CC}(0)^{id}$, i.e., $D > 1$, the fluctuations in the system have been removed, and the dominant trend in the solution is compound formation (heterocoordination). In this case, the system is more stable than ideal. The $S_{CC}(0)$ function clearly shows the features examined. The large and positive values of $S_{CC}(0)$ for aniline + alkane mixtures (Table 9) indicate strong homocoordination between aniline molecules. Systems with 1-alkanols are also characterized by homocoordination ($S_{CC}(0) > S_{CC}^{ideal}$, Table 9). This even occurs for the solution containing methanol, which shows $H^E < 0$ at equimolar composition (Table 6) (and $U_V^E > 0$). In contrast, interactions between dissimilar molecules are more important in the propylamine + 1-propanol mixture, as the $S_{CC}(0)$ results underline (Fig. 8 (12)). On the other hand, systems involving 1-propanol or longer 1-alkanols are characterized

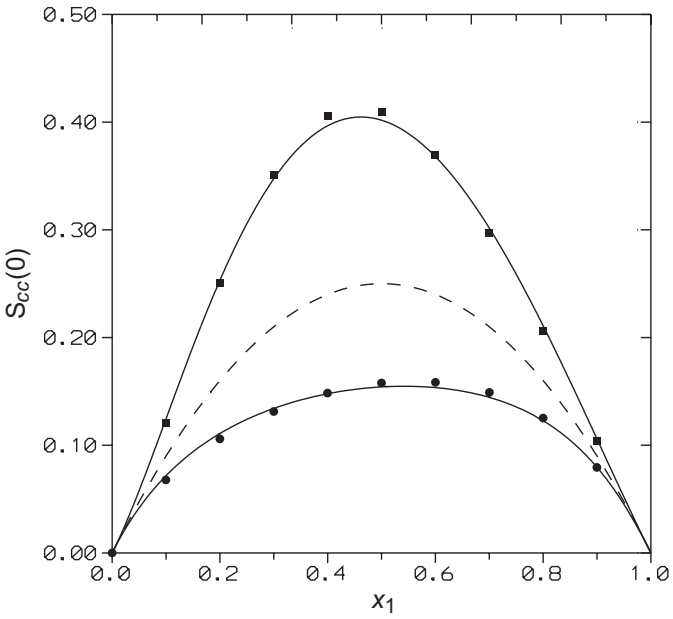
[a]Experimental value.
[b]DISQUAC values calculated with interaction parameters from Table 1.

by TS^E (= $H^E - G^E$) > 0 (Table A1 of the Appendix). The interactions present in such solutions may be then be assumed to be of the dipole–dipole type. Mixtures with methanol or ethanol show $TS^E < 0$ (Table A1 of the Appendix). To obtain more information on the studied systems, we have also examined the temperature dependence of $S_{CC}(0)$, which is well-represented by DISQUAC (Table 9). We note that $S_{CC}(0)$ seems to decrease rather weakly with increasing T (Table 9). In the framework of the quasichemical theory developed by Guggenheim (25), Cobos (43) has shown that

$$[11] \qquad \frac{\partial S_{CC}(0)}{\partial T} = \frac{S^2_{CC}(0)}{T} \frac{\partial^2 (U^E_v/RT)}{\partial x_1^2}$$



For the investigated mixtures,

$$U^E_V > 0, \quad \frac{\partial^2 (U^E_v/RT)}{\partial x_1^2} < 0$$

and $S_{CC}(0)$ should decrease with T. For the system containing methanol, $S_{CC}(0)$ remains practically constant, reflecting a rather flat U^E_V curve. This weak temperature dependence of $S_{CC}(0)$ implies that low C^E_P values should be expected, a characteristic of systems where dipole–dipole, or dipole-induced dipole interactions are present ((14); see the results for the solution with benzene, Table 9). This newly underlines the importance of the high polarizability of the aniline molecule (Table A1 of the Appendix).

We note that $S_{CC}(0)$(2-propanol) > $S_{CC}(0)$(1-propanol) (Table 9), in agreement with the fact that dipolar interactions between 2-alkanol molecules are stronger than between those of 1-alkanols.

Fig 8. Concentration–concentration structure factors ($S_{CC}(0)$) for amine(1) + 1-alkanol(2) mixtures. Experimental results: propylamine(1) + 1-propanol (T = 302.95 K (131)) (■); aniline(1) + methanol(2) (T = 338.15 K (106)) (●). DISQUAC calculations (solid lines); ideal mixture (dashed line).

Finally, it should be mentioned that for the mixture with *N*,*N*-dialkylamides DISQUAC predicts $S_{CC}(0) < S^{ideal}_{CC}(0)$, remarking that heterocoordination here plays the dominant role, particularly for the DMF system.

Conclusions

DISQUAC accurately represents a whole set of thermodynamic properties: LLE, VLE, G^E, H^E, and $S_{CC}(0)$ of the investigated binary mixtures. The model also correctly predicts VLE and H^E of ternary systems involving aniline.

Solutions with alkane or alkanol are characterized by strong homocordination between aniline molecules. Structural effects, not represented properly by the ERAS model, are also present in systems with alcohols. Mixtures with *N*,*N*-alkylamides are characterized by heterocoordination.

Microwave- and ultrasound-assisted semisynthesis of natural methoxylated propiophenones from isomeric mixture of phenylpropenes in minutes[1]

Bhupendra P. Joshi, Anuj Sharma, and Arun K. Sinha

Abstract: A rapid and practical semisynthesis of natural methoxylated propiophenones (**3a**–**3f**) is realized by reacting stereo- and regio-isomeric mixture of phenylpropenes (**1a**–**1f**) with a catalytic amount of palladium chloride – sodium formate in formic acid, methanol, and water (2:1:2) into single product phenylpropanes (**2a**–**2f**) followed by its oxidation with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) in wet dioxane, containing a few drops of formic acid. Conventional, ultrasound, and microwave heating were compared through these studies.

Key words: focused microwave, ultrasound, phenylpropene, propiophenone, DDQ.

Résumé : On a mis au point une semi-synthèse rapide et pratique des propiophénones méthoxylées naturelles (**3a**–**3f**) en faisant réagir des mélanges stéréo- et régio-isomères de phénylpropènes (**1a**–**1f**) avec une quantité catalytique de chlorure de palladium – formiate de sodium dans l'acide formique, le méthanol et l'eau (2 : 1 : 2) qui conduisent à des phénylpropanes isolés sous la forme de produits uniques (**2a**–**2f**) qui ont été isolés par du 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) dans du dioxane humide contenant quelques gouttes d'acide formique. Dans toutes les études mentionnées ci-dessus, on a comparé les méthodes de chauffage traditionnelle, aux ultrasons et aux micro-ondes.

Mots clés : micro-onde focalisée, ultrason, phénylpropène, propiophénone, DDQ.

[Traduit par la Rédaction]

Introduction

Methoxylated propiophenones (1) are isolated from a large number of medicinally important plants and possess a wide range of biological (2–5) activities such as choleretic (2), antiplatelet activating factor (anti-PAF) (3), antifungal (4), and hypolipidemic (5) activities. In addition, methoxylated propiophenones are utilized as intermediates for the production of various bioactive molecules (6) and are also used as modifiers in flavour and perfumery formulations (7).

Various methods are reported for the preparation of propiophenones (C_6–C_3). These methods fundamentally fall under three categories: (*a*) combination of a C_6 unit with a C_3 unit, (*b*) combination of a C_6–C_1 unit with a C_2 unit, and (*c*) semisynthetic route from an already existing C_6–C_3 unit. The methods in category (*a*) include reactions of substituted benzene with phenyllithium – lithium propionate (8) and Zn-Cu–Pd$(PPh_3)_4$–CO (9). Similarly, Friedel–Crafts propionylation (6) of an aromatic ring with a Lewis acid (10) also falls under this category and remains a well-exploited method. Propionylation of a methoxylated aromatic ring, however, suffers from some degree of demethoxylation (11) with Lewis acids such as aluminium chloride (12). The methods in category (*b*) include the reaction of substituted benzaldehydes (13–15), benzonitrile (16), or benzoic acids (17, 18) with cyanohydrin – vinyl ether (13), chlorotrimethylsilane–KCN (14), Grignard (15), isobutylmagnesium bromide (16), thionyl chloride – $Cd(C_2H_5)_2$ (17), or propionic acid – iron(II) salt (18), respectively. Overall, all of the synthetic methods in categories (*a*) and (*b*) are limited by expensive starting material, maintenance of anhydrous conditions, and environmentally hostile reagents (19).

In this regard, the methods in category (*c*) hold a better semisynthetic approach (20, 21) than categories (*a*) and (*b*) because the former utilizes an already existing C_6–C_3 unit in the form of substituted phenylpropenes for the formation of methoxylated propiophenones. Hence, only slight modifications in the structure are desired, which may not require harsh conditions if a suitable choice of substrate and reagent is made.

Scheme 1.

Scheme 2.

(a) $R_2=R_4=R_5=OMe$; $R_3=R_6=H$ (b) $R_3=R_4=OCH_2O$; $R_2=R_5=R_6=H$ (c) $R_3=R_4=R_5=OMe$; $R_2=R_6=H$
(d) $R_3=R_4=OMe$; $R_2=R_5=R_6=H$ (e) $R_4=OMe$; $R_2=R_3=R_5=R_6=H$ (f) $R_3=OMe$; $R_4=OH$; $R_2=R_5=R_6=H$

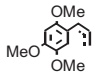
Phenylpropenes are readily available natural phenylpropanoids (22)[3] whose structures and economical prices make them excellent precursors for the semisynthesis of a large number of products (23, 24) including propiophenones. Some methoxylated propiophenones (20, 21) (**3a** and **3b**) have already been synthesized from phenylpropenes utilizing either *N*-bromosuccinimide – H_2O – palladium acetate or $PdCl_2$–$CuCl$–O_2 (Scheme 1). However, the extension of these semisynthetic methods for a large-scale preparation of propiophenones is not viable due to a longer reaction time (20), the maintenance of anhydrous conditions, and the use of expensive reagents (21). In addition, phenylpropenes are usually available from natural sources as an isomeric (22) mixture, and their purification into a pure single isomer is tedious (25). Consequently, chemical modification of any isomer of phenylpropenes results in the formation of side products owing to the presence of its other two isomers (23).[4]

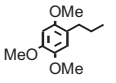
Against this backdrop, we report microwave- (26) and ultrasound-assisted (27) rapid and practical semisynthesis of methoxylated propiophenones (**3a**–**3f**) where toxic (28) *cis*-phenylpropenes with their stereo- and regio-isomeric mixtures (**1a**–**1f**) were first hydrogenated into a single product phenylpropane (**2a**–**2f**). This method thus eliminated the possibility of the formation of side products arising from the isomeric nature of phenylpropenes. These phenylpropanes (**2a**–**2f**) were then oxidized to provide bioactive propiophenones (**3a**–**3f**) (Scheme 2). The above microwave- and ultrasound-assisted reactions were also conducted under conventional conditions to compare all three methods viz. microwave, ultrasound, and conventional methods to establish the superiority of the microwave-assisted reactions.

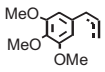
Experimental

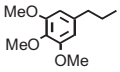
Melting points were determined with a Metler FP80 micromelting point apparatus and are uncorrected. Column chromatography was performed on silica gel (60–120 mesh size). ^1H (300 MHz) and ^{13}C (75.4 MHz) NMR spectra were recorded in $CDCl_3$ on a Bruker Avance-300 spectrometer. A CEM Discover® focused microwave (2450 MHz, 300 W) and a Sonics ultrasonicator (20 kHz, 750 W) were used for all the given reactions. GC and HR-ES-MS were determined using Shimadzu-2010 and Micromass Q-TOF Ultima spectrometers, respectively.

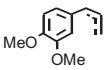
Representative experimental for conversion of stereo- and regio-isomeric mixtures of phenylpropenes (1a–1f) into phenylpropane (2a–2f)

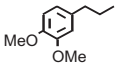


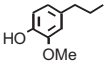


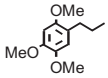


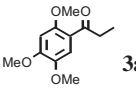


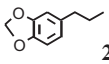


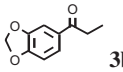


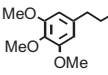


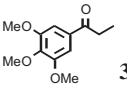


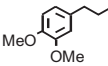


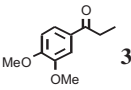


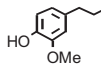


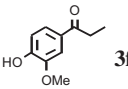












A homogeneous mixture containing $PdCl_2$ (0.01 g) and sodium formate (0.01 g) was prepared by completely mixing both in a mortar. To this powdered mixture, the isomeric

[3] A large number of methoxylated phenylpropenes are found in high concentration (22) up to 90% in many essential oil-bearing plants, but generally exist as an isomeric mixture of three isomers namely trans (α), cis (β), and γ-isomers whose purification into a pure single isomer is tedious by column chromatography (25). On the other side, *cis*-phenylpropenes (e.g., *cis*-2,4,5-trimethoxyphenylpropene) are proven carcinogenic and toxic (26), which overall restrict the market potential of an essential oil rich in cis isomer, therefore, utilization of a stereo- and regio-isomeric mixture of phenylpropene (**1a**–**1f**) is an added benefit for phenylpropenes towards the formation of useful products including propiophenones (**3a**–**3f**).

[4] For example, the oxidation of *cis*- and (or) *trans*-phenylpropenes provides phenylaldehyde; however, contamination of γ-phenylpropene will lead to phenylacetaldehyde (23).

[b]Sonics with pulse length 9 s, 75% duty, pause after every 10 min.
[c]At reflux temp.
[d]Dotted lines over the phenylpropenes represent an isomeric mixture of cis, trans, and allyl isomers.
[e]The mentioned reaction period required for maximum yield.

mixture of substituted phenylpropene **1a–1f** (2.9 mmol) and an 8–10 mL reagent mixture of HCOOH–MeOH–H_2O (2:1:2) was added. The mixture was then either irradiated using a focused monomode microwave system (in a round bottom flask fitted with a reflux condenser at 110–120 °C, power 150–250 W) for 10 min, or ultrasonicated (power 560 W) for 60 min, or refluxed for 300 min using the conventional method. After completion of the reaction, the catalyst[5] was removed by filtration and the filtrate was evaporated. The residue was partitioned between ethyl acetate (70 mL) and water (15 mL), and the ethyl acetate layer was washed with water (2 × 10 mL), $NaHCO_3$ (10%), brine (10 mL), dried over Na_2SO_4, and filtered. The filtrate was evaporated, and the obtained residue was purified by column chromatography (hexane – ethyl acetate, 9:1) to afford phenylpropane **2a–2f** in 89%–96% yield (Table 1).

Liquid. ^{1}H NMR ($CDCl_3$) δ: 6.80 (2H, m, H-2′, H-6′), 6.62 (1H, d, *J* = 8.3 Hz, H-5′), 6.01 (1H, s, -OH), 3.91 (3H, s, -OCH_3), 2.48 (2H, t, *J* = 7.9 Hz, H-1), 1.58 (2H, m, H-2), 0.96 (3H, t, *J* = 7.3 Hz, H-3). ^{13}C NMR ($CDCl_3$) δ: 146.5 (C-3′), 143.7 (C-4′), 134.6 (C-1′), 121.4 (C-6′), 114.4 (C-5′), 111.4 (C-2′), 55.8 (-OCH_3), 37.7 (C-1), 24.9 (C-2), 13.8 (C-3).

General procedure for the preparation of methoxylated propiophenones 3a–3f from the oxidation of phenylpropanes 2a–2f with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ)

A mixture of substituted phenylpropane **2a–2f** (2.4 mmol), DDQ (4.8–5.24 mmol), and HCOOH (1 to 2 drops) in wet dioxane (30 mL, water–dioxane 1:9) was irradiated using focused microwave irradiation (in a round bottom flask fitted with a reflux condenser at 110–120 °C, power 150–250 W) for 25 min, or ultrasonicated (power 560 W) for 20 min, or refluxed for 240 min under conventional method. The precipitated hydroquinone ($DDQH_2$) was filtered, and the red-coloured filtrate was evaporated and subsequently chromatographed on silica gel (hexane – ethyl acetate, 7:3) to provide methoxylated propiophenone **3a–3f** in 56%–81% yield (Table 1).

1-(2′,4′,5′-Trimethoxyphenyl)propan-1-one (3a)

White solid; mp 108 to 109 °C (lit. value (6*b*) mp 108–110 °C). ^{1}H NMR ($CDCl_3$) δ: 7.45 (1H, s, H-6′), 6.77 (1H, s, H-3′), 3.96, 3.93–3.89 (each 3H, s, three OCH_3), 2.99 (2H, q, *J* = 6.9 Hz, H-2), 1.18 (3H, t, *J* = 6.9 Hz, H-3). ^{13}C NMR ($CDCl_3$) δ: 201.1 (C-1), 155.5 (C-2′), 153.9 (C-4′), 143.3 (C-5′), 118.9 (C-1′), 112.6 (C-6′), 96.7 (C-3′), 56.1 (4′-OCH_3, 5′-OCH_3), 55.9 (2′-OCH_3), 36.9 (C-2), 8.4 (C-3).

1-(3′,4′-Dioxymethylenephenyl)propan-1-one (3b)

White solid; mp 35 to 36 °C (lit. value (30*a*) mp 38 to 39 °C). ^{1}H NMR ($CDCl_3$) δ: 7.60 (1H, d, *J* = 8.1 Hz, H-6′), 7.50 (1H, s, H-2′), 6.86 (1H, d, *J* = 8.1 Hz, H-5′), 6.34 (2H, s, -OCH_2O-), 2.91 (2H, q, *J* = 6.9 Hz, H-2), 1.25 (3H, t, *J* = 6.9 Hz, H-3). ^{13}C NMR ($CDCl_3$) δ: 199.1 (C-1), 151.8 (C-4′), 148.2 (C-3′), 132.1 (C-1′), 122.4 (C-6′), 110.1 (C-2′), 109.7 (C-5′), 100.5 (-OCH_2O-), 31.4 (C-2), 8.6 (C-3).

1-(3′,4′,5′-Trimethoxyphenyl)propan-1-one (3c)

White solid; mp 52 to 53 °C (lit. value (17) mp 51.5–52.5 °C). ^{1}H NMR ($CDCl_3$) δ: 7.23 (2H, s, H-2′, H-6′), 3.90 (9H, s, three OCH_3), 2.95 (2H, q, *J* = 7.2 Hz, H-2), 1.22 (3H, t, *J* = 7.2 Hz, H-3). ^{13}C NMR ($CDCl_3$) δ: 199.5 (C-1), 153.1 (C-3′, C-5′), 141.4 (C-4′), 137.6 (C-1′), 105.4 (C-2′, C-6′), 60.8 (4′-OCH_3), 56.3 (3′-OCH_3, 5′-OCH_3), 31.8 (C-2), 8.4 (C-3).

1-(3′,4′-Dimethoxyphenyl)propan-1-one (3d)

White solid; mp 59 to 60 °C (lit. value (30*b*) mp 59 to 60 °C). ^{1}H NMR ($CDCl_3$) δ: 7.62 (1H, d, *J* = 8.0 Hz, H-6′), 7.56 (1H, s, H-2′), 6.88 (1H, d, *J* = 8.0 Hz, H-5′), 3.96 (6H, s, two OCH_3), 2.97 (2H, q, *J* = 7.2 Hz, H-2), 1.23 (3H, t, *J* = 7.2 Hz, H-3). ^{13}C NMR ($CDCl_3$) δ: 200.0 (C-1), 153.4 (C-4′), 149.3 (C-3′), 130.5 (C-1′), 122.9 (C-6′), 110.4 (C-2′), 110.3 (C-5′), 56.5 (3′-OCH_3, 4′-OCH_3), 31.7 (C-2), 9.0 (C-3).

1-(4′-Methoxyphenyl)propan-1-one (3e) (30c)

Liquid. ^{1}H NMR ($CDCl_3$) δ: 7.58 (2H, d, *J* = 8.05 Hz, H-2′, H-6′), 6.85 (2H, d, *J* = 8.05 Hz, H-3′, H-5′), 3.90 (3H, s, OCH_3), 2.93 (2H, q, *J* = 7.2 Hz, H-2), 1.18 (3H, t, *J* = 7.2 Hz, H-3). ^{13}C NMR ($CDCl_3$) δ: 199.2 (C-1), 163.2 (C-4′), 130.4 (C-1′), 129.9 (C-2′, C-6′), 113.5 (C-3′, C-5′), 55.3 (4′-OCH_3), 31.2 (C-2), 8.2 (C-3).

1-(4′-Hydroxy-3′-methoxyphenyl)propan-1-one (3f)

White solid; mp 61 to 62 °C (lit. value (2) mp 63 °C). ^{1}H NMR ($CDCl_3$) δ: 7.58 (2H, m, H-2′, H-6′), 6.95 (1H, d, *J* = 8.4 Hz, H-5′), 6.08 (1H, s, Ar-OH), 3.92 (3H, s, three OCH_3), 2.96 (2H, q, *J* = 6.9 Hz, H-2), 1.23 (3H, t, *J* = 6.9 Hz, H-3). ^{13}C NMR ($CDCl_3$) δ: 199.7 (C-1), 151.3 (C-3′), 147.8 (C-4′), 130.9 (C-1′), 123.7 (C-6′), 112.1 (C-5′), 111.9 (C-2′), 55.2 (OCH_3), 31.7 (C-2), 8.4 (C-3).

[a]CEM monomode Discover synthesizer at temp. 110–120 °C, power 150–250 W.
[b]Yields based on GC (Shimadzu).
[c]The reaction was performed using a domestic microwave oven at power 300 and 900 W (entries 11 and 12, respectively) resulting in either unreacted starting material (entry 11) or evaporation of the product (entry 12).

Results and discussion

In recent years, there has been a tremendous shift in the use of microwave (26) and ultrasound (27) irradiation in organic reactions owing to the shorter reaction time, higher yields, operational simplicity, and most importantly, the fact that it is a more eco-friendly process compared with conventional heating. As per our ongoing interest in semisynthesis of phenylpropanoids, we decided to prepare 2,4,5-trimethoxypropiophenone (**3a**), a hypolipidemic (5) active compound, from abundantly available toxic (28) 2,4,5-trimethoxyphenylpropene (**1a**) through catalytic transfer hydrogenation (31) (CTH) of **1a** in the first step to form 2,4,5-trimethoxyphenylpropane (**2a**), which would then be oxidized by addition of the suitable oxidant in the next step to form **3a**. For catalytic transfer hydrogenation, a stereo- and regioisomeric mixture of phenylpropene **1a** was treated with $PdCl_2$ in formic acid (98%) as a hydrogen transferring agent for 80 min under focused monomode (32) microwave (CEM Discover® synthesizer); but only 20% of product **2a** formed (Table 2, entry 1), the rest being a number of side products. Similarly, a combination of HCOOH and NaOH (33) did not improve the yield of the product (Table 2, entry 2). The addition of isopropanol (34) or high boiling ethylene glycol (31*a*, 35) to formic acid also did not improve the yield of product **2a** (Table 2, entries 3 and 4). Later on, hydrogenating a mixture comprising $PdCl_2$–HCOOH in methanol was found suitable, and **2a** was obtained up to 54% yield (Table 2, entry 5). Prompted by reports on water–methanol assisted yield enhancement of products (36), we decided to utilize a combination of methanol and water as solvents in this reaction. After a lot of experimentation, a 2:1:2 mixture of HCOOH–MeOH–H_2O in catalytic amounts of $PdCl_2$ for 40 min under microwave proved to give the optimum results, and provided an 82% yield of **2a** (Table 2, entry 6). Later on, we realized that the addition of a catalytic amount of either sodium formate, potassium formate, or ammonium formate,[6] along with this hydrogenating system, was important in increasing the yield of the product (**2a**) up to 94% with a drastic reduction in reaction time up to 9 min under focused monomode (32) microwave (Table 2, entries 7–9). For comparison, the same reaction performed in a domestic microwave oven provided the product (**2a**) in 79% yield and the loss in yield may be due to the easy evaporation of the product in the domestic microwave oven (Table 2, entries 11 and 12).

In the next step, comprising oxidation of phenylpropane **2a** into **3a**, several common oxidizing reagents (37) such as pyridinium chlorochromate and potassium permanganate were tried, but none of the oxidants was found to be effective and a number of side products were obtained with little or no product **3a**. Use of excess potassium permanganate – copper sulphate (10 mol equiv. of reactant **2a**) under ultrasound and microwave irradiation (38) was also unfruitful. Similarly, under various conditions, chromium(IV) oxide (37*b*, 39) also failed to convert **2a** into **3a**, although a yellow-colored solid was obtained; NMR studies revealed it to be 2-propyl-5-methoxy-1,4-benzoquinone (40). The reason for the failure of all the above general oxidants (37–39) was believed to be due to the substituent effect of methoxy groups present at the 2, 4, and 5 positions of phenylpropane, while oxidation of unsubstituted phenylpropane into propiophenones is well-reported with potassium permanganate (38*c*).

Later on, 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) (41) was found to be an appropriate oxidant for successfully converting **2a** into **3a**. Initially, **2a** was reacted with 1.25–

[6]Ammonium formate itself is a well-known hydrogen-transferring agent for reduction of various functional groups (31, 32) including carbon–carbon double bonds; however, a large excess of ammonium formate (10 equiv.) and its sublimation on the walls of the vessels somewhat limit its use.

© 2005 NRC Canada

1.5 equiv. of DDQ in the presence of various organic solvents such as methanol, ethanol, THF, and dioxane. Dioxane along with 3 to 4 mL of water (42), considered most suitable, provided **3a** only up to 47% along with 11% of α-asarone (23).[7] An increased amount of DDQ, varying from 2 to 2.2 equiv., provided a little more improvement in the yield (58%) of **3a**, but no more improvement in the yield resulted from a further addition of DDQ. Interestingly, the addition of a few drops of HCOOH (98%) in this reaction mixture increased the yield of propiophenone **3a** up to 69% (Scheme 2) within 16 min under focused microwave irradiation.

After choosing DDQ as the reagent, we decided to carry out both hydrogenation of **1a** into **2a** and oxidation of **2a** into **3a** in one pot. One-pot synthesis has recently attracted interest, providing a simple and efficient entry to compounds by amalgamating two or more operations into a single step. Hence, after performing hydrogenation of **1a** into **2a** for 10 min, DDQ was added in the same reaction pot and irradiated under microwave irradiation intermittently for 20 min. We had thought that HCOOH, besides acting as hydrogen source, would not interfere in the DDQ-assisted oxidation of phenylpropane **2a** into propiophenone **3a** in the same pot, as the importance of an acidic (42) medium in DDQ-assisted oxidation is well-understood. Unfortunately, the conversion of **2a** into **3a** resulted in a poor yield (up to 22%). This implied that oxidation could not occur completely in one pot probably owing to the presence of $PdCl_2$, which would keep on reacting with formic acid to release hydrogen, thus hampering the abstraction of the benzylic proton of **2a** with DDQ for the formation of **3a**. Hence, we decided to remove $PdCl_2$ by mere filtration in the first step before the addition of the oxidant (DDQ) in the same pot. Although product **3a** was formed in this case, the yield was still no higher than 34% and there was no further increase in the yield by either lengthening the reaction period or changing the amount of DDQ. This implied that the hydrogenating solvent mixture must have interfered in the oxidation of **2a** into **3a**, which is otherwise performed effectively in dioxane in the two-step methodology. Finally, all this prompted us to change the one-pot two-step methodology, and retain the two-step methodology by performing the hydrogenation in methanol and oxidation in a dioxane medium.

After the success of these reactions for the conversion of **1a** into **2a** followed by the oxidation of **2a** into **3a**, the same methodology was employed for the oxidation of other natural methoxylated phenylpropenes **1b**–**1f**, which successfully provided the corresponding propiophenones **3b**–**3f** in moderate yields (56%–81%). To make a comparative analysis, these reactions (hydrogenation and oxidation) were performed under ultrasonication as well as refluxed under conventional heating and the results are shown in Table 1. The results clearly show that microwave activation afforded better yields of **3a**–**3f** with shorter reaction time than those obtained under other classical or sonication methods. Moreover, the reactions using microwave are more environment friendly than conventional heating in terms of a reduced reaction time and the use of less solvent for the reaction.

Conclusion

In conclusion, we have realized a microwave and ultrasound-assisted rapid and mild semi-synthetic approach towards preparation of a number of natural bioactive methoxylated propiophenones (**3a**–**3f**) from abundantly available stereo- and regio-isomeric mixtures of phenylpropenes (**1a**–**1f**) via phenylpropanes (**2a**–**2f**). Moreover, such a comparative analysis among microwave, ultrasound, and conventional methodologies, to the best of our belief, is disclosed for the first time. Overall, this is an environment friendly process with none of the steps requiring maintenance of anhydrous conditions or hazardous chemicals. The intermediates (**2a**–**2f**) may have general utilities in the convenient synthesis of many other phenylpropanoids (26*d*, 27*c*).

[7] DDQ is a well-known dehydrogenating agent used to provide carbon–carbon double bonds in anhydrous (41) conditions and also used as an oxidizing agent to provide benzylic ketones in aqueous (45) conditions. However, formation of dehydrogenated product, α-asarone (11%), during oxidation of **2a** with DDQ and dioxane in wet conditions is a surprise finding.

Enhancement of aqueous solubility of itraconazole by complexation with cyclodextrins using supercritical carbon dioxide

Ibrahim Shehatta, Ali Hassan Al-Marzouqi, Baboucarr Jobe, and Ali Dowaidar

Abstract: The formation of inclusion complexes between itraconazole, a highly hydrophobic drug, and α-, β-, γ-, and hydroxylpropyl-β-cyclodextrin (HP-β-CD) were assessed using phase-solubility techniques. The solubility of itraconazole increased as a function of cyclodextrin concentration showing an AL phase diagram indicating the formation of soluble complexes with 1:1 stoichiometry. The Gibbs free energies of transfer of the drug from aqueous solution to the cavity of cyclodextrin are negative and increase in magnitude with increasing cyclodextrin concentration. The solubility of itraconazole, as well as the stability constant of its complex with HP-β-CD, are found to be affected by the pH of the medium. The HP-β-CD cavity was found to have a greater affinity for the unionized itraconazole than the protonated one. It was found that the interaction between the drug and the cyclodextrin is weakened as the medium becomes more apolar by the addition of methanol. Also, the size of the cavity of the cyclodextrins plays an important role in the association process. Furthermore, the thermodynamic parameters of the complexation process were calculated, by monitoring the isothermic solubility diagrams of itraconazole–HP-β-CD and itraconazole–β-CD at various temperatures, to gain information on the driving forces for the formation of inclusion complexes. Drug formulations of itraconazole were prepared by complexation of the drug into different cyclodextrins using supercritical carbon dioxide in a static mode. The effects of cyclodextrins on the prepared inclusion complexes were studied and characterized by differential scanning calorimetry.

Key words: cyclodextrin, itraconazole, inclusion complex, solubility, stability constant.

Résumé : Faisant appel à des techniques de solubilité de phase, on a évalué la formation de complexes d'inclusion entre l'itraconazole, un médicament fortement hydrophobe, et les α-, β- et γ-cyclodextrines et la hydroxypropyl-β-cyclodextrine (HP-β-CD). La solubilité de l'itraconazole augmente en fonction de la concentration de cyclodextrine en présentant un diagramme de phase AL qui indique la formation de complexes de stoechiométrie 1 : 1. Les énergies libres de Gibbs de transfert du médicament de la phase aqueuse à la cavité de la cyclodextrine sont négatives et leur valeur augmente en amplitude avec une augmentation de la concentration de cyclodextrine. On a observé que la solubilité de l'itraconazole ainsi que la constante de stabilité de son complexe avec la HP-β-CD sont affectées par le pH du milieu. On a trouvé que l'affinité de la cavité de la HP-β-CD pour l'itraconazole non ionisé est plus élevée que pour la forme protonée. On a trouvé que l'interaction entre le médicament et la cyclodextrine est affaiblie quand le milieu devient plus apolaire par addition de méthanol. De plus, la taille de la cavité des cyclodextrines joue un rôle important dans le processus d'association. De plus, dans le but d'obtenir des informations relatives aux facteurs influençant la formation des complexes d'inclusion, on a calculé les paramètres thermodynamiques du processus de complexation en évaluant les diagrammes de solubilité isothermes de l'itraconazole–HP-β-CD et de l'itraconazole–β-CD à diverses températures. Utilisant du bioxyde de carbone hypercritique en un mode statique, on a préparé des formulations d'itraconazole par complexation du médicament dans différentes cyclodextrines. On a étudié les effets des cyclodextrines sur les complexes d'inclusion préparés et on les a caractérisés par calorimétrie à balayage différentiel.

Mots clés : cyclodextrine, itraconazole, complexe d'inclusion, solubilité, constante de stabilité.

Introduction

Itraconazole is a broad-spectrum antifungal agent (1–3). However, some difficulties are encountered in preparing the pharmaceutical formulation of oral or injectable solutions owing to the very poor aqueous solubility of the drug at physiological pH conditions, leading to a minimal bioavailability (4). Itraconazole is a weak base (pK_a = 4.0) and

Fig. 1. Phase-solubility diagrams of itraconazole in phosphate buffer (pH 7.4) solution in the presence of different concentrations of α-CD (■), β-CD (●), γ-CD (▲), and HP-β-CD (◆) at 298.15 K.

poorly soluble in aqueous solutions (less than 1 μg/mL at pH values ranging from 1 to 12.7) (5). To overcome this problem, efforts must be made to improve the aqueous solubility of itraconazole.

The commercially available itraconazole capsules are highly effective for the treatment of superficial fungal maladies and disseminated infections. For good absorption, the itraconazole capsule should be administrated with food where gastric secretion is stimulated, leading to a low pH in the stomach allowing for drug dissolution and thereby improving bioavailability. Unfortunately, itraconazole is not effective for the treatment of AIDS and cancer patients. This is due to the inhibition or neutralization of gastric secretion, common in AIDS patients, leading to a decrease in the bioavailability of itraconazole. For insoluble drugs, the formulations involve the use of solvents, surfactants, microemulsion dosage forms, and (or) pH adjustment for ionizable drugs. However, these formulations are often found to cause some adverse reactions and to reduce the efficacy and safety of the drug. To enhance the efficacy and safety of antifungal drugs, another approach has been applied in which a cyclodextrin is used as a drug carrier.

Cyclodextrins are cyclic oligosaccharides consisting of six or more D(+)-glucopyranose units. They are linked to each other by α(1→4) bonds to form macrocyclic rings having the shape of a truncated hollow cone. The interiors, which are the sites for the guest molecules, are largely hydrophobic. Due to their ability to form inclusion complexes with lipophilic drugs and consequently changing their physicochemical and biopharmaceutical properties, cyclodextrins have great potential to be used as pharmaceutical excipients (6). Drug–cyclodextrin complexes have shown to improve the aqueous solubility, dissolution rates, chemical stability, and bioavailability of various drug molecules that are poorly soluble in water. In addition, the complexation may also mask unpleasant odors or tastes (7–9).

As a continuation of our previous work (10–18), the present work is undertaken to improve the solubility of itraconazole and thereby its bioavailability characteristics by complexation with cyclodextrins. Four different types of cyclodextrins (α-, β-, γ-, and hydroxypropyl-β-cyclodextrin (HP-β-CD)) were used. The thermodynamic parameters of itraconazole complexed with HP-β-CD and β-CD are calculated from the temperature dependence of the stability constant. Itraconazole–CD inclusion complexes are prepared using supercritical carbon dioxide (SC CO_2), which is a nontoxic, nonhazardous solvent. Properties of supercritical fluids (SCFs) can be changed from gaslike to liquidlike values by simply adjusting the pressure and temperature.

Experimental

Materials and reagents

Itraconazole was generously donated by the College of Pharmacy at Oregon State University. α-, β-, HP-β- and γ-CDs were obtained from Sigma-Aldrich Chemical Co. (Milwaukee, Wisconsin). All cyclodextrins were subjected to a thermogravimetric (TG) analysis to find the degree of hydration, which was considered in the calculations of their concentrations. The phosphate buffer solutions (pH 7.4) were prepared by adding appropriate amounts of orthophosphoric acid (0.2 mol/L) to trisodium phosphate (0.2 mol/L). All chemicals were reagent grade (Merck, Darmstadt) and were used as received. All solutions were prepared using deionized water (specific conductivity <2 μS cm^{-1}) and were used within 24 h. Bidistilled water was purified by using a Millipore Super Q system and was also degassed prior to the preparation of the solutions. The homogeneity of the initial solutions was assured by sonification for 15 min in an ultrasonic bath.

Solubility study

Solubility measurements were performed as described by Higuchi and Connors (19). Excess amounts of itraconazole were added to 10 mL of phosphate buffer solutions (pH 7.4) containing various concentrations of the cyclodextrins. The suspensions formed were sonicated for 15 min and then shaken for 3 days in a water bath (40 °C). After equilibrium was attained an aliquot was filtered through a Millipore

[a]A value of 785 (mol/L)$^{-1}$ was reported earlier for the stability constant of itraconazole–β-CD inclusion complex at 298.15 K (31).

membrane (0.45 μm). The filtered solutions were appropriately diluted, and the amount of dissolved itraconazole was determined via absorbance measurements in matched quartz cells using a Shimadzu UV-2101PC UV–vis scanning spectrophotometer at 265 nm. Previous determinations showed that the CDs did not interfere with the spectrophotometric measurements.

Preparation of inclusion complexes using supercritical carbon dioxide

The supercritical fluid experimental apparatus consisted of a 260 mL capacity syringe pump and controller system (ISCO 260D) and an ISCO series 2000 SCF extraction system (SFX 220) consisting of a dual-chamber extraction module with two 10 mL stainless steel vessels as discussed previously (17, 18). Temperature and pressure within the vessels were measured and could be independently adjusted. Inclusion experiments with SC CO_2 were performed using the SCF experimental apparatus similar to the procedures of Van Hees et al. (20). The 10 mL cell was filled with a physical mixture of itraconazole–cyclodextrin at a drug to cyclodextrin molar ratio of 1:2 (0.125 mmol drug : 0.25 mmol cyclodextrin). The system was pressurized and heated to the desired pressure and temperature and left in a static mode for 3 h. At the end of the process, the pressure in the cell was suddenly dropped to atmospheric pressure. The contents of the cell were ground and homogenized in a mortar.

Thermal analysis

Thermal characteristics of the products were determined using a differential scanning calorimeter (DSC 7, PerkinElmer) with a nitrogen flow rate of 40 mL/min and a heating rate of 10 °C/min from 50 to 250 °C.

Results and discussion

Effect of cyclodextrins on the aqueous solubility of itraconazole

The phase-solubility diagrams of itraconazole in different cyclodextrins were constructed by plotting the total dissolved itraconazole against the total concentration of the respective cyclodextrin. Figure 1 shows that all the studied cyclodextrins were able to increase the poor aqueous solubility of itraconazole. The aqueous solubility of the drug increased linearly as a function of the cyclodextrin concentration. Therefore, in the CD concentration range studied, the solubility diagrams can be classified as A_L type following the Higuchi and Connors classification (19). This would lead to the conclusion that soluble complexes were formed between the drug and the host substances. In aqueous solutions of itraconazole–CD complexes, the free drug molecules are in equilibrium with the drug molecules entrapped within the cavity. Thus, as the concentration of CD is increased, more itraconazole molecules will transfer from the aqueous solution to the hydrophobic cavity of CD. Therefore, one can expect that more itraconazole will dissolve in aqueous CD solutions than in pure water, and consequently, the solubility of itraconazole would increase when the concentration of CD is increased.

Table 3. Stability constant and the standard Gibbs free energy of complexation between itraconazole and HP-β-CD in the presence of various methanol concentrations at 298.15 K.

% (*v*/*v*) Methanol	K (mol/L)$^{-1}$	$-\Delta G°$ (kJ mol^{-1})
0	1168±101	17.51±0.22
5	1043±88	17.23±0.21
10	902±73	16.87±0.20
20	662±57	16.10±0.22
30	455±34	15.17±0.19
40	213±20	13.29±0.23

The Gibbs free energies of transfer of itraconazole from aqueous solution to the cavity of CD (Table 1) were calculated from the following equation:

$$[1] \qquad \Delta_{trans}G° = -RT \ln(S/S_o)$$

where S and S_o are the solubilities of itraconazole in the presence and absence of CD, respectively. As evident from Table 1, the $\Delta_{trans}G°$ values are negative and increase in magnitude with increasing CD concentration. This indicates that CD is a more favorable environment for itraconazole than water. Moreover, the interaction between itraconazole and CD increases as the CD content is increased. With regard to the linear solubility diagrams, a 1:1 itraconazole–CD formulation was suggested for the complex in the aqueous solutions of all the studied cyclodextrins (slope of the solubility diagram was smaller than 1 for each CD).

The apparent stability constants (K) were calculated from eq. [2] using the slope of the solubility diagrams.

$$[2] \qquad K = \text{slope}/S_o(1 - \text{slope})$$

© 2005 NRC Canada

As shown in Fig. 1 and Table 2, there were noticeable differences among the CDs, with respect to both the solubilization efficiency and the stability of their complexes with itraconazole. The apparent 1:1 stability constants for the complex of itraconazole with the studied cyclodextrins (Table 2) were within the range of 200–5000 $(mol/L)^{-1}$, suggesting that these cyclodextrins are suitable candidates for the improvement of bioavailability of poorly water-soluble drugs such as itraconazole (21).

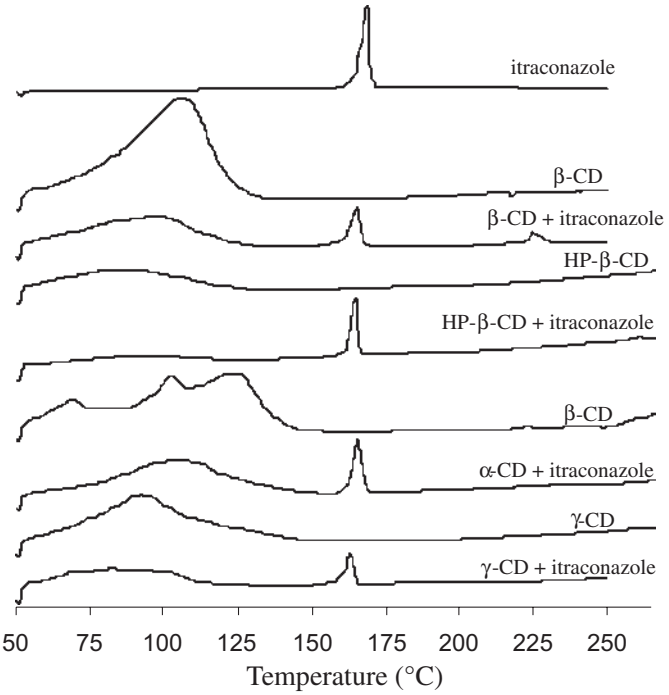
Effect of temperature

Since the stability constant is related to the Gibbs free energy ($\Delta G°$) of complexation, which has contributions from enthalpic ($\Delta H°$) and entropic ($\Delta S°$) terms, the estimation of these thermodynamic parameters may provide additional insight into the driving forces for complexation. Generally, a change in thermodynamic properties during CD complexation is an intricate phenomenon, resulting from changes in van der Waals interaction energy, hydrogen bonding, and hydrophobic interactions between the guest and cyclodextrin.

The thermodynamic parameters for inclusion processes were determined from the temperature dependence of the stability constants using van't Hoff plots ($\ln(K)$ vs. $1/T$). These plots for itraconazole–HP-β-CD and itraconazole–β-CD complexes were linear (plots not presented here) with correlation coefficients ≥0.99 within the temperature range considered in the present study, indicating that the changes in the heat capacity could be safely neglected.

The standard Gibbs free energy change of the binding was calculated using the following relation:

$$[3] \qquad \Delta G° = -RT \ln K = \Delta H° - T\Delta S°$$



where $\Delta H°$ and $\Delta S°$ can be deduced from the slope and intercept of the van't Hoff plots, respectively. The stability constants of itraconazole–HP-β-CD and itraconazole–β-CD at 288, 293, 298, 303, and 308 K, as well as the corresponding thermodynamic parameters ($\Delta G°$, $\Delta H°$, and $\Delta S°$) are listed in Table 2. In view of the values shown in Table 2, it appears that

(1) the K values decrease with increasing temperature because the formation of the complexes is exothermic ($\Delta H° < 0$);
(2) the negative value of $\Delta G°$ suggests that complexation is thermodynamically favored; and
(3) the drug binds to CD with a favorable enthalpic term ($\Delta H° < 0$) and an unfavorable entropic term ($\Delta S° < 0$).

Effect of pH

The influence of pH on the apparent stability constant of the itraconazole–HP-β-CD inclusion complex, as a representative example, and on the efficacy of the solubility-enhancing effect was studied. A decrease in pH resulted in a decrease in the apparent stability constant (K = 1168 $(mol/L)^{-1}$ at a pH of 7.4; whereas at a pH of 2, K = 310 $(mol/L)^{-1}$) indicating that for the itraconazole–HP-β-CD complex K was larger in the less protonated form (pK_a = 4.0). Thus, the inclusion process with itraconazole was more favorable than that with itraconazoleH$^+$. At pH 2, the slope of the phase-solubility diagram and the S_o value (the solubility of itraconazole in the absence of CD) were larger than the corresponding values for a solution with pH of 7.4. At the lower pH, itraconazole, which is a basic drug, is present in the protonated form and is more water-soluble (has a weaker interaction with CD) than the unionized form of itraconazole (22, 23). This is in accordance with the fact that when the drug aqueous solubility increases, the K value decreases as a result of decreasing hydrophobicity of the drug (24).

Fig. 2. DSC curves of pure itraconazole, pure cyclodextrins, and itraconazole–CD (1:2) complexes prepared by the SC CO_2 method at 130 °C, 3 h of static mode, and 45 MPa.

Effect of solvent

To evaluate the effect of the medium on apolar host–guest associations, the K values of itraconazole–HP-β-CD were determined at 298.15 K in the presence of different methanol concentrations. Methanol was selected owing to its low affinity for binding with CD (25), thus making it a poor competitor for CD compared with itraconazole. Therefore, all the effects observed in the presence of methanol can be attributed only to a change in the solvophobic characteristics of the medium.

As illustrated in Table 3, the change in the Gibbs free energy decreased negatively as the hydrophobicity of the medium increased owing to the increase in percentage of methanol. This reveals a clear contribution of the hydrophobic effect as a driving force of complexation. Therefore, water is the best solvent for inducing strong association between apolar binding partners, and this property is essential for sustaining all functions of life.

Obviously, on the basis of the previous discussion one can conclude that the formation of a complex between itraconazole and CD is hydrophobically driven. On the other hand, although the hydrophobic interaction is characterized (26) by $\Delta H° \approx 0$ and $\Delta S° > 0$, the derived enthalpy and entropy changes (Table 2) do not agree with those expected for the classical hydrophobic interaction. Similar results (27, 28) were obtained for association between guest molecules and

© 2005 NRC Canada

an apolar cavity in water. These processes are exothermic and enthalpy driven ($|\Delta H°| > T|\Delta S°|$). This suggests that forces other than hydrophobic interactions significantly contribute to the stabilization of itraconazole–CD complexes. Such processes have been considered as nonclassical hydrophobic interactions. The favorable $\Delta H°$ values may be a result of the van der Waals interaction ($\Delta H° < 0$ and $\Delta S° < 0$) of the host and guest molecules. Another contribution to the favorable $\Delta H°$ values comes from the changes in the behavior of water associated with the host and guest molecules, the replacement of the incorporated water molecules (unstable) from the CD cavity by the drug and (or) the conformational change of CD (29). Lewis and Hansen (30) attributed the large enthalpy change to the formation of hydrogen bonds between water molecules displaced from the cyclodextrin cavity, which become bulk water and form hydrogen bonds. The unfavorable entropy change results from the greater ordering of the displaced water molecules from the cyclodextrin cavity.

Effect of cyclodextrin size

Because the cyclodextrin cavity has a fixed size, only the compounds with a similar molecular size and an appropriate structure could be included into the cavity. Other compounds with larger or smaller size or inappropriate structure could only achieve partial inclusion, causing decreased solubilization.

The stability of inclusion complexes between itraconazole and different cyclodextrins was in the following order: HP-β-CD > β-CD > γ-CD > α-CD (Table 2). This fact emphasizes the importance of the size–fit relation between the host and the guest in the complexation process. Also, the side chain substitutions of β-CD have a remarkable effect on the binding of itraconazole.

The K value of itraconazole–β-CD complexes is in good agreement with the literature value (K = 785 $(mol/L)^{-1}$) (31). The interaction of itraconazole with α- and γ-CDs was weak, as expressed by the lower K values (284 and 453 $(mol/L)^{-1}$, respectively), compared with β-CD. Higher stability constants were observed for β-CD and its substituted derivative, confirming that itraconazole interacts more strongly with these CDs than with α- or γ-CDs. Obviously the higher stability constants reflect a favorable positioning of the guest molecule inside the cavity of the CD host molecule (32). Therefore, the itraconazole structure is not compatible with the internal cavity of α- or γ-CD. These cavities are too small to allow penetration or too large to allow a close fit, respectively. Interaction of itraconazole with β- and HP-β-CD is more sterically favorable than with α- or γ-CD. Diaz et al. (33) reached similar conclusions for drug–CD complexation. The highest stability constant was found for the inclusion complex between itraconazole and HP-β-CD. This may be due to the fact that alkyl chains may provide additional hydrophobic binding sites, thus interacting with hydrophobic portions of itraconazole outside the cyclodextrin cavity (34).

Analysis of inclusion complexes prepared by supercritical carbon dioxide

Our previous results showed that the solubility of itraconazole in SC CO_2 is a function of temperature and pressure, and the maximum solubility (96.86 μg/g of CO_2) was obtained at 130 °C and 45 MPa (18). Although inclusion complexes were prepared using SC CO_2 at different temperatures and pressures, the maximum inclusion yield was obtained at 130 °C and 45 MPa (CO_2 density = 0.70321 g/mL). Therefore, the results presented here are for this optimum condition.

Preliminary studies showed that increasing the exposure time ensured a higher inclusion yield. Therefore, 3 h was selected as the exposure time in this investigation. Van Hees et al. (20) also mentioned that such a long exposure time is required to ensure a better inclusion yield for piroxicom–β-cyclodextrin inclusion complexes.

DSC curves for pure itraconazole, pure cyclodextrins, as well as itraconazole–CD (1:2) products obtained by physical mixing and the SC CO_2 method at 130 °C (3 h of exposure and 45 MPa) are shown in Fig. 2. Pure itraconazole showed a sharp melting endotherm at 165.2 °C. Pure β-CD showed two peaks: a broad endothermal effect, ranging between 50 and 150 °C corresponding to the dehydration of β-CD and a second peak at 219 °C characteristic of pure β-CD, which was also observed by other authors (35). In the product obtained by the SC CO_2 method, the endothermal peak for β-CD disappeared and a new peak with a different shape appeared at about 226 °C (approximately 7 °C higher than that of β-CD), which is most likely attributed to the formation of an inclusion complex. The endothermic peak corresponding to pure itraconazole, although reduced in size, was observed, indicating an incomplete inclusion of the drug in the cyclodextrin cavity.

The formation of an inclusion complex depends on the extent of the solubility of cyclodextrin and itraconazole in CO_2. As mentioned previously, the solubility of itraconazole in CO_2 is very low (96.86 μg/g of CO_2) and cyclodextrin is also expected to have a low solubility in CO_2, since it is a large polar molecule. The composition of mixtures in the cell containing CO_2, cyclodextrin, and itraconazole at 130 °C and 45 MPa was estimated to be between 93 and 95 wt% CO_2 for different cyclodextrin mixtures. However, this amount of CO_2 would only dissolve a small portion of itraconazole and cyclodextrin present in the cell, resulting in incomplete inclusion of itraconazole by cyclodextrin. This is in agreement with the DSC curves shown in Fig. 2 and the UV analysis of the inclusion complexes, which indicated an inclusion yield of about 8.28% for the case of the β-cyclodextrin–itraconazole system (18). The inclusion yield could be enhanced by increasing the wt% of CO_2 in the mixture or by the addition of a solvent, which enhances the solubility of the cyclodextrin and itraconazole in CO_2. The later option is now under investigation.

Pure HP-β-CD showed one broad endothermal peak, ranging between 50 and 150 °C, corresponding to the dehydration of HP-β-CD. No peak corresponding to pure HP-β-CD was observed. In the product obtained by the SC CO_2 method a small peak appeared at about 260.5 °C, which is probably attributed to the formation of an inclusion complex.

DSC curves for the products containing α- or γ-CD prepared by the SC CO_2 method did not show any new peaks, indicating no drug–CD interactions and thus no formation of inclusion complexes. This is expected, since the structure of itraconazole is not compatible with the internal cavity of α- or γ-CD, as was observed by the lower solubility and stabil-

© 2005 NRC Canada

ity constants of itraconazole with α- and γ-CD compared with β- and HP-β-CD. As mentioned earlier, this can be explained by the fact that the cavity of α-CD is too small to allow penetration and the cavity of γ-CD is too large to allow a close fit with itraconazole. Although the solubility and stability constant of itraconazole with HP-β-CD are higher than those of itraconazole with β-CD, DSC curves show a smaller inclusion complex in the product containing HP-β-CD. This is unexplained up to now and other analytical techniques (i.e., UV spectroscopy for determination of inclusion yield) are underway to explain this discrepancy.

Conclusions

Phase-solubility techniques were used to assess the formation of inclusion complexes between itraconazole and four different cyclodextrins (α-, β-, γ-, and HP-β-CD). The stability constant and thermodynamic parameters of the complexation process were calculated. The effects of cyclodextrin size and side chains, temperature, pH, and solvent on drug–cyclodextrin interactions were studied. The results showed that each cyclodextrin significantly improves the solubility of itraconazole in aqueous solutions according to the order HP-β-CD > β-CD > γ-CD > α-CD. Moreover, the inclusion process with itraconazole is more favorable than that with itraconazoleH^+, and the formation of the inclusion complex between itraconazole and CD is hydrophobically driven.

Itraconazole–cyclodextrin formulations were prepared by complexation of the drug into different cyclodextrins using SC CO_2. The solvent-free inclusion complexes obtained by this method were characterized by differential scanning calorimetry. No inclusion complexes were indicated by the DSC curves for drug formulations containing α- or γ-CD, while inclusion complexes were observed for drug formulations containing β- and HP-β-CD. The DSC curves showed higher inclusion in the product containing β-CD than that containing HP-β-CD. Itraconazole produced using SC CO_2 should provide minimal side effects in the human body since this method has no toxic solvent residuals. The SC CO_2 method will be tested at other conditions (varying exposure time and drug:cyclodextrin ratio). Efficacy, safety, and pharmacokinetics of the new inclusion complexes obtained by SC CO_2 will be investigated in both in vitro and in vivo. This method will also be tested on other drugs.

Gas-phase reactions of atomic lanthanide cations with methyl chloride — Periodicities in reactivity[1]

Xiang Zhao, Gregory K. Koyanagi, and Diethard K. Bohme

Abstract: Room temperature reactions of lanthanide atomic cations (excluding Pm^+) with CH_3Cl are surveyed systematically in the gas phase using an inductively coupled plasma/selected-ion flow tube (ICP/SIFT) tandem mass spectrometer. Reaction rate coefficients are reported along with product distributions in He at 0.35 Torr (1 Torr = 133.3224 Pa) and 295 K. Cl atom transfer is the predominant reaction channel observed with all 14 lanthanide cations, but minor CH_3Cl addition also occurs with the late lanthanide cations Dy^+, Ho^+, Er^+, Tm^+, and Yb^+. The reaction efficiency for Cl atom transfer is shown to be governed by the energy required to promote an electron to achieve a d^1s^1 excited electronic configuration in which two non-f electrons are available for bonding: it decreases as the promotion energy increases and the periodic trend in reaction efficiency along the lanthanide series matches the periodic trend in the corresponding electron-promotion energy. This behaviour is consistent with a C—Cl bond insertion mechanism of the type proposed previously for insertion reactions of Ln^+ cations with hydrocarbons and methyl fluoride. Direct Cl atom abstraction by a harpoonlike mechanism was excluded because of an observed noncorrelation of reaction efficiency with IE(Ln^+). A remarkable Arrhenius-like correlation is observed for the dependence of reactivity on promotion energy: the early and late lanthanide cations exhibit characteristic temperatures of $(1.4 \pm 0.2) \times 10^4$ and $(4.5 \pm 0.3) \times 10^3$ K, respectively. A rapid second Cl atom transfer occurs with $LaCl^+$, $CeCl^+$, $GdCl^+$, $TbCl^+$, and $LuCl^+$, but there was no evidence for a third chlorine atom abstraction with any of the $LnCl_2^+$ cations. Both $LnCl^+$ and $LnCl_2^+$ add up to five methyl chloride molecules under the experimental operating conditions of the ICP/SIFT tandem mass spectrometer.

Key words: lanthanide cations, Cl atom transfer, electron promotion, methyl chloride.

Résumé : Faisant appel à un spectromètre de masse en tandem avec plasma à couplage induit/tube d'écoulement d'ion choisi (« ICP/SIFT »), on a étudié d'une façon extensive les réactions en phase gazeuse et à la température ambiante du CH_3Cl avec les cations atomiques des lanthanides, à l'exception du Pm^+. On a mesuré les coefficients des vitesses réactionnelles ainsi que les distributions des produits dans He, à 0,35 Torr (1 Torr = 133,3224 Pa) et à 295 K. On a observé que le transfert d'un atome de chlore est la voie réactionnelle prédominante pour les quatorze cations de lanthanides, mais il se produit aussi une faible addition de CH_3Cl avec les derniers cations de lanthanides, Dy^+, Ho^+, Er^+, Tm^+ et Yb^+. On a démontré que l'efficacité de la réaction de transfert de l'atome de chlore est gouvernée par l'énergie requise pour faire passer un électron à la configuration électronique excitée d^1s^1 dans laquelle deux électrons non-f sont disponibles pour créer une liaison: elle diminue avec une augmentation de l'énergie nécessaire pour atteindre ce niveau et la tendance périodique observée dans l'efficacité de la réaction dans la série des lanthanides suit bien la tendance dans l'énergie correspondante nécessaire pour la promotion de l'électron. Ce comportement est en accord avec le type de mécanisme d'insertion dans une liaison C—Cl qui a été suggéré antérieurement pour les réactions d'insertion des cations de Ln^+ dans les hydrocarbures et le fluorure de méthyle. On a exclu un mécanisme de type harpon avec enlèvement direct d'un atome de chlore en raison du manque de corrélation qui a été observé pour la dépendance de la réactivité sur l'énergie de promotion: les cations du début et de la fin de la série des lanthanides des températures caractéristiques de $(1{,}4 \pm 0{,}2) \times 10^4$ et $(4{,}5 \pm 0{,}3) \times 10^3$ K, respectivement. Un deuxième transfert rapide d'un atome de chlore se produit avec le $LaCl^+$, le $CeCl^+$, le $GdCl^+$, le $TbCl^+$ et le $LuCl^+$, mais on n'a pas trouvé de données pouvant supporter un troisième transfert d'un atome de chlore à partir d'un cation quelconque de $LnCl_2^+$. Le $LnCl^+$ et le $LnCl_2^+$ ajoutent chacun jusqu'à cinq molécules de chlorure de méthyle dans les conditions expérimentales d'opération du spectromètre de masse en tandem ICP/SIFT.

Mots clés : cations de lanthanides, transfert d'atomes de chlore, promotion d'un électron, chlorure de méthyle.

Introduction

Recent laboratory measurements have shown that the unique electronic configurations of lanthanide cations lead to unique trends in the kinetics of chemical bond activation by these cations across the periodic table. As early as 1988, Shilling and Beauchamp (1) proposed that electron promotion from the $4f^n6s^1$ ground state to the $4f^{n-1}5d^16s^1$ excited state was required for these cations to be effective in C—H and C—C bond activation and insertion. A plethora of investigations into lanthanide ion chemistry followed, in part to further characterize this requirement, but also motivated by general interests in the gas-phase and solution chemistry of lanthanides (2). Reactions of Ln^+ cations now have been investigated systematically with various inorganic and organic molecules, including hydrogen (3), oxygen (4), nitrous oxide (4), alkanes and cycloalkanes, alkenes (1, 5, 6), alcohol (7–9), benzene and substituted benzenes (10, 11), phenol (12), orthoformates (10, 13), ferrocene, and iron pentacarbonyl (14). Generally these studies show that the reactivity of Ln^+ varies along the 4f series often in a manner that appears to be determined by the accessibility, through electron promotion, of excited electronic configurations of the Ln^+ cations with two unpaired non-f electrons. Results with N_2O (4), O_2 (4), and CH_3F (15) have also revealed intriguing Arrhenius-like dependencies of the reactivity of the Ln^+ cation on the electron promotion energy, which exhibit different characteristic temperatures for the early and late lanthanide cations.

Here we present a survey of gas-phase reactions of all the lanthanide cations (except Pm^+, which does not have a stable isotope) using inductively coupled plasma/selected-ion flow tube (ICP/SIFT) tandem mass spectrometry (4, 16, 17). The aim of this work is to expand on our previous studies of gas-phase reactions of lanthanide cations with CH_3F (15). We are not aware of any previous studies of reactions of atomic lanthanide cations with chlorinated hydrocarbons.

Experimental section

The experiments were performed with the ICP/SIFT tandem mass spectrometer that has been described in detail previously (4, 16, 17). The atomic ions were generated within an atmospheric pressure argon plasma at 5500 K fed with a vaporized solution containing the lanthanide salt. The ions emerging from the ICP were injected through a differentially pumped sampling interface into a quadrupole mass filter and after mass analysis, introduced through an aspiratorlike interface into flowing helium carrier gas at 0.35 Torr (1 Torr = 133.3224 Pa) and 295 ± 2 K. After experiencing about 10^5 collisions with He atoms, the ions were allowed to react with CH_3Cl added into the flow tube.

The lanthanide ions emerging from the plasma initially have a Boltzmann internal energy distribution characteristic of the plasma temperature. However, these emerging hot populations are expected to be downgraded during the approximately 20 ms duration before entry into the reaction region in the flow tube. Energy degradation can occur by radiative decay as well as by collisions with argon atoms and the 10^5 collisions with He before entry into the reaction region. The extent to which quenching of any electronically excited states of the lanthanide cations that may be formed within the ICP is complete is uncertain and could be inferred only indirectly from the observed decays of primary ion signals. The observed semilogarithmic decays of the reacting lanthanide cations were invariably linear, often over as much as four decades of ion depletion, and so were indicative of single-state populations. This was also the case in our earlier studies with methyl fluoride (15). The many collisions with Ar and He between the source and the reaction region should ensure that the atomic ions reach a translational temperature equal to the tube temperature of 295 ± 2 K prior to entering the reaction region.

Reactant and product ions were sampled at the end of the flow tube with a second quadrupole mass filter and were measured as a function of added reactant. The resulting profiles provide information about reaction rate coefficients and product–ion distributions. Rate coefficients for primary reactions were determined with an uncertainty estimated to be less than ±30% from the semilogarithmic decay of the reactant ion intensity as a function of added reactant.

Methyl chloride was introduced into the reaction region of the SIFT as a dilute mixture in helium (~10%). The methyl chloride was obtained commercially and was of high purity (Matheson Gas Products, Whitby, Ontario, 99.5%).

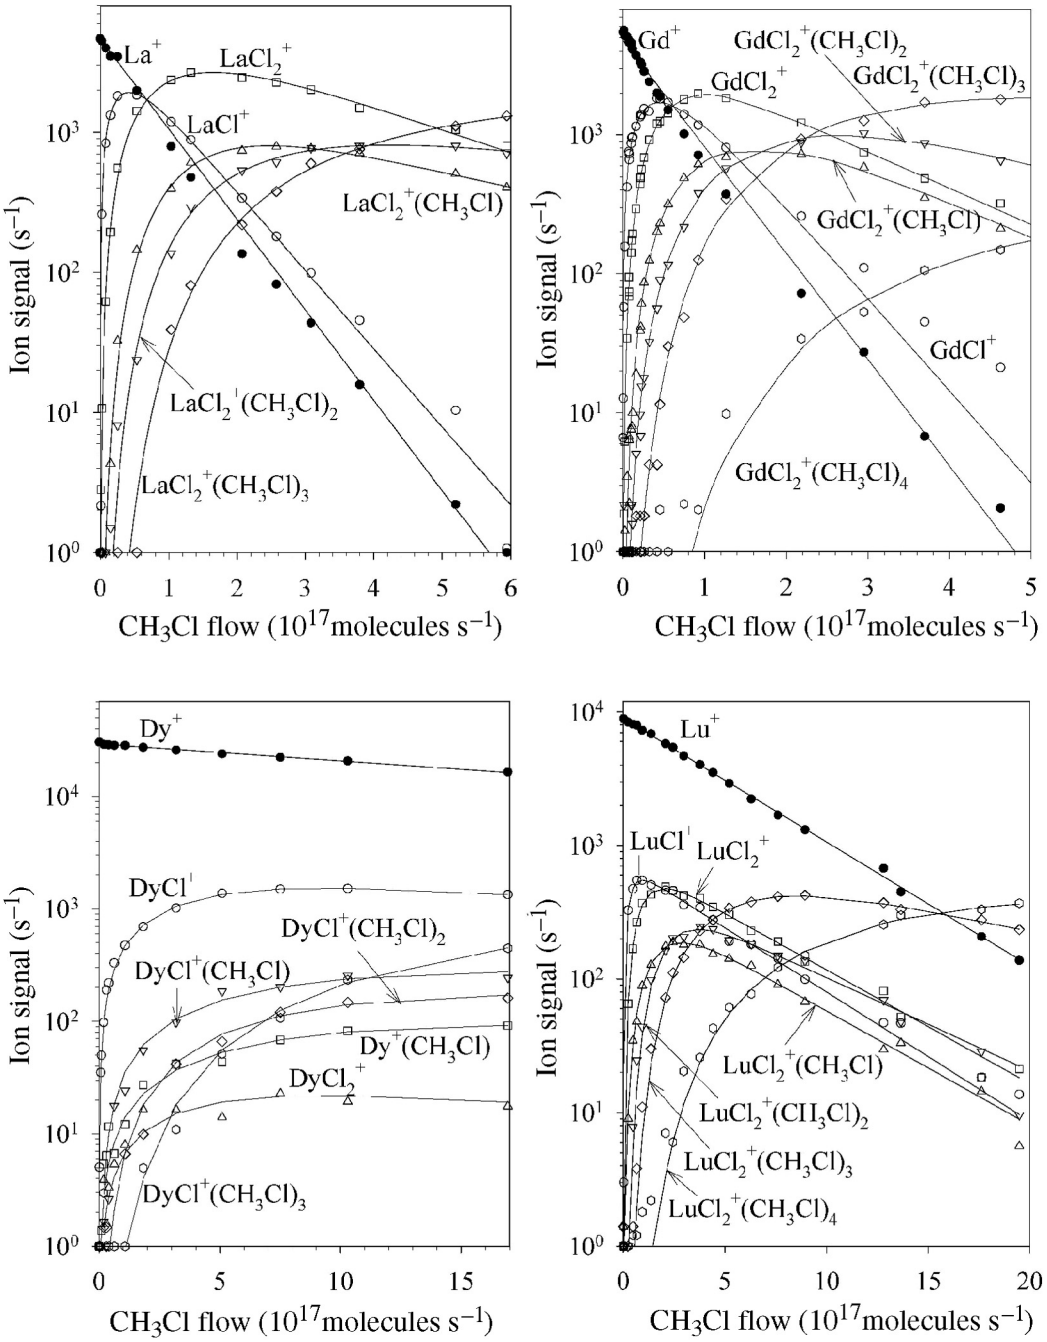
Results and discussion

The reactions of 14 lanthanide cations were investigated with CH_3Cl. Both the primary and higher order reactions were monitored. Results obtained for the reactions of La^+, Gd^+, Dy^+, and Lu^+ are shown in Fig. 1. Table 1 summarizes the measured rate coefficients, reaction efficiencies, and product distributions. The reaction efficiency is taken to be equal to the ratio k/k_c, where k is the experimentally measured rate coefficient and k_c is the capture or collision rate coefficient. k_c was computed using the algorithm of the modified variational transition-state/classical trajectory theory developed by Su and Chesnavich (18) with $\alpha(CH_3Cl) = 4.72 \times 10^{-24}$ cm^3 (19) and $\mu_D(CH_3Cl) = 1.896$ D (19).

Only Cl atom transfer (rxn. [1*a*]) and adduct formation (rxn. [1*b*]) were observed as primary reaction channels.

$$[1a] \quad Ln^+ + CH_3Cl \rightarrow LnCl^+ + CH_3$$

$$[1b] \quad \rightarrow Ln^+(CH_3Cl)$$



Adduct formation is a minor channel (≤30%) and was observed to compete only with the late Ln^+ cations Dy^+, Ho^+, Er^+, Tm^+, and Yb^+. As expected from the much lower first ionization energy of the lanthanides (IE(Ln)), all <6.3 eV, than that for CH_3Cl (11.29 eV) (20), electron transfer was not observed with any of the Ln^+ cations. The C—H bond activation channel (rxn. [1*c*]) is not competitive because it is quite endothermic since $D(H\text{-}CH_2Cl) >> HA(Ln^+)$, the H-atom affinity of the atomic lanthanide ions. $D(H\text{-}CH_2Cl) = 100.2 \pm 0.6$ kcal mol^{-1} (19), whereas, for example, $HA(La^+) = 57.1 \pm 2.8$ kcal mol^{-1} and $HA(Lu^+) = 48.8 \pm 3.6$ kcal mol^{-1} (21).

$$[1c] \quad Ln^+ + CH_3Cl \rightarrow LnH^+ + CH_2Cl$$

A fast ($k \geq 1.4 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) second chlorine atom abstraction (rxn. [2]) was observed with $LaCl^+$ (25), $CeCl^+$ (28), $GdCl^+$ (16), $TbCl^+$ (14), $DyCl^+$ (1.4), $HoCl^+$ (2.3), and $LuCl^+$ (17), where the rate coefficient is

Fig. 1. Composite of ICP/SIFT results for the reactions of the lanthanide metal ions La^+, Gd^+, Dy^+, and Lu^+ with CH_3Cl in helium buffer gas at 0.35 ± 0.01 Torr (1 Torr = 133.3224 Pa) and 295 ± 2 K.

given in parentheses in units of 10^{-10} cm^3 $molecule^{-1}$ s^{-1}. These rate coefficients were obtained by curve fitting of the ion profiles for $LnCl^+$ and are less accurate than those for the primary reactions (the first few have values above k_c). The remaining $LnCl^+$ cations react with CH_3Cl with rate coefficients equal to or less than that measured for the first abstraction. No third Cl atom abstraction was observed with any of the $LnCl_2^+$ cations.

[2] $LnCl^+ + CH_3Cl \rightarrow LnCl_2^+ + CH_3$

CH_3Cl addition according to rxn. [3] was also observed for almost all of the lanthanide chloride cations. These addition reactions are expected to be termolecular with He buffer – gas atoms acting as the stabilizing third body.

[3] $LnCl_m^+(CH_3Cl)_n + CH_3Cl \rightarrow LnCl_m^+(CH_3Cl)_{n+1}$ $(m = 0–2)$

Secondary and higher order CH_3Cl addition was observed for $LnCl^+$ = $YbCl^+$ (m = 1, n = 0 to 1), $PrCl^+$, $DyCl^+$ (m = 1, n = 0–2), $NdCl^+$, $SmCl^+$, $EuCl^+$, $HoCl^+$ (m = 1, n = 0–3), $PrCl^+$ (m = 1, n = 1–4), and $LnCl_2^+$ = $LaCl_2^+$ (m = 2, n = 0–2), $CeCl^+$, $PrCl^+$, $GdCl_2^+$, $HoCl_2^+$, $LuCl_2^+$ (m = 2, n = 0–3). Table 1 includes a listing of all the higher order prod-

uct ions that were observed. The higher order chemistry initiated by La^+, Gd^+, Dy^+, and Lu^+ can be tracked in Fig. 1.

Periodicities in reaction efficiencies

The primary CH_3Cl reaction efficiencies of the 14 Ln^+ cations change dramatically along the 4f row. The efficiencies of the reactions of La^+ (0.62), Ce^+ (0.55), and Gd^+ (0.59) are all higher than 0.50, and it is interesting to note that these cations all have two non-f electrons in their electronic ground state. In contrast, the efficiencies of the reactions of the early lanthanide cations Sm^+ (0.064) and Eu^+ (0.019) are ≤0.1 and those of the late lanthanide cations Dy^+ (0.013), Ho^+ (9.5×10^{-3}), Er^+ (7.7×10^{-3}), Tm^+ ($\leq 6.0 \times 10^{-4}$), and Yb^+ ($\leq 6.0 \times 10^{-4}$) are all <0.02, near or below the detection limit. An overview of the variation in reaction efficiency across the lanthanide series is included in Fig. 2.

Thermodynamics of Cl atom abstraction

Cl atom abstraction was observed with all the lanthanide cations. Rate coefficients measured for Cl atom abstraction are in the range $\leq 1.0 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} (for Tm^+ and Yb^+) to 1.1×10^{-9} cm^3 molecule^{-1} s^{-1} (for La^+). Assuming that only exothermic or thermoneutral reaction can be observed under our experimental operating conditions, we estimate that the chlorine atom affinity ($ClA(Ln^+)$) is higher than $ClA(CH_3)$ = 83.7 kcal mol^{-1} (19) for all the lanthanide cations investigated. Unfortunately, no Cl atom affinities appear to be available for any lanthanide cations, either from theory or from experiment. The lower limit of 83.7 kcal mol^{-1} for the 14 lanthanide cations investigated therefore represents the first such determination.

Mechanism for Cl atom abstraction by Ln^+

Two mechanisms have been proposed for the reactions of lanthanide cations with fluorinated hydrocarbons (22): a harpoonlike abstraction and C—F bond insertion. The first mechanism involves the transfer of an electron within the encounter complex $LnFR^+$, perhaps at long range, from the lanthanide cation to the fluorinated substrate. This favors the homolytic cleavage of the C—F bond to form LnF^+ according to rxn. [4]. The reaction efficiency predicted by this mechanism should correlate with the second ionization energy of Ln ($IE(Ln^+)$) as has been proposed by Cornehl et al. (22) in their attempt to account for their measured reaction rates with fluoromethane, 1,1-difluoroethane, fluorobenzene, and hexafluorobenzene.

$$[4] \qquad Ln^+ + R\text{-}F \rightarrow [Ln^+\cdots F\text{-}R \rightarrow Ln^{2+}\text{-}F^-\cdots R] \rightarrow LnF^+ + R$$

In the C—F bond insertion mechanism, a cyclic ion complex is initially formed, which is then transformed through a three-centre transition state into a complex in which Ln^+ is

Fig. 2. Reaction efficiency (closed circle for CH_3Cl and left ordinate axis) and the energy required to promote an electron and leave the Ln^+ cation in a d^1s^1 configuration (solid square and right ordinate axis) plotted along the lanthanide row of elements. There is an apparent correlation between reaction efficiency and electron promotion energy.

inserted into the R—F bond. The inserted complex can then eliminate the LnF^+ and R species. This mechanism requires that at least two Ln^+ electrons reside in non-f valence orbitals. The reaction efficiency predicted by this mechanism should correlate with the $4f^n6s^1$ to $4f^{n-1}5d^16s^1$ promotion energy (E_p). Our previous measurements of reactions of lanthanide cations with CH_3F provide reactivity correlations that demonstrate a preference for the C—F bond insertion mechanism, which also has been shown to apply to hydrocarbon activation by Ln^+ (1).

The experimental results reported here clearly show that the ability of Ln^+ to abstract a chlorine atom from methyl chloride does not correlate well with the second IE of the lanthanide (see Table 2 and Fig. 3). So we cannot assign a harpoonlike Cl abstraction mechanism to these reactions with CH_3Cl on the basis of such a correlation.

Our experimental results indicate that La^+ ($5d^2$) with two non-f valence electrons exhibits the highest efficiency for Cl atom abstraction followed closely by Gd^+ ($4f^75d^16s^1$) and Ce^+ ($4f^15d^2$) all of which also have two non-f valence electrons. The reactivities of the remaining Ln^+ cations (except Lu^+), all of which have available only one non-f electron (s^1), are all less and decrease along the early and late lanthanide series. So apparently the s electron at most plays a small role in determining these reactivities. Indeed, as shown in Figs. 2 and 4, these decreasing reactivities correlate well with the variation in the electron-promotion energy of Ln^+ required to achieve a $4f^{n-1}5d^16s^1$ configuration. Thus, f to d electron promotion appears crucial for the efficient occurrence of Cl atom transfer. This correlation indicates that two non-f electrons are required for Cl atom abstraction from CH_3Cl and that the reaction occurs via a C—Cl bond insertion mechanism. We note that the trend exhibited in Fig. 4 is remarkably similar to that presented by Cornehl et al. (23) for reactions of Ln^+ cations with saturated and unsaturated hydrocarbons and to that we have reported for reactions of Ln^+ with methyl fluoride (15) for which a C—X (X = C, H, or F) bond insertion mechanism also has been advanced. The small amounts of $Ln^+(CH_3Cl)$ adduct ions observed with the late lanthanide cations may be collisionally stabilized remnants of the inserted reaction intermediate. It is interesting to see that Lu^+, although having two electrons in non-f orbitals ($4f^{14}6s^2$), has a much lower reaction efficiency compared with La^+, Ce^+, and Gd^+; this can be attributed to the closed 6s and 4f subshells of Lu^+.

Inspection of our results for the addition of another Cl atom to $LnCl^+$ in a second reaction with CH_3Cl indicates that the second Cl atom transfers are fast ($k > 1.4 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) with those Ln^+ cations with low

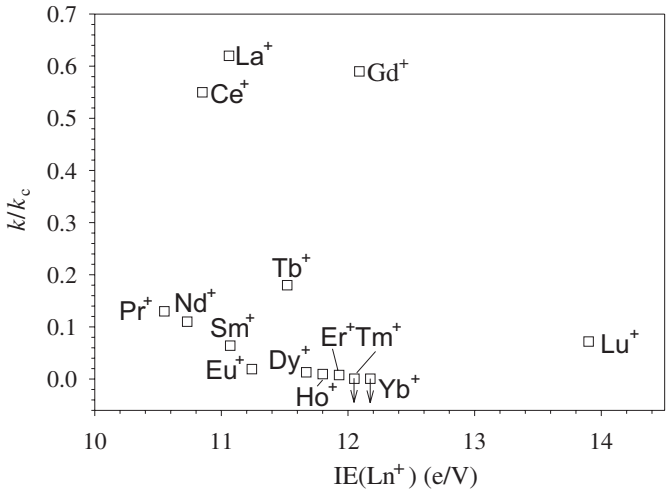
Fig. 3. The dependence of the efficiencies for Cl atom abstraction in reactions of Ln^+ with CH_3Cl on the second ionization energy of Ln ($IE(Ln^+)$).



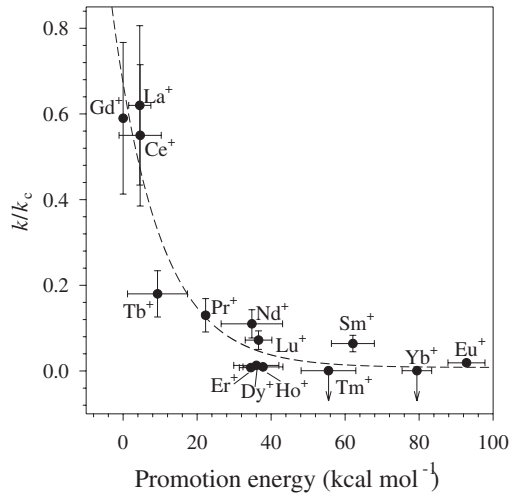


Fig. 4. Correlation of reaction efficiency for Cl atom abstraction from CH_3Cl with the energy E_p required to promote an electron and leave the Ln^+ cation in a d^1s^1 configuration. The dashed curve represents a fit with $k/k_c = 0.0081 + 0.66 \exp(-0.078E_p)$.

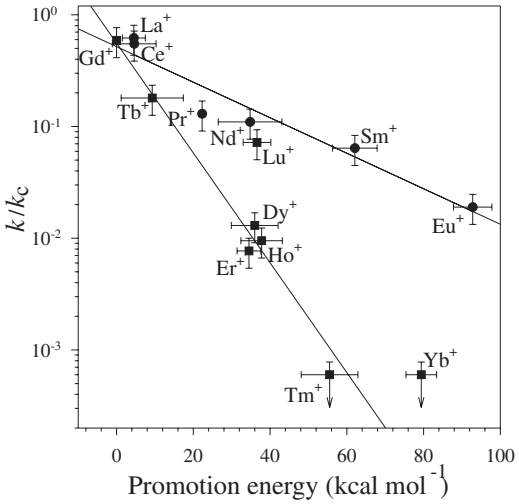
promotion energies (E_p < 9.3 kcal mol^{-1}) and slow (k < 5.4 × 10^{-11} cm^3 molecule^{-1} s^{-1}) with those Ln^+ cations with high promotion energies (E_p > 92.8 kcal mol^{-1}). Such a reactivity pattern again is not inconsistent with an insertion mechanism that requires two unpaired valence electrons.



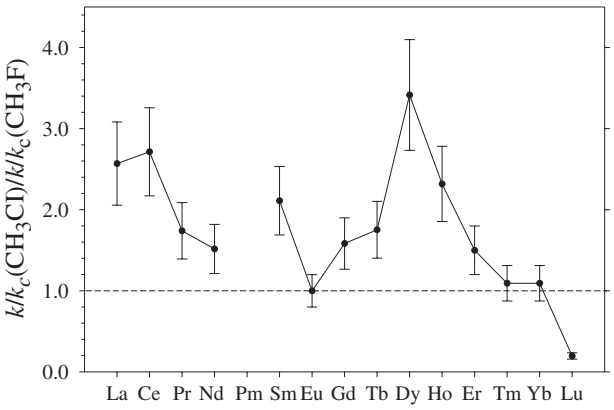
Arrhenius-like plots

Figure 5 demonstrates, in an Arrhenius-like plot, that the reaction efficiency of the Ln^+ reactions with CH_3Cl, here measured at constant temperature (295 K), exhibits an exponential dependence on the promotion energy according to eq. [5].

$$[5] \qquad k/k_c = \exp(-XE_p)$$

A remarkable aspect of these results is the distinct difference in this dependence between the early and late lanthanide ions. If interpreted as $1/RT_{eff}$, the slopes of the

Fig. 5. Correlation of reaction efficiency with the electron promotion energy that is proposed to be required for Ln^{2+}—Cl^- bond formation in the reactions of early and late Ln^+ ions with CH_3Cl. Lu^+ clearly is an exception to the trend observed for the late Ln^+ ions. The slopes of these van't Hoff-like plots provide characteristic temperatures of (1.4 ± 0.2) × 10^4 and (4.5 ± 0.3) × 10^3 K for Cl atom abstraction with the early and late lanthanide cations, respectively.



semilogarithmic plots in Fig. 5 indicate "characteristic temperatures" of (1.4 ± 0.2) × 10^4 and (4.5 ± 0.3) × 10^3 K for Cl atom abstraction with the early and late lanthanide cations, respectively. The indicated accuracy is the standard error derived from the fit. The exact physical meaning of these characteristic temperatures is not completely clear, but we postulate, as we have done before for reactions of Ln^+ with CH_3F (15), that the difference in characteristic temperature can be attributed to an energy associated with the electron promotion. Electron promotion in the early lanthanide ions involves an unpaired f electron while that in the late lanthanide ions involves a paired f electron. Thus, electron promotion in the late lanthanide ions involves electron–electron repulsion and so can be expected to be more effective and exhibit a lower characteristic temperature. It is noteworthy that the characteristic temperatures obtained for the Cl atom abstraction from CH_3Cl with the early and late lanthanide cations are similar to those for F atom abstraction from CH_3F, (1.80 ± 0.24) × 10^4 and (4.4 ± 0.2) × 10^3 K, respectively (15). This would be expected since F atom abstraction from CH_3F also requires the electronic excitation of Ln^+ by electron promotion (15).

Comparison of the reactivities of lanthanide cations towards CH_3Cl and CH_3F

A comparison of the reactivities that we have measured previously with CH_3F (15) shows that all the lanthanide cations, except for Lu^+, react more efficiently with CH_3Cl than with CH_3F; Fig. 6 indicates that values for $k/k_c(CH_3Cl)/k/k_c(CH_3F)$ range from 1.0 (for Eu^+) to 3.4 (for Dy^+). This can be attributed to at least two causes. The Cl—CH_3 bond is much weaker than the F—CH_3 bond (the bond dissociation energies for Cl—CH_3 and F—CH_3 are 83.7 and 112.9 kcal mol^{-1}, respectively (19)), and this makes

© 2005 NRC Canada

Fig. 6. Comparison of the reaction efficiencies of the reactions of Ln^+ with CH_3F and CH_3Cl.

the Cl abstraction more exothermic than the F atom abstraction, which reduces the kinetic barrier. Also, the electrostatic interaction between Ln^+ and CH_3Cl is stronger than that between Ln^+ and CH_3F since CH_3Cl has a much higher polarizability (4.72×10^{-24} cm^3 compared with 2.97×10^{-24} cm^3 for CH_3F (19)) and a slightly higher dipole moment (1.896 D vs. 1.858 D (19)), and this also lowers the kinetic barrier with respect to the initial energy of the reactants.

The T_{eff} ($(4.5 \pm 0.3) \times 10^3$ K) for the reactions of the late lanthanide cations with CH_3Cl obtained in Fig. 5 is close to the value for CH_3F ($(4.4 \pm 0.2) \times 10^3$ K) (15), while the T_{eff} ($(1.4 \pm 0.2) \times 10^4$ K) for the reactions of the early lanthanide cations with CH_3Cl is close to, but distinctly below, the value for CH_3F ($(1.80 \pm 0.24) \times 10^4$ K) (15). This may imply that stronger carbon–halogen bonds result in higher values for T_{eff}, but the effect on the reaction efficiency for the late lanthanide cations is much weaker than that for the early lanthanide cations.

We have previously found (15) that Lu^+ is quite reactive with CH_3F ($k/k_c = 0.37$) even though it has a $4f^{14}6s^2$ ground electronic configuration and a high s to d promotion energy (36.6 kcal mol^{-1}). We suggested that this apparent anomaly might be explained by the overlap of the $6s^2$ orbital with the antibonding orbital of methyl fluoride. This will weaken the F—CH_3 bond sufficiently to enable F atom transfer without the need for s to d promotion. In this work, Lu^+ was found to be much less reactive towards CH_3Cl ($k/k_c = 0.072$) compared with CH_3F. This may imply that the orbital levels of $6s^2$ of Lu^+ and the antibonding orbital of CH_3Cl do not match for overlapping so that the promotion energy governs the reactivity in this case.

Conclusions

Lanthanide cations have been observed to react with methyl chloride at room temperature predominantly by Cl atom transfer. The efficiency of this transfer correlates with the energy required to promote an electron to achieve a d^1s^1 excited electronic configuration in which two non-f electrons are available for bonding. The efficiency decreases as the promotion energy increases and the periodic trend in reaction efficiency along the lanthanide series matches the periodic trend in the corresponding electron promotion energy. This behavior is consistent with a C—Cl bond insertion mechanism of the type previously proposed for C—F, C—H, and C—C bond activation reactions of Ln^+ cations with alkanes and alkenes (23). Direct Cl atom abstraction by a harpoonlike mechanism can be excluded on the basis of an observed noncorrelation of reaction efficiency with IE(Ln^+). A remarkable Arrhenius-like correlation is observed for the dependence of reactivity on promotion energy: the early and late lanthanide cations exhibit characteristic temperatures of $(1.4 \pm 0.2) \times 10^4$ and $(4.5 \pm 0.3) \times 10^3$ K, respectively. A rapid, second Cl atom transfer occurs with $LaCl^+$, $CeCl^+$, $GdCl^+$, $TbCl^+$, and $LuCl^+$, but there was no evidence for a third chlorine atom abstraction with any of the $LnCl_2^+$ cations. Both $LnCl^+$ and $LnCL_2^+$ can sequentially add up to five methyl chloride molecules under the experimental operating conditions of the ICP/SIFT tandem mass spectrometer.

Acknowledgments

Continued financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) is greatly appreciated. The water elimination from the ethyl acetate radical cation — Answers from theory to a longstanding mechanistic problem[1]

Richard Lee, Paul J.A. Ruttink, Peter C. Burgers, and Johan K. Terlouw

Abstract: Previous experimental studies of the water elimination from ionized ethyl acetate (**EA-1**) and its enol, CH_2=C(OH)$OC_2H_5^{\cdot+}$ (**EA-2**), provide no mechanistic proposals, but note that the reaction is complex because all hydrogen atoms and both oxygen atoms participate. Loss of H_2O is the predominant process observed for the metastable ions, yielding ionized methyl vinyl ketone, $CH_3C(=O)CH=CH_2^{\cdot+}$ (**MVK**), as the product ion. Metastable keto-alcohol ions $CH_3C(=O)CH_2CH_2OH^{\cdot+}$ (**HB-1**) also abundantly lose H_2O, yielding **MVK** at the thermochemical threshold. Using the CBS-QB3 model chemistry and complementary RRKM calculations, we have examined plausible mechanisms for the water elimination from metastable ions **EA-1/2** and **HB-1**. Our calculations support the proposal that (*i*) ions **HB-1** dissociate into **MVK** at the thermochemical threshold via a 1,4-H shift and a consecutive [1,2]-hydroxycarbene shift, and (*ii*) ions **EA-1/2** undergo a three-step isomerization reaction into **HB-1**, which serves as the precursor for the ensuing water elimination. It is further shown that synergy between theory and experiment leads to a complex, yet transparent, mechanistic picture of the isomerization and dissociation behaviour of ionized ethyl acetate, which accounts for the labelling results.

Key words: tandem mass spectrometry, CBS-QB3 model chemistry, reaction mechanism, hydroxycarbene shift.

Résumé : Les études expérimentales antérieures sur l'élimination d'eau à partir d'acétate d'éthyle ionisé (**EA-1**) et de son énol, CH_2=C(OH)$OC_2H_5^{\cdot+}$ (**EA-2**) ne permettent pas de faire des propositions relatives au mécanisme, mais indiquent que la réaction est complexe parce que tous les atomes d'hydrogène ainsi que les deux atomes d'oxygène participent. La perte de H_2O est le processus prédominant qui est observé avec les ions métastables et elle conduit à la formation de méthylvinylcétone ionisée, $CH_3C(=O)CH=CH_2^{\cdot+}$ (**MVK**), comme produit ionique. Au seuil thermodynamique, les ions du céto-alcool métastable, $CH_3C(=O)CH_2CH_2OH^{\cdot+}$ (**HB-1**) perdent aussi abondamment de l'eau pour conduire à la formation de **MVK**. Utilisant la modélisation chimique CBS-QB3 et des calculs RRKM complémentaires, on a examiné divers mécanismes plausibles pour l'élimination d'eau à partir des ions métastables **EA-1/2** et **HB-1**. Les résultats de ces calculs confirment la proposition à l'effet que (*i*) au seuil thermodynamique, les ions **HB-1** se dissocient en **MVK** par le biais d'un déplacement 1,4 d'hydrogène et un déplacement [1,2]-hydroxycarbène consécutif et (*ii*) les ions **EA-1/2** subissent une réaction d'isomérisation en trois étapes qui conduit au **HB-1** qui sert de précurseur pour l'élimination d'eau qui suit. On a aussi démontré qu'une synergie entre la théorie et les expériences conduisent à une proposition de mécanisme, transparente malgré sa complexité, pour l'isomérisation de l'acétate d'éthyle ionisé et le comportement de sa dissociation qui permet de tenir compte des résultats de marquage.

Mots clés : spectroscopie de masse en tandem, modélisation chimique CBS-QB3, mécanisme réactionnel, déplacement d'hydroxycarbéne.

[Traduit par la Rédaction]

Introduction

Since the inception of electron ionization (EI) mass spectrometry as a powerful method for the structure analysis of organic molecules in the mid 1950s, the gas-phase ion chemistry of ethyl acetate has been studied extensively. Two dissociations of the ethyl acetate radical cation ($CH_3C(=O)OCH_2CH_3^{\cdot+}$, **EA-1**) have received particular attention: **EA-1** $\rightarrow C_2H_5O_2^+ + C_2H_3^{\cdot}$ and **EA-1** $\rightarrow C_4H_6O^{\cdot+} + H_2O$. Peaks at *m*/*z* 61 and 70 resulting from these rearrangement reactions prominently feature in the conventional EI mass spectrum of the ester, as shown in Fig. 1*a*.

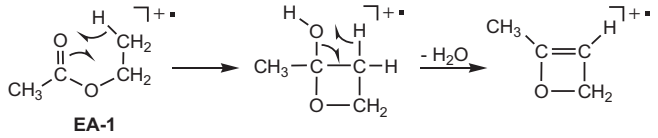
Fig. 1. (*a*) 70 eV EI mass spectra of ethyl acetate and (*b*) its 4-hydroxy-2-butanone isomer.



In 1962, Godbole and Kebarle (1) using deuterium labeling found that the acetyl methyl group remained intact during the formation of $C_2H_5O_2^+$, while hydrogen atoms were randomly transferred from the ethyl group. In 1977, Benoit et al. (2) concluded that the *m*/*z* 61 product ion is carbonyl-protonated acetic acid ($CH_3C(OH)_2^+$), rather than its higher energy isomer ($CH_3C(=O)OH_2^+$) (3), and that the keto ester ion **EA-1** may isomerize to its more stable (4) enol form ($CH_2=C(OH)OCH_2CH_3^{\cdot+}$, **EA-2**) prior to dissociation. Dissociation into $CH_3C(OH)_2^+$ has become a textbook example of a "McLafferty + 1" rearrangement (5). The first step of the proposed mechanism (5) leads to the distonic ion $[CH_3C(OH)OCH_2CH_2]^{\cdot+}$ (**EA-3**) via a 1,5-H shift in **EA-1**. A consecutive 1,3-H shift from the terminal CH_2 group to the ether O atom in **EA-3** then initiates the C_2H_3 loss. We will examine this proposal in more detail in the Results and discussion.

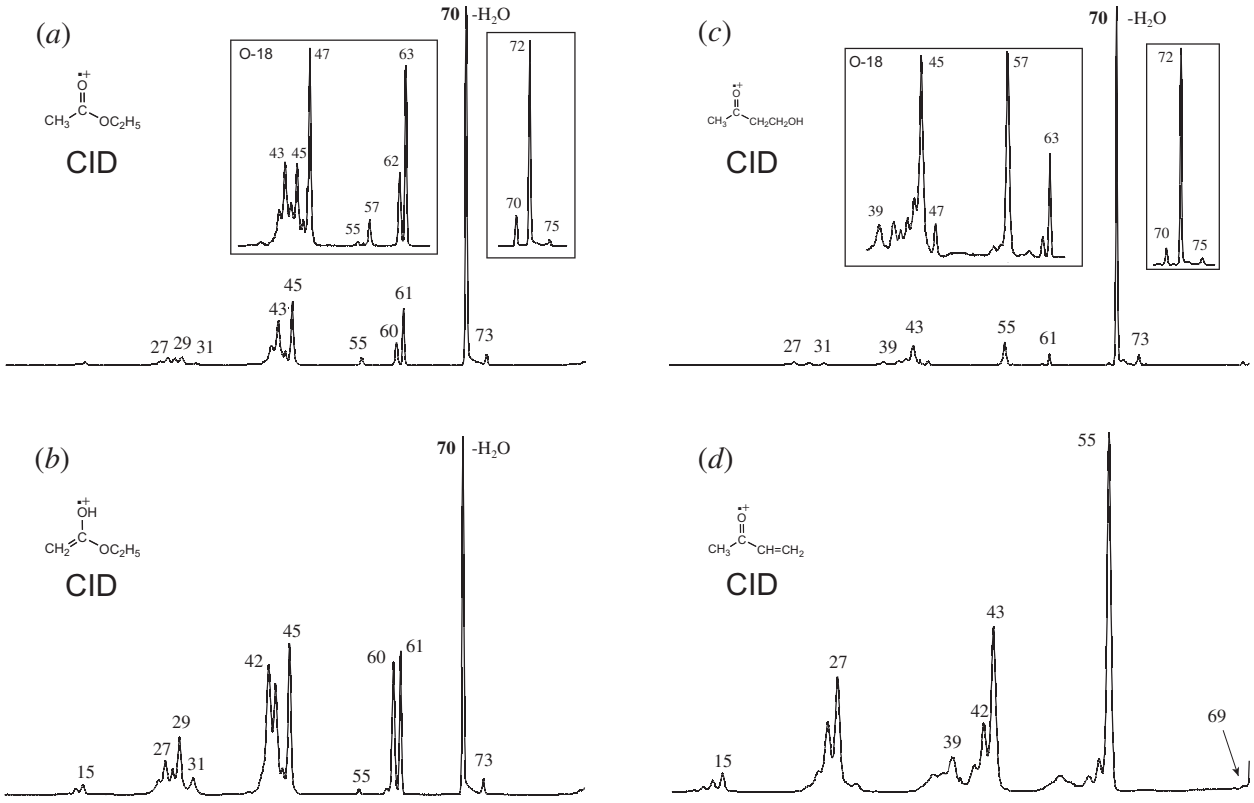
The elimination of H_2O into ions $C_4H_6O^{\cdot+}$ (*m*/*z* 70) has been studied in much greater detail (6–8) than the $C_2H_3^{\cdot}$ loss, but its mechanism is still shrouded in mystery. Loss of water represents the unimolecular reaction of lowest energy requirement for ionized ethyl acetate (7, 8). In line with this, it is the predominant process observed for metastable (9) ions **EA-1** dissociating in the μs time frame: loss of $C_2H_3^{\cdot}$ competes unfavourably as its metastable peak is only 0.02 as intense as that for the H_2O loss process (7).

The reaction was first studied by Yeo (6) in 1970. He studied both metastable ions and ions dissociating in the source and found that deuteriums on the ethyl group more readily end up in the neutral water fragment than do the deuteriums on the acetyl group. The degree of hydrogen exchange becomes greater as the lifetime of the precursor ion increases, which is when the internal energy content of the ion becomes lower. Yeo proposed that the intra- and inter-alkyl H–H exchange reactions take place from the *unrearranged* keto ion **EA-1** and that the actual mechanism for H_2O loss involves ring closure of **EA-1** into the 2-hydroxy-2-methyloxetane ion, as depicted in Scheme 1.

Scheme 1.

The cyclic ion would then undergo H_2O elimination yielding ionized 2-methyloxetene, the four-membered ring – closed form of ionized methyl vinyl ketone ($CH_3C(=O)CH=CH_2^{\cdot+}$, **MVK**). Yeo formulated this proposal some 20 years before the role of distonic ions as stable key intermediates was fully established (10). A more plausible formulation of the cyclization step in his mechanism would involve formation of the distonic ion **EA-3** as the first step (as in the mechanism for $C_2H_3^{\cdot}$ loss discussed previously), followed by cyclization. We further note that Yeo's proposal remains speculative because there is no experimental evidence for the proposed product ion structure.

In 1981, Holmes et al. (7) investigated the H_2O loss from **EA-1** and its independently generated enol **EA-2**, employing most of the presently available methodology for the detailed study of unimolecular ionic dissociations (11). These included metastable ion (MI) and collision-induced dissociation (CID) mass spectra, appearance energy (AE) measurements using electron ionization (EI), thermochemical data (12), and analysis of D- and ^{18}O-labelled isotopologues. Shortly thereafter, Baer and co-workers (8) used photoionization (PI) to study the energetics of the five primary dissociations of **EA-1**; in addition, they studied the rate of the H_2O elimination using photoion–photoelectron coincidence (PIPECO) experiments in conjunction with RRKM/QET calculations.



Although these two papers contain a wealth of experimental observations on the gas-phase ion chemistry of ethyl acetate, they do not provide a clear mechanistic picture of the H_2O loss. The most important results and conclusions pertaining to the H_2O elimination are the following:

(*i*) Holmes et al. (7) found that metastable enol ions **EA-2** also abundantly lose H_2O and deduce from their D- and ^{18}O-labelling experiments that the reaction probably occurs via the reacting configuration(s) of the less stable keto tautomer **EA-1**. The isomers have different CID spectra (see Figs. 2*a* and 2*b* of this study), but this does not imply that keto ions cannot partially tautomerize: the CID spectrum of **EA-1** is not necessarily that of a *single* ionic species.

(*ii*) Analysis of ^{18}O-labelled ions (7) showed that for ion source decompositions and all metastable ion observation times, the keto and enol O atoms in both **EA-1** and **EA-2** are similarly preferentially lost: ion source, 65%; metastable ions, 70%–90%. It is likely that this process has a lower energy requirement than the H_2O loss that involves the ester O atom. This is because (*i*) the associated kinetic energy release (9) is lower than that for the

Fig. 2. CID mass spectra of the radical cations of (*a*) ethyl acetate, (*b*) its enol, and (*c*) the 4-hydroxy-2-butanone isomer (**HB-1**). Partial spectra of $CH_3C(=O)^{18}OC_2H_5$ and $CH_3C(=O^{18})CH_2CH_2OH$ are shown in the insets of (*a*) and (*c*), respectively. (*d*) Represents the CID mass spectrum of the *m/z* 70 product ion generated by the loss of water from metastable ion **HB-1**.

ester O atom and (*ii*) the degree of exchange becomes increasingly less important at longer ion lifetimes, which is just the opposite of the H atom exchange results (6, 7). These data indicate that there is a significant barrier to O atom migration, whereas the H atoms have no significant barrier for exchange but do so at a slow rate because of circuitous (high entropy) pathways (7, 8).

(*iii*) From their analysis of the CID spectra of various $C_4H_6O^{+}$ isomers (13), Holmes et al. (7) concluded that $CH_3C(=O)CH=CH_2^{\cdot+}$ (**MVK**) is generated by H_2O loss from either metastable ions **EA-1** and **EA-2** or those fragmenting in the ion source. They further noted that the CID results do not exclude that a *minor* fraction of the ions would be $CH_2=C(OH)CH=CH_2^{\cdot+}$, the enol of **MVK** that is 13 kcal mol^{-1} lower in energy than **MVK** (11*a*). They entertained this possibility because their AE measurements on **EA-1** yielded an apparent $\Delta_f H^0_{298}$ = 190 kcal mol^{-1} for the $C_4H_6O^{+}$ ion, which lies below the proposed value for **MVK** (195 kcal mol^{-1}) (13*a*).

(*iv*) Baer and co-workers (8) note that this enthalpy difference is on the border line of being significant. They conclude from their experiments on **EA-1** that **MVK** ions (for which they derive $\Delta_f H^0_{298}$ = 194 kcal mol^{-1}) are also generated at threshold. They further conclude that **EA-1** isomerizes to a more stable structure prior to dissociating, possibly the enol ion **EA-2**.

In the summary of their paper Baer and co-workers state: "we know the energy of the isomerized molecular ion, but not its structure; we suspect that the transition state is cyclic; and we believe that the product ion is **MVK**. With all this information it should be possible to derive a mechanism and determine the structure of the molecular ion. However, as was already pointed out by Holmes et al. the loss of H_2O is a very complicated reaction." Yeo's mechanistic proposal of Scheme 1 is mentioned in these studies but not discussed.

At the time these studies were published, the use of ab initio MO calculations as a complementary tool in studying structures and reactions of gas-phase organic ions was only in its infancy. However, theory steadily progressed, and in 1989 a review of structures and reactions of gas-phase ions (10*b*) stated that the computational results of Heinrich et al. (14) on ionized methyl acetate offer some hope that the chemistry of ionized ethyl acetate may some day be understood. A hydrogen-bridged radical cation (15) (CH_3-CH=O···H···OCH=$CH_2^{\cdot+}$) was suggested to play a key role in the water elimination from **EA-1**. It was also stressed that ab initio calculations are required to solve this problem but that, considering the size of the system and the number of possible intermediates, this would be a formidable task.

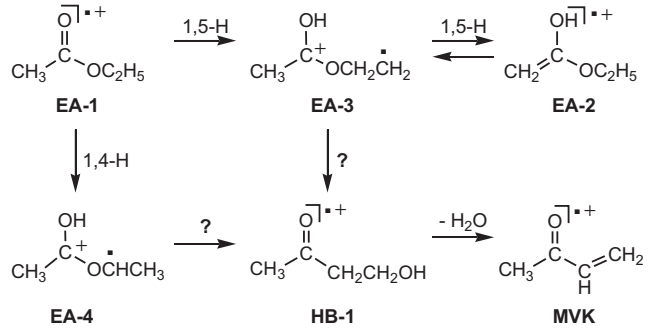
Fortunately, the following decade witnessed a development in methodology and computing power short of a revolution, enabling computational chemistry to become a key player in the field of gas-phase ion chemistry (11). The G-3 variant of the Gaussian methods of Pople and co-workers (16) and the CBS-QB3 variant of the complete basis set methods of Petersson and co-workers (17) provide absolute enthalpies of chemical accuracy for medium-sized ions and neutrals. This makes both model chemistries attractive for a study of the gas-phase ion chemistry of ethyl acetate. During the past 5 years we have successfully used the CBS-QB3

© 2005 NRC Canada

method in mechanistic studies of organophosporus ester ions (18) and proton-transport catalysis in various organic radical cations (19). We therefore decided to use this CBS variant, which uses density functional geometries and frequencies in the calculations, as the primary computational tool in probing the elusive mechanism for the H_2O elimination from metastable ions **EA-1** and **EA-2**.

It will be shown that synergy between theory and experiment leads to a complex yet transparent mechanistic proposal for the H_2O elimination into **MVK**, which satisfies the energetic constraints imposed by experiment and accounts for the labelling results.

Results and discussion



Experimental and theoretical preliminaries

In our computational quest of plausible mechanisms for the H_2O elimination from **EA-1** and **EA-2** we focussed on the behaviour of the *metastable* ions. For such ions the experiments (7, 8) stipulate that none of the stable intermediates or connecting transition states of a viable calculated mechanism should lie significantly higher in energy than the thermochemical threshold for the formation of **MVK** + H_2O. The experimental and calculated enthalpies for this threshold are close (137 ± 3 and 139 kcal mol^{-1}, respectively, see Table 1). The experimental value suffers from a rather large uncertainty because the heat of formation of neutral methyl vinyl ketone has not been measured with great precision. The computed enthalpies of the stable structures (minima) presented in Tables 1 and 2 of this study are expected to be reliable to 2 kcal mol^{-1} (17, 18*a*); for the uncertainty in computed barrier heights we affix ±4 kcal mol^{-1} as a conservative estimate (18*a*).

As mentioned in the Introduction, Holmes et al. (7) in their detailed experimental study do not propose a mechanism for the water loss from **EA-1/2**. However, they do make the intriguing suggestion that the isomeric 4-hydroxy-2-butanone ion ($CH_3C(=O)CH_2CH_2OH^{\cdot+}$, **HB-1**) is a participating structure in the complex behaviour of the keto and enol ions of ethyl acetate. This suggestion is based upon their observations that metastable ions **HB-1** readily lose H_2O, with a small kinetic energy release, and that the source generated ions **HB-1** (see Fig. 1*b*) also generate *m*/*z* 61 ions $CH_3C(OH)_2^+$. The CID mass spectrum of **HB-1** (see Fig. 2*c*) also displays a *m*/*z* 61 peak, supporting the idea that **EA-1/2** and **HB-1** can (inter)convert via a fairly low energy route. There is no mechanistic proposal for the loss of H_2O from **HB-1** but, as will be discussed in the next section, there is little doubt that the product ion generated is **MVK** and that the reaction occurs at the thermochemical threshold.

We decided to further explore the idea that ions **EA-1/2** can access the potential energy surface (PES) that describes the water elimination from **HB-1**. Ions **EA-1** may well undergo a facile isomerization into distonic ions **EA-3** or **EA-4** as depicted in Scheme 2. Ion **EA-3** could in principle connect to the PES of **HB-1** via a well-documented skeletal rearrangement, the [1,3]-hydroxycarbene shift (10*b*). In this rearrangement the CH_3-C-OH moiety of **EA-3** migrates, via a cyclic transition state, to the radical position, yielding $[CH_3C(OH)CH_2CH_2O]^{\cdot+}$, a 1,5-hydrogen-shift isomer of **HB-1**.

Scheme 2.

Our computational results for this reaction sequence are presented in the energy level diagram of Fig.3*a*, which will be discussed in detail in a following section. Here we note that the barrier for the hydroxycarbene shift is too high to account for the loss of water at the thermochemical threshold.

In the same vein, ion **EA-4** could undergo a [1,2]-hydroxycarbene shift (10*b*), leading to $[CH_3C(OH)C(H)(CH_3)O]^{\cdot+}$, a 1,5-hydrogen-shift isomer of $CH_3C(=O)CH(OH)CH_3^{\cdot+}$ (ionized acetoin). This reaction does not play a role in the water elimination either, since (*i*) the isomerization barrier is not sufficiently low and (*ii*) low energy acetoin ions do not lose H_2O but rather dissociate into $CH_3C(H)OH^+$ + $CH_3C{=}O^{\cdot}$, via a remarkable hidden rearrangement (20). However, as will be discussed in a following section in conjunction with the energy diagram of Fig. 3*b*, this rearrangement sheds light on another intriguing aspect of the ion chemistry of ethyl acetate (8). This concerns the formation of the prominent *m*/*z* 45 $C_2H_5O^+$ ions in the CID mass spectra of **EA-1/2**, shown in Figs. 2*a* and 2*b*.

Despite these negative answers from theory, we further pursued the idea that the water loss from **EA-1/2** occurs via the PES of **HB-1** and considered the distonic ion **EA-3** to be the most likely intermediate for the conversion. This indeed proved to be the case: as shown in the calculated energy diagram of Fig. 4*a*, **EA-3** can rearrange into **HB-1** via a two-step low energy route. This finding and its implication on the interpretation of the labelling results will be discussed in a following section. However, we will first deal with our mechanistic proposal for the water elimination from **HB-1** which, as we shall see, involves a [1,2]-hydroxycarbene shift (10*b*) as the key step of the reaction.

The water elimination from ionized 4-hydroxy-2-butanone (HB-1)

Before we discuss our mechanistic proposal for the water loss from **HB-1**, we will first briefly review the experimental observations. The spectrum of metastable ions **HB-1** displays a single narrow peak at *m*/*z* 70, indicating that loss of H_2O represents the reaction of lowest energy requirement. The kinetic energy release derived from the *m*/*z* 70 peak at half-height ($T_{0.5}$) is only 7 meV (7), indicating that the water elimination may well occur at the thermochemical threshold. The CID mass spectrum of the resulting $C_4H_6O^{\cdot+}$ product ion, generated from metastable ions **HB-1**, is shown in Fig. 2*d*. Comparison of this spectrum with that of $CH_3C(=O)CH{=}CH_2^{\cdot+}$ (**MVK**) and other isomeric $C_4H_6O^{\cdot+}$ ions (7, 13) leaves little doubt that **MVK** is the product ion

generated from **HB-1**. We note in particular that the peak at *m/z* 69 (loss of H$^{\cdot}$) in the spectrum of Fig. 2*d* is barely visible (<1% of the base peak at *m/z* 55). Since loss of H$\cdot$ represents (7, 13*a*) a major collision-induced dissociation of the enol ion of **MVK** ($CH_2=C(OH)CH=CH_2^{\cdot+}$), it is unlikely that this more stable isomer (see Table 1) is cogenerated from **HB-1** to any significant extent.

Our CID mass spectrum of the $C_4H_6O^{\cdot+}$ ion generated from metastable ethyl acetate ions is identical with that of Fig. 2*d*. This reinforces the conclusion of the PI study of Baer and co-workers (8) that the water elimination from **EA-1** yields **MVK** at the thermochemical threshold. Their derived $\Delta_f H^0_{298}$ value of 194 ± 2 kcal mol^{-1} is close to its experimental estimate of 195 ± 3 kcal mol^{-1} (see Table 1). On the other hand (see the Introduction), Holmes et al. (7) invoked the co-generation of the enol ion because the $\Delta_f H^0_{298}$ ($C_4H_6O^{\cdot+}$) they derived from their AE (EI) measurements (190 kcal mol^{-1}) lies 5 kcal mol^{-1} below the experimental estimate for **MVK**. We note that the AE values from the PI and EI studies are virtually the same (10.31 ± 0.1 eV), and that the discrepancy between the derived $\Delta_f H^0_{298}$ values arises from differences in the thermochemical treatment of the appearance energies (8).

The ambiguities in defining appearance energies and their conversion into $\Delta_f H^0_{298}$ values of the reaction products has been a matter of considerable debate (21). Here we note that applying the Traeger–McLoughlin correction term (21*a*) ($\Delta H_{cor} = \Delta H_{298}$ (**MVK** + H_2O) – 1.48 kcal mol^{-1}) raises the

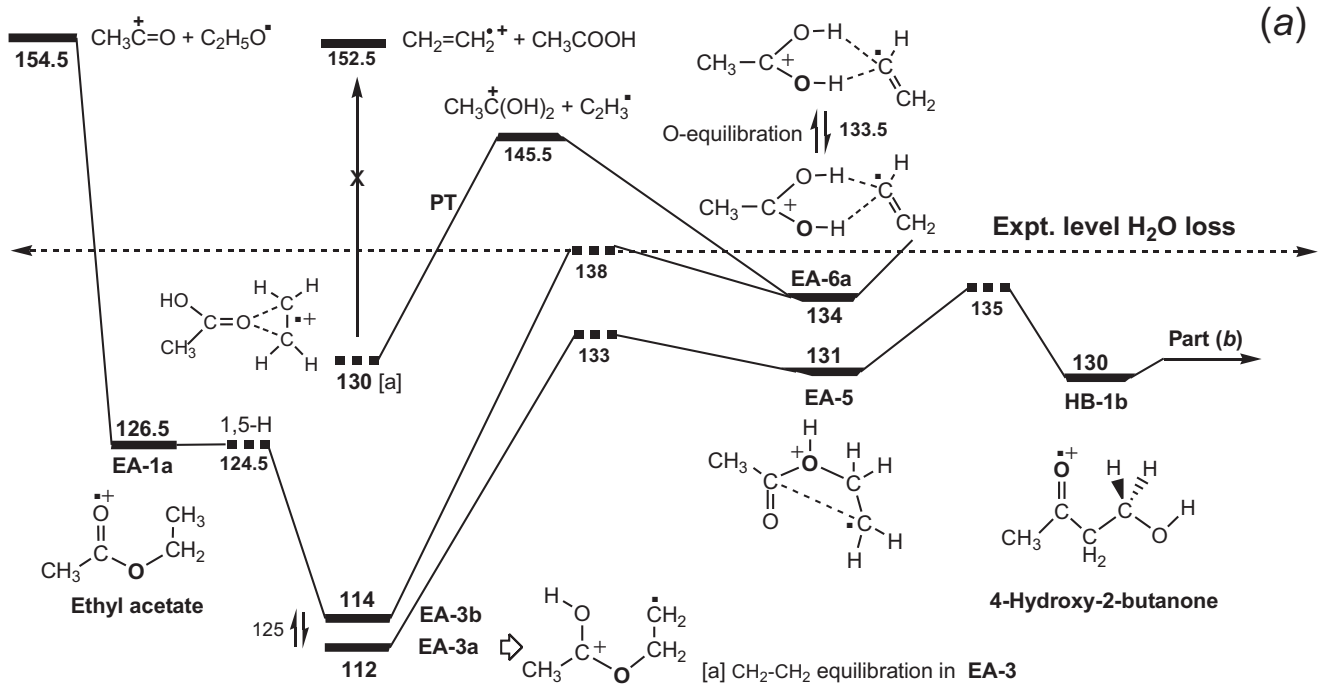
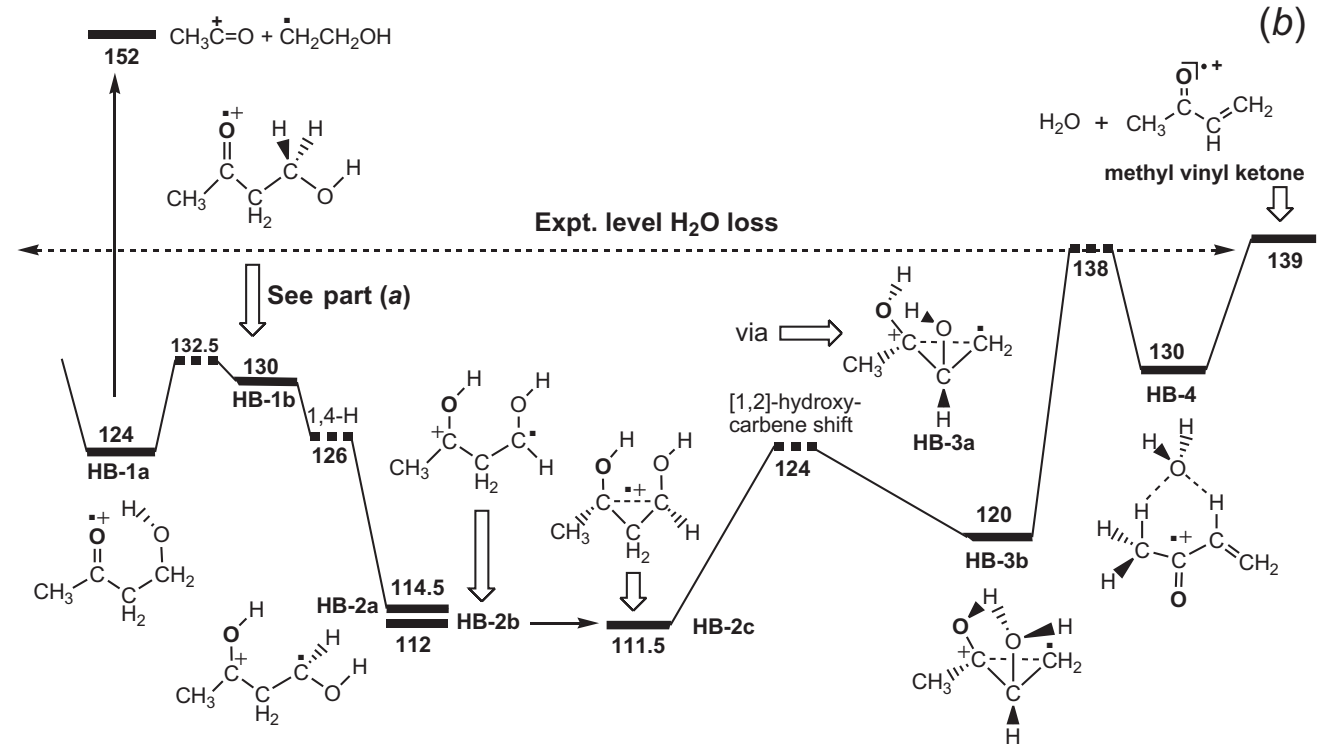
[c] This TS represents the reverse barrier for the dissociation into $CH_3C(H)OH^+$ (see Fig. 3*a*).

Fig. 3. Energy level diagrams derived from CBS-QB3 calculations for the isomerization of ionized ethyl acetate (AE-1) into the distonic ions (*a*) EA-3 and (*b*) EA-4, and the subsequent [1,3]- and [1,2]-hydroxycarbene shift. The numbers refer to $\Delta_f H_{298}^0$ values in kcal mol^{-1}.

$\Delta_f H_{298}^0$ ($C_4H_6O^{+\cdot}$) value derived by Holmes et al. by 5.3 to 195 kcal mol^{-1} (using the ΔH_{298} values available from the CBS-QB3 calculations). Note that ΔH_{cor} is negative and this negative number is subtracted from the measured AE, thereby raising the derived $\Delta_f H_{298}^0$. This correction holds rigorously if all the available internal energy of the precursor ion is used for dissociation, which is, the products are formed at 0 K. The actual thermal content of the products is not known and hence, the correction term only provides an upper limit to the derived enthalpy.



Interestingly, the same situation obtains for the water loss from **HB-1**. The available AE (9.78 eV)[3] leads to a $\Delta_f H_{298}^0$ ($C_4H_6O^{+\cdot}$) value of only 190.3 kcal mol^{-1};[4] when the above correction term is applied, the number increases to 195.6 kcal mol^{-1} and becomes compatible with the formation of **MVK**.



The previous observations lead us to conclude that the water elimination from both **HB-1** and **EA-1** yields **MVK** at the thermochemical threshold. Further, the MI spectrum of the ^{18}O-labelled isotopologue $CH_3C(=O^{18})CH_2CH_2OH^{+\cdot}$ reveals that the H_2O molecule lost from metastable ions **HB-1** largely (~95%) consists of the hydroxyl ^{16}O atom. The inset of the CID mass spectrum of Fig. 2*c* shows that this is also true for stable ions undergoing collision-induced dissociation, although it should be noted that the larger part (~70%) of the dominating peak for water loss in the CID spectrum is of metastable origin. This also applies to the *m*/*z* 70 peak in the CID mass spectrum of **EA-1**, but now the water loss (see inset of Fig. 2*a*) largely (~90%) involves the keto ^{16}O atom. For both isomers the kinetic energy release ($T_{0.5}$ value) associated with the major loss of $H_2{}^{16}O$ from the labelled isotopomers is significantly lower than that of the minor

[3] From unpublished EI results of the late Dr. F.P. Lossing (J.L. Holmes. Personal communication. 2005).
[4] Using $\Delta_f H_{298}^0$ (4-hydroxy-2-butanone) = –93 kcal mol^{-1} from a Benson additivity (12*e*) estimate. Our CBS-QB3 value is –93.4 kcal mol^{-1}.

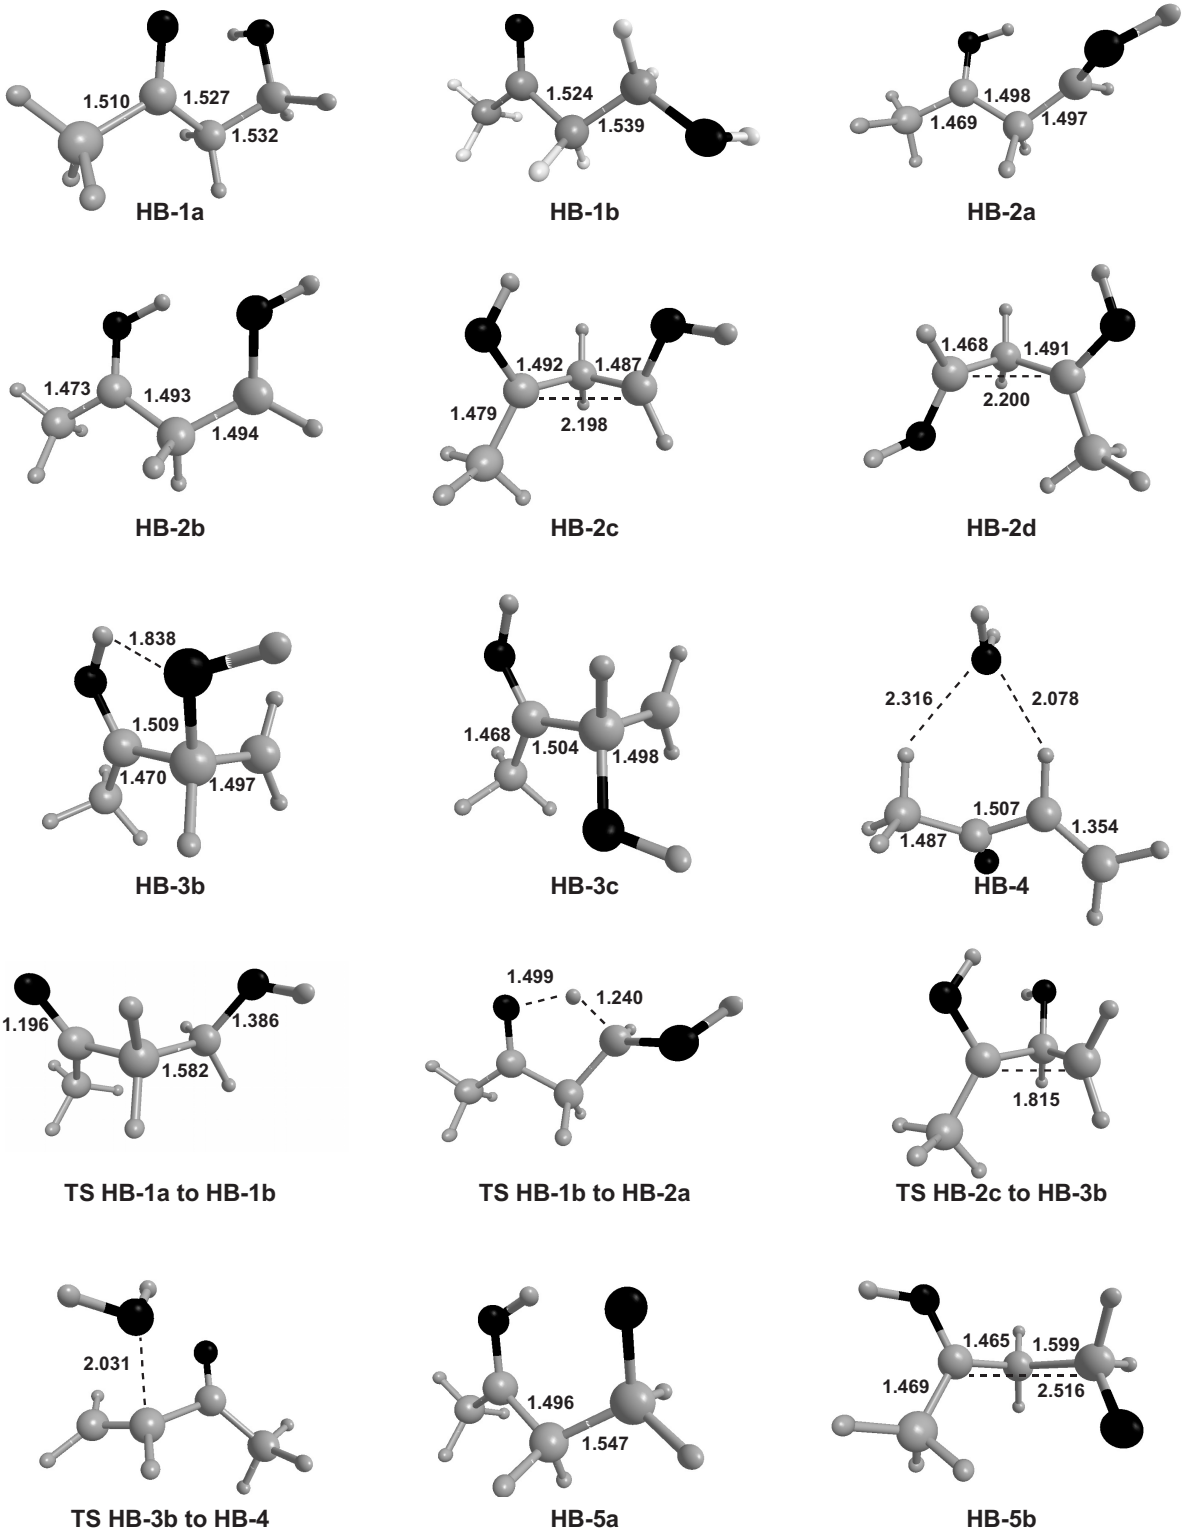
Fig. 4. Energy level diagram derived from CBS-QB3 calculations describing the water elimination from metastable ethyl acetate ions (**EA-1**). Part (*a*) describes the isomerization of **EA-1** into ionized 4-hydroxy-2-butanone (**HB-1**); part (*b*) presents the mechanisms by which ions **HB-1** lose H_2O. The numbers refer to $\Delta_f H^0_{298}$ values in kcal mol^{-1}.

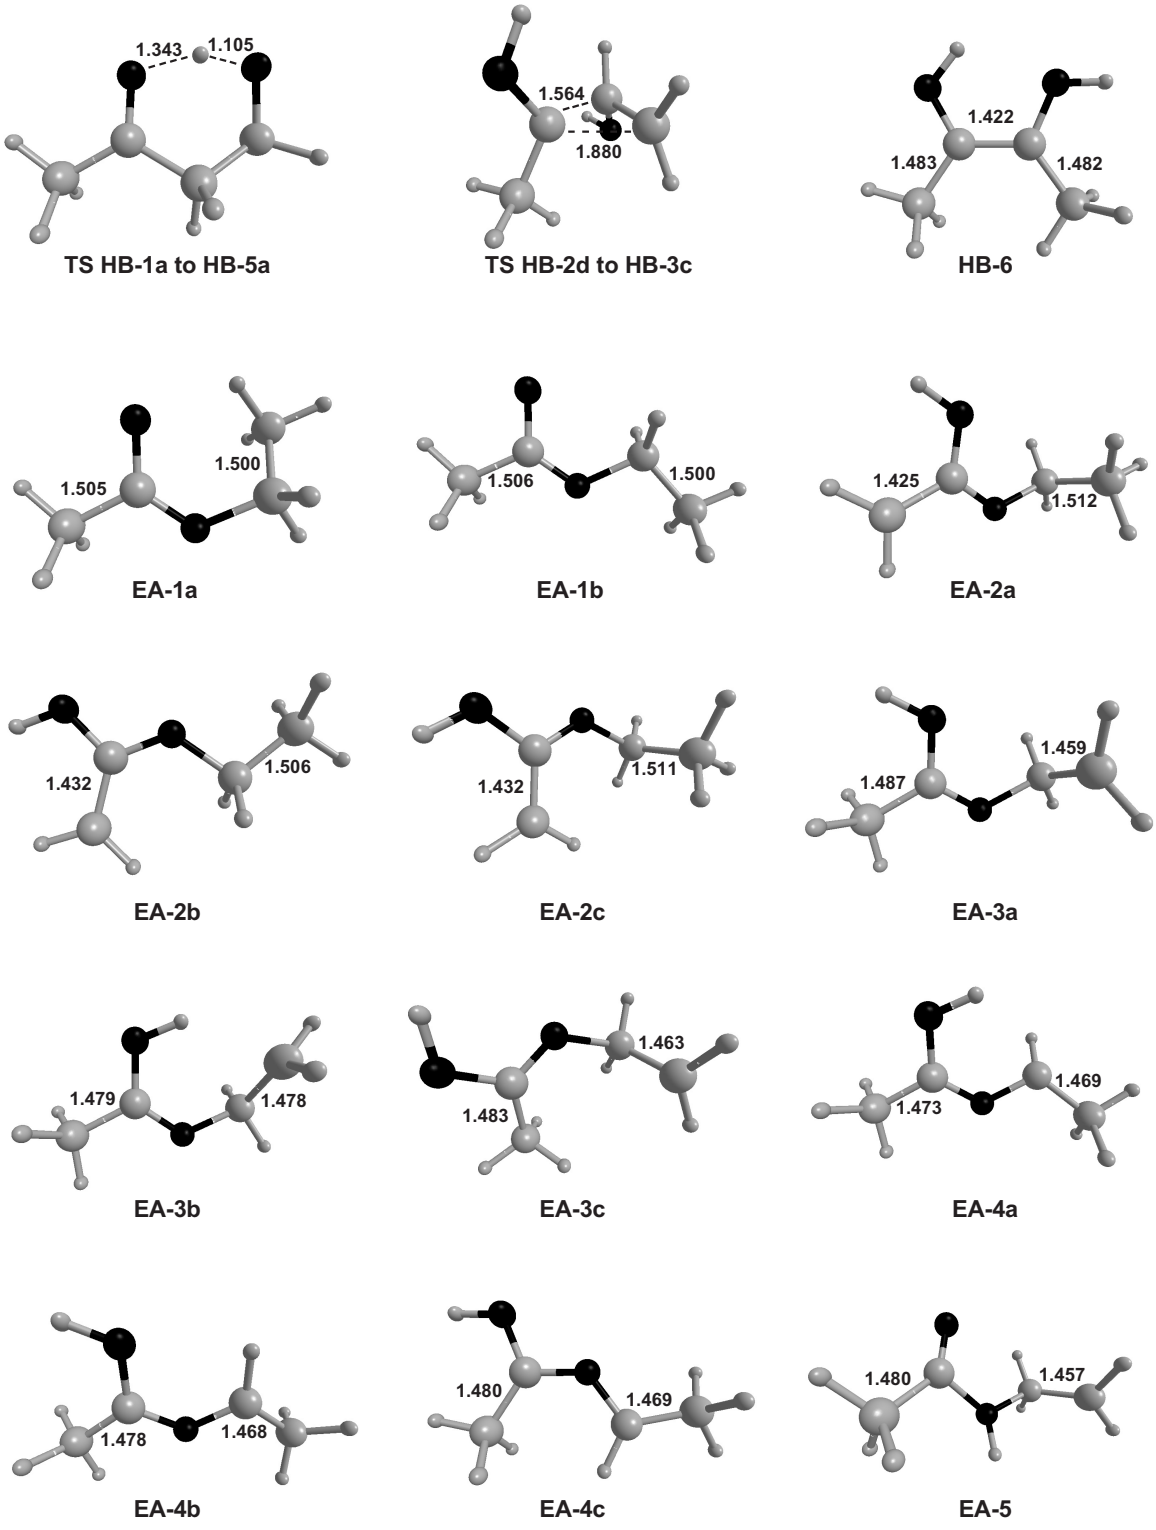


$H_2{}^{18}O$ loss: 8.6 vs. 13.0 meV for **EA-1** (7) and 5.5 vs. 11.5 meV for **HB-1** (this work). This observation suggests that the $H_2{}^{18}O$ loss from **EA-1** and **HB-1** involves an oxygen equilibration reaction whose energy requirement is somewhat higher than the atom specific water loss. As we shall see, the mechanistic proposal of Fig. 4 provides a rationale for these labelling results.

Our mechanistic proposal for water loss from metastable ions **HB-1** is presented in the bottom part of the energy diagram of Fig. 4. Starting from the lowest energy conformer

© 2005 NRC Canada

Fig. 5. The CBS-QB3 optimized geometries for ionized 4-hydroxy-2-butanone (**HB-1**) and ethyl acetate (**EA-1**) isomers, and selected transition states.



HB-1a, a facile rotation of the CH_2OH moiety yields conformer **HB-1b**, which forms the connection with the PES of ethyl acetate in the top part of the energy diagram. Ion **HB-1b** then rearranges into the very stable distonic ion **HB-2a** via a 1,4-H shift. The TS for this shift is undoubtedly not high but the calculated value is clearly too low; this point is further discussed in the Theoretical methods section.

Ion **HB-2a** may undergo a facile rotation of its HCOH moiety to yield the slightly more stable conformer **HB-2b**, which has a planar structure. However, its HCOH and

© 2005 NRC Canada

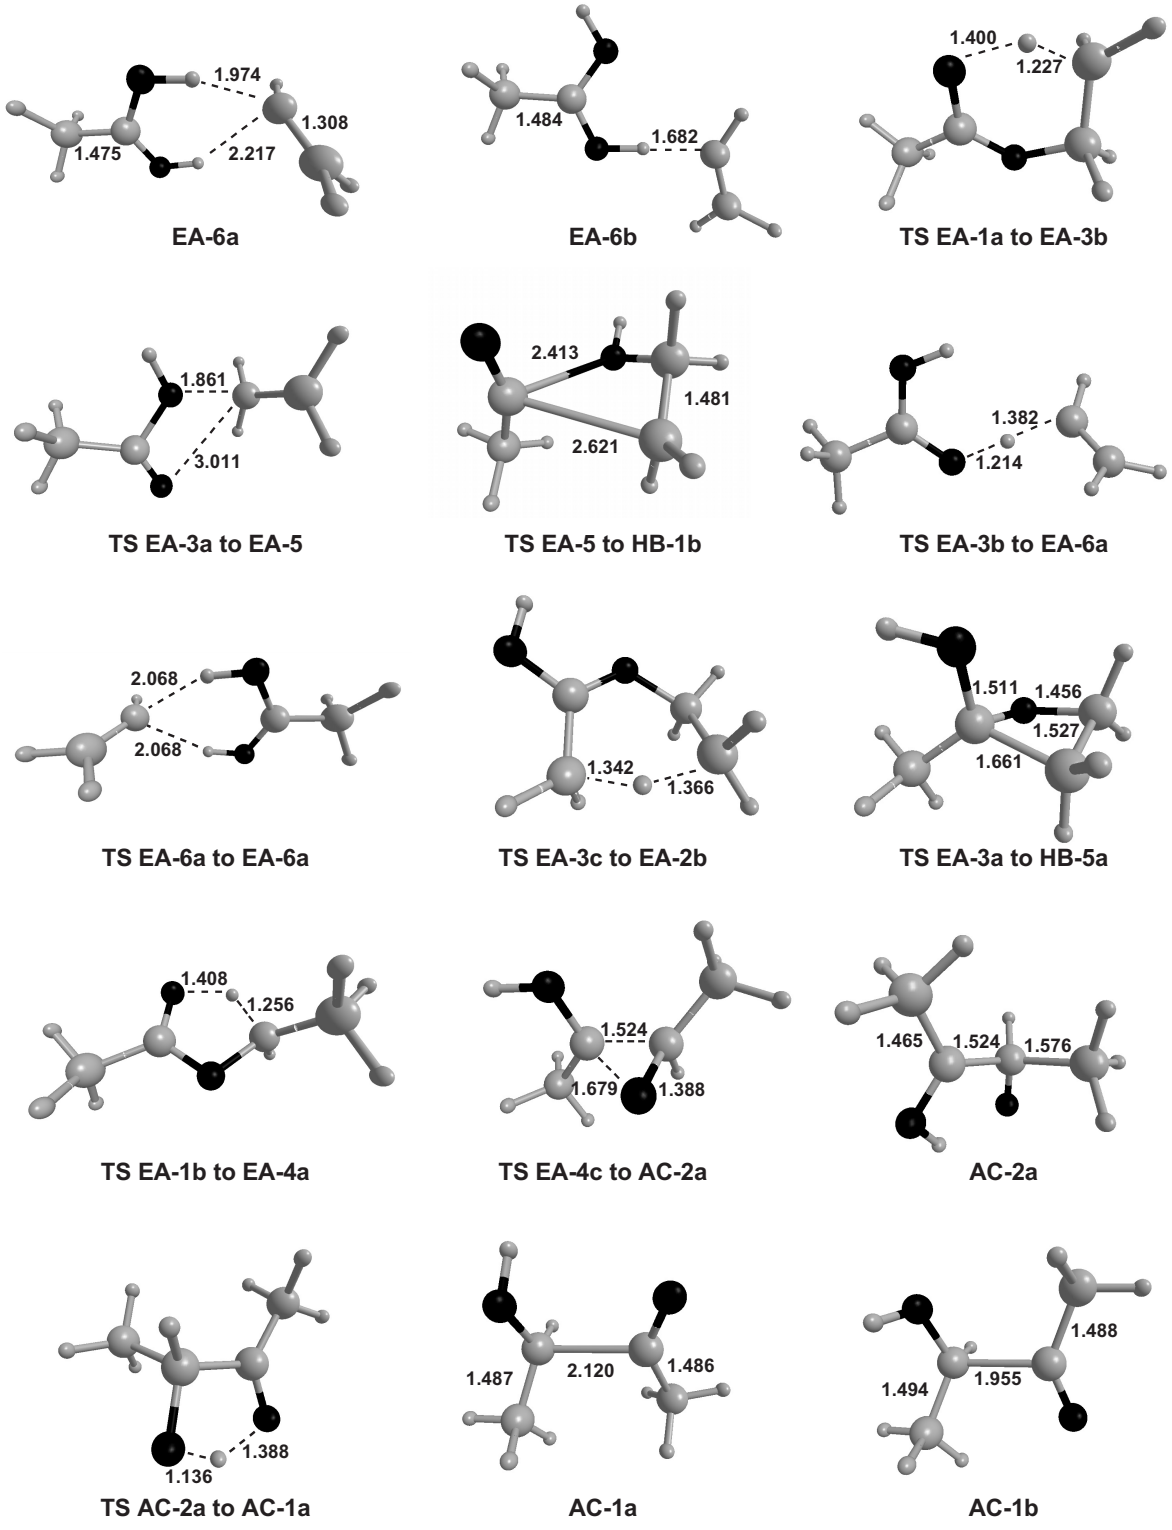


Fig. 5 (*continued*).

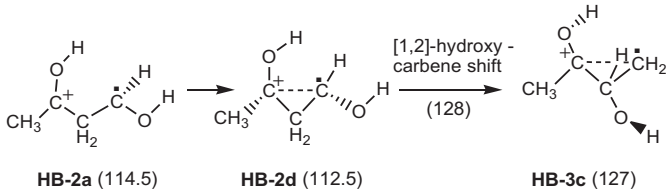
CH_3COH moieties can slightly move out of the plane (with a negligible energy requirement, see Table 2*b*) to form **HB-2c**, which (also see Fig. 5) can be viewed as a one-electron long bonded species. Contraction of its one-electron bond was expected to initiate the isomerization of **HB-2c** into **HB-3a** (see Fig. 4*b*) via a [1,2]-hydroxycarbene shift (10*b*). However, **HB-3a** does not appear to be a minimum on the PES: all attempts to optimize its geometry yielded its conformer **HB-3b** in which the hydroxyl groups are bridged in such a way that an ensuing loss of water into **MVK** can easily be envisaged. We were able to locate the transition state connecting **HB-2c** and **HB-3b** and it appears to lie at only 124 kcal mol^{-1}, well below the threshold for the water elimination. **HB-3b** does not

© 2005 NRC Canada

Fig. 5 (*concluded*).



directly lose water but rather it isomerizes (TS at 138 kcal mol^{-1}) into an ion–dipole type complex between **MVK** and H_2O (**HB-4**), which then dissociates into its components at the thermochemical threshold.

We note that other conformers of **HB-2b** may also undergo a [1,2]-hydroxycarbene shift, as illustrated in Scheme 3 for **HB-2a**. However, the stable **HB-3** conformers then generated cannot immediately lose water but must first isomerize via rotation(s) into **HB-3b**. We have examined several of these pathways but they all appear to have a slightly higher energy requirement than the direct route (**HB-2b** → **HB-3b**) depicted in Fig. 4*b*.

Scheme 3.

Three points deserve further comment:

(*i*) The minor loss of $H_2{}^{18}O$ from $CH_3C(=O^{18})CH_2CH_2OH^{+}$ could be ascribed to a partial equilibration of **HB-3b** with its 1,2-H shift isomer $CH_3C(OH)=C(OH)CH_3^{+}$ (**HB-6**): the associated TS (see Table 2*b*) lies at 139 kcal mol^{-1}, i.e., at the threshold for the water elimination.

(*ii*) The H_2O molecule in **HB-4** is not expected to promote enolization of the ketone moiety by proton transport catalysis (19). This is because the proton affinity (PA) of water (164 kcal mol^{-1}) is much lower than the (calculated) topical PAs at $^{\cdot}CH_2$ and C=O in the deprotonated ketone $^{\cdot}CH_2C(=O)CH=CH_2$, 187 and 200 kcal mol^{-1}, respectively.

(*iii*) A McLafferty type rearrangement in **HB-1** would yield enol ions $CH_3C(OH)=CH_2^{\cdot+}$ at *m*/*z* 58 by loss of CH_2=O. As seen from Table 1, the minimum energy requirement for this reaction is only 136 kcal mol^{-1}, i.e., lower than that for the loss of water. However, our calculations indicate that the formaldehyde loss involves a reverse barrier of 4 kcal mol^{-1} (see Fig. 3 and Table 2*b*), which makes the energy requirements for the losses of formaldehyde and water comparable. Yet, neither the MI nor the CID spectrum (see Fig. 2*c*) of **HB-1** displays a signal at *m*/*z* 58!

Standard RRKM calculations for the formaldehyde loss from **HB-5a** and the water loss from **HB-3b** indicate that the internal energy needed for the formaldehyde loss in the metastable time frame is lower than that for the water loss. However, this model is misleading because it does not take into account that both isomers communicate with the much more stable isomers **HB-2a**–**HB-2c** via low barriers (see Fig. 4). This leads to a rapid interconversion of the various isomeric ions involved in the competing losses of formaldehyde and water.

The extended RRKM model as described by Baer et al. (22) (also see the Theoretical methods section) does account for the competition between the two dissociation channels. Calculations based on this model revealed that equilibration via the low-lying distonic ions **HB-2a**–**HB-2c** leads to a much lower yield (by a factor of 140) of the *m*/*z* 58 product ion formed by loss of formaldehyde compared with the yield of *m*/*z* 70 **MVK** ions formed by loss of water. As a result, loss of formaldehyde from **HB-1** cannot effectively compete with its water loss.

The water elimination from ionized ethyl acetate (EA-1)

As discussed in the previous section, 4-hydroxy-2-butanone ions **HB-1** lose water via the mechanism presented in the bottom part of the energy diagram of Fig. 4. The top part of this diagram (Fig. 4*a*) shows that ionized ethyl acetate can undergo a three-step isomerization reaction into **HB-1**, which may then serve as the precursor for its subsequent water elimination. The first step involves the conversion of **EA-1** into its stable distonic isomer **EA-3** via a facile 1,5-H shift. This reaction involves a conformer of ionized ethyl acetate (**HB-1a**) and it yields a conformer of the distonic ion (**EA-3b**). Rotation of its hydroxyl group via a low-lying transition state converts **EA-3b** into **EA-3a**. Next, the O—CH_2 bond in **EA-3a** stretches and breaks while the methylene group moves to the hydroxyl O atom to make a new bond, yielding distonic ion **EA-5**. Ion **EA-5**, akin to the well-documented (23) distonic $C_2H_6O^{\cdot+}$ isomer H_2O^{+}-CH_2-$CH_2^{\cdot}$, lies in a shallow potential well and requires only 4 kcal mol^{-1} to further rearrange into a conformer of ionized 4-hydroxy-2-butanone (**HB-1b**). This rearrangement can be viewed as a 1,3-acetyl shift.

This three-step isomerization route of **EA-1** into **HB-1** takes place at energies below that required for the water loss and it thus satisfies the energetic constraints imposed by experiment. It further converts the ^{18}O-labelled **EA-1** isotopologue $CH_3C(=O)^{18}OC_2H_5^{\cdot+}$ into the **HB-1** isotopologue $CH_3C(=O^{18})CH_2CH_2OH^{\cdot+}$, which (see Fig. 4*b*) is expected to specifically lose $H_2{}^{16}O$. This too is in agreement with the experimental observations, albeit that a small fraction of high energy metastable ions (~5%) appears to lose $H_2{}^{18}O$. The loss of $H_2{}^{18}O$ from both labelled isotopologues probably results from a weakly competing oxygen equilibration reaction rather than a different dissociation pathway. Two equilibration mechanisms are feasible: (*i*) the equilibration of **HB-3b** with its 1,2-H shift isomer **HB-6** mentioned in the previous section and (*ii*) the route **EA-3b** → **EA-6a** depicted in Fig. 4*a*. The transition-state energies for the two processes are very close but the first route is kinetically less attractive because the equilibration **HB-3** ↔ **HB-6** is associated with a very large activation energy (44 kcal mol^{-1} relative to **HB-6**) and a tight transition state. This makes it unlikely that this equilibration can effectively compete with the dissociation **HB-3** → **HB-4** → **MVK** + H_2O, even at elevated energies. The dynamic picture is more favourable for the second route, which converts **EA-3b** by elongation of its O—CH_2 bond into the hydrogen-bridged radical cation **EA-6a**. As depicted in Fig. 4*a*, **EA-6a** can undergo a facile exchange of its vinyl moiety via a low-lying transition state, which makes its oxygen atoms equivalent.

We further note that elongation of the O—CH_2 bond in other conformers of **EA-3** leads to various **EA-6** conformers, including **EA-6b** whose structure is shown in Fig. 5, which are similar in energy and may dissociate into $CH_3C(OH)_2^{+}$ + $C_2H_3^{\cdot}$ at elevated energies. Elongation of the O—CH_2 bond in **EA-3** can also lead to ion–dipole complexes of ionized ethylene and acetic acid. Such species can be formed from **EA-3** at fairly low internal energies, as seen in Fig. 4*a* where the symmetrical ion–dipole structure at 130 kcal mol^{-1} represents the transition state for switching the acetic acid dipole molecule between the methylene moieties of ionized ethylene (see the Deuterium labelling section). This switching reaction makes the C and H atoms of the ethyl group in **EA-1** equivalent and accounts in part for the H–D exchange reactions of D-labelled isotopologues of **EA-1** as will be discussed later in this paper. At elevated energies, the ion–dipole complexes do not dissociate into

© 2005 NRC Canada

$C_2H_4^{\cdot+}$ + CH_3COOH. Instead, proton transfer (PT) occurs from the ionized ethylene moiety to the acetic acid dipole, which allows the energetically more favourable dissociation into $CH_3C(OH)_2^+$ + $C_2H_3^{\cdot}$ to take place.

In this context we note that the PI study by Baer and co-workers (8) reports an AE of 10.67 ± 0.08 eV for the dissociation of **EA-1** into $CH_3C(OH)_2^+$ (*m/z* 61) + $C_2H_3^{\cdot}$. From the experimental enthalpies of Table 1 and using ΔH_{cor} = 4.7 kcal mol^{-1}, we derive a thermochemical AE of 10.75 eV. These results indicate that this dissociation takes place virtually at the thermochemical threshold, i.e., it has no reverse activation barrier. As previously discussed, loss of $C_2H_3^{\cdot}$ from **EA-1** (see Fig. 4*a*) may be envisaged to occur from the hydrogen-bridged ion **EA-6** or by proton transfer from ethylene – acetic acid ion–dipole complexes, rather than by a formal 1,3-H shift as mentioned in the Introduction.

The [1,3]-hydroxycarbene shift in the distonic ion $[CH_3C(OH)OCH_2CH_2]^{\cdot+}$ (EA-3)

The energy level diagram of Fig. 3*a* describes the communication of ionized ethyl acetate with its enol (**EA-2**), which will be addressed in the next section. It also shows the energetics associated with a [1,3]-hydroxycarbene shift in distonic ion **EA-3**. This isomerization leads to **HB-1** via its 1,5-hydrogen-shift isomer **HB-5** and it could in principle provide an alternative pathway for the loss of water. The energy requirement for this rearrangement precludes this possibility: Fig. 3*a* shows that TS **EA-3** → **HB-5** lies some 10 kcal mol^{-1} above the threshold for the dissociation of the incipient **HB-5** ions into $CH_3C(OH)=CH_2^{\cdot+}$ (*m/z* 58) + CH_2=O by direct bond cleavage. The fact that this dissociation is not observed in either the MI, the CID, or the conventional mass spectrum of **EA-1** implies that the [1,3]-hydroxycarbene shift does not even occur. This is not surprising considering the discussion of the previous section, where it was shown that ions **EA-3** are able to undergo several isomerization and dissociation reactions at energies well below that required for the [1,3]-hydroxycarbene shift.

The energy diagram of Fig. 3*a* also shows that the mechanism proposed by Yeo (Scheme 1) can be refuted: his proposed intermediate is not a minimum on the PES but rather corresponds to the high lying TS **EA-3b** → **HB-5b** associated with the [1,3]-hydroxycarbene shift. Interestingly, our calculations (see Table 1) indicate that the cyclic product ion structure proposed in his scheme (ionized 2-methyloxetene) has the same heat of formation as its ring-opened isomer **MVK**.

Another simple mechanism for water loss from ionized ethyl acetate that complies with the finding that its keto oxygen atom is preferentially lost, would involve a double H transfer to its keto oxygen atom. This reaction would generate an ionized oxycarbene via the sequence **EA-1** (1,4H) → **EA-4** (1,4H) → CH_3-C-O-$CH=CH_2^{\cdot+}$ + H_2O. Ionized oxycarbenes are well-documented species in the gas phase, which may be as stable as their keto or aldehyde counterparts (24). However, CH_3-C-O-$CH=CH_2^{\cdot+}$ appears to be much higher in energy than CH_3-C(=O)-$CH=CH_2^{\cdot+}$, by 21 kcal mol^{-1} (see Table 1) and so its formation, certainly as a product ion in the metastable time frame, can effectively be ruled out.

Table 3. Relative abundances for the loss of water from selected D-labelled isotopologues of ionized ethyl acetate and its enol.

[b]Metastable ions 2ffr ZAB or MS902.

Figure 3*a* also shows that the thermochemical energy requirement for the dissociation **EA-1/2** → $CH_2=C(OH)_2^{\cdot+}$ (*m/z* 60) + C_2H_4 is lower than that for the loss of H_2O. However, metastable ions **EA-1/2** do not lose C_2H_4, indicating that the associated dissociative rearrangement, possibly a 1,3-H shift in **EA-2**, has a high activation energy. As seen in Figs. 2*a* and 2*b*, this dissociation becomes prominent upon collisional activation. A double collision experiment confirmed that the *m/z* 60 ions in the CID spectra are ions $CH_2=C(OH)_2^{\cdot+}$, not $CH_3COOH^{\cdot+}$.

Deuterium-labelling experiments — The relationship between ionized ethyl acetate (EA-1) and its enol (EA-2), and identification of the rate-determining step for the loss of H_2O

Table 3 provides selected deuterium-labelling results taken from refs. 6 and 7. Metastable ions fragmenting in the second field free region (2ffr) of the ZAB and MS902 instruments do so at the same average rate so that the data are comparable (7). From the results of Table 3, it can be deduced that there are two H/D equilibration reactions.

In the first reaction, which is so fast that it readily occurs for ions dissociating in the source, the H atoms of the ethyl chain become positionally equivalent (see the results for $CD_3C(=O)OCD_2CH_3$). A complete exchange of these H atoms would yield a H_2O:HDO:D_2O ratio of 33:67:00, which is close to the observed ratio of 39:52:09. Reversible rearrangement of **EA-1** into **EA-3** followed by isomerization into the ion–dipole complex $CH_3C(OH)=O\cdots C_2H_4^{\cdot+}$, as previously discussed, accounts for this exchange reaction.

In the longer lived metastable ions, the H atoms of the acetyl group also participate in the exchange reactions, almost to the statistical limit. This can be rationalized by invoking a slow but reversible isomerization of **EA-3** into the enol ion **EA-2**. It leads to exchange of the H atoms of the acetyl group with those of the methyl H atoms of the ethyl group and together with the above fast exchange reaction, an (almost) complete equilibration of all H atoms now takes place. This would imply that metastable ethyl acetate ions consist of an (almost) equilibrated mixture of the keto, distonic, and enol isomers.

© 2005 NRC Canada

Our calculations (see Fig. 3*a*) indicate that ions **EA-2** and **EA-3** are lower in energy than **EA-1** and that they can be produced at energies just above the formation of **EA-1**. This makes it very likely that metastable ions **EA-1** primarily exist as enol ions **EA-2** and distonic ions **EA-3**. This is in good agreement with a Fourier transform ion cyclotron resonance study by Kiminkinen et al. (25), who concluded that the long-lived (timescale > 1 s) radical cation of ethyl acetate exists as its enol form in the gas phase. Their experiments further indicated, in agreement with our calculations, that the energy barriers for isomerization of **EA-1** to the distonic ion **EA-3** and of **EA-3** to the enol ion **EA-2** must be near or below the enthalpy of formation of **EA-1**, and that this radical cation is kinetically unstable.

As expected from this scenario, the enol ion also shows fast H/D equilibration reactions of the ethyl side chain (see Table 3). Earlier work (7) has noted that enol ions dissociating in the source rearrange irreversibly to the distonic ion, i.e., $CH_2{=}C(OH)OCD_2CD_3^{\cdot+} \rightarrow CH_2DC^{+}(OH)OCD_2CD_2^{\cdot}$. As previously discussed, the latter ion can then access the ion–dipole complex $CH_2DC(OH){=}O\cdots C_2D_4^{\cdot+}$ and fall back to the distonic form leading to equilibration of the OH hydrogen and the four C_2D_4 deuterium atoms. Again, in the metastable time frame, almost complete equilibration of all H and D atoms occurs.

The labelled ion $CD_3C(=O)OCH_2CH_3^{\cdot+}$ shows a H_2O/HDO loss ratio of 1.69, while the D_2O/HDO loss ratio for the inversely labelled compound $CH_3C(=O)OCD_2CD_3$ is 1.25, and so an H/D isotope effect is operative. According to the energy diagram of Fig. 4*b*, the final step is rate-determining. This step is a H transfer, and so we propose that the isotope effect can be connected with this step.

From the data in Table 3 we can calculate that for the metastable ions loss of H_2O is 36% specific for the keto ions and 41% specific for the enol ions: the final entry in Table 3, for example, can be broken down into a 41% specific H_2O loss and random H_2O, HDO, and D_2O losses of 32%, 26%, and 1%, respectively. This small increase in specificity may well indicate that the starting enol ions fragment at a slightly higher internal energy than the keto ions. This is corroborated by the finding that the kinetic energy release ($T_{0.5}$) for loss of water is slightly larger for the enol ion than for the keto ion (7). The larger $T_{0.5}$ value cannot be taken as showing that a rate-determining isomerization precedes fragmentation of the enol ion, paralleling the behaviour of the acetamide system (26).

Baer and co-workers (8) note that the measured activation energy for loss of H_2O from ionized ethyl acetate (0.3 eV) is too small to allow the molecular ion to be metastable, unless it rearranges into a more stable form. By modelling their experimentally derived *k* vs. *E* curve with standard RRKM calculations, Baer and co-workers concluded that the rearranged form has a $\Delta_f H^0_{298}$ of 110 kcal mol^{-1}, which can be associated with **EA-2**, **EA-3**, or **HB-2**. The slow rate constant is the result of the participation of all the low energy isomers leading to a large density of states of the dissociating ions.

The [1,2]-hydroxycarbene shift in the distonic ion $[CH_3C(OH)OCHCH_3]^{\cdot+}$ (EA-4)

Using the energy diagram of Fig. 3*b* as a guide, we note that the distonic ion **EA-4** is readily accessible from **EA-1** via a low energy 1,4-H shift. The ion can communicate with **EA-2** via its conformer **EA-4c**, but the TS for the associated 1,4-H shift (see Table 2*a*) is ca. 8 kcal mol^{-1} higher in energy than that for the enolization of its slightly less stable distonic isomer **EA-3** (see Fig. 3*a*).

The energy diagram of Fig. 3*b* further shows that conformer **EA-4c** may serve as the immediate precursor for a [1,2]-hydroxycarbene shift that connects **EA-1** with the PES of the acetoin radical cation ($CH_3C(=O)CH(OH)CH_3^{\cdot+}$, **AC-1**). This rearrangement, whose transition state lies ca. 6 kcal mol^{-1} above the level for the water loss, does not contribute to the loss of water because low energy acetoin ions exclusively dissociate into $CH_3C(H)OH^+ + CH_3C{=}O^{\cdot}$. This reaction involves a remarkable hidden rearrangement — metastable ions $CH_3C(=O^{18})CH(OH)CH_3^{\cdot+}$ generate $CH_3C(H)^{18}OH^+$ and $CH_3C(H)^{16}OH^+$ in a 1:1 ratio — and a mechanism involving the hydrogen-bridged radical cation ($CH_3C(=O^{18})\cdots H\cdots O{=}C(H)CH_3^{\cdot+}$) as the key intermediate has been proposed (20).

Metastable ions **EA-1** do not dissociate into $CH_3C(H)OH^+ + CH_3C{=}O^{\cdot}$, but the reaction becomes important upon collisional activation, as seen from the prominent *m*/*z* 45 peak in the CID mass spectrum of Fig. 2*a*. From the inset of Fig. 2*a*, it is seen that this peak shifts almost completely to *m*/*z* 47 in the CID spectrum of $CH_3C(=O)^{18}OCH_2CH_3$. This observation is in line with the expectation that the energy-rich acetoin ions ($CH_3C(=O)CH(^{18}OH)CH_3^{\cdot+}$) resulting from the [1,2]-hydroxycarbene shift will not rearrange but immediately dissociate.

Baer and co-workers (8) have reported the experimental AE for this reaction (10.70 ± 0.1 eV). They note that this value is too high to account for the threshold generation of the above products and suggest that the reaction may have a significant reverse activation barrier. From the evaluated experimental enthalpies of Table 1 and using ΔH_{cor} = 4.7 kcal mol^{-1}, we derive a thermochemical AE of 10.46 eV, implying that a reverse barrier of ca. 5.5 kcal mol^{-1} may indeed be present. Our calculations support this proposal: the barrier for the [1,2]-hydroxycarbene shift (see Fig. 3*b*) lies 5 kcal mol^{-1} above the dissociation level $CH_3C(H)OH^+ + CH_3C{=}O^{\cdot}$.

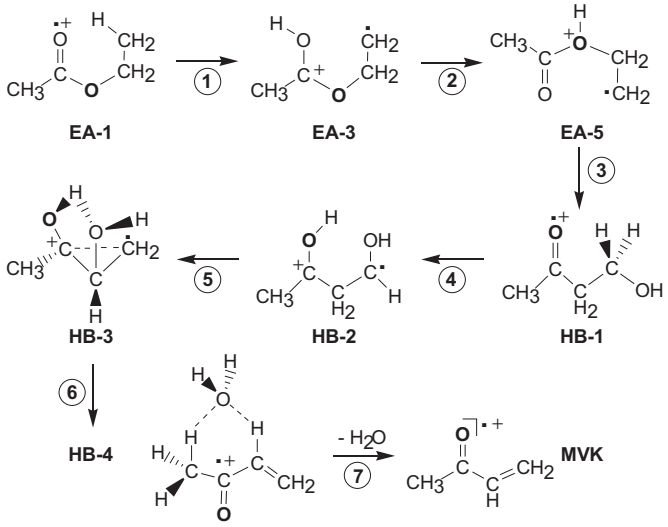
As previously mentioned, metastable acetoin ions do not lose water. Nevertheless, our CBS-QB3 calculations indicate that **AC-1** can communicate with **HB-3b** of Scheme 3 at the threshold for the water loss. The barrier for the isomerization of conformer **AC-1b** into **HB-3c** lies at 139 kcal mol^{-1}, while TS **HB-3c** → **3b** lies at 130 kcal mol^{-1} (Tables 2*a* and 2*b*). Thus, the overall energy requirement for this rearrangement of **AC-1** is very close to that of the products formed by its direct bond cleavage into $CH_3C(H)OH^+$ (140 kcal mol^{-1}, see Table 1). However, the dynamical situation for these two reactions is very different. The rearrangement has a tight transition state, whereas the dissociation, which has no reverse activation energy, corresponds to a loose transition state. A standard RRKM calculation predicts that the excess energy needed for the rearrangement to take place in the metastable time window (10 μs) exceeds 5 kcal mol^{-1}. This is caused by the large activation energy associated with the rearrangement. For the direct bond cleavage reaction we have used the model derived from the statistical adiabatic channel theory (27). Here the excess energy

© 2005 NRC Canada

needed is less than 1 kcal mol^{-1} because the acetyl radical lost has a large dipole moment (2.5 D at the B3LYP/CBSB7 level of theory). Therefore, low energy acetoin ions **AC-1** prefer the direct dissociation pathway above rearrangement into **HB-3c** and the subsequent loss of water. In the same vein, the rearrangement **HB-3b** → **AC-1** → $CH_3C(H)OH^+$ + $CH_3C{=}O^{\cdot}$ does not occur, as demonstrated by the complete shift of the *m*/*z* 45 peak to *m*/*z* 47 in the CID spectrum of ^{18}O-labelled **HB-1** (see the inset of Fig. 2*c*).

Summary

Our computational study, in concert with previous and present experimental work, leads to the following mechanistic proposal for the loss of water from ionized ethyl acetate in the metastable time frame. As shown in Scheme 4, the mechanism involves seven steps. These are: (1) a 1,5-hydrogen shift in ionized ethyl acetate yielding its distonic isomer **EA-3**; (2) an ethylene shift in **EA-3** generating another distonic ion (**EA-5**); (3) a 1,3-acetyl shift in **EA-5** yielding a conformer of ionized 4-hydroxy-2-butanone (**HB-1**); (4) a 1,4-hydrogen shift in **HB-1** yielding its distonic isomer **HB-2**; (5) a 1,2-hydroxycarbene shift in **HB-2**. This step leads to **HB-3**, a one-electron long bonded species whose hydroxyl groups are bridged. (6) A formal 1,4-hydrogen shift in which the bridging hydrogen moves to the adjacent hydroxyl group to form the water molecule of the ion–dipole complex **HB-4**. This step is rate-determining and may account for the kinetic H/D isotope effect. (7) Dissociation into ionized methyl vinyl ketone and a water molecule.



Each step is a simple transformation in itself, and all consecutive steps yield a transparent picture of the seemingly complex dissociation behaviour of ionized ethyl acetate. Our mechanism satisfies the energetic constraints imposed by experiment and provides a rationale for the ^{18}O- and D-labelling results.

Experimental and theoretical methods

The experiments were performed with the VG Analytical ZAB-R mass spectrometer of BEE geometry (B, magnet; E, electric sector) (28). MI mass spectra were recorded in the second field free region (2ffr); CID mass spectra were recorded in the 2 and 3ffr using oxygen as the collision gas (transmittance, T = 70%). The CID mass spectra of the 2ffr metastable peaks were obtained in the 3ffr using O_2 as the collision gas. For these experiments the maximum available accelerating voltage (10 kV) was used. CID spectra of reference ions having a translational energy close to that of the product ions resulting from (MI or CID) dissociations in the 2ffr were also obtained in the 3ffr. All spectra were recorded using a PC-based data system developed by Mommers Technologies Inc. (Ottawa, Ontario).

Ethyl acetate, methyl vinyl ketone, and 4-hydroxy-2-butanone were of research grade (Aldrich) and used without further purification. The ^{18}O-labelled ester $CH_3C(=O)^{18}OCH_2CH_3$ was synthesized on a microscale by esterification of acetic acid with $C_2H_5{}^{18}OH$ (MSD Canada); samples of $CH_3C(=O^{18})OCH_2CH_3$ and $CH_3C(=O^{18})CH_2CH_2OH$ were prepared by exchange of the carbonyl oxygen of the unlabelled precursors with $H_2{}^{18}O$ (Prochem 90 atom%) under slightly acidic conditions.

Scheme 4.

The calculations were performed with the CBS-QB3 model chemistry (17) using Gaussian 2003, Rev C.02 (29) and (for selected transition state searches) GAMESS-UK (30). In this model chemistry, the geometries of minima and connecting transition states are obtained from B3LYP density functional theory in combination with the 6-311G(2d,d,p) basis set (also denoted as the CBSB7 basis set). The resulting total energies and enthalpies of formation for minima and connecting transition states (TS) in the ethyl acetate (**EA**), acetoin (**AC**), and 4-hydroxy-2-butanone (**HB**) systems of ions are presented in Tables 2*a* and 2*b*. Computational and experimental enthalpies for various dissociation products are presented in Table 1. We have also used the G3 model chemistry (16*b*) to calculate the enthalpies of the species of Table 1: agreement with the results of the CBS-QB3 method (and experiment) was quite satisfactory, within ±1 to 2 kcal mol^{-1}.

Spin contaminations were within an acceptable range. The correct identity of transition states was verified (where not trivially evident) by means of intrinsic reaction coordinate (IRC) calculations using the algorithm implemented in Gaussian 2003.

For several facile isomerization reactions, including **EA-1a** → **EA-3a** in Fig. 4, the CBS-QB3 energy of the TS is calculated to be slightly lower than that of the least stable of the connecting isomers. This may happen since transition states are more sensitive to correlation effects than minima and the ZPE also tends to favour transition states.

However, the TS connecting **HB-1b** and **HB-2a** (see Fig. 4 and Table 2*b*) is calculated to lie much lower in energy: 4.5 kcal mol^{-1} below that of **HB-1b**. Here, the discrepancy between the B3LYP/CBSB7 energies and the final CBS-QB3 results is probably due to the fact that the B3LYP and the MP2 parts of the CBS-QB3 calculation disagree about the geometry of the transition state. We have compared the contributions to the CBS-QB3 energy for **HB-1b** and two transition states relating to this isomer. It was found that for **HB-1b** and TS **HB-1a** → **1b** the various contributions are

© 2005 NRC Canada

nearly the same, but this is not case for TS **HB-1** $\rightarrow$ **2a**. Here, the ΔE(MP2) contribution is much larger and the effect is enhanced in the ΔE(CBS) component, which is based on the MP2 energies. In contrast, the ΔE(MP4) contribution for this TS is smaller. This analysis suggests that for this transition state the MP2 method is not reliable enough to give satisfactory results.

Figure 5 displays the optimized geometries for the principal species. The complete set of computational results is available from the authors upon request.

RRKM theory (22) was used to calculate microcanonical rate constants. The harmonic frequencies and rotational constants were taken from the B3LYP/CBSB7 part of the CBS-QB3 calculations. The internal energies were calculated from the CBS-QB3 heats of formation at 0 K.

The extended RRKM model used is that described by Baer and Hase (22). Here several reaction steps are combined to get an overall rate constant. As will be discussed in a separate publication (in preparation) this procedure also makes it possible to compare the yields of various dissociation products.

Predicting ion rearrangement reactions — The energetics of the internal S_N2 reaction in gas-phase proton-bound molecular pairs[1]

Julie A.D. Grabowy and Paul M. Mayer

Abstract: A common rearrangement reaction for gas-phase proton-bound molecular pairs corresponds to an internal S_N2 reaction that results in the loss of a small neutral molecule. For pairs $(RCN)(ROH)H^+$, the energies of the two transition states (TS_a and TS_b) and the intermediate complex (IC) in the isomerization reaction (relative to the proton-bound pair, in kJ mol^{-1}) can be estimated using the following relationships: $E(TS_a) = 87 - 9(n) - 0.33(\Delta PA)$, $E(IC) = 83 - 9(n) - 0.33(\Delta PA)$, and $E(TS_b) = 107 - 9(n) - 0.10(\Delta PA)$, where 87, 83, and 107 kJ mol^{-1} are the values for $(CH_3CN)(CH_3OH)H^+$. Here, n is the number of stablizing alkyl groups on the central S_N2 carbon and ΔPA is the difference between the proton affinity of the migrating moiety and that for the base system (in this case, CH_3CN). For the analogous pairs $(ROH)(R'OH)H^+$, only the first value in each expression is different (98, 94, and 121 kJ mol^{-1}, respectively, calculated for $(CH_3OH)_2H^+$).

Key words: proton-bound molecular pairs, isomerization, internal S_N2 reaction, energetics, metastable ions.

Résumé : Les réactions S_N2 internes qui résultent de la perte d'une petite molécule neutre sont des réactions de réarrangements communes en phase gazeuse pour des paires moléculaires liées par un proton. Pour les paires $(RCN)(ROH)H^+$, il est possible d'évaluer les énergies des deux états de transition (ET_a et ET_b) et le complexe intermédiaire (CI) dans la réaction d'isomérisation (relatives à la paire liée par un proton, en kJ mol^{-1}) en utilisant les relations suivantes: $E(ET_a) = 87 - 9(n) - 0{,}33(\Delta PA)$, $E(CI) = 83 - 9(n) - 0{,}33(\Delta PA)$ et $E(ET_b) = 107 - 9(n) - 0{,}10(\Delta PA)$, dans lesquelles les valeurs 87, 83 et 107 kJ mol^{-1} sont les valeurs pour $(CH_3CN)(CH_3OH)H^+$, n est le nombre de groupes alkyles stabilisants sur l'atome de carbone central de la réaction S_N2 et ΔPA est différence entre les affinités protoniques de la portion qui migre et celle du système basique, dans ce cas le CH_3CN. Pour les paires analogues $(ROH)(R'OH)H^+$, seule la première valeur de chaque expression diffère, soit 98, 94 et 121 kJ mol^{-1} respectivement pour $(CH_3OH)_2H^+$.

Mots clés : paires moléculaires liées par un proton, isomérisation, réaction S_N2 interne, énergie, ions métastables.

Introduction

The search for meaningful trends in chemical reactivity and their correlation with molecular parameters is one of the fundamental goals of chemistry. One well-established mechanism for the reaction of gas-phase and solution ions is the bimolecular nucleophilic substitution or S_N2 reaction (1). This type of reaction has been used to study the role of steric and solvent effects (2), and structure–reactivity correlations (3) in chemical reactivity. While the S_N2 reaction has been studied extensively in solution, interpretation of the results is often complicated by the effects of solvation. It is these solvent effects that result in the large difference between the rates and mechanisms of gas-phase and solution-phase S_N2 reactions. Both experimental and theoretical studies have shown that a gas-phase S_N2 reaction can be characterized by a double-well potential energy surface (PES) with a central barrier separating two ion–molecule complexes (4–9); this discovery is in sharp contrast with the PES derived for an S_N2 reaction occurring in solution, which consists of a transition state that directly connects reactants and products (Fig. 1). In aqueous solution, the ion–dipole attraction (responsible for the two minima shown in the gas-phase PES) is nullified by the energy required to partially desolvate the ion, resulting in a unimodal energy profile with a large central barrier.

One class of gas-phase ions that undergo a unimolecular rearrangement that is similar to the above mentioned S_N2 reaction is the family of proton-bound pairs of alcohols and nitriles $(RCN)(ROH)H^+$ and $(ROH)(R'OH)H^+$ (where R represents substituents). The mass spectrometry of these proton-bound pairs has been extensively studied in this laboratory (10–14) and by Fridgen and McMahon (15, 16) and Audier et al. (17). A feature common to each system is an isomerization reaction (leading to a kinetically unstable isomer that loses water) that competes on the microsecond timescale with the cleavage of the hydrogen bond. The competition between the two reaction channels indicates that a

Scheme 1.

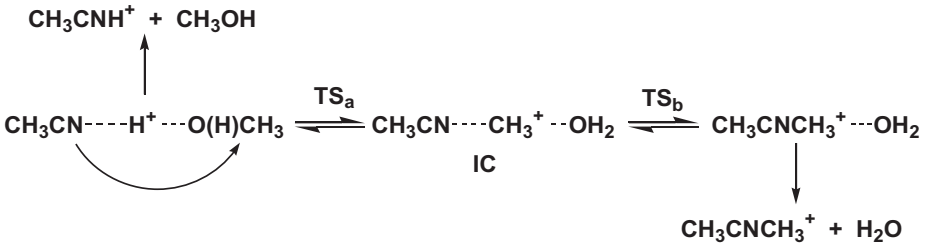

Fig. 1. Schematic energy profiles highlighting the differences between gas-phase and solution-phase S_N2 reactions.

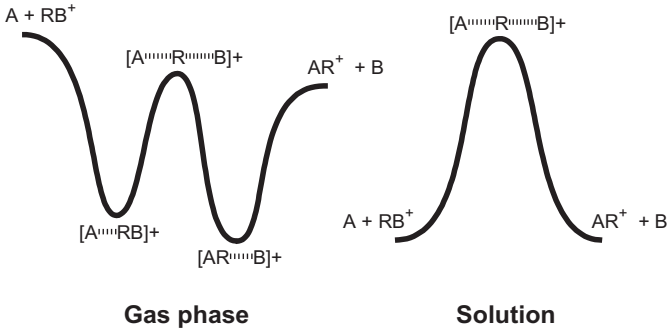

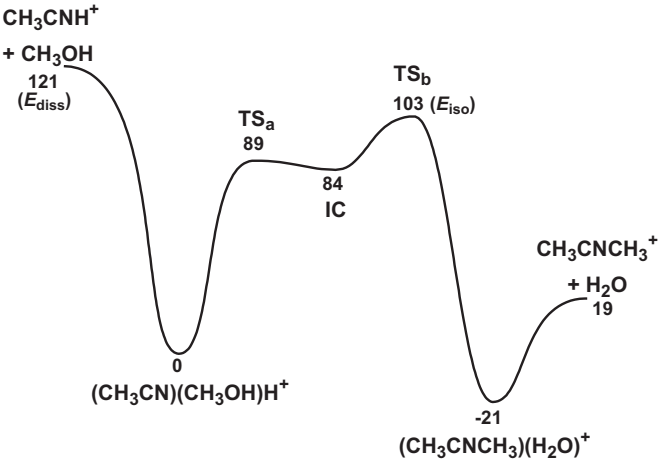

Fig. 2. MP2/6-31+G(d) potential energy diagram for the unimolecular process of the proton-bound pair consisting of acetonitcrile and methanol. The structures of TS_a, TS_b, and IC are illustrated in Scheme 1 and can be found in a previous publication (12). The labels E_{diss} and E_{iso} refer to the two energy levels used in the peak height intensity ratio vs. ΔE modeling.

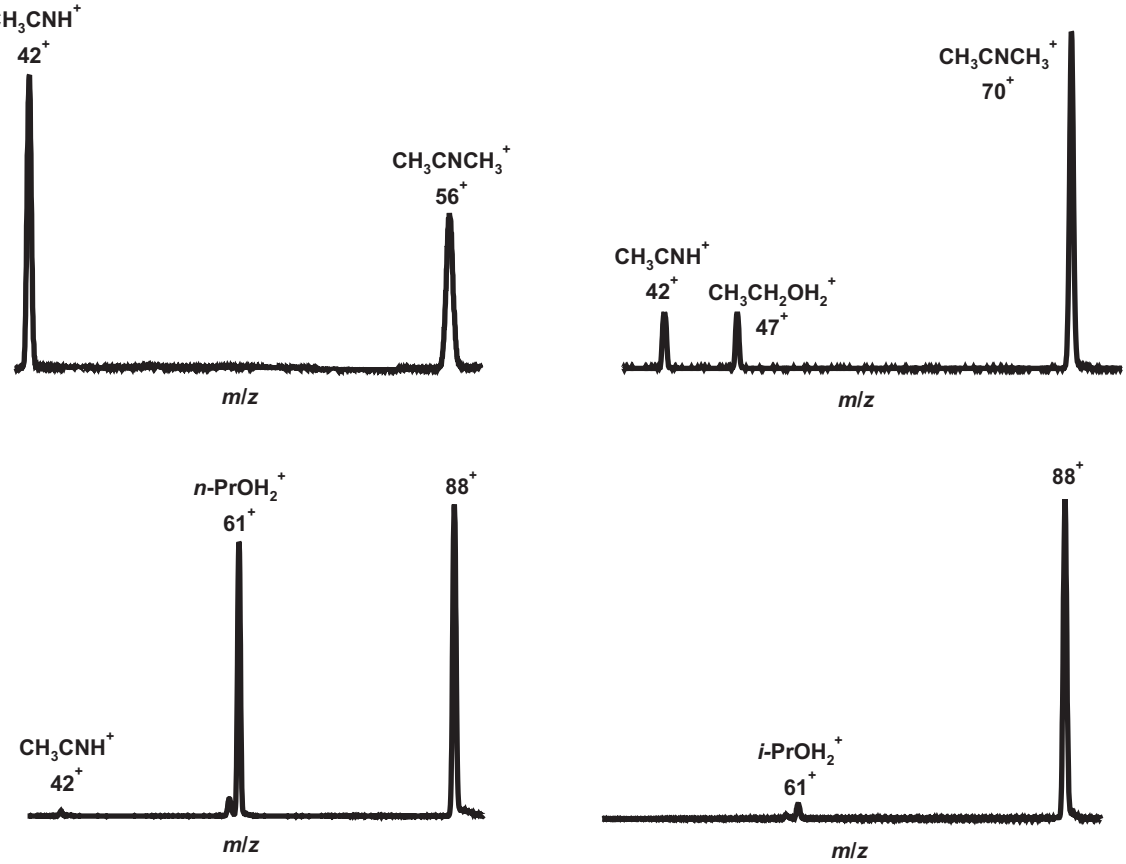
fine balance exists between the relative energy barriers for dissociation and isomerization. The isomerization mechanism is outlined in Scheme 1 and a typical PES is shown in Fig. 2 for $(RCN)(ROH)H^+$ (12). The mechanism and surface are analogous to that for $(ROH)(R'OH)H^+$. Computationally, it has been found that methyl substitution of the central carbon of the intermediate complex (IC) will stabilize this ion and the transition states TS_a and TS_b (12). RRKM modelling of the kinetics on the reaction surface has shown that even though it is lower in energy, TS_a can play an important role in determining the fraction of ions that undergo isomerization (14).

Empirical relationships exist indicating that the key factor in determining the strength of the hydrogen bonds in these ions (18, 19) is the difference in proton affinity (PA) of the two molecules. The present work addresses the unimolecular S_N2 reaction by first examining the relationship between the energetics and relative peak intensities in tandem mass spectra and then by deriving empirical formulae for predicting the energies of the IC and transition states, thereby allowing the entire potential energy surface to be mapped out without experimental or computational input.

Experimental and computational procedures



The experiments were performed on a modified VG ZAB-2HF mass spectrometer, which incorporates a magnetic sector followed by two electrostatic analysers (BEE geometry) (20). Protonated cluster ions were generated in the chemical ionization ion source of the instrument. The pressures in the ion source chamber, read with an ionization gauge located above the ion source diffusion pump, were typically between 10^{-5} and 10^{-4} Torr (1 Torr = 133.3224 Pa) (the pressure in the ion source itself being approximately two orders of magnitude higher). The accelerating voltage was held constant at 8 kV. Metastable ion (MI) mass spectra were recorded in the usual manner in the second field-free region (2FFR) of the mass spectrometer (21). All chemicals were commercially obtained and used without further purification.

Standard ab initio molecular orbital calculations (22) were performed using the Gaussian 98 suite of programs (23). Geometries were optimized at the MP2/6-31+G(d) level of theory as previous work from this group has shown that relative energies on these surfaces are adequately described at this level of theory (24). Vibrational frequency analysis was performed to verify transition states and equilibrium structures. Transition-state structures were further confirmed by the intrinsic reaction coordinate (IRC) method in Gaussian 98. The zero-point energies were scaled by a factor of 0.967 recommended by Scott and Radom (25). Readers are directed to Supplemental data[3] available from this journal for the full list of calculated relative energies for TS_a, IC, and TS_b used in this study.

Fig. 3. Representative MI mass spectra of the proton-bound pairs (*a*) $(CH_3CN)(CH_3OH)H^+$, (*b*) $(CH_3CN)(CH_3CH_2OH)H^+$, (*c*) $(CH_3CN)(CH_3CH_2CH_2OH)H^+$, and (*d*) $(CH_3CN)((CH_3)_2CHOH)H^+$.

Microcanonical rate constants were calculated using the RRKM expression (26)

$$k(E) = \frac{\sigma}{h}\frac{N^{\ddagger}(E - E_0)}{\rho(E)}$$

where σ is the reaction symmetry number, h is Planck's constant, $N^{\ddagger}(E - E_0)$ is the sum-of-states for the transition state, and $\rho(E)$ is the density of states of the reacting ion. Sums and densities of states were calculated using the direct count algorithm of Beyer and Swinehart (27).

Results and discussion

General mechanistic features

The mechanism outlined in Scheme 1 has features that are common with and distinct from the gas-phase bimolecular S_N2 reaction. The most obvious similarity is TS_b, which resembles the transition state in Fig. 1. The main distinctions are in the initial isomerization step from the proton-bound pair to the IC via TS_a. It has been shown that the bimolecular reaction of CH_3CNH^+ with neutral methanol skips the proton-bound pair and forms the IC directly before crossing TS_b (15). The long lifetime (and lower internal energy) of metastable ions means that any IC formed will rearrange back to the proton-bound pair prior to dissociation.

Peak intensity ratio vs. ΔE

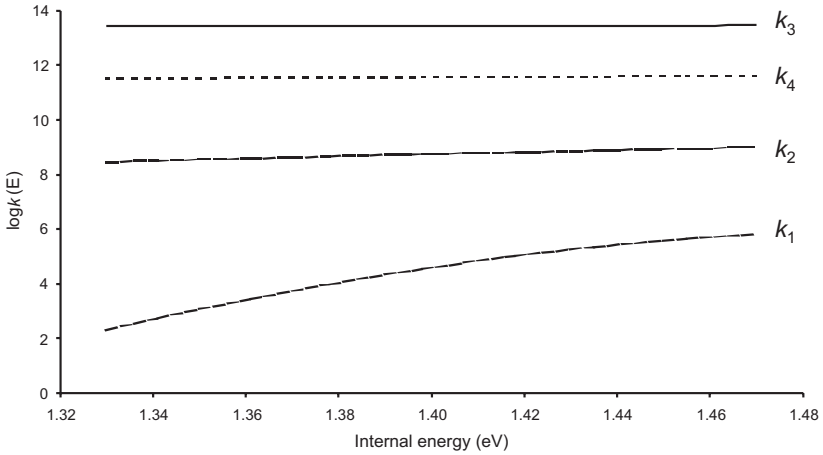
Characteristic MI mass spectra for the acetonitrile–alcohol proton-bound pairs involving methanol, ethanol, and 1- and 2-propanol are shown in Fig. 3 (these spectra have been previously published (10–12)). It is tempting to simplify the potential energy surfaces from that shown in Fig. 2 to single-well surfaces whose product channels are simple hydrogen bond cleavage and isomerization through the high energy transition state TS_b leading to water loss. This simplification makes sense when the rate constants for the fundamental process in Fig. 2 are compared (Fig. 4). The $k(E)$ vs. E curves in Fig. 4 suggest that the IC will not have a significant lifetime and may be considered, to a first approximation, as kinetically irrelevant. With this simplification, there should be a relationship between the ratios of the intensities of the peaks in the MI mass spectra for the two processes and the relative barrier heights, similar to the commonly used kinetic method (28)

$$\ln\left(\frac{k_{diss}}{k_{iso}}\right) = \ln\left(\frac{I_{diss}}{I_{iso}}\right) = \ln\left(\frac{A_{diss}}{A_{iso}}\right) - \frac{\Delta E}{RT}$$

where k_{diss} and k_{iso} are the rate constants for the dissociation and isomerization of the proton-bound pair, I_{diss} and I_{iso} are the ion peak intensities measured in the mass spectrum of metastable proton-bound pairs, A_{diss} and A_{iso} are the pre-exponential factors, ΔE is the difference between the calculated barrier heights to dissociation and isomerization

© 2005 NRC Canada

Fig. 4. RRKM rate constants ($k(E)$) of the four elementary processes in the S_N2 mechanism for $(CH_3CN)(CH_3OH)H^+$. k_1 = dissociation of $(CH_3CN)(CH_3OH)H^+$ to $CH_3CNH^+ + CH_3OH$, k_2 = $(CH_3CN)(CH_3OH)H^+$ to IC via TS_a, k_3 = IC to $(CH_3CN)(CH_3OH)H^+$ via TS_a, and k_4 = IC to $(CH_3CNCH_3)(H_2O)^+$ via TS_b.



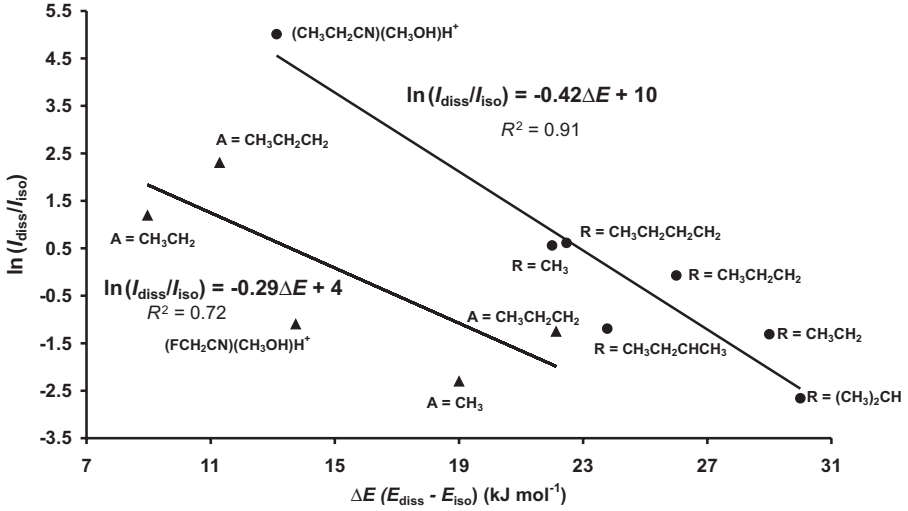


Fig. 5. Plot of $\ln(I_{diss}/I_{iso})$ vs. ΔE for the following proton-bound pairs: $(CH_3CN)(ROH)$ (●), unless otherwise noted and $(ClCH_2CN)(AOH)$ (▲), unless otherwise noted.

(which consist of the difference between the energy of the proton-bound pair and the lowest energy dissociation products (E_{diss}) and the high energy transition state, $TS_b(E_{iso})$), R is the gas constant, and T is the temperature. By plotting the natural logarithm of the ratio of peak intensities ($\ln(I_{diss}/I_{iso})$) against the difference in the calculated barrier heights, a linear relationship is obtained (Fig. 5). The equation of the line was determined to be $\ln(I_{diss}/I_{iso}) = -0.42\Delta E + 10$. This relationship is based upon the calculated relative energies for the proton-bound pairs of acetonitrile with methanol, ethanol, 1-propanol, 2-propanol, 1-butanol, and 2-butanol, but extends to proton-bound pairs involving propionitrile, suggesting that this equation can be used to determine the barrier height ratio between the two channels for any alkylnitrile–alcohol pair. Thus, by measuring the relative peak intensities in the MI mass spectra of proton-bound pairs involving alkylnitriles and alcohols, the difference in the barrier heights for the two dissociation channels may be obtained (Table 1). Coupled with the empirical expression for E_{diss} (19), E_{iso} can be extracted (Table 1). The slope ($1/RT$) of 0.42 mol kJ^{-1} yields a temperature of 286 K. This "effective" temperature has been discussed in relation to the kinetic method (28) and has been found to be related to the internal energy content of dissociating proton-bound pairs (29).

The single-well approximation breaks down when halogenated nitriles are examined. MP2/6-31+G(d) calculations for $(ClCH_2CN)(CH_3OH)H^+$ (14) showed that chloro substitution lowered the relative energy of TS_a, but left TS_b unaffected, resulting in a more abundant isomerization reaction compared with $(CH_3CN)(CH_3OH)H^+$. Plotting $\ln(I_{diss}/I_{iso})$ vs. ΔE for the proton-bound pairs $(ClCH_2CN)(AOH)H^+$ and $(FCH_2CN)(CH_3OH)H^+$ (where A = CH_3, CH_3CH_2, $CH_3CH_2CH_2$, and $(CH_3)_2CH$)) results in a displaced line with $\ln(I_{diss}/I_{iso}) = -0.29\Delta E + 4$. The lower PAs of the halogenated alkyl nitriles (745.7 kJ mol^{-1} for $ClCH_2CN$ vs. 779.2 kJ mol^{-1} for CH_3CN) make it easier for them to migrate to the backside of the alcohol moiety, resulting in a lower energy for TS_a (14). This slope yields an effective temperature of 414 K, which means that these dissociating

[a]Derived employing the relationship $E_{diss} = -0.26|\Delta PA| + 125$ kJ mol^{-1} (19).

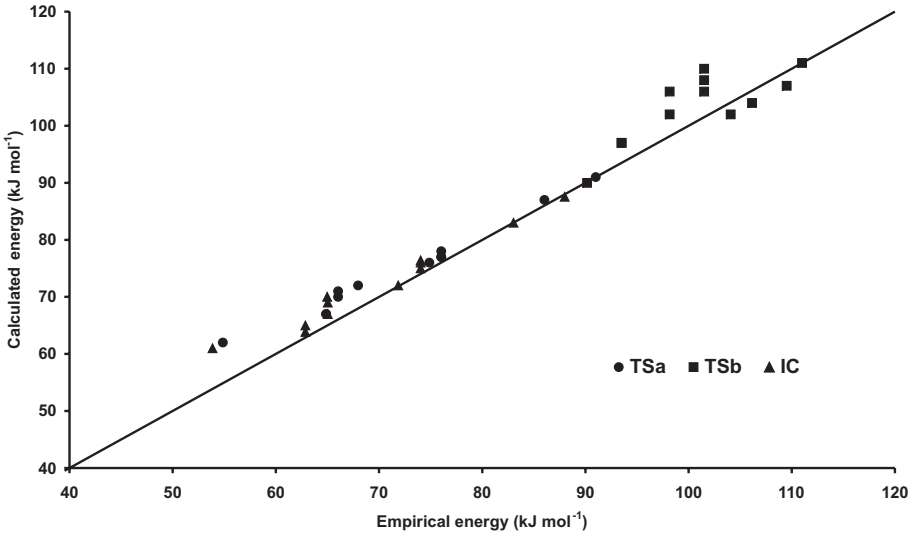
ions may have a broader internal energy distribution than those for the alkyl nitriles discussed earlier.

Clearly, two main factors in determining the energetics of the species in this rearrangement reaction are the stabilization of the charge in TS_b and the proton affinity of the migrating moiety. These two parameters are employed in the following to produce more general relationships for the energetics of the S_N2 rearrangement.

Empirical relationships

The preceding discussion clearly illustrates the relationship between the peak intensities observed in mass spectra and the barrier heights calculated with theory. Although this method for extracting energetics is simple to use, it has the drawback that only the energy of TS_b is found and that considerable mass spectrometric and theoretical work must be done to establish the linear relationships to begin with. More desirable would be the ability to predict the relative energies of TS_a, TS_b, and IC without the use of mass spectrometry or theory. The MP2/6-31+G(d) relative energies of TS_a, TS_b, and IC for the proton-bound pairs were calculated for $(CH_3CN)(ROH)H^+$, $(CH_3CH_2CN)(CH_3OH)H^+$, $(ClCH_2CN)(AOH)H^+$, and $(FCH_2CN)(CH_3OH)H^+$ (where R = CH_3, CH_3CH_2, $CH_3CH_2CH_2$, $(CH_3)_2CH$, $CH_3CH_2CH_2CH_2$, $CH_3CH_2CHCH_3$ and A = CH_3, CH_3CH_2, $CH_3CH_2CH_2$, $(CH_3)_2CH$)). Using $(CH_3CN)(CH_3OH)H^+$ as the base system, the data provides the following empirical corrections to the relative energies of TS_a, TS_b, and IC.

$$E(TS_a) = 87 - 9(n) - 0.33(\Delta PA)$$
$$E(IC) = 83 - 9(n) - 0.33(\Delta PA)$$
$$E(TS_b) = 107 - 9(n) - 0.10(\Delta PA)$$



Similar results are obtained when the family of alcohol proton-bound pairs are investigated (here the base system is $(CH_3OH)_2H^+$). For these ions, one alcohol migrates to the back of the protonated alcohol resulting in the formation of an isomer consisting of a protonated ether bound to H_2O.

$$E(TS_a) = 98 - 9(n) - 0.33(\Delta PA)$$
$$E(IC) = 94 - 9(n) - 0.33(\Delta PA)$$
$$E(TS_b) = 121 - 9(n) - 0.10(\Delta PA)$$

PA effects were probed in the latter series using $(CF_3OH)(CH_3OH)H^+$ and $(CF_3OH)(CH_3CH_2OH)H^+$ and alkyl substitution with $(CH_3OH)(ROH)H^+$ (where R = CH_3,

CH_3CH_2, $CH_3CH_2CH_2$, $(CH_3)_2CH$). The first number in each equation is the energy calculated for the reference proton-bound pair, namely $(CH_3CN)(CH_3OH)H^+$ and $(CH_3OH)_2H^+$. The *n* term represents the number of alkyl substituents on the central S_N2 carbon (e.g., *n* = 0, 1, and 2 for methyl, ethyl/1-propyl, and 2-propyl, respectively), and the 9 kJ mol^{-1} was deduced by comparing the relative energies for TS_a, TS_b, and IC among pairs having a constant migrating group (i.e., $(CH_3CN)(ROH)H^+$ and $(CH_3OH)(ROH)H^+$). The ΔPA term is the difference between the proton affinities of the migrating moieties (e.g., for $(ClCH_2CN)(CH_3OH)$, ΔPA = PA (CH_3CN) – PA $(ClCH_2CN)$). The *n* term is identical for the equations owing to the fact that alkyl substitution of the alcohol results in alkyl substitution of the charge-bearing site in all three species, the central carbon in the S_N2 process (see Scheme 1). In the proton-bound pair, however, this alkyl substitution is not at the charge-bearing site (the proton), but remote from it. Thus, TS_a, TS_b, and IC are stabilized to a greater extent than the original proton-bound pair by approximately 9 kJ mol^{-1} per alkyl group. This is comparable to that found in covalently bound ions. Let us consider alkyl substitution on $CH_3CH_2OH^{+\cdot}$ (ΔH_f = 775 kJ mol^{-1}). If the H on the charge-bearing oxygen is replaced with a methyl group to form the methyl ethyl ether ion $(CH_3CH_2OCH_3^{+\cdot})$, the heat of formation decreases by 54 kJ mol^{-1} to 721 kJ mol^{-1}. Similarly, if a methyl group hydrogen is replaced instead to form the *n*-propanol ion, the heat of formation decreases by only 44 kJ mol^{-1} to 731 kJ mol^{-1}, a difference of 10 kJ mol^{-1} with the previous case. So it can be reasonably inferred that substituents that stabilize or destabilize charge in conventional ions will also do so to the same extent in the species in this S_N2 mechanism.

The second parameter that influences the relative energy of TS_a, TS_b, and IC is the proton affinity of the migrating molecule. A slightly larger proton affinity effect is observed for TS_a and IC than for TS_b. To rearrange to IC via TS_a the migrating molecule must break a hydrogen bond, whereas for the second transition state (TS_b), no migration is involved. The larger the proton affinity of the migrating species, the stronger the hydrogen bond to the proton and thus the higher the energy barrier. For example, the relative energies of TS_a, TS_b, and IC for $(CH_3OCH_2CN)(CH_3OH)H^+$ are 82, 106, and 78 kJ mol^{-1}, respectively. The differences between these values and those for the $(CH_3CN)(CH_3OH)H^+$ base system are 5, 1, and 5 kJ mol^{-1}, in agreement with the predictions from the empirical equations of 7, 2, and 7 kJ mol^{-1} (the PA of CH_3OCH_2CN is 758.1 kJ mol^{-1}) (30). In general, there is excellent agreement between the original calculated MP2/6-31+G(d) relative energies and those derived from the empirical equations described earlier (Fig. 6).

Table 2. Calculated relative energies of TS_a, TS_b, and IC for four base system proton-bound pairs involving the listed migrating molecule and methanol. The S_N2 reaction leads to water loss in each case.

Migrating molecule	PA[a] (kJ mol^{-1})	TS_a (kJ mol^{-1})	IC (kJ mol^{-1})	TS_b (kJ mol^{-1})
CH_3OH	754.3	98	94	121
CH_3CN	779.2	87	83	107
CH_3CHO	768.5	86	82	112
CH_3NO_2	754.6	80	63	99

Note: Values in kJ mol^{-1} and are relative to the proton-bound pair.
[a]Reference 30.

Base systems for other proton-bound pairs between different migrating molecules and methanol (all resulting in H_2O loss) are listed in Table 2. Note that the empirical formulae can only be used within a particular family of proton-bound molecular pairs (e.g., any nitrile with any alcohol or any nitroalkane with any alcohol). The relative energy values for TS_a, TS_b, and IC can be used in conjunction with the correction factors described earlier to provide a wide range of isomerization energies.

Conclusions

A relationship has been demonstrated between relative peak intensities measured in metastable ion mass spectra and calculated barrier heights to dissociation and isomerization

reactions in gas-phase proton-bound pairs. A series of empirical relationships have been derived for the energetics of S_N2 reaction surfaces involving alcohol–alcohol and alcohol–acetonitrile proton-bound pairs. The relative energies of the species involved in the isomerization reactions are lowered by charge-stabilizing substituents at the S_N2 carbon. The PA of the migrating molecule in the mechanism can cause the relative energy of the first barrier and the intermediate complex in the mechanism to be raised or lowered. By calculating the first member in a family of proton-bound pairs, the three empirical equations can be used to determine the energetics of other members of the series. The family of nitroalkane proton-bound pairs have been recently studied in our group and they have been found to also undergo the internal S_N2 rearrangement to lose nitrous acid (HONO, subject of a future publication). It is reasonable to conclude that all proton-bound pairs obey the S_N2-type mechanism, the observation of the products simply being determined by the energetics.

Electrospray ionization Fourier transform mass spectrometry of polycyclic aromatic hydrocarbons using silver(I)-mediated ionization[1]

E. Peter Maziarz III, Gary A. Baker, and Troy D. Wood

Abstract: Here, a methodology employing doped Ag(I) salt as an in situ cationization reagent for efficient ionization of nonpolar molecules within a conventional electrospray ionization source is described. The effectiveness of Ag(I)-mediated ionization is demonstrated using ESI Fourier transform mass spectrometry for the rapid detection and identification of priority pollutant polyaromatic hydrocarbon (PAH) species. In contrast to earlier coordination ESI-MS reports employing silver salts, argentated species are *not* typically observed for PAH species. Instead, oxidation of the PAH occurs to produce only the $[PAH]^{+\cdot}$ odd-electron molecular parent ion, simplifying spectral analysis. In addition, the method demonstrates linear quantitative performance. The Ag(I) reagent provides quantifiable PAHs (not ordinarily amenable to ESI-MS) from 64 ppb, and suggests the immediate potential for sampling and on-line monitoring of complex, real world, and otherwise intractable environmental samples. Finally, the high mass accuracy of ESI Fourier transform mass spectrometry further allows unequivocal identification of molecular formulas within PAH mixtures.

Key words: electrospray ionization, nonpolar, hydrocarbons, polyaromatic, Fourier transform mass spectrometry.

Résumé : Dans ce travail, on décrit une méthodologie utilisant un sel de Ag(I) dopé comme réactif de cationisation in situ pour effectuer une ionisation efficace des molécules non polaires dans une source à ionisation par électronébulisation conventionnelle. L'efficacité de l'ionisation favorisée par le Ag(I) est démontrée en utilisant un spectromètre de masse à ionisation par électronébulisation (SM-IEN) à transformée de Fourier pour effectuer la détection rapide et l'identification d'espèces prioritaires de polluants de la famille des hydrocarbures polyaromatiques (HPA). En comparaison avec les rapports antérieurs de coordination SM-IEN utilisant des sels d'argent, on n'observe généralement pas d'espèces argentées avec les HPA. On observe plutôt une oxydation des HPA qui ne conduisent qu'à l'ion moléculaire parent à électron célibataire, $[HPA]^{+\cdot}$, ce qui simplifie l'analyse des spectres. De plus, la méthode a démontré une performance quantitative linéaire. Le réactif de Ag(I) fournit des valeurs quantifiables de HPA à partir de 64 ppb, ce qui n'est généralement pas le cas avec la SM-IEN; ceci suggère que la méthode présente un potentiel immédiat pour l'échantillonnage et l'évaluation en ligne d'échantillons environnementaux complexes, provenant de situations réelles et autrement inextricables. Enfin, l'exactitude de la spectroscopie de masse avec ionisation par électronébulisation à transformée de Fourier permet de faire une identification sans équivoque des formules moléculaires des composés formant des mélanges de HPA.

Mots clés : ionisation par électronébulisation, non polaire, hydrocarbures, polyaromatique, spectrométrie de masse à transformée de Fourier.

Introduction

Electrospray ionization (ESI) has established itself as a versatile means for generating intact, gas-phase molecular or pseudomolecular ions (e.g., $(M + nH)^{n+}$) from nonvolatile analyte species with little or no fragmentation (1–4). Further benefits of ESI include the ability to multiply charge macromolecules at relatively low mass-to-charge ratios (generally $m/z < 2000$) to obtain direct mass information on species present, minimal consumption of solvent and other consumables, high ionization efficiency, and the ability to couple high-resolution separation techniques such as capil-

lary electrophoresis (CE), capillary electrochromatography (CEC), and capillary HPLC. Thus, ESI has been considered an ideal ionization source for polar species including peptides, proteins, and oligonucleotides.

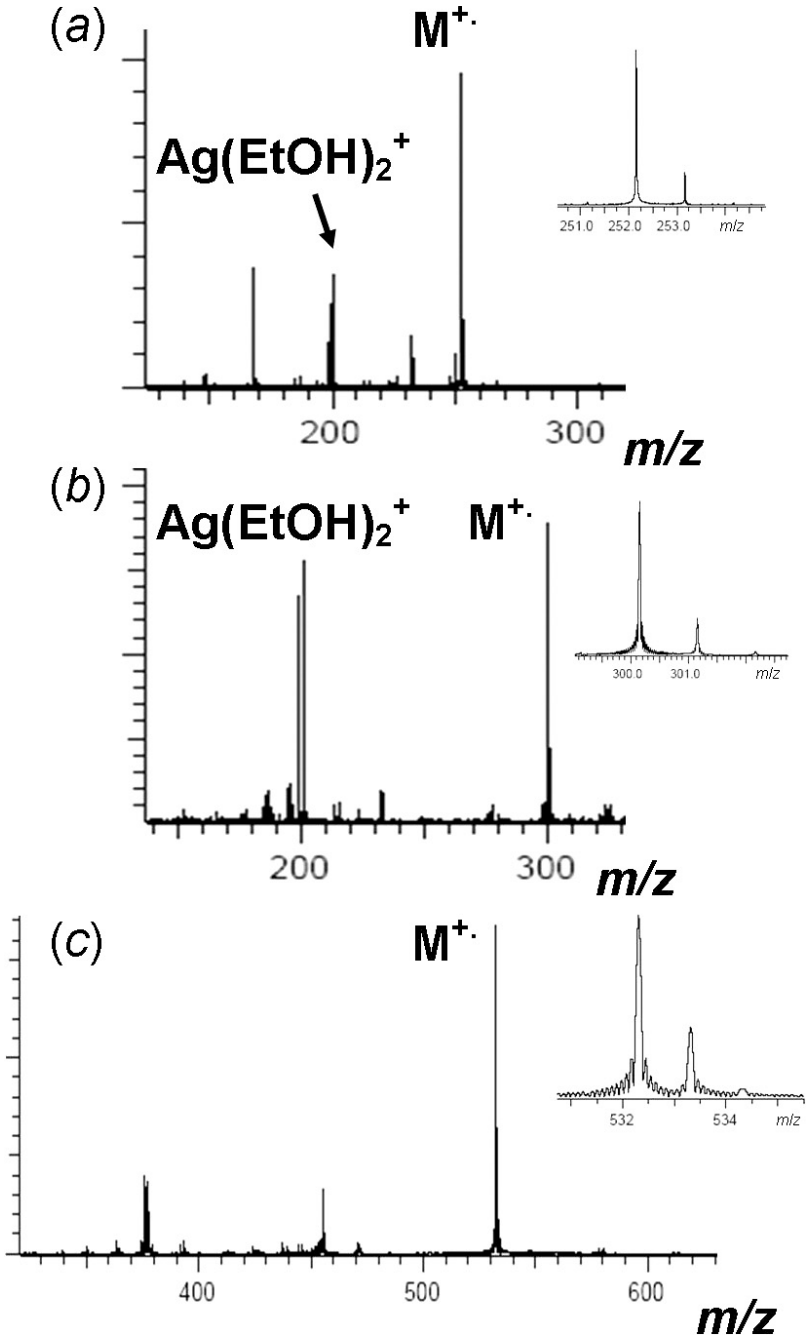
It is appropriate in this special issue honoring Paul Kebarle to note his important contributions toward gaining a greater fundamental understanding of the ESI process. Kebarle's group proposed the electrophoretic mechanism for droplet charging in the ESI process from experimental evidence (5, 6). This result was of importance because it indicated that analyte ions were preformed in the spray and supported the charged droplet model proposed by Iribarne and Thomson (7). A consequence of the electrophoretic charge separation mechanism in ESI is that charge balance requires a conversion of ions to electrons. The Kebarle group provided evidence of this in using zinc and stainless steel ESI emitters that produced Zn^{2+} (the amount of which corresponded to the amount required to carry the electrospray current) and Fe^{2+}, respectively (8). Kebarle and co-workers (9, 10) also explored the corona discharge phenomenon, and in particular provided experimental verification of the quantitative prediction for the onset voltage of charged-droplet emission. In addition, Tang and Kebarle's paper (11) on the influence of conductivity of the solution on total electrospray current yield and analyte ion yield provided important insight into why ESI produces decreased sensitivity at higher analyte concentrations. A detailed account by Kebarle and Tang (12) on these early advances in understanding the mechanism of ESI is available in a now classic review paper, with a more recent update by Kebarle (13).

In spite of the many fine features of ESI for analysis of biological molecules, analysis of nonpolar analytes has been limited. Two different approaches have shown promise in the analysis of nonpolar analytes by ESI. The first, developed by Bayer and co-workers (14–16), is known as coordination ion spray mass spectrometry (CIS-MS) in which minute amounts of a silver salt are injected into a nebulizer spray. This renders slightly polar or nonpolar molecules such as terpenes, sugars, aromatics, vitamins, or protected peptides amenable to ESI-MS. In these reports, substances were detected primarily as the silver coordination complexes $[M + Ag]^+$ (14–16). This method has been recently extended to hydrocarbons, including nonpolar hydrocarbons (17) and polar aromatic hydrocarbons (18). A second promising approach has been to exploit the oxidation–reduction behavior inherent in ESI noted by Kebarle and co-workers (8); in a series of papers, Van Berkel and co-workers (19–35) have shown that electrochemical effects of ESI can be exploited to enable detection of low polarity analytes.

Borrowing from these two approaches, here we report on the analysis of nonpolar polyaromatic hydrocarbons (PAHs) by ESI-FTMS. In this method, $[PAH]^{+\cdot}$ radical cations are produced upon exposure to Ag(I) salt. The suppression of silver-attached species (and conversion to the corresponding radical cations) is attributable to an electrospray-assisted oxidation of the PAH species or by dissociation of argentated PAH species in the ESI source. PAHs were chosen to test this methodology because they are ubiquitous environmental pollutants representing a family of molecules lacking sites for protonation (36). Interest in the direct analysis of PAHs in mixtures has increased in recent years stemming from concerns over their mutagenic and carcinogenic properties, coupled with the fact that these environmental pollutants originate from a wide variety of natural and anthropogenic sources. The technique demonstrates linear MS response for PAHs from ca. 64 ppb to the low ppm range. The high mass accuracy of Fourier transform mass spectrometry (FTMS) further allows identification of analytes within a multicomponent mixture of PAHs. Recently, the combination of ESI-FTMS, which is known for its utility in biomolecule characterization (37–48), has been shown to be an extremely useful technique in the characterization of complex mixtures of relatively nonpolar compounds, including hydrocarbons (49–55), humic acids (56–59), and fulvic acids (60–65). More recently, field desorption ionization has been coupled to FTMS for hydrocarbon analysis (52, 66, 67). The current results suggest the potential for ESI-FTMS for quantification and molecular identification analysis of even nonpolar molecules such as PAHs.

Experimental section

ESI-FTMS instrumentation



All experiments were performed on a Bruker (Billerica, Massachusetts) BioApex 30es Fourier transform mass spectrometer. The instrument design and a description of the 3.0 T magnet and pumping system used here have been reported elsewhere (68). This instrument is equipped with an Analytica of Branford (Branford, Connecticut) ESI source that contains an rf-only hexapole ion guide that is used to externally accumulate ions. A Cole-Palmer (Vernon Hills, Illinois) series 74900 infusion pump was used to continuously inject analyte samples into the ESI source at a rate of 1 μL min^{-1}. A second Cole-Palmer 74900 pump was used to inject a solution containing silver nitrate. The analyte sample solution and the silver nitrate solution were placed in separate Hamilton syringes connected to Teflon tubing, and the two solutions were mixed in a model MT1CS6 0.25 mm bore microvolume tee (Valco, Houston, Texas). The tee was connected to the stainless steel needle of the ESI outlet with a short segment of the Teflon tubing. Nitrogen countercurrent drying gas (300 °C) at a flow rate of 5–7 L min^{-1} was used to desolvate droplets produced by the ESI source. A potential between –2.9 and –3.2 kV (relative to the grounded needle) was applied to the metal-capped glass capillary. Ions were injected into the Infinity cell (2.0 V trapping potential unless otherwise noted) using the patented Sidekick method (69). Frequency-sweep excitation from m/z 100 to 2800 was applied at an amplitude of ~44–63 V_{pp} and detection was in direct mode (500 kHz Nyquist bandwidth) from 128K data sets (10 scans per experiment). The data sets were apodized with a Gaussian function, Fourier transformed, and displayed in magnitude mode.

Sample preparation

The following materials were used in these experiments. Silver nitrate solution was prepared as a 10 mmol/L stock solution in methanol–ethanol (50:50, HPLC grade, Mallinckrodt), then diluted to 1%–5% of this concentration (0.1–0.5 mmol/L) in methanol–ethanol (50:50) when used for the ESI experiments. The use of silver nitrate for ioniz-

ing hydrocarbon polymers in laser desorption has been known for some time (70). The PAHs pyrene, perylene, anthracene, coronene, and rubrene (Aldrich, Milwaukee, Wisconsin) were all prepared initially as stock solutions in ethanol. Final solutions used in ESI experiments were produced from serial dilution of these intial stock solutions. All reagents and solvents were used as received and without further purification.

Results and discussion

Characterization of the PAHs by Ag(I)-mediated ESI

As shown in Fig. 1, the mixing of Ag(I) salt with the PAH analyte does not generally result in production of argentated species $[PAH + Ag]^+$, as is typically observed in ESI-MS when silver salt is added to samples containing polar molecules (14–16). Instead, it is clear that the ESI mass spectra are dominated by the production of odd-electron radical parent ions ($[PAH]^{+\cdot}$). For example, in Fig. 1*a*, Ag(I)-mediated ESI-MS of perylene shows exclusively $[PAH]^{+\cdot}$ and no $[PAH + Ag]^+$; a similar result is found using Ag(I)-mediated ESI-MS of coronene (Fig. 1*b*). In both of these mass spectra, peaks at *m*/*z* 185 and 187, corresponding to the silver-cationized $Ag(CH_3OH)(C_2H_5OH)^+$, and at *m*/*z* 199 and 201, corresponding to the silver-cationized $Ag(C_2H_5OH)_2^+$, are observed. These ions clearly result from the cationization

© 2005 NRC Canada

of small solvent clusters by silver. In the ESI-MS of coronene, a doublet at ~2% relative to the odd-electron radical cation is observed at *m/z* 407/409, consistent with argentated coronene $[PAH + Ag]^+$.

A simple explanation for the production of odd-electron radical parent ions ($[PAH]^{+\cdot}$) is that a single electron transfer event occurs in which an electron from the PAH molecule is transferred to the Ag(I), thereby reducing it to silver metal, as shown in eq. [1].

$$[1] \quad PAH + Ag(I) \rightarrow PAH^{+\cdot} + Ag(0)$$

This is sensible because the ionization potential of Ag (7.57 eV) is above that of the PAHs used in this study, whose ionization energy (IE) values are: anthracene, 7.44 eV; pyrene, 7.43 eV; perylene, 6.96 eV; coronene, 7.29 eV; rubrene, 6.41 eV (71). Macha et al. (72) have indicated such an electron-transfer process can occur in matrix-assisted laser desorption ionization (MALDI) between nonpolar hydrocarbons, and such nonpolar matrixes are valuable for MALDI of high boiling point crude oil fractions (73). However, an alternative ionization route (eqs. [2*a*] and [2*b*]) proposed by Ng et al. (17) in silver-assisted ESI of PAHs may be more likely here.

$$[2a] \quad [Ag + 2PAH]^+ \rightarrow PAH + [PAH + Ag]^+$$

$$\rightarrow PAH + Ag(I)$$

$$[2b] \quad \rightarrow PAH^{+\cdot} + Ag(0)$$

Their proposed mechanism was supported by the presence of $[Ag + 2PAH]^+$ in the mass spectra (17). While such species are not indicated in the silver-assisted ESI of PAHs reported here, it is worth noting that all of the present results were collected at nozzle-skimmer potential differences above 100 V, in contrast to the report by Ng et al. (17). Furthermore, Ng et al. noted that $[PAH + Ag]^+$ tended to dominate the odd-electron radical cations ($[PAH]^{+\cdot}$) at low (20–60 V) nozzle-skimmer potential differences. Here, $[PAH]^{+\cdot}$ dominates in Figs. 1*a* and 1*b* as well as in Fig. 1*c* at *m/z* 532 in the ESI mass spectrum of rubrene (Fig. 1*c*), although ~3% relative abundance argentated species $[PAH + Ag]^+$ at *m/z* 639/641 (Fig. 1*c*) is also observed, as is the silver-cationized $Ag(C_2H_5OH)_2^+$. Varying the concentration of silver nitrate in the range 0.1–0.5 mmol/L has virtually no effect on the observed ion abundances for the analytes, probably owing to the large molar excess of Ag(I) relative to PAH.

Quantification of PAHs

Having identified the odd-electron radical cations in the ESI mass spectra as the ionic species produced after exposure to Ag(I), the linearity of ESI-FTMS response as a function of PAH concentration was examined. Linearity in ESI-FTMS response for individual biomolecules has been demonstrated over approximately three orders of magnitude (68, 74, 75). Miyabayshi et al. (50) reported linearity in quantitation for *total* hydrocarbon content in a complex crude oil sample containing over 500 distinguishable molecular formulas. A calibration curve of MS response (determined from the peak height (76) of the odd-electron radical cation, $M^{+\cdot}$) vs. perylene concentration was constructed using three replicate measurements; the results are shown in Table 1. As indicated in Table 1, ESI-FTMS response is linear ($R^2 = 0.9794$) with perylene concentration over a range of 64 ppb to 3.2 ppm, fit to the equation $y = 8.4 \times 10^4 x - 4.0 \times 10^5$. At perylene concentrations above 3.2 ppm, the peak height begins to deviate strongly from the calibration curve. This saturation effect has been previously reported with ESI-FTMS (68), and may be due to saturation of ESI ionization efficiency or from number of trapped ions in the FTMS trap. Coefficients of variation (CV) in the $[PAH]^{+\cdot}$ ICR magnitudes were calculated to determine the relative precision of the ion signal measurements using eq. [3].

Table 1. Calibration curve of ESI-FTMS response vs. perylene concentration.

Concentration (ppb)	$M^{+\cdot}$ peak height	SD $M^{+\cdot}$ peak height	%CV
64	5.8×10^5	1.0×10^5	18
160	1.6×10^6	5.7×10^4	3.5
320	2.7×10^6	2.2×10^5	8.1
1600	1.0×10^7	1.8×10^6	18
3200	2.8×10^7	4.7×10^6	17

Table 2. Calibration curve of ESI-FTMS response vs. coronene concentration.

Concentration (ppb)	$M^{+\cdot}$ peak height	SD $M^{+\cdot}$ peak height	%CV
76	3.4×10^5	1.6×10^4	4.8
190	1.1×10^6	7.6×10^4	7.0
380	6.8×10^6	8.0×10^5	12
1900	2.6×10^7	9.6×10^6	3.7
3800	4.3×10^7	1.2×10^6	2.8

$$[3] \quad CV = (SD/I) \times 100\%$$

where SD refers to the standard deviation in the ion ICR magnitude measurements and *I* refers to the mean ion ICR magnitude. CVs ranged from 3.5% to 18%, consistent with earlier ESI-FTMS results for biomolecules (68, 74, 75). Further experiments using Ag(I)-mediated ionization for PAHs using other mass analyzers are warranted and currently underway.

In a similar fashion, a calibration curve of MS response (determined from the peak height of the odd-electron radical cation, $M^{+\cdot}$) vs. coronene concentration was constructed (three replicate measurements) and the results are shown in Table 2. As indicated, ESI-FTMS response is linear ($R^2 = 0.9833$) with coronene concentration over a range of 76 ppb to 3.8 ppm, fit to the equation $y = 1.2 \times 10^5 x - 8.2 \times 10^5$. CVs are generally slightly better (2.8%–12%) than those observed with perylene. At coronene concentrations above 3.8 ppm, the signal intensity levels off and the calibration curve begins to deviate strongly from linear behavior, as was discussed earlier.

High mass accuracy of Ag(I)-mediated ESI-FTMS

FTMS, using a variety of ionization sources, has a long-standing history of identifying hydrocarbons from com-

Fig. 2. ESI mass spectrum of a five-component PAH sample (anthracene, pyrene, perylene, coronene, and rubrene) by silver(I)-mediated ionization. Peaks labeled with an asterisk are silver-cationized.

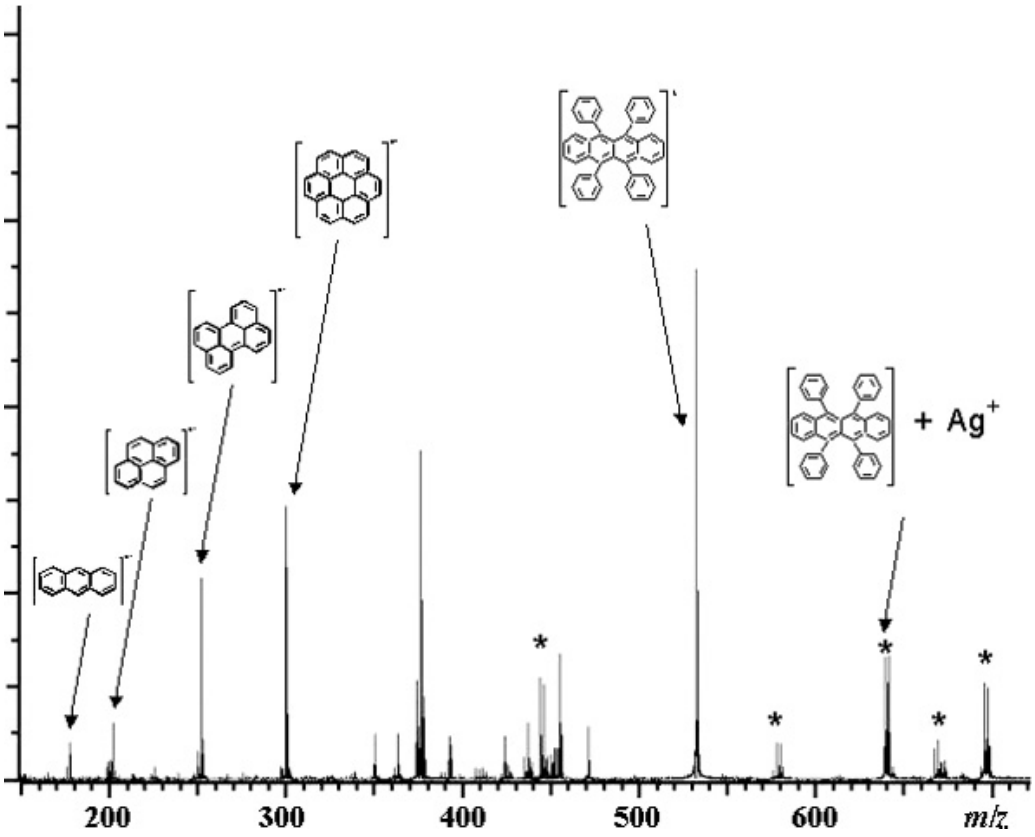

Table 3. High mass accuracy measurements by ESI-FTMS of PAH components using Ag(I)-mediated ionization.

Molecular species, $M^{+\cdot}$	Reference mass (amu)	Experimental mass (amu)	Error (ppm)
Anthracene, $C_{14}H_{10}$	178.0777	178.0776	0.3
Pyrene, $C_{16}H_{10}$	202.0777	202.0778	0.4
Perylene, $C_{20}H_{12}$	252.0934	252.0941	2.5
Coronene, $C_{24}H_{12}$	300.0934	300.0931	1.2
Rubrene, $C_{42}H_{28}$	532.2186	532.2188	0.5

plex mixtures because of its inherent high mass accuracy, on the order of a few ppm (49–55, 77–81). Here, a mixture of five PAHs (anthracene, pyrene, perylene, coronene, and rubrene, 3 μmol/L each in methanol–ethanol (50:50)) was exposed to 0.1 mmol/L $AgNO_3$ solution at the mixing tee to produce the spectrum shown in Fig. 2. As noted previously, Ag(I) mediates oxidation of the PAHs to produce $[PAH]^{+\cdot}$ odd-electron molecular parent ions for each of the compounds. From the isotope pattern, several peaks due to silver cationization are observed (as denoted in Fig. 2), but of the sample analytes, only rubrene produces an $[PAH + Ag]^+$, as shown by the *m/z* 639 and 641 doublet. High mass accuracy measurements of the five $[PAH]^{+\cdot}$ using external calibration is given in Table 3. As can be noted from Table 3, mass accuracy of the $[PAH]^{+\cdot}$ ions ranges from 0.3 to 2.5 ppm, consistent with FTMS performance. The peaks at 372.0908 and 374.1078 Da are closely matched to hydrocarbons with the molecular formulae $C_{30}H_{12}$ (–7.0 ppm error) and $C_{30}H_{14}$ (–4.6 ppm error), respectively. Even though these species differ in mass by 2 Da, examination of the ion intensities suggests these peaks are very unlikely to be silver-cationized species. Further, peaks at 348.0939 and 350.1130 Da are tentatively identified as the molecular formulae $C_{28}H_{12}$ (1.5 ppm error) and $C_{28}H_{14}$ (10.9 ppm error), respectively. Other low ICR magnitude peaks at 361.0999, 363.1219, and 393.1258 Da are also observed. The exact mass difference between the species at 361.0999 and 393.1259 Da is 32.0260 Da, consistent with the mass of neutral methanol, which is used in the ESI solvent. However, their odd nominal masses indicate the presence of an odd number of nitrogen atoms, and it is not clear chemically how these might have been formed from neat PAH samples unless the nitrate from silver nitrate is somehow being incorporated into the molecular structure.

Conclusions

The methodology shown here demonstrates the applicability of using Ag(I) salt as an in situ ionization reagent for nonpolar molecules (PAHs) in a conventional ESI source. The effectiveness of Ag(I)-mediated cationization is demonstrated using ESI Fourier transform mass spectrometry for the detection and identification of priority pollutant polyaromatic hydrocarbon (PAH) species. In contrast to earlier coordination ESI-MS reports employing silver salts, argentated species are generally *not* observed for PAH spe-

© 2005 NRC Canada

cies, but instead radical cations ($[PAH]^{+\cdot}$) are produced. The high mass accuracy of FTMS used as the detector allows for identification of PAH molecular formulas. The low detection limits and linear response of the FTMS with solution concentration of PAH suggests the potential for quantitative analysis, although in complex, real-world environmental samples this will need to be tested because the presence of other analytes may significantly influence ion yield for the analyte of interest. In addition, if coupled to a miniaturized mass spectrometer such as an ion trap equipped with ESI (82), Ag(I)-mediated cationization of PAHs might be well-suited for on-line determination of PAHs from environmental water and soil samples.

Acknowledgments

We would like to congratulate Professor Kebarle on an outstanding career and to thank him in particular for all of his contributions to understanding the ESI mechanism; without his inspiration, this manuscript would never have been possible. Acknowledgment is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, the American Society for Mass Spectrometry (Research Award sponsored by the Exxon Education Foundation), and the State University of New York at Buffalo for support of this research.

Fragmentation pathways of negative ions produced by electrospray ionization of acyclic dicarboxylic acids and derivatives[1]

J. Stuart Grossert, Paul D. Fancy, and Robert L. White

Abstract: Fragmentation pathways have been studied on the monoanions formed during electrospray ionization of a wide range of aliphatic dicarboxylic acids and their monoesters. All negative ion spectra were obtained from alcoholic or aqueous methanolic solutions without buffers or adjustment of pH, using either a Finnigan LCQ ion trap or a VG-Micromass Quattro triple quadrupole mass spectrometer. Fragmentation pathways were studied using collision-induced dissociation and isotopic-labelling techniques. Two primary fragmentation pathways of the dicarboxylic acid monoanions were observed, namely decarboxylation of the non-ionized carboxyl group and loss of water from this group. The fragmentations were strongly dependent on the chain lengths of the diacids. In the case of a monoester anion, loss of a molecule of alcohol paralleled the loss of water from the diacid monoanion. Losses of water or alcohol were shown to lead to formation of reactive ynolate anions ($HOOC(CH_2)_xC{\equiv}CO^-$, x = 3–9), which in the ion trap spectrometer engaged in complex ion – molecule reactions consistent with the chemistry of these anions. For the longer chains ($x > 6$), the interactions between the ionized and non-ionized carboxyl groups led to readily formed ion–neutral complexes, which are described as a neutral molecule (ROH, R = H or alkyl) held by a pair of molecular tweezers.

Key words: ESI-MS/MS on negative ions, fragmentation pathways of acyclic carboxylic acid monoanions, ion–molecule reactions in an ion trap mass spectrometer, hydrogen–deuterium exchange in a gas-phase anion–neutral complex.

Résumé : Faisant appel à un spectromètre de masse Finnigan LCQ à piège d'ion ou VG-Micromass Quattro quadripolaire triple, on a étudié les voies de fragmentation des monoanions qui se forment lors de l'ionisation par électronébulisation d'un large éventail d'acides dicarboxyliques aliphatiques et de leurs monoesters. On a obtenu tous les spectres d'ions négatifs à partir de solutions alcooliques ou méthanoliques aqueuses, sans tampon ou ajustement de pH. On a étudié les voies de fragmentation en faisant appel à des techniques de dissociation induite par des collisions et par marquage isotopique. On a observé deux voies primaires de fragmentation des monoanions des acides dicarboxyliques, soit la décarboxylation du groupe carboxyle qui n'est pas ionisé et une perte d'eau à partir de ce groupe. Les fragmentations dépendent fortement des longueurs de chaînes des diacides. Dans le cas d'un anion d'un monoester, la perte d'une molécule d'alcool est parallèle à celle de la perte d'une molécule d'eau à partir du monoanion du diacide. On a montré que la perte d'eau ou la perte d'alcool conduit à la formation d'anions ynolates réactifs, $HOOC(CH_2)_xC{\equiv}CO^-$, x = 3–9 qui, dans le spectromètre à piège d'ion participe à une série complexe de réactions ion–molécule qui est en accord avec la chimie de ces anions. Pour les chaînes plus longues ($x > 6$), les interactions entre les groupes carboxyles ionisés et non ionisés conduisent à la formation facile de complexes ion – entité neutre qui sont décrits comme une molécule neutre (ROH, R = H ou alkyle) retenu par des pinces moléculaires.

Mots clés : ESI-MS/MS d'ions négatifs, voies de fragmentations de monoanions d'acides dicarboxyliques acycliques, réactions ion–molécule dans un piège à ion d'un spectromètre de masse, échange hydrogène–deutérium dans un complexe anion–produit neutre en phase gazeuse.

[Traduit par la Rédaction]

Introduction

The importance of negative ion mass spectrometry has increased since the advent of chemical ionization (CI) and fast atom bombardment (FAB) methods (1–3). More recently, the proliferation of mass spectrometers equipped with electrospray ionization (ESI) and quadrupole, ion trap, or time-of-flight mass analyzers has allowed negative ions to be studied as easily as positive ions. Using ESI-MS, negative ions are easily generated from solutions of molecules

containing readily ionizable functional groups (4). The approach has been applied successfully to fatty acids (5, 6), peptides (7–11), and pharmaceuticals containing carboxylic acids (12).

Fragmentation pathways examined by collision-induced dissociation (CID) using linked-scan methods at high collision energies (2) or more recently, at low collision energies (8, 9), have provided evidence from which structural information about the ions can be deduced. Bowie and co-workers (8–10), in particular, have shown that CID experiments at low collision energies on deprotonated peptide ions, generated by ESI, complement the results obtained from studies of protonated peptides. Although CID spectra of negative ions are easily obtained using modern mass spectrometers, work on the fragmentation pathways of negative ions remains limited, compared with that on positive ions.

In earlier studies on the fragmentation of carboxylate anions (2, 13, 14), CID experiments at high collision energies showed that different pathways exist for anions formed by O–H deprotonation and enolate anions formed by α-C–H deprotonation of aliphatic carboxylic acids. It appeared that the pathway for loss of water from the anion of carboxylic acids was via the enolate anion and an ion–neutral complex, followed by the formation of an ynolate anion and water (see the following). However, protons were observed to exchange on collisions, complicating the interpretation of the spectra. Further details of the mechanism for the loss of water from a carboxylate anion emerged from the work of Jensen et al. (15) who found that the ion $[CH_3(CH_2)_5CD_2COO]^-$ prepared in a FAB source on collisional activation cleanly lost D_2O (>90%), whereas the corresponding 2,3-dideutero compound lost HOD. These authors presented evidence to support the concept that a carboxylate anion could be converted into the corresponding enolate anion, which can fragment into a complex of a hydroxide anion and a ketene from which water can be lost (eq. [1]).

$$[1] \quad RCD_2COO^- \rightarrow R^-CDCOOD \rightarrow [RCD{=}C{=}O + OD]^- \rightarrow RC{\equiv}CO^- + D_2O$$

Loss of water as the only fragmentation pathway of deprotonated saturated fatty acids was shown by MS/MS studies at low collision energies using a SCIEX API III triple quadrupole spectrometer having an ESI source (5). This was achieved by varying the orifice voltage and the collision gas thickness, with increases above the optimum producing no other reaction pathway.

Another approach to studying the loss of water from the anions derived from fatty acids used resonant electron capture mass spectrometry and high-energy CID (16). These experiments led, via an unobserved radical anion, either to the carboxylate anion or to an anion on the chain. Studies on the labelled carbanion ($[CH_3(CH_2)_{13}CD_2COOH–H/D]^-$) showed losses of both H_2O and HOD, indicating a selective rearrangement process, but the ions in these experiments appear to be different from those described in the previous FAB experiments (15).

A recent survey of the MS/MS spectra of over 100 carboxylic acids, including some dicarboxylic acids, attempted to correlate structures with the loss of carbon dioxide (12). The work was focused on analytical applications and did not describe other possible fragmentations. Other ESI-MS studies on a wide range of dicarboxylic acids were limited to the formation of halide ion complexes (17) and to the effects of solvents on ionization (6); neither work reported on fragmentations of dicarboxylic acid anions. The work by Aplin et al. (6) showed predominantly monoanion formation; dianions were formed as the most abundant ion only when $\geq C_{12}$ dicarboxylic acids were dissolved in MeOH–water (1:1). Preferred monoanion formation by the diacids having shorter chain lengths was attributed to stabilization by intramolecular hydrogen bonding between the ionized and non-ionized carboxyl groups (6), analogous to the cluster ions formed between aliphatic carboxylic acids (14, 18). Similarly, the high proton affinities of diamines (19–22) and diols (23), as well as the acidities of diols (24), have been attributed to the stabilization of gas-phase ions by intramolecular hydrogen bonding between an ionized and a non-ionized functional group. Furthermore, the fragmentation of protonated lysine has been interpreted on the basis of considerable hydrogen bonding between a proton and the two amino groups (25).

Understanding the mass spectral fragmentation pathways of ions generated by electrospray ionization is important for the structural characterization of polyfunctional compounds such as peptides (7–9), drug metabolites (12), and products of bacterial metabolism (26). In the present investigation, we focus on low-energy fragmentation mechanisms as a function of chain length for a series of monoanions from dicarboxylic acids and some diacid monoesters. The gas-phase ions studied show interactions among remote functional groups in an acyclic chain (24, 27). Moreover, they point to the importance of considering interactions between ionized and nonionized carboxyl groups in studying the fragmentation pathways of more complex polyfunctional ions, such as the anions derived from aminodicarboxylic and hydroxydicarboxylic acids as well as from peptides.

Experimental

All acid samples were obtained from Sigma-Aldrich (Oakville, Ontairo) or Acros Organics (Nepean, Ontario), unless otherwise specified; 2,2,9,9-tetradeuterosebacic (decanedioic) (99.3% d_4) and [1-^{13}C]- and [5-^{13}C]-glutamic acids were from CDN isotopes (Montreal, Quebec); [4-^{13}C]aspartic acid was from MSD isotopes (Montreal, Quebec); α-methyl aspartate and glutarate were from CHEM-IMPEX (Wood Dale, Illinois). The isotopic purity of the 2,2,9,9-tetradeuterosebacic acid was checked by ESI-MS and found to be as indicated by the manufacturer. The side chain methyl ester of aspartic acid was available from a previous study (28).

Negative ion ESI spectra were obtained by flow injection analysis (20 μL min^{-1}) of the aliphatic dicarboxylic acids and their derivatives dissolved in HPLC grade methanol, or in aqueous methanol (1:1), at concentrations ranging from 0.2 to 1 mg mL^{-1}. Regular mass spectra and MS/MS spectra at low collision energies were obtained on either a Finnigan LCQ Duo ion trap or a Micromass Quattro triple quadrupole mass spectrometer. Spectra from the LCQ were run with the ESI needle at 4000 V and the capillary at 200 °C. Nitrogen was used as the nebulizing gas, with helium as the damping and collision gas in the trap under regular conditions. CID

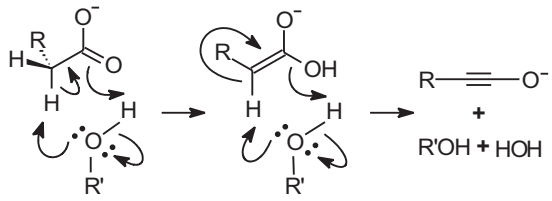
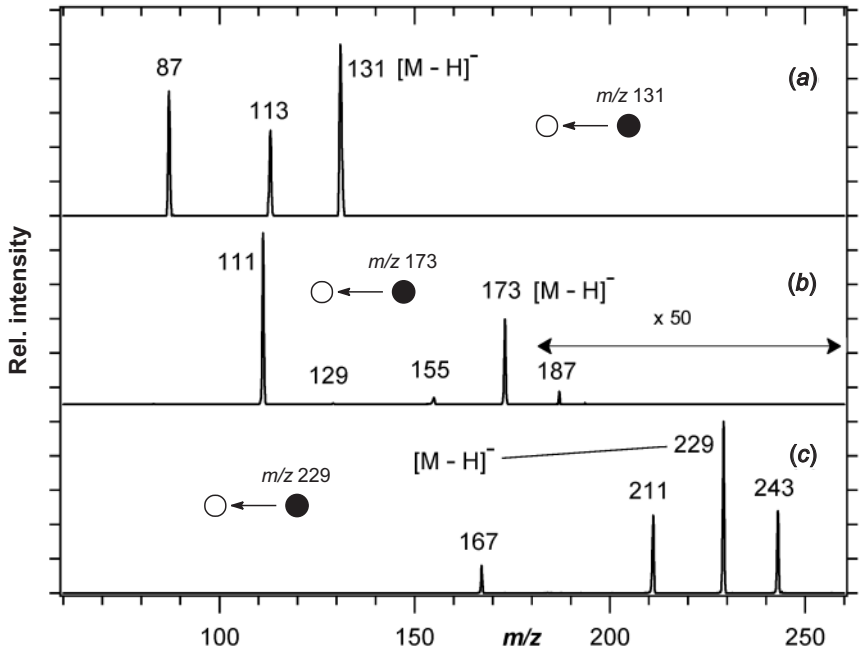
experiments are reported in arbitrary percentage units from the Xcalibur software in which an energy of 16% began to produce fragmentation of most ions studied, but an energy of 40% typically reduced the intensity of the ion being fragmented to almost zero. In a few experiments noted in the text, a voltage was applied to promote source-induced collisions. In the case of the Quattro MS, the bath and nebulizer gases were nitrogen at optimized flow rates, the source temperature was set between 90 and 100 °C, the electrospray needle was at 3000 V, and the source cone voltage varied between 10 and 40 V, depending on the spectrum being acquired. CID experiments were carried out using argon collision gas at energies reported in eV (laboratory frame). The argon was at a pressure to reduce the main beam by 50%–80%. Spectra from the LCQ ion trap were averaged and processed using the supplied Xcalibur software; in the case of the Quattro MS, 10–30 spectra were combined, background-subtracted, and smoothed using MassLynx software.



Results and discussion

Acyclic monocarboxylic acids

Using either the LCQ or the Quattro MS, electrospray ionization of a methanolic solution of dodecanoic (lauric) acid readily led to full-scan mass spectra showing the deprotonated molecule ($CH_3(CH_2)_{10}COO^-$). In the LCQ ion trap MS, loss of water from this ion was observed in the MS/MS spectrum only at a relatively high collision energy (see Table 1), about 70% greater than the energy needed to fragment the monoanions of dicarboxylic acids. Using the Quattro MS, neither loss of water nor any other fragmentation was observed from $CH_3(CH_2)_{12}COO^-$, even at collision energies up to 40 eV.



Previously, loss of water from carboxylic acid anions has been observed in negative ion CI and high-energy CID studies by Bowie (2) and in lower energy CID experiments conducted by Kerwin et al. (5) using electrospray ionization on a SCIEX API III MS. The latter authors noted that increased fragmentation could be brought about by increasing the collision gas pressure, which suggests that ion–molecule collisions are important for the conversion of carboxylate anions to the enolate anions needed for the loss of water to be observed. From our later experiments on the LCQ MS (vide infra), it became apparent that collisions in the trap occur not only with the helium damping gas, but also with solvent molecules. These collisions of ions with solvent molecules could facilitate other reaction pathways in the trap and lead to a variety of ions that might not have been expected. Accordingly, we suggest that elimination of water from a carboxylate anion in the LCQ ion trap is a process involving an ion – solvent molecule complex, as outlined in Scheme 1, and is not induced simply by collisions of an ion with an inert gas. The reactions proposed in Scheme 1 are directly comparable to those outlined in eq. [1], except that they are bimolecular and solvent assisted. In the Quattro MS, the solvent molecules are pumped away in the source volume and very few, if any, would penetrate into the chamber holding the quadrupole mass analyzers and the collision cell. Finally, we have no evidence that the direct loss of carbon dioxide from the laurate anion to form a carbanion occurred in either mass spectrometer nor is this pathway likely under the conditions employed in these spectrometers (29).

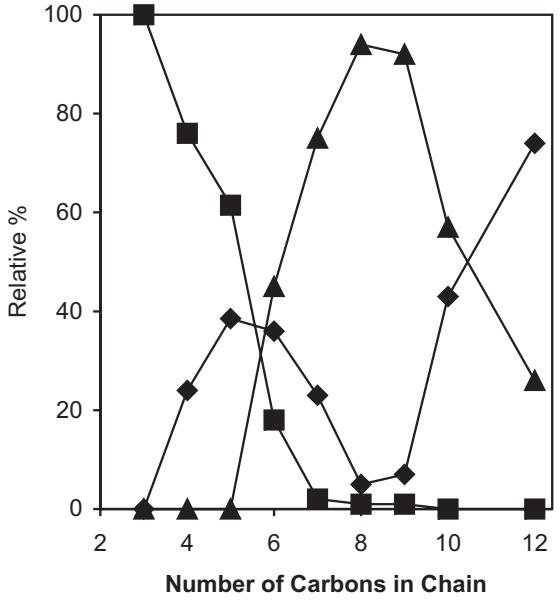
Acyclic dicarboxylic acids

The negative ion ESI mass spectra collected for the series of C_3–C_{12} dicarboxylic acids dissolved in methanol showed a major ion at an *m/z* value corresponding to $[M - H]^-$, indicating facile anion formation from a weakly acidic solution (4) and the ionization of only one of the two acidic groups in the dicarboxylic acid during electrospray ionization. No evidence of dianion formation was apparent in any of the spectra. For dianion formation to occur, a second ionization step would require much higher energy to overcome the stabilization provided by intramolecular hydrogen bonding in the monoanion (6). This hydrogen bonding between the ionized carboxyl group and the proton of the second carboxyl group (the most acidic hydrogen in the molecule) is possible only if the chain is long enough and if the monoanion adopts a coiled conformation placing the two functional groups in close proximity. The concept of coiled conformations in the gas phase leading to stabilizing interactions between ionized and non-ionized functional groups is well-documented (19–21, 24).

Intermolecular interactions leading to the association of ionized and non-ionized carboxylic acids have been studied using CI-MS (18). In ESI-MS, a low source cone voltage allows intermolecular adducts to remain intact. For dodecanedioic acid, a regular Quattro MS scan (10 V on the source cone) showed that the intermolecular proton-bound anion dimer ($[C_{24}H_{43}O_8]^-$) was present at *m/z* 459 at about 10% of the intensity of the unsolvated monoanion at *m/z* 229. For glutaric and adipic acids, similar intermolecular dimers were observed by using the Quattro MS but not by using the LCQ MS. The low relative abundances of these dimer anions indicates the greater importance of intramolecular vs. intermolecular interactions.

General trends in fragmentation patterns of dicarboxylic acid monoanions



Typical MS/MS spectra, using the LCQ ion trap MS, of dicarboxylic acid monoanions from glutaric (C_5), suberic (C_8), and dodecanedioic (C_{12}) acids are shown in Fig. 1 as representative examples of the series examined. For the purpose of comparison with Fig. 1*c*, MS/MS spectra from the Quattro MS of the monoanion from dodecanedioic acid has been included in the Supplementary data for this paper.[4]

At the same nominal collision energies in the LCQ MS, the independent and combined losses of water and carbon dioxide were strongly dependent on chain length (Fig. 2). An overview of the results is given in Table 1. Except for malonic acid, a primary fragmentation resulting in loss of water was evident in the spectrum of each dicarboxylic acid. For shorter chain diacids ($\leq C_6$), decarboxylation was a competing primary process, decreasing in importance with increasing chain length and becoming negligible for diacids $\geq C_7$. For diacids $\geq C_6$, the combined loss of ($H_2O + CO_2$) was observed, becoming the dominant process at intermediate chain lengths (i.e., C_6–C_{10}). Loss of water was the dominant process for the C_{12} diacid. The strong dependence of the fragmentation pathways on the chain length of the dicarboxylic acids suggested a close relationship between chain length and mechanism. Mechanistic information was obtained by studying a selected range of compounds, by using

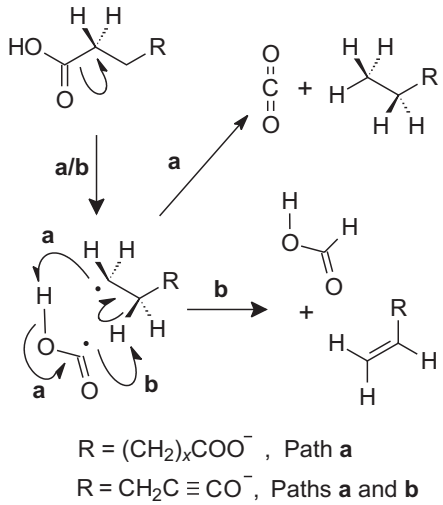
Fig. 2. Fragmentation patterns of $[M - H]^-$ ions from acyclic dicarboxylic acids vs. chain length (LCQ MS), with the intensity of each fragmentation being relative to the sum of the three fragmentation processes ($-CO_2$ (■), $-H_2O$ (◆), $-(H_2O + CO_2)$ (▲)).



fragment ion, precursor ion and neutral loss scans on the Quattro MS, as well as by using compounds labelled at specific atoms with ^{13}C or deuterium.

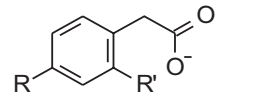
Decarboxylations of short-chain dicarboxylate monoanions

The malonate anion has the shortest chain of the ions examined. Malonic acid solutions produced only peaks at *m/z* 103 and 59; no precursor ions and only fragment ions were observed at 24% collision energy, whereas precursor ions from the anions of all the other acids were present at this collision energy. The fragmentation of *m/z* 103 is explicable in terms of a simple bond heterolysis to yield carbon dioxide and the enolate anion of acetic acid.

The greater separation between the carboxyl groups in the diacids having more than three carbon atoms decreased the likelihood that decarboxylation would occur by simple bond heterolysis. Furthermore, the monoanion from a dicarboxylic acid contains both an ionized and a non-ionized carboxyl group, either one of which could in principle lose carbon dioxide. Distinction between the groups was readily achieved using aspartic and glutamic acids. Negative ions, localized at the more acidic α-carboxyl group, were generated from aqueous methanol. On CID, they showed losses of 18 u (water) and 44 u (carbon dioxide); in the case of Asp, 17 u (ammonia) was lost also. Clear evidence supporting decarboxylation of the α- or the side-chain carboxyl group came from aspartic (Asp) and glutamic (Glu) acids labelled with ^{13}C. Fragmentation of the $[M - H]^-$ ion at *m/z* 147 from [1-^{13}C]glutamate gave a series of fragment ions analogous to those observed for unlabelled glutamate. Each ion in the CID mass spectrum of [1-^{13}C]glutamate was, however, one mass unit higher, indicating retention of the ^{13}C label during all fragmentation processes. In the CID spectra of [4-^{13}C]aspartic acid and [5-^{13}C]glutamic acid, losses of 17 and 18 u from the $[M - H]^-$ ion were consistent with losses of ammonia and water, respectively, and retention of the ^{13}C label in the side chain. For these samples, a loss of 45 u from the $[M - H]^-$ ion signified that ^{13}C was associated with the $^{13}CO_2$ being formed upon fragmentation, clearly associating decarboxylation with the non-ionized side-chain carboxyl group. This result is complementary to that obtained in the positive ion CID mass spectra of acidic amino acids where the α-carboxyl group is lost by sequential losses of water and carbon monoxide (25, 30, 31).

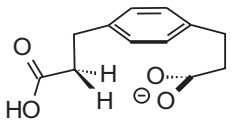
Scheme 2.

The spectra obtained point to the elimination of carbon dioxide being a unimolecular process, which must be initiated by homolytic cleavage of a C—C bond, followed by hydrogen atom abstraction by the resulting carbon radical, as outlined in Scheme 2*a*. A consequence of this proposed mechanism is that its facility depends on the strength of the C—C bond being cleaved and conceivably this is a function of the chain length of the dicarboxylic acid monoanions. However, it may also be that other reaction pathways simply become more important as the chain length increases. Support for the process being unimolecular and involving a tightly held radical pair comes from the fact that the anion from deuterated glutaric acid (R-COOD) cleanly retained the deuterium label on decarboxylation with no sign of scrambling. Evidence that the structures of product anions from these eliminations must be carboxylates of acyclic monoacids could be deduced from the fact that these ions could not be further fragmented in the collision cell of the Quattro MS. The elimination of carbon dioxide could be mechanistically analogous to the thermal decomposition of formic acid into dihydrogen and carbon dioxide (32). Further details of the decarboxylation process are presented in the next section.



Using the Quattro mass spectrometer, a full range of fragment, precursor, and neutral loss scans was made for the fragmentation of the adipic acid monoanion ($[C_6H_9O_4]^-$, in methanol), the shortest chain anion to show combined losses of both water and carbon dioxide. Fragment ion spectra on the anion at *m/z* 145 showed essentially no fragmentation at a collision energy of 5 eV (lab. frame); however, at 10 eV fragmentation was observed (*m/z* 127, 101, and 83). In all cases from 10 to 30 eV, the loss of carbon dioxide predominated and a neutral loss scan showed the loss of 44 u from

© 2005 NRC Canada



ions at both *m*/*z* 145 and 127. On the contrary, water was only lost from the ion at *m*/*z* 145 (loss of water discussed in a later section). The fragment ion at *m*/*z* 101 could not be fragmented further, which is consistent with it being the anion of a monocarboxylic acid (vide supra). The fragment ion observed at *m*/*z* 127 could be fragmented further into two ions at *m*/*z* 83 and 81. The loss of both 44 u (carbon dioxide) and 46 u (formic acid) from the ion (*m*/*z* 127) can be rationalized by postulating the structures and fragmentation pathways outlined in Scheme 2 (the alkyne oxide structure is justified later). Again, the initial step is a bond homolysis to give a radical pair that can further react in either of two ways, leading to two different fragment ions and two neutral species. This competitive fragmentation was only observed in a few cases by using the Quattro MS and it appears that loss of carbon dioxide is generally preferred.

Fragmentations of conformationally and structurally constrained diacids

To probe conformational effects on the primary fragmentation pathways, MS/MS spectra of the monoanions from 1,2- and 1,4-phenylenediacetic acids ($HOOCCH_2C_6H_4CH_2COO^-$, **a** and **b** respectively, *m*/*z* 193), were studied using the LCQ MS. Both anions **a** and **b** cleanly lost two molecules of carbon dioxide, but the ions at *m*/*z* 193, 149, and 105 (only ions in the spectra) under the same nominal collision energies (16%) had ratios of 100:475:160 for **a** and 100:82:12 for **b**. Thus, the ortho compound showed more facile decarboxylation than the para compound. The facile loss of carbon dioxide from these molecules is consistent with the mechanism proposed for this process in Scheme 2*a*, the phenyl ring providing stabilization for the intermediate carbon-centred radical. The loss of the second molecule of carbon dioxide from ions **a** and **b** would lead to a carbanion stabilized by the benzene ring (29), an interesting process but one which is not directly relevant to the fragmentations of the acyclic diacid monoanions.

a: R = H, R' = CH_2COOH
b: R = CH_2COOH, R' = H

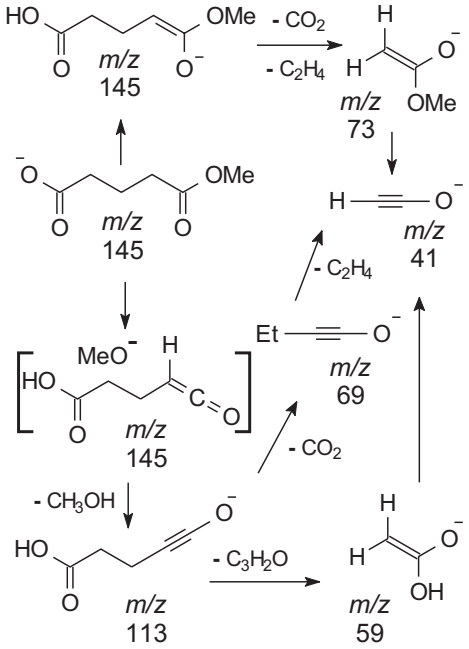
c

The spacing between the two carboxyl groups in 1,2-phenylenediacetic acid is comparable to that in the C_5–C_7 aliphatic diacids. The anions of these latter diacids readily lost water on CID, whereas, under comparable conditions, neither **a** nor **b**, the anions from the phenylenediacetic acids, did. The orientations of the carboxyl groups in 1,2-phenylenediacetic acid are more conformationally restricted than those in the aliphatic diacids and even though loss of water from anions **a** or **b** is structurally possible, the pathway for the loss of carbon dioxide must enjoy a lower critical energy than that for the loss of water.

As a further example of the behaviour of anions with less conformational mobility than those of the acyclic diacids, the MS/MS spectrum of the monoanion from 1,4-phenylenedipropionic acid (**c**, *m*/*z* 221, LCQ ion trap) was recorded. The spectrum of this anion was more complex, as might reasonably be expected for a species with more degrees of freedom than **a** or **b** and in which the ionized and non-ionized carboxyl groups can interact. While elimination of one molecule of carbon dioxide (*m*/*z* 177) was the major loss, this was less facile than for either **a** or **b** since a higher relative collision energy (24%) was needed. The fact that loss of carbon dioxide from anion **c** is more difficult than the loss from either **a** or **b** is consistent with the mechanism for this process as laid out in Scheme 2 in which a radical site is stabilized by the phenyl ring. Loss of the second molecule of carbon dioxide from **c** to give an ion at *m*/*z* 133 was also disfavoured (rel. intensities of ions at *m*/*z* 221, 203, 177, and 133 were 100:30:200:12). Loss of a molecule of water (*m*/*z* 203) from anion **c** was clearly apparent. The fragmentation behaviour of **c** (LCQ ion trap, 24% rel. CID) is comparable to that of the monoanion from glutaric acid (C_5, Table 1). This observation has further mechanistic implications that are discussed later.

To examine the participation of protons α to carboxyl groups in fragmentation pathways, the spectra of the monoanion from 2,2,6,6-tetramethylheptanedioic acid were acquired. This has the same chain length as pimelic acid (C_7), which showed essentially no loss of carbon dioxide (Table 1), but rather a loss of water, followed by a loss of carbon dioxide, the combined loss being the major fragmentation process. By contrast, the tetramethylpimelic acid showed essentially only loss of carbon dioxide (LCQ ion trap, 28% rel. CID), thus establishing decarboxylation as a perfectly viable process for a diacid monoanion having a chain length of seven carbon atoms. However, the presence of the α protons in pimelic acid opens up an alternative reaction pathway with a lower critical energy; this process was studied in more detail using acyclic diacids and some monomethyl esters.

Loss of water from diacid monoanions and methanol from diacid monomethyl ester anions



By way of comparison with results from the LCQ ion trap MS (summarized in Table 1 and Fig. 2), fragment ion spectra using the Quattro MS were obtained from the monoanions of sebacic and dodecanedioic acids, as well as from the monomethyl esters of glutaric and sebacic acids. The monoanions of the dicarboxylic acids ($HOOC(CH_2)_nCOO^-$) and dicarboxylic acid monoesters ($MeOOC(CH_2)_nCOO^-$) showed analogous MS/MS behaviour, losing water or methanol, respectively, to generate the same fragment ion.

The fragment ion spectra (not shown) on the monoanion of sebacic acid (**d**, *m*/*z* 201) and the anion from the monomethyl ester of sebacic acid (**e**, *m*/*z* 215) using the Quattro MS both showed additional peaks only at *m*/*z* 183 and 139. Fragmentation was very facile, since fragment ions were observed at collision energies of 10 and 5 eV (lab. frame), respectively, the absolute intensity of both peaks reaching a maximum around 15 eV and thereafter decreasing as the collision energy was increased to 30 eV. Similar MS/MS spectra were obtained from the monoanion of dodecanedioic acid (**f**, *m*/*z* 229).[4] For each of these longer chain monoanions, the losses of water and methanol were accompanied by a combined loss of water–methanol and carbon dioxide. No other fragmentation pathways were indicated by the MS/MS spectra.

The spectra from the anion of the monomethyl ester of glutaric acid showed a prominent loss of methanol at a colli-

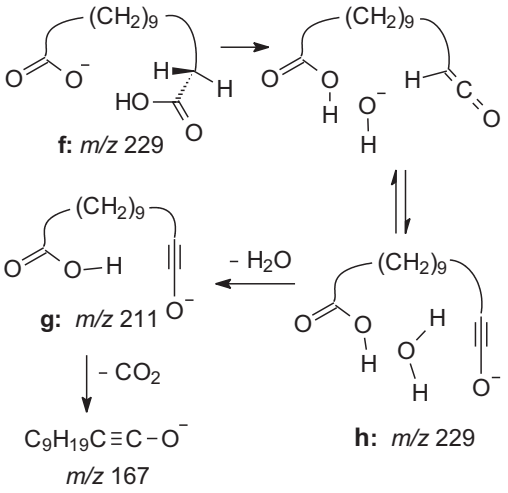
Scheme 3.

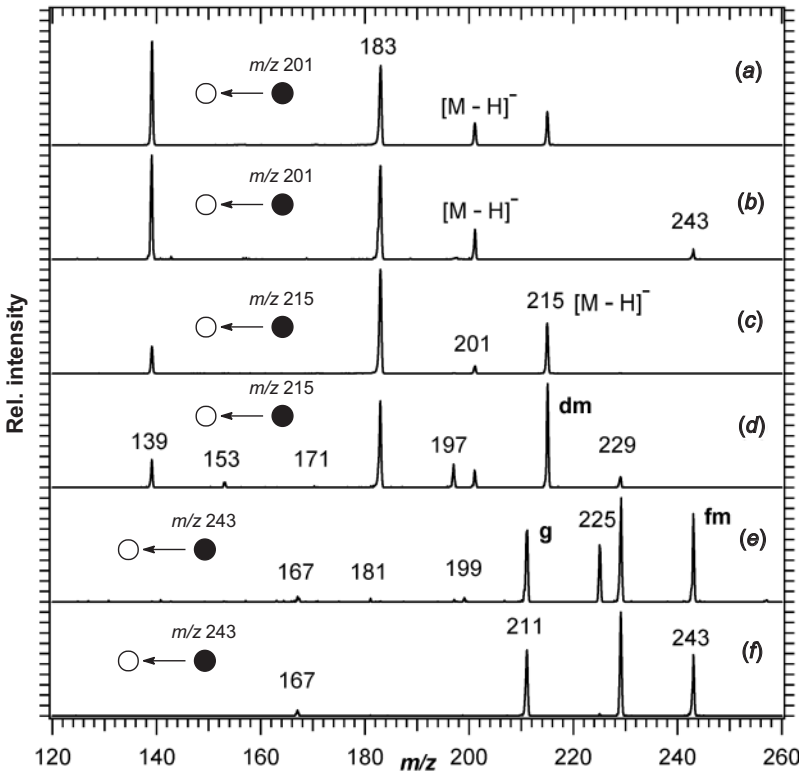


sion energy in the Quattro MS as low as 5 eV (lab. frame). No decarboxylation of the ester anion was observed, but fragment, parent, and neutral loss spectra[4] obtained on the Quattro MS could be interpreted in terms of a rich set of other fragmentation pathways. The pathways proposed in Scheme 3 are fully consistent with the ion chemistry outlined in this work, together with that already published (2). The deprotonated molecule observed at *m/z* 145 fragmented in two ways, the major pathway being loss of methanol to give *m/z* 113 and the minor pathway giving an ion at *m/z* 73. The major ion at *m/z* 113 also fragmented into major (*m/z* 69 and 41) and minor (*m/z* 59 and 41) pathways. The minor ion at *m/z* 73 lost methanol on further fragmentation to give an ion at *m/z* 41. The loss of 72 u (*m/z* 145 → 73) must result from the loss of $C_3H_4O_2$ since the ion at *m/z* 73 contains the elements of CH_4O (32 u) and C_2HO (*m/z* 41). The loss of $C_3H_4O_2$ corresponds to the elements of CO_2 and C_2H_4 and we suggest that this loss is a synchronous process since there was no evidence in the various spectra for a stepwise process. These two stable neutral species would assist in promoting the fragmentation process (*m/z* 145 → 73).

The CID spectra of the anions from both the α- and side-chain methyl esters of Asp and Glu also showed a prominent loss of 32 u (MeOH), but no loss of water or carbon dioxide. As previously noted, these spectra show the specific loss of methanol from the ester group, which can be extrapolated to serve as a probe for the regiochemistry of the dehydration reactions in the diacid monoanions occurring at the non-ionized carboxyl group.

The facile losses of water from a dicarboxylic acid monoanion and methanol from the anion of a dicarboxylic acid monomethyl ester (at collision energies as low as 10 and 5 eV, respectively) contrast strongly with the difficult loss of water from the anions of monocarboxylic acids. In the latter, the process required high collision energies in the LCQ MS and was not observed in the Quattro MS. The different fragmentation behaviour for monocarboxylic and dicarboxylic acids suggests that intramolecular interactions of the ionized and non-ionized carboxyl groups facilitate the losses of water or methanol; this is undoubtedly a consequence of the coiled conformation that these ions adopt (19–21, 24). These fragmentations are therefore not examples of charge-remote fragmentations occurring under conditions of low-energy CID (27, 33, 34).

Scheme 4.



Given the very low CID energies at which fragment ions formed from the monoanions of sebacic acid (**d**), sebacic acid monomethyl ester (**e**), and dodecanedioic acid (**f**), these spectra also provided an important clue to the structures of the various fragment and adduct (see the next section) ions arising from **d**, **e**, and **f**, namely, that at least some fraction of each ion must have the structure of an ion–molecule complex. Mechanistic proposals incorporating such cluster ions are outlined in Scheme 4, which features ions derived from **f**; several points are noteworthy. The facile loss of water or methanol from **d**, **f**, or **e** ultimately arises from intramolecular interactions between the ionized and non-ionized carboxyl groups, which in turn must be a function of the chain length, longer chains allowing for more conformational flexibility so that the two groups can interact closely. The initial dehydration product of a non-ionized carboxyl group will be a ketene-containing cluster ion, but these can readily undergo proton transfer to the alkyne oxide cluster ion (**h**). Ethynol, isolated in a mass spectrometer, was first described almost 20 years ago (35) and alkynols have been extensively studied photochemically. They are stronger acids than carboxylic acids (36, 37), which provides good support for the ionic structures outlined in Scheme 4.

Other coiled conformers of these anions are undoubtedly present, but were not included to keep Scheme 4 reasonably uncluttered. In principle, the proton exchange processes for the conversion **f** → **h** outlined in Scheme 4 are reversible and could occur in electrospray ion sources. However, we note that we have found no evidence for deuterium exchange in the electrospray source (vide infra), and all details of the processes are therefore not at this time clear. However, we believe that all the evidence we have accumulated requires that at least some of the ions observed in either the Quattro or LCQ ion trap MS at, for example, *m/z* 229, have a struc-

Fig. 3. MS/MS fragment ion spectra from the LCQ MS for the (*a*) monoanion from sebacic acid (**d**, *m*/*z* 201) in methanol (24%, CID), (*b*) ion **d** (*m*/*z* 201) in 2-propanol solution (24% CID), (*c*) monoanion from sebacic acid monomethyl ester (**e**, *m*/*z* 215, methanol, 20% CID), (*d*) adduct ion **dm** (*m*/*z* 215) from sebacic acid monoanion in methanol, acquired at 20 V SID, 22% CID, (*e*) adduct ion **fm** (*m*/*z* 243) from dodecanedioic acid monoanion in methanol, acquired at 0 V SID, 24% CID, (*f*) adduct ion at *m*/*z* 243 from dodecanedioic acid monoanion in methanol, acquired at 30 V SID, 24% CID.

ture such as **h**. This would explain the very low collision energies needed to facilitate loss of water or alcohol from anions such as **d**, **e**, or **f**.

Ion–molecule reactions in the LCQ ion trap MS

When studying the spectra of the dicarboxylic acid monoanions using the LCQ MS, it became apparent that, in some cases, ion–molecule reactions were occurring as a result of solvent molecules in the ion trap, leading to more complex spectra than were obtained from the Quattro MS. The first indication of these reactions came from the MS/MS spectrum of the deprotonated molecule of sebacic acid in methanol ($HOOC(CH_2)_8COO^-$, **d**, *m*/*z* 201, Fig. 3*a*), which showed not only loss of water as an intense peak (*m*/*z* 183) and the combined loss of water plus carbon dioxide (*m*/*z* 139), but also a peak at *m*/*z* 215 from adduct ion **dm**, corresponding to [**d** – H_2O + MeOH]. Similarly, if the solvent was 2-propanol (Fig. 3*b*), a peak at *m*/*z* 243 from adduct ion **dp**, [**d** – H_2O + *i*-PrOH], was observed, in addition to the same fragment ions that were observed when the solvent was methanol. The peaks from these two solvent-derived adduct ions could be found in the full-scan mass spectra (not shown) by increasing the in-source collision (SID) energy from 0 to 20 V. It should be noted that others have previously described similar reactions between ions and solvent molecules in ion traps (38).

The mass spectra obtained on the anion from the monomethyl ester of sebacic acid ($MeOOC(CH_2)_8COO^-$, **e**, *m*/*z* 215, LCQ ion trap) showed behaviour comparable to that of the free acid. The MS/MS spectrum from a methanolic solution of **e** is shown in Fig. 3*c* and is very similar to the spectrum from **d** (Fig. 3*a*), with the fragment ion (*m*/*z* 183) being prominent. The ion **ew**, [**e** – MeOH + H_2O], observed at *m*/*z* 201 must arise from ion–molecule reactions between water present in the ion trap and the fragment ions seen at *m*/*z* 183, a phenomenon observed routinely when acquiring spectra for the present work. When the spectrum of **e** was run in 2-propanol,[4] an adduct ion **ep** (*m*/*z* 243, [**e** – MeOH + *i*-PrOH]) was also found, as was observed in the case of **d** (Fig. 3*b*).

The MS/MS spectrum from the adduct ion **dm** is shown in Fig. 3*d*. It was initially expected that the ion **dm** would have the same structure as that of the monoester ion **e** (both *m*/*z* 215), but on comparison of the MS/MS spectra shown in Figs. 3*c* and 3*d*, it is apparent that this is not the case. The spectrum in Fig. 3*d* shows that the adduct ion **dm** can lose either water (*m*/*z* 197) or methanol (*m*/*z* 183), with the addition of a molecule of methanol to *m*/*z* 197 leading to the peak observed at *m*/*z* 229 and the addition of a molecule of water to *m*/*z* 183 leading to the peak observed at *m*/*z* 201. Similar complex behaviour was shown by the adduct ion **dp** (*m*/*z* 243), formed when sebacic acid was dissolved in

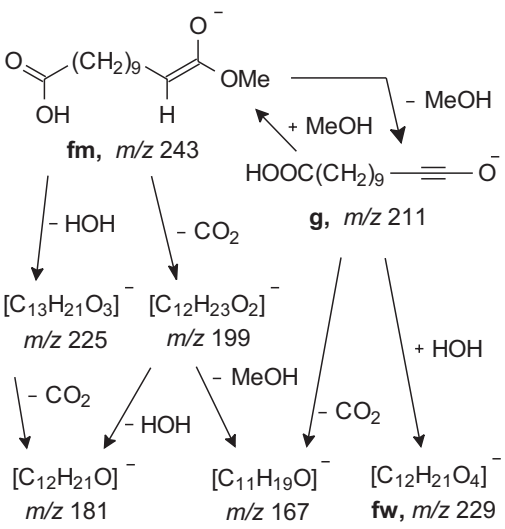
[a]Ion selected for MS/MS fragmentation.

[b]Major ions observed.

[c]Ions also observed at *m/z* 167 = [211 – CO_2] and at *m/z* 211 = [**k** + *i*-PrOH – 32], which gave adduct ions at *m/z* [211 + 18] and [211 + 60].

[d]**k** = reactive fragment ion derived from sebacic acid, [**d** – H_2O]; from dodecandioic acid, [**f** – H_2O]; from monomethyl sebacate, [**e** – MeOH].



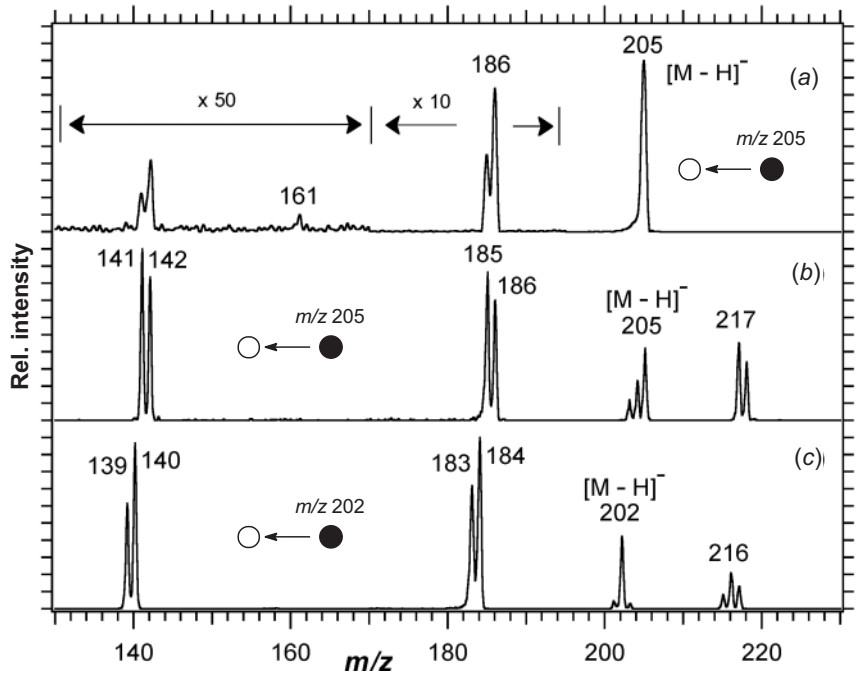
2-propanol.[4] The spectra of these adduct ions will be discussed in more detail later.

Some results from dodecanedioic acid were similar to those from sebacic acid. In addition to the fragment ions described previously, such as **g** (*m/z* 211, [**f** – H_2O]), the MS/MS spectrum from the monoanion $HOOC(CH_2)_{10}COO^-$ (**f**, Fig. 1*c*) also showed an abundant adduct ion **fm** (*m/z* 243, [**g** + MeOH]). By facilitating in-source fragmentation (40 V SID) on the LCQ MS, the MS/MS spectrum on *m/z* 211 (**g**) was acquired. At 0% CID (not shown) two additional peaks, corresponding to **fw** = [**g** + H_2O] at *m/z* 229 and **fm** (*m/z* 243 $[C_{13}H_{23}O_4]^-$) were notable. Therefore, the anion **g** must be a reactive species that combines with weakly acidic HX reagents (water or methanol) during the lifespan of the ion in the trap. When the experiment was repeated with the application of collision energy to the trap (40 V SID, 24% CID), the adduct ions were observed, but the base peak was now the fragment ion corresponding to [**g** – CO_2] (*m/z* 167, spectrum not shown). This loss of carbon dioxide is consistent with anion **g** containing a non-ionized carboxyl group.

In contrast to the results from sebacic acid, when the adduct ion from dodecanedioic acid observed at *m/z* 243 was formed with or without in-source fragmentation voltage in the LCQ MS, two different MS/MS spectra (Figs. 3*e* and 3*f*) were obtained. At 0 V SID (24% CID) the spectrum (Fig. 3*e*) paralleled that of **dm** (Fig. 3*d*), but at 30 V SID (24% CID), the spectrum (Fig. 3*f*) paralleled that from the monoester anion (**e**, Fig. 3*c*), suggesting that ions (*m/z* 243) of two different structures lead to the MS/MS spectra shown in Figs. 3*e* and 3*f*.

The reactivity of the fragment ions observed at *m/z* 183 (from **d** or **e**, Figs. 3*a* and 3*b*) and *m/z* 211 (**g**, from **f**, Fig. 1*c*) with water or alcohols, within their residence time in the ion trap, is consistent with the behaviour of a structure containing an alkyne oxide functionality. Addition of a species in the form of HX to an alkyne oxide is facile (36), and addition products with water, methanol or 2-propanol were observed in all cases. It is reasonable to assume that the structures of these addition products are enolate anions. As already mentioned, the fragmentation patterns of these ions were studied further using MS/MS on the LCQ MS and methanol solvent (Figs 3*d*–3*f*). When the solvent was

Scheme 5.



2-propanol, the adduct ions were generally of lower intensity and their spectra were therefore less detailed, but were reproducible. A summary of the MS/MS spectra of the adduct ions is presented in Table 2. A useful feature of the fragmentation of anion **dm** (*m/z* 215) was the low-intensity peak at *m/z* 171 for the loss of carbon dioxide (Fig. 3*d*); a similar fragmentation (*m/z* 199) was observed from **fm** (*m/z* 243, Fig 3*e*). This loss, a major feature in the MS/MS spectra of monoanions of the short-chain diacids, became progressively less important as the chain length increased and was not seen in the spectra of **d** or **f** from the LCQ MS. However, loss of carbon dioxide was present when ions of different structures from **d** or **f** were fragmented; it was also present as a low-intensity signal in the MS/MS spectrum of **f** from the Quattro MS.[4] We suggest that this fragmentation provides evidence for the structures of the adduct ions **dm** and **fm** having both a non-ionized carboxyl group and a charge-bearing enolate anion group. This is shown in Scheme 5, which is illustrated using species arising from fragmentation of anion **f**.

Although a reasonable structure for the adduct ion **fm** is proposed in Scheme 5, it does not allow for a simple expla-

Fig. 4. MS/MS fragment ion spectra for the (*a*) monoanion from 2,2,9,9-tetradeuterosebacic acid (**i**, *m*/*z* 205, MeOH, Quattro MS, 15 V cone, 20 eV CID), (*b*) monoanion from 2,2,9,9-tetradeuterosebacic acid (**i**, *m*/*z* 205, MeOH, LCQ ion trap MS, 24% CID), (*c*) monoanion from sebacic acid (**j**, *m*/*z* 202, MeOD, LCQ ion trap MS, 28% CID).

nation of all the features found in the spectrum shown in Fig. 3*e*. For example, the loss of 18 u (H_2O, *m*/*z* 225) is a prominent ion in this spectrum. It is tempting to suggest that a molecule of water is lost from the non-ionized carboxyl group, yet the spectrum reproducibly contains a low-intensity peak at *m*/*z* 181. If the carboxyl group has lost a molecule of water, it cannot also decarboxylate, which suggests that the ion **fm** (*m*/*z* 243) has rearranged or comes from more than one structure. It is difficult to explain the loss of both water and carbon dioxide from the structure given for **fm** in Scheme 5, but this structure can obviously rearrange as seen from the spectrum shown in Fig. 3*f*. Thus, the adduct ion observed at *m*/*z* 243 and labelled **fm** must represent several structures. The MS/MS spectrum of **fp** (Table 2), the adduct ion formed when dodecanedioic acid was dissolved in 2-propanol, was of low intensity but showed ions comparable to the major ones in the spectrum of **fm** (Table 2). Comparable MS/MS spectra to that of **fm** were seen when sebacic acid was dissolved in methanol (**dm**, Fig. 3*d*) or 2-propanol (**dp**, Table 2);[4] again, the adduct ion was able to lose either a molecule of alcohol or water (Table 2).

The MS/MS spectrum of the anion **e** (*m*/*z* 215) from monomethyl sebacate in methanol is shown in Fig. 3*c*. Any adduct ion with methanol would also be observed at *m*/*z* 215 and could not be distinguished from the anion itself under these conditions. However, the 2-propanol solution clearly gave an adduct ion at *m*/*z* 243 and details of the MS/MS spectra of this ion have been provided (Table 2).[4] Again, as noted in Table 2, structures for some lower intensity ions cannot be explained readily, but most major ions were directly comparable to those formed when sebacic acid was dissolved in 2-propanol.

We believe that the ion–molecule reactions occurring in the LCQ ion trap provide important evidence that loss of water from the longer chain diacid monoanions (or alcohol from monoester anions) leads to the formation of ynolate anions such as **g**. However, the reactions of these ynolate anions are not only simple addition processes, but also appear to involve rearrangements that depend on the operating conditions of the electrospray source and the ion trap. A study of these rearrangements would be interesting but is beyond the scope of the present work.

Studies on fragmentation pathways using deuterium-labelled compounds

Further evidence for the role of both the α-hydrogen atoms and ion–molecule complexes (Scheme 4) in the neutral loss of water was obtained by studying fragment ion spectra from the monoanion of 2,2,9,9-tetradeuterosebacic acid (**i**). This anion, observed at *m*/*z* 205, cleanly and reproducibly fragmented in the Quattro MS to give peaks at both *m*/*z* 186 and 185, in a ratio of ca. 2:1 (Fig. 4*a*). These ions correspond to the loss of HOD and DOD, respectively, and they fragmented further by losing carbon dioxide to give peaks at *m*/*z* 142 and 141. The observed 2:1 ratio is consistent with an equal distribution of two deuterium labels over three positions. This result must mean that the ketene and alkyne oxide cluster ions (Scheme 4) have sufficient time to interconvert before fragmenting in the collision cell. The collision cell of the Quattro MS allows for multiple collisions at the collision gas pressures employed. The information gained from the fragment ion spectra was supported by precursor ion and neutral loss scans.

When this tetradeuterated sebacic acid was studied using the LCQ ion trap MS, the MS/MS spectrum from **i** (24%

© 2005 NRC Canada

nominal CID energy) is shown in Fig. 4*b*. The phenomena observed are similar to those observed in the Quattro MS in that both HOD and DOD were lost from **i**, followed by a further loss of carbon dioxide. However, as discussed in the previous section, the ion trap is a reactive milieu and the addition of methanol (major) and water (minor) to both ions at *m*/*z* 185/186 was observed also. The other major difference between the results from the two spectrometers lies in the intensity ratios of the fragment ions observed at *m*/*z* 185/186 and *m*/*z* 141/142. The intensity ratio of *m*/*z* 185/186 in the Quattro was 0.5, but was 1.2 in the ion trap, indicating a process in the ion trap leading to greater loss of the deuterium label. The similar relative intensities of the peaks in the pairs at *m*/*z* 141/142 and *m*/*z* 185/186 suggest that the isotopic exchange process in the LCQ ion trap is faster than decarboxylation. It was intriguing to observe that, unlike all other ions studied, the MS/MS spectrum of anion **i** in the LCQ ion trap at 0% CID energy did not give a single peak for the precursor ion (*m*/*z* 205), but reproducibly showed another ion (*m*/*z* 204) at 15% of the precursor ion intensity. Therefore, some proton–deuterium exchange with the solvent in the trap was occurring, even with no added collisional excitation energy.

When the tetradeutero anion **i** was studied by CID on the Quattro MS, only intramolecular deuterium exchange processes are possible for the deuterated ions similar to the alkyne oxide **h** and the ketene cluster ions shown in Scheme 4. A similar process would occur in the LCQ ion trap, but in this instrument, other exchange processes with the solvent (e.g., between deuterated ions, comparable to **h** and **g**) occur also. Therefore, the spectra in Figs. 4*a* and 4*b* should be different. From the spectra (Figs. 4*a* and 4*b*) only two deuterium atoms are lost, indicating that exchange in both spectrometers is limited to one end of the anion **i**, consistent with processes shown in Schemes 4 and 5.

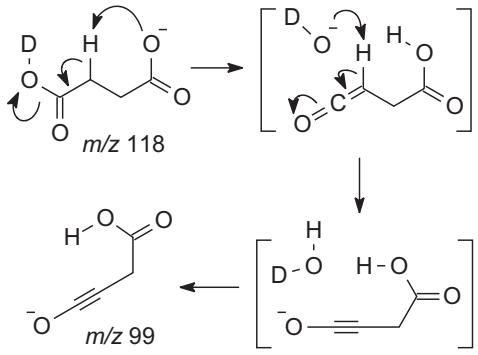
Complementary results were obtained when sebacic acid was dissolved in MeOD to generate an anion monodeuterated on the non-ionized carboxyl group ($DOOC(CH_2)_8COO^-$, **j**, *m*/*z* 202). This ion fragmented in the LCQ ion trap MS to give peaks at *m*/*z* 184 and 183, corresponding to the loss of both HOH and HOD, in a ratio of ca. 1.4:1 as shown in Fig. 4*c*. Since the ion trap MS also contains both deuterated and undeuterated solvent molecules (vide infra), this fragment ion spectrum is more complex than that of the sebacic acid monoanion **g**, although all the observed peaks can be explained by postulating the addition of MeOD, MeOH, HOD, or H_2O to the ions giving the pair peaks seen at *m*/*z* 184/183; loss of carbon dioxide from these ions leads to the peaks at *m*/*z* 140/139. An analogous spectrum (not shown) was obtained from $DOOC(CH_2)_{10}COO^-$.

Acquiring full-scan spectra (not shown) on the LCQ MS from a solution of the monomethyl ester of sebacic acid in MeOD produced a major ion at *m*/*z* 215 ($MeOOC(CH_2)_8COO^-$, **e**) and showed little evidence of deuterium exchange, except for a minor ion at *m*/*z* 202, which could be attributed to a small amount of diacid impurity ($DOOC(CH_2)_8COO^-$, **j**). The presence of a small amount of diacid in the sample of monoester was seen also in other full-scan spectra, including those taken on the Quattro MS. Other minor ions observed in the full-scan spectra on the LCQ MS were at *m*/*z* 229, 230, and 231. The various ions observed in these full-scan spectra on the LCQ MS were studied by MS/MS fragment ion scans. An important result from these spectra was the fragment ion spectrum (not shown) on *m*/*z* 215 (22% CID) which, in addition to the expected fragment ions at *m*/*z* 183 and 139, also gave an ion at *m*/*z* 216 with some 40% of the intensity of the ion at *m*/*z* 215. The intensity of this deuterated ion could be increased by increasing the collision energy and it must arise from addition of residual MeOD in the trap with the ion at *m*/*z* 183, as described previously. MS/MS scans on *m*/*z* 216 under the same conditions gave a minor ion at *m*/*z* 215 together with an ion at *m*/*z* 217, again at about 40% of the intensity of the ion at *m*/*z* 216. Since there was no evidence for direct, in-source deuterium exchange in **e**, it appears that any formation of an enolate anion leads rapidly only to other species. In addition, the formation of an enolate anion is not directly reversible during in-trap CID, but as observed previously (Figs. 3*e* and 3*f*) it appears that this can be brought about by application of in-source SID.

To examine whether enolate anions could be formed from more acidic species using ESI-MS under neutral solvent conditions, we examined the behaviour of methanolic solutions of dimethyl and diethyl malonate using the LCQ ion trap MS. In both cases enolate anions (*m*/*z* 131 and 159, respectively) were formed readily and both ions easily (16% relative collision energy) lost a molecule of alcohol. This fragmentation can be interpreted as leading to the formation of an alkynyl oxide anion (eq. [2]), in agreement with the major fragmentation observed in earlier work using high-energy collisions (39).

$$[2] \quad {}^-CH(COOR)_2 \rightarrow [(ROOC)CH{=}C{=}O + OR]^- \rightarrow (ROOC)C{\equiv}CO^- + ROH$$

Thus, the fact that enolate anions do not appear to be forming by deprotonation processes in the case of anions such as **e** simply reflects unfavourable energetics, compared with other accessible fragmentation pathways.



In contrast to the complex fragmentation behaviour exhibited by anions such as **d** and **f** from longer chain diacids, the short chain diacids in MeOD gave simple spectra. For example, the monoanion from succinic acid (C_4) in MeOH (seen at *m*/*z* 117) gave only two fragment ions, namely *m*/*z* 99 and 73 (Table 1). In MeOD, the anion at *m*/*z* 118 cleanly fragmented to give *m*/*z* 99 and 74. No adduct ions were observed, which could be explained by the fact that an ynolate anion in this case would be internally stabilized by the non-ionized carboxyl group, as shown in Scheme 6. In the case of adipic acid (C_6), the chain is now long enough that the anion exhibits very similar behaviour (in both MeOH and MeOD) to monoanions such as **d** (C_{10} chain). The difference between the six- and ten-carbon chains is that in the case of the latter anions the direct loss of carbon dioxide becomes a minor process (Table 1).

Conclusions

We have found no evidence for the formation of dianions in the spectra of the dicarboxylic acids, in either the LCQ ion trap or the Quattro MS (6, 40). All spectra in the present study were run in methanol, 2-propanol, or methanol–water

© 2005 NRC Canada

Scheme 6.

solutions without the addition of salts or bases. At low source cone voltages on the Quattro MS, the expected cluster ions of the diacids and their deprotonated molecules, $[2M - H]^-$, were readily observed (18). As previously discussed, stabilization of anions in the gas phase by interaction with another functional group is important (19–21, 24). In the present work this is illustrated by the exclusive formation of monoanions from dicarboxylic acids. Typically, most smaller ions would carry only a single charge, but most of the ions described in this work are undoubtedly stabilized by intramolecular interactions between the ionized and non-ionized carboxyl groups and dianion formation would thus be less favourable.

When subjected to CID, the pattern of reactivity of the monoanions from the series of dicarboxylic acids turned out to be complex, showing a strong dependence on chain length. Loss of carbon dioxide from a non-ionized carboxyl group is important for ions of structure $HOOC(CH_2)_xCOO^-$ only when $x \leq 4$. When $x > 4$, then the loss of carbon dioxide is preceded by an initial loss of water. For larger molecules, fragment ions that are formed by loss of water in the LCQ ion trap MS also form adduct ions. The properties of the anions that have lost water are consistent with structures in the form $HOOC(CH_2)_xC{\equiv}CO^-$, x = 3–7 or 9, based on the fact that the MS/MS spectra of the parent anions in the LCQ ion trap MS consistently showed low-intensity peaks for solvent adduct ions (see Fig. 1). These signals were absent in the spectra of the short-chain dicarboxylic acid monoanions.

The experiments that showed the loss of water or alcohol (ROH) from ions of structure $ROOC(CH_2)_xCOO^-$, x = 8 or 10, are noteworthy. The facility with which this process occurs points to a process with a very low critical energy. The remarkable results from the tetradeuterated anion **i**, $[HOOCCD_2(CH_2)_6CD_2COO^-]$, mean that the elimination of water cannot be a direct, simple process, but rather should be interpreted as involving a tightly held ion–molecule complex with a structure such as **h** (see Scheme 4) and having sufficient lifetime to permit exchange of the deuterium label during the multiple collisions of its passage through the Quattro collision cell. Perhaps the most appropriate structural description of the ion–molecule complex is that of a neutral molecule being held by a pair of molecular tweezers, which implies an adequate chain length of the starting diacid. A measure of the length of chain needed for the loss of water can be gauged from the MS/MS spectra of the phenylenediacetate ions (**a** and **b**) and the phenylenedipropanoate ion (**c**). In the case of the first two ions only carbon dioxide, but no water, was lost and the molecular geometry in **b** (1,4-disubstituted) is such that the ionized and non-ionized carboxyl groups are too far apart to interact. By contrast, in **c** interaction is possible and loss of both carbon dioxide and water was observed.

The lack of deuterium exchange when the monodeuterated anion **j**, $[DOOC(CH_2)_8COO^-]$, was studied points to the unimportance of enolate anion formation in the electrospray ionization process of these compounds. Finally, limited studies on the complex series of ion–molecule reactions occurring in the LCQ ion trap have provided good evidence for the formation of alkyne oxides in the form of $HOOC(CH_2)_xC{\equiv}CO^-$, x = 3–9. It has also become apparent from current work that the processes described in this work are dominant in the fragmentation of monoanions from both amino- and hydroxy-substituted diacids; the amino or hydroxy groups of these species appear to play a minor role in the fragmentation processes (Grossert, Fancy, and White, to be published).

An overview of organic molecule soft ionization using vacuum ultraviolet laser radiation[1]

Y.J. Shi and R.H. Lipson

Abstract: The utility of coherent vacuum ultraviolet (VUV) single-photon ionization (SPI) combined with time-of-flight mass spectrometry (TOF-MS) for organic molecule detection by parent mass is explored in this short review. Nonresonant tripling in phase-matched Xe–Ar gas mixtures was used to generate photons at a fixed energy of 10.5 eV. Representative organic molecules with different functional groups were examined, including aliphatic and aromatic alkanes, alkenes, alkynes, alkanols, ethers, amines, aldehydes, ketones, carboxylic acids, and esters. In almost every case, the intensity of the resultant parent molecular ion peak detected by TOF-MS was found to be superior to that obtained using 70 eV electron impact (EI), and comparable to that obtained with 12 eV EI. In those instances when fragmentation reactions did occur, the resultant ions were similar to those found using EI but with significantly reduced mass spectral intensities. It was still possible to establish one dominant fragmentation pathway that could be used for molecular identification even if the parent molecular ion was not the strongest feature in the spectrum, for example, in the case of alcohols, alcohol clusters, and alcohol–ether adducts. Several of the fragment ions were metastably broadened. Not surprisingly, their known appearance energies or estimated reaction enthalpies were very similar to the fixed photon energy used. The success of using VUV for organic molecule soft ionization is attributed to the low photon energy that removes predominantly a π- or non-bonding electron from the functionalized species. As most organic compounds have ionization potentials in the 10.5 eV region, this approach is expected to be near universal.

Key words: vacuum ultraviolet laser, single photon ionization, organic molecule detection, soft-ionization, mass spectrometry.

Résumé : Dans cette courte revue, on examine l'utilité d'une ionisation par un photon unique dans l'ultraviolet lointain cohérent combinée avec un spectromètre de masse à temps d'envol (SM-TDE) pour la détection de molécules organiques à l'aide de la masse parente. Le triplage non résonant de mélanges de gaz Xe–Ar en phase a été utilisé pour générer des photons d'énergie fixe de 10,5 eV. Des molécules organiques représentatives portant divers groupes fonctionnels ont été examinées, y compris des alcanes, des alcènes, des alcynes, des alcools, des éthers, des amines, des aldéhydes, des cétones, des acides carboxyliques et des esters aliphatiques et aromatiques. Dans pratiquement tous les cas, il a été trouvé que l'intensité du pic de l'ion moléculaire parent qui en résulte telle que détectée par SM-TDE est supérieure à celle obtenue en utilisant un impact électronique (IE) de 70 eV, et qu'elle est comparable à celle obtenue avec un IE de 12 eV. Dans les cas où des réactions de fragmentation se sont produites, les ions qui en résultent sont semblables à ceux observés avec un IE, mais les intensités des masses spectrales sont de beaucoup réduites. Il est toujours possible d'établir une voie de fragmentation dominante qui pourrait être utilisée pour l'identification moléculaire, même si l'ion moléculaire parent n'est pas la caractéristique la plus forte du spectre, par exemple, dans le cas des alcools, des agrégats d'alcools et des adduits alcool-éther. Plusieurs fragments ioniques sont élargis par leurs ions métastables. Il n'est pas surprenant que leurs énergies d'apparition connues ou les enthalpies réactionnelles évaluées soient très semblables à celle de l'énergie photonique fixe utilisée. Le succès obtenu en utilisant l'ionisation douce des molécules organiques à l'aide d'ultraviolet lointain est attribué à la faible énergie photonique qui élimine principalement un électron π ou non liant des espèces fonctionnalisées. Comme les potentiels d'ionisation de la plupart des molécules organiques se situent autour de 10,5 eV, il semble que cette approche pour être universelle.

Mots clés : laser ultraviolet lointain, ionisation photonique unique, détection de molécules organiques, ionisation douce, spectrométrie de masse.

Introduction

Several ionization schemes have been developed for mass spectrometry of gas-phase organic molecules. Electron impact (EI) and chemical ionization (CI) (1, 2) predominate. While claims for each have been made for some degrees of "soft ionization", that is, ionization without parent ion fragmentation, more often than not, the base peaks are due to fragment ions. Indeed, a considerable portion of the mass spectrometry literature is concerned with the mechanisms and energetics of fragment ion formation, as these species can be used as markers to identify the parent precursor. It follows that any technique that can provide a direct measure of the parent mass would be a valuable addition to the arsenal of tools available to analytical chemistry.

In this paper, we explore the utility and universality of organic molecule soft single-photon ionization (SPI) and detection using the combination of coherent vacuum ultraviolet (VUV) radiation and time-of-flight mass spectrometry (TOF-MS). VUV SPI is generally considered to be a "soft" ionization method because only modest amounts of excess energy are deposited in the resulting photoions. Furthermore, efficient ionization can occur with relatively low laser intensities, minimizing the probability of multiphoton absorption. This technique works for all compounds whose ionization potentials lie below the VUV photon energy (in most experiments, less than 10.5 eV). As VUV SPI is nonresonant, spectral tuning or prior knowledge of the electronic properties of the molecular species is not required. Furthermore, although the absolute photoionization cross sections are difficult to measure, it is known that they tend to differ little from one another for molecules, compared to resonant multiphoton ionization. This makes quantitative measurements using VUV SPI much more feasible. This burgeoning field has been previously reviewed (3–6).

In our initial experiments, derivatives of the common *O*-alkyl dithiocarbonate (xanthate) salts used in mineral sulphide flotation were examined. We showed conclusively that VUV SPI (7) coupled with TOF-MS (8) could readily identify the components of gas-phase xanthate mixtures by parent mass with detection sensitivity in the femtomole (picomolar) regime (9). More recently, we used VUV laser – TOF-MS to determine the gas-phase distributions of hydrogen-bonded alcohol clusters and alcohol–ether clusters formed above their respective liquids (10).

In this work, TOF mass spectra of various representative aliphatic and aromatic compounds were recorded using a fixed 118.2 nm (10.5 eV) "laser" generated by nonresonantly tripling the UV output of a Nd:YAG laser in phase-matched Xe–Ar mixtures. The resultant TOF mass spectra are compared with those obtained by conventional 70 eV EI, and where possible, lower energy 12 eV EI. Needless to say, not every possible organic compound could be examined. Furthermore, our choice of species in these experiments was limited to those with ionization potentials below 10.5 eV, and to gases or liquids with sufficiently high enough vapour pressures to be detected in the gas phase. Still, strong evidence is provided here that such an experimental approach is a powerful and general tool for identification of organic molecules with a wide variety of functional groups by parent mass.

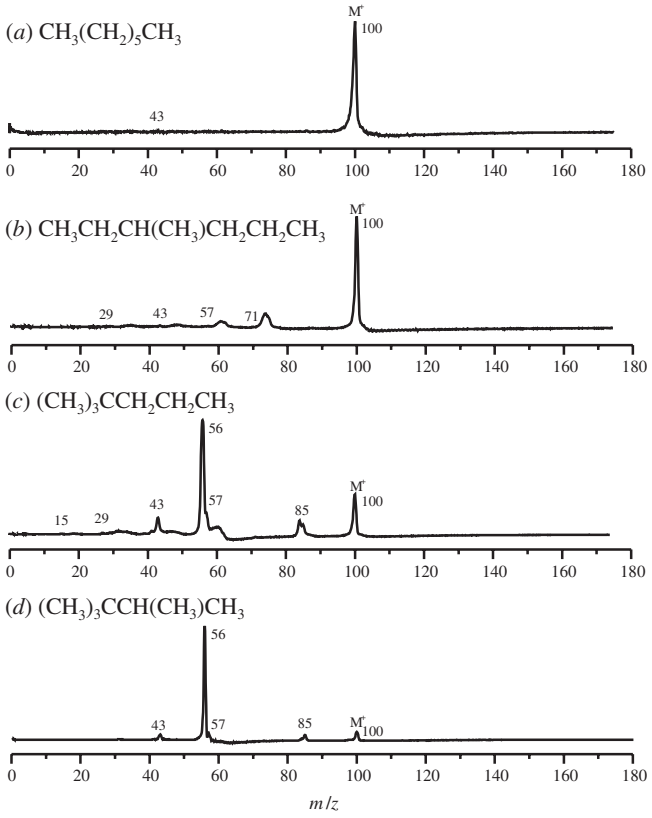
Experimental

The experimental arrangement used to record 118.2 nm VUV laser – TOF mass spectra of various organic compounds is identical to that described in detail elsewhere (10–12). Briefly, coherent VUV radiation at 118.2 nm was generated by nonresonantly tripling the 355 nm (UV) third harmonic output of a Nd:YAG laser in a phase-matched 1:10 Xe–Ar gas mixture at a total pressure of ~100 Torr (1 Torr = 133.3224 Pa). A dispersive MgF_2 lens was inserted into the optical path after the Xe–Ar gas cell to minimize the possibility of ion formation by a multiphoton process involving the 118.2 nm beam and one or more 355 nm UV photons. The vapour of organic compounds mixed with 1 atm (1 atm = 101.325 kPa) of ultra pure helium was introduced into a vacuum chamber through a 1.0 mm diameter pinhole of a pulsed nozzle operating at 10 Hz. Ions, produced by VUV SPI, were mass dispersed in the 1 m long field-free flight tube of a linear TOF mass spectrometer, and detected by a two-stage microchannel plate (MCP). Although the mass resolving power of the TOF mass spectrometer ($m/\Delta m$) is designed to be >500, the typical mass resolution obtained from our mass spectra is 120. This lower mass resolution is attributed to the fact that an unskimmed pulsed jet was used for sample delivery that increases the spatial distribution of the sample. In addition, at the fixed VUV wavelength used for soft ionization, it is quite possible that the generated molecular ions could end up in a number of internal energy states, resulting in a wider velocity distribution. These factors, however, were not felt to distract from the goals of this work and technically, could be rectified with some modification of the apparatus.

Results

TOF mass spectra of various aliphatic and aromatic compounds with different functional groups were recorded with the fixed short wavelength VUV laser to determine the extent of fragmentation and any characteristic patterns.

Aliphatic compounds



Alkanes

Four isomeric heptanes (*n*-heptane, 3-methylhexane, 2,2-dimethylpentane, and 2,2,3-trimethylbutane) were examined to determine the effect of branching on the degree of fragmentation resulting from VUV SPI. The resultant TOF mass spectrum for *n*-heptane (ionization potential, IP = 9.93 eV (13)) is shown in Fig. 1*a*. The base peak at m/z = 100 in the mass spectrum is due to the parent ion. The 10.5 eV SPI spectra of *n*-octane (14) and *n*-hexane (15) exhibit similar behaviour. The very weak feature at m/z = 43 in Fig. 1*a* is attributed to the propyl cation ($C_3H_7^+$).

Both the 70 eV (16) and 12.1 eV (17) EI mass spectra of *n*-heptane have been studied in detail. A photoionization study using incoherent VUV sources has also been reported (18). A comparison summary between VUV SPI and EI methods for *n*-heptane and all other compounds examined in

Fig. 1. Vacuum ultraviolet (VUV) (118.2 nm) single-photon ionization (SPI) – time-of-flight (TOF) mass spectra of *n*-heptane and its isomers: (*a*) *n*-heptane, (*b*) 3-methylhexane, (*c*) 2,2-dimethylpentane, and (*d*) 2,2,3-trimethylbutane. The features indicated by M^+ correspond to parent ion peaks.

this work is given in Table 1. The ion intensity distribution in Fig. 1*a* is opposite to that obtained by 70 eV EI. Since *n*-alkanes do not possess a natural focal point for ionization, EI nonselectively ionizes a C-C σ electron (19) leading to random cleavage down the chain, producing, in the case of *n*-heptane, ion fragments at *m*/*z* = 85, 71, 57, 43, and 29. The actual mechanism is more complex than the description above. ^{13}C and ^{2}H isotope labelling experiments suggest that the behaviour of isolated $C_nH_{2n+2}^{+\cdot}$ radicals can be rationalized in terms of a radical bound to an incipient carbonium ion (20, 21). Depending on the size of the alkane, isomerization reactions of the incipient carbonium ion can compete effectively with direct cleavage. For example, in the case of *n*-heptane ions, there is only a 22% probability that direct C_4H_9 scission will produce $C_3H_7^+$. On the other hand, there is a 72% chance that C_2H_5 will be lost from $C_7H_{16}^{+\cdot}$ to produce a $C_5H_{11}^+$ intermediate that then eliminates ethylene to form $C_3H_7^+$. A minor pathway (6% probability) also exists where methyl radicals are lost to produce a $C_6H_{13}^+$ intermediate followed by loss of C_3H_6 to form an ion with *m*/*z* = 43, which is the strongest peak in the mass spectrum of *n*-heptane using EI. However, only one fragment at *m*/*z* = 43 can be discerned just above the noise when using VUV SPI, while all other fragment mass peaks disappear.

It is well-known that branching in alkanes causes a decrease in the parent ion signal and characteristic increases in the intensities of the $C_nH_{2n+1}^+$ and $C_nH_{2n}^+$ homologous ion series through cleavage and charge retention at the branched carbon. Typically, the loss of the largest alkyl group is favoured. Furthermore, as the electron energy in the ionization is decreased, the higher mass fragments begin to predominate, as does the probability of alkene formation. Similar trends are found for the more branched alkanes examined in this work, as illustrated in Figs. 1*b*–1*d*, corresponding to the VUV SPI TOF mass spectra of 3-methylhexane, 2,2-dimethylpentane, and 2,2,3-trimethylbutane, respectively. Still, the parent ion mass in the VUV laser SPI TOF mass spectrum of 3-methylhexane is the base peak, compared to an abundance of 2% by 70 eV EI. Unless otherwise cited, the parent ion abundance data using 70 eV EI of all molecules studied in this work comes from the NIST Chemistry WebBook (13).

The base peaks in the VUV SPI mass spectra of the more highly branched 2,2-dimethylpentane and 2,2,3-trimethylbutane are both due to the $C_4H_8^+$, 2-methyl-1-propene ion, at *m*/*z* = 56. This feature is characteristic of dimethyl substitution at the 2-position in the low-energy 12 eV EI mass spectra of alkanes (17). The fragment ions, their corresponding *m*/*z* values, their assignments and relative intensities for alkanes and other organic molecules examined in this paper are listed in Table 2. A series of $C_nH_{2n+1}^+$ fragment ions, with *m*/*z* at 15, 29, 43, 57, 71, and 85, were observed in Figs. 1*b*–1*d*. This cleavage series appear to be metastably broadened, corresponding to fragmentation taking place in the flight tube of the mass spectrometer. Such observations can be rationalized for these two isomers as the enthalpies of reaction ($\Delta H°$) leading to the formation of these ions, $C_nH_{2n+2} \rightarrow C_{n-m}H_{2(n-m)+1}^+ + C_mH_{2m+1}$, are comparable to the energy of the ionizing photon used (22, 23), particularly if the ions formed are tertiary in nature. The parent ion abundances for these branched alkanes are 35% and 7%, respectively. Although these abundances are relatively low, it should be appreciated that the parent ions are essentially absent in the 70 eV EI mass spectra. Instead, their base peak is the very stable $(CH_3)_3C^+$ tertiary butyl carbocation at *m*/*z* = 57. Similar trends have also been seen in branched hexanes (15).

Cyclohexane (IP = 9.80 eV (24)) was also examined. Its 10.5 eV VUV laser SPI TOF mass spectrum is presented in Fig. 2*a*. The lowest energy feature in the cyclohexane dispersive photoelectron spectrum is attributed to ionization from the degenerate $4e_g$ molecular orbitals, which have both σ (C-C) and π (CH_2) character (25, 26). The strongest feature in the VUV laser SPI TOF mass spectrum is due to the parent ion at *m*/*z* = 84, in agreement with an earlier work (15). The weak fragment at *m*/*z* = 56 is attributed to the loss of ethylene from the parent molecule ($[M - C_2H_4]^+$), while the small peak at *m*/*z* = 42 is assigned to the loss of propene ($[M - C_3H_6]^+$). The broad peak at *m*/*z* = 59 is not readily assigned.

While the cyclohexane parent ion peak is strong in the 70 eV EI mass spectrum, the dominant feature is the fragment peak at *m*/*z* = 56 owing to the loss of ethylene. Strong parent ion peaks are not uncommon in cycloalkanes because ring fragmentation requires breaking two C—C bonds. Nevertheless, VUV SPI appears to be superior in this regard.

Alkenes and alkynes

The VUV SPI mass spectrum of 1-hexene (IP = 9.46 eV (24, 27)) is shown in Fig. 2*b*. The ionization threshold corresponds predominately to the loss of an electron from the π π orbital of the double bond (28). In this work, the parent molecular ion at m/z = 84 is the base peak, while the strongest feature in the 70 eV EI spectrum is assigned to $C_4H_8^+$ at m/z = 56. The parent ion abundance by 70 eV EI is considerably

less (only 29% of the base peak). A small feature at m/z = 168 in the VUV SPI mass spectrum is attributed to the 1-hexene dimer. At this time however, details about the structure or formation of this ion are uncertain.

Weak fragments corresponding to $C_nH_{2n}^+$ (n = 2, 3, and 4 at m/z = 28, 42, and 56) and $C_nH_{2n-1}^+$ (n = 2, 3, and 4 at m/z = 27, 41, and 55) are evident in Fig. 2*b*. The broader peaks at higher m/z values relative to the sharper features are attributed to metastable ion decomposition in the mass spectrometer flight tube. This is consistent with reaction enthalpies for $C_6H_{12} \rightarrow C_nH_{2n}^+ + C_{6-n}H_{12-2n}$, which are estimated to be comparable to the ionization photon energy used in this work. The fragment ions observed are common for alkenes that are known to exhibit allylic cleavage. The intensities of the fragment peaks are similar, which indicates that the double bond can easily migrate within the molecule after ionization. This conclusion is supported by an earlier VUV laser ionization study of 1-octene, 2-octene, and 4-octene (14), where the fragmentation patterns and intensities observed for those compounds are similar to the findings here.

The VUV TOF mass spectrum of cyclohexene is shown in Fig. 2*c* and once again, the base peak is due to the parent ion at m/z = 82. The ionization process is also due to loss of a π electron (29) (IP = 8.94 eV (26)). The feature at m/z = 67 is due to loss of a methyl radical from the parent molecule to form the C_5H_7 diene radical cation, and is the base peak in the 70 eV EI mass spectrum of the parent compound. Its formation is ascribed to a hydrogen abstraction mechanism that transfers the unpaired electron to an allylic radical site prior to methyl loss. The weak feature at m/z = 54 is another characteristic fragment for cyclohexene, which arises from a retro Diels–Alder reaction that forms the $C_4H_6^+$ diene radical cation and ethylene. The two broad peaks at m/z = 58 and 69 in Fig. 2*c* remain unassigned.

The lowest energy ionization of 1-hexyne (IP = 10.07 eV (30)) yields a photoelectron from a π orbital of the triple bond (31). As shown in Fig. 2*d*, the base peak obtained by VUV SPI corresponds to $[M - CH_3]^+$ at m/z = 67, similar to that obtained by high energy EI (32). VUV SPI however, considerably enhances the intensity of the parent peak (21%) compared with that observed using 70 eV EI where the relative abundance of the parent ion is only 1%. A strong feature is observed by VUV SPI at m/z = 81 (14%) that corresponds to a well-known fragmentation mode for terminal alkynes; namely the loss of the terminal H atom. The remaining fragment ions at m/z = 39, 41, 43, and 54, owing to the $C_3H_3^+$ (propargyl ion), $C_3H_5^+$ (allyl carbocation), $C_3H_7^+$ (propyl cation), and $C_4H_6^+$ (1-butyne fragment), respectively, are also observed in the EI spectrum, but are considerably depressed using VUV laser soft ionization.

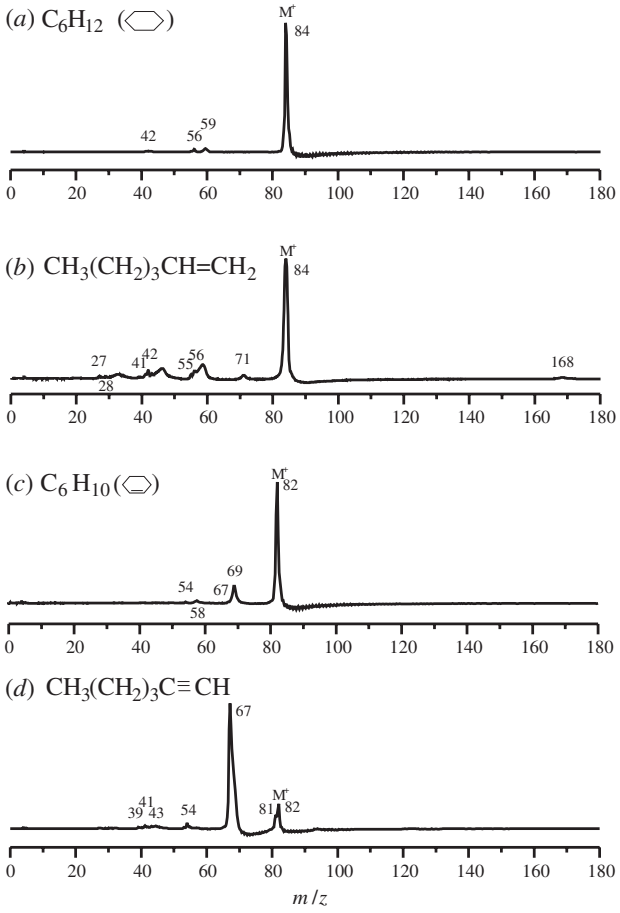

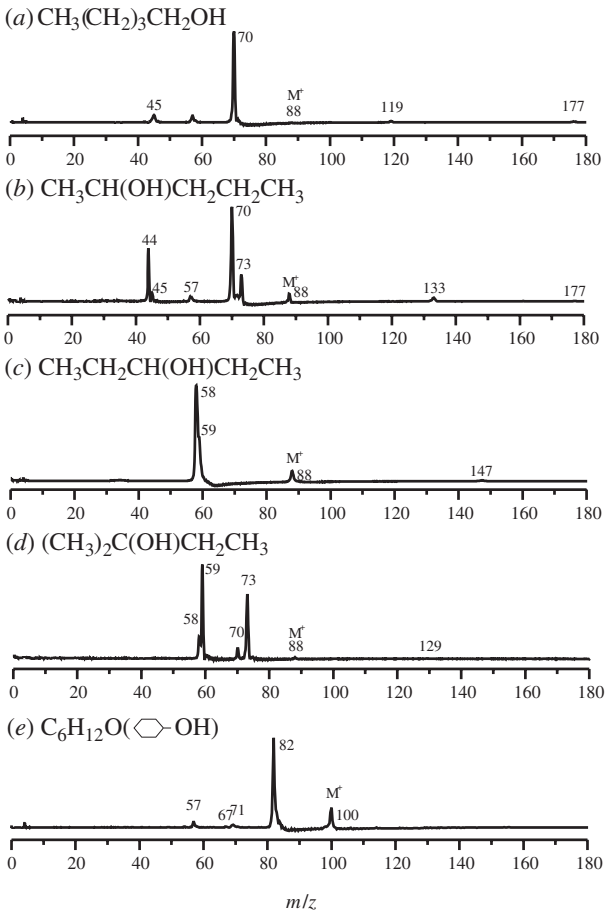

Fig. 3. 118.2 nm VUV SPI–TOF mass spectra of alkanols: (*a*) 1-pentanol, (*b*) 2-pentanol, (*c*) 3-pentanol, (*d*) 2-methyl-butan-2-ol, and (*e*) cyclohexanol. The features indicated by M^+ correspond to parent ion peaks.

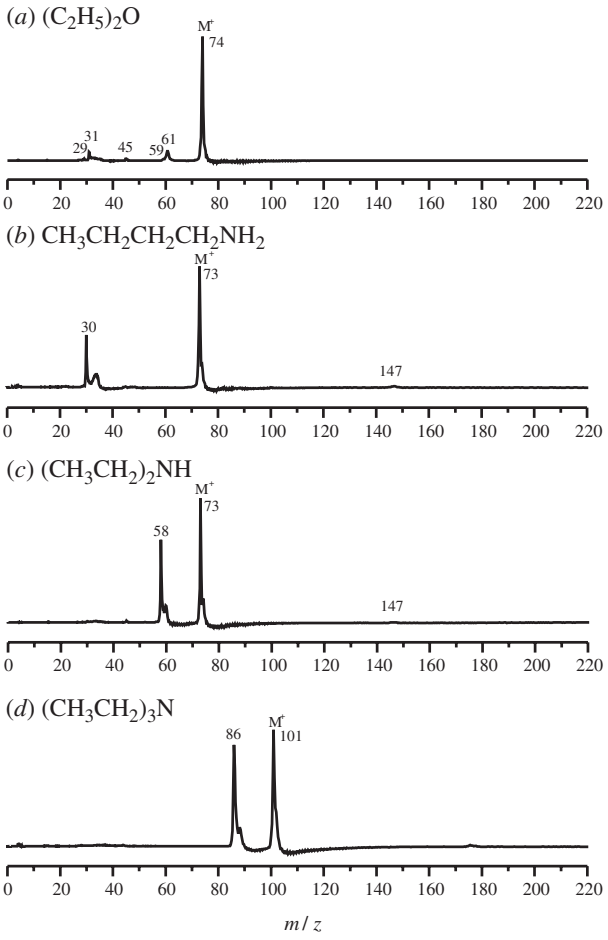
Alkanols

In this work, four isomeric pentanols were examined: 1-pentanol, IP = 10.42 eV; 2-pentanol, IP = 9.78 eV; 3-pentanol, IP = 9.76 eV; and 2-methyl-butan-2-ol, IP = 10.16 eV; their VUV SPI mass spectra are shown in Figs. 3*a*, 3*b*, 3*c*, and 3*d*, respectively. Calculations have shown that the molecular orbitals of the larger alcohols are considerably more delocalized than those of their smaller alkyl counterparts (33). Thus, while the main effect associated with the lowest ionization potential of an alcohol is often viewed as the removal of an oxygen lone-pair electron, the actual amount of atomic oxygen character is only ~54%.

The parent ion peak at m/z = 88 was observed for all four isomeric alcohols, albeit weakly. The relative intensities of this feature are 0.9%, 8%, 11%, and 2% for 1-pentanol, 2-pentanol, 3-pentanol, and 2-methyl-butan-2-ol, respectively. In contrast, only 1-pentanol exhibits a parent ion peak by 70 eV EI, with an abundance that is 0.4% of the base peak at m/z = 42. In a low-energy 12 eV EI study, parent ions were observed for 2- and 3-pentanol, (abundance ~ 2%), but not for the other isomers (17, 34). Interestingly, in an earlier 118.2 nm VUV laser ionization – mass spectrometric study of 1-pentanol and 1-, 2-, and 3-octanol (14), only 1-octanol was found to exhibit a very weak parent ion peak.



Base peak formation at m/z = 70 in our mass spectra of 1-pentanol and 2-pentanol is due to parent molecule dehydration $[M - H_2O]^+$, which is a common fragmentation mode for alcohols having five carbons or more. In contrast, α cleavage appears to be more important for 3-pentanol and 2-methyl-butan-2-ol. The strongest fragment ion from the former compound at m/z = 58 is attributed to the loss of ethane (C_2H_6 (35)), while a feature at m/z = 59 for the latter is due to the loss of the ethyl radical C_2H_5 resulting from α cleavage. More α-cleavage ion peaks are observed for 2-pentanol at m/z = 73 ($[M - CH_3]^+$) and m/z = 45 ($[M - C_3H_7]^+$), for 3-pentanol at m/z = 59, and for 2-methyl-butan-2-ol at m/z = 73. Two fragment ions observed at m/z = 45 and 57 for 1-pentanol are assigned to $C_2H_5O^+$ and $C_4H_9^+$, respectively. The peak at m/z = 44 for 2-pentanol is due to the $C_2H_4O^+$ ion.

Alkanols are also known to dissociate further in a manner analogous to olefins (36), to yield $C_nH_{2n}^+$ and $C_nH_{2n-1}^+$ ions. However, unlike previous mass spectrometric studies using VUV laser radiation (14), these features are not evident in our TOF mass spectra.

Several heavier mass peaks are present for all four pentanols, which suggests the presence of dimers and associated fragments. Van Bramer and Johnston (14) made a similar observation and suggestion for 1-pentanol, but did not

Fig. 4. 118.2 nm VUV SPI–TOF mass spectra of ether and amines: (*a*) diethyl ether, (*b*) 1-butylamine, (*c*) diethylamine, and (*d*) triethylamine. The features indicated by M^+ correspond to parent ion peaks.

exclude the possibility of impurities. Our group has used VUV lasers to map out the nascent gas-phase distributions of hydrogen-bonded clusters above liquid ethanol, methanol, and butanol (10), and in this regard, clusters are almost certainly being detected. For example, the feature at m/z = 119 for 1-pentanol can be assigned to $[M_2 - C_4H_9]^+$, the one at m/z = 133 to $[M_2 - C_3H_7]^+$ for 2-pentanol, the one at m/z = 147 to $[M_2 - C_2H_5]^+$ for 3-pentanol, and the one at m/z = 129 to $[M_2 - C_2H_7O]^+$ for 2-methyl-butan-2-ol. The features at m/z = 177 for 1- and 2-pentanol are attributed to the protonated alcohol dimer HM_2^+.

The VUV SPI mass spectrum of cyclohexanol (shown in Fig. 3*e*) also exhibits a base peak at m/z = 82 corresponding to water loss. The parent ion peak at m/z = 100 is the second strongest feature with a relative intensity of 22%. Two fragment ions at m/z = 57 and 71 are due to the loss of C_3H_7 and C_2H_5 from the parent molecule, respectively, while a weak feature at m/z = 67 is tentatively assigned to the loss of a methyl group from the dehydrated parent ion. These results can be compared with those obtained by 70 eV EI where the parent ion abundance is 3% relative to the base peak at m/z = 57, and to those in the 12 eV EI spectrum where the parent ion peak is 10% as intense as the base feature at m/z = 82.

Ethers

Three ethers were chosen for study: diethyl ether (Fig. 4*a*, IP = 9.51 eV), methyl *tert*-butyl ether (MTBE, IP = 9.24 eV), and tetrahydrofuran (IP = 9.40 eV). In each case, the first photoionization threshold is expected to involve an electron with predominately lone-pair character centred on the oxygen atom.

The base peak of the VUV laser TOF mass spectrum of diethyl ether is due to the parent ion mass at m/z = 74. A similar result was obtained using 12 eV EI (17), while the parent ion peak in the 70 eV EI mass spectrum is only 23% of the base peak at m/z = 31.

The main fragments observed for diethyl ether by 10.5 eV SPI are similar to those seen with 12 eV EI, and follow the expected trend for *n*-alkyl ethers. The spectrum exhibits a series of $C_nH_{2n+1}O^+$ oxonium ions at m/z = 31 (CH_3O^+), m/z = 45 ($C_2H_5O^+$), and m/z = 59 ($C_3H_7O^+$). The $C_2H_5^+$ ion at m/z = 29 formed from α cleavage is also observed. The peak at m/z = 61 is attributed to metastably broadened $C_3H_7O^+$ ions. The CH_3O^+ feature is also metastably broadened. It is noted that the intensities of all fragment ions of diethyl ether using VUV SPI are depressed significantly as compared with those in the 70 eV EI mass spectrum.

It is not particularly surprising that the parent ion peak for MTBE (mass spectrum not shown) at m/z = 88 is found to be relatively weak since the neutral contains a tertiary alkyl group. Its intensity is only 6% of the base peak at m/z = 73 which is attributed to α cleavage of a methyl group. Still, it should be appreciated that the parent ion is not observed at all by 12 eV (17) or 70 eV EI. The m/z = 73 feature is also the base peak in both the 12 eV and 70 eV EI mass spectra, but VUV SPI appears to give a much cleaner spectrum that contains only the base peak at m/z = 73 and the parent ion peak. MTBE is the main ether additive to gasoline and may accumulate in the atmosphere through automobile exhaust. Butcher et al. (37) has reported the real-time determination of aromatics and oxygenates in automobile exhaust using SPI – ion trap mass spectrometry (IT-MS). Their 118 nm SPI mass spectrum of MTBE also showed a predominant fragment peak at m/z = 73, along with two very weak fragment peaks at m/z = 56 and 57.

The strongest feature in the VUV laser TOF mass spectrum of tetrahydrofuran (not shown) is due to the parent ion at m/z = 72. A weak feature observed at m/z = 45 is assigned to $C_2H_5O^+$. The ion signal at m/z = 116 is tentatively assigned to its dimer fragment ($[M_2 - C_2H_4]^+$). In the 70 eV EI mass spectrum, the parent ion intensity is only 29% of the base peak at m/z = 42 ($C_3H_6^+$), where $C_nH_{2n}^+$ fragments are attributed to be formed following parent ion dehydration.

Alkyl amines

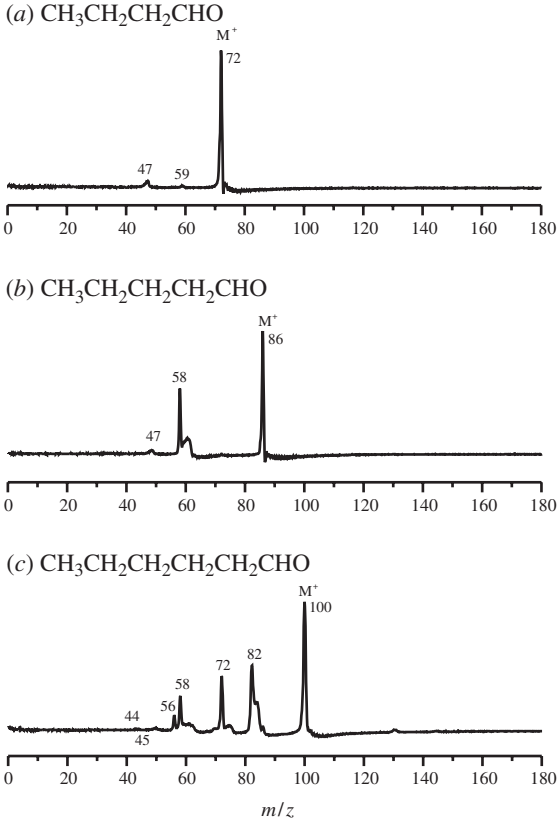
One primary amine (1-butylamine, IP = 8.71 eV (38), Fig. 4*b*), one secondary amine (diethylamine, IP = 8.01 eV (38), Fig. 4*c*), and one tertiary amine (triethylamine, IP = 7.50 eV (38), Fig. 4*d*) were considered in this category. The lowest ionization potential of these compounds represents the energy required to remove a near nonbonding $3a_1$ electron associated with the N atom (38).

As seen in Fig. 4*b*, the parent ion peak is the strongest feature in the VUV SPI mass spectrum of 1-butylamine. Similar results were previously obtained using 10.5 eV laser

© 2005 NRC Canada

photons to *n*-heptylamine and *n*-octylamine (14). Our study on two other alkylamines (diethylamine and triethylamine) shows that their VUV SPI mass spectra also exhibit the parent ion peak as the base peak. These results indicate that alkylation on the nitrogen atom has relatively little effect.

Like the 12 eV EI mass spectrum for 1-butylamine (39), the α-cleavage ion $[M - C_3H_7]^+$ at m/z = 30 is relatively strong using VUV SPI. Metastable decomposition is experimentally evident even though a thermodynamic estimate for the enthalpy of reaction for $C_4H_{11}N \rightarrow C_3H_7 + CH_4N^+$ (40) is ~0.75 eV lower than the photon energy used. With 70 eV EI, the α-cleavage ion is the base peak, while the relative intensity of the parent ion peak is only 7%. The β-cleavage ions ($[M - CH_3]^+$) are the only fragment ions observed in this work for the other two amines and in both cases, these features are metastably broadened. Here, the reaction enthalpy of diethylamine to form the β-cleavage fragment ion is estimated to be lower than the 10.5 eV (41) photon used. However, for the triethylamine, the appearance energy of the $[M - CH_3]^+$ ion has been determined to be 11.48 eV (42), which suggests that the UV light used to generate the VUV photons is participating in the ionization scheme. The 12 eV EI mass spectra for both compounds (39) are similar to those obtained by VUV SPI, whereas the 70 eV spectra are congested with additional fragment ion peaks, and the parent ion abundances are ~19%. These results indicate that in this work, for the alkylamines considered, ammonia elimination is not favoured compared to water elimination for alcohols, which dominates over α cleavage. In the previous study of the heavier *n*-heptyl amines and *n*-octyl amines using VUV SPI (14), however, a series of $[M - C_nH_{2n+1}]^+$ ions ($[M - NH_3]^+$ and ammonium NH_4^+) at m/z = 18 were all observed.



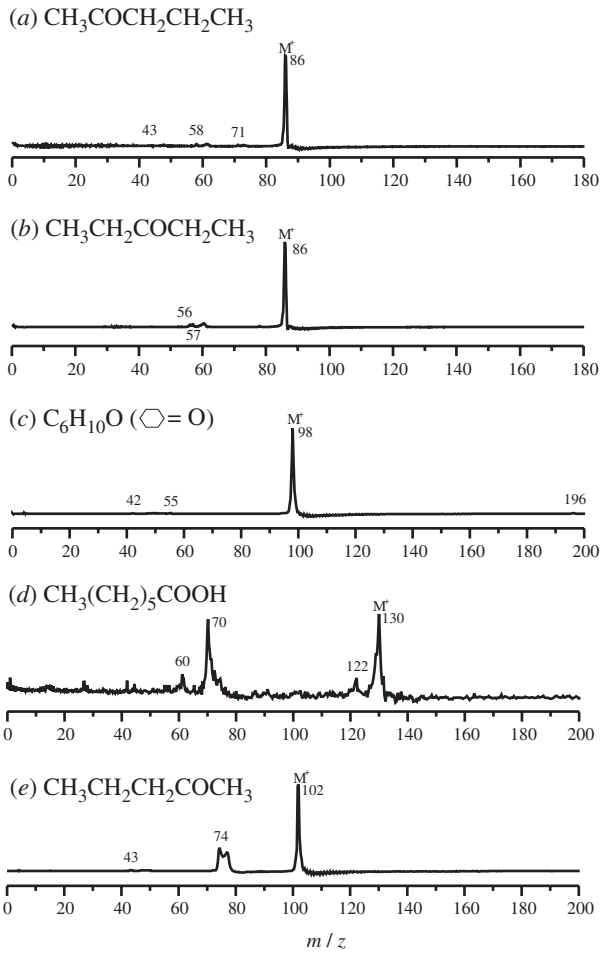
Similar to alcohols, both 1-butylamine and diethyl amine spectra show a weak, protonated HM_2^+ dimer peak at m/z = 147. Not unexpectedly, however, a protonated dimer ion peak was not observed for triethylamine, since it has no hydrogen atom directly bonded to its nitrogen atom.

On the basis of the nitrogen rule, a compound with an odd number of nitrogen atoms must have an odd-valued molecular weight. Thus, unlike conventional 70 eV EI mass spectrometry, amine identification should be relatively straightforward using VUV SPI for parent ion formation.

Alkanals

VUV SPI mass spectra were obtained for *n*-butanal (vertical IP = 9.73 eV (43)), *n*-pentanal (IP = 9.65 eV (44)), and *n*-hexanal (IP = 9.62 eV (44)). The resultant spectra can be inspected in Figs. 5*a*, 5*b*, and 5*c*, respectively. The ionized electron originates from the lone-pair orbital on the oxygen atom in the plane of the carbon chain, and perpendicular to the carbon–oxygen bond (45). In all three TOF mass spectra, the base peak corresponds to the parent ion, which therefore, to the best of our knowledge, represents the softest ionization ever achieved for aldehydes. The same three molecules have been studied using SPI by the same type of laser sources (14, 37). There, only *n*-butanal yielded a base peak at the m/z = 72. The pentanal parent ion intensity (m/z = 86) was 52% of the base peak at m/z = 58 ($[M - C_2H_4]^+$), and the hexanal parent ion (m/z = 100) was 57% of the base peak at m/z = 72, also due to $[M - C_2H_4]^+$ (14).

Fig. 5. 118.2 nm VUV SPI–TOF mass spectra of alkanals: (*a*) *n*-butanal, (*b*) *n*-pentanal, and (*c*) *n*-hexanal. The features indicated by M^+ correspond to parent ion peaks.



In the 12 eV EI mass spectrum of butanal, the parent ion generates the base peak, while the relative intensities of the parent ion signals for pentanal and hexanal drop to 17% and 11%, respectively (46). A mass spectrum using 70 eV EI shows a relative abundance of 74% for the butanal parent ion, although it is not the base peak, while the parent ions for *n*-pentanal and *n*-hexanal are only 6% and 1%, respectively, of the McLafferty ion ($C_2H_4O^+$) (47) base peak at m/z = 44.

The number of fragment peaks increases with the length of the alkyl chain using VUV SPI. For *n*-hexanal, but not butanal or pentanal, the dehydrated species $[M - H_2O]^+$ is seen at m/z = 82 in addition to the $[M - C_nH_{2n}]^+$ ions at m/z = 72 (n = 2) and 58 (n = 3). The McLafferty and McLafferty + 1 ions are also weakly observed at m/z = 44 and 45, respectively, as is the McLafferty complimentary ion ($C_4H_8^+$) at m/z = 56. The McLafferty fragment ion intensities are the reverse of what is observed by 70 eV EI, but are consistent with the trend obtained with 12 eV electrons (48).

The strongest fragment ions in the aldehyde mass spectra are metastably broadened, which is consistent with the reaction enthalpies listed in ref. 46 (ΔH ~ 10.5 eV). The exception is *n*-butanal where the formation of $[M - C_nH_{2n}]^+$ ions requires >11 eV energy (46) and therefore, are not observed experimentally. In each spectrum a feature at m/z = 47 is observed that remains unassigned, although an impurity or elimination of protonated ethanol from the parent molecule can not be discounted at this time. This peak was not ob-

Fig. 6. 118.2 nm VUV SPI–TOF mass spectra of (*a*) 2-pentanone, (*b*) 3-pentanone, (*c*) cyclohexanone, (*d*) *n*-heptanoic acid, and (*e*) butanoic acid, methyl ester. The features indicated by M^+ correspond to parent ion peaks.

served by 12 eV or 70 eV EI, or in previous VUV laser studies.

Alkanones

The VUV SPI mass spectra were recorded for 2-pentanone (IP = 9.39 eV (49), Fig. 6*a*) and 3-pentanone (IP = 9.32 eV (49), Fig. 6*b*). Ionization is expected to remove a lone-pair electron from the highest occupied molecular orbitals of aliphatic ketones that are predominantly composed of oxygen atomic orbitals. The proportion of atomic character, however, is expected to decrease with increasing alkyl chain length (41, 50, 51).

The parent ion feature at m/z = 86 is the base peak for both ketones in their VUV SPI mass spectra, and the fragment ions are weak. The mass spectrum of 2-pentanone shows two α-cleavage ions at m/z = 43 $[M - C_3H_7]^+$ and m/z = 71 $[M - CH_3]^+$, and a McLafferty ion at m/z = 58. These bands are metastably broadened, which is reasonable given the known appearance energies of these ions (50, 52). The only exception is the $[M - C_3H_7]^+$ ion, which has an appearance energy of 11.54 eV. This suggests that the UV fundamental used to generate the coherent VUV light is also involved in the ionization process. Similar fragmentation patterns have been obtained using 12 eV EI, but the relative intensity of the features at m/z = 43, 58, and 71 are considerably higher at 22%, 17%, and 12%, respectively (17). In the 70 eV EI mass spectrum, the fragment at m/z = 43 becomes the base peak, and the relative intensity of the parent ion is 20%.

The symmetrical 3-pentanone exhibits only one α-cleavage feature at m/z = 57 ($[M - C_2H_5]^+$), and a feature at m/z = 56, which is assigned to $C_3H_4O^+$. Both appear to be metastably broadened, a reasonable result given that the appearance energy of the heavier fragment is 9.90 eV (53). The intensity of the parent ion peak in the 70 eV EI spectrum of 3-pentanone is only 17% of the base peaks at m/z = 57 and 29 [$C_2H_5^+$].

The VUV SPI mass spectrum of cyclohexanone (Fig. 6*c*, IP = 9.16 eV) is also very clean, with the strongest feature due to the parent ion at m/z = 98. Again, photoionization involves an electron from a nonbonding orbital on the oxygen atom that is destabilized by interactions with σ orbitals associated with the alkyl ring (54). Weak fragment peaks at m/z = 42 (relative intensity: 0.45%) and 55 (0.51%) result from rearrangement processes after fragmentation. The former is attributed to the $C_3H_6^+$ ion due to loss of C_2H_4 and CO after ionization, while the latter is assigned to $C_3H_3O^+$ formed as a result of the loss of one C_3H_7 radical. In the 70 eV EI mass spectrum, the feature due to $C_3H_3O^+$ forms the base peak, while the relative parent ion intensity is 33%. A feature due to the cyclohexanone dimer at m/z = 196 is also present in our VUV laser TOF mass spectrum.

Alkanoic acids and alkyl alkanoates

The overall signal intensity of the VUV laser – TOF mass spectrum of *n*-heptanoic acid (shown in Fig. 6*d*) is weak owing to the low vapour pressure of the compound (boiling point = 222.2 °C (55)). The lowest energy ionization event from an alkyl carboxylic acid is expected to involve an electron with primarily lone-pair character on the oxygen atom of the carbonyl group of the acid moiety (56). The base peak observed by VUV SPI is due to the parent ion at m/z = 130. The strongest fragment ion is the McLafferty complementary ion at m/z = 70, while the McLafferty ion at m/z = 60 is weaker. The overlapping peak near m/z = 73 is assigned to the $[M - C_4H_9]^+$ β-cleavage ion. These ions and their relative intensities agree very well with an earlier VUV laser study (14), except for an additional feature at m/z = 102 owing to $[M - C_2H_4]^+$, which is not observed in this work.

The 12 eV (57) and 70 eV EI mass spectra are considerably more congested, with the McLafferty ion at m/z = 60 in both cases providing the base peak. There, the relative intensities of molecular ion peaks are ~6% and 0.7%, respectively.

The VUV SPI mass spectrum of methyl butanoate (IP = 10.07 eV (49)) exhibits a strong parent ion peak at m/z = 102 (Fig. 6*e*). Electron ionization here most likely involves the oxygen of the carbonyl group (58), although fragmentation reactions are expected to involve both the keto and enol forms of the resultant gas-phase parent molecular ion (59). The main fragment peak at m/z = 74 is the McLafferty ion, which appears to be metastably broadened. The result is consistent with the known appearance energy of the ion (10.08 eV) (60). A signal at m/z = 43, just discernible above

© 2005 NRC Canada

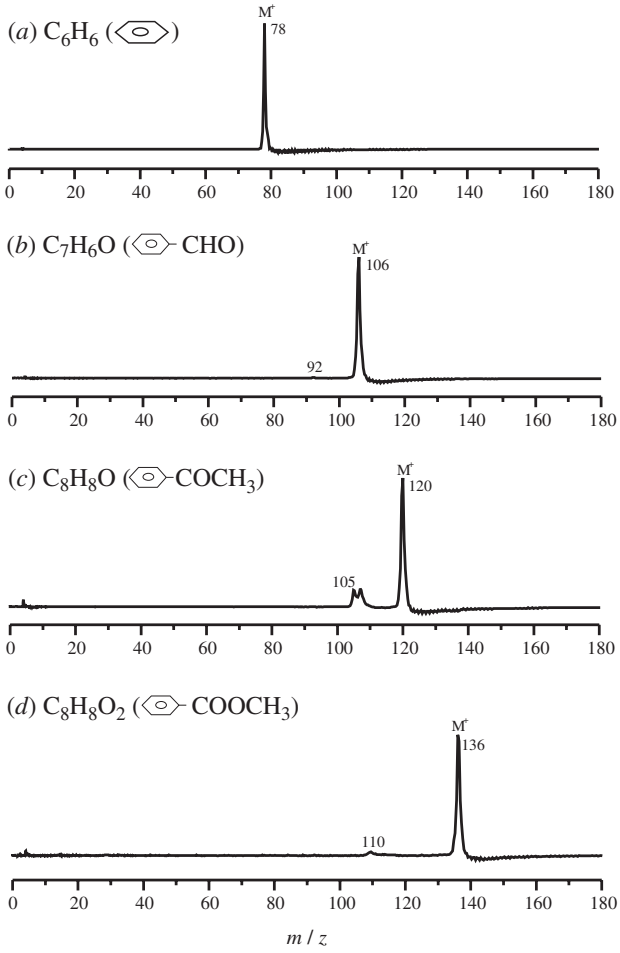
the noise, is due to $C_3H_7^+$. The McLafferty ion is not significant, but its complementary ion becomes the origin for the base peaks of butyl ethanoate and larger esters using 12 eV EI mass spectrometry (17). Similarly, the parent ion abundance of methyl butanoate formed by ionization with 70 eV electrons falls to only 4% of the base peak at m/z = 74. Interestingly, however, while methyl butanoate has not been examined previously by VUV SPI mass spectrometry, single-photon ionization data for propyl propionate and butyl butyrate exhibit only weak parent ions peaks (0.4% and 12%, respectively) (14).

Aromatic compounds

Aromatic hydrocarbons

Three aromatic hydrocarbons, benzene (IP = 9.24 eV, Fig. 7*a*), methylbenzene (toluene, IP = 8.83 eV), and 1,2-dimethylbenzene (*o*-xylene, IP = 8.56 eV), were studied in this category. In all three cases, ionization removes a π electron from the aromatic ring orbital, which has e_{1g} symmetry for benzene (D_{6h} point group), and b_1 symmetry for toluene and *o*-xylene (C_{2v}) (61, 62). A single parent ion peak dominates each SPI mass spectrum. These three molecules have also been studied by Butcher et al. (37) using 118 nm SPI–IT-MS, where the parent ion peak is the base peak for all three compounds. The relative abundances of the base peaks as a percentage of the total ion signals were 100, 100, and 90 for benzene, toluene, and *o*-xylene, respectively.

The absence of any fragmentation for benzene is not particularly surprising as this aromatic ring is very stable. Even in the 70 eV EI mass spectrum, while some fragment ions are observed, the parent ion with m/z = 78 is the base peak. In the case of both toluene and *o*-xylene, the base peak in the 70 eV EI mass spectrum is due to the formation of the tropylium ion ($C_7H_7^+$) at m/z = 91, while the parent ion abundances are 62% and 42% for toluene and *o*-xylene, respectively.



Formation of the tropylium rearrangement product is sensitive to the internal energy of the parent molecular ion first formed. In this context, 10.5 eV VUV SPI is particularly effective in minimizing the formation of $C_7H_7^+$, as its appearance potential for both methyl substituted benzenes is >11 eV (63).

Aromatic aldehydes, ketones, and esters

VUV SPI mass spectra of benzaldehyde (IP = 9.5 eV), acetophenone (IP = 9.28 eV), and methyl benzoate (IP = 9.32 eV) are shown in Figs. 7*b*, 7*c*, and 7*d*, respectively. Photoelectron spectroscopy has been particularly effective in establishing whether the lowest energy ionization involves a predominately nonbonding electron associated with the oxygen of the carbonyl group, or a π electron from the aryl ring. The dominant electron character is thought to be nonbonding for benzaldehyde (64) and acetophenone (65), but π type for the ester (66).

Each spectrum is relatively clean in that the molecular parent ions form the base peaks (m/z = 106 for benzaldehyde, m/z = 120 for acetophenone, and m/z = 136 for methyl benzoate). The result for benzaldehyde is consistent with a previous study (37). The metastably broadened feature in the acetophenone spectrum at m/z = 105 is assigned to the α-cleavage ion $[M - CH_3]^+$ (67), while the weak bands at m/z = 92 and 110 in the benzaldehyde and methyl benzoate spectra, respectively, are unassigned. The parent ion compounds are seen by 70 eV EI and in the case of benzaldehyde this feature is 95% of the base peak at m/z = 77 ($C_6H_5^+$). For the other two species the 70 eV EI base peak is due to the formation of $C_7H_5O^+$ at m/z = 105, while the relative parent ion abundances are 29% and 39% for acetophenone and methyl benzoate, respectively.

Fig. 7. 118.2 nm VUV SPI–TOF mass spectra of aromatic compounds: (*a*) benzene, (*b*) benzaldehyde, (*c*) acetophenone, and (*d*) benzoic acid, methyl ester. The features indicated by M^+ correspond to parent ion peaks.

Discussion and conclusions

While a complete survey of all organic compounds is obviously not possible, the choices presented in this work, and the range of functional groups examined clearly demonstrate that VUV SPI TOF mass spectrometry is superior to electron-based ionization methods for generating parent molecular ions. In those cases where fragmentation reactions were observed, the ions produced were similar to those generated by EI, but were almost always much weaker in intensity.

It could be argued that a considerable amount of useful structural information is lost through such dramatic mass spectral simplification. For example, in the case of aromatic compounds such as benzaldehyde, acetophenone, and methyl

benzoate, the important fragment ion at m/z = 77 indicating the existence of a benzene ring is not observed in the VUV laser SPI TOF mass spectra of all three compounds. Isomeric distinction is also impossible. However, since VUV laser SPI enhances the intensity of parent ions and relatively high mass fragment ions, it should be a useful ionization technique for tandem mass spectrometry. Also, VUV SPI TOF mass spectrometry is expected to be particularly valuable for the analysis of mixtures of similar compounds whose fragmentation patterns by higher energy EI techniques are similar, and where parent ion formation is either very weak or absent.

It was found when using a 10.5 eV photon source that many metastable parent molecular ion decomposition reactions compete effectively with direct soft ionization. Overall, however, these reactions did not detract significantly from the primary goal of this work, namely, parent ion mass identification. In fact, these observations suggest that using *tunable* coherent VUV radiation generated by nonresonant tripling or two-photon resonance enhanced four-wave mixing may in fact be an ideal method of establishing accurate appearance energies of these fragment ions.

Some fragment ions were observed in the TOF mass spectra despite having appearance energies >10.5 eV because our experiment was carried out with the residual UV 355 nm (~3.5 eV) fundamental beam propagating colinearly with the coherent VUV light after nonresonant tripling. Although the focal length of the MgF_2 lens used to focus the VUV light into the supersonic jet is strongly wavelength dependent, the UV intensity in the VUV focal region may be sufficient to initiate multiphoton ionization. One possible solution to this problem involves placing either a prism, an off axis lens, or a monochromator before the analyte ionization region, although optical alignment and light loss may then become issues. These issues are being explored in our lab.

The success of VUV laser SPI for organic molecule identification by parent mass is attributed to two main factors. The first is that almost all organic compounds have IPs that lie in the VUV spectral region, and therefore, the approach described in this work is near universal. The second reason is that except for alkanes, the first ionization threshold of most functionalized organic molecules involves a chromophore having either π- or non-bonding character. As a result, ionization is not expected to significantly perturb the structural framework of the molecule. The lower energy IP trends for aliphatic and aromatic compounds containing nitrogen and sulphur moieties are well-known (68). Thus, VUV SPI may be useful for biomolecule characterization as routine methods emerge to deliver these species, intact, into the gas phase.

It has been demonstrated that modern desorption techniques such as secondary ion mass spectrometry (SIMS) and matrix-assisted laser desorption and ionization (MALDI) have the ability to achieve a softer ionization. However, as the sputtering or desorption processes also lead to ionization, there is little control over the ionization efficiency. Furthermore, most of the desorbed material using SIMS and MALDI are neutrals rather than ions. Typically, the ion to neutral ratios are in the range of 10^{-3} to 10^{-5}. A significant enhancement in sensitivity can be expected if these neutral species are post ionized. In this aspect, VUV laser radiation is expected to be a potentially powerful post ionization source that could improve the sensitivity of these mass spectrometric techniques.

A study of the isomerization and dissociation of formal [acetone–methanol]$^{+\cdot}$ ion–molecule complexes[1]

Xian Wang and John L. Holmes

Abstract: The energy barrier for the keto–enol isomerization of the isolated acetone ion to its distonic (enol) isomer lies above its lowest dissociation limit and so the spontaneous isomerization can never be observed. Keto–enol isomerizations can be catalyzed within appropriate ion–molecule complexes. The present study involved two systems, $[(CH_3)_2C{=}O\cdots H^+\cdots O(H)CH_2^{\cdot}]$ (ion **1**) and $[(CH_3)_2C{=}O\cdots H^+\cdots {}^{\cdot}OCH_3]$ (ion **2**), in both stable and metastable adducts. When acetone is bound to $^{\cdot}CH_2OH$ though a proton bridge, shown as ion **1**, an enol acetone ion is produced. This reaction results from a proton attaching to the acetone, which then gives an $H^{\cdot}$ atom back to the radical site by a 1,6-H transfer, involving a transition state of low energy requirement. In contrast, when the acetone is protonated and bound to the radical $CH_3O^{\cdot}$ (ion **2**), the above rearrangement does not take place. The metastable complex ion **2** loses a methyl radical, producing a new $[C_3H_7O_2]^+$ isomer of structure $[CH_3C^+(O)\cdots(H)OCH_3]$. Tandem mass spectrometry combined with ab initio calculations were used to investigate the two systems. Potential energy surface diagrams were obtained by calculations at the MP2/6-31+G(d) level of theory to aid further elucidation of the reaction mechanisms.

Key words: ion–molecule complexes, keto–enol mechanisms, ion rearrangements and structures.

Résumé : La barrière d'énergie pour l'isomérisation céto–énolique de l'ion acétone isolé vers son isomère énolique (distonique) se trouve au-dessus de sa plus basse limite de dissociation et on n'observe donc jamais d'isomérisation spontanée. Les isomérisations céto–énoliques peuvent être catalysées à l'intérieur de complexes ion-molécule appropriés. La présente étude implique deux systèmes, $[(CH_3)_2C{=}O\cdots H^+\cdots O(H)CH_2^{\cdot}]$ (ion **1**) et $[(CH_3)_2C{=}O\cdots H^+\cdots {}^{\cdot}OCH_3]$ (ion **2**) chacun dans les adduits stables et métastables. Quand l'acétone est liée au $^{\cdot}CH_2OH$ par un proton agissant comme pont telle que représentée dans l'ion **1**, il y a production de l'ion énolique de l'acétone. Cette réaction résulte du fait qu'un proton se lie à l'acétone qui redonne ensuite l'atome $H^{\cdot}$ au site radicalaire par le biais d'un transfert 1,6 d'hydrogène impliquant un état de transition de bas niveau d'énergie. Au contraire, lorsque l'acétone est protonée et liée au radical $CH_3O^{\cdot}$, tel que représentée dans l'ion **2**, ce réarrangement ne se produit pas. Le complexe ionique métastable **2** perd un radical méthyle conduisant à la formation d'un nouvel isomère $[C_3H_7O_2]^+$ de structure $[CH_3C^+(O)\cdots(H)OCH_3]$. On a utilisé la spectrométrie de masse en tandem combinée à des calculs ab initio pour étudier les deux systèmes. Afin d'élucider les mécanismes réactionnels, on a déterminé les diagrammes de surface d'énergie potentielle par des calculs au niveau MP2/6-31+G(d) de la théorie.

Mots clés : complexes ion–molécule, mécanismes céto–énolique, réarrangements et structures d'ions.

Introduction

Keto–enol isomerization is a well-known process in solution in which the keto species is readily isomerized by acid or base catalysis into the corresponding enol (1). In the gas phase, isolated ketone or aldehyde radical cations do not enolize spontaneously. High-energy barriers that exceed the ions' first dissociation threshold effectively prevent this reaction (2). For example, experiments and theoretical calculations show that the acetone radical cation in the gas phase is 58 kJ/mol (3, 4) less stable than its enol isomer, and the energy barrier for the required intra-ionic 1,3-H shift lies 74 kJ/mol higher than the dissociation threshold of the lowest energy reaction (5, 6).

$$(CH_3)_2C{=}O^{+\cdot} \rightarrow CH_3CO^+ + CH_3^{\cdot}$$

Therefore, acetone cations undergo dissociation rather than enolization.

Recent studies have shown, however, that within an ion–molecule complex, i.e., in which an ion is electrostatically bound to a neutral molecule, the isomerization barrier of the ion can be greatly reduced by the presence of the neutral

substrate. Significant mechanisms for such isomerizations have been identified and named "proton transport catalysis" (PTC), the "H-atom transfer" mechanism (ATM), (also known as the quid-pro-quo mechanism), and the "spectator" mechanism. The PTC processes involve H^+ transport between the partners.

$$HAB^{+\cdot} + M \rightarrow [AB^{\cdot}\cdots{}^{+}HM] \rightarrow ABH^{+\cdot} + M$$

The PTC mechanism has to meet a necessary criterion that has been established by the calculations of Chalk and Radom (7), namely that when the proton can return to two sites in the radical (see above), the proton affinity (PA) of the catalyst must lie between the PA values for the radical and heteroatom sites.

The keto–enol isomerization of the acetone cation is a good subject for catalyzed isomerizations and has been investigated by many groups. Trikoupis et al. (8–10) have reported that benzonitrile and acetone itself convert ionized acetone into its enol isomer in a chemical ionization (CI) source of a sector mass spectrometer. Mourgues et al. (11) have studied the isomerization using a variety of substrates having a wide range of PA values, using FT-ICR experimental conditions in which only bimolecular reactions are observed. A disadvantage of this latter method is that the initially formed ion–substrate complex has a high internal energy, equal to or greater than the dissociation energy of the complex. It therefore investigates only those processes, e.g., H^+-transport, that can take place at such an elevated energy. The method cannot therefore study the many stable equilibrium structures that lie in potential wells far below the energy of the biomolecular adduct.

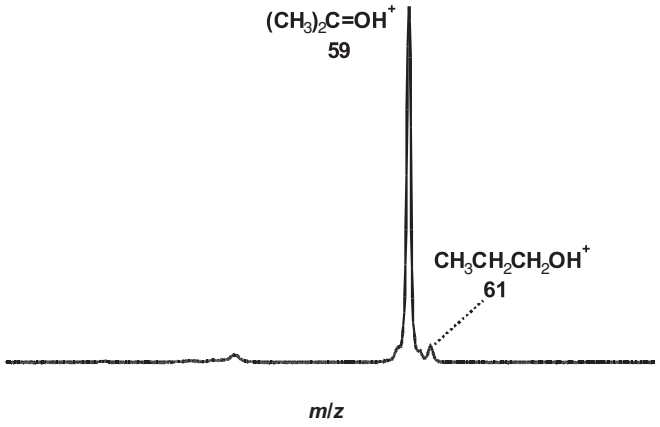
We have employed an alternative strategy in which we explicitly make ions of structure(s) corresponding to adduct isomers that occupy deep potential wells. In such an experiment, a variety of stable or metastable isomeric species are made in which a formal H^+ or $H^{\cdot}$ transfer may already be in place. Detailed studies of the complete potential energy surface (PES) for acetaldehyde and methanol ion–molecule pairs have been described (12, 13). On the PES of the $[CH_3CHO/{}^{\cdot}CH_2OH_2{}^{+}]$ system, the adduct ion structure, $[CH_3CHO\cdots H^+\cdots O(H)CH_2{}^{\cdot}]$, corresponds to the ground state of the ion–molecule complex made by a bimolecular process. Calculations show that in this proton-bridged stable structure, the proton is attached to the acetaldehyde, rather than to ${}^{\cdot}CH_2OH$, in keeping with the PA of CH_3CHO (at O) being greater than that for the ${}^{\cdot}CH_2OH$ radical at oxygen. This complex ion ($CH_3CHO\cdots H^+\cdots O(H)CH_2{}^{\cdot}$) lies in a well on the PES and its metastable dissociation produces an unexpected product, the vinyl alcohol ion $CH_2CHOH^{+\cdot}$. This shows that there is a rearrangement, prior to the loss of CH_3OH. Because it is a metastable ion (MI) process, the isomerization must involve a low internal energy. Isotopic labelling experiments and ab initio calculations were then employed for mechanistic studies and ion structure assignments. In the previous study (12) of $[CH_3CHO/{}^{\cdot}CH_2OH_2{}^{+}]$, the chemistry proceeded via protonated acetaldehyde attached to a ${}^{\cdot}CH_2OH$ radical, and yielded ionized vinyl alcohol and a methanol molecule, $[CH_2CHOH^{+\cdot}\cdots OHCH_3]$, via a $H^+/H^{\cdot}$ transfer mechanism. In contrast, if the protonated acetaldehyde is instead attached to a methoxyl radical, $[CH_3CHOH^+\cdots{}^{\cdot}OCH_3]$, the enol ion is not produced and the precursor ion directly dissociates to the keto ion and methanol.

The stable ion–molecule complexes of desired structure were generated in the mass spectrometer by selecting the appropriate fragment ions in the CID mass spectra of proton-bound molecular pairs (14).

In a previous study, the reaction mechanism was established for a methanol ion associated with the simpler keto molecule, acetaldehyde. The present work was to investigate whether the above mechanism was a general one that could apply to larger polyatomic keto species and so we here describe the behaviour of $[\text{acetone–methanol}]^{+\cdot}$ ion–molecule complexes, having structures $[(CH_3)_2C{=}O\cdots H^+\cdots O(H)CH_2{}^{\cdot}]$ (ion **1**) and $[(CH_3)_2C{=}O\cdots H^+\cdots{}^{\cdot}OCH_3]$ (ion **2**). The mechanisms of rearrangements and dissociations of ions **1** and **2** have been explored by experiment and by computation, and the PESs for these two systems will be discussed in the Results and discussion section of this paper.

Experimental and theoretical section

All experiments were carried out on a modified ZAB-3F tandem mass spectrometer (15) with BEE geometry (VG Analytical, Manchester, UK). MI and collision-induced dissociation (CID) mass spectra of selected proton-bound pairs were acquired, and the desired ion–molecule complex was produced by CID of the proton-bound ion in the second field-free region (2FFR) of the mass spectrometer. MI and CID dissociations of the ion–molecule complex were observed in the third field-free region (3FFR). The ion accelerating voltage on the proton-bound pairs was 8 kV. In the 2FFR and 3FFR helium was used as the collision gas for the CID experiments. All spectra were recorded with the ZABCAT program developed by Mommers Technologies (Ottawa, Ontario) (15).



The proton-bound dimer of acetone and propanol was generated by admitting the mixed reagents $CH_3CH_2CH_2OH$ and $(CH_3)_2C{=}O$ into a high pressure ion source at a total observed pressure of ca. 8×10^{-5} mbar (1 bar = 100 kPa), indicating an ion pressure of 0.5 mbar (16). The proton-bound dimer $(CH_3)_2C{=}O\cdots H^+\cdots O(H)CH_2CH_2CH_3$ (*m*/*z* 119) was mass-selected by the magnet and dissociated by collision in the second field-free region. The fragment ion $[(CH_3)_2C{=}OH^+\cdots O(H)CH_2{}^{\cdot}]$ (*m*/*z* 90) resulted from the loss of $CH_3CH_2{}^{\cdot}$ from the precursor ion (*m*/*z* 119) and it was transmitted into the third field-free region to observe its MI and CID characteristics.

A similar experiment was used for the acetone – dimethyl ether proton-bound dimer, $(CH_3)_2C{=}O\cdots H^+\cdots O(CH_3)_2$ (*m*/*z* 105), to collisionally generate the ion $[(CH_3)_2C{=}OH^+\cdots{}^{\cdot}OCH_3]$ (*m*/*z* 90) by the specific loss of $CH_3{}^{\cdot}$ from the ether moiety. An experiment with $(CD_3)_2C{=}O\cdots H^+\cdots O(CH_3)_2$ (*m*/*z* 111) showed that it was an ether methyl group that was specifically lost following collisional activation. Dimethyl ether was introduced through the gas inlet at an observed pressure of 5×10^{-5} mbar, producing ca. 0.3 mbar in the high pressure ion source.

The molecules $(CH_3)_2C{=}O$, $CH_3CH_2CH_2OH$, $(CH_3)_2O$, and the isotopically labelled compounds, $(CD_3)_2C{=}O$, $CH_3CH_2CD_2OH$, and $CH_3CH_2{}^{13}CH_2OH$, were used to generate various isotopomeric ion–molecule pairs. The

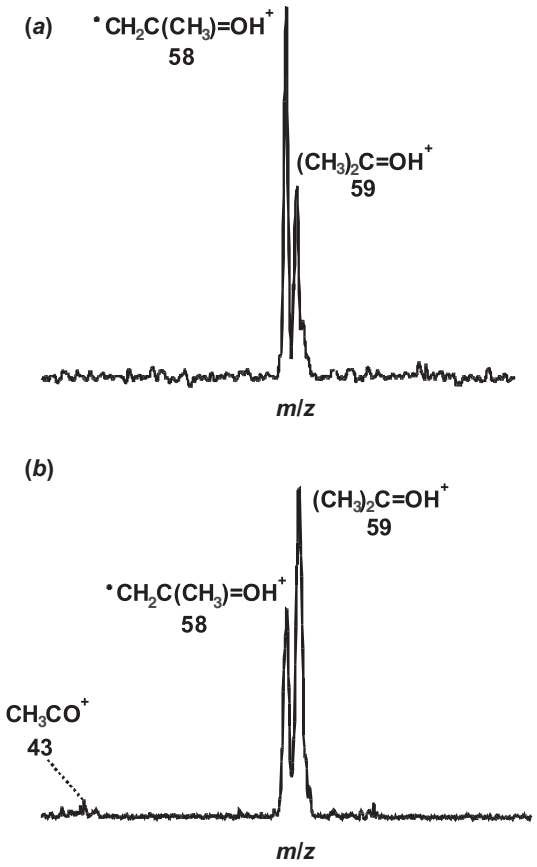
Fig. 1. MI mass spectrum of the proton-bound pair $(CH_3)_2C{=}O{\cdots}H^+{\cdots}O(H)CH_2CH_2CH_3$ (*m/z* 119).

unlabeled chemicals were purchased from Aldrich and all the labelled samples, of 99.5%–99.9% isotopic purity, were obtained from CDN Isotopes (Montreal, Quebec) and were used without further purification.

The GAUSSIAN 98 programs were used to perform standard ab initio molecular orbital calculations to investigate the potential energy surface. Optimized geometries and the energies of all minima and transition states were calculated at the MP2/6-31+G(d) level of theory. Zero-point energies obtained from calculations of vibrational frequencies at the same level of theory were scaled by a factor of 0.943 (17).

Results and discussion

Experimental observations for ion 1 $[(CH_3)_2C{=}0{\cdots}H^+{\cdots}O(H)CH_2^{\cdot}]$ and ion 2 $[(CH_3)_2C{=}0{\cdots}H^+{\cdots}{}^{\cdot}OCH_3]$



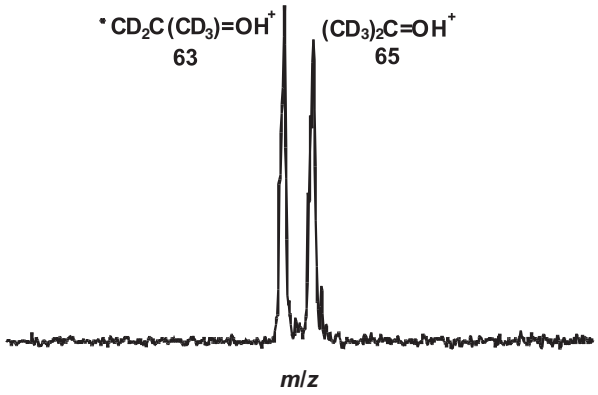
Ion 1

An ion of structure **1** was obtained by the collision-induced loss of a $CH_3CH_2^{\cdot}$ radical from the proton-bound dimer $(CH_3)_2C{=}O{\cdots}H^+{\cdots}O(H)CH_2CH_2CH_3$ (*m/z* 119), ion **P1**. The PA of acetone (812.0 kJ/mol) (18) is greater than that of propanol (786.5 kJ/mol) (18), and so the proton is preferentially attached to the alcohol thus resembling protonated acetone electrostatically bound to a propanol molecule, i.e., $(CH_3)_2C{=}OH^+{\cdots}O(H)CH_2CH_2CH_3$. Its MI mass spectrum has *m/z* 59 (100%), $(CH_3)_2C{=}OH^+$, as the most intense peak and a small signal for protonated propanol (*m/z* 61, 5%) as shown in Fig. 1. These are the only MI processes, showing that no rearrangement of the proton-bound dimer can likely take place at internal energies up to those for MI dissociations. In its CID mass spectrum, in addition to the above major peaks, there is now a small signal for $CH_3CH_2^{\cdot}$ loss (*m/z* 76, <<1%).

[1] $(CH_3)_2C{=}OH^+{\cdots}O(H)CH_2CH_2CH_3$ (*m/z* 119) $\rightarrow [(CH_3)_2C{=}OH^+{\cdots}O(H)CH_2^{\cdot}]$ (*m/z* 90, Ion **1**) + $CH_3CH_2^{\cdot}$ (CID)

The MI spectrum of ion **1** (Fig. 2*a*) contains two peaks: protonated acetone, $(CH_3)_2C{=}OH^+$ (*m/z* 59, 53%), and as base peak (*m/z* 58), which was shown to be the distonic acetone ion ($^{\cdot}CH_2C(CH_3) = OH^+$, see the following discussion).

Fig. 2. (*a*) MI mass spectrum of $[(CH_3)_2C{=}OH^+{\cdots}O(H)CH_2^{\cdot}]$ (*m/z* 90). (*b*) CID mass spectrum of $[(CH_3)_2C{=}OH^+{\cdots}O(H)CH_2^{\cdot}]$ (*m/z* 90).



In the CID mass spectrum of ion **1** (Fig. 2*b*), the intensity of the peak at *m/z* 59 ($(CH_3)_2C{=}OH^+$) is increased and is now the base peak. The formation of $(CH_3)_2C{=}OH^+$ is thus collision sensitive, being a simple bond cleavage in ion **1**. The observation that a metastable ion peak is insensitive to collision gas signifies that the mass selected ion has undergone a rearrangement to an isomeric species over an energy barrier close to the lowest energy fragmentation for that ion. In cases where this energy barrier is lower or nonexistent, the collision sensitivity of the peak is correspondingly greater. If the MI peak is for a simple bond cleavage in the mass selected ion, the collision sensitivity is greatest and often produces the base peak in a CID mass spectrum (19). Ion **1** keeps the proton-bridged form of the precursor proton-bound pair (*m/z* 119), and so it is represented as $[(CH_3)_2C{=}OH^+{\cdots}O(H)CH_2^{\cdot}]$. This is also in keeping with the PA of $(CH_3)_2C{=}O$ at O (812.0 kJ/mol) being higher than the PA of $^{\cdot}CH_2OH$ (695.0 kJ/mol). However, note that the peak at *m/z* 58 ion is *not* collision sensitive, indicating that ion **1** rearranges before it fragments by this route.

The dissociation channel that leads to the enol form of ionized acetone is energetically the most favourable process. If the ion *m/z* 58 has the enol structure, the dissociation threshold energy is at 459 kJ/mol (from $\Delta_f H[^{\cdot}CH_2C(CH_3){=}OH^+]$ = 661 kJ/mol and $\Delta_f H[CH_3OH]$ = –202 kJ/mol) (20). This is lower than the dissociation limit (470 kJ/mol) for the formation of protonated acetone *m/z* 59 (from $\Delta_f H[(CH_3)_2C{=}OH^+]$ = 489 kJ/mol and $\Delta_f H[^{\cdot}CH_2OH]$ = –19 kJ/mol) (20). If the *m/z*

Fig. 3. MI mass spectrum of $[(CD_3)_2C{=}OH^+\cdots O(H)CD_2^{\cdot}]$ (**1-d$_8$**, *m/z* 98).

58 ion had the keto structure, the threshold energy for this dissociation would be much higher, at 517 kJ/mol (from $\Delta_f H[(CH_3)_2C{=}O^{+\cdot}]$ = 719 kJ/mol and $\Delta_f H[CH_3OH]$ = −202 kJ/mol) (20), and would be unable kinetically to compete with the simple bond cleavage to *m/z* 59. That the enol ion is produced is fully supported by the results of isotopic labelling.

The deuterium-labelled ion–molecule pairs, $[(CH_3)_2C{=}OH^+\cdots O(H)CD_2^{\cdot}]$ (**1-d$_2$** (*m/z* 92)), $[(CD_3)_2C{=}OH^+\cdots O(H)CD_2^{\cdot}]$ (**1-d$_8$** (*m/z* 98)), and $[(CD_3)_2C{=}OD^+\cdots O(H)CD_2^{\cdot}]$ (**1-d$_9$** (*m/z* 99)), were examined to help assign the structure of the *m/z* 58 ion to that of the enol of acetone. The MI mass spectrum of **1-d$_8$** (*m/z* 98) (Fig. 3) shows intense peaks at *m/z* 63 and *m/z* 65, corresponding to the ions $^{\cdot}CD_2C(CD_3){=}OH^+$ and $(CD_3)_2C{=}OH^+$, respectively. No peak at *m/z* 64 was observed; had the keto ion been the product, it would have resulted in *m/z* 64 ($(CD_3)_2C{=}O^{+\cdot}$) being observed instead. The relative abundance of the two product ions for the labelled complexes differs from that for the unlabelled ion **1** owing to an isotope effect in the H transport in the isomerization process. In general, the rate constant for k_{isom} (H) has been found to be greater than k_{isom} (D), resulting in smaller distonic acetone peaks in the mass spectra of labelled ions. The MI mass spectra of **1-d$_2$** (*m/z* 92) and **1-d$_9$** (*m/z* 99) showed only two dissociation reactions, again resulting from the explicit formation of distonic acetone and protonated acetone. These two ions carry different labels for the hydroxyl or methyl H atoms of the radical site, indicating that the H atoms from $^{\cdot}CH_2OH$ were not found in the product ions. Thus, there was no H/D mixing involved in the ion dissociations. The rearrangement process is described as follows. Before the ion–molecule complex **1**, $[(CH_3)_2C{=}OH^+\cdots O(H)CH_2^{\cdot}]$, dissociates to the distonic acetone ion and methanol, a H$^{\cdot}$ atom from $CH_3C(CH_3){=}OH^+$ is transferred to the $^{\cdot}CH_2OH$ radical via a 1,6-H shift. This process involves a low energy barrier, shown as TS1 on the PES of ion **1** (see Fig. 4 and the discussion of the computations).

Ion 2

The MI mass spectrum of the proton-bound acetone – dimethyl ether ion pair, $(CH_3)_2C{=}O\cdots H^+\cdots O(CH_3)_2$ (*m/z* 105) (**P2**), showed two major peaks, namely protonated acetone (*m/z* 59) and protonated dimethyl ether (*m/z* 47), indicating that the ion keeps its original structure prior to dissociation. A minor $CH_3^{\cdot}$ loss peak (*m/z* 90) is produced by collision-induced dissociation; this reaction is shown in eq. [2].

$$[2]\quad (CH_3)_2C{=}O\cdots H^+\cdots O(CH_3)_2\ (m/z\ 105) \rightarrow [(CH_3)_2C{=}OH^+\cdots{}^{\cdot}OCH_3]\ (m/z\ 90,\ \text{Ion } \mathbf{2}) + CH_3^{\cdot}\ (\text{CID})$$

The lost methyl radical could come from either molecule, and so deuterium labelling was used to identify the methyl groups, e.g., $(CD_3)_2C{=}O\cdots H^+\cdots O(CH_3)_2$ (**P2-d$_6$**) and $(CD_3)_2C{=}O\cdots D^+\cdots O(CH_3)_2$ (**P2-d$_7$**), which lost only $^{\cdot}CH_3$ in their CID mass spectra, showing that only an ether methyl group is involved.

Compared with its isomer **1**, where the radical is located on the carbon atom, ion **2** carries the radical on methoxyl group owing to a removal of a radical from the oxygen atom. Their MI dissociation profiles are different. For example, the MI mass spectrum of $[(CD_3)_2C{=}OH^+\cdots OCH_3]$ (**2-d$_6$**, *m/z* 96) showed that there are three competing dissociation channels, giving protonated acetone (*m/z* 65), the acetone ion (*m/z* 64), and $CD_3^{\cdot}$ loss (*m/z* 78) (see Fig. 5).

The smaller peak *m/z* 58 in the MI mass spectrum of unlabeled ion **2** must be the acetone cation, not the enol ion, even though the latter is more energetically favoured than protonated acetone (see the Discussion for ion **1**), showing no rearrangement of ion **2** to its enol form. The deuterium-labelling results indicate that the lost methyl group comes exclusively from the acetone moiety and that H/D atoms in ion **2** have retained their original positions before it fragments, i.e., no H/D mixing between the two moieties in the complex. Surprisingly, the methyl loss peak is collision insensitive, indicating that it does not arise from a simple C—C bond cleavage. It was concluded from the computations that the product ion from the methyl lost from ion **2** is an ion–molecule complex of the acetyl ion and methanol, $[CH_3C^+(O)\cdots O(H)CH_3]$, an ion that comprises a new member of the $[C_3H_7O_2]^+$ isomers. The detailed path for the generation of the ion $[CH_3C^+(O)\cdots O(H)CH_3]$ is discussed in the Calculations section. To date, the other three identified ion $[C_3H_7O_2]^+$ structures were characterized, which are $[CH_3OCH{=}OCH_3]^+$ and the proton-bound complex of acetaldehyde and formaldehyde, $CH_3CHO\cdots H^+\cdots OCH_2$, by McLafferty and Proctor (21), and protonated ethyl formate, $CH_3CH_2OC^+(H)OH$, by Larson and McMahon (22).

Theoretical calculations

The two ion–molecule complexes, $[(CH_3)_2C{=}OH^+\cdots O(H)CH_2^{\cdot}]$ and $[(CH_3)_2C{=}OH^+\cdots{}^{\cdot}OCH_3]$, display different chemistries in their mass spectra. Thus, these two systems do not communicate with each other, presumably because a high energy barrier prevents them from freely interconverting in the metastable ion dissociation time frame. Calculations were performed to produce a PES for each ion and to investigate the mechanisms of the isomerizations and fragmentations. The energies (in kJ/mol) shown on the PES are relative to the calculated energy of the stable complex IV of distonic acetone and methanol, $[^{\cdot}CH_2C(CH_3) = OH^+\cdots O(H)CH_3]$, obtained at the MP2/6-31+G(d) level of theory, and are given in Table 1. Intrinsic reaction coordinate (IRC) calculations have been used to follow the reaction paths from all transition states to identify intermediates. IRCs were also used to

test whether a transition state is the correct structure that connects two minimum wells.

The $[(CH_3)_2C{=}O\cdots H^+\cdots O(H)CH_2^{\cdot}]$ system

The 0 K potential energy profile is shown in Fig. 4. The optimized structure of ion **1** is indeed $[(CH_3)_2C{=}O\cdots H^+\cdots O(H)CH_2^{\cdot}]$. In the stable species III, the proton is closer to the keto oxygen than to the hydroxyl oxygen of the radical, the two bond lengths being 1.031 Å for $(CH_3)_2C{=}O$-H and 1.565 Å for $^{\cdot}CH_2O(H)$-H (see Fig. 6*a*). This is in keeping with the PA of $(CH_3)_2C{=}O$ being greater than that for $^{\cdot}CH_2OH$ at oxygen. Ion III rearranges to the stable complex IV, distonic acetone ion and methanol, $[^{\cdot}CH_2C(CH_3){=}OH^+\cdots O(H)CH_3]$, via a cyclic transition state (TS1). This rearrangement requires only ca. 113 kJ/mol and the TS1 lies below the dissociation threshold of III to protonated acetone and the hydroxylmethyl radical (120 kJ/mol). The energy for the isolated ionized acetone ion to isomerize to its enol form is at 213 kJ/mol (6, 23), above the heat of formation of the latter and lies well above the dissociation limit for the keto ion's loss of $CH_3^{\cdot}$ (139 kJ/mol) (23). Note that TS1, the seven-membered ring intermediate structure, would be favoured by entropy considerations. Complex IV then dissociates to produce the enol ion and a methanol molecule, the dissociation limit for which is 117 kJ/mol. This process involves the low energy barrier TS1 and is the competing dissociation channel with an energy lower than that for the production of protonated acetone (*m/z* 59), and thus distonic acetone (*m/z* 58) gives rise to the most intense peak in the MI mass spectrum of ion **1**. Thus, the initial acetone molecule has been ionized and isomerized to its enol ion form by the transferring of H^+ and $H^{\cdot}$ from the substrate in which the free radical site functions as a good $H^{\cdot}$ or H^+ acceptor, facilitating the enolization of acetone.

The $[(CH_3)_2C{=}O\cdots H^+\cdots{}^{\cdot}OCH_3]$ system

Ion **2** is shown as the stable complex I on the 0 K PES (Fig. 7). In this proton-bound complex, acetone is more strongly associated with the proton because the PA of acetone (812 kJ/mol) is significantly higher than that of $CH_3O^{\cdot}$ (658 kJ/mol). A simple bond cleavage produces $(CH_3)_2C{=}OH^+$ (*m/z* 59) and $CH_3O^{\cdot}$ at a dissociation threshold of 155 kJ/mol. The ion I, $[(CH_3)_2C{=}OH^+\cdots{}^{\cdot}OCH_3]$, is able to rearrange to a complex of the acetone ion and methanol, stable complex II $[(CH_3)_2C{=}O^{+\cdot}\cdots HOCH_3]$. However, no transition-state structure has been found to connect these two minima. The same problem has been encountered when calculating the transition state between the stable $[CH_3CHOH^+\cdots{}^{\cdot}OCH_3]$ complex and of CH_3CHOH^+ with CH_3OH on the PES for the acetaldehyde–methanol ion complex (12, 13, 24). Similarly, here, with the complex II, $[(CH_3)_2C{=}O^{+\cdot}\cdots HOCH_3]$, the O atom of CH_3OH is associ-

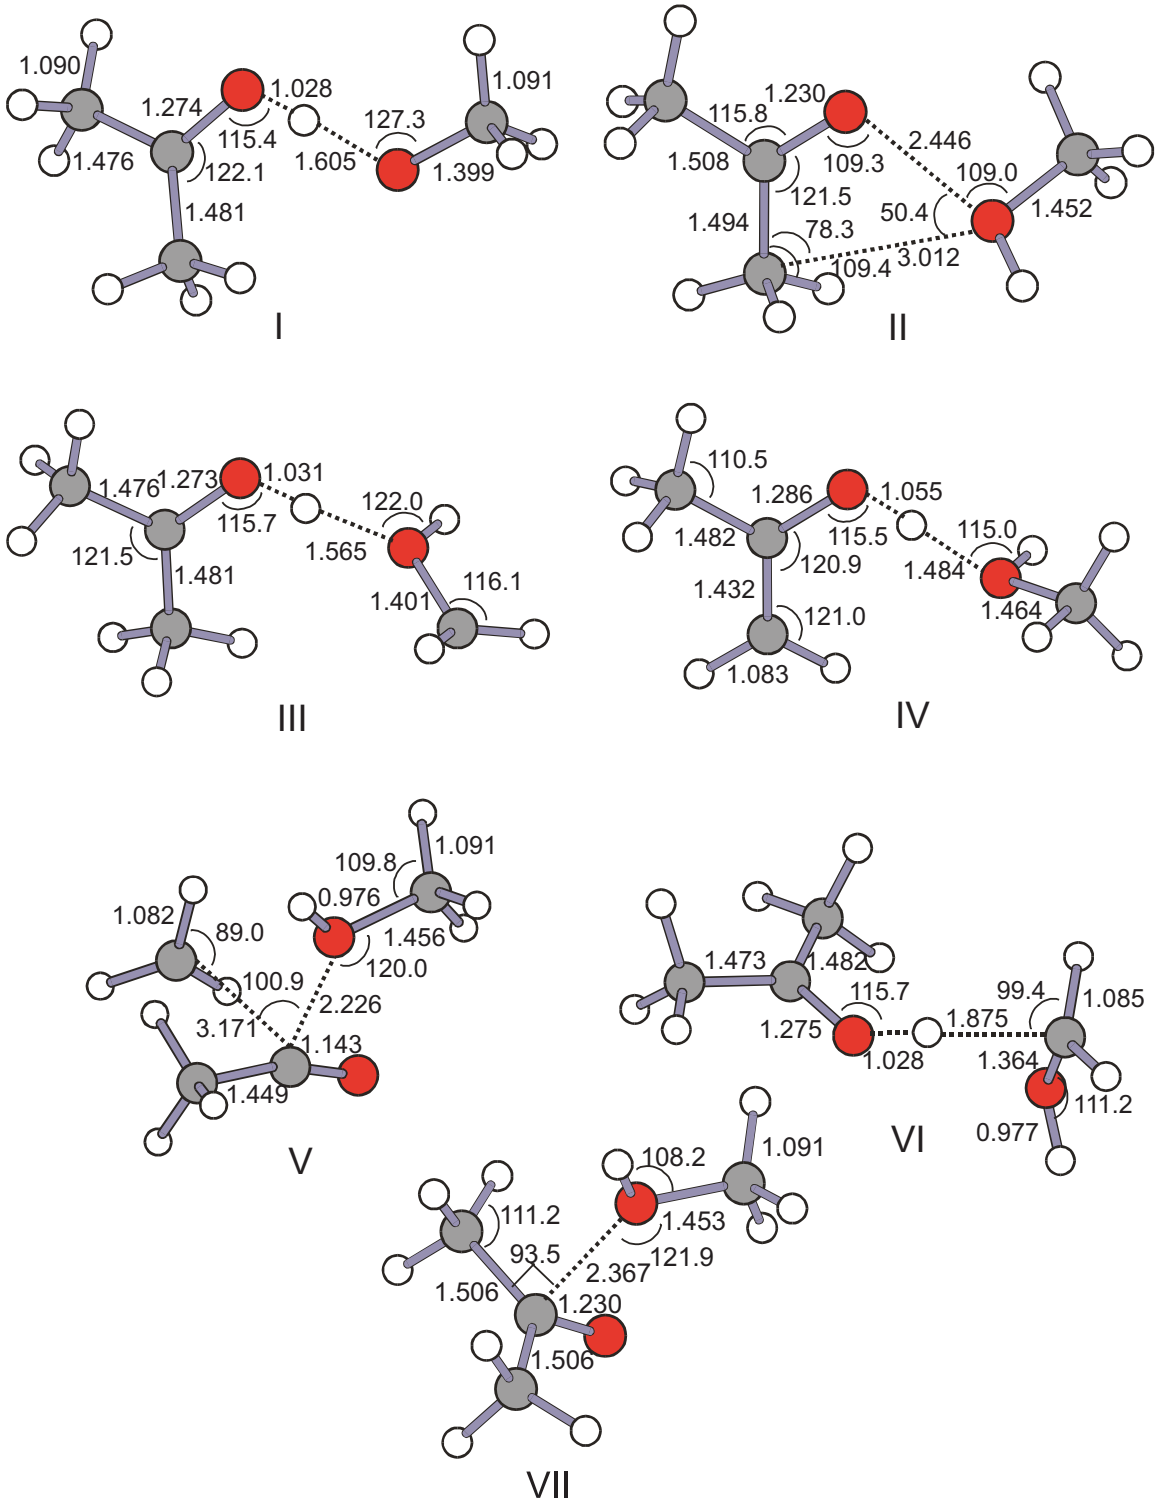
[a]The relative energies (at 298 K) can be also normalized using the established energies of a selected product pair, e.g., $\Delta_f H[{}^{\cdot}CH_2C(CH_3){=}OH^+] + \Delta_f H[CH_3OH]$ = 459 kJ/mol, and so adding 341 kJ/mol (= 459 kJ/mol – 118 kJ/mol) to all values achieves this.



ated with the carbonyl O and methyl C of $(CH_3)_2C{=}O^{+\cdot}$ in the form of a four-membered ring structure. The computational difficulty arises when I converts to II, the charge centre migrates from the proton to the acetone C atom and a $H^{\cdot}$ atom moves to $CH_3O^{\cdot}$. A minimum energy crossing point (MECP) has been suggested by Ruttink and co-workers (8) and by Haranczyk et al. (13), which is defined as the geometry corresponding to the minimum energy complex for the intersection of the two discontinuous PES. Because the acetone ion (*m*/*z* 58) is observed in the MI mass spectrum of ion **2**, this transition state (TS2) should be below the dissociation limits of the precursor ion–molecule complex I (at 155 kJ/mol). Complex II can also fragment to the acetone ion (*m*/*z* 58) and methanol.

Another competing dissociation channel of ion **2** is the generation of $(CH_3)_2C{=}OH^+$ (*m*/*z* 59) and a ${}^{\cdot}CH_2OH$ radical, a reaction that is energetically more favourable than the simple bond dissociation to $(CH_3)_2C{=}OH^+$ and $CH_3O^{\cdot}$ because the heat of formation of ${}^{\cdot}CH_2OH$ (–19 kJ/mol) (20) is lower than that of $CH_3O^{\cdot}$ (16 kJ/mol) (20). This reaction involves an ion rearrangement from complex II to ion VI, $[(CH_3)_2C^+(=OH)\cdots O(H)CH_2^{\cdot}]$. The latter is an isomer of complex III, $[(CH_3)_2C{=}OH^+\cdots O(H)CH_2^{\cdot}]$. In structure VI, $CH_2OH^{\cdot}$ is bound to $(CH_3)_2C{=}OH^+$ through a C(of ${}^{\cdot}CH_2OH$)···H···O(of acetone) bridge, different from the O···H···O proton bridge in complex III. In TS3, the H atom moves from the methyl group of methanol to carbonyl O. TS3 between complex II and VI lies at 158 kJ/mol, close to the dissociation threshold of complex I (155 kJ/mol). Thus, the two reactions can compete in terms of their energy requirements.

The MI mass spectrum of ion **2** shows as a base peak the loss of methyl from the acetone moiety, and the mechanism explored by the calculations is as follows. Interconversion between complex II and its isomer, i.e., complex VII, takes place via transition state TS4 (165 kJ/mol). In complex VII, the methanol is perpendicular to the acetone plane and separated by an elongated C···O bond of 2.367 Å between the two species. Note that in ion VII the rearrangement of the methanol molecule leads to stabilization of the charge on the carbonyl C atom, facilitating the ensuing methyl loss. In TS5, the extension of the C—C bond in acetone leads to the elimination of a methyl radical, leaving a new complex of an acetyl ion and methanol, $[CH_3C^+(O)\cdots(H)OCH_3]$. The geometry of this ion is shown in Fig. 8. The dissociation limit for **2** to produce $[CH_3C^+(O)\cdots(H)OCH_3]$ and $CH_3^{\cdot}$ is 128 kJ/mol at 298 K (Table 1). Heats of formation of new products can be calculated by normalizing the computed relative energies (at 298 K) using the well-established experimental energies of a selected product pair, e.g., $\Delta_f H[{}^{\cdot}CH_2C(CH_3){=}OH^+] + \Delta_f H[CH_3OH]$ = 459 kJ/mol (20); adding 341 kJ/mol to all relative energies achieves this (see Table 1). The heat of formation of the product ion $[CH_3C^+(O)\cdots(H)OCH_3]$ (322 kJ/mol) is obtained by subtracting $\Delta_f H[{}^{\cdot}CH_3]$ = 147 kJ/mol from the dissociation limit for the ion (469 kJ/mol (= 128 kJ/mol + 341 kJ/mol)). Thus, the binding energy in this ion to the products $CH_3CO^+ + CH_3OH$ is 129 kJ/mol, using $\Delta_f H[CH_3C^+O]$ = 653 kJ/mol (18) and $\Delta_f H[CH_3OH]$ = –202 kJ/mol (18). The relatively high energy of the electrostatic bond in this ion is similar to that of -O···H^+···O- (~130 kJ/mol) in proton-bound pairs (25), although this ion does not contain a proton bridge. It follows therefore that the attachment of methanol to ionized acetone (shown as complex VII) results in a remarkable weakening of the H_3C—C bond from 81 kJ/mol in the isolated ion ($\Delta_f H[(CH_3)_2CO^{+\cdot}]$ = 719 kJ/mol) (20) to only 26 kJ/mol (the

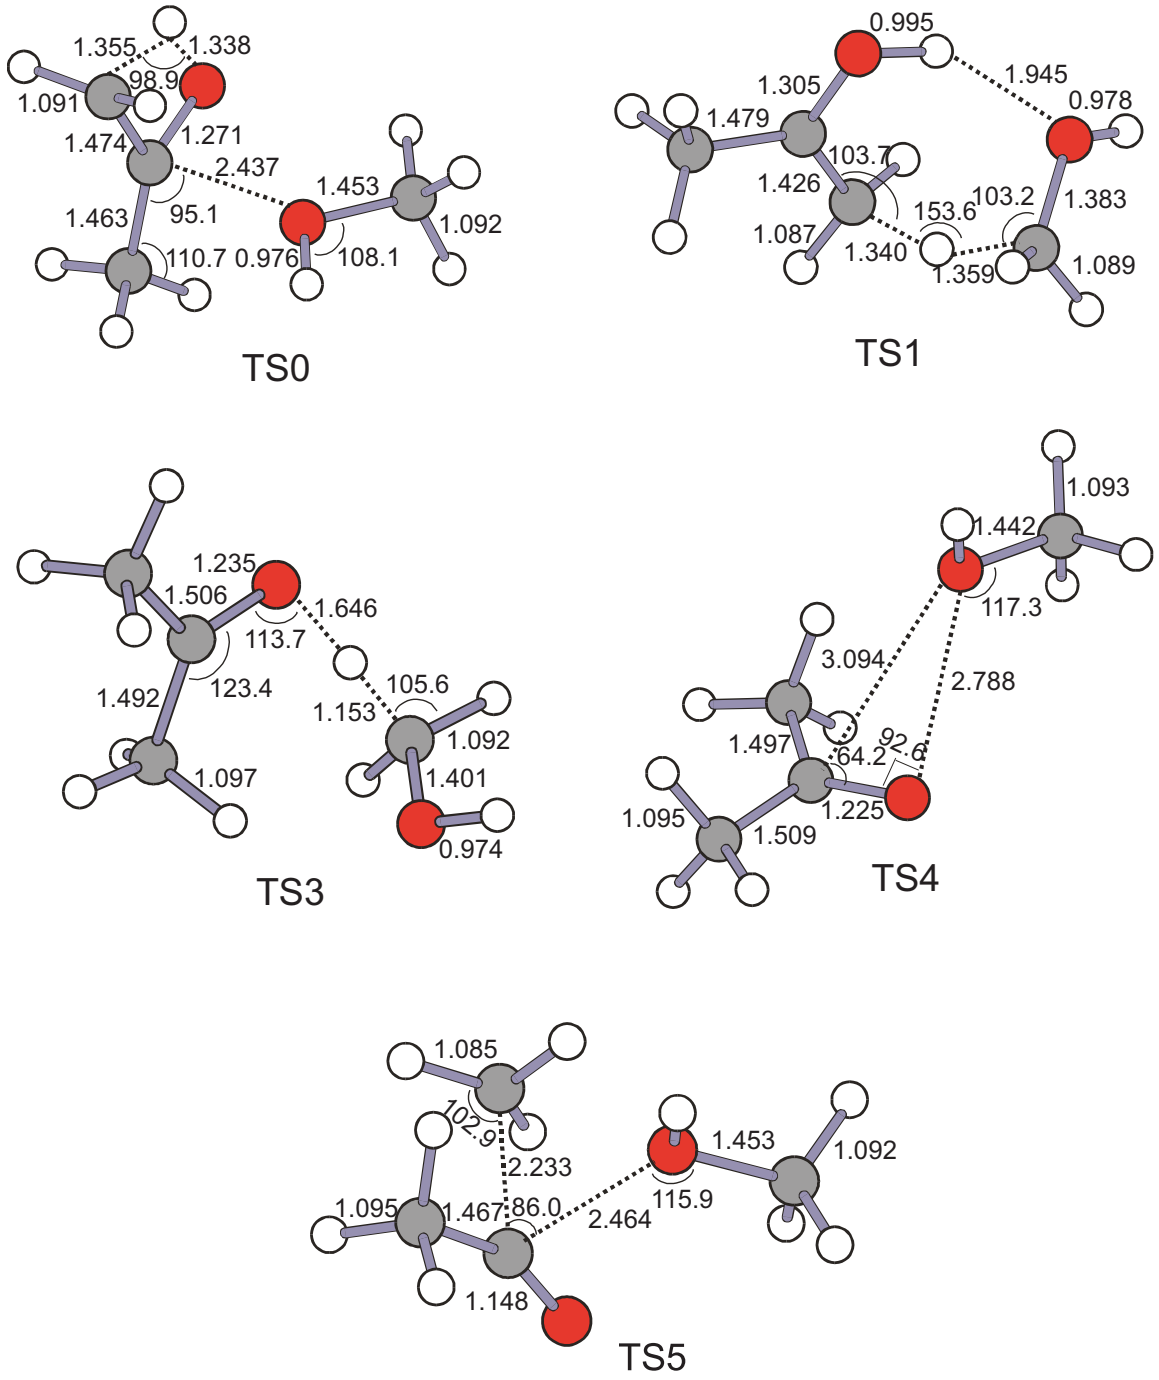
Fig. 6. (*a*) Optimized geometries of the stable complexes at MP2/6-31+G(d). (*b*) Optimized geometries of the transition states at MP2/6-31+G(d).



298 K energy difference between TS5 and ion VII) in the complex, and this results from the high stability of the $[CH_3C^+(O)\cdots(H)OCH_3]$ product ion.

The flat transition state of this reaction (TS5) lies at 128 kJ/mol in Fig. 7, but the overall energy-determining barrier for this process is TS4 at 165 kJ/mol. As previously mentioned, these three reactions for the production of protonated acetone (*m*/*z* 59), the acetone ion (*m*/*z* 58), and the methyl loss product at *m*/*z* 75 are all MI processes and so they have closely similar energy requirements. The PES of ion **2** shows that the major energy barriers for these three reactions lie within a small energy range of 18 kJ (the highest

© 2005 NRC Canada

Fig. 6 (*concluded*).

energy limit, 173 kJ/mol; the lowest energy limit, 155 kJ/mol), which ensures the observation of all three products in the MI time frame.

Another transition-state energy has been calculated, that for TS0, by which complex VII, the acetone ion and methanol, converts to ion IV, the distonic acetone ion and methanol. TS0 lies at a rather high energy (251 kJ/mol). In the metastable time frame of the mass spectrometer, a reaction requiring such a high relative internal energy is usually not competitive and therefore is not observed. This is confirmed by the experimental observation that ion **2** does not isomerize to an enol form.

Conclusions

In summary, the proton-bound complex of acetone and $CH_2OH^{\cdot}$ (ion **1**) isomerizes into the enol ion, i.e., distonic acetone, attached to a methanol molecule. In contrast, ion **2** does not produce the enol ion. It simply dissociates into the keto ion, i.e., ionized acetone and the methanol neutral counterpart.

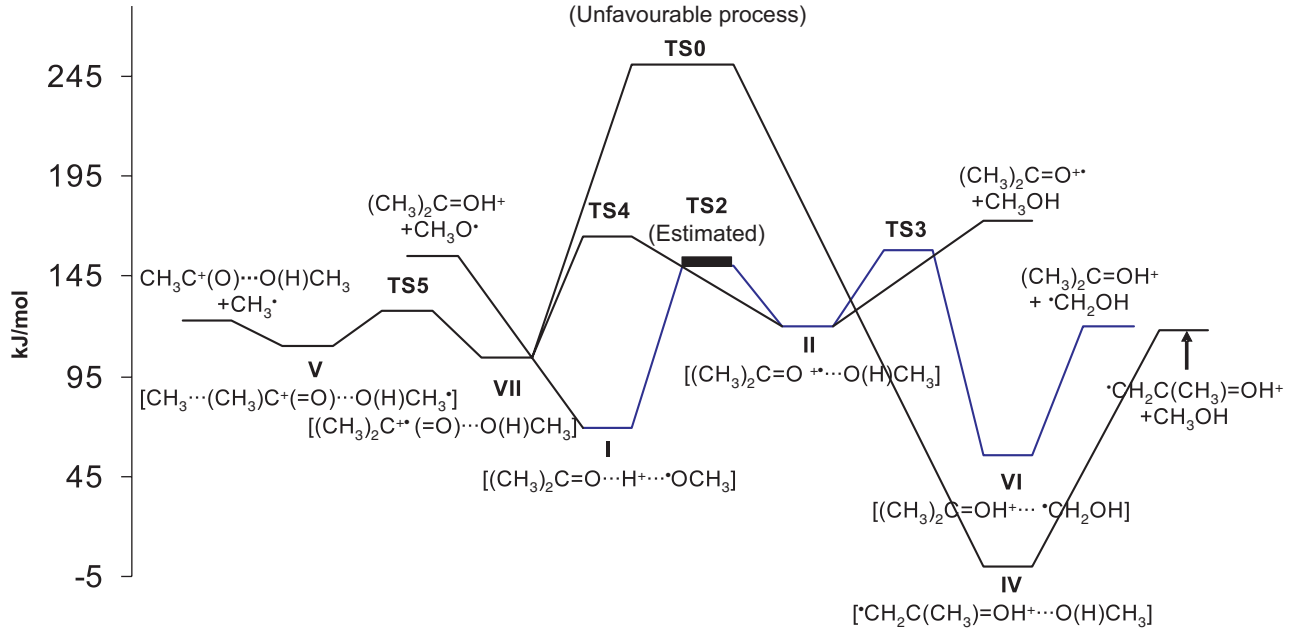

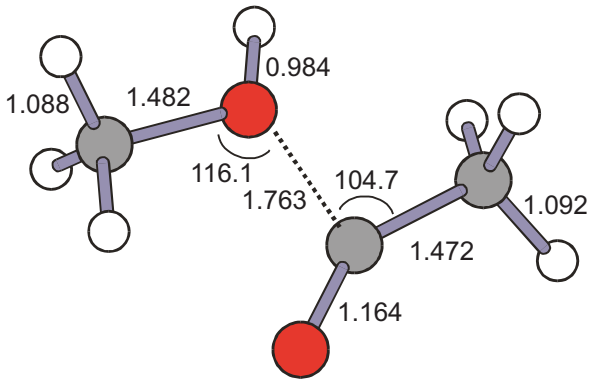

Fig. 8. Geometry of $[CH_3C^+(O)\cdots O(H)CH_3]$.

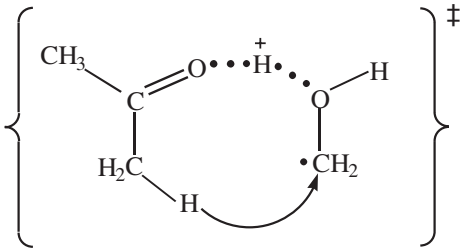

[4] $[(CH_3)_2C{=}O\cdots H^+\cdots{}^{\cdot}OCH_3]$

$\rightarrow [(CH_3)_2C{=}O^{+\cdot}\cdots HOCH_3]$

These observations are in keeping with the chemistries of $[CH_3CHO\cdots H^+\cdots O(H)CH_2^{\cdot}]$ and $[CH_3CHO\cdots H^+\cdots{}^{\cdot}OCH_3]$. We believe that the first reaction proceeds because the charge and radical sites are on separate groups in ion **1**. In rxn. [3], a proton is given to a keto group and the radical moiety takes back an $H^{\cdot}$ atom. The ketone is thus readily converted to its enol ion form. The key transition state (TS1, shown in Fig. 9) transfers an $H^{\cdot}$ atom back to the methyl hydroxyl radical by an *$H^{\cdot}$ atom transfer mechanism*. The important result from ion **1** is that the enol ion results from proton transfer to acetone, which then gives an $H^{\cdot}$ atom back to the $^{\cdot}CH_2OH$ radical by a 1,6-H transfer, producing the enol ion. In contrast, when the protonated acetone is attached to the radical $CH_3O^{\cdot}$ (ion **2**) the above rearrangement does not take place. Ion **2** cannot communicate with ion **1** on their PES. A high barrier prevents the complex of the acetone ion with methanol (complex VII) from rearranging to distonic acetone and methanol (complex IV, see Fig. 7).

Fig. 9. 1,6-Hydrogen shift for TS1.

Radom's rule predicts that PTC cannot facilitate the isomerization either because the PA of methanol (755 kJ/mol) is lower than PA values of $^{\cdot}CH_2(CH_3)C{=}O$ at the O atom (811 kJ/mol) and the C site (769 kJ/mol). Instead, ion **2** dissociates to a stable complex of an acetyl ion with methanol. The energy barriers calculated at the MP2/6-31+G(d) level of theory for all the MI processes fully support the experimental observations.

Gas-phase ion chemistry of Ti(O-*i*-Pr)$_4$[1]

Luciano A. Xavier and José M. Riveros

Abstract: The positive and negative gas-phase ion chemistry of Ti(O-*i*-Pr)$_4$ was investigated at low pressures by FT-ICR. The fragment ion, (*i*-PrO)$_3$Ti-O$^+$=C(H)Me, reacts with the parent neutral by proton transfer and by a nucleophilic addition–elimination reaction. The nature of the fragment ion and the ensuing ion–molecule reactions clearly indicate that Ti(O-*i*-Pr)$_4$ exists as a monomer in the gas phase. In the negative ion mode, F$^-$ was found to react easily with Ti(O-*i*-Pr)$_4$ to yield the pentacoordinated complex FTi(O-*i*-Pr)$_4^-$ ion. This hypervalent Ti species undergoes a series of sequential fragmentations induced by IR multiphoton excitation. The first step is unusual because two channels are observed by IRMPD: one involves loss of HF, and the other loss of *i*-PrOH. The subsequent dissociation processes are characterized by progressive elimination of propene giving rise to a number of different titanaoxirane-containing anions with the general formula [(η^2-CMe$_2$O)Ti(OH)$_{3-n}$(*i*-PrO)$_n$]$^-$. FTi(O-*i*-Pr)$_4^-$ was also observed to undergo multiple alkoxide–fluoride exchanges with BF_3 leading to the eventual formation of TiF_5^-.

Key words: titanium tetraisoproxide, gas-phase ion chemistry, hypervalent Ti, ion–molecule reactions, IRMPD.

Résumé : On a étudié la chimie en phase gazeuse des ions positifs et négatifs du Ti(O-*i*-Pr)$_4$ en opérant à basse pression et en faisant appel à la spectrométrie de masse à résonance cyclotronique ionique avec transformée de Fourier (SM-RCI-TF). Le fragment ionique (*i*-PrO)$_3$Ti-O$^+$=C(H)Me réagit avec une molécule parente neutre par un transfert de proton et par une réaction nucléophile d'addition–élimination. La nature de l'ion fragment et les réactions subséquentes ion–molécule indiquent clairement que le Ti(O-*i*-Pr)$_4$ existe sous la forme de monomère en phase gazeuse. Dans le mode d'ion négatif, on a trouvé que l'ion F$^-$ réagit facilement avec le Ti(O-*i*-Pr)$_4$ pour conduire à la formation de l'ion complexe pentacoordiné FTi(O-*i*-Pr)$_4^-$. Cette espèce hypervalente du titane subit une série de fragmentations en séquence induites par une excitation multiphotonique infrarouge. La première étape est inhabituelle parce qu'on observe deux voies par photodissociation multiphotonique par infrarouge (DMPIR): une implique une perte de HF et l'autre une perte de *i*-PrOH. Les processus subséquents de dissociation sont caractérisés par une élimination progressive de propène qui conduit à la formation d'un certain nombre d'anions différents contenant du titanaoxirane de formule générale [(η^2-CMe$_2$O)Ti(OH)$_{3-n}$(*i*-PrO)$_n$]$^-$. On a aussi observé que le FTi(O-*i*-Pr)$_4^-$ subit de multiples échanges alcoolate–fluorure avec le BF_3 qui conduisent à la formation éventuelle de TiF_5^-.

Mots clés : isopropylate de titane, chimie ionique en phase gazeuse, titane hypervalent, réactions ion–molécule, photodissociation multiphotonique par infrarouge (DMPIR).

[Traduit par la Rédaction]

Introduction

Metal alkoxides (M(OR)$_n$) are recognized as excellent and versatile precursors for deposition of metal oxides by chemical vapor deposition (CVD) and for the synthesis of advanced materials and ceramics (1–3). For example, titanium tetraisopropoxide (Ti(O-*i*-Pr)$_4$) has been extensively characterized as a precursor for deposition of titanium dioxide (4), and the titanium alkoxides have found a wide range of applications in the design of multifunctional materials by sol-gel processes (5–9).

Thermal decomposition of titanium isopropoxide yields TiO_2 via rxns. [1] and [2],

[1] $$Ti(O\text{-}i\text{-}Pr)_4 \rightarrow TiO_2 + 4CH_3CH{=}CH_2 + 2H_2O$$

[2] $$Ti(O\text{-}i\text{-}Pr)_4 \rightarrow TiO_2 + 2CH_3CH{=}CH_2 + 2i\text{-}PrOH$$

whereas sol-gel processes of Ti alkoxides are based on hydrolysis of the alkoxy groups. The latter reaction proceeds by progressive replacement of the R groups as shown in rxn. [3].

[3] $$Ti(OR)_4 + H_2O \rightarrow Ti(OR)_3(OH) + ROH$$

Although complete hydrolysis eventually leads to TiO_2, there are also competing reactions initiated by the partially hydrolyzed Ti(OR)$_{4-n}$(OH)$_n$ species that can result in condensation products as shown in rxns. [4] and [5] (10–12).

[4] $Ti(OR)_3(OH) + Ti(OR)_4 \rightarrow (RO)_3Ti\text{-}O\text{-}Ti(OR)_3 + ROH$ (Alkoxolation)

[5] $Ti(OR)_3(OH) + Ti(OR)_3(OH) \rightarrow (RO)_3Ti\text{-}O\text{-}Ti(OR)_3 + H_2O$ (Oxolation)

Understanding the detailed mechanisms of these processes is of paramount importance because of the possibility of tailoring the structure of materials (13–15). A variety of oxytitanium species are presumably key intermediates in the chemistry of these systems, but they have not been well-characterized. Oxytitanium species are also of interest because of: (*a*) their possible role in chemical vapor deposition processes aimed at preparing catalytic materials (16); (*b*) the increasing catalytic, ferroelectric, and nanostructure capabilities found for titanate-type compounds (17–20); and (*c*) the mechanisms of growth and nucleation of TiO_2 nanoparticles (12).

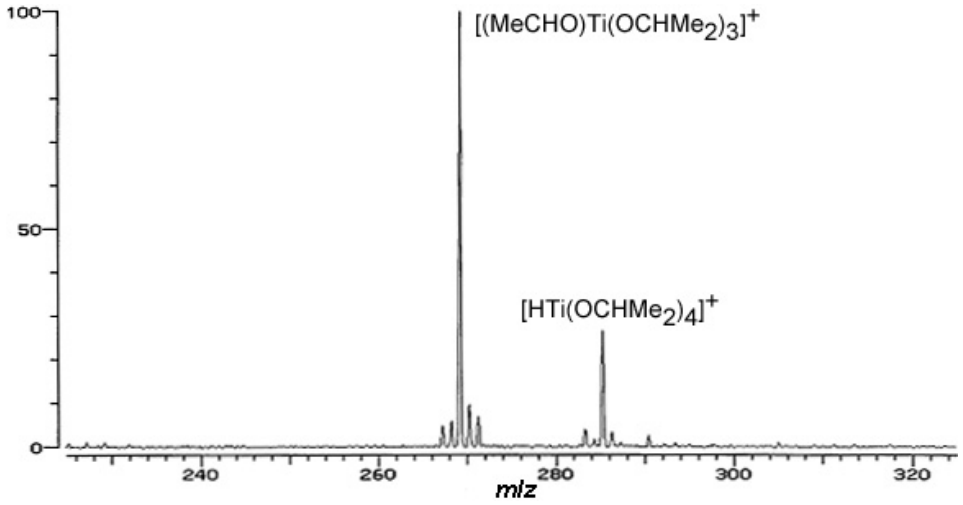
Some insight into the underlying basic chemistry involved in sol-gel reactions and in metal organic chemical vapor deposition can be gained by probing the gas-phase behavior of simple processes involving titanium alkoxides. This approach was pioneered by Traldi and co-workers (21) in their study of model acid- and base-induced hydrolysis of $Si(OEt)_4$ in the gas phase. By comparison, little is known about the gas-phase ion chemistry of titanium alkoxides or of other titanium-containing substrates. The question of the nuclearity of the different $Ti(OR)_4$ species in the gas phase is particularly intriguing. There is strong evidence that $Ti(OMe)_4$ and $Ti(OEt)_4$ form polynuclear species in the solid state, but $Ti(O\text{-}i\text{-}Pr)_4$, a liquid at room temperature, is suspected to be mostly monomeric because of steric inhibition by the bulky substituents (22). A recent study by desorption chemical ionization mass spectrometry (23) reveals that $Ti(O\text{-}i\text{-}Pr)_4$ yields substantial amounts of the molecular ions $[M]^{-\cdot}$ and $[M_2]^{-\cdot}$ in the negative ion mode, and the fragment binuclear ion $[M_2\text{-}O\text{-}i\text{-}Pr]^+$ in the positive ion mode. By comparison, the mass spectrum of $Ti(OMe)_4$ obtained by the same technique does not exhibit any mononuclear Ti-containing ions. On the other hand, electrospray ionization of very dilute solutions of $Ti(O\text{-}i\text{-}Pr)_4$ and $Ti(OBu)_4$ in methanol reveals the formation of ions resulting from polycondensation reactions following solvent exchange of the *i*-PrO and BuO ligands (24).

In this report, we describe some basic aspects of (*a*) the positive ion chemistry derived from the main mononuclear fragment ion of $Ti(O\text{-}i\text{-}Pr)_4$ and (*b*) the negative ion chemistry resulting from nucleophilic attack of F^-, and the sequential IR multiphoton dissociation of the hypervalent anionic adduct $[FTi(O\text{-}i\text{-}Pr)_4]^-$. This study follows our early investigation of the ion–molecule reactions of the fragment ions of $Si(OR)_4$ (R = Me, Et) and $Ge(OMe)_4$ with their neutral precursors (25, 26), as well as the ion–molecule reactions of a number of anionic nucleophiles with these same substrates (27, 28). Much of the motivation for this type of work stems from the increasing interest in the gas-phase ion chemistry of organometallics (29) and our very limited knowledge about the gas-phase behavior of Ti-containing substrates when compared with that of silicon (30) or germanium derivatives (31).

Experimental

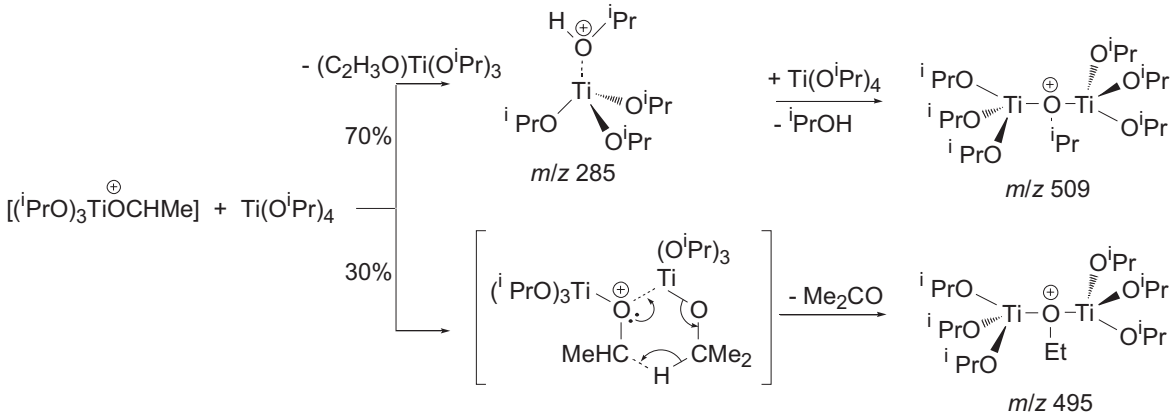
Experiments were carried out in our FT-ICR spectrometer interfaced to an IonSpec Omega Fourier transform data system. The general characteristics of this spectrometer for studying gas-phase ion reactivity have been illustrated in several publications from these laboratories (32–35). The spectrometer operates with a water-cooled 9 in. (1 in. = 25.4 mm) electromagnet that is normally set at 1.0 T and contains a ~15.6 cm^3 cubic cell with center holes drilled on both transmitter plates that allow for laser light to go through the cell. The vacuum chamber housing the ICR cell is provided with two opposing ZnSe windows that act as entry and exit ports for IR laser radiation.

$Ti(O\text{-}i\text{-}Pr)_4$ (Strem Chemicals, Newburyport, Massachusetts) was handled in an inert atmosphere and introduced in the spectrometer through an inlet system and high vacuum tubing leading to the ICR cell heated to about 100 °C. Volatile impurities and free *i*-PrOH were removed by repeated freeze–pump–thaw cycles. Typical times for seasoning the vacuum system and obtaining good quality and reproducible spectra (free of *i*-PrOH) were in the order of 4 h. The partial pressures of $Ti(O\text{-}i\text{-}Pr)_4$ used in this work were in the range of (2–6.5) × 10^{-8} Torr (1 Torr = 133.3224 Pa) as measured by an ion gauge located just before the turbomolecular pump.



Positive ions were generated by 21 eV electron ionization during a 50 ms electron beam pulse. The subsequent ion–molecule reactions were studied by isolating the ion of interest through a combination of single frequency and swept frequency ejection pulses, and by varying the trapping time prior to ion detection. In the case of Ti-containing ions, the isolation process retained the full Ti isotopic composition.

Negative ion–molecule reactions were investigated following the formation of fluoride ions by electron impact on NF_3 (Pennwalt Ozark-Mahoning, Folcroft, Pennsylvania) with 80 ms pulses at pressures around 3.8 × 10^{-8} Torr (ion gauge reading). The electron energy was maintained at 1.5 eV and the trapping voltage at –1.9 V. A radio-frequency field of ~7 MHz was applied to one of the trapping plates during ~140 ms to eject trapped thermal electrons from the cell. $Ti(O\text{-}i\text{-}Pr)_4$ was then introduced in the cell to a final pressure of 9 × 10^{-8} Torr. Under these conditions, the fluoride ions react completely in less than 2 s. At these electron energies, no negative ions were observed to originate directly from neat $Ti(O\text{-}i\text{-}Pr)_4$.



Infrared multiphoton dissociation experiments were carried out after selective isolation of the ion of interest. In the case of the stepwise photodissociation experiments, each primary photoproduct was reisolated after ~300 ms of irradiation time. A grating tunable CW CO_2 laser (model 48G-1, Synrad, Mukilteo, Washington) was used as the IR source in the multiphoton dissociation experiments. The laser was typically operated on the P(20) line of the 10.6 μ band at 944 cm^{-1}. Varying the width of a 10 kHz modulation pulse from a Hewlett-Packard pulse generator allowed for external control of the laser power level. The laser power measured at the exit window of the vacuum system of the spectrometer was typically 1–3 W. An electromechanical shutter placed in front of the laser was used to control the irradiation time, and a pulse from the IonSpec data system determined the

trigger and aperture times of the shutter. Sequential IRMPD can be studied conveniently with this arrangement by using several laser pulses programmed for different delay times. This arrangement is similar to a procedure previously described in the literature (36).

Results and discussion

Mass spectrum of Ti(O-*i*-Pr)$_4$ and positive ion–molecule reactions

Figure 1 shows the positive ion mass spectrum of Ti(O-*i*-Pr)$_4$ obtained in our FT-ICR at 21 eV, trapping time of 70 ms, and a pressure of 6×10^{-8} Torr. This spectrum reveals essentially a single fragment ion, namely (*i*-PrO)$_3$Ti-O$^+$=CHMe, with its cluster of Ti isotopic peaks centered at *m*/*z* 269 corresponding to the ion containing the most abundant ^{48}Ti isotope. At these short trapping times, the protonated species, [Ti(O-*i*-Pr)$_4$]H$^+$ (*m*/*z* 285 for the ^{48}Ti ion), is already noticeable and results from an ion–molecule reaction of the fragment ion with the parent molecule. From the isotopic distribution for the protonated species, it is unclear whether Ti(O-*i*-Pr)$_4$ yields traces of the molecular ion. However, the present mass spectrum yields unequivocal evidence of monomeric Ti(O-*i*-Pr)$_4$ in the gas phase and differs significantly from the polynuclear Ti-containing fragment ions observed in the desorption chemical ionization mass spectrum (23) and the polycondensation ions revealed in the ESI spectrum of Ti(O-*i*-Pr)$_4$ (24).

An interesting observation of the mass spectrum of Ti(O-*i*-Pr)$_4$ obtained by electron ionization is the fact that the fragment ion originates from the cleavage of a carbon–carbon bond. This is quite unlike the case observed in the mass spectrum of the group 14 (E = Si, Ge, Sn) derivatives where the preferential cleavage always occurs on an E—L (L = ligand) bond to give rise to very stable EL$_3^+$ ions (31).

Two ion–molecule reactions are observed to occur upon isolation of the (*i*-PrO)$_3$Ti-O$^+$=C(H)Me ion as shown in Scheme 1. The most important one leads to protonated Ti(O-*i*-Pr)$_4$, and the second one to a condensation product of *m*/*z* 495 for the isotopomer containing ^{48}Ti$_2$. The condensation product ((*i*-PrO)$_3$Ti-O$^+$(Et)-Ti(O-*i*-Pr)$_3$) results from an addition–elimination reaction in which neutral Me$_2$CO is presumably expelled. The mechanism shown in Scheme 1 provides a rationale for the elimination of acetone, but no further evidence is available to favor this neutral product over the isomeric EtCHO.

The protonated species ([Ti(O-*i*-Pr)$_4$]H$^+$) undergoes further reaction with the parent molecule to yield a nucleophilic

Scheme 2.

$$[(^{i}PrO)_4Ti]H^+ + (^{i}PrO)_4Ti \rightarrow [(^{i}PrO)_3TiO(^{i}Pr)\cdots Ti^+(O^{i}Pr)_3\cdots(^{i}PrOH)] \rightarrow (^{i}PrO)_3TiO^+(^{i}Pr)Ti(O^{i}Pr)_3 + {}^{i}PrOH$$

displacement reaction (Scheme 2) to yield the putative ion $(i\text{-PrO})_3\text{Ti-O}^+(i\text{-Pr})\text{-Ti(O-}i\text{-Pr})_3$ for which the most intense isotopic peak corresponds to *m/z* 509. No further reactions are observed at longer reaction times, a fact that is consistent with the proposed structures for the *m/z* 509 and 495 ions.

The positive ion chemistry of the $(i\text{-PrO})_3\text{Ti-O}^+\text{=CHMe}$ ion with its parent substrate, as well as the secondary reaction of $[\text{Ti(O-}i\text{-Pr})_4]H^+$, bear strong resemblance to the ion chemistry previously reported for Si(OEt)_4 (25). In the Si case, the main fragment ion ($(\text{EtO})_3\text{Si-O}^+\text{=CH}_2$) was shown to react with the parent neutral to yield the corresponding protonated Si(OEt)_4 and $(\text{EtO})_3\text{Si-O}^+\text{(Me)-Si(OEt)}_3$. Likewise, the $[\text{Si(OEt)}_4]H^+$ ion was found to undergo a displacement reaction similar to that outlined in Scheme 2.

Negative ion–molecule reactions

One of our main interests in the titanium alkoxides was to explore nucleophilic type reactions to establish the relative reactivity of the Ti center compared with that of an S_N2 reaction at the C centers of the alkoxide groups. Fluoride was chosen as our model reagent because it is a strong gas-phase nucleophile and it is a weaker base than the simple alkoxides. Some early work by Nibbering and co-workers (37) reported the ion–molecule reactions of $\text{EtO}^-\text{(HOMe)}$ with $\text{Ti(O-}i\text{-Pr})_4$ and showed that reactions proceed exclusively and rapidly by ligand exchange to yield the solvated alkoxide ions $i\text{-PrO}^-\text{(HOMe)}$ and $i\text{-PrO}^-\text{(HOEt)}$. The mechanistic details of these reactions were not explored, and the possible participation of a pentacoordinated Ti adduct was not observed experimentally.

Reaction of F^- with $\text{Ti(O-}i\text{-Pr})_4$ under our experimental conditions proceeds readily by addition to form the pentacoordinated Ti species (*m/z* 303 for the ^{48}Ti isotopomer) as shown in eq. [6].

$$[6] \qquad F^- + \text{Ti(O-}i\text{-Pr})_4 \rightarrow [\text{FTi(O-}i\text{-Pr})_4]^-$$

This reaction leading to a hypervalent Ti adduct is analogous to what has been observed as the main reaction channel in the alkoxide derivatives of Si (27) and Ge (28) and confirms the fact that the Ti center is much more prone to nucleophilic attack than the C center. This pentacoordinated Ti anion is expected to have a near trigonal bipyramid geometry with the fluorine occupying an apical position in the most stable isomer. This proposed geometry is based on the calculations reported for related hypervalent species such as FSi(OMe)_4^- (35), FGe(OMe)_4^- (28), and SiCl_4F^- and GeCl_4F^- (38). These calculations and earlier studies on hypervalent Si anions (39) suggest that the electronegative fluorine ligand prefers the apical position in these trigonal bipyramid structures.

The fluoride binding energy of $\text{Ti(O-}i\text{-Pr})_4$ is a matter of some interest because there is little thermochemical data for hypervalent species of Ti. For comparison purposes, it is interesting to point out that the relative fluoride affinity of TiF_4 has been established on the basis of gas-phase ionic equilibrium reactions studied by high-temperature mass spectrometry (40, 41). Because of the uncertainties in the absolute values for the fluoride affinities of the reference substrates used in the experiments, namely AlF_3 and VF_3, the $\text{TiF}_4\cdots\text{F}^-$ can be estimated to be larger than 80 kcal mol^{-1} (1 cal = 4.184 J). The fluoride affinity of $\text{Ti(O-}i\text{-Pr})_4$ is probably somewhat less than this value because the fluoride affinity has been found to increase with a larger number of very electronegative substituents (like F) in species like Si and Ge (38, 42). Our previous ab initio calculations estimated a fluoride affinity of 60 kcal mol^{-1} for the prototype Ge(OH)_4 substrate, and of 79 kcal mol^{-1} for GeF_4 (28). Thus, these numbers suggest that the fluoride affinity of $\text{Ti(O-}i\text{-Pr})_4$ is very high and very likely in excess of 50 kcal mol^{-1}.

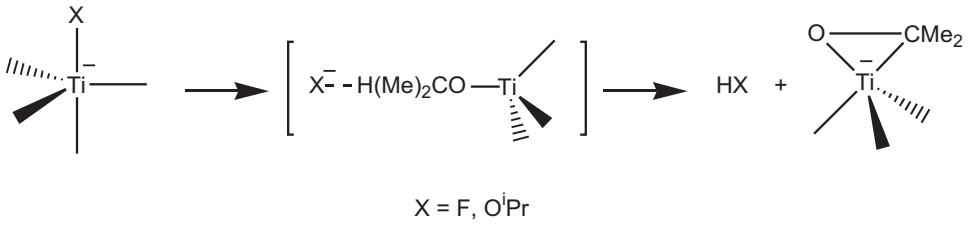
Scheme 3.

$$[\text{FTi(O}^{i}\text{Pr)}_4]^- + n\text{h}\upsilon_{IR} \xrightarrow{80\%} \text{HF} + [(\text{CMe}_2\text{O})\text{Ti(O}^{i}\text{Pr)}_3]^-$$

$$[\text{FTi(O}^{i}\text{Pr)}_4]^- + n\text{h}\upsilon_{IR} \xrightarrow{20\%} {}^{i}\text{PrOH} + [\text{FTi(OCMe}_2)(\text{O}^{i}\text{Pr)}_2]^-$$

Dissociation of $[\text{FTi(O-}i\text{-Pr})_4]^-$

Further information on structural features of the pentacoordinated $[\text{FTi(O-}i\text{-Pr})_4]^-$ ion can be gained from dissociation experiments as recently illustrated for a number of silane adducts (43). This is particularly true in the present case because no competing reactions are observed with respect to direct addition of the nucleophile (rxn. [6]). As in previous studies from these laboratories (26, 28), we chose to study the dissociation induced by IR multiphoton dissociation (IRMPD). The use of a low power CW CO_2 laser in IRMPD is a very soft technique for ion dissociation (44, 45) that can be particularly useful when the ion of interest has a strong absorption band that overlaps with the operating range of the laser. Neutral $\text{Ti(O-}i\text{-Pr})_4$ displays a very strong absorption in the IR at 988 cm^{-1} that is downshifted to 940 cm^{-1} for associated $\text{Ti(O-}i\text{-Pr})_4$ species (46). The strong absorption in this region has been identified to both the C-O and Ti-O stretches, and thus provides a convenient feature for vibrational multiphoton excitation.



Initial IR multiphoton dissociation experiments of the isolated $[\text{FTi(O-}i\text{-Pr})_4]^-$ ion with our CO_2 laser revealed the facile formation of two primary dissociation products as shown in Scheme 3 with their respective yields.

There are two interesting aspects about the results of these experiments: (*a*) the nature of the product ions and the mechanism of their formation and (*b*) the energetics associated with the processes. Scheme 4 outlines a simple mechanism that can account for the dissociation pathways observed. In this scheme, progressive vibrational excitation is envisioned to loosen up the pentacoordinated complex to yield either an F^- or an $i\text{-PrO}^-$ ion–molecule complex followed by proton abstraction by the nascent base to yield the photoproducts shown in Scheme 4.

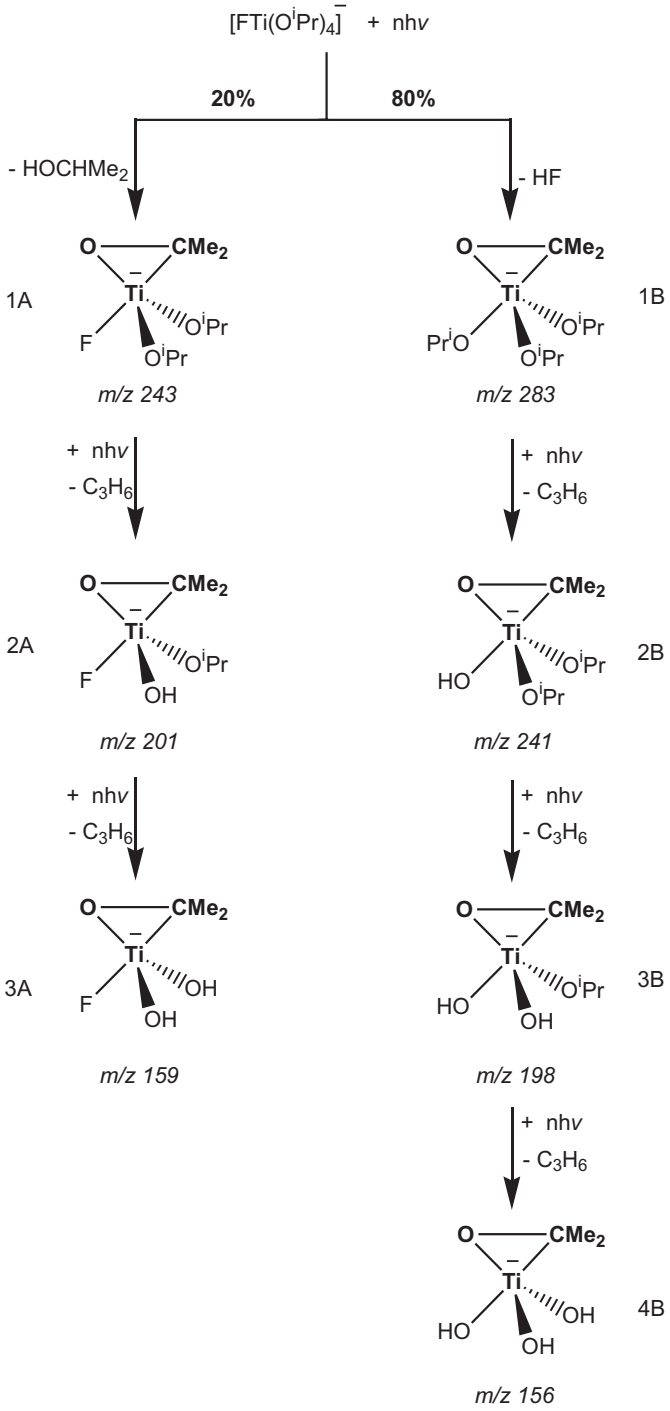
The resulting product ions are assumed to take the titanaoxirane structure shown in Scheme 4 rather than an

© 2005 NRC Canada

Scheme 4.

open structure corresponding to a carbanion or a substituted alkoxide ion. This assumption is based on our previous work on the related $FSi(OMe)_2(cyc\text{-}OCH_2)^-$ species (47) for which the cyclic oxirane structure was found to be more stable than either the carbanion or alkoxide form. Although the characterization of titanaoxiranes has been elusive, these species have been claimed to be stable and key intermediates in titanium-mediated reductive coupling reactions (48).

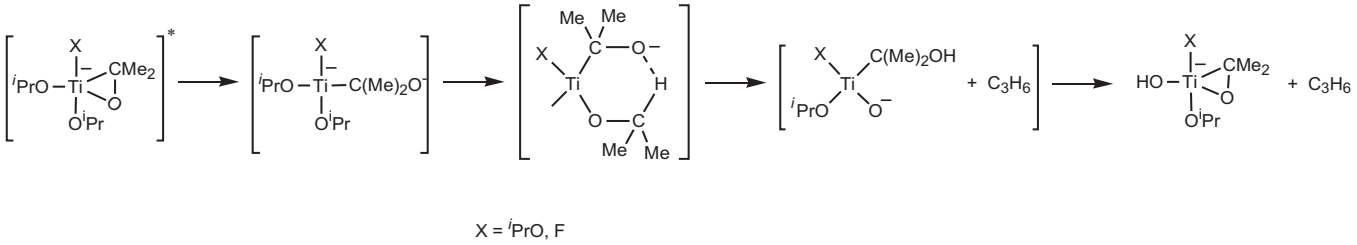
The second interesting aspect of Scheme 4 is the photophysical and energetic aspects of the two dissociation channels. IRMPD processes promoted by low power CW CO_2 lasers typically occur when the stepwise IR photon absorption produces ions with internal energies above their dissociation threshold. For "small" ions, dissociation typically takes place through the lowest energy channel because further vibrational pumping is normally slower than the unimolecular dissociation rate constant. Thus, and as a rule of thumb for these cases, competitive reactions can be promoted by CW CO_2 lasers in the special case where activation energies for two or more reaction channels differ at most by the energy of a single IR photon from the laser (~3 kcal mol^{-1} in this case). Thus, we can conclude that the activation energies for the two processes in Scheme 4 are probably within 3 kcal mol^{-1} of each other, and that elimination of HF is the lowest dissociation channel.



Each one of the primary photoproducts shown in Scheme 4 was further investigated by isolating these ions typically after 300–400 ms of laser irradiation time. A full range of sequential dissociation processes induced by IR multiphoton excitation was observed for both photoproducts as shown in full detail in Scheme 5 with the ions identified by the *m*/*z* value of the ^{48}Ti isotopomer.

The sequential loss of propene in the consecutive IRMPD processes is an interesting case in which the ions progressively "peel off" an olefin. The mechanism for these consecutive elimination processes is envisioned to proceed initially by ring opening of the titanaoxirane moiety followed by proton abstraction. Elimination of propene is then followed by ring closure again to yield a titanaoxirane species, $[(i\text{-}PrO)_2Ti(cyc\text{-}CMe_2O)OH]^-$, that is expected to be more stable than the open $(i\text{-}PrO)_2Ti(CMe_2OH)O^-$ species. Scheme 6 illustrates the proposed mechanism for the representative case of **1A** forming **2A**, and likewise **1B** leading to **2B**.

It is clear that this same mechanism can account for all the secondary dissociation processes. The fact that further dissociation is not observed for ions **3A** and **4B** is a strong indication that the ions retain a titanaoxirane structure, and thus no *i*-PrO groups are left to promote olefin elimination.



The anions produced in the sequential IRMPD processes correspond to different types of titanols. These species are of

Scheme 5.

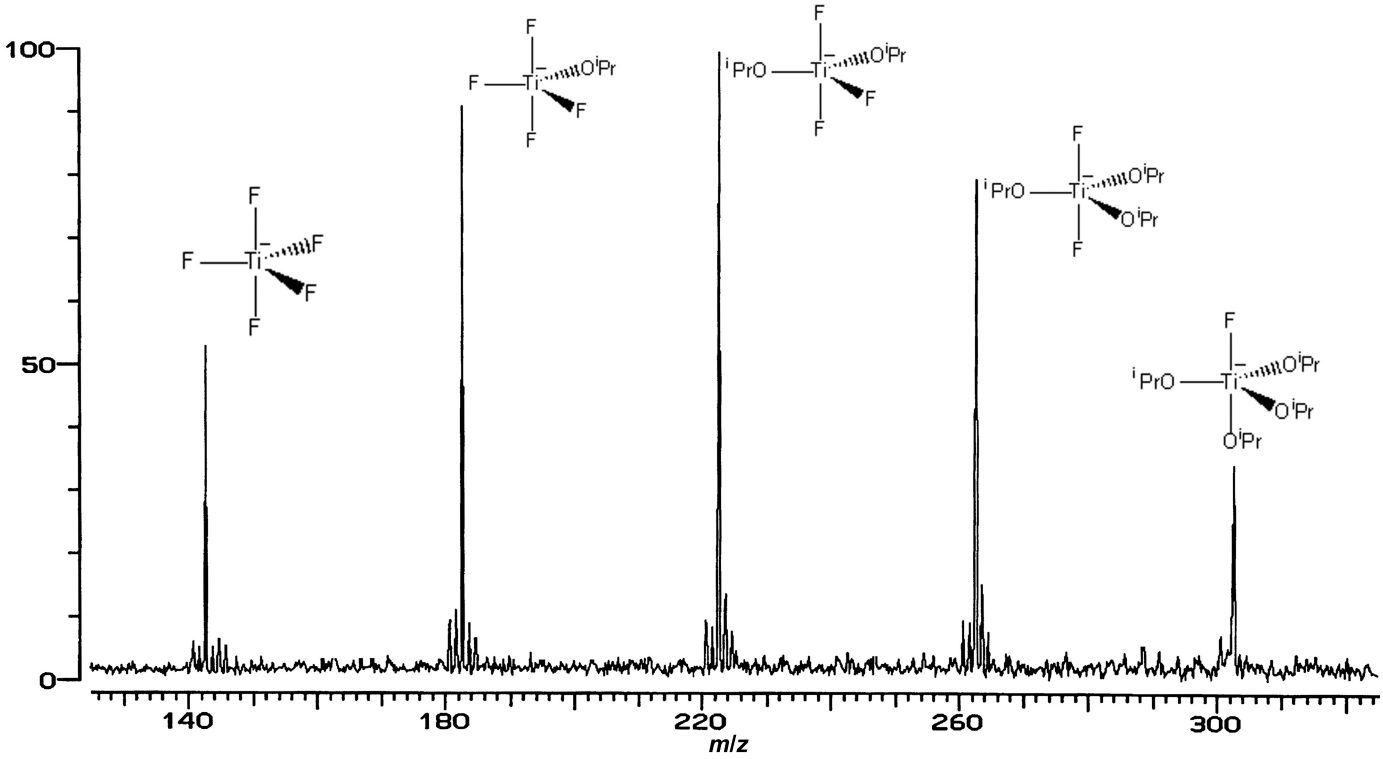

Scheme 6.

Scheme 7.

Fig. 2. FT-ICR spectrum obtained after a 2 s reaction between $[FTi(O\text{-}i\text{-}Pr)_4]^-$ and 1×10^{-8} Torr (1 Torr = 133.3224 Pa) of BF_3, showing progressive substitution of the alkoxy groups by fluorine.

great interest because titanols are intermediates in the reactions that lead to the formation of TiO_2 nanoparticles (12). Attempts to bracket the acidity of these species were not successful because of the difficulties in finding neutral substrates of well-known gas-phase acidities that could be easily introduced via a pulsed valve in our system. The use of a pulsed valve for these experiments is necessary because of the characteristics of our cell and spectrometer. However, work is under way to estimate the acidity of these species by theoretical calculations using the general methodology recently illustrated for the gas-phase acidity of tetrahedral oxyacids (49) to compare with those obtained for related silanols (50).

Reaction of $[FTi(O\text{-}i\text{-}Pr)_4]^-$ with BF_3

It has long been known that alkoxy ligands in $Ti(OR)_4$ undergo rapid exchange with halides from a Lewis acid such as $TiCl_4$ (51). A more recent investigation of these exchange reactions suggests that these reactions proceed via an oxo (from the O-*i*-Pr ligand) bridge between the two Ti centers followed by a halide migration (52). Alkoxy–fluoride exchanges were reported to occur in our previous studies of pentacoordinated Si (47) and Ge (28) anions with BF_3 acting as the Lewis acid. We therefore decided to investigate the behavior of the $[FTi(O\text{-}i\text{-}Pr)_4]^-$ ion in similar reactions.

$[FTi(O\text{-}i\text{-}Pr)_4]^-$ was found to undergo rapid exchange reactions with BF_3 as shown in rxn. [7].

[7] $$[FTi(O\text{-}i\text{-}Pr)_4]^- + BF_3 \rightarrow [F_2Ti(O\text{-}i\text{-}Pr)_3]^- + i\text{-}PrOBF_2$$

These exchange reactions proceed rapidly for all the different $[F_{1+n}Ti(O\text{-}i\text{-}Pr)_{4-n}]^-$ species (with $n = 0$–4), and Fig. 2 reproduces the spectrum obtained after 2 s of reaction where

© 2005 NRC Canada

all the different exchange species are present, leading eventually to the formation of TiF_5^-. The proposed mechanism for these reactions involves initial transfer of *i*-PrO^- to BF_3 in the collision complex followed by F^- transfer from the B center to the Ti center (see Scheme 7).

This exchange reaction is driven by the increasing stability of the Ti hypervalent species upon fluorine substitution.

Conclusions

We have shown that the 21 eV electron ionization mass spectrum of Ti(O-*i*-Pr)$_4$ yields a single fragment ion and that this mass spectrum is consistent with a monomeric Ti species in the gas phase. The monomeric character is also reinforced by the ion–molecule reactions of the (*i*-PrO)$_3$Ti-O$^+$=C(H)Me fragment ion. Furthermore, the addition–elimination reaction of the fragment ion and the secondary reaction of protonated Ti(O-*i*-Pr)$_4$ are identical to those observed in Si(OEt)$_4$, and indicate strong similarities between the ion chemistry of silicon and titanium alkoxides.

The pentacoordinated [FTi(O-*i*-Pr)$_4$]$^-$ ion has been shown to be an interesting starting species for the synthesis of a number of titanol ions by sequential IR multiphoton dissocation processes. In fact, this represents a facile approach for generating species that are of great interest in sol-gel processes and will be further investigated in the future. Furthermore, these alkoxy-containing hypervalent Ti complexes have been shown to undergo a number of alkoxide–fluoride exchanges in the presence of a suitable Lewis acid and open up new ways of generating a variety of pentacoordinated Ti anions in the gas phase.

A collisionally activated dissociation (CAD) and computational investigation of doubly and singly charged DMSO complexes of Cu^{2+} [1]

John A. Stone, Timothy Su, and Dragic Vukomanovic

Abstract: The singly and doubly charged Cu(II)–DMSO complexes formed by electrospray have been examined by CAD and computation. The CAD spectra were obtained as a function of collision energy. The doubly charged ions, $[Cu(DMSO)_n]^{2+}$, were observed only for $n \geq 2$. For $n = 3$, dissociation leads mainly to $[Cu(DMSO)_2]^+ + DMSO^+$, with only a trace of $[Cu(DMSO)_2]^{2+}$. Although $[Cu(DMSO)]^{2+}$ was never detected, computation shows that the $n = 1$ complex exists in a potential well. Loss of $DMSO^+$ is computed to be exothermic for $n = 1$–3, the exothermicity decreasing as n increases. The singly charged complexes in the ESI spectra were $[CuX(DMSO)_n]^+$ (X = Cl, Br, NO_3, HSO_4, $n = 1$ or 2). The CAD spectra showed competition between electron transfer from anion to metal followed by loss of X and loss of $DMSO^+$. Experiment and computation show that for $[CuX(DMSO)]^+$, loss of X is the preferred decomposition at low collision energy. NBO analysis shows that electron transfer to Cu from DMSO decreases in $[Cu(DMSO)_n]^{2+}$ as n increases, the bonding becoming more electrostatic and less covalent. In $[CuX(DMSO)_n]^+$, the negative charge on X is much less than unity with most of the difference appearing on the DMSO ligand(s).

Key words: copper–DMSO complexes, electrospray, CAD, structures.

Résumé : Faisant appel à des calculs théoriques et aux spectres de décomposition par activation collisonnelle (DAC), on a étudié les complexes Cu(II)–DMSO portant une ou deux charges qui se forment par électronébulisation. On n'observe la présence d'ions doublement chargés, $[Cu(DMSO)_n]^{2+}$ qui si $n \geq 2$. Pour $n = 3$, la dissociation conduit principalement à la formation de $[Cu(DMSO)_2]^+ + DMSO^+$ et à seulement une trace de $[Cu(DMSO)_2]^{2+}$. Même si la présence de $[Cu(DMSO)_2]^{2+}$ n'a jamais été détectée, les calculs montrent que le complexe avec $n = 1$ se trouverait dans un puits de potentiel. On a calculé que la perte de $DMSO^+$ est exothermique pour $n = 1$ à 3 et que le caractère exothermique diminue avec une augmentation de la valeur de n. Dans les spectres de masse avec électronébulisation ionique (ENI), la structure générale des complexes ne portant qu'une charge est $[CuX(DMSO)_n]^+$ dans laquelle X = Cl, Br, NO_3, HSO_4 et $n = 1$ ou 2. Les spectres de décomposition par activation collisionnelle montrent qu'il existe une compétition entre le transfert d'électron de l'anion au métal, suivi d'une perte de X et la perte de $DMSO^+$. Les données expérimentales et les calculs montrent que pour $[CuX(DMSO)]^+$, la perte de X est la décomposition privilégiée à de faibles énergies de collision. Une analyse de l'orbitale de liaison naturelle (OLN) montre que le transfert d'électron du DMSO au cuivre diminue dans le $[Cu(DMSO)_n]^{2+}$ quand la valeur de n augmente alors que la liaison devient plus électrostatique et moins covalente. Dans le $[CuX(DMSO)_n]^+$, la charge négative sur X est de beaucoup inférieure à l'unité et presque toute la différence apparaît sur le(s) ligand(s) DMSO.

Mots clés : complexes cuivre–DMSO, électronébulisation, décomposition par activation collisionnelle (DAC), structures.

[Traduit par la Rédaction]

Introduction

Liquid DMSO is an excellent solvent for metal cations but a poor solvent for anions. The oxygen atom carries a negative charge while the methyl groups are positive so that coordination with a metal cation is through oxygen, while the interaction with an anion is with the methyl groups (1, 2). Since DMSO is a valuable and widely used solvent, it is not surprising that its solvation properties on the microscale in the gas phase have been the subject of study by mass spectrometry. High-pressure mass spectrometry showed that the enthalpy of association of a singly charged metal cation with DMSO was approximately twice that of a singly charged anion of the same size (1, 3). The advent of electospray ioniza-

tion (ESI) allowed the facile formation of DMSO complexes of multiply charged metal cations. Complexes of metal di- and tri-cations are readily formed by ESI using neat DMSO, or aqueous solutions containing DMSO, together with a low concentration of an appropriate metal salt (4–11). When water comprises the majority of the solvent, the complexes $[M(DMSO)_n]^{2+}$ rather than hydrated cations such as $[M(H_2O)_n]^{2+}$ and $[M(H_2O)_m(DMSO)_n]^{2+}$ may be obtained even though the DMSO is at a concentration only in the millimolar range. This can usually be accomplished by a judicious selection of low electric fields in the intermediate pressure region between cone and lens (9). $[M(DMSO)_n]^{2+}$ (n = 2 or 3) in such spectra is usually accompanied by the ions $[M(CH_3SO)(DMSO)_{n-1}]^{2+}$ formed by collisionally activated dissociation (CAD) in the source (8, 9, 12).

[1] $$[M(DMSO)_n]^{2+} \rightarrow [M(CH_3SO)(DMSO)_{n-1}]^{2+} + CH_3$$

Shvartsburg and Wilkes (8) found that of all the DMSO complexes of the divalent metals that they studied, only those of Cu^{2+} could definitely be said not to show loss of methyl by eq. [1]. In addition only a trace of $[Cu(DMSO)_2]^{2+}$ was found, but no $[Cu(DMSO)]^{2+}$. The low intensity and (or) absence of these two ions and the absence of methyl loss was attributed to the very high second ionization energy of Cu (20.3 eV) favoring charge transfer to the DMSO ligand and subsequent Coulombic explosion (eq. [2]) rather than methyl loss from the higher complexes, the usual precursors of such ions.

[2] $$[M(DMSO)_n]^{2+} \rightarrow [M(DMSO)_{n-1}]^{+} + DMSO^{+}$$

Verification of this unique behavior of copper and a search for a possible explanation is warranted and in this paper we report on a more extended study of the ions observed in the ESI spectra of aqueous solutions containing cupric salts and DMSO. The Cu(II)–DMSO complexes observed were not only the doubly charged $[Cu(DMSO)_n]^{2+}$, but also the singly charged $[Cu(X)(DMSO)_n]^{+}$, where X^- (NO_3^-, Cl^-, Br^-, HSO_4^-) is the counterion of the cupric salt. We have determined the dependence of product formation on the collision energy in the CAD of mass selected ions. The results of ab initio calculations to determine ion structures and the energetics of ligand association are found to be consistent with the energy dependence of the CAD spectra.

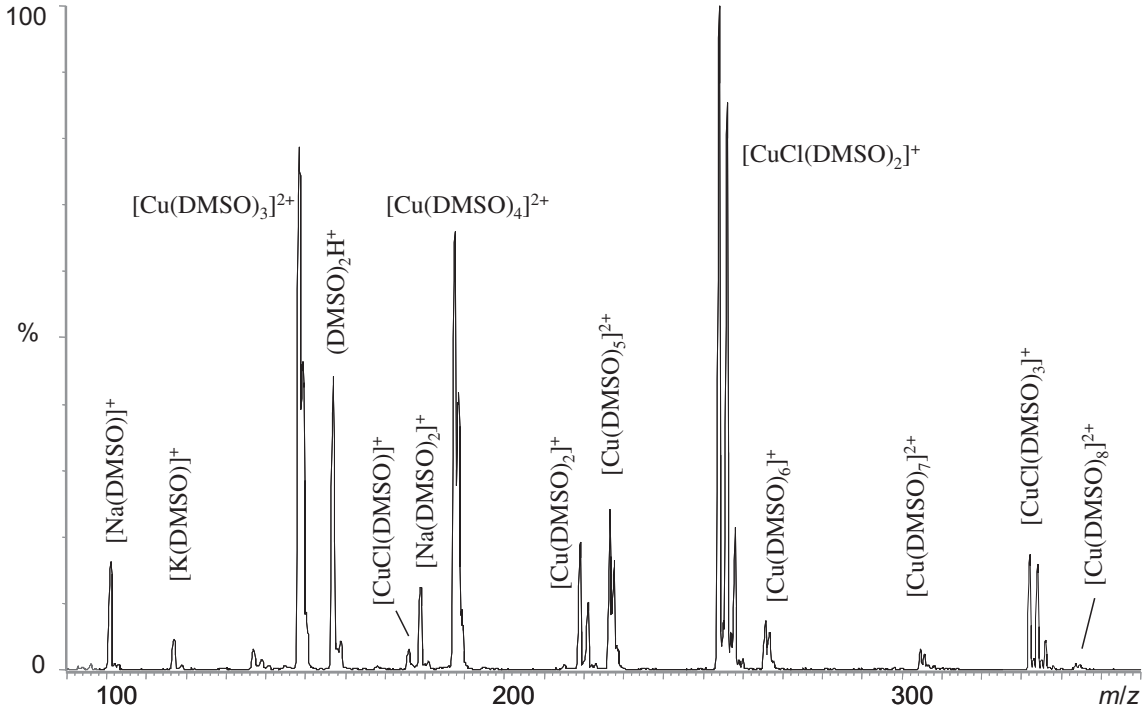
Experimental

ESI spectra were obtained using a triple sector mass spectrometer (quadrupole/hexapole/quadrupole, Quattro, Fisons, UK) in the manner previously described (9, 13–15). Aqueous solutions containing 1.0×10^{-2} mol/L DMSO or DMSO-d_6 and 1.0×10^{-3} mol/L of a cupric salt (nitrate, chloride, bromide, or sulfate) were infused using a syringe pump at a flow rate of 5 μL min^{-1}. The metal capillary potential, optimized for the various positive ion spectra of interest, was in the range +2.5 to +3.0 kV, and the counter electrode was in the range +50 to +100 V. Optimization for maximum intensity of individual ions depended on the adjustment of the electric field in the intermediate pressure region of the source between the sampling cone and the grounded skimmer lens. The temperature of the desolvation chamber through which dry nitrogen flowed was 80 °C.

CAD spectra were obtained using argon as the collision gas. The energies of the incident ions were determined by the potential difference between the grounded skimmer lens and the collision cell. The potential of the latter (V_{lab}) was used in the range 0 to –40 V with respect to ground. Collision energies are quoted as centre of mass (c of m) energies determined as

$$E_{cm} = -V_{lab}\left(\frac{m_{ion}M_{argon}}{m_{ion} + M_{argon}}\right)$$

Computations were carried out using the Gaussian 03W suite of programs (16). The calculations required for the large complexes and the limited available computing capacity enforced the use of the density functional method at the B3LYP/6-31+G(d,p) level for both optimization and energy calculations. No negative frequencies were present in any of the optimized structures. No scaling factors were employed in calculating the energies (17). The atomic charges were calculated with the natural bond orbital (NBO) program that is a constituent part of the Gaussian G03W suite of programs.



Results and discussion

Figure 1 shows a typical ES spectrum obtained with a cupric ion – DMSO aqueous solution, in this case using $CuCl_2$ as the source of the cation. The cone voltage was 22 V. The isotopic patterns of copper (^{63}Cu:^{65}Cu = 60:31) and chlorine (^{35}Cl:^{37}Cl = 75:25) aid peak identification, and doubly and singly charged ions are distinguished by the respective 1 and 2 m/z unit peak separation in the isotopic clusters. The use of DMSO-d_6 and CAD experiments provided additional confirmation. Two main series of peaks, both due to Cu(II) complexes, are present, viz. the doubly charged $[Cu(DMSO)_n]^{2+}$ with n ranging from 3 to 8, and the singly charged $[CuCl(DMSO)_n]^{+}$ with n in the range 1 to 3. No $[Cu(DMSO)_2]^{2+}$ or $[Cu(DMSO)]^{2+}$ is observed in the spectrum, but higher complexes of very low intensity containing as many as 11 DMSO molecules were observed that are beyond the m/z scale of the figure. The only other copper-containing peak of significance is at m/z 219 owing to the Cu(I) complex, $[Cu(DMSO)_2]^{+}$. When $CuBr_2$ replaced $CuCl_2$ in the electrosprayed solution, the only difference in the spectrum was the presence of $[CuBr(DMSO)_n]^{+}$ rather than $[CuCl(DMSO)_n]^{+}$. Similarly $Cu(NO_3)_2$ formed $[CuNO_3(DMSO)_n]^{+}$ and $CuSO_4$ formed $[Cu(HSO_4)(DMSO)_n]^{+}$. It is noticeable that there are no ions with water as a ligand, even though the solvent in the infused solution was 99.9% water.

The two series of Cu(II) ions, $[Cu(DMSO)_n]^{2+}$ and $[CuX(DMSO)_n]^{+}$ (X = Cl, Br, NO_3, HSO_4), were collisionally activated and the resulting spectra were studied as a function of collision energy. The CAD spectra described in this paper were obtained at an argon collision gas pressure of $1.0 \pm 0.1 \times 10^{-4}$ Torr (1 Torr = 133.3224 Pa) in a 7 cm long hexapole collision cell. Even at this low pressure some ions may experience multiple collisions and product ions may also be collisionally activated and decompose (18). Two products that were present in many of the CAD sprectra of the doubly charged complexes were the Cu(I) ions

Fig. 1. ESI mass spectrum of an aqueous solution containing 1.0×10^{-3} mol/L $CuCl_2$ and 1.0×10^{-2} mol/L DMSO.

$[Cu(DMSO)_2]^+$ and $[Cu(DMSO)]^+$. The CAD spectra of these ions were therefore examined to assess the contributions from their dissociations to the product ions observed in other spectra. In the following sections the copper complexes and products that are shown in the figures are those containing ^{63}Cu, ^{32}S and where appropriate, ^{35}Cl. CAD spectra of other isotopomers were always obtained for conformation of ion identities.

CAD of $[Cu(DMSO)_2]^+$ and $[Cu(DMSO)]^+$

The ions formed as a function of collision energy from $[Cu(DMSO)_2]^+$ and $[Cu(DMSO)]^+$ are shown in Figs. 2*a* and 2*b*, respectively. $[Cu(DMSO)_2]^+$ has one major, $[Cu(DMSO)]^+$, and one minor, $[Cu(CH_3SO)(DMSO)]^+$, product at low collision energy.

[3] $[Cu(DMSO)_2]^+ \rightarrow [Cu(DMSO)]^+ + DMSO$

[4] $[Cu(DMSO)_2]^+ \rightarrow [Cu(CH_3SO)(DMSO)]^+ + CH_3$

Loss of methyl, as described by eq. [1] for multiply charged metal – DMSO complexes, is therefore not dependent on a high metal cation charge. The yield of $[Cu(CH_3SO)(DMSO)]^+$ shows little dependence on collision energy, but the apparent minimum at ~4.5 eV shows the possibility of two pathways for the reaction of eq. [4], one at low energy and one at high energy. The extremely low abundances of Cu^+ and $[Cu(CH_3SO)]^+$ that appear at the higher collision energies originate from the further decomposition of $[Cu(DMSO)]^+$, as demonstrated by its decline in relative abundance and by the CAD results in Fig. 2*b* for $[Cu(DMSO)]^+$. The very small yield of $CH_3SCH_2^+$ is observed for $[Cu(DMSO)_2]^+$ but not for $[Cu(DMSO)]^+$. $[Cu(DMSO)_2]^+$ is a very stable ion since even at 6 eV collision energy, only 10% has decomposed.

The major lowest energy process in the activated dissociation of $[Cu(DMSO)]^+$ is loss of methyl (eq. [5]), while at higher energies the product, $[Cu(CH_3SO)]^+$, decomposes further to either $Cu^+ + CH_3SO$ or $CH_3SO^+ + Cu$ (eqs. [6] and [7]).

[5] $[Cu(DMSO)]^+ \rightarrow [Cu(CH_3SO)]^+ + CH_3$

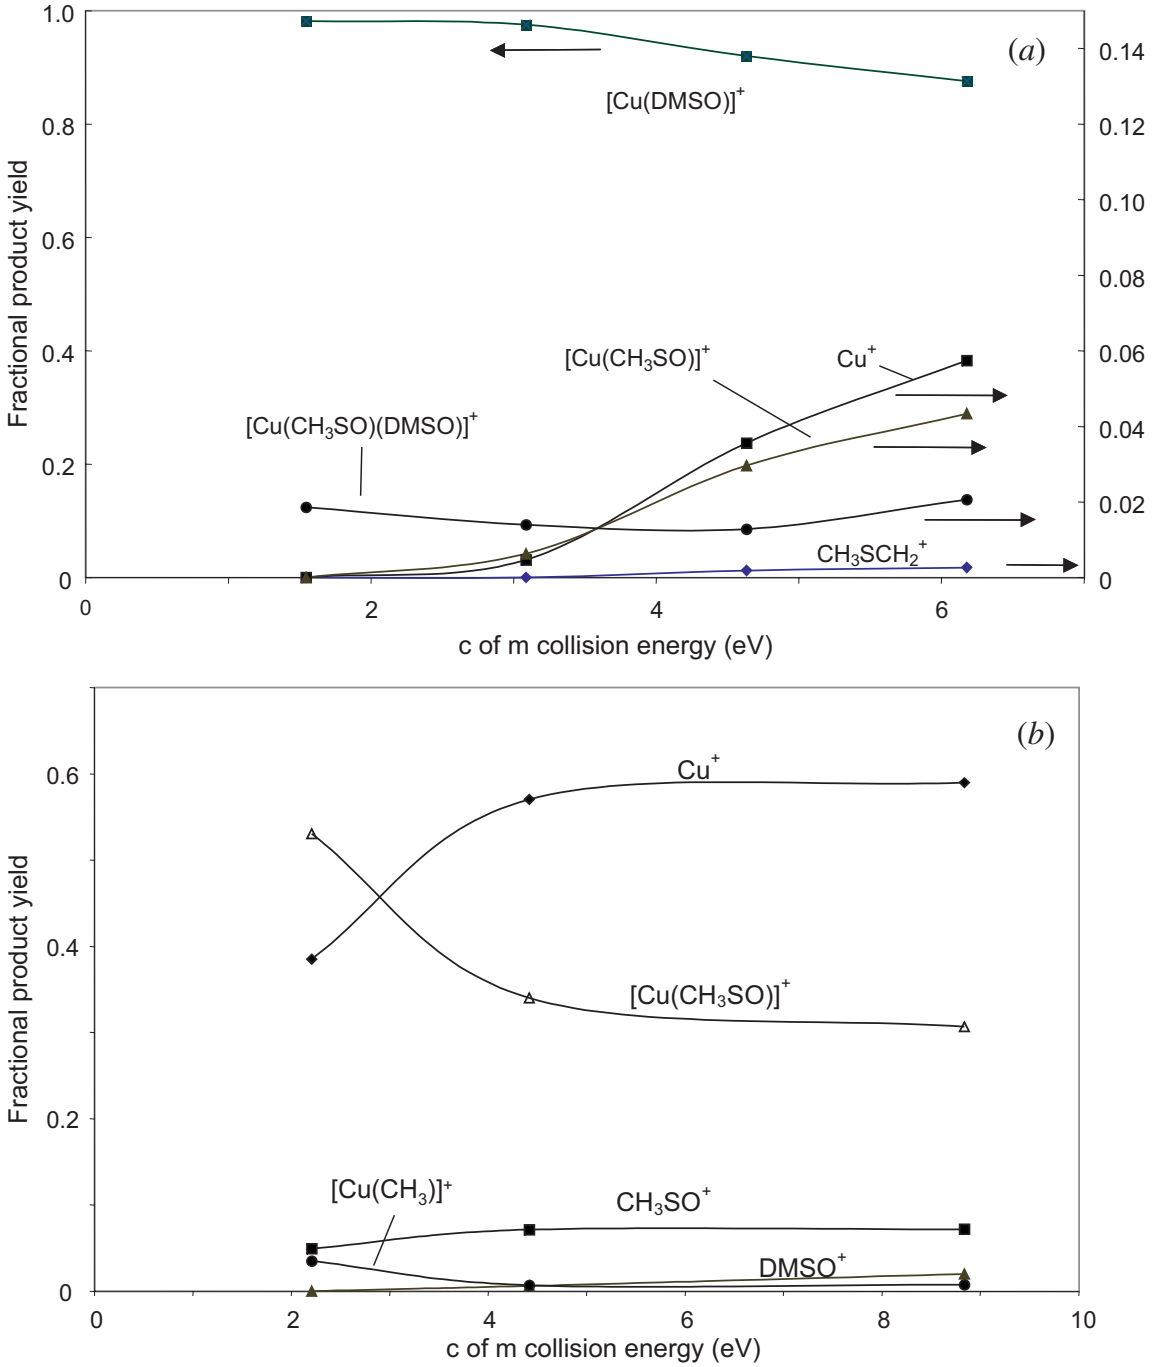
[6] $[Cu(CH_3SO)]^+ \rightarrow Cu^+ + CH_3SO$

[7] $[Cu(CH_3SO)]^+ \rightarrow Cu + CH_3SO^+$

The formation of $[Cu(CH_3)]^+$ (eq. [8]) at very low energy is competitive with the formation of CH_3SO^+, which is surprising since, as seen later, computation shows it as a high energy product.

[8] $[Cu(DMSO)]^+ \rightarrow [Cu(CH_3)]^+ + CH_3SO$

CAD of $[Cu(DMSO)_n]^{2+}$



Loss of one or more ligands with no loss of charge was the only CAD reaction for $[Cu(DMSO)_n]^{2+}$ complexes with $n \geq 4$. The CAD spectrum of $[Cu(DMSO\text{-}d_6)_4]^{2+}$, obtained at a collision energy of 0.1 eV, showed only the loss of DMSO (eq. [9]). In particular, in agreement with Shvartsburg and Wilkes (8), loss of methyl with retention of charge (eq. [1]) was not observed, and all other product ions observed at higher collision energies from $[Cu(DMSO)_n]^{2+}$ ($n \geq 4$) could be ascribed to the further decomposition of $[Cu(DMSO)_3]^{2+}$.

[9] $[Cu(DMSO)_4]^{2+} \rightarrow [Cu(DMSO)_3]^{2+} + DMSO$

The CAD spectrum of $[Cu(DMSO\text{-}d_6)_3]^{2+}$ (*m*/*z* 157.5), obtained at a collision energy of 4.5 eV, is shown in Fig. 3*a*. There is excellent agreement with the spectrum obtained by Shvartsburg and Wilkes (8) at the slightly higher energy of 4.74 eV. In particular, there was an extremely weak signal for $[Cu(DMSO\text{-}d_6)_2]^{2+}$ (*m*/*z* 115.5), which is too small to be

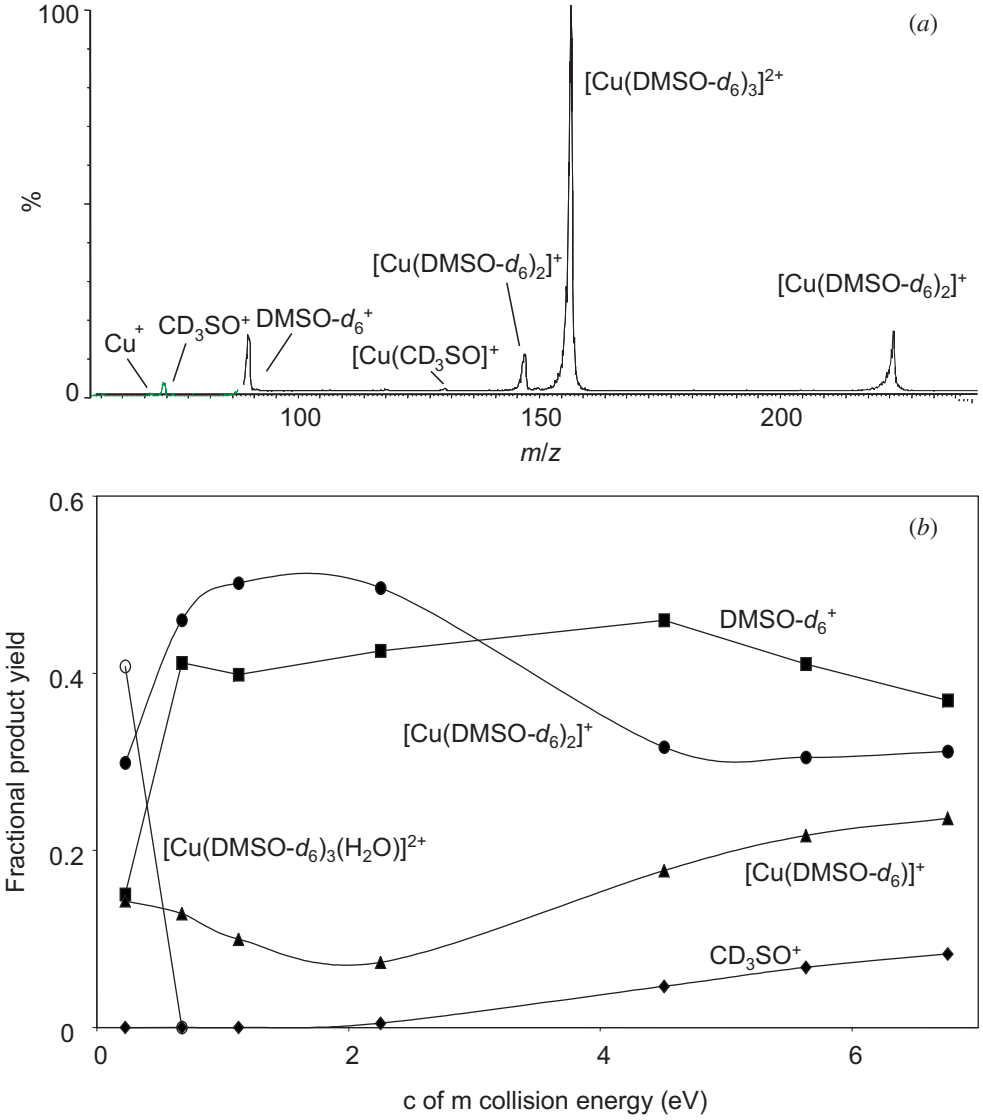
Fig. 2. Fractional product yields in the CAD spectra of (*a*) $[Cu(DMSO)_2]^+$ and (*b*) $[Cu(DMSO)]^+$ as a function of collision energy.



shown in the figure. The major products, $[Cu(DMSO\text{-}d_6)_2]^+$, $[Cu(DMSO\text{-}d_6)]^+$, and DMSO-d_6^+, are all singly charged. There are small yields of $[Cu(CD_3SO)]^+$, CD_3SO^+, and Cu^+. No $[Cu(DMSO\text{-}d_6)]^{2+}$ (*m*/*z* 73.5) is present in the spectrum and this ion was never observed in any CAD spectrum at any collision energy. Stace and co-workers (19), using the pick-up technique, an alternative method of producing gas-phase metal cation complexes, and a wide variety of N and O potential ligands, found no Cu^{2+} ions solvated by a single DMSO molecule either in the spectra or in the CAD spectra of the isolated higher solvates. The conclusion is that $[Cu(DMSO)]^{2+}$ is not experimentally observable in the gas phase with the present ESI technique. This does not mean that it is not a stable entity. As the initial doubts and final observation of $[Cu(H_2O)]^{2+}$ has demonstrated, it is unwise to make bold statements regarding the possibility or impossibility of the existence of a species (18–25). As shown later, calculation does suggests that the monoligated ion may be viable.

The evolution of the intensities of the major products from $[Cu(DMSO\text{-}d_6)_3]^{2+}$ as a function of collision energy is shown in Fig. 3*b*. The intensities of $[Cu(CD_3SO)]^+$, CD_3SO^+, and Cu^+ that were too small to quantitate can be ascribed to the further decomposition of the singly charged products $[Cu(DMSO\text{-}d_6)_n]^+$ (n = 1 or 2) as detailed earlier. At very low energy, background water adds to the precursor ion giv-

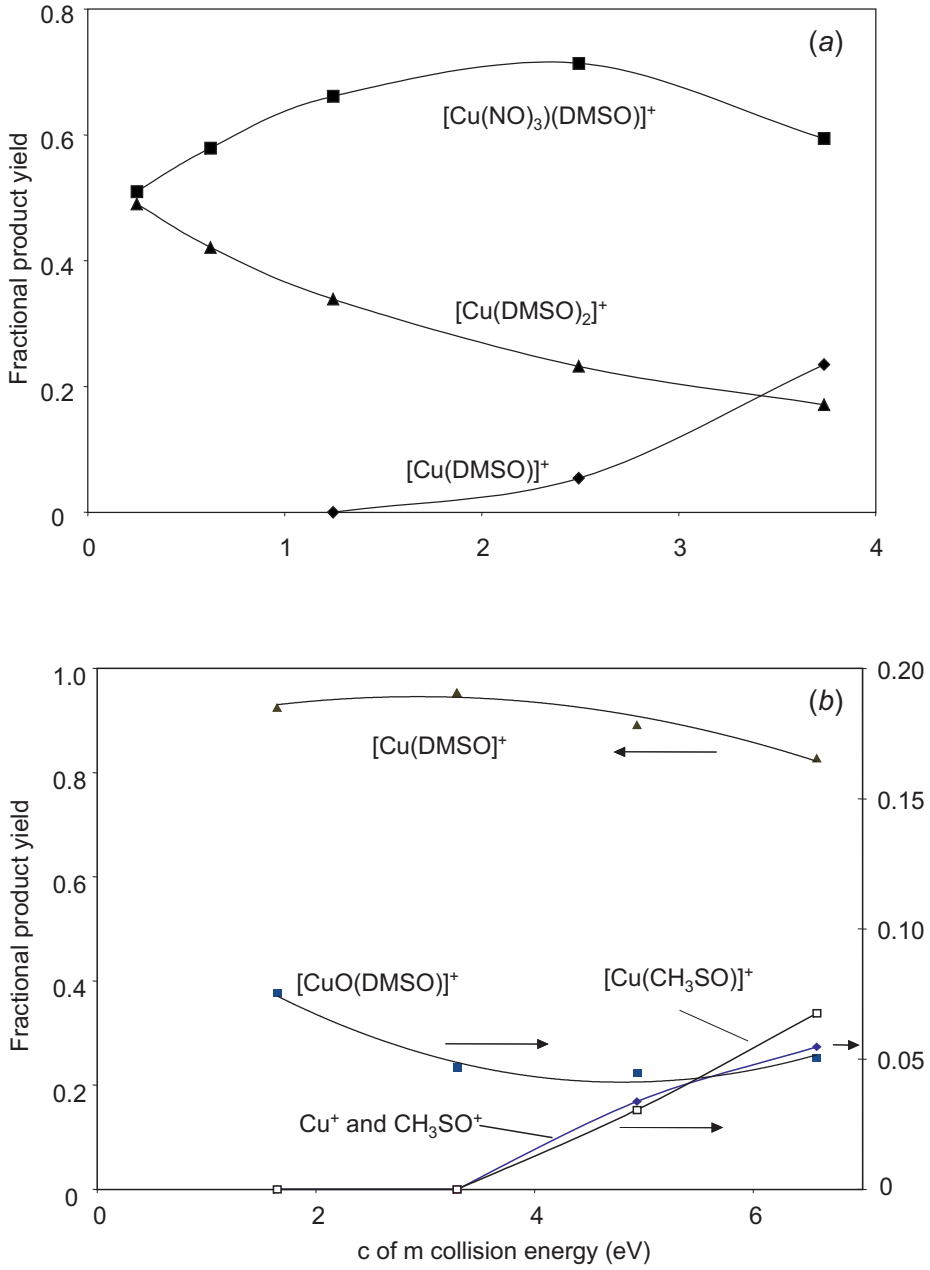
© 2005 NRC Canada

Fig. 3. (*a*) CAD spectrum of $[Cu(DMSO\text{-}d_6)_3]^{2+}$ at 4.5 eV collision energy. (*b*) Fractional product yields in the CAD spectra of $[Cu(DMSO\text{-}d_6)_3]^{2+}$ as functions of collision energy.

ing $[Cu(H_2O)(DMSO\text{-}d_6)_3]^{2+}$, but the addition is absent above 0.5 eV, as expected for the product of an association reaction. This water addition leads to a geometry with four ligands about the central Cu^{2+}, each coordinated through oxygen. DFT calculation shows that the preferred geometry for both $[Cu(H_2O)_4]^{2+}$ and $[Cu(NH_3)_4]^{2+}$ is planar tetragonal, a fifth ligand preferring hydrogen bonding in an outer shell rather than occupying a vacant axial position (26). The same tetragonal geometry should be present in $[Cu(H_2O)(DMSO\text{-}d_6)_3]^{2+}$ and also presumably in $[Cu(DMSO\text{-}d_6)_4]^{2+}$.

The initial activated decomposition of $[Cu(DMSO\text{-}d_6)_3]^{2+}$ involves electron transfer from one ligand to the metal, followed by dissociation (eq. [10]), both the products, $[Cu(DMSO\text{-}d_6)_2]^+$ and DMSO-d_6^+, appearing in high yield.

$$[10] \quad [Cu(DMSO\text{-}d_6)_3]^{2+} \rightarrow [Cu(DMSO\text{-}d_6)_2]^+ + DMSO\text{-}d_6^+$$



The loss of two DMSO-d_6 ligands from $[Cu(DMSO\text{-}d_6)_3]^{2+}$, giving $[Cu(DMSO\text{-}d_6)]^+$, appears to have two components since there is a shallow minimum in yield at 2 eV. The increasing yield at higher energies complements the decrease in $[Cu(DMSO\text{-}d_6)_2]^+$, but the origin of the low energy contribution is not known. The increasing yield of CD_3SO^+ at the higher energies must arise from the further decomposition of DMSO-d_6^+ since as described earlier, the decomposition of $[Cu(DMSO\text{-}d_6)_2]^+$ and $[Cu(DMSO\text{-}d_6)]^+$ yield approximately equal intensities of Cu^+ and CD_3SO^+. Cu^+, seen in the CAD spectrum of $[Cu(DMSO\text{-}d_6)_3]^{2+}$ in Fig. 3*a*, was too low in intensity to appear in Fig. 3*b*, and was never more than 15% of that of CD_3SO^+ at even the highest collision energy.

The collisionally assisted dissociation of singly charged Cu(II) complexes

The complexes investigated were: $[Cu(NO_3)(DMSO)_n]^+$, $[CuCl(DMSO)_n]^+$, $[CuBr(DMSO)_n]^+$ (n = 1 or 2), and $[Cu(HSO_4)(DMSO)]^+$. All these are Cu(II) complexes that are singly charged because of the presence of an anionic ligand. When the anion is retained in a singly charged cop-

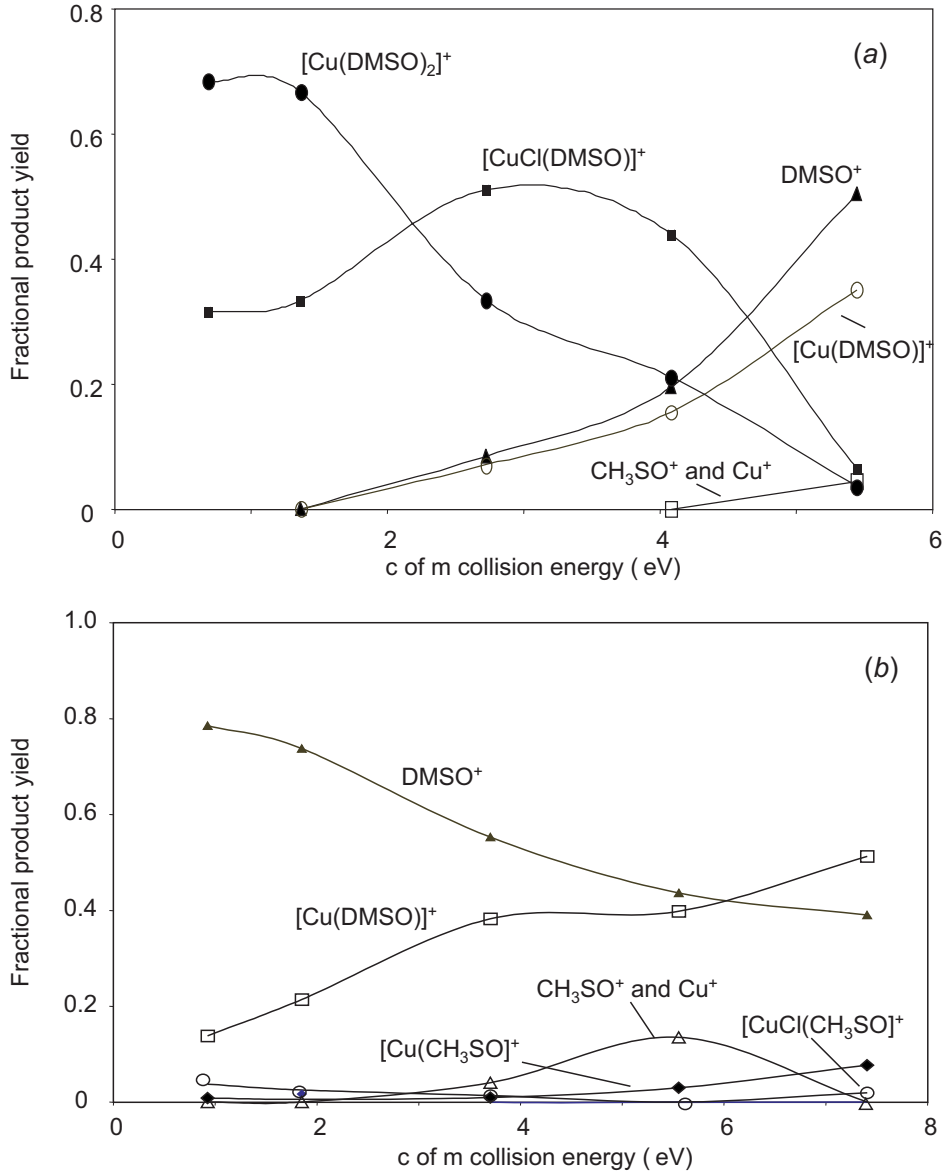
per-containing product ion in a CAD spectrum then no metal reduction has occurred, but if no anion is present then the complex contains Cu(I). The CAD spectra show the competition between reductive and nonreductive processes. Spectra were obtained as functions of collision energy for all ions except $[Cu(HSO_4)(DMSO)]^+$, whose intensity was too low for all but a qualitative examination.

Figure 4*a* shows the results obtained for $[Cu(NO_3)(DMSO)_2]^+$ and the results obtained for $[Cu(NO_3)(DMSO)]^+$ are shown in Fig. 4*b*. At all energies there is competition in the decomposition of $[Cu(NO_3)(DMSO)_2]^+$ between loss of NO_3 (eq. [11]) and loss of DMSO (eq. [12]).



[11] $[Cu(NO_3)(DMSO)_2]^+ \rightarrow [Cu(DMSO)_2]^+ + NO_3$

[12] $[Cu(NO_3)(DMSO)_2]^+ \rightarrow [Cu(NO_3)(DMSO)]^+ + DMSO$

Equation [11] describes a reduction of copper from Cu(II) to Cu(I), while in eq. [12] the oxidation state of the metal remains Cu(II). Extrapolation of the results suggests that, at very low energy, loss of NO_3 is the favored mode. With increased collision energy, loss of DMSO rather than NO_3 becomes dominant. At the highest energy, the appearance of $[Cu(DMSO)]^+$ shows loss of both DMSO and NO_3. This ion can arise from the decomposition of both $[Cu(DMSO)_2]^+$ (vide supra) and $[Cu(NO_3)(DMSO)]^+$. Both may be occurring since the CAD products of $[Cu(NO_3)(DMSO)]^+$ shown in Fig. 4*b* demonstrate that $[Cu(DMSO)]^+$ is the major product at all collision energies (eq. [13]), and it was shown ear-

Fig. 5. Fractional product yields in the CAD spectra of (*a*) $[CuCl(DMSO)_2]^+$ and (*b*) $[CuCl(DMSO)]^+$ as functions of collision energy.

lier that $[Cu(DMSO)]^+$ is the major product from $[Cu(DMSO)_2]^+$. There is a small competing, nonreductive process, the loss of NO_2 (eq. [14]), a reaction verified by the use of DMSO-d_6. Further decomposition of $[Cu(DMSO)]^+$ gives the usual products, $[Cu(CH_3SO)]^+$, CH_3SO^+, and Cu^+.

[13] $[Cu(NO_3)(DMSO)]^+ \rightarrow [Cu(DMSO)]^+ + NO_3$

[14] $[Cu(NO_3)(DMSO)]^+ \rightarrow [CuO(DMSO)]^+ + NO_2$

$[CuCl(DMSO)_2]^+$ behaves in a similar but more pronounced manner than $[Cu(NO_3)(DMSO)_2]^+$ in that reductive loss of the halogen is much preferred over loss of DMSO at the lowest energy (Fig. 5*a*).

At intermediate energies, as for $[Cu(NO_3)(DMSO)_2]^+$, loss of DMSO becomes the preferred reaction. Both $[CuCl(DMSO)]^+$ and $[Cu(DMSO)_2]^+$ decompose further, the products being $DMSO^+$ and $[Cu(DMSO)]^+$. The decomposition of $[CuCl(DMSO)]^+$ as a function of energy is shown in Fig. 5*b*. Of particular note is the absence of Cl in any of the ions with the exception of the appearance of a trace of $[CuCl(CH_3SO)]^+$ at the highest energy. The major process at all but the highest energy is the loss of CuCl following electron transfer from the DMSO ligand (eq. [15]).

[15] $[CuCl(DMSO)]^+ \rightarrow CuCl + DMSO^+$

When $CuBr_2$ was the cupric salt employed, $[CuBr(DMSO)_2]^+$ was produced in good yield in the ESI spectrum, but $[CuBr(DMSO)]^+$ was present with low intensity. Loss of Br from $[CuBr(DMSO)_2]^+$ was the only reaction at collision energies up to 2 eV and even at 5 eV, loss of DMSO to give $[CuBr(DMSO)]^+$, the only other reaction, constituted less than 10% of the products. Loss of Br from $[CuBr(DMSO)_2]^+$ was more facile than loss of Cl from $[CuCl(DMSO)_2]^+$, presumably because of the lower electron affinity of the halogen and its lower energy of association with copper. The intensity of $[CuBr(DMSO)]^+$ was too low in the ESI spectrum for a quantitative study, but qualitative

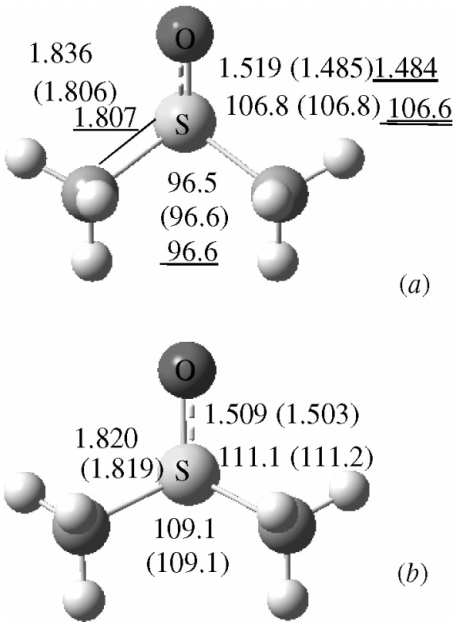
© 2005 NRC Canada

results showed that loss of Br constituted >95% of the reaction at the highest collision energy.

The intensity of $[Cu(HSO_4)(DMSO)]^+$ was very low and it was only possible to obtain sufficient signal for qualitative CAD experiments at collision energies above 3.6 eV. By comparing results obtained at 3.6 and 5.4 eV, it appears that the lowest energy decomposition pathway was OH transfer to the metal together with loss of SO_3 (eq. [16]) and at higher energy, losses of HSO_4 and $CuHSO_4$ were evident.

$$[16] \quad [Cu(HSO_4)(DMSO)]^+ \rightarrow [Cu(OH)(DMSO)]^+ + SO_3$$

Ab initio calculations



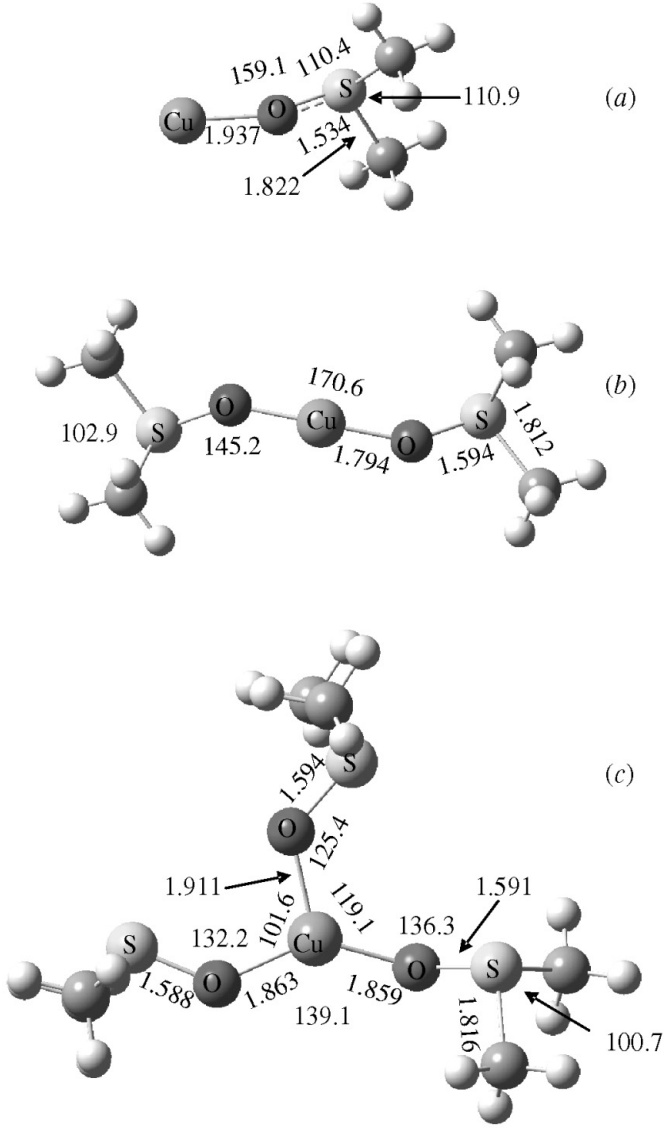
The optimized geometries and energies of most of the complexes and some of the major CAD products were calculated using the B3LYP functional with the 6-31+G(d,p) basis set. Metal cations coordinate with DMSO at oxygen (2, 9, 27, 28). This was verified for Cu^{2+} by optimizing the structure of $[Cu(DMSO)]^{2+}$ from a variety of initial configurations. Only one potential minimum was found, that with Cu-O coordination. All initial geometries for the complexes studied were therefore set up with that geometry, and no other initial geometries were examined. Each optimized structure was at a minimum on the potential energy surface.

DMSO and $DMSO^+$

The structure of DMSO is shown in Fig. 6*a*. For comparison, experimental results and those from higher levels of theory are also shown. Typke and Dakkouri (29) have presented an extensive study of the structural parameters for DMSO from both ab initio calculations with different levels of theory and have also reevaluated extant experimental data. The results obtained with the B3PW91/6-311++G(3df,3pd) method were found to be in best agreement with experiment. Figure 6*a* shows that our B3LYP/6-31+G(d,p) results slightly overestimate the experimental S—O and C—S bond lengths but show excellent agreement for bond angles. The dipole moment of DMSO is calculated to be 4.41 D at an angle of 12° to the O—S bond in the direction of the methyls. The experimental dipole moment is 3.9 D. The angle is considerably smaller than the value of 25 ± 1° obtained by both B3LYP and MP2 methods with a variety of basis sets (2). Since limitation of computational capacity prevented the use of higher levels of calculation for the large metal cation – DMSO complexes of interest in this study, higher level calculations for DMSO were not appropriate.

The association of DMSO with Cu^{2+} was expected to transfer some electron density from the ligand to the metal and therefore, for reference, the geometry of $DMSO^+$ is shown in Fig. 6*b*. Ionization causes a shortening of the O—S bond from 1.519 to 1.509 Å and of the S—C bond from 1.836 to 1.820 Å. The C—H bond lengths remain constant at 1.092 ± 0.001 Å. Of significance are the accompanying increases in the bond angles, < O-S-C increases by 4.3° and < C-S-C by 12.6°. The geometry about S is assuming a more planar character than in DMSO. The angle between the S—O bond and the C-S-C plane is 116° in DMSO, in agreement with Typke and Dakkouri's value of 115.4° (29), and this increases to 128° in $DMSO^+$. The structure of $DMSO^+$ is in good agreement with that computed previously at the

Fig. 6. Structures obtained at B3LYP/6-31+G(d,p) of (*a*) DMSO (values underlined are evaluated experimental results given in ref. 29) and (*b*) $DMSO^+$. The values in brackets in both structures are computational results at the B3LYP/6-311+G(d,p) level from ref. 31. Distances are in angstroms and angles are in degrees.



B3LYP/6-311++G(d,p) level (30), and the structures of both DMSO and $DMSO^+$ are almost identical with those obtained using B3LYP/6-311+G(d,p) (31). The latter values are shown in Fig. 6.

Doubly charged Cu(II) complexes — $[Cu(DMSO)_n]^{2+}$

Figure 7 shows the structures of $[Cu(DMSO)_n]^{2+}$ (n = 1–3). When DMSO is coordinated with Cu^{2+} in $[Cu(DMSO)]^{2+}$, the S—O bond is lengthened by 0.015 Å and the S—C bonds are decreased by 0.014 Å (Fig. 7*a*). The Cu is situated trans to the two methyl groups. The angles about S are almost identical (< O-S-C = 110.4° and < C-S-C = 110.9°) and compared to DMSO, the angle between the S—O bond and the C-S-C plane is increased to 128°. These angles are essentially the same as those of $DMSO^+$, but the S—O distances and to a lesser extent the S—C distances are considerably different. The Cu-O-S angle is 159.1°, which may be compared to the M-O-S angles in doubly charged $[M(DMSO)]^{2+}$ for closed shell cations: Mg (153.9° at the B3LYP/6-31G(d) level (9)), and Zn (129.8°), Ca (167.9°), Mg (152.8°), and Be (166.8°) at the B3LYP/6-31+G(d) level (27). El-Nahas (27) has suggested that nonlinear M-O-S geometry denotes the presence of charge transfer, whereas a linear geometry is consistent with a purely electrostatic interaction. Since the dipole moment of DMSO is not colinear with the O—S bond and since a purely electrostatic interaction would involve the dipole, then the M-O-S bond would not be expected to be 180°, whether or not the bond was purely electrostatic. If Cu^{2+} were interacting only with the DMSO molecular dipole then < Cu-O-S would be 168°, significantly larger than the computed 159.1°. Not only the dipole but the higher multipoles and the polarizability must

Fig. 7. Structures of (*a*) $[Cu(DMSO)]^{2+}$, (*b*) $[Cu(DMSO)_2]^{2+}$, and (*c*) $[Cu(DMSO)_3]^{2+}$. Distances are in angstroms and angles are in degrees.

also be taken into consideration for a pure electrostatic interaction. The Cu—O distance of 1.937 Å is larger than that for the analogous DMSO complexes of Zn^{2+} and Mg^{2+}. El-Nahas obtained a Zn—O distance of 1.819 Å at the B3LYP/6-31+G(d) level (27) and a value of 1.806 Å was obtained at the B3LYP/6-31G(d) level for Mg—O (9). These M—O distances are in the same order as the metal cation radii: Cu^{2+} (0.62 Å), Zn^{2+} (0.60 Å), and Mg^{2+} (0.49 Å).

Figure 7*b* shows the structure of the diligated cupric ion, $[Cu(DMSO)_2]^{2+}$. The most remarkable feature of this structure is that the Cu—O distance has decreased to 1.794 Å from the 1.937 Å in $[Cu(DMSO)]^{2+}$. It is usual, as was seen for the analogous Mg^{2+}–DMSO complexes (9) and for other symmetrical complexes of divalent metal cations (31–33), that the presence of a second identical ligand increases the metal–ligand bond length. Copper, however, is unusual, both the Cu^+ and the Cu^{2+} complexes with both H_2O and NH_3 have, respectively, smaller computed Cu—O and Cu—N distances in the diligated than in the monoligated complex (20, 22). The O-Cu-O angle in $[Cu(DMSO)_2]^{2+}$ is 170.6°. For comparison, the lowest energy form of $[M(H_2O)_2]^{2+}$ has a linear conformation for M = Mg (9, 33), but for M = Ca, Sr, Ba, and Ra, the angles are much less than 180° (33). The DMSO groups in $[Cu(DMSO)_2]^{2+}$ are identical but staggered, with a S-O-O-S dihedral angle of 101.7° and the C-Cu-C angle defined by proximate carbons from the two ligands of 143.1°.

The three oxygen atoms and copper in $[Cu(DMSO)_3]^{2+}$ are almost coplanar, as shown by the sum of the three O-Cu-O angles (359.7°) (Fig. 7*c*). However, the individual angles (101.6°, 119.1°, and 139.1°) are very different. This difference is reflected in the significant differences in the Cu—O distances (1.859, 1.863, and 1.911 Å). An unsuccessful attempt was made to find an energy minimum for a structure with three equal Cu—O distances. An initial starting geometry with equal Cu—O bond lengths of 1.870 Å optimized to the same asymmetric structure shown in the figure. The geometry around the central metal ion in both $[Cu(H_2O)_3]^{2+}$ and $[Cu(NH_3)_3]^{2+}$ is similar to that of $[Cu(DMSO)_3]^{2+}$, being almost planar with one Cu—X bond significantly longer than the other two (26). With all three ligands (DMSO, H_2O, and NH_3) the largest X-Cu-X angle is diametrically opposed to the longest Cu—X bond.

As the number of DMSO ligands in $[Cu(DMSO)_n]^+$ increases, the geometry of the CH_3SCH_3 group changes monotonically. The C-S-C angle decreases from 110.9° for n = 1 to 100.8° for n = 3. At the same time, the S—C bond length decreases from 1.822 to 1.814 Å. The trend is towards, but the values are still significantly different from, those of neutral DMSO. Figure 7 shows that the O—S distance is most influenced by the metal cation. The shortest, and nearest to the value for DMSO, occurs for n = 1. The distances for n = 2 and 3 are considerably larger. It was expected that the O—S distance would vary inversely with the Cu—O distance, but this is not the case.

Singly charged Cu(I) complexes — $[Cu(DMSO)_n]^+$

The structures of $[Cu(DMSO)_n]^+$ (n = 1 or 2) are shown in Fig. 8. Comparison with Fig. 7 shows that the computed Cu—O bond in $[Cu(DMSO)]^+$ is shorter than that in $[Cu(DMSO)]^{2+}$ by 0.08 Å, while the O—S bond is longer by 0.035 Å. When the second ligand is added to $[Cu(DMSO)]^+$, the Cu—O bond increases slightly by 0.005 Å, which contrasts with the observation of a decrease in the Cu—X (X = O or N) bond length for $Cu(H_2O)_2^+$ and $Cu(NH_3)_2^+$. Both these ions have linear X-Cu-X geometry, whereas O-Cu-O in $[Cu(DMSO)_2]^+$, which has C_1 geometry, is slightly bent with an angle of 173.8°. The two identical DMSO groups are staggered with a S-O-O-S dihedral angle of 108.5° and a C-Cu-C angle defined by the proximate carbons of the two ligands of 52.9°.

Singly charged Cu(II) complexes — $[CuX(DMSO)_n]^+$

Figure 9 shows the optimized structure of $CuCl^+$ and the structures of its DMSO adducts $[CuCl(DMSO)]^+$ and $[CuCl(DMSO)_2]^+$. The Cu—Cl distance is greater in CuCl than in $[CuCl(DMSO)]^+$ by 0.041 Å, but when a second DMSO is present in the complex, the Cu—Cl distance is

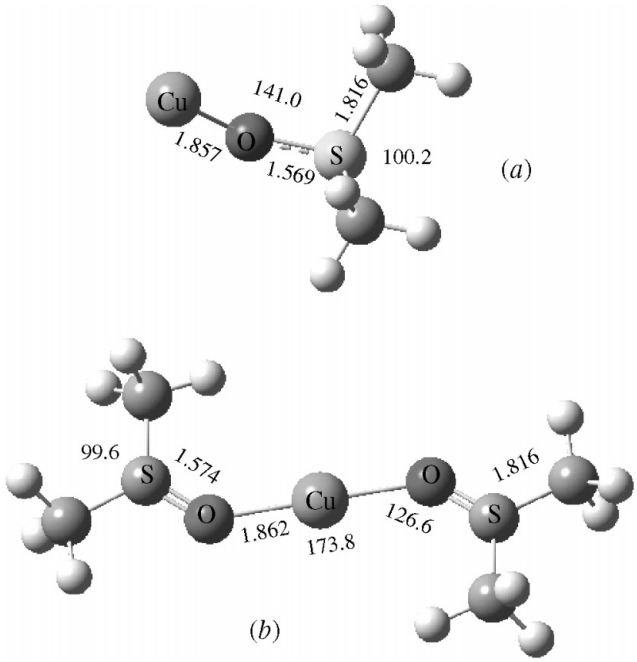
Fig. 8. Structures of the Cu(I) ions (*a*) $[Cu(DMSO)]^+$ and (*b*) $[Cu(DMSO)_2]^+$. Distances are in angstroms and angles are in degrees.



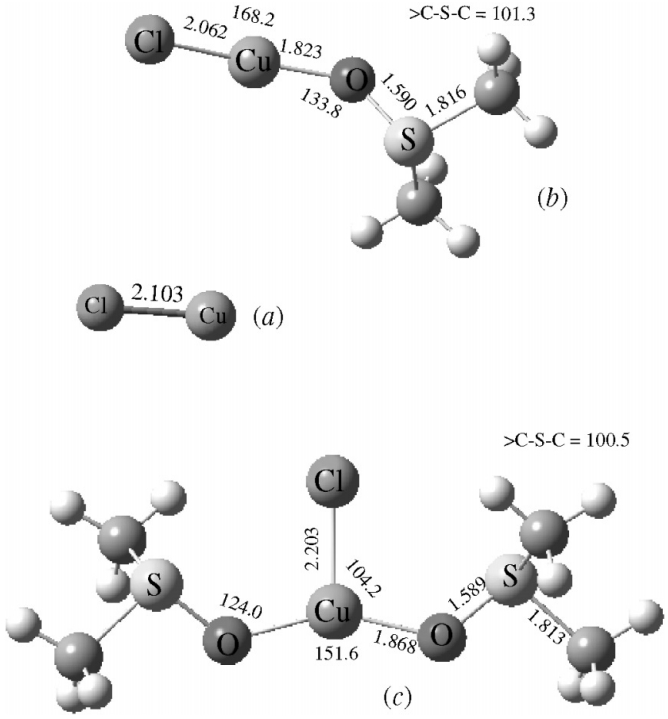


Fig. 9. Structures of (*a*) CuCl, (*b*) $[CuCl(DMSO)]^+$, and (*c*) $[CuCl(DMSO)_2]^+$. Distances are in angstroms and angles are in degrees.

greater than in Cu—Cl by 0.100 Å, presaging the preferred loss of neutral Cl in the CAD spectrum. The geometry of $[CuCl(DMSO)]^+$ has some similarities to that of the diligated $[Cu(DMSO)_2]^{2+}$, especially in the Cl-Cu-O angle, which is 168.2° compared to 170.6° for O-Cu-O, and the O—S distance, 1.590 compared to 1.594 Å. The geometries of the CH_3SCH_3 groups are also very similar.

When a second DMSO is added to $[CuCl(DMSO)]^+$, the two ligands have identical structures, but unlike in $[Cu(DMSO)_2]^+$ and $[Cu(DMSO)_2]^{2+}$, the O—S bonds are in the cis position rather than trans. This positioning allows each bond dipole ($O^{\delta-}$–$S^{\delta+}$) to interact favorably with Cl, whereas in the absence of the halogen, the two dipoles repel and the bonds occupy the trans position.

The nitrate anion is planar and symmetric with a N—O bond length of 1.265 Å (Fig. 10*a*). No potential minimum could be found for monodentate coordination of nitrate with Cu^{2+}; the only minimum is for bidentate coordination in which the NO_3 symmetry is broken in the planar $[CuNO_3]^+$ (Fig. 10*b*). The N—O distance for the two coordinating oxygens increases by 0.048 Å, while the third N—O bond, diametrically opposed to Cu, decreases by 0.088 Å. All atoms in $[CuNO_3(DMSO)]^+$, with the exception of those of the methyl groups, are coplanar (Fig. 10*c*). The NO_3 group remains bidentate, but the two Cu—O bonds are not equal in length; one is larger and the other smaller than the Cu—O distance in $[CuNO_3]^+$. The bond cis to O—S has increased by 0.046 Å and the other has decreased by 0.032 Å. This orientation of NO_3 relative to DMSO again shows the interaction between the O—S bond dipole and the anion. Comparison of the interatomic distances and angles for $[CuNO_3(DMSO)]^+$ and $[CuCl(DMSO)]^+$ shows very minor changes in the Cu(DMSO) moiety; the Cu—O distance is 0.009 Å smaller with nitrate, and all other parameters are the same within 1%.

The structure of $[CuNO_3(DMSO)_2]^+$ (Fig. 10*d*) has four coplanar oxygens surrounding Cu, the two DMSO oxygens being closer to the metal by 0.064 Å. The N—Cu distance is greater than in either $[CuNO_3(DMSO)]^+$ or $[CuNO_3]^+$ as NO_3 reverts towards the structure of the free anion. Both coordinating nitrate oxygens are identically positioned and as for $[CuCl(DMSO)_2]^+$, the two DMSO ligands are oriented so that interaction between the S—O dipole and the anion is favored, allowing long-range interaction between an O of the nitrate and the electropositive S of the DMSO.

Figure 11 shows that HSO_4^- behaves as a ligand very much like NO_3^- when in association with Cu^{2+}. It is bidentate in $[Cu(HSO_4)]^+$, the presence of the copper decreasing two of the S—O distances and increasing the other two. The O—H bond increases by 0.023 Å and the O-S-O angles change, the angle defined by copper decreasing by 19.6° and the opposite one increasing by 8.4°. The presence of DMSO as a second ligand leads to asymmetry in the bidentate bonding, as was seen for the nitrate analogue. One Cu—O increases by 0.071 Å and the other decreases by 0.013 Å. Again, as for complexes containing either Cl or NO_3, the structure (Fig. 11*d*) of $[Cu(HSO_4)(DMSO)]^+$ shows that the cis orientation of DMSO with the HSO_3 group is determined by bond dipole interactions.

NBO analysis

The ground state of Cu has the $4s^13d^{10}$ configuration, Cu^+ has a closed shell $4s^03d^{10}$ configuration, and Cu^{2+} has an open $4s^03d^9$ configuration. In any Cu(I) complex, charge transfer from ligand to Cu^+ is demonstrated by electron den-

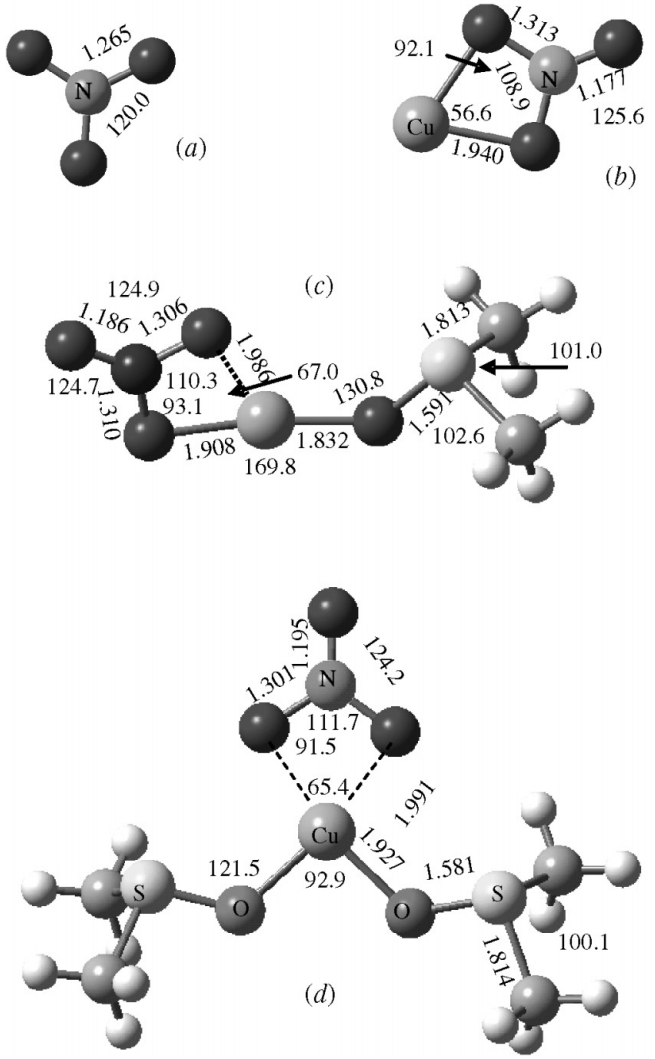
Fig. 10. Structures of (*a*) NO_3^-, (*b*) $CuNO_3^+$, (*c*) $[CuNO_3(DMSO)]^+$, and (*d*) $[CuNO_3(DMSO)_2]^+$. Distances are in angstroms and angles are in degrees.



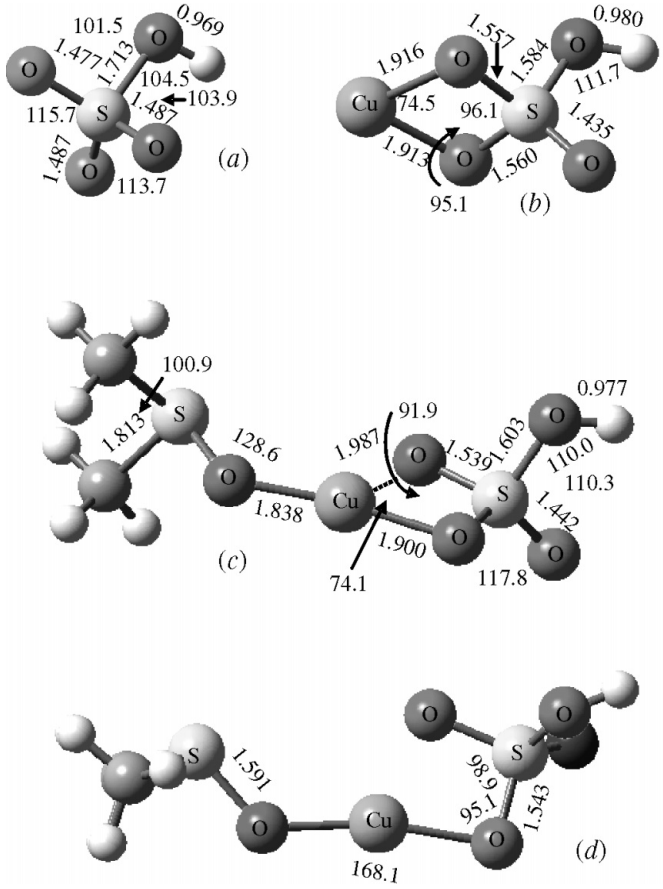


Fig. 11. Structures of (*a*) HSO_4^-, (*b*) $[Cu(HSO_4)]^+$, (*c*) $[Cu(HSO_4)(DMSO)]^+$, and (*d*) another view of (*c*). Distances are in angstroms and angles are in degrees.

sity in the 4s orbital, and charge transfer in a Cu(II) complex is demonstrated by increased population in either or both the 3d and 4s orbitals. The results of NBO calculations for DMSO, $DMSO^+$, and the complexes are shown in Table 1. Listed are the natural charges on copper as well as the populations of its 4s and 3d orbitals, the charges on the S, O, and methyl groups of the DMSO ligands, the charge associated, where applicable, with the anion, and the spin populations on the atoms of some of the odd electron ions.

The reason DMSO preferentially coordinates through O with metal cations is the large S—O bond dipole. The large negative charge of –0.968*e* on O is accompanied by the even larger positive charge of 1.207*e* on S. The two methyl groups combined have the small charge of –0.239*e*. When DMSO is ionized the effect is seen in substantial changes in all parts of the molecule. The change is greatest for O, which becomes more positive by 0.427*e* and least for S, 0.186*e*. The majority of the odd electron spin density is on O. The charge on the methyls increases by 0.387*e* so that they collectively switch from being negative to being positive.

In $[Cu(DMSO)_n]^{2+}$ the positive charge attributed to Cu increases as *n* increases, from 1.103*e* for *n* = 1 to 1.396*e* for *n* = 3. Charge transfer from all ligands to the metal cation therefore decreases as the number of ligands increases, implying that the interaction is becoming less covalent and more electrostatic in nature. Almost one unit of electronic charge has been transferred in $[Cu(DMSO)]^{2+}$ from ligand to metal, the majority increasing the 3d population to almost its maximum value of 10, with little entering the 4s orbital. The electron transfer from H_2O to Cu^{2+} in $[Cu(H_2O)]^+$ was also found to be mainly into 3d (population 9.36e) with only 0.04e into 4s (34). For $[Cu(DMSO)_n]^{2+}$ (*n* = 2 or 3) there is significant electron density in the 4s orbital and the population of the 3d orbital is much less than 10e, electron transfer into 3d being comparable to that into 4s. The charge distribution in DMSO when complexed with Cu^{2+} is very different to that of $DMSO^+$, where much of the electron density is lost from the O atom. In $[Cu(DMSO)]^{2+}$ the most marked change is shown by S and the methyls. These become more positive by 0.247 and 0.543*e*, respectively, while O becomes more positive by only 0.106*e*. As the number of DMSO ligands increases, the charge distribution of each ligand tends towards that of neutral DMSO.

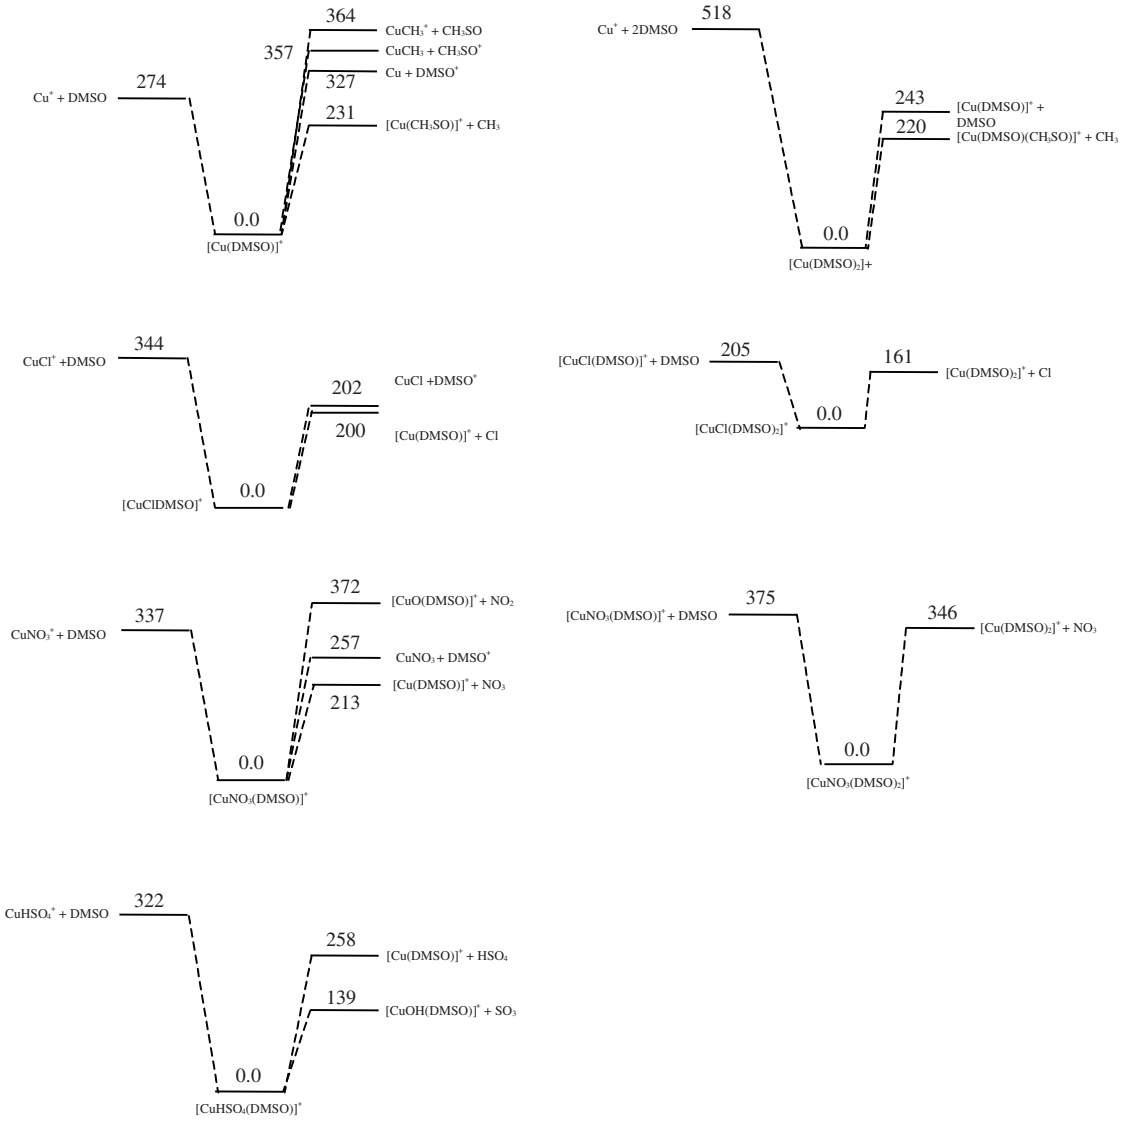
[a]Orbital populations of Cu.
[b]Charges on O and S in DMSO.
[c]Total charge on Cl, NO_3, or HSO_4.
[d]Total charge on methyls of all DMSO ligands.
[e]Unpaired spin.
[f]Average values.

All the $[Cu(DMSO)_n]^{2+}$ are odd-electron species and the location of the unpaired electron in each complex may be obtained by the difference in the populations of the α and β electrons on each atom. These differences are shown in Table 1. In $[Cu(DMSO)]^{2+}$ the spin is almost equally located on the O and S atoms, with only 12% on Cu consistent with the metal having an almost completely filled 3d shell. In $[Cu(DMSO)_2]^{2+}$ the spin is almost equally located on the copper and the oxygens, with only 5% on each of the two sulfurs. With three DMSO ligands, 60% of the spin is on the metal, 35% is on the three oxygens, and only 1% is on the three sulfurs. These spin locations are in accord with the earlier conclusion that as the number of ligands increases, the interaction becomes more electrostatic in nature with decreasing charge transfer.

In contrast to $[Cu(DMSO)_n]^{2+}$, the singly charged $[Cu(DMSO)_n]^+$ show electron transfer to the 4s orbital for both $n = 1$ and 2. The positive charge on Cu is decreased by $0.108e$ ($n = 1$) and $0.215e$ ($n = 2$), but in both cases there is also electron transfer from the 3d to the 4s orbital, implying sd hybridization is important for both complexes. Such transfer has been reported for $[Cu(H_2O)_n]^+$ and for $[Cu(NH_3)_n]^+$ obtained at the B3LYP/cc-pVDZ level; however, the effect and the total charge transferred to the metal were found to be attenuated for $n = 3$ and 4 (22). Another similarity of DMSO with H_2O and NH_3 as ligands, and in contrast to the behaviour of all the ligands with Cu^{2+}, is that the positive charge on Cu for the diligated complex is less than it is for the monoligated ion.

Surprisingly, the NBO charge on copper shows little change when Cl^- is coordinated to Cu in both $[Cu(DMSO)]^{2+}$ and $[Cu(DMSO)_2]^{2+}$, even though the negative charge on Cl is very low ($–0.327e$). The presence of the negatively charged anion results in increased negative charges on the DMSO ligand. Comparison of the charges on the S and O atoms of DMSO in $[Cu(DMSO)]^{2+}$ with those for $[CuCl(DMSO)]^+$ illustrates this statement. While the positive charge on copper decreases by only 0.012 and the charge on Cl is only $–0.327e$, the charges on O, S, and the two methyl groups have become more negative by $0.164e$, $0.220e$, and $0.277e$, respectively. A similar comparison of $[CuCl(DMSO_2]^+$ and $[Cu(DMSO)_2]^{2+}$ shows that the charge associated with Cu is slightly greater ($0.049e$) with a Cl^- ligand, only $–0.387e$ is transferred from the anion, but 85% of the transfer is to the DMSO ligands.

Table 2. Enthalpy changes for Cu^{2+}–DMSO complexes.



Reaction	H^0_{298} (kJ mol^{-1})
$Cu^{2+} + DMSO = [Cu(DMSO)]^{2+}$	–975
$[Cu(DMSO)]^{2+} + DMSO = [Cu(DMSO)_2]^{2+}$	–421
$[Cu(DMSO)_2]^{2+} + DMSO = [Cu(DMSO)_3]^{2+}$	–258
$[Cu(DMSO)_3]^{2+} = [Cu(DMSO)_2]^+ + DMSO^+$	–35.6
$[Cu(DMSO)_2]^{2+} = [Cu(DMSO)]^+ + DMSO^+$	–50.2
$[Cu(DMSO)]^{2+} = Cu^+ + DMSO^+$	–197
$[Cu(DMSO)_3]^{2+} = [Cu(CH_3SO)(DMSO)_2]^{2+} + CH_3$	294

Enthalpy changes for association and dissociation reactions

Harmonic frequency calculations were performed for all the structures shown in the figures and for a few other ions and molecules. It was thus possible to obtain from the Gaussian program the standard enthalpies of formation for precursor ions and ion and neutral products pertinent to the CAD experiments. The standard enthalpy changes for the association reactions forming $[Cu(DMSO)_n]^{2+}$ and for the dissociation by electron transfer from DMSO to metal are shown in Table 2. The enthalpy changes for the formation of

Fig. 12. Standard enthalpy levels (kJ mol^{-1}) of products relative to those of the precursor ions in the CAD spectra of singly charged Cu(I) and Cu(II) complexes.

and the activated dissociations of the singly charged complexes are given in Fig. 12.

When possible, computational results should always be compared with experimental results, and vice versa. Unfortunately only one experimental thermodynamic measurement for the association of DMSO with a copper ion has been reported. Deng and Kebarle (35), using high-pressure mass spectrometry, determined the enthalpy of association of Cu^+ with two molecules of DMSO from a ladder of relative free energies obtained with many ligands (L) for the reaction $CuL_2^+ = Cu^+ + 2L$. The high level theoretical $\Delta H^0 = -441$ kJ mol^{-1}, computed by Bauschlicher and co-workers (36) for L = NH_3 together with computed entropies at the HF/3-21G* level, enabled the scale of free energies to be converted to a scale of enthalpies, leading to the value of –472 kJ mol^{-1} for DMSO. Our computed enthalpy change for L = DMSO is –518 kJ mol^{-1}. For L = NH_3 at the B3LYP/6-31G+(d,p) level of computation we obtain $\Delta H^0 =$ –485 kJ mol^{-1}. Our values for both DMSO and NH_3 are approximately 45 kJ mol^{-1} more negative than the values reported by Deng and Kebarle. This constitutes an acceptable agreement considering the reported difficulties encountered with computations involving even simple Cu^+ complexes (37). The enthalpy of association of the second DMSO molecule with $[Cu(DMSO)]^+$ (–237 kJ mol^{-1}) is 16% less negative than that for the first. A decrease in binding energy for the second ligand compared with the first is usually, but not always, the case for most metal cations (33, 36, 38–40).

$[Cu(DMSO)_n]^{2+}$

The enthalpy changes for the association of one, two, and three DMSO molecules and the enthalpy changes for dissociative charge transfer to a DMSO ligand for each of the $[Cu(DMSO)_n]^{2+}$ complexes is shown in Table 2. The association of Cu^{2+} with one DMSO ligand is 975 kJ mol^{-1} exothermic. The exothermicity decreases to 421 kJ mol^{-1} for the second ligand and further still to 258 kJ mol^{-1} for the third. There are no experimental data with which to compare

© 2005 NRC Canada

these values, but several computational studies are extant for other metal cations. In a B3LYP/6-311+G(d,p) calculation, we found the enthalpy change for the association of the closed shell cation Mg^{2+} with DMSO to be –611 kJ mol^{-1} (9). El-Nahas (27) computed the energies of association of Be^{2+}, Mg^{2+}, Ca^{2+}, and Zn^{2+} with formaldehyde, acetone, and DMSO by both ab initio and DFT methods and concluded that DFT overestimates the stability in comparison to CCSD with the same basis set by 40–80 kJ mol^{-1}. The binding energy of $[Zn(DMSO)]^{2+}$ was –715 kJ mol^{-1}. The energy of association of the triply charged Sc^{3+} with DMSO was –1394 kJ mol^{-1}, as expected much higher than that of Cu^{2+} (31).

Electron transfer from ligand to metal cation (eq. [10]) was the major CAD reaction for $[Cu(DMSO)_3]^{2+}$ and is computed to be exothermic by 35.6 kJ mol^{-1}. A Coulomb barrier must ensure the stability of $[Cu(DMSO)_3]^{2+}$ against this process. $[Cu(DMSO)_2]^{2+}$ was observed in the ESI spectrum of the cupric–DMSO aqueous solutions, but $[Cu(DMSO)]^{2+}$ was not. $[Cu(DMSO)_2]^{2+}$ exists in a potential minimum that is higher in energy by 50.2 kJ mol^{-1} than $[Cu(DMSO)]^{+}$ + $DMSO^{+}$ and must be protected by a Coulomb barrier. The potential minimum for $[Cu(DMSO)]^{2+}$ is 197 kJ mol^{-1} higher than for the charge-separated products (Cu^{+} and $DMSO^{+}$). A large enough Coulombic barrier may not be present to afford sufficient stability for the ion to be observed experimentally by the technique of collisionally exciting and hence desolvating more highly solvated doubly charged complexes. The ion might possibly be observed by charge-stripping mass spectrometry commencing with $[Cu(DMSO)]^{+}$, as has been demonstrated for the formation of $[Cu(H_2O)]^{2+}$ and $[Cu(NH_3)]^{2+}$ from $[Cu(H_2O)]^{+}$ and $[Cu(NH_3)]^{+}$, respectively (41).

As noted by Shvartsburg and Wilkes (8) and as observed in this work, unlike most metal dication – DMSO complexes, $[Cu(DMSO)_3]^{2+}$ shows no evidence of methyl loss in its CAD spectrum. Methyl loss is computed to be endothermic by 294 kJ mol^{-1}, a high value that must make competition with dissociative electron transfer to DMSO impossible.

Enthalpy changes for the formation of the CAD products of singly charged Cu(II) complexes

Figure 12 shows the relative standard enthalpy levels of the major CAD products of $[CuX(DMSO)_n]^{+}$. The order of the levels for each complex is, in general, consistent with that observed or surmised by extrapolation of the curves in the energy resolved spectra. For example, it was surmised from Fig. 4 that $[Cu(NO_3)(DMSO)_2]^{+}$ would preferentially lose NO_3 rather than DMSO at low collision energy. Figure 12 is in accord, loss of NO_3 is favored by 29.7 kJ mol^{-1}. $[Cu(NO_3)(DMSO)]^{+}$ is an exception in that the relative enthalpy levels are inconsistent with the spectrum. Although loss of NO_3 is correctly predicted to be the lowest energy path, neither formation of $CuNO_3$ + $DMSO^{+}$ nor of $CuNO_3^{+}$ + DMSO are observed. However the formation of $[CuO(DMSO)]^{+}$ + NO_2, which requires 34.7 kJ mol^{-1} more than the formation of $CuNO_3^{+}$ + DMSO, does occur. Loss of DMSO from $[CuCl(DMSO)_2]^{2+}$ requires 43.5 kJ mol^{-1} more than loss of Cl and becomes the major CAD product above 2 eV collision energy due only to the further decomposition of $[Cu(DMSO)_2]^{+}$ (Fig. 5).

All these results show that electron transfer from X, the less endothermic path for Cu(II) reduction in $[CuX(DMSO)_n]^{+}$ (n = 1 and 2), is energetically favored over the alternate electron transfer from DMSO.

Conclusions

The ESI spectra of dilute aqueous solutions of a cupric salt and DMSO contain Cu(II)–DMSO complexes in two forms. The doubly charged $[Cu(DMSO)_n]^{2+}$ are present as major ions, with n = 3 and 4 prominent, but ions with n up to 11 are observed. $[Cu(DMSO)_2]^{2+}$ is present but with very low intensity, and no $[Cu(DMSO)]^{2+}$ is found under any experimental conditions. In CAD experiments, $[Cu(DMSO)_n]^{2+}$ ($n \geq 4$) decomposes only by loss of neutral DMSO. The only significant primary products of collisional activation of $[Cu(DMSO)_3]^{2+}$ are the Cu(I) ion $[Cu(DMSO)_2]^{+}$ and $DMSO^{+}$. No $[Cu(DMSO)_2]^{2+}$ or $[Cu(DMSO)]^{2+}$ formed by loss of neutral ligand(s) is observed. Computation shows that each of these ions exists at a minimum on the potential energy surface, which may mean that it might be possible to form them with useful intensities by alternate methods. Although the loss of a methyl radical is a ubiquitous process for other doubly charged metal complexes, $[M(DMSO)_3]^{2+}$, no loss of methyl was observed for $[Cu(DMSO)_3]^{2+}$. This is presumably because the endothermicity of methyl loss (294 kJ mol^{-1}) is significantly higher than the Coulomb barrier for dissociative electron transfer from DMSO that is exothermic by 35.6 kJ mol^{-1}.

The second type of Cu(II)–DMSO complex is singly charged and has the form $[CuX(DMSO)_n]^{+}$, where X^{-} is the anion of the cupric salt (Cl^{-}, Br^{-}, NO_3^{-}, or HSO_4^{-}). The CAD spectra, obtained as a function of collision energy, show that for $[CuX(DMSO)_n]^{+}$ (n = 1 or 2) and all X, dissociation by charge retention and charge reduction compete. At the lowest collision energy, electron transfer from X^{-} to Cu^{2+} and loss of neutral X (Cl, Br, NO_3, HSO_4) is the preferred reaction, while at higher collision energy, electron transfer from DMSO to Cu^{2+} can compete. The computed structures of $[CuX(DMSO)_n]^{+}$ (n = 1 or 2) show that the interaction between X and the $S^{\delta+}$–$O^{\delta-}$ dipole influences the orientation of the DMSO ligands and introduces symmetry in the n = 2 complexes.

Activation of methane by gaseous platinum(II) ions PtX^+ (X = H, Cl, Br, CHO)[1]

Detlef Schröder and Helmut Schwarz

Abstract: The gas-phase reactions of methane with the platinum(II) ions PtX^+ with X = H, Cl, Br, and CHO are studied by mass spectrometry. The PtX^+ ions are generated by electrospray ionization of methanolic solutions of hexachloroplatinic acid and hexabromoplatinic acid, respectively. Small to moderate intramolecular kinetic isotope effects determined for the C—H(D) bond activation of CH_2D_2 suggest that the activation of methane by gaseous PtX^+ cations is subject to thermochemical control by the product channels. In addition, the $PtCl_2^+$ cation is also able to activate methane, whereas $PtCl_3^+$ is unreactive under the conditions chosen.

Key words: gas-phase reactions, mass spectrometry, methane activation, platinum bromide, platinum chloride.

Résumé : Faisant appel à la spectrométrie de masse, on a étudié les réactions en phase gazeuse du méthane avec les ions du platine(II), PtX^+ dans lesquels X = H, Cl, Br et CHO. On a généré les ions PtX^+ par électronébulisation ionique de solutions méthanoliques respectivement d'acide hexachloroplatinique et d'acide d'hexabromoplatinique. Les effets isotopiques cinétiques intramoléculaires allant de faibles à modérés qui ont été observés pour l'activation de la liaison C—H(D) en CH_2D_2 suggèrent que l'activation du méthane par des cations gazeux de PtX^+ est sujette à un contrôle thermochimique par les canaux conduisant aux produits. De plus, le cation $PtCl_2^+$ peut aussi activer le méthane alors que le cation $PtCl_3^+$ n'est pas réactif dans les conditions choisies.

Mots clés : réactions en phase gazeuse, spectrométrie de masse, activation du méthane, bromure de platine, chlorure de platine.

[Traduit par la Rédaction]

Introduction

Platinum can certainly be regarded as the catalytically most active element, as it is capable of mediating a wide variety of reactions, such as hydrogenation as well as dehydrogenation, combustion processes, and the oxidation of ammonia (1, 2). In addition to heterogeneous catalysis, platinum compounds occupy an outstanding position in homogeneous catalysis. In the present context, the Shilov systems are particularly relevant in which platinum(II) species permit the activation of hydrocarbons under ambient conditions (3–6). Accordingly, a number of gas-phase studies on the chemistry of transition metals also dealt with platinum in either neutral or ionic form (7). Small platinum clusters ($Pt_m^{-/0/+}$), for example, whether they are neutral or either anionic or cationic can activate methane to afford the corresponding carbenes $Pt_mCH_2^{-/0/+}$ concomitant with liberation of molecular hydrogen (8–14). Likewise, several covalently bound platinum ions such as $PtCH_2^+$, PtO^+, and PtO_2^+ react with methane under thermal conditions (11, 15, 16). Under fortunate circumstances, these gas-phase studies may even allow predictions for the mechanistic schemes operative in applied catalysis (7, 17–19).

With good reasons, however, it has been argued that gaseous platinum ions such as Pt^+, PtO^+, or PtO_2^+ cannot be regarded as useful models for the catalytically active intermediates in real-life scenarios, as the metal does not occur in its most common oxidation states, i.e., Pt^0, Pt^{II}, Pt^{IV}, and Pt^{VI}. A more appropriate model for the Shilov systems would be, for example, mononuclear platinum halide cations PtX^+ (X = Cl, Br) with or without additional ligand or solvent molecules. Accordingly, we have already previously attempted to generate PtX^+ ions, but failed to achieve reasonable yields of these ions with several types of mass spectrometric approaches. Thus, direct ionization of gaseous PtX_2 is hampered by the high temperatures required for evaporation, higher valent platinum halides are too corrosive for the instrument, and all attempts to generate PtX^+ in ion–molecule reactions of mass-selected Pt^+ with appropriate reagents RX failed (R = CH_3, CH_2X, CHX_2, CX_3, etc.) in that

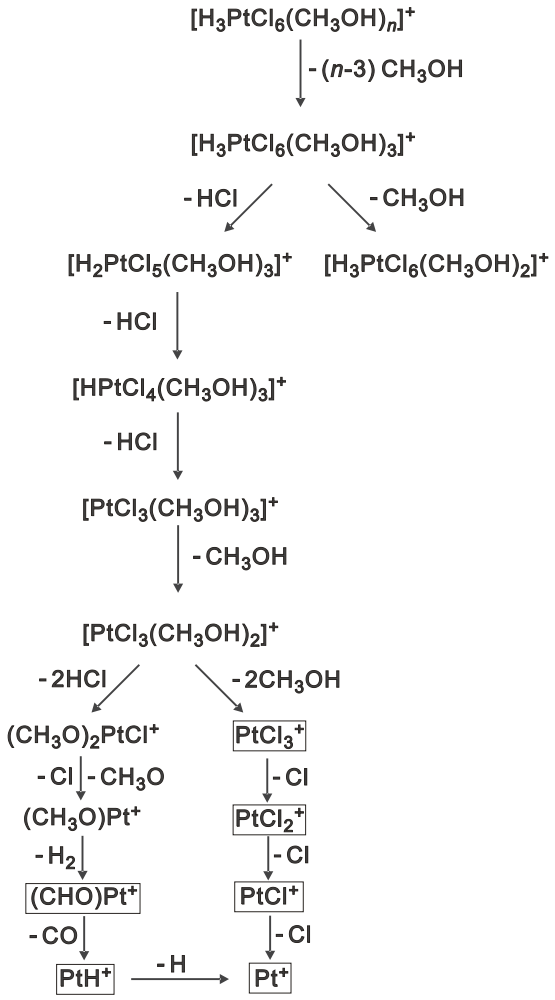
if C—X bond activation takes place at all, it is associated with electron transfer leading to neutral PtX and the corresponding carbenium ion. We note in passing that this finding implies a fairly large ionization energy of PtX, thereby also explaining the difficulties encountered with the generation of PtX^+ (X = Cl, Br). An exception is the reaction of Pt^+ with Cl_2, which affords $PtCl^+$ as ionic product (20), but the usage of molecular chlorine as a reagent is not suitable in the instrumentation available to us.



Here, we report a facile and conceptually straightforward route for the generation of PtX^+ cations by means of electrospray ionization (ESI) (21) of transition-metal salts in dilute solution (22, 23), which provides the ions of interest in yields sufficient for subsequent reactivity studies.

Experimental details

The experiments were performed with a VG BIO-Q instrument that consists of an ESI source followed by a mass spectrometer of QHQ configuration (quadrupole, Q; hexapole, H) as described elsewhere (24, 25). In the experiments, mmolar solutions of H_2PtCl_6 in methanol were introduced via a syringe pump (flow rate 5 μL/min) to the fused silica capillary of the ESI source. Nitrogen was used as nebulizing and drying gas at a source temperature of 80 °C. As both platinum as well as chlorine have several isotopes and moreover, depending on the ESI conditions, more or less broad distributions of several ionic species are formed, particular care has to be taken in mass selection to avoid isobaric overlaps. In the case of $PtCl^+$, for example, only the $^{194}Pt^{35}Cl^+$ cation with *m*/*z* 229 is of sufficient purity and intensity for MS/MS experiments, whereas all other $PtCl^+$ isotopes formed under these conditions suffer from isobaric interferences; note that $^{194}Pt^{35}Cl^+$ is inherently accompanied by about 1% of $^{192}Pt^{37}Cl^+$. In the MS/MS studies, the first as well as the second mass analyzer were kept at mass resolutions $m/\Delta m > 500$ to warrant proper mass selection of the reactant ions and an appropriate accuracy in the mass analysis of the ionic products.

For collision-induced dissociation (CID) and ion–molecule reactions, the ions of interest were mass-selected using Q1, interacted with an appropriate neutral gas (ca. 3×10^{-4} mbar, 1 bar = 100 kPa) in the hexapole collision cell, while scanning Q2 to monitor the product ions formed. CID experiments were performed with xenon at various collision energies (E_{Lab} = 0–20 eV), and reactivity studies were conducted at a collision energy nominally set to E_{Lab} = 0 eV. As pointed out previously (24), the VG Bio-Q does not allow direct extraction of quantitative energetic information from these kinds of experiments because of some limitations of the commercial instrument. Even at E_{Lab} = 0 eV, for example, nonnegligible ion decay is observed for weakly bound ions, which is in part attributed to the presence of a collision partner not only in the hexapole, but also in the focusing regions between the mass analyzers. To a first approximation, however, the reactions observed can be ascribed to thermally activated processes, rather than collisionally driven reactions (26–28).

Scheme 1.

Results and discussion

Under mild conditions of ionization, electrospray of a dilute solution of hexachloroplatinic acid (H_2PtCl_6) in methanol–water (1:1) affords cations of the type $[H_3PtCl_6(CH_3OH)_n]^+$ with n = 4–6, which can be regarded as the protonated acid solvated by several methanol molecules. With increasingly harsher ionization conditions, sequential losses of solvent molecules take place as commonly observed in ESI (22, 29). However, for the ion $[H_3PtCl_6(CH_3OH)_3]^+$ formal degradation of the metal halide core via expulsion of HCl can also take place as shown by CID of the mass selected ion (-CH_3OH:-HCl ≈ 2:1). This route continues to be dominant until formation of $[PtCl_3(CH_3OH)_3]^+$ from which homolytic bond cleavages concomitant with the loss of open-shell fragments lead to several Pt-containing ions in yields sufficient for further reactivity studies. The formation of PtH^+ finally occurring under harsh ESI conditions can be rationalized by consecutive fragmentation of $PtOCH_3^+$ and (or) $PtCHO^+$ via β-hydrogen transfer (30–34) concomitant with liberation of formaldehyde and carbon monoxide, respectively. In Scheme 1, a simplified view of the consecutive fragmentation sequences from $[H_3PtCl_6(CH_3OH)_n]^+$ to diatomic PtX^+ species and

Table 1. Reactions of mass-selected PtX^+ cations with methane.

Reaction	Products	x_i[a]	k_{rel}	ϕ_i[b] (%)
$Pt^+ + CH_4$	$PtCH_2^+ + H_2$	100	40	35
$PtH^+ + CH_4$	$PtCH_3^+ + H_2$	100	50	45
$PtCHO^+ + CH_4$			<1[c]	
$PtCl^+ + CH_4$	$PtCH_3^+ + HCl$	100	70	65
$PtCl_2^+ + CH_4$	$ClPtCH_3^+ + HCl$	100	60	55
$PtBr^+ + CH_4$	$BrPtCH_2^+ + H_2$	15	100	90
	$PtCH_3^+ + HBr$	85		
$PtCl_3^+ + CH_4$			<1	

[a]Branching ratio x_i with $\Sigma x_i = 100$.
[b]Reaction efficiencies (ϕ_i) derived from $k_r(Pt^+) = 4.8 \times 10^{-10}$ cm^3 s^{-1} (11–13).
[c]H–D exchange was observed with deuterated methane.

Table 2. Apparent H–D kinetic isotope effects (KIEs) in the reactions of mass-selected PtX^+ cations with [D_2]-methane.

Reaction	Products	KIE[a]
$Pt^+ + CH_4$	$PtCH_2^+ + H_2$	1.70±0.04[b,c], 1.6±0.1[c,d]
$PtH^+ + CH_4$	$PtCH_3^+ + H_2$	1.11±0.05[b,c]
$PtCl^+ + CH_4$	$PtCH_3^+ + HCl$	1.16±0.04
$PtCl_2^+ + CH_4$	$ClPtCH_3^+ + HCl$	1.38±0.04
$PtBr^+ + CH_4$	$BrPtCH_2^+ + H_2$	1.25±0.08[b,c]
	$PtCH_3^+ + Hbr$	1.03±0.03

[a]Determined from the ratios of the isotopologs.
[b]For dehydrogenation, the KIE is determined by assuming a statistical distribution, where the latter assumption is self-consistently confirmed by comparison of the modeled and measured ratios of H_2, HD, and D_2 losses.
[c]In the case of dehydrogenation, the fact that a single KIE per deuterium atom involved can be used to model the ratios of H_2, HD, and D_2 formation further supports the proposed H–D equilibration prior to product formation and moreover, implies that both H(D) atoms involved participate in the rate-determining barrier to a similar extent; also see ref. 11.
[d]KIE found for thermalized Pt^+ in independent ICR experiments; see ref. 11.

even Pt^+ is provided as derived from the evolution of the ion intensities as a function of cone voltage as well as a number of CID experiments. Nevertheless, note that for the pathways shown some alternatives may exist, e.g., the combined elimination of two radicals ($Cl^·$ and $CH_3O·$) in the sequence from $(CH_3O)_2PtCl^+$ to CH_3OPt^+ may also involve elimination of the more stable neutral molecules HCl and CH_2O. Thus, even though the details of ion formation in the course of the ESI process may be quite complex, the key aspect in the present context is that this method of ionization allows the generation of gaseous platinum(II) species in yields fully sufficient for reactivity studies.

The ions of interest, namely, $PtCl_n^+$ (n = 0–3), $PtCHO^+$, and PtH^+, were then mass-selected by means of the first quadrupole Q1, reacted with several neutral reagents admitted to the hexapole collision cell at a collision energy nominally set to 0 eV, and the product ions were detected by scanning the second quadrupole analyzer Q2. Likewise, the platinum bromide cation $PtBr^+$ was generated by ESI of a diluted solution of hexabromoplatinic acid. Given the enormous interest in metal-mediated C—H bond activations (3–7), the first and obvious choice as a neutral reagent is methane, and it is indeed found that most of the ions investigated efficiently react with methane (Table 1). In the multipole mass spectrometer used in the present experiments, a direct measurement of absolute rate constant is difficult. However, the amount of conversion of the different precursor ions at given static pressures of the neutral reagent can be used for the determination of relative rate constants (k_{rel}) (26–28, 35). In the present case, the well-studied reaction of bare Pt^+ with methane (9–17) may further be used as a reference for the conversion of the relative into absolute rate constants (k_r); hence, reaction efficiencies (ϕ), defined as the ratio of k_r and the gas-kinetic collision rate (k_c) calculated from capture theory (36), can also be derived.

Bare Pt^+ reacts with methane via a formal oxidative addition to first afford the insertion product $H\text{-}Pt^+\text{-}CH_3$ and subsequently $PtCH_2^+$ and molecular hydrogen associated with a change of the formal oxidation state from Pt^I in atomic Pt^+ to Pt^{III} in the platinum carbene cation. In contrast, the reactions of the PtX^+ cations studied here occur as a formal substitution concomitant with loss of neutral HX, thereby retaining the oxidation state Pt^{II} in reactants and products. Likewise, formal substitution is observed with $PtCl_2^+$, whereas the $PtCl_3^+$ cation does not react with methane to a notable amount, even though of all ions studied here platinum has the highest formal valence in $PtCl_3^+$. A direct conclusion about the reaction mechanisms cannot be inferred from this observation, however, because the lack of reactivity towards CH_4 may be either due to thermochemical or kinetic reasons. While $PtCHO^+$ also does not react with CH_4, occurrence of H/D exchange with labeled methane indicates that activation itself is feasible. Absence of products other than the reactants, such as $PtCH_3^+ + CH_2O$, for example, is therefore most likely because of a lack of thermochemical driving force. For $PtBr^+$, oxidative addition is inferred to a small extent, as indicated by the side reaction leading to dehydrogenation concomitant with the formation of the bromo platinum carbene cation $BrPtCH_2^+$.

As another probe for reactivity, the reactions with partially deuterated methane (CH_2D_2) were investigated for which the ratio of isotopologous products can be regarded as a direct measure for the intramolecular kinetic isotope effect associated with C—H(D) bond activation (Table 2). Analysis of the isotope patterns results in comparably small kinetic isotope effects (KIEs; here, defined as KIE = k_H/k_D) and moreover, H–D equilibration is observed for the reaction of PtH^+ with CH_2D_2 in that H_2, HD, as well as D_2 are lost as neutral molecules. The experimentally found isotope patterns can be modeled with the KIEs given in Table 2 by taking into account the corresponding statistical weights (11).

For the reaction of $PtCl^+$ with methane, the thermochemical data derived by Armentrout and co-workers (13, 20) also provide more detailed energetic insight. Thus, the bond dissociation energy $D(Pt^+—Cl)$ = 2.55 ± 0.15 eV (20) in conjunction with $D(H—CH_3)$ = 4.48 ± 0.01 eV and $D(H—Cl)$ = 4.43 ± 0.01 eV from supplementary thermochemical data (37), as well as $D(Pt^+—CH_3)$ = 2.67 ± 0.08 eV (13), imply a total exothermicity of 0.07 ± 0.17 eV for bond activation of methane according to rxn. [1].

[1] $PtCl^+ + CH_4 \rightarrow PtCH_3^+ + HCl$

[2] $PtH^+ + CH_4 \rightarrow PtCH_3^+ + H_2$

© 2005 NRC Canada

In contrast, activation of methane by PtH^+ according to rxn. [2] is predicted to bear a slight endothermicity of 0.13 ± 0.09 eV (13, 20), which is, nevertheless, within the margin of ion–molecule reactions occurring under thermal conditions (38). Note, however, that the formation of PtH^+ under the harsh conditions of electrospray ionization can also be associated with some excess energy content in the cations mass-selected from the ESI source (27). Nevertheless, the near thermoneutrality of the reactions in conjunction with the low KIEs observed with partially labeled methane indicate that the bond activation of methane by PtX^+ cations is primarily subject to thermochemical control of the exit channels, as also predicted by theory for the reaction of bare Pt^+ with methane (12, 13, 15). As far as the reaction mechanism is concerned, the present results do not permit a distinction whether or not oxidative addition to an $XPt(H)(CH_3)^+$ intermediate is operative in the course of the formal substitution reactions. Furthermore, theoretical studies of related systems have predicted quite low reaction barriers for the direct electrophilic substitution of methane by PtX species, thus a route with parallel H—X as well as Pt—C bond formation, without involving a change of the metal's oxidation state (39–41). In fact, with regard to the low kinetic isotope effect observed, the mechanism of the gas-phase processes described here is most likely difficult to assess by experimental means for the time being, and instead adequate theoretical studies might provide more detailed insight.

Given the facile activation of methane by most of the PtX^+ cations investigated, the reactions of $PtCl^+$ with some other substrates were explored briefly. Thus, $PtCl^+$ reacts with molecular hydrogen to afford PtH^+ according to rxn. [3] for which an exothermicity of 0.25 ± 0.16 eV is predicted from literature thermochemistry (13, 20, 37). With a larger hydrocarbon substrate such as propane, single and multiple C—H bond activations (rxns. [4*a*] and [4*b*]), as well as a small amount of C—C bond cleavage (rxn. [4*c*]), are observed with a branching ratio of [4*a*]:[4*b*]:[4*c*] ≈ 5:90:5.

$$[3] \quad PtCl^+ + H_2 \rightarrow PtH^+ + HCl$$

$$[4a] \quad PtCl^+ + C_3H_8 \rightarrow PtC_3H_7^+ + HCl$$

$$[4b] \quad \rightarrow PtC_3H_5^+ + HCl + H_2$$

$$[4c] \quad \rightarrow PtC_2H_3^+ + HCl + CH_4$$

Similarly, multiple C—H bond activation prevails in the reaction of mass-selected $PtCl^+$ with isomeric butenes, which afford $PtC_4H_5^+$ as the major product ion. Likewise, PtH^+ as well as $PtBr^+$ react with these hydrocarbons via multiple dehydrogenation, indicating the high reactivity of gaseous Pt^{II} cations for the activation of hydrocarbons.

Conclusions

Electrospray ionization can be used for the efficient generation of reactive PtX^+ cations in the gas phase, which are difficult to produce by other means. Reactivity studies of mass-selected PtX^+ reveal that these species are able to activate hydrocarbons including methane. Thermochemical considerations as well as the kinetic isotope effects associated with the C—H(D) bond activation of CH_2D_2 suggest that the reactions are subject to thermochemical control by the product channels. In a more general perspective, the present gas-phase studies imply that cationic species might also play a distinct role in C—H bond activation of alkanes in the condensed phase, for example, as in the system $Pt^{(II)}$–H_2SO_4–CH_4 developed by Periana et al. (42).

Carbonate, carbamate, urea, and guanidine as model species for functional groups in biological molecules — A combined density functional theory and mass spectrometry examination of polysodiation and gas-phase dissociation[1]

Tujin Shi, Junfang Zhao, P.Y. Iris Shek, Alan C. Hopkinson, and K.W. Michael Siu

Abstract: Electrospray mass spectrometric analyses of carbonate, carbamate, urea, and guanidine in the presence of sodium ions results in polysodiated complexes of the type, $[M - (n - 1)H + nNa]^+$, where M is the species analyzed and $n = 2$ and (or) 3. These complexes are unusual in their high sodium contents and their attractive structures. The $[M - H + 2Na]^+$ complexes fragment to produce $[Na_2NH_2]^+$, Na^+, and a product ion resulting from the loss of NH_3. The $[M - 2H + 3Na]^+$ complexes dissociate to give a number of fragment ions, including $[Na_3O]^+$, $[Na_2OH]^+$, $[NaOCNNa]^+$, $[Na_2NH_2]^+$, $[Na_3CN_2]^+$, and Na^+, depending on the elemental composition of M. These dissociation reactions were examined both experimentally by mass spectrometry and theoretically by density functional theory. Reaction profiles as calculated at B3LYP/6-311G** for disodiated carabamate, urea, and guanidine, and for all the bases in trisodiated form are given. Both experimental and theory show $[Na_3CO_3]^+$ to have high stability towards collisional activation and to preferentially dissociate to give $[Na_3O]^+$ and CO_2, rather than Na^+ and Na_2CO_3.

Key words: carbonate, carbamate, urea, guanidine, electrospray, collision-induced dissociation, density functional theory, sodium ion binding energies.

Résumé : Les analyses par spectrométrie de masse avec ionisation par électronébulisation des carbonates, des carbamates, de l'urée et de la guanidine en présence d'ions sodium conduit à la formation de complexes polysodés du type $[M - (n - 1)H + nNa]^+$ dans lesquels M est l'espèce analysée et $n = 2$ et (ou) 3. Ces complexes sont inhabituels en raison de leur teneur élevée en sodium et leurs structures intéressantes. Les complexes $[M - H + 2Na]^+$ se fragmentent pour conduire à la formation de $[Na_2NH_2]^+$, Na^+ et un ion qui résulte de la perte de NH_3. Les complexes $[M - 2H + 3Na]^+$ se dissocient pour donner, suivant la composition élémentaire de M, un certain nombre de fragments ioniques, dont le $[Na_3O]^+$, le $[Na_2OH]^+$, le $[NaOCNNa]^+$, le $[Na_2NH_2]^+$, le $[Na_3CN_2]^+$ et le Na^+. On a étudié ces réactions de dissociation tant d'une façon expérimentale par spectrométrie de masse que d'une façon théorie par la théorie de la densité fonctionnelle. On rapporte les profils de réaction calculés au niveau B3LYP/6-311G** pour le carbamate, l'urée et la guanidine sous la forme disodée et pour toutes les bases sous la forme trisodée. Les résultats tant expérimentaux que théoriques montrent que le $[Na_3CO_3]^+$ est très stable vis-à-vis des activations par collision et qu'il se dissocie d'une façon privilégiée pour donner du $[Na_3O]^+$ et du CO_2 plutôt que du Na^+ et du Na_2CO_3.

Mots clés : carbonate, carbamate, urée, guanidine, électronébulisation, dissociation induite par une collision, théorie de la densité fonctionnelle, énergie de fixation de l'ion sodium.

[Traduit par la Rédaction]

Introduction

The sodium ion is ubiquitous in biology. It plays many roles and has many important functions; these include regulating metabolism and signaling through trans-membrane concentration gradients, and stabilizing the structure of proteins and membranes (1–4). To carry out its regulatory and structural functions, the sodium ion must interact with the appropriate peptides or proteins. This interaction is specific and can be quite complex as peptides and proteins are

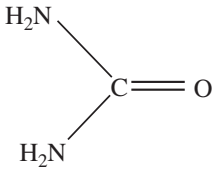
multifunctional molecules with several to many potential binding sites. By contrast, nonspecific sodium binding, resulting in the complexes $[M - (n - 1)H + nNa]^+$ (where M = the peptide or protein), is often observed when a peptide or protein is analyzed using electrospray mass spectrometry (MS), especially in the presence of sodium hydroxide or a sodium salt (5–8). Rodriquez et al. (6, 7) postulated that these polysodiated ions are formed in the lens region of the mass spectrometer as a result of gas-phase reactions: the relative yield of the $[M - (n - 1)H + nNa]^+$ complexes increases with increasing collision energy in the lens region, in accordance with the interpretation of their gas-phase origin. It was shown that substitution reactions are a consequence of amidic and carboxylic protons being replaced by Na^+. Indeed, hexaglycine forms a series of $[M - (n - 1)H + nNa]^+$ complexes; the complex with the largest n, $[M - 6H + 7Na]^+$, has all its five amidic protons and one carboxylic proton replaced by six Na^+ with the seventh Na^+ "ionizing" the peptide (8). Na^+ substitution for amidic protons has also been observed in dinucleotides containing guanine and thymine (9).

Ion affinities, properties that reveal intrinsic binding strengths unencumbered by solvation, are often measured with mass spectrometry (10). Sodium ion affinities of amino acids have been reported (11–17). Kebarle and co-workers (12) were the first to report the Na^+ affinity of diglycine, measured using the threshold collision-induced dissociation (CID) technique. This work was followed by others that examined more complex peptides.



Here we report a combined mass spectrometric and density functional theory examination of the polysodiation of four model species — carbonate (CN), carbamate (CM), urea (UR), and guanidine (GU) — that mimic functional groups on peptides and the nucleobases, guanine, cytosine, and thymine. Polysodiation results in novel and attractive structures that dissociate to give interesting, highly sodiated products.

Experimental section

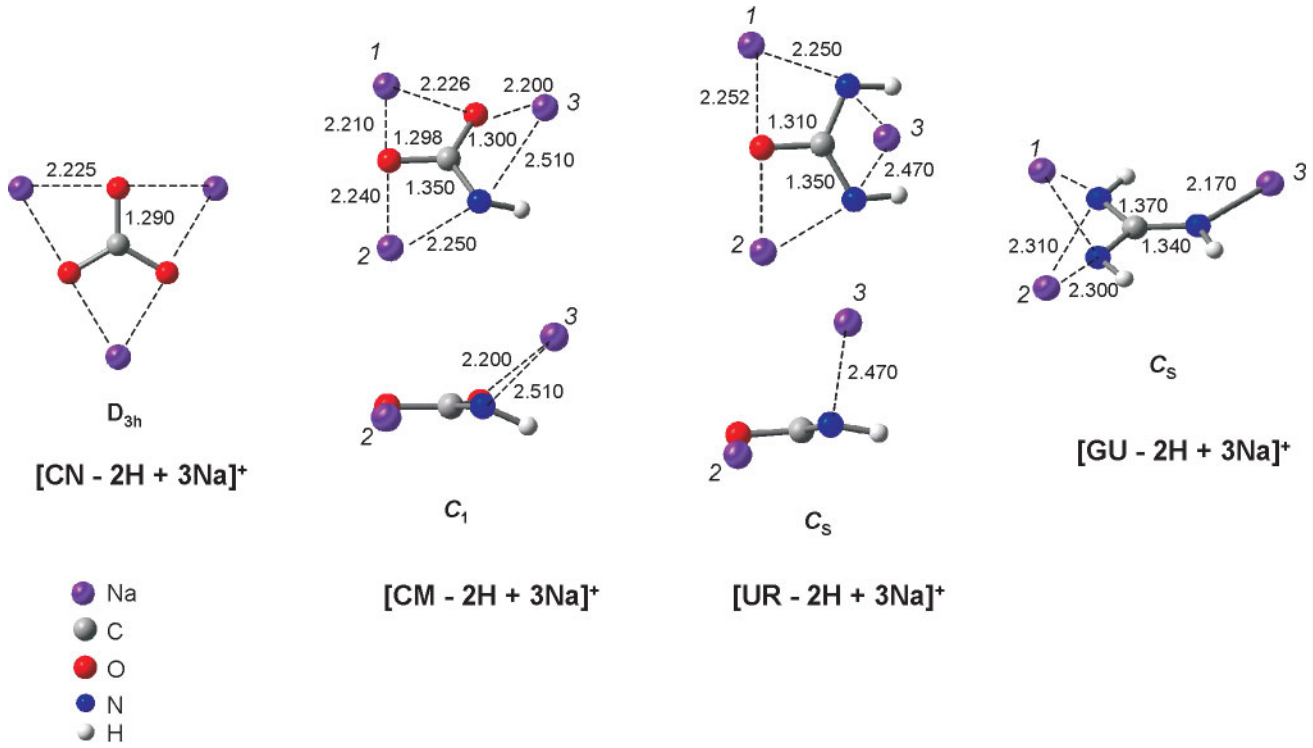
Mass spectrometry

Experiments were performed on MDS SCIEX (Concord, Ontario) triple-quadrupole mass spectrometers, API III and a prototype of the API 3000. Samples were 50 μmol/L model species and 200 μmol/L sodium nitrate at typically pH 12 (adjusted with sodium hydroxide) in water–methanol (50:50). All chemicals and solvents were available from Sigma-Aldrich (St. Louis, Missouri). Sample solutions were introduced into the ion source via pneumatically assisted electrospray at a typical flow rate of 3 μL/min. The lens voltages, including the orifice voltage, were optimized to produce optimal abundance of $[M - (n - 1)H + nNa]^+$ ($n \leq 3$) complexes. MS/MS experiments were performed by mass selecting the precursor ions using the first quadrupole mass analyzer (Q1), colliding them with argon (API III) or nitrogen (API 3000) in the second quadrupole (Q2), and mass analyzing with the third quadrupole (Q3). Energy-resolved CID experiments were performed under on-average, single-collision conditions on only the API III.

Computations

Density functional theory calculations were implemented with Gaussian 98 (18). Geometry optimization and energy calculations were performed using the B3LYP exchange correlation functional (19–21) with the 6-311G** triply split valence basis set (22–25). All stationary points were characterized by harmonic vibrational frequency calculations. Connections between transition states and corresponding minima were verified using the intrinsic reaction coordinate (IRC) method developed by Gonzalez and Schlegel (26, 27). Relative enthalpies at 0 K (ΔH_0°) are reported and used to compare relative energies. Natural population atomic (NPA) charges were determined using the natural bond orbital analysis of Reed, Weinhold, and co-workers (28–31). Cartesian coordinates and electronic energies for key structures are available as Supplementary material.[3]

Results and discussion



Polysodiated complexes

Electrospraying a solution of the model species in the presence of Na^+ produces abundant sodiated complexes. The relative abundances of the $[M - (n - 1)H + nNa]^+$ complexes for $n = 2$ and 3 increase with collision energy in the lens region, which is in accordance with previous observations (6–8) and is in direct support of a gas-phase origin of these polysodiated complexes. In short, the electrosprayed ions react with sodium hydroxide or sodium salt in the ion source and (or) the lens region of the mass spectrometer, which results in substitution of a carboxylic or amidic proton by a Na^+, in addition to ionization via direct sodiation (6–8). The

Fig. 1. The optimized structures of $[M - 2H + 3Na]^+$ for M = carbonate (CN), carbamate (CM), urea (UR), and guanidine (GU) calculated at the B3LYP/6-311G** level. Bond distances are in angstroms. Italicized numbers are referred to in the text for distinguishing sodium atoms.

maximum number of sodium atoms incorporated observed in this study is three, which results in sodium binding to each O and N atom in the four model species — carbonate, carbamate, urea, and guanidine. Three of the four resulting $[M - 2H + 3Na]^+$ complexes have high degrees of symmetry resulting in interesting structures (Fig. 1).

$[CN - 2H + 3Na]^+$ has several unusual geometric and electronic structural features. It is planar with each sodium equidistant from two oxygen atoms, i.e., the ion has D_{3h} symmetry. The atoms in Na-O-Na are essentially collinear (angle 179.7°) and the Na—O distances are 2.225 Å; these compare with an angle of 180° and a Na—O distance of 1.980 Å in the triatomic molecule Na_2O. NPA analysis gave charges of +0.95 on the sodium atoms, –0.95 on the oxygen atoms, and +1.00 on the carbon. There are three occupied π orbitals in the valence shell, an a_2''-type and doubly degenerate e_2''-types. The latter have nodes passing through the carbon atom and the contribution from the carbon atom to the a_2'' orbital is 0.80 *e*; hence the majority of the π-electron density is on the oxygen and sodium atoms on the perimeter. $[CN - 2H + 3Na]^+$ has remarkable stability, as will be discussed in terms of Na^+ binding energies, and it is tempting to suggest that this stability is attributable to the presence of some aromatic character.

$[CM - 2H + 3Na]^+$ belongs to the C_1 point group. The O, C, and N atoms are close to being coplanar. Na_1 and Na_2 are just below the "plane". The hydrogen atom is also below, whereas Na_3 is above, the plane. Interestingly, the three Na atoms carry an identical charge of +0.94, almost identical to the charge on Na in $[CN - 2H + 3Na]^+$. $[UR - 2H + 3Na]^+$ has C_s geometry. The plane of symmetry contains the O, C, and Na_3 atoms. The O, C, and the two N atoms are essentially coplanar, in a plane that is perpendicular to the C_s plane. Na_1 and Na_2 have a charge of +0.93 and lie just below the former plane, whereas Na_3 (+0.95 charge) lies above it. $[GU - 2H + 3Na]^+$ also has C_s geometry with the plane of symmetry containing the C, the three H, the three N, and Na_3 atoms. Na_1 lies above, whereas Na_2 lies below, this plane. Both Na_1 and Na_2 carry a charge of +0.92; Na_3 is almost identically charged at +0.93.

Table 1. Na^+ binding energies (kcal/mol) as calculated at B3LYP/6-311G**.

Molecule	Monosodiated	Disodiated	Trisodiated
Carbonate	NA[a]	NA	79.4
Carbamate	NA	47.4	63.6
Urea	43.7	51.8	58.2
Guanidine	42.8	52.7	62.2

[a]NA = not detected experimentally and not calculated.

$[M + Na]^+$ and $[M - H + 2Na]^+$ complexes

Under appropriate conditions, fairly abundant $[M + Na]^+$ complexes were observed for urea and guanidine. The CID of these complexes is uninteresting, as the only product ion observed was Na^+. In all these structures, the charge on Na was calculated to be +0.94 ± 0.01. Na^+ binding energies were calculated to be 43.7 and 42.8 (see Table 1). Possible alternative pathways to dissociation, loss of NH_3 (see later), although not observed here, were calculated to have barriers of 50.8 and 48.9 kcal/mol for M = UR and GU, respectively.

Abundant $[M - H + 2Na]^+$ complexes were observed for carbamate, urea, and guanidine. CID of these complexes re-

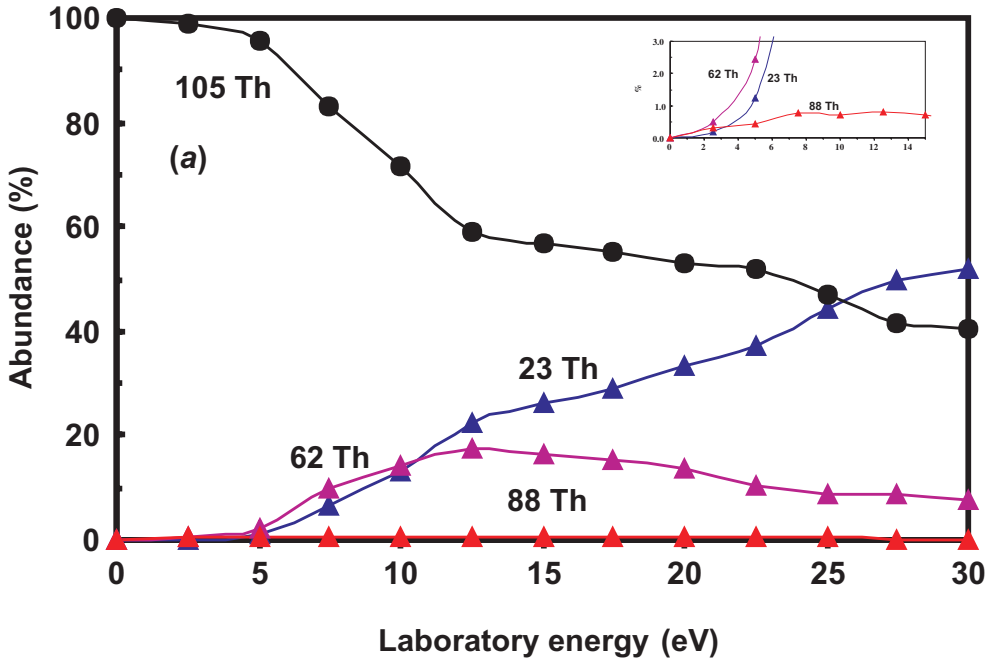
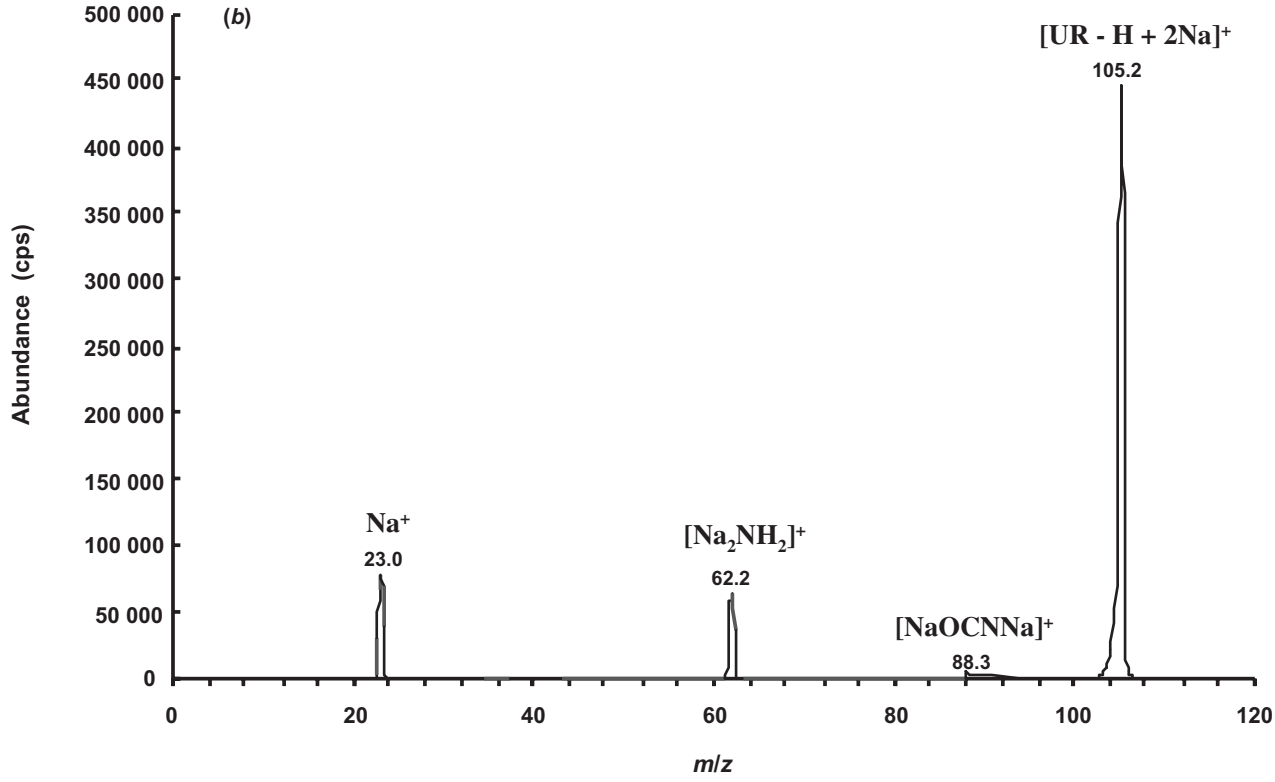
Fig. 2. Dissociation of [UR – H + 2Na]$^+$. (*a*) Energy-resolved CID plots; the inset shows low-energy details; (*b*) CID spectrum at a laboratory collision energy of 10 eV; and (*c*) reaction profiles. Bond distances are in angstroms, relative energies are ΔH°_0 in kcal/mol, and transition states are indicated as such by ‡.





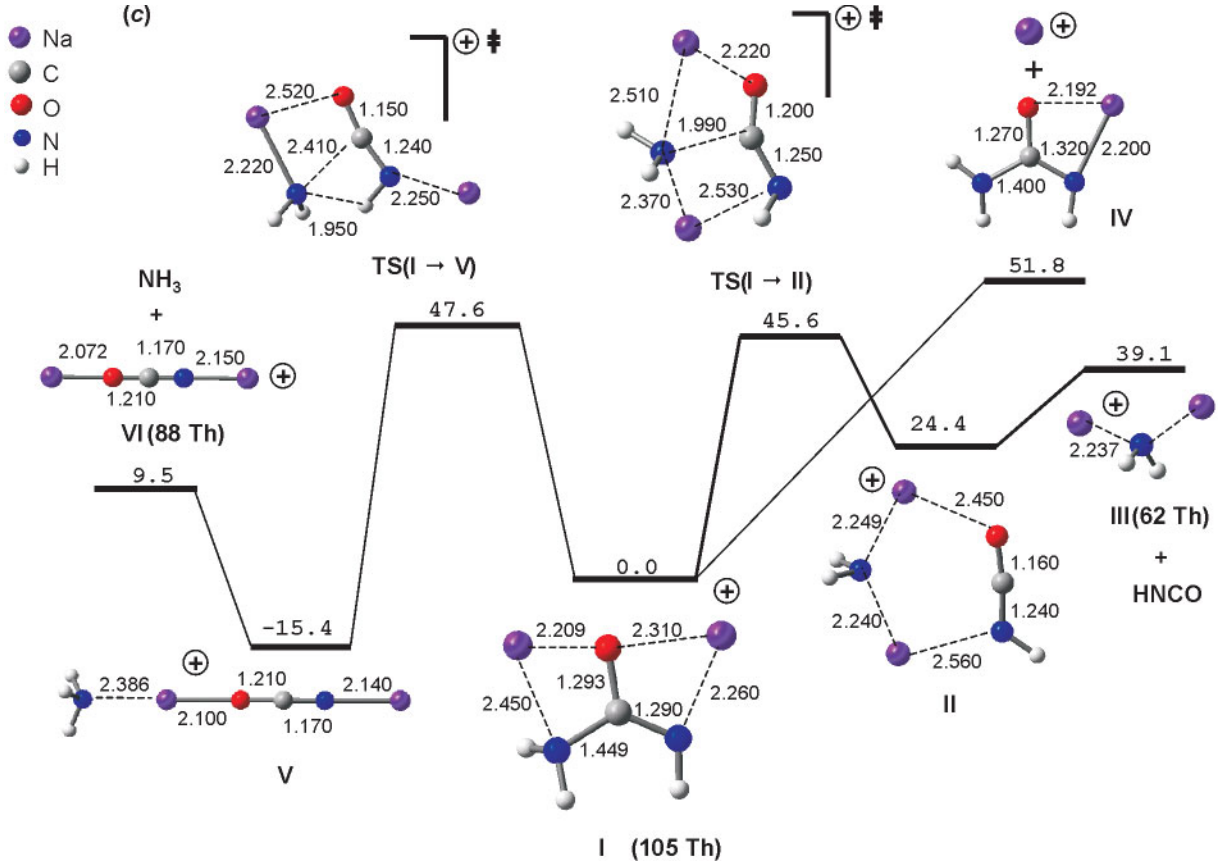


Fig. 2 (*b*).

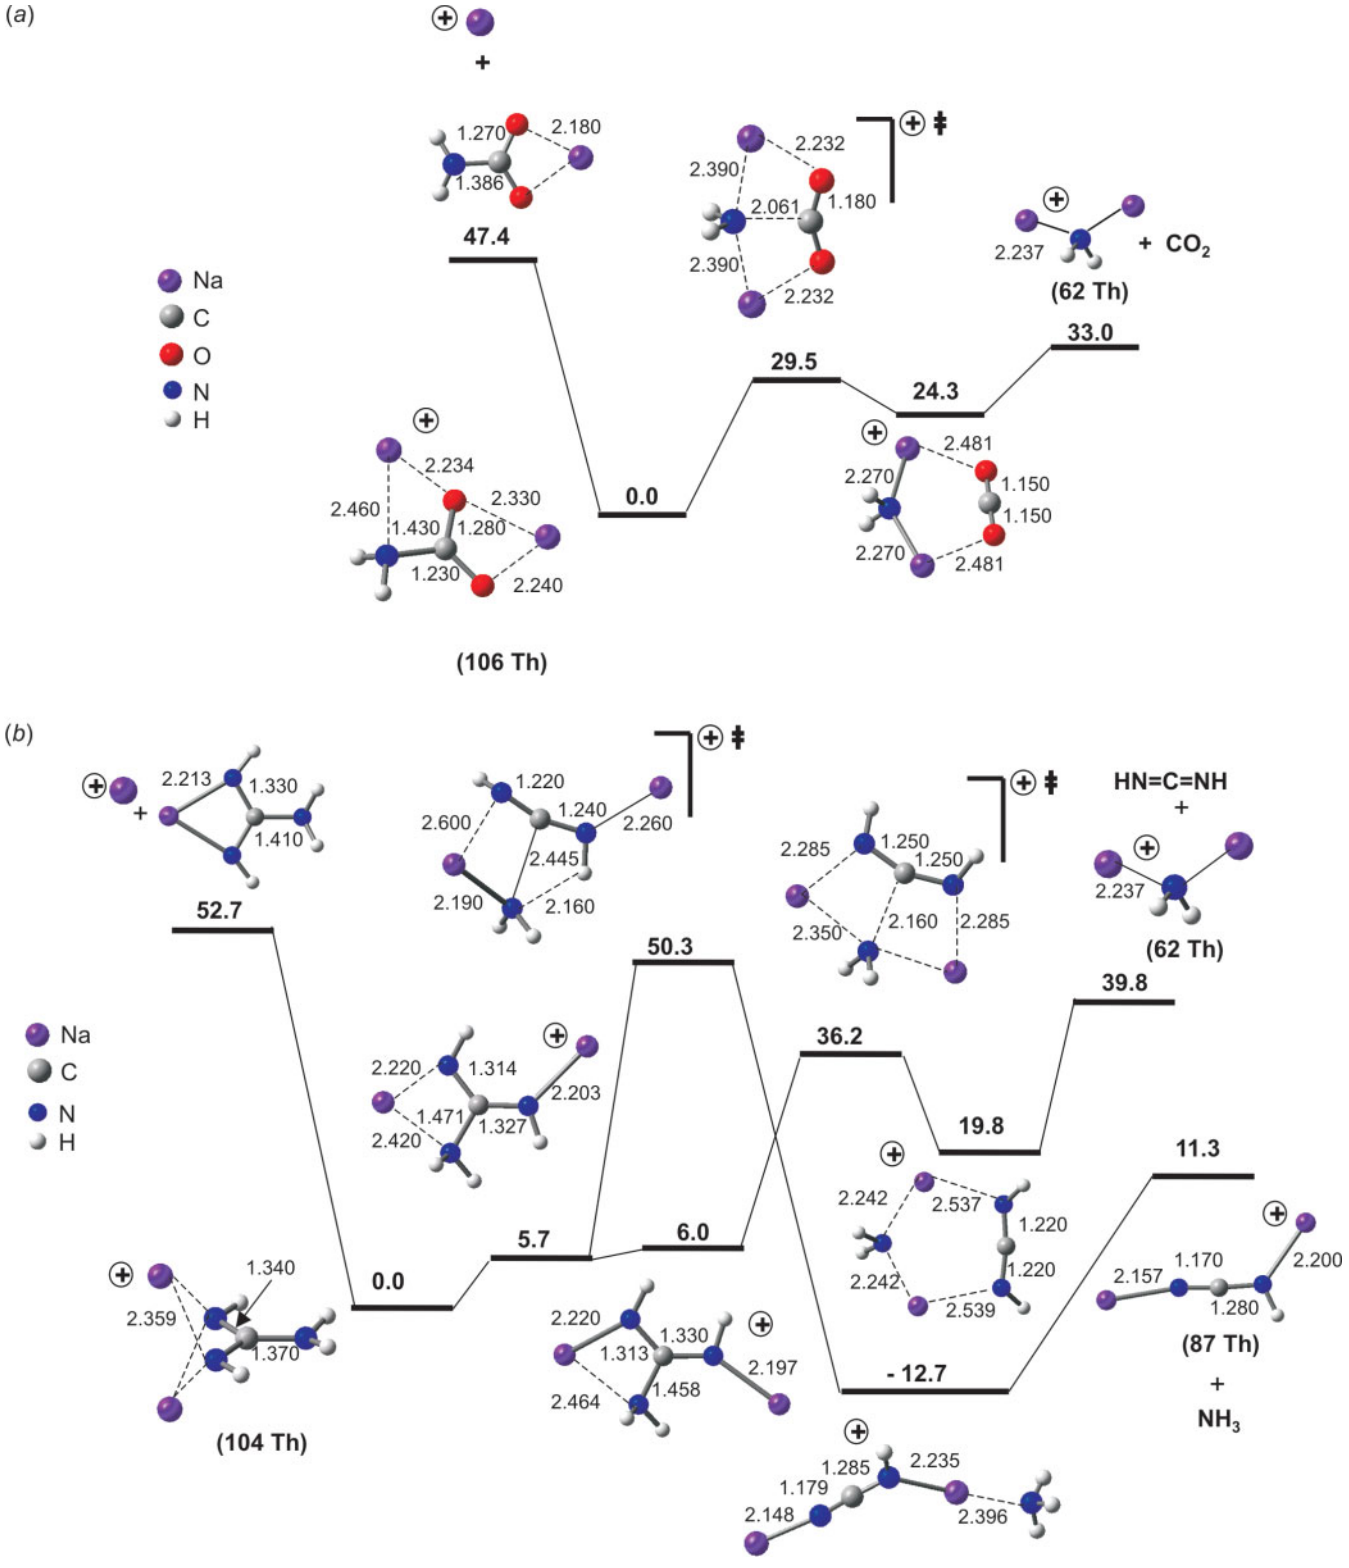
sults in the observation of Na^+ (23 Th), $[Na_2NH_2]^+$ (62 Th), and a product ion resulting from the loss of NH_3. The last reaction is not observed in carbamate as it contains only two hydrogen atoms. Figure 2*a* shows the energy-resolved CID results for [UR – H + 2Na]$^+$; the CID spectrum at a laboratory collision energy of 10 eV is shown in Fig. 2*b*. The dissociation reaction to give $[Na_2NH_2]^+$ appears to require the least amount of energy, followed by that to give $[NaOCNNa]^+$. This latter product ion at 88 Th, resulting from elimination of NH_3, has a low abundance (<1%) under all energies. Na^+ is formed at slightly higher energies and becomes the dominant product at high collision energy (see

© 2005 NRC Canada

Fig. 2 (*c*).



the inset in Fig. 2*a* for details). The abundance of the $[Na_2NH_2]^+$ ion maximizes at about 12.5 eV and decreases substantially at higher energies. By contrast, the abundance of Na^+ increases with increasing collision energy, initially more steeply between 5 and 12.5 eV, and then more gently between 12.5 and 30 eV. These observations are indicative that $[Na_2NH_2]^+$ dissociates to Na^+ at laboratory energies above 12.5 eV.

Figure 2*c* shows the reaction profiles for the dissociation of $[UR - H + 2Na]^+$ (structure **I**). Formation of $[Na_2NH_2]^+$ initially requires a Na^+ transfer resulting in both Na being bound to $-NH_2$ to give structure **II**, an ion–neutral complex in which $[Na_2NH_2]^+$ is solvated by HNCO. Separation of the parts yields **III**, $[Na_2NH_2]^+$, and HNCO. The transition state (**TS(I→II)**) lies 45.6 kcal/mol (1 cal = 4.184 J) above **I** and is higher than the products of dissociation. Fragmentation of **I** to Na^+ and structure **IV** does not have a transition state; the endothermicity of this reaction is 51.8 kcal/mol. Elimination of NH_3 from **I** requires transfer of the -NH proton to $-NH_2$ to give **V**, which is $[NaOCNNa]^+$ solvated by NH_3. Separating the ion–neutral complex results in ion **VI** and NH_3. The transition state (**TS(I→V)**) lies 47.6 kcal/mol above **I**. Of the three reaction pathways, formation of $[Na_2NH_2]^+$ has the lowest activation energy, which is in qualitative agreement with the experimental results shown in Fig. 2*a*.[4] Formation of Na^+, the process shown to have the highest energy experimentally, requires only an additional 6.2 kcal/mol (~0.3 eV) and is calculated to be 8.1 kcal/mol higher than the dissociation energy of $[UR + Na]^+$. The sodium ion affinity of $NaNH_2$ is 60.3 kcal/mol, higher than the sodium ion affinity of **IV**, by only 8.5 kcal/mol. Under high CID energies (>12.5 eV), dissociation of $[Na_2NH_2]^+$ is apparent. By contrast, the sodium ion affinity of NaOCN is 52.9 kcal/mol, which is lower than the affinity of $NaNH_2$ by 7.4 kcal/mol. In addition, the products **VI** and NH_3 lie 38.1 kcal/mol below the critical transition state (**TS(I→V)**), which leads to their formation. This value is considerably larger than the difference of 6.5 kcal/mol between the energy of products **III**, $[Na_2NH_2]^+$, plus HNCO, and **TS(I→II)**, the corresponding critical transition state. This means that nascent $[NaOCNNa]^+$ is probably a lot hotter than nascent $[Na_2NH_2]^+$. This higher internal energy content, coupled with the comparatively lower sodium ion affinity of NaOCN relative to that of $NaNH_2$, means that $[NaOCNNa]^+$ must dissociate readily to yield Na^+ at a low collision energy (even $[Na_2NH_2]^+$ dissociates at energy > 12.5 eV), and accounts for its low abundance in all collision energies examined (Fig. 2*a*).

[4] The energy-resolved CID results show that the $[Na_2NH_2]^+$ abundance becomes nonzero at ~2 eV. Our data analyses are qualitative because, although the experiments were carried out under on-average single collision conditions, there were multiple collisions that led to an apparent decrease of the critical energy. In addition, the experiments were carried out at 298 K, which also led to a decrease in the critical energy. A factor that led to an increase in the critical energy was the kinetic shift, a consequence of the limited observation window in the MS/MS experiment.

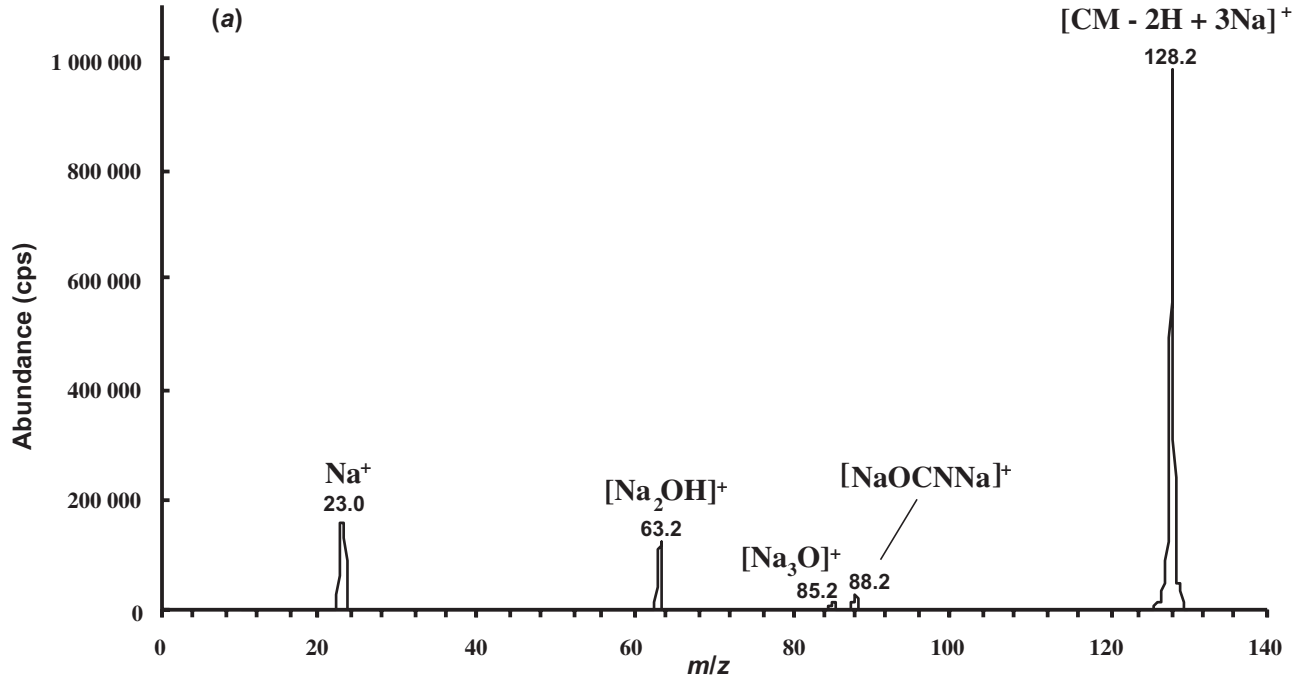

Fig. 3. Reaction profiles of (*a*) $[CM - H + 2Na]^+$ and (*b*) $[GU - H + 2Na]^+$.

Reaction profiles for $[CM - H + 2Na]^+$ and $[GU - H + 2Na]^+$ are shown in Fig. 3. The profile for $[CM - H + 2Na]^+$ (Fig. 3*a*) is the simplest of all three $[M - H + 2Na]^+$ complexes, as $[CM - H + 2Na]^+$ contains only two hydrogen atoms and thus cannot lose NH_3. As in $[UR - H + 2Na]^+$, the first step in forming $[Na_2NH_2]^+$ is an Na^+ transfer resulting in both Na atoms being bound to $-NH_2$ to give an ion–neutral complex in which $[Na_2NH_2]^+$ is solvated by CO_2. Dissociation of this complex yields the products $[Na_2NH_2]^+$ and CO_2. However, in contrast to $[UR - H + 2Na]^+$, formation of

Fig. 4. Dissociation of $[CM - 2H + 3Na]^+$. (*a*) CID spectrum at a laboratory collision energy of 12.5 eV; (*b*) energy-resolved CID plots; the inset shows low-energy details; and (*c*) reaction profiles. Bond distances are in angstroms, relative energies are ΔH°_0 in kcal/mol, and transition states are indicated as such by ‡.

$[Na_2NH_2]^+$ proceeds with an activation energy that is lower than the endothermicity of the reaction at 33.0 kcal/mol. This is considerably lower than the endothermicity (39.1 kcal/mol) and the activation energy (45.6 kcal/mol) of the analogous reaction in $[UR - H + 2Na]^+$. Dissociation of $[CM - H + 2Na]^+$ to give Na^+ requires 47.4 kcal/mol, which is also lower in energy than the analogous reaction in $[UR - H + 2Na]^+$ by 4.4 kcal/mol.

Relative to the profiles of $[CM - H + 2Na]^+$ and $[UR - H + 2Na]^+$, that of $[GU - H + 2Na]^+$ (Fig. 3*b*) is the most complicated. Contributing to this complexity is the lowest energy structure of $[GU - H + 2Na]^+$, which has the two Na bound to only two (nitrogen) atoms, as opposed to those of $[CM - H + 2Na]^+$ and $[UR - H + 2Na]^+$ that have Na^+ binding to three atoms. Both the formation of $[Na_2NH_2]^+$ and elimination of NH_3 in $[GU - H + 2Na]^+$ require, as a first step, transfer of one Na^+ from the two -NH groups to the $-NH_2$ group, which initially has no Na^+. Transfer of the second Na^+ leads to an ion–neutral complex, the dissociation of which gives $[Na_2NH_2]^+$ and HN=C=NH. Alternatively, transfer of a hydrogen eventually results in elimination of NH_3. As in the other profiles, formation of Na^+ from the complex requires the highest energy of 52.7 kcal/mol.

$[M - 2H + 3Na]^+$ complexes

As alluded to earlier, abundant $[M - 2H + 3Na]^+$ ions were observed at relatively energetic collision energies in the lens region. Collision-induced dissociations of the trisodiated ions have a lot in common and yield the following product ions: $[Na_3O]^+$ (85 Th), except for GU, which has no oxygen atom; $[Na_2OH]^+$ (63 Th), except for CN, which has no hydrogen (in the trisodiated complex), and GU, which has no oxygen atom; $[NaOCNNa]^+$ (88 Th), except for CN, which has no nitrogen, and GU, which has no oxygen atom; $[Na_2NH_2]^+$ (62 Th), except for CN, which has neither nitrogen nor hydrogen atom, and CM, which has only one hydrogen atom; $[Na_3CN_2]^+$ (109 Th), except for CN and CM, both of which contain fewer than two nitrogen atoms; and Na^+ (23 Th). A representative CID spectrum of $[CM - 2H + 3Na]^+$ at 12.5 eV is shown in Fig. 4*a*. Energy-resolved CID results show that dissociation to the product ions ($[Na_2OH]^+$ and $[NaOCNNa]^+$) require the lowest critical energies (Fig. 4*b*). As the abundance of Na^+ is much higher than those of any other product ions (see inset), estimation of the Na^+ critical energy relative to $[Na_2OH]^+$ and $[NaOCNNa]^+$ is more difficult; it is probably comparable to or slightly larger than those of the two disodiated fragment ions. These two ions can also subsequently fragment to give Na^+ at collision energies beyond 15 eV.

Figure 4*c* shows the energy profiles for the various dissociation pathways of $[CM - 2H + 3Na]^+$ (structure **VII**). Dissociation to give $[Na_2OH]^+$ (63 Th) requires first migration of the hydrogen from N to O to form complex **VIII**, and then a sodium moving in the opposite direction to form complex **IX**. This latter complex dissociates to yield $[Na_2OH]^+$ (structure **X**) and NaNCO. Alternatively, **IX** can dissociate to give $[NaOCNNa]^+$ (88 Th), ion **VI**, and NaOH. It is noteworthy that both product combinations lie below the critical transition state **TS(VII→VIII)**, which lies 54.1 kcal/mol above **VII**. This means that the dissociations to $[Na_2OH]^+$ and $[NaOCNNa]^+$ have an identical reaction barrier. The abundance of $[Na_2OH]^+$ is expected to be higher than that of $[NaOCNNa]^+$, as the product combination containing the former, at 40.7 kcal/mol, is lower lying than that containing the latter, at 50.8 kcal/mol. This prediction is consistent with experimental results shown in Fig. 4*b*. Elimination of Na^+ from structure **VII** results in product **XI**; the endothermicity of the reaction is 63.6 kcal/mol, larger than the critical bar-

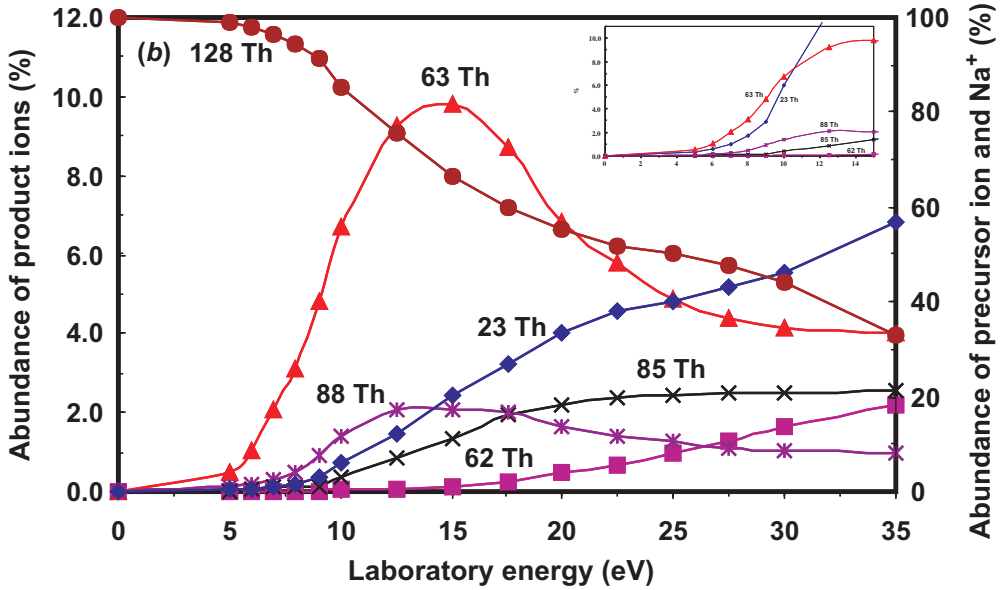

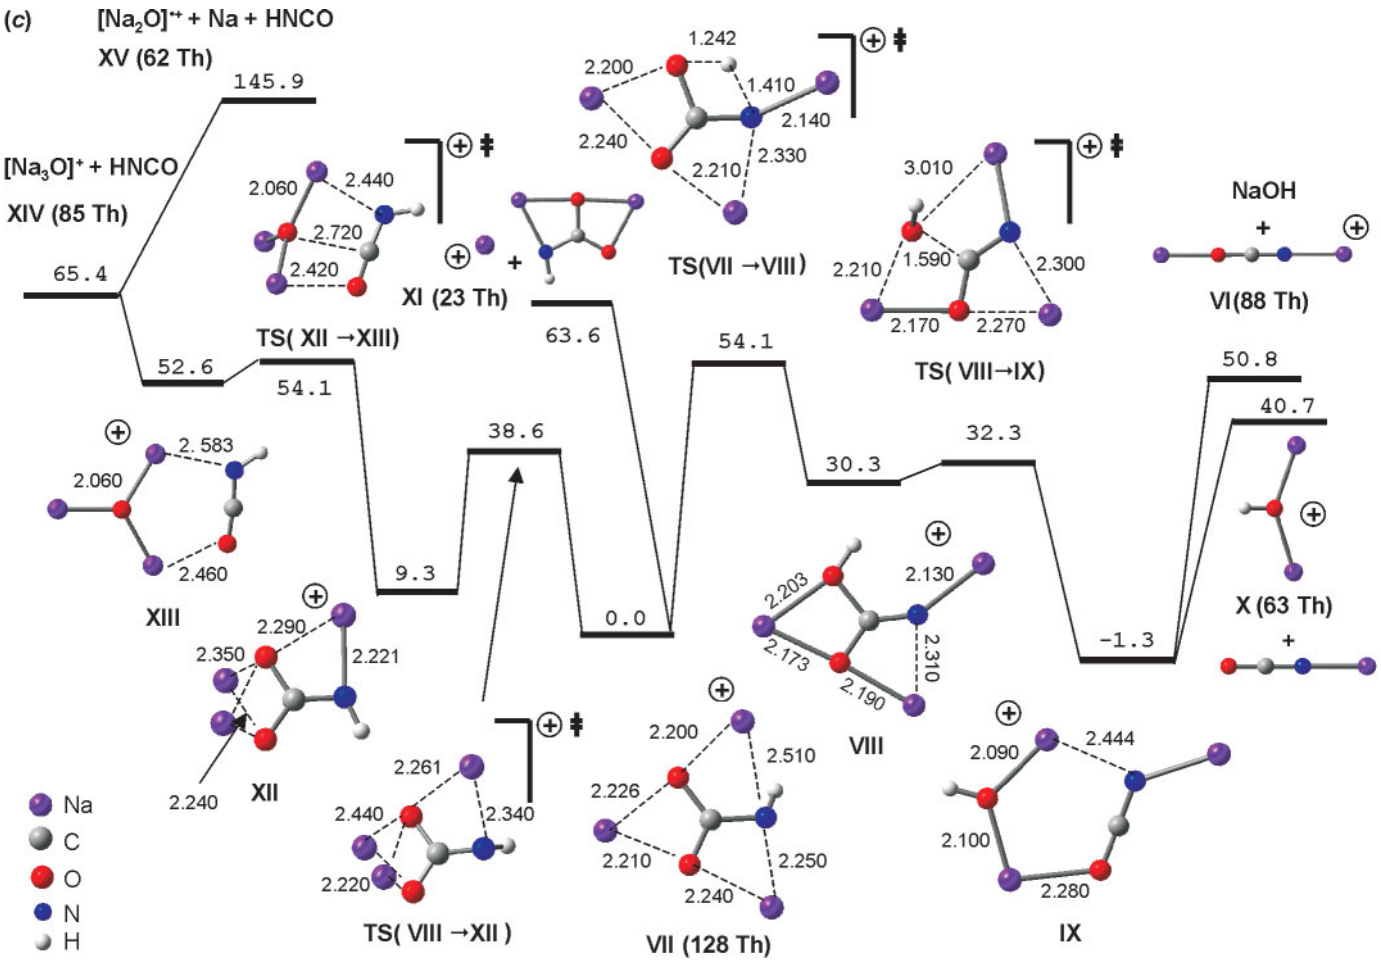

Fig. 4 (*c*).

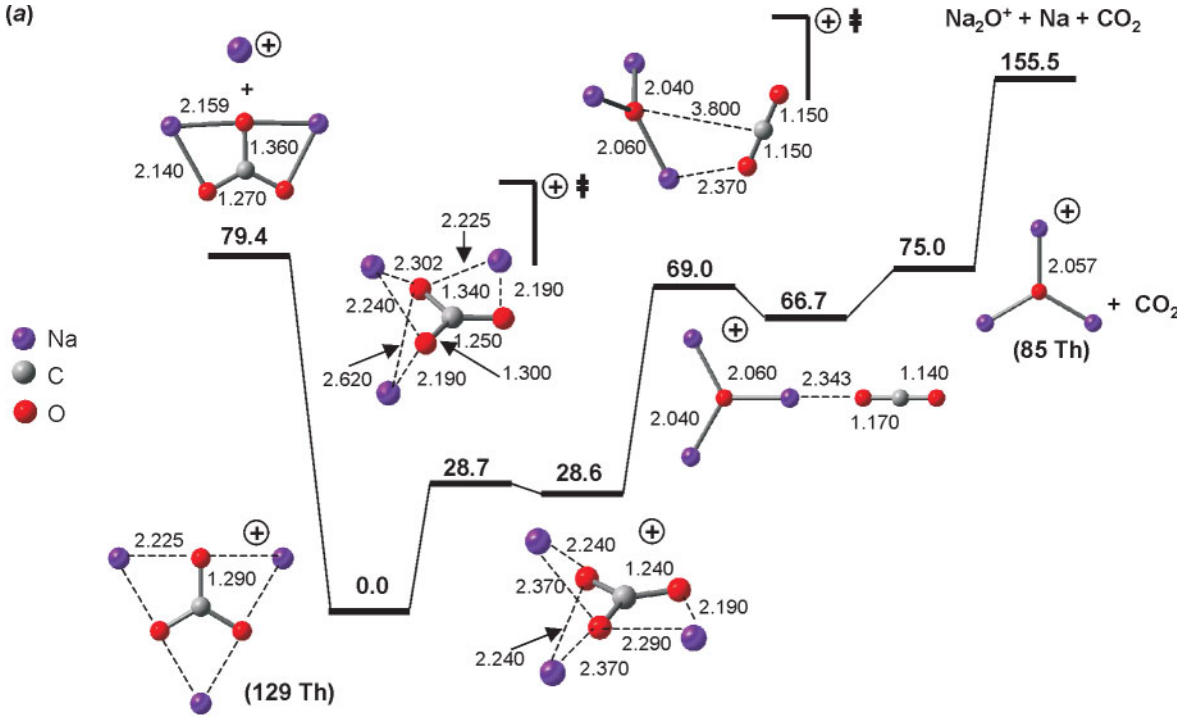

rier against the dissociations to $[Na_2OH]^+$ and $[NaOCNNa]^+$ by 9.5 kcal/mol. Dissociation to yield $[Na_3O]^+$ (85 Th), **XIV**, and HNCO requires eventual transfer of all three sodium onto a single oxygen atom. This reaction is endothermic by 65.4 kcal/mol, the largest barrier for the processes examined. These relative energetics are all in accordance with experimental results (Fig. 4*b*).

Reaction profiles for the other three $[M - 2H + 3Na]^+$

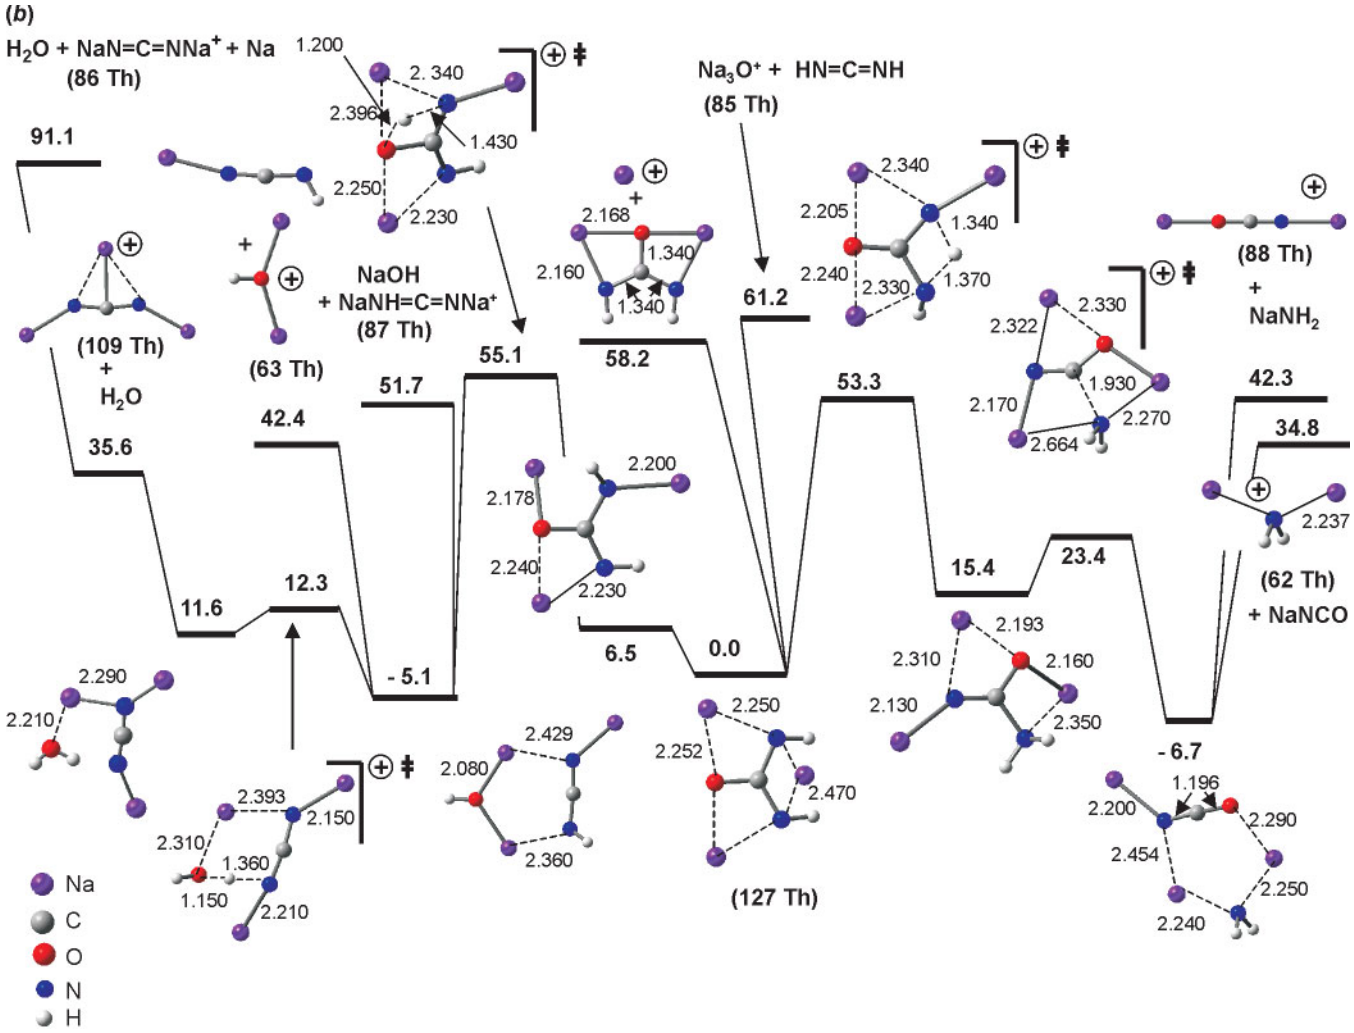
Fig. 5. Reaction profiles of (*a*) [CN – 2H + 3Na]$^+$, (*b*) [UR – 2H + 3Na]$^+$, and (*c*) [GU – 2H + 3Na]$^+$.

complexes are shown in Fig. 5. The [CN – 2H + 3Na]$^+$ complex gives the simplest profile (Fig. 5*a*) as it contains only carbon, oxygen, and sodium atoms. As observed in [CM – 2H + 3Na]$^+$, formation of $[Na_3O]^+$ (85 Th) requires transfer of all three sodium onto a single oxygen atom, resulting in an ion–neutral complex in which $[Na_3O]^+$ is solvated by CO_2. Dissociation of this ion–neutral complex yields the separated products, $[Na_3O]^+$ and CO_2. The activation energy for formation of $[Na_3O]^+$ and CO_2 is lower than the endothermicity of the reaction at 75.0 kcal/mol. Elimination of Na from $[Na_3O]^+$ to give $[Na_2O]^+$ is endothermic by 80.5 kcal/mol. Elimination of Na$^+$ from [CN – 2H + 3Na]$^+$ is endothermic by 79.4 kcal/mol.

The reaction profile of [UR – 2H + 3Na]$^+$ (Fig. 5*b*) is considerably more complicated, but it has similarities with those of [CM – H + 2Na]$^+$ and [CM – 2H + 3Na]$^+$. Formations of $[Na_2NH_2]^+$ (62 Th) and [NaOCNNa]$^+$ (88 Th) require an intermediate analogous to complex **IX**, which then dissociates to give either $[Na_2NH_2]^+$ and NaNCO, 34.8 kcal/mol above the lowest energy structure of [UR – 2H + 3Na]$^+$, or [NaOCNNa]$^+$ and $NaNH_2$, 42.3 kcal/mol above the same. By contrast, formation of $[Na_3O]^+$ and HN=C=NH requires a relatively large energy of 61.2 kcal/mol, which, however, is lower than the 75.0 kcal/mol required for the formation of $[Na_3O]^+$ and CO_2 from [CN – 2H + 3Na]$^+$, and the 65.4 kcal/mol required for the formation of $[Na_3O]^+$ and HNCO from [CM – 2H + 3Na]$^+$. Formation of $[Na_2OH]^+$ (63 Th) also proceeds via an intermediate analogous to complex **IX** in the dissociation of [CM – 2H + 3Na]$^+$. In addition, migration of the hydrogen from N to O involves the highest transition state.

Similar to those of [CM – 2H + 3Na]$^+$ and [UR – 2H + 3Na]$^+$, dissociation of [GU – 2H + 3Na]$^+$ (Fig. 5*c*) proceeds via an ion–neutral complex that can be viewed as either $[Na_2NH_2]^+$ solvated by NaN=C=NH or [NaN=C-N(H)Na]$^+$ (87 Th). Dissociation of the complex yields the two sets of separated products; these reactions have an identical barrier of 54.6 kcal/mol, encountered in the migration of a sodium ion. Elimination of Na$^+$ has the largest barrier at 62.2 kcal/mol.



Additional interesting fragment ions

An interesting fragment is $[Na_3CN_2]^+$ (109 Th) ion, formed after elimination of water and ammonia, respectively, from trisodiated UR and GU. Details of its DFT-predicted structure are shown in Fig. 6. The ion has C_{2v} symmetry. The dissociation products Na$^+$ and NaN=C=NNa lie 55.1 kcal/mol above $[Na_3CN_2]^+$. Electrospraying the amino acids, arginine, lysine, and serine in the presence of Na$^+$ also produces abundant [M – 2H + 3Na]$^+$. CID of these ions produce the fragment ion $[Na_3CO_2]^+$ (113 Th),[5] whose DFT-predicted structure is also shown in Fig. 6. This ion also has C_{2v} symmetry. The dissociation products are $[Na_3O]^+$ (85 Th) and CO; this compares with the products $[Na_3O]^+$ and CO_2 formed in the dissociation of $[Na_3CO_3]^+$. Thus, $[Na_3O]^+$ turns out to be a rather common polysodiated fragment ion. Dissociation requires first transfer of Na$^+$ such that all three Na are bound to the same O atom, resulting in an ion–neutral complex of $[Na_3O]^+$ solvated by CO_n (where n = 1 or 2). Separation of the parts produces $[Na_3O]^+$ and CO_n. Although the rearrangement reactions involve a number of steps, the transition states are low lying, and the over-

[5] Full details will be presented elsewhere.

Fig. 5 (*b*).

all reaction is limited by only the endothermicities (39.4 kcal/mol for $n = 1$ and 79.4 kcal/mol for $n = 2$). The high value for the latter dissociation underlines the remarkable stability of the cyclic (possibly aromatic) $[Na_3CO_3]^+$ ion.

Dissociation to Na^+ and ligand

One of the unusual features of these sodiated complexes is that the energy required for dissociation to Na^+ and ligand *increases* with an increasing number of sodium atoms. Table 1 gives the Na^+ binding energies as calculated at B3LYP/6-311G**. These binding energies increase by approximately 10 kcal/mol for each additional sodium atom present. For example, for guanidine, the values are: monosodiated, 42.8; disodiated, 52.7; and trisodiated, 62.2 kcal/mol. The interaction between Na and GU is essentially electrostatic. In $[GU + Na]^+$, the binding is between Na^+ and neutral GU. By contrast, in $[GU - H + 2Na]^+$, the binding is between $2Na^+$ and $[GU - H]^-$; in other words, each Na^+ is attracted by 0.5 negative charge. Similarly, in $[GU - 2H + 3Na]^+$, the binding is between $3Na^+$ and $[GU - 2H]^{2-}$, or each Na^+ is attracted by 0.67 negative charge. Thus, it makes sense that binding energy increases with the extent of sodiation. Examination of any one column of data in Table 1 reveals that complexes with a fixed number of sodium atoms have similar Na^+ binding energies, consistent with the electrostatic nature of sodium binding. The one notable exception is $[Na_3CO_3]^+$, where the Na^+ binding energy is ~20 kcal/mol higher than those for the other trisodiated ions.

Conclusions

$[M - (n - 1)H + nNa]^+$ complexes ($n = 1$–3) of carbonate, carbamate, urea, and guanidine are observed in electrospray experiments. Na^+ binding energies follow the order monosodiated < disodiated < trisodiated with almost monotonic increases of ~10 kcal/mol with additional sodiation. The $[M - 2H + 3Na]^+$ complexes have particularly interesting structures in which the positive charge is almost evenly distributed among the sodium atoms. Collision-induced dissociations lead to a number of common, polysodiated fragment ions that can, in turn, fragment to give Na^+. The smallest polysodiated ion observed is $[Na_3O]^+$, which is also formed from $[Na_3CO_2]^+$, itself a fragment ion of singly charged trisodiated amino acids. The $[M - H + 2Na]^+$ complexes fragment to give $[Na_2NH_2]^+$ and Na^+. A number of fragment ions are common to both types

of complexes. Results of density functional theory calculations are consistent with mass spectrometric results.

Do electrospray mass spectra reflect the ligand binding state of proteins in solution?[1]

Belal M. Hossain, Douglas A. Simmons, and Lars Konermann

Abstract: Electrospray ionization (ESI) mass spectrometry (MS) has become a popular tool for monitoring ligand–protein and protein–protein interactions. Due to the "gentle" nature of the ionization process, it is often possible to transfer weakly bound complexes into the gas phase, thus making them amenable to MS detection. One problem with this technique is the potential occurrence of fragmentation events during ESI. Also, some analytes tend to cluster together during ionization, thus forming nonspecific gas-phase assemblies that do not represent solution-phase complexes. In this work, we implemented a hydrogen–deuterium exchange (HDX) approach that can reveal whether or not the free and (or) bound constituents of a complex observed in ESI-MS reflect the binding situation in solution. Proteins are subjected to ESI immediately following an isotopic labeling pulse; only ligand-free and ligand-bound protein ions that were formed directly from the corresponding solution-phase species showed different HDX levels. Using myoglobin as a model system, it is demonstrated that this approach can readily distinguish scenarios where the heme–protein interactions were disrupted in solution from those where dissociation of the complex occurred in the gas phase. Experiments on cytochrome c strongly suggest that dimeric protein ions observed in ESI-MS reflect aggregates that were formed in solution.

Key words: electrospray mass spectrometry, ligand–protein interaction, noncovalent complex, hydrogen–deuterium exchange, protein folding.

Résumé : La spectrométrie de masse (SM) avec ionisation par électronébulisation (IEN) est devenue un outil populaire pour étudier les interactions ligand–protéine et protéine–protéine. En raison de la nature douce du processus d'ionisation, il est souvent possible de transférer des complexes à faiblement liés dans la phase gazeuse et de les rendre ainsi d'être détectés en SM. Un problème lié à cette technique tient au fait qu'elle est susceptible de provoquer des fragmentations au cours de l'IEN. De plus, quelques analytes ont tendance à former des agrégats durant l'ionisation et ceci conduit à la formation d'assemblages en phase gazeuse qui ne sont pas spécifiques et qui ne représentent pas les complexes de la phase en solution. Dans ce travail, on a mis au point une approche impliquant un échange hydrogène–deutérium (HDX) qui permet de mettre en évidence si les constituants libres et (ou) liés d'un complexe observé en SM-IEN représentent ou pas la situation de liaison en solution. Les protéines sont soumises à l'IEN immédiatement après avoir subi une pulsation de marquage isotopique; seuls les ions ne contenant pas ligand et les protéines liées au ligand qui se sont formés directement à partir des espèces correspondantes de la phase en solution présenteront des niveaux de HDX différents. Utilisant la myoglobine comme système modèle, on a démontré que cette approche permet de distinguer facilement le scénario dans lequel les interactions hème–protéine ont été rompues en solution de celui où la dissociation du complexe s'est produite en phase gazeuse. Des expériences avec le cytochrome c suggèrent fortement que les ions dimères de protéine observés dans les SM-IEN sont un reflet d'agrégats qui se seraient formés en solution.

Mots clés : spectrométrie de masse avec ionisation par électronébulisation, interaction ligand–protéine, complexe monovalent, échange hydrogène–deutérium, repliement d'une protéine.

Introduction

Noncovalent ligand–protein interactions are involved in virtually all biological processes, and they play a central role in numerous drug action mechanisms. Ligands that may bind to a given protein receptor include metal ions, prosthetic groups, nucleic acids, saccharides, peptides, and other proteins. Experimental methods capable of detecting and mapping these interactions are of considerable interest (1–6). The use of electrospray ionization (ESI) mass spectrometry (MS) for experiments of this kind is a particularly promising approach (7, 8). The "gentle" nature of the ESI process al-

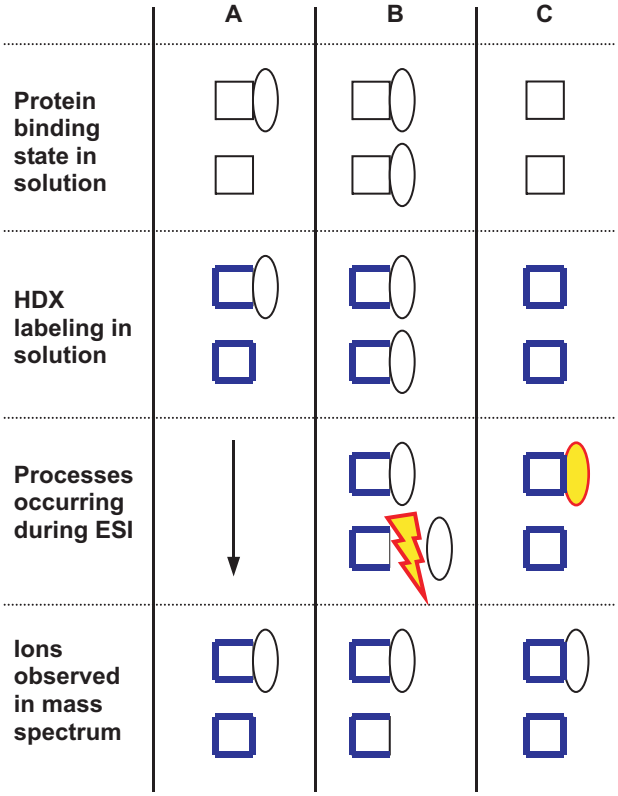
lows the transfer of intact biological complexes into the gas phase, thus making them amenable to MS detection. Systems that have been studied in this way range from metal–protein complexes to cell organelles and whole virus particles (9–16). The advantages of ESI-MS as a tool for monitoring ligand–protein interactions include speed, sensitivity, ease of use, and the ability to provide direct information on the binding stoichiometry. Due to its "mix-and-measure" nature, this approach is very attractive for the high-throughput screening of compound libraries in the context of drug discovery (17). Difficult sample preparation steps, such as chemical immobilization or fluorescence labeling, are not required.

The use of ESI-MS for studying ligand–protein interactions requires the composition of the observed ions to be the same as that of the corresponding solution-phase complexes. For many ligand–protein systems, this is indeed the case. This is evident from the agreement of dissociation constants measured by solution-phase methods with those obtained from gas-phase ion abundance ratios (13, 18–20). However, it is undisputed that the ion abundance ratio can be affected by a number of processes that may occur during ESI. Charge-balancing redox reactions taking place within the emitter capillary can result in significant pH changes, which may induce complex disruption immediately prior to ion formation (19, 21, 22). Dissociation events in the gas phase can occur during or after desolvation, e.g., by collisions with background gas molecules (19, 23). Generally, it is thought that complexes stabilized by ionic and polar noncovalent bonds are more likely to survive the ESI process than those held together by hydrophobic interactions (17, 24, 25). Despite this widely accepted notion, there are electrostatically stabilized complexes that are not particularly amenable to ESI-MS detection (26) and, conversely, some hydrophobically bound systems that do not get disrupted during ESI (27, 28). Clustering events taking place during ESI can lead to the formation of nonspecific aggregates in the gas phase, i.e., complexes that did not exist in solution prior to ionization (25, 29, 30). Clustering is expected to occur especially at high ligand to protein concentration ratios (31). A detailed account of all these processes, and their implications for the detectability of noncovalent complexes, has recently been given by Kebarle and co-workers (32).

The preceding discussion shows that the presence or absence of noncovalent complex ions in an ESI mass spectrum does not always allow conclusions to be drawn regarding specific solution-phase interactions. Several strategies have been devised to circumvent this problem. One alternative is the use of MS-based methods that do not rely on the preservation of specific interactions in the gas phase (20, 33–37). However, these techniques are often considerably more complicated and labor-intensive than the direct ESI-MS approach. Another possibility is the use of reference systems that can serve as internal standards for tuning the conditions of the ESI-MS experiment. An obvious limitation of this method is that appropriate reference systems may not always be available, especially when studying ligand–protein complexes that are biochemically not well characterized.



In this study, we propose a new strategy to determine whether the ligand binding state of a protein in solution is correctly represented by its ESI mass spectrum. For a spectrum that shows ions corresponding to both free and ligand-bound protein, we considered three scenarios. (A) The mass spectrum accurately reflects the binding state of the protein in solution. The free, as well as the ligand-bound protein ions observed in ESI-MS, originate from the corresponding solution-phase species. (B) All the proteins in solution are ligand-bound, but a certain percentage of these complexes gets disrupted during ESI. (C) The protein does not bind the ligand in solution. Instead, ligand-bound protein ions in the mass spectrum represent nonspecific complexes resulting from clustering processes during ionization. Various combinations of these scenarios are possible, but for the sake of simplicity, we restricted the discussion to these three cases. In the following, they will be referred to as "scenario A", "scenario B", and "scenario C", respectively.

For the method used here, proteins in solution were exposed to a hydrogen–deuterium exchange (HDX) pulse-labeling step immediately prior to ESI. HDX techniques are widely used for exploring the folding and dynamics of proteins in solution (8, 38, 39). Exposure of a protein to D_2O can lead to HDX of all the hydrogens in N—H, O—H, and S—H bonds, including those in amide groups, side chains, and on the chain termini. However, rapid exchange will only occur at the sites that are exposed to the solvent and not involved in hydrogen bonds. The mass shifts resulting from these exchanges can easily be monitored by ESI-MS (8, 38). Ligand–protein interactions will generally decrease the extent of HDX. This effect can result from (*i*) the steric protection of exchangeable sites owing to the presence of the ligand, (*ii*) the formation of intermolecular hydrogen bonds, and (*iii*) the fact that ligand-bound proteins often adopt more tightly folded solution-phase conformations than their ligand-free counterparts (40, 41). For pulsed HDX studies it has to be ensured that the intrinsic HDX rate constant is large enough to allow significant labeling during the brief exposure of the protein to the deuterated solvent. This can be achieved by controlling the pD of the labeling solution. For pD values in the range of 9 to 10, labeling of unprotected sites occurs in the millisecond time range (42, 43).

Figure 1 illustrates how pulsed HDX can be used to distinguish the "well-behaved" case, A, from the artifactual scenarios B and C. In scenario A, the extent of HDX for ligand-bound protein is lower than for free protein. In case B, the HDX level is the same for all protein molecules in the sample. This labeling behavior is unaffected by the dissociation events taking place during ESI, thus resulting in ligand-bound gas-phase proteins that exhibit the same exchange behavior as their ligand-free counterparts. Similarly, the clustering events taking place in scenario C are not expected to modify the HDX levels, such that the exchange behavior of free and ligand-bound protein ions are identical. In summary, the observation of identical HDX levels for free and ligand-bound protein ions indicates the occurrence of either dissociation or clustering events during ESI. In cases where the ESI mass spectrum correctly reflects the solution-phase binding equilibrium, the HDX levels observed for the free and ligand-bound protein should be different. The

Fig. 1. Schematic representation of the experimental approach used in this work. Pulsed HDX can be used to determine whether ligand-free and ligand-bound protein ions observed in ESI-MS represent the corresponding solution-phase species. Thick blue lines indicate regions on the protein that have undergone HDX. Three scenarios are considered: (A) Both ligand-bound and ligand-free protein ions observed in ESI-MS are formed directly from the corresponding solution-phase species. (B) Ligand-free protein ions are the product of dissociation events taking place during ESI. (C) Ligand-bound protein ions are the product of clustering processes taking place during ESI. Without isotope exchange, the mass spectra obtained for the three scenarios would be indistinguishable (last row). With labeling, however, only scenario A will result in different HDX levels for ligand-free and ligand-bound protein ions.

proposed method is expected to be applicable if the interconversion between the free and bound forms of the protein is slow compared to the duration of the labeling pulse. This study demonstrates the validity of this concept by applying it to a number of model systems.

Experimental

Chemicals

Ammonium-d_4 deuteroxide, acetic acid-OD (Isotec, Inc., Miamisburg, Ohio), deuterium oxide (Cambridge Isotope Laboratories, Inc., Andover, Massachusetts), acetic acid, ammonium hydroxide (Fisher Scientific, Nepean, Ontario), acetonitrile (Caledon Laboratories, Georgetown, Ontario), ammonium acetate (Fluka, Buchs, Switzerland), and bradykinin (Bachem, King of Prussia, Pennsylvania) were used without further purification. Horse ferrimyoglobin and cytochrome c (Sigma, St. Louis, Missouri) were dialyzed against 20 mmol/L ammonium acetate in water and subsequently acidified to pH 3.0 with acetic acid. Ammonium hydroxide and (or) acetonitrile were then added to obtain the protein solutions used in the experiments. pH and pD values were measured with an AB15 pH meter (Fisher Scientific, Nepean, Ontario). Reported pD values were corrected for isotope effects based on the relation pD = pH meter reading + 0.4 (44).

Pulsed HDX

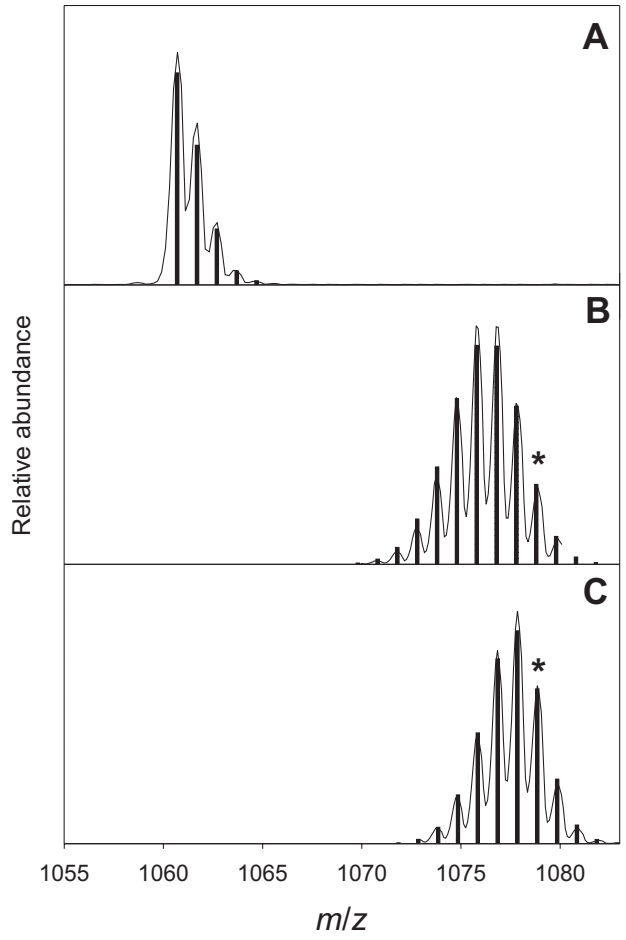
ESI-MS with on-line pulsed HDX was carried out by employing a continuous-flow rapid-mixing setup similar to that used for earlier studies from our laboratory (45). Briefly, two syringes, containing aqueous protein solution at pH 9.3 and D_2O-containing labeling solution at pD 9.3, respectively, were advanced simultaneously by syringe pumps (Harvard Apparatus, South Natick, Massachusetts). Solutions expelled from the two syringes were combined at a mixing tee that emptied into a 1 cm long fused silica capillary (TSP075150, 75 μm i.d., Polymicro Technologies, Phoenix, Arizona) where isotope labeling took place. This labeling capillary was connected to the ESI source of the mass spectrometer. The residence time of the solution within the capillary (labeling time) was 26 ms at a total flow rate of 100 μL/min. Other flow rates used for this work were 20 and 150 μL/min, corresponding to labeling times of 130 and 17 ms, respectively. Mass spectra were recorded on an API 365 triple quadrupole mass spectrometer (SCIEX, Concord, Ontario). Ions were generated by pneumatically assisted ESI in positive ion mode at a sprayer voltage of 6 kV. Approximately 500 scans at a dwell time of 1 ms per data point were averaged for each HDX experiment.

Isotope back-exchange and mixing efficiency

In ESI-MS-based HDX experiments, it is common to observe some back-exchange in the ion source, i.e., deuterons on the protein can exchange with hydrogens originating from residual water vapor. The approach used here requires that the solution-phase labeling of the protein be preserved as much as possible, and it is therefore important to minimize the extent of back-exchange. Previous studies have reported that back-exchange can be suppressed by continuously purging the ion source region with dry air (46, 47). Figure 2 provides a quantitative assessment of this effect for the conditions of the current study, using the peptide bradykinin (Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg, monoisotopic mass 1059.57) as a test compound. The isotope distribution of unlabeled bradykinin is shown in Fig. 2A. All 17 labile hydrogens in bradykinin are accessible to the solvent and should be readily exchangeable (46). For pulse-labeling of this peptide, syringe 1 (5 μL/min) contained 250 μmol/L bradykinin in water at pH 9.3 and syringe 2 (95 μL/min) contained D_2O at pD 9.3. Figure 2B shows the mass spectrum of singly charged bradykinin recorded after 26 ms of labeling, without air purging of the ion source; whereas the external air flow was activated for the spectrum depicted in Fig. 2C. It is evident that air purging causes the peak cluster to shift to higher m/z values. Based on the D_2O content of

© 2005 NRC Canada

Fig. 2. Partial ESI mass spectra, showing singly charged bradykinin ions: (A) bradykinin in water without isotope labeling; (B) bradykinin after solution-phase isotope labeling for 26 ms, ion source not purged; (C) as (B), except that the ion source was purged with dry air. The monoisotopic peak of the fully exchanged peptide in panels B and C (marked with an asterisk) is shifted 18 mass units compared with that of the unlabeled peptide in A. This mass shift corresponds to 17 exchangeable sites plus 1 charge carrier. Bar diagrams represent theoretical isotope distributions for hydrogen exchange probabilities of 0 (A), 0.81 (B), and 0.89 (C).



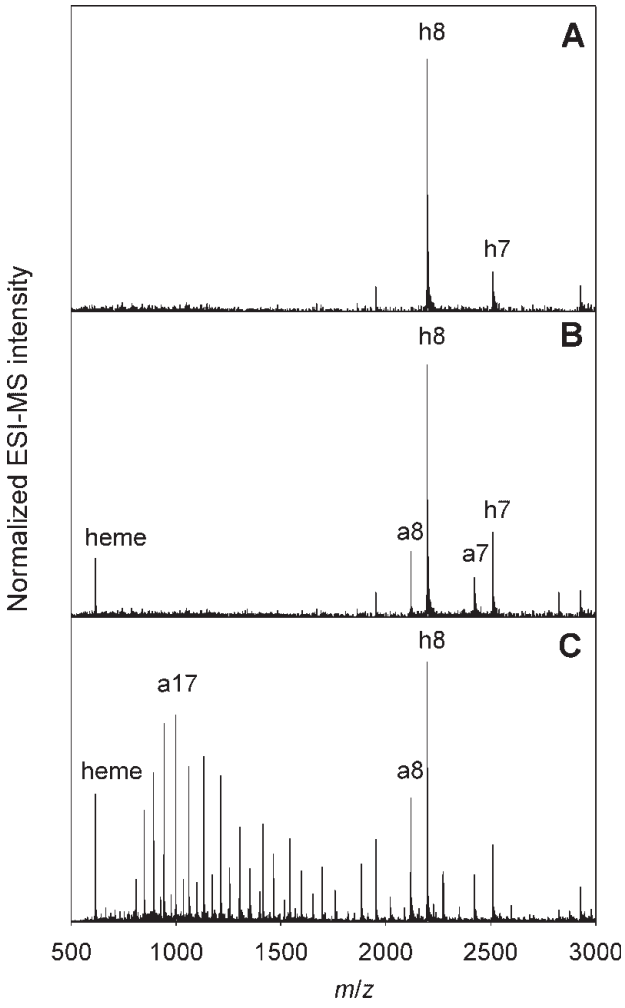


Fig. 3. ESI mass spectra of myoglobin at pH 9.3 recorded under different conditions: (A) myoglobin in water, orifice-skimmer voltage 20 V; (B) like (A), but recorded under harsher desolvation conditions (orifice-skimmer voltage 100 V); (C) myoglobin in water–acetonitrile (73:27 *v*/*v*), orifice-skimmer voltage 20 V. Notation: h and a indicate holomyoglobin and apomyoglobin (hMb and aMb), respectively. Numbers represent the charge states of protein ions, e.g., h8 ≡ hMb^{8+} ≡ (holomyoglobin + 8H)$^{8+}$.

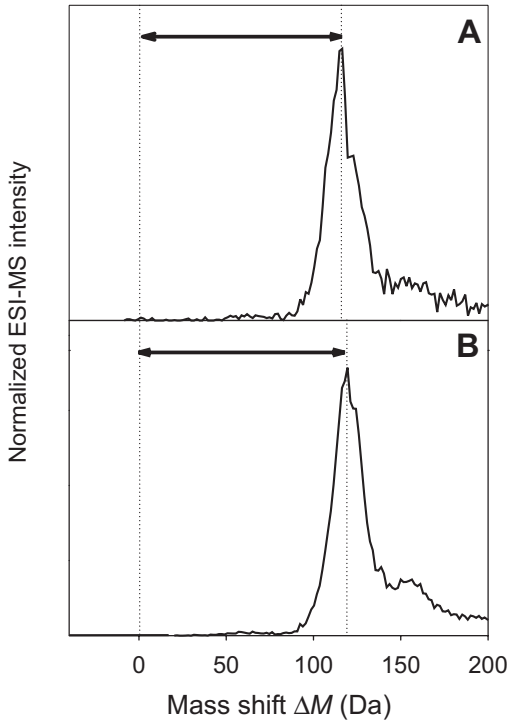
the labeling solution, the exchange probability for each of the 18 exchangeable sites on singly charged bradykinin (17 labile hydrogens and 1 charge carrier) should be 0.95. The bar diagrams in Fig. 2 represent simulated isotope distributions for different exchange probabilities. The best match with the experimental data in Fig. 2B is obtained for a probability of 0.81. In contrast, the data in Fig. 2C are best described by a labeling probability of 0.89. This result shows that air purging leads to a significant suppression of back-exchange. Therefore, all the subsequent protein HDX experiments for this work were carried out by using the source conditions of Fig. 2C. It is noted that the data in Fig. 2C also demonstrate an efficient mixing of the labeling setup. Incomplete mixing would result in a much lower average exchange probability. In addition, the broad isotope distributions expected under those conditions would not be describable by the modeling approach used here. Efficient mixing was also demonstrated at elevated solution flow rates, corresponding to labeling times down to 7 ms (data not shown).

Results and discussion

Myoglobin ESI mass spectra

Myoglobin is one of the most common model systems for studying ligand–protein interactions (11). Native myoglobin contains a heme group which is seated in a hydrophobic binding pocket where it makes numerous contacts with the protein, including ligation of the heme iron with His93 (48). The intact heme–protein complex is readily observable in ESI-MS, as long as gentle declustering conditions are used in the ion-sampling interface of the mass spectrometer. Figure 3A shows a spectrum of myoglobin recorded in aqueous solution at pH 9.3, using an orifice-skimmer voltage of 20 V.

© 2005 NRC Canada



The spectrum exclusively shows ions corresponding to the intact heme–protein complex (holo-myoglobin, hMb), whereas heme-free protein (apo-myoglobin, aMb) is not observed. Figure 3B shows a spectrum recorded under the same solvent conditions, but at an orifice-skimmer voltage of 100 V. It can be seen that some fraction of proteins loose their heme group in the gas phase by collision-induced dissociation, such that both aMb and hMb ions are observed in the spectrum (23). Also shown is a spectrum of myoglobin recorded at pH 9.3 in the presence of 27% acetonitrile, using gentle declustering conditions (orifice-skimmer voltage 20 V, Fig. 3C). Owing to the presence of the organic cosolvent, the protein is partially denatured and adopts several aMb and hMb solution-phase conformations that are in equilibrium with each other. The different protein conformations give rise to various charge-state distributions. In general, highly charged protein ions represent more unfolded solution-phase structures (8). Our group recently conducted a detailed study of the solution-phase conformational dynamics of myoglobin under the solvent conditions of Fig. 3C (45). For the current work, it is important to note that Fig. 3C represents a situation where the aMb and hMb ions observed in the spectrum are thought to reflect the presence of the corresponding solution-phase species (Fig. 1, scenario A). In contrast, Fig. 3B represents fully intact solution-phase complexes that undergo partial dissociation during ESI (Fig. 1, scenario B).

Pulse-labeling experiments on myoglobin

The total number of exchangeable hydrogens in hMb is 263, 148 of which are located along the amide backbone, 110 on the amino acid side chains, 3 on the termini, and 2 on the heme propionates. Figure 4 shows the HDX data obtained for native myoglobin that has undergone partial dissociation in the ion source of the mass spectrometer, i.e., under the conditions of Fig. 3B. After 26 ms of labeling at pD 9.3 in D_2O–H_2O (95:5 *v*/*v*), the measured mass shifts for aMb and hMb are (116 ± 1) and (120 ± 1) Da, respectively. When taking into account the presence of two additional exchangeable sites on the hMb heme group, these exchange levels are indistinguishable within error limits. This result confirms the validity of the proposed labeling strategy for an example of scenario B. It is likely that the majority of the exchange events under the conditions of Fig. 4 are due to side chain hydrogens, since most of the amides in native myoglobin are protected by the presence of an α-helical hydrogen bonding network.

Figures 5A and 5B depict the results obtained in an experiment analogous to that in Fig. 4. However, the solution in this case contained 27% acetonitrile, and the orifice-skimmer voltage was reduced to 20 V. As discussed previously, aMb ions observed under these conditions are expected to originate from heme-free proteins in solution (scenario A). The extent of HDX after 26 ms of labeling is dramatically higher for aMb than for hMb. The mass shifts observed for the two ionic species are (196 ± 1) and (92 ± 1) Da, respectively. The different HDX levels are consistent with the known fact that the removal of the heme group induces the polypeptide chain to adopt a partially disordered structure that is more conducive to rapid HDX (40, 45, 49). The lower extent of HDX for hMb in this experiment compared with the data in Fig. 4 is attributed to the reduced D_2O concentration in the labeling solution, caused by the presence of acetonitrile.

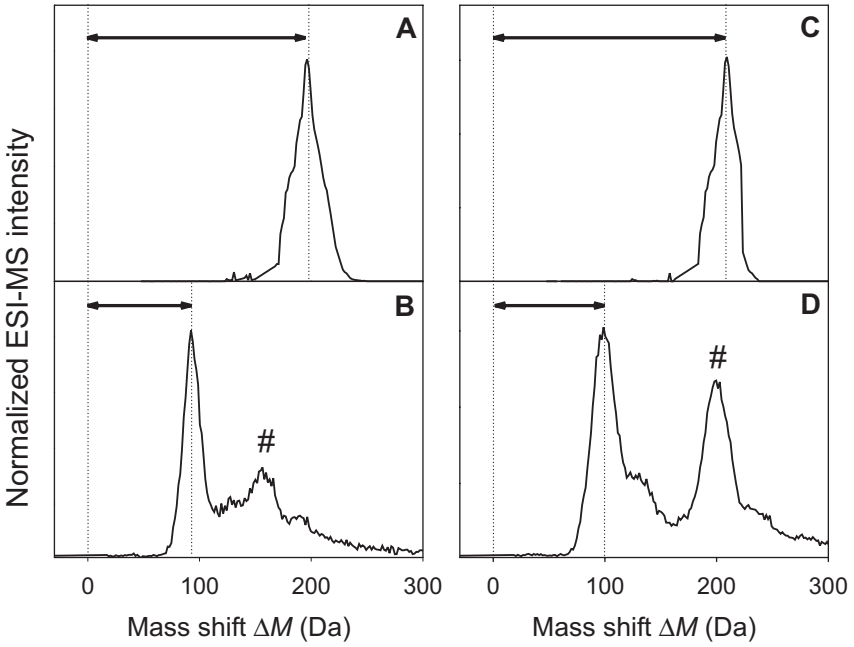


Fig. 4. Ions of (A) aMb and (B) hMb in the 8+ charge state, observed after pulse-labeling the protein at pD 9.3 for 26 ms. The mixing ratio of deuterated to non-deuterated solution during labeling was 95:5. No organic cosolvents were used for this experiment, aMb ions in panel (A) are the product of collision-induced dissociation in the gas phase (orifice-skimmer voltage 100 V). To allow a direct comparison of the HDX level (visualized by double-headed arrows), the *x*-axes were converted from m/z to mass shift (ΔM), according to $\Delta M = (m/z \times 8) - (0.95 \times 2 \times 8) - (0.05 \times 1 \times 8) - M_0$. M_0 is the mass of the unlabeled protein, 16 952 Da for aMb and 17 568 Da for hMb.

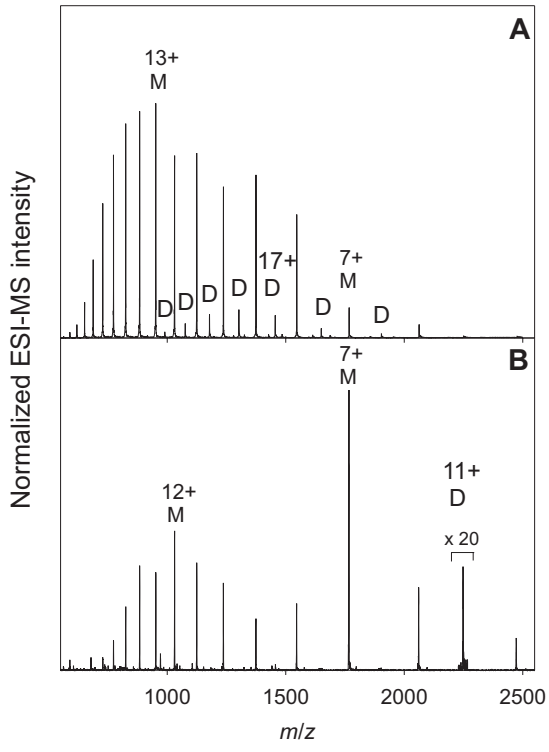
To assess the effects of labeling pulse length, the same experiment was repeated at a lower flow rate. The data in Figs. 5C and 5D corresponding to a pulse duration of 130 ms show mass shifts of (209 ± 1) and (99 ± 1) Da for the dominant aMb and hMb signals, respectively. The main conclusion to be drawn from the data in Fig. 5 is that the pulse-labeling strategy used here can clearly pinpoint a situation where the ligand-binding state of a protein in solution is directly represented by its ESI mass spectrum. The interconversion of free and ligand-bound proteins in this case is slow enough to differentiate the two forms, even when the time resolution of the experiment is reduced. Interestingly, the occurrence of interconversion processes is directly evident in our experimental data. The satellite peaks in Figs. 5B and 5D (marked with "#") are attributed to protein molecules that underwent a transition from aMb to hMb during labeling. Such a process necessarily leads to EX1 characteristics that are accompanied by peak splitting in ESI-MS. The intensity increase of the satellite peak observed for longer labeling times is fully consistent with this scenario (45, 50, 51).

© 2005 NRC Canada

Fig. 5. Ions of (A) aMb and (B) hMb in the 8+ charge state, observed after pulse-labeling the protein at pD 9.3 for 26 ms. The solvent used in this case contained 27% acetonitrile, leading to partial denaturation of the protein in solution (orifice-skimmer voltage 20 V). The data shown in (C) and (D) are analogous to those in (A) and (B), except that the labeling time was increased to 130 ms. The appearance of a satellite peak, marked with "#", is discussed in the text. Mass axis conversion was performed as for the preceding figure.



Dimerization of cytochrome c

When studying noncovalent protein–protein complexes by ESI-MS, it is fairly common to not only observe ions of the expected quaternary structures, but also larger assemblies (52, 53). The origin of these larger structures is not always clear. On one hand, it is possible that they represent weakly bound solution-phase complexes that may go undetected by other methods. Another possible scenario is the occurrence of clustering processes during ESI (scenario C) (25, 29, 30). The extent of clustering during ESI shows a strong dependence on protein concentration (32), but a similar dependence might be expected for the formation of protein aggregates in solution (54). To illustrate this issue using a very simple model system, we chose to apply our labeling approach to cytochrome c (MW 12 360 Da), a commonly studied model protein that possesses 198 exchangeable hydrogens (55). It has previously been reported that the mass spectra of cytochrome c recorded under acidic conditions and at elevated protein concentrations show noncovalently bound protein dimers (56, 57). This observation is corroborated by the data in Fig. 6A, which were recorded at a protein concentration of 1 mmol/L. Previous studies in the literature have not thoroughly addressed the question of whether these complexes represent clusters formed during ESI or assemblies that were formed in solution. Unfortunately, the acidic conditions used for acquiring the data in Fig. 6A are not conducive to rapid HDX (42). However, dimeric species are also observed at more basic pH and in the presence of acetonitrile, albeit with a very low ion abundance (Fig. 6B).

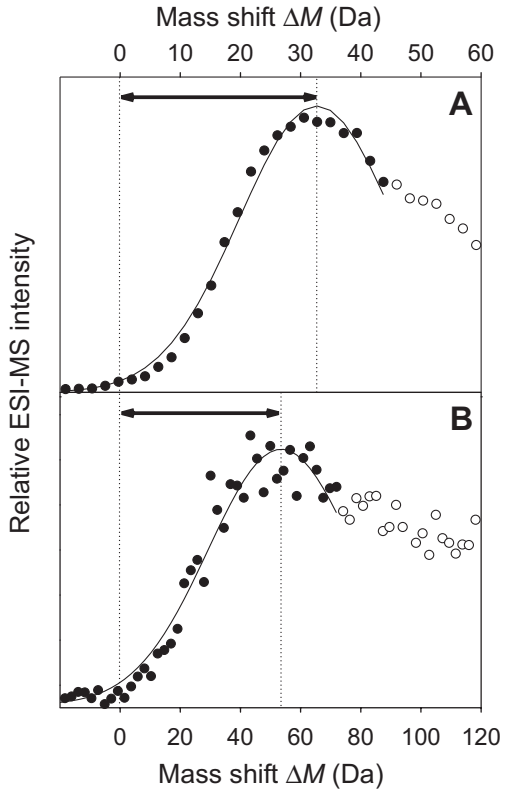


Figure 7 shows the results of pulsed HDX experiments obtained under the solvent conditions analogous to those used for Fig. 6B, with a labeling time of 17 ms. To maintain a high protein concentration after labeling, the mixing ratio was changed from 95:5 to 1:1. The analysis of the HDX data

Fig. 6. ESI mass spectra of cytochrome c recorded at a protein concentration of 1 mmol/L. (A) Aqueous solution containing 10% acetonitrile and 2% glacial acetic acid. (B) Aqueous solution containing 47% acetonitrile at pH 9.3. Peaks corresponding to monomeric and dimeric protein ions are marked with M and D, respectively, and some charge states are indicated. Note that the region around the dimeric 11+ signal in panel B has been magnified by a factor of 20 for better visualization.

© 2005 NRC Canada

Fig. 7. Ions of (A) monomeric and (B) dimeric cytochrome c in the 11+ charge state, observed after pulse-labeling the protein at pD 9.3 for 17 ms. The mixing ratio of deuterated to non-deuterated solution during labeling was 1:1 (final protein concentration 1 mmol/L). Solid lines are Gaussian fits to the low mass portion of the peaks. The high mass portion (indicated by open symbols) could not be considered for the analysis owing to extensive tailing. The *x*-axes were converted from *m*/*z* to mass shift (ΔM), according to $\Delta M = (m/z \times 11) - (0.5 \times 2 \times 11) - (0.5 \times 1 \times 11) - M_0$, with M_0 = 12 360 Da (A) and $M_0 = 2 \times 12\,360$ Da (B).

obtained under these conditions was complicated by the fact that the overall mass shifts obtained were relatively small. Moreover, the low intensity of the dimer ions resulted in data with poor signal-to-noise ratio, and the measured peaks showed considerable tailing. A Gaussian fitting procedure, based on a strategy developed in earlier HDX studies (47), was employed to estimate the mass shifts incurred by the two types of ions. If the protein dimer ions were a product of clustering events during ESI (scenario C), the mass shift observed for the dimer should be exactly twice that of monomeric cytochrome c. Interestingly, a comparison of the two data sets in Fig. 7 reveals that this is *not* the case. Based on the mass shift of (33 ± 2) Da that is observed for the monomeric ions in Fig. 7A, the dimer mass would have to be shifted by ca. 66 Da to be compatible with scenario C. However, the measured value of (54 ± 3) Da is significantly lower, thus suggesting that the dimer ions are derived from an aggregated species in solution. In other words, our data imply that cytochrome c follows scenario A under the conditions of this experiment. This interpretation is compatible with the known tendency of many proteins to undergo partial aggregation under mildly denaturing solution-phase conditions, especially at elevated concentrations (54).

Conclusions

The use of ESI-MS as a tool for studying noncovalent ligand–protein interactions is an extraordinarily powerful approach. However, there still is a need to gain a better understanding of factors that can potentially lead to disparities between the solution-phase and gas-phase composition of these complexes. As a first step, it is important to identify cases in which such disparities exist. The pulse-labeling approach proposed in this work provides a tool that can distinguish the "undisturbed" transfer of proteins and ligand–protein complexes into the gas phase from scenarios that involve the occurrence of dissociation or clustering processes. It appears that this technique works best when studying interactions of protein receptors with ligands that would be expected to (*i*) induce major conformational changes, and (or) (*ii*) cause a significant degree of steric shielding upon binding in solution. Basic pD conditions were chosen for the current work to ensure intrinsic HDX rate constants in the millisecond range. The use of near-neutral solutions reduces the extent of HDX, thus leading to less clear-cut labeling signatures for the different scenarios. In cases where the solution-phase interconversion of free and bound forms of the protein is slow, it is possible to compensate the lower HDX rate by extending the duration of the labeling pulse. When studying systems where both the protein of interest and its ligand(s) can undergo extensive HDX, it is beneficial to study the HDX behavior of individual constituents by tandem mass spectrometry. We are currently applying this approach to various multiprotein assemblies. It is hoped that those studies will provide novel insights into the processes that occur upon transferring macromolecular complexes from solution into the gas phase.

Combining H–D exchange and ESI-FAIMS-MS for detecting gas-phase conformers of equine cytochrome c[1]

Randy W. Purves, Barbara Ells, David A. Barnett, and Roger Guevremont

Abstract: Conformers of equine cytochrome c were investigated in the gas phase using a combination of high-field asymmetric waveform ion mobility spectrometry (FAIMS) and hydrogen–deuterium (H–D) exchange. Electrospray generated ions of equine cytochrome c were exposed to a low concentration of D_2O vapour while being transported by a flow of nitrogen through a FAIMS device. During this transport period of about 250 ms in the FAIMS analyzer, the various conformers of multiply charged ions of cytochrome c were simultaneously undergoing H–D exchange and being separated from each other. The extent of H–D exchange was calculated from the observed *m*/*z* of conformers after exposure to D_2O vapour in FAIMS. The complementary nature of these two methods resulted in observations supporting a greater number of conformers (e.g., at least 11 conformers were identified for the +16 charge state) than would be expected by analyzing the FAIMS data and the H–D exchange data independently.

Key words: FAIMS, H–D exchange, mass spectrometry, protein conformations, electrospray ionization.

Résumé : On a étudié les conformères du cytochrome c équin en phase gazeuse en utilisant une combinaison d'échange d'hydrogène et de deutérium et de spectrométrie de la mobilité ionique, de forme d'onde asymétrique et à haut champ (« FAIMS »). Les ions générés par électronébulisation du cytochrome c équin sont exposés à une faible concentration de vapeur de D_2O pendant qu'ils sont entraînés par un courant d'azote à travers un analyseur FAIMS. Au cours de la période de 250 ms de ce transport dans l'analyseur FAIMS, les divers conformères des ions du cytochrome c à charges multiples subissent des échanges H–D simultanés et se séparent les uns des autres. On a calculé le degré d'échange H–D à partir des valeurs *m*/*z* observées pour les conformères après leur exposition à la vapeur de D_2O dans l'analyseur FAIMS. La nature complémentaire de ces deux méthodes permet de faire des observations qui suggèrent l'existence d'un beaucoup plus grand nombre de conformères (par exemple, on a identifié au moins 11 conformères pour l'état de charge +16) que le nombre attendu sur la base d'une analyse des données FAIMS et des données d'échange H–D prises indépendamment.

Mots clés : « FAIMS », échange H–D, spectrométrie de masse, conformations de protéines, ionisation par électronébulisation.

Introduction

The ability to produce intact ions from large molecules (1, 2) has led to the development of several methods for studying biomolecular ions in the gas phase (3, 4). These methods have been divided into two categories (5): chemically reactive and nonreactive. Chemically reactive studies, including hydrogen–deuterium (H–D) exchange (4, 6–10), examine the reactivity of different conformations. Nonreactive studies, including drift tube ion mobility spectrometry (DTMS) (3, 4, 11, 12), use collisions with inert species to derive ion collision cross sections, and indirectly, conformational information. Compiling data from gas-phase methods having independent mechanisms of operation may bring to light new information. Additional benefits are derived from combining complementary methods experimentally, where ions separated by a first mechanism are subjected to further investigation using the second, orthogonal technique. For example, a combination of DTMS and H–D exchange was used to investigate electrosprayed ions of equine cytochrome c (5). This study showed two different H–D exchange levels for the +8 to +10 charge states (one each for either a compact or a diffuse conformer), whereas for charge states +11 through +18, a single exchange level was observed.

Recently, high-field asymmetric waveform ion mobility spectrometry (FAIMS) has emerged as an effective method for separating conformers in the gas phase at room temperature and atmospheric pressure (13–15). The FAIMS separa-

tion mechanism is based on changes in the mobilities of ions at high electric fields relative to low fields (16–19). Recent studies have helped elucidate several of the experimental parameters that impact sensitivity and separation in FAIMS (20–23). The importance of the bath gas composition on the FAIMS separation (20) and in particular, on separation of protein conformers (24–26), is only beginning to be studied.

The first FAIMS conformational studies showed that multiple peaks within the compensation voltage (CV) spectra of the individual charge states of bovine ubiquitin were attributable to different conformations (13, 14). Further work with this protein (15) showed that FAIMS provided information that pointed to the existence of a greater number of conformers for the elongated charge states than have been previously reported using either DTMS (27) or H–D exchange in an FTICR (8, 9). In a recent study (28), FAIMS was used in combination with pH and solvent studies to investigate conformers of β_2-microglobulin and a mutant variant of this protein, and concluded that FAIMS could potentially be used to study the role played by different conformers in disease.

Although FAIMS and DTMS are related techniques based on ion mobility, there are several key differences between them. Several of these differences are critical to the discussion of the present work and are therefore summarized in the following.

Transit time

The electric fields that are used for separating ions in a FAIMS device are applied perpendicular to the flow of gas that carries the ions through the device. Since the ions are transported through the device by a flow of gas, all of the ions spend equal time in transit through the device. For the FAIMS device used in this study, the transit time is ~250 ms. In DTMS, the applied electric fields are used to transport the ions through a drift tube and consequently, ions will spend different times in the device. In general, the ion drift times in DTMS are short relative to the transit time through a FAIMS device.

Ion heating

The strong electric fields (E/N) used in a FAIMS device result in heating of an ion. The heating of an ion in a strong electric field is a function of the electric field strength, the ion drift velocity, and the mass of the molecules of the bath gas. The heating of an ion is an inverse function of the mass of the ion since the drift velocity decreases as the mass of the ion increases (when the charge is constant). The effect of heating on protein conformation is discussed later in this report. In most DTMS experiments, the electric fields are weak and ion heating is minimal. However, in DTMS where the ion source is decoupled from the drift tube, ion conformation can be manipulated by changing the energy used to inject ions into the drift tube (29).

Changes to ion structure during analysis

The CV is used to separate ions in a FAIMS device. At a given CV, only ions that are stable within the device at that CV are transferred through the device; all other ions are lost to the walls of the device. Consequently, if an ion changes structure during transit through the FAIMS device, the resulting ion may be transmitted at a new CV. This ion will be lost to the walls and will not be observed in the spectrum. This is analogous to an ion changing m/z during transit through a quadrupole mass analyzer. With DTMS, a change in structure (resulting in a change in the low field ion mobility) would result in a shift in the drift time; however, the ion would still be observed in the spectrum.

Continuous vs. discrete

Ion separation in FAIMS is electrically controlled. Ions can be selectively and continuously transmitted through the FAIMS device and introduced into a mass spectrometer for further investigation. With DTMS, ions will pass through the drift tube as discrete, transient ion packets.

Ion transmission

An ion focusing mechanism exists in cylindrical FAIMS devices. Ion focusing helps minimize ion losses to the walls of the device caused by diffusion and space charge repulsion (30), thereby resulting in high ion transmission efficiency. With DTMS, there is no mechanism for preventing the spread of ions owing to diffusion and space charge repulsion during transit through the drift tube. Ion spreading is minimized by reduction of ion drift times.

For use in protein conformational studies, the FAIMS device offers several benefits (many of which have been described earlier) and is an ideal technique for use in combination with other gas-phase methods. For example, an energy loss method (31, 32) in a triple quadrupole MS has been applied to obtain cross sections of bovine ubiquitin (13, 15) and bradykinin (33) conformers separated by FAIMS. In these examples, the energy loss method for determination of ion collision cross sections is readily applicable to FAIMS separated conformers, but would provide very little information if the mixture was not resolved prior to the measurement. Recently, further studies of ubiquitin were reported where conformers of ubiquitin were separated by FAIMS and the H–D characteristics of individual FAIMS-separated species were studied in an FTICR instrument (34). The objective was to establish the relationship (if any) between gas-phase collision cross section and the degree of H–D exchange of a gas-phase protein ion.

An experiment is described herein where conformers of equine cytochrome c undergo ion separation and H–D exchange simultaneously while being transported through the FAIMS device. Equine cytochrome c was selected for this experiment because several gas-phase H–D exchange studies of this protein have been described in the literature (5, 7, 35, 36).

Experimental

The ESI-FAIMS-MS instrument used in this study has been described previously (13, 15). In brief, gas-phase ions were produced using ESI and passed through a desolvation region before entering the FAIMS device. The annular region in FAIMS was 2.0 mm along the length of the device and adjustable near the ion outlet by translating the inner electrode (distance was set to ~2.5 mm). A nitrogen (Air Products, Nepean, Ontario) curtain gas, which was passed through a charcoal–molecular sieve filter, entered the desolvation region at a flow rate of 2 L/min. The gas flow

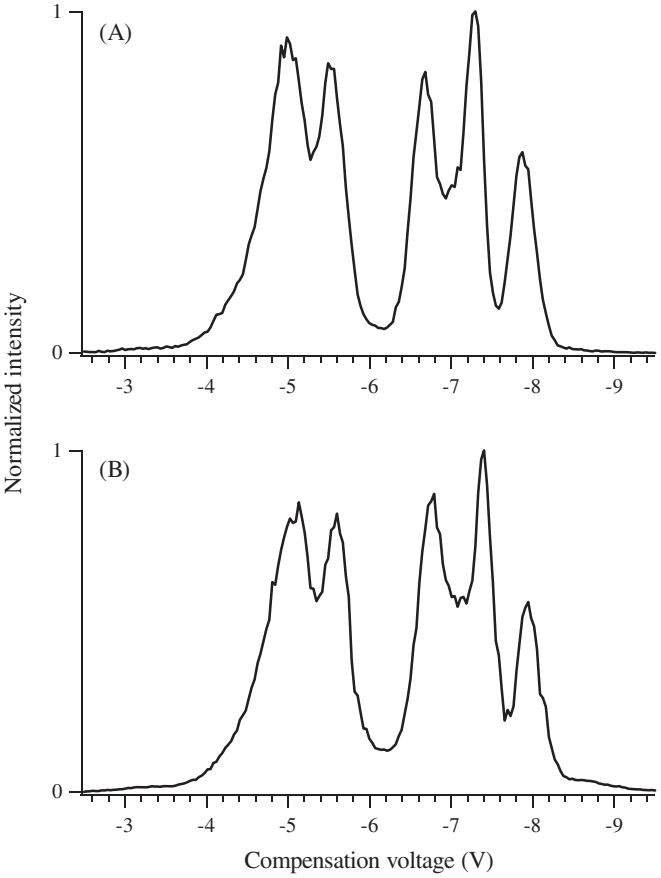
© 2005 NRC Canada

rate was adjusted using a mass flow meter (MKS type 179A, MKS Instruments, Andover, Massachusetts) that was controlled using an MKS type 1179A mass flow controller (MKS Instruments). A portion of the curtain gas carried the ions through the FAIMS device (i.e., carrier gas) at a flow rate of ~0.5 L/min (dictated by the gas throughput of the mass spectrometer). The remainder of the gas flowed out of the desolvation region towards the ESI needle (i.e., desolvation gas).

For H–D exchange experiments, a syringe containing 99.9% purity D_2O (Cambridge Isotope Laboratories, Andover, Massachusetts) was inserted into the curtain gas line (via a Tee, after the filter) such that D_2O vapour from the headspace of the syringe was entrained into the gas stream. The pressure of D_2O in the gas stream was not measured, however, H–D exchange experiments were repeated and the amount of exchange for each conformer was reproducible. Since the ions were carried through FAIMS by the flow of gas, the ion transit time (and reaction time for H–D exchange) was determined only by the gas flow rate and was equal for every species (charge states and conformers) investigated here. The reaction time for all experiments (and all types of ions) was the same (~250 ms). Since the curtain gas contained D_2O, the possibility of a limited amount of H–D exchange occurring external to the FAIMS device cannot be eliminated. However, since the ions spend only a short time external to the FAIMS device (relative to 250 ms), this contribution is not expected to be significant.

A 750 kHz asymmetric waveform generator was used and the dispersion voltage (i.e., maximum peak voltage, DV) was –4200 V for all experiments. The "OR" power supply from the mass spectrometer was used to apply the compensation voltage so that the LCTune™ (PE Sciex, Concord, Ontario) software synchronized the scanning function with the data acquisition. A separate DC power supply was used to control the OR voltage on the mass spectrometer. Ions transmitted by the FAIMS device were detected using an API 300 triple quadrupole mass spectrometer (PE Sciex, Concord, Ontario). Total ion current compensation voltage (TIC-CV) spectra were generated by collecting mass spectra (steps of 0.1 amu with a 25 ms dwell time) over specified *m/z* ranges at each CV value (in steps of 0.035 V). Ion-selected (IS)-CV spectra were acquired by monitoring a specific *m/z* value as the CV was ramped. Mass spectra, acquired at fixed values of CV, are a sum of 10 scans.

For the determination of the *m/z* of maximum ion intensity, the mass spectrum generated at each CV value was smoothed to reduce noise and improve the reliability of the measurement. The *m/z* value was recorded on the figures to an accuracy of ±0.1 amu. Mass spectra whose intensities were too low to obtain reliable measurements were omitted.



Equine cytochrome c was purchased from the Sigma Chemical Company (St. Louis, Missouri) and used without further purification. Solutions of equine cytochrome c were prepared at a concentration of 2 μmol/L in a solvent of water–methanol (1:1, *v/v*) and either 0.2% or 1% acetic acid.

Results and discussion

High charge states

A solution acidified to 1% acetic acid was used to favour the formation of the higher charge states of equine cytochrome c during the electrospray process. Figure 1 shows two CV spectra obtained for the +17 charge state. Figure 1A is an IS-CV spectrum (*m/z* 728.1) acquired with no D_2O present in the nitrogen gas stream. Experiments were carried out at the CV of maximum transmission for each of the five peaks to ensure that each peak was attributable to (at least) one different conformer and was not the result of adducts, multimers, or impurities (14). All of the peaks in the CV spectra presented in this document were treated similarly. Figure 1B is a total ion current (TIC) CV spectrum summing all ions between *m/z* 728.0 and 734.0, collected using the same experimental conditions as Fig. 1A except that D_2O was present in the nitrogen gas stream. The presence of water in the nitrogen carrier gas has been reported to have adverse effects on the performance of the FAIMS device (30), including significant changes in the CV value and complete loss of ion transmission in extreme cases. A comparison of Figs. 1A and 1B reveals that the level of D_2O used in this study did not significantly alter the appearance of the CV spectrum, and only a very small shift toward higher magnitude CV values was observed. Additionally, proton transfer reactions were not observed to substantially change the distribution of conformers of this charge state. Figures 1A and 1B indicate the presence of at least five conformers for the +17 charge state of equine

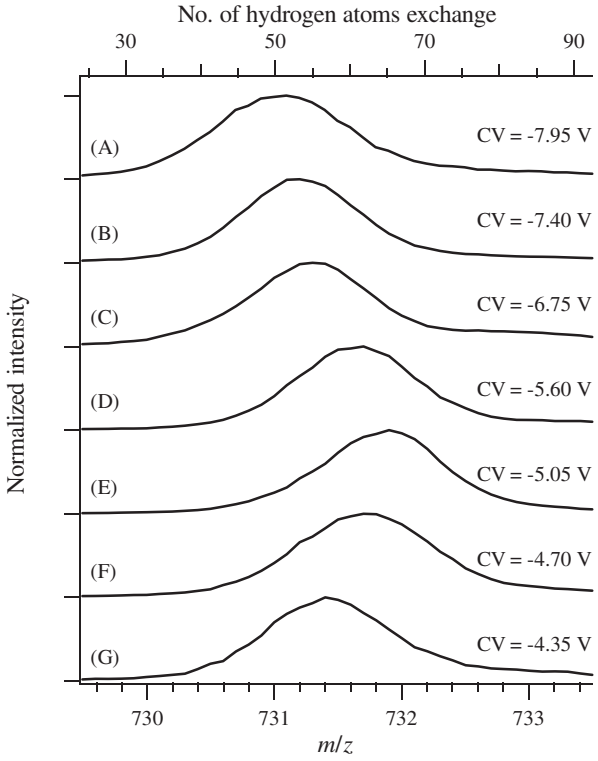
cytochrome c. The observation of multiple conformers for this charge state is consistent with H–D exchange studies reported by McLafferty et al. (36) using an FTICR-MS, where the existence of five conformational states for the elongated charge states (+11 through +18) were shown.



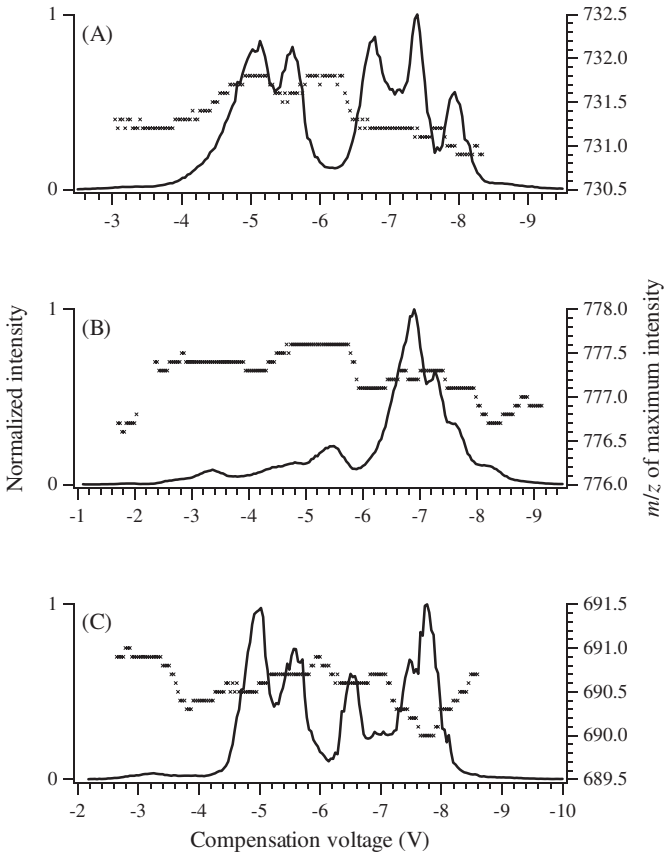
All of the mass spectra acquired in generating Fig. 1B were summed to effectively eliminate the separation by the FAIMS device and to allow an examination of only the H–D exchange data obtained in this experiment. The resulting mass spectrum (not shown) consisted of a single, broad peak centred at *m*/*z* 731.5, representing an average of 58 H–D exchanges among all conformers of this charge state. Individual mass spectra (i.e., at each CV value) were examined to determine the degree of H–D exchange of each conformer, and to determine if additional conformers could be identified using an experimental combination of FAIMS and H–D exchange. Mass spectra acquired at seven CV values, including each of the five peak maxima in Fig. 1B, are shown in Figs. 2A–2G. Although the low resolution of the quadrupole mass spectrometer made mass separation of the distribution of isotopomeric subspecies of a conformer impossible, the average mass of this ensemble was determined with an accuracy of about 0.2 *m*/*z*. Significant differences in the mass spectra are observed in going from the most negative (Fig. 2A) to the least negative CV (Fig. 2G).

The *m*/*z* values of the maximum intensity in the mass spectra were used to estimate average hydrogen atom exchange levels (top axis in Fig. 2). For example, the conformer of the +17 charge state, transmitted through FAIMS at CV –7.95 V (trace A in Fig. 2), was *m*/*z* shifted from 728.1 (without H–D exchange) to about 731.1 (with H–D exchange), corresponding to about 51 exchanges (top axis in Fig. 2). For conformers of the +17 charge state, the number of hydrogen atoms that were exchanged for deuterium ranged from about 50 to 65. The extent of exchange in this experiment was limited by the fixed exchange time using the FAIMS device (i.e., ~250 ms ion transit time) and the D_2O pressure range tolerable to FAIMS. Thus, the relationship between the maximum number of hydrogen atoms that could be exchanged for deuterium and the observed exchange levels were not available. Consequently, comparisons of the absolute exchange levels observed in this experiment with levels reported in previous studies (in which the exchange essentially went to completion) were not possible.

Figure 2 also shows that the use of the experimental combination of FAIMS and H–D exchange provides an opportunity to detect additional conformers. In particular, the traces in Figs. 2E–2G are mass spectra obtained between CV –4 and –5 V, corresponding to CV values to the left of the major peak (centred at about CV = –5 V) in Fig. 1. The gradually sloping trace in Fig. 1, between CV –4 and –5 V, suggests the possibility of several coexisting unresolved species. The three mass spectra collected in this range (Figs. 2E–2G) show different levels of deuterium incorporation, further establishing the presence of at least two overlapping conformers within this region of CV.

Individual mass spectra were examined at incremental CV values to determine the *m*/*z* value of maximum intensity (and thus, the hydrogen atom exchange level) across the CV range shown in Fig. 1B. This data is summarized for the +17 charge state of equine cytochrome c in Fig. 3A. The solid line in the figure represents the normalized intensity for the summation of all isotopomers of the +17 ion (same plot as Fig. 1B) and the individual data points (represented by "x" in the figure) indicate the *m*/*z* value (in 0.1 amu steps) of the maximum intensity in each mass spectrum. The figure shows that the CV of transmission appears to be independent of the hydrogen atom exchange level. In other words, the physical properties of the ions that lead to separation by FAIMS are quite distinctly different from the physical properties of the ions that determine the level of H–D exchange (34).

Fig. 2. Mass spectra (*m*/*z* 729.5–733.5) acquired with D_2O present in the nitrogen curtain gas. (A) CV = –7.95 V, (B) CV = –7.40 V, (C) CV = –6.75 V, (D) CV = –5.60 V, (E) CV = –5.05 V, (F) CV = –4.70 V, and (G) CV = –4.35 V.



The independence of the FAIMS CV value and the level of H–D exchange provides an experimental combination that leads to new information. For example, the presence of additional conformers that did not appear as separate peaks in the CV spectrum could be deduced from the data in Fig. 3A. In Fig. 3A, the level of H–D exchange increases (*m*/*z* shifts to a higher value) at the valley between two more intense conformers(CV ~ –6 V), indicating the presence of a low abundance conformer at this CV. The H–D exchange level also revealed that the low abundance ions transmitted near a CV of –3.5 V were not part of the tail of the peak centred at CV = –5 V, but were from a different conformer.

The hydrogen atom exchange level changes rapidly as a function of CV in some cases. A steep slope (e.g., near a CV of –6.5 V) in the H–D exchange level is consistent with the presence of only two conformers each having distinctly different levels of H–D exchange, whereas a gradual slope

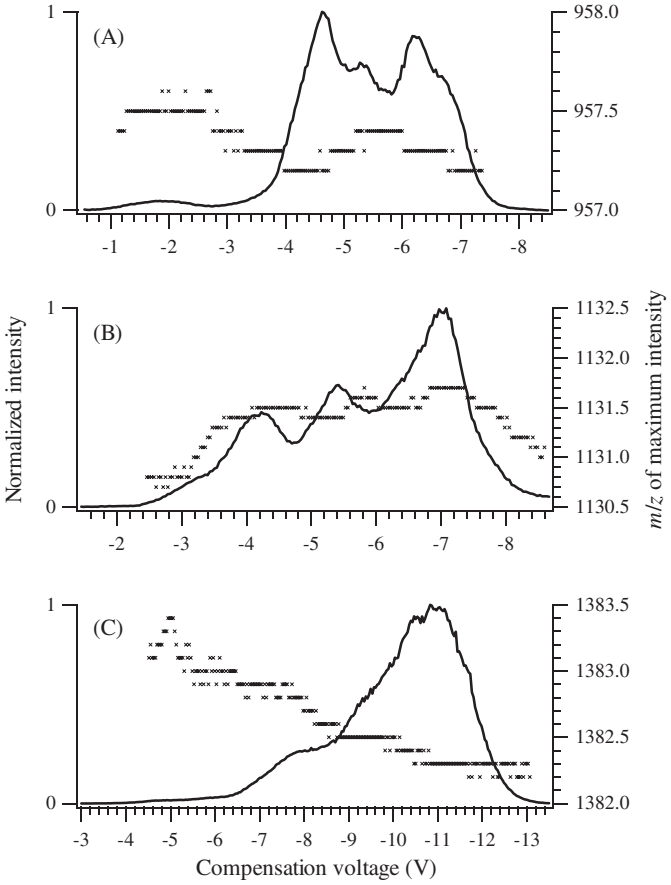
Fig. 3. Hydrogen atom exchange level as a function of CV for high charge states of equine cytochrome c. TIC-CV spectra of the (A) +17 (*m*/*z* 728.0–734.0), (B) +16 (*m*/*z* 773.0–780.0), and (C) +18 (*m*/*z* 687.0–693.0) charge states. The *m*/*z* value of the maximum intensity in each mass spectrum (right vertical axis) collected at incremental CV values (given by x) is superimposed on the figure.

(e.g., between CV –4 and –5 V) suggests that two or more conformers coexist with relatively similar levels of H–D exchange. The relative abundance of the conformer transmitted at CV ~ –3.5 V is much lower than the conformer transmitted at CV ~ –5 V and would have little effect on the measured *m*/*z* at intermediate CV values. Therefore, the H–D exchange data illustrates that there must be at least one additional conformer present in the region between CV = –3.5 and –5 V. The use of combined data analysis (as described earlier) has resulted in the detection of at least eight conformers for the +17 charge state of equine cytochrome c.

Other high charge states of equine cytochrome c (i.e., +14 to +21) were examined in a similar manner using a solution containing 1% acetic acid. Figures 3B and 3C show data for the +16 and +18 charge states, respectively. The solid line in Fig. 3B shows the normalized intensity for the +16 charge state (*m*/*z* 773.0–780.0) plotted as the CV was scanned from –1 to –9.5 V. The individual data points (x) in the figure represent the *m*/*z* of the maximum intensity in the mass spectra acquired at each CV value. The CV spectrum shows at least eight peaks (CV ~ –1.9 (low abundance), –3.4, –4.8, –5.5, –6.9, –7.3, –7.6, and –8.2 V), each of which was confirmed in separate experiments (not shown) to represent at least one different conformer of the +16 charge state. The combination of FAIMS with the H—D exchange data enables at least three additional conformers to be detected (i.e., at CV~ –4.1, –6.0, and –9.0 V). Thus, the data in Fig. 3B supports the assignment of at least 11 conformers for the +16 charge state. Figure 3C shows a plot of the normalized intensity (solid line, *m*/*z* 687.0–693.0) and the *m*/*z* of the maximum intensity (individual data points, x) plotted as the CV was ramped from –2 to –10 V, for the +18 charge state of equine cytochrome c. As was observed for both the +16 and +17 charge states, the CV of transmission appears to be independent of the number of hydrogen atoms exchanged. In addition to conformers identified by the FAIMS device at CV values of ~–3.2, –4.9, –5.6, –6.5, –7.0, –7.5, and –7.7 V, the presence of additional conformers at CV values of ~–4.0, –5.9, and at least one at –8.5 V can be derived from the H–D exchange information. Thus, the presence of at least 10 conformers for the +18 charge state can be extracted from Fig. 3C.

The number of conformers detected for the +16, +17, and +18 charge states of equine cytochrome c (at least 11, 8, and 10, respectively) are significantly higher than reported previously. For these charge states, results using H–D exchange (36) showed five conformational states, whereas DTMS studies (5, 37) showed only one ion cross section value for charge states +11 through +18. In acquiring the DTMS data, however, the authors indicated that they favoured a single conformer with the injection process (5).



Low charge states

Low charge states of equine cytochrome c (i.e., +7 through +13) were examined using a solution of 0.2% acetic acid. In the mass spectra of the +7 and +8 charge states, the intensity of the sodiated peak relative to the protonated peak was significant (these ions were not separated by FAIMS). After H–D exchange, the wide *m*/*z* distributions of the sodiated and protonated peaks of these charge states overlapped, thereby making the determination of the amount of hydrogen atom exchange extremely difficult. Consequently, plots for these charge states have been omitted from this discussion. This limitation could be overcome by performing H–D exchange in an ion-trapping device after the FAIMS separation (34).

The data acquired using a combination of FAIMS and H–D exchange is described for three of the low charge states in Fig. 4. Figures 4A–4C show plots of the TIC-CV spectrum for the +13 (*m*/*z* 955.5–959.5), +11 (*m*/*z* 1129.0–1133.0), and +9 (*m*/*z* 1380.0–1385.0) charge states, respectively. Again, the *m*/*z* of maximum intensity is superimposed on each of the figures (shown as x). Figure 4A shows that conformers of the +13 charge state experienced similar hydrogen atom exchange levels (only a range of 0.4 amu). Nonetheless, there are several stepwise changes that occur, indicating small, but distinguishable differences. For this charge state, the experimental combination of the two techniques did not result in strong evidence to support the detection of additional conformers (likely because of the limited range of exchange for this charge state). Conversely, the data in Fig. 4B shows that the experimental combination of FAIMS and H–D exchange enabled the detection of addi-

© 2005 NRC Canada

Fig. 4. Hydrogen atom exchange level as a function of CV for low charge states of equine cytochrome c. TIC-CV spectra of the (A) +13 (*m*/*z* 955.5–959.5), (B) +11 (*m*/*z* 1129.0–1133.0), and (C) +9 (*m*/*z* 1380.0–1385.0) charge states. The *m*/*z* value of the maximum intensity in each mass spectrum (right vertical axis) collected at incremental CV values (given by x) is superimposed on the figure.

tional conformers. In particular, the presence of at least five more conformers (i.e., CV ~ –3.0, –5.9, –6.4, and at least two more conformers at CV values more negative than –7.0 V) were observed in addition to the three conformers detected by FAIMS alone (i.e., CV ~ –4.2, –5.4, –7.0 V). The +9 charge state (Fig. 4C) is different from the other charge states discussed thus far in that the number of hydrogen atoms exchanged appears to gradually decrease as the CV becomes more negative. In addition, the TIC-CV spectrum shows only two main peaks, however, the shoulders on the main peak at CV ~ –9.4 and –10.5 V are reproducible. Although the presence of only four conformers is confirmed (i.e., CV ~ –5.0, –7.5, –9.5, and –11.0 V), the data suggests that this charge state is composed of additional conformers with similar H–D exchange levels that were only partially separated using the FAIMS device.

In addition to examining hydrogen atom exchange levels within charge states, a comparison of the exchange levels between different charge states can also be made. For the six charge states shown in Figs. 3 and 4, the greatest amount of exchange was observed for the +9 charge state (i.e., range from 71 to 81) and the lowest amount was observed for the +18 charge state (i.e., range from 42 to 60). The maximum amount of average hydrogen atom exchange observed for all of the charge states in Figs. 3 and 4 in decreasing order was: +9 (81), +11 (77), +13 (76), +16 (66), +17 (65), +18 (60). The decrease in the number of hydrogen atoms exchanged with increasing charge state is consistent with previous work by McLafferty et al. (36).

Influence of DV on conformation

The high electric fields (E/N) used in FAIMS will cause "heating" of a protein conformer because of the high velocities that the ions experience as they move through the bath gas. This heating could cause the ion to adopt new structures. The two-temperature kinetic theory of gaseous ion transport (38, 39) uses the effective temperature (T_{eff}) to characterize the total random energy of the ions, which consists of a thermal part and a field part (40). Since the applied electric field in FAIMS changes with time, an expression for the average effective temperature ($\overline{T}_{eff}$) in a FAIMS device was used and is given as (15, 40)

$$[1] \qquad \overline{T}_{eff} = T\left[1 + \frac{M\overline{v}_d^2}{3RT}\right]$$

where T is the gas temperature, M is the molar mass of the gas, R is the ideal gas constant, and $\overline{v}_d$ is the average velocity of the ion as given by

$$[2] \qquad \overline{v}_d = N_0 K_0 \left(\frac{\overline{E}}{N}\right)$$

Here, N_0 is Loschmidt's constant, K_0 is the reduced mobility, $\overline{E}$ is the average electric field in the FAIMS separation region, and N is the number density of the bath gas at ambient conditions. The maximum value of E (and hence v_d) can also be used in eqs. [1] and [2] to calculate the maximum effective temperature (T^{m}_{eff}) when the waveform is at its peak value. Previous calculations (15) of the values of $\overline{T}_{eff}$ and T^{m}_{eff} for conformers of bovine ubiquitin showed increases of ion temperature of ~7 and 31 K, respectively, at the highest DV used (DV = –4400 V).

To illustrate the effects of heating, calculations of the effective temperature were carried out for the +16 charge state. Experimental values of K_0 for several charge states (including +16) of equine cytochrome c were determined using an ion mobility spectrometer containing nitrogen gas (41). Based on this data, the reduced mobility value at room temperature for the +16 charge state (required in eq. [2]) was ~0.9 $cm^2\ V^{-1}\ s^{-1}$. At the DV (i.e., DV = –4200 V) used in this study, the calculated values of $\overline{T}_{eff}$ and T^{m}_{eff} were 10 and 47 K, respectively.

Previous work with DTMS has shown that gas-phase heating occuring via transport of an ion at high E/N can modify conformer structure. An increase of ion injection energy during introduction of a protein into the drift tube of a low-pressure IMS was shown to unfold compact conformers to less compact conformations (3, 29). In addition, the FAIMS-energy loss method showed that the measured cross section of a compact conformer increased as the energy drop into the second quadrupole of the mass spectrometer was increased (13). From these studies, the compact conformers

© 2005 NRC Canada

that are observed for the lower charge states appear to be most susceptible to structural changes induced by heating.

The effect of heating on protein conformation in the FAIMS device will require further investigation. Consider the situation in which heating leads to a change of conformation of an ion during its transit through the FAIMS device. The resulting CV spectrum is expected to be modified relative to a spectrum in which all ions retain their structure during the separation. As described in the Introduction, if an ion changes conformation during transit through the FAIMS device, and the CV of the ion changes, this ion will no longer be stable within the FAIMS device. The ion will be lost to the walls of the FAIMS device and not observed in the CV spectrum. In this example, a particular conformer can only be observed if the CV of transmission does not significantly change during transport through FAIMS. For this reason, and because of a relatively low value of the average $\overline{T}_{\text{eff}}$ of about 10 K in the present work, evidence of field-induced changes of conformation are not apparent in this work. This will be investigated further when instruments capable of higher voltages become available.

This study has illustrated that a relatively simple experiment in which ions simultaneouly undergo H–D exchange and separation in FAIMS, offers new opportunity for the study of protein ions. Further work is required to help identify the chemical (interaction with the bath gas) or mechanical (shape, flexibility) properties of the ions that contribute to the nonlinear behavior of K_h/K upon which the FAIMS separation is based. This knowledge may offer insight into ion structure. The extent to which FAIMS operational parameters, such as using strong electric fields for ion heating and using trace modifiers in the FAIMS carrier gas, can be used to probe structure, also requires investigation.

Conclusions

An experimental combination of FAIMS and H–D exchange was employed to investigate gas-phase conformers of equine cytochrome c. The ions exposed to low concentrations of D_2O vapour in the FAIMS bath gas simultaneously undergo H–D exchange and separation during transport through the FAIMS analyzer. In general, the CV of ion transmission was found to be independent of the number of hydrogen atoms exchanged. The experimental combination of these complementary techniques enabled a greater number of conformers to be detected (i.e., at least 11 conformers for the +16 charge state) than have previously been reported for equine cytochrome c using gas-phase techniques.

Structural and sequence effects in the fragmentation of protonated tripeptides containing tyrosine[1]

Alex G. Harrison

Abstract: The fragmentation reactions of a variety of protonated tripeptides containing tyrosine in the three possible positions have been studied by energy-resolved collision-induced dissociation mass spectrometry. The primary fragmentation reactions involve cleavage of the N-terminal and (or) C-terminal amide bond with the relative importance of the two cleavages depending strongly on the identity and position of the amino acid residues in the tripeptide. The results are interpreted in terms of the a_1–y mechanism for cleavage of the N-terminal amide bond and the b_x–y_z mechanism for cleavage of the C-terminal amide bond and, indeed, provide support for these mechanisms. However, it appears likely that, for protonated H-Val-Tyr-Pro-OH, the neutral accompanying formation of the y_1 (protonated proline) ion is a cyclic dipeptide (cyclo-Val-Tyr) rather than the oxazolone predicted by the b_x–y_z mechanism.

Key words: tyrosine-containing peptides, fragmentation mechanisms, tandem mass spectrometry.

Résumé : Faisant appel à la spectrométrie de masse avec dissociation induite par une collision et résolue en énergie, on a étudié les réactions de fragmentation d'une variété de tripeptides protonés contenant de la tyrosine dans les trois positions possibles. Les réactions primaires de fragmentation implique un clivage de la liaison amide N-terminale et (ou) C-terminale; l'importance relative de ces deux modes de clivage dépend fortement de l'identité et la position des résidus d'acides aminés dans le tripeptide. On interprète les résultats en fonction du mécanisme a_1–y pour le clivage de la liaison amide N-terminale et en fonction du mécanisme b_x–y_z pour le clivage de la liaison amide C-terminale et les résultats expérimentaux supportent ces mécanismes. Toutefois, il semble probable que, pour le H-Val-Tyr-Pro-OH, le produit neutre qui accompagne la formation de l'ion y_1 (proline protonée) est un dipeptide cyclique (cyclo-Val-Tyr) plutôt que l'oxazolone à laquelle on s'attend sur la base du mécanisme b_x–y_z.

Mots clés : peptides contenant de la tyrosine, mécanismes de fragmentation, spectrométrie de masse en tandem.

[Traduit par la Rédaction]

Introduction

With the introduction of the soft ionization techniques of electrospray ionization (ESI) (1–3) and matrix-assisted laser desorption–ionization (MALDI) (4, 5) tandem mass spectrometry (6, 7) of protonated peptides has become an important method for determining the amino acids present, as well as their sequence, in peptides. As a result of many studies, the main fragmentation reactions occurring on collision-induced dissociation (CID) of protonated peptides are well-established (8–11), at least in a qualitative sense, as illustrated in Scheme 1. However, in many cases the factors that determine relative fragment ion abundances are not clearly understood. Upon low-energy CID the fragment ion spectrum typically consists of a series of b, a, and y ions arising from amide bond cleavage in the protonated peptide; these fragment ions normally provide the necessary information for amino acid identification and sequencing.

It has been shown (12, 13) that the y ions are protonated amino acids (y_1) or truncated peptides (y_n). The b ions originally were considered to be acyclic acylium ions (8, 10, 11); however, extensive experimental and theoretical studies (14–20) have shown that, in many cases, at least the lower mass b_n (n = 2 or 3) ions have a cyclic protonated oxazolone structure arising by nucleophilic attack of the next-nearest carbonyl function as the amide bond is being cleaved. When there are strong nucleophilic side-chain groups, alternative cyclic structures may be formed by attack of the side-chain nucleophile as amide bond cleavage occurs; this appears to be the case for protonated peptides containing lysine (21–24), arginine (23, 25), or histidine (26–28). As a result, b_1 ions normally are not seen unless cyclization occurs involving the side-chain nucleophile. The a ions frequently arise by loss of CO from the b ions (14, 15, 28, 29), although other pathways do exist. Despite the extensive studies, relatively little is known concerning the structural and sequence factors that determine the propensity for b, a, and y ion formation. The present study has examined the fragmentation reactions of a variety of protonated peptides containing tyrosine in an effort to obtain information on the structural and

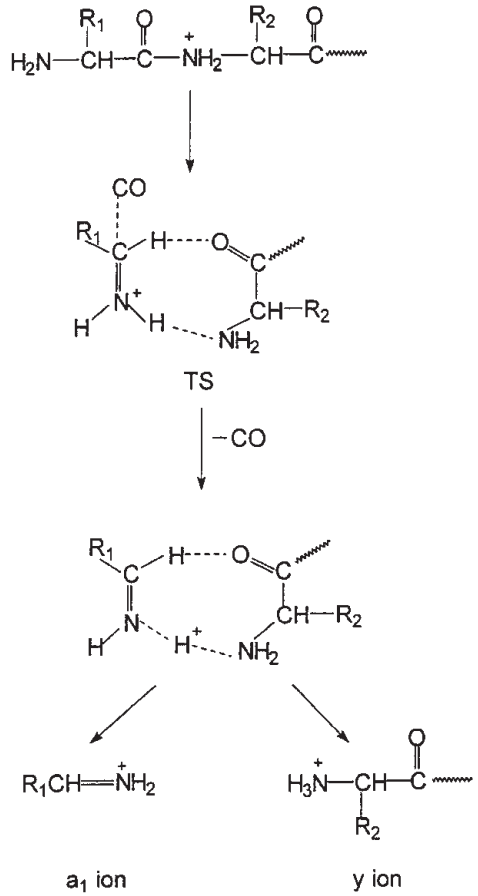
Scheme 1.

sequence effects that influence the fragmentation of the protonated species upon low-energy collisional activation.

Experimental

Collision-induced dissociation studies were carried out using an electrospray / quadrupole mass spectrometer (VG Platform, Micromass, Manchester, UK) with CID in the interface region between the atmospheric pressure source and the quadrupole mass analyzer, so-called cone voltage CID. It has been clearly established (30–34) that by varying the field in this interface region, energy-resolved mass spectra (35) similar to those obtained by variable low-energy CID in quadrupole cells can be obtained. The results of these cone voltage CID studies are presented in the following as breakdown graphs expressing the percentage of total ion signal as a function of the cone voltage, a measure of the field in the interface region. Ionization was by electrospray with the sample dissolved at micromolar concentration in CH_3CN – 1% aqueous formic acid (1:1). The sample was introduced into the ion source at a flow rate of 30 μL min^{-1} with nitrogen as both nebulizing and drying gas.



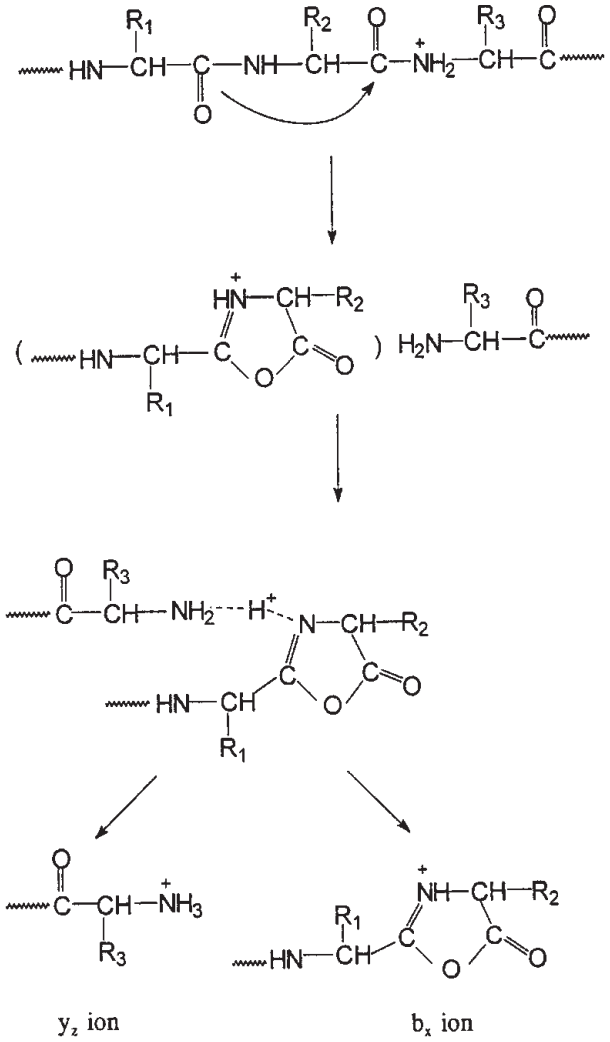
All peptide samples were obtained from Bachem Biosciences (King of Prussia, Pennsylvania) and were used as received.

Results and discussion

The major fragmentation reactions of protonated peptides frequently involve cleavage of an amide bond. For tripeptides there are two amide bonds that can be cleaved, the N-terminal and the C-terminal amide bond. Although not definitively established, it appears most likely that amide bond cleavage occurs from the amide–nitrogen protonated species. Ab initio calculations have shown that protonation at the amide nitrogen leads to considerable weakening of the amide bond, while protonation at the amide oxygen results in strengthening of the amide bond (36–38). For peptides not containing strongly basic residues there is general agreement that the most basic site is the N-terminal amino group, although usually there are other stable structures only slightly higher in energy (39–41). It also has been clearly established (12, 42, 43) that, at least for simple peptides, the proton added in the ionization process is mobile and can readily migrate to an amide nitrogen at internal energies below that required for fragmentation, the so-called mobile proton model (26, 44).

The detailed mechanisms of amide bond cleavage are not firmly established. For cleavage of the N-terminal amide bond there is substantial evidence (45–47) that fragmentation occurs by way of the a_1–y mechanism outlined in Scheme 2, which involves, at least at low internal energies, elimination of CO to form a proton-bound complex of an

Scheme 2.

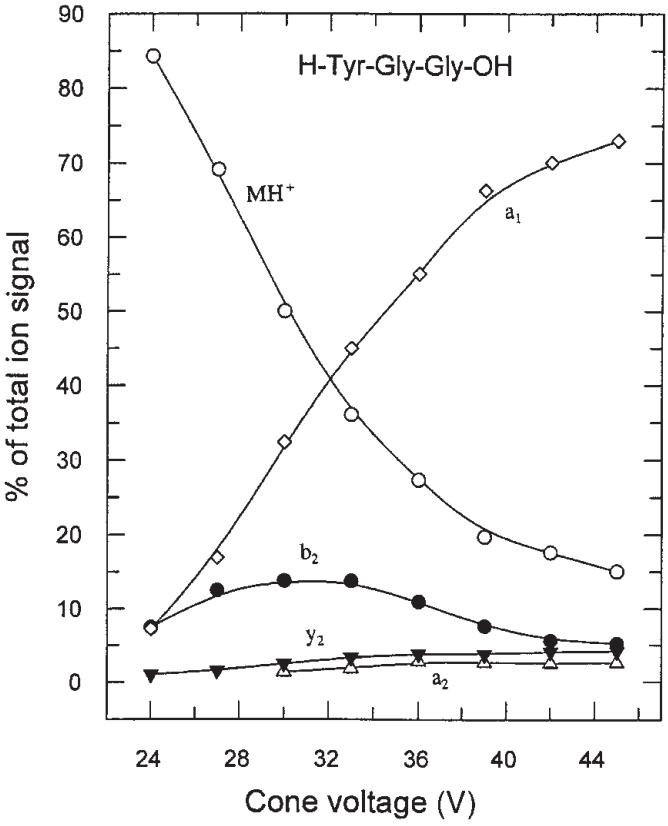


imine and an amino acid/peptide. On fragmentation of this complex the proton preferentially resides with the species (imine or amino acid or peptide) with the higher proton affinity resulting in the formation of an iminium ion and (or) a protonated amino acid or truncated peptide. Again, there is substantial evidence (47–51) that cleavage of amide bonds, other than the N-terminal amide bond, occurs by way of the b_x–y_z mechanism outlined in Scheme 3 for a tripeptide. At least at low internal energies, this mechanism involves formation of a proton-bound complex of a cyclic oxazolone and an amino acid (or a truncated peptide for larger peptides). On fragmentation of this complex, the proton would be expected to reside with the species of higher proton affinity resulting, for a tripeptide, in formation of a protonated oxazolone (b_2 ion) and (or) a protonated amino acid (y_1 ion). The results of the present study will be interpreted in terms of these mechanisms and, indeed, provide support for the detailed pathways outlined in Schemes 2 and 3.

H-Tyr-Aaa-Bbb-OH

Figure 1 shows the breakdown graph obtained for protonated H-Tyr-Gly-Gly-OH. At the lowest collision energies the b_2 ion (C-terminal amide bond cleavage) and the a_1 ion (N-terminal amide bond cleavage) are of similar intensity with very minor formation of the y_2 ion. It appears that the two possible amide bond cleavage reactions have similar critical reaction energies. As the collision energy increases the a_1 ion dominates the CID mass spectrum indicating that

© 2005 NRC Canada



Scheme 3.

cleavage of the N-terminal amide bond is entropically favoured in comparison with cleavage of the C-terminal amide bond. The proton affinity of $HOC_6H_4CH_2CH{=}NH$ has been calculated (46) to be 225.1 kcal mol^{-1} (1 cal = 4.184 J), which is considerably greater than the value of ca. 219 kcal mol^{-1} for the proton affinity of diglycine (estimated from the gas-phase basicity, GB(diglycine) = 210.8 kcal mol^{-1} (52)). Thus, it is not surprising that, in terms of Scheme 2, the a_1 ion is favoured rather than the y_2 ion on cleavage of the N-terminal amide bond.

Figure 2 presents the breakdown graph for protonated H-Tyr-Gly-Val-OH. The b_2 ion is more prominent than for H-Tyr-Gly-Gly-OH (Fig. 1) presumably because neutral H-Val-OH, derived by cleavage of the C-terminal amide bond, is more stable than H-Gly-OH. The a_1 ion dominates the breakdown graph at higher collision energies. It arises both by cleavage of the N-terminal amide bond and, most likely, by further fragmentation of the b_2 ion. The cleavage reaction $b_2 \rightarrow a_1$ has been noted previously (18); the fragmentation mechanism proposed by Siu and co-workers (53, 54) is presented in Scheme 4. The formation of the a_1 ion from the b_2 ion is in competition with fragmentation of b_2 to a_2 by loss of CO.

Fig. 1. Breakdown graph for protonated H-Tyr-Gly-Gly-OH. In this and the following figures MH^+ represents the protonated peptide subject to collisional activation.

The breakdown graph obtained for protonated H-Tyr-Ala-Gly-OH is shown in Fig. 3. The replacement of H by CH_3 as the side chain on the central amino acid residue has made the formation of the b_2 ion (C-terminal amide bond cleavage) the dominant primary fragmentation reaction (compare with Fig. 1). In this respect one notes that the proton affinity of 2-aminomethyl-5-oxazolone has been calculated to be 217.6 kcal mol^{-1}, while that of 2-aminomethyl-4-methyl-5-oxazolone has been calculated to be 220.5 kcal mol^{-1} (50). The main pathway to the a_1 ion, which dominates the breakdown graph at higher collision energies, appears to be by fragmentation of the b_2 ion (Scheme 4), although at higher collision energies formation of a_1 by cleavage of the N-terminal amide bond may be occurring. The b_2 ion also shows minor fragmentation to the a_2 ion by loss of CO.

Figure 4 shows the breakdown graph for protonated H-Tyr-Val-Gly-OH. The b_2 ion is the dominant low-energy fragmentation product (C-terminal amide bond cleavage), although there is some formation of the y_2 ion (N-terminal amide bond cleavage) at higher collision energies. The b_2 ion fragments primarily to the a_2 ion which, in turn, fragments to form both the a_1 ion (tyrosine iminium ion) and the internal valine iminium ion at *m/z* 72. The mechanism proposed (55) for fragmentation of a_2 ions to iminium ions, outlined in Scheme 5, involves formation of a proton-bound complex of two imines; on decomposition of this complex one would expect the proton to preferentially reside with the species of higher proton affinity. In this respect we note the

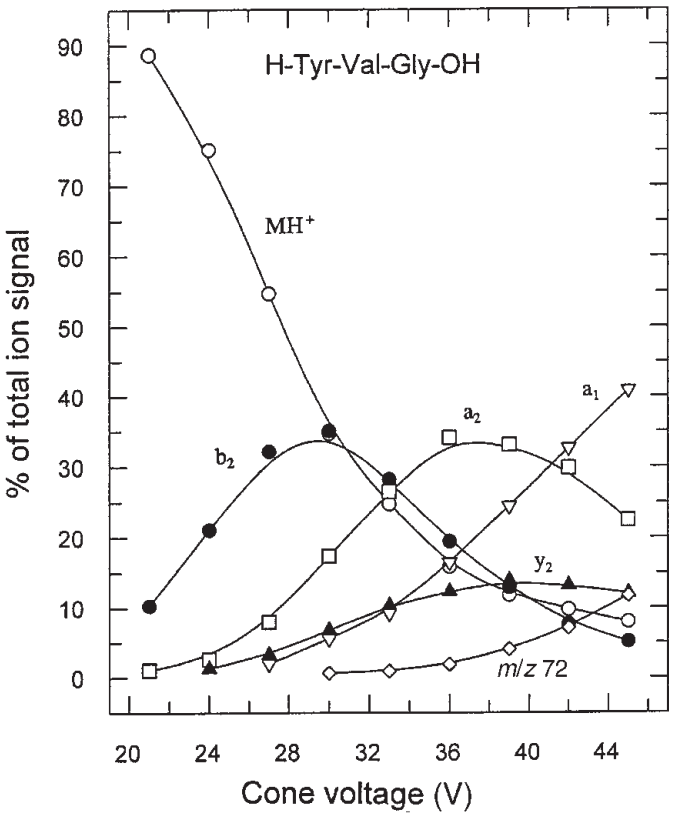

Scheme 4.

calculated (46) proton affinities, PA($HOC_6H_4CH_2CH{=}NH$) = 225.1 kcal mol^{-1} and PA($(CH_3)_2CHCH{=}NH$) = 221.7 kcal mol^{-1}; in line with these relative proton affinities, the tyrosine iminium ion (*m/z* 136) is more abundant than the valine iminium ion (*m/z* 72).

Fig. 4. Breakdown graph for protonated H-Tyr-Val-Gly-OH (*m/z* 72 represents the internal valine iminium ion).

H-Aaa-Tyr-Bbb-OH

The breakdown graphs for protonated H-Gly-Tyr-Ala-OH, H-Val-Tyr-Val-OH, and H-Leu-Tyr-Leu-OH (Figs. 5–7) are similar in showing that the major primary fragmentation reaction involves cleavage of the C-terminal amide bond to form predominantly the appropriate b_2 ion. In each case the

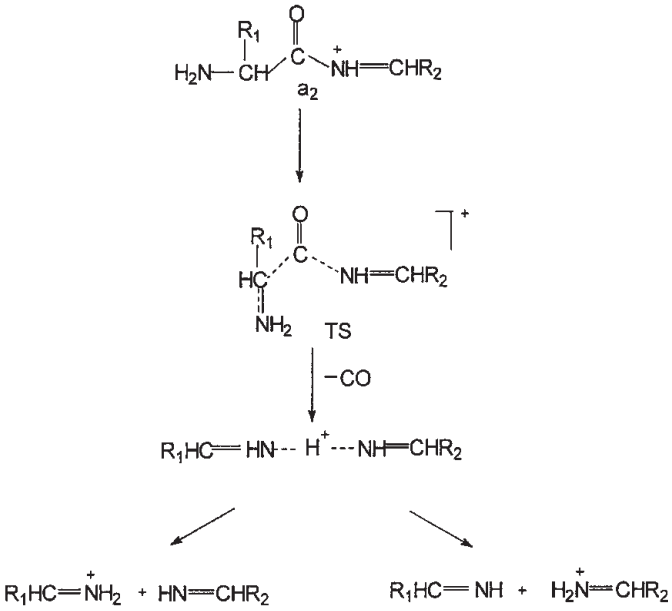
Scheme 5.



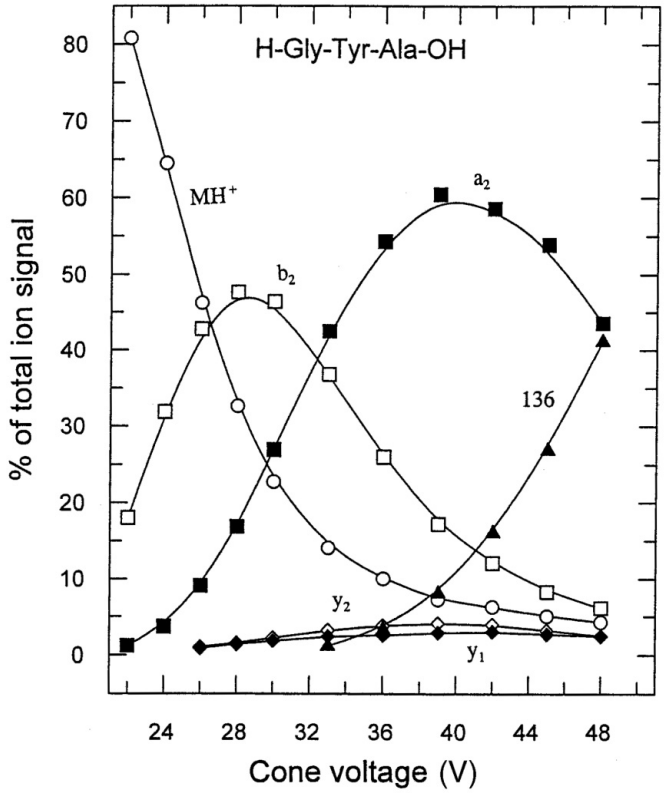


Fig. 5. Breakdown graph for protonated H-Gly-Tyr-Ala-OH (136 represents the internal tyrosine iminium ion).

b_2 ion fragments primarily by loss of CO to give the a_2 ion. The Gly-Tyr a_2 ion fragments (Scheme 5) to give only the internal tyrosine iminium ion (*m/z* 136) because the calculated (46) proton affinity of $HOC_6H_4CH_2CH{=}NH$ (225.1 kcal mol^{-1}) is considerably greater than the proton affinity of $CH_2{=}NH$ (207.2 kcal mol^{-1}). However, the Val-Tyr and Leu-Tyr a_2 ions fragment to both possible iminium ions;

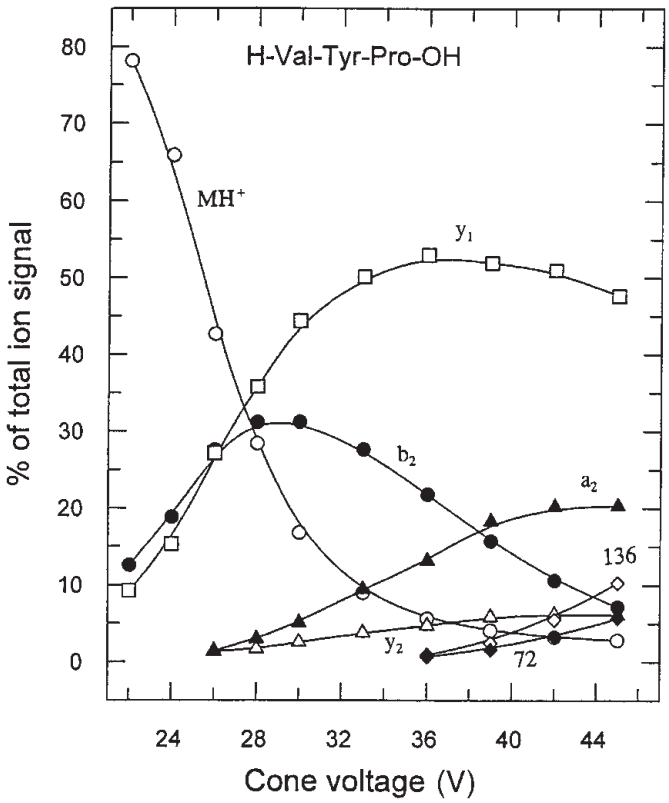
Fig. 8. Breakdown graph for protonated H-Val-Tyr-Pro-OH (136 represents the internal tyrosine iminium ion, 72 the valine iminium ion).



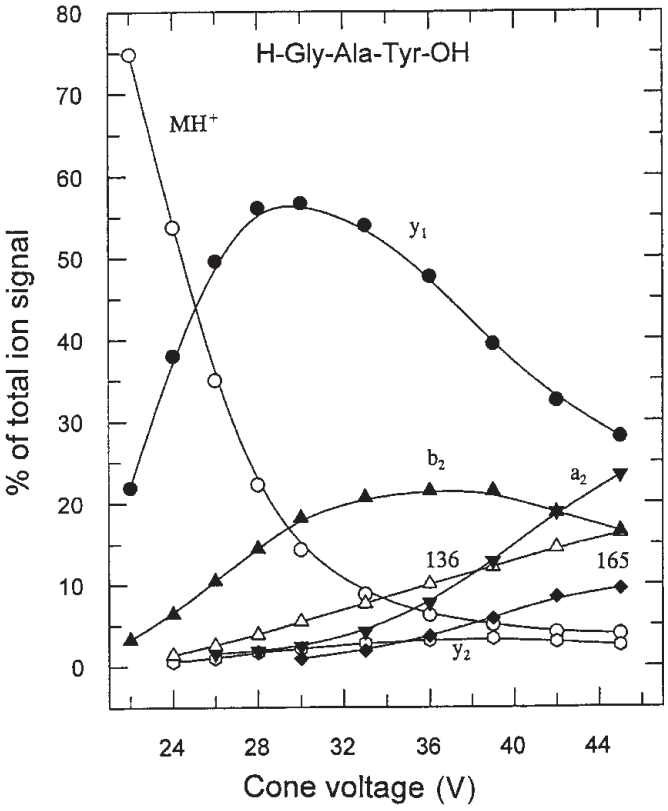


Fig. 9. Breakdown graph for protonated H-Gly-Ala-Tyr-OH (136 represents the tyrosine iminium ion, 165 represents y_1-NH_3).

in both cases the a_1 iminium ion may arise, in part, by initial cleavage of the N-terminal amide bond and, indeed, significant ion signals are observed for the corresponding y_2 ion in both systems.

Protonated Val-Tyr-Pro-OH (Fig. 8) shows a different behaviour in that the b_2 and y_1 ions are of approximately equal abundance at low collision energies indicating dominant cleavage of the C-terminal amide bond. The equal formation of the b_2 and y_1 ions is somewhat surprising in terms of the b_x–y_z mechanism outlined in Scheme 3. The oxazolone derived from Gly-Phe (2-aminomethyl-4-benzyl-5-oxazolone) has been calculated (49) to have a proton affinity of 224.2 kcal mol^{-1}; the proton affinity of the oxazolone derived from Val-Tyr would be expected to be higher than this value. There is some uncertainty in the proton affinity of proline with values ranging from 220 to 226 kcal mol^{-1} having been reported (52, 56–60). The most recent experimental value (60) is 221.3 kcal mol^{-1} in agreement, within expected error, with the value of 220.8 kcal mol^{-1} calculated by Maksić and Kovačević (56); it appears likely that the recent determinations by the kinetic method of 225.7 (58) and 224.9 kcal mol^{-1} (59) are too high for reasons unknown. It thus appears likely that the proton affinity of proline is significantly less than that of the oxazolone derived from Val-Tyr; given this difference, the pathway of Scheme 3 would predict a more abundant formation of the b_2 ion than the y_1 ion. However, there is substantial evidence from neutral fragment reionization (61) studies that, in the fragmentation of protonated H-Leu-Gly-Pro-OH, the neutral accompanying the y_1 ion (proline·H^+) is a cyclic peptide (cyclo-Leu-Gly) rather than an oxazolone (16). Calculations (62) have shown that the proton affinities of cyclic peptides are much lower than the proton affinities of the isomeric oxazolones. For example, the calculated proton affinity of cyclo-Leu-Gly has been calculated to be 210 kcal mol^{-1} (62), while the proton affinity of the isomeric 2-aminomethyl-4-isobutyl-5-oxazolone has been calculated to be 223.7 kcal mol^{-1} (49). Consequently, if a cyclic peptide is formed in concert with cleavage of the C-terminal amide bond in fragmentation of H-Val-Tyr-Pro-OH, formation of the y_1 ion will be strongly favoured. Thus, it appears likely that for H-Val-Tyr-Pro-OH a protonated oxazolone is formed as a b_2 ion, but that the neutral accompanying formation of the y_1 ion is a cyclic peptide (cyclo-Val-Tyr) not an oxazolone. It appears that this dichotomy of mechanism may be peculiar to tripeptides with a C-terminal proline for reasons that are unknown. Certainly, if a similar mechanism was operative for formation of y_1 ions from H-Leu-Tyr-Leu-OH, one would expect a much grater abundance of the y_1 ion since the proton affinity of leucine (217–219 kcal mol^{-1} (52, 56, 57)) is not greatly less than that of proline.

H-Aaa-Bbb-Tyr-OH

Figure 9 presents the breakdown graph for protonated H-Gly-Ala-Tyr-OH. The major primary fragment ion is the y_1 ion (protonated tyrosine) with a more minor yield of the b_2 ion. Clearly, fragmentation has involved almost entirely cleavage of the C-terminal amide bond. The proton affinity of tyrosine is 221 to 222 kcal mol^{-1} (52, 56, 57), while that

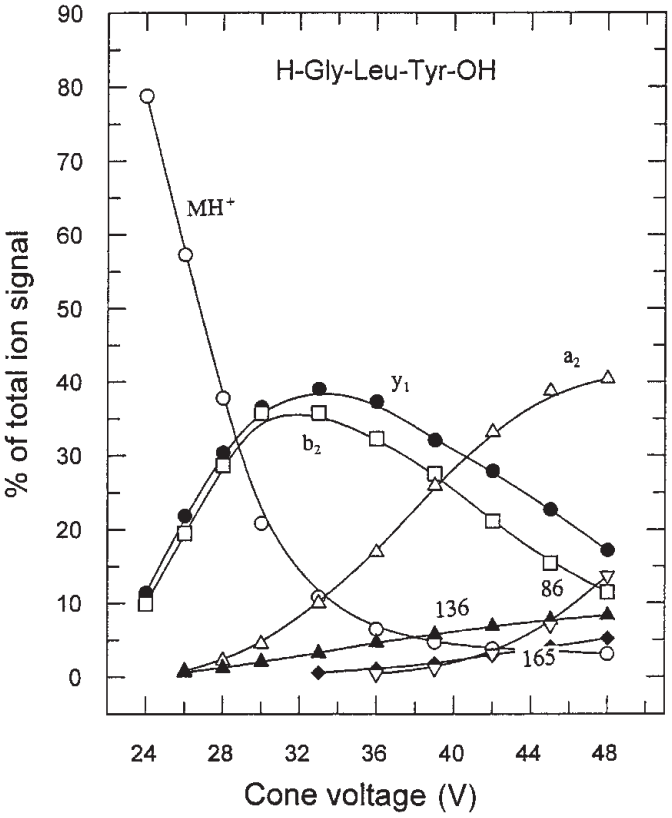

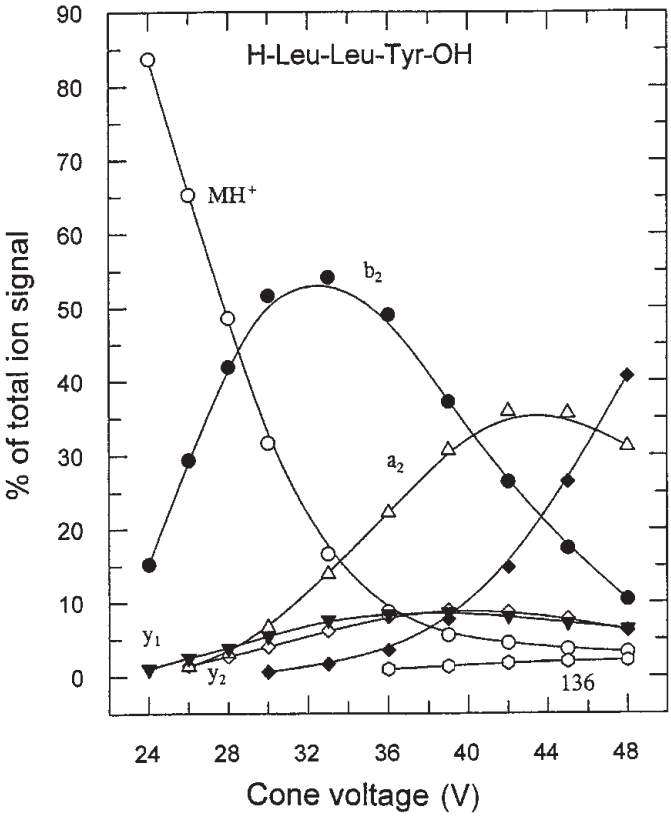

Fig. 11. Breakdown graph for protonated H-Leu-Leu-Tyr-OH.

of the oxazolone (2-aminomethyl-4-methyl-5-oxazolone) has been calculated to be 220.5 kcal mol^{-1} (49). Within combined uncertainties, these proton affinities can be considered to be the same; however, the results of Fig. 9 suggest that the proton affinity of tyrosine is, indeed, greater than that of the oxazolone. The y_1 ion shows further fragmentation to *m/z* 165 (loss of NH_3) and to *m/z* 136 (loss of H_2O + CO) at higher collision energies, both of which are known fragmentation products of protonated tyrosine (63, 64). The b_2 shows fragmentation to the a_2 ion at higher collision energies.

When the central alanine is replaced by leucine, the breakdown graph (Fig. 10) shows that the b_2 and y_1 ions are formed in essentially equal abundance at low collision energies, although the sum of the b_2 ion and its main a_2 fragmentation product are more dominant at higher collision energies. The proton affinity of the oxazolone (2-aminomethyl-4-isobutyl-5-oxazolone) has been calculated to be 223.7 kcal mol^{-1} (49) compared to a proton affinity of 221 to 222 kcal mol^{-1} (52, 56, 57) for tyrosine. Within combined uncertainties these two proton affinities could be considered to be the same, in line with the similar abundances of the b_2 and y_1 ions at low collision energies. The a_2 ion shows fragmentation to the internal leucine iminium ion at higher collision energies.

Figure 11 shows the breakdown graph obtained for protonated H-Leu-Leu-Tyr-OH. The N-terminal leucine has increased the proton affinity of the oxazolone (compared with Gly-Leu) to the extent that the b_2 ion is now the dominant primary fragmentation product with only minor formation of the y_1 ion. Again dominant cleavage of the C-terminal amide bond is observed. The b_2 ion shows extensive fragmentation by loss of CO to form the a_2 ion, which fragments further at high collision energies to form the leucine iminium ion (*m/z* 86) originating from either or both of the leucine residues of the peptide.

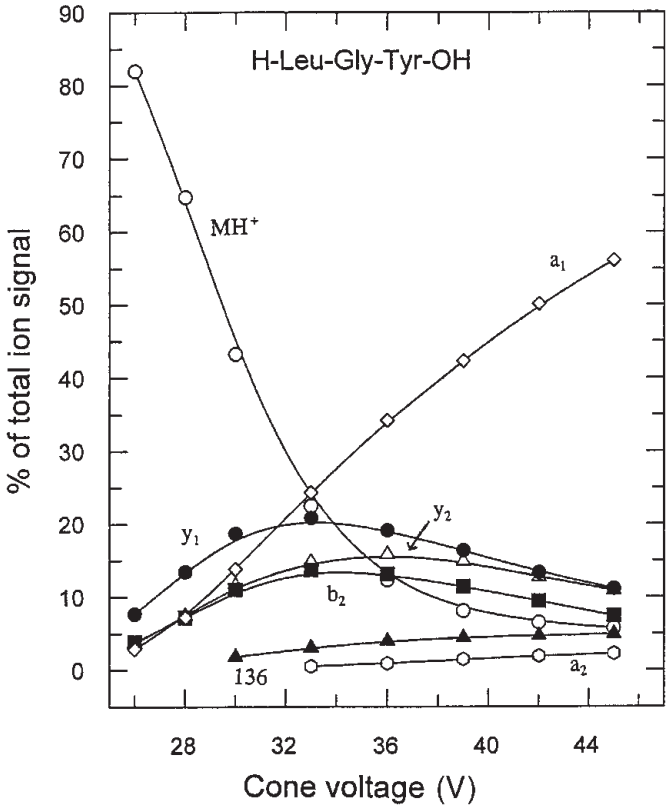

Figure 12 presents the breakdown graph for protonated H-Leu-Gly-Tyr-OH. The switching of the positions of the first two residues (compare with Fig. 10) has substantially changed the fragmentation modes observed. In contrast to H-Gly-Leu-Tyr-OH, where cleavage of the C-terminal amide bond dominated and formed the y_1 and b_2 ions in approximately equal yields, cleavage of the C-terminal amide bond for H-Leu-Gly-Tyr-OH results in more prominent formation of the y_1 ion than the b_2 ion. There also is significant cleavage of the N-terminal amide bond resulting in formation of the y_2 and a_1 ions (Scheme 2) with the latter dominating the breakdown graph at higher collision energies. The a_1 ion also may arise, in part, by further fragmentation of the b_2 ion. The enhanced cleavage of the N-terminal amide bond presumably reflects the stability of the leucine iminium (a_1) ion.

Conclusions

The fragmentation reactions of a variety of protonated tripeptides containing tyrosine have been studied and the energy evolution of the fragmentation reactions occurring elucidated by energy-resolved CID studies. Depending on the identity and location of the amino acid residues contained in the peptide, N-terminal and (or) C-terminal amide bond

cleavage occurs as primary fragmentation. The results are rationalized in terms of the a_1–y mechanism (Scheme 2) for N-terminal amide bond cleavage and the b_x–y_z mechanism (Scheme 3) for C-terminal amide bond cleavage and, indeed, provide support for these mechanisms. The one exception is C-terminal amide bond cleavage for protonated H-Val-Tyr-Pro-OH, where it appears likely that the neutral accompanying formation of the y_1 (protonated proline) ion is a cyclic dipeptide (cyclo-Val-Tyr) rather than the oxazolone predicted by Scheme 3.

An investigation of the ion–molecule interactions of protonated glycine with ammonia by high pressure mass spectrometry and ab initio calculations[1]

Ronghu Wu and Terry B. McMahon

Abstract: The thermochemistry of gas-phase ion molecule interactions and the structures of various clusters between protonated glycine ($GlyH^+$), glycine, and ammonia have been studied by high pressure mass spectrometry (HP-MS) and ab initio calculations. For the association reactions of $GlyH^+$ with NH_3, $Gly(NH_3)H^+$ with NH_3, and $(Gly)_2H^+$ with NH_3, the enthalpy changes experimentally determined are –23.2, –18.3, and –19.1 kcal mol^{-1} (1 cal = 4.184 J), respectively. For all clusters investigated, the measured binding enthalpies are in excellent agreement with those obtained from ab initio calculations at the B3LYP/6-311+G(d,p) level of theory. Different isomers of each of these clusters have been obtained and the corresponding binding energies have been computed. The potential energy surface for isomerization of the clusters of protonated glycine with ammonia has also been computed at the same level. For this cluster, the three most stable isomers all involve a proton transfer from protonated glycine to ammonia. According to the calculated potential energy surface, the barrier between **GN4**, the least stable isomer, and the most stable isomer (**GN1**) is 11.5 kcal mol^{-1} at 298 K. Thus, this isomerization will be facile given the exothermicity of the association reaction. Therefore, a statistical distribution of isomers will be present under thermal equilibrium conditions. Single point energy calculations at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level of theory reveal that the isomer **GN2** in which glycine has a zwitterionic structure has the same energy as the most stable non-zwitterionic isomer **GN1**. NH_4^+ evidently may stabilize the zwitterionic structure of glycine. In contrast, $N_2H_7^+$ and $GlyH^+$ are not as effective in stabilizing the zwitterionic structure of glycine. This likely results from the more localized charge in NH_4^+ giving rise to stronger hydrogen bonds with the carboxylate moiety of zwitterionic glycine. This conjecture is supported by the computational results.

Key words: high pressure mass spectrometry, glycine, gas-phase ion thermochemistry, ab initio calculations, cluster structure.

Résumé : Faisant appel à des calculs ab initio et à la spectrométrie de masse à haute pression (SM-HP), on a étudié la thermochimie des interactions ion–molécule en phase gazeuse et les structures de divers agrégats entre la glycine protonée ($GlyH^+$), la glycine et l'ammoniac. On a déterminé expérimentalement les changements d'enthalpie des réactions de $GlyH^+$ avec NH_3, de $Gly(NH_3)H^+$ avec NH_3 et de $(Gly)_2H^+$ avec NH_3 qui sont respectivement de –23,2, –18,3 et –19,1 kcal mol^{-1} (1 cal = 4,184 J). Pour tous les agrégats étudiés, les enthalpies de liaison mesurées sont en excellent accord avec celles obtenues par des calculs ab initio au niveau B3LYP/6-311+G(d,p) de la théorie. Divers isomères de chacun de ces agrégats ont été obtenus et on a calculé les énergies de liaison correspondantes. On a aussi calculé au même niveau la surface d'énergie potentielle pour l'isomérisation des agrégats de la glycine protonée avec l'ammoniac. Pour cet agrégat, les trois isomères les plus stables impliquent tous un transfert de proton de la glycine protonée à l'ammoniac. Sur la base de la surface d'énergie potentielle calculée, la barrière entre **GN4**, l'isomère le moins stable, et l'isomère le plus stable, **GN1**, est de 11,5 kcal mol^{-1} à 298 K. Cette isomérisation sera donc facile compte tenu du caractère exothermique de cette réaction d'association. Dans des conditions d'équilibre thermique, on retrouvera donc une distribution statistique des isomères. Des calculs d'énergie ponctuelle au niveau MP2(complet)//6-311++G(2d,dp)//B3LYP/6-311+G(d,p) de la théorie révèlent que l'énergie de l'isomère **GN2**, dans lequel la glycine assume une structure zwitterionique, est la même que celle de l'isomère non zwitterionique **GN1** le plus stable. Le cation NH_4^+ peut évidemment stabiliser la structure zwitterionique de la glycine. À l'opposé, les cations $N_2H_7^+$ et $GlyH^+$ ne stabilisent pas d'une façon efficace la structure zwitterionique de la glycine. Ceci résulte probablement du fait que la charge du NH_4^+ est plus localisée, ce qui conduit à des liaisons hydrogènes plus fortes avec la portion carboxylate de la glycine zwitterionique. Cette hypothèse est supportée par des résultats de calculs théoriques.

[Traduit par la Rédaction]

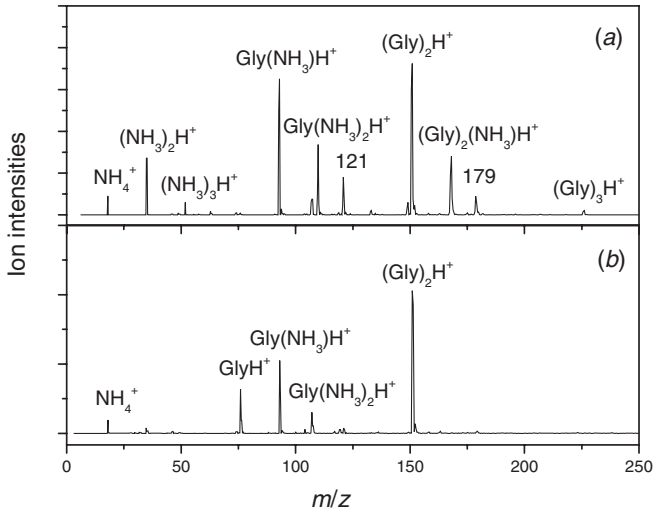
Introduction

Amino acids are among the most fundamental of the biochemical building blocks. They form polymeric chains known as peptides and polypeptides which, in turn, form proteins. Twenty amino acids make up the standard genetic code and are known as proteinogenic or standard amino acids. Glycine is the smallest and simplest of these proteinogenic amino acids and all other amino acids can be regarded as derivatives of glycine substituted by different side chains (1). There have been many studies of the structures of glycine and protonated glycine and their interaction with other ions or molecules, especially by theoretical methods. As early as 1977, Vishveshwara and Pople (2) studied the possible minima on the potential energy surface of glycine by ab initio methods using, by today's standards, relatively small basis sets (RHF/4-31G). Jensen and Gordon (3) later investigated the glycine structure using MP2/6-31G*//HF/6-31G* methods and a total of eight structures corresponding to minima on the potential energy surface (PES) were found. Subsequently, protonated glycine and the complexes of glycine with Li^+ and Na^+ were also investigated by these authors (4) An extensive computational investigation of protonated glycine has been performed by Zhang and Chung-Phillips (5) in which they carried out geometry optimizations to find many N-protonated and O-protonated species at the MP2 level of theory. The most stable isomer was found to be one in which a proton is attached to the most basic site, the amino nitrogen. Campbell et al. (6) used the experimental lone-pair ionization energies to infer experimentally that the nitrogen should be the most favorable protonation site. The proton affinity of glycine has been determined to be 208.2 kcal mol^{-1} from equilibrium measurements of the thermocemistry of proton transfer between glycine and reference bases (7). It has also been assigned as 211.6 kcal mol^{-1} based on kinetic method experiments (8), as well as 215.4 (9) and 213.5 kcal mol^{-1} (10) by proton-transfer reaction bracketing experiments. Recently, the interactions between protonated glycine and ammonia (11) and either one or two water molecules have been calculated (12). For the water clusters, no proton transfer to H_2O occurs; however, in the ammonia clusters, proton transfer to NH_3 is suggested to be favorable.

The high pressure mass spectrometry (HP-MS) technique has played an extremely important role in developments in gas ion thermochemistry. Among the important thermochemical data produced are: proton affinities, gas-phase acidities, ionization energies, electron affinities, hydrogen bond energies, Lewis acid affinities, and metal cation affinities (13). HP-MS has also been a powerful tool for the study of ion–molecule association reactions leading to cluster formation (14–18) and investigations of the solvation of ionic species (19–23). The exact binding enthalpy and entropy changes can be directly obtained by measuring equilibrium constants as a function of temperature. When combined with ab initio calculations, the HP-MS energetic measurements lead as well to significant structural insights that permit an in-depth understanding of potential energy surfaces for complex ion–molecule interactions. Meot-Ner and Field (24) used high pressure mass spectrometry to study the solvation of protonated amino acids some 30 years ago but, until very recently, there have been very few reported investigations concerning the interaction between amino acids and common solvents, including such basic and simple systems as the interaction between protonated glycine and water or ammonia.

In the current study, the binding enthalpy and entropy changes of the clusters of protonated glycine with one and two ammonia molecules, and of the protonated glycine dimer with one ammonia molecule have been determined by HP-MS. By using ab initio calculations, various isomers of these clusters have been revealed and the potential energy surface for the interconversion of these isomers has been elucidated. The calculated binding energetics agree extremely well with the experimental values. At the same time, very interesting structural information for the various isomers has been obtained.

Experimental and computational



Experimental

All experiments were carried out on a high pressure mass spectrometer constructed at the University of Waterloo and whose general design has been described in detail elsewhere (25–27). The instrument used in the present work is configured around a double-focusing reversed geometry (B-E) magnetic sector mass spectrometer (VG ZAB-2F) mated to the home-built high pressure ion source. Experiments were carried out in positive ion mode with an ion energy of 4 keV.

Gas mixtures were prepared in a 2.54 L reservoir using N_2 as the bath gas at a pressure of 500–1200 Torr (1 Torr = 133.3224 Pa). The partial pressure of ammonia was typically in the range of 0.5–50 Torr, depending upon the ion signal intensities desired for the particular equilibrium to be examined. A small amount of CCl_4 was added to the reservoir to increase the signal intensity at long ion source residence times by slowing the rate of ion diffusion to the source walls. The gas mixture was flowed into the ion source to a total pressure of 3–7 Torr. A solid sample of glycine (>99.7%, EM Science) was placed directly inside the high-pressure source. When the high-pressure source is heated, glycine vapor forms inside. Ionization is initiated by energetic electrons, from an electron gun external to the ion source, focused onto the 100 μm electron entrance aperture of the ion source. Chemical ionization processes then lead to formation of the desired ions in the high-pressure source. The electron gun can function in either continuous or pulsed modes. In continuous mode, mass spectra can be obtained such as those shown in Fig. 1, which illustrate the effect of changing temperature and partial pressure in the ion source.

© 2005 NRC Canada

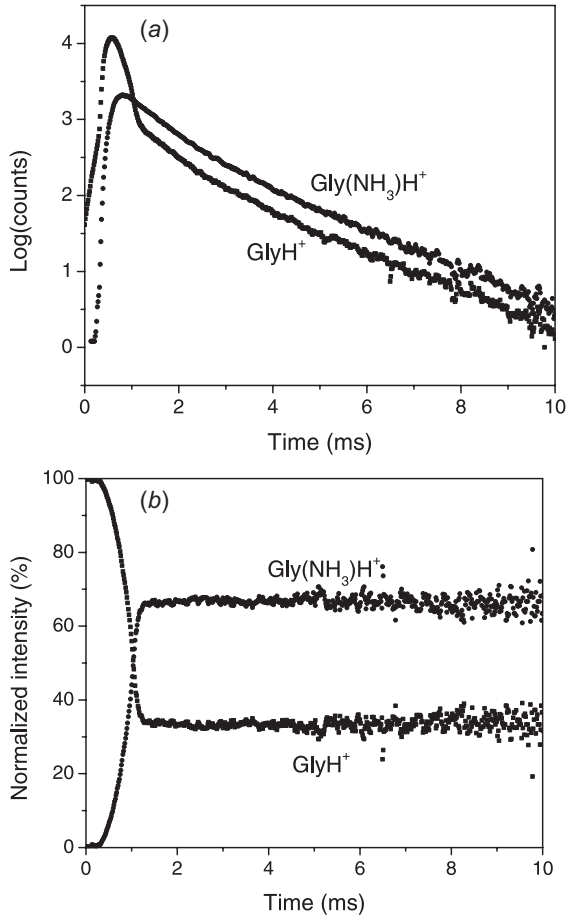


Fig. 1. Mass spectra of protonated glycine and ammonia. (*a*) 2.86 Torr NH_3 (1 Torr = 133.3224 Pa) in a 2.54 L reservoir with a total pressure of 1011 Torr. The temperature of the ion source was 375 K. (*b*) 0.94 Torr NH_3 and a total reservoir pressure of 912 Torr at 435 K. The ion source pressure was 5 Torr in each case.

In Fig. 1*a*, the ion source temperature is 375 K and the pressure of ammonia in the source is 14 mTorr. The two strongest peaks in the spectrum are the protonated dimer of glycine and the cluster of protonated glycine with one ammonia molecule, with additional significant peaks corresponding to $Gly(NH_3)_2H^+$ and $(Gly)_2(NH_3)H^+$. The protonated trimer of glycine also appears as a very small peak at *m*/*z* 226. In addition, peaks owing to the protonated monomer, dimer, and trimer of ammonia are also evident in the mass spectrum. The peaks at *m*/*z* 121 and 179 are likely due to weakly bound adducts of $Gly(NH_3)H^+$ and $(Gly)_2H^+$ with the abundant bath gas, N_2. The mass spectrum of Fig. 1*b* was obtained at an ion source temperature of 435 K and an ammonia ion source pressure of 5 mTorr. The strongest peak is still $(Gly)_2H^+$, but the peak owing to $(Gly)_3H^+$is no longer present, even though the amount of glycine in the gas phase should be greater because of the increased ion source temperature. This indicates that the abundance of species present is determined, not only by the amount of ammonia and glycine in the gas phase, but also by the equilibrium constant for the association reaction at a given temperature. The intensities of NH_4^+, $GlyH^+$, and $Gly(NH_3)H^+$ are also significant.

The ion intensities obtained from the continuous ionization mode mass spectra do not necessarily reflect equilibrium ion abundances owing to the fact that it may take equilibrium some time to be established after initial ionization. To obtain equilibrium abundances, the electron gun is operated in pulsed mode. Mass-selected ion intensity temporal profiles are monitored using a PC-based multichannel scaler data acquisition system, typically configured between 10 and 30 μs dwell time per channel. A total of 1024 channels were acquired, and at least 3000 electron gun pulses were accumulated. For example, the temporal profiles for protonated glycine and the adduct of protonated glycine with ammonia are shown in Fig. 2*a*. At sufficiently long time after the ionization pulse, these decaying intensities become

Fig. 2. (*a*) Variation of ion intensities with time for protonated glycine and its ammonia cluster; 0.66 Torr NH_3 (1 Torr = 133.3224 Pa) in a 2.54 L reservoir with a total pressure of 1180 Torr. The temperature of the ion source was 430 K and the pressure was 5 Torr. (*b*) Normalized intensities for the data shown in (*a*).

parallel, indicating that equilibrium has been reached. The corresponding association reaction is described by eq. [1], and the associated equilibrium constant is given by eq. [2].

$$[1] \qquad GlyH^+ + NH_3 \leftrightarrows Gly(NH_3)H^+$$

$$[2] \qquad K_{eq} = \frac{I_{GLY(NH_3)(H^+)}}{I_{GlyH^+}} \frac{1}{P_{NH_3}}$$

This is seen even more clearly in Fig. 2*b* where the two ion intensities are normalized and, after equilibrium is established, the normalized ion abundances are constant. The equilibrium constants can be calculated from the relative ionic abundance and the partial pressure of ammonia. The relative ionic abundance is simply the constant ratio of intensities, measured by the HP-MS experiment, at sufficiently long reaction time in the ion intensity temporal profiles. The partial pressure of ammonia is readily determined from the known partial pressure of ammonia added to the gas mixture in the gas sample reservoir and the measured total pressure in the ion source. This pressure can be easily changed over several orders of magnitude by simply changing the partial pressure of ammonia in the gas sample reservoir. As the

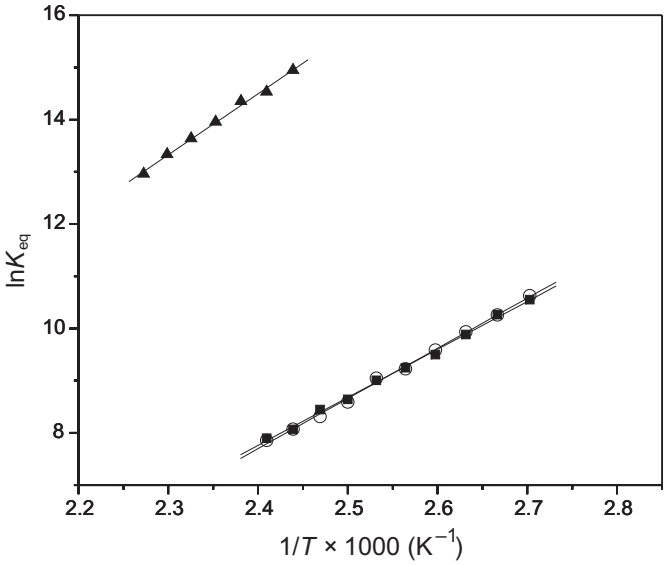
Table 1. Experimental values of enthalpy and entropy changes of the association reactions measured by HP-MS.

Reaction	ΔH (kcal mol^{-1})	ΔS (cal mol^{-1} K^{-1})
$GlyH^+ + NH_3 \leftrightarrow Gly(NH_3)H^+$	–23.2±1.0	–26.9
$Gly(NH_3)H^+ + NH_3 \leftrightarrow Gly(NH_3)_2H^+$	–18.3±1.0	–28.4
$(Gly)_2H^+ + NH_3 \leftrightarrow (Gly)_2(NH_3)H^+$	–19.1±1.0	–30.5

temperature is changed, K_{eq} can be determined at each temperature. Then, as given by the van't Hoff equation (eq. [3]), the enthalpy change (ΔH) and the entropy change (ΔS) for the reaction can be obtained from a plot of K_{eq} vs. reciprocal temperature.

$$[3] \qquad \ln(K_{eq}) = -\frac{\Delta H}{RT} + \frac{\Delta S}{R}$$



Ab initio calculations

Ab initio calculations have been carried out using the Gaussian 03 program (28). The structures of the protonated glycine and its clusters with ammonia and (or) glycine were calculated at the density functional theory level, employing the B3LYP exchange-correlation functional and the 6-311+G(d,p) basis set. The calculations of the potential energy surfaces for the transformation of the isomers of protonated glycine clusters with ammonia and the protonated glycine dimer have also been carried out using the same method. Vibrational frequencies were calculated for all structures using the harmonic approximation to verify that no imaginary frequencies were present for species determined to be local and global minima on the potential energy surface. For the transition states obtained, only one imaginary frequency is found and, by examination of these imaginary frequencies, every transition state could be confirmed to be directly related to the corresponding reactant and product. Zero point energies and thermal energy corrections at 298 K were also obtained. Basis set superposition error (BSSE) was computed after the geometry optimization using the counterpoise correction method (29).

The entropies of the association reactions were also computed at the B3LYP/6-311+G(d,p) level. The use of the harmonic approximation for calculation of vibrational frequencies introduces some uncertainty in the calculation of vibrational entropies because of the anharmonic nature of the intermolecular vibrational modes of ion–molecule complexes. The relative free energies of the isomers of several of the cluster species reported in this work dictate that in an equilibrium mixture of these species a significant population of more than one isomer will be present. As such, for comparison with the experimental energetics, the calculated entropies should also include a term for the entropy of mixing of these isomers.

To obtain somewhat more accurate interaction enthalpies, single point energies have also been computed for the local minima at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level. The enthalpies derived from these MP2 calculations do not include BSSE corrections. All values of enthalpy changes reported include appropriate zero point energy and thermal energy corrections.

Results and discussion

Equilibrium measurements and computational energetics

The experimental van't Hoff plots for the three association reactions investigated (eqs. [1], [4], and [5]) are shown in Fig. 3, and the thermochemical data extracted from these van't Hoff plots are summarized in Table 1.

$$[4] \qquad Gly(NH_3)H^+ + NH_3 \leftrightarrows Gly(NH_3)_2H^+$$

$$[5] \qquad (Gly)_2H^+ + NH_3 \leftrightarrows (Gly)_2(NH_3)H^+$$

For the association reaction of protonated glycine with ammonia (eq. [1]), the measured enthalpy and entropy changes are –23.2 kcal mol^{-1} and –26.9 cal mol^{-1} K^{-1}, respectively. The computed enthalpy change for the formation of the most stable isomer (**GN1**) obtained at the B3LYP/6-311+G(d,p) level of –25.8 kcal mol^{-1} is somewhat greater than the measured value. When enthalpy changes are taken from the single point energies determined at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level, this value is reduced to –24.4 kcal mol^{-1} for both the **GN1** and **GN2** structures, in excellent agreement with the experimental value. The calculated entropy changes for formation of **GN1** and **GN2** are –27.8 and –30.9 cal mol^{-1} K^{-1}, respectively, again in very good agreement with the experimentally determined value.

For the association reaction of $Gly(NH_3)H^+$ with ammonia (eq. [4]), the measured enthalpy and entropy changes are –18.3 kcal mol^{-1} and –28.4 cal mol^{-1} K^{-1}, respectively. Sim-

© 2005 NRC Canada

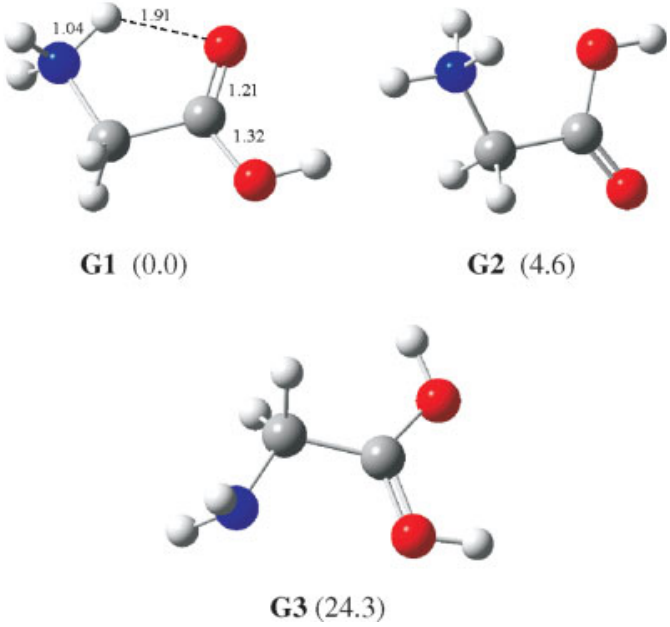
ilarly, the experimental data for the association reaction of the protonated glycine dimer with ammonia (eq. [5]) give enthalpy and entropy changes of –19.1 kcal mol^{-1} and –30.5 cal mol^{-1} K^{-1}, respectively. The computed enthalpy changes from the single point energies at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level for the formation of the corresponding most stable isomers (**GNN1** and **GGN1**) of –18.2 and –19.2 kcal mol^{-1}, respectively, are also in excellent agreement with the experimental data. The corresponding values computed at the lower B3LYP/6-311+G(d,p) level of –17.7 and –19.5 kcal mol^{-1} are only slightly different than the measured values. After correction with BSSE, these data become slightly lower than the measured values. It is well-known that the BSSE correction often introduces an underestimation of the binding energies when the basis set used is not large enough and when the structure computed is sufficiently loose such as those previously reported (30, 31). The computed entropy changes for formation of the corresponding most stable isomers in eqs. [4] and [5] are found to be –28.7 and –28.5 cal mol^{-1} K^{-1}, respectively, again in very good agreement with analogous measured values. Note that this discussion is limited to computed values for the most stable isomers involved in each of these equilibria. A more detailed discussion follows in which many other structures are reported and their implication in the potential energy surface for the reactions is discussed.

Kebarle and co-workers (32, 33) and Meot-Ner (34) have previously reported extensive data for strong hydrogen-bonded dimers (BH^+A), where B is a nitrogen base, and they have shown that a good correlation exists between the binding enthalpy and the proton affinity difference (ΔPA) between the two bases (A and B) involved in the hydrogen bond. The binding enthalpy is found to decrease as the difference between the proton affinities of A and B increases. This may be understood in terms of the occurrence of a partial proton transfer from BH^+ to A within the cluster in the hydrogen bond formation between BH^+ and A. Partial proton transfer will thus be facilitated when BH^+ becomes a more efficient proton donor, which will result either when the proton affinity of neutral B decreases or when A becomes more efficient proton acceptor, i.e., when the proton affinity of A increases. This general trend has also been confirmed in several further investigations (35–38). Viewed in the light of this trend, since the neutral dimer of glycine will have a higher proton affinity than glycine itself, the proton affinity difference between glycine dimer and ammonia will be larger than that between glycine and ammonia and therefore, the binding enthalpy of protonated glycine dimer to ammonia (–19.1 kcal mol^{-1}) will be less than that of protonated glycine to ammonia (–23.2 kcal mol^{-1}). This is, in fact, exactly what was experimentally and computationally observed here.

Computed structures and energetics of clusters

$Gly(NH_3)H^+$

As a first step in determining the computational binding energetics of the protonated glycine–ammonia cluster, various possible stable isomers of protonated glycine were explored. The three most stable species found at the B3LYP/6-311+G(d,p) level are shown in Fig. 4. **G1** is found to be the most stable isomer in which the proton is bound to the amine nitrogen and an intramolecular hydrogen bond is formed between one of the acidic hydrogens of the resulting ammonium group and the carbonyl oxygen. The second most stable structure is **G2**, which lies 4.6 kcal mol^{-1} higher in energy than the most stable isomer that is also amine protonated, but in this case with an intramolecular hydrogen bond between an ammonium hydrogen and the hydroxyl oxygen. A similar structure had also been found previously (5, 11). Protonation on the carbonyl oxygen results in a much higher energy structure (**G3**), which has no intramolecular hydrogen bonding. If rotation about the C—O bond syn to the amino group takes place, an intramolecular proton transfer occurs and **G3** collapses to **G1**. Thus, according to these computed data, **G1** will constitute more than 99% of the protonated glycine species present throughout the temperature range of our experiments. Therefore, **G1** has been used as the basis for all computations of the energetics of eq. [1].



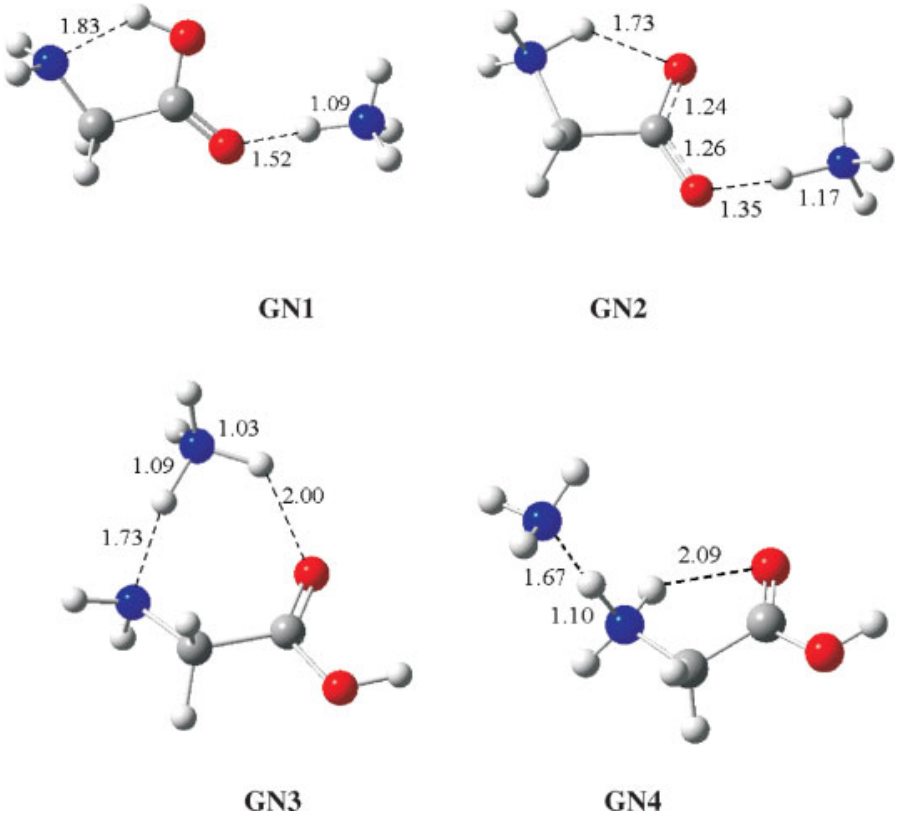


Fig. 4. The different isomers of protonated glycine calculated at the B3LYP/6-311+G(d,p) level. The relative energies are given in parentheses (kcal mol^{-1}, 1 cal = 4.184 J).

The four most stable isomers found for the 1:1 cluster ($Gly(NH_3)H^+$) are shown in Fig. 5. For the first three of these isomers (**GN1, GN2** and **GN3**), a proton transfer from protonated glycine to ammonia has occurred, despite the fact that the proton affinity of glycine is some 8 kcal mol^{-1} greater than that of ammonia (39). This results in species that can be more appropriately regarded as glycine-solvated ammonium ions. The corresponding computed binding enthalpies are 25.8, 24.9, and 24.3 kcal mol^{-1} for **GN1** through **GN3**, respectively, at the B3LYP/6-311+G(d,p) level, and 24.4, 24.4, and 23.7 kcal mol^{-1}, respectively, using the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) calculation. A similar finding has been reported in the literature (11). The isomer **GN1** can be thought of as being derived from separated protonated glycine and ammonia by two proton transfers. The first of these can be viewed as an intermolecular proton transfer from the hydroxyl group of the protonated glycine to ammonia and the second as an intra-

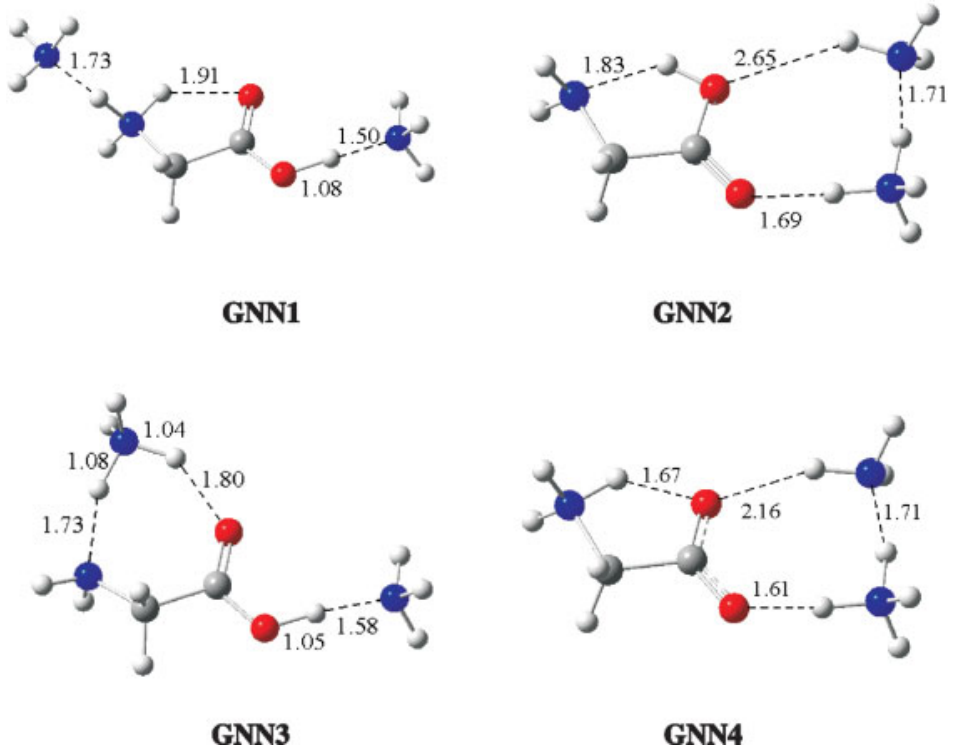
Fig. 5. The different isomers of the cluster of protonated glycine and one ammonia obtained at the B3LYP/6-311+G(d,p) level.

molecular proton transfer from the protonated amino group to the carboxyl oxygen. The resulting structure is an ammonium ion solvated by neutral glycine at the carbonyl oxygen.

The isomer **GN2** similarly is derived from separated reactants by proton transfer; however, in this case, only a single transfer occurs from the hydroxyl oxygen of protonated glycine to ammonia. This leads to the novel structure of a gas-phase ammonium ion solvated by a gas-phase zwitterionic glycine molecule at one of its carboxylate oxygens. The two C—O bond lengths in this structure are very similar (1.24 and 1.26 Å), in contrast to the values of 1.21 and 1.32 Å found in **G1** for the bonds to the carboxyl and hydroxyl oxygens, respectively. The hydrogen bonding in **GN2** appears to be particularly favorable. The bond length of 1.35 Å between the ammonium hydrogen and carboxylate oxygen is significantly reduced by 0.17 Å relative to the analogous bond in **GN1**, while the length of the N—H bond involved increases only by 0.08 Å. In addition, the intramolecular hydrogen bond also appears to be significantly enhanced, decreasing by 0.18 Å, from 1.91 Å in **G1** to 1.73 Å in **GN2**. In the cases of both isomers **GN1** and **GN2**, attempts were made to locate analogous structures in which the intermolecular proton transfer from protonated glycine to ammonia did not occur. All such attempts were unsuccessful, however, indicating that this intermolecular proton transfer is a virtually barrierless process.



The isomer **GN3** is derived from separated reactants by a single proton transfer from the protonated amino group of protonated glycine to ammonia. At the same time, two intermolecular hydrogen bonds are formed, one between the two nitrogens and a second between another ammonium hydrogen and the carbonyl oxygen of glycine. The two hydrogen bond lengths of 1.73 and 2.00 Å to the amine nitrogen and carbonyl oxygen, respectively, are together longer than the combination of intermolecular and intramolecular hydrogen bonds in **GN1** and **GN2**.

Isomer **GN4** is perhaps what might initially have been regarded as being the most intuitively logical species derived from protonated glycine and ammonia. Its binding enthalpy is, however, more than 2 kcal mol^{-1} less favorable than that in **GN1**. Here ammonia functions as a hydrogen bond acceptor, forming an intermolecular hydrogen bond of 1.67 Å to a hydrogen of the protonated amine group of protonated glycine. At the same time, the intramolecular hydrogen bond length from the protonated amino group to the carboxyl oxygen increases to 2.09 Å from the original 1.91 Å in isolated protonated glycine. This is the only isomer, among these four most stable species, in which no intermolecular proton transfer occurs.

Presuming a Boltzmann distribution of possible isomers, the dominant species present throughout our experimental temperature range would be **GN1** (78%) and **GN2** (16%) with smaller amounts of **GN3** (2%) and **GN4** (4%) present using the enthalpy data from the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) calculation and entropies from the B3LYP/6-311+G(d,p) calculation. Assuming such a statistical mixture and average entropy change, including the entropy of mixing term, becomes –27.7 cal mol^{-1} K^{-1}, essentially unchanged from the value determined for the most stable isomer. In addition, the question can also be posed of the possibility of facile interconversion of these isomers to arrive at a statistical distribution. This question will be ad-

Fig. 6. The different isomers of the cluster of protonated glycine and two ammonia molecules obtained at the B3LYP/6-311+G(d,p) level of theory.

dressed in the following section in a discussion of the potential energy surface for the **GN** species.

Gly(NH$_3$)$_2$H$^+$

The four most stable structures found for the cluster of protonated glycine and two ammonia molecules are shown in Fig. 6. In the most stable isomer (**GNN1**), two ammonia molecules act as hydrogen bond acceptors interacting with both the protonated amine and hydroxyl hydrogen of the protonated glycine moiety. In contrast to the most stable isomers of Gly(NH$_3$)H$^+$, no proton transfer to ammonia is observed. However, from the shorter OH···N hydrogen bond length (1.50 Å) compared with the NH···N hydrogen bond length (1.73 Å), it appears that the hydrogen bond strength to the hydroxyl hydrogen may be stronger than that to the amino hydrogen. This would indicate that the positive charge density at the hydrogen of the carboxylic acid group is likely greater than that of a single hydrogen of the ammonium moiety in protonated glycine. The calculated binding enthalpy of 18.2 kcal mol^{-1} is nearly identical to the measured value and, similarly, the calculated entropy change for addition of the second ammonia molecule (–28.7 cal mol^{-1} K^{-1}) is also very close to the measured value of –26.9 cal mol^{-1} K^{-1}.

The second most stable isomer (**GNN2**) has a binding enthalpy of 18.0 kcal mol^{-1}, very similar to that of the most stable isomer (**GNN1**). It should be noted, however, that at the B3LYP/6-311+G(d,p) level, this species is the most stable isomer. **GNN2** might be thought of as being derived from **GN1** by the addition of a second ammonia molecule hydrogen bonded to the ammonium ion already interacting with a neutral glycine molecule at the carboxyl oxygen. In effect, this resembles an asymmetric $N_2H_7^+$ species interacting with neutral glycine primarily via a hydrogen bond to the carboxyl oxygen (1.69 Å) but with a weaker, secondary intermolecular hydrogen bond to the hydroxyl oxygen (2.65 Å). The intramolecular hydrogen bond between the hydroxyl hydrogen and amino nitrogen is identical in length (1.83 Å) to that in **GN1** from which it is derived.

The binding enthalpy of **GNN3** is computed to be 1.5 kcal mol^{-1} less than that of the most stable isomer at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level. Given its remarkable structural similarity, it seems clear that it is derived from **GN3** by the interaction of ammonia as a hydrogen bond acceptor at the hydroxyl hydrogen of the glycine moiety. In **GNN3** a proton transfer has once again occurred from protonated glycine to the first ammonia molecule leading to the doubly hydrogen-bonded configuration in which NH_4^+ hydrogen bonds to both the amino nitrogen and carbonyl oxygen of neutral glycine. The only significant structural change in this configuration relative to **GN3** is the contraction of the NH···O hydrogen bond from 2.00 to 1.80 Å. This is likely the result of the increased negative charge density at the carbonyl oxygen caused by the interaction of the hydroxyl hydrogen of the carboxyl group with the second ammonia molecule, giving a partial proton transfer and hence increased negative charge density at both oxygens of the carboxyl group. This latter hydrogen bond in **GNN3** is slightly longer (1.58 Å) than the analogous hydrogen bond in **GNN1** (1.50 Å), likely because of the partial proton transfer to the carbonyl oxygen in the adjacent double hydrogen bond to NH_4^+.

In exactly the same way that **GNN2** can be thought of as being derived from **GN1**, **GNN4** can be considered to be derived from **GN2**. The most significant difference between

Table 2. Calculated values of enthalpy (298 K) and entropy changes of the association reactions related to different isomers.

	B3LYP/6-311+G(d,p)			MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p)
Isomer	ΔH (kcal mol^{-1})	ΔH with BSSE (kcal mol^{-1})	ΔS (cal mol^{-1} K^{-1})	ΔH (kcal mol^{-1})
GN1	–25.8	–25.4	–27.8	–24.4
GN2	–24.9	–24.6	–30.9	–24.4
GN3	–24.3	–23.4	–32.9	–23.7
GN4	–22.8	–21.7	–27.2	–22.4
GNN1	–17.7	–15.5	–28.7	–18.2
GNN2	–18.0	–16.8	–30.2	–18.0
GNN3	–16.5	–14.4	–33.3	–16.7
GNN4	–14.3	–13.1	–36.4	–15.2
GG1	–29.1	–28.6	–34.2	–29.7
GG2	–27.0	–26.0	–35.7	–28.4
GG3	–26.5	–25.9	–37.2	–28.0
GGN1	–19.5	–18.0	–28.5	–19.2
GGN2	–19.6	–17.4	–28.5	–19.0
GGN3	–16.7	–15.3	–24.9	–16.9
GGN4	–17.2	–15.0	–27.3	–16.8

GNN4 and **GNN2** is the fact that in the former an intramolecular proton transfer has occurred to yield a zwitterionic glycine neutral, which is now hydrogen bonded to the asymmetric $N_2H_7^+$ species. Although the number of hydrogen bonds (4) is nominally the same in **GNN4** as in **GNN2**, the hydrogen bond lengths in **GNN4** are notably shorter at 1.61, 1.71, 2.16, and 1.67 Å, meaning that they are stronger overall than the corresponding bonds in **GNN2**. The ~3.0 kcal mol^{-1} higher energy of **GNN4** is thus the result of the higher energy of zwitterionic neutral glycine relative to the molecular form. Viewed in terms of cationic interactions with the molecular form of neutral glycine, it thus appears that the interaction with NH_4^+ is much better able to promote the isomerization to zwitterionic neutral glycine (**GN1** → **GN2**) than is $N_2H_7^+$ (**GNN2** → **GNN4**).

Given the values of ΔH and ΔS for eq. [4] summarized in Table 2, it would be predicted that, under thermal equilibrium conditions, the population of **GNN1** and **GNN2** would be 75% and 25%, respectively, with **GNN3** and **GNN4** having very minor contributions throughout our entire experimental temperature range. A calculation of the average entropy change, including entropy of mixing, gives a value of ΔS of –28.5 cal mol^{-1} K^{-1}. The experimental ΔH and ΔS values for eq. [4] are in excellent agreement with the values computed for **GNN1** and **GNN2**, the dominant species observed.

(Gly)$_2$H$^+$

As demonstrated previously (27), the three most stable isomers of the protonated dimer of glycine may contribute to a statistical population at HP-MS temperatures. The structures and energetics obtained in the present work agree very well with the previous study (27). These three isomers are shown in Fig. 7. The thermochemical data for **GG1**–**GG3** represent the enthalpy and entropy changes associated with the reaction of protonated glycine (**G1**) with the most stable conformer of neutral glycine (eq. [6]) (27).

[6] $(Gly)H^+ + Gly \leftrightarrows (Gly)_2H^+$

The most stable isomer (**GG1**) is a direct analogue of **GN1** in which a nitrogen-protonated glycine has replaced the ammonium ion in an interaction with the carbonyl oxygen of neutral glycine. At the same time, there are intramolecular hydrogen bonds in both the glycine and protonated glycine moieties with the bond length in the former being identical to that in the analogous **GN1** structure. It is of interest to compare the enthalpy of binding of 29.7 kcal mol^{-1} with that for the analogous reaction leading to **GN1** (eq. [1]) of 24.4 kcal mol^{-1}. As noted as a general phenomenon in previous studies, the greater hydrogen bond energy in **GG1** relative to **GN1** can be understood from the 7.9 kcal mol^{-1} lower proton affinity of ammonia relative to glycine.

The **GG2** structure is the analogue of **GN3** in which one hydrogen of a nitrogen-protonated base interacts with the neutral glycine molecule via a hydrogen bond to the amino nitrogen of neutral glycine, while a secondary hydrogen bond is formed between another hydrogen of the protonated-nitrogen base and the carbonyl oxygen of the neutral glycine. In addition, an intramolecular hydrogen bond interaction within the protonated glycine moiety results in a hydrogen bond length of 2.16 Å. This dimer species has a binding enthalpy of 28.4 kcal mol^{-1}, 1.3 kcal mol^{-1} less than that in **GG1**.

GG3 is very similar in structure to **GG1**, with the exception that an intramolecular proton transfer from the hydroxyl hydrogen of the carboxyl group to the amino nitrogen has occurred in the neutral glycine moiety, such that the structure of neutral glycine becomes zwitterionic. This is again reminiscent of the difference between **GN1** and **GN2**. The intermolecular hydrogen bond length of 1.50 Å is less than the corresponding value of 1.61 Å in **GG1**, a result of the increased negative charge density on the carboxylate oxygens following the intramolecular proton transfer. The binding energy of 28.0 kcal mol^{-1} at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level is only 1.7 kcal mol^{-1} less than that in the more stable **GG1**.

These calculated values for the binding enthalpy in the protonated glycine dimer are all very close to those previ-

ously computed in this laboratory at the MPW1PW91/6-31+G(*d*) level of 29.2, 27.7, and 27.5 kcal mol^{-1} for **GG1**, **GG2**, and **GG3**, respectively. The experimentally determined binding enthalpy of 27.2 kcal mol^{-1} obtained from HP-MS experiments is in reasonable agreement with the computed values (27). In addition, as discussed in the following, no barrier for proton transfer between **GG1** and **GG3** is found at 298 K. The following discussion of binding of ammonia to $(Gly)_2H^+$ is based on structures **GG1** and **GG2**.

$(Gly)_2(NH_3)H^+$

The four most stable structures located for $(Gly)_2(NH_3)H^+$ species are shown in Fig. 8. Two of these (**GGN1** and **GGN3**) can be considered to be derived from **GG1**, while

© 2005 NRC Canada

the remaining two are derived from **GG2**. In none of these species does any proton transfer occur, consistent with the much greater proton affinity of the neutral glycine dimer relative to that of ammonia. In the most stable isomer (**GGN1**), ammonia forms a strong hydrogen bond to the hydroxyl hydrogen of the carboxyl group within the protonated glycine moiety with a hydrogen bond length of 1.53 Å. This is similar to the bond length found in the analogous hydrogen-bonding situation in **GNN1**. The computed enthalpy of binding is 19.2 kcal mol^{-1} at the MP2(full)/6-311++G(2d,2p)// B3LYP/6-311+G(d,p) level. In **GGN3**, ammonia forms a hydrogen bond with one of the hydrogens at the protonated amino group of glycine with a hydrogen bond length of 1.78 Å. This species can also be considered to be an analogue of **GNN1**, at its other ammonia binding site, where the corresponding hydrogen bond length from the amino proton to ammonia is 1.73 Å. The computed enthalpy of binding in **GGN3** of 16.9 kcal mol^{-1} is considerably less than that in **GGN1**, however, the calculated entropies of association for the two isomers are essentially identical, –28.5 and –28.4 cal mol^{-1} K^{-1}, respectively, for **GGN1** and **GGN3**.

The two structures derived from **GG2** both involve hydrogen bonds to ammonia at a hydroxyl hydrogen of either the protonated glycine or neutral glycine moieties. **GGN2** results from binding of ammonia as a hydrogen bond acceptor at the hydroxyl hydrogen of the protonated amino acid entity with a hydrogen bond length of 1.53 Å, essentially identical to that found in **GGN1**. The binding enthalpy of 19.0 kcal mol^{-1} is only 0.2 kcal mol^{-1} less than that in **GGN1**. The interaction of ammonia with **GG2** at the hydroxyl hydrogen of the neutral glycine moiety yields **GGN4**, which is a new structural motif. Somewhat surprisingly, the new hydrogen bond length of 1.59 Å is only slightly greater than that in **GGN2**. The enthalpy of binding is, however, considerably less at 16.8 kcal mol^{-1}. It is of interest to note that when ammonia interacts with **GG2** to form a hydrogen bond with the hydroxyl group of the protonated glycine entity, the intramolecular hydrogen bond length between the protonated amine and carbonyl oxygen decreases from 2.16 Å in **GG2** to 1.95 Å in **GGN2**. Similarly, when ammonia forms a hydrogen bond with the hydroxyl hydrogen of the neutral glycine moiety, the intermolecular hydrogen bond length for the bond between an amino hydrogen of the protonated amine and the carbonyl oxygen of the neutral glycine moiety decreases from 2.03 Å in **GG2** to 1.84 Å in **GGN4**. The shortening and strengthening of these two hydrogen bonds is the direct result of the increased negative charge density on the two carbonyl oxygens induced by partial proton transfer to the bound ammonia.

Based on the calculated energetics, a statistical mixture would contain 53% **GGN1**, 38% **GGN2**, 7% **GGN3**, and 2% **GGN4**. The measured enthalpy of the association reaction is 19.1 kcal mol^{-1}, which is essentially identical to the computed values for **GGN1** and **GGN2**. In addition, the calculated entropy changes for the association reaction for **GGN1** and **GGN2** are each the same (–28.5 cal mol^{-1} K^{-1}) and in excellent agreement with the experimentally determined value of –30.5 cal mol^{-1} K^{-1}. Including the entropy of mixing term, an average entropy change of –27.2 cal mol^{-1} K^{-1} is obtained, again in good agreement with the experimental value. Since, as shown in the following, **GG1** and **GG2** can readily interconvert at our experimental temperatures, it is likely that the experimental measurement does constitute a statistical mixture of **GGN1** and **GGN2**.

Potential energy surfaces for isomerization

Gly(NH$_3$)H$^+$

Even though the ab initio calculations reveal stable minima corresponding to several different stable isomers of each of the cluster species investigated here are possible, the question remains as to whether all such species are energetically accessible under the experimental conditions employed. To answer this question an exhaustive search of the potential energy surface for several key cluster ions was undertaken to examine their interconversion. These potential energy surfaces for isomer transformation have been investigated at the B3LYP/6-311+G(d,p) level. The results of such

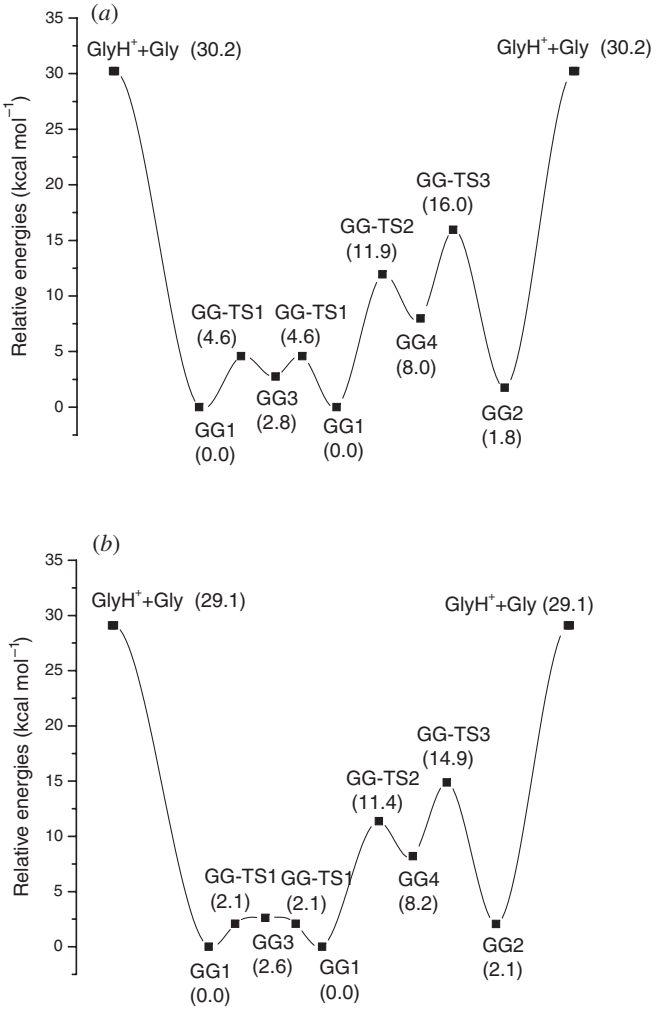
Fig. 9 (*concluded*).

a search for the potential energy surface of the cluster of protonated glycine with ammonia are shown in Fig. 9. Figure 9*a* shows a vibrationless 0 K potential energy surface, based on differences in electronic energies, for interconversion of the various $Gly(NH_3)H^+$ cluster species, while Fig. 9*b* shows the potential energy surface using 298 K enthalpy differences that include zero point energy contributions and thermal energy corrections at 298 K. This surface is somewhat different than that at 0 K, and the energy of one transition state (**TS1**) becomes lower in energy than either of the two minimum energy structures to which it is linked. However, this constitutes a more accurate representation of the actual experimental situation. The structures of every stationary point located are shown in Fig. 9*c*, including two new energy minima (**GN5** and **GN6**) and five transition states (**TS1** through **TS5**).

Two different approaches of NH_3 to the **G1** form of protonated glycine might be envisaged, either at the protonated amino group or at the hydroxyl hydrogen. In the former case, ammonia acts as a hydrogen bond acceptor and **GN4** is formed. Alternatively, in the approach at the hydroxyl hydrogen, a barrierless proton transfer occurs leading to **GN2**, which, through the intramolecular proton transfer via **TS5**, can also rearrange to the most stable **GN1**. In



© 2005 NRC Canada

the first case, **GN4** may undergo an intermolecular proton transfer to ammonia and form an additional hydrogen bond via **TS1** to arrive at **GN3**. Although transition state **TS1** lies 0.6 kcal mol^{-1} above **GN4** at 0 K, at 298 K it is 1.7 kcal mol^{-1} lower in energy than **GN4** and even 0.2 kcal mol^{-1} lower in energy than the rearranged **GN3**. This thus constitutes an extremely facile transformation. The conversion of **GN3** to **GN1** involves additional higher energy intermediates. Rotation about the C—OH bonds leads to a slight shift of the NH_4^+ moiety toward the carbonyl oxygen, transforming **GN3** into the new species **GN5** via **TS2**. As the hydrogen bond between the ammonium ion and the amino nitrogen is broken, a rotation about the O···H-N hydrogen bond transforms **GN5** to **GN6** via **TS3**. **GN5** and **GN6** are 7.9 and 11.1 kcal mol^{-1}, respectively, higher in energy than the most stable isomer **GN1**, while the barrier at **TS2** is 13.0 and 6.6 kcal mol^{-1}, respectively, higher in energy than either **GN3** or **GN5**, which it separates. **TS3**, separating **GN5** and **GN6**, lies 3.2 kcal mol^{-1} higher in energy than the former and 0.6 kcal mol^{-1} above the latter. Finally, **GN6** may find the global minimum (**GN1**) via rotation about the C—C bond through **TS4**, which permits formation of the intramolecular hydrogen bond between the hydroxyl hydrogen and the amino nitrogen. This process has a very small barrier, with the energy of **TS4** lying only 0.5 kcal mol^{-1} above **GN6**. Thus, at the temperature of the HP-MS experiments conducted here, the complete potential energy surface will be explored leading to a statistical distribution of isomeric species.

(Gly)$_2$H$^+$

Both **GG1** and **GG2** can be considered to be formed directly, without barrier, from separated protonated glycine (**G1**) and neutral glycine by intermolecular hydrogen bond formation between a protonated amino group hydrogen of **G1** and either the carbonyl oxygen or amino nitrogen of neutral glycine. The potential energy surface for interconversion of protonated glycine dimer isomers, computed at the B3LYP/6-311+G(d,p) level of theory, is shown in Fig. 10. The vibrationless 0 K potential energy surface, based on differences in electronic energies, is given in Fig. 10*a*, and the 298 K surface, based on enthalpy differences including zero point energy contributions and thermal energies, is given in Fig. 10*b*. The transformation of **GG1** to **GG3** involves a barrier at **GG-TS1** of 4.6 kcal mol^{-1} at 0 K, which falls to 2.1 kcal mol^{-1} at 298 K, at which point this transition state lies lower in energy than **GG3** by 0.5 kcal mol^{-1}. While **GG2** had previously been considered to be the most stable of the isomers of protonated glycine dimer (40), in fact it lies 2.1 kcal mol^{-1} higher in energy than **GG1** at 298 K at the B3LYP/6-311+G(d,p) level of theory and 1.3 kcal mol^{-1} higher at the MP2(full)/6-311++G(2d,2p)//B3LYP/6–311+G(d,p) level. The interconversion of **GG1** and **GG2** involves an additional stable intermediate and two transition states. Starting from **GG1**, the intramolecular hydrogen bond in the neutral glycine moiety is broken, accompanied by rotation about the neutral C—C bond, to give **GG-TS2** lying 11.4 kcal mol^{-1} higher in energy. From this transition state, the C—C bond rotation continues, accompanied by an angular deformation of the intermolecular O···H-N hydrogen bond, to arrive at **GG4**, 8.2 kcal mol^{-1} higher in energy than

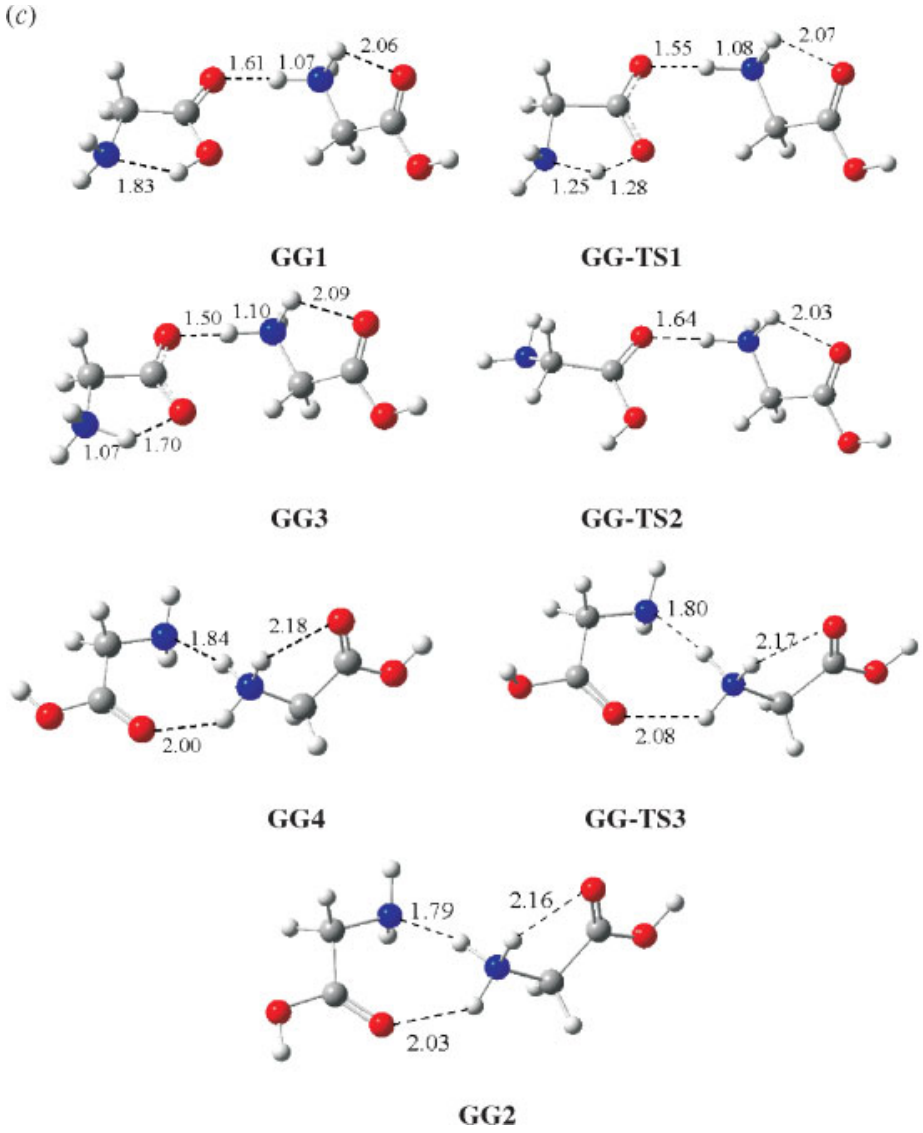


Fig. 10. (*a*) Vibrationless potential energy surface (0 K) for isomerization of the protonated glycine dimer at 0 K calculated at the B3LYP/6-311+G(d,p) level. The relative electronic energies of each stationary point are given in parentheses (kcal mol^{-1}, 1 cal = 4.184 J). (*b*) Potential energy surface including zero point energy contributions (ZPC) and thermal energy corrections at 298 K. The relative enthalpies at 298 K of each stationary point are given in parentheses (kcal mol^{-1}). (*c*) The structures of each stationary point.

GG1. Rotation about the C—OH bond in the neutral glycine moiety gives rise to **GG-TS3**, which is 14.9 kcal mol^{-1} higher in energy than **GG1** and which then collapses to **GG2**. The protonated glycine dimer has also recently been studied by infrared photodissociation spectroscopy (IRPD) (41) in the 3000–4000 cm^{-1} range. The experimental IRPD spectrum has only two peaks, with the strongest peak at 3584 cm^{-1} presumably associated with the stretching vibration of the free OH group in the protonated glycine moiety. A second, weaker peak at 3372 cm^{-1} was assigned to the free NH asymmetric stretch at the ammonium nitrogen of a **GG2** dimer structure. However, the free NH symmetric stretch and the stretching vibration of bonded NH are also possible at this position. In addition, in **GG1**, the symmetric stretch of the free NH at the ammonium nitrogen is 3375 cm^{-1}, and the stretching vibrational frequency of free

© 2005 NRC Canada

Fig. 10 (*concluded*).

OH is 3599 cm^{-1} at the B3LYP/6-311+G(d,p) level, which, after a scaling of 0.965, is also in the correct range. Thus, on the basis of these two peaks, it is not possible to assign the structure unambiguously as **GG1** or **GG2**. Again, it is to be anticipated that, either by direct association or by rearrangement, a statistical population of G**G1** and **GG2** can be achieved.

Gly(NH$_3$)$_2$H$^+$

Detailed calculations of the potential energy surface for Gly(NH$_3$)$_2$H$^+$ species were not carried out. However, structure **GNN1** would appear to be readily accessible without a barrier from direct association of **GN2** with ammonia. Similarly, structure **GNN2** could be presumed to be directly accessed via barrierless association of **GN1** with ammonia. The higher energy structure **GNN3** can be likely formed reasonably readily from **GNN1** via a transition state analogous to **TS1** on the Gly(NH$_3$)H$^+$ potential energy surface. Similarly, the transformation of **GNN2** to **GNN4** should proceed via a low-lying transition state resembling **TS5**. Thus, it seems highly likely that the Gly(NH$_3$)$_2$H$^+$ system can freely explore all four of the stable minima calculated here.

(Gly)$_2$(NH$_3$)H$^+$

Extensive calculations of the potential energy surface for (Gly)$_2$(NH$_3$)H$^+$ species similarly were not carried out. Structures **GGN1** and **GGN3** should be formed without a barrier from direct association of **GGN1** with ammonia. Similarly, structures **GGN2** and **GGN4** could be presumed to be directly accessed via barrierless association of **GG2** with ammonia. The interconversion of these four species should also be reasonably facile via transition states resembling those on the (Gly)$_2$H$^+$ potential energy surface. Thus, it also seems highly likely that the (Gly)$_2$(NH$_3$)H$^+$ system can freely explore all four of the stable minima calculated here.

Zwitterionic structure of glycine

In the gas phase, neutral glycine, as well as all other amino acids, are known to exist in the non-zwitterionic form. The non-zwitterionic form of glycine is computed to

© 2005 NRC Canada

be 22 ± 2 kcal mol^{-1} lower in energy than the zwitterionic form at the *thermodynamically calibrated* BAC/MP4/6-31G(d,P)/6-31G(*d*) level of theory (42), although the existence of an actual stable minimum for the zwitterionic form seems unlikely because of facile proton transfer. Two water molecules can make the zwitterionic form of glycine a local minimum on the potential energy surface, but this hydrated zwitterion is still about 12 kcal mol^{-1} higher in energy than the non-zwitterionic analogue (43). For amino acids interacting with metal ions, two different structural motifs can be envisaged, either a charge-solvated structure in which the amino acid is non-zwitterionic or alternatively, a salt bridge structure in which the amino acid is zwitterionic. Alkali cation attachment does have the effect of stabilizing the salt bridge structure relative to the charge-solvated analogue but, for example, upon sodium ion attachment the relative energy of the salt bridge structure of glycine, is still 1–3 kcal mol^{-1} higher than the charge-solvated structure according to the calculations (4, 44–47). Hodyau and Ohanessian (44) carried out a systematic series of calculations of the interaction of glycine with all alkali metal cations (Li^+ to Cs^+) in the gas phase and found that the most stable alkali cation – glycine species always had a non-zwitterionic structure. The most stable non-zwitterionic structure was lower in energy, by from 1.4 to 3.3 kcal mol^{-1}, than the salt bridge form for the Li^+ to Cs^+ adducts. For Na^+, the most stable non-zwitterionic isomer had a relative energy lower by either 1.4 or 2.7 kcal mol^{-1} than the zwitterionic one using either a MP2/6-31G* or MP2/6-311+G (2d,2p)//MP2/6-31G* calculation, respectively, including correction for BSSE. Similarly, a B3LYP/DZVP calculation gives the energy of the most stable non-zwitterionic isomer to be 2.5 kcal mol^{-1} lower than the salt bridge structure in Na^+(Gly) (46).

For the structures of ammonia adducts of protonated glycine investigated here, structures **GN1**–**GN3** involve neutral glycine interacting with NH_4^+, while **GN4** is a true adduct of neutral ammonia with an intermolecular hydrogen bond at the protonated nitrogen of glycine. However, the **GN2** adduct involves NH_4^+ interacting with a zwitterionic glycine molecule and this species is comparable in stability to the most stable of the non-zwitterionic forms (**GN1**). It is likely that the identical energies of **GN1** and **GN2** calculated at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level are more accurate than the B3LYP/6-311+G(d,p) results, since the agreement between the experimental and calculated values for each of the three adducts investigated in the present work is better at the former computational level. Thus, it appears that the interaction of NH_4^+ is very effective in stabilizing the zwitterionic structure of glycine. In comparison to NH_4^+, the $N_2H_7^+$ and $GlyH^+$ ions are not as effective in stabilizing the zwitterionic structure of glycine, as evidenced by the greater energetic difference between structures **GG3** and **GG1** (1.7 kcal mol^{-1}) and between **GNN4** and **GNN2** (2.8 kcal mol^{-1}). This is likely due to the fact that the positive charge on each of the hydrogens of NH_4^+ is quite substantial, so that a very strong hydrogen bond with the anionic carboxylate moiety in zwitterionic glycine can be formed. In contrast, the charges on the possible hydrogen-bonding sites of $N_2H_7^+$ and $GlyH^+$ are substantially less, which makes them less able to stabilize the zwitterionic form of glycine very effectively. According to the Mulliken population analysis calculated at the B3LYP/6-311+G(d,p) level, when atomic charges on the hydrogens are summed with those on the heavy atoms, in **GG1** the sum of charges on the nitrogen of $GlyH^+$ is 0.664, and that in **GG3** becomes 0.639. The charge on the nitrogen in NH_4^+ in **GN1** is 0.973, while that in **GN2** is dramatically less at 0.787, which indicates that NH_4^+ effectively shares the partial negative charge on the carboxylate group of the zwitterionic glycine.

It is of interest to compare the interactions of NH_4^+ and Na^+ with glycine. The binding energy of Na^+ to glycine has been determined by four different experimental methods as either 36.3 ± 1.4 (48), 38.5 ± 1.9 (49), 39.7 ± 1.4 (50), or 36.6 ± 2.3 kcal mol^{-1} (51). Based on the data from the present work and the known proton affinity difference between glycine and ammonia of 7.8 kcal mol^{-1}, the binding energy between neutral glycine and NH_4^+ can be determined to be 31.0 kcal mol^{-1}, which is some 5–9 kcal mol^{-1} lower than the binding energy between glycine and Na^+. However, if the calculation is based upon supposing, albeit naively, that the $Gly(NH_3)H^+$ cluster structure is derived from association of NH_4^+ with the most closely corresponding neutral conformer, then, using the calculated energetic differences between glycine conformers, the binding energy for NH_4^+ to glycine to yield the **GN1** conformer is 32.7 kcal mol^{-1}. Thus, to arrive at **GN2** in a similar fashion, it is necessary to presume a zwitterionic glycine neutral species. As noted earlier, such a structure is not found to be a stable minimum, but if the result from ref. 42 is taken in which the zwitterionic form was given as 22 ± 2 kcal mol^{-1} higher in energy than the most stable conformer, the binding energy for NH_4^+ to zwitterionic glycine to yield **GN2** is about 54 kcal mol^{-1}. Such a strong interaction energy is not surprising given that this is effectively a polyatomic cation – polyatomic anion interaction.

Conclusions

Gas-phase ion–molecule interactions involving glycine and ammonia have been studied by high pressure mass spectrometry. The association reaction of protonated glycine with ammonia yields the enthalpy and entropy changes of –23.2 kcal mol^{-1} and –26.9 cal mol^{-1} K^{-1}, respectively. The subsequent addition of a second molecule of ammonia to the product ion thus formed results in corresponding thermochemical values of –18.3 kcal mol^{-1} and –28.4 cal mol^{-1} K^{-1}. Finally, addition of ammonia to the protonated dimer of glycine gives enthalpy and entropy changes of –19.1 kcal mol^{-1} and –30.5 cal mol^{-1} K^{-1}, respectively. These interactions have also been examined by computational methods and several different isomers for each of the cluster species involved in these equilibria have been located at the B3LYP/6-311+G(d,p) level of theory, and binding enthalpies and entropies have been obtained for each possible isomer. The potential energy surface for the interconversion of the isomers of the protonated glycine clusters with ammonia has been calculated by the same method. Single point energy calculations have been carried out at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level of theory, which yield binding energies that are in excellent agreement with the experimentally measured values.

© 2005 NRC Canada

For the $Gly(NH_3)H^+$ cluster, the three most stable isomers all involve a proton transfer from protonated glycine to ammonia to yield various glycine-solvated ammonium ion structures. Calculations of the potential energy surface for this system show that the highest barrier on the surface lies 14.5 kcal mol^{-1} above the global minimum energy structure. Given that the exothermicity of formation of the minimum energy structure is ~10 kcal mol^{-1} greater than this, the entire surface, involving six stable minima and five transition states, can be fully sampled during the association–dissociation equilibrium process. One of the stable isomers on this surface (**GN2**) involves NH_4^+ bound to glycine in a zwitterionic form and this adduct is found to be one of two isoenergetic species that constitute the global minimum structure at the MP2(full)/6-311++G(2d,2p)//B3LYP/6-311+G(d,p) level.

The global minimum energy isomer for the cluster of protonated glycine with two ammonia molecules is found to be one in which a protonated glycine moiety acts as a double hydrogen bond donor to bind one ammonia molecule at the protonated amino site and a second at the hydroxyl hydrogen site of the carboxylic acid functionality. Thus, in this species, no proton transfer occurs. However, a nearly isoenergetic structure of this composition also exists, derived from the most stable $Gly(NH_3)H^+$ cluster in which a $N_2H_7^+$ moiety interacts with neutral glycine as a double hydrogen bond donor with resulting interactions at both the carbonyl and hydroxyl oxygens. A third, intramolecular hydrogen bond also exists in this species between the hydroxyl hydrogen and the amino nitrogen.

The most stable form of the protonated dimer of glycine involves an intermolecular hydrogen bond between a hydrogen of the protonated amino functionality and the carbonyl oxygen of the neutral glycine. This is supplemented by one intramolecular hydrogen bond between a second hydrogen of the protonated amino group and the carbonyl oxygen of this molecule and a second between the hydroxyl hydrogen of the neutral glycine moiety and the amino nitrogen of the same molecule. Correspondingly, the most stable isomer of the adduct of the protonated dimer of glycine and ammonia is one in which ammonia forms a strong hydrogen bond with the remaining free hydroxyl hydrogen of the protonated glycine moiety. An only slightly less stable isomer of this adduct also exists, derived from the second most stable protonated dimer of glycine.

For each of the clusters examined, the measured enthalpies are in excellent agreement with the corresponding calculated values of the most stable isomers obtained at the MP2(full)/6-311++G(2d,2p)//B3LYP/311+G(d,p) level of theory. Considering the calculated differences in binding energies of the various isomers, the most stable isomers would be predicted to be the dominant species under our experimental conditions.

In this work, NH_3 has served as a model compound to probe the interaction of important functional groups and protonated glycine as a model for amino acids and other biomolecules. Continuing investigations from this laboratory will extend such studies to other systems of biochemical and biological significance. In particular, the study of isomerizations on the potential energy surfaces for these species may serve as an aid to the understanding of biological structure and function.

Gas-phase experiments on the chemistry and coordination of Zn(II) by aprotic solvent molecules[1]

Bridgette J. Duncombe, Lijlijana Puškar, Bohan Wu, and Anthony J. Stace

Abstract: Experiments have been performed in the gas phase on a series of doubly charged zinc–ligand complexes to elucidate their solvation structure and available fragmentation pathways. Production of such complexes was achieved by the formation of neutral argon–ligand clusters followed by the subsequent addition of a single zinc atom using a pickup technique. Multiply charged ions were then produced by electron impact within a high resolution, double-focusing mass spectrometer. Studies have been undertaken on a number of zinc(II) – aprotic solvent complexes including those consisting of argon and carbon dioxide in association with the zinc cation. Investigation of these novel metal–solvent clusters took the form of recorded parent ion intensity distributions and the measurement of fragmentation patterns promoted via collision-induced dissociation (CID). Discussion of the intensity distributions is presented in terms of the solvation of Zn(II) by each solvent, drawing on existing theoretical and experimental data from the gaseous and condensed phases. Investigation of collision-induced dissociation processes includes identifying charge transfer reactions in each solvated system, and analysis of the results in terms of kinetic energy release as well as possible mechanisms for fragmentation pathways.

Key words: zinc, clusters, dications, gas phase, solvation.

Résumé : Dans le but d'élucider leur structure de solvatation et les voies qui leur sont disponibles pour la fragmentation, on a effectué des expériences en phases gazeuses sur une série de complexes zinc–ligand doublement chargés. La production de tels complexes a été réalisée par la formation d'agrégats argon–ligand neutres, suivie d'une addition subséquente d'un seul atome de zinc en utilisant la technique du « ramassage ». On a ensuite produit les ions à multiples charges par une ionisation électronique dans un spectromètre de masse à double focalisation, à haute résolution. On a entrepris des études sur un certain nombre de complexes de zinc(II) – solvants aprotiques, y compris ceux formés d'argon et de dioxyde de carbone en association avec le cation zinc. L'examen de ces nouveaux agrégats métal–solvant a pris la forme de distributions enregistrées de l'intensité de l'ion précurseur et la mesure des patrons de fragmentation qui résultent d'une dissociation induite par une collision (DIC). On présente une discussion des distributions de l'intensité en fonction de la solvatation du Zn(II) par chaque solvant en se basant sur des données théoriques et expérimentales existantes pour les phases gazeuses et condensées. L'étude des processus de dissociation induits par une collision inclut l'identification des réactions de transfert de charge dans chaque système solvaté et une analyse des résultats en termes d'énergie cinétique émise ainsi que des mécanismes possibles pour les voies de fragmentation.

Mots clés : zinc, agrégats, dications, phase gazeuse, solvatation.

Introduction

Gas-phase studies of multiply charged metal ion solvation have been extremely fruitful over the past decade (1). Two principal methods, notably *electrospray* (2–4) and *pick-up*, have been used with considerable success to investigate a wide range of systems. The pick-up method, first utilized by Scoles and co-workers (5) to investigate the solvation of molecules within argon clusters, is now routinely used to produce a wide variety of heterogeneous clusters. It is, however, within our group that the pick-up technique has been utilized, with considerable success, for the production of multiply charged metal–ligand complexes (6–15).

Although the intensities of solvated multiply charged metal ions formed via the pick-up technique can be relatively low, there are a number of advantages in using this method of preparation when compared with electrospray or laser vaporization. A wide variety of solvent entities can be used, including species that are frequently involved in matrix isolation experiments rather than complexation. For example, carbon dioxide and argon would fall into the latter group. Furthermore, a wide variety of metals can be studied,

frequently in oxidation states that are not easily accessible in the condensed phase i.e., gold(II) (11).

In the experiments reported here the pick-up technique has been used to prepare a range of Zn(II) complexes in association with aprotic solvents. In addition to recording ion intensities, we also report on the fragmentation patterns and chemistry of individual complexes. Below a critical size, many of the Zn(II)–molecule combinations are found to exhibit extensive chemical reactivity, driven primarily by charge transfer from the metal cation to a molecule.

Experimental Section

The experiments described herein were performed using instrumentation that has been described in detail in earlier publications (7, 12). In brief, argon carrier gas at a pressure of 30–50 psi (1 psi = 6.894757 kPa) was seeded with the desired solvent, which then underwent adiabatic expansion through a pulsed, 200 μm diameter conical nozzle, leading to the formation of neutral mixed argon–solvent clusters. Most of the solvents used in this study were in the liquid state and were held in a stainless steel reservoir through which the carrier gas passed. It was frequently found necessary to keep the reservoir in an ice bath to reduce the vapour pressure of the solvent concerned such that it remained constant over the average time of a single experimental period lasting approximately 10 h. In the case of carbon dioxide, a premixed cylinder of Ar–CO_2 in the ratio 99:1 was used. Collimation of the beam took place downstream from the nozzle with a 1 mm diameter skimmer before passing into the pick-up region. In this next section of the apparatus, zinc pieces (Aldrich, Gillingham, UK) held in a pyrolytic boron nitride crucible (Sintec, Halblech, Germany) were heated in an effusion cell (model EC-40-63-21, DCA Instruments, Turku, Finland) to a temperature of 320–340 °C, as measured with a standard C-type thermocouple. These conditions were found to be sufficient to produce zinc vapour of approximately 10^{-2} mbar (1 bar = 100 kPa) partial pressure. The metal vapour flowed into the path of the molecular beam where the mixed argon–solvent clusters "picked-up" a metal atom to produce neutral clusters of varying composition, including $Zn(L)_N(Ar)_M$, $Zn(L)_N$, and $Zn(Ar)_M$. If the temperature of the oven was too high, the molecular beam intensity diminished because of scattering by zinc atoms. A shutter positioned at the exit of the oven acted as a guide to the relative intensity of zinc–ligand signals within a series, such that parent ion intensity distributions were recorded by taking the difference in intensity between the shutter being open and closed.

Zinc has five naturally occurring isotopes, of which three, ^{64}Zn, ^{66}Zn, and ^{68}Zn, have relatively high intensities, and when recording parent ion intensity distributions and reaction pathways, complexes containing these isotopes were used. On entering the ion source of a reverse geometry Vacuum Generators ZAB-E mass spectrometer, the clusters were ionized using high-energy electron impact (70–100 eV). The positively charged clusters were then accelerated at 5 kV through the first field free region (FFR) into the magnetic sector of the mass spectrometer where they were selected according to their mass to charge ratio. The ion clusters then passed through the second FFR into a gas cell that allowed the controlled introduction of a collision gas. Collision-induced dissociation (CID) was promoted by the introduction of air (at a background pressure of ~1×10^{-6} mbar), and the m/z values of any ionic fragments were identified by passing the ion beam through an electrostatic analyser (ESA). This particular linked-scanning technique is normally referred to as a MIKE (mass-analysed ion kinetic energy) scan (16). Although the loss of neutral ligands from a multiply charged metal–solvent complex is of interest, it is the appearance or absence of charge transfer pathways that can frequently yield more useful information on the structure and composition of parent ions.

When doubly charged species are produced in the ion source, they appear with twice the kinetic energy of mass coincident singly charged ions. Accordingly, when charge transfer occurs to produce two singly charged daughter ions, these are transmitted at kinetic energies double that of a mass coincident singly charged species formed in the ion source. With the ion source operating at 5 kV, it was necessary to scan the ESA such that ions with kinetic energies between 0 and 10 keV were transmitted through to the detector to identify all possible charge transfer products. Singly charged ions created by charge transfer are frequently accompanied by an extensive release of kinetic energy, which appears as a consequence of repulsion between the two separating positively charged daughter ions (Coulomb explosion). Thus, peaks associated with charge transfer processes are often much broader than neutral loss peaks, which makes identification easier, but accurate mass assignment difficult. Ion detection was via a Daly scintillation detector linked to a lock-in amplifier (SR850, Stanford Research Systems, Sunnyvale, California), which provided phase-sensitive detection referenced with respect to the train of nozzle pulses.

Results and discussion

Experiments have been undertaken on the solvation properties of Zn(II) with a variety of aprotic solvents (loosely defined as solvents that are unable to hydrogen bond). In previous studies, parent ion intensity distributions have acted as a guide as to the coordination of a central metal ion by surrounding ligand molecules. Several factors control the size distribution, with the method of preparation being of particular significance. As a consequence of the expansion process, clusters of the form Ar_ML_N are probably present in the seeded beam for $N + M \leq 200$. Cluster size plays a significant role in the pick-up of metal as the collision between a "hot" atom and a "cold" cluster probably results in a phase transition (cluster melting) accompanied by the evaporation of a large number of argon atoms and some solvent molecules. However, it cannot be assumed that the neutral metal atom becomes surrounded by solvent molecules, rather that a variety of interactions including metal–solvent, solvent–solvent, and metal–argon will determine where the metal atom "resides" at this point in the preparation process.

Final composition and structure of the multiply charged metal–solvent complexes are most strongly influenced by the final step in the production process, namely electron impact (EI) ionization. This is a complicated process and with increasing electron energy a wide variety of reaction channels exist, creating a diverse range of ionized and neutral products (17). Using a simple analysis of the ionization en-

© 2005 NRC Canada

ergies of the constituents of the neutral cluster undergoing EI, it can be seen that since the first ionization energies of most metals are below those of a typical solvent species studied, it is to be expected that the metal will be preferentially ionized. However, for multiple ionization, the route to forming $[M(L)_N]^{Z+}$ is not so obvious. The first ionization energy of a solvent species is usually lower than the second ionization energy of the metal or any argon atoms left within the cluster, therefore, the solvent molecule would be expected to be preferentially ionized in any sequential double ionization step. However, for most small clusters ($N < \sim 30$) this should result in Coulomb explosion and the appearance of two singly charged entities. Hence, the formation of $[M(L)_N]^{Z+}$ species is most likely to be a single electron event centred on the metal atom.

In relation to the ionization process, there are a number of observations that are of significance: since no species of the form $[M(L)_N Ar_M]^{Z+}$ are detected, this gives credence to the belief that argon atoms act as a heat sink to dispose of any thermal energy that appears as a consequence of the metal–cluster collision in the pick-up process. The pivotal role played by argon is confirmed by the fact that similar experiments performed using helium fail to produce multiply charged metal–ligand complexes. Ions of the form $[M(Ar)_M]^{Z+}$ produced via the pick-up technique have been detected for a number of transition metals M (14), but their initial formation is presumably as a consequence of a collision with a large cold argon cluster, and their stability is due to a combination of a high first ionization energy on the part of argon (15.75 eV) and its moderate polarizability. However, in competition with a solvent molecule, which would probably have a much stronger electrostatic interaction with the metal cation, the formation of metal–solvent complexes would be preferred over containing a metal atom combined with argon.

The signal intensities of $[M(L)_N]^{Z+}$ ions are frequently quite low ($\sim 10^{-12}$ A) and a comparison of relative ion intensity would suggest that many more ionization and (or) fragmentation events lead to singly charged species. However, there are examples of systems where singly and doubly charged metal-containing ions have been found to have comparable intensities (cf. Cu(I) and Cu(II)) (18). Since electron impact ionization is such a violent process, multiply charged ions will have high internal energies with contributions from electronic as well as vibrational excitation. However, the ions are approximately 10^{-4} s "old" before detection and as such can undergo radiative decay and (or) evaporation of molecules to reduce their internal energy content (1). Since on leaving the ion source there is no mechanism available to promote ion growth, the system can be classed as being *nonequilibrium* (1). The rate of evaporative or radiative decay will be dependent on the intrinsic stability of the cluster ion. Thus, ions with high internal energies and (or) low binding energies will have rapid rates of decay (1). As a consequence, anomalies or magic numbers (clusters of greater intensity, hence stability) are to be found in cluster ion distributions, that is, as a function of time and under collision-free conditions, stable ions gain in intensity relative to less stable neighbours (1).

Thus, parent ion intensity is influenced by experimental parameters such that the distribution is weighted towards small N, which is a common feature of many cluster ion experiments. In the case of multiply charged ions, however, very small values of N are either not seen or are of very low intensity, as to stabilize the multiple charge with respect to charge transfer the presence of at least a partial solvent shell is required (18). Nevertheless, intensity distributions can be insightful as to the factors that influence a specific metal–solvent system. A number of quantities can be identified from mass spectral measurements: a minimum stable size N_{min}, the parent ion with greatest intensity I_{max}, and N_{crit}, the minimum number of ligands needed to prevent a complex from decomposition via charge transfer.

Zn(II) – carbon dioxide and Zn(II)–acetone complexes

Although there is currently no experimental evidence for $[Zn(CO_2)_N]^{2+}$ complexes in the condensed phase, data are available on other (atomic) transition metals interacting with CO_2 in a matrix (19, 20). Low temperature (under 60 K) Fourier transform infrared (FT IR) studies in CO_2 matrices show that along the first row transition metals the mode of bonding changes such that the insertion of a metal atom into a C—O bond can occur. Previous gas-phase pick-up experiments involving such metal cations as Cu(II), Ag(II), Au(II), and Mg(II), show that although carbon dioxide is an atypical ligand, it is very proficient at stabilizing doubly charged cations in the gas phase (12, 13, 18, 21). Much of this stability is derived from the high ionization energy of the molecule, which helps to prevent charge transfer between the ligand and the metal cation.

The fact that carbon dioxide can bond in so many different ways, viz. η^1-C, η^1-O, η^2-O,O, or η^2-C,O, has led to a great deal of theoretical interest in bonding with both atomic and cationic first row transition metals (22–24). Sodupe et al. (22) point out that the interaction of a metal ion with carbon dioxide can best be described as electrostatic. The molecule has no permanent dipole moment; consequently, the interaction can be seen as a charge-quadrupole interaction, such that linear η^1-O (end-on) coordination can be expected. However, there is undoubtedly a charge-induced dipole interaction, which because it depends on z^2 could make a dominant contribution to bonding with metal dications. However, recent experiments with Al(III) have shown carbon dioxide to be far less successful with trications (25). Calculations found the ionic charge transfer structures $M^{2+}CO_2^-$ to be much higher in energy than M^+CO_2 configurations; however, the negative charge on CO_2 would cause the molecule to bend, which in turn would weaken any end-on structure with a metal dication. Obviously, similar considerations do not apply to the complexes studied here.

Figure 1 shows the relative parent ion intensity distributions recorded for complexes of zinc(II) with carbon dioxide. The series show a clear maximum at $N = 3$, although the drop in intensity at $N = 4$ for the ^{64}Zn and ^{66}Zn isotopes is minimal. A further important feature is that a single carbon dioxide molecule is able to stabilize the zinc(II) ion; however, the intensity of the ion is comparatively low. Figure 2 shows similar data for Zn(II)–acetone complexes where, for the three main isotopes, the relative intensities follow a similar pattern to that seen for zinc(II) – carbon dioxide: a maximum at $N = 3$, followed by a slight decline at $N = 4$. Unlike the zinc – carbon dioxide system, it was not possible to lo-

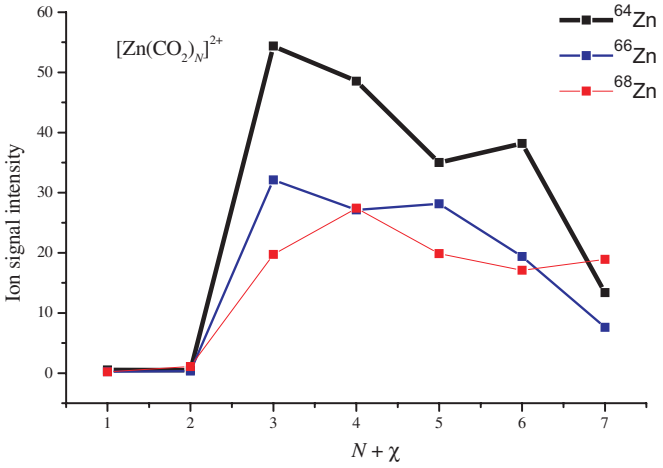

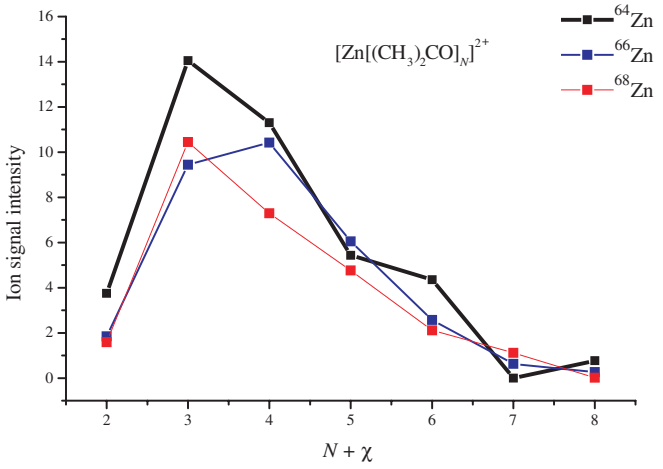

Fig. 2. Relative intensities of $[Zn[(CH_3)_2CO]_N]^{2+}$ complexes plotted as a function of size (N).

cate an ion corresponding to $[Zn(CH_3COCH_3)_1]^{2+}$, which is in contrast with recent calculations (26). El-Nahas (26) has used ab initio and DFT methods to analyse a number of metal dications interacting with aprotic solvents, including the $[Zn(CH_3COCH_3)_1]^{2+}$ system, and it was found that the complex formed a stable structure that was bent at the oxygen atom. This behaviour was attributed to substantial charge transfer occurring between the acetone molecule and the Zn^{2+} ion, and the author argued that, in the absence of such a step, the structure would be linear. Kebarle and co-workers (27) also used theory to examine $[Zn(CH_3COCH_3)_N]^{2+}$ cations. With DFT (B3LYP/6-311++G(d,p)), the optimized geometries for $[Zn(CH_3COCH_3)_1]^{2+}$ and $[Zn(CH_3COCH_3)_2]^{2+}$ were found, in each case, to be bent at the oxygen atom. It was concluded that electrostatic bonding would be strengthened by the large dipole moment and high polarizability, whilst the electron-donating ability of the lone pair on oxygen would result in ligand-to-metal charge transfer strengthening the cation–oxygen bond. Thus, with regard to the measurements presented here, it is quite possible that $[Zn(CH_3COCH_3)_1]^{2+}$ is present, but that it has an intensity that is too low to be detected in our experiment. Problems of this nature have been identified in previous work (28).

In the only other experimental study of zinc dications solvated by acetone, Kebarle and co-workers (27) used electrospray to generate $[Zn(CH_3COCH_3)_{5-7}]^{2+}$ complexes and determined enthalpies and entropies by establishing an equilibrium in the gas phase. They concluded that the transition to an outer shell occurred at the fifth molecule (i.e., 4+1 structure), and coincided with a pronounced decrease in enthalpy difference caused, in part, by the inability of acetone to form a hydrogen-bonded network. However, it was not possible to undertake experiments at smaller values of N (<5) as the temperature needed to establish equilibrium, was outside the range of the apparatus. Thus, although the maximum at $N = 3$ seen in the data presented here would seem slightly low, it is possible that the maximum reflects the high charge density present on the small zinc ion. The strong ion–dipole and ion-induced dipole interactions will pull the ligands in close to the cation and the effects of ligand–ligand repulsion will begin to have an influence at small values of N. The results presented in Figs. 1 and 2 show a sharp reduction in intensity with increasing N. Such behaviour is to be expected, as the molecules involved have no mechanism for inducing a strong secondary solvent network of the type previously seen for protic solvent systems. In the case, for example, of $[Mg(CH_3OH)_N]^{2+}$, a significant plateau in the parent ion distribution was observed and thought to be related to the formation of an extended network of charge-enhanced hydrogen bonds (7).

To investigate further the interaction between carbon dioxide and zinc(II), collision-induced fragmentation studies were undertaken. Figure 3 shows a selection of results taken from MIKE scans from which the following fragmentation patterns could be identified:

$$[1] \quad [Zn(CO_2)_N]^{2+} \rightarrow [Zn(CO_2)_{N-K}]^{2+} + K CO_2$$

$$[2] \quad \rightarrow Zn^+(CO_2)_{N-K-1} + CO_2^+ + K CO_2$$

$$[3] \quad \rightarrow Zn^+O(CO_2)_{N-K-2} + CO_2^+ + CO + K CO_2$$

Several features of these MIKE scans should be noted. For $N = 1$, there is no neutral loss, whilst for $N = 2$–4, neutral loss leads to $[Zn(CO_2)_1]^{2+}$, which supports the argument that this latter species is stable (cf. Fig. 1). For $N = 5$ and 6, neutral loss proceeds all the way to $[Zn(CO_2)_2]^{2+}$. For small N, charge transfer processes have significant intensity (relative to neutral loss) and moreover, the charge transfer peaks are comparatively narrow. Previous experiments have noted similar behaviour when ligands with high ionization energies are used to prepare complexes. Of significance is the observation that collisions promote not only direct charge transfer (rxn. [2]), but also reactivity in the form of rxn. [3]; however, the latter is a minor pathway relative to rxn. [2]. For $N = 1$ and 2, reactive charge transfer leads to ZnO^+, a process that is undoubtedly driven, in part, by the high stability of this ion. For $N = 2$–6, the most intense charge transfer product is Zn^+CO_2 whilst, for N in the range 3–6, the most prominent reaction product is OZn^+CO_2. These charge trans-

fer pathways have some significance when attempting to recognize the mode of bonding between carbon dioxide and zinc(II). If the interaction were considered to be purely electrostatic, then the ion-induced dipole interaction would favour η^1-O (end-on) coordination. Side-on coordination would be unlikely as metal–ligand repulsion between filled d orbitals on the metal and the π electrons of CO_2 would be significant in such a geometry. Calculations show that, for singly charged ions of the early transition metals (Sc^+, Ti^+, and V^+), insertion into the C—O bond leading to OM^+CO formation is exothermic owing to the strength of the M^+—O bond formed (22). Therefore, it is important to identify whether or not the $[Zn(CO_2)_N]^{2+}$ complexes formed here have isomers of the form $[(O)_MZn(CO_2)_{N-M}(CO)_M]^{2+}$ (where $M \geq 1$), which would naturally lead to the loss of CO fragments (rxn. [3]). Alternatively, this reaction could be driven by a combination of collisional activation and charge transfer, with the possibility that the process is aided by a significant fraction of charge being transferred prior to the collision, with the result that the O—C bond is weakened.

As stated earlier, we are not aware of any data in the literature on Zn^{2+}-CO_2; however, calculations have been undertaken on the isoelectronic ion Cu^+-CO_2 (22). It should be borne in mind that although isoelectronic, the size of the metal ion is determined largely by its charge (z) such that aspects of bonding influenced by charged density would not be fully accounted for. The relative energies of the products of rxns. [4] and [5] are –105.02 and +421.33 kJ mol^{-1} when compared with the ground-state asymptote $Cu^+ + CO_2$ (22).

[4] $\quad Cu^+ + CO_2 \rightarrow Cu^+OCO$

[5] $\quad \rightarrow OCu^+CO$

However, the binding energies (D_0) for the product species are 101.67 and 162.76 kJ mol^{-1}, respectively. This difference is due to the electrostatic interaction for OCu^+CO being larger than Cu^+CO_2 since CO_2 does not have a permanent dipole moment (22). Thus, although the binding energy for the product from rxn. [5] is larger, the barrier to its formation is sufficiently high that the most stable configuration is η^1-O end-on CO_2 coordination in the form of the product of rxn. [4]. Further support in the case of linear $[ZnCO_2]^{2+}$ comes from recognition that the strength of the ion–dipole interaction depends on z^2. The most likely cause of rxn. [3] is the charge transfer loss of CO_2^+ accompanied by the fragmentation of CO_2 to lose neutral carbon monoxide and some carbon dioxide molecules; a process which is aided, in part, by the comparatively high bond dissociation energy of Zn^+O (161 ± 5 kJ mol^{-1} (29)). This mechanism is supported by the fact that the loss of carbon monoxide is always associated with charge transfer. In contrast, if $[(O)_MZn(CO_2)_{N-M}(CO)_M]^{2+}$ isomers were present, then neutral loss of CO or CO_2 + CO might be expected.

© 2005 NRC Canada

Figure 4 shows MIKE scans recorded following the collisional activation of $[^{64}Zn(Me_2CO)_N]^{2+}$ complexes where $N = 3$–5. The asterisks on several of the peaks in the scan for $[^{64}Zn(Me_2CO)_3]^{2+}$ denote coincidental nonmetal-containing ions, which were verified by repeating the scans, firstly, without collision gas and secondly at a low oven temperature. Compared with the results presented earlier and with neutral loss signals, the intensities of collision-induced charge transfer fragments from zinc(II)–acetone complexes were found to be relatively low. However, it was still possible to identify the following fragmentation pathways:

[6] $$[Zn(Me_2CO)_N]^{2+} \rightarrow [Zn(Me_2CO)_{N-K}]^{2+} + KMe_2CO$$

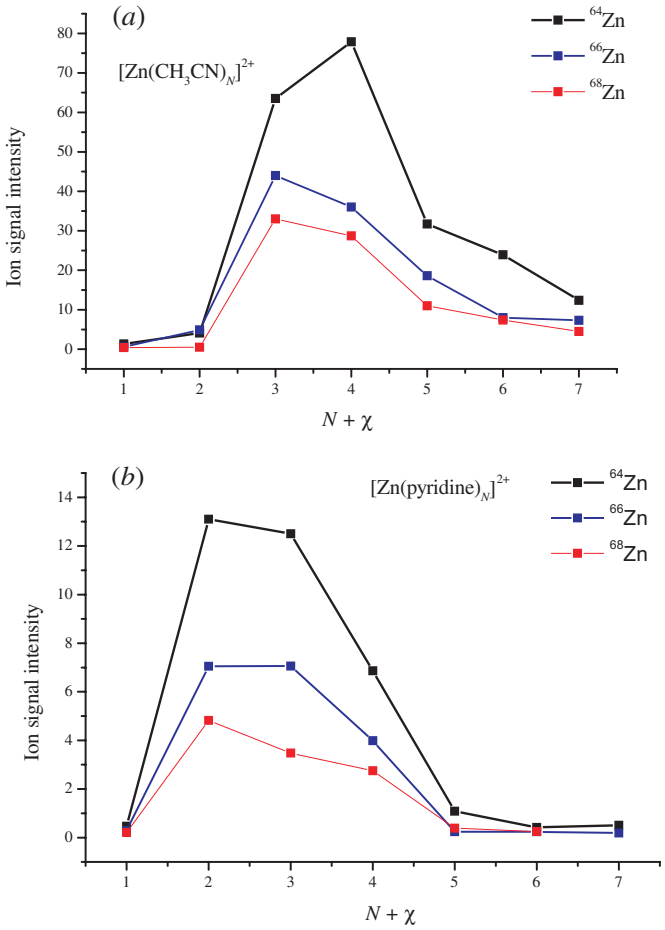
[7] $$\rightarrow Zn^+ (Me_2CO)_{N-K-1} + Me_2CO^+ + KMe_2CO$$

[8] $$\rightarrow Zn^+CH_3(Me_2CO)_{N-K-2} + Me_2CO^+ + OCH_3 + KMe_2CO$$

Although the breadth of the charge transfer peak that accompanies rxn. [8] does not allow an unambiguous assignment, loss of a methyl group is the most facile fragmentation route found in gas-phase acetone ions. An alternative route might be the formation of ZnO^+ in association with one or more acetone molecules. This route is clearly seen in the case of Zn–CO_2, but in those circumstances, there is no less exothermic alternative. In addition, the Zn^+—CH_3 bond strength has been calculated to be 240 kJ mol^{-1}, which is considerably higher than that found for Zn^+—O (30).

It should be noted from Fig. 4 that neutral loss of two acetone molecules from $[^{64}Zn(Me_2CO)_3]^{2+}$ leaves $[^{64}Zn(Me_2CO)_1]^{2+}$, which clearly contradicts the findings of the parent ion intensity distribution shown in Fig. 1. However, it is also obvious from Fig. 3 that the intensity of the fragment ion is extremely low, which would make its presence in a normal mass spectrum hard to detect. With respect to the charge transfer processes shown in Fig. 3, there are a number of conclusions to be made. First, electron transfer (rxn. [7]) is the preferred charge transfer process. The reactive charge transfer process (rxn. [8]) is probably assisted by the strength of the Zn^{2+}—O interaction, which results in ligand-to-metal electron donation, thus causing the C—CH_3 bond to weaken. It is noticeable that for $N = 5$ (and presumably for all $N > 5$), rxn. [8] is not present, which is again an indication of the low probability of this process.

Theoretical and experimental evidence presented by other groups (26, 27) points to the interaction of zinc(II) ion with acetone being more than just electrostatic in nature. Emphasis has been placed on the bent geometry (Zn-Ô-C) being an indication that factors other than electrostatic interactions play a role in bonding. Ion–dipole, ion-induced-dipole interaction (electrostatic model) would presumably prefer a linear geometry to maximize the interaction of the charge on the zinc(II) ion and dipole on acetone. A bent geometry can be rationalized in terms of an increased alignment between an empty sd hybridized orbital on zinc with the lone pair on oxygen such that charge transfer is made easier; however, full alignment is not possible because of repulsion between Zn^{2+} and the hydrogen atoms on the methyl groups. Kebarle and co-workers (27) calculated the atomic charge on Zn^{2+} as 1.65 for the addition of one Me_2CO. It is an indication of the complex nature of the zinc–acetone interaction that on addition of a second ligand, these authors also found that no further charge was transferred to the zinc ion and that the geometry became slightly more linear, seemingly to increase the electrostatic contribution to the bonding. It is also clear that an effective reduction in charge will lead to a drop in magnitude of the electrostatic interaction with increasing N. This means that, along with ligand–ligand repulsion, the bonding of further ligands is weaker than would be expected from a purely electrostatic model, and thus the parent ion intensity distribution decays rapidly with increasing N.



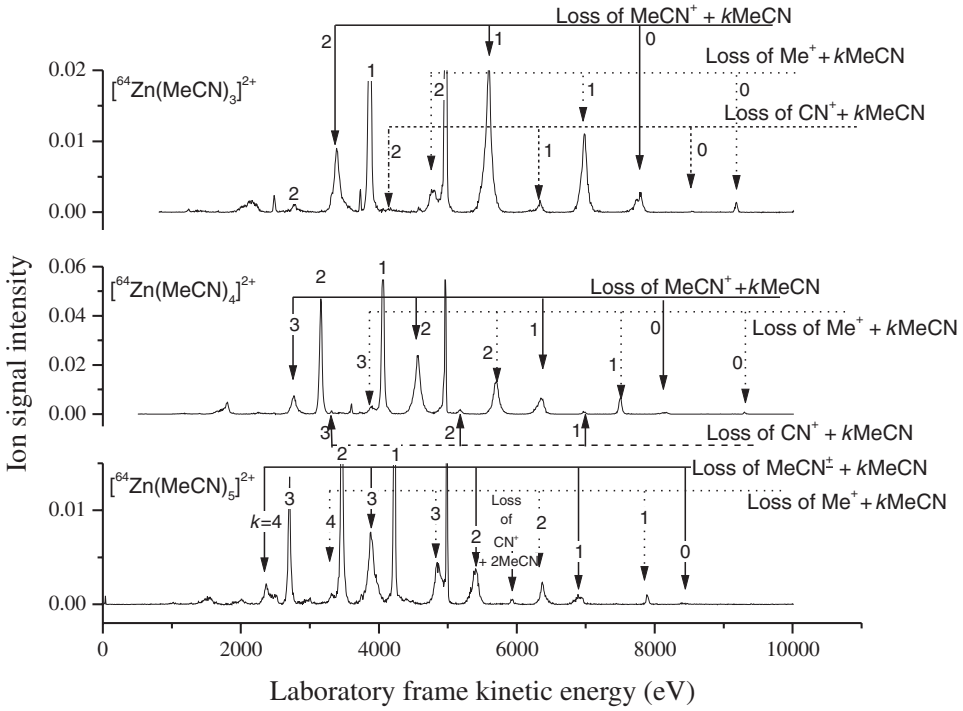


Fig. 5. (*a*) Relative intensities of $[Zn(CH_3CN)_N]^{2+}$ complexes plotted as a function of size (N). (*b*) Relative intensities of $[Zn(pyridine)_N]^{2+}$ complexes plotted as a function of size (N).

Zn(II)–acetonitrile and Zn(II)–pyridine complexes

Figure 5 shows parent ion intensity distributions recorded for $[Zn(MeCN)_N]^{2+}$, with $1 \le N \le 7$, and $[Zn(Py)_N]^{2+}$ for the three most intense isotopes of zinc. As seen before, a discrepancy exists between the three major isotopes of zinc as to the maximum in the parent ion intensity distribution recorded for zinc(II)–acetonitrile complexes. For ^{64}Zn, the most intense isotope, it is $N = 4$, whilst for ^{66}Zn and ^{68}Zn it is $N = 3$. It is suggested from these distributions that the primary solvation shell has the form $[Zn(MeCN)_4]^{2+}$, which compares favourably with the results from other studies on

Fig. 6. Fragmentation patterns recorded following the collisional activation of $[Zn(MeCN)_N]^{2+}$ complexes for N = 3, 4, and 5.

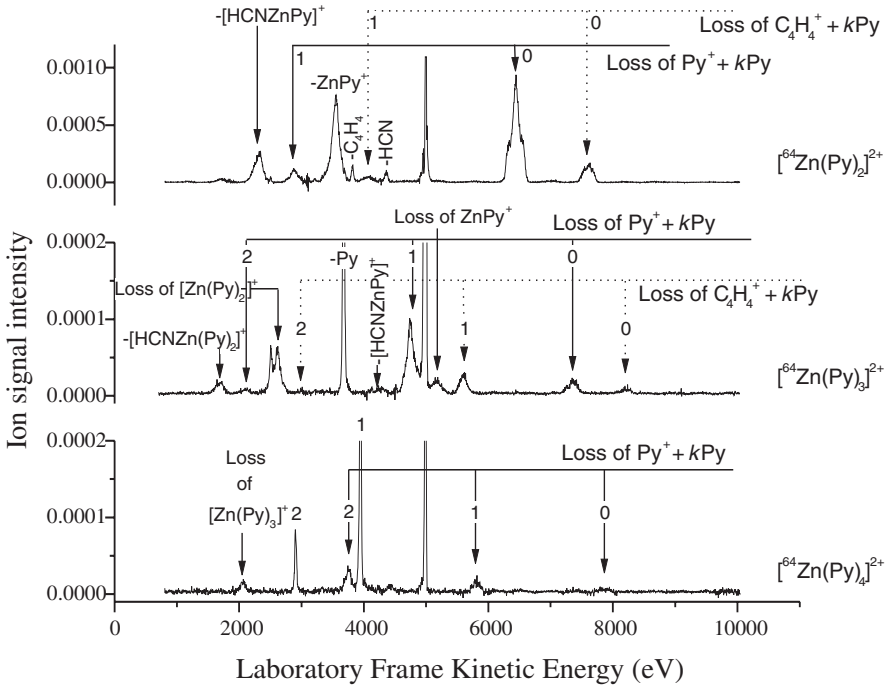
metal dication $[M(MeCN)_N]^{2+}$ systems (12, 13, 18). For the zinc(II)–pyridine complexes, the maximum intensity peak is at N = 2 for all isotopes; however, the relative intensity does not decline significantly for N = 3, which suggests that these two particular parent ions may be stable relative to others within the distribution. It should also be noted that $[Zn(Py)_1]^{2+}$ is a kinetically stable entity, which we have not found for other transition metals (31, 32). Shvartsburg et al. (33) have studied the fragmentation patterns of a number of gas-phase complexes between acetonitrile and divalent metal ions, including zinc(II). This group used electrospray ionization to produce the ions, and for zinc(II)–acetonitrile complexes also found a single acetonitrile molecule was sufficient to stabilize zinc(II) with respect to charge transfer.

To elucidate the fragmentation channels available to the $[Zn(MeCN)_N]^{2+}$ system, collision-induced dissociation studies were undertaken and the results are shown in Fig. 6. Overall, the following fragmentation channels were found:

[9] $[Zn(MeCN)_N]^{2+} \rightarrow [Zn(MeCN)_{N-K}]^{2+} + K\text{MeCN}$

[10] $\rightarrow Zn^+(MeCN)_{N-K-1} + MeCN^+ + K\text{MeCN}$

[11] $\rightarrow Zn^+CN(MeCN)_{N-K-1} + Me^+ + K\text{MeCN}$



[12] $\rightarrow Zn^+CH_3(MeCN)_{N-K-1} + CN^+ + K\text{MeCN}$

For the two smallest complexes (N = 1 and 2, not shown in Fig. 6), charge transfer processes dominate the observed fragmentation patterns; however, as Fig. 6 shows, such processes also make a significant contribution to the range of fragmentation pathways recorded at larger values of N. Equations [9]–[12] summarize the diversity of processes identified from the results. For N = 2 and 3, the final product of neutral loss via rxn. [9] is $[Zn(MeCN)_1]^{2+}$; for all other values of N neutral loss leads to $[Zn(MeCN)_2]^{2+}$. Of the three charge transfer pathways identified above, the most intense product arises from straight electron transfer (see the following). For N = 2–5, this pathway leads predominantly to the appearance of $Zn^+(MeCN)_1$; for N = 7 the most intense product increases in size to $Zn^+(MeCN)_2$. For N = 2–5, rxn. [11] yields $[ZnCN(MeCN)_1]^+$ as the dominant charge transfer product. When compared with rxns. [10] and [11], rxn. [12] is a minor charge transfer pathway; however, it is also a process that has not previously been identified in earlier studies of $[M(MeCN)_2]^{2+}$ complexes (33, 34). An unusual feature of the latter process is that its presence appears to be restricted to selected values of N. For N = 1 and 2, the dominant charge transfer pathways are rxns. [10] and [11]; as N increases to between 3 and 5, all three charge transfer processes appear and finally, by the time N = 7, rxns. [10] and [11] are again the only charge transfer pathways observed. The dominant product from rxn. [12] is always Zn^+CH_3 and, as noted above, the high Zn^+—C bond strength, probably drives the appearance of this ion. The size constraint on the appearance of this ion would suggest that the reaction pathway is strongly influenced by the geometric arrangement of participating ligands; either in the form of access to the metal cation on the part of CH_3 (bearing in mind that the methyl group is unlikely to be the primary site for coordination to the metal ion), or through the configuration required for an intracluster reaction.

The mass resolution that can be achieved for charge transfer reactions, such as those shown in Fig. 6, is limited; therefore, it is not possible to distinguish between CN and HCN as possible products in rxn. [11]. However, previous studies by Kohler and Leary (34) and Shvartsburg et al. (33) on

acetonitrile clustered with a wide range of doubly and triply charged metal cations, show evidence of rxn. [11]. Cleavage of the C—C bond being attributed to the electron-withdrawing properties and high second ionization enthalpy of zinc, such that the acetonitrile ligand is polarized through the metal–nitrogen interaction weakening the C—C bond (34). Both Kohler and Leary (34) and Shvartsburg et al. (33) have also identified a proton transfer reaction that accompanies rxn. [10], but we are unable to detect (resolve) this feature. More recently, Shvartsburg (35) has studied a similar range of reactions in metal trications complexed with acetonitrile.

In their study of the $[Zn(MeCN)_N]^{2+}$ system, Shvartsburg et al. (33) reported that only complexes up to N = 4 underwent charge transfer and above this dissociation occurred solely via acetonitrile evaporation. It was reasoned that unlike $[Zn(H_2O)_N]^{2+}$, the threshold size for charge transfer had to be lower owing to the smaller range over which intermolecular forces can occur because of a lack of hydrogen bonding (33). Although there is clear evidence for charge transfer in kinetic energy scans recorded from complexes containing up to seven acetonitrile molecules, the largest product ion observed is $Zn^+(MeCN)_4$. This suggests one of two possibilities: either the doubly charged precursor loses neutral molecules until it reaches a critical size needed to promote charge transfer, or charge transfer occurs in complexes larger than N = 4, and the process of Coulomb explosion then promotes the lose of additional, neutral molecules. The latter process has certainly been observed in large multiply charged molecular clusters (36).

There have been several recent electrospray studies of gas-phase metal(II)–pyridine complexes (31, 32). The pick-up technique has previously been used to prepare a number of different metal(II)–pyridine systems including Mg (13), Mn (37), Ag (12), Au, and Cu (18). Shvartsburg (32) has used electrospray to study pyridine complexed with doubly charged cations of the metals Ca, Mg, Mn, Fe, Co, and Cu. A number of charge transfer processes were observed including electron, proton transfer and two π-ring cleavage processes, although these latter two processes were not observed for the $[Cu(Py)_N]^{2+}$ system (32).

To elucidate the fragmentation channels available to $[Zn(Py)_N]^{2+}$ complexes, collision-induced dissociation studies were undertaken for several values of N and the results are summarized in Fig. 7. In general, the following fragmentation channels were found:

[13] $$[Zn(Py)_N]^{2+} \rightarrow [Zn(Py)_{N-K}]^{2+} + K\text{Py}$$

[14] $$\rightarrow Zn^+(Py)_{N-K-1} + Py^+ + K\text{Py}$$

[15] $$\rightarrow Zn^+CN(H)(Py)_{N-K-1} + C_4H_{4,5}{}^+ + K\text{Py}$$

Once again, Fig. 7 shows that the fragmentation channels available vary significantly with the size of the complex. No neutral loss is found for N = 1; however, for all other ions studied (N = 3–6), fragmentation is dominated by the loss of neutral pyridine and terminates with the appearance of $[Zn(Py)_2]^{2+}$, which could be taken as evidence that the latter is a particularly stable complex. This observation would also appear to support the data shown in Fig. 7. All of the ions studied underwent electron transfer. For N = 1, this led naturally to reduction of zinc(II) to the bare zinc(I) ion, whilst for N = 2–5, the most prominent charge transfer pathway led to the appearance of $Zn^+(Py)_1$. Shvartsburg (32) concluded that for N = 3, proton transfer is prevalent over electron transfer; however, owing to the width of the charge transfer peaks in the MIKE scan for $[Zn(Py)_3]^{2+}$, it is not possible to reach a similar conclusion.

© 2005 NRC Canada

It would appear from the data that rxn. [15], the heterolytic cleavage reaction leading to $C_4H_{4,5}^+$ is present only for $N = 2$ and 3, where the complementary peaks $Zn^+CN(H)Py_M$ can also seen in each of the MIKE scans shown in Fig. 7. Once again, the widths of the peaks prevent the resolution of Zn^+CNPy from $Zn^+CN(H)Py$.

It is known from studies in aqueous solution that the CN^- ion forms strong complexes with Zn^{2+} (38) in which binding occurs via the carbon atom. However, the lone pair on nitrogen leads to bridging in crystalline complexes such as $Zn(CN)_2$ (38). Density functional theory calculations on complexes of singly charged metal cations with pyridine, including Cu^+–pyridine (isoelectronic with the Zn^{2+}–pyridine system) favour in-plane bonding to the nitrogen of pyridine over a π-electron interaction within the carbon ring (39). The evidence from gas-phase experiments suggests that the cyanide ion is also bonded via the nitrogen atom; however, collisional excitation coupled with charge transfer imparts a considerable amount of energy to a complex. Therefore, it is quite feasible that rearrangement does occur and that, as suggested by Shvartsburg (32) and Kohler and Leary (31), the cyanide negative ion is actually bound via carbon to zinc(II).

Zn(II) with carbon disulfide, thiophene, and 2-methyl thiophene

A survey of the Cambridge Structural Database showed that 50% of all zinc-containing crystal structures had four-coordination and of these approximately 20% had sulfur-donating ligands (40). Although it was possible to prepare singly charged zinc–sulphur complexes with carbon disulfide, thiophene, and 2-methyl thiophene in the gas phase, it was not possible to isolate any equivalent doubly charged species. Further experiments are underway to investigate this behaviour.

Zn(II)–argon complexes

Figure 8 shows an intensity distribution recorded for $[ZnAr_N]^{2+}$ complexes plotted as a function of N. As noted earlier, it is not always possible to derive agreement between all of the different isotopic combinations, however, the general trend would suggest that $[ZnAr_5]^{2+}$ is a stable combination. Figure 9 shows the consequences of size-selected $[ZnAr_N]^{2+}$ being subjected to collisional activation. In comparison to some of the earlier examples, the difference in ionization energy between Zn^+ and argon is comparatively small (~2.2 eV), which means that first, the dimer ion $[ZnAr]^{2+}$ is stable and secondly, the kinetic energy release values determined from the MIKE scans are all low. The dominant charge transfer process for the examples shown is

$$[16] \quad [ZnAr_N]^{2+} \rightarrow Zn^+Ar + (N-2)Ar + Ar^+$$

which is probably influenced by the underlying stability of Zn^+Ar. An estimated kinetic energy release for the dominant charge transfer process seen following the CID of $[ZnAr_3]^{2+}$ is ~0.14 eV. An exception to rxn. [16] is $[ZnAr_5]^{2+}$, which gives rise to an unusual feature seen at ~2424 eV. This result is reproducible and possibly arises from a combination of charge transfer leading to $Zn^+ + Ar^+ + 4Ar$ to give the two outer peaks via Coulomb explosion, plus a central low energy feature owing to electron capture from the collision gas to give $Zn^+ + 5Ar$. Since it is not possible to assign the sequence in which atoms and (or) ions leave the complex following collisional activation, an accurate kinetic energy release cannot be calculated from the usual two-body equation.

Fig. 10. (*a*) Relative intensities of $[Zn(C_6H_6)_N]^{2+}$ complexes plotted as a function of size (*N*). (*b*) Fragmentation pattern recorded following the collisional activation of the $[Zn(C_6H_6)_2]^{2+}$ complex.

number of earlier examples (12, 18), the most intense ion is $[Zn(C_6H_6)_2]^{2+}$, which has been attributed to the formation of a stable sandwich structure. Figure 10*b* shows the result of a CID experiment on $[Zn(C_6H_6)_2]^{2+}$, which is interesting for a number of reasons. Firstly, there is no evidence for the loss of neutral benzene; this confirms the result give in Fig. 10*a*, which is that the dimer dication is unstable. Secondly, there are peaks corresponding to the formation of $[ZnC_6H_6]^+$ and $C_6H_6^+$ via one or more charge reduction processes. The peak at ~6400 eV, which is due to the appearance of $[ZnC_6H_6]^+$, has a composite structure similar to that analysed recently in a detailed study of charge reduction mechanisms.[4] There are two mechanisms that can lead to the formation of this ion: electron transfer from the ligand to the metal and electron capture from the collision gas (air). The large potential energy difference associated with the first mechanism leads to a substantial release of kinetic energy and, as a consequence, the peaks are dish-shaped. In this particular example, that energy difference is represented by the first IE of Zn(I) minus the IE of benzene and is ~8.5 eV. In the second mechanism, the energy available for partitioning to kinetic energy is far less as it is given by the difference between the first IE of Zn(I) and the IE of the collision gas ($\sim N_2$), which is ~2 eV. As a consequence, the peak profiles are much narrower and Gaussian-like.

The peak at ~3500 eV could be taken as being due to $C_6H_6^+$ in the form of the complementary charge transfer product to $Zn^+C_6H_6$; however, this may not be the case for two reasons. First, it is unusual in charge transfer studies of multiply charged metal complexes to have a nonmetallic ion with intensity comparable to that of the metallic ion. Secondly, given the large amount of (potential) kinetic energy available, a dish-shaped peak might have been expected. An alternative pathway leading to a benzene cation with a small

[4] B. Wu, B.J. Duncombe, and A.J. Stace. Unpublished results.

© 2005 NRC Canada

release of kinetic energy arises from electron capture and the fact that the IE of benzene (9.24 eV) is lower than that of zinc at 9.37 eV. As noted before, such a mechanism would leave the single charged $[Zn(C_6H_6)_2]^+$ ion with ~2.5 eV and the most stable state, based on ionization energy data, would have the charge residing on a benzene molecular ion. Any excess energy would then promote the loss of both neutral zinc and the extra benzene molecule to leave $C_6H_6^+$ with a kinetic energy of ~1 eV (FWHM).

Conclusion

The chemistry and coordination of a number of zinc(II) – aprotic solvent complexes have been studied using ligands that coordinate primarily through either an oxygen or nitrogen atom. Within this group, charge transfer, promoted by collisional activation, led to extensive chemical reactivity. In a number of cases, chemical bonds with high dissociation energies, for example those of CO_2, were observed to break. Contributing factors to the ease of reactivity were seen as: (*i*) the degree of electron transfer taking place between the metal dication and the molecules concerned, which might lead to a weakening of bonds; (*ii*) the stability of the product metal-containing ion, and the formation of Zn^+CH_3 from $[Zn(CH_3CN)_N]^{2+}$ was seen as a good example of the latter. This particular fragment had not been observed in any of the earlier studies of metal cations with acetonitrile. Even though extensive evidence of complexes between zinc(I) and sulfur-donor ligands was found, attempts to identify similar complexes containing Zn(II) failed completely. Such behaviour contrasts with that seen in the condensed phase where there is an extensive range of stable Zn(II)–sulfur complexes. This is clearly not a failure of the pick-up technique, since it succeeds in generating the singly charged ions. It would appear that, using the ligands selected, Zn(II)–sulfur complexes are not stable in isolation.

The gas-phase acidities of the elemental hydrides are functions of electronegativity and bond length[1]

John E. Bartmess and Robert J. Hinde

Abstract: The gas-phase Brønsted acidities of the group 1, group 2, and main group elemental hydrides (XH_n) are shown to be a combined function of the bond length, electronegativity, and position in the periodic table, via a separation of the acidity into coulombic and electronic reorganization enthalpy parts. The Coulombic acidity is defined as the enthalpy to separate unit positive and negative charges from the neutral acid's X—H bond length to infinity; the reorganization enthalpy is the difference between that and the measured acidity, and represents the enthalpy required to reorganize the electrons of the neutral acid, creating an ion pair at the original bond distance. Predictions are made for the gas-phase Brønsted acidities of several elemental hydrides for which this quantity is not known.

Key words: acidity, gas phase, coulomb, elements, hydride.

Résumé : On démontre que les acidités de Brønsted des hydrures de formule générale XH_n des éléments du groupe 1, du groupe 2 et du groupe principal sont une fonction qui combine la longueur de liaison, l'électronégativité et la position dans le tableau périodique par le biais d'une séparation de l'acidité en deux parties impliquant des enthalpies de réorganisation coulombique et électronique. L'acidité coulombique est définie comme l'enthalpie qui sépare une unité de charges positive et négative de la liaison X—H d'un acide neutre de la longueur de liaison jusqu'à l'infini; l'enthalpie de réorganisation est la différence entre ceci et l'acidité mesurée et elle représente l'enthalpie nécessaire pour réorganiser les électrons de l'acide neutre en créant une paire d'ions à la distance originale de la liaison. On fait des prédictions relatives aux acidités de Brønsted de plusieurs hydrures d'éléments pour lesquels cette valeur n'est pas connue.

Mots clés : acidité, phase gazeuse, coulomb, éléments, hydrure.

[Traduit par la Rédaction]

Gas-phase acidities of neutral species have traditionally been analyzed in terms of (and the values often obtained from) the thermochemical cycle of Scheme 1, involving the homolytic bond dissociation enthalpy of the generic acid AH, the electron affinity of $A^{\cdot}$, and the ionization energy of the hydrogen atom (1). This cycle has been used to explain observed variations in the acidities of the main group elemental hydrides, wherein the electron affinity is the principal factor in determining the acidities across a row of the periodic table, and the bond dissociation energy the major factor determining the acidities down a column (2).

[1] $$\Delta_{acid}H(AH) = BDE(A\text{-}H) + IE(H^{\cdot}) - EA(A^{\cdot})$$

Although Scheme 1 is mathematically rigorous, chemical intuition suggests that there should be some relationship between acidities and electronegativity, and thus perhaps a different method of deriving such acidities. We present here an empirical alternative, using only the relatively low-level quantities of bond lengths, electronegativities, and position in the periodic table. The Coulombic acidity, $\Delta_{CA}H(AH)$, is here defined as the absolute value of the enthalpy change for separating the acidic proton of an acid AH from its anionic conjugate base A^-, from the distance corresponding to the A—H bond length in the neutral acid to infinity, without any electronic reorganization. This then would be a measure of the gas-phase acidity if only Coulombic forces were involved (3). Coulomb's law along with the necessary physical constants (4) yields:

[2] $$\Delta_{CA}H(AH) = 332.1/d(A\text{—}H) + RT$$

where the Coulombic acidity, $\Delta_{CA}H(AH)$, is in units of kcal/mol (1 cal = 4.184 J) and the bond length d(A—H) is in angstroms. The constant 332.1 kcal-Å/mol represents the Coulombic acidity at $T = 0$ K for a standard 1.0 Å bond. This falls in the middle of the scale of known gas-phase ΔH_{acid} values, which range from 294 kcal/mol for $(n\text{-}C_4F_9SO_2)_2NH$ to 420 kcal/mol for ethane (5).

If $\Delta_{CA}H(AH)$ is subtracted from the measured or calculated enthalpy of acidity, $\Delta_{acid}H(AH)$, defined by Scheme 1 (5), the resulting electronic reorganization enthalpy ($\Delta_{ER}H$, eq. [3]) represents the energetics of creating the A^-H^+ pair of ions, without having to pay the enthalpy

Scheme 1.

$$\begin{array}{ccc} & \Delta_{acid}H(AH) & \\ AH & \rightarrow & A^- + H^+ \\ \downarrow \text{BDE(A-H)} & & \uparrow \text{-EA}(A^\cdot) \\ A^\cdot + H^\cdot & \rightarrow & A^\cdot + H^+ + e^- \\ & \text{IE}(H^\cdot) & \end{array}$$

$$\Delta_{acid}H(AH) = \text{BDE(A-H)} + \text{IE}(H^\cdot) - \text{EA}(A^\cdot)$$

[3] $$\Delta_{ER}H(\text{A-H}) = \Delta_{acid}H(AH) - \Delta_{CA}H(AH)$$

price for separating them so that they do not influence each other's structure via their electric field. It also can be taken as the energy to relax both the atomic and electronic structures (save for the departed proton) from those in the acid to those in the anion.

Experimental data and calculations

Values of experimental bond lengths for the elemental hydrides were compiled from standard sources (6–10). Equilibrium bond lengths (r_e) were the selected ones; when only r_0 values were available, notably for the group 14 hydrides, the r_e values were estimated to be 0.01 Å shorter than the r_0 value. This is consistent with experimental data for H_2, NH_3, H_2O, HCl, PH_3, and H_2Se (6, 10), and with computational approaches (10, 11). For the third through fifth rows, many experimental values were either absent or of considerable uncertainty. The only available experimental bond length for CaH_2, for example, is from a crystal structure, and that is the average of two disparate values in the crystal. For use in the estimation of these missing values, bond lengths obtained from a variety of computational methods are also presented in Table 1. The Gaussian 98 (12) program was utilized, with some of the basis sets taken from the online compilation (13).

It has been noted that correlated computational methods tend to consistently give bond lengths that are longer than those found experimentally, especially for X—H bonds (14–17). As seen in Table 1, for the elemental hydrides under consideration here, the MP2(full)/6-31G(d) geometries used in the Gn methods (18) deviate from experimental values almost exclusively in the direction of being too long. Highly electronegative or electropositive elements seem to deviate the most from agreement, with the alkali metal hydrides being the worst. For the compounds shown, the rms deviation is 0.024 Å. The worst case, KH at 0.075 Å too long, yields a $\Delta_{CA}H$ 5 kcal/mol numerically smaller than that from the experimental bond length. If this trend holds true for the various computational geometries used from the literature, the theoretical ΔH_{ER} values will be slightly too large.

In Table 1, the values overall closest to the experimental ones are from the B3LYP/6-311G(3df,3pd) calculations. These are used to estimate missing experimental values for the first three rows. The 3-21G** basis set, although likely too small for accuracy in itself, is included because it extends to elements in the fourth row, and thus can be used as guidance for estimations there. Computational values for bond lengths of fifth row elements are from a variety of methods in the literature, and from a basis set with the heavy atom modeled with (or using) the CRENBL ECP basis set and pseudopotential (13) and the hydrogen as 3-21G**. This latter choice is also carried through for the fourth row elements, where it is found to deviate by less than 0.05 Å from experimental bond lengths for the main group elements. Gas-phase enthalpies of acidity were obtained via Scheme 1, save that a few were from equilibrium data anchored to values from Scheme 1 (5). Again, there are a number of elemental hydrides for which experimental $\Delta_{acid}H$ values are not available. For MgH_2 and AlH_3, we have computed $\Delta_{acid}H(AH)$ at T = 298 K from a series of ab initio CCSD(T)/aug-cc-pVxZ calculations (x = D, T, Q), which are then extrapolated to the complete basis set limit (19). For HF, HCl, H_2O, and H_2S, this method of computation reproduces the experimentally obtained acidities to within 0.5 kcal/mol, comparable to the experimental error (19).

From the data for these quantities given in Tables 1 and 2, values of $\Delta_{CA}H$ and $\Delta_{ER}H$ are derived as per eqs. [2] and [3]. To examine the generality of the concepts developed here, we have also examined the corresponding experimental and computational data for the elemental monohydrides, as given in Table 3.

Results

The values obtained for $\Delta_{ER}H$ in Table 2 range from 9 kcal/mol for FH to 211 kcal/mol for CsH, with an anomalous value of –48 kcal/mol for H_2 (which is discussed separately in the following). Are these values of a reasonable magnitude? Gas-phase basicities likewise involve loss of a proton with no Coulombic cost of charge separation (rxn. [4]), only the energetics of bond breaking. That experimental basicity scale ranges from 42.5 kcal/mol for He (giving HeH^+) to 248 kcal/mol for NaOH (5). The magnitudes of the values obtained for the reorganization enthalpies are thus reasonable in this light.

[4] $$BH^+ \rightarrow B + H^+$$

Examination of the $\Delta_{ER}H$ values in Table 2 reveals a distinct periodic trend: $\Delta_{ER}H$ decreases across a row of the periodic table, and increases down a column. The smallest positive $\Delta_{ER}H$ is for HF. This is reasonable in that HF is the elemental hydride with the largest difference in electronegativity between the hydrogen and the heavy atom. The electrons in HF are thus already well on the way to being reorganized toward the products of F^- and H^+, and relatively little further reorganization is necessary. The other extreme, of very large $\Delta_{ER}H$ values for the alkali hydrides, reflect the opposite polarization of charge. Considerable energy is required to move electrons to an electropositive element.

The negative $\Delta_{ER}H$ for H_2 appears anomalous. The Coulombic acidity of H_2 is the weakest in Table 2, weaker even than the experimental acidity, owing to the very short bond length engendered by the 1s—1s bonding in H_2. The negative $\Delta_{ER}H$ in this case would seem to imply that H_2 should exist as H^-H^+ rather than H—H at the equilibrium bond length, a situation clearly at odds with observations. However, it has been noted (20) that the H—H bond requires

about a 5% ionic contribution to the "pure" covalent bond predicted by electronegativity to explain the bond length and enthalpy; this may be the reason for this unusual result. In addition, a plot of the homolytic bond dissociation energies of the elemental hydrides (5) against the reciprocal of the X—H bond length yields a moderately linear (r = 0.96, sd = 8.4 kcal/mol) correlation, with H_2 as an outlier. Its bond dissociation energy is 62 kcal/mol stronger than expected from its bond length. One additional possibility is that the electronegativity value is not applicable in this case, although it would require an X of <1.94 or a bond length of >0.84 Å to make $\Delta_{ER}H$ (H_2) positive. We emphasize that this "anomalous" $\Delta_{ER}H$ is really a problem with the $\Delta_{CA}H$ being too weak, not the $\Delta_{ER}H$ being too strong.

If the $\Delta_{ER}H$ values are plotted as a function of the Mulliken–Jaffé electronegativity (21–23), the main group hydrides and the alkali metal hydrides yield excellent (r = 0.979 and 0.999, respectively) correlations, as shown in Fig. 1. This electronegativity scale is based on the equation of Mulliken (21), involving ionization energies and electron affinities, but with more recent values of those quantities used to obtain the numeric electronegativity, and separate values for different hybridization states (23). For the main group compounds with eight valence electrons:

$$[5] \qquad \Delta_{ER}H(\mathrm{AH}) = -67.2 \times X_A + 295.6 \text{ kcal/mol}$$

$$r = -0.9778$$

where X_A is the Mulliken–Jaffé electronegativity of atom A (23). The largest deviation from eq. [5] is that of methane at 19 kcal/mol, and the average deviation is 8.2 kcal/mol. Other electronegativity scales, such as the Allred–Rochow (24), Sanderson (25), and Pauling (20) scales, yield similar,

though not quite as good, correlations, with r values of 0.95 or higher.

Closer examination of the main group compounds (shown in Fig. 2) reveals that the correlation between $\Delta_{ER}H$ and electronegativity X_A is even stronger when each row of the periodic table is considered individually

[6] CH_4 through HF: $\Delta_{ER}H = (-54.8 \pm 1.5) \times X + (244 \pm 5)$ $r = -0.9992$, sd = 1.5

[7] SiH_4 through HCl: $\Delta_{ER}H = (-68.1 \pm 6.3) \times X + (298 \pm 17)$ $r = -0.9913$, sd = 4.2

[8] SiH_4 without SiH_4: $\Delta_{ER}H = (-59.5 \pm 0.8) \times X + (271 \pm 2)$ $r = -0.9999$, sd = 0.3

[9] GeH_4 through HBr: $\Delta_{ER}H = (-63.3 \pm 4.4) \times X + (290 \pm 11)$ $r = -0.993$, sd = 0.6

[10] SnH_4, TeH_2, HI: $\Delta_{ER}H = (-64.0 \pm 2.2) \times X + (296 \pm 6)$ $r = -0.9994$, sd = 0.7

where $\Delta_{ER}H$ is in kcal/mol and the correlated data are confined to experimental values.

© 2005 NRC Canada

It is evident that SiH_4 deviates from eq. [8], being 11 kcal/mol more weakly acidic than predicted by this correlation. There is no obvious chemical reason for silane being special. The deviation must lie in the measured geometry, acidity, or electronegativity. The silyl anion and radical are both clearly pyramidal (26), so it is not a matter of using the wrong hybridization state in choosing the electronegativity (23). The experimental bond length agrees with computations. To put the measured $\Delta_{ER}H$ on the line of eq. [8] requires either $X = 2.1$, or a strengthening of the measured acidity by 11 kcal/mol. An error of the latter size seems unlikely, considering the internal consistency of the experimental gas-phase acidity scale (5), and its agreement with the value from Scheme 1 for silane. It is noteworthy, however, that the difference between the Mulliken–Jaffé electronegativity for tetrahedral Si ($X_{Si} = 2.28$) and the Pauling electronegativity for the same element and hybridization state ($X_{Si} = 1.90$) is the greatest for any main group element listed in the Bratsch tables (23). A smaller X_{Si} value would put the silane point closer to the least-squares line.

Both the slopes and intercepts of eqs. [6]–[10] show periodic trends: the acids in rows lower in the periodic table are more sensitive to electronegativity in determining their $\Delta_{ER}H$ value. The intercepts of these equations indicate weaker intrinsic $\Delta_{ER}H$ at zero electronegativity, as one goes lower in the table. Because electronegativity also follows periodic trends, this implies that perhaps a somewhat higher power function might be more applicable. However, we believe that the precision of both the experimental data and the electronegativities does not support further extension of this.

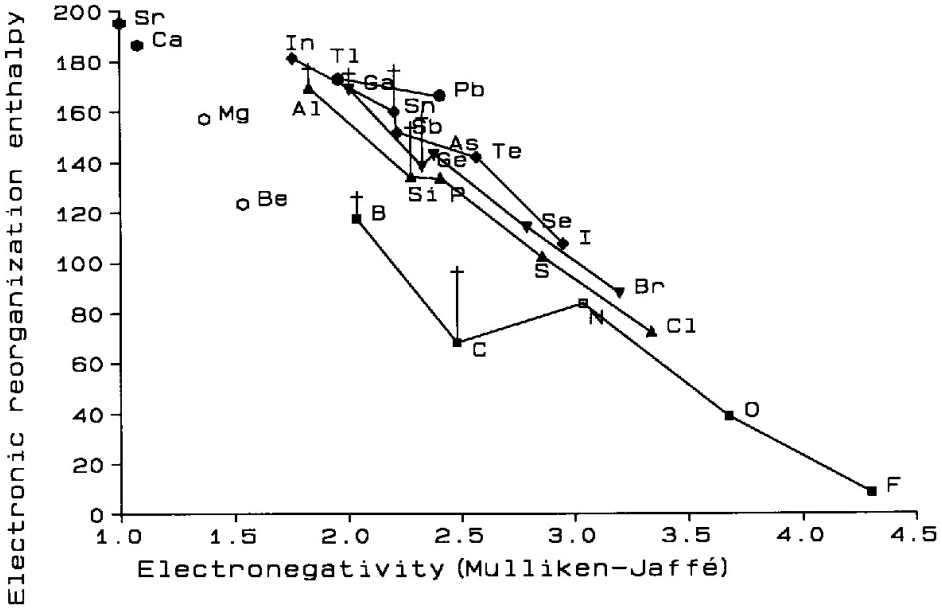
In contrast, the alkali metal hydrides (and hydrogen), with two valence electrons, fall on a separate line from the main group elements, and $\Delta_{ER}H$ is stronger than expected relative to the main group. Proton loss for these group 1 hydrides involves an s orbital, as opposed to the p shell of the main group species, so a different correlation is not surprising. The group 2 acids BeH_2, MgH_2, and CaH_2 fall between the group 1 and main group lines. It is therefore clear that orbital occupation is another variable that affects the gas-phase acidities of the elemental hydrides. The greater sensitivity of $\Delta_{ER}H$ of the group 1 and 2 acids to electronegativity than for the main group species, may reflect the proximity of the bonding s orbital to the nucleus, compared with the participation of the more distant p electrons for the main group elements.

There are several elemental hydrides for which the experimental gas-phase acidity is not known and for which reliable computational approaches fail because the necessary basis sets are unavailable, or because relativistic effects are important. Using eq. [3] in combination with eqs. [2] and [7], [9], or [10] yields predictions in Table 2 for these unknown gas-phase acidities including those of SrH_2, InH_3, SbH_3, and the row 5 species BaH_2, TlH_3, PbH_4, BiH_3, and PoH_2. Because of the uncertainty in even the order of bond length in the row 5 acids, as noted earlier, the derived acidities are expected to be uncertain by at least ±10 kcal/mol.

Likewise, a rearrangement of eqs. [2] and [5] allows prediction of an effective group electronegativity for hydrocarbon fragments from known bond lengths and gas-phase acidities. For -CH=CH_2 and -C≡CH, as seen in Table 2, derived electronegativities of 2.73 and 3.16, respectively, are obtained. The first value is somewhat larger than that of the sp^3 carbon at 2.48, but the value for -C≡CH places the electronegativity of an sp carbon between that of N and O, as expected (27). From the Pauling definition of electronegativity in eq. [11], we can utilize currently available

$$[11] \quad |X_A - X_B| = 0.208[D(A—B) - D(A—A) + D(B—B)/2]^{1/2}$$

thermochemistry (5) to obtain Pauling electronegativities for the groups -CH_2CH_3, -CH=CH_2, and -C≡CH of 2.56, 2.58, and 2.93, respectively, relative to $X_F = 4.0$ (28). Wells (29) reports group electronegativities for these of 2.3, 3.0, and 3.3, but the derivation of these values is not clear. Taft and co-workers (30) give polar σ values of 0.16, 0.17, and 0.28 for the groups based on calculated charge densities on the acidic hydrogen in the acids, implying again that ethenyl is only slightly more electronegative than ethyl, but ethynyl considerably more so. Boyd and Boyd (31) present group electronegativity values of 2.55, 2.58, and 2.66. The Mulliken–Jaffé electronegativities (23) for these hybridization states are 2.48, 2.66, and 2.99, relative to $X_F = 4.30$. Guillermin et al. (32) likewise comment on these points.



For the elemental monohydrides (in Table 3 and Fig. 3), it is evident that while there is a general correlation with electronegativity, there is considerably more scatter here than for the saturated hydrides. A complicating factor with these monohydride acidities is that the most thermochemically stable monohydride acid and atomic conjugate base can have different spin states, i.e., CH is a ground-state doublet while C^- is a quartet, with the anion doublet state 28 kcal/mol higher in energy. The group 13 and 14 monohydrides are all such cases. Such a multiplicity change during a proton transfer can result in an appreciable barrier and a concomitant lack of reactivity (34). Also, several of the atomic anions (N^-, Be^-, Mg^-) are not bound with respect to electron loss; values for these are obtained computationally at the G3(MP2) (18) level, and are shown as open symbols in Fig. 3. Finally, the electronegativities used here are hybridization state dependent (23), and it is not clear whether the hybridization of the acid or conjugate base should be used. We thus take Fig. 3 as indicating semiquantitative agreement at best with the general concept presented here. The monohydride $\Delta_{ER}H$ values are in general within a few kcal/mol of the saturated hydride ones, save that CH is notably 41 kcal/mol weaker than methane.

This correlation of acidity with bond length and electronegativity is an empirical one, unlike the rigorous thermochemical cycle in Scheme 1. Is there a physical rationale for this? We argue that for a limited series of structurally related compounds, such as the elemental hydrides here, it is not unreasonable that a longer bond should be proportionately weaker, in the homolytic sense. As noted earlier, excluding H_2, this holds to within a standard deviation of 7.1 kcal/mol for these species.

Likewise, the Mulliken definition of electronegativity involves an average of the electron affinity and ionization energy of the species involved. Thus, qualitatively both bond dissociation energies and electron affinities are related to the quantities used here. It appears that there are canceling ef-

Fig. 3. Reorganization enthalpy (kcal/mol) vs. Mulliken–Jaffé electronegativity, all elemental monohydrides. Open symbols denote computational values for unbound anions. Species of a row are connected. Vertical lines to a cross show the effect of promotion of the anion to the same multiplicity state as the acid.

fects in the differences between Scheme 1 and eqs. [2] and [6]–[10].

The gas-phase acidities of sp^3 carbon acids, all of which have the same nominal C—H bond length and electronegativity, are spread across a range of values 122 kcal/mol wide, from ethane to $(C_4F_7SO_2)_2CH_2$ (5). The correlations found here are thus not general ones, but valid only for the elemental hydrides, where the additional effects of resonance, polarity, and polarizability arising from the substituents on the central atom are not present or cancel out. Nevertheless, within this chemically related family of molecules, the gas-hase acidities can be shown to be simply and intuitively related to molecular geometry, atomic electronegativity, and position in the Periodic table.

The bond dissociation energies of SO_3—X^- (X = F, Cl, Br, and I)[1]

Changtong Hao, Thomas M. Gilbert, and Lee S. Sunderlin

Abstract: The gas-phase strengths of the SO_3—X^- bonds (X = Cl, Br, and I) have been determined to be 222 ± 13, 179 ± 11, and 161 ± 9 kJ/mol, respectively, by measuring thresholds for collision-induced dissociation in a flowing afterglow-tandem mass spectrometer. An upper limit of $D(SO_3—F^-) \leq 488 \pm 19$ kJ/mol was also determined. The periodic trends in the halide affinities of SO_3 closely parallel those for SO_2 and other Lewis acids. Bond strengths computed using the B3LYP, MP2, QCISD(T), and other models with several basis sets are generally lower than experiment.

Key words: bond dissociation energies, computational chemistry, Lewis acids, superacids, halide affinities.

Résumé : Utilisant un spectromètre de masse en tandem à écoulement postluminescence, on a mesuré les seuils de dissociation induite par une collision et on en déduit que les forces, en phase gazeuse, des liaisons SO_3—X^- (X = Cl, Br et I) sont respectivement de 222 ± 13, 179 ± 11 et 161 ± 9 kJ/mol. On a aussi déterminé que la limite supérieure de $D(SO_3—F^-)$ est ≤ 488 ± 19 kJ/mol. Les tendances périodiques dans les affinités des halogénures pour le SO_3 sont parallèles à celles pour le SO_2 et pour d'autres acides de Lewis. Les forces des liaisons calculées par les méthodes B3LYP, MP2, QCISD(T) et d'autres modèles en utilisant plusieurs ensembles de bases sont généralement inférieures aux valeurs expérimentales.

Mots clés : énergies de dissociation de liaison, calculs théoriques, acides de Lewis, superacides, affinités pour les halogénures.

[Traduit par la Rédaction]

Introduction

The thermodynamic properties of halosulfuric acids ($HXSO_3$, X = F, Cl, Br, and I) in solution have been studied in detail and are well-known (1–3). The halosulfuric acids can be thought of as strong acids (HX) modified to superacids by the attraction between the Lewis acid SO_3 and the halide X^- (4, 5). While they are important catalysts in solution (1, 5), information about these superacids and their conjugate bases (the halosulfonate anions) in the gas phase is limited. Larson and McMahon (6) estimated a fluoride affinity for SO_3 of 326 ± 42 kJ/mol. Viggiano et al. (7) estimated an electron affinity for SO_3F of 4.8 eV based on bracketing experiments; they later (8) revised this number to 5.2 eV and calculated a value of 5.53 eV using the G2 model. Structures of SO_3F^- (9) and SO_3Cl^- (10) were determined by X-ray crystallography; the solid-state anions show lower symmetries and shorter bond lengths than calculated gas-phase structures (8). Steudel and Otto (4) carried out ab initio calculations on chlorosulfonate and fluorosulfonate anions as part of a study of superacids.

In 1985, Caldwell and Kebarle (11) measured the gas-phase SO_2—X^- bond enthalpies for X = Cl, Br, and I, while Larson and McMahon measured $D(SO_2—F^-)$ and $D(SO_3—F^-)$ (6). This work is an example of how systematic measurement of gas-phase energetics, a field largely pioneered by Kebarle after his development of high-pressure mass spectrometry (12), can be used to understand chemical interactions. Measurements of the dissociation energies of SO_3—X^- (X = Cl, Br, I) would allow new comparisons to the previous gas-phase data and solution-phase results. In this paper, the energetics of halosulfonate anions SO_3X^- (X = F, Cl, Br, I) are examined experimentally and computationally.

Experimental

Bond dissociation energies (BDEs) were measured using the energy-resolved collision-induced dissociation (CID) technique (13–16) in a flowing afterglow-tandem mass spectrometer (MS) (17). The instrument consists of an ion source region, a flow tube, and the tandem MS. The DC discharge ion source used in these experiments is typically set at 2000 V with 2 mA of emission current. The flow tube is a 92 cm × 7.3 cm i.d. stainless steel pipe that operates at a buffer gas pressure of 0.35 Torr (1 Torr = 133.3224 Pa), a flow rate of 200 standard $cm^3\ s^{-1}$, and an ion residence time of 100 ms. The buffer gas is helium with up to 10% argon added to stabilize the DC discharge.

To make SO_3F^- for this study, SF_6 and fuming H_2SO_4 (20%–30% SO_3) were added to the ion source. Dissociative

electron impact on SF_6 gives F^-, which adds to SO_3 to give SO_3F^-. Similarly, C_2Cl_4, CBr_4, and I_2 were added as Cl^-, Br^-, and I^- ion sources to make SO_3Cl^-, SO_3Br^-, and SO_3I^-. The C_2Cl_4 and H_2SO_4 precursors were cooled in an ice bath to improve control of the vapor flow.

The tandem MS includes a quadrupole mass filter, an octopole ion guide, a second quadrupole mass filter, and a detector contained in a stainless steel box that is partitioned into five interior chambers. Differential pumping on the five chambers ensures that further collisions of the ions with the buffer gas are unlikely after ion extraction. During CID experiments, the ions are extracted from the flow tube and focused into the first quadrupole for mass selection. The reactant ions are then focused into the octopole, which passes through a reaction cell that contains an unreactive collision gas. Ar and Xe were used for SO_3F^- and SO_3I^-, respectively. Ar, Kr, and Xe were used on SO_3Cl^- and SO_3Br^-; the effect of using different collision gases is discussed in the following. After the dissociated and unreacted ions pass through the reaction cell, the second quadrupole is used for mass analysis. The detector is an electron multiplier operating in pulse-counting mode.

The energy threshold for CID is determined by modeling the cross section for product formation as a function of the reactant ion kinetic energy in the center-of-mass (CM) frame (E_{cm}). The octopole is used as a retarding field analyzer to measure the reactant ion beam energy zero. The ion kinetic energy distribution for the present data is typically Gaussian with a full-width at half-maximum of 0.7–2.1 eV (1 eV = 96.5 kJ/mol). The octopole offset voltage measured with respect to the center of the Gaussian fit gives the laboratory kinetic energy (E_{lab}) in eV. Low offset energies are corrected for truncation of the ion beam (18). To convert to the CM frame, the equation $E_{cm} = E_{lab}m(m + M)^{-1}$ is used, where m and M are the masses of the neutral and ionic reactants, respectively. All experiments were performed with both mass filters at low resolution to improve ion collection efficiency and reduce mass discrimination. For SO_3Cl^- and SO_3Br^-, the two major isotopic peaks were used simultaneously, and average atomic masses were used for all elements in determining the energy scale conversions.

The total cross section for a reaction (σ_{total}) is calculated using eq. [1], where I is the intensity of the transmitted reactant ion beam, I_o is the intensity of the incoming beam ($I_o = I + \Sigma I_i$), I_i is the intensity of each product ion, n is the number density of the collision gas, and l is the effective collision length (13 ± 2 cm). Individual product cross sections (σ_i) are equal to $\sigma_{total}(I_i/\Sigma I_i)$.

$$[1] \qquad I = I_o \exp(-\sigma_{total} nl)$$

Threshold energies are derived by fitting the data to a model function given in eq. [2], where $\sigma(E)$ is the cross section for formation of the product ion at CM energy E, E_T is the desired threshold energy, σ_o is the scaling factor, n is an adjustable parameter, and i denotes rovibrational states having energy E_i and population g_i ($\Sigma g_i = 1$). Doppler broadening and the kinetic energy distribution of the reactant ion are also accounted for in the data analysis, which is done using the CRUNCH program written by Armentrout and coworkers (18).

$$[2] \qquad \sigma(E) = \sigma_o \Sigma_i g_i (E + E_i - E_T)^n / E$$

Collisionally activated metastable complexes can have sufficiently long lifetimes that they do not dissociate on the experimental timescale (ca. 50 μs). Such kinetic shifts are accounted for in the CRUNCH program by RRKM lifetime calculations. Reactant and product vibrational frequencies are needed to determine both the RRKM lifetimes and the reactant internal energy distribution.

Complete experimental fundamental vibrational frequency sets are available for the neutral SO_3 molecule and the SO_3F^- and SO_3Cl^- anions (19–21). However, they are unavailable for the SO_3Br^- and SO_3I^- species, such that the dissociation modeling described earlier cannot be performed using solely experimental data. Furthermore, the values for the ionic species are from condensed-phase experiments, and are likely to differ from gas-phase values. Therefore, vibrational harmonic frequencies and rotational constants were calculated using the B3LYP hybrid density functional method with the 6-311+G(*d*) basis set to give a consistent set of frequencies for all analyses of CID data. The calculated and experimental frequencies are given in Table 1. Other work on similar molecules suggests that the closely related B3LYP/6-311+G(d,p) approach gives generally good agreement with experiment without scaling (22), but for the systems studied here, the calculated values are too high (by 7%, 17%, and 14% for SO_3, SO_3F^-, and SO_3Cl^-, respectively). Because the derived thermochemistry is most sensitive to the *ratio* of the reactant and product frequencies,

© 2005 NRC Canada

unscaled computational results were used for all molecules. Uncertainties in the derived thresholds owing to possible inaccuracies in the calculated spectroscopic constants were estimated by multiplying the entire sets of frequencies by 0.8 and 1.2, and by multiplying the time window for dissociation by 10 and 0.1. The effect of this scaling on the calculated thresholds is less than 2 kJ/mol for all the anions in this study. The neutral SO_3 product polarizability also has a minor effect on the derived thresholds; the B3LYP/ 6-311+G(d,p) value of 3.90 Å^3 is used in this work.

An ion not sufficiently energized by one collision with the target gas may gain enough energy in a second collision to exceed the dissociation threshold. This effect is eliminated by linear extrapolation of the data taken at several pressures to a zero pressure cross section before fitting the data (23).

The reagents C_2Cl_4, CBr_4, I_2, and fuming H_2SO_4 were obtained from Acros (Pittsburgh, Pennsylvania). He, Ar, and SF_6 were obtained from BOC (Murray Hill, New Jersey), and Xe was obtained from Spectra Gases (Irvington, New Jersey). All reagents were used as received.

Computational details

Computational work for this project was performed using the Gaussian program suite (24). All molecular structures were initially optimized without symmetry constraints, and plausible alternative structures, such as geometries with O-bonded halogens, were tested. These studies showed that C_{3v} structures are minima for SO_3X^-, and the D_{3h} structure is the minimum for SO_3. Thus, in most further calculations, symmetry was enforced. The nature of all stationary point structures was determined by analytical frequency analysis, which also provided zero-point energies (ZPEs). The ZPEs were not scaled when used to correct the raw energy values except in the G3X and CBS-Q calculations. Several basis sets were used. The 6-311+G(*d*) basis set (25) and the smaller LANL2DZpd basis set (26, 27), which uses the LANL effective core potential, were used for all of the molecules involved in this study. Other calculations employed the larger aug-cc-pVTZ basis set (28) for S, O, F, Cl, and Br, and the SDB-aug-cc-pVTZ basis set (29) (which uses the SDB effective core potential) for I. Several single-energy models, including MP2 (30), CCD (31), QCISD (32), QCISD(T), CCSD(T) (33), and B3LYP (34), as well as the CBS-Q (35), G3(MP2) (36), and G3X (37) composite models, were used to predict bond dissociation energies. Not all of these methods are available for the heavier halogens, and some possible calculations were beyond the available computational resources, so not every method was used with each basis set.

Results and discussion

Experimental bond dissociation energies

CID of all species studied in this work gives loss of X^- (X = F, Cl, Br, and I) as the only dissociation pathway. Appearance curves for dissociation of SO_3F^-, SO_3Cl^-, SO_3Br^-, and SO_3I^- are given in Figs. 1–4. The eq. [2] fitting parameters are given in Table 2, and the fits are shown in the figures. The effects of reactant and product internal energy are included in the fitting procedure; therefore, the dissociation thresholds correspond to BDEs at 0 K. The final uncertainties in the BDEs are derived from the standard deviation of the thresholds determined for individual data sets, the uncertainty in the reactant internal energy, the effects of kinetic shifts, and the uncertainty in the energy scale (±0.15 eV lab). These results are given in Table 3.

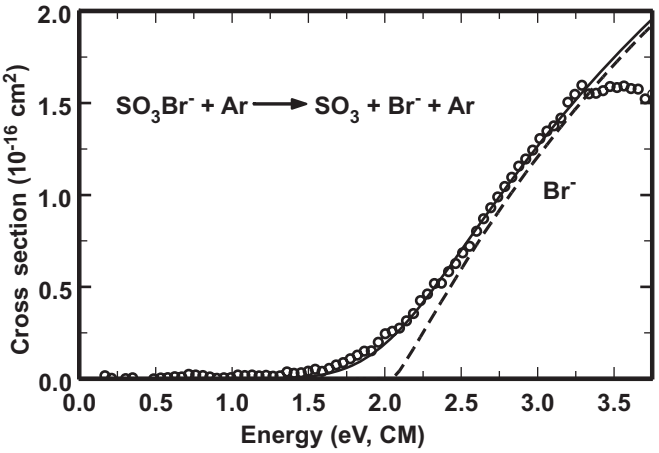
Fig. 3. Cross section for collision-induced dissociation of SO_3Br^- as a function of energy in the center-of-mass frame. The solid and dashed lines represent convoluted and unconvoluted fits to the data, as discussed in the text.



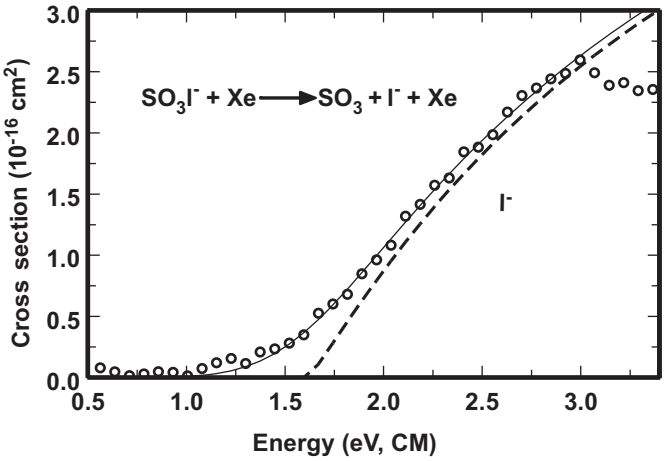


Fig. 4. Cross section for collision-induced dissociation of SO_3I^- as a function of energy in the center-of-mass frame. The solid and dashed lines represent convoluted and unconvoluted fits to the data, as discussed in the text.

The relative locations of the solid and dashed lines are different in these four figures, but the reasons are straightforward. The dashed lines (unconvoluted fits) represent the cross sections expected if the reactant ions had no internal energy and no translational energy broadening, and the activated ions always dissociated if given sufficient energy. The solid lines (convoluted fits) include the effect of ion internal energy, translational broadening, and delayed dissociation, as discussed earlier. For SO_3I^-, the main effect is the internal energy of the ion (0.20 eV on average), which shifts the solid line to the left. For SO_3F^-, the higher BDE leads to a significantly larger kinetic shift, nearly canceling the effect of the internal energy.

Several collision gases (Ar, Kr, and Xe) were used with SO_3Cl^- and SO_3Br^-, and the results are listed in Table 2. The CID threshold of SO_3Br^- with Ar collision gas is 0.13 eV higher than with Kr, and 0.23 eV higher than with Xe gas. SO_3Cl^- has a similar trend with the three collision gases. While this could conceivably be due to the experimental uncertainties, it is probably a systematic effect: previous cases have been noted where the heavier, more polarizable collision gas Xe (which is more likely to form a complex with the CID target and efficiently transfer energy from translational into internal degrees of freedom) gives lower thresholds that are more consistent with known thermochemistry (14, 38, 39). This is not always the case (40); systems with strong bonds and low densities of states (few atoms and high vibrational frequencies) are more likely to show this collision gas effect. Since the SO_3Cl^- and SO_3Br^- systems appear to show a moderate threshold shift of this type, SO_3F^- is likely to have a greater one. However, collecting reliable data on SO_3F^-–Xe collisions requires a very narrow Gaussian ion translational energy distribution. This has proven challenging so far; efforts to improve the experimental procedure for this molecule continue. Thus, the results with Xe collision gas are reported as final values for the three heavier systems, and the SO_3F^-–Ar results should be viewed as an upper limit on the actual threshold energy, $D(SO_3$—$F^-) \leq 488 \pm 19$ kJ/mol. The Larson–McMahon value of 326 ± 42 kJ/mol should therefore be taken as the best current experimental determination of this value.

Computed geometries

The optimized geometries are very similar for all models employed. Calculated bond lengths using B3LYP with the aug-cc-pVTZ (SDB-aug-cc-pVTZ for I) basis set are given in Table 4. The calculated S—O bond distance in SO_3 is 0.02 Å larger than the experimental value (41). The addition of halogen ions to SO_3 makes the S—O bonds 0.020–0.022 Å longer, in addition to pyramidalizing the geometry. The X-ray structures (9, 10) of crystals containing SO_3Cl^-

and SO_3F^- show anions that are slightly distorted by lattice effects, with S—O bond lengths averaging 0.03 Å less than the B3LYP/aug-cc-pVTZ values (Table 4). The S—X bond length increases in the order F < Cl < Br < I. The calculated S—X distances are significantly longer than the X-ray diffraction values, a difference attributed to lattice effects (8). The calculated O-S-X angle varies from 101.5° for SO_3F^- to 102.0° for SO_3I^-.

Computational bond dissociation energies

BDEs calculated at various levels of theory are summarized in Table 3. All the computational results predict BDEs smaller than experiment, although the differences decrease with the size of the halide. The computational results parallel the experimental trend in that BDEs increase in the order I < Br < Cl < F.

Comparison of BDEs predicted using the B3LYP model and increasingly large basis sets suggests that the differences between theory and experiment do not result from basis set incompleteness for this hybrid density functional approach (Table 3). Only the BDEs of SO_3F^-, where the value calculated using the aug-cc-pVTZ basis set is 12 kJ/mol higher than that from the 6-311+G(*d*) basis set and 16 kJ/mol higher than that from the LANL2DZpd basis set, show any sizable basis set effect. For the other three anions, the predicted BDEs differ little with basis set size.

However, the ab initio perturbational models show signs of basis set incompleteness. For example, the QCISD/LANL2DZpd results match the experiment well, but changing to the larger triple-ζ 6-311+G* basis set led to poorer agreement (Table 3). Consequently, we employed the G3X and CBS-Q composite models to approximate full configuration interaction and large basis set calculations, even though they could not be used for SO_3Br^- (CBS-Q) and SO_3I^- (G3 methods). These models lessen the problem of basis set incompleteness by providing corrections to lower level calculations. The G3X methods are comparable to QCISD(T)/G3Large computations, while the CBS-Q method approximates a QCISD(T)/6-311++G(3d2f,2df,2p) calculation.

As can be seen, the composite approaches predict BDEs nearer experimental values than do the single-energy methods. The G3 models perform particularly well for SO_3Br^-, with the G3X prediction of 173 kJ/mol lying within 6 kJ/mol of the experimental result of 179 ± 11 kJ/mol. The agreement for SO_3Cl^- is less good, but the composite energies lie within 2σ of the experimental value. The Larson–McMahon value for SO_3F^- of 326 ± 42 kJ/mol is somewhat lower than, but consistent with, most of the computational results (330–380 kJ/mol); the composite model values lie within 1σ of the experimental value.

That some difference in BDEs between experiment and theory remains for SO_3X^- suggests that we have not yet determined and compensated for all the sources of error in the methodologies. The computational models may still be inadequate in terms of basis set and (or) configuration interaction. In this regard, we have found no evidence that a

multireferential description of the bond-breaking process is required. Moreover, scans of the potential energy surface for dissociation show no barrier in excess of the endothermicity for all four halogens. Thus, it seems unlikely this represents a source of error. The effect of collision gas described earlier points to issues of efficient energy transfer in the anions; it may be there is some residual inefficiency of collisional energy transfer, even with Xe. Such an effect has been observed for extremely strongly bound ions such as SbF_6^-.[3]

Periodic trends

The trend in the halide affinities correlates with the large difference between the electronegativities (or radii) of fluorine and chlorine, and much smaller differences between the electronegativities of chlorine, bromine, and iodine (11, 42, 43). Caldwell and Kebarle (11, 43) collected an extensive set of measurements of the binding energies of three or four halide ions to different ligands, and other studies have added to this work (44–46). Representative experimental data are shown in Table 5. Several trends can be noted in this data. The average L—Cl^- bond (L = ligand) is 0.48 ± 0.07 times as large as the average L—F^- bond. The corresponding D(L—Br^-)/D(L—Cl^-) ratio is 0.75 ± 0.08, and the D(L—Br^-)/D(L—Cl^-) ratio is 0.75 ± 0.07. In this regard, the properties of SO_3 appear to be typical.

SO_3 is a much stronger Lewis acid with respect to halide anions than SO_2, but it is not the strongest. For example, the fluoride and chloride affinities of $AlCl_3$ are determined to be 506 ± 0.7 and 321 ± 0.6 kJ/mol (47).

Conclusions

The gas-phase strengths of the S—X^- bonds in SO_3X^- (X = Cl, Br, and I) have been determined by measuring thresholds for collision-induced dissociation in a flowing afterglow-tandem mass spectrometer. The experimental BDEs increase in the order I < Br < Cl < F. The trend in halide affinities correlates with a large difference between the electronegativities of fluorine and chlorine, and smaller differences between the electronegativities of chlorine, bromine, and iodine. All computational BDEs in this study are systematically lower than the experimental values, with the G3(MP2) and G3X composite models giving predictions closest to experimental results.

Acknowledgments

We acknowledge the taxpayers of the State of Illinois and the US Department of Education (Grant P116Z020095) for their support of the NIU Computational Chemistry Laboratory. We thank Peter Armentrout, Mary Rodgers, and Kent Ervin for use of the CRUNCH software for data analysis.

TRIBUTE

Most of Paul Kebarle's research was due to his early venture into unique, near atmospheric pressure ionization conditions, with a mass spectrometer. He and his co-workers designed and home built this apparatus for studies of reactions in gas phase radiation chemistry. However, they soon discovered that the created conditions were also suited for other much more interesting work. Due to the slow diffusion of the ions to the walls of the ion source at these pressures, the ions had a lot of time to react with any trace gases that were also present in the ion source. The time was also long enough for many of the reactions to reach equilibrium. They soon realized that the determinations of ion–molecule reaction equilibria was of far greater importance than the initially planned studies in radiation chemistry.

Results from measurements of ion equilibria in solution, compiled in the form of acid–base dissociation constants, stability constants for ion–ligand complexes, and electrochemical oxidation–reduction potentials, represent the quantitative backbone of chemistry in solution. Also very notable is the use of equilibrium data in modern biochemistry, such as determinations of the stability constants of protein–Zn^{2+} ions in metalloenzymes such as carbonic anhydrase. The same type of fundamental reactions, proton transfer, ion–ligand association, ion–solvent molecule(s) association, and electron transfer, can occur also in the gas phase. Recognizing the great importance of such determinations, Paul and co-workers, in a series of papers starting in 1965, showed that the equilibria involving a variety of reactions can be determined reliably with the new mass spectrometer. For the first time, comparison of the gas-phase data with those for the same reactions in solution were possible and these showed, in most cases, similar trends. However, the free energy change ($\Delta G^0 = RT \ln K$), with change of substituent, was about 10 times larger in the gas phase than in solution (water). Quite often, there were also reversals of the order. Thus, in the gas phase, substituted acetic acids experienced a larger increase of acidities when Cl was the substituent rather than F, while the opposite is the case in solution. The reverse order observed in aqueous solution must be due to a solvent effect. These results showed that many of the properties that had been attributed in conventional texts to the reactant ions alone, were actually strongly dependent also on the solvent. The presence of specific solvent effects could be further examined by the determinations in the gas phase of the stepwise solvation of the ions involved. Thus, for A^- ions and water as solvent the equilibria:

$$A^- + H_2O = A(H_2O)^- \ (0,1)$$

$$A(H_2O)^- + H_2O = A(H_2O)_2^- \ (1,2)$$

$$A(H_2))_{n-1}^- + H_2O = A(H_2O)_n \ (n-1,n)$$

could be determined. Summation of the $\Delta G^0_{n-1,n}$ values leads then to the solvation energy, $\Delta G^0_{0,n}(A^-)$, and when n is large, the $\Delta G^0_{0,n}$ values for given ions can predict the total solvation energies of the ion in the given solvent.

The uniqueness and fundamental importance of the results based on gas-phase ion–molecule equilibria was immediately recognized by experimentalists, and particularly by the practitioners of ion cyclotron resonance (ICR) mass spectrometry who found that ICR also can provide equilibrium data for certain types of reactions. A number of theoretical chemists, such as M. Newton, E. Clementi, A. Pullman, B. Pullman, P. Kollman, G. Diercksen, L.C. Allen, P.v.R. Schleyer, P. Kollman, J. Pople, L. Radom, and others, who were involved in ab initio calculations, also found the new experimental gas-phase data of great interest. The gas-phase ion–molecule reactions provided the energy changes for closed shell even electron compounds and these were also best suited for the theoretical calculations. In the early 1970s, ab initio calculations used small basis sets. The gas-phase thermochemical data showed that much larger basis sets and electron correlation corrections had to be used to obtain agreement with the experiment. Early developers of Monte Carlo modeling of ion hydration, such as E. Clementi and co-workers, F.F. Abraham and M.R. Mruzick, and J. Jortner, also made use of the detailed stepwise ion hydration data to develop pair potential functions needed for the modeling of ion–solvent molecule assemblies.

Prominent workers in physical organic chemistry, such as E. Grunwald, F. Bordwell, E.M. Arnett, W. Doering, R.W. Taft, and G. Olah, also recognized the value of the data and became involved in interactions with the gas phase researchers or even switched to gas-phase determinations, such as R.W. Taft.

Physical and analytical chemists, such as K.S. Pitzer, I.M. Kolthoff, and G. Zundel, as well as electrochemists, such as B.E. Conway, J.O.M. Bockris, and Y. Marcus, began using and reporting the data in the specialized electrochemical literature.

The combined output of Kebarle's laboratory and others led to thermochemical data for gas phase ions and ion–molecule reactions involving many thousands of compounds. These data are now compiled by the US National Institute of Standards and Technology (NIST), in printed databases on gas-phase ion thermochemistry now also available on the Web. They are used in many areas of research.

Paul's research is remarkable because he and his co-workers not only developed the method and did the determinations, but also actively entered different areas to which the data could be applied and managed to solve outstanding, unresolved problems. Contributions were made to several areas: (*i*) ion chemistry in the D region of the ionosphere; (*ii*) the solvation of ions in different solvents; (*iii*) applications in physical organic and organic chemistry; (*iv*) binding energies of ion–ligand complexes. Multiply charged metal ions and particularly transition metal ions are difficult to produce in the gas phase. Kebarle and co-workers were the first to show that these ions are readily produced with electrospray and design an equilibrium chamber attached to a mass spectrometer with which the ion–ligand equilibrium constants could be determined; (*v*) applications to analytical mass spectrometry and particularly atmospheric chemical ionization (APIMS); and (*vi*) mechanisms and electrospray mass spectrometry.

Paul's contributions were recognized by the following awards: Fellow, New York Academy of Sciences (1965); Fellow of the Chemical Institute of Canada (1969); Fellow of the Royal Society of Canada (1978); Elected Member of the Sigma Xi Research Society (1980); Award for Excellence in Chemistry, Province of Alberta (1980); member of the Board of Directors of the American Society for Mass Spectrometry (1982–1984); University of Alberta McCalla Professor (1984); the Medal of the Canadian Institute of Chemistry (1986); the J. Gordin Kaplan Award for Excellence in Research, University of

Alberta (1989); first recipient of the Lossing Award of the Canadian Society of Mass Spectrometry (1994); the Frank H. Field and Joe L. Franklin Award for Outstanding Achievement in Mass Spectrometry, American Chemical Society (1994); and a Special Issue of the *International Journal of Mass Spectrometry and Ion Processes* with an Honor Biography, dedicated to Paul Kebarle (Vol. 109, 1 November 1991).

Paul has authored 165 publications in various chemistry journals and five invited chapters in books.

Paul was born in Bulgaria. He was to enter his father's business. However, the nationalization of business by the Communist regime at that time changed this. Paul managed to leave Bulgaria via Czechoslovakia and then managed to make it to the Eidgenössiche Technische Hochschule (ETH) in Zurich, Switzerland, where he obtained his undergraduate degree in chemistry in 1952. This was followed by a Ph.D. at the University of British Columbia (UBC) in Vancouver, British Columbia, where he also met his wife Beverly Harris. Post doctoral work with Fred Lossing at the National Research Council of Canada (NRC) in Ottawa (1956–1958), made Paul a real mass spectrometrist and led to his appointment at the University of Alberta where he has stayed ever since.

HOMMAGE

L'œuvre scientifique de Paul Kebarle est en grande partie le fruit d'une série d'essais réalisés tôt dans sa carrière avec un spectromètre de masse, dans des conditions uniques d'ionisation à pression quasi atmosphérique. C'est avec l'aide de ses collègues qu'il met au point le spectromètre conçu pour étudier des réactions en chimie sous rayonnement en phase gazeuse. Toutefois, ils découvrent rapidement que les conditions créées se prêtent également très bien à d'autres travaux beaucoup plus intéressants. En effet, sous de telles pressions, ils observent que la diffusion ralentie vers les parois de la source d'ions permet aux ions de réagir avec les gaz avoisinants. De plus, ils notent que la plupart des réactions avaient même le temps d'atteindre un état d'équilibre. Paul et ses collègues constatent rapidement que la détermination des équilibres des réactions ions–molécules est de plus grande importance que les études en chimie sous rayonnement prévues originalement.

Les résultats des mesures de l'équilibre ionique en phase aqueuse — compilés à partir des constantes de dissociation des acides et des bases, les constantes de stabilité pour les complexes ions–ligands et les potentiels électrochimiques d'oxydoréduction — constituent la base quantitative de la chimie en solution. Un fait aussi remarquable est l'utilisation des données d'équilibre dans la biochimie contemporaine, par exemple pour déterminer les constantes de stabilité de l'interaction protéines–ions Zn^{2+} dans les métalloenzymes, tels que l'anhydrase carbonique. Le même type de réactions fondamentales — transfert de protons, association ions–ligands, association ions–molécules de solvant et transfert d'électrons — peut également se produire en phase gazeuse. Reconnaissant la grande importance de telles déterminations, Paul et ses collègues montrent, à l'aide d'une série d'articles, dont le premier est publié en 1965, que l'équilibre qui met en jeu diverses réactions peut être déterminé, d'une manière fiable, avec le nouveau spectromètre de masse. Ils comparent ensuite les données en phase gazeuse avec celles en phase aqueuse pour une même réaction, une première dans ce domaine, et remarquent des tendances réactionnelles comparables dans la plupart des cas. Toutefois, ils observent aussi que le changement d'énergie libre ($\Delta G^0 = RT \ln K$), avec le changement de substituant, est environ dix fois plus important en phase gazeuse qu'en phase aqueuse et que, très souvent, il y a un renversement de l'ordre. Ainsi, en phase gazeuse, les acides acétiques substitués subissent une augmentation plus marquée de l'acidité lorsque le chlore est l'agent de substitution, plutôt que le fluor; le contraire est observé en solution. Or, l'ordre inversé observé en phase aqueuse doit nécessairement provenir de l'effet du solvant. Cette constatation leur permet de confirmer que de nombreuses propriétés traditionnellement attribuables uniquement aux ions participant à la réaction sont en réalité aussi fortement tributaires du solvant. De plus, les effets particuliers de certains solvants peuvent être examinés plus en détail par la détermination, en phase gazeuse, de la solvatation progressive des ions mis en jeu. Ainsi, pour les ions A^- et l'eau comme solvant, l'équilibre se caractérise de la façon suivante :

$$A^- + H_2O = A(H_2O)^- \ (0,1)$$

$$A(H_2O)^- + H_2O = A(H_2O)_2^- \ (1,2)$$

$$A(H_2))_{n-1}^- + H_2O = A(H_2O)_n \ (n-1,n)$$

La sommation des valeurs $\Delta G^0_{n-1,n}$ mène ensuite à l'énergie de solvatation, $\Delta G^0_{0,n}(A^-)$, et lorsque la valeur de n est élevée, les valeurs $\Delta G^0_{0,n}$ pour les ions en cause peuvent être utilisées pour calculer les énergies de solvatation totales d'un ion en présence d'un solvant donné.

Les expérimentalistes ont immédiatement reconnu l'importance distinctive et fondamentale des résultats tirés des équilibres ions–molécules en phase gazeuse. Plus particulièrement, les utilisateurs du spectromètre de masse à résonnance cyclotronique ionique (ICR) ont remarqué que l'ICR pouvait également fournir des données sur les équilibres pour certains types de réaction. Bon nombre de chimistes théoriciens, dont M. Newton, E. Clementi, A. Pullman, B. Pullman, P. Kollman, G. Diercksen, L.C. Allen, P.v.R. Schleyer, P. Kollman, J. Pople et L. Radom, qui ont participé aux calculs dès le début, ont également reconnu l'intérêt manifeste des nouvelles données expérimentales en phase gazeuse. Par ailleurs, les réactions ions–molécules en phase gazeuse ont fourni les changements d'énergie pour les composés à couches fermées d'électrons appariés et celles-ci convenaient également mieux aux calculs théoriques. Au début des années 1970, les calculs se faisaient à l'aide d'un nombre restreint d'ensembles de base. Les données thermochimiques en phase gazeuse ont démontré qu'un bien plus grand nombre d'ensembles de base et de corrections de corrélation des électrons devait être utilisé afin d'obtenir une bonne corrélation avec les résultats expérimentaux. Les pionniers de la méthode de Monte Carlo pour l'analyse de l'hydratation ionique, y compris E. Clementi et ses collègues, F.F. Abraham et M.R. Mruzick, et J. Jortner, ont aussi utilisé les données détaillées d'hydratation progressive des ions pour élaborer les fonctions du potentiel d'appariement nécessaires à la modélisation des assemblages ions–molécules de solvant.

D'éminents chercheurs du domaine de la chimie organique physique (p. ex. E. Grunwald, F. Bordwell, E.M. Arnett, W. Doering, R.W. Taft et G. Olah) ont attesté le mérite de ces données en collaborant avec des spécialistes de la recherche en phase gazeuse; certains, dont R.W. Taft, ont même réorienté leurs travaux de recherche vers la détermination en phase gazeuse.

Des chercheurs spécialisés en chimie physique et chimie analytique, tels que K.S. Pitzer, I.M. Kolthoff et G. Zundel, ainsi que des électrochimistes, tels que B.E. Conway, J.O.M. Bockris et Y. Marcus, se sont également intéressés à ces données en les utilisant dans leurs recherches et dans la littérature spécialisée du domaine de l'électrochimie.

Les travaux de recherche du laboratoire de Kebarle et ceux des autres spécialistes du domaine ont permis l'obtention de données thermochimiques sur des ions en phase gazeuse et des réactions ions–molécules pour plusieurs milliers de composés. Le National Institute of Standards and Technology des États-Unis (NIST) compile ces données sous la forme de bases de données en format imprimé sur la thermochimie des ions en phase gazeuse. Maintenant accessibles sur le Web, ces données sont utilisées dans de nombreux domaines de recherche.

La contribution de Paul est d'autant plus remarquable que ses collègues et lui ont non seulement mis au point la méthode et effectué les déterminations, mais aussi activement tiré parti des différents domaines capables d'exploiter et de gérer ces données afin de dénouer des problèmes de longue date jusque-là non résolus. Ses contributions se manifestent dans plusieurs domaines : (*i*) la chimie des ions dans la région

D de l'ionosphère; (*ii*) la solvatation des ions dans différents solvants; (*iii*) les applications dans le domaine de la chimie organique physique et de la chimie organique; (*iv*) les énergies de liaison des complexes ions-ligands (il est difficile de produire des ions métalliques multiples et plus particulièrement des ions de métaux de transition en phase gazeuse; Paul et ses collègues ont été les premiers à démontrer que ces ions sont facilement produits par électronébulisation, et ont mis au point une chambre d'équilibre fixée à un spectromètre de masse avec laquelle ils ont pu déterminer les constantes d'équilibres des complexes ions–ligands); (*v*) les applications dans le domaine de la spectrométrie analytique de masse, en particulier dans l'ionisation chimique à pression atmosphérique (APIMS); (*vi*) les mécanismes de la spectrométrie de masse avec électronébulisation.

De nombreuses distinctions lui ont été décernées pour ses diverses contributions : membre de la New York Academy of Sciences (1965); membre de l'Institut de chimie du Canada (1969); membre de la Société royale du Canada (1978); membre élu de la Sigma Xi Research Society (1980); prix d'excellence en chimie (Alberta) (1980); membre du conseil d'administration de l'American Society for Mass Spectrometry (1982–1984); McCalla Professor à l'Université de l'Alberta (1984); médaille de l'Institut de chimie du Canada (1986); prix J. Gordin Kaplan pour l'excellence en recherche, Université de l'Alberta (1989); premier lauréat du prix Lossing de la Société canadienne de spectrométrie de masse (1994); prix Frank H. Field and Joe L. Franklin pour réalisations exceptionnelles en spectrométrie de masse, American Chemical Society (1994). En outre, un numéro spécial de l'*International Journal of Mass Spectrometry and Ion Processes* a consacré une biographie honorifique à Paul Kebarle (vol. 109, le 1er novembre 1991).

Paul a rédigé 165 publications destinées à des revues du domaine de la chimie, ainsi que cinq chapitres pour des livres spécialisés.

Paul est né en Bulgarie. Alors qu'il est appelé à œuvrer au sein de l'entreprise de son père, la nationalisation de ce commerce par le régime communiste lui fait changer ses plans. Paul quitte la Bulgarie en passant par la Tchécoslovaquie pour se rendre à l'École polytechnique fédérale de Zurich (Suisse), où il reçoit le grade de premier cycle en chimie en 1952. Il obtient ensuite un doctorat de l'Université de la Colombie-Britannique (UBC) à Vancouver. C'est aussi là qu'il rencontre sa femme Beverly Harris. Il fait ensuite un stage postdoctoral sous la supervision de Fred Lossing du Conseil national de recherches du Canada (CNRC), à Ottawa (1956–1958), et devient véritable spécialiste en spectrométrie de masse, avant de décrocher un poste à l'Université de l'Alberta, poste qu'il occupe encore aujourd'hui.

Theoretical, thermal, and coordination chemistry of the amphoteric thiazate (NSO^-)[1] ion

D. Scott Bohle, Chen-Hsiung Hung, and Bryan D. Smith

Abstract: The isomers of thiazate (NSO^-) have a rich chemistry that is examined theoretically and experimentally for their thermal and coordination characteristics. The intramolecular isomerization of NSO^- to monothionitrite (ONS^-) is predicted (B3LYP/6-311+G*) to have a substantial barrier, greater than 418 kJ mol^{-1}. Thus, thiazates are expected to be relatively thermally stable towards isomerization, and DSC indicates that KNSO undergoes a two stage irreversible thermolytic decomposition only beginning at 132 °C with ΔH = –116.3 kJ mol^{-1}. As a ligand, the thiazate can adopt a range of geometries in response to the metal's oxidation state and ligand sphere. For example, in Ru(TTP)(NO)(NSO) the ligand has a markedly bent Ru-N-S geometry, and when contrasted with other structurally characterized thiazate coordination compounds, it is concluded that in addition to σ donation the thiazate binds to metals in an amphoteric manner because of either a forward or reverse OSN $\rightarrow$ M π donation similar to transition metal nitrosyl, amido, and imido complexes.

Key words: thiazate, isomerization, thermolysis, amphoteric ligand, coordination chemistry.

Résumé : Les isomères du thiazate (NSO^-) offrent une chimie riche qu'on a examinée d'un point de vue expérimental et théorique dans le but de déterminer leurs caractéristiques thermiques et de coordination. Selon des calculs théoriques (B3LYP/6-311+G*) l'isomérisation intramoléculaire du NSO^- en monothionitrite (ONS^-) doit présenter une barrière importante, supérieure à 418 kJ mol^{-1}. On s'attend donc à ce que les thiazates soient thermiquement relativement stables vis-à-vis l'isomérisation et la calorimétrie à balayage différentiel indique que le KNSO subit une décomposition thermolytique irréversible en deux étapes qui ne commence qu'à 132 °C, avec un ΔH = –116,3 kJ mol^{-1}. Comme ligand, le thiazate peut adopter une grande variété de géométries en réponse à l'état d'oxydation du métal et à la sphère du ligand. Par exemple, dans le Ru(TTP)(NO)(NSO), le ligand adopte une géométrie Ru-N-S très tendue et, quand on le met en opposition à d'autres composés de coordination du thiazate dont la structure a été caractérisée, on en conclut que, en plus d'une donation σ, le thiazate se lie aux métaux d'une façon amphotère qui est due une donation π OSN $\rightarrow$ M (ou l'inverse) semblable celle des complexes nitrosyles, amido et imido des métaux de transition.

Mots clés : thiazate, isomérisation, thermolyse, ligand amphotère, chimie de coordination.

[Traduit par la Rédaction]

The remarkably complex family of thiazyl anions, collectively described by the formula $[N_xS_yO_z]^{-n}$, include two comparatively simple isomeric species with $x = y = z = 1$, the thiazate anion (NSO^-) and monothionitrite (ONS^-). Although many alkyl derivatives RNSO (2–4) and RSNO (5) are known, discrete, well-characterized ionic solids of the parent anions have only recently been described (6, 7). There is now an emerging structural (7–9), coordination (10), and theoretical (11–14) basis for understanding the chemistry of these triatomic anions. In general, the chemistry of the thiazate anion is much more developed owing to the comparative ease of synthesis and thermal stability. Surprisingly, a convenient synthesis of potassium thiazate was only described in 1979 (6). Metathesis of the potassium for a range of other cations has led to a number of new salts with considerable solubility in organic solvents (8, 15).

What is still needed for the thiazate anion is a correlation of the various theoretical descriptions with the observed thermal reactivity and coordination chemistry. In this paper we describe: (1) the thermal chemistry of KNSO as characterized by DSC; (2) theoretical predictions for the ground-state structures, frequencies, and isomerization transition-state geometries with density functional and second-order Møller–Plesset levels of theory; and (3) a framework for understanding the coordination chemistry particularly in reference to Ru(TTP)(NO)(NSO). Some of these results have been briefly described before (10).

Fig. 1. Optimized ground-state structures for thiazate, monothionitrite, and cyclic thiazate, as well as the transition-state structure for the thiazate monthionitrite isomerization. Bond lengths are given in angstroms and bond angles in degrees. The first value corresponds to the density functional result (B3LYP/6-311+G*), and the value in the brackets corresponds to the MP2/6-311+G* result.

chamber was used for the routine thermal analyses. Potassium thiazate (6) and Ru(TTP)(NO)Cl (10) were prepared by literature methods. All reactions and transformations were performed under an inert atmosphere.

The calculations described here were performed using GAUSSIAN 98 (17) implemented on a Silicon Graphics Iris Indigo workstation. Full optimizations were initially performed at the restricted Hartree–Fock (HF) level using the polarized split valence 6-31G* basis sets before the final optimizations with density functional theory using Becke's three-parameter functional (18) and triple split contracted basis sets (6-311+G*).

After determination of the ground-state geometries for the thiazate and monothionitrite isomers, the transition state for their conversion was determined using the synchronous transit-guided quasi-Newton algorithm developed by Peng and Schlegel (19). The optimized transition states were tested by stepping through the internal reaction coordinate to verify that the saddle separated the minima described by the isomeric structures.

Preparation of Ru(TTP)(NO)(NSO)

Ru(TTP)(NO)Cl (150 mg, 0.18 mmol) in 25 mL dry dichloromethane was treated with KNSO (80 mg, 0.8 mmol) at room temperature for 2 h. The solution was filtered and dried in vacuo. The resulting purple solid was recrystallized three times from dichloromethane–hexanes and dried in vacuo to afford **3** (144 mg, 92% yield) as a fine purple crystalline solid. UV–vis (in CH_2Cl_2, λ_{max}, nm) (log ε ((mol/L)$^{-1}$ cm^{-1})): 416 (5.40), 572 (3.96), 606 (sh). IR (KBr, cm^{-1}): ν(NO) 1829.3 (s), ν_{as}(NSO) 1255 (s), ν_s(NSO) 1075 (w), δ(NSO) 515 (w). ^{1}H NMR (22 °C, $CDCl_3$, ppm) δ: 8.90 (s, 8H, H_β), 8.07 (d, $^3J_{HH}$ = 7.7 Hz, 4H, H_m), 8.00 (d, $^3J_{HH}$ = 8.6 Hz, 4H, $H_{m'}$), 7.48 (t, $^3J_{HH}$ = 9.0 Hz, 8H, H_o, $H_{o'}$), 2.62 (s, 12H, *p*-CH_3). Elemental anal. calcd. for $C_{48}H_{36}N_6SO_2Ru$: C 66.88, H 4.21, N 9.75; found: C 66.70, H 4.49, N 9.50. The ^{1}H NMR and IR spectra were identical to the corresponding spectra of Ru(TTP)(NO)(NSO) prepared by treating Ru(TTP)(NS)Cl with $AgNO_2$ (10).

Results and discussion

Thermal analysis

A range of alkali metal thiazate salts have recently been prepared and structurally characterized by Mann and Jansen (9). These salts melt between 125 and 190 °C and reportedly decompose on further heating between 210 and 225 °C. We have reexamined this thermal behavior with differential scanning calorimetry to more exactly define the nature of these transformations and the nature of their reversibility. The first exothermic transition for potassium thiazate initiates at 132 °C and has exothermic maxima at 154 and 178 °C. These temperatures correspond well to the darkening first described by Armitage and Brand (6) at 135 °C and the suggested melting described by Mann and Jansen (9). However, the net transformation up to this temperature is irreversible and exothermic, both indicating decomposition rather than a phase transition. Further heating above 200 °C leads to the evolution of an unknown with an exothermic maximum at 262 °C. The integrated total exothermic release is ΔH = –1095.8(5) J g^{-1} or –116.3(3) kJ mol^{-1} for all processes between 132 and 278 °C. It has been reported that heating potassium thiazate leads to nitrogen evolution (9).

Ab initio calculations

To more fully understand both the thermal behavior of thiazates and their coordination chemistry we have reexamined the ground states of thiazate, monothionitrite, and a cyclic isomeric thiazate, as well as the transition state corresponding to isomerization by O-atom transfer from S to N. Prior studies have examined thiazate with a range of theoretical methods including CNDO/2 (12), MNDO (13), HF (13), HF/CPF (20), and MP2 (11). In addition, the gas-phase structures of thiazate salts of metals of the groups 1, 2, and

[g]cy- is So's (11) designation for the cyclic NSO structure, while sp is the desigination for the saddle-point for the isomerization barrier.

13 derivatives have also been recently described (14). Prior attempts to examine thiazate to monothionitrite isomerization have only used an estimated structure for the transition state in one case (13), and a very constrained three-membered ring that corresponds to a local minimum and not a saddle point in the other (11).

To improve our understanding of these anions and their relative energetics we have recalculated all three ground-state structures and the transition energy surface with both MP2 and density functional theory with large triple-ζ quality basis sets. Optimized ground- and transition-state structures, corresponding to their gas-phase structures as isolated anions, are shown in Fig. 1. These results are contrasted in Table 1 with the relevant crystallographic data for these anions. For the thiazate anion all crystallographic determinations have been hampered by disorder of the nitrogen and oxygen. While this is clear and not readily resolvable for the structures of KNSO and RbNSO determined by powder diffrac-

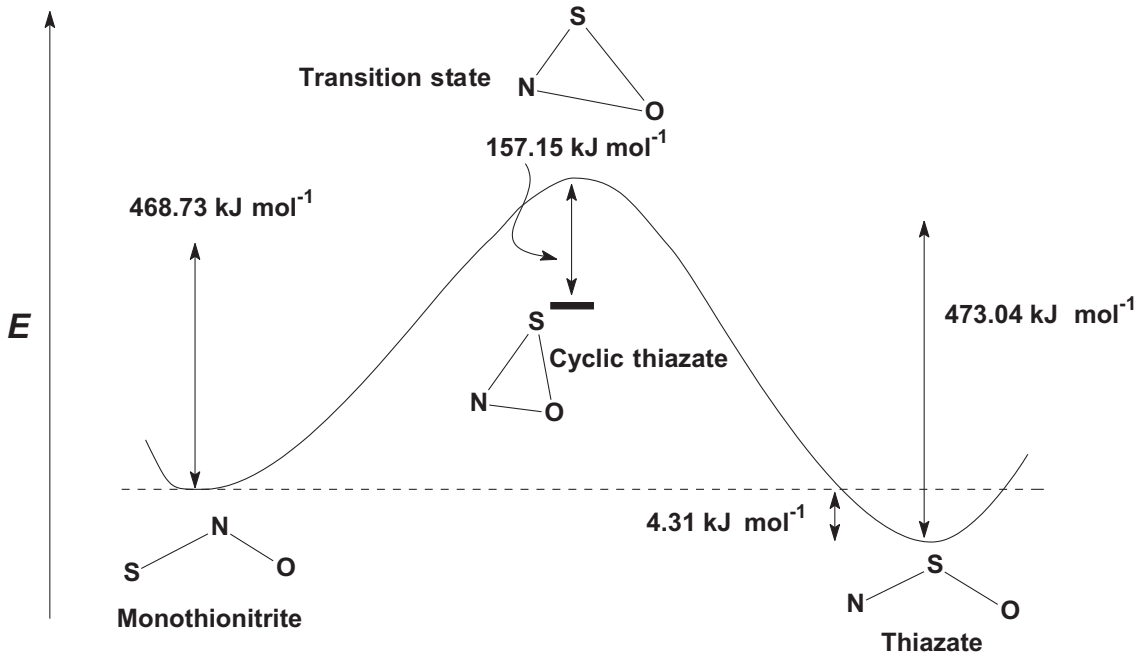
tion (9), the single crystal structure of tetramethylammonium thiazate also suffers from this, with the basis for assigning the oxygen and nitrogen atoms to the peaks found in the Fourier difference syntheses being the small differences in the two S—E (E = N and O) bond lengths. Nevertheless, in all of these studies the relatively large bond angle at the sulfur is not only reliably determined, it is much larger than most theoretically predicted angles. The optimized geometries, contrasted in Table 1 with prior theoretical reports, illustrate a number of trends: (1) for the anion, incorporation of diffuse and polarizable functions leads to lengthening of both bonds, and increases in the bond angle to values close to those experimentally observed; (2) inclusion of even approximate methods to account for configuration interaction leads to substantial alterations in optimized geometries; (3) coordination of *both ends of the thiazate* to a Lewis acid results in lengthening of both bonds and a decrease in the bond angle; and (4) coordination of HBe^+ to *either the N or the O of thiazate* leads to lengthening of the bond length of the element–sulfur bond, which is bound to the Lewis acid. A note of caution needs to be sounded about the calculations of the Lewis acid adducts of thiazate (14); the optimized gas-phase structures with η^2-NSO geometries do not correspond to what is found in the lattice of the potassium and rubidium salts (9). It has recently been shown that related nitrogen oxide anions exhibit Hartree–Fock instability and that an effective method to model this is with Becke's three-parameter hybrid functionals (21). The choice of basis set in our calculations stems from the well-known difficulty in calculations of anions with limited basis sets. In general the best models for these systems include polarization functions on all heavy atoms and preferably on the hydrogen atoms as well (22–24).

There is only one structurally characterized monothionitrite that we are aware of, and this corresponds to an ordered structure with a short N—O bond and relatively long N—S bond (7). Most theoretically calculated structures have significantly shorter N—O bonds and more compact bond angles. While our results with a 6-311+G* basis sets result in optimized geometries with longer N—O bonds, even this relatively large basis set returns an angle 2° less than the experimental value at both the MP2 and B3LYP levels of theory.



The absolute energies shown in Table 2 for all available optimized geometries reflects many of these same trends. At relatively low levels of theory the monothionitrite isomer is markedly more stable, but this is reversed for the CPF and MP2 levels of theory. Although the energy differences are basis set dependent, the B3LYP calculation gives a very small (4.31 kJ mol^{-1}) difference in gas-phase energies between NSO^- and SNO^-. The transition state connecting these two isomers has been located by finding the saddle point with a quasi-Newton synchronous transit algorithm (19). In Fig. 2, plots of energy vs. the internal reaction coordinate

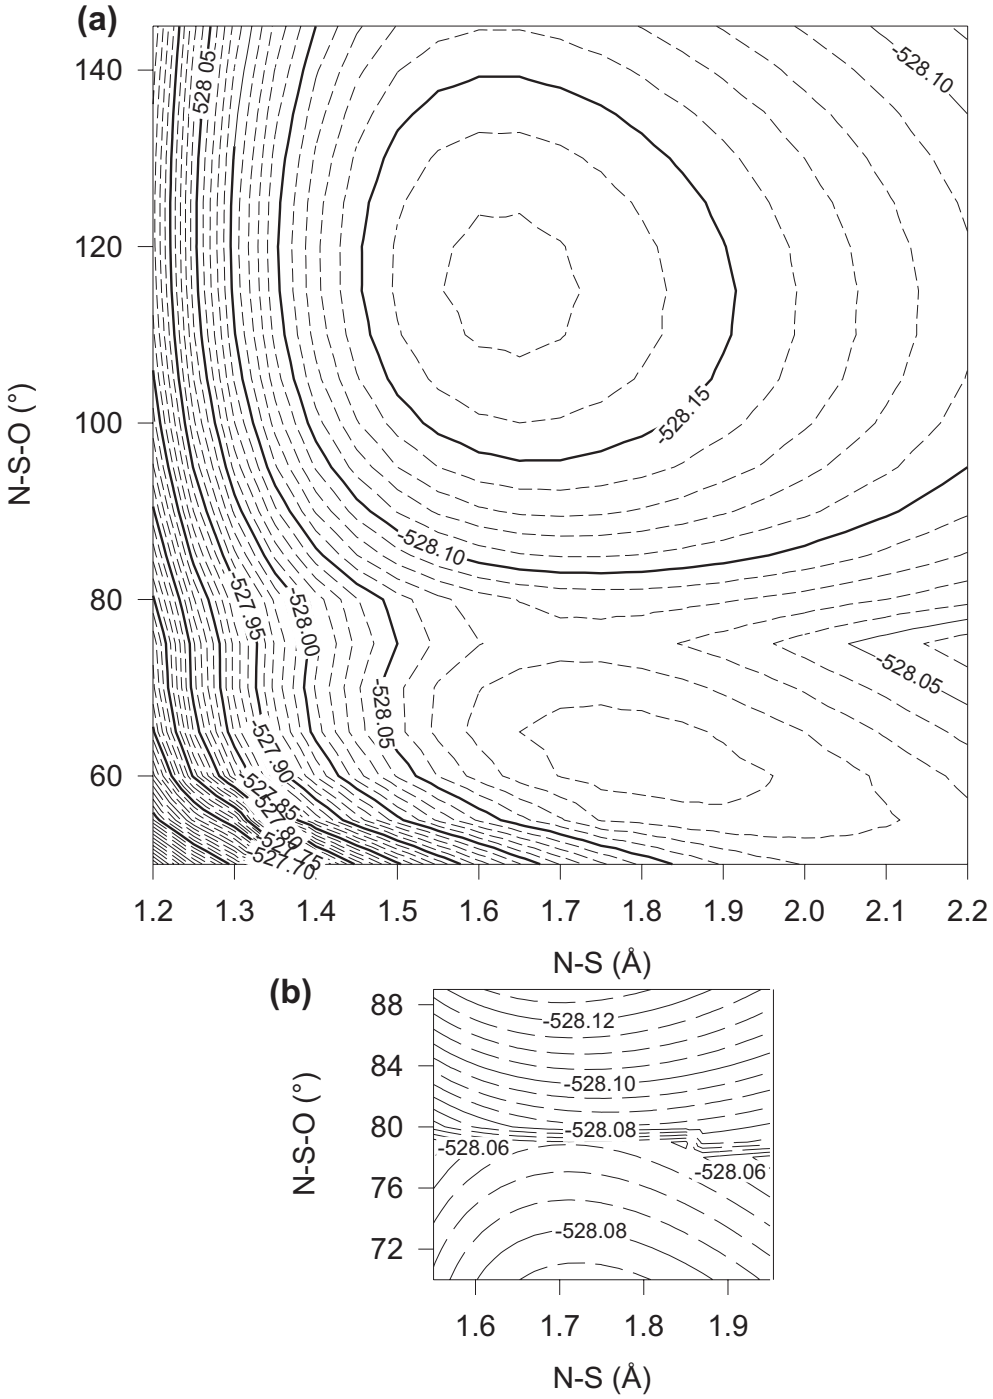
(IRC) and key atomic separations are shown. These plots clearly demonstrate that stepping along the IRC leads to a smooth correlation of each isomer to the saddle point, and that for the isomerization of thiazate along this pathway the transition state retains strong N≡S bond character. Prior to N—S bond rupture or weakening, there is substantial S—O bond deformation and elongation. We have also found that a cyclic thiazate, first described by So (11), is also present near these structures. Its geometry (Fig. 1) corresponds to a local minimum in these calculations, and it is ca. 167.4 kJ mol^{-1} less than the transition state.

To visualize these relationships we have plotted a schematic view of their energies in Fig. 3. Although the cyclic thiazate is much lower in energy, it is not an intermediate in the $NSO^- \rightarrow SNO^-$ transformation, since the IRC profile in Fig. 2 never approaches this geometry. To verify this conclusion we have calculated the potential energy surface near the cyclic thiazate structure, and a contour plot of these results is shown in Fig. 4. The expansion shown in Fig. 4*b* for the region where the two potential energy wells for the SNO^- and cyclic thiazate anion intersect, demonstrates that there is a cusp between the two surfaces and that this region does not contain saddle points, which correlates cyclic thiazate with SNO^-. Similar results are also found for the region connecting the potential energy surfaces of the cyclic thiazate and the thiazate anions. Thus, there is an orbital crossover separating cyclic thiazate from the other isomers, and that its thermal formation is prohibited, most likely owing to the conservation of orbital symmetry. Although this is not a thermally allowed process, it may be achievable by photochemical methods or by bimolecular pathways.

Finally, we note that the theoretical and experimental frequencies for these anions, collected in Table 3, indicate the close match in experiment and theory presented here. Unfortunately, the values for the bands of [PNP][SNO] are obscured by the cation and were thus not reported (7). However, even though it is difficult to comment on the values for the SNO^- calculations, the extensive sets of results for the thiazate anion both illustrate the utility of B3LYP theory in these calculations and suggest that the values for the other thiazate isomers are probably close to these calculated values. Density functional theory also comes closest to the experimental vibrational frequencies for $[NMe_4][NSO]$, where MP2 is consistently 60 cm^{-1} too high. This case is especially diagnostic owing to the soft nature of the cation, which delocalizes cation–anion ionic bonding in the salt.



Thiazate coordination chemistry

Substituted thiazates (RNSO) are potent dieneophiles and react exothermically at low temperatures in a [4+2] fashion across the N=S bond (25). The organic, electronic, and spectroscopic properties of these species have been recently reviewed in detail (4), but little comment was made concerning their metal adducts, that is when R = transition metal. RSNO form strong π adducts with low valent transition metals, and this has been shown in the reactions of *p*-tolylNSO with d^8 and d^{10} centers to give η^2-arylthiazate complexes such as the structurally characterized $OsCl(NO)(\eta^2\text{-}p\text{-tolylNSO})(PPh_3)_2$ and $Ni(\eta^2\text{-}p\text{-tolylNSO})(PPh_3)(CN\text{-}t\text{-Bu})$, where the thiazates are bound through the N and the S (26, 27). However, when there are bulky ligands such as tris(isopropyl)phosphine in $Rh[\eta^1\text{-}(p\text{-tolylNSO})](CO)(P\text{-}i\text{-}Pr_3)_2$, then the RNSO ligand can also bind in an η^1 manner through the sulfur (28). Finally, thiazates with electron-donating substituents (R = AsR_2' and PR_2') have been shown to bind through the group 15 element to the transition metal (13, 15).

For the thiazate anion, however, only one coordination mode is known. This is the terminal N-bound ligand for which a range of complexes (Table 4) have been structurally characterized. The most frequently used method to prepare these complexes is by metathesis of a suitable metal-bound X group with a thiazate salt, often an alkali metal salt. Another variation on this approach is to couple the metathesis to an oxidative addition, for example, with the use of

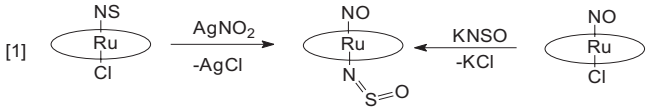
Fig. 4. Contour plot for the potential energy surface near the cyclic thiazate region. Energies calculated with B3LYP/6-311+G* with an N—O bond length of 1.5161 Å, the N—O separation in the thiazate anion. Energies given in au (Hartrees) with the N—S separation in angstroms and the S-N-O angle in degrees. Plot (*a*) shows global surface with the minimum near N—S = 1.7 Å and S-N-O = 110°, corresponding to the monothionitrite anion and the minimum near near N—S = 1.8 Å and S-N-O = 65°, corresponding to cyclic thiazate. Plot (*b*) is an expanded detail of the cusp region where the two potential surfaces for each well cross to give a discontinuity.

$Hg(NSO)_2$. Here the other by-product is elemental mercury (30, 33). For late-transition-metal thionitrosyl complexes, there are two cases where O-atom transfer results in a thiazate complex. In the first example of a thiazate complex, when $IrCl_2(CO)(NS)(PPh_3)_2$ is treated with dioxygen the result is the thiazate complex $IrCl_2(NSO)(CO)(PPh_3)_2$ (34, 35). More recently we described the result of O-atom transfer from nitrite to thionitrosyl when Ru(TTP)(NS)Cl is treated with $AgNO_2$ (eq. [1]) (10). Finally, there is a report of O-atom transfer to an unspecified acceptor in the reaction of NSO_2^- to give the thiazate complex $Rh(CO)(NSO)(PPh_3)_2$ (31). However, it has subsequently been shown that the salt used in this reaction is most likely Cs[NSO] (36).



Our interest in this topic began with an effort to prepare a

diamagnetic d^6 Ru(II) porphyrin complex with a trans arrangement of nitrosyl and thionitrosyl ligands. These complexes would be isoelectronic with the known osmium octaethylporphyin dinitrosyl complexes, which have only been spectroscopically characterized (37, 38). Our synthetic approach was via O-atom transfer from an N-bound nitrite ligand is a well-known synthetic approach for the preparation of ferrous porphyrin complexes with bent nitrosyl ligands (39). However, attempts to prepare a putative Ru(TTP)-(NS)(NO_2) complex as an intermediate, which would then be trapped out with excess nitrite or trimethylphosphine, resulted only in the formation of Ru(TTP)-(NO)(NSO), typically in yields greater than 60%. This complex can also be prepared by the direct metathesis of Ru(TTP)(NO)Cl with KNSO, as described in the Experimental section.

Prior to its complete identification by convergent syntheses and X-ray crystallography, we also prepared a series of ^{15}N-substituted derivatives by both (2) treating Ru(TTP)-(^{15}NS)Cl with $Ag^{14}NO_2$ (eq. [2]) and Ru(TTP)(^{14}NS)(Cl) with $^{15}NO_2^-$ (eq. [3]). IR spectra of the resulting products, summarized in Table 5, indicate that ^{14}N/^{15}N isotopic substitution in the nitrosyl ligand leads to a shift of 36.5 cm^{-1}, which is extremely close to that predicted from a simple Hook's law calculation of 37.8 cm^{-1}. However, incorporation of ^{15}N into the thionitrosyl, prepared from $^{15}NH_4Cl$ and $^{15}N_3S_3Cl_3$, lead to an isotopic shift of only 22.6 cm^{-1} in the product, significantly less than the shift expected for a thionitrosyl ligand of 30.1 cm^{-1}. For example, ^{15}N/^{14}N isotopic exchange in the thionitrosyl ligand in Ru(TTP)(NS)Cl leads to a shift of 36 cm^{-1}, which is in closer agreement with the result predicted by a simple harmonic oscillator model. The observed shifts in Table 5 are in accord with those predicted from the ab initio calculations for the thiazate. That is, while $[NMe_4][^{14}NSO]$ has bands at 1268, 992, and 496 cm^{-1} (8), the force constants calculated at the B3LYP/6-311+G* level predict that in $^{15}NSO^-$ the bands will be at 1224.0, 941.6, and 466.9 cm^{-1}, and will thus shift by 25.7, 3.3, and 6.1 cm^{-1}, respectively, for the three bands. These isotopic shifts fit very well with the observed shifts in for Ru(TTP)(NO)(^{15}NSO) (Table 5).

Unambiguous identification of the ligand sphere in Ru(TTP)(NO)(NSO) came from a single crystal X-ray diffraction structure (10). The well-ordered structure has a lin-

ear nitrosyl (Ru-N-O = 170.3(4)°), which is trans to an N-bound thiazate ligand, which in turns adopts a cis–cis geometry and is bent towards a meso carbon. The porphyrin exhibits a very slight S_4 ruffling with the mean average displacement from the best fit plane for the 24 ring atoms being 0.0401 Å. The ruthenium is displaced 0.12 Å out of the plane toward the nitrosyl ligand. Most of these structural features are shared by other Ru(TTP)(NO)X complexes (16).

The contrast of the thiazate geometry in Ru(TTP)-(NO)(NSO) with other thiazate complexes and the anion (Table 4) is striking. Upon binding to a transition metal there is a very modest lengthening of the N—S and S—O bonds, although the combination of the inherently large esds for these atoms with the disorder problem described previously for the reference structures, limits further interpretation of these data. However, the contrast with the theoretical results indicates that sharp changes occur in thiazate geometry upon binding to a metal. Not only is there a severe contraction in the N—S and S—O bonds, there is a marked decrease in the N-S-O angle. This latter trend is also seen in the contrast of the experimental data. Coordination to a metal leads to a slight decrease in the $\nu(NSO)_{asym}$ and increases in $\nu(NSO)_{sym}$ and δ(NSO). The asymmetric and symmetric stretching modes are dominated by the N—S and S—O bond stretches, respectively, and this suggests population of an orbital that is antibonding with respect to N—S and bonding with respect to S—O. This point will be discussed later in this paper.

The contrasts in the metric parameters in Table 4 for the complexes themselves are also revealing. Clearly the most sensitive parameter is the angle at the nitrogen (M-N-S), where the observed range is 160°–130°. Inspection suggests that there is a rough correlation of the angle with the relative electron densities at the metal; earlier transition metals bind thiazate in a more linear fashion, while the later transition metals bind it in a slightly more bent configuration. However, there is also a dependence on the trans ligand, which is exemplified by the platinum PMe_3 results where the thiazates are cis to one another but trans to a strong phosphine donor; here the thiazates are more strongly bent than in the related PPh_3 complex where the two thiazates are trans to one another and less bent. In the structurally characterized ruthenium and rhodium examples in Table 4, the thiazates are trans to strong π-accepting ligands.

In general the geometry the thiazate adopts appears to be responsive to the metal's environment, and thus NSO^- is in a small class of ligands such as NO, N_2R, and PR_2. These amphoteric ligands have geometries that respond to the metal's electronic structure in distinct ways (40). For thiazate the data base is too small to draw conclusive trends from the emerging data; however, the theoretical results previously presented allow us to pose a theoretical framework for the origin of these trends.

The best way to understand the electronic structure of the thiazate is to consider the frontier molecular orbitals (Fig. 5). The C_s geometry of the thiazate anion results in

orbitals with either A′ (in plane) or A′′ (out of plane) symmetry. The A′ set are a mixture of nonbonding lone pairs, σ bonding, and π_x bonding from NS^- and O. This can be readily seen in the HOMO shown in Fig. 5; orbital 16 is a mix of predominantly p_xN, nS, and a minor amount of S—O antibonding. The largest lobe for this orbital is on the bent side of the anion, so the σ bonding to the transition metal will clearly favor the geometry **A** where the anion bends towards the metal and has a M-N-S-O torsion angle of 0°,

© 2005 NRC Canada

rather than the trans arrangement with a M-N-S-O torsion angle of 180°, shown in **B**. For the η^1-RNSO species this orbital is most likely responsible for the strong σ bonding leading to the η^1-S(O)(=NR) geometry (28). Orbital 15 with A′ symmetry is slightly lower in energy. This orbital has a substantial p_xN contribution, and its proximity in energy and extent suggests that it may engage in forward π donation to the metal. This is most likely an important factor in the observed trends in M-N-S angles (Table 4), especially for the electron-deficient metals, cf. the M(IV) d^0 examples where empty metal-based dπ orbitals with the correct symmetry can accept electrons from orbitals 16 and 15 of the thiazate. A strong interaction here will tend to linearize the M-N-S angle. Forward π donation will decrease bonding electron density between the nitrogen and the sulfur, while at the same time decreasing the occupation of orbitals antibonding with respect to the S—O bond.

The thiazate ligand is also a potential π-acceptor ligand if there is substantial overlap between filled dπ metal orbitals and the A″ LUMO. In this case any electron donation into this orbital will be both antibonding with respect to both the N—S and S—O bonds. Occupation of this orbital will lead to an increase in the electron density at the sulfur and nitrogen, and results in a decrease of both the O-S-N and S-N-M bond angles.

Conclusion

This paper establishes the structural and electronic basis for the amphoteric character of the thiazate ligand. Surprisingly, although organothiazates are potent dienophiles, there are no reports describing this reaction for a coordinated thiazate. One prediction based on the electronic structural model developed in this report is that those metal centers that have more linear M-N-S thiazate ligands are expected to promote dienophile addition through lowering of the energy of the NSO^- HOMO in a manner similar to electron-withdrawing organic substitutents. Thus, early transition-metal thiazate complexes may be synthons for a range of other new nitrogen–sulfur containing ligands prepared in situ. Alternatively, thiazate complexes of more electron-rich centers, such as those found for the already characterized later transition metals, may attenuate this same dieneophile reactivity or it may lead to unusual examples of inverse electron demand from the diene/thiazate cycloaddition. In either case, there clearly are a range of new horizons for thiazate complexes, and we note that very little is known about their coordination sphere reactivity.

Thermodynamics of electrolytes in mixed solvent media — Application of the Pitzer ion interaction approach

Bijan Das

Abstract: Although for a long time considerable attention has been paid to the application of the Pitzer ion interaction approach to describe the thermodynamic properties of a variety of aqueous electrolyte solutions, such studies in mixed solvent media are still scarce. The present paper discusses the application of the Pitzer ion interaction approach in the case of electrolyte solutions in mixed solvent media. In particular, a comprehensive equation for the thermodynamic properties of hydrochloric acid in dioxane–water mixtures within the temperature range 273.15 to 323.15 K has been generated in the ion interaction (Pitzer) equation form on the basis of electrochemical cell measurements of the hydrochloric acid available in the literature. It was necessary to set varying values of the exponential coefficients α_1 and α_2 of the standard Pitzer model in different mixed solvent media to achieve a satisfactory fit. The present model quantitatively reproduces the experimental cell electromotive forces over the entire concentration and temperature range used for the experiments. The Pitzer ion interaction approach is, thus, proved to be a very valuable method for the correlation and prediction of thermodynamic properties of electrolytes in mixed solvent media. The implications of the Pitzer ion interaction parameters ($\beta^{(0)}$, $\beta^{(1)}$ $\beta^{(2)}$, and C^{ϕ}) have also been discussed in terms of interionic forces. The present study also stresses the need for additional emf measurements to help interpolation through the dioxane composition.

Key words: Pitzer's equations, Pitzer ion interaction parameter, activity coefficients, emf, hydrochloric acid.

Résumé : Même si l'approche de l'interaction ionique de Pitzer a reçu beaucoup d'attention, depuis longtemps, pour décrire les propriétés thermodynamiques de diverses solutions d'électrolytes aqueux, il existe peu d'études semblables dans des solvants mixtes. Dans ce travail, on discute de l'application de l'interaction ionique de Pitzer dans le cas de solutions d'électrolytes dans des solvants mixtes. En particulier, en se basant sur des mesures de cellules électrochimiques de l'acide chlorhydrique disponibles dans la littérature, on a développé une équation générale de la forme de celle de l'interaction ionique de Pitzer pour décrire les propriétés thermodynamiques de l'acide chlorhydrique dans des mélanges d'eau et de dioxane, à des températures allant de 273,15 à 323,15 K. Afin d'obtenir de bonnes corrélations dans divers milieux de solvants mixtes, il a été nécessaire d'attribué des valeurs diverses aux coefficients exponentiels α_1 et α_2 du modèle standard de Pitzer. Le présent modèle reproduit quantitativement les valeurs expérimentales de forces électromotrices de cellules pour la plage entière de concentrations et de températures utilizées dans cette étude. On a donc démontré que l'approche d'interaction ionique de Pitzer peut être très utile pour établir des corrélations et pour prédire les propriétés thermodynamiques d'électrolytes dans divers solvants mixtes. En se basant sur les forces interioniques, on discute aussi des implications des paramètres d'interactions ioniques de Pitzer $\beta^{(0)}$, $\beta^{(1)}$, $\beta^{(2)}$ et $C^{(\phi)}$. La présente étude met aussi en relief l'importance de pouvoir disposer de mesures additionnelles de f.é.m. si on veut pouvoir interpoler à toutes les compositions de dioxane.

Mots clés : équations de Pitzer, paramètre d'interaction ionique de Pitzer, coefficients d'activité, f.é.m., acide chlorhydrique.

[Traduit par la Rédaction]

Introduction

At present, the most frequently used model to describe the thermodynamic properties of a variety of aqueous electrolyte solutions is the ion interaction or virial coefficient approach developed by Pitzer and his scientific school in the early 1970s (1–4). The Pitzer model extended the Debye–Hückel method, using a virial expansion to account for the ionic strength dependence of the short-range forces in binary and ternary ion interactions. The model is applicable to solutions of high ionic strength as well. Moreover, these equations can be used in iterative calculations since the ion interaction parameters are expressed as explicit functions of ionic strength and need very few parameters to estimate properties of both single and mixed electrolytes. The Pitzer model finds extensive application for the correlation and prediction of thermodynamic properties of electrolyte solutions (5–15). Many publications (5, 16–18) have shown that this model results in excellent predictions of thermodynamic quantities. An important compilation of the ion interaction parameters of a

large number of electrolytes in aqueous solutions is available in ref. 5. Although for a long time attention has been paid to the application of the Pitzer ion interaction approach in aqueous electrolyte solutions (5–18), such studies in nonaqueous or in mixed solvent media are still scarce (19, 20), and the theory is not as developed as in the case of aqueous systems.

It is the twofold purpose of this research to obtain the Pitzer ion interaction parameters required to represent as compactly and as accurately as possible the literature experimental data (21–24) on the cell electromotive forces of hydrochloric acid in dioxane–water mixtures over a wide range of concentrations and temperatures using the Pitzer ion interaction model, with a view of testing the applicability of Pitzer equations in mixed solvent media and interpreting the resulting Pitzer parameters in terms of interionic forces.

Working equations for the model

We will be using the ion interaction model of Pitzer (1–4) as the basic framework for the mathematical description of the thermodynamic properties as functions of molality and temperature.

In the Pitzer ion interaction model, the pertinent equations for the osmotic coefficient (ϕ) and the activity coefficient (γ) for single electrolyte solutions can be expressed as

$$[1] \qquad \phi = 1 + \left|z_M z_X\right| f^{\phi} + \frac{2\nu_M\nu_X}{\nu} mB^{\phi} + \frac{2(\nu_M\nu_X)^{3/2}}{\nu} m^2C^{\phi}$$

and

$$[2] \qquad \ln\gamma = \left|z_M z_X\right| f^{\gamma} + \frac{2\nu_M\nu_X}{\nu} mB^{\gamma} + \frac{2(\nu_M\nu_X)^{3/2}}{\nu} m^2C^{\gamma}$$

where ν_M and ν_X are the numbers of ions in the formula and z_M and z_X give their respective charges in electronic units; also $\nu = \nu_M + \nu_X$, and m is the conventional molality. The other quantities have the form

$$[3] \qquad f^{\phi} = -A_{\phi}\left[\frac{I^{1/2}}{1 + bI^{1/2}}\right]$$

$$[4] \qquad f^{\gamma} = f^{\phi} + (2/b)A_{\phi}\ln(1 + bI^{1/2})$$

$$[5] \qquad B^{\phi} = \beta^{(0)} + \beta^{(1)}e^{-x_1} + \beta^{(2)}e^{-x_2}$$

$$[6] \qquad B^{\gamma} = 2\beta^{(0)} + \frac{2\beta^{(1)}}{x_1^2}[1 - e^{-x_1}(1 + x_1 - 0.5x_1^2)] + \frac{2\beta^{(2)}}{x_2^2}[1 - e^{-x_2}(1 + x_2 - 0.5x_2^2)]$$

$$[7] \qquad x_1 = \alpha_1 I^{1/2}$$

$$[8] \qquad x_2 = \alpha_2 I^{1/2}$$

Here, I is the ionic strength of solution and the term b is an empirical parameter equal to 1.2 $mol^{-1/2}$ $kg^{1/2}$, which is assumed to be the same throughout the calculation (2), α_1 and α_2 are two numerical parameters whose assigned values are discussed in the following, and A_{ϕ} is the Debye–Hückel coefficient for the osmotic function and is given by

$$[9] \qquad A_{\phi} = \frac{1}{3}\left(\frac{2\pi N_0 d_s}{1000}\right)^{1/2}\left(\frac{e^2}{\varepsilon kT}\right)^{3/2}$$

where N_0 is Avogadro's number, k is the Boltzmann constant, d_s is the density of solvent, ε is the relative permittivity of solvent, and T is the temperature in absolute scale. For SI units, ε is multiplied by $4\pi\varepsilon_0$, with ε_0 the permittivity of free space.

Experimental electromotive force (emf) data from the literature

In the present analysis, the experimental data on the electromotive forces of HCl in dioxane–water mixtures were taken from the literature reported by the Harned group (21–24) in the late 1930s. These authors obtained HCl activities from electromotive force measurements of the cells

$$[10] \qquad H_2|HCl(m),\ \text{dioxane}\ (x),\ H_2O|AgCl,Ag$$

with m being the molality of HCl and x being the weight % of dioxane in dioxane–water mixtures. Harned and coworkers (21–24) gave quadratic expressions for the cell emf (E) as functions of temperature (t) at the experimental molal concentrations (m) used. $E(t,m)$ calculated with these quadratic expressions for the experimental m and t are thus the closest to the experimental data as can be achieved.

The values of the activity coefficients (γ) can be computed by employing the equation of the cell

$$[11] \qquad \ln\gamma = \frac{E - E^0}{2k} + \ln m$$

where E^0 is the standard potential of the cell and k equals RT/F.

The literature sources of these data along with the concentration and temperature ranges are listed in Table 1.

Results and discussion

The numerical values of A_{ϕ} were computed using the temperature-dependent values of the density (d_s) and the relative permittivity (ε) of the mixed solvent media obtained from the literature (25) and these were used in the present analysis. However, for the convenience of using the A_{ϕ} values at any temperature in the temperature interval under study, we presented the calculated temperature dependence of A_{ϕ} in the polynomial form with temperature as a variable

$$[12] \qquad A_{\phi} = p_0 + p_1(T - 298.15\text{K}) + p_2(T - 298.15\text{K})^2 + p_3(T - 298.15\text{K})^3$$

where p_0 is equal to A_{ϕ} at 298.15 K. The temperature-independent coefficients (p_0, p_1, p_2, and p_3) were calculated by the least-squares method and are presented in Table 2.

In the vast majority of cases involving the application of the ion interaction model, α_1 is taken (5) to be 2.0 $kg^{1/2}$ $mol^{-1/2}$ and in some cases (26, 27) a value of 1.4 $kg^{1/2}$ $mol^{-1/2}$ gives a better fit when only this parameter is necessary. In cases where both α_1 and α_2 are required, the values α_1 = 1.4 $kg^{1/2}$ $mol^{-1/2}$ and α_2 = 12.0 $kg^{1/2}$ $mol^{-1/2}$ fitted the experimental thermodynamic properties very well (5). However,

Pitzer and Silvester (28) found that $\alpha_1 = 2.0$ kg$^{1/2}$ mol$^{-1/2}$ and $\alpha_2 = 50$ kg$^{1/2}$ mol$^{-1/2}$ were nearly optimum for 3–2 and 2–3 electrolytes. Reardon (29) has also considered $Al_2(SO_4)_3$ with the same set of values of α_1 and α_2. Rard (30), on the other hand, gives alternate sets of values for $Lu_2(SO_4)_3$. The commonly used values for these two parameters do not give an acceptable fit for the system under study. In the present treatment, therefore, the following values for these numerical parameters were used: $\alpha = 2.3$ kg$^{1/2}$ mol$^{-1/2}$ for the 20% dioxane–water system, $\alpha = 2.8$ kg$^{1/2}$ mol$^{-1/2}$ for the 45% mixture, $\alpha_1 = 3.7$ kg$^{1/2}$ mol$^{-1/2}$ and $\alpha_2 = 36$ kg$^{1/2}$ mol$^{-1/2}$ for the 70% mixture, and $\alpha_1 = 6.4$ kg$^{1/2}$ mol$^{-1/2}$ and $\alpha_2 = 87$ kg$^{1/2}$ mol$^{-1/2}$ for the 82% mixture, and these were assumed to be independent of temperature. In fact, a series of values of α_1 (or α_1 and α_2, as the case may be) were tested for each solvent mixture. While the optimum values of the parameters varied a little from one temperature to the other for a given solvent mixture, the above values fitted all cases

© 2005 NRC Canada

very well. It is important to keep this in mind when employing the present model to other studies.

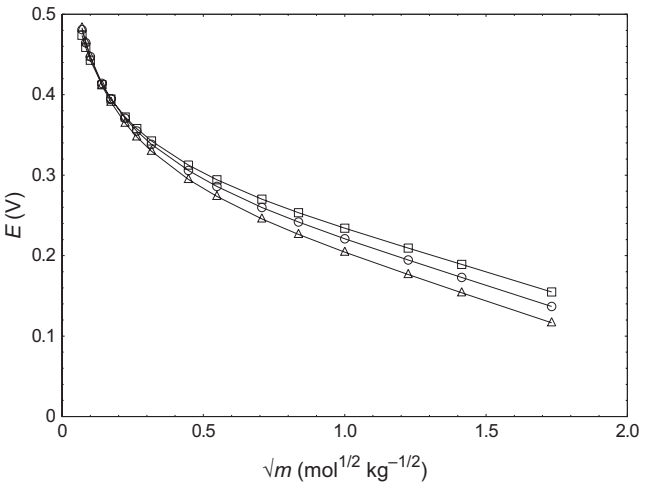
The parameters β^{ϕ} and β^{γ}, which describe the interaction of pairs of oppositely charged ions, represent measurable combinations of the second virial coefficients $\beta^{(0)}$, $\beta^{(1)}$, and $\beta^{(2)}$. These two parameters are functions of ionic strength (I). The single electrolyte third virial coefficients (C^{ϕ} and C^{γ}) account for the short-range interaction of ion triplets and are important only at high concentrations. These two are related by

$$[13] \quad C^{\gamma} = \frac{C^{\phi}}{2\left|z_M z_X\right|^{1/2}}$$

Isothermal least-squares fits of the experimental emf data using eq. [2] in conjunction with eq. [11] clearly demonstrated that the simple three-parameter ion interaction model (involving $\beta^{(0)}$, $\beta^{(1)}$, and C^{ϕ}) is capable of satisfactorily describing the results for HCl activity in 20% and 45% dioxane–water mixtures where ionic association is not expected (see later discussion). For the other two mixed solvent media comprising 70% and 82% dioxane, HCl ion association is appreciable (also see later discussion), and it has been observed that the quality of fit can be improved significantly only if we include the parameter $\beta^{(2)}$ in the Pitzer equation.

For the mixed solvent media containing 20% and 45% of dioxane, the ion interaction parameters along with the standard potentials (E^0) were obtained from the experimental emf data by the least-squares method. For the other two systems exhibiting ionic association, however, the standard potentials were first evaluated following the method described in the literature (31) using the appropriate form of the Debye–Hückel term consistent with the Pitzer formalism employed here. The required ionization constants of HCl in these mixtures were taken from the conductometric study of Owen and Waters (32).

The temperature dependence of the Pitzer ion interaction parameters ($\beta^{(0)}$, $\beta^{(1)}$, $\beta^{(2)}$, and C^{ϕ}) and the standard potentials (E^0) have been conveniently described by an arbitrary form of $f(T)$ as given below:



$$[14] \quad f(T) = q_0 + q_1\,(T - 298.15\text{K}) + q_2\,(T - 298.15\text{K})^2 + q_3\,(T - 298.15\text{K})^3$$

where q_0 is equal to $f(T)$ at 298.15 K, and q_0 through q_3 are temperature-independent constants.

Parameters resulting from the least-squares calculations along with their standard deviations (σ) are listed in Table 2.

The parameter $\beta^{(2)}$ is not always necessary; it is taken to be zero for nonassociated electrolytes. One needs to include this parameter in the second virial coefficient to fit the unusual behavior of electrolytes with ionic association. Special attention was given to the problem of calculating the $\beta^{(2)}$ parameter. Earlier, Pitzer and Mayorga (3) observed the peculiar behavior of the activity coefficients of 2–2 valence type electrolytes. This phenomenon was discussed by these authors in terms of various theories, some of which assume formation of ion pairs in such solutions while others do not. Bjerrum and Silskab (33) showed that an ionic association could be expected on the basis of purely electrostatic forces

Fig. 1. Comparison of the experimental values of the electromotive forces (E) of HCl in a 20% dioxane–water mixture with those calculated from the present correlation. Experimental values: 273.15 K (□), 298.15 K (○), 323.15 K (Δ). Calculated values: lines.

for 2–2 electrolytes, even in water. In some cases, the existence of ion pairs in aqueous solutions was proven by spectroscopic or ultrasonic data. Various authors (34) treated their experimental data for bivalent sulfates by using the ion association model. Although this approach fit the experimental data well, there were serious disadvantages that led one to seek a simpler method of correlation. The $\beta^{(2)}$ parameter was designed by Pitzer and Mayorga (3) to apply the Pitzer ion interaction approach to 2–2 aqueous electrolyte solutions characterized by a partial ionic association of M^{2+} and X^{2-} ions. These authors suggested that there were many advantages in representing the thermodynamic properties (activity and osmotic coefficients) of 2–2 electrolytes by introducing an appropriate second virial coeffcient containing $\beta^{(2)}$ parameter into the Pitzer equation instead of including the parameters determined by a chemical association model. Such a modified equation has been successfully applied for the calculation of thermodynamic quantities for single 2–2 electrolyte solutions, for mixed electrolytes involving one component of the 2–2 type (3), and also for other valence-type electrolytes (e.g., 2–3, 3–2, etc.) with significant ionic association. Various authors (35–38) demonstrated that the experimental data for 2–2 electrolytes could be treated without the assumption of an ionic association equilibrium, provided one avoids the Debye–Hückel approximation of linearization of the exponential term in the Boltzmann distribution. However, the equations now become so complex that one has only a few numerical results for a particular ionic model. Thus, it was desirable to deal with the development of equations that were simpler, but which still adequately reflect the thermodynamic behavior of electrolyte solutions. Therefore, the principal aim of the present study was the development of the Pitzer ion interaction approach for activity coefficients of HCl in dioxane–water mixtures.

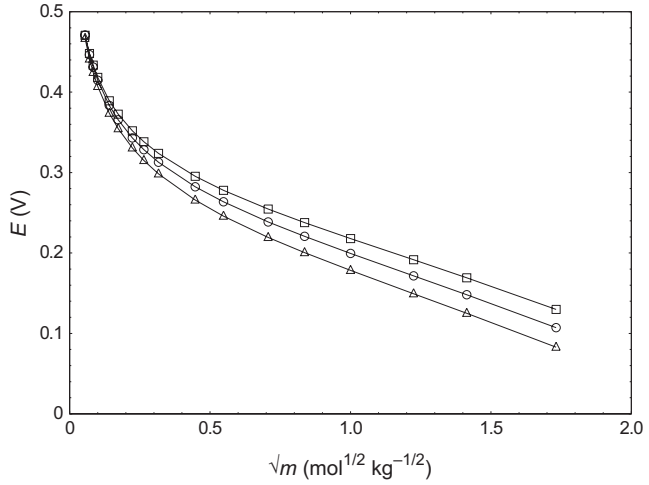
Fig. 2. Comparison of the experimental values of the electromotive forces (E) of HCl in a 45% dioxane–water mixture with those calculated from the present correlation. Experimental values: 273.15 K (□), 298.15 K (○), 323.15 K (Δ). Calculated values: lines.



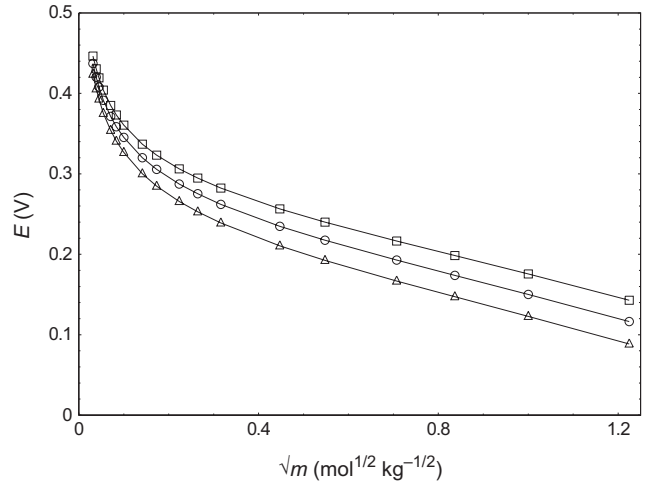


Fig. 3. Comparison of the experimental values of the electromotive forces (E) of HCl in a 70% dioxane–water mixture with those calculated from the present correlation. Experimental values: 273.15 K (□), 298.15 K (○), 323.15 K (Δ). Calculated values: lines.

tromotive forces obtained using the ion interaction parameters evaluated in this study to the experimental values have been included in Table 3. From the standard deviations recorded in this table, as well as from an inspection of these figures, it is directly evident that the ion interaction parameters reported here reproduce the experimental results excellently throughout the entire composition range.

The negative values of the ion interaction parameter $\beta^{(2)}$ observed in 70% and 82% dioxane–water mixtures indicate ionic association of HCl in these mixed solvent media. Greater ionic association with increasing temperature or with increasing amounts of dioxane in the mixture is reflected in the more negative values of $\beta^{(2)}$ at higher temperatures or in a mixture richer in organic solvent. This is in good agreement with the findings from an earlier conductivity study (32).

Fig. 4. Comparison of the experimental values of the electromotive forces (E) of HCl in a 82% dioxane–water mixture with those calculated from the present correlation. Experimental values: 278.15 K (□), 298.15 K (○), 318.15 K (Δ). Calculated values: lines.

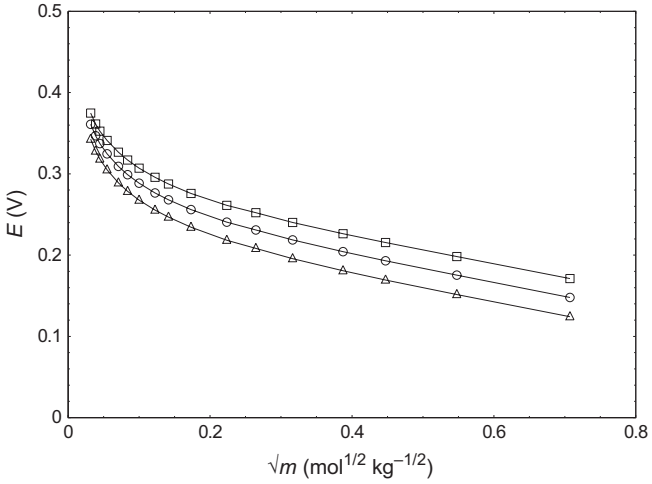

Table 3. Standard deviations (σ) for estimated vs. experimental electromotive forces for HCl in dioxane–water mixtures.

	Standard deviation			
T (K)	20% Dioxane	45% Dioxane	70% Dioxane	82% Dioxane
273.15	1	2	2	
278.15				6
283.15	1	2	2	
288.15				5
293.15	1	1	2	
298.15	1	1	2	5
303.15	1	1	2	
308.15				5
313.15	1	1	2	
318.15				5
323.15	1	2	3	

Note: $10^4\sigma$ values have been tabulated.

The third virial coefficients (C^{ϕ}), which account for ion triplet interaction, are found to be negative for HCl in the mixed solvent media investigated over the temperature interval 273.15–323.15 K. The very small negative values in 20% and 45% dioxane–water mixtures indicate the possible absence of ion association in those solutions (2). The large negative values for C^{ϕ} in the remaining two mixtures over the entire temperature range, on the other hand, suggest some tendency towards ion-pair formation for this electrolyte. Moreover, the more the dioxane content of the mixed solvent media at a given temperature or the higher the temperature for a given mixture, the more negative are the values for the third virial coefficients. This clearly indicates greater ionic association with increasing temperature or with increasing amounts of dioxane in the mixture.

Table 4. Association constants (K_A) and $\beta^{(2)}$ values for HCl in 70% and 82% dioxane–water mixtures.

	70% Dioxane		82% Dioxane	
Temperature (K)	K_A	$\beta^{(2)}$	K_A	$\beta^{(2)}$
288.15	9.1	–11.758	3922	–579.904
298.15	12.5	–14.292	4950	–588.380
308.15	14.6	–15.846	6098	–889.382
318.15	16.6	–17.080	9346	–1256.716

Note: Association constants derived from ref. 32.

Thus, the values of the parameters $\beta^{(2)}$ and C^{ϕ} point to the same conclusion concerning the ion association behaviour of HCl in dioxane–water mixtures.

It is thus apparent that the solvent mixtures comprising 20% and 45% dioxane behave differently from the other two that are richer in dioxane as far as the ion association of HCl is concerned. Although a three-parameter Pitzer equation is sufficient to describe the data for 20% and 45% mixtures, a four-parameter equation capable of taking into account the ion association is essential for 70% and 82% mixtures. That is, effectively we have only two sets of Pitzer parameters in the nonassociating regime and two sets in the associating regime. An attempt to perform interpolation to other dioxane percentages with these limited sets of parameters (except $\beta^{(2)}$) did not yield satisfactory fits; for two sets of $\beta^{(2)}$ values, no such attempt could be made. It is, thus, at this stage not possible to perform an interpolation of the Pitzer ion interaction parameters over the solvent composition essentially because of the availability of the emf data in a limited number of mixtures. More extensive emf measurements in a large number of dioxane–water mixtures is required for a meaningful interpolation of the data. However, the present analysis clearly demonstrates the medium effect on the ion interaction parameters, although correlating equations are yet to be developed pending further measurements on the cell [10] both in the nonassociating and associating regimes.

In the limit of infinite dilution it has been shown that (3) $\beta^{(2)}$ becomes equal to $-K_A/2$, where K_A is the association constant for HCl in the relevant dioxane–water mixture. The dissociation constants for HCl are available in 70% and 82% mixtures from the conductometric study of Owen and Waters (32). No accurate estimate can be made of the results in 20% and 45% dioxane solutions, although these investigators judge that the dissociation constant is of the order of unity in the latter and hence HCl may be treated as completely dissociated in 20% and 45% solutions. The association constant values for HCl obtained from ref. 32, along with the $\beta^{(2)}$ values at 288.15, 298.15, 308.15, and 318.15 K in 70% and 82% mixtures, are given in Table 4. It is evident from this table that the above relationship between $\beta^{(2)}$ and the association constant does not hold true in the present case. The failure of this relationship has also been observed by Rard (30) for $Lu_2(SO_4)_3$ in aqueous medium.

Finally, it can be concluded that the present set of ion interaction parameters would be useful to predict the emf as well as the activity and osmotic coefficients of hydrochloric acid in dioxane–water mixtures over a wide concentration and temperature range. This analysis thus yields a set of parameters from which these important and useful thermodynamic properties can be reproduced. Thus, the Pitzer ion interaction approach is proved to be a valuable method for correlation and prediction of thermodynamic properties of electrolytes in mixed solvent media also. Although correlating equations to perform interpolation of the Pitzer ion interaction parameters over the solvent composition are yet to be developed pending further measurements on the cell [10] both in the nonassociating and associating regimes, the present study amply served the twofold purpose to obtain the Pitzer parameters required to represent as compactly and as accurately as possible the literature experimental data on the cell electromotive forces of hydrochloric acid in dioxane–water mixtures over a wide range of concentration and temperature with a view to test the applicability of Pitzer equations in mixed solvent media and to interpret the resulting Pitzer parameters in terms of interionic forces.

Synthesis and characterization of alkyl- and acyl-substituted oxime–phosphazenes

Erol Çil, Mustafa Arslan, and Ahmet Orhan Görgülü

Abstract: Two oxime–cyclophosphazenes were prepared from the hexakis(4-formylphenoxy)cyclotriphosphazene (**2**) and hexakis(4-acetylphenoxy)cyclotriphosphazene (**8**). The reactions of these oximes with ethyl bromide, allyl bromide, propanoyl chloride, and acriloyl chloride were studied. Hexasubstituted compounds were obtained from the reactions of hexakis{4-[(hydroxyimino)methyl]phenoxy}cyclotriphosphazene (**3**) with ethyl bromide (**4**), allyl bromide (**5**), and propanoyl chloride (**6**), however, the oxime groups on **3** rearranged to nitrile (**7**) in the reaction of **3** with acriloyl chloride. Hexasubstituted compounds were also obtained from the reactions of hexakis{4-[(1)-*N*-hydroxyethaneimidoyl]phenoxy}cyclotriphosphazene (**9**) with allyl bromide (**11**) and propanoyl chloride (**12**). Tetra- and penta-substituted products were obtained from the reactions of **9** with ethyl bromide (**10**) and acriloyl chloride (**13**), respectively. All products were generally obtained in high yields. The structures of the compounds were defined by elemental analysis, IR, ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy.

Key words: hexachlorocyclotriphosphazene, phosphazene, oxime, oxime derivatives, oxime–phosphazenes.

Résumé : On a préparé deux oximes de cyclophosphazènes à partir de l'hexakis(4-formylphénoxy)cyclotriphosphazène (**2**) et de l'hexakis(4-acétylphénoxy)cyclotriphosphazène (**8**). On a étudié les réactions de ces oximes avec le bromure d'éthyle, le bromure d'allyle, le chlorure de propanoyle et le chlorure d'acryloyle. Les réactions de l'hexakis{4-[(hydroxyimino)méthyl]phénoxy}cyclotriphosphazène (**3**) avec le bromure d'éthyle (**4**), le bromure d'allyle (**5**) et le chlorure de propanoyle (**6**) conduit à la formation de produits hexasubstitués; toutefois, par réaction avec le chlorure d'acryloyle, les groupes oximes du composé **3** se réarrangent en nitrile (**7**). On a aussi obtenu des produits hexasubstitués lors des réactions de l'hexakis{4-[(1)-*N*-hydroxyéthaneimidoyl]phénoxy}cyclotriphosphazène (**9**) avec le bromure d'allyle (**11**) et le chlorure de propanoyle (**12**). Les réactions du composé **9** avec le bromure d'éthyle (**10**) et le chlorure d'acryloyle (**13**) conduisent respectivement à des produits tétra- et pentasubstitués. Tous les produits ont généralement été obtenus avec des rendements élevés. Les structures des composés ont été définies par des analyses chimiques et par les spectroscopies IR et RMN du ^{1}H, ^{13}C et ^{31}P.

Mots clés : hexachlorocyclotriphosphazène, phosphazène, oxime, dérivés d'oximes, oxime de phosphazène.

[Traduit par la Rédaction]

Introduction

The linear, cyclo- and poly-phosphazenes are the best known and most intensively studied phosphorus–nitrogen compounds (1–5). These compounds are reported to possess interesting biomedical properties and promising applications (6–9). Phosphazene polymers bearing flouroalkoxy or aryloxy groups stimulated considerable interest in the past as biologically inert, water insoluble polymers for blood vessel or heart valve construction (10). Cyclophosphazene derivatives, substituted with aziridine groups, were investigated as biomedical products because of their strong antitumor activity (11). Antimicrobial and biological effects of some phosphazenes on bacterial and yeast cells have been studied (12–14). On the other hand, it is known that phosphorus and nitrogen compounds are effective flame retardants for fibre materials (15). Some other applications include model compounds for polyphosphazenes, starting materials for the preparation of cyclolinear and (or) cyclomatrix phosphazene substrates, commercial polymers with carbon backbones containing pending cyclophosphazene groups, inorganic hydraulic fluids and lubricants, biologically important substrates such as anticancer agents, insect chemosterilants, pesticides and fertilizers, supports for catalysts, dyes, and crown ether phase-transfer catalysts for nucleophilic substitution reactions, core substrates for dendrimers, thermal initiators for anionic polymerization reactions, and photosensitive materials (16).

The literature contains reports on the synthesis of different linear, cyclic or polyphosphazenes (17–27). There are also a large number of literature reports on reactions of the functional groups on phosphazene substituents (10, 28). Typical of these include coupling reactions of trimeric phosphazene azides with aryloxy, alkoxy, and dialkylamino cosubstituents (29), *N*-vinylic phosphazenes with azodicarboxylic and

acetylenic esters (30), polymers from 4-formylphenoxy (31, 32), from maleic (33), and from 3,4-methylenedioxyphenoxy substituents (34).

In this paper we have prepared oxime–cyclophosphazenes from hexakis(4-formylphenoxy)cyclotriphosphazene and hexakis(4-acetylphenoxy)cyclotriphosphazene, and studied their reactions with alkyl and acyl halides such as ethyl bromide, allyl bromide, propanoyl chloride, and acriloyl chloride.

Experimental

General remarks

Solvents and other liquids used in the experimental works were dried by conventional methods. Hexachlorocyclotriphosphazene ($N_3P_3Cl_6$) (**1**) was recrystallized from hexane. Other chemicals were used as purchased. Hexakis(4-formylphenoxy)cyclotriphosphazene (**2**) and hexakis(4-acetylphenoxy)cyclotriphosphazene (**8**) were prepared as described by Carriedo et al. (25). The reactions of ($N_3P_3Cl_6$) with the phenols were carried out under dry nitrogen.

The IR spectra were recorded on an ATI Unicam Mattson 1000 FT IR spectrometer. ^1H, ^{13}C, and ^{31}P NMR spectra were recorded using a Bruker DPX-300 spectrometer operating at 300.13, 75.46, and 121.49 MHz, respectively. The ^1H and ^{13}C NMR chemical shifts were measured using $SiMe_4$ as an internal standard and the ^{31}P chemical shifts were measured using 85% H_3PO_4 as an external standard. Chemical shifts downfield from the standard were assigned positive δ values. Microanalysis was carried out by a LECO 932 CHNS-O apparatus.

Synthesis of compound 2

A mixture of **1** (10.34 g, 29.74 mmol), 4-hydroxybenzaldehyde (22.05 g, 180.56 mmol), and K_2CO_3 (50.00 g, 361.76 mmol) was stirred in THF (250 mL) at 0 °C and then was reacted at ambient temperature for 48 h. The solvent was removed under vacuum. The residue was extracted with CH_2Cl_2 (4 × 75 mL). After the solvent was removed, a white solid (**2**) formed in 92% (23.57 g) yield.

Synthesis of compound 3

A mixture of **2** (20.00 g, 23.21 mmol) and hydroxylaminehydrochloride (10.00 g, 143.90 mmol) was refluxed in pyridine (15 mL) for 3 h. After the reaction was complete, the mixture was allowed to cool and was slowly poured into water (100 mL) and reprecipitated twice from water. The white solid (**3**) was washed with alcohol and dried at 50 °C in a vacuum. Yield: 83% (18.33 g).

Reaction of 3 with ethyl bromide

A solution of 0.40 mL (0.74 g, 6.79 mmol) ethyl bromide in acetone (10 mL) was slowly added dropwise to a stirred and cooled (0–5 °C) mixture of **3** (0.80 g, 0.84 mmol) and K_2CO_3 (2.00 g, 14.47 mmol) in acetone (30 mL). The reaction was carried out at room temperature for 1 h and then was refluxed for 24 h. After the reaction was complete, the mixture was slowly poured into water (50 mL) and reprecipitated twice from water. The white solid (**4**) was recrystallized from chloroform. Yield: 59% (0.55 g).

Reaction of 3 with allyl bromide

A solution of 0.50 mL (0.7 g, 5.77 mmol) allyl bromide in acetone (10 mL), **3** (0.80 g, 0.84 mmol), and K_2CO_3 (1.60 g, 11.57 mmol) in acetone (30 mL) was used for the preparation of **5** as for **4**. The reflux period was 48 h. The white solid (**5**) was recrystallized from alcohol. Yield: 84% (0.85 g).

Reaction of 3 with propanoyl chloride

A solution of 0.40 mL (0.42 g, 4.58 mmol) propanoyl chloride in acetone (10 mL), **3** (0.60 g, 0.63 mmol), and Et_3N (2 mL) in acetone (30 mL) was used for the preparation of **6** as for **4**. The reaction was carried out at room temperature for 12 h. The white solid (**6**) was recrystallized from alcohol. Yield: 74% (0.60 g).

Reaction of 3 with acriloyl chloride

A solution of 0.40 mL (0.44 g, 4.86 mmol) acriloyl chloride in acetone (10 mL), **3** (0.60 g, 0.63 mmol), and Et_3N (2 mL) in acetone (30 mL) was used for the preparation of **7** as for **4**. The reaction was carried out at room temperature for 12 h. The orange colour solid (**7**) was washed with alcohol. Yield: 94% (0.50 g).

Synthesis of compound 8

A mixture of **1** (7.00 g, 20.13 mmol), 4-hydroxyacetophenone (16.72 g, 122.80 mmol), and K_2CO_3 (34.00 g, 245.99 mmol) was refluxed in acetone (250 mL) for 3 h. The solvent was evaporated in vacuum and the residue was extracted with CH_2Cl_2 (4 × 75 mL). After the evaporation of the solvent in vacuum, a white solid (**8**) formed in 87% (16.50 g) yield.

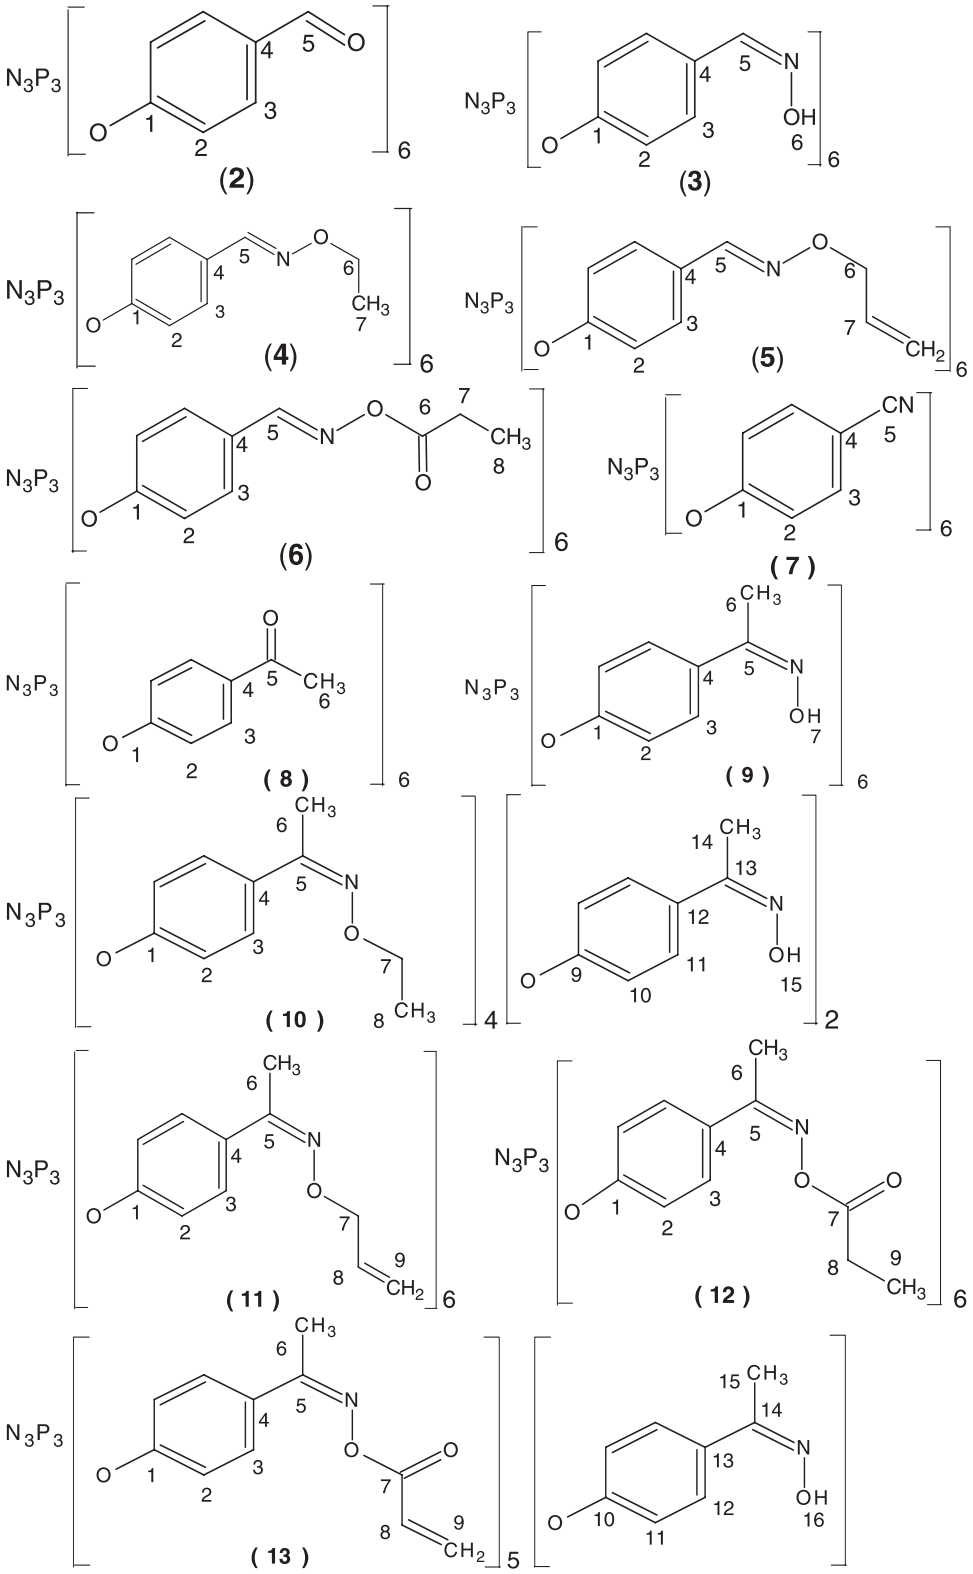
Synthesis of compound 9

Hydroxylaminehydrochloride (4.50 g, 64.75 mmol) and **8** (10.00 g, 10.57 mmol) were used for the preparation of **9** as for **3**. After the reaction was complete, the mixture was allowed to cool and the mixture was slowly poured into water (100 mL) and reprecipitated twice from water. The white solid (**9**) was obtained in 99% (10.89 g) yield.

Reaction of 9 with ethyl bromide

A solution of 0.40 mL (0.59 g, 5.43 mmol) ethyl bromide in acetone (10 mL), **9** (0.60 g, 0.58 mmol), and K_2CO_3 (2.00 g, 14.47 mmol) in acetone (30 mL) was used for the preparation of **10** as for **4**. The oily product (**10**) was obtained and dried under vacuum for 48 h. Yield: 62% (0.41 g).

Reaction of 9 with allyl bromide



A solution of 0.40 mL (0.55 g, 4.56 mmol) allyl bromide in acetone (10 mL), **9** (0.60 g, 0.58 mmol), and K_2CO_3 (2.00 g, 14.47 mmol) in acetone (30 mL) was used for the preparation of **11** as for **4**. The reflux period was 48 h. The oily product (**11**) was obtained and dried under vacuum for 48 h. Yield: 89% (0.65 g).

Reaction of 9 with propanoyl chloride

A solution of 0.40 mL (0.42 g, 4.60 mmol) propanoyl chloride in acetone (10 mL), **9** (0.60 g, 0.58 mmol), and K_2CO_3 (2.00 g, 14.47 mmol) in acetone (30 mL) was used for the preparation of **12** as for **4**. The oily product (**12**) was

Scheme 1. The structures of compounds **2**–**13**.

obtained and dried under vacuum for 24 h. Yield: 89% (0.70 g).

Reaction of 9 with acriloyl chloride

A solution of 0.40 mL (0.44 g, 4.86 mmol) acriloyl chloride in acetone (10 mL), **9** (0.60 g, 0.58 mmol), and Et_3N (2 mL) in acetone (30 mL) was used for the preparation of **13** as for **4**. The reaction was carried out at room temperature for 24 h. The yellowish solid (**13**) was washed with alcohol three times. Yield: 59% (0.45 g).

Results and discussion

The reaction of **1** with 6 equiv. of 4-hydroxybenzaldehyde and 4-hydroxyacetophenone in the presence of K_2CO_3 in THF gave hexakis(4-formylphenoxy)cyclotriphosphazene (**2**) and hexakis(4-acetylphenoxy)cyclotriphosphazene (**8**). Oxime compounds hexakis{4-[(hydroxyimino)methyl]phenoxy}cyclotriphosphazene (**3**) and hexakis{4-[(1)-*N*-hydroxyethaneimidoyl]phenoxy}cyclotriphosphazene (**9**) were synthesized from the reactions of **2** and **8** with hydroxylaminehydrochloride in pyridine, respectively.

Hexasubstituted oxime derivatives were obtained from the reactions of oxime compound **3** with ethyl bromide, allyl bromide, and propanoyl chloride in acetone (in the presence of K_2CO_3 for ethyl and allyl bromide, of Et_3N for propanoyl and acriloyl chloride) via replacement of all the oxime protons with ethyl, allyl and propanoyl groups. However, the oxime groups on **3** rearranged to nitrile (**7**) in the reaction of **3** with acriloyl chloride via the dehydration of oximes (35, 36). Compound **7** was previously synthesized by Carriedo (25). $N_3P_3(OC_6H_4\text{-}CN)_6$ was directly obtained from the reaction of $N_3P_3Cl_6$ with 4-cyanophenol and characterized by elemental analysis and ^1H, ^{13}C, and ^{31}P NMR spectra (25). The analysis results of **7** are in good accordance with the literature values (25). Similar compounds, $N_3P_3(OPh)_5(OC_6H_4\text{-}CN\text{-}p)$ and $N_3P_3(OC_6H_4\text{-}R\text{-}4)_5(OC_6H_4\text{-}CN\text{-}4)$ (R = H or *t*-Bu), were synthesized by Allcock et al. (37) and Carriedo et al. (38), respectively. Hexasubstituted derivatives were obtained from the reactions of **9** with allyl bromide and propanoyl chloride. Tetra- and penta-substituted products were obtained from the reactions of **9** with ethyl bromide and acriloyl chloride in acetone (in the presence of K_2CO_3 for ethyl bromide, of triethylamine for acriloyl chloride), respectively.

The structures of the compounds were defined by elemental analysis, IR, and ^1H, ^{13}C, and ^{31}P NMR spectroscopy (structures **2**–**13** are shown in Scheme 1). Physical properties and analytical data for **2**–**13** are given in Table 1. Compounds **2**–**13** were synthesized in high yields except **4**, **10**, and **13**. The solvents used for the purification of compounds **7**, **10**, and **11** could not be removed completely as observed by ^1H and ^{13}C NMR spectra. Thus, the presence of these trace amounts of solvent affect the elemental analysis, in particular the carbon value.

The characteristic stretching peaks in the IR spectra of the phosphazenes have been assigned as in Table 2. The P=N stretching vibrations, which are observed between 1173 and 1208 cm^{-1}, are characteristic of cyclophosphazenes. Compared to **1**, which appeared at 1218 cm^{-1}, these peaks are shifted to longer wavelengths for **2**–**13**. The OH stretching vibrations in the IR spectra of **3**, **9**, **10**, and **13** indicate the oxime compounds. While **3** and **9** are initial oximes, all hydrogen atoms of the OH groups of **10** and **13** could not be replaced by the alkyl and acyl substituents.

The NMR data for **2**–**13** are presented in Tables 3–5. The ^{31}P NMR shifts of **2**–**13** change between 8.05 and 17.21 ppm. Although there is only one peak in the ^{31}P NMR spectra of **1**, **2**, **4**, **5**, **7**, **8**, **10**, **12**, and **13** at 20.12, 8.33, 7.49, 9.49, 7.51, 8.05, 9.07, 8.80, and 8.73 ppm, respectively, two peaks, with very weak second signals, are observed at δ 17.21, 17.26, δ 8.33, 8.21, δ 9.04, 9.01, and δ 9.01 and 8.98 ppm for **3**, **6**, **9**, and **11**, respectively. It is assumed that the weak peaks due to the cyn and anti isomerism of the -C=N- groups. The effects of the cyn and anti isomerism are also observed in the ^{13}C NMR spectra of **3**, **6**, and **11** (Table 5). This data demoinstrates that compounds **3**, **6**, **9**, and **11** consist of a mixture of two isomers, but others have one isomer. Although there are the different phosphorus environments in the molecules of **10** and **13**, the main peak is observed as a singlet. It is understood that the phosphorus peaks are not affected by these changes because the substituted groups are far off the phosphorus atoms.

The ^1H and ^{13}C NMR data also confirm the structures of **2**–**13** (Scheme 1). In the ^1H NMR spectra (Table 4), the OH protons are observed at 10.17, 11.25, 11.30, and 11.25 ppm for **3**, **9**, **10**, and **13**, respectively. It is understood from the integral intensities that there are six OH protons in **3** and **9**, which are original oxime–phosphazenes, two OH protons in **10**, one OH proton in **13**. This observation for **10** and **13** indicates that alkyl or acyl groups have not replaced all OH protons in **3** and **9**. The aldehyde proton for **2** appears at

and **9**, the azomethine carbon atoms in the substituted moiety of the molecules are shifted to the lower downfield for compound **6**, **11**, **12**, and **13**, except **4**, **5**, and **10** in which the alkyl groups release an electron to the molecule. But the azomethine resonances do not change or change very little in the nonsubstituted moieties of **10** and **13**. In addition, the ^{13}C NMR data clearly show that compound **10** is referred to as the geminal isomer. There are essentially two different sets of carbon atoms within the geminal structures, but three sets within the nongeminal structures for the tetrasubstituted cyclotriphosphazenes. The resonances of two sets of carbon atoms were observed in the ^{13}C NMR spectrum of **10**. These results indicate the geminal structure. A triplet and a doublet are expected in the ^{31}P NMR spectra of geminal structures for tetrasubstituted cyclotriphosphazene (**10**), but the main peak was observed as a singlet. These results show that the phosphorus signals are not affected from the binding groups because the substituents at the end of the molecule are far from the phosphorus atoms.

Conclusion

Hexasubstituted compounds were obtained from the reactions of hexakis{4-[(hydroxyimino)methyl]phenoxy}cyclotriphosphazene (**3**) with ethyl bromide, allyl bromide, and propanoyl chloride; however, the oxime groups on **3** rearranged to nitrile in the reaction of **3** with acriloyl chloride. Hexasubstituted compounds were also obtained from the reactions of hexakis{4-[(1)-*N*-hydroxyethaneimidoyl]phenoxy}cyclotriphosphazene (**9**) with allyl bromide and propanoyl chloride. The tetrasubstituted product, which is a geminal isomer, and pentasubstituted products were obtained from the reactions of **9** with ethyl bromide and acriloyl chloride, respectively.

$SnCl_4$–I_2 mediated regioselective 6-endo- and 5-exo-cyclization of *ortho*-allylenols

K.C. Majumdar, A. Biswas, and P.P. Mukhopadhyay

Abstract: 3-Allyl-4-hydroxycoumarins and 4-allyl-3-hydroxycoumarins are obtained in 90%–92% yields by the thermal [3,3] sigmatropic rearrangement of the corresponding ethers. 3-Allyl-4-hydroxy-6-methylpyrone is obtained from the direct alkylation of 4-hydroxy-6-methylpyrone with allyl halide. These substrates on treatment with $SnCl_4$–I_2 at 25 °C give a mixture of both *5*-exo- and 6-endo-cyclization products. However, regioselective formation of 5-exo products is observed when the reactions are conducted at lower temperatures (0–5 °C, kinetically controlled), while the reaction at a higher temperature (50 °C, thermodynamically controlled) affords regioselectively 6-endo cyclization products.

Key words: stannic chloride, iodine, claisen rearrangement, 6-endocyclization, 5-exocyclization, kinetically controlled reaction, thermodynamically controlled reaction.

Résumé : On a obtenu les 3-allyl-4-hydroxycoumarines et les 4-allyl-3-hydroxycoumarines avec des rendements de 90 % à 92 % par un réarrangement sigmatropique [3,3] thermique des éthers correspondants. On a obtenu la 3-allyl-4-hydroxy-6-méthylpyrone par alkylation directe de la 4-hydroxy-6-méthylpyrone avec un halogénure d'allyle. Le traitement de ces substrats avec du $SnCl_4$–I_2, à 25 °C, conduit à un mélange des deux produits cyclisation, 5-exo- et 6-endo-. Toutefois, on observe la formation sélective des produits 5-exo- quand les réactions sont effectuées à des températures plus basses, 0 à 5 °C (contrôle cinétique) alors que la réaction à une température plus élevée, 50 °C (contrôle thermodynamique) conduit régiosélectivement aux produits de cyclisation 6-endo-.

Mots clés : chlorure stannique, iode, réarrangement de Claisen, cyclisation 6-endo, cyclisation 5-exo, réaction cinétiquement contrôlée, réaction sous contrôle thermodynamique.

[Traduit par la Rédaction]

Introduction

Coumarins fused with other heterocyclic rings are known to have interesting biological and photodynamic properties (1). This has encouraged a flurry of research activities with regard to methodologies for the preparation of these compounds. Thus, a number of protocols have been reported (2) for the synthesis of various 3,4-fused furo- and pyranocoumarins as some members belonging to these two families have shown (3) useful levels of biological activity. 4-Hydroxy-6-methyl-2-pyrone and its derivatives are known to act as specific inhibitors of human leukocyte elastase (4) and also as anticoagulant agents (5).

Recently, we have reported *N*-iodosuccinimide (NIS) mediated heterocyclization of *ortho*-cyclohex-2′-enyl phenols (6) and 3-cyclohex-2′-enyl-4-hydroxycoumarin (7) in acetonitrile at 0–5 °C in almost quantitative yield. We have also reported heterocyclization using pyridine hydrotribromide (8), mercuric acetate (9), and hexamethylenetetramine hydrotribromide (10). However, no study on the temperature dependence of these reactions was conducted. NIS has been used for 6-endo heterocyclization of different substrates via an iodonium intermediate. Recently (11), $SnCl_4$–I_2 has been found to be a convenient and practical reagent for providing positive iodine. This prompted us to undertake a study on the heterocyclization of 3-allyl-4-hydroxycoumarin, 4-allyl-3-hydroxycoumarin, and 3-allyl-4-hydroxy-6-methylpyrones. Herein we report the results.

The starting materials 3-allyl-4-hydroxycoumarins (12) (**4a**–**4e**) and 4-allyl-3-hydroxycoumarins (13) (**5a**, **5b**) were obtained in 90%–92% yield by the thermal rearrangement of the corresponding allyl ethers in refluxing chlorobenzene (132 °C) for 8 h. 3-Allyl-4-hydroxy-6-methylpyrones (**6**) were prepared from the direct alkylation of 4-hydroxy-6-methylpyrones (**1e**) with allyl halide (**2a**). The ethers **3a**–**3g** were in turn prepared by the reaction of substrates **1a**–**1d** with allylic halides (**2a**, **2b**) in refluxing acetone in the presence of anhydr. K_2CO_3 (Scheme 1).

Results and discussion

Substrate **4a** was treated with $SnCl_4$–I_2 in dichloromethane or acetonitrile at 25 °C for 6 h to give a mixture of two products. The mixture on separation afforded kinetically controlled 2,3-dihydro-2-iodomethylfuro[3,2-*c*]coumarin (**7a**, 65%) as the major product and thermodynamically controlled 3-iodo-2,3,4-trihydropyrano[3,2-*c*]coumarin (**8a**, 25%) as the minor product (Scheme 2). The other substrates (**4b**–**4e**, **5a**, **5b**, and **6**) were also similarly treated to give a mixture of products, which were separated by chromatogra-

Scheme 1. Reagents and conditions: (*i*) Me_2CO, KCO_3, reflux, 6–8 h; (*ii*) chlorobenzene, reflux, 8 h.

Scheme 2. Reagents and conditions: (*i*) $SnC1_4$–I_2, $CHC1_2$, r.t., stirring, 6 h.

phy (Table 1). However, if the reaction mixture obtained at 25 °C in acetonitrile was heated to 50 °C. only the six-membered ring products (**8a**–**8e**, **10a**, **10b**, **12**) were obtained. The five-membered ring products (**7a**–**7e**, **9a**, **9b**, **11**) when heated at 50 °C also afforded exclusively the six-membered ring products (**8a**–**8e**, **10a**, **10b**, **12**).

These reactions were then conducted at different temperatures to ascertain the effect of temperature on the selectivity of the heterocyclization. Substrate **4a** was allowed to react with $SnCl_4$–I_2 at 0–5 °C in dichloromethane or acetonitrile for 2 h and to our surprise we obtained a single product (**7a**, kinetically controlled) in almost quantitative yield. The other substrates (**4b**–**4e**, **5a**, **5b**, **6**), when treated under the same reaction conditions also afforded the single products **7b**–**7e**, **9a**, **9b**, and **11** in 85%–92% yields. The same reaction was then conducted in acetonitrile at 50 °C for 1 h to give a thermodynamically controlled six-membered heterocyclic product (**8a**, 72%) without formation of the five-membered product that we obtained when the reaction was conducted at 0–5 °C. In all other cases (**4b**–**4e**, **5a**, **5b**, **6**), the six-membered ring products (**8b**–**8e**, **10a**, **10b**, **12**) were exclusively obtained in 65%–72% yield at 50 °C. The reactions were also conducted in various solvents. Dichloromethane and acetonitrile were found to provide a clean reaction for the exclusive formation of the five-membered ring and acetonitrile gave the best result for the synthesis of six-membered cyclic products (Table 1).

A literature search revealed that $SnCl_4$–I_2 has been used for the cyclization of *ortho*-allyl phenols by Orito et al. (11). The formation of five-membered and six-membered products has been explained in terms of substituent effects. In the present study we have successfully demonstrated the

Note: Reaction conditions: A = $SnCl_4$–I_2 added at room temp. in CH_2Cl_2 solution and stirring for 6 h. B = $SnCl_4$–I_2 added at 0–5 °C in CH_2Cl_2 solution and stirring for 2 h. C = $SnCl_4$–I_2 added at 50 °C in CH_3CN solution and stirring for 1 h at the same temperature.

[a]Yield given represents isolated yield. In the case of reaction at 50 °C, five-membered products were obtained with additional amounts (5%–10%) of by-products arising out of the addition of iodine to the olefinic double bond were also detected.

temperature-dependent regioselectivity (kinetic and thermodynamic control) for the formation of five- and six-membered heterocyclic compounds.

Scheme 3.

The key step of the synthesis that we report here is based on the intramolecular cyclization allowed by the activation of an olefinic double bond by means of an iodonium intermediate (**A**). The intramolecular ring closure may occur via a 5-exo-trig at 0–5 °C (kinetically controlled) and by a 6-endo-trig at 50 °C (equilibrium controlled) to give five-membered and six-membered heterocyclic rings, respectively (Scheme 3). As the five-membered ring products (**7a**–**7e**, **9a**, **9b**, **11**) are converted to the six-membered ring products (**8a**–**8e**, **10a**, **10b**, **12**) at 50 °C, we can say that the thermodynamic mixture must be formed through the reversible conversion of the five-membered ring to the six-membered ring via a common intermediate (**A**), i.e., the five-membered ring is in reversible equilibrium with the iodonium ion intermediate (**A**).

Thus, we have been able to demonstrate the selectivity in the formation of five- and six-membered oxygen heterocyclic rings by the combined Claisen rearrangement fol-

© 2005 NRC Canada

lowed by temperature-dependent ring closure methodology. The reagent $SnCl_4$–I_2 used for this protocol is quite cheap and easily accessible compared with other reagents for similar cyclizations (12). This offers a facile synthesis for potentially bioactive heterocycles.

Experimental

Melting points were determined in a open capillary and are uncorrected. IR spectra were recorded on a PerkinElmer L 120-000A spectrometer (ν_{max} in cm^{-1}) and solid samples were recorded in KBr disks. UV absorption spectra were recorded in EtOH on a Shimadzu UV-2401PC spectrophotometer (λ_{max} in nm). ^1H NMR (300 and 500 MHz) and ^{13}C NMR (75.5 and 125 MHz) spectra were recorded on Bruker DPX-300 and Bruker DPX-500 spectrometers in $CDCl_3$ (chemical shifts in δ) with TMS as internal standard. Elemental analyses and mass spectra were recorded on a LECO 932 CHNS analyser and on a JEOL JMS600 instrument, respectively. ^1H NMR and ^{13}C NMR spectra were recorded at the Indian Institute of Chemical Biology, Kolkata, India and the Bose Institute, Kolkata, India. Silica gel (60–120 mesh, Spectrochem, India) was used for chromatographic separation. Silica gel G (E-Merck, India) was used for TLC. Petroleum ether refers to the fraction boiling between 60 and 80 °C.

General procedure for the alkylation of compounds 1a–1e

A mixture of 4-hydroxy coumarin or 4-hydroxy-6-methyl-2-pyrone or 3-hydroxy coumarin **1a**–**1e** (5 mmol), appropriate halides **2a** and **2b** (5 mmol), and anhydr. K_2CO_3 (3 g) was refluxed in dry acetone (150 mL) for 6–8 h. The reaction mixture was then cooled, filtered, and the solvent was removed. The residual mass was subjected to column chromatography over silica gel. Compounds **3a**–**3g** and **6** were obtained when the column was eluted with petroleum ether – ethyl acetate (9:1).

Compounds **3b**–**3d**, **3f**, and **3g** were reported earlier (12, 13).

Compound 3a

White solid, mp 124–126 °C; yield: 82%. UV (EtOH, nm) λ_{max}: 311, 279, 268, 229. IR (KBr, cm^{-1}) ν_{max}: 1439, 1574, 1707. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.8 (d, J = 6 Hz, 3H, CH_3), 2.41 (s, 3H, ArCH_3), 4.60 (d, J = 6 Hz, 2H, -OCH_2), 5.66 (s, 1H, COCH), 5.72–5.80 (m, 1H, CH_3CH), 5.90–5.99 (m, 1H, -OCH_2CH), 7.19–7.62 (m, 3H, ArH). MS *m*/*z*: 230 (M^+). Anal. calcd. for $C_{14}H_{14}O_3$ (%): C 73.03, H 6.13; found: C 73.21, H 6.28.

Compound 3e

White solid, mp 133–135 °C; yield: 80%. UV (EtOH, nm) λ_{max}: 310, 278, 268, 230. IR (KBr, cm^{-1}) ν_{max}: 1437, 1572, 1706. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.36 (s, 9H, C(CH_3)$_3$), 4.71 (d, J = 6 Hz, 2H, -OCH_2), 5.41–5.54 (m, 2H, =CH_2), 5.68 (s, 1H, COCH), 6.04–6.17 (m, 1H, CH=CH_2), 7.24–7.82 (m, 3H, ArH). MS *m*/*z*: 258 (M^+). Anal. calcd. for $C_{16}H_{18}O_3$ (%): C 74.40, H 7.02; found: C 74.22, H 7.24.

Compound 6

White solid, mp 154–156 °C; yield: 90%. UV (EtOH, nm) λ_{max}: 290, 208. IR (KBr, cm^{-1}) ν_{max}: 1589, 1624, 1668, 3251. ^1H NMR ($CDCl_3$, 300 MHz) δ: 2.22 (s, 3H, CH_3), 3.24 (d, J = 6.0 Hz, 2H, CH_2), 5.05–5.19 (m, 2H, =CH_2), 5.86–5.99 (m, 1H, CH_2=CH), 6.15 (s, 1H, =CH). MS *m*/*z*: 166 (M^+). Anal. calcd. for $C_9H_{10}O_3$ (%): C 65.05, H 6.06; found: C 65.31, H 5.84.

General procedure for rearrangement of compounds 3a–3g

The starting ether (**3a**–**3g**, 2 mmol) was refluxed in chlorobenzene (4 mL) in an oil bath for 8 h. The chlorobenzene was removed in vacuo and the residual mass was chromatographed over silica gel. Elution of the column with petroleum ether (60–80 °C) removed the residual chlorobenzene and then a white solid was obtained by eluting the column with petroleum ether – ethyl acetate (9:1).

Compounds **4b**–**4d** and **5a** and **5b** were reported earlier (12*a*, 13).

Compound 4a

White solid, mp 162–164 °C; yield: 92%. UV (EtOH, nm) λ_{max}: 315, 285, 273, 229. IR (KBr, cm^{-1}) ν_{max}: 1564, 1611, 1693, 3218. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.39 (d, J = 7 Hz, 3H, CHCH_3), 2.40 (s, 3H, ArCH_3), 4.02–4.07 (m, 1H, CH_3CH), 5.51–5.61 (m, 2H, =CH_2), 6.35–6.46 (m, 1H, CH_2=CH), 7.18–7.56 (m, 3H, ArH). MS *m*/*z*: 230 (M^+). Anal. calcd. for $C_{14}H_{14}O_3$ (%): C 73.03, H 6.13; found: C 73.19, H 6.02.

Compound 4e

White solid, mp 142–144 °C; yield: 90%. UV (EtOH, nm) λ_{max}: 314, 284, 273, 230. IR (KBr, cm^{-1}) ν_{max}: 1580, 1618, 1695, 3250. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.36 (s, 9H, C(CH_3)$_3$), 3.49 (d, J = 6.4 Hz, 2H, CH_2), 5.28–5.43 (m, 2H, =CH_2), 6.97–6.11 (m, 1H, CH_2=CH), 7.24–7.81 (m, 3H, ArH). MS *m*/*z*: 258 (M^+). Anal. calcd. for $C_{16}H_{18}O_3$ (%): C 74.40, H 7.02; found: C 74.59, H 6.86.

General procedure for the cyclization of compounds 4a–4e and 5a, 5b, and 6

$SnCl_4$ (0.13 mL, 2 mmol) and I_2 (512 mg, 2 mmol) were added to a CH_2Cl_2 (10 mL) solution of the compounds **4a**–**4e** or **5a**, **5b**, or **6** (2 mmol) at room temperature. The mixture was then magnetically stirred for 6 h. The mixture was treated with ice-cold water (40 mL), and then washed with 5% $Na_2S_2O_3$ (2 × 20 mL) and water (2 × 20 mL) and dried over Na_2SO_4. The final residual mass after removal of the solvent was subjected to column chromatography over silica gel and the cyclic products were separated out.

Compound 7a

White solid, mp 130–132 °C; yield: 65%. UV (EtOH, nm) λ_{max}: 334, 277, 233. IR (KBr, cm^{-1}) ν_{max}: 1461, 1688, 2958. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.49 (d, J = 7.0 Hz, 3H, CH_3), 2.45 (s, 3H, ArCH_3), 3.35–3.49 (m, 3H, -CH_2I and CH_3CH), 4.54 (dt, J = 7.0, 5.0 Hz, 1H, -OCH), 7.29–7.99 (m, 3H, ArH). ^{13}C NMR ($CDCl_3$, 75.5 MHz) δ: 5.4 (d), 19.6 (q), 20.8 (q), 40.1 (d), 89.7 (t), 98.8 (s), 117.1 (d), 123.7 (s), 125.3 (d), 133.5 (d), 135.5 (s), 151.6 (s), 167.4 (s), 175.2 (s).

Compound 8d

White solid, mp 150–152 °C; yield: 28%. UV (EtOH, nm) λ_{max}: 328, 298, 273, 231. IR (KBr, cm^{-1}) ν_{max}: 756, 1259, 1720. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.38 (d, *J* = 6.8 Hz, 3H, CH_3), 3.39–3.43 (m, 1H, C*H*CH_3), 4.55–4.63 (m, 3H, -OCH_2C*H*I), 7.29–8.18 (m, 4H, Ar*H*). MS *m*/*z*: 242 (M^+). Anal. calcd. for $C_{13}H_{11}O_3I$ (%): C 45.64, H 3.24; found: C 45.49, H 3.41.

© 2005 NRC Canada

Compound 8e

White solid, mp 152–154 °C; yield: 22%. UV (EtOH, nm) λ_{max}: 331, 295, 274, 232. IR (KBr, cm^{-1}) ν_{max}: 756, 1261, 1713. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.38 (s, 9H, $C(CH_3)_3$, 2.97 (dd, J = 16.0, 8.5 Hz, 1H, $=CCH_2$), 3.26 (dd, J = 16.0, 4.6 Hz, 1H, $=CCH_2$), 4.46–4.51 (m, 2H, $-OCH_2$), 4.56–4.59 (m, 1H, CHI), 7.24–7.81 (m, 3H, ArH). MS *m*/*z*: 384 (M^+). Anal. calcd. for $C_{16}H_{17}O_3I$ (%): C 50.02, H 4.46; found: C 50.21, H 4.58.

Compound 10a

White solid, mp 150–152 °C; yield: 32%. UV (EtOH, nm) λ_{max}: 357, 311, 290, 234. IR (KBr, cm^{-1}) ν_{max}: 754, 1296, 1724. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 3.24 (dd, J = 18.0, 8.5 Hz, 1H, $=CCH_2$), 3.49 (dd, J = 18.0, 5.8 Hz, 1H, $=CCH_2$), 4.26 (dd, J = 9.3, 10.8 Hz, 1H, $-OCH_2$), 4.49–4.54 (m, 1H, CHI), 4.55 (dd, J = 10.8, 5.2 Hz, 1H, $-OCH_2$), 7.29–7.45 (m, 4H, ArH). ^{13}C NMR ($CDCl_3$, 75.5 MHz) δ: 13.2 (t), 33.2 (t), 71.9 (d), 116.7 (d), 118.9 (s), 122.1 (d), 122.4 (s), 124.7 (d), 129.0 (d), 138.0 (s), 149.2 (s), 156.6 (s). MS *m*/*z*: 328 (M^+). Anal. calcd. for $C_{12}H_9O_3I$ (%): C 43.93, H 2.76; found: C 43.72, H 2.59.

Compound 10b

White solid, mp 178–180 °C; yield: 30%. UV (EtOH, nm) λ_{max}: 358, 311, 290, 234. IR (KBr, cm^{-1}) ν_{max}: 754, 1285, 1724. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.48 (d, J = 7.0 Hz, 3H, CH_3), 3.56–3.59 (m, 1H, CH_3CH), 4.37–4.48 (m, 3H, OCH_2CHI), 7.28–7.43 (m, 4H, ArH). ^{13}C NMR ($CDCl_3$, 75.5 MHz) δ: 21.2 (t), 22.5 (q), 37.5 (d), 68.2 (d), 117.4 (d), 119.2 (s), 122.6 (d), 124.9 (d), 125.9 (s), 128.9 (d), 137.1 (s), 149.8 (s), 156.8 (s). MS *m*/*z*: 342 (M^+). Anal. calcd. for $C_{13}H_{11}O_3I$ (%): C 45.64, H 3.24; found: C 45.79, H 3.11.

Compound 12

White solid, mp 98–100 °C; yield: 28%. UV (EtOH, nm) λ_{max}: 292, 258, 234, 215. IR (KBr, cm^{-1}) ν_{max}: 977, 1261, 1451, 1582, 1713. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 2.25 (s, 3H, CH_3), 2.87 (dd, J = 16.0, 7.0 Hz, 1H, $=CCH_2$), 3.17 (dd, J = 16.0, 5.0 Hz, 1H, $=CCH_2$), 4.31–4.40 (m, 2H, $-OCH_2$), 4.47–4.52 (m, 1H, ICHCHI), 6.06 (s, 1H, $=CH$). MS *m*/*z*: 292 (M^+). Anal. calcd. for $C_9H_9O_3I$ (%): C 37.01, H 3.11; found: C 37.19, H 3.31.

Dihydropyrimidinones containing boronic acids

Johanna M. Blacquiere, Oana Sicora, Christopher M. Vogels, Miroslava Čuperlović-Culf, Andreas Decken, Rodney J. Ouellette, and Stephen A. Westcott

Abstract: The addition of formylphenylboronic acid derivatives to urea and ethyl acetoacetate proceeds in the absence of an additional Lewis acid catalyst to give the corresponding dihydropyrimidinones (Biginelli products) in good yields. Novel boron-containing dihydropyrimidinones have been investigated for their ability to act as anticancer agents against the breast cancer cell line MCF7.

Key words: anticancer, Biginelli compounds, boronic acids, breast cancer, dihydropyrimidinones.

Résumé : L'addition de dérivés de l'acide formylphénylboronique sur l'urée et l'acétoacétate d'éthyle se produit, même en l'absence d'un catalyseur acide de Lewis additionnel, pour conduire à la formation de dihydropyrimidinones (produits de Biginelli), avec de bons rendements. On a examiné les propriétés antitumorales des nouvelles dihydropyrimidinones contenant du bore en faisant appel à des cellules de cancer du sein de la souche MCF7.

Mots clés : antitumorale, composés de Biginelli, acides boroniques, cancer du sein, dihydropyrimidinones.

[Traduit par la Rédaction]

Introduction

Compounds containing boronic acids [$RB(OH)_2$] or boronate esters [$RB(OR')_2$] have found remarkable utility in Suzuki–Miyaura cross-coupling reactions (1) and as molecular recognition sensors (2). Interest in these compounds also arises from their potent biological activities (3). For instance, boronic-amino acid derivatives (Fig. 1*a*) are strong inhibitors of human arginase II, whose primary function appears to be in L-arginase homeostasis (3*b*). Indeed, related α-aminoboronic acid derivatives are well-known for their ability to act as serine protease inhibitors (3*c*). Serine proteases are a diverse group of proteolytic enzymes whose numerous physiological functions include digestion, growth, differentiation, and apoptosis. Proteases are also vital in the generation of most disease processes. As a result, a considerable amount of research has focussed on these potentially valuable compounds. Analogous amino acids containing boron have been investigated for their use in boron neutron capture therapy (BNCT) for the treatment of cancer (4). BNCT is a bimodal form of therapy that depends on selectively depositing boron-10 atoms into the cancerous tumor prior to irradiation by slow neutrons. 4-Dihydroxyborylphenylalanine (Fig. 1*b*) has shown promise in the treatment of brain tumours (4*b*). Likewise, substituted C_2B_{10} carborane cages have been attached to the sides of single-wall carbon nanotubes. The nanotubes have been used as an attractive nanovehicle for delivering boron to tumour cells in BNCT (4*f*). More relevant to this study, however, is the recent observation that novel boronic-chalcone derivatives (Fig. 1*c*) display considerable activity against human breast cancer cell lines (5).

The Biginelli reaction is a simple and convenient method of preparing dihydropyrimidinones (DHPMs) from the three-component condensation of aliphatic or aromatic aldehydes, acetylacetonate esters, and urea. The original reaction reported by Pietro Biginelli in 1893 was conducted in boiling ethanol using a catalytic amount of concentrated aqueous hydrochloric acid (6*a*). The major drawback of this classical Biginelli reaction is the low to moderate yields, particularly for substituted aromatic or aliphatic aldehydes (6*b*–6*d*). As a result, a considerable amount of research has focussed on using Lewis acid catalysts to improve the efficiency of the Biginelli DHPM synthesis (7). DHPMs are an interesting class of compounds that have extensive pharmacological properties owing, in part, to their similarity to the well-known Hantzsch dihydropyridine calcium channel modulators (8). Of relevance to the present study is the observation that certain DHPMs also display significant anticancer activities (9). For instance, monastrol (Fig. 2) is known to specifically inhibit mitotic kinesin Eg5 and is considered a lead compound in the search for a new anticancer drug (8*a*).

As part of our ongoing investigation into making novel

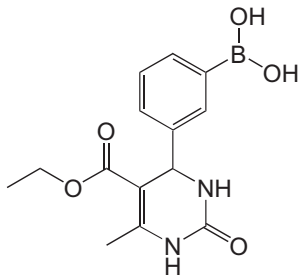
boron compounds (10), and considering the wealth of bioactivities found in aminoboronic acid derivatives, we decided to examine the synthesis and the anticancer properties of Biginelli products derived from formylphenylboronic acids. Initial results are presented herein.

Experimental

General

Reagents and solvents used were obtained from Aldrich Chemicals. ^{1}H and ^{13}C NMR spectra were recorded on a Varian 200 Mercury NMR spectrometer. ^{11}B NMR spectra were recorded on a JEOL JNM-GSX270 FT NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and referenced to residual protons in deuterated solvent at 200 MHz. ^{11}B NMR chemical shifts are referenced to external $F_3B{\cdot}OEt_2$ at 87 MHz. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 50 MHz. Multiplicities are reported as singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), broad (br), and overlapping (ov). Infrared spectra were obtained using a Mattson Genesis FT-IR spectrometer and reported in cm^{-1}. Elemental analyses were performed by Guelph Chemical Laboratories Ltd. (Guelph, Ontario).

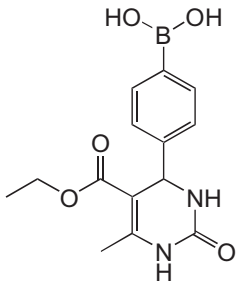


Synthesis

Compound **1**

Compound 1

2-Formylphenylboronic acid (500 mg, 3.3 mmol), ethyl acetoacetate (541 mg, 4.1 mmol), and urea (248 mg, 4.1 mmol) were added together with CH_3CN (12 mL). The reaction mixture was heated at reflux for 24 h, cooled to room temperature, and the solvent removed under vacuum. The mixture was dissolved in MeOH (5 mL) and passed through a silica plug (1 cm). The solvent was removed under vacuum and the resulting solid dried. Yield: 607 mg (60%); mp 192 to 193 °C. FT-IR (Nujol): 3398 (m), 3321 (s), 2920 (s), 2856 (m), 1689 (s), 1643 (s), 1568 (w), 1444 (m), 1371 (m), 1338 (m), 1313 (m), 1228 (m), 1097 (m). ^{1}H NMR (DMSO-d_6) δ: 0.99 (t, J = 7 Hz, 3H, CH_3CH$_2$), 2.26 (s, 3H, CH_3), 3.88 (m, 2H, CH$_3$CH_2), 5.45 (d, J = 2 Hz, 1H, PhCH), 7.03 (br s, 1H, NH), 7.14–7.45 (ov m, 4H, Ar), 8.19 (s, 2H, B(OH)$_2$), 9.18 (br s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 14.7, 18.4, 54.4, 59.8, 100.2, 126.3, 127.0, 130.4, 134.0, 135.6 (br, CB), 148.8, 149.0, 152.1, 166.1. ^{11}B NMR (THF) δ: 29 (br). Anal. calcd. for $C_{14}H_{17}O_5N_2B$ (%): C 55.29, H 5.63, N 9.21; found: C 55.23, H 5.15, N 9.64.

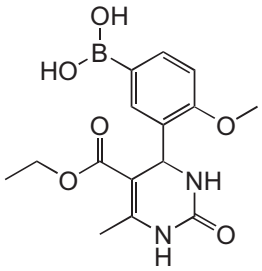


Compound **2**

Compound 2

3-Formylphenylboronic acid (502 mg, 3.3 mmol), ethyl acetoacetate (539 mg, 4.1 mmol), and urea (249 mg, 4.1 mmol) were added together with CH_3CN (12 mL). The reaction mixture was heated at reflux for 46 h, cooled to room temperature, and the solvent removed under vacuum.

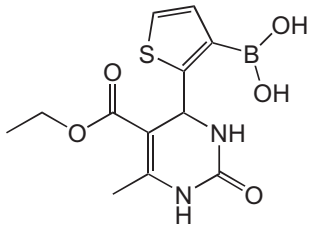
© 2005 NRC Canada



The mixture was dissolved in MeOH (5 mL) and passed through a silica plug (1 cm). The solvent was removed under vacuum and the resulting solid dried. Yield: 769 mg (76%); mp 198–202 °C. FT-IR (Nujol): 3280 (m), 3271 (m), 2951 (s), 2935 (s), 2910 (s), 2856 (s), 1697 (s), 1657 (m), 1462 (m), 1375 (m), 1232 (m), 1103 (m). ^{1}H NMR (DMSO-d_6) δ: 1.06 (t, J = 7 Hz, 3H, CH_3CH$_2$), 2.21 (s, 3H, CH_3), 3.93 (q, J = 7 Hz, 2H, CH$_3$CH_2), 5.10 (d, J = 3 Hz, 1H, PhCH), 7.23 (ov m, 2H, Ar and NH), 7.66 (ov m, 3H, Ar), 7.96 (s, 2H, B(OH)$_2$), 9.10 (br s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 14.7, 18.5, 55.0, 59.8, 100.0, 128.0, 128.8, 133.0, 133.7, 134.9 (br, CB), 144.6, 148.8, 152.7, 166.0. ^{11}B NMR (THF) δ: 27 (br). Anal. calcd. for $C_{14}H_{17}O_5N_2B$ (%): C 55.29, H 5.63, N 9.21; found: C 54.88, H 5.20, N 9.04.

Compound **3**

Compound 3



4-Formylphenylboronic acid (501 mg, 3.3 mmol), ethyl acetoacetate (540 mg, 4.1 mmol), and urea (247 mg, 4.1 mmol) were added together with CH_3CN (10 mL). The reaction mixture was heated at reflux for 55 h, cooled to room temperature, and solvent was removed under vacuum. The resulting solid was washed with H_2O (40 mL) and ether (20 mL). Yield: 818 mg (82%); mp 214–218 °C. FT-IR (Nujol): 3253 (s), 3109 (s), 2939 (s), 2848 (s), 1695 (s), 1610 (m), 1416 (m), 1369 (m), 1331 (s), 1294 (m), 1238 (s), 1090 (m), 773 (m), 708 (m). ^{1}H NMR (DMSO-d_6) δ: 1.09 (t, J = 7 Hz, 3H, CH_3CH$_2$), 2.24 (s, 3H, CH_3), 3.97 (q, J = 7 Hz, 2H, CH$_3$CH_2), 5.14 (d, J = 3 Hz, 1H, PhCH), 7.16 (d, J = 7 Hz, 2H, Ar), 7.65–7.96 (ov m, 3H, NH and Ar), 8.02 (s, 2H, CB(OH)$_2$), 9.13 (br s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 14.7, 18.5, 54.6, 59.9, 99.8, 126.0, 134.7 (br, CB), 134.9, 147.2, 149.0, 152.8, 166.0. ^{11}B NMR (THF) δ: 27 (br). Anal. calcd. for $C_{14}H_{17}O_5N_2B$ (%): C 55.29, H 5.63, N 9.21; found: C 55.32, H 5.97, N 8.84.

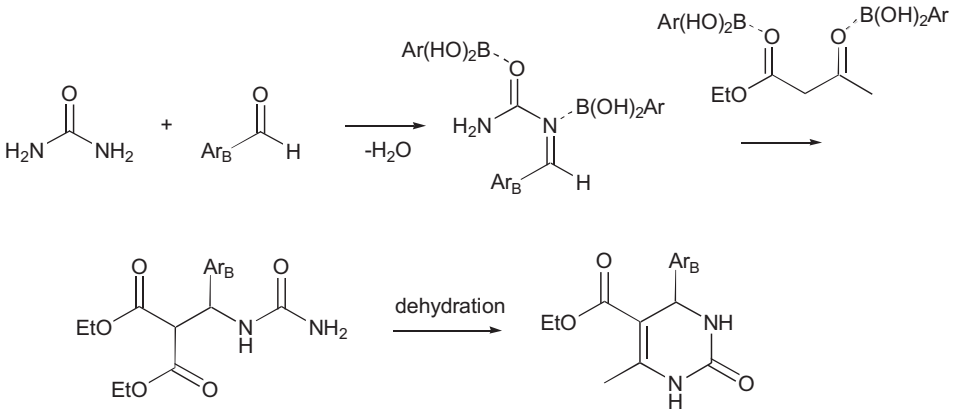
Compound **4**

Compound 4

3-Formyl-4-methoxyphenylboronic acid (501 mg, 2.8 mmol), ethyl acetoacetate (453 mg, 3.4 mmol), and urea (205 mg, 3.4 mmol) were added together with CH_3CN (11 mL). The reaction mixture was heated at reflux for 41 h, cooled to room temperature, and the solvent removed under vacuum. The mixture was dissolved in wet MeOH (5 mL) and passed through a silica plug (1 cm). The solvent was removed under vacuum and the resulting solid dried. Yield: 601 mg (65%); mp 196–199 °C. FT-IR (Nujol): 3319 (s), 3253 (m), 2919 (s), 2854 (s), 1705 (s), 1668 (s), 1601 (m), 1460 (m), 1394 (m), 1365 (s), 1335 (m), 1292 (m), 1246 (s), 1099 (m), 771 (w). ^{1}H NMR (DMSO-d_6) δ: 0.98 (t, J = 7 Hz, 3H, CH_3CH$_2$), 2.24 (s, 3H, CH_3), 3.76 (s, 3H, CH_3O), 3.86 (q, J = 7 Hz, 2H, CH$_3$CH_2), 5.45 (d, J = 2 Hz, 1H, PhCH), 6.91 (d, J = 8 Hz, 1H, Ar), 7.17 (br s, 1H, NH), 7.49 (d, J = 2 Hz, 1H, Ar), 7.66 (dd, J = 8, 2 Hz, 1H, Ar), 7.80 (s, 2H, B(OH)$_2$), 9.04 (br s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 14.6, 18.5, 49.9, 55.9, 59.6, 98.1, 110.7, 125.7 (br, CB), 131.3, 134.4, 135.8, 149.4, 152.8, 159.0, 166.1. ^{11}B NMR (DMF) δ: 28 (br). Anal. calcd. for $C_{15}H_{19}O_6N_2B\cdot 1H_2O$ (%): C 51.15, H 6.02, N 7.96; found: C 51.82, H 5.91, N 7.89.

Compound **5**

Compound 5



2-Formyl-3-thiopheneboronic acid (500 mg, 3.2 mmol), ethyl acetoacetate (507 mg, 4.0 mmol), and urea (239 mg, 4.0 mmol) were added together with CH_3CN (10 mL). The reaction mixture was heated at reflux for 41 h, cooled to room temperature, and the solvent was removed under vacuum. The solid was washed with H_2O (5 mL) and dried. Yield: 597 mg (60%); mp 158–160 °C. FT-IR (Nujol): 3392 (m), 3338 (m), 3288 (m), 3232 (m), 3109 (m), 2951 (s), 2926 (s), 2856 (s), 1699 (s), 1686 (s), 1460 (m), 1421 (m), 1365 (m), 1342 (m), 1319 (m), 1290 (m), 1236 (s), 1099 (m), 1068 (m), 897 (w), 777 (m), 713 (w). ^{1}H NMR (DMSO-d_6) δ: 1.03 (t, J = 7 Hz, 3H, CH_3CH$_2$), 2.23 (s, 3H, CH_3), 3.94 (q, J = 7 Hz, 2H, CH$_3$CH_2), 5.81 (d, J = 2 Hz, 1H, PhCH), 7.06 (br s, 1H, NH), 7.21 (s, 2H, Ar), 8.20 (s, 2H, B(OH)$_2$), 9.33 (br s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 14.7, 18.4, 49.6, 59.9, 100.7, 123.6, 133.5 (br, CB), 134.1, 149.8, 152.5, 158.6, 165.9. ^{11}B NMR (THF) δ: 27 (br). Anal. calcd. for $C_{12}H_{15}O_5N_2BS$ (%): C 46.48, H 4.88, N 9.03; found: C 46.54, H 4.75, N 9.06.

X-ray crystallography

Crystals of **1** and **5** were grown from satd. CH_3CN solutions at 20 °C. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold stream of the goniometer. A hemisphere of data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and exposure times of 30 s (**1**) and 10 s (**5**). The detector distances were 5 cm. The data were reduced (11*a*) and corrected for absorption (11*b*). The structures were solved by direct methods and

refined by full-matrix least-squares on F^2 (11*c*). All nonhydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically.

Biological studies

Cell culture

MCF7 (human breast cancer) cell line was obtained from American Type Culture Collection and grown in optimal medium (DMEM supplemented with 10% FBS, 2 mmol/L L-glutamin and 50 μg/mL gentamicin).

Cell growth inhibition assay

Cells were seeded in 96-well plates at a concentration of 1×10^5 cells/mL in 100 μL of complete media and incubated for 24 h at 37 °C in a 5% CO_2 atmosphere to allow for cell adhesion. The stock solutions of compounds **1**–**3** and **5** were made in EtOH. Compound **4** was not soluble in EtOH and therefore not tested. Stock solutions of compounds **1** and **3** were prepared at 20 mg/mL. Compound **2** and **5** stock solutions were prepared as 33.3 and 7.7 mg/mL, respectively. The stock solutions were first sterilized and then diluted with EtOH to final concentrations between 20 and 0.07 μg/μL for compounds **1** and **3**, 33.3 and 0.1 μg/μL for compound **2**, and 7.7 and 0.06 μg/μL for compound **5**. Solutions of compound **1** and **3** were diluted 10× in fresh medium and testing was performed with 100 μL of solution added to 100 μL of fresh medium. Compound **2** was diluted 3.33× in fresh medium and testing was done with 20 μL of solution added to 180 μL of fresh medium. Compound **5** was diluted 7.7× in fresh medium and from this dilution 100 μL was added to 100 μL of medium. All assays were performed in quadruplicate tests. The control group for each compound contained only EtOH in the medium in the same concentration as in the compound solutions. The cells were incubated in the solution for 24 h, and the evaluation of cell proliferation was performed by the MTT colorimetric assay.

MTT colorimetric assay

MTT solution (8 μL, 4 mg/mL in PBS, Sigma Chemical Co.) along with 50 μL of fresh, complete media was added to each well and plates were incubated for 3 h. Following incubation, the purple formazan precipitate in each well was solubilized in 120 μL lysis buffer (5% Triton X-100, 0.37% HCl in isopropanol). Absorbance was measured using a SpectroMax microplate reader (Molecular Devices) at 570 nm. The reduction of cell proliferation was determined as a fraction of the absorbance values for each drug treatment (*T*) and the mean absorbance of the nondrug control (*C*) and calculated using the expression $1 - (T/C) \times 100\%$.

IC_{50} determination

Stock solutions of selected compounds were freshly prepared. The nine step dilutions were prepared in EtOH as described earlier. The final range of concentrations used was 1 mg/mL to 3 μg/mL. Approximate IC_{50} values were obtained graphically using Excel Software from the control-corrected values of the MTT colorimetric assay.

Results and discussion

In this study, we have found that commercially available aldehydes containing boronic acids add to ethyl acetylacetonate ester and urea in *the absence of an additional Lewis acid* to give moderate to high yields of the desired boron-containing Biginelli products (Fig. 2). It appears that the boronic acid group in the aldehydes acts to mediate this reaction, presumably in a manner similar to that reported for other Lewis acid catalyzed Biginelli reactions (12). The Lewis acidic boron atom presumably activates the transient imine nitrogen, the carbonyl oxygens of the urea, and the β-keto ester through coordination (Scheme 1). An excellent review by Ishihara and Yamamoto (13*a*) describes the use of arylboron compounds as Lewis acid catalysts in organic transformation. Although other Lewis acids, such as LiBr, could also be used to facilitate this reaction, no significant improvement in product yields were observed.

All new compounds have been characterized by a number of physical methods including multinuclear NMR spectroscopy. A broad peak at around 30 ppm in the ^{11}B NMR spectra suggests that the boron atom lies in a three-coordinate environment in solution (14), even for the ortho derivatives **1** and **5**. This result is somewhat surprising in light of boron's propensity to form coordinate bonds with Lewis basic atoms (15). Previous studies have shown that compounds containing boronic acids can be extremely difficult to characterize in terms of elemental composition, owing to the ease with which they partially dehydrate to the corresponding trimeric and oligomeric anhydrides (16). Compounds **1** and **5** have

[b] $wR2 = (\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[F_o^4])^{1/2}$, where $w = 1/[\sigma^2(F_o^2) + (0.0787P)^2 + (0.2917P)]$ (**1**) and $w = 1/[\sigma^2(F_o^2) + (0.0691P)^2 + (0.2521P)]$ (**5**), where $P = (\max(F_o^2, 0) + 2F_c^2)/3$.

therefore been characterized by X-ray diffraction studies and crystallographic data[4] are given in Table 1. The molecular structure of **1** is shown in Fig. 3 and compound **5** is shown in Fig. 4. The B—O bond distances of B(3)—O(1) (1.370(2) Å) and B(3)—O(2) (1.356(2) Å) for **1** and B(3)—O(1) (1.367(2) Å) and B(3)—O(2) (1.359(2) Å) for **5** are typical for those observed in related structures where the boron is three coordinate (17). Likewise, the sum of the angles around boron for **1** are 360.0(1)° and 360.1(1)° for **5**, indicating that both boron atoms are three coordinate. Bond distances and angles for the six-membered ring are similar to those reported for analogous compounds (18).

As mentioned previously, DHPMs are biologically active compounds and several, such as monastrol, are potent anticancer agents. With this in mind, we have examined four new boron Biginelli compounds for their potential antitumour activity. Breast cancer is the most common form of cancer among women and is the second leading cause of cancer-related death in women of the western world. The identification of an optimal treatment for breast cancer is therefore of crucial importance. In this context, the most often utilized method for the initial testing of potential drug activity is performed on breast cancer cell lines (19*a*). MCF7 cell lines have been used frequently as standards for various cell culture testing experiments (19*b*, 19*c*).

Selected bond lengths (Å) and angles (°): B(3)—O(2) 1.359(2), B(3)—O(1) 1.367(2), B(3)—C(4) 1.568(2), O(12)—C(11) 1.234(2); O(2)-B(3)-O(1) 118.2(1), O(2)-B(3)-C(4) 118.8(1), O(1)-B(3)-C(4) 123.1(1), C(11)-N(13)-C(14) 124.2(1), C(11)-N(10)-C(9) 126.5(1), O(12)-C(11)-N(13) 119.7(1).

Initial studies of boron compounds were tested against the MCF7 breast cancer cell line. When the boron compounds **1**–**5** were dissolved in DMSO, a significant decrease in activity was observed the longer these compounds stayed in this media. This result suggests that DMSO may be reacting with, and deactivating, the compounds and is not surprising as the strongly coordinating DMSO solvent can interact with the three-coordinate boron atom. Indeed, we have found that addition of excess DMSO to these compounds gave a number of identified products. Unfortunately, the insolubility of compound **4** in other media precluded testing at this time. All four compounds (**1**–**3** and **5**) tested in EtOH, however, have shown some level of activity against the cells at their highest concentrations (Fig. 5). Unfortunately, the low solubility of compounds **1**–**3** prevented further investigation at higher concentrations, therefore the respective IC_{50} concentrations are unattainable. The thiophene derivative **5** was significantly more active with respect to the other compounds. The reduction of cell proliferation caused by **5** is given as the average % reduction of the cell proliferation of MCF7 cells relative to the EtOH treated controls (Table 2). The effect of the compound at low concentrations is negligible but becomes significant above ca. 15 μg/mL. The estimated IC_{50} value relative to the control group (cells exposed to EtOH only) for compound **5** is ca. 0.46 mmol/L (140 μg/mL). Although the IC_{50} value determined is relatively large, these initial studies show that the thiophene derivative **5** has potential as an agent against the breast cancer cell line. Further in vitro studies are underway to address the activity of this compound against other breast cancer cell lines.

Conclusion

We have prepared new boron-containing DHPMs in moderate yields, and reactions proceed without the need of an additional Lewis acid catalyst. These initial compounds have also been examined for their ability to inhibit the MCF7 breast cancer cell line. Although compounds **1**–**4** suffered from poor solubilities, tests with the thiophene derivative **5** showed considerable promise. Future work in this area will focus on making more soluble thiophene derivatives as well as boron-containing DHPMs derived from thiourea, the results of which will be published in due course.

A convenient solid-phase synthesis methodology for preparing peptide-derived molecular imaging agents — Synthesis, characterization, and in vitro screening of Tc(I) – chemotactic peptide conjugates

Karin A. Stephenson, Sangeeta Ray Banerjee, Nicole McFarlane, Douglas R. Boreham, Kevin P. Maresca, John W. Babich, Jon Zubieta, and John F. Valliant

Abstract: A versatile solid-phase synthesis strategy for preparing peptide–chelate conjugates was developed. The methodology was optimized using a series of ligands, designed to bind Tc(I)/Re(I), and a chemotactic peptide fMFL, which was exploited as a model targeting vector. The peptide derivatives were prepared in parallel using a conventional automated peptide synthesizer in multi-milligram quantities, which provided sufficient material to perform complete characterization, radiolabelling, and in vitro screening studies. Because of the robust nature of the metal–chelate complexes, the Re complex of a chelate–peptide conjugate was prepared on the resin using the same methodology employed to prepare the free ligand conjugates. As such, the reported methodology is amenable to the preparation of libraries of novel Tc radiopharmaceutical ligands and their corresponding Re reference standards in which several factors, including peptide sequence, site of derivatization, and both the type and length of the spacer, can be easily varied.

Key words: radiopharmaceuticals, technetium, rhenium, peptides, solid-phase synthesis.

Résumé : On a développé une stratégie versatile de synthèse en phase solide de produits conjugués peptide–chélate. On a optimisé la méthodologie en utilisant une série de ligands qui ont été développés pour se lier au Tc(I)/Re(I) et au peptide chimiotactique fMFL qui a été exploité comme vecteur modèle de ciblage. On a préparé les dérivés peptidiques en parallèle en faisant appel à un synthétiseur automatique conventionnel de peptides à des niveaux de plusieurs milligrammes, ce qui fournissait des quantités suffisantes de matériel pour en faire une caractérisation complète, un marquage radiochimique et des études in vitro. En raison du fait que les complexes métal–chélate sont très robustes, un complexe du Re d'un produit conjugué chélate peptide a été préparé sur la résine en faisant appel à la même méthodologie qui avait été utilisée pour préparer les conjugués libres du ligand. De cette façon, la méthodologie qui a été mise au point peut être amener à la préparation de librairies de nouveaux ligands radiopharmaceutiques du Tc et des produits de référence du Re dans lesquels il est possible de faire varier plusieurs facteurs, y compris la séquence peptidique, le site de formation du dérivé ainsi que le type et la longueur du groupe d'écartement.

Mots clés : radiopharmaceutiques, technitium, rhénium, peptides, synthèse en phase solide.

[Traduit par la Rédaction]

Introduction

Small peptides have been shown to be highly effective targeting agents for delivering radionuclides to specific receptors, including those associated with tumours, infection, and thrombosis (1–8). Peptides are able to reach their target rapidly, thus avoiding the need to use radionuclides with excessively long half-lives, and they typically clear from nontarget tissues quickly, which improves image contrast and quality (1, 9). Peptides can be prepared in a cost-effective manner via automated solid-phase synthesis, and they can be designed to target practically any receptor (10–12).

The traditional strategy for linking radiometals to peptides involves appending a bifunctional chelate (BFC) to either the N or C termini of the peptide. This was typically performed in solution (1, 6), which can lead to numerous side products, particularly if lysine residues are present in the peptide. To avoid the poor regioselectivity of this approach, which often results in the need to employ extensive HPLC purification to isolate the desired product (13), several groups began to exploit the advantages of solid-phase synthesis (SPS) to prepare peptide–ligand conjugates directly on polymer supports

(14, 15). Using this approach, orthogonal protecting groups can be employed, and large excesses of reagents can be used to drive reactions to completion while byproducts are removed by simple filtration (10, 15–17). SPS of this type is amenable to automation and can therefore be used to prepare libraries of compounds (18–21).

Current SPS methods used to prepare peptide-targeted radiotracers derived from ^{99m}Tc (the most widely used radionuclide in diagnostic medicine (22–24)) typically involve conjugating a ligand to the N-terminus of the resin-bound peptide. For instance, Hoffman and co-workers (25) prepared a series of bombesin derivatives using N_3S triamide chelates linked to the N-terminal amino acid through different spacer groups. Egli et al. (26) attached a protected histidine derivative to the N-terminus of neurotensin as a way of tagging the peptide with the $[^{99m}Tc(CO)_3]^+$ core. More recently, two strategies for incorporating ligands within the backbone of the peptide have been reported. Blower and co-workers (15) prepared a derivative of Fmoc-lysine that contained a hydrazine substituent as a way of incorporating a ^{99m}Tc binding ligand within peptides. We recently reported the synthesis of amino acid derived chelates for Tc(I), which can also be incorporated regioselectively into the backbone of a peptide (17, 27). A unique feature of this system is that the Re complex can be prepared in parallel with the free ligand, owing to the stability of the low spin d^6 Re(I) complex.

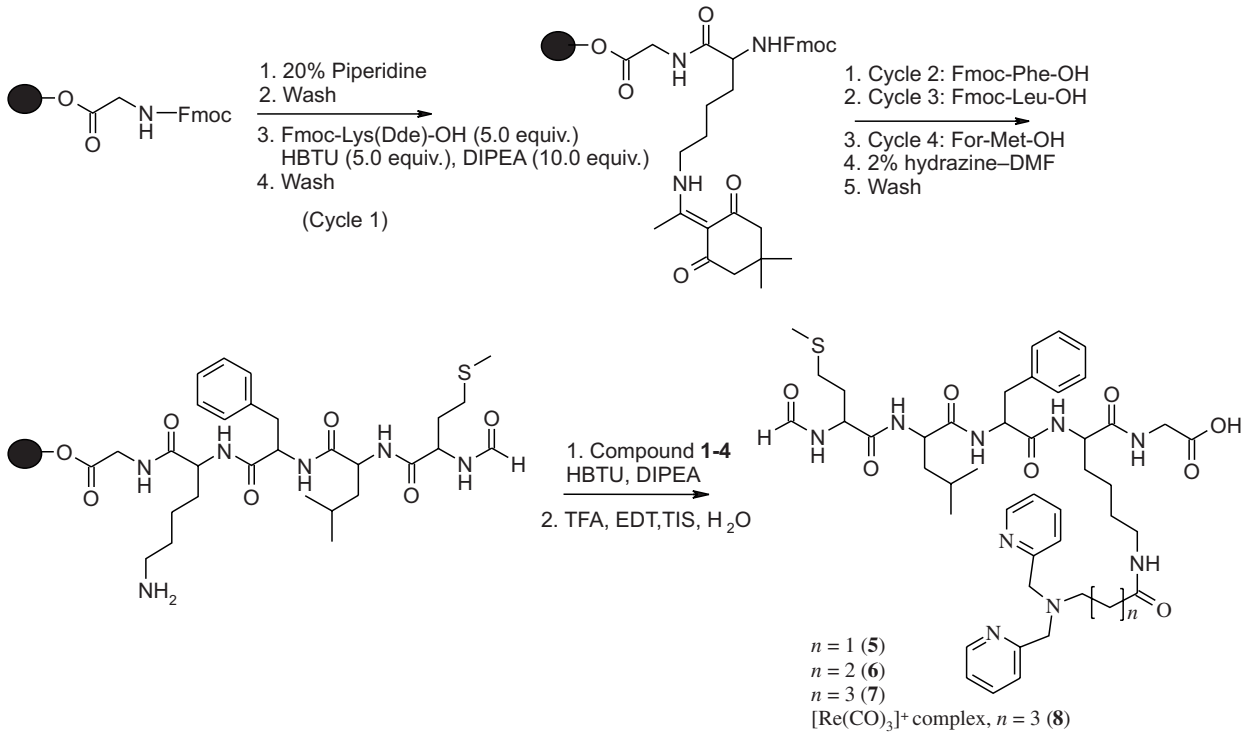
This paper describes a new approach for preparing peptide–Tc ligand conjugates. The reported method is attractive in that a chelate can be attached at any position within the backbone of the peptide and not simply to the terminal amino or acid groups. Specifically, the approach involves using an on-resin orthogonal protecting group strategy, where a Tc(I) chelate is linked to a specific lysine residue. This methodology will ultimately be useful for creating libraries of tracers as a means of rapidly identifying new radiopharmaceuticals.

Experimental section

Unless otherwise stated, all reagents and solvents were ACS grade or higher and used without further purification. Polystyrene-based *N*-α-9-fluorenylmethoxycarbonyl (Fmoc)-glycine loaded SASRIN resin (0.69 mmol/g, 1% divinylbenzene, 200–400 mesh) was obtained from Bachem Inc. Fmoc-protected amino acids were purchased from NovaBiochem Inc., Bachem Inc., and Advanced ChemTech Inc. Fluorescein-labelled fNLFNTK was purchased from Molecular Probes Inc. (product No. F-1314).

Peptides were analyzed by electrospray mass spectrometry using a Micromass Quattro Ultima instrument in positive ion mode. Samples were dissolved in 50:50 ACN–H_2O prior to analysis. FT IR spectra were acquired on a Bio-Rad FTS-40 FT IR spectrometer. Analytical HPLC on nonradioactive compounds was performed using a Varian Pro Star model 330 PDA detector, model 230 solvent delivery system, and a C-18 Microsorb column (4.6 × 250 mm, 300 Å – 5 μm). Semipreparative HPLC on nonradioactive compounds was carried out using a Varian Pro Star HPLC fitted with a model 320 UV detector, a model 215 solvent delivery system, and a C-18 Microsorb column (10 × 250 mm, 300 Å – 5 μm). The elution protocol for both analytical and semipreparative experiments was a linear gradient of from 25% acetonitrile containing 0.1% TFA to 50% acetonitrile containing 0.1% TFA over 15 min. The flow rates were 1.0 and 4.2 mL/min for the analytical and semipreparative experiments, respectively. All HPLC experiments were monitored at λ = 254 and 214 nm. Radio–HPLC experiments were performed on a Varian Prostar HPLC equipped with an autosampler (model 410), a UV–vis detector (model 345), an NaI radiometric detector, Prostar Pumps (model 210), and a Vydac C18 25 cm × 4.6 mm column (5 μm pore size) fitted with a 2 cm guard column. The mobile phase consisted of the following: solvent A = pH 2–2.5 triethylammonium phosphate buffer (7 mL NEt_3, 4 mL concd. H_3PO_4 in 1000 mL water); solvent B = CH_3OH. The method employed a gradient run over 30 min at a flow rate of 1 mL/min. The gradient ramped from 5% to 100% B, beginning at 3 min and ending at 20 min.

Solid-phase peptide synthesis



Fmoc-glycine loaded SASRIN resin (150 mg/well, 0.69 mmol/g) was added to four wells of an Advanced ChemTech 348 automated synthesizer, suspended in DMF (2 mL/well), and shaken at 600 rpm for 1 min. The wells were subsequently filtered, suspended in THF (2 mL/well), shaken at 600 rpm for 1 min, and drained for 90 s. The THF wash was repeated two more times. The DMF wash was then repeated a final two times to complete the general wash cycle. This procedure was used between every deprotection and coupling step. Fmoc deprotection was accomplished through the addition of a 20% *v*/*v* piperidine–DMF solution to the active vessels (2 mL/well) and shaking for 5 min at 600 rpm. Following filtration, the process was repeated, but with shaking for 10 min. The deprotected resin-bound amino acid was washed using the general wash procedure and subsequently coupled to the next Fmoc-protected amino acid using a standard HBTU coupling technique. A "cycle", according to Scheme 1, consists of Fmoc deprotection, a wash, and coupling the specified amino acid, followed by an additional wash.

Coupling reactions initially involved adding DMF (200 μL) to the active vessels followed by a fivefold excess of the protected amino acid as a 0.5 mol/L solution in DMF. Five equivalents of HBTU as a 0.5 mol/L solution in DMF were then added, followed by a 10-fold excess of DIPEA as 2.0 mol/L solution in DMF. The reaction block was subsequently shaken for 80 min at 600 rpm. Following filtration, the resin was washed using the general washing procedure prior to the start of the next cycle. Dde deprotection was accomplished through the addition of a 2% *v*/*v* hydrazine–DMF solution to the active vessels (2 mL/well) and shaking for 5 min at 600 rpm. Following filtration, the process was repeated, with shaking for 10 min. The free ε amine was then subjected to the general wash cycle and coupled to the desired chelate using the HBTU protocol described above, which was followed with a final wash.

Peptides were cleaved from the resin using a cocktail of TFA containing (*v*/*v*/*v*) EDT (2%), water (2%), and TIS (2%). The cleavage cocktail, cooled to 0 °C, was added to the resin, and the mixture was allowed to warm to room temperature over 60 min. The suspension was filtered into

cold diethyl ether, and the resulting heterogeneous solution was centrifuged at 3000 rpm and –5 °C for 10 min. The resulting pellet was washed with cold ether (3 × 25 mL), dissolved in distilled–deionized water, and lyophilized, yielding a white solid.

Preparation of fMLFK(4m-Tc(CO)$_3^+$)G (9)

Technetium-99m was obtained in saline from a commercial ^{99}Mo/^{99m}Tc generator (Cardinal Health), and $[^{99m}Tc(CO)_3(H_2O)_3]^+$ was prepared using the commercially available Isolink kits (Mallinckrodt). Compound **7** (0.1 mg, 0.11 μmol) and 370 MBq (10 mCi) $[^{99m}Tc(CO)_3(H_2O)_3]^+$ were combined and heated at 75 °C for 60 min. After cooling to room temperature, the product was purified by HPLC (R_t = 12.1 min).

Ligand challenge experiments

Compound **9** in methanol (50 μL) and PBS buffer (1 mL, pH 7.2) was added to 0.1 mol/L solutions of cysteine in PBS buffer (pH 7.2) and histidine in PBS buffer (pH 7.2). The solutions were incubated at 37 °C for 24 h.

Leukocyte preparation

Whole human blood (10–15 mL) was collected in vacutainer tubes (Becton Dickinson) containing sodium heparin. The red blood cells were lysed using a modified ammonium chloride method (1 part whole blood to 23 parts 0.145 mol/L ammonium chloride solution containing 1.5 mmol/L potassium bicarbonate and 0.1 mmol/L EDTA). Tubes were incubated at room temperature for 15 min and then centrifuged in a Beckman Coulter Allegra 6R centrifuge at 900 rpm (400 g) for 7 min at 5 °C. The supernatant was removed, and the pellet of leukocytes were subsequently resuspended in Hank's Balanced Salt Solution (HBSS), containing 0.1% BSA, 10 mmol/L HEPES, and 1.5 mmol/L $CaCl_2$ (HBSS+). The cells were spun for 7 min at 400 g at 5 °C, the supernatant was removed, and the pellet was resuspended in HBSS+. Cell counts were performed using a hemacytometer and a Beckman Coulter Z2 Coulter particle count and size analyzer. Cell concentrations were adjusted to 2×10^6 mL^{-1}.

Flow cytometry

Samples were run on a Beckman Coulter EPICS XL, equipped with an argon laser (488 nm excitation wavelength). Fluorescence was measured using a 525 ± 15 nm band pass filter. The flow cytometer was calibrated with fluorescein isothiocyanate (FITC)-labeled beads (Quantum 26 beads, Bangs Laboratories, Inc, Fishers, Indiana) prior to sample analysis. The fluorescence intensity of the standard was provided by the manufacturer in units of molecules of equivalent soluble fluorochrome (MESF) and ranged from 5300 to 468 800. A linear fit of MESF vs. mean channel number of the beads was used to convert all subsequent mean channel values to MESF values.

Equilibrium-binding assay

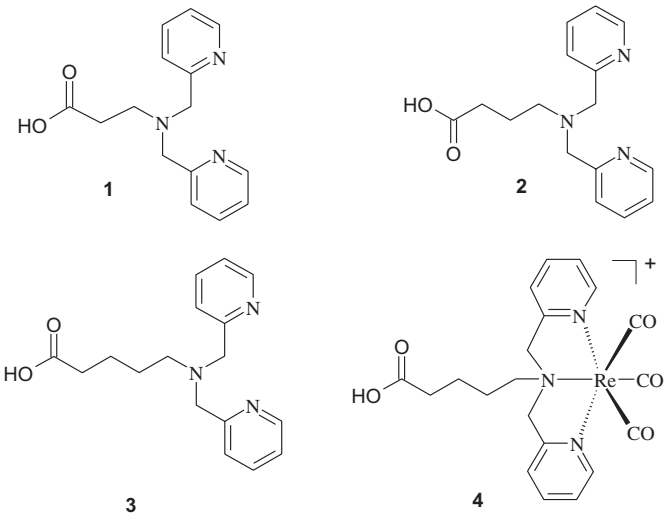
The equilibrium-binding assay was used to determine the number of formyl peptide receptors (FPRs) on the surface of the neutrophils and the dissociation constant (K_d) of the fluorescein-labeled fNLFNTK (Molecular Probes) by preparing a saturated binding curve of peptide concentrations vs. fluorescence intensity (28, 29). Peptide stock solutions were made by dissolving the peptide derivative in DMSO and then diluting with HBSS+ to the desired concentrations, ensuring the concentration of DMSO was less than 0.1%. Cells at 1×10^6 mL^{-1} were equilibrated with 0.25, 0.50, 1.0, 3.0, 5.0, 10.0, and 20.0 nmol/L solutions of the peptide de-

© 2005 NRC Canada

rivative (L) in duplicate. The samples were incubated for 2 h at 4 °C in the dark and then run on the flow cytometer. Granulocytes were gated on the basis of forward and side scatter parameters using Expo 32 ADC software (Beckman Coulter). All samples were repeated in the presence of 30 μmol/L fMLF to account for nonspecific binding. The number of receptor–ligand complexes per cell (*B*) was determined using the following equation, where Q is a normalization factor used by Waller and *F* is the total fluorescence per cell:

$$B\,(\text{in ligand bound per cell}) = F\left(\frac{\text{MESF}}{\text{cell}}\right)\times \text{Q}$$

The level of nonspecific binding did not vary significantly with concentration of labeled peptide; thus, an average value of nonspecific binding was subtracted from the total fluorescence per cell, *F*, when determining the number of receptor–ligand complexes. The total number of *N*-formyl peptide receptors, R_{tot}, and the equilibrium dissociation constant, K_d, were evaluated by minimizing the squared residual of the equilibrium solution using a one-site binding model. The values of R_{tot} and K_d for each donor were solved simultaneously.



Results and discussion

The aim of this study was to develop a versatile bioconjugation strategy in which Tc ligands could be linked to peptides using a conventional automated peptide synthesizer. The method entailed incorporating lysine into the backbone of a peptide in such a manner that the ε-nitrogen could be selectively liberated and a Tc chelate added while the peptide was still linked to the resin. Using this approach, a number of important structural features, including the position and nature of the chelate, can be easily varied.

The blocking group selected for the ε-nitrogen of lysine was the 1-(4,4-dimethyl-2,6-dioxocyclohexyldiene)ethyl (Dde) protecting group, which is stable to the conditions used in typical Fmoc solid-phase synthesis, and which can be selectively liberated without affecting Boc protecting groups (30–32). The planned approach is amenable to any bifunctional chelating system containing a pendent acid group; however, for the work described here a series of dipyridyl amine ligands with linker arms of varying length were employed (Fig. 1) (17). These ligands form stable complexes with Tc(I), and their Re(I) complexes are sufficiently robust that the metal complex can be incorporated into peptides using the same methodology employed for the free ligand (33–37).

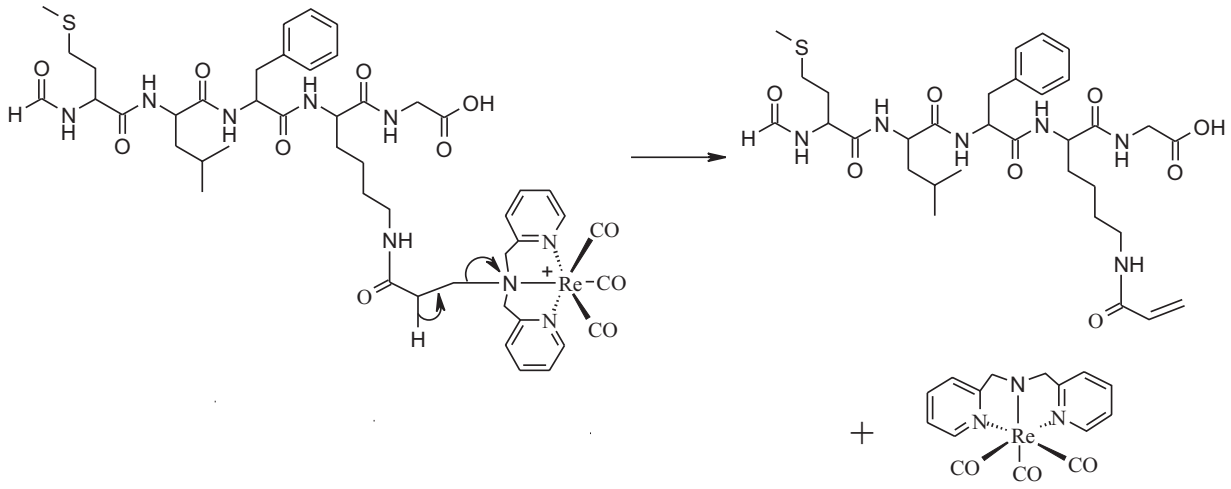
To develop the approach, the chemotactic peptide fMLFKG, which binds to the formyl peptide receptor (FPR) expressed on granulocytes, was used as a model system. Labelled versions of fMLF have shown potential utility for imaging sites of infection and inflammation (38–47). fMLF bioconjugates have traditionally been prepared in solution by conjugating hydrazine-type ligands (HYNIC) to the ε amine of fMLFK. This approach is not easily amenable to preparing libraries of fMLF derivatives, which would accelerate the process of identifying the appropriate derivative for clinical applications.

Fig. 1. Tc(I)/Re(I) ligands and the Re(I) complex of **3**.

The peptide fMLFK(Dde)G was prepared on an Advanced ChemTech 348 synthesizer using standard Fmoc–HBTU protecting groups – coupling protocols (Scheme 1). The Dde protecting group was removed by employing 2% hydrazine in DMF, and the reaction time was optimized using ninhydrin to ensure complete deprotection (48). Following removal of the Dde protecting group, the bifunctional chelates (**1**–**3**) were coupled to the resin-bound peptides using HBTU and DIPEA, and reaction times were again monitored to ensure complete coupling (48). The time required (80 min) for conversion to the desired product did not differ from standard amino acid coupling procedures.

Peptide conjugates **5**–**7** were cleaved from the resin using a cleavage cocktail containing 94% TFA, 2% triisopropylsilane, 2% ethanedithiol, and 2% water. Nitrogen was bubbled through the cocktail at 0 °C prior to and during use, to help prevent oxidation of methionine. Peptides were precipitated by trituration with cold diethyl ether and centrifuged, and the resulting pellet was washed with cold ether to remove any trace of the cleavage cocktail. Precipitates were then dissolved in distilled water and lyophilized to yield white solids.

Peptides **5**–**7** were analyzed using electrospray mass spectrometry (ESMS), and in each case the observed molecular ion was consistent with the mass of the desired compound (Table 1). Analytical HPLC and LC–MS studies of each peptide indicated the presence of two peaks in a 3:1 ratio, corresponding to the same *m*/*z* values. Previous studies in our group and by others showed that the two peaks in the HPLC chromatogram are the result of epimerization of methionine, which is promoted by the electron-withdrawing nature of the formyl group (17, 49). Notwithstanding, the two isomers were readily separated using semipreparative HPLC.



One of the advantages of using M(I) (M = Tc, Re) ligands for methods involving solid-phase synthesis is the ability to prepare the Re complex in parallel with compounds containing the free ligand. Preparation of Re complexes is vitally important as they are needed for proper characterization of the ^{99m}Tc-analogues and for performing in vitro screening studies. For the method described here, the Re complex of **7**

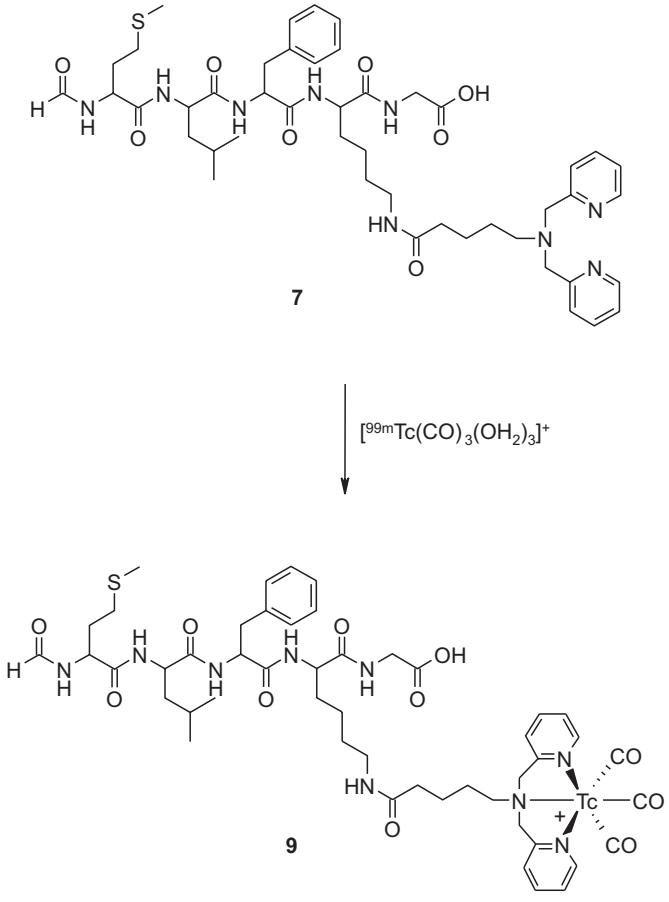
Table 1. HPLC and ESMS data for compounds **5**–**8**.

Compound number	Elution time (min)	Found *m/z*	Calcd. *m/z*	Yield (%)	νCO (cm^{-1})
5	6.6	876.4	876.1	34	—
6	6.5	890.5	890.1	35	—
7	6.9	904.5	904.1	33	—
8	8.7	1174.4	1174.3	30	1933, 2041

Fig. 2. Proposed mechanism for the degradation of an Re(I)–peptide conjugate.



(**8**) was prepared successfully in parallel with the synthesis of compounds **5**–**7**, without modifying the basic strategy. After cleavage of the conjugate from the resin using the same cocktail described above, the product was isolated in comparable yields to the free ligands. Mass spectrometry clearly indicated the presence of the desired product (**8**), while IR showed two distinct metal CO stretches (1933 and 2041 cm^{-1}), which are consistent with values reported for analogous Re complexes (17, 33–37).

As an aside, attempts to prepare the peptide containing the Re(I) complex of **1** lead to a complex mixture of products according to HPLC. MS analysis of the precipitate formed after the addition of ether to the reaction mixture indicated the presence of the target compound, along with several degradation products. The likely cause of these impurities is elimination to form an αβ-unsaturated amide, which concomitantly results in liberation of a neutral metal complex (Fig. 2). By-products of this nature were not observed for the other ligands.

To ensure the products from the solid-phase synthesis can be radiolabeled, compound **7** (100 μg) was combined with 370 MBq (10 mCi) of $[^{99m}Tc(CO)_3(OH_2)]^+$, which was prepared using the commercially available Isolink kit (Scheme 2). After 60 min at 75 °C, the desired product **9** was isolated by HPLC in greater than 98% radiochemical purity in 63% radiochemical yield. Analytical HPLC of the purified product is shown in Fig. 3. The stability of the purified peptide **9** towards metal substitution was tested using a large excess of cysteine and histidine. The peptide and the two amino acids were heated at 37 °C for 24 h, whereupon HPLC analysis showed that the product was intact in both cases and that the radiochemical purities remained above 95% (Fig. 4).

Scheme 2. Synthesis of fMLFK(4m-$Tc(CO)_3^+$)G (**9**).

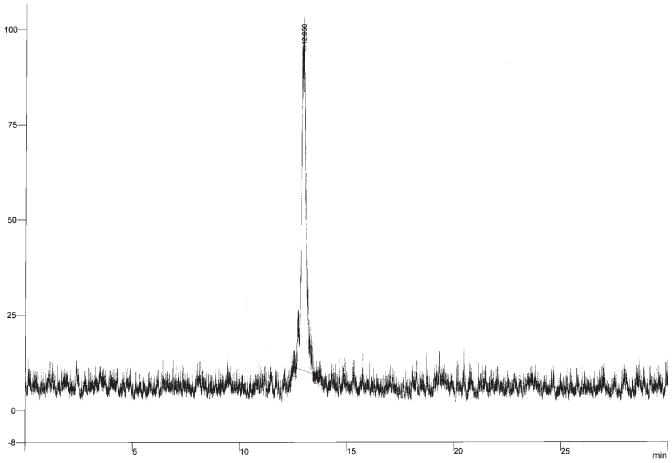

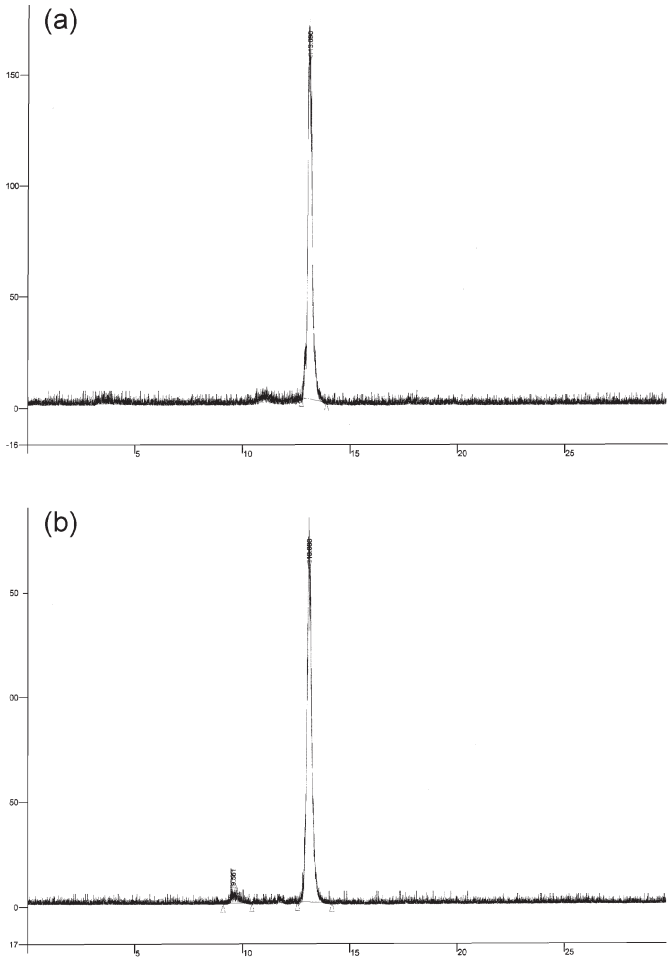

Fig. 4. γ-HPLC radio chromatograms (mV vs. time (min)) of the (*a*) cysteine and (*b*) histidine challenges of **9** after 24 h at 37 °C.

With the above methodology in hand it is possible to generate diverse libraries of compounds. The next step is to select the appropriate in vitro screening method that will indicate what compounds are the most promising for more advanced biological studies. In the example presented here, the ability of peptides **5–8** to bind to the FPR receptor was determined using flow cytometry. Flow cytometry is an attractive tool for screening novel molecular imaging agents because it is amenable to automation, which means that libraries can be evaluated rapidly, and it affords the opportunity to investigate specific cell populations. To evaluate the fMLF derivatives, human white blood cells were incubated with 1.0 nmol/L fluorescein-labelled fNLFNTK and varying amounts of the competitor in duplicate for 2 h at 0 °C in the dark. fMLF, which was used as a reference standard, exhibited a K_d that was in good agreement with the value reported in the literature (28, 50). Conjugates **5–8** had dissociation constants (Table 2) in the low nanomolar range, which is similar to the value for fMLF, thus demonstrating that incorporation of the ligand or Re complex does not have a negative impact on the ability of the peptides to bind the FPR.

Table 2. Dissociation constants (K_d) for compounds **5–8**.

Compound Number	Peptide sequence	K_d (nmol/L)
	fMLF	32±3
5	fMLFK(2M)G	21±6
6	fMLFK(3M)G	52±3
7	fMLFK(4M)G	55±8
8	fMLFK(4M-Re(CO)$_3^+$)G	67±6

Conclusions

The reported strategy offers a new alternative to existing solid-phase synthetic methodologies for preparing peptide-based radiotracers. The ligands and their rhenium complexes employed in this study can be incorporated into the backbone of peptides using traditional automated solid-phase synthesis methods. For instruments that have multiple reaction wells, the free ligand and Re–peptide conjugates can be prepared in parallel. The peptide derivatives described here were prepared in parallel in multi-milligram quantities, which provided sufficient material to allow for complete characterization, radiolabelling, and in vitro screening studies to be performed from the products of a single run of the synthesizer. The reported methodology can be used to prepare libraries of compounds in which several factors, including peptide sequence, site of derivatization, nature of the chelate, and both the type and length of the spacer can be varied, which will decrease the time and effort required to identify lead compounds.

Fluorescence quenching of Safranine T by inorganic anions in Tween micelles

Stephanie A. Moore, Sarah E. Moore, Karen M. Glenn, Subhash C. Bhattacharya, and Rama M. Palepu

Abstract: The fluorescence quenching of the dye Safranine T by various inorganic anions such as $[Fe(CN_6)]^{-3}$, $[Fe(CN_6)]^{-4}$, I^-, Br^-, NO_2^-, and N_3^- in aqueous solution and in nonionic micellar solutions of Tweens (Tween 20, Tween 40, and Tween 80) was studied. The Stern–Volmer quenching constants and quenching rate constants were evaluated. Compared to the quenching efficiency in aqueous media, that of the micellar media was found to be lower, except when iodide ion was used as a quencher. With the exception of the iodide ion, it has been established that collisional quenching plays a major role in the photophysical process. In the case of the iodide ion, both static and collisional quenching processes play a major role, owing to the complexation of iodide ion with Tween micelles. The Stern–Volmer quenching constants were found to be dependent on the ionic strength of the medium.

Key words: fluorescence, static quenching, Tweens, Stern–Volmer constant, micellar media.

Résumé : Opérant en solutions aqueuses et dans des solutions micellaires non-ioniques de Tween (Tween 20, Tween 40 et Tween 80), on a étudié le piégeage de la fluorescence du colorant safranine T par divers anions inorganiques, tels que $[Fe(CN)_6]^{-3}$, $[Fe(CN)_6]^{-4}$, I^-, Br^-, NO_2^- et N_3^-. On a évalué les constantes de piégeage et les constantes de vitesse de piégeage de Stern–Volmer. Comparées aux constantes de piégeage en milieu acide, on a trouvé que les constantes dans les milieux micellaires sont plus faibles, excepté dans le cas où l'ion iodure est utilisé comme piège. À l'exception de l'ion iodure, on a pu établir que le piégeage par collision joue un rôle prépondérant dans le processus photophysique. Dans le cas de l'ion iodure, les processus tant statique et collisionnel jouent tous les deux un rôle important en raison de la complexation de l'ion iodure par les micelles de Tween. On a trouvé que les constantes de piégeage de Stern–Volmer dépendent de la force ionique du milieu.

Mots clés : fluorescence, piégeage statique, Tween, constante de Stern–Volmer, milieu micellaire.

Introduction

Cationic organic dyes are an important class of compounds that are employed as laser dyes, dyes for textiles, and initiators for photopolymerization (1–3). Knowledge of the reaction mechanism involving the excited dyes used as photo-initiators is important in order to understand the processes occurring in the early stages of photo-induced polymerization (4, 5).

The photophysical properties of many dyes are influenced by surfactant micelles and reverse micelles (6–12). Studies of these systems are important for understanding the photophysical–photochemical activities of dyes in organized media. The fluourescence quenching of dyes or photoactive compounds by neutral or charged species in organized assemblies has been done to characterize these assemblies (13–19). With regards to fluorescence quenching in micellar media, there are two factors that affect the mutual encounter of the probe and the quencher molecules. These factors are: (*i*) the partitioning of the fluorescent probe and the quencher between the micellar and the aqueous phases and (*ii*) the dynamic distribution of these species during the quenching process.

The quenching of the dye Safranine T (ST) in different nonionic micellar and reverse micellar media using transition metal ions as quenchers was studied earlier (20–22). The results indicated the absence of charge interactions between the probe and the quencher, but collisional quenching interplay without electron transfer was found to occur. For further correlation, the cationic fluorescent probe ST with anionic quenchers could be informative. With this objective, the fluorescence quenching of ST in Tween micelles using I^-, Br^-, N_3^-, NO_2^-, $[Fe(CN_6)]^{-4}$, and $[Fe(CN_6)]^{-3}$ as quenchers is investigated in the present study.

Table 1. Stern–Volmer constants (K_{sv}) and bimolecular rate constants (k_q) for the quenching of the fluorescence of ST by inorganic anions in aqueous and micellar media at 298 K.

	K_{SV} (dm^3 mol^{-1})				$k_q \times 10^{-9}$ (dm^3 mol^{-1} s^{-1})			
Quencher ions	Aqueous	TW 20	TW 40	TW 80	Aqueous	TW 20	TW 40	TW 80
$[Fe(CN)_6]^{-3}$	45.0	23.8	21.4	19.1	30.8	16.3	14.7	13.1
$[Fe(CN)_6]^{-4}$	34.0	18.2	16.6	8.1	23.3	12.5	11.4	5.5
Br^-	8.0	1.72	1.61	1.57	5.5	1.2	1.1	1.1
NO_2^-	6.3	3.65	3.42	2.76	4.3	2.5	2.3	1.9
N_3^-	11.9	5.23	4.80	4.20	8.2	3.6	3.3	2.9

Note: Concentration of Tweens 25 mmol dm^{-3}; lifetime of ST, τ = 1.46 ns (ref. 15); viscosity values: 0.92, 0.90, and 1.02 cP for Tweens 20, 40, and 80, respectively.

Tweens are nonionic surfactants composed of a fixed length of 20 polyethylene oxide polar head groups, a sorbitan moiety, and a variable-length polymethylene chain (monolaurate, monopalmitate, and monooleate in Tween 20, Tween 40, and Tween 80, respectively).

Experimental details

ST (Merck) was recrystallized from ethanol–water mixtures before use. Tween 20, Tween 40, and Tween 80 were Aldrich products. Their light-sensitive characteristics within the region of interest were checked by absorption and emission measurements. Doubly distilled conductivity water was used for solution preparation. BDH (AR grade) salts $K_4[Fe(CN)_6]$, $K_3[Fe(CN)_6]$, KI, KBr, $NaNO_2$, and NaN_3 were used as quenchers.

The fluorescence of ST was measured using a spectrofluorometer (Spex Fluoro Max-3) with a slit width of 2.0 nm. The excitation and emission wavelengths are 520 and 586 nm, respectively. The concentration of ST used in the aqueous and micellar solutions was of the order of 10^{-5} mol dm^{-3}. The quencher concentrations were varied in the range of 0.1–0.9 mol dm^{-3} for Br^- and 1–50 mmol dm^{-3} for the other anions. The fluorescence spectra of the dye at a constant surfactant concentration with different quencher concentrations were recorded. Different sets of surfactant concentrations, varying from 10 to 50 mmol dm^{-3}, were used. Also, the quenching of ST by various anions was investigated as a function of ionic strength. The ionic strength of the solution was varied with sodium chloride. All the measurements were repeated at least three times, and the accuracy in calculated parameters was within ±0.5%.

Results and discussion

The inorganic ions $[Fe(CN_6)]^{-3}$, $[Fe(CN_6)]^{-4}$, I^-, Br^-, NO_2^-, and N_3^- were found to have quenched the fluorescence of ST in the aqueous Tween 20, Tween 40, and Tween 80 micellar media. Figure 1 illustrates the quenching process of ST as a function of concentration of ferrocyanide as quencher. The values of the Stern–Volmer quenching constants (K_{SV}) were obtained using the Stern–Volmer equation

$$[1] \qquad \frac{F_0}{F} = 1 + K_{SV}[Q]$$

where F_0 and F are the fluorescence intensities without and with quencher and [Q] is the concentration of the quencher.

Fig. 1. Quenching of Safranine T fluorescence in 50 mmol/L Tween 20 solution where [ferrocyanide] = (1) 0.0 mmol dm^{-3}; (2) 1.0 mmol dm^{-3}; (3) 2.0 mmol dm^{-3}; (4) 3.0 mmol dm^{-3}; (5) 5.0 mmol dm^{-3}; (6) 6.0 mmol dm^{-3}; (7) 7.0 mmol dm^{-3}; (8) 8.0 mmol dm^{-3}; and (9) 9.0 mmol dm^{-3}, respectively.

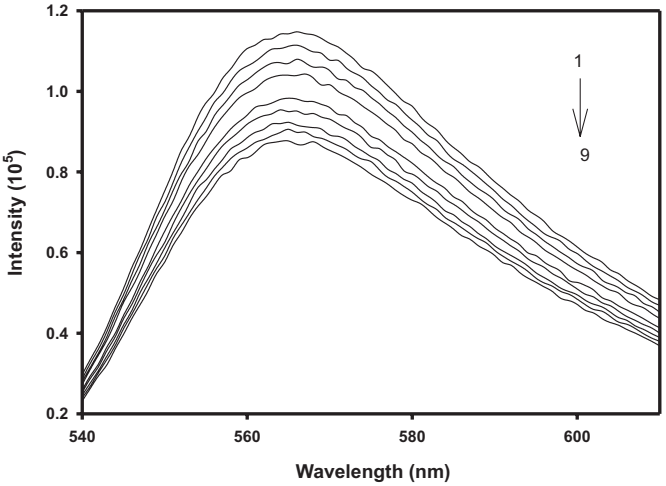

Table 2. Stern–Volmer constants (K_{sv}), fraction of inaccessible fluorophore (f_b), and r^2 values for the quenching of ST by iodide ions in Tween micellar media at 25 °C.

	K_{sv}	f_b	r^2
Tween 20	303±18	0.513±0.011	0.998
Tween 40	232±6	0.481±0.005	0.999
Tween 80	169±12	0.216±0.025	0.998

By employing single-photon counting techniques, the singlet state lifetime (τ_0) of ST in water was found to be 1.46 ns (20). The rate constants for quenching (k_q) were calculated from the relationship $K_{sv} = k_q\tau_0$, employing the value of 1.46 ns for τ_0. The results of the present study are given in Tables 1 and 2. The lifetime of ST is expected to be influenced by the presence of micelles. El-Kemary et al. (23) reported a value of 2.30 ns in methanol and a value of 2.81 ns for methanol – Triton X100 solutions. Therefore, the rate constants obtained in this study may tend to be slightly higher than the true values. The quenching efficiency of various anions was assessed from the relative magnitude of the Stern–Volmer constant (K_{sv}). Nonequivalent quenching manifestations of the inorganic ions were observed. The effi-

Table 3. Hydrated radius of different quencher ions, and free energy change, calculated from Rehm and Weller's equation.

		$-\Delta G^0$ (eV)			
Quencher ion	Radius (nm)	Water	Tween 20	Tween 40	Tween 80
$[F_e(CN)_6]^{-4}$	0.402	3.53	3.67	3.67	3.94
I^-	0.300	3.78	3.96	3.94	4.2
Br^-	0.300	4.26	4.42	4.42	4.66
N_3^-	0.300	5.05	5.21	5.26	5.45
NO_2^-	0.300	3.33	3.49	3.49	3.73

Note: K_{eq} values for I^- with Tween 20: 288 ± 10; Tween 40: 377 ± 13; and Tween 80: 259 ± 9.

Fig. 2. (A) Absorption spectrum of ST in water (1×10^{-5} mol/L); (B) absorption spectrum of ST in 35 mmol/L Tween 40 solution in the presence of varying concentrations of KI (0–10 mmol/L).

ciencies of the quencher ions in aqueous medium follow the order $[Fe(CN_6)]^{-3} > [Fe(CN_6)]^{-4} > I^- > Br^- > N_3^- > NO_2^-$. In micellar media, however, the quenching efficiencies follow the order $I^- > [Fe(CN_6)]^{-3} > [Fe(CN_6)]^{-4} > N_3^- > NO_2^- > Br^-$.

The quencher ions, except for the iodide ion, have no effect on the absorption spectrum of ST in aqueous and micellar media. In aqueous media the iodide ion has no effect on the absorption spectrum of ST. In aqueous Tween micellar media, however, there is an enhancement in the absorbance with bathochromic spectral shift (Fig. 2). This is indicative of complex formation between the iodide ion and the Tween micelles. The equilibrium constants for the complex formation were calculated by employing Lang's equation (24) from the absorption spectral data. The values are reported as a note below Table 3.

The reduction potential of ST is –0.467 V, calculated with reference to a standard hydrogen electrode (SHE) (20). Knowing the excitation energy (ΔE_{00}) of ST, the reduction potential of the first excited singlet state of ST can be calculated. A value of 2.68 eV was obtained for ΔE_{00}, and a value of 2.21 V was computed as the reduction potential of ST in the excited state. The reduction potentials of the $[Fe(CN_6)]^{-3}/[Fe(CN_6)]^{-4}$, I_2/I^-, Br_2/Br^-, $NO_2^-/N_2O_2^-$, and N_3^-/N_2 couples are 0.36, 0.62, 1.08, 0.15, and 1.87 V, respectively (25). The reduction of the dye in the excited state by the quenchers via an electron-transfer (ET) mechanism was therefore energetically feasible (Fig. 3).

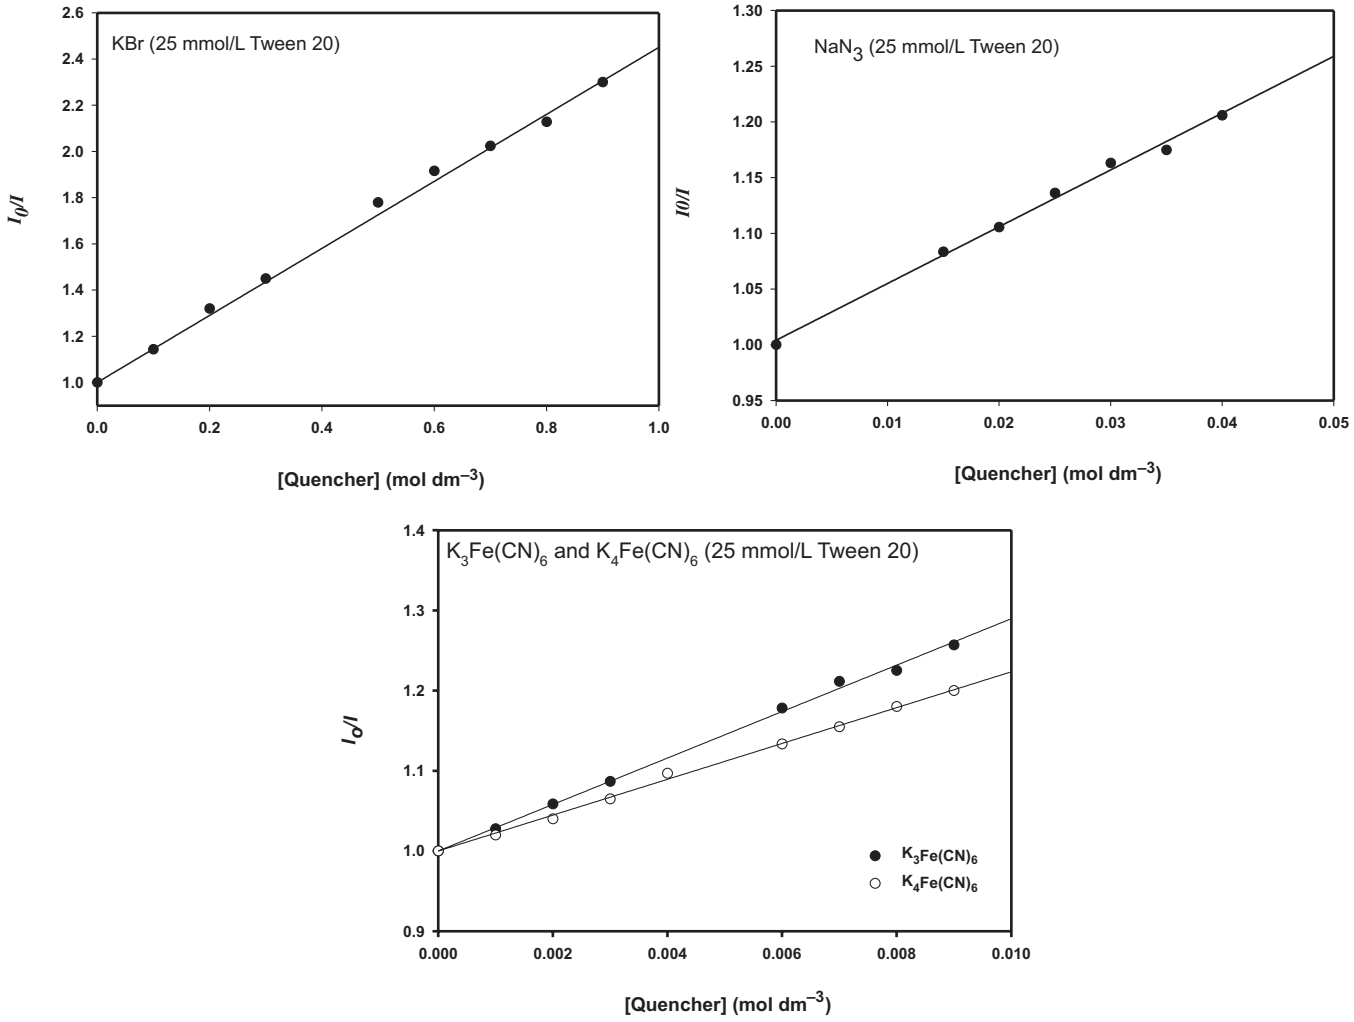
In the case of $[Fe(CN)_6]^{-3}$, the quencher ion is in its maximum oxidized state; therefore, quenching of the fluorescence of ST should not take place by an electron-transfer mechanism. As mentioned earlier, the quenching efficiency trends of the anions (except for the iodide ion) are the same in aqueous and in micellar media.

Earlier studies (20) reported that the dye ST can reside at the micellar interface, penetrating it only partially. The poor solubility of ST in the nonpolar hydrocarbon media is indicative of its nonresidency in the hydrophobic micellar interior. In polar nonaqueous media, such as ethanol, ethylene glycol, and formamide, a sharp but red-shifted spectra is produced when compared with water. In very weak polar solvents, such as 1,4-dioxane, a broad spectrum with a minor red shift is obtained. In micellar media, a reasonable red shift is also observed. The spectral change in polar nonaqueous and micellar media supports the suggestion that ST resides on the outer surface of the micelles, particularly in the palisade layer, which consists of the ethylene oxide residues of the Tween micelles. There is a distribution of the dye between the aqueous bulk and the micellar outer surface. The quenching process is therefore believed to occur in both regions.

For an interpretation of the fluorescence quenching in terms of the electron-transfer mechanism for the quenchers $[Fe(CN_6)]^{-4}$, I^-, Br^-, NO_2^-, and N_3^-, the free energy change (ΔG) for the process may be evaluated from the following equations (26, 27):

$$[2] \qquad \log_{10} k_q = \log_{10} k_{diff} - \frac{\Delta G}{2.303RT}$$

where



$$[3] \qquad \Delta G = \left\{ E(D^+/D) - E(A/A^-) - \frac{e^2}{\epsilon a} \right\} - \Delta E_{00}$$

The values of $E(D^+/D)$ and $E(A/A^-)$ represent reduction potentials of the donor and acceptor, respectively, $e^2/\epsilon a$ is the free energy change gained by bringing two radical ions to encounter distance a in the solvent of dielectric constant ϵ, and k_{diff} is the rate constant for the diffusion *interaction* between the reacting species.

Plots of log k_q vs. ΔG (not shown) were nonlinear for both aqueous and micellar media for the quenching of the fluores-

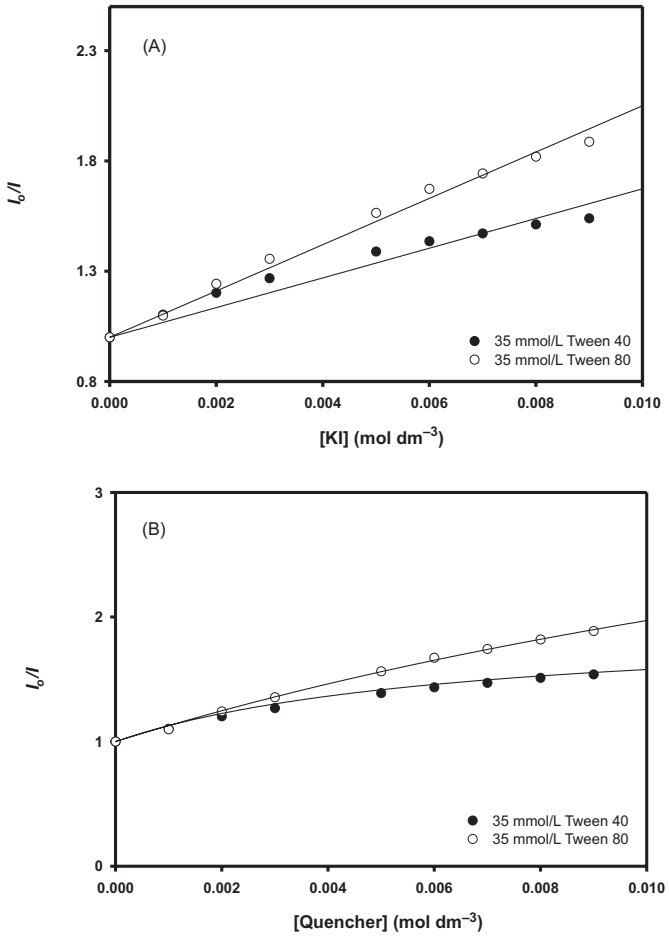
Fig. 3. Stern–Volmer plots of fluorescence quenching of ST in micellar media by various inorganic anions.

cence of ST. Therefore, an electron-transfer mechanism can be ruled out for this quenching process.

Although the quencher $[Fe(CN)_6]^{-3}$ is in its maximum oxidation state, its quenching efficiency is similar to the other ions in their reduced states. This suggests that the transfer of electrons from the quencher to ST is not solely responsible for the quenching process. It is likely that the collisional quenching plays a major role in this process. In micellar media, the probability of a collision of quenchers with dye molecules decreases as a result of the barrier provided by the organised interfacial layer of micelles, as represented by the viscosity coefficients of the micellar medium (Table 1). The collisional quenching is also supported by the decreased k_q value in micellar media, except for the iodide ion.



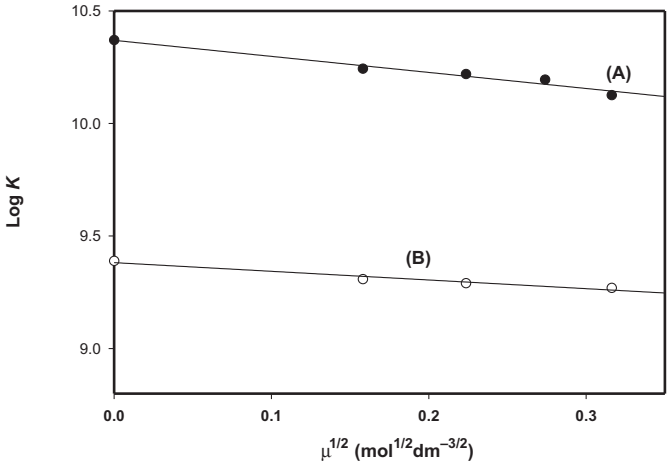
The counterions K^+ (for the ferro, ferri cyanide, iodide, and bromide salts) and Na^+ (for the nitrite and azide salts) played no role in the quenching process. The dye ST underwent collisional quenching by the inorganic ions. The efficiency order of these ions did not follow the order of their hydrated radius. The valency and ionic charges also did not correlate with the effects. It is not easy to rationalize why the collisional quenching effect for Br^- is weaker. One explanation could be the difference in the degree of fruitful collisions by the different ions. Since ST is distributed between the aqueous bulk and the micellar interface, the quenching process is the result of the effects in these two regions. The ionic size and the charge determine the access of the ions to these two regions and essentially guide the overall quenching process. Except for the case of I^-, the effect of the quenchers in aqueous media is greater than the effect in the micellar media because the dye takes shelter at the micellar interface, which has a lower fluidity. This lower fluidity is caused by hydration of the polyethylene oxide head groups of the nonionic surfactant molecules. Therefore, the ionic quencher molecules have relatively low access to the dye, resulting in a lower quenching effect. Also, the K_{sv} values decrease with increasing concentrations of Tween micelles.

Quenching of the fluorescence of ST by the iodide ion does not obey the Stern–Volmer equation (Fig. 4A), indicating that a single type of quenching does not apply in the present case. The experimental results are therefore analysed by employing a modified Stern–Volmer equation, as follows:

$$[4] \qquad \frac{F_0}{F} = \frac{1 + K_{sv}[Q]}{1 + f_b K_{sv}[Q]}$$

© 2005 NRC Canada

Fig. 4. Stern–Volmer plots of quenching of ST fluorescence in (A) Tween 40 and 80; (B) curve fit according to eq. [4].



where f_b is the fraction of fluorophore inaccessible to quencher. The modified equation is based on the scenario that a fraction of either the quencher or the probe population is inaccessible to the other population (28, 29). In the present study, since the quencher ions are involved in the complexation with the Tween micelles, the application of the modified Stern–Volmer equation is justified. Plots of the data vs. the predicted values using eq. [4] are presented in Fig 4B. The resulting constants derived from the fit to eq. [4], along with correlation coefficient values (r^2), can be found in Table 2.

Since both the fluorophore and the quencher are ionic species, and since they have opposite charges, it is expected that the quenching phenomenon will be dependent on the ionic strength of the medium (μ). Following the Bronsted–Bjerrum equation (30),

$$[5] \qquad \log_{10} k = \log_{10} k^0 + 1.02 z_A z_B \sqrt{\mu}$$

where z_A and z_B represent the charge of cation and anion, respectively. The rate of quenching and the K_{sv} values therefore decrease with an increase in ionic strength. In the absence of lifetime values (τ_o) as a function of electrolyte concentrations, the validity of eq. [3] cannot be verified at the present time. However, it is expected that the k and, therefore, K_{sv} values will decrease with increasing ionic strength. In the present study the values of K_{sv} decreased in all cases with increasing ionic strength. Representative plots of $\log_{10} k$ vs. $\mu^{1/2}$ are given in Fig. 5. The approximate values of k were calculated using the lifetime τ_0 as 1.46 ns. As predicted by eq. [3], the rate constants decreased with an increase in ionic strength.

Fig. 5. Effect of ionic strength on the K_{sv} values: (A) 50 mmol/L Tween 20 and $[Fe(CN)_6]^{-4}$; (B) 50 mmol/L Tween 40 and NO_2^-.

Conclusions

(1) Inorganic ions such as $[Fe(CN_6)]^{-3}$, $[Fe(CN_6)]^{-4}$, I^-, Br^-, NO_2^-, and N_3^- quench the fluorescence of ST in aqueous media.
(2) In nonionic Tween micellar media, the quenching effects of the above ions on the fluorescence of ST are significantly weaker. The effect of I^- is significantly different from the other ions.
(3) The quenching phenomenon is not guided by the transfer of electrons from the quencher to the dye molecule, but is controlled by collisional quenching.
(4) For the iodide ion, the modified Stern–Volmer equation, based on the inaccessibility of a fraction of fluorophore (f_b), is employed to calculate the K_{sv} values.
(5) The Stern–Volmer constants are found to be dependent on both the concentration of the Tween micelles and the ionic strength of the solution.

Synthesis, characterization, and single crystal X-ray structures of $[Co^{III}(acacen)(thioacetamide)_2]ClO_4$ and $[Co^{III}((BA)_2en)(thioacetamide)_2]PF_6$ — Solvatochromic properties of $[Co^{III}(acacen)(thioacetamide)_2]ClO_4$

Mehdi Amirnasr, Vratislav Langer, Nahid Rasouli, Mehdi Salehi, and Soraia Meghdadi

Abstract: The *trans*-$[Co^{III}(acacen)(ta)_2]ClO_4$ (**1**) and *trans*-$[Co^{III}((BA)_2en)(ta)_2]PF_6$ (**2**) complexes, where H_2acacen = bis(acetylacetone)ethylenediimine, $H_2(BA)_2$en = bis(benzoylacetone)ethylenediimine, and ta = thioacetamide, have been synthesized by a solid-state method, and characterized by elemental analyses, IR, UV–vis, and ^{1}H NMR spectroscopy. The crystal and molecular structures of **1** and **2** were determined by X-ray crystallography. Both compounds crystallize in the monoclinic space group *P*2/*n*. The ClO_4 and PF_6 ions are both disordered, ClO_4 on a twofold axis in **1** and PF_6 on an inversion center in **2**. Also bridging N-CH_2-CH_2-N is disordered in both compounds. The octahedral coordination of Co(III) is slightly distorted in both cases. The thioacetamide ligands are S-bonded and occupy the axial position. The IR, UV–vis, and ^{1}H NMR spectra of the two complexes and their solvatochromic properties are also discussed. The longest wavelength absorption that appears at 517 nm for **1** and at 528 nm for **2** in chloroform is solvent dependent, and is assigned as a metal-mediated ligand-to-ligand charge transfer (LLCT).

Key words: solid-state synthesis, thioactamide, Co(III) (Schiff base), crystal structure, solvatochromism, metal-mediated LLCT.

Résumé : Utilisant une méthode en phase solide, on a synthétisé les complexes *trans*-$[Co^{III}(acacen)(ta)_2]ClO_4$ (**1**) et *trans*-$[Co^{III}((BA)_2en)(ta)_2]PF_6$ (**2**) dans lesquels H_2acacen = bis(acétylacétone)éthylènediimine, $H_2(BA)_2$en = bis(benzoylacétone)éthylènediimine et ta = thioacétamide, et on les a caractérisés par le biais d'analyses élémentaires, de spectroscopies IR, UV–vis et RMN du ^{1}H. On a déterminé les structures cristallines et moléculaires des composés **1** et **2** par diffraction des rayons X. Les deux composés cristallisent dans le groupe d'espace monoclinique *P*2/*n*. Les ions ClO_4 et PF_6 sont tous les deux désordonnés, le ClO_4 sur un axe binaire dans **1** et le PF_6 sur un centre d'inversion dans **2**. Le chaînon N-CH_2-CH_2-N qui agit comme pont est aussi désordonné dans les deux composés. La coordination tétraédrique du Co(III) est légèrement déformée dans les deux cas. Les ligands thioacétamides sont liés par le soufre et occupent une position axiale. On discute aussi des spectres IR, UV–vis et RMN du ^{1}H des deux complexes et de leurs propriétés solvatochromiques. La bande d'absorption de plus grande longueur d'onde qui apparaît, dans le chloroforme, à 517 nm pour le composé **1** et à 528 nm pour le composé **2**, dépend du solvant et elle est attribuée à un transfert de charge de ligand à ligand aidée par le métal.

Mots clés : synthèse à l'état solide, thioacétamide, base de Shiff du Co(III), structure cristalline, solvatochromie, transfert de charge de ligand à ligand aidée par le métal.

[Traduit par la Rédaction]

Introduction

Cobalt(III) is normally considered a hard metal center that favors coordination to second-row atoms like oxygen and nitrogen. This is clearly evident from numerous Co(III) complexes bearing ambidentate ligands such as thiocyanate (1), selenocyanate (2), formamide, acetamide (3), methanesulfinamide, and methanesulfinate (4). However, when other ligands on the metal center tend to make the metal softer, bonding to soft donor atoms like S is favored. For instance,

the S-bonded form of the complex $[Co(CN)_5SCN]^{3-}$, which is the primary product of the reduction of $Co(NH_3)_5NCS^{2+}$ by $Co(CN)_5^{3-}$, is the stable linkage isomer (2).

Schiff base ligands also play an effective role in the modification of the electronic structure of metal centers. Co(II) Schiff base complexes are among the most versatile compounds that are of potential interest in many different areas such as catalysis (5, 6), modeling of antiviral agents (7), and oxygen-binding biomolecules (8). This remarkable diversity of functions is achieved by suitable modification of their basic electronic structure. Several elegant theoretical studies have been carried out to elucidate the electronic structure of Co(II) Schiff base complexes and to rationalize their reactivity (9, 10). The Schiff base ligand may modify the electron density on the metal center in such a way that the coordination of a soft atom like S of thioacetamide to cobalt is favored. In the course of our studies on the structural and electronic effects that may influence the reactivity of cobalt Schiff base complexes (11) we report the synthesis, characterization, and X-ray crystal structure of *trans*-$[Co^{III}(acacen)(ta)_2]ClO_4$ (**1**) and *trans*-$[Co^{III}((BA)_2en)(ta)_2]PF_6$ (**2**). The structures of **1** and **2** are the first reported structures of Co(acacen) and Co($(BA)_2$en) complexes containing S-donor axial ligands.

Experimental

Caution! Transition-metal complex perchlorate salts are known to be hazardous and must be treated with care, especially in the presence of organic solvents.

Materials and methods

The Schiff base ligands, bis(acetylacetone)ethylenediimine (H_2acacen) and bis(benzoylacetone)ethylenediimine ($H_2(BA)_2$en), and their cobalt(II) complexes were prepared as described in the literature (12). Silica gel 60 (70–230 mesh, Merck) was used as the solid-state reaction media. All other chemicals were commercial reagent grade and used as received from Aldrich and Merck. Elemental analyses were performed by using a Heraeus CHN-O-RAPID elemental analyzer.

Electronic absorption spectra were recorded on a JASCO V-570 spectrophotometer. Fourier transform IR spectroscopy on KBr pellets was performed on a JASCO-680 Plus instrument. ^{1}H NMR spectra were obtained on a Bruker Avance DRX500 (500 MHz) spectrometer. Proton chemical shifts are reported in part per million (ppm) relative to an internal standard of Me_4Si.

Synthesis

trans-*[Co^{III}(acacen)$(ta)_2$]ClO_4 (1)*

A homogenized mixture of 951 mg (3 mmol) of $[Co^{II}$(acacen)], 900 mg (12 mmol) of thioacetamide, and 1.2 g of silica gel in a porcelain dish was heated at 80 °C for 30 min. The color changed from orange to dark purple. The reaction mixture was then cooled to room temperature and treated with 50 mL of chloroform. A solution of 368 mg (3 mmol) sodium perchlorate in 3 mL methanol was then added and the mixture was stirred for 10 min and finally filtered off. The filtrate was left in the open air and slow evaporation of the solvent at room temperature gave a dark violet microcrystalline powder. The powder was then dissolved in chloroform and the resulting solution was filtered off. An equal volume of toluene was added to the filtrate and left undisturbed at room temperature. Dark violet crystals suitable for X-ray crystallography were obtained after 2 days. The crystals were isolated by filtration and washed with a mixture of chloroform–toluene (1:9, *v*/*v*) and dried in vacuo. Yield: 340 mg (64%). IR (KBr, cm^{-1}) ν_{max}: 3323 (m, N-H), 1515 (s, C=N), 1318 (m, C-N), 708 (m, C=S), 1116 (s, ClO_4). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.02 (s, $6H_a$, CH_3), 2.20 (s, $6H_b$, CH_3), 2.37 (s, $6H_c$, CH_3), 3.5 (s, $4H_d$, H_2C-CH_2), 5.05 (s, $2H_e$, C*H*), 8.73 (s, $2H_g$, N*H*), 10.22 (s, $2H_f$, N*H*). Anal. calcd. for $C_{16}H_{28}N_4O_6ClS_2Co$: C 36.20, H 5.30, N 10.50; found: C 36.20, H 5.40, N 9.80.

trans-*[Co^{III}($(BA)_2$en)$(ta)_2$]PF_6 (2)*

A homogenized mixture of 203 mg (0.5 mmol) of $[Co^{II}((BA)_2en)]$, 113 mg (1.5 mmol) of thioacetamide, and 900 mg of silica gel in a porcelain dish was heated at 80 °C for 60 min. The bright orange color of the mixture turned dark orange. The reaction mixture was then cooled to room temperature, transferred to a 100 mL beaker, and treated with a mixture of 50 mL of dichloromethane and 20 mL ethyl acetate. After adding 37.5 mg (0.5 mmol) of additional thioacetamide, the reaction mixture was stirred in open air for an extra 6 h. A solution of 98 mg (0.6 mmol) of NH_4PF_6 in 10 mL ethyl acetate was then added and the reaction mixture was stirred for an additional 30 min and finally filtered off. After adding 15 mL of carbon tetrachloride to the filtrate, the resulting solution was left in open air, and slow evaporation of the solvent at room temperature gave dark cherry red crystals. Yield: 420 mg (60%). The product was recrystallized by slow evaporation of its solution in a mixture of ethyl acetate – benzene – dibutyl ether – carbon tetrachloride (15:1:3:18, *v*/*v*) at room temperature and dark cherry red crystals suitable for X-ray crystallography were obtained after 4 days. The crystals were isolated by filtration and washed with a mixture of ethyl acetate – carbon tetrachloride (1:9, *v*/*v*) and dried in vacuo. IR (KBr, cm^{-1}) ν_{max}: 3386 (m, N-H), 1515 (s, C=N), 1311 (m, C-N), 699 (m, C=S), 852 (s, PF_6). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.23 (s, $6H_a$, CH_3), 2.39 (s, $6H_c$, CH_3), 3.73 (s, $4H_d$, H_2C-CH_2), 5.78 (s, $2H_e$, C*H*), 7.44–7.83 (m, 10H, Ar), 8.04 (s, $2H_g$, N*H*), 10.59 (s, $2H_f$, N*H*). Anal. calcd. for $C_{26}H_{32}N_4O_2S_2PF_6Co$: C 44.57, H 4.57, N 8.00; found: C 43.0, H 4.70, N 8.00.

X-ray crystallography

Data were collected on a Siemens SMART CCD diffractometer equipped with LT-2A low temperature device, using graphite-monochromated Mo Kα (λ = 0.710 73 Å) radiation. A full sphere of reciprocal lattice was scanned by 0.3° steps in ω with a crystal-to-detector distance of 3.97 cm. Preliminary orientation matrices were obtained from the first frames using SMART (13). The frames were integrated using the preliminary orientation matrices, which were updated every 100 frames. Final cell parameters were obtained by the refinement on the positions of 6923 (for **1**) and 8192 (for **2**) reflections with $I > 10\sigma(I)$, after integration of all the frames using SAINT (13). The data were empirically corrected for absorption and other effects using SADABS (14). The structures were solved by direct methods and refined by the full-

matrix least-squares method on F^2 data using the SHELXTL (15). All non-H atoms were refined anisotropically. Oxygen atoms of both perchlorate ions, which are disordered on the twofold axis with occupancy factors of 0.5, were refined with restraints to form regular tetrahedrons. Also PF_6 ion was found to be disordered on an inversion center and refined with geometrical restraints. The H atoms were constrained to idealized geometries and refined isotropically. The crystallographic and refinement data are summarized in Table 1.

Results and discussion

Synthesis

The cobalt(III) complexes (**1** and **2**) were prepared by air oxidation of a homogenized mixture of the corresponding cobalt(II) (Schiff base) complex and thioacetamide, in the presence of silica gel at 80 °C. The solid reaction mixture was heated in an oven for 30 min during which the color changed from orange to dark purple for **1** and from red orange to dark orange for **2**. In addition to providing a suitable reaction medium to ensure that the reactive molecules achieve contact with each other, silica gel is apparently effective in adsorbing the water molecules that are loosely coordinated to Co(II) in [Co^{II}(Schiff base)] complexes. It is also likely that the nitrogen atom of thioacetamide binds more tightly to the Lewis acid sites of silica gel, therefore facilitating the coordination of thioacetamide through its S atom.

It has been postulated that the tendency of a given [Co^{II}(Schiff base)] complex towards oxidation is dependent on the available charge density on cobalt (10). For example, the [Co^{II}(acacen)] complex is more readily oxidized in air than [Co^{II}(salen)]. The common explanation for this property is that the presence of the extended conjugation system in the salen ligand reduces the charge density at oxygen and reduces the reactivity of [Co^{II}(salen)] towards oxidation. It is interesting to note that the oxidation process in the preparation of **1** from [Co^{II}(acacen)] occurs within a short period, while it takes a bout 12 h in the synthesis of **2** from [Co^{II}($(BA)_2$en)]. This would be expected considering the presence of two additional phenyl rings and extended conjugation in the bis(benzoylacetone)ethylenediimine Schiff base complex.

Structures of *trans*-[Co(acacen)$(ta)_2$]ClO_4 (1) and *trans*-[Co($(BA)_2$en)$(ta)_2$]PF_6 (2)

A view of the cations of **1** and **2** can be seen in Figs. 1 and 2, respectively. The atom labeling scheme used is presented in the figures with the unlabeled atoms being related

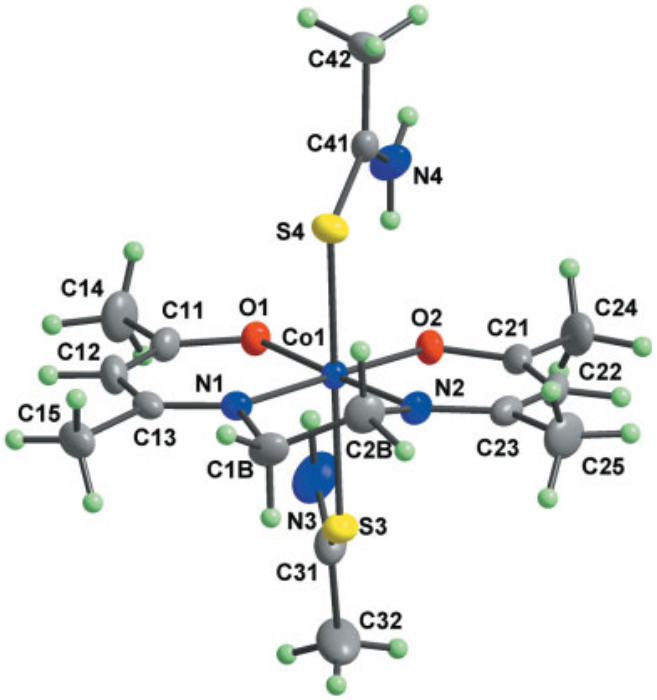
Fig. 1. Numbering scheme with thermal ellipsoids at 30% probability level. The disordered section N1-C1B-C2B-N2 with higher occupancy (0.686) is shown.



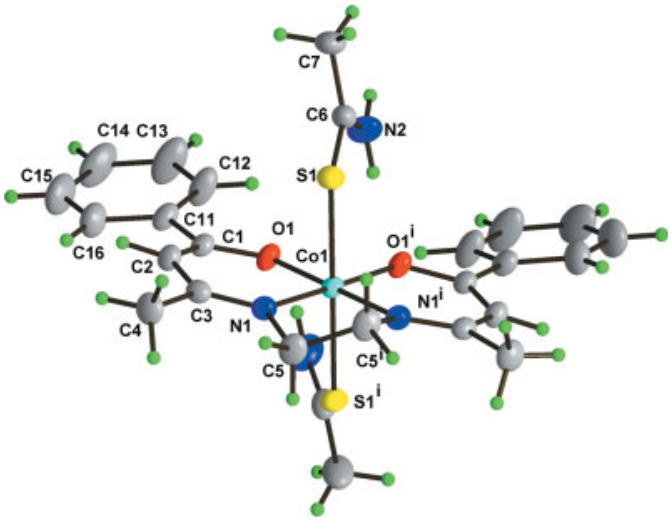


Fig. 2. Numbering scheme with thermal ellipsoids at 30% probability level. The disordered section N1-C5-C5^{i}-N1^{i} with higher occupancy (0.80) is shown. Symmetry code: $-x + 3/2$, y, $-z + 1/2$ (i).

to the labeled atoms by a twofold axis upon which the cobalt cation in **2** resides. Selected bond lengths and angles are listed in Table 2. In both cases, the octahedral coordination of Co(III) is slightly distorted, the Schiff base ligand (ONNO ligand) coordinates the cobalt ion in four equatorial positions, and the two thioacetamide molecules occupy the two axial positions of the octahedral complexes.

The Co—O and Co—N bond distances of the acacen and $(BA)_2$en ligands in the equatorial plane of **1** and **2** are symmetric within the limits of the experimental error. In *trans*-[Co^{III}(acacen)(ta)$_2$]ClO$_4$ (**1**), Co—O(1) = 1.8992(15) Å, Co—O(2) = 1.9023(15) Å, Co—N(1) = 1.9018(17) Å, Co—N(2) = 1.8967(18) Å, which compare well with the Co—O and Co—N distances found in *trans*-[Co(acacen)(piperidine)$_2$]NCS (Co—O$_{av}$ = 1.897 Å, Co—N$_{av}$ = 1.902 Å) (16) and *trans*-[Co(3-Cl-acacen)(NH$_3$)$_2$]BPh$_4$ (Co—O = 1.881(4) Å, Co—N = 1.8918(9) Å) (7). In *trans*-[Co^{III}((BA)$_2$en)(ta)$_2$]PF$_6$ (**2**), Co—O(1) = Co—O(1)i = 1.9004(9) Å, Co—N(1) = Co—N(1)i = 1.9010(10) Å, which compare well with the Co—O and Co—N distances found in *trans*-[Co((BA)$_2$en)(morpholine)$_2$]ClO$_4$ (Co—O$_{av}$ = 1.897 Å, Co—N$_{av}$ = 1.902 Å) (17). The average cobalt–sulfur bonds in the axial positions are different in **1** and **2** (Co—S$_{av}$ = 2.3013(6) Å in **1** and 2.3169(3) Å in **2**) and are in good agreement with the Co—S distances in cobalt–thiourea (e.g., [Co(NioxH)$_2$(Thio)$_2$]$_2$SiF$_6$, Co—S = 2.300–2.318 Å) complexes (18).

The C—S and C—N bond distances for the axial thioacetamide ligands, C(31)—S(3) = 1.675(3) Å, C(41)—S(4) = 1.682(2) Å, C(31)—N(3) = 1.305(4) Å, C(41)—N(4) = 1.288(3) Å in **1**, and C(6)—S(1) = 1.6944(16) Å, C(6)—N(2) = 1.298(2) Å in **2**, agree with those reported for the related complexes (17) and are close to the C=S double

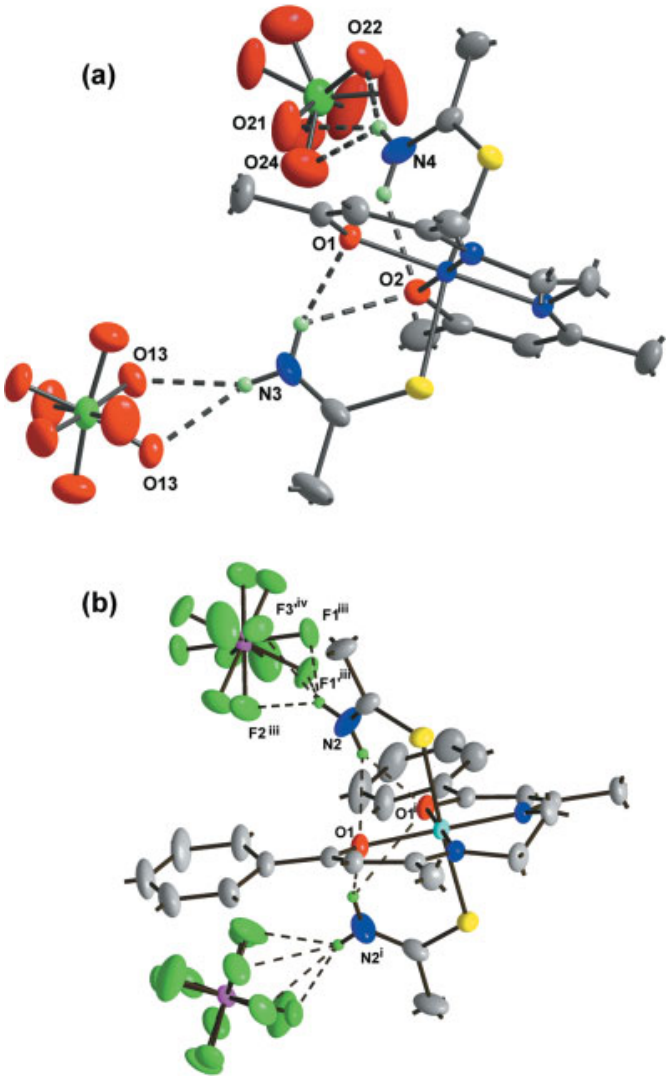
bond (1.6854(10) Å) and C—N single bond (1.3126(12) Å) in free thioacetamide (19).

All angles around the Co center deviate significantly from 90° indicating a rectangular distortion. The ligand-cobalt-ligand bond angles in the equatorial plane consist of two that are larger than 90° (O(1)-Co(1)-N(1) = 95.45(7)° and N(2)-Co(1)-O(2) = 95.59(8)° in **1** and O(1)-Co(1)-N(1) = (N(1)i-Co(1)-O(1)i = 94.85(4)° in **2**), and two smaller angles (O(1)-Co-O(2) = 82.84(7)° and N(1)-Co-N(2) = 86.16(8)° in **1** and O(1)-Co-O(1)I = 84.09(5)° and N(1)-Co-N(1)i = 86.22(6)° in **2**) (Table 2), which are close to the corresponding values in *trans*-[Co(acacen)(piperidine)$_2$]NCS (94.1(1)°, 95.2(1)°, 84.6(1)°, 86.2(1)°) (16) and *trans*-[Co((BA)$_2$en)(morpholine)$_2$]ClO_4 (93.89(1)°, 94.26(11)°, 86.10(9)°, 85.87(11)°) (17).

The trans angles of 178.03(8)° and 177.46(7)° in **1** and 178.83(4)° in **2** are indicative of a slight tetrahedral distortion of the basal coordination of Co(III), which in the case of perfect planarity have values of 180°. This distortion is also reflected by the torsion angles of ~2° in the six-membered rings of basal coordination in **1** and ~6 ° in **2** (Table 3), and the angle between the best least-squares planes (Co1-O1-C11-C12-C13-N1 and Co1-O2-C21-C22-C23-N2) in **1** being 5.61(9)°, and (Co1-O1-C1-C2-C3-N1 and Co1-$O1^i$-$C1^i$-$C2^i$-$C3^i$-$N1^i$) in **2** being 0.08(4)°.



The (N-H) atoms of the axial thioacetamide ligands are involved in hydrogen bonding with the oxygen atoms of ClO_4^- (in **1**) and PF_6^- (in **2**) anions and the equatorial Schiff base ligand (Fig. 3). As a result, the two axial thioacetamide ligands are tilted away from the *Z* axis by ~9° in **1** (S(3)-Co(1)-S(4) = 171.37(3)°) and ~5° in **2** (S(1)-Co(1)-S(1)i = 175.309(19)°). Some features of this hydrogen bonding are also observed in the IR and ^{1}H NMR spectra of the compound (vide infra). The geometry of the hydrogen bonds is given in Table 4.

Spectral studies

Thioamides are potential ambidentate ligands that can coordinate to the transition-metal ions through either the sulfur or the nitrogen atoms. Thioacetamide exists as the two resonance structures presented in Scheme 1. When N-bonded, **I** is the dominant structure and as a result the C—N stretching frequency is lowered while the C=S stretching frequency is raised relative to the free thioacetamide. In the S-bonded complex, **II** is the dominant structure and consequently the C—N stretching frequency is raised while the C=S stretching frequency is lowered relative to the free thioacetamide.

Yet another possibility for the S-bonded form is structure **I** in which the CS group acts as a thione. The shift in the vibrational frequencies and the bond lengths of C—N and C=S indicate which of the thione or thiolate structures is the major contributor to the ligand–metal coordination.

Fig. 3. (*a*) Hydrogen bonds in **1**. Both perchlorate ions are disordered on the twofold axis. Hydrogens not taking part in the bonding scheme were omitted for clarity. (*b*) Hydrogen bonds in **2** (for details and symmetry codes see Table 4). Both PF_6 ions are disordered on the inversion center. The main sections with occupancy 0.702(5) and the other with occupancy 0.298(5) (atom labels with a prime) are shown. Atomic displacement ellipsoids are shown at 30% probability level. Hydrogens not taking part in the bonding scheme were omitted for clarity.

Except for the aromatic region, the IR spectral pattern is essentially the same for **1** and **2**. The fairly strong band appearing at 1305 cm^{-1} in the IR spectrum of free thioacetamide, due to ν(CN) (20), shifts to 1318 cm^{-1} in **1** and 1311 cm^{-1} in **2**, respectively. The ν(CS), appearing at

Scheme 1.

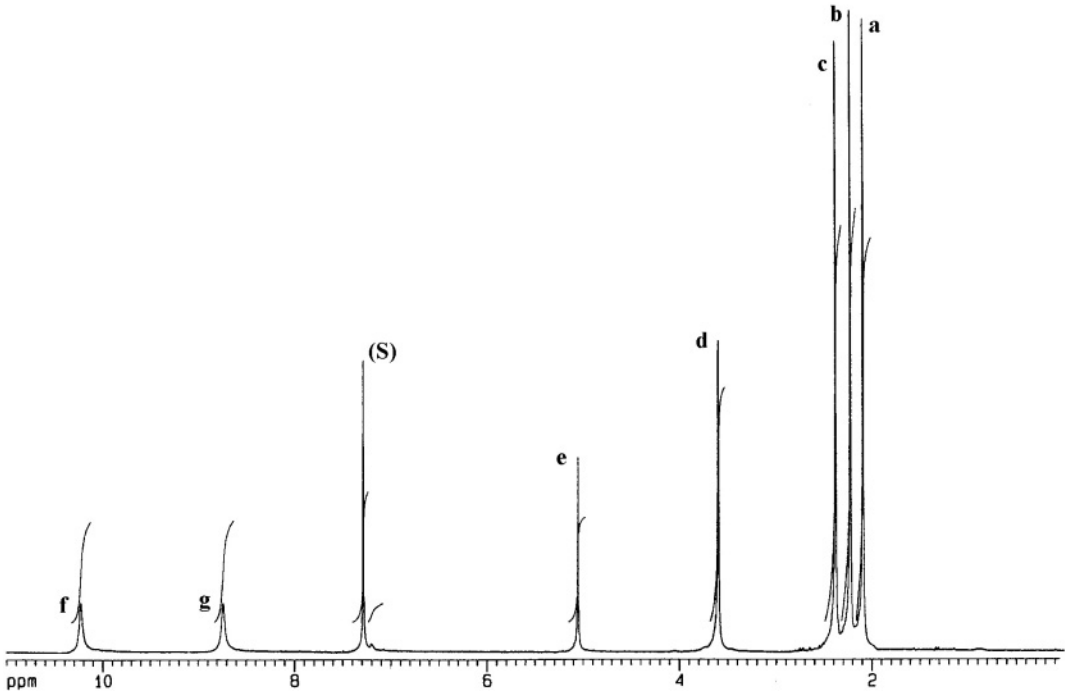
(I) **(II)**

708 cm^{-1} in free thioacetamide, appears at 708 cm^{-1} in **1** and 699 cm^{-1} in **2**, respectively. The small increase in ν(CN) and the small decrease in ν(CS) of the coordinated thioacetamide is consistent with a metal sulfur coordination of the thione form, and conform with the X-ray molecular structure. The N—H stretching vibrational band of NH_2 appears at 3323 and 3386 cm^{-1} in **1** and **2**, respectively. This band is relatively broad and appears at a lower frequency in the IR spectrum of **1** because of the formation of strong hydrogen bonds with the oxygen atoms of the perchlorate anions and the equatorial Schiff base ligand.

The ν(C=N) of the equatorial Schiff base ligands that appears at about 1540 cm^{-1} in the IR spectra of the free ligands is shifted to a lower frequency by ~25 cm^{-1} and appears at 1515 cm^{-1} in the IR spectra of the two complexes. The stretching vibrations of ClO_4^- (1116 cm^{-1}) and PF_6^- (852 cm^{-1}) anions are observed in the corresponding regions (21).

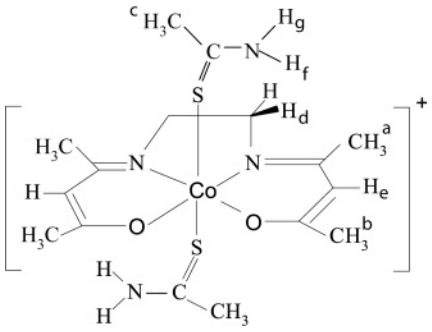
The ^1H NMR spectrum of **1** in $CDCl_3$ is shown in Fig. 4 (assignment as in Scheme 2). The signals at 2.02 and 2.20 ppm are assigned to two sets of CH_3 protons, H_a and H_b, respectively. The four ethylenediamine protons (H_d) appear as a singlet at 3.50 ppm. The singlet at 5.05 ppm corresponds to the H_e protons of acacen. The six methyl protons (H_c) of the axial thioacetamide ligands appear as a singlet at 2.37 ppm.

The amide protons are usually observed at δ 5–8.5 ppm (22). The free thioacetamide in $CDCl_3$ shows two NH proton resonances at 7.27 and 7.75 ppm. Upon coordination, these two signals move to lower fields. Since the two N-H protons of the coordinated thioacetamide (H_f and H_g) are involved in different hydrogen-bonding patterns (Fig. 3, Table 4), the two protons will presumably appear at considerably different chemical shifts if the hydrogen bonding retains its character in solution. This is most probably the origin of observing a higher chemical shift for the H_f proton (10.22 ppm), which is more strongly involved in an intramolecular hydrogen bonding relative to the H_g proton (8.73 ppm).



The ^1H NMR spectrum of **2** in $CDCl_3$ shows a pattern similar to that of **1** except for the signals due to the aromatic protons of the two phenyl rings that appear in the 7.44–7.83 ppm region. Other protons are also slightly shifted downfield as expected from the electron-withdrawing character of the rings. The signal at 2.23 ppm is assigned to the six methyl protons (H_a) of the equatorial ligand. The six methyl protons (H_c) of the axial thioacetamide ligands appear as a singlet at 2.39 ppm. The signal at 3.73 ppm is assigned to the four ethylenediamine protons (H_d) and the singlet at 5.78 ppm corresponds to the H_e protons of the equatorial ligand. The NH_2 protons (H_g and H_f) of the coordinated thioacetamide appear as singlets at 8.04 and 10.59 ppm, respectively.

UV–vis and solvatochromism studies



The absorption spectrum of *trans*-[Co^{III}(acacen)(ta)$_2$]ClO_4 in chloroform features a band with a true maximum at 518 nm. Based on the relatively high ε (3654 $(mol/L)^{-1}$ cm^{-1}) of this band it may be assigned to a combination of d–d and CT transitions. The position of this band is solvent dependent and shows negative solvatochromic shifts in a dozen organic solvents of various polarities (Table 5). This change

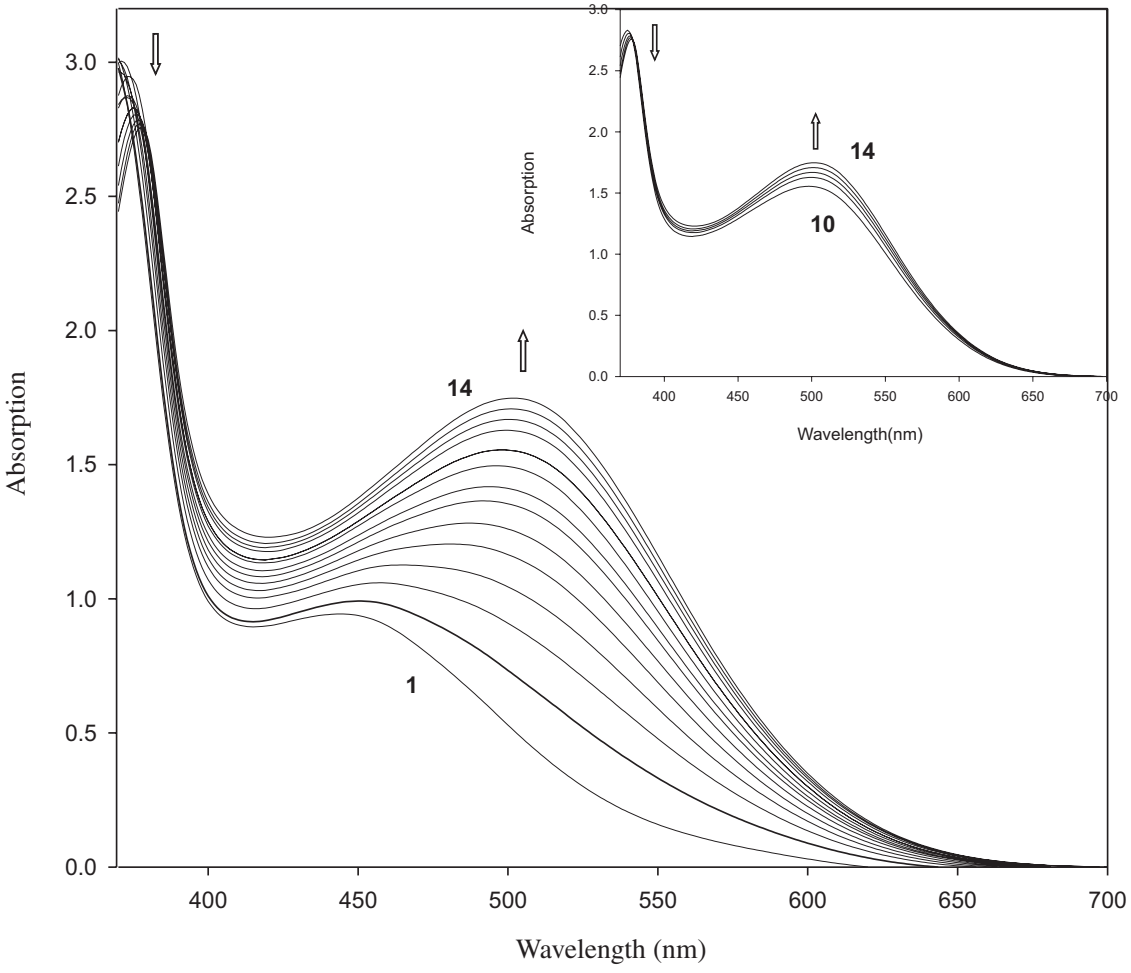
does not agree with the change in the polarity of the solvent. Therefore, it can be considered to correspond to the net of several solvent effects such as polarity, basicity, and H-bond accepting ability. The solvents can be divided into two groups based on the degree of solvatochromic shift. Solvents with dielectric constants below 20.7 (Nos. 1–6), exhibit small solvatochromic shifts of the band (14 nm) and relatively large ϵ. It is reasonable to assume that the first coordination sphere of the bis(thioacetamide) complex remains intact in these solvents. The structural integrity of the complex in solution is confirmed by its ^{1}H NMR spectrum in $CDCl_3$ (Fig. 4). The larger shift is observed in the solvent potentially capable of forming stronger hydrogen bonds with the NH_2 protons of the coordinated thioacetamide. This observation may be rationalized based on the assumption that the CT band is mainly of LLCT character and the electronic transition occurs from the p_π(C=S) of the coordinated thioacetamid to a π^* of acacen chelate, mediated by the central Co atom. A stronger hydrogen bonding stabilizes the ground state of the complex (Scheme 3) and has an unfavorable effect on the S $\rightarrow$ Co $\rightarrow$ acacen charge transfer transition and shifts the band to a higher energy.



In solvents of high dielectric constant and those that can coordinate to the metal center such as methanol, acetonitrile, DMSO, and water, there is a drastic change in both the position (up to 72 nm) and ϵ of the band. This hints at the possibility of a substitution process in which the two axial thioacetamide ligands are replaced by solvent molecules. Additional evidence for the substitution of the axial ligands comes from the ^{1}H NMR of the complex in DMSO-d^6 and CD_3OD. The appearance of a signal centered at about 7.2 ppm, which can be attributed to the NH_2 protons of the free thioacetamide, is supportive of a dissociation process leading to the free ligand. A further clue to this point is obtained from the electronic absorption spectral changes of the methanolic solution of the complex in the presence of excess thioacetamide. This is achieved by adding increasing amounts of thioacetamide to a solution of *trans*-[Co^{III}(acacen)$(ta)_2$]ClO_4 in methanol and monitoring the absorption spectral changes (Fig. 5). The absorption maximum moves from 450 nm in pure methanol to 510 nm (a red shift of about 60 nm) after adding excess (56 times molar ratio) thioacetamide. While no isosbestic points are observed during the first nine additions, an isosbestic point at 382 nm appears from then on and persists to the final stages of the reaction (Fig. 5. inset). These results indicate the existence of a two-step reversible equilibrium in methanolic solution

mide ligands in methanol and other coordinating solvents is evident.

As a typical pseudooctahedral low-spin d^6 complex, *trans*-$[Co^{III}(acacen)(ta)_2]^+$ contains the thioacetamide ligand that can function as a CT donor ligand for ligand-to-metal charge transfer (LMCT). The acacen is a π-donor and π-acceptor ligand that can contribute to a metal-to-ligand charge transfer transition (MLCT). The relatively high ϵ of the band at 517 nm in a chloroform solution of **1** and the solvatochromic properties of the complex are in agreement with the LLCT assignment of the longest wavelength absorption, which is mediated by the metal center. Some Co-centered character is also possible. This is in analogy to certain low-spin d^6 complexes such as Mo(diphos)(CO)(NO)(dtc) (23) and several d^8, Ni(diimine)(dithiolate) (24), and d^{10}, $Zn(phen)(C_6H_5S)_2$ (25) and $Zn(SC_6H_4\text{-}CH_3\text{-}p)_2$(dic), complexes (26).

The spectral properties of **2** fully support these conclusions (Table 5). The first transition in the electronic spectrum of *trans*-$[Co((BA)_2en)(ta)_2]PF_6$ in chloroform solution appears at a longer wavelength (528 nm) relative to that observed for *trans*-$[Co(acacen)(ta)_2]ClO_4$ (518 nm). This is a direct consequence of increasing the π-acceptor character of the equatorial Schiff base ligand by the two additional phenyl rings in $(BA)_2$en, which facilitates the metal-mediated LLCT. The π–π* intraligand transition of the Schiff base is also red-shifted. While the first electronic absorption of **1** in methanol is well-resolved (λ = 454 nm), it is obscured by the π–π* intraligand transition in **2** and appears as a shoulder to the π–π* transition, which tails down to 450 nm. The overall solvatochromic behavior of complex **2** in different solvents is similar to that of **1** and can be used as further evidence for the LLCT nature of the first absorption band in the electronic spectra of these complexes.

Conclusions

The preparation and detailed crystallographic and spectroscopic characterization of *trans*-$[Co^{III}(acacen)(ta)_2]ClO_4$ (**1**) and *trans*-$[Co((BA)_2en)(ta)_2]PF_6$ (**2**) have been carried out.[2] The thioacetamide ligands are S-bonded and occupy the axial positions. The donor ability of thioacetamide falls below that of common solvents: MeOH, CH_3CN, Me_2SO, and H_2O. The compounds exhibit a long wavelength LLCT, mediated by the metal center. The observed solvatochromism is explained by the effect that solvents of low dielectric constant have on the LLCT and a facile replacement of the thioacetamide ligands by the coordinating solvents.

Ab initio study of the decomposition of formamidine

M.H. Almatarneh, C.G. Flinn, and R.A. Poirier

Abstract: The decomposition of formamidine yielding hydrogen cyanide and ammonia has been investigated by ab initio calculations. Optimized geometries for reactants, transition states, and products were determined at the HF/6-31G(d) and MP2/6-31G(d) levels of theory. Energies were also determined at the G1, G2, G2MP2, G3, G3B3, G3MP2, and G3MP2B3 levels of theory. The role of water in the decomposition reaction of formamidine was examined. Intrinsic reaction coordinate (IRC) analysis was carried out for all transition states. Activation energies, enthalpies and free energies of activation were also calculated for each reaction pathway. G3 level of theory predicts the gas-phase decomposition of formamidine to have a high activation energy of 259.1 kJ mol^{-1}. Adding one water molecule catalyses the reaction by forming a cyclic hydrogen-bonded transition state, reducing the barrier to 169.4 kJ mol^{-1} at the G3 level. Addition of a second water, which acts as a "solvent" molecule, further reduces the barrier to 151.1 kJ mol^{-1} at the G3 level. These values are still high and explain why rather extreme conditions are necessary to achieve this reaction experimentally. Thermodynamic properties (ΔE, ΔH, and ΔG) for each reaction pathway studied were also calculated. The G3 heats of reaction (ΔE) of the gas-phase decomposition of formamidine, its complex with one water molecule, and its complex with two water molecules are 0.9, 2.2, and –5.1 kJ mol^{-1}, respectively. The G3 heat of reaction for the gas-phase decomposition to yield separated products is 22.3 kJ mol^{-1}. Free energies of reaction and of activation in aqueous solution were calculated with PCM using the KLAMT cavity model. At MP2 the formamidine reaction is found to be exergonic in aqueous solution and to favour formation of the separated products (NH_3 + HCN). The solvent model predicts a significant lowering of the free energy of activation (16–18 kJ mol^{-1}) for the unimolecular reaction and 21–42 kJ mol^{-1} for the water-mediated reaction in aqueous solution relative to the gas phase.

Key words: decomposition reaction, formamidine, Hartree–Fock, post Hartree–Fock, Gaussian-n theories, IRC, solvation models, PCM, KLAMT.

Résumé : Faisant appel à des calculs ab initio, on a étudié la décomposition de la formamidine qui conduit à la formation de cyanure d'hydrogène et d'ammoniac. On a déterminé les géométries optimisées des réactifs, des états de transition et des produits aux niveaux HF/6-31G(d) et MP2/6-31G(d) de la théorie. On a aussi déterminé les énergies aux niveaux G1, G2, G2MP2, G3, G3B3, G3MP2 et G3MP2B3 de la théorie. On a réalisé une analyse de tous les états de transition par le biais des coordonnées intrinsèques de la réaction. On a aussi calculé les énergies d'activation, les enthalpies et les énergies libres d'activation de chaque voie réactionnelle. Au niveau G3 de la théorie, les prédictions suggèrent que l'énergie d'activation de la décomposition de la formamidine en phase gazeuse est élevée et se situe à 259,1 kJ mol^{-1}. Au niveau G3, l'addition d'une molécule d'eau catalyse la réaction, avec formation d'un état de transition comportant une liaison hydrogène cyclique, et la barrière est réduite à 169,4 kJ mol^{-1}. Toujours au niveau G3, l'addition d'une deuxième molécule d'eau qui agit comme solvant réduit à nouveau la barrière à 151,1 kJ mol^{-1}. Ces valeurs sont toujours élevées et elles expliquent pourquoi il est nécessaire d'utiliser des conditions extrêmes pour effectuer cette réaction expérimentalement. On a aussi calculé les propriétés thermodynamiques (ΔE, ΔH et ΔG) pour chaque voie réactionnelle étudiée. Au niveau G3, chaleurs de réaction (ΔE) de décomposition en phase gazeuse de la formamidine, de son complexe avec une molécule d'eau et de son complexe avec deux molécules d'eau sont respectivement de 0,9, 2,2 et –5,1 kJ mol^{-1}. Au niveau G3, la chaleur de réaction pour la décomposition en phase gazeuse conduisant à des produits séparés est de 22,3 kJ mol^{-1}. On a calculé les énergies libres de réaction et d'activation en solution aqueuse « PCM », en utilisant le modèle de cavité de « KLAMT ». Au niveau MP2, on a trouvé que, en solution aqueuse, la réaction de la formamidine est exogernique et qu'elle favorise la formation de produits séparés (NH_3 + HCN). Le modèle du solvant permet de prédire que, pour la réaction en solution par rapport à la réaction en phase gazeuse, il y aura une diminution significative de l'énergie libre d'activation, de l'ordre de 16 à 18 kJ mol^{-1} pour la réaction unimoléculaire et de 21 à 42 kJ mol^{-1} pour la réaction catalysée par l'eau.

Introduction

Amidine compounds are of interest because of their medical and biochemical importance, having many biological and pharmaceutical uses (1). Formamidine is the simplest of the amidine class and has been found to exhibit antibiotic, antifungal, and anaesthetic properties. Amidines play a significant role in the biosynthesis of other biologically important compounds, such as purines, imidazoles, and the catabolism of histidine (1). Due to its small size, formamidine has been a prime target of both experimental and theoretical investigation. In addition to serving as a model for hydrogen-transfer reactions in bases of nucleic acids, formamidine has been extensively studied theoretically since it forms hydrogen-bonded complexes with itself and other molecules such as water.

The intramolecular 1,3-sigmatropic hydrogen rearrangement and intermolecular hydrogen transfers have been studied theoretically for various formamidine systems (2–9) including formamide–formamidine (10–17) and formamidine – formic acid (18, 19). Since most hydrogen transfers occur in aqueous solution, one must consider the role of water molecules in hydrogen transfer. Water can act not only as a solvent but also as a catalyst by both donating and accepting a hydrogen to promote long-range hydrogen transfer (water-mediated pathway).

Tautomerization by intramolecular hydrogen transfer involving formamidine and its complexes with one, two, and three water molecules was studied by Zhang et al. (20) using ab initio and density functional methods. They reported the importance of hydrogen-bonded water molecules that lowered the barrier to tautomerization. Nguyen et al. (6) investigated double hydrogen transfer in formamidine dimers using ab initio methods. The barrier for the prototropic tautomerization in these systems is reduced by about 84 kJ mol^{-1} at the Hartree–Fock level of theory when the hydrogen transfer is mediated by a water molecule. The solvent effect on the potential energy surface for double hydrogen transfer in formamidine dimers has also been studied (21). Solvent effects on the potential energy surface have also been investigated for formamidine hydrogen bonded to a water molecule using the chemical molecular dynamic simulation method (22).

Since biological activity depends greatly on the molecular conformation, Tortajada et al. (23) have investigated the relative stabilities of the E(trans) and Z(cis) conformers of formamidine and the relative stabilities of the complexes of both conformers with different monocations. They found that the (E) conformer of formamidine is 7.5 kJ mol^{-1} more stable than the Z conformer at both G2MP2 and G2 levels of theory. Dynamics and kinetic isotope effects for tautomerization of the formamidine-monohydrated complex using direct semiempirical dynamic calculation and the G2 level of theory was studied by Kim (24). Primary and solvent kinetic isotope effects in the water-mediated tautomerization of formamidine using an ab initio direct dynamic study was investigated by Bell and Truong (25).

A number of reactions of formamidine have been considered to be model reactions for more complex molecules with structural similarities to formamidine, such as single hydrogen transfer in bases of nucleic acids (6, 8, 26) as well as double hydrogen-transfer reactions. Recently, the deamination of the more stable E-isomer of formamidine with OH^-, H_2O, and H_3O^+ to yield formamide has been studied by Flinn et al. (26). This investigation was undertaken as a precursor to a study of the deamination of the DNA base cytosine. The E(trans) isomer of formamidine forms part of the cytosine structure, notably in the region of cytosine where the deamination of cytosine to uracil can take place. Cytosine is the most unstable of the DNA bases, deaminating spontaneously to uracil with an activation energy of 117 ± 4 kJ mol^{-1} (27). The mechanism for the deamination of formamidine was investigated using high level ab initio methods. Flinn et al. (26) found that deamination with OH^- yields a tetrahedral intermediate with a much lower activation energy barrier than for the reaction with H_2O and H_3O^+ using G2 theory.

Amidine is also known to undergo decomposition at elevated temperatures, yielding hydrogen cyanide and ammonia. Some experimental results suggest that the decomposition of amidine is an unimolecular process (28). The unimolecular decomposition mechanism of formamidine to give ammonia and hydrogen cyanide has been investigated by Andres et al. (28, 29) at the HF level of theory using the 4-31G basis set. They determined the activation energy to be 333 kJ mol^{-1} and the energy of reaction to be 0.04 kJ mol^{-1} for the formation of the NH_3–HCN complex. A potential energy hypersurface was established. The first step was the isomerization of the E(trans) to Z (cis) isomer followed by a 1,3-shift of the hydrogen bonded to the imino nitrogen to the amino nitrogen accompanied by the cleavage of the bond between the carbon and the amino nitrogen. At present, no computational studies of water-mediated or solution-phase decomposition of formamidine to yield hydrogen cyanide and ammonia have been reported. In this work, a detailed study of the unimolecular and the water-mediated (mono- and di-hydrated complexes) decomposition of formamidine, both in the gas phase and in solution, is presented. Because of the size of the system, it is possible to perform the calculations at high levels of theory, such as the Gaussian-n theories, which are known to give reliable energetics. The role played by water as a catalyst as well as its role as solvent on the energetics and mechanism of this reaction were also investigated. The results serve as a benchmark for similar reactions in solution for more complex systems, few of which have been studied in depth computationally.

Computational method

The MUNgauss (30) computational program was used for most of the geometry optimizations at HF/6-31G(d) for reactants, products, and transition state structures. All other calculations were performed with either Gaussian 98 (31) or

Gaussian 03 (32). The geometries of all reactants, transition states, and products were fully optimized at the restricted HF and second-order Møller–Plesset (MP2) levels of theory using the 6-31G(d) and 6-31+G(d) basis sets. Energies have also been calculated using the Gaussian-n theories, G1, G2, G2MP2, G3, G3B3, G3MP2, and G3MP2B3. B3LYP/6-31+G density functional theory calculations were also performed. Intrinsic reaction coordinate (IRC) analysis was carried out for all transition states. Free energies of reaction and activation in aqueous solution for the unimolecular decomposition reaction of formamidine were calculated with the polarizable continuum model (PCM) as implemented in Gaussian03. The choice of cavity in PCM is important because the computed energies and properties depend on the cavity size. By default, the PCM model builds up the cavity using the united atom (UA) model, i.e., by putting a sphere around each solute heavy atom; hydrogen atoms are enclosed in the sphere of the atom to which they are bonded. The three UA models that are available in Gaussian03 are not suitable for reactions involving hydrogen transfers and hence were not used. In this study, the PCM solvent calculations were performed using the KLAMT cavity. All free energy calculations involving solvation were performed using both gas- and solution-phase structures optimized at the RHF/6-31G(d) and MP2/6-31G(d) levels. Other cavities were also investigated (UFF and PAULING), but it was impossible to obtain all the optimized structures for these models. Single point calculations based on gas-phase optimized geometries using UFF and PAULING cavities gave results that were very close to the KLAMT cavity.

Results and discussion

The results for the decomposition reaction of formamidine and its mono- and di-hydrated complexes in the gas phase and in aqueous solution are given in Tables 1–3.

Thermodynamic results for the decomposition of formamidine

The thermodynamic properties for the decomposition reaction of formamidine are listed in Table 1. The reaction for the decomposition of formamidine is found to be endothermic at the Gaussian-n theories (with enthalpies of 26.6–30.1 kJ mol^{-1}) and less endothermic for the formation of the NH_3–HCN complex (4.8–9.3 kJ mol^{-1}). These results do not differ by more than 4.5 kJ mol^{-1}, which is within the expected error of the Gaussian-n theories. The HF/6-31G(d) enthalpies are consistently in better agreement with the Gaussian-n theories than the MP2/6-31G(d) enthalpies. The difference between the enthalpy for the formation of the complex and the formation of separated products (–22.5 kJ mol^{-1} at G3) represents the stability of the NH_3–HCN complex. Adding a single water molecule has little effect on the enthalpy of reaction (6.5 vs. 6.7 kJ mol^{-1} at G3). Addition of the second water molecule has a larger effect on the enthalpy of reaction, which is now only slightly endothermic (0.6 kJ mol^{-1} at G3). The decomposition reaction of formamidine with separated products is more exergonic than the formation of the HCN–NH_3 complex. This difference is simply due to the increase in the entropy for the formation of the separated products. Except for the HF solution results, all other levels of theory predict the reaction to be exergonic, where formation of the separated species (HCN + NH_3) is favoured over formation of the complex (HCN–NH_3)

Activation energy, enthalpy and free energies of activation for the decomposition of formamidine

The gas-phase unimolecular decomposition of formamidine

The geometries for the reactant, transition state, and products for the unimolecular gas-phase decomposition of formamidine are shown in Scheme 1 along with the atom-numbering scheme.

Scheme 1.

R1 TS1 Products

Vibrational analysis for the two structures in Fig. 1 shows that the C_s structure, used in a previous study (28), has one imaginary frequency, and the nearly planar C_1 structure to be a minimum. From these results, the equilibrium structure with C_1 symmetry was considered as the starting point for this reaction in this study.

The IRC analysis of TS1 for the gas-phase decomposition reaction of formamidine is shown in Fig. 2. The formamidine decomposition transition state can be described in terms of two bond ruptures (N3—H5 and N4—C1) and one bond formation (N4—H5). The transition state structure is highly strained, with an N3-C1-N4 angle of 106.7° com-

Scheme 2.

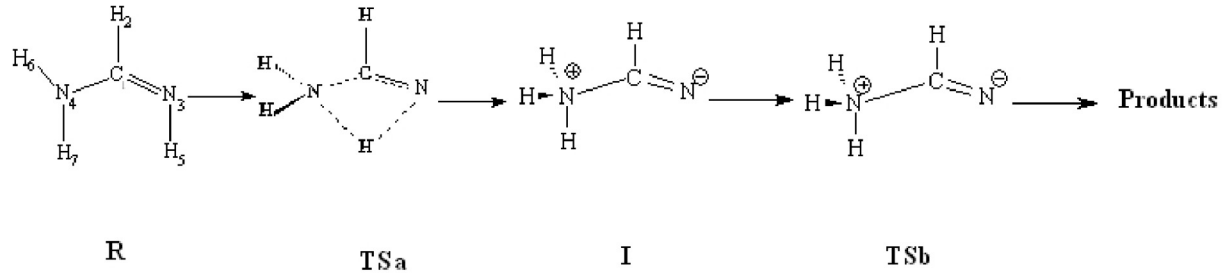

Fig. 1. The C_s and C_1 structures of formamidine.

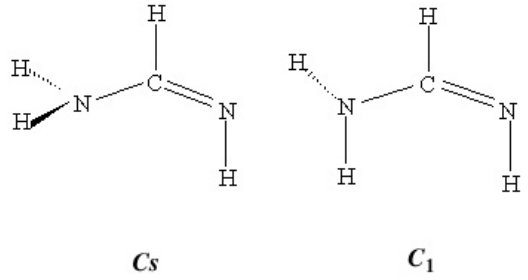

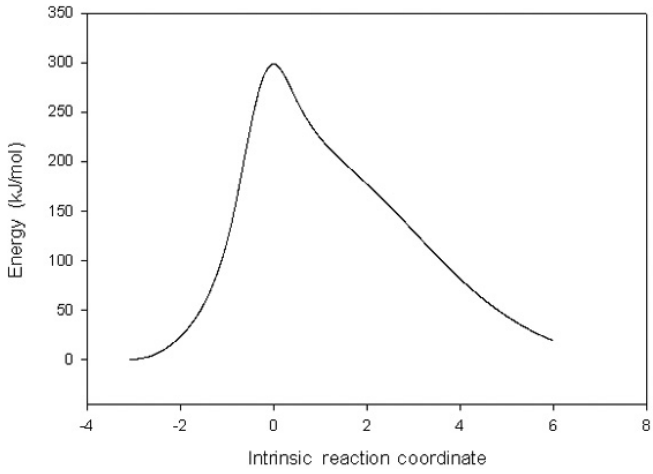

Fig. 2. Energy vs. the IRC for the gas-phase decomposition of formamidine at HF/6-31G(d) with the CalcFC option. Zero energy taken as the reactant.

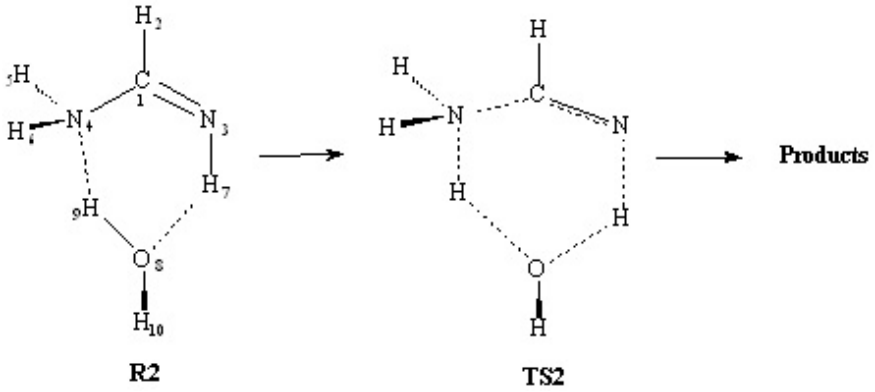
pared with 128.7° for the reactant. The product is a hydrogen-bonded complex of ammonia with hydrogen cyanide. The activation energy for the unimolecular gas-phase decomposition reaction of formamidine at various levels of theory are listed in Table 2. An activation energy of 333.1 kJ mol^{-1} was reported for this reaction at HF/4-31G(d) (28). In this study, the activation energy is 331.5, 253.5, and 259.1 kJ mol^{-1} at HF/6-31G(d), G1, and G3 levels, respectively. The free energy of activation for the reaction is 315.3, 253.8, and 259.4 kJ mol^{-1} at HF/6-31G(d), G1, and G3 levels, respectively. These values are high and explain why rather extreme conditions are necessary to achieve this reaction experimentally.

Applying the solvent model yields a different mechanism for this reaction from the one in the gas phase. The decomposition reaction in solution involves a two-step mechanism for both the unimolecular and the water-catalyzed decomposition. In solution, the first step involves transfer of a hydrogen from the imino nitrogen to the amino nitrogen forming a zwitterionic intermediate that is stabilized in solution. The transition state (TSa) and the zwitterionic intermediate for this reaction are shown in Scheme 2.



The structures of the reactant and products for the unimolecular decomposition in the gas and solution phases are only slightly different. The first transition state structure for the reaction in solution is similar to the gas-phase structure, but more productlike. For example, the N4—C1 bond length increased from 1.47 Å in the gas phase to 1.53 Å in solution. The zwitterionic intermediate has a slightly longer N4—C1 bond length (1.58 Å), which increases significantly to 1.74 Å in the second transition state, giving a very productlike structure, with a very small activation energy (2.5 kJ mol^{-1}). In solution, the N3-C1-H2 angle of the second transition state (TSb) is 140.3° compared with 132.6° for the first transition state (TSa). The solvent models used in this study predict that the free energy of activation for the unimolecular decomposition would be reduced in aqueous solution. Using the PCM–KLAMT model, $\Delta G^{\ddagger}$ is lowered by 16 and 18 kJ mol^{-1} at HF/6-31G(d) and MP2/6-31G(d) levels, respectively. As given in Table 2, the free energy of activation for the unimolecular decomposition in solution is 237.9 kJ mol^{-1} at the MP2/6-31G(d) level of theory, not that different from the single point value of 236.1 kJ mol^{-1}.

The decomposition of formamidine with one water molecule

Scheme 3 shows the one-step decomposition mechanism for the monohydrated complex of formamidine. This scheme shows that the water molecule catalyses the decomposition by forming a nearly planar six-membered ring with formamidine. In this case, the N3-C1-N4 angle in the transition state TS2 shown in Fig. 3 is 119.4° compared with 106.7° in the unimolecular reaction transition state (TS1, Scheme 1), an increase of 12.7°. The activation energy, the enthalpy of activation, and free energy of activation for this reaction are listed in Table 2. Adding one water molecule significantly relaxes the transition state, reducing the angle strain and consequently reducing the barrier height from 259.1 to 169.4 kJ mol^{-1} at the G3 level of theory. The free energy of activation for this system is 246.3, 178.3, and 182.4 kJ mol^{-1} at HF/6-31G(d), G1, and G3 levels, respectively. These results clearly show that the kinetically difficult reaction takes place more easily when catalyzed by a single water molecule. The IRC analysis of the transition state TS2 for this system is shown in Fig. 4.

Scheme 3.

Scheme 4.

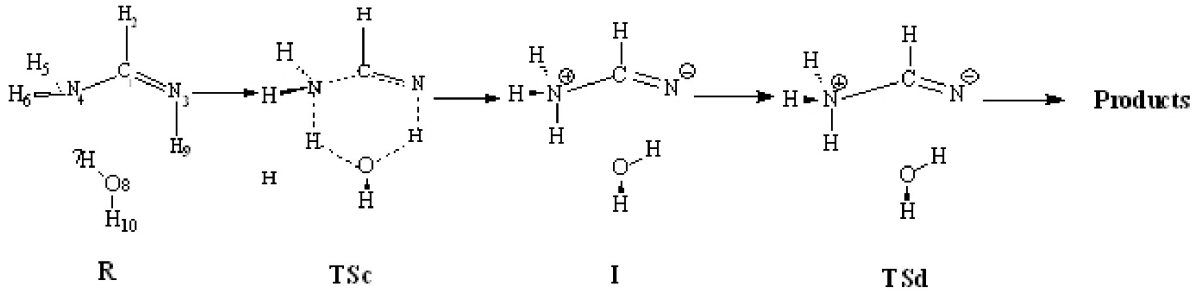

Fig. 3. The transition state structure for the decomposition reaction of formamidine with one water molecule.

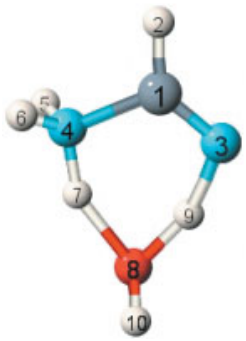

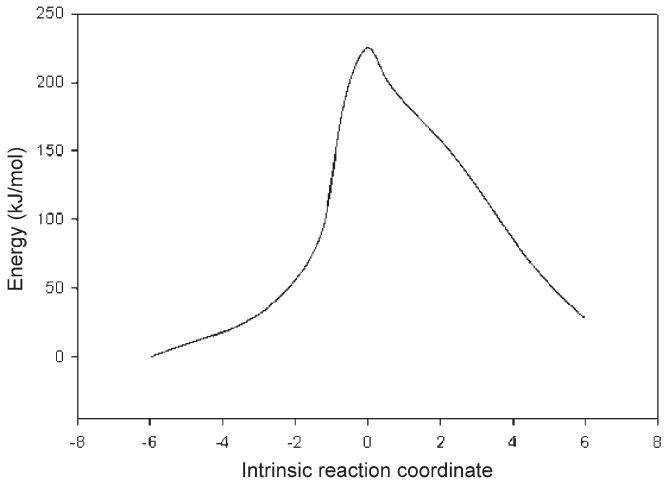

Fig. 4. Energy vs. the IRC for the decomposition of monohydrated formamidine at HF/6-31G(d) with the CalcFC option. Zero energy taken as the reactant.

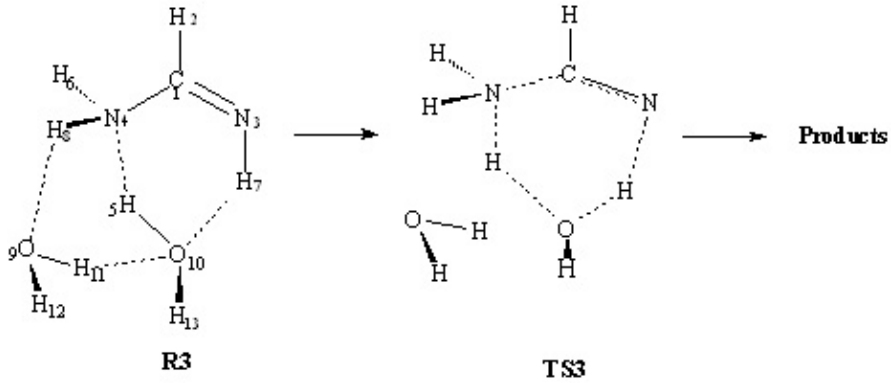
In solution, the one-water-catalyzed decomposition reaction of formamidine also involves a two-step mechanism forming a zwitterionic intermediate as shown in Scheme 4. The structure of the reactant and products for the one-water-catalyzed decomposition in both gas and solution phases also only differ slightly. As for the unimolecular reaction, the N4—C1 bond increases from 1.50 Å in the gas phase to 1.55 Å in the solution phase in the first step of the reaction. In solution, the N3-C1-H2 angle of the second transition state (TSd) is 141.4° compared with 128.6° for the first transition state (TSc).



The zwitterionic intermediate has a slightly longer N4—C1 bond length (1.59 Å), which increases significantly to 1.77 Å in the second transition state, giving an even more productlike structure with a very small activation energy (6.0 kJ mol^{-1}). In solution, the free energy of activation would further be reduced by 21 to 42 kJ mol^{-1} (depending on the level of theory used). The free energy of activation for the single water-mediated decomposition in solution is 148.9 kJ mol^{-1} at the MP2/6-31G(d) level, not significantly different from the single point value (157.6 kJ mol^{-1}), although the mechanism changes to a two-step mechanism in solution.

The decomposition reaction of formamidine with two water molecules

Previous research on 1,3-hydrogen shift tautomerization reactions (20) has identified transition state structures in which two water molecules participate in the hydrogen

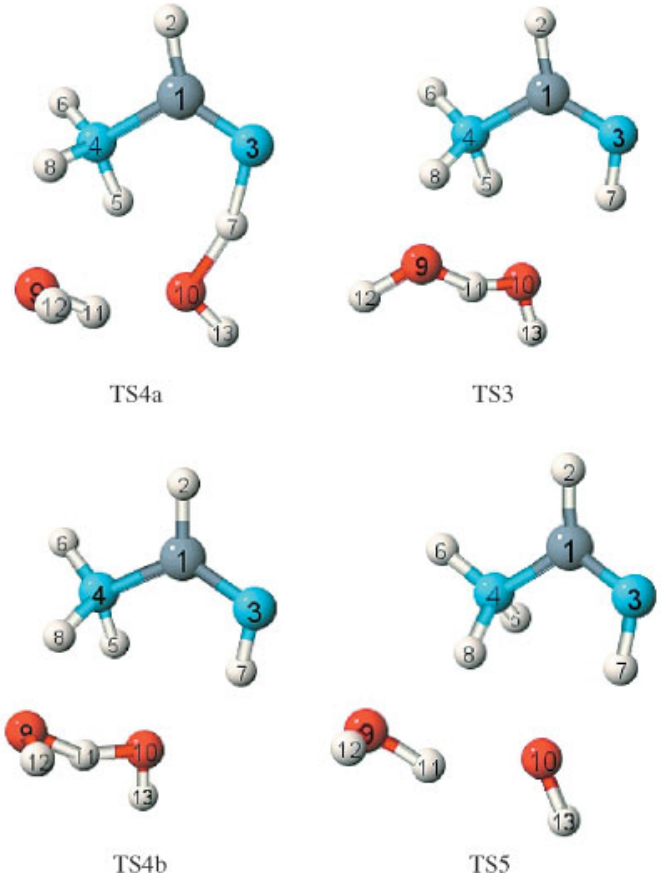

Scheme 5.

transfer by forming an eight-membered ring. Addition of the second water molecule further relieves angle strain, lowering the activation energy for the reaction. However, all attempts to optimize the cyclic eight-membered dihydrated formamidine transition state structure failed. This investigation did, however, lead to four different transition state structures containing a six-membered ring as shown in Fig. 5. Scheme 5 shows the only transition state (TS3) that connects the reactants and the products, as determined from the IRC analysis. This transition state is very similar in structure to TS2 for the one-water-mediated decomposition reaction of formamidine. In TS3, one water molecule directly participates in the hydrogen transfer, as shown in Scheme 5. The second water molecule does not directly participate in hydrogen transfer, but further stabilizes the transition state by hydrogen bonding to both an N4 hydrogen and O10.

Activation energies, enthalpies of activation, and free energies of activation are listed in Table 2 for the decomposition of dihydrated formamidine. Adding the first water molecule reduces the activation energy by 89.7 kJ mol^{-1} at the G3 level. Adding the second water molecule reduces the activation energy of the formamidine decomposition to a much smaller extent, further decreasing the activation energy by only 18.3 kJ mol^{-1}. This is because the first water molecule catalyses the reaction, whereas the second water molecule simply stabilizes the transition state by "solvation". Thus, the water can both stabilize the transition state and act as a catalyst for these reactions. The present results support a single water-mediated decomposition mechanism and that a two-water-mediated transition state does not appear to exist, in the gas phase or in aqueous solution, for this reaction.

Fig. 5. The transition state structures for dihydrated formamidine.

Intermolecular hydrogen-transfer transition states

Three additional transition states were found (TS4a, TS4b, and TS5), which represent intermolecular hydrogen transfer between formamidine and either one or two water molecules and do not result in product formation. Activation energies, enthalpies of activation, and free energies of activation for these intermolecular hydrogen transfers are listed in Table 3. TS4a and TS4b are rotational isomers, differing from each other for the most part with respect to the orientation of H12 (Fig. 5). These two transition states involve the exchange of a hydrogen between formamidine and the two hydrogen-bonded water molecules through a six-membered cyclic structure. The IRC confirms that these transition states lead to the reactant in both directions. TS5 has the highest activation energy among the transition states, and involves a hydrogen (H5) transfer from a single water to N4 of formamidine followed by rotation about the C—N bond and transfer of a hydrogen (H8) back to water (Fig. 5). The IRC confirms that this transition state goes to the reactant in both directions.

IRC analysis

IRC analysis was carried out for all transition states. The IRC analysis for the gas-phase transition state (TS1, Fig. 2) and the monohydrated transition state (TS2, Fig. 4) confirmed that these transition states connected the expected reactants and products. However, the IRC analysis of the

dihydrated transition states (TS3, TS4, and TS5), using the CalcFC option, did not give the complete reaction pathway in several cases, stopping prematurely as shown in Figs. 6–8. Initially, this suggested the existence of an intermediate. Further analysis was carried out using the CalcFC or CalcALL options with structures optimized at different levels of theory and basis set. None of these options consistently gave a complete reaction pathway. In each of the cases in which the complete reaction pathway was obtained, shoulders are found to exist, as can be seen in Figs. 6–8. Such shoulders for some of the options listed above may be indicative of zwitterionic species, unstable in the gas phase but stable in solution phase.

Conclusions

The high degree of stability of formamidine toward decomposition to ammonia and hydrogen cyanide is confirmed by this investigation. We have performed ab initio calculations on water-mediated hydrogen transfer in the decomposition reaction of formamidine. We found that a single water molecule can act as a catalyst, stabilizing the transition state, and thus lowering the barrier height for the gas-phase decomposition reaction. At the G3 level of theory, the one-water-catalyzed mechanism lowers the barrier to 169.4 kJ mol^{-1} from the gas-phase value of 259.1 kJ mol^{-1} for the decomposition reaction of formamidine. Addition of a second water, which simply acts as a solvent molecule, further lowers the barrier to 151.1 kJ mol^{-1}. A two-water-mediated transition state has not been found despite a thorough investigation.

The decomposition reaction of formamidine in solution involves a two-step mechanism for both the unimolecular and the water-catalyzed decomposition. The solvent model predicts a significant lowering of the free energy of activation (16–42 kJ mol^{-1}, depending on the level of theory) for the reaction in aqueous solution relative to the gas phase.

Intrinsic reaction coordinate (IRC) analysis was carried out for all transition state structures to obtain the complete reaction pathway. Thermodynamic properties were calculated for each reaction. The activation energies and the heats of reaction calculated at the Gaussian-n theories agree to within 10 kJ mol^{-1}.[2]

α- and β-Cyclodextrin [2]rotaxanes with (diethylenetriamine)platinum(II) stoppers

Victor X. Jin, Donal H. Macartney, and Erwin Buncel

Abstract: A series of dinuclear platinum(II) complexes, $[(dien)Pt(NH_2(CH_2)_nNH_2)Pt(dien)]Cl_4$ (dien = diethylenetriamine, n = 8, 9, 10, and 12) and their corresponding [2]rotaxanes with α-cyclodextrin (α-CD), $[(dien)Pt\{NH_2(CH_2)_nNH_2{\cdot}\alpha\text{-}CD\}Pt(dien)]Cl_4$, have been synthesized and characterized by ^1H, ^{13}C, and ^{195}Pt NMR spectroscopy and electrospray mass spectrometry. The rotaxanes were prepared by reacting the $\{NH_2(CH_2)_nNH_2{\cdot}\alpha\text{-}CD\}$ pseudorotaxanes with [Pt(dien)]Cl, to stopper the included linear α,ω-diaminoalkane chains with the inert Pt(II) end groups. The kinetics of the self-assembly and dissociation of the β-CD rotaxane, $[(dien)Pt\{NH_2(CH_2)_{10}NH_2{\cdot}\beta\text{-}CD\}Pt(dien)]^{4+}$, were investigated by using ^1H NMR and are indicative of a *slippage* mechanism, owing to the comparable sizes of the β-CD cavity and the $[Pt(dien)]^+$ end group. A relatively weak inclusion of the end group in the β-CD cavity precedes a thermally promoted passage of the β-CD over the $[Pt(dien)]^+$ end group onto the hydrophobic polymethylene chain of the bridging ligand of the thread.

Key words: rotaxanes, pseudorotaxanes, cyclodextrin, platinum complexes, slippage mechanism.

Résumé : On a synthétisé une série de complexes binucléaires du platine(II), de formule générale $[(dien)Pt(NH_2(CH_2)_nNH_2)Pt(dien)]Cl_4$ (dien = diéthylènetriamine; n = 8, 9, 10 et 12), ainsi que les [2]rotaxanes correspondants avec la α-cyclodextrine (α-CD), de formule générale $[(dien)Pt\{NH_2(CH_2)_nNH_2{\cdot}\alpha\text{-}CD\}Pt(dien)]Cl_4$ et on les a caractérisés par spectroscopie RMN du ^1H, du ^{13}C et du ^{195}Pt et par spectrométrie de masse avec électronébulisation. On a préparé les rotaxanes en faisant réagir les pseudorotaxanes $\{NH_2(CH_2)_nHN_2{\cdot}\alpha\text{-}CD\}$ avec du [Pt(dien)]Cl pour bloquer les chaînes linéaires α,ω-diaminoalcanes incluses avec des groupes terminaux Pt(II) inactifs. Faisant appel à la RMN du ^1H, on a étudié la cinétique de l'autoassemblage et de la dissociation du β-CD rotaxane, $[(dien)Pt\{NH_2(CH_2)_{10}NH_2{\cdot}\beta\text{-}CD\}Pt(dien)]^{4+}$ et les résultats suggèrent l'existence d'un mécanisme de glissement en raison des tailles comparables de la cavité de la β-CD et du groupe terminal $[Pt(dien)]^+$. Une faible inclusion du groupe terminal dans la cavité de la β-CD précède un passage favorisé par la chaleur de la β-CD par-dessus le groupe terminal $[Pt(dien)]^+$ et sur la chaîne polyméthylène hydrophobe du ligand qui assure le pont du filament.

Mots clés : rotaxanes, pseudorotaxanes, cyclodextrine, complexes du platine, mécanisme de glissement.

[Traduit par la Rédaction]

Introduction

Cyclodextrins (CD) (1) are a homologous family of cyclic oligosaccharides that are constructed of α-(1→4)-linked glucopyranose units (1–5). The three most common cyclodextrins consist of six (α-CD), seven (β-CD), and eight (γ-CD) monosaccharide subunits, and in terms of molecular architecture can be viewed as toroidal baskets. This intrinsic cyclic nature enables them to function as hosts in the formation of inclusion complexes, and thus they have found widespread medicinal applications as carriers of pharmaceuticals and biochemicals (6). Cyclodextrins are also widely employed as the cyclic component in the syntheses of rotaxanes (7, 8), which are supramolecular complexes (9) in which this cyclic bead is threaded by a linear chain that is terminated by bulky organic or transition-metal-complex stopper groups to prevent dissociation. Several mechanisms for the formation of metal-complex-stoppered [2]rotaxanes of cyclodextrins ($[L_5M\{L—L{\cdot}CD\}ML_5]^{2n+}$) have been identified. The *threading* process involves the attachment of bulky metal complexes (ML_5^{n+}) to donor atoms on each end of the linear thread (L—L) of a preassembled pseudorotaxane (10–14). Alternatively, if the bond between the metal center and the thread donor atom is sufficiently labile, the dissociation of one metal center of a bridged dimer complex ($[L_5M\{L—L{\cdot}CD\}ML_5]^{2n+}$), followed by inclusion of the bridging ligand in the CD cavity, would yield a semirotaxane species ($[L_5M\{L—L{\cdot}CD\}]^{n+}$). The recomplexation of the terminal donor atom by the metal center would yield the [2]rotaxane. We have reported the employment of both methods in the self-assemblies of a series of stable α-cyclodextrin rotaxanes of the types $[(NC)_5Fe\{R(CH_2)_nR{\cdot}\alpha\text{-}CD\}Fe(CN)_5]^{4-}$ (R = 4,4′-bipyridine and (or) pyrazine, and 3- and 4-cyanopyridine) (15–18) and $[[(NC)_5Fe\{pyRpy{\cdot}\alpha\text{-}CD\}Fe(CN)_5]^{6-}$ (pyRpy is a neutral bis(4-pyridyl) ligand such as 4-azopyridine) in aqueous solution (19, 20).

Scheme 1. Structure and proton labeling scheme for $[(dien)Pt(NH_2(CH_2)_{12}NH_2)Pt(dien)]^{4+}$.

When the cavity of the cyclodextrin and the diameter of the metal complex are closely matched in size, the threading of the cyclic component may only occur efficiently at elevated temperatures (21, 22), using a method of preparing rotaxanes termed *slippage* (23). We have used this mechanism for the assembly of a number of α-cyclodextrin rotaxanes with dicationic organic threads $R(CH_2)_nR^{2+}$ (R = NR_3^+, $P(CH_3)_3^+$, 4-*tert*-butylpyridinium, and 4-(α-alkyl-α-methanolpyridinium), and n = 8–12) (24–26). The application of this method to the synthesis of a cyclodextrin [2]rotaxane of β-cyclodextrin, for example, would require an end unit that is comparable in size to the 7.0 Å diameter of the β-cyclodextrin cavity. While octahedral metal centers, such as substituted pentacyanoferrate(II), are typically too large to pass through β-CD, a square-planar coordination geometry at the metal center, such as platinum(II), might permit a slippage process to occur. Cyclodextrin inclusion complexes with mononuclear platinum(II) complexes such as $Pt(P(CH_3)_3)(NH_3)Cl_2$ have been reported by Stoddart and co-workers (27, 28). Dinuclear platinum complexes with bridging α,ω-diaminoalkane linkers, $[\{cis\text{-}PtCl(NH_3)_2\}_2\{\mu\text{-}NH_2(CH_2)_nNH_2\}]^{2+}$, constitute a class of compounds displaying novel DNA-binding properties and high activity in vitro and in vivo against tumor cell lines resistant to cisplatin (29). This activity, however, is accompanied by high toxicity. Other cyclic molecular hosts, such as cucurbiturils, have been proposed (30) and investigated (31, 32) for the encapsulation of dinuclear platinum antitumor agents, to reduce toxicity through slow release and hindered access. Based on the potential medical applications of cyclodextrins for platinum complexes and on an interest in expanding the library of metal complex rotaxane stoppers with different coordination geometries, we have been investigating the syntheses and the kinetics and mechanisms of the assembly and dissociation of cyclodextrin [2]rotaxanes with α,ω-diaminoalkane threads and platinum(II) stoppers with different spectator ligands. We have shown that with a stopper such as (ethylenediamine)(pyridine)platinum(II), the pyridine can act as a "hook" in preventing the dissociation of the cyclodextrin [2]rotaxanes.[2] In this paper, the (diethylenetriamine)platinum(II) center has been employed to stopper α- and β-cyclodextrin [2]rotaxanes, using $NH_2(CH_2)_nNH_2$ (n = 8, 9, 10, and 12) bridging ligands as the threads (Scheme 1).

A series of dinuclear platinum(II) complexes, $[(dien)Pt(NH_2(CH_2)_nNH_2)Pt(dien)]Cl_4$ (**1**–**4**), and their corresponding [2]rotaxanes with α-cyclodextrin (α-CD), $[(dien)Pt\{NH_2(CH_2)_nNH_2\cdot\alpha\text{-}CD\}Pt(dien)]Cl_4$ (**1**α–**4**α), have been synthesized and characterized by ^1H, ^{13}C, and ^{195}Pt NMR spectroscopy and electrospray mass spectrometry. The results of a kinetic investigation of the thermally promoted self-assembly and dissociation of the β-cyclodextrin [2]pseudorotaxane with the $[(dien)Pt(NH_2(CH_2)_{10}NH_2)\text{-}Pt(dien)]^{4+}$ ion are described in terms of a *slippage* mechanism.

Experimental section

Materials

α- and β-Cyclodextrins (Aldrich) were dried at 80 °C under reduced pressure for at least 10 h prior to use. Potassium tetrachloroplatinate(II), diethylenetriamine, 1-adamantanecarboxylic acid, 1,8-diaminooctane, 1,9-diaminononane, 1,10-diaminodecane, and 1,12-diaminododecane (Aldrich) were used as received. Chloro(diethylenetriamine)platinum(II) chloride, [Pt(dien)Cl]Cl, was prepared by literature methods (33, 34).

Preparation of dinuclear platinum complexes

[(dien)Pt(NH$_2$(CH$_2$)$_n$NH$_2$)Pt(dien)]Cl$_4$ (1–4)

The complexes were prepared by stirring a mixture of 1 mmol of the appropriate α,ω-diaminoalkane and 2 mmol of chloro(diethylenetriamine)platinum(II) chloride in 15 mL of distilled water for 4 h at 50 °C. The solutions were reduced in volume to less than 5 mL and cooled. The products were precipitated by adding 15 mL of ethanol, and white crystals were obtained upon recrystallization from 95% ethanol.

[(dien)Pt(NH$_2$(CH$_2$)$_8$NH$_2$)Pt(dien)]Cl$_4$ (1)

Yield: 0.758 g (86%). ^1H NMR (D_2O, ppm) δ: 3.2–2.6 (m, 16H, $H_{1,2}$), 2.56 (t, 4H, H_α), 1.53 (m, 4H, H_β), 1.24 (m, 8H, $H_{\gamma-\delta}$). ^{13}C NMR (D_2O, ppm) δ: 53.65 (C_1), 50.80 (C_2), 47.26 (C_α), 31.07 (C_β), 28.75 (C_γ), 26.15 (C_δ). ^{195}Pt NMR (D_2O, ppm) δ: –2936.

[(dien)Pt(NH$_2$(CH$_2$)$_9$NH$_2$)Pt(dien)]Cl$_4$ (2)

Yield: 0.744 g (83%). ^1H NMR (D_2O, ppm) δ: 3.2–2.6 (m, 16H, $H_{1,2}$), 2.50 (t, 4H, H_α), 1.48 (m, 4H, H_β), 1.17 (m, 10H, $H_{\gamma-\varepsilon}$). ^{13}C NMR (D_2O, ppm) δ: 53.31 (C_1), 50.46 (C_2), 46.93 (C_α), 30.74 (C_β), 28.58 (C_γ), 28.43 (C_ε), 26.15 (C_δ). ^{195}Pt NMR (D_2O, ppm) δ: –2932.

[(dien)Pt(NH$_2$(CH$_2$)$_{10}$NH$_2$)Pt(dien)]Cl$_4$ (3)

Yield: 0.791 g (87%). ^1H NMR (D_2O, ppm) δ: 3.2–2.6 (m, 16H, $H_{1,2}$), 2.56 (t, 4H, H_α), 1.53 (m, 4H, H_β), 1.22 (m, 12H, $H_{\gamma-\varepsilon}$). ^{13}C NMR (D_2O, ppm) δ: 53.56 (C_1), 50.72 (C_2), 45.57 (C_α), 31.06 (C_β), 29.01 (C_γ), 28.85 (C_ε), 26.15 (C_δ). ^{195}Pt NMR (D_2O, ppm) δ: –2937.

[(dien)Pt(NH$_2$(CH$_2$)$_{12}$NH$_2$)Pt(dien)]Cl$_4$ (4)

Yield: 0.750 g (80%). ^{1}H NMR (D_2O, ppm) δ: 3.2–2.6 (m, 16H, $H_{1,2}$), 2.57 (t, 4H, H_α), 1.53 (m, 4H, H_β), 1.22 (m, 16H, $H_{\gamma-\xi}$). ^{13}C NMR (D_2O, ppm) δ: 53.18 (C_1), 50.34 (C_2), 46.81 (C_α), 30.67 (C_β), 28.74 (C_γ), 28.47 (C_ε), 25.80 (C_δ), 20.97 (C_ξ). ^{195}Pt NMR (D_2O, ppm) δ: –2937.

Preparation of α-CD rotaxanes of dinuclear platinum complexes

[(dien)Pt{NH$_2$(CH$_2$)$_n$NH$_2$·α-CD}Pt(dien)]Cl$_4$ (1α–4α)

The rotaxane complexes were prepared by mixing 1 mmol of the α,ω-diaminoalkane with 2 mmol of α-CD in 20 mL of distilled water for 30 min at 40 °C, followed by adding 2 mmol of chloro(diethylenetriamine)platinum(II) chloride and stirring for at least 4 h. The volume of the solution was reduced to less than 5 mL, and the product was precipitated by adding 20 mL of ethanol to the cooled reaction solution. Pale yellow crystals were obtained upon recrystallization from 95% ethanol.

Physical measurements

The ^{1}H NMR kinetic measurements and chemical shift titrations were performed on Bruker Avance-400 and Avance-500 instruments in D_2O (the residual solvent proton signal served as the reference), with the NMR probe temperature maintained to within ±0.5 °C. The ^{195}Pt NMR spectra were recorded on the Avance-400 instrument in D_2O, using K_2PtCl_4 as the external reference at –1620 ppm. In the kinetics experiments on the formation of the [2]rotaxane, a weighed amount of dried β-CD (1–10 mg) was directly added to a 5 mm NMR tube containing a thermostatted solution of the dinuclear [(dien)Pt(NH$_2$(CH$_2$)$_{10}$NH$_2$)Pt(dien)]$^{4+}$ complex (1.0 mmol/L) in D_2O (0.05 mol/L NaCl). Spectra were collected at fixed time intervals for at least four half-lives and then again after 10–15 half-lives until an equilibrium was reached. The concentration of the threaded molecules [L·CD] formed from the guest (L) and host (CD) was determined by integrating the H_β resonances of the alkyl chain of the guest. The plots of $\ln\{([L\cdot CD]_e - [L\cdot CD]_0)/([L\cdot CD]_e - [L\cdot CD]_t)\}$ against time were linear for at least 3 half-lives, with the slopes from the linear regressions yielding rate constants with error limits in the range of 3%–7%. For the kinetics of dissociation of the [2]pseudorotaxane, a weighed amount (11.5 mmol/L) of a competing guest, 1-adamantanecarboxylic acid (35), was added to the equilibrated solution of the [2]pseudorotaxane [(dien)Pt{NH$_2$-(CH$_2$)$_{10}$NH$_2$-β-CD}Pt(dien)]$^{4+}$ (prepared by equilibrating a mixture of 1.0 mmol/L [(dien)Pt{NH$_2$(CH$_2$)$_{10}$NH$_2$}Pt-(dien)]$^{4+}$ and 3.0 mmol/L β-CD). The H_β resonance was again employed to monitor the release of the platinum(II) dimer from the CD cavity.

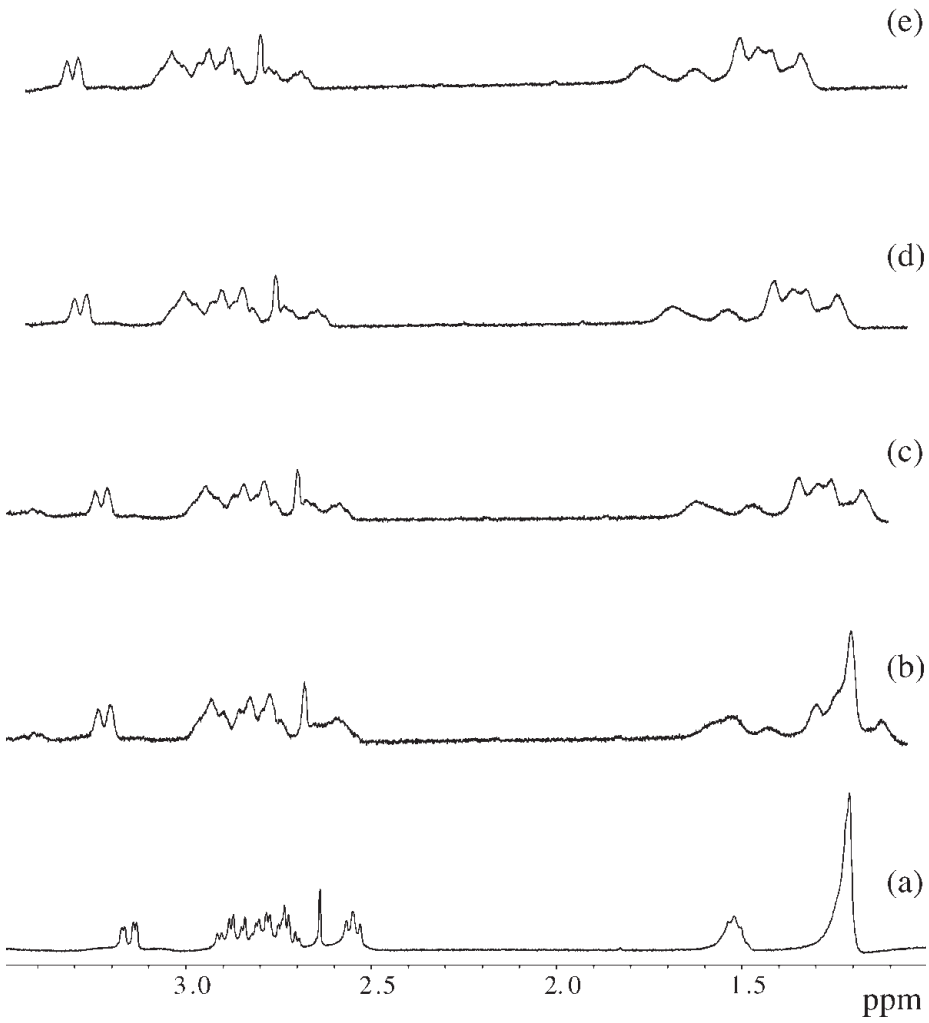
The mass spectrometry measurements were obtained on a VG Quattro quadrupole mass spectrometer, with an atmospheric pressure electrospray source. The samples, as solutions in distilled water, were introduced into the source at a flow rate of 5 mL min^{-1}.

Results and discussion

Syntheses

The dinuclear platinum complexes, [(dien)Pt(NH$_2$(CH$_2$)$_n$-NH$_2$)Pt(dien)]$^{4+}$, were prepared by the reaction of 2 equiv. of the monomeric chloro(diethylenetriamine)platinum(II) ion with the appropriate α,ω-diaminoalkane bridging ligand. The α-cyclodextrin [2]rotaxanes were synthesized by first mixing the α-CD with the α,ω-diaminoalkane to form pseudorotaxanes (eq. [1]).

[1] $$NH_2(CH_2)_nNH_2 + \alpha\text{-CD} \underset{}{\overset{K_{CD}}{\rightleftharpoons}} \{NH_2(CH_2)_nNH_2\cdot\alpha\text{-CD}\}$$



Stability constants for $\{NH_2(CH_2)_nNH_2\cdot\alpha\text{-CD}\}$ of $\log K_{CD}$ = 2.83 (n = 8), 4.13 (n = 10), and 3.85 (n = 12) have been reported previously (36). Adding 2 equiv. of the chloro(diethylenetriamine)platinum(II) ion to the pseudorotaxane at room temperature yielded the following rotaxane (eq. [2]).

[2] $$2[Pt(dien)Cl]^+ + \{NH_2(CH_2)_nNH_2\cdot\alpha\text{-CD}\} \rightarrow [(dien)Pt\{NH_2(CH_2)_nNH_2\cdot\alpha\text{-CD}\}Pt(dien)]^{4+} + 2Cl^-$$

To minimize the production of non-rotaxane dinuclear platinum complexes, it was necessary to carry out the reaction at room temperature. Purification was achieved by recrystallization from a mixture of water and ethanol. All of the complexes were characterized by ^{1}H NMR, ^{13}C NMR, ^{195}Pt NMR spectroscopy, and electrospray mass spectrome-

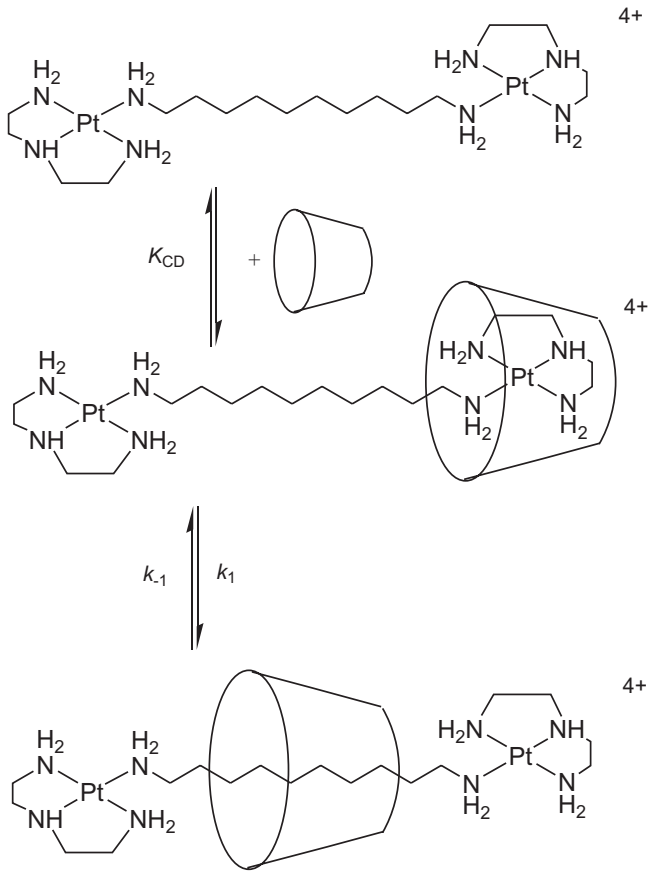
Fig. 1. ^{1}H NMR spectra of the formation of the [2]rotaxane [(dien)Pt{$NH_2(CH_2)_{10}NH_2$·β-CD}Pt(dien)]$^{4+}$: (*a*) the dimer [(dien)Pt(NH_2-$(CH_2)_{10}NH_2$)Pt(dien)]$^{4+}$ (1.0 mmol/L) and (*b*) 2 min, (*c*) 6 min, (*d*) 19 min, and (*e*) 345 min after mixing with β-CD (10 mmol/L) in D_2O (0.05 mol/L NaCl) at 25 °C.

try. The elemental analyses were consistent with the formation of the rotaxanes with some solvent (water or ethanol) of crystallization. The ^{195}Pt NMR resonance of all of the complexes is found at about –2942 ppm, indicating that a complex with a PtN_4 environment is formed (37, 38).

The presence of the [2]rotaxanes, [(dien)Pt{NH_2-$(CH_2)_nNH_2$·α-CD}Pt(dien)]$^{4+}$ (n = 8–10, 12), in solution were confirmed by electrospray mass spectrometry (ES-MS). In the ES-MS spectra of [(dien)Pt{$NH_2(CH_2)_nNH_2$·α-CD}Pt(dien)]$^{4+}$, signals were observed for the parent molecular ion and for the chloride adducts [(dien)Pt{$NH_2(CH_2)_n$-NH_2·α-CD}Pt(dien)]Cl^{3+} and [(dien)Pt{$NH_2(CH_2)_nNH_2$·α-CD}Pt(dien)]Cl_2^{2+}.

Slippage mechanism



The slippage mechanism was investigated with the dinuclear platinum compound [(dien)Pt{$NH_2(CH_2)_{10}NH_2$Pt-(dien)]$^{4+}$. The threading of linear components of the α,ω-diaminoalkane chain through the β-CD cavity to form [2]rotaxane may be followed by ^{1}H NMR spectroscopy, as the symmetry-related proton resonances of the polymethylene chains of the bridging ligand are split into pairs of peaks upon inclusion in the asymmetric cyclodextrin host. The addition of an excess of β-CD to the [(dien)Pt($NH_2(CH_2)_{10}$-NH_2)Pt(dien)]$^{4+}$ ion results in the very slow, spontaneous threading of the host by the guest molecule, as illustrated by the spectra in Fig. 1, with the splitting of the α (2.6 ppm) and β (1.6 ppm) methylene protons easiest to observe.

The slippage process may be envisaged as occurring by, first, weak and reversible inclusion of the Pt(dien)$^{2+}$ group by the β-CD cavity (Scheme 2), followed by a very slow passage over the Pt(dien)$^{2+}$ to finally position the β-CD over the hydrophobic decamethylene chain to yield the [2]rotaxane. Upon initial addition of β-CD, the resonances for the α and β protons of the methylene chain exhibit small downfield shifts. These induced chemical shifts support an inclusion preequilibrium prior to the slippage process.

The formation of the [2]pseudorotaxane, [(dien)Pt{NH_2-$(CH_2)_{10}NH_2$·β-CD}Pt(dien)]$^{4+}$, is also indicated by electrospray mass spectrometry. An aqueous solution of an equimolar (1.0×10^{-3} mol/L) mixture of two compounds exhibited three signals at m/z 475.9, consistent with

Scheme 2. Slippage mechanism for the formation of the [(dien)Pt{$NH_2(CH_2)_{10}NH_2$·β-CD}Pt(dien)]$^{4+}$ [2]rotaxane.

[(dien)Pt{$NH_2(CH_2)_{10}NH_2$·β-CD}Pt(dien)]$^{4+}$, *m/z* 646.3 for [(dien)Pt{$NH_2(CH_2)_{10}NH_2$·β-CD}Pt(dien)]Cl^{3+}, and *m/z* 987.2 for [(dien)Pt{$NH_2(CH_2)_{10}NH_2$·β-CD}Pt(dien)]Cl_2^{2+}.

The observed first-order rate constants for the slippage process increase with increasing β-CD concentration, with plots of k_{obs} vs. [β-CD] displaying curvatures towards rate saturation at high [β-CD]. Assuming that k_{-1} (Scheme 1) is negligible with respect to k_1, the observed first-order rate constant may be fit to eq. [3].

$$[3] \qquad k_{obs} = \frac{k_1 K_{CD}[\beta\text{-CD}]}{1 + K_{CD}[\beta\text{-CD}]}$$

Double reciprocal plots of k_{obs}^{-1} against $[\beta\text{-CD}]^{-1}$ have been constructed for the rate constants measured at 25, 30, 35, and 40 °C (Fig. 2), with the slopes providing the values of k_1 (Table 1) and activation parameters of $\Delta H^{\ddagger}$ = 97 ± 4 kJ mol^{-1} and $\Delta S^{\ddagger}$ = +44 ± 11 J K^{-1} mol^{-1}. The inclusion stability constant K_{CD}, determined from eq. [3], was relatively constant, ranging from 28 to 38 (mol/L)$^{-1}$ for the temperatures investigated. The kinetic and thermodynamic parameters associated with the self-assembly of the [2]pseudorotaxanes are listed in Table 1.

The kinetics of the dissociation (eq. [4]) of [(dien)Pt{$NH_2(CH_2)_{10}NH_2$·β-CD}Pt(dien)]$^{4+}$ rotaxane (0.5 mmol/L) were investigated (using ^{1}H NMR spectroscopy) in the presence of an excess (11.5 mmol/L) of a competing guest, 1-adamantanecarboxylic acid (ADCOOH).

$$[4] \qquad [(\text{dien})\text{Pt}\{NH_2(CH_2)_{10}NH_2\cdot\beta\text{-CD}\}\text{Pt}(\text{dien})]^{4+} + \text{ADCOOH} \underset{k_1}{\overset{k_{-1}}{\rightleftharpoons}} [(\text{dien})\text{Pt}(NH_2(CH_2)_{10}NH_2)\text{Pt}(\text{dien})]^{4+} + \{\text{ADCOOH}\cdot\beta\text{-CD}\}$$

Rapid and efficient capture of the released β-CD by the 1-adamantanecarboxylic acid guest (K_L = 7.8 × 10^4 (mol/L)$^{-1}$ at pH 6.5 (39)) is expected (eq. [4]) such that the observed first-order rate constant corresponds to the rate-limiting dissociation of the [(dien)Pt{$NH_2(CH_2)_{10}NH_2$·β-CD}Pt(dien)]$^{4+}$ rotaxane. At 25 °C, k_{-1} was determined to be (2.14 ± 0.3) × 10^{-5} s^{-1}, with $\Delta H^{\ddagger}$ = 93 ± 9 kJ mol^{-1} and $\Delta S^{\ddagger}$ = –23 ± 17 J K^{-1} mol^{-1}, calculated from measurements between 25 and 40 °C (Table 1).

The stability constant, K_1, for the [2]rotaxane with respect to its dissociated linear and cyclic components may be calculated from $K_1 = k_1 K_{CD}/k_{-1}$. The values are approximately 1.5 × 10^4 (mol/L)$^{-1}$ (Table 1) and exhibit little dependence on temperature. The stability constant may be compared with those for β-CD rotaxanes of the type {3CNpyr-$(CH_2)_{10}$3CNpyr·β-CD}$^{2+}$ (3CNpyr = 3-cyanopyridine, 810 ± 160 (mol/L)$^{-1}$) and {4CNpyr$(CH_2)_{10}$4CNpyr·β-CD}$^{2+}$ (4CNpyr = 4-cyanopyridine, 2020 ± 160 (mol/L)$^{-1}$) (18). The larger value for the dinuclear platinum(II) thread may be due to the higher positive charge on the end units and possible hydrogen bonding of the dien ligand with the cyclodextrin hydroxyl groups.

The result of this study indicates that the complementary sizes of the square-planar (diethylenetriamine)platinum(II) center and the cavity of the β-cyclodextrin result in a very slow threading of the cyclic component by the linear guest. The enthalpies of activation for the threading (97 ± 4 kJ mol^{-1}) and dethreading (93 ± 9 kJ mol^{-1}) processes in this study are very similar to one another, suggesting that the required distortions in the cyclodextrin and the Pt(dien)$^{2+}$ in these two slippages are nearly the same. The differences in the rates of these processes, therefore, may be related to the entropies of activation. The positive entropy of activation for the threading (k_1) of β-CD (+44 ± 11 J K^{-1} mol^{-1}) likely results from the desolvation of the cationic Pt(dien)$^{2+}$ group as it passes through the β-CD cavity. The unfavourable entropy of activation (–23 ± 17 J K^{-1} mol^{-1}) associated with k_{-1} would correspondingly result from the net resolvation of the end group as it emerges from the β-CD cavity.

plexes may be prevented by increasing the bulk of the platinum end groups with respect to the diameter of the β-CD cavity. We are currently investigating the use of (*a*) bulkier ligand(s) on the square-planar platinum(II) center and (*b*) oxidization of the square-planar platinum(II) center to octahedral platinum(IV). In view of the demonstrated antitumor activity of platinum(IV) complexes (40), a dinuclear platinum(IV) β-CD rotaxane analogous to those described in this paper would be more inert to dissociation until its reduction to the square-planar platinum(II) oxidation state.

Fluorinated 9-borafluorenes vs. conventional perfluoroaryl boranes — Comparative Lewis acidity

Preston A. Chase, Patricio E. Romero, Warren E. Piers, Masood Parvez, and Brian O. Patrick

Abstract: Perfluorinated 9-phenyl-9-borafluorene, **1**, is an antiaromatic analog of the well-known tris(pentafluorophenyl)borane. Spectroscopic, structural, and electrochemical studies have been performed on **1** and its Lewis base adducts with MeCN, THF, and PMe_3 with a view to assessing its comparative Lewis acid strength relative to $B(C_6F_5)_3$. For the sterically undemanding Lewis base MeCN, **1** and $B(C_6F_5)_3$ have comparable LA strengths, while for more sterically prominent THF, **1** is clearly the stronger Lewis acid (LA) based on competition experiments. We conclude that steric factors, rather than antiaromaticity, are the most important determinants in the LA strength differences between **1** and $B(C_6F_5)_3$.

Key words: boranes, Lewis acids, fluorinated compounds, heterocycles.

Résumé : Le 9-phényl-9-borafluorène perfluoré (**1**) est un analogue antiaromatique du tris(pentafluorophényl)borane bien connu. Afin d'évaluer son acidité relative à celle du $B(C_6F_5)_3$, on a effectué des études spectroscopiques, structurales et électrochimiques sur le composé **1** et sur les adduits qui résultent de sa réaction avec les bases de Lewis MeCN, THF et PMe_3. Sur la base d'expériences de compétition, on a observé que dans le cas de la base de Lewis MeCN qui n'impose pas de demandes stériques spéciales, les forces des acides de Lewis du composé **1** et du $B(C_6F_5)_3$ sont comparables alors que, avec le THF qui impose des contraintes stériques plus grandes, l'acidité de Lewis du composé **1** est nettement plus grande. On en conclut que les facteurs stériques, plutôt que l'antiaromaticité, sont plus importants dans la détermination des différences des forces d'acidité de Lewis entre le composé **1** et le $B(C_6F_5)_3$.

Mots clés : boranes, acides de Lewis, composés fluorés, hétérocycles.

[Traduit par la Rédaction]

Introduction

Highly fluorinated aryl boranes are an important class of Lewis acids because of their high thermal stability, resistance to hydrolysis, and Lewis acid strength (1). Although they have been known for many years (2), their application as activators for single-site olefin polymerization catalysts (3) has sparked interest in defining other applications in areas as diverse as organic synthesis (4), weakly coordinating anion development (5), and cationic polymerization initiation (6). Since Lewis acid strength is related to the effectiveness of the boranes in many of these applications (7), efforts to modulate the Lewis acid properties of the parent tris(pentafluorophenyl)borane have utilized several strategies, including the use of larger, more fluorinated aryl groups (8) and the replacement of one C_6F_5 group with poorly π-donating but electronegative substitutents like $-NC_4H_4$ (9). In some instances, weakening the Lewis acid strength by substitution with nonfluorinated aryl groups is beneficial for a given application (10). It is thus clear that the ability to modulate Lewis acid strength is beneficial for the applications of this family of boranes.

One intriguing strategy for increasing the Lewis acid strength of $B(C_6F_5)_3$ without drastically elevating the steric imposition of the aryl groups about boron is to incorporate the boron center into an antiaromatic ring framework. Using this strategy, we and Marks and co-workers (11) independently prepared the perfluorinated 9,10-diboraanthracene Lewis acid shown in Chart 1. Marks found it to be an exceptionally strong Lewis acid (12), eclipsing $B(C_6F_5)_3$ in competition experiments with low-steric-demand Lewis bases like acetonitrile. In fact, the second boron center is also highly Lewis acidic in these compounds, often performing independently from the first. Taking a cue from early work on boroles by Eisch et al. (13), we developed a second family of antiaromatic perfluoroaryl boranes, the 9-borafluorene compounds **1** and **2** (14) (Chart 1), a closer structural analog of the parent $B(C_6F_5)_3$. A detailed study on the coordination chemistry of compounds **1** and **2** with the unusual Lewis base "Cp*Al^I" showed that they exhibit chemical behavior that is more borane-like than borole-like (15); that is, compounds **1** and **2** coordinate the aluminum Lewis base in an η^1 fashion, rather than undergoing two-electron reduction to give higher hapticity π complexes. Here we show that these reactivity patterns can be extended to more conventional Lewis bases and discuss the relative LA strength of **1** relative to the parent borane $B(C_6F_5)_3$. Structural, competition,

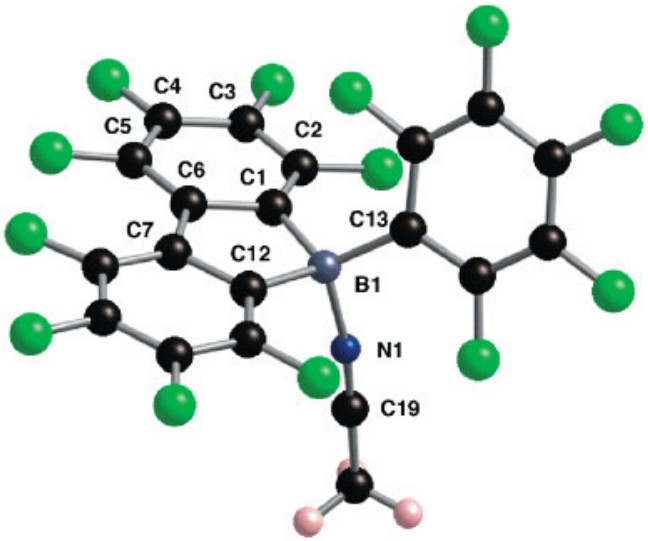
and electrochemical studies suggest that steric factors dominate in determining the relative Lewis acidity in these compounds and that the antiaromaticity of **1** is not a significant progenitor of its high Lewis acidity.

Results and discussion

The pentafluorophenyl (**1**) and methyl (**2**) 9-borafluorene derivatives were prepared as previously reported (14) and reacted with the sterically differentiated but comparably basic (16) Lewis bases acetonitrile (MeCN) and tetrahydrofuran (THF) and the stronger base trimethylphosphine (PMe_3) to form 1:1 Lewis acid – Lewis base adducts (eq. [1]). In the case of MeCN and THF, an excess of base was used, while for PMe_3 near stoichiometric amounts were employed. In all cases, the compounds **1·LB** and **2·LB** were isolated in good yields as solids simply by removal of the solvent in vacuo. Immediately upon introduction of the Lewis base (LB), orange solutions of **1** and lime green solutions of **2** decolorized, as coordination of the Lewis base disrupted the strong π–π transition involving the low-lying boron-based LUMO, which is responsible for the colors in **1** and **2**. Lewis base coordination fills this orbital, and the LUMO is now a higher energy formally π* orbital; the increase in the energy gap causes the absorption to shift out of the visible range. Similar behavior has been observed in unfluorinated 9-borafluorenes, which have been employed as colourimetric sensors for fluoride ions (17). Although labile (vide infra), the equilibria strongly favor the adducts **1·LB** and **2·LB**; for the stronger Lewis acid **1**, adducts **1·LB** do not relinquish their Lewis bases even with gentle heating under vacuum. All were formed as analytically pure, colorless solids that could be fully characterized using standard methods.

Upon complexation, resonances in the ^{1}H NMR spectra for the coordinated bases in **1·LB** shift downfield significantly; for example, the resonance for the methyl group of the MeCN base in **1·MeCN** shifts to 2.66 ppm vs. 2.10 ppm for free MeCN (18) as electron density is removed by the Lewis acid. For **2·MeCN**, the opposite trend is observed for the B–Me signal, which shifts upfield by 0.7 ppm upon complexation. In the ^{19}F NMR spectra of **1·LB**, similar effects to those observed in the adducts of $B(C_6F_5)_3$ are exhibited: namely, a contraction of the chemical shift difference between the *para*- and *meta*-fluorines ($\Delta\delta_{p,m}$) (19). In $B(C_6F_5)_3$, this value is approximately 18 ppm in noncoordinating solvents, but upon treatment with acetonitrile a value of 8.4 ppm is found (20). The changes observed in **1·MeCN** vs. free **1** indicate that the $\Delta\delta_{p,m}$ value in the -C_6F_5 ring goes from 14.7 to 6.4 ppm upon complexation of MeCN. Upfield shifts of varying severity are also observed in the fluorines of the borafluorene framework and analogous patterns are revealed in the THF and PMe_3 adducts.

The ^{11}B NMR spectra also show a distinct difference between the tricoordinate, base-free Lewis acids and the tetracoordinated adducts (21). In the case of the free acids, the ^{11}B NMR chemical shift for the synthesized 9-borafluorene derivatives ranges from δ 56.0 to δ 67.3. In general, the range in ^{11}B chemical shift for tetrahedral boron occurs at much higher field than related tricoordinate systems. The ^{11}B NMR chemical shifts for the adducts of **1·LB** and **2·LB** occur between δ 8.6 and δ –15.2 ppm. Both **1·PMe$_3$** and **2·PMe$_3$** exhibit coupling in the ^{11}B NMR spectra (δ –14.2 and –11.4, $^1J_{B\text{-}P}$ = 87 and 66 Hz, respectively).



The IR spectra of both **1·MeCN** and **2·MeCN** were recorded, and a diagnostic band for the C≡N stretching mode was observed at 2361 and 2364 cm^{-1}, respectively, similar to that observed for the $B(C_6F_5)_3$ adduct ($\nu_{C\equiv N}$ = 2367 cm^{-1}). The frequency of the C≡N stretching mode for the free base is found at significantly lower wavenumbers ($\nu_{C\equiv N}$ = 2253 cm^{-1}), indicative of a weaker carbon–nitrogen bond compared with that in the adducts. As the donor orbital of MeCN has slight antibonding character with respect to the CN linkage, complexation will remove some of the electron density from this orbital, which will strengthen the CN bond and result in the observed shift in $\nu_{C\equiv N}$ (20).

A crystal structure of **1·MeCN** was obtained, and a view with selected metrical data is presented in Fig. 1 (see also Table 1).[2] Compared to the structure of **1**, there is elongation

Fig. 1. Crystalmaker model of the molecular structure of **1·MeCN** with atom labeling scheme. Selected bond lengths (Å): B(1)—N(1) 1.581(3), B(1)—C(1) 1.620(3), B(1)—C(12) 1.612, B(1)—C(13) 1.617(3), N(1)—C(19) 1.133(3), C(1)—C(2) 1.366(3), C(1)—C(6) 1.413(3), C(2)—C(3) 1.384(3), C(3)—C(4) 1.364(3), C(4)—C(5) 1.384(3), C(5)—C(6) 1.389(3), C(6)—C(7) 1.481(3). Selected bond angles (°): C(1)-B(1)-N(1) 106.5(2), C(1)-B(1)-C(12) 98.8(2), B(1)-N(1)-C(19) 171.0(2), C(1)-C(6)-C(7)-C(12) 1.6(2).

of the B—C bonds in both the C_6F_5 ring and the 9-borafluorene fragment. In **1·MeCN**, B(1)—C(1), B(1)—C(12), and B(1)—C(13) are 1.620(3), 1.612(3), and 1.617(3) Å, respectively (cf. 1.555(4) and 1.547(3) Å, respectively, for the analogous bonds in **1**). This is the result of the rehybridization of the boron from sp^2 to sp^3 and the increase in coordination number. The N(1)-B(1)-C(1) and N(1)-B(1)-C(13) angles are 106.5(2)° and 110.2(2)°, respectively, indicative of a distorted tetrahedral environment about boron. The internal angle in the 9-borafluorene is even more compressed than in the free acid; the C(1)-B(1)-C(12) angle is 98.8(2)°, compared with 103.5(2)°. The MeCN base has remained linear (N(1)-C(19)-C(20) = 179.1(2)°) and is bonded in an essentially linear orientation with the boron center. The B(1)-N(1)-C(19) angle is 171.0(2)°, and the acetonitrile methyl group is oriented slightly over the 9-borafluorene ring. The B(1)—N(1) distance (1.581(3) Å) and the C≡N triple bond (N(1)—C(19) = 1.133(3) Å) are quite close to those observed in the MeCN adduct of $B(C_6F_5)_3$ reported by Erker and co-workers (20) (for the equivalent bonds, the B—N and C—N distances are 1.616(3) and 1.124(3) Å, respectively). The same group has performed an accurate determination of the crystal structure of free acetonitrile using a Laser zone melting apparatus (22). From this, the bond length of the C≡N triple bond (α phase, T = 208 K) was found to be 1.141(2) Å. Thus, there is a measurable contraction of the C≡N bond upon complexation in both cases. This correlates with the observed bond strengthening in the IR spectra of **1·MeCN** as the $\nu_{C\equiv N}$ band shifts to considerably higher wavenumbers.

In the case of the structure of base free **1**, Marks and co-workers (12) noted a small but statistically relevant elongation of one of the aryl C=C bonds in the 9-borafluorene framework, namely the C=C bond of the five-membered core ring. This result was also noted in the structures of perfluorinated 9,10-diphenyl-9,10-diboranthracene (11) and 1,2-bis[bis(pentafluorophenyl)boryl] tetrafluorobenzene (11*b*, 23). This effect is also apparent in the adduct, **1·MeCN**. The bond lengths for C(1)—C(6) and C(7)—C(12) are 1.413(3) and 1.415(3) Å, respectively, while the average of the remaining bonds is 1.376(3) Å. The difference in the bond lengths is similar to those observed in the aforementioned cases.

In our original communication, we noted that **1** exhibits LA strength comparable with that of $B(C_6F_5)_3$ by both the Childs method (24) and that of Laszlo and Teston (25), which uses the relative energies of the π* orbital of LA-complexed crotonaldehyde to assess LA strength. Furthermore, in a competition experiment for the sterically undemanding MeCN, we found a slight preference for **1·MeCN** over MeCN·$B(C_6F_5)_3$, the equilibrium constant being 1.3 at 25 °C. This preference is further emphasized when the sterically more bulky base THF is used in this experiment. Thus, when a 1:1:1 mixture of **1**, $B(C_6F_5)_3$, and THF in d_8-toluene was analyzed by ^1H and ^{19}F NMR spectroscopy, it was found that the equilibrium lies completely towards **1·THF** within the detection limits of NMR spectroscopy. Remarkably, even though $B(C_6F_5)_3$ is known to form a stable, isolable complex with THF, in a competitive situation, **1** dominates the competition for this Lewis base. That this is a thermodynamic preference is illustrated by the fact that identical results are obtained when equilibrium is approached from either side of the equation and by EXSY NMR experiments in the MeCN system, which show that the acetonitriles coordinated to both Lewis acids are exchanging with each other on this timescale. Unfortunately, similar competition experiments using PMe_3 were precluded by the

© 2005 NRC Canada

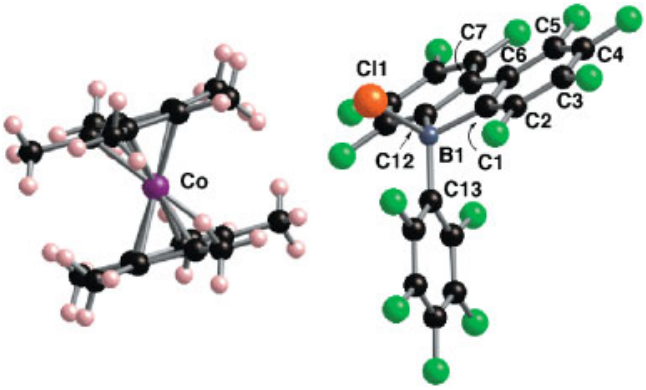
nearly total insolubility of the $Me_3P{\cdot}B(C_6F_5)_3$ adduct in common solvents (1).

The rather marked dependence of the relative LA strength on the steric properties of the Lewis base employed suggests that the differences in Lewis acidity observed between **1** and $B(C_6F_5)_3$ are grounded in steric factors, rather than the fact that **1** exhibits antiaromaticity. Indeed, a comparison between the bond lengths associated with the borafluorene moiety in **1** vs. **1·MeCN** shows that little change in the C—C distances is observed upon complexation of the base. This suggests that the π character of the ring framework is not perturbed significantly, i.e., the system does not become more aromatic (or less antiaromatic) as the base coordinates the boron center. Accordingly, the Julg *A* values (26) (a measure of aromaticity based on metrical bond distances (27)) for both the five- and six-membered rings do not change significantly in **1·MeCN** vs. **1**. In fact, while the *A* values for the flanking six-membered rings remain essentially the same, at 0.96 and 0.97 in **1** and **1·MeCN**, respectively,[3] the *A*(5) value for **1·MeCN** is actually less (0.89) than that for uncomplexed **1** (0.92). The *A*(5) value in **1·MeCN** is comparable to that of 0.88 observed by West and co-workers (27*b*) for the neutral 9-sila- and 9-germa-fluorenyl systems, which also contain pyramidal atoms in the 9 position.

Given this discussion, we conclude that the reason 9-borafluorene **1** is a Lewis acid of competitive or superior strength to $B(C_6F_5)_3$ (despite being less fluorinated) stems from the greater steric accessibility of the boron center and the lowered back strain encountered upon the pyramidalization of the boron center, which occurs upon complexation of a Lewis base. The flatness of the borafluorene ring substitutent is the main reason for the relaxing of these steric factors; further, the pyramidalization of boron in going from **1** to **1·LB** likely relieves strain in the C-B-C moiety of the five-membered ring. Although long a matter of debate, it has been recently acknowledged that steric factors, particularly the onset of back strain, dominate in determining the relative Lewis acidity of the boron trihalides BX_3 (28, 29).

Although antiaromaticity is likely not playing a strong role in determining the relative Lewis acidity of **1**, given the propensity of boroles to undergo two-electron reduction to form aromatic borollides (30), it seemed reasonable to presume that **1** could be reduced more readily than $B(C_6F_5)_3$. Norton and co-workers (31) have reported on the difficulties associated with reduction of $B(C_6F_5)_3$, but estimate an E_{red} of –0.9 V vs. SCE based on measured E_{red} values for Mes_3B, $Mes_2B(C_6F_5)$, and $MesB(C_6F_5)_2$ (Mes = 2,4,6-$Me_3C_6H_2$) (31*c*). While the electron-withdrawing pentafluorophenyl groups make the boranes easier to reduce from a thermodynamic perspective, the lack of steric protection afforded by the C_6F_5 groups (as opposed to the Mes substitutent, for example) renders the radical anion extremely reactive, even with the surfaces of electrodes.

Cyclic voltammetry (CV) studies were performed on **1** in a variety of solvents using tetrabutylammonium tetrakis(pentafluorophenyl)borate (32) as the supporting electrolyte. Experiments in the noncoordinating solvents CH_2Cl_2 and α,α,α-trifluorotoluene were unsuccessful, so THF was employed. Model experiments on the unfluorinated analogue of **1**, 9-phenyl-9-borafluorene, show that, at scan rates of 500 mV s^{-1} (33), a reversible reduction and oxidation process occurs with a reduction potential of –2.16 V vs. ferrocene (Fc), a similar value to that found for BPh_3. From the available data, it is not possible to determine if the CV of 9-phenyl-9-borafluorene is indicative of a one- or a two-electron process. Under the same conditions, the CV of **1** revealed an irreversible process with a reduction potential at –2.42 V vs. Fc. The very negative potential obtained for **1** in THF was puzzling since it implies that **1** is more difficult to reduce than the unfluorinated analog and runs counter to the expected trend evidenced in the $Mes_nB(C_6F_5)_{3-n}$ series. On the other hand, the value for the reduction potential of **1** in THF is similar to those reported by Campbell (34) on the electrochemistry of simple aromatic fluorinated compounds. Although not directly comparable, since they are determined in different solvents, pentafluorobenzene and decafluorobiphenyl showed a first reduction wave at –2.84 and –2.20 V, respectively. These observations suggest the possibility that the reduction process does *not* actually take place at the boron center, but at the fluorinated aromatic framework, i.e., we are observing the reduction of **1·THF** rather than **1** under these conditions. Campbell also detected the presence of species arising from the rupture of aromatic C—F bonds, which suggests that a similar decomposition pathway might be operating in our case, i.e., via Ar—F scission. Alternatively, the high negative potential for the onset of reduction of **1** may be due to a large kinetic barrier to its reduction, as was observed for $B(C_6F_5)_3$ (31).



Since attempts to generate $\mathbf{1}^{2-}$ via electrochemical means failed, chemical reduction of **1** was attempted. Given that an earlier study indicated that Al(I) reagents were not sufficiently reducing (15), harsher reducing agents (C_8K, Li, Na, or K) were employed in a variety of solvents (Et_2O, THF, toluene, benzene, bromobenzene, or α,α,α-trifluorotoluene). Unfortunately, these invariably produced ill-defined mixtures. Not surprisingly, reactions involving alkali metals in nondonor solvents proved extremely slow, and after work up, the main products recovered were unreacted **1** and decomposition by-products. Furthermore, attempts to stabilize the putative $\mathbf{1}^{2-}$ by addition of crown ethers were also unsuccessful; only coordination of one of the ether oxygen atoms to the boron center was observed in the ^{19}F NMR spectrum. Given the slow kinetics associated with heterogeneous reductants, we sought a reducing agent that would allow the process to be carried out under homogeneous conditions.

Norton and co-workers (31) have shown that Cp^*_2Co is an effective reductant for $B(C_6F_5)_3$. Reaction between **1** and 2 equiv. of Cp^*_2Co in benzene or toluene led to the precipitation of an oily phase with recovery of 2 equiv. of unreacted Cp^*_2Co from the supernatant. Analysis of the oily material by ^{19}F NMR spectroscopy showed an extremely complex pattern arising from decomposition. However, this oily material was diamagnetic in nature, as judged by its silent EPR spectrum, even at low temperatures (ca. –50 °C). The presence of one remaining equivalent of reducing agent suggests

[3] These values are slightly depressed from the expected values near 1.00 because of the observed lengthening of the C—C bond that the six- and five-membered rings share compared with the other C—C bonds in the flanking six-membered rings observed in these and other systems. Despite the slightly lower *A* value, these rings are essentially fully aromatic.

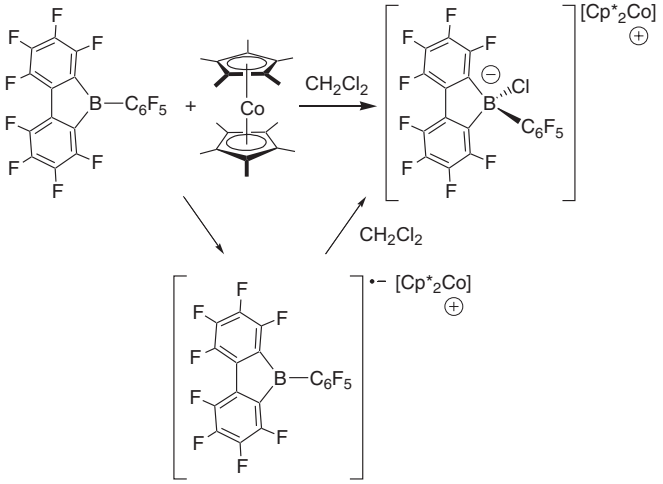
Fig. 2. Crystalmaker model of the molecular structure of $[Cp^*_2Co]^+[\mathbf{1}\cdot\mathbf{Cl}]^-$ with atom labeling scheme. Selected bond lengths (Å): B(1)—Cl(1) 1.910(9), B(1)—C(13) 1.618(11), B(1)—C(1) 1.617(10), C(1)—C(2) 1.381(10), C(2)—C(3) 1.373(10), C(3)—C(4) 1.350(11), C(4)—C(5) 1.397(11), C(5)—C(6) 1.368(9), C(6)—C(7) 1.491(10). Selected bond angles (°): C(1)-B(1)-C(12) 97.9(6), C(1)-B(1)-C(13) 113.1(7), C(12)-B(1)-C(13) 114.9(6), C(1)-B(1)-Cl(1) 109.8(5), C(12)-B(1)-Cl(1) 106.9(6), C(13)-B(1)-Cl(1) 113.1(6).



that the initially formed radical anion is highly reactive and that Cp^*_2Co is not sufficiently reducing to produce $\mathbf{1}^{2-}$. In accord with this postulate, the reaction of Cp^*_2Co and **1** in CH_2Cl_2 took place cleanly within seconds, as judged by NMR spectroscopy. The ^1H NMR spectrum showed only a singlet at δ 1.70, corresponding to the expected hydrogen resonances for the Cp* units of the diamagnetic $Cp^*_2Co^+$ cation. ^{19}F NMR spectroscopy clearly revealed a pattern of seven different well-defined signals in the expected range. The difference in chemical shift between the *meta*- and *para*-fluorines of the C_6F_5 ring ($\Delta\delta_{m,p}$ 4.7 ppm) was indicative of borate formation and a significant degree of charge separation. The negative value obtained by $^{11}B\{^1H\}$ NMR spectroscopy of δ –14 is also consistent with formation of a borate center.

Single crystals of the product of this reaction were obtained by slow diffusion of hexanes into a CH_2Cl_2 solution of the compound, generated as described above. The molecular structure of the salt $[Cp^*_2Co]^+[\mathbf{1}\cdot\mathbf{Cl}]^-$ is shown in Fig. 2 and is in accord with all the spectral data. There are no unusual contacts in the structure, and the ions are well separated with a boron—cobalt distance of 7.556(59) Å. The B(1)—Cl(1) distance of 1.910(9) Å is in the expected range for chloroborates, and the boron center in $[Cp^*_2Co]^+[\mathbf{1}\cdot\mathbf{Cl}]^-$ shows a distorted tetrahedral environment with a C(1)-B(1)-C(12) angle of 97.9(6)°, also within the expected range by comparison with related compounds.

The outcome can be rationalized in terms of chloride abstraction from the CH_2Cl_2 solvent, the sole possible source of chloride in the reaction (Scheme 1). A potential direct abstraction of Cl^- by **1** is negated, since **1** is an indefinitely stable species in CH_2Cl_2, as well as in most chlorinated solvents. Thus, the first step may involve the direct reaction between **1** and Cp^*_2Co. Based on the previous observations for the reaction of **1** with Cp^*_2Co in less polar solvents, where only 1 equiv. of Cp^*_2Co was found to react with **1**, a plausible mechanism might involve the intermediacy of a highly reactive, monoanionic radical species. The radical

Scheme 1.

anion rapidly abstracts $Cl^\cdot$ from solvent to form $[Cp^*_2Co]^+[\mathbf{1}\cdot\mathbf{Cl}]^-$. Alternatively, the CH_2Cl_2 solvent may mediate this reaction by electron transfer from Cp^*_2Co to the solvent, which then gives up a chloride ion to **1**. Although this option is not depicted in the scheme, our data do not exclude this as a possibility.

Taken together, the observations garnered from the experiments aimed at two-electron chemical and electrochemical reduction of **1** suggest that this compound behaves more similarly to its perfluoroaryl borane brethren than its nonfluorinated 9-borafluorene analogs. While one-electron reduction is fairly facile, the resulting radical anion is extremely reactive, abstracting atoms from solvent and (or) undergoing dimerization processes.

In conclusion, we find the antiaromatic perfluorinated 9-phenyl-9-borafluorene **1** to be of comparable or greater Lewis acid strength than the noncyclic parent borane $B(C_6F_5)_3$, mainly because of the lesser back strain engendered in adducts upon pyramidalization of the boron center, owing to the flat $C_{12}F_8B$ ring system. The antiaromaticity associated with this function does not appear to play a significant role in determining the Lewis acidity of the system. The high Lewis acidity of **1** contributes to the difficulty in carrying out two-electron reduction chemistry that is facile in unfluorinated analogs.

Experimental section

General procedures

An Innovative Technologies or Vacuum Atmospheres argon-filled glove box was employed for manipulation and storage of oxygen and moisture-sensitive compounds. Reactions were performed using a double manifold argon/vacuum line and modified Schlenk line techniques. Matheson Oxisorb-W gas purification cartridges were used to remove residual oxygen and moisture in the argon stream. Glassware was dried overnight (80–110 °C) and then assembled warm and evacuated on the vacuum line or placed in the glovebox antechamber while hot. Glassware consisted of swivel frit apparatus and line connectors equipped with Kontes valves and round-bottom flasks equipped with ground glass joints. Unless otherwise noted, the introduction of solvent in all

© 2005 NRC Canada

manipulations using the argon/vacuum line was via vacuum transfer with condensation at –80 °C (acetone – dry ice bath). Solvents were purchased from Aldrich and dried and deoxygenated before use in the following procedures. Hexanes, toluene, and THF were dried and deoxygenated via passage through a Grubbs/Dow purification system (35) and were stored in evacuated bombs over titanocene (36) (hexanes and toluene) or sodium – benzophenone ketyl (THF). Benzene was deoxygenated by bubbling argon through the solvent and was dried over sodium and stored over the sodium – benzophenone ketyl. Diethyl ether and methylene chloride were predried over $LiAlH_4$ and CaH_2, respectively, and subsequently stored over sodium – benzophenone ketyl and CaH_2, respectively. All deuterated solvents for NMR experiments were purchased from Cambridge Isotopes. Deuterated benzene, toluene, and THF were dried over 4 Å molecular sieves, stored over sodium – benzophenone ketyl, and distilled prior to use. Deuterated methylene chloride and bromobenzene were dried over 4 Å molecular sieves, stored over CaH_2, and distilled prior to use. After distillation, the deuterated solvents were stored in the glove box, in glass bombs equipped with Kontes valves. NMR spectra were obtained on Bruker AC 200 MHz (^{1}H), AMX 300 MHz (^{1}H, ^{19}F, ^{11}B{^{1}H}), DRX 400 MHz (^{1}H, ^{13}C{^{1}H}), or Varian 200 MHz (^{11}B, ^{11}B{^{1}H}, ^{31}P{^{1}H}) spectrometers. All NMR spectral data are reported in ppm, and NMR spectra of ^{1}H and ^{13}C were internally referenced to the residual solvent peak. The other nuclei were referenced externally with the following standards: ^{11}B ($BF_3{\cdot}OEt_2$, δ 0), ^{19}F (C_6F_6, δ –163.0), ^{31}P (H_3PO_4, δ 0). For all air- and (or) moisture-sensitive compounds and reactions, NMR samples were prepared in the glove box and the NMR tubes were capped with rubber septa. Temperature calibration for the NMR spectra was achieved by monitoring the ^{1}H NMR spectrum of methanol or ethylene glycol (37).

Cyclic voltammetry studies were carried out in a three-electrode cell using a PerkinElmer EG & G instrument (Princeton Applied Research) potentiostat, model 283, connected to a drybox and equipped with a PowerCV™ PowerSuite cyclic voltammetry software. A platinum disk electrode (1.6 mm diameter) and a platinum wire were used as the working electrode and the counter electrode, respectively. A silver wire was employed as a pseudoreference electrode. All the electrodes were purchased from BAS, Inc. All cyclic voltammetry experiments and handling of solids were performed in an argon-filled drybox at room temperature. THF (5 mL, previously dried and degassed) was syringed into an electrochemical cell containing [*n*-Bu_4N][$B(C_6F_5)_4$], and the mixture was stirred until complete dissolution to give a solution of concentration 0.1 mol L^{-1}. A background test was run, and in cases where traces of oxygen were detected, the system was additionally degassed by blowing argon through the solution with the aid of a Pasteur pipette. The samples (0.01 mol L^{-1}) were then run at 50, 100, 200, 500, and 1000 mV s^{-1} using Cp_2Fe (0.01 mol L^{-1}) as an internal standard. Electrochemical grade [*n*-Bu_4N][$B(C_6F_5)_4$] was synthesized according to literature procedures (32) and dried overnight at 130 °C.

Elemental analysis was performed by Dorothy Fox or Roxanna Smith within the department using a Control Equipment Corporation (CEC) 440 elemental analyzer. IR spectral samples were analyzed as KBr plates using a NEXUS 470 FT-IR ESP spectrometer. Electron paramagnetic spectra (EPR) were recorded on a Bruker EMX spectrometer at –50 °C, referencing externally against diphenylpicrylhydrazyl (DPPH, g = 2.0036) as a standard. $C_6F_5BC_{12}F_8$ (**1**), $CH_3BC_{12}F_8$ (**2**), $C_6H_5BC_{12}H_8$, and $B(C_6F_5)_3{\cdot}$MeCN were synthesized via literature procedures. $B(C_6F_5)_3$ was purchased from Boulder Scientific and purified by reaction with $Me_2SiH(Cl)$ in hexanes followed by vacuum sublimation (120 °C, dynamic vacuum). Reagent quantities of PMe_3 and MeCN were dried using 4 Å molecular sieves and CaH_2, respectively, then freshly distilled before use or vacuum transferred directly into reaction vessels. All other reagents were purchased from Aldrich Chemicals and used as received.

Preparation of $C_{12}F_8BC_6F_5(CH_3CN)$ (1·MeCN)

$C_{12}F_8BC_6F_5$ (0.081 g, 0.17 mmol) was placed in a round-bottom flask, and the flask was evacuated and cooled to –78 °C. Methylene chloride (10 mL) was condensed onto the solid, and the solution was stirred. CH_3CN (excess) was then condensed onto the stirred solution. Immediately on exposure to the CH_3CN vapours, the green colour of the 9-borafluorene discharged. The reaction was warmed to room temperature and stirred for 30 min. The solvent was removed in vacuo, and a white powder was obtained. Yield: 0.088 g, 99%. IR (KBr, cm^{-1}) ν: 2361 (C≡N stretch). ^{1}H NMR (CD_2Cl_2) δ: 2.66 (s, 3H, *Me*CN). ^{11}B{^{1}H} NMR (C_6D_6) δ: –8.7 (br). ^{19}F NMR (CD_2Cl_2) δ: –134.6 (m, 4F, overlapped 2F *o*-C_6F_5), –136.3 (m, 2F), –155.6 (m, 2F), –156.9 (m, 2F), –157.7 (m, 1F, *p*-C_6F_5), –164.1 (m, 2F, *m*-C_6F_5). Anal. calcd. for $C_{16}H_3BF_{13}N$: C 46.64, H 0.59, N 2.72; found: C 46.25, H 0.85, N 2.71.

Preparation of $C_{12}F_8BC_6F_5$(THF) (1·THF)

Synthesis was identical to the method employed for $C_{12}F_8BC_6F_5(CH_3CN)$ using $C_{12}F_8BC_6F_5$ (0.084 g, 0.18 mmol). Yield: 0.097 g, 100%. ^{1}H NMR (CD_2Cl_2) δ: 4.24 (m, 4H, THF), 2.15 (m, 4H, THF). ^{11}B{^{1}H} NMR (C_6D_6) δ: 4.1. ^{19}F NMR (CD_2Cl_2) δ: –126.2 (m, 2F, *o*-C_6F_5), –132.6 (m, 2F), –133.7 (m, 2F), –134.5 (m, 2F), –154.6 (m, 2F), –157.1 (m, 1F, *p*-C_6F_5), –163.7 (m, 2F, *m*-C_6F_5). Anal. calcd. for $C_{18}H_8BF_{13}O$: C 48.39, H 1.48; found: C 48.19, H 1.27.

Preparation of $C_{12}F_8BC_6F_5(PMe_3)$ (1·PMe_3)

Synthesis was identical to the method employed for $C_{12}F_8BC_6F_5(CH_3CN)$ using $C_{12}F_8BC_6F_5$ (0.082 g, 0.17 mmol). Yield: 0.094 g, 99%. ^{1}H NMR (CD_2Cl_2) δ: 1.31 (d, 9H, $^2J_{H\text{-}P}$ = 11.0 Hz). ^{11}B{^{1}H} NMR (C_6D_6) δ: –15.2 (d, $^1J_{B\text{-}P}$ = 87 Hz). ^{19}F NMR (CD_2Cl_2) δ: –130.4 (m, 2F, *o*-C_6F_5), –133.4 (m, 2F) –133.7 (m, 2F), –156.0 (m, 2F), –156.6 (m, 2F), –157.8 (m, 1F, *p*-C_6F_5), –163.7 (m, 2F, *m*-C_6F_5). ^{31}P{^{1}H} NMR (C_6D_6) δ: –14.2 (m). Anal. calcd. for $C_{17}H_9BF_{13}P$: C 45.85, H 1.65; found: C 45.57, H 1.60.

Typical conditions for competition experiments

1·THF (0.008 g, 15 μmol) and $B(C_6F_5)_3$ (0.008 g, 16 μmol) were weighed into an NMR tube and d_8-toluene (~0.5 mL) was added. The signals in the NMR spectra were identified by comparison to authentic samples. Equilibrium

© 2005 NRC Canada

constants were evaluated by integration of the ^{19}F NMR spectra of all peaks that were baseline separated.

Preparation of $[Cp^*_2Co]^+[\mathbf{1}\cdot Cl]^-$

Cp^*_2Co (35 mg, 0.11 mmol) was dissolved in ca. 3 mL of CH_2Cl_2 in a vial and added dropwise to a solution of **1** (50 mg, 0.11 mmol), also dissolved in ca. 3 mL of CH_2Cl_2. The brown solution was stirred for 20 min and then layered with hexanes. After cooling overnight at –35 °C, brown crystals of $[Cp^*_2Co]^+[\mathbf{1}\cdot Cl]^-$ were obtained. Yield: 45 mg, 53%. ^1H NMR (CD_2Cl_2) δ: 1.70 (s, 15H, $C_5(CH_3)_5$). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: 94.0 (s, $C_5(CH_3)_5$), 7.1 (s, $C_5(CH_3)_5$). $^{11}B\{^1H\}$ NMR (C_6D_6) δ: –14.0. $^{19}F\{^1H\}$ NMR (CD_2Cl_2) δ: –130.2 (2F, *o*-F), –136.5 (2F), –137.2 (2F), –158.5 (2F), –159.9 (2F), –161.0 (1F, *m*-F), –165.7 (2F, *p*-F). Anal. calcd. for $C_{38}H_{30}F_{13}BClCo$: C 54.36, H 3.58; found: C 54.21, H 3.35.

Preparation of $C_{12}F_8BMe(CH_3CN)$ (2·MeCN)

$C_{12}F_8BMe$ (0.053 g, 0.16 mmol) was weighed into a round-bottom flask, which was evacuated and cooled to –78 °C. Methylene chloride (10 mL) was condensed onto the solid, and the solution was stirred. CH_3CN (~2 mL, excess) was then condensed onto the stirred solution. Immediately on exposure to the CH_3CN vapors, the green colour of the 9-borafluorene discharged. The reaction was warmed to room temperature and stirred for an additional 30 min. The solvent was removed in vacuo, and a white powder was obtained. Yield: 0.058 g, 97%. IR (KBr, cm^{-1}) ν: 2364 (C≡N stretch). ^1H NMR (CD_2Cl_2) δ: 2.42 (s, 3H, *Me*CN), 0.38 (s, 3H, B*Me*). $^{11}B\{^1H\}$ NMR (C_6D_6) δ: –5.1. ^{19}F NMR (CD_2Cl_2) δ: –135.5 (m, 2F), –138.4 (m, 2F), –157.6 (m, 2F), –158.1 (m, 2F). Anal. calcd. for $C_{15}H_6BF_8N$: C 49.87, H 1.67, N 3.86; found: C 49.54, H 1.37, N 3.57.

Preparation of $C_{12}F_8BMe(THF)$ (2·THF)

Synthesis was identical to the method employed for $C_{12}F_8BMe(CH_3CN)$ using $C_{12}F_8BMe$ (0.057 g, 0.18 mmol). Yield: 0.069 g, 99%. ^1H NMR (CD_2Cl_2) δ: 4.04 (m, 4H, THF), 2.04 (m, 4H, THF), 0.40 (s, 3H, B*Me*). $^{11}B\{^1H\}$ NMR (C_6D_6) δ: 8.6. ^{19}F NMR (CD_2Cl_2) δ: –135.0 (m, 2F), –136.2 (m, 2F), –156.9 (m, 2F), –157.5 (m, 2F). Anal. calcd. for $C_{17}H_{11}BF_8O$: C 51.81, H 2.81; found: C 51.65, H 2.65.

Preparation of $C_{12}F_8BMe(PMe_3)$ (2·PMe_3)

Synthesis was identical to the method employed for $C_{12}F_8BMe(CH_3CN)$ using $C_{12}F_8BMe$ (0.053 g, 0.17 mmol). Yield: 0.060 g, 92%. ^1H NMR (CD_2Cl_2) δ: 1.20 (d, 9H, $^2J_{H\text{-}P}$ = 11.0 Hz, P*Me*$_3$), 0.36 (d, 3H, $^3J_{H\text{-}P}$ = 19.0 Hz, B*Me*). $^{11}B\{^1H\}$ NMR (C_6D_6) δ: –14.0 (d, $^1J_{B\text{-}P}$ = 66 Hz). ^{19}F NMR (CD_2Cl_2) δ: –134.5 (m, 2F), –134.7 (m, 2F), –158.1 (m, 2F), –158.3 (m, 2F). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: –11.4 (m). Anal. calcd. for $C_{16}H_{12}BF_8P$: C 48.28, H 3.04; found: C 48.20, H 2.47.

Theoretical, dynamic, and structural studies of the phenyl rotation in bispentafluorophenyl palladium complexes with scorpion-type ligands

M. Carmen Carrión, Félix A. Jalón, Isabel López-Solera, Blanca R. Manzano, Francisco Sepúlveda, Lucía Santos, Ana María Rodríguez, Miquel Moreno, and Martín Martínez-Ripoll

Abstract: A theoretical study at a DFT level has been carried out on the pentafluorophenyl rotation in the compounds $[Pd(C_6F_5)_2(bpzmPh)]$ (**1**) and $[Pd(C_6F_5)_2(bpz*mPh)]$ (**2**) (bpzm = bis(pyrazol-1-yl)phenylmethane and bpz*mPh = bis(3,5-dimethylpyrazol-1-yl)phenylmethane). The orientation of one C_6F_5 with respect to the coordination plane was forced to adopt specific values to simulate ring rotation and several parameters, such as the disposition of the other C_6F_5 group, the energy of the system, and the skeletal conformation of the bpz′m ligand, were analysed. The maximum energy value was found when the C_6F_5 ring was nearly coplanar with the coordination plane. In both complexes the minimum energy corresponds to a situation where the two rings are nearly parallel. A number of distortions that mainly affect the NPdN bite angle were predicted for the complex containing the bpz*mPh ligand (methylated pyrazoles). Four structures of complexes from this family were determined by X-ray diffraction and the same types of distortion were found. The differences in the free energies of activation for the pentafluorophenyl rotation in complexes containing methylated and non-methylated ligands were theoretically calculated. The calculated values were consistent with the data experimentally determined by NMR spectroscopy. The origin of the difference was attributed to the aforementioned distortions of the complexes containing the bpz*mPh ligand, which were more remarkable in the configuration of maximum energy.

Key words: N ligands, palladium, theoretical studies, DFT calculations, dynamics.

Résumé : Nous présentons les résultats d'une étude théorique de calculs DFT sur la rotation des groupes pentafluorophényles dans les composés $[Pd(C_6F_5)_2(bpzmPh)]$ (**1**) et $[Pd(C_6F_5)_2(bpz*mPh)]$ (**2**) (bpzm = bis(pyrazol-1-yl)phénylméthane et bpz*mPh = bis(3,5-diméthylpyrazol-1-yl)phénylméthane). L'orientation d'un groupe C_6F_5 par rapport au plan de coordination a été forcée à adopter des valeurs spécifiques pour simuler la rotation du cycle et nous avons analysé plusieurs paramètres comme la disposition de l'autre groupe C_6F_5, l'énergie du système et la conformation du ligand bpz′m. La valeur maximale d'énergie a été trouvée quand le cycle C_6F_5 est presque coplanaire avec le plan de coordination. Pour les deux composés l'énergie minimale correspond à une situation où les deux cycles sont presque parallèles. Nous avons prédit un nombre de distorsions qui affectent principalement l'angle de chélatation NPdN pour le composé portant le ligand bpz*mPh (pyrazoles méthylés). Nous avons déterminé par diffraction de rayons X quatre structures de composés de cette famille et nous avons trouvé les mêmes types de distorsion. Nous avons calculé théoriquement les différences d'énergie libre d'activation pour la rotation des groupes C_6F_5 dans les composés portant des ligands méthylés et non-méthylés. Les valeurs calculées sont cohérentes avec les donnés expérimentales déterminées par spectroscopie RMN. L'origine de la différence a été attribuée aux distorsions des composés contenant le ligand bpz*mPh explicitées plus haut, lesquelles sont plus importantes dans la configuration d'énergie maximale.

Mots clés : ligands N, palladium, étude théorique, calculs DFT, dynamiques.

Introduction

The chemistry of polyfluorophenyl derivatives of Pd and Pt has been extensively developed in organometallic chemistry (1). In contrast to other metal–aryl groups, the polyfluorophenyl ligands stabilize the metal–carbon bond because of their special electronic properties (2). Far from being simply spectator ligands, there are several examples in which the polyfluorophenyl groups have been shown to be reactive. For instance, it has been possible to study processes of insertion into Pd—C_6F_5 bonds (3), the activation of C—F bonds (4), aryl exchange (5), and other reactions (6, 7). Another aspect worth highlighting here related to polyfluoroaryl palladium and platinum complexes is the rotation of the aryl group around the M—C bond. Examples of both free (8, 9) and restricted rotation of the polyfluorophenyl groups have been described (9, 10–19). Kinetic activation parameters have been calculated for some cases (11, 18–21). Of particular interest is the use of the 3,5-dichlorotrifluorophenyl ligand, whose presence simplifies the ^{19}F NMR spectra (22–24). When bulkier groups are present, such as 2,4,6-tris(trifluoromethyl)phenyl (Fmes), the rotation is quenched because of severe steric hindrance (25). The presence of a larger atom, such as a bromo substituent, in the ortho position also increases the energy barrier of the polyhalophenyl rotation (26). It is important to note that a mirror plane coincident with the coordination plane can exist either in a static situation or because of fluxional processes (15, 18, 27, 28) involving the ancillary ligands. In this case the rotational process cannot be studied unless atropisomers are formed because of the presence of two (or more) asymmetrically substituted polyhalophenyl groups (haloaryls with C_s local symmetry) (18, 26, 29, 30). It has been demonstrated that in certain examples the rapid rotation takes place in a contact ion pair formed by halide dissociation (21), where the decrease in the steric hindrance facilitates the rotation around the metal–carbon bond. In other examples, it has been found that the rotation takes place in square-planar derivatives (11), and a case with a dual mechanism involving four- and three-coordinate species (30) has even been reported. The use of heteroscorpion-type ligands with the formula bis(pyrazol-1-yl)Rmethane (bpz′mR) (see Scheme 1) as ancillary ligands in bispentafluorophenyl palladium complexes gives rise to systems that are appropriate for studying the pentafluorophenyl rotation process. Such complexes do not have a symmetry plane coincident with the coordination plane and the process of boat-to-boat inversion (see Scheme 2) has never been observed when the spacer carbon situated between the pyrazole rings is substituted with a relatively bulky R group (31–34). The isomer in which the R group is situated in an axial orientation in the metallacycle is the only one that has been observed in these derivatives (31–34). In any case, the presence of only one R group would prevent the existence of a "dynamic plane" even if the boat-to-boat process were operating because this process would induce the change of the unique R group from an axial to an equatorial disposition. The use of bis(pyrazol-1-yl)Rmethane ligands offers the possibility of introducing different R substituents with distinct characteristics and sizes. Equally, the pyrazole rings can be substituted differently. In a previous study (34) we observed restricted rotation of the C_6F_5 groups

in the complexes depicted in Scheme 1 (except **1**, which is described here for the first time), all of which contain this type of ligand. The free energies of activation were calculated at the coalescence temperature. The absence of dissociative processes and a negligible influence of the R groups were demonstrated in this work. On studying this family of complexes, we unexpectedly found that derivatives where the bpz′mR ligands incorporate unsubstituted pyrazoles showed higher energy barriers than those with 3,5-dimethylated pyrazoles. A similar case, concerning the effect of the substituents on pyrazolate bridges cis to the polyhaloaryl rings, has also been recently reported (24). However, at first sight, a higher level of steric hindrance in the region close to the aryl group would be expected to hinder aryl rotation. In an attempt to explain this apparent contradiction we proposed the existence of a structural deformation when substituents are present on the pyrazole groups that would facilitate the fluoroaryl rotation (34). Indeed, comparison of the X-ray structures of similar complexes that differ in the presence of substituents in the 3-position of the pyrazole ring show that such substituents produce a significant distortion in the boat metallacycle, thus reducing the N-Pd-N/N_4 dihedral angle and also the bite angle of the N-donor ligand (32, 35) (see Scheme 3). This effect was more marked when a *tert*-butyl group was present in the 3-position of the pyrazole ring (35). In our complexes, this deformation would push away the Pd(C_6F_5)$_2$ moiety from the Me^3 pyrazole substituents and decrease the steric hindrance. The closure of the N-Pd-N angle would facilitate the rotation of the C_6F_5 groups by opening the C-Pd-N and (or) the C-Pd-C angles and decrease the steric crowding between the F_{ortho} and the atoms in the cis disposition. In fact, in previous works, higher energy barriers were found for the aryl rotation when the size of the donor atoms flanking the polyhaloaryl group in the coordination plane was increased (11, 23, 26), more so when the rotation took place in square-planar species. On the basis of these ideas, we decided to perform a theoretical study at a DFT level of the whole process of pentafluorophenyl rotation in two systems of this type containing the ligands bis(pyrazol-1-yl)phenylmethane (complex **1**) and bis(3,5-dimethylpyrazol-1-yl)phenylmethane (complex **2**). Our goals in this study were: (*i*) to determine

Scheme 2.

Scheme 3. (*a*) Distortion in the boat metallacycle owing to the steric hindrance of the substituent in position 3 of the pyrazole ring (R^3). The N-Pd-N/N_4 angle is reduced. (*b*) The distortion indicated in (*a*) decreases the N-Pd-N angle and consequently, the steric hindrance decreases between the pyrazole N-donor atom and the C_6F_5 groups.

whether the deformations observed in some X-ray structures can be predicted by theoretical calculations; (*ii*) to analyse the energy and the conformations of the systems in the different steps of the pentafluorophenyl rotation. We were particularly interested in determining whether the aforementioned deformations also occur in the situation of maximum energy in the rotation process. Finally, (*iii*) to establish if a higher energy barrier is theoretically predictable for the complexes containing unsubstituted pyrazoles and to analyze whether the origin of this difference is the aforementioned deformation. To the best of our knowledge, this type of study has never been performed and only a brief paragraph concerning molecular mechanics calculations has previously been published (36). This reference indicated that the most stable conformation of a Pd(II) complex containing a substituted phenyl ligand is that in which the aryl ring is approximately perpendicular to the coordination plane. We believe that these studies and the methodology used can be useful when applied to other types of systems in connection with the rotation of different types of aryl rings that may influence, for example, the enantioselectivity in catalytic processes. In fact, several examples of enhancement of the enantioselectivities (up to 40%–50%) (37, 38) in different catalytic processes when substituents are introduced in an aryl ring present in the asymmetric ligand have been described. This fact has recently been attributed to the restricted rotation of this ring, which gives rise to a more rigid chiral pocket (39). The formation of chiral conformations has also been reported for pentachlorophenyl derivatives that exhibit restricted ring rotation (40).

We have also synthesized and studied the fluxional behaviour of complex **1** (Scheme 1) to complete this family of complexes. The molecular structures of several derivatives of this type were also determined by X-ray diffraction to ascertain whether the stated deformations can be considered a general trend.

Experimental

Methods

All manipulations were carried out under an atmosphere of dry, oxygen-free nitrogen using standard Schlenk techniques. Solvents were distilled from the appropriate drying agents and degassed before use. Elemental analyses were performed with a PerkinElmer 2400 CHN microanalyzer. IR spectra were recorded on a Nicolet Impact 410 spectrophotometer as KBr pellets. NMR spectra were recorded at room temperature (≈25 °C) on a Varian UNITY-300 (300 MHz for ^{1}H, 75.4 MHz for ^{13}C) spectrometer. ^{1}H and ^{13}C NMR shifts were recorded using the residual proton or carbon signal of the solvent as internal standard. A ^{1}H–^{13}C correlation experiment (gHMQC) was used to assign the ^{13}C NMR resonances (Varian INOVA 500 MHz spectrometer). Free energies of activation were calculated (20) from the coalescence temperature (T_c) and the frequency difference between the coalescing signals (extrapolated at the coalescence temperature) with the formula $\Delta G_c^{\ddagger} = aT_c[9.972 + \log(T_c/\delta\nu)]$ ($a = 1.914 \times 10^{-2}$). The estimated error in the calculated free energies of activation is ±0.2 kcal/mol (1 cal = 4.184 J). The probe temperature (±1 K) was controlled by a standard unit calibrated with a methanol reference.

Materials

$[Pd(C_6F_5)_2(cod)]$ was prepared according to the literature procedure (41). Preparation and structural information of complexes **2–8** have been previously reported (32, 34). bpzmPh was prepared according to the literature method (42).

Theoretical calculations

Calculations have been performed using the Gaussian 98 series of programs (43). Density functional theory (DFT) was applied with the B3LYP functional (44, 45). Effective core potentials (ECPs) were used to represent the innermost electrons of the palladium atom. The basis set for the Pd atom was that associated with the pseudopotential (46), with a standard double-ξ LANL2DZ contraction (43). All calcula-

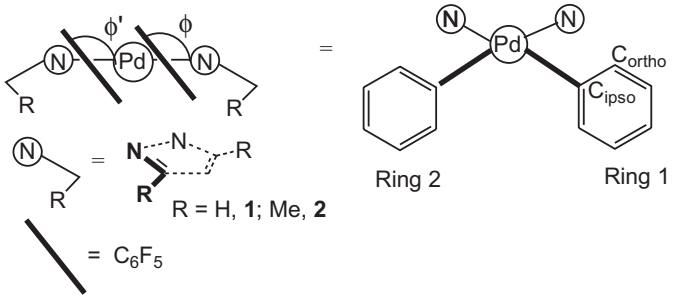
© 2005 NRC Canada

tions were done with the split-valence 6-31G basis set for the hydrogen, carbon, nitrogen, and fluoride atoms (47). Within this basis set, the total number of basis functions was already high for complex **1** where 397 basis functions were needed, whereas complex **2** required 449 basis functions at this level of calculation. The equilibrium geometries were also localized with the higher 6-31G(d) basis set that includes polarization functions on heavy atoms.

Full geometry optimization and direct location of equilibrium geometries were carried out by means of the Schlegel gradient optimization algorithm (48) by using redundant internal coordinates as implemented in the Gaussian 98 package (43). Diagonalization of the energy second-derivative matrix was performed to provide the vibrational harmonic frequencies that were used for evaluating the thermodynamic corrections at 1 atm (1 atm = 101.325 kPa) and 298.15 K to the initially obtained electronic energy. As per usual, we made the approximations of the rigid rotor and the harmonic model for the rotational and the harmonic degrees of freedom, respectively (49).

Preparation of $[Pd(C_6F_5)_2(bpzmPh)]$ (1)

$[Pd(C_6F_5)_2(cod)]$ (100 mg, 0.18 mmol) was dissolved in CH_2Cl_2 (20 mL) and bpzmPh (40.9 mg, 0.18 mmol) was added. The solution was stirred at room temperature for 16 h. Complex **1** was obtained as a white powder after evaporation of the solvent to dryness and washing with pentane (2 × 10 mL). Yield: 89% (106.1 mg). Complex **1**, thus obtained, is spectroscopically pure, but it can be crystallized from dichloroethane–hexane. Monocrystals suitable for analysis by X-ray diffraction were obtained in this way. IR (KBr, cm^{-1}): 956, 1633, 1058 (C_6F_5). ^1H NMR (300 MHz, 1,1′,2,2′-$CDCl_2CDCl_2$, 25 °C, ppm) δ: 6.42 (t, $^3J_{H,H}$ = 2.4 Hz, 2H, H^4_{pz}), 6.60 (d, $^3J_{H,H}$ = 7.3 Hz, 2H, H_{ortho}), 7.25 (d, $^3J_{H,H}$ = 2.0 Hz, 2H, H^3_{pz}), 7.44 (t, $^3J_{H,H}$ = 7.3 Hz, 2H, H_{meta}), 7.50 (t, $^3J_{H,H}$ = 7.3 Hz, 1H, H_{para}), 7.52 (s, 1H, H_α), 7.85 (d, $^3J_{H,H}$ = 2.4 Hz, 2H, H^5_{pz}). ^{13}C NMR (75 MHz, 1,1′,2,2′-$CDCl_2CDCl_2$, 25 °C, ppm) δ: 76.1 (s, 1C, C_α), 107.3 (s, 2C, C^4_{pz}), 125.3 (s, 2C, C_{ortho} Ph), 129.2 (s, 2C, C_{meta} Ph), 130.1 (s, 1C, C_{para} Ph), 132.6 (s, 2C, C^5_{pz}), 135.2 (dm, $^1J_{C,F}$ = 248 Hz, 4C, C_{meta}, C_6F_5), 137.0 (dm, $^1J_{C,F}$ = 248 Hz, 2C, C_{para}, C_6F_5), 144.0 (s, 2C, C^3_{pz}), 147.0 (dm, $^1J_{CF}$ = 248 Hz, 4C, C_{ortho}, C_6F_5). Anal. calcd. for $C_{25}H_{12}F_{10}N_4Pd$ (664.8): C 45.17, H 1.82, N 8.43; found: C 44.90, H 1.96, N 8.18.



Preparation of monocrystals for X-ray diffraction studies

Monocrystals of **1** were obtained by a slow evaporation of hexane over a concentrated solution of 1,2-dichloroethane. Monocrystals of **2** were obtained by a slow evaporation of acetone-d_6 in an NMR tube. Monocrystals of **3·$C_2H_4Cl_2$** were obtained by slow vaporization of pentane over a 1,2-dichloroethane solution of this complex. A sample of monocrystals of **8** was obtained by slow evaporation of pentane over a solution of this complex in acetone.

X-ray structure determinations for compounds 1, 2, 3·$C_2H_4Cl_2$, and 8

For **1** the intensity data were collected on a Bruker SMART CCD diffractometer using MoKα radiation (λ = 0.710 73 Å) at 23 °C. The data were collected with a frame width of 0.3° in ω and a counting time of 25 s per frame at a crystal-to-detector distance of 4 cm. The diffraction frames were integrated using the SAINT (50) package and corrected for absorption with SADABS (51). For **2** and **3** the intensity data were collected on a NONIUS-MACH3 diffractometer equipped with a graphite monochromator MoK_α radiation (λ = 0.710 73 Å) using an ω/2θ scan technique at room temperature. For **8** the intensity data were collected on a Seifert XRD3000-S diffractometer equipped with a graphite monochromator CuK_α radiation (λ = 1.541 78 Å) at room temperature. The final unit cell parameters were determined from 25 well-centered reflections and refined by the least-squares method. The space group was determined from the systematic absences and this was vindicated by the success of the subsequent solutions and refinements. The structures were solved by direct methods using SHELXS (52) (for **1**, **2**, and **3**) and SIR92 (53) (for **8**) computer programs and refined on F^2 by full-matrix least-squares (SHELXL-97) (54). All nonhydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in calculated positions and were refined with an overall isotropic temperature factor using a riding model. Weights were optimized in the final cycles. Complex **3** crystallizes as a solvate with a molecule of 1,2-dichloroethane.

Scheme 4.

Results and discussion

The complexes $[Pd(C_6F_5)_2(bpzmPh)]$ (**1**) and $[Pd(C_6F_5)_2(bpz*mPh)]$ (**2**) have been theoretically analyzed by a DFT study. A number of different parameters that depend on the dihedral angle ϕ have been analyzed for each complex. The dihedral angle ϕ is defined by the torsion angle N-Pd-C_{ipso}-C_{ortho} as shown in Scheme 4. This angle was forced to adopt specific values (in the range from 0° to 180°) and the energy of the structure was minimized until convergence (see Tables 1 and 2). Only the data that correspond to ΔE = 0 in the tables have not been forced (ϕ = 63.5° for complex **1** (Table 1) and ϕ = 83.4° for complex **2** (Table 2)). In these cases, the system was allowed to adopt the structure of lower energy without any restrictions. We have performed some calculations with the SCF=TIGHT keyword. We have seen that the energies are totally unaffected and the geometries are almost equal (differences are less than 1° or 0.01 Å).

The dependence on ϕ of different parameters that are directly or indirectly related with the rotation of the perfluorophenyl groups of the complexes will be discussed in the following sections.

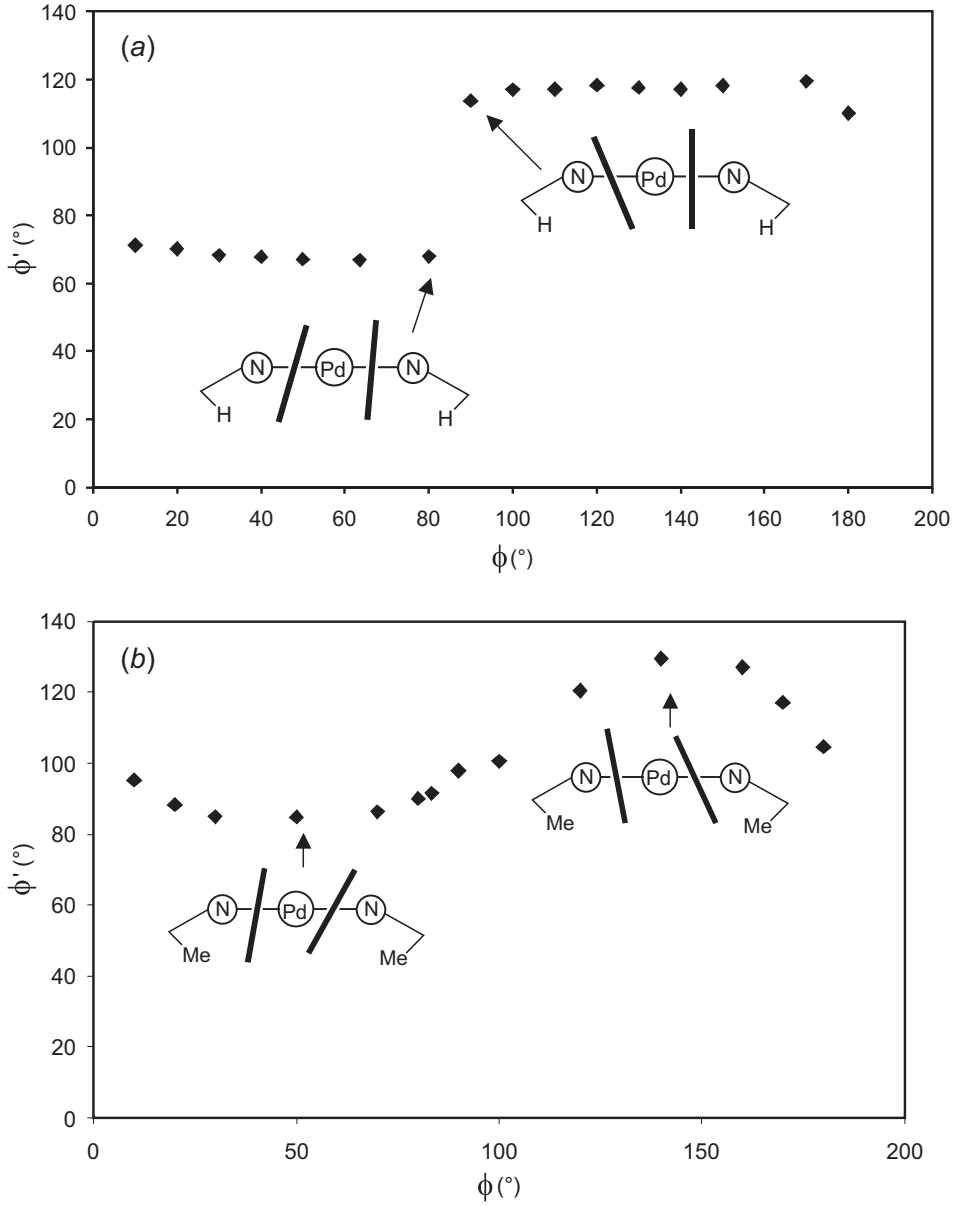
Mutual dependence of the rotation of the two C_6F_5 rings — ϕ vs. ϕ'

It is expected that the rotation of the two C_6F_5 rings will be mutually dependent and, as a consequence, the dependence of the dihedral angle ϕ' with ϕ was first studied. The angle ϕ' was defined according to Scheme 4 and its dependence on ϕ in **1** and **2** is indicated in Tables 1 and 2 and represented in Fig. 1. It is noteworthy that the two graphics of Fig. 1 are not symmetrical, e.g., the ϕ' values for small and large ϕ values are different. This is due to the asymmetry of the nitrogen donor ligand so that the coordination plane is not a plane of symmetry (see Scheme 1). Consequently, small or large ϕ values represent different situations of the pentafluorophenyl ring in the complex (see Scheme 4). Finally, note that $\phi = 0°$ and $\phi = 180°$ correspond to the same structure.

For complex **1**, two values of ϕ' are clearly preferred. For values of ϕ between 10° and 88°, the values of ϕ' are from 67.2° to 71.2°, but for values of ϕ between 90° and 180°, ϕ' is slightly below 120°. ϕ' suddenly changes when ϕ changes from 88° to 90°. In complex **2** the behaviour is different, although some similarities are observed. In this case, a more gradual variation in ϕ' is observed as ϕ is changed. However, two limiting values also exist. A minimum of 84.8° when ϕ is 50° and a maximum of 129.4° when ϕ is 140°. It is noticeable that the minimum value of ϕ' is higher in **2** than in **1**. This can likely be attributed to the higher steric repulsion expected between the F_{ortho} of ring 2 and the methyl group in the 3-position of the pyrazole ring when this angle is small. It is also noticeable that ϕ' does not adopt values that are too low or too high in either of the two complexes, very likely because of the repulsions of the second C_6F_5 ring when it is nearly coplanar with the complex coordination plane.

The mutual dependence found between ϕ and ϕ' can be understood in terms of the second C_6F_5 ring adapting to the rotation of the first, with ϕ' values within the allowed range.

ϕ vs. energy



The dependence of the relative energy of the structures of complexes **1** and **2** as a function of ϕ is indicated in Fig. 2 (see also Tables 1 and 2).

As expected, in both cases the maximum energy value is achieved when ϕ is near 180°. This value corresponds to a situation where a C_6F_5 ring is nearly coplanar to the coordination plane and leads to the highest steric repulsion between the F_{ortho} of the rotating ring and the vicinal coordinated atoms (N and C). Comparison of the two diagrams in Fig. 2 shows that the conformations of the C_6F_5 rings are similar for the two complexes in the maximum energy configurations. However, in both complexes the minimum of energy corresponds to conformations with different values of ϕ and ϕ'. For complex **1**, two states of minimum energy (0 and 0.04 kcal/mol) are found. It is outstanding that in these conformations the two C_6F_5 groups are not perpendicular to the coordination plane, but they are nearly parallel ($\phi = 63.5°$, $\phi' = 66.9°$ and $\phi = 110°$, $\phi' = 117.1°$) leading to a hypothetical minimum steric hindrance between the F_{ortho} of both rings. For complex **2**, the minimum of energy is found when both rings are nearly parallel and approximately perpendicular to the coordination plane ($\phi = 83.4°–90.0°$, $\phi' = 91.5°–97.8°$). In this complex the conformation of the rings found in **1** would probably involve considerable steric hindrance between the F_{ortho} of one C_6F_5 ring and the Me substituent of the pyrazole ring cis to it. For this reason such an arrangement cannot correspond to an energy minimum. In an effort to provide evidence for this proposal, the values $\phi = 63.5°$ and $\phi' = 66.9°$ were imposed on the structure of **2** and the energy was then minimized until convergence. A value of 2.4 kcal/mol above the minimum was calculated for this conformation of **2**, thus showing its relative lack of stability with respect to the minimum energy situation.

For a better comparison with the data obtained from the NMR studies, we also calculated the free energy of activation for the higher energy situation for both complexes in the gas phase. The value obtained for complex **1** is

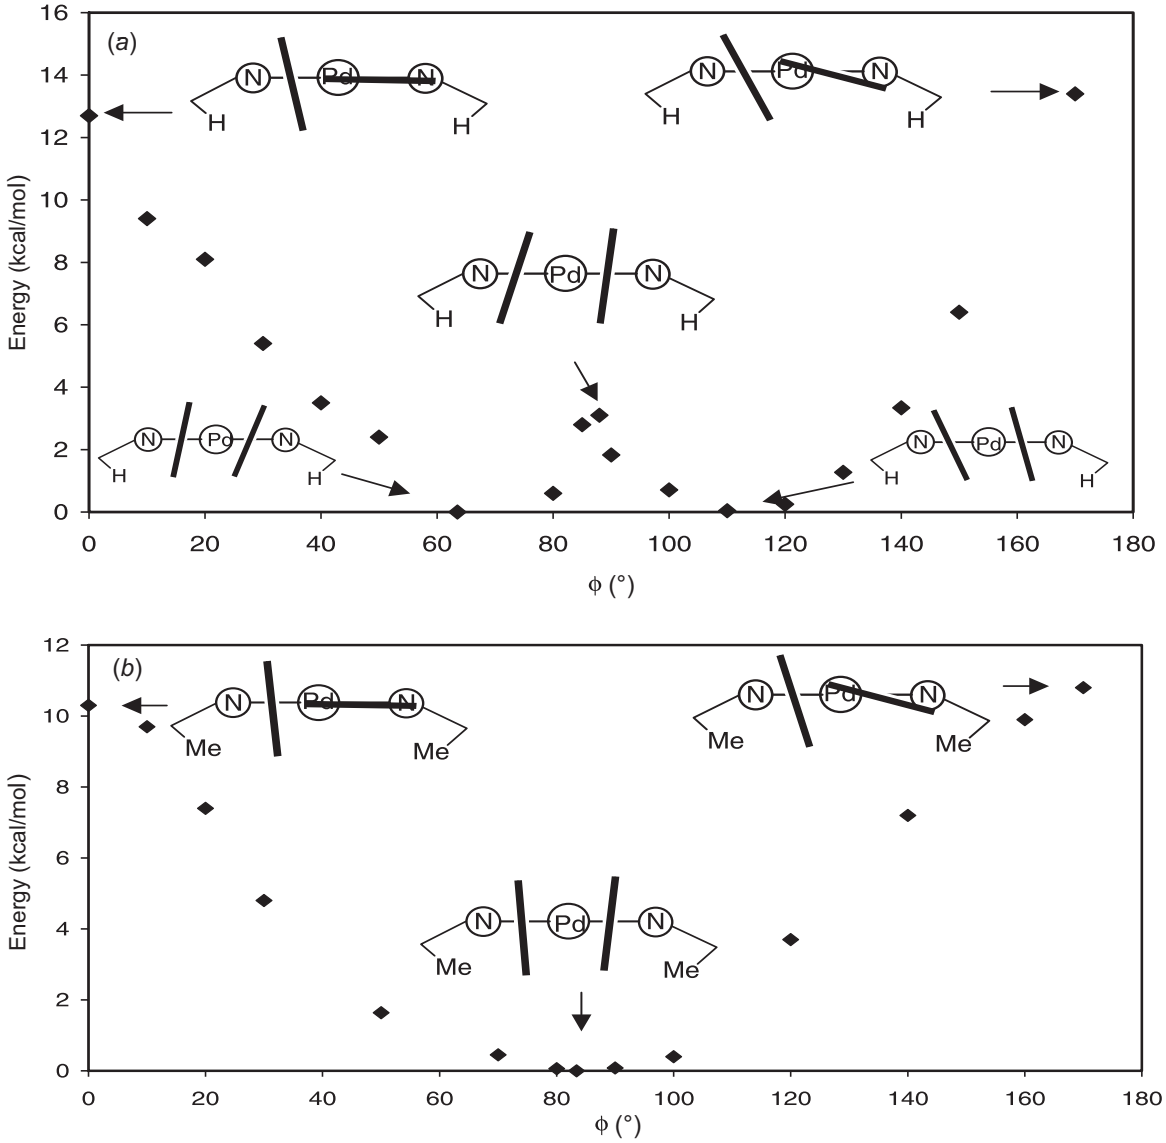
Fig. 1. Plot of the values (obtained from the theoretical calculations) of ϕ′ (°) vs. ϕ (°) for the rotamers of complexes (*a*) **1** and (*b*) **2**.

13.0 kcal/mol and that for complex **2** is 12.2 kcal/mol. These values imply that the methylated complex has a lower free energy activation barrier with a difference of 0.8 kcal/mol.



ϕ vs. the skeletal conformation of the coordinated bpz′m ligand — N-Pd-N bite angle and N-Pd-N/N_4 dihedral angle

The skeletal conformation of the bpz′mR ligands must be affected by the rotation of the C_6F_5 groups in the sense that the ligand should adapt its conformation to facilitate this rotation. Bearing in mind our previous proposal concerning the distortions observed in complexes with substituted pyrazoles, we considered two skeletal parameters for the coordinated N-donor ligand (see Scheme 3): (*i*) the bite angle N-Pd-N and (*ii*) the dihedral angle between the coordination plane (N-Pd-N) and the averaged plane of the four pyrazolic nitrogens atoms (NNNN = N_4).

An overview of Fig. 3 shows that these two parameters are linearly related in the sense that the dihedral angle increases as the bite angle N-Pd-N opens. Given this mutual relationship between these parameters, we chose the N-Pd-N bite angle to report the conformation of the N-donor ligand in the different steps of the C_6F_5 rotation. The effect on the bite angle is due to both C_6F_5 groups and, to estimate how much both rings deviate from normality (with respect to the coordination plane), we defined the parameter $\alpha + \alpha'$ as $\alpha = |\phi - 90°|$ and $\alpha' = |\phi' - 90°|$ (absolute values in both cases) and studied its relation with the bite angle. One must also take into account that the situation in which the two rings are orthogonal (α and $\alpha' = 0°$) is the state of minimum energy for complex **2**, but in the case of complex **1** this disposition does not correspond to the minimum state but is not far from it. The variation of the bite angle with $\alpha + \alpha'$ for **1** and **2** is represented in Fig. 4. The whole set of values fits

© 2005 NRC Canada

Fig. 2. Plot of the relative energy (kcal/mol) as a function of the ϕ angle for the rotamers of complexes (*a*) **1** and (*b*) **2**.

well in a branch of a quadratic parabola. Then, it is clear that an inverse relationship exists between these two parameters. In the case of **2**, the variation in the value of the bite angle is reasonably gradual, whereas for **1** it changes very slightly for small α + α′ values (e.g., when the pentafluorophenyl rings are near the normal position), but decreases quite markedly when higher α + α′ values are reached. Considering the relationship previously established, one would expect that the dihedral angle N-Pd-N/N_4 would also be reduced when α + α′ is higher (this has been confirmed). In conclusion, when one C_6F_5 ring is near coplanar with the coordination plane (high value of α + α′), the bpz′mR facilitates, as far as possible, the rotation of the C_6F_5 groups by reducing the N-Pd-N angle.

When comparing both complexes it can be seen that the theoretical values found for the N-Pd-N angle are smaller for the methylated complex for all values of α + α′. The same applies to the N-Pd-N/N_4 angle (see Tables 1 and 2 and Fig. 4). In other words, the methylated complex **2** has more favourable structures for ring rotation in all steps of the process. This situation is consistent with our proposal concerning the distortions induced in the complexes owing to the presence of substituents in the 3-position of the pyrazolyl rings (see Scheme 3).

X-ray structures of [Pd(C_6F_5)$_2$(bpzmPh)] (1), [Pd(C_6F_5)$_2$(bpz*mPh)] (2), [Pd(C_6F_5)$_2${bpzm(2-C_6H_4OMe)}]·$C_2H_4Cl_2$, 3·$C_2H_4Cl_2$, and [Pd(C_6F_5)$_2$(bpz*mPy)] (8)

To complete the family of complexes we synthesized complex **1** in a similar way to the complexes previously reported (33). The corresponding analytical and spectroscopic data are given in the Experimental section.

As previously stated, we were interested in evaluating whether the distortions previously found in complexes of this type with substituted pyrazoles were also present in the solid state. With this aim in mind, we tried to obtain crystals of several derivatives to determine their X-ray molecular structures. Fortunately, suitable crystals could be obtained for complexes **1** and **2** — on which the theoretical calcula-

tions were performed for the isolated molecules — and two other complexes previously reported (**3** and **8**). The ORTEP plots of the molecules are shown in Figs. 5–8. The crystallographic data (Table 3) and a list of selected bond distances and angles (Tables 4 and 5) are given. Two molecules are present in the asymmetric unit of complex **1**. These two molecules are quite similar except for the orientation of the phenyl ring of the CHR group (see the following). The data corresponding to only one molecule are given in Table 4. A comparison of experimental data (from X-ray studies) and the calculated equilibrium geometries for **1** and **2** is also given in Table 4. To see whether the 6-31G basis set is good enough to study this system, we have also performed calculations with the larger 6-31G(d) basis set that includes polarization functions on heavy atoms. Comparison of results show that no major improvement emerges from the use of the larger basis set. In fact, the bond length distances involving the palladium are better described by the 6-31G basis set (probably because of cancellation of errors). In general we see quite a good agreement between the X-ray and calculated geometries within both basis sets as the bond lengths differ by less than 0.1 Å and angles agree within an error no larger than 4° (less than 0.07 rad).

For all the complexes, the geometry around the palladium atoms is approximately square-planar, with two coordinated pyrazole nitrogens and the carbons of the pentafluorophenyl rings. The distances of the Pd—N coordination bonds are comparable to those of other bis(pyrazol-1-yl)methane complexes (31–35, 55). Significant differences concerning the Pd—N bond distances were not found on changing the

This difference probably arises because of the presence of the OMe group, which lies almost in the anisole plane and points away from the molecule. The disposition of the anisole ring is similar to that found in an allylpalladium complex containing the same N-donor ligand (33).

A selection of the structural parameters related to our previous discussion is compiled in Table 6. The data obtained from the theoretical calculations for complexes **1** and **2** have also been included in brackets (for **1** the values for the minimum of ΔE = 0.04 kcal/mol are given). The parameters for the structure of the previously reported ferrocenyl complex **7** are also included (33). A clear difference can be observed between the data for complexes **1** and **3**, where the pyrazole rings are unsubstituted, and complexes **2**, **7**, and **8**, which contain 3,5-dimethylated rings. Both N-Pd-N and N-Pd-N/N_4 angles are higher in compounds **1** and **3** and lower and quite similar for the other three compounds. The difference in the stated angles that depends on the type of pyrazole present in the ligand is in accordance with previous observations (33, 35) and with our theoretical predictions. The values of the two C-Pd-N angles are also reflected in Table 6. It is possible to see that these angles are larger in the methylated complexes, a fact that should facilitate the C_6F_5 rotation. As far as ϕ and ϕ' are concerned, in complexes **1** and **3** these angles are comparable, far from the orthogonal position and very similar to those calculated for the minimum

energy structure of 0.04 kcal/mol. In the methylated complex **2**, one of the C_6F_5 rings is not too far from the orthogonal position (according to calculations), whereas the second ring is tilted. For this ϕ' value, less agreement with the theoretical results is observed. To analyze this point the values of ϕ and ϕ' were fixed according to the X-ray structure of **2** and the rest of the structure was minimized using the same theoretical basis as in the preceding discussion. The energy value for this hypothetical structure was 0.8 kcal/mol above the minimum of this system. Perhaps the observed differences in the values of these angles with respect to the gas-phase minimum can be ascribed to the effect of packing in the solid state.[2]

Dynamics of the C_6F_5 rotation in [$Pd(C_6F_5)_2$(bpz′mR)] complexes in solution

The dynamics of the restricted rotation of C_6F_5 groups directly bonded to the square-planar Pd(II) centres for complexes **2**, **8** (32), and **3**–**7** (34) have been previously studied in solution by ^{19}F NMR spectroscopy. The corresponding study for new complex **1** was also carried out in 1,1′,2,2′-$CDCl_2CDCl_2$. At 253 K, one F_{para}, one F_{meta}, and two F_{ortho} signals were observed. The coalescence temperature was reached at 338 K and the free energy of activation was calculated. The data for all complexes are gathered in Table 7.

A plot of the free energies of activation vs. the coalescence temperatures is given in Fig. 9. Two straight lines for methylated and non-methylated derivatives can be plotted. The fact that the points fit approximately to a straight line independently of the solvent used ($CDCl_3$ or 1,1′,2,2′-$CDCl_2CDCl_2$) indicates that this is not an important factor governing the C_6F_5 rotation. Furthermore, the nature of the R groups in the ligands does not seem to have a clear influence either. It is evident from the data that higher values are obtained in complexes with scorpion-type ligands that do not contain substituents in the pyrazole groups than in those with 3,5-dimethylated rings. If we compare the corresponding two straight lines at room temperature, it can be estimated that the free energy of activation is about 2.3 kcal/mol higher for the non-methylated derivatives. The difference in the free energies of activation between complexes **1** and **2** obtained in the theoretical calculations is 0.8 kcal/mol. Although the two results are not quite close, in both cases lower energy barriers are found for the methylated complexes. At this point it is important to stress the fact that theoretical free energy calculations imply assuming that the system behaves as an ideal gas and that the rotational and vibrational degrees of freedom are well-described through the rigid rotor and harmonic approximations, respectively. Besides, the theoretical calculations of free energy of activation are referred to the gas phase and the experimental data correspond to the complexes in solution. As stated, the values of the bite and the N-Pd-N/N_4 dihedral angles are higher for **1** than for **2**. This is also true for the states of maximum and minimum energy. It is remarkable that the differences between the two complexes are higher in the maximum than in the minimum of energy. Consequently, one origin of the different experimental values obtained for the free energy of activation in the two types of complex could lie in the fact that the methylated complexes are more able to adapt the nitrogenated ligand to the ring rotation steric requirements that are more important in the maximum state of energy. In the higher energy structure, the rotating C_6F_5 ring lies approximately in the coordination plane of the complex. In this conformation it is reasonable to assume that the steric hindrance with the substituent in position 3 of the pyrazole could be neglected and then the bite angle N-Pd-N is the main factor to consider. Let us finally emphasize that our calculations have allowed comparison of the structures in the maximum energy situation and not only structures that should correspond approximately to the minimum of energy, such as those obtained from the X-ray determinations.

Conclusion

The rotation of a C_6F_5 group around the Pd—C axis in the complexes [$Pd(C_6F_5)_2$(bpz′mPh)] (bpz′mPh = bis(pyrazol-1-yl)phenylmethane (**1**) and bpz′mPh = bis(3,5-dimethylpyrazol-1-yl)phenylmethane (**2**)) has been theoretically stud-

ied at a DFT level. Results have been compared with experimental information obtained in solution (free energies of activation determined by NMR) and in the solid state (X-ray diffraction studies). Different structural parameters such as the perfluorophenyl ring orientation, energy of the system, and conformation of the nitrogenated ligand have been analyzed. It has been found that when one ring is forced to rotate, the other ring adapts its disposition. The most stable structure for both complexes involves the two pentafluorophenyl rings at a nearly parallel position. In the minimum energy structure of complex **2**, these rings are approximately orthogonal to the coordination plane. This is not the case for complex **1**. Two skeletal parameters related with the coordination of the nitrogenated ligand, namely the bite angle and the N-Pd-N/N_4 dihedral angle, have also been analyzed. Both angles are smaller when the pentafluorophenyl rings deviate more from orthogonality with respect to the coordination plane. The values for these parameters are always smaller in the case of the methylated complex **2**, the effect being more noticeable in the maximum energy geometry.

Lower free activation energies at the coalescence temperature ($\Delta G_c^{\ddagger}$) for the ring rotation process have been found both theoretically and experimentally for the methylated derivatives when compared with the complexes containing unsubstituted pyrazolyl ligands. The origin of the energy differences found in solution for the C_6F_5 rotation may be found in the smaller values obtained from our theoretical calculations for the N-Pd-N bite angle and for the skeletal N-Pd-N/N_4 dihedral angle in **2** as compared with **1** in the state of maximum energy. This finding is consistent with previous proposals that one important effect in the aryl rotation was the "in-plane" hindrance of the donor atoms cis to

© 2005 NRC Canada

the polyhaloaryl group. According to our theoretical and experimental results, the direct steric repulsion of the Me^3 of the pyrazole groups with the pentafluorophenyl rings does not have a clear effect over the C_6F_5 rotation.

Several X-ray structure determinations have been performed for complexes **1**, **2**, and other derivatives of this family. It has been found that the values of the bite angle and the N-Pd-N/N_4 dihedral angle are always smaller in the methylated derivatives, in accordance with theoretical predictions.

Glycosides from the sea cucumber *Cucumaria frondosa*. IV. Structure of frondosides A_2-4, A_2-7, and A_2-8, three new minor monosulfated triterpene glycosides

Alexandra S. Silchenko, Sergey A. Avilov, Alexandr S. Antonov, Anatoly I. Kalinovsky, Pavel S. Dmitrenok, Vladimir I. Kalinin, Carl Woodward, and Peter D. Collin

Abstract: Frondosides A_2-4 (**1**), A_2-7 (**2**), and A_2-8 (**3**) are new monosulfated triterpene glycosides isolated from the sea cucumber *Cucumaria frondosa*. Their structures have been elucidated on the basis of spectral data (2D NMR and MS). Frondosides A_2-7 (**2**) and A_2-8 (**3**) are isomers and differ from each other only by the position of a double bond in their non-holostane-type aglycones.

Key words: Cucumaria frondosa, sea cucumbers, frondosides, triterpene glycosides.

Résumé : Les frondosides A_2-4 (**1**), A_2-7 (**2**) et A_2-8 (**3**) sont de nouveaux glycosides de triterpènes monosulfatés qui ont été isolés du concombre de mer *Cucumaria frondosa*. Leurs structures ont été élucidées sur la base de données spectrales (spectrométrie de masse et RMN 2D). Les frondosides A_2-7 (**2**) et A_2-8 (**3**) sont des isomères qui ne diffèrent l'un de l'autre que par la position d'une double liaison dans leurs aglycones de type nonholostane.

Mots clés : Cucumaria frondosa, concombres de mer, frondosides, glycosides de triterpène.

[Traduit par la Rédaction]

As a continuation of our studies of triterpene glycosides from the Atlantic sea cucumber *Cucumaria frondosa* (1–3) we report herein the isolation and structure elucidation of three new monosulfated glycosides. The fraction of monosulfated glycosides of the A_2 group consists of a complex mixture of minor glycosides that differ from each other by the structure of aglycones and have identical pentasaccharide-branched carbohydrate moieties.

Sea cucumbers were collected in the Gulf of Maine, Penobscot Bay, Maine. The ethanolic extract of *C. frondosa* was sequentially submitted to column chromatography on polychrom-1 (powdered Teflon) and silica gel to give the fraction of monosulfated frondosides of the A_2 group (3). Separation of the A_2 fraction by HPLC on the reverse-phase column yielded three individual glycosides (frondosides A_2-4 (**1**), A_2-7 (**2**), and A_2-8 (**3**)).

The signals of the carbohydrate moieties in the NMR spectra of isolated glycosides (**1**–**3**) were coincident to each other and also with the corresponding signals in the spectra of frondosides A_2-1, A_2-2, A_2-3, and A_2-6, isolated earlier from *C. frondosa* (3). All these data indicated an identity of the pentaoside branched carbohydrate chains of these compounds having one sulfate group. Indeed, the presence of five characteristic doublets (J = 6.6–7.8 Hz) in the ^{1}H NMR spectra of **1**–**3** and corresponding signals of anomeric carbons in the ^{13}C NMR were indicative of a pentasaccharide chain and β configuration of all glycoside bonds (4). The characteristic chemical shift (75.75 ppm) of C-4 of the first xylose residue in the ^{13}C NMR spectra of glycosides **1**–**3** demonstrated the binding of a sulfate group to this position. Positions of interglycosidic bonds were elucidated from the corresponding carbon resonances (taking into account the effects of glycosylation (4)) and were also confirmed by corresponding NOESY and HMBC correlations (Table 1). The structures of carbohydrate chains of **1**–**3** were also confirmed by MALDI TOF MS.

The HR MALDI TOF MS (positive ion mode) of glycoside **1** showed the pseudomolecular ion peak $[M_{Na} + Na]^+$ at m/z 1327.5271, calculated for $C_{59}H_{93}O_{28}SNa_2$ as 1327.5368 m/z, which allowed the determination of a molecular formula of $C_{59}H_{93}O_{28}SNa$ for glycoside **1**.

The MALDI TOF MS of glycoside **1** exhibited the pseudomolecular ion peaks at m/z 1327 $[M_{Na} + Na]^+$ and 1343 $[M_{Na} + K]^+$, and fragmentation ion peaks at m/z 1225 $[M_{Na} - SO_3Na + Na + H]^+$, 1207 $[M_{Na} - OSO_3Na + Na - H]^+$, 1195 $[M_{Na} - Xyl + Na + H]^+$, 1151 $[M_{Na} - 3\text{-O-Me-Glc} + Na + H]^+$, and 1093 $[M_{Na} - SO_3Na - Xyl + Na + 2H]^+$ in the positive ion mode, as well as a pseudomolecular ion peak at

m/z 1281 $[M - Na]^-$ along with peaks at *m/z* 1149 $[M - Na - Xyl + H]^-$ and 1105 $[M - Na - 3\text{-O-Me-Glc} + H]^-$ in the negative ion mode. MS data confirmed the presence of a sulfate group, xylose, and 3-*O*-methylglucose residues as terminal monosaccharide units in the carbohydrate chain of **1**.

The aglycon moiety of glycoside **1** was found by extensive NMR spectroscopy (^1H and ^{13}C NMR, DEPT, HSQC, HMBC, COSY, and NOESY) (Table 2) to have a holostane-type aglycon. Actually, the signal of the carbonyl group belonging to 18(20)-lactone at 179.94 ppm and the signals at

[b]Recorded at 500 MHz in C_5D_5N.
[c]Mixing time in NOESY is 460 ms.

119.84 (C-7) and 146.63 (C-8) ppm in the ^{13}C NMR spectrum, as well as the signal at 5.73 (m, H-7) ppm in the ^{1}H NMR spectrum, showed that the aglycon of **1** has the same pentacyclic skeleton system as in the aglycon of cucumarioside A_7-3 from *C. japonica* (5) and frondosides A_2-2 and A_2-3 from *C. frondosa* (3). However, the signals of the side chains in the NMR spectra of these substances were different. ^{13}C NMR and DEPT spectra of frondoside **1** demonstrated the signals of a tertiary carbon at 123.92 (C-24) ppm and a quaternary carbon at 131.71 (C-25) ppm. The corresponding proton signal at 5.17 (m, H-24) ppm was observed in the ^{1}H NMR spectrum. These data indicated that there is a 24(25)-double bond in the side chain of **1**. The cross-peaks between the protons of terminal methyl groups H_3-26 (δ 1.61 ppm, s) and H_3-27 (δ 1.69 ppm, s) and C-24 and C-25 in the HMBC spectrum of **1** confirmed the structure of the aglycon side chain. Hence, frondoside A_2-4 (**1**) is 3-*O*-{3-*O*-methyl-β-D-glucopyranosyl-(1→3)-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β-hydroxyholosta-7,24-diene.

In the HR MALDI TOF MS (positive ion mode) of glycoside **2** the pseudomolecular ion peak $[M_{Na} + Na]^+$ at *m/z* 1373.5874 was observed, calculated for $C_{61}H_{99}O_{29}SNa_2$ as 1373.5786 *m/z*, which allowed the determination of a molecular formula of $C_{61}H_{99}O_{29}SNa$ for glycoside **2**.

The MALDI TOF MS (positive ion mode) of glycoside **2** exhibited a pseudomolecular ion peak at *m/z* 1373 $[M_{Na} + Na]^+$ and characteristic ion peaks at *m/z* 1271 $[M - SO_3Na + Na + H]^+$, 1139 $[M - SO_3Na - Xyl + Na + 2H]^+$, and 1095 $[M - SO_3Na - 3\text{-O-Me-Glc} + Na + 2H]^+$, demonstrating the loss of a sulfate group and terminal monosaccharide residues, along with the characteristic ion peak at *m/z* 1231 $[M - 141 + Na - H]^+$, owing to the cleavage of the C-20–C-22 linkage in the aglycon side chain. The pseudomolecular ion peak at *m/z* 1327 $[M_{Na} - Na]^-$, along with fragmentation ion peaks at *m/z* 1195 $[M_{Na} - Na - Xyl + H]^-$ and 1151 $[M_{Na} - Na - 3\text{-O-Me-Glc} + H]^-$ (owing to the loss of terminal monosaccharide residues), were revealed in the negative ion mode.

The NMR spectra (^{1}H and ^{13}C, DEPT, HSQC, HMBC, COSY, and NOESY) (Table 3) of glycoside **2** indicated the

[a]Recorded at 125.77 MHz in C_5D_5N.
[b]Recorded at 500 MHz in C_5D_5N.
[c]Mixing time in NOESY is 460 ms.
[d]The signals are interchangeable.

absence of a 18(20)-lactone cycle (lacking the corresponding signal of a C-18 carbonyl group at 180 ppm and the presence of the signal of a C-18 methyl group at 16.40 ppm in the ^{13}C NMR spectrum). Therefore, the presence of a nonholostane aglycon having a 9(11)-double bond (signals at 149.43 (C-9), 114.82 (C-11), and 5.32 (m, H-11) ppm in the ^{13}C and ^{1}H NMR spectra, correspondingly) was detected in **2**.

There were also signals at 121.36 (C-24) and 133.06 (C-25) ppm in the ^{13}C NMR spectrum indicating the presence of a 24(25)-double bond. The signals at 170.58 and 20.98 ppm demonstrated the presence of an acetate group attached to C-22 (79.35 ppm). The signal of a quaternary carbon (C-20) bonded with a hydroxyl group was found at 75.81 ppm.

The comparison of the aglycon parts of the NMR spectra of **2** and known frondoside C isolated from *C. frondosa* (2) revealed the identity of the aglycons of these compounds. Hence, frondoside A_2-7 (**2**) is 3-*O*-{3-*O*-methyl-β-D-glucopyranosyl-(1→3)-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β,20(*R*)-dihydroxy-22(*R*)-acetoxylanosta-9,24-diene.

In the HR MALDI TOF MS (positive ion mode) of glycoside **3** the pseudomolecular ion peak $[M_{Na} + Na]^+$ at *m/z* 1373.5881 was observed, calculated for $C_{61}H_{99}O_{29}SNa_2$ as 1373.5786 *m/z*, which permitted the determination of a molecular formula of $C_{61}H_{99}O_{29}SNa$ for frondoside **3a**.

The MALDI TOF MS of glycoside **3** exhibited pseudomolecular ion peaks at *m/z* 1373 $[M_{Na} + Na]^+$ and 1389 $[M_{Na} + K]^+$, along with a fragmentation ion peak at *m/z* 1271 $[M - SO_3Na + Na + H]^+$ (demonstrating the loss of a sulfate group) in the positive ion mode and a pseudomolecular ion peak at *m/z* 1327 $[M_{Na} - Na]^-$, along with fragmentation ion peaks at *m/z* 1195 $[M_{Na} - Na - Xyl + H]^-$, 1151 $[M_{Na} - Na - 3\text{-O-Me-Glc} + H]^-$ (owing to the loss of terminal monosaccharide residues), 1185 $[M - Na - 141 - H]^-$ (owing to C-20 – C-22 cleavage of side chain), and 1285 $[M - Na - 43 + H]^-$ (demonstrating the loss of an acetyl group) in the negative ion mode.

The analysis of NMR spectra (^{1}H and ^{13}C, DEPT, HSQC,

© 2005 NRC Canada

HMBC, COSY, and NOESY) (Table 4) along with MS data (**2** and **3** having the same molecular formulas) showed that glycoside **3** is an isomer of glycoside **2**, differing from it only by the position of the double bond in the lanostane nucleus of the aglycon. In fact, the NMR spectra of these compounds were very similar to each other, but there were the signals of a 7(8)-double bond in the ^{13}C NMR spectrum of **3** (at 121.46 (C-7) and 148.94 (C-8) ppm) instead of the signals corresponding to the 9(11)-double bond in the spectrum of glycoside **2**. Hence, frondoside A_2-8 (**3**) is 3-*O*-{3-*O*-methyl-β-D-glucopyranosyl-(1→3)-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β,20(*R*)-dihydroxy-22(*R*)-acetoxylanosta-7,24-diene.

Glycosides **1**–**3** are new natural products. Lanostane-type aglycons (without a lactone) having "nonshortened" side chains, as in the glycosides **2** and **3**, are rare for sea cucumber glycosides. So far, only three glycosides with this type of aglycon structure have been found in sea cucumbers, namely frondoside C, a trisulfated pentaoside from *C. frondosa* (2), and penaustrosides A and B from *Pentacta australis* (6). It is important to note that glycosides **2** and **3** were obtained as native substances; in contrast to frondoside C and penaustrosides A and B, which were obtained as desulfated derivatives of natural compounds. Glycosides **2** and **3** differed from each other only by the location of a double bond in the aglycon nucleus. This is of special interest because, in most cases, sea cucumbers accumulate glycosides having one type of polycyclic system: either with a 7(8)- or 9(11)-double bond. To date, similar pairs of isomers (disulfated cucumariosides A_3-2 and A_3-3 and trisulfated koreoside A and isokoreoside A) have been found only in one species of sea cucumber, namely, *C. conicospemium* (7).

Experimental section

General experimental procedures

All melting points were determined with a Kofler–Thermogenerate apparatus. Specific rotation was measured on a PerkinElmer 343 polarimeter. NMR spectra were recorded on a AMX Bruker 500 spectrometer at 500.12 MHz for ^1H and 125.67 MHz for ^{13}C and a Bruker DPX 300 spectrometer at 300 MHz for ^1H and 75 MHz for ^{13}C in C_5D_5N with TMS as an internal reference (δ 0). The MALDI TOF MS (positive and negative ion modes) were recorded using a Bruker apparatus, model BIFLEX III, with impulse extraction of ions on an α-cyano-4-hydroxycinnamic acid matrix. HPLC was performed using an Agilent 1100 chromatograph equipped with a differential refractometer on a Diasphere-110 C_{18} column.

Animal material

The sea cucumber *C. frondosa* (family Cucumariidae; order Dendrochirotida) was collected in Penobscot Bay (Gulf of Maine, Maine) in September 2000 by commercial dragging. Taxonomic identification was carried out by Dr. E.N. Gudimova. A voucher specimen is on deposit in the collection of the Murmansk Marine Biological Institute of the Kolsky Scientific Center of the Russian Academy of Sciences, Murmansk, Russia.

Extraction and isolation of the fraction of glycosides belonging to the frondosides A_2 group

Body walls of the sea cucumbers were separated, cut and lyophylized to dryness, then extracted twice with refluxing ethanol (dry weight of the residue was 943 g). The combined extracts were evaporated to dryness and chromatographed on a polychrom-1 column (powdered Teflon, Biolar, Olaine, Latvia) previously loaded in EtOH and washed with water. The glycoside fraction was loaded in H_2O, and inorganic salts and polar impurities were eluted with H_2O. The fraction containing glycosides was eluted with 50% acetone. This glycoside fraction was then chromatographed on silica gel columns eluting with $CHCl_3$–EtOH–H_2O (100:100:17 and 100:75:10) solvent systems to obtain a homogenous (on TLC) crude subfraction of frondosides of the A_2 group (500 mg).

Isolation of glycosides 1–3

The subfraction was subsequently subjected to HPLC on a Diasphere-110 C_{18} (4 mm × 250 mm) column, using solvent systems (MeOH, water, $Na_2HPO_4 \cdot 12H_2O$ (540 mg in 100 mL of water), 72:25:3 and 65:33:2) as the mobile phase followed by desalting on a Teflon column as described previously to give 9.5 mg of glycoside **1**, mp 235–237 °C. $[\alpha]_D^{20}$ –90 (*c* 0.1, pyridine). (See Tables 1 and 2 for NMR data). MALDI TOF MS (positive ion mode) *m/z* (rel. intensity): 1327 ($C_{59}H_{93}O_{28}SNa_2$ $[M + Na]^+$, 1.0), 1343 ($C_{59}H_{93}O_{28}SNaK$ $[M + K]^+$, 0.23), 1225 ($[M - SO_3Na + Na + H]^+$, 0.3), 1207 ($[M - OSO_3Na + Na - H]^+$, 0.06), 1195 ($[M - Xyl + Na + H]^+$, 0.06), 1151 ($[M - 3\text{-O-Me-Glc} + Na + H]^+$, 0.07), 1093 ($[M - SO_3Na - Xyl + Na + 2H]^+$, 0.08). Reactions of β-alkoxyvinyl trifluoromethyl ketones with terminal alkynes — Reagent-controlled regioselectivity addition reactions

Shizheng Zhu, Guifang Jin, and Huiling Jiang

Abstract: Reactions of β-alkoxyvinyl trifluoromethyl ketones ROCH=CHCOCF$_3$ (**1**, R = Et, Me$_2$CHCH$_2$), and their cyclic analogues 4-trifluoroacetyl-2,3-dihydrofuran (**2a**) and 5-trifluoroacetyl-3,4-dihydro-2*H*-pyran (**2b**), with terminal alkynes R-C≡CH (**3**, R = Ph, PhCH$_2$, HOCH$_2$, C$_5$H$_{11}$) mainly gave the 1,2-addition products (carbonyl alkynylation) in the presence of *n*-BuLi. However, promoted by ZnCl$_2$–Et$_3$N, the reaction of **1** or **2** with equivalent alkyne predominately provided 1,4-addition products.

Key words: β-alkoxyvinyl trifluoromethyl ketones, alkynes, 1,2-addition, 1,4-addition, catalysts.

Résumé : En présence de butyl lithium, les réactions des β-alcoxyvinyl trifluorométhyl cétones de formule générale ROCH=CHCOCF$_3$ (**1**; R = Et, Me$_2$CHCH$_2$) et de leurs analogues cycliques, tels le 4-trifluoroacétyl-2,3-dihydrofurane (**2a**) et le 5-trifluoroacétyl-3,4-dihydro-2*H*-pyrane (**2b**) avec des alcynes vrais de formule générale R-C≡CH (**3**; R = Ph, PhCH$_2$, HOCH$_2$, C$_5$H$_{11}$) conduisent principalement à des produits d'additions 1,2 (alcynylation du carbonyle). Toutefois, lorsque la réaction est catalysée par du ZnCl$_2$ en présence de Et$_3$N, les réactions des composés **1** et **2** avec un équivalent d'alcyne conduisent principalement aux produits d'additions 1,4.

Mots clés : β-alcoxyvinyl trifluorométhyl cétones, alcynes, addition 1,2, addition 1,4, catalyseurs.

[Traduit par la Rédaction]

Introduction

The present strongly developed interest in organofluorine chemistry has led to considerable studies of trifluoromethyl ketones (1) and, in particular, α,β-unsaturated trifluoromethyl ketones (2). Such ketones have been used as intermediates in heterocyclic synthesis (3) and have also been viewed as synthetic targets owing to their possible pharmacological interest (4). β-Alkoxylvinyl trifluoromethyl ketones (ROCH=CHCOCF$_3$, **1**) are potential fluorinated 1,3-dicarbonyl compounds. Since they were first prepared in 1967 (5), their preparations and chemical transformations have been extensively investigated (6). Our group and others have studied the reactions of acyclic β-alkylvinyl trifluoromethyl ketones with Grignard reagents derivated from alkyl and aryl halides. Generally, acyclic β-alkoxyvinyl trifluoromethyl ketones and the cyclic analogues **2a** and **2b** reacted with Grignard reagents gave the corresponding α,β-unsaturated trifluoromethyl ketone as the sole product, which arose from 1,4-addition on the β-position of the double bond and was followed by β-elimination of alkoxyl group (7). In contrast, the organic zinc compounds prepared in situ reacted with β-alkoxyvinyl trifluoromethyl ketones giving only the 1,2-addition products (Scheme 1) (6*d*, 8).

The factors determining the selectivity between 1,2- and 1,4-additions to a wide range of α,β-unsaturated carbonyl compounds have received much attention and, in particular, asymmetric conjugate additions have been developed (9). The hard acid – soft base concepts have been used to permit the generalizations that among organometallic reagents, organolithiums, which are hard nucleophiles, react by 1,2-addition, and organocopper reagents, which are softer ones, react by 1,4-addition (10). Grignard reagents were seen to lie somewhere between them. Since then there have been major advances in explaining the selectivity of these additions. In reactions that proceed by kinetic control with organometallic reagents having a highly localized negative charge, a charge-controlled 1,2-addition can be expected. In contrast, in additions of nucleophiles having charge dislocalization where the reaction is frontier orbital controlled, a 1,4-addition is expected. However, other factors, notably steric and solvent effects and the nature of the nucleophile, disturb these simple generalizations.

During our continuous study on the fluorinated push–pull

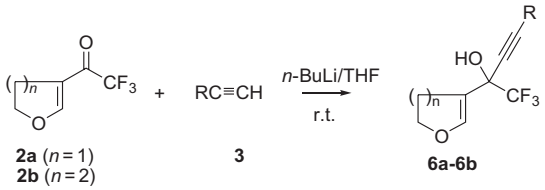
ethylene compounds (11), we investigated the alkynylation of β-substituted unsaturated trifluoromethyl ketones **1** and **2** with terminal alkynes in detail. We found that the reaction products mainly depend on the promoted reagents. *n*-Butyl lithium promoted addition reactions gave 1,2-addition products, a process favored by charge control. $ZnCl_2$–Et_3N promoted addition reactions provided 1,4-addition products, a process favored by orbital control. Herein we report these results.

Results and discussion

Reaction of β-alkoxyvinyl trifluoromethyl ketone **1a** with PhC≡CH **3a** proceeded smoothly at room temperature in the presence of 1 equiv. of *n*-BuLi in THF and finished in 2 h (monitored by TLC). Flash chromatographic purification on silica gel (*n*-hexane – ethyl acetate) gave two products, 1-ethoxy-5-phenyl-3-trifluoromethyl-1penten-4-yne-3-ol (**4a**, 41%) and 1,7-diphenyl-3-trifluoromethyl-4-heptene-1,6-diyn-3-ol (**5a**, 20%), which is an over addition product. When 2 equiv. of *n*-BuLi and **3a** were used, the yield of **5a** increased to 52% (See Scheme 2, Table 1).

The proton NMR spectra of **4a** and **5a** showed that both of them are *trans*-alkenes. The coupling constants between the two alkene's protons were 13 Hz in **4a** and 15 Hz in **5a**, and the chemical shifts of the two alkene's protons in **4a** were 7.12 and 5.00 ppm owing to the presence of the ethoxyl group on the double bond; while in compound **5a** they were 6.56 and 6.31 ppm. Under the same reaction conditions, the reaction of β-isobutoxyvinyl trifluoromethyl ketone (**1b**) with **3a** gave the same results as **1a**.



Interestingly, terminal alkynes **3b**–**3d** reacted with **1** affording only 1,2-addition products. No further addition products were detected or isolated even when excessive equivalents of alkynes **3** and *n*-BuLi were used or by prolonging the reaction time to 24 h. When reacted with ketones **1a** and **1b**, the terminal alkynes **3** have excellent regioselectivity except for **3a**. The selectivity could be explained by the structures of the nucleophiles. The phenylacetylene ion is charge delocalized owing to its conjugation structure, therefore, it gave both 1,2-addition and 1,4-addition products. The alkynes **3b**–**3d** only gave 1,2-addition products because their ions have highly localized negative charges without conjugation structures.

Table 1. Reactions of β-alkoxyvinyl trifluoromethyl ketone with alkynes promoted by *n*-BuLi.

Entry	Reactants	Mol. ratio	Time (h)	Products and yields (%)[a]

In contrast, the cyclic analogues, 4-trifluoroacetyl-2,3-dihydrofuran (**2a**) and 5-trifluoro-3,4-dihydro-2*H*-pyran (**2b**) are less reactive. In the presence of *n*-BuLi, the reactions between **2** and **3a** needed a longer time period (typical 4 h) and only 1,2-addition products **6a** and **6b** were obtained in good yields (Scheme 3). With 2 equiv. of **3a** and *n*-BuLi, no further reaction product was observed. These results indicated the considerable difference between the phenylacetylene lithium reagent and the Grignard reagents that gave exclusively the 1,4-addition products, carbon–carbon double bond attacking products (7, 8).

Recently, considerable progress has been developed in the alkynylation of carbonyl compounds using Lewis acids in combination with bases (12). For example, Jiang and Si (13) prepared a series of propargylic alcohols by treatment of the aromatic aldehydes with terminal alkynes promoted by zinc chloride and triethyl amine. In the subsequent studies on the alkynylation of the β-substituted unsaturated trifluoromethyl ketones **1** and **2**, we also used the $ZnCl_2$–Et_3N system as the promotor. Thus, a mixture of **3a** (1.5 mmol), anhydr. $ZnCl_2$ (2.25 mmol), and Et_3N (2.25 mmol) in toluene was stirred at room temperature for 1 h, then **1a** (1.5 mmol) in 10 mL THF was added. After it was stirred overnight, TLC analysis showed that the reaction was finished, and chromatography purification gave the ketone **7a** (14) in 81% yield. When 2 equiv. of **3a** was used, this reaction gave two products, **7a** (58%) and the double-alkylated product **5a** (25%) (Scheme 4).

Under the same reaction conditions, the reaction of equivalent **3a** to **2a** afforded product **8a** (53%) (Table 2). How-

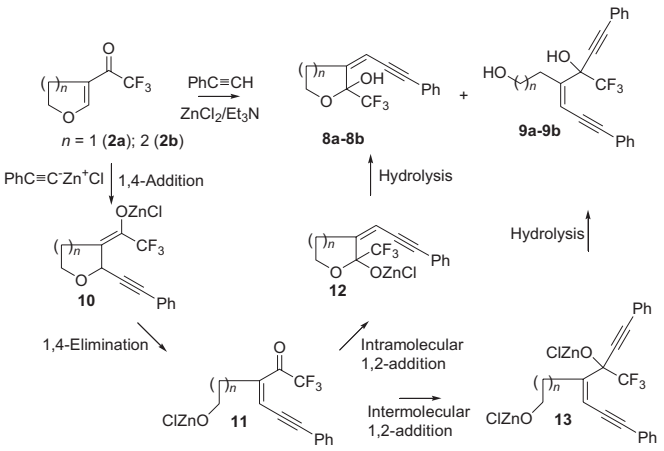
[b]The reactions were carried out at 80 °C, the other reactions were at room temperature.



ever, for the reaction of **2b** with **3a**, the alkynylation only occurred at the double bond carbon atom giving the product **8b**. The final product was obtained from a rearrangement of 1,4-addition intermediate **10**, followed by an 1,4-elimination of the alkoxyl group to produce intermediate **11**, then an intramolecular 1,2-addition occurred and gave the final stable product (Scheme 5). The driving force for the rearrangement might be the conjugation of the double bond with the triple bond. Since the intermediate **11** has a ketone functional group, the intermolecular 1,2-addition gave the double addition intermediate **13**, which was hydrolyzed and produced product **9**. It is noteworthy that five-membered **2a** produced two addition products **8a** and **9a**, while six-membered ketone **2b** only afforded **8b**. This difference is aroused from the intermediate **11**. When n = 1 (**2a**), the ethoxyl **11a** is not as flexible as the propoxyl chain **11b** (n = 2, **2b**). Therefore, **11b** can occur through an intramolecular 1,2-addition reaction exclusively, and **11a** can proceed to both intra- and inter-molecular 1,2-addition reactions. Unfortunately, the ketones did not react with 3-phenylpropyne (**3b**) under several different reaction conditions, even at high temperature. The possible reason is that 3-phenylpropyne is not as active as phenylacetylene and $ZnCl_2$–Et_3N could not promote the addition reaction.

In summary, we have studied the reaction and regioselectivity of terminal alkyne addition to β-alkoxyvinyl trifluoromethyl ketone, which is very sensitive to the promoted reagents and ketone structure. Promoted by n-BuLi, the addition of terminal alkynes gave 1,2-addition products in high yields, in marked contrast to the 1,4-additions promoted by $ZnCl_2$–Et_3N. The high regioselectivity and its tenability of the terminal alkynes to enones and the accessibility of fluorine-contained adducts may be useful in the application of these reactive compounds for the effective synthesis of bioactive fluorine-containing substances.

uncorrected. ^{1}H NMR and ^{19}F NMR spectra were recorded on Varian-360 or Bruker AM-300 instruments with Me_4Si and $CFCl_3$ (with upfield negative) as internal and external standards, respectively; NMR spectra were recorded in chloroform-*d* unless otherwise stated. IR spectra were obtained with a PerkinElmer 983G spectrophotometer using KBr disks of the compound. Low- and high-resolution mass spectra were obtained on HP 5989a and Finnigan MAT instruments, respectively. This institute performed the elemental analyses.

General procedure for the reaction of the alkyne with ketone in the presence of *n*-BuLi

A solution of n-butyl lithium – THF (3 mL, 4.8 mmol) and 10 mL THF was added dropwise to a 50 mL three-necked flask containing phenylacetylene (0.49 g, 4.8 mmol) in 15 mL THF, after stirring at room temperature for 15 min, β-alkoxylvinyl trifluoromethyl ketone (**1a**) (0.806 g, 4.8 mmol) in 10 mL THF was added. The solution was stirred for 2 h and TLC analysis showed the reaction was completed, and then 40 mL of a satd. NH_4Cl solution was added and extracted with ether (3 × 20 mL). The organic layer was washed with brine (30 mL), dried over Na_2SO_4, and concentrated in vacuum. The residue was purified by flash chromatography by using n-hexane–EtOAc as eluent to give two products, **4a** (26%) and **5a** (51%).

2-(5,6-Dihydro-4H-pyran-3-yl)-1,1,1-trifluoro-4-phenyl-3-butyn-2-ol (6b)

Yield: 81%. FT-IR (KBr, cm^{-1}) ν: 3412 (s), 2955 (m), 2232 (s), 1658 (s), 1491 (s), 1167 (vs). ^1H NMR ($CDCl_3$) δ: 7.41 (m, 5H, Ph), 7.08 (s, 1H, CH), 4.04 (m, 2H, OCH_2), 2.97 (s, 1H, OH), 2.27 (m, 2H, CH=C-C*H*$_2$), 1.90 (m, 2H, CH_2). ^{19}F NMR ($CDCl_3$): –79.24 (s, CF_3). MS (70 eV) *m/z* (%): 282 (M^+, 6.91), 213 ($M^+ - CF_3$, 100.00), 111 ($M^+ - CF_3 -$ PhC≡CH, 5.67), 83 ($OCH_2CH_2CH_2C{=}CH^+$, 8.40), 77 (Ph^+, 10.85). HR-MS (EI) M^+ calcd. for $C_{15}H_{13}F_3O_2$: 282.0893; found: 282.0868.

General procedure for the reaction of acetylene with ketone in the presence of $ZnCl_2$–Et_3N

Phenylacetylene (0.153 g, 1.5 mmol) was added under an argon atmosphere at room temperature to a solution of anhydr. $ZnCl_2$ (0.306 g, 2.25 mmol) and triethylamine (0.32 mL, 2.25 mmol) in dried toluene (10 mL). After stirring for 1 h, β-alkoxylvinyl trifluoromethyl ketone (0.252 g, 1.5 mmol) was added dropwise. The mixture was stirred overnight and TLC analysis confirmed that the reaction was finished, then the mixture was washed with 40 mL of a satd. NH_4Cl solution, followed by extraction with ether (3 × 20 mL). The organic layer was washed with brine (30 mL), dried over Na_2SO_4, and concentrated in vacuum to give a residue, which was purified by flash chromatography by using *n*-hexane–EtOAc as eluent to give the product.

1,1,1-Trifluoro-6-phenyl-hex-3-en-5-yn-2-one (7a)

Yellow liquid; yield: 58%–81%. FT-IR (KBr, cm^{-1}) ν: 2195 (s), 1722 (s), 1602 (s), 1582 (s), 1205 (s), 1148 (s). ^1H NMR ($CDCl_3$) δ: 7.42 (m, 5H, Ph), 7.25 (d, J = 15.3 Hz, 1H, CF_3COCH=), 6.85 (d, J = 15.0 Hz, 1H, C*H*=C). ^{19}F NMR ($CDCl_3$): –77.80 (s, CF_3). MS (70 eV) *m/z* (%): 224 (M^+, 90.95), 155 ($M^+ - CF_3$, 100.00), 127 ($M^+ - COCF_3$,

Structural analysis of acetylated hardwood lignins and their photoyellowing properties

Yunqiao Pu and Arthur J. Ragauskas

Abstract: Lignin was isolated from aspen bleached chemithermomechanical pulp by employing a mild acid hydrolysis procedure, and the extracted material was acetylated with acetic anhydride. Nuclear magnetic resonance analyses indicated that the relative ease of acetylating lignin hydroxyl groups was phenolic >> γ-side chain > α-side chain. Non-acetylated and acetylated lignins were impregnated onto cellulosic test sheets, and the photo-behavior of the lignins was examined under irradiation with two light sources, a fluorescent lamp and a black lamp. Optical reflective studies indicated acetylation efficiently inhibited the photodiscoloration of aspen bleached chemithermomechanical pulp lignin under visible and near-UV light irradiation. The photostability of the lignin was correlated to the extent of lignin acetylation. The observed photo-stabilization of acetylated lignin during light irradiation was attributed to the acetylation of phenoxy and aliphatic hydroxyl groups in lignin.

Key words: green chemistry, hardwood lignin, acetylation, photo-stabilization, photoyellowing, NMR.

Résumé : Faisant appel à une méthode d'hydrolyse acide douce, on a isolé la lignine de la pulpe chimique/thermique/mécanique blanchie de peuplier et le produit isolé a été acétylé avec de l'anhydride acétique. Des analyses de résonance magnétique nucléaire ont permis de déterminer que les facilités relatives d'acétylation des groupes hydroxyles de la lignine sont dans l'ordre phénolique >> chaîne latérale γ > chaîne latérale α. Les lignines acétylées et non-acétylées ont été imprégnées sur des feuillets d'essai en cellulose et le photocomportement des lignines a été étudié sous irradiation de deux sources lumineuses, une lampe fluorescente et une lampe noire. Des études de réflexion optique indiquent que l'acétylation inhibe efficacement la photodécoloration de la lignine de la pulpe chimique/thermique/mécanique blanchie de peuplier par des irradiations avec des lumières visible ou du proche UV. La photostabilité de la lignine est directement reliée au degré d'acétylation de la lignine. La photostabilisation observée pour la lignine acétylée lors d'une irradiation à la lumière est attribuée à l'acétylation des groupes phénoxy et des groupes hydroxyles aliphatiques de la lignine.

Mots clés : chimie verte, lignine de bois dur, acétylation, photostabilisation, photojaunissement, RMN.

[Traduit par la Rédaction]

Introduction

The need to develop environmentally compatible industrial processes based on renewable resources is an important societal goal. The conversion of wood into pulp fibers using mechanical energy is an example of an environmental green chemistry process. Unlike most chemical pulps, which largely utilize the cellulose component of wood, mechanical pulps utilize all three of the major wood polymers: cellulose, hemicellulose, and lignin, and are accompanied with +90% yields (1). In comparison, chemical pulping and bleaching technologies usually afford pulp yields in the mid to low 40% range (2). The high conversion of lignocellulosics into mechanical pulp insures minimal generation of waste products and improved environmental performance. In summary, mechanical pulping is an environmentally friendly, efficient method of utilizing wood resources for the purpose of generating value-added materials.

Increased usage of mechanical pulps is limited owing to their well-known tendency to rapidly undergo photoyellowing when exposed to near-UV light sources, such as office lighting and sunlight (3–8). Research studies have demonstrated that the photoyellowing process is initiated by the absorption of 300–400 nm light by several lignin functionalities summarized in Fig. 1, including phenacyl-α-*O*-aryl ethers (9), β-*O*-aryl ethers (10–15), extended conjugated structures (16), stilbenes (15, 17, 18), coniferyl alcohol (19), phenolic phenylpropenol (20), and quinone structures (21, 22). The photoabsorption process generates a series of reactive radical intermediates that result in the oxidation of lignin-yielding chromophoric products, including *ortho*- and *para*-quinone lignin derivatives (14, 22–24).

A number of photostabilization treatments have been pursued to photostabilize high-lignin fibers. These technologies can be broadly described as either additive dependent or fiber modification technologies (25–29). The recent studies by Davidson et al. (26) and Cook and Ragauskas (27) have documented the ability of utilizing binary additive systems to significantly hinder the photoinduced discoloration process. One of the most promising fiber modification methods of halting the photoyellowing process involves acetylation of mechanical pulp, employing acetic anhydride and an acid catalyst (25, 30–32). Model compound studies investigating the chemistry of acid-catalyzed lignin acetylation indicate that phenolics are preferentially acetylated over aliphatic hydroxyl groups when employing structures such as 1-(4-hydroxy-3-methoxyphenyl)-2-(2-methoxyphenoxy)-1,3-propanediol (33). Recently, Pu et al. (34) established that acetylated lignin is the stabilizing component of the softwood acetylated bleached chemithermomechanical pulp.

Argyropoulos and Sun (35) have investigated the structural characteristics of softwood milled wood lignin and lignin model compounds irradiated under nitrogen and oxygen atmosphere. They demonstrated that photoirradiation cleaved β-O-4 ethers present in lignin, with the concomitant formation of new phenolic units, especially C5-related condensed phenolic. Heitner et al. (36) examined the photoreactivity of acetylated softwood milled wood lignin (MWL) in solution and concluded that lignin acetylation decreased the extent of photodegradation by hindering the cleavage of the β-O-aryl ether groups. This stabilization effect hindered the production of phenoxy radicals and lignin chromophores. In our previous study, we examined the photo-oxidative chemistry of the acetylated softwood lignin from chemithermomechanical pulp via a mild acid hydrolysis procedure and found that phenoxy groups were formed during the near-UV light irradiation (37). These previous studies have focused primarily on the photobehavior and chemistry of softwood lignin. Little research effort has been devoted to the hardwood lignin, despite the fact that hardwood mechanical pulps are produced on a substantial scale and known to undergo photodiscoloration when exposed to near-UV light sources. It is well-known that hardwood lignin exhibits differences in structural characteristics in comparison to softwood lignin owing to the presence of syringyl units in the lignin biopolymer (38). These fundamental parameters also influence its photoyellowing properties (39). This paper examines the structural characteristics and photoreactivity of acetylated lignin isolated from hardwood mechanical pulp by NMR.

Experimental

Materials

All chemicals were commercially purchased and used as received, except *p*-dioxane, which was purified by distillation over sodium borohydride before use. A commercially produced aspen bleached chemithermomechanical pulp (BCTMP) was employed in this study. Test sheets (150 g/m^2) were prepared from Whatman filter paper (Qualitative, No. 5), according to standard literature method (40).

Lignin isolation

Lignin was isolated from the aspen BCTMP following the literature method (34, 41). In brief, the pulp was extensively washed, air-dried, and soxhlet-extracted with acetone for 24 h. Air-dried pulp (150 g) was then refluxed in a 0.01 mol/L HCl dioxane–water (3 L, 8.5:1.5) solution under

© 2005 NRC Canada

argon for 1 h. The extracted pulp was filtered and washed with fresh *p*-dioxane (200 mL × 3). The combined aliquots were neutralized with an aqueous saturated solution of sodium bicarbonate and then concentrated under reduced pressure at ≤40 °C. The concentrated solution was added to 700 mL of 0.006 mol/L aq. HCl, and the precipitated lignin was centrifuged, washed with acidic water (pH 2 ~ 3), and freeze dried. The lyophilized lignin was subsequently dried under high vacuum at 40 °C for 24 h. This method produced a low-yield lignin (2.8% yield) with a light-white color.

Lignin acetylation

Lignin acetylation was carried out according to the published method (34), which involved dissolving lignin (0.2000 g) in refluxing dioxane (200.00 mL) and treating this mixture with acetic anhydride (40.00 mL). This mixture was refluxed for selected time periods, then cooled, concentrated, and dried under reduced pressure. The acetylated lignin was dissolved in chloroform and precipitated with the addition of diethyl ether. The precipitated lignin acetate was collected after centrifugation and dried under high vacuum for 24 h (>77% recovery yield).

Photoirradiation

Photoirradiation with fluorescent and black lamps was carried out according to the literature method (37). In brief, non-acetylated lignin (0.0450 g) was dissolved in a 9:1 dioxane–water solution (10.00 mL), uniformly applied onto filter paper test sheets, and subsequently air-dried in the dark. Acetylated lignins were processed in the same manner, except that chloroform was employed as the solvent. The treated test sheets were attached to a merry-go-round apparatus and photolyzed in a Rayonet photochemical reactor (model RPR-100, The Southern New England Ultraviolet Company, Branford, Connecticut, USA) with RPR 5750 UV–vis fluorescent lamps (λ: 350–700 nm) and RPR 3500 UV lamps (black light, λ: 300–400 nm).

The degree of photodiscoloration of the test sheets was expressed as the post-color (PC) values following published method (42). The PC number was calculated according to eqs. [1] and [2],

$$[1] \qquad PC = ((k/s)_{after} - (k/s)_{before}) \times 100$$

$$[2] \qquad k/s = (1 - R_\infty)^2/2R_\infty$$

where k = specific absorption coefficient, s = specific scattering coefficient, R_∞ = reflectance at λ = 457 nm. Reflectance values of the test sheets were determined with a Brightimeter Micro S-5 reflectometer manufactured by Technidyne Corporation (43).

NMR characterization

All NMR spectra were recorded on a 400 MHz Bruker Advance/DMX NMR spectrometer. Quantitative ^{13}C NMR spectra were acquired using DMSO as solvent for non-acetylated and acetylated lignins, with an inverse gated decoupling sequence, 90° pulse angle, 12 s pulse delay, and 10 000 scans (44–46). The integration and carbon content calculation of the functional groups in the ^{13}C NMR spectra were performed in accordance with the literature method (44). The carbon content of a functional group was calculated as the ratio of the integral of the given carbon signal to one-sixth the integral of the aromatic carbons (signals between δ 102 and 156 ppm). Therefore, integration regions can be quantified and reported as the number of carbon atoms per aromatic unit.

The lignin samples were also derivatized with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane and analyzed by ^{31}P NMR following literature methods (47, 48). Cyclohexanol was used as the internal standard. ^{31}P NMR spectra were recorded using an inverse gated decoupling sequence, 90° pulse angle, 25 s pulse delay, and 150 transients at room temperature. The integration regions for the hydroxyl groups were in accordance with the literature method (47, 48). The signal for the phosphitylated cyclohexanol was separated from the lignin hydroxyl group signals and was integrated and calibrated to 1.0 unit. The content of the hydroxyl group in cyclohexanol was used as the internal standard factor. For various hydroxyl functional groups in lignin, this internal standard factor was multiplied by the integrated intensity and divided by the weight of the lignin sample. The contents of lignin hydroxyl groups were reported as mmol/g lignin.

NMR spectral acquisition and analyses were controlled by Bruker's XWINNMR 2.6 software running on an SGI (Silicon Graphics Indigo) server using the Irix 7.0 operating system. The lignin functional groups characterized by ^{13}C and ^{31}P NMR had standard errors of 3.0% and 1.2%, respectively.

Results and discussion

Structural characteristics of non-acetylated and acetylated lignins

Li and Ragauskas (41) have previously demonstrated the applicability of employing extracted softwood lignin for photochemical studies. Following this procedure, aspen BCTMP lignin was acquired, and this material was subsequently treated with acidic anhydride in *p*-dioxane. Structural changes in lignin during acetylation were monitored by ^{13}C and ^{31}P NMR spectra.

Hardwood lignin is comprised of syringyl and guaiacyl lignin units as summarized in Fig. 1 (38, 44). The changes in acetylated hardwood lignin as determined by ^{13}C NMR are summarized in Figs. 2–4, and the structural assignments are summarized in Table 1. As can be seen in Fig. 2 and Table 1, the acetylation treatment significantly impacts the structure of hardwood lignin. The signal centered at δ 147.1 ppm in non-acetylated lignin has been assigned to C_3/C_5 in syringyl β-O-4 non-etherified unit (44). After acetylation, this signal is shifted downfield to δ 152.2 ppm. The signal centered at δ 145.3 ppm in non-acetylated lignin has been assigned to C_4 in guaiacyl β-O-4 non-etherified unit (44, 51), and this signal is absent in the acetylated lignin. The signal centered at δ 115 ppm in non-acetylated lignin is assigned to C_5-H in guaiacyl unit, and this signal decreases significantly in intensity after acetylation. The corresponding acetylated signal is centered at δ 123 ppm, which is in accord with lignin model compound studies (49). The signal at δ 59.6 ppm has been attributed to the aliphatic C-γ in β-O-4 syringyl and guaiacyl units, and it shifts downfield by 4 ppm after acetylation to δ 63.8 ppm.

Fig. 2. ^{13}C NMR spectra of pre- and post-acetylated (150 min) aspen BCTMP lignins.

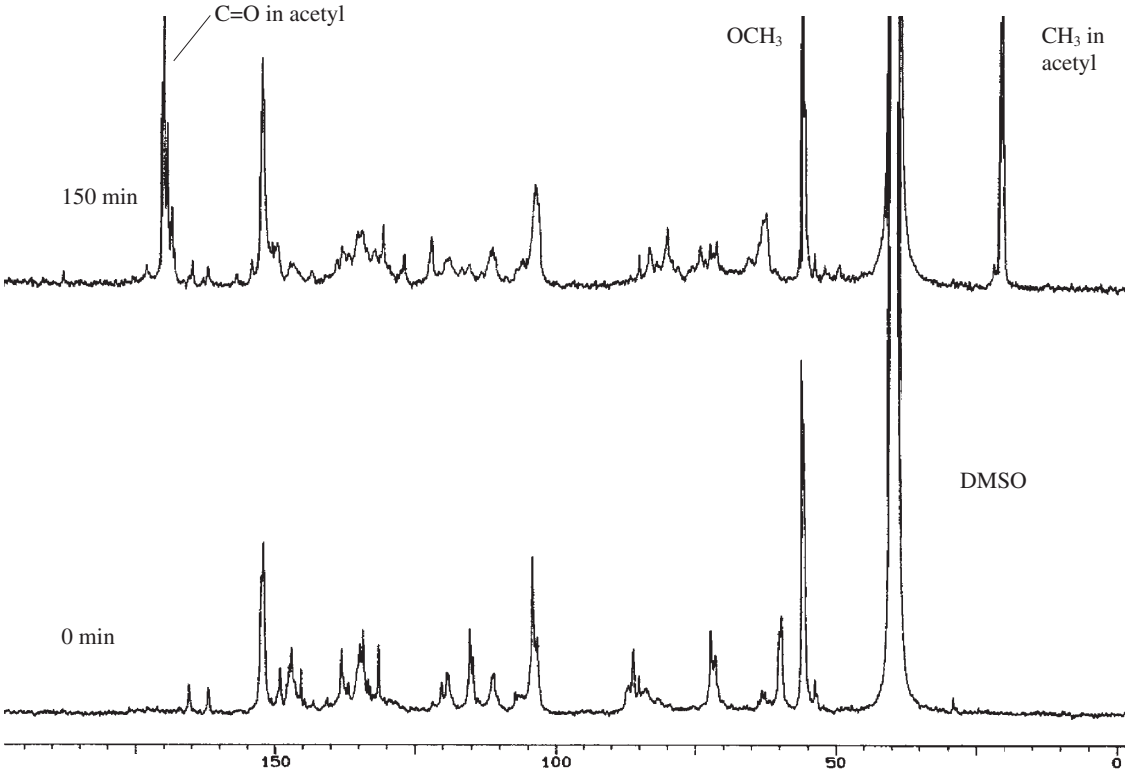

Fig. 3. Acetate methyl group in hardwood BCTMP lignins determined by ^{13}C NMR spectra (expressed as number of C atoms per aromatic ring).

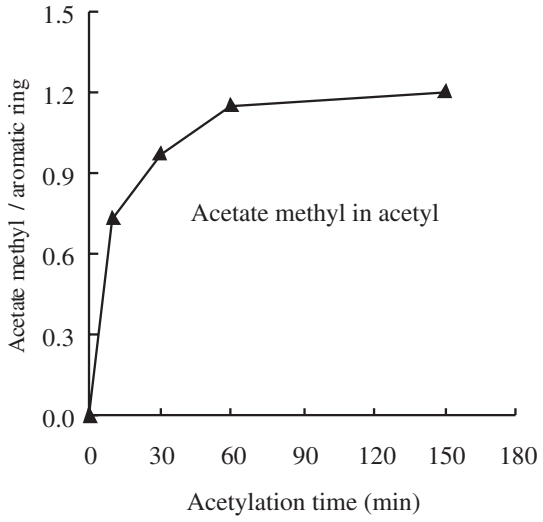

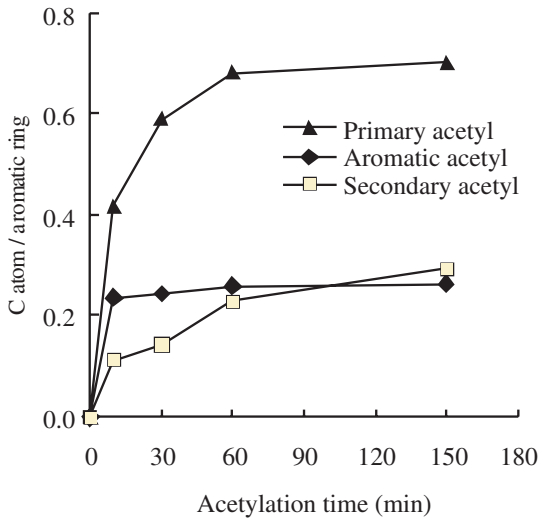

Fig. 4. Carbonyl (C=O) content of acetyl group in hardwood BCTMP lignins determined by ^{13}C NMR spectra (expressed as number of C atoms per aromatic ring).

The acetate methyl group content was calculated by integrating the chemical regions from δ 19.5 to 21.6 ppm. Figure 3 presents the changes of acetate methyl group content in the hardwood lignins at different acetylation times, as determined by quantitative ^{13}C NMR analysis. This result indicates the bulk of the acetylation of lignin is completed within the first 60 min under the reaction conditions employed.

The acetyl carbonyl content was calculated by integrating over the chemical shift regions from δ 168.5 to 169.4 ppm for aromatic acetyl, from δ 169.4 to 170.3 ppm for secondary aliphatic acetyl, and from δ 170.3 to 172.0 ppm for primary aliphatic acetyl. Figure 4 shows the acetyl carbonyl group content in the lignin samples at differing acetylation times. It can be seen in Fig. 4 that the primary aliphatic acetyl content of lignin increases rapidly during the initial 10 min acetylation, and it is higher than the secondary aliphatic acetyl content when lignin was acetylated for the same time. After acetylating lignin for 60 min, the primary aliphatic acetyl content remains almost unchanged, and a

slow increase of secondary aliphatic acetyl content is observed at 150 min acetylation. This indicates that the aliphatic primary hydroxyl group in lignin is more rapidly, and preferentially, acetylated over the secondary hydroxyl group. This is consistent with the lignin model compounds studies, which have indicated that the γ-hydroxyl group is easily acetylated and the α-hydroxyl group is comparatively resistant toward treatment with acetic anhydride (33). It can also be seen from Fig. 4 that aromatic acetyl content increases rapidly after the first 10 min of the acetylation reaction and then remains relatively unchanged for the remaining 150 min.

Figure 5 summarizes the aliphatic hydroxyl group content from ^{31}P NMR analysis of phosphitylated lignin samples. These results indicate that the aliphatic lignin hydroxyl group content decreases significantly during the initial 60 min acetylation, which could be mostly attributed to acetylation of the aliphatic primary hydroxyl group. For the 60 min acetylation treatment, the aliphatic hydroxy group content was decreased 71.7%, suggesting that 71.7% of the aliphatic hydroxy group was acetylated. For the 150 min acetylation treatment, the aliphatic hydroxy group content was observed to decrease by 73.8%, suggesting that 73.8% of the aliphatic hydroxy group was acetylated. These results also suggest that the lignin biopolymer has a series of residual aliphatic OH groups that are very resistant to acetylation.

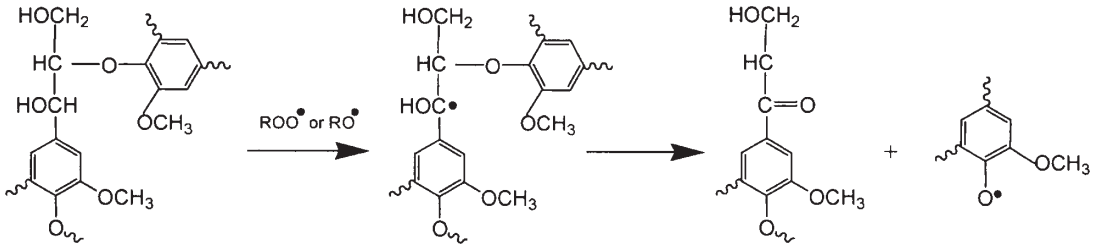
treatment, compared with 80% for the syringyl and C_5-condensed phenolic groups, indicating that the syringyl and C_5-condensed phenolic hydroxyl groups are slower to acetylate. After 10 min acetylation, 88.0% of the total aromatic OH were acetylated, while at 150 min acetylation, 91.1% of the total aromatic OH were acetylated. The ^{31}P NMR results confirm the trends observed by ^{13}C NMR analyses: that the bulk of the phenolic hydroxyl groups in lignin are readily acetylated in the acid-catalyzed acetylation procedure studied.

Photobehavior of non-acetylated and acetylated lignins

To examine the photobehavior of hardwood lignin and the corresponding acetylated samples in the solid state, samples were dissolved in an organic solvent and applied onto cellulose test sheets. The effect of acetylation on the photobehavior of lignin was evaluated by employing a slightly acetylated sample (i.e., acetylated for 10 min) and an extensively acetylated sample (i.e., acetylated for 150 min). The test sheets were irradiated with RPR 5750 UV–vis fluorescent lamps (office light, λ: 350–700 nm), and the results are summarized in Fig. 7. As shown in Fig. 7, the non-acetylated lignin has a higher PC number than the acetylated lignins, suggesting that acetylation treatment efficiently inhibits the photoyellowing of hardwood lignin under office light irradiation. After 60 h of irradiation, non-acetylated lignin test sheets exhibited an increase of 5.8 in PC value, while the acetylated lignin test sheets exhibited an increase of only 1.1 in PC value for 10 min acetylation time, and 0.8 for 150 min acetylation time. The smaller increase in PC values for the acetylated lignin samples, in comparison with the nonacetylated lignin samples, demonstrates that the acetylation process retards the photoyellowing of lignin. Lignin with 10 min of acetylated treatment shows a higher PC number than that with 150 min of acetylation, indicating that acetylation at longer acetylation time results in reduced photodiscoloration.

To examine the effects of acetylation on lignin photodiscoloration under accelerated irradiation, cellulose test sheets impregnated with non-acetylated and acetylated lignins

Fig. 8. PC number of filter paper test sheets applied with non-acetylated and acetylated lignins during black light irradiation.



were irradiated with RPR 3500 UV lamps (black light, λ: 300–400 nm). The results in Fig. 8 indicate that the non-acetylated lignin has a higher PC number than acetylated lignin during irradiation. Compared with non-acetylated lignin, acetylated lignin shows a much lower extent of photodiscoloration. After 14 h of irradiation, the treated test sheets exhibit a PC value of 3.2 for lignin acetylated for 150 min, a 5.9 PC value for lignin acetylated for 10 min, and an 18.6 PC value for non-acetylated lignin. This clearly indicates that the acetylation treatment strongly retards the photoreversion of lignin during the accelerated irradiation, and acetylation at longer acetylation time leads to a more pronounced photoyellowing inhibition, which agrees with the observations acquired with the UV–vis fluorescent lamps.

Phenoxy radicals generated from photoreactions during light irradiation have been suggested as a major contributor to the photoyellowing of mechanical pulps (50). The acetylation of hardwood lignin effectively blocks the photo-

Fig. 9. Lignin β-O-4 aryl ether cleavage during photoirradiation.

formation of phenoxy radicals by acetylating these phenolic hydroxyl groups reactive sites, thus inhibiting the photoreversion of lignin. Schmidt and Heitner (12) and Heitner et al. (36) have proposed that cleavage of the β-O-4 group, which produces phenoxy radicals and lignin chromophores, is a main degradation pathway of photoyellowing of mechanical pulps (Fig. 9). The acetylation of side chain α- and γ-hydroxyl groups has been suggested to be, potentially, a means of inhibiting the β-O-4 cleavage, thereby resulting in the photostabilization of lignins (36).

Conclusion

This paper examined the structural characteristics and photobehavior of acetylated lignin extracted from aspen-bleached chemithermomechanical pulp. Analysis of acetylated hardwood lignin demonstrated that the γ-hydroxyl group in the side chain of lignin is easily acetylated and the α-hydroxyl group is comparatively resistant towards acetylation. The phenolic hydroxyl groups of lignin are very easily acetylated, and under the reaction conditions examined, this was accomplished within 10 min. The acetylated lignins exhibit substantially decreased photodiscoloration behaviour under visible and near-UV light irradiation, with enhanced photostabilization being correlated to the overall degree of lignin acetylation. The acetylation of phenolic hydroxyl groups blocks the generation of phenoxy radicals during light irradiation, resulting in the photostabilization of hardwood-acetylated lignin. The acetylation of the side chain α- and γ-hydroxyl groups of hardwood lignin could also inhibit the β-O-4 cleavage, contributing to the observed photostabilization.

A rapid, microwave-assisted, one-pot cyclopropanation reaction to synthesize (4-ferrocenyl)benzoylcyclopropane in the solid state

Juxing Yin, Xiaolong Li, Xiaoli Wu, Baohua Chen, Zenglu Liu, and Qingbao Song

Abstract: Some new (4-ferrocenyl)benzoylcyclopropanes were prepared rapidly via a microwave-assisted, one-pot cyclopropanation reaction in the solid state, directly using 4-ferrocenylacetophenone, aldehyde, and sulfur ylide as the starting materials. The main advantages of this procedure are convenient operation, shorter reaction time, lower environmental pollution, and no need to isolate the intermediate product (chalcone) in a separate step.

Key words: 4-ferrocenylacetophenone, sulfur ylide, microwave-assisted, one-pot, solid state.

Résumé : Faisant appel à une réaction de cyclopropanation monotope, à l'état solide, assistée de micro-ondes et utilisant directement la 4-ferrocnénylacétophénone, l'aldéhyde et un ylure de sulfure comme produits de départs, on a réalisé rapidement la synthèse de nouveaux (4-ferrocényl)benzoylcyclopropanes. Les principaux avantages de cette méthode impliquent son côté pratique, son court temps de réaction, sa faible pollution de l'environnement et le fait qu'il n'est pas nécessaire d'isoler le produit intermédiaire (la chalcone) dans une étape séparée.

Mots clés : 4-ferrocénylacétophénone, ylure de soufre, assistée de micro-ondes, monotope, état solide.

[Traduit par la Rédaction]

Introduction

Ferrocene derivatives have been attracting much interest because of their possible biological activities (1), asymmetric catalytic effects (2), electron transfer features (3) (used as liquid crystals (4) and conductors (5)), and so on. Also, many compounds containing ferrocenyl exhibit good nonlinear optics (NLO) properties in which the ferrocenyl is used as the electron-donating group (6). Carbonyl cyclopropanes containing ferrocenyl are important members of those derivations that may offer a variety of potential applications such as photoactive semiconductors (7) and liquid crystals. They were commonly synthesized by a sulfur ylide reaction in solution (8). However, this method requires high temperatures, harsh reaction conditions, large amounts of solvents, a long reaction time, and tedious workup. In particular, the use of large amounts of solvents leads to the generation of waste as well as environmental pollution. So there is a need to develop a rapid, convenient, and clean method to synthesize this kind of compound.

In the past few years, the utilization of microwave irradiation (9, 10) and solid-state reaction (11, 12) in chemical transformations has attracted considerable interest and is of significant importance in the search for green synthesis (13) and sustainable chemistry. More attractively, many reactions that typically require hours or days to complete full conversion with conventional heating could be realized in several minutes by utilizing microwave irradiation in the solid state. It should be pointed out that the cyclopropanation reaction via the one-pot method, which adopts high-speed microwave techniques in the solid state, was seldom described. In the present work, we will report a microwave-assisted, one-pot cyclopropanation reaction in the solid state to synthesize some (4-ferrocenyl) benzoyl cyclopropanes, which directly used 4-ferrocenylacetophenone (14), aldehyde, and sulfur ylide (15) as the starting materials. This reaction has a series of advantages: (1) it does not require the isolation of chalcones in a separate step; (2) it requires a shorter reaction time; (3) it simplifies the process and handling; and (4) it avoids using large amounts of solvent, reducing waste and pollution. The reaction is shown in Scheme 1.

Results and discussion

First we examined the reactivity of different bases for the reaction among 4-ferrocenylacetophenone, liquid benzaldehyde (absorbed on 0.1 g Al_2O_3), and $Me_3S(O)I$ under MW irradiation. The results are shown in the Table 1. It can be seen that the reactivity of NaOH was found to be the best and **2a** was converted to **4a** in high yield. Then, on the basis of these results, we expanded the scope of this transformation to a series of aldehydes, using NaOH as the base. The results are summarized in Table 2.

As expected, a series of (4-ferrocenyl)benzoyl cyclopropanes (**4**) were obtained in high yields. Compound **1** (1.0 mmol) could react completely with aldehyde **2** (1.0 mmol) and some excess sulfur ylide **3** (1.1 mmol) using NaOH as the catalyst. Table 1 shows that both electronic and

[c]No product obtained.

steric effects influence the yield obtained. For example, among the substituted benzaldehydes used, the aldehyde bearing the electron-withdrawing group in the para position (Table 1, entry 2) gave a better result. In contrast, unfavorable electronic effects of substituted benzaldehydes (Table 1, entries 5, 7–9) led to some lower yields than for PhCHO. Steric effects of the ortho-substituted aldehyde (Table 1, entry 3) or the aldehyde containing a large group (Table 1, entries 8 and 11) also gave lower yields for the cyclopropanation reaction. For the aldehyde that contains a nitro group, each irradiation period needed to be shortened to 15 s and the frequencies enhanced, otherwise the mixture quickly turned black and only a small amount of the product would be obtained.

In the isolation of the crude product, we obtained a main product, though the other isomers or by-products were difficult to identify, which indicates the high diastereoselectivity of this reaction. The main product is the one we expected, and its 1D NOE spectra of ^{1}H NMR shows that it possesses a trans configuration.

Experimental

General information

4-Ferrocenylacetophenone (14) and trimethylsulfoxonium iodide (15) were prepared as per the literature method, and other reagents were commercial grade and used directly. MW irradiation was carried out with a commercial microwave over Medea WT022J at 2450 MHz in a mortar. ^{1}H NMR and ^{13}C NMR spectra were performed on a Mercury 4N-PFG-300 (**4a**–**4c**, **4e**, **4j**, **4l**) or AVANCE-DRX-200 (**4d**, **4f**–**4i**, **4k**) sensitivity spectrometer in $CDCl_3$ with TMS as an internal standard. Mass spectrometers were obtained by fast atom bombardment (FAB) on a VG ZBA-HS mass spectrograph. IR spectra were recoded in KBr on a Niolet 670FT-IR spectrophotometer. Elemental analyses were carried out on a Carlo-Erba 1106 element analyzer. The melting points reported are uncorrected.

General procedure

A mixture of powdered 4-ferrocenylacetophenone (**1**, 1.0 mmol), NaOH (1.1 mmol, powder), and neutral Al_2O_3 (0.1 g, 200–300 mesh) was ground in a mortar for 2 min, 1.0 mmol aldehyde **2** (liquid aldehyde was absorbed on 0.1 g Al_2O_3) was added in, ground for another 2 min, and the mixture was microwave irradiated six times for 20–25 s each. Then another ground mixture of trimethylsulfoxonium iodide (**3**, 1.1 mmol), NaOH (1.2 mmol), and Al_2O_3 (0.1 g) was added into the former system, and grinding continued for 2 min. All of the mixture in the mortar was irradiated by MW 15–20 times (for 20–25 s each) until the reaction was completed by TLC monitoring. The mixture was washed with EtOH (3 × 10 mL) on a filter funnel by reducing pressure and the EtOH was evaporated. The residue was separated on a flash chromatography column with silica (eluent: petroleum (bp 30–60 °C) – ethyl acetate) and gave the desired products (**4**).

1-(4′-Ferrocenyl)benzoyl-2-(4″-bromo)phenylcyclopropane (4b)

Orange-red crystals, mp 145–147 °C. IR (KBr, cm^{-1}) ν: 1648 (C=O). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.54 (m, 1H, CH), 1.93 (m, 1H, CH), 2.67 (m, 1H, CH_2), 2.86 (m, 1H, CH_2), 4.04 (s, 5H, cp-ring), 4.40 (s, 2H, cp-ring), 4.72 (s, 2H, cp-ring), 7.07 (d, J = 7.8 Hz, 2H, C_6H_4Br), 7.44 (d, J = 7.8 Hz, 2H, C_6H_4Br), 7.53 (d, J = 8.1 Hz, 2H, C_6H_4), 7.91 (d, J = 8.1 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 198.1, 145.9, 140.0, 135.6, 131.8, 128.6, 128.2, 126.0, 120.6, 70.2, 70.1, 67.2, 29.4, 29.3, 19.2. MS (FAB) *m*/*z* (%): 486.3 (M^+, 41), 484.4 (M^+, 41), 289.4 (5), 261.3 (10), 197.3 (7). Anal. calcd. for $C_{26}H_{21}BrFeO$ (485.2): C 64.36, H 4.36; found: C 64.23, H 4.32.

1-(4′-Ferrocenyl)benzoyl-2-(2″-chloro)phenylcyclopropane (4c)

Brown-red solid. IR (KBr, cm^{-1}) ν: 1660 (C=O). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.59 (m, 1H, CH), 1.92 (m, 1H, CH), 2.81 (m, 1H, CH_2), 2.93 (m, 1H, CH_2), 4.06 (s, 5H, cp-ring),

12	CH_3-CH=CH-	**4l**	10	94	>95:5

Note: Fc = ferrocenyl; d.r. = diastereoisomeric ratio.
[a]Total irradiation time.
[b]Isolated yields.
[c]Determined by ^{1}H NMR spectroscopy.

4.42 (s, 2H, cp-ring), 4.74 (s, 2H, cp-ring), 7.23 (br, 3H, C_6H_4Cl), 7.40 (d, J = 7.8 Hz, 1H, C_6H_4Cl), 7.54 (d, J = 8.4 Hz, 2H, C_6H_4), 7.97 (d, J = 8.4 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 198.1, 145.6, 138.3, 136.2, 135.2, 129.7, 128.7, 128.2, 127.6, 127.0, 126.0, 70.3, 67.3, 28.0, 27.6, 17.8. MS (FAB) *m/z* (%): 442.2 (M^+, 32), 440.2 (M^+, 70), 289.1 (16), 261.1 (21). Anal. calcd. for $C_{26}H_{21}ClFeO$ (440.8): C 70.85, H 4.80; found: C 70.69, H 4.76.

1-(4′-Ferrocenyl)benzoyl-2-phenylvinylcyclopropane (4d)

Brown-red crystals, mp 150–152 °C. IR (KBr, cm^{-1}) ν: 1653 (C=O). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 1.54 (m, 1H, CH), 1.83 (m, 1H, CH), 2.31 (m, 1H, CH_2), 2.79 (m, 1H, CH_2), 4.09 (s, 5H, cp-ring), 4.45 (s, 2H, cp-ring), 4.78 (s, 2H, cp-ring), 5.83 (dd, J = 9.0, 16.2 Hz, 1H, C=CH), 6.58 (d, 1H, J = 16.2 Hz, C=CH), 7.32 (br, 5H, C_6H_5), 7.50 (d, 2H, J = 8.0 Hz, C_6H_4), 7.92 (d, J = 8.0 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 198.2, 145.7, 139.2, 136.0, 130.8, 130.5, 128.6, 128.3, 127.3, 127.2 125.9, 70.0, 67.0, 29.4, 22.7, 14.1. MS (FAB) *m/z* (%): 433.3 (M^+ + 1, 27), 432.3 (M^+, 61), 328.2 (16), 289.1 (22), 261.1 (58). Anal. calcd. for $C_{28}H_{24}FeO$ (432.3): C 77.79, H 5.60; found: C 76.65, H 5.58.

1-(4′-Ferrocenyl)benzoyl-2-(3″,4″-methylenedioxy)phenylcyclopropane (4e)

Orange-red crystals, mp 110–112 °C. IR (KBr, cm^{-1}) ν: 1658 (C=O). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.48 (m, 1H, CH), 1.88 (m, 1H, CH), 2.63 (m, 1H, CH_2), 2.81 (m, 1H, CH_2), 4.06 (s, 5H, cp-ring), 4.43 (s, 2H, cp-ring), 4.75 (s, 2H, cp-ring), 5.95 (s, 2H, OCH_2O), 6.67 (s, 1H, C_6H_3), 6.69 (d, J = 7.5 Hz, 1H, C_6H_3), 6.76 (d, J = 7.5 Hz, 1H, C_6H_3), 7.51 (d, J = 8.1 Hz, 2H, C_6H_4), 7.91 (d, J = 8.1 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 198.0, 145.6, 135.3, 135.0, 128.6, 128.5, 126.1, 126.0, 120.0, 108.5, 106.8, 101.3, 70.3, 67.3, 29.9, 29.3, 19.1. MS (FAB) *m/z* (%): 451.3 (M^+ + 1, 38), 450.3 (M^+, 72), 329.3 (7), 289.2 (15), 261.2 (19), 189.2 (41), 121.1 (100). Anal. calcd. for $C_{27}H_{22}FeO_3$ (450.3): C 72.02, H 4.92; found: C 71.90, H 4.89.

1-(4′-Ferrocenyl)benzoyl-2-(4″-nitro)phenylcyclopropane (4f)

Purple-red solid. IR (KBr, cm^{-1}) ν: 1662 (C=O). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 1.58 (m, 1H, CH), 2.01 (m, 1H, CH), 2.79 (m, 1H, CH_2), 2.98 (m, 1H, CH_2), 4.04 (s, 5H, cp-ring), 4.42 (s, 2H, cp-ring), 4.73 (s, 2H, cp-ring), 7.33 (d, J = 9.8 Hz, 2H, C_6H_4), 7.58 (d, J = 9.8 Hz, 2H, C_6H_4), 7.91 (d, J = 8.4 Hz, 2H, C_6H_4), 8.19 (d, J = 8.4 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 199.4, 147.3, 141.2, 135.9, 128.9, 128.4, 126.8, 125.9, 123.9, 69.9, 67.1, 29.7, 28.8, 19.8. MS *m/z* (%): 452.1 (M^+ + 1, 18), 451.1 (M^+, 42), 329.0 (15), 289.0 (37), 261.0 (11). Anal. calcd. for $C_{26}H_{21}FeNO_3$ (451.3): C 69.20, H 4.69, N 3.10; found: C 69.13, H 4.71, N 3.12.

1-(4′-Ferrocenyl)benzoyl-2-(4″-dimethylamino)phenylcyclopropane (4g)

Orange-red crystals, mp 160–162 °C. IR (KBr, cm^{-1}) ν: 1646 (C=O). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 1.55 (m, 1H, CH), 1.90 (m, 1H, CH), 2.65 (m, 1H, CH_2), 2.83 (m, 1H, CH_2), 2.97 (s, 6H, $2CH_3$), 4.06 (s, 5H, cp-ring), 4.40 (s, 2H, cp-ring), 4.72 (s, 2H, cp-ring), 6.70 (d, J = 9.0 Hz, 2H, C_6H_4), 7.12 (d, J = 9.0 Hz, 2H, C_6H_4), 7.52 (d, J = 8.6 Hz, 2H, C_6H_4), 7.92 (d, J = 8.6 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 190.3, 132.1, 132.0, 128.3, 127.2, 125.7, 112.9, 111.1, 111.0, 69.8, 66.9, 40.7, 40.1, 40.0, 29.9, 29.2. MS *m/z* (%): 450.2 (M^+ + 1, 25), 449.2 (M^+, 74), 289.1 (8), 261.1 (10). Anal. calcd. for $C_{28}H_{27}FeNO$ (449.4): C 74.84, H 6.06, N 3.12; found: C 74.78, H 6.03, N 3.10.

1-(4′-Ferrocenyl)benzoyl-2-(4′-ferrocenyl)phenylcyclopropane (4h)

Brown-red crystals, mp 80–82 °C. IR (KBr, cm^{-1}) ν: 1657 (C=O). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 1.56 (m, 1H, CH), 1.94 (m, 1H, CH), 2.68 (m, 1H, CH_2), 2.90 (m, 1H, CH_2), 4.03 (s, 5H, cp-ring), 4.07 (s, 5H, cp-ring), 4.33 (s, 2H, cp-ring), 4.39 (s, 2H, cp-ring), 4.65 (s, 2H, cp-ring), 4.71 (s, 2H, cp-ring), 7.10 (d, J = 7.8 Hz, 2H, C_6H_4), 7.40 (d, J = 7.8 Hz, 2H, C_6H_4), 7.53 (d, J = 8.2 Hz, 2H, C_6H_4), 7.94 (d, J = 8.2 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 50 MHz) δ:

197.7, 138.2, 137.6, 135.1, 128.5, 128.4, 126.2, 126.1, 125.7, 70.2, 69.8, 69.0, 66.9, 66.5, 29.8, 29.1, 19.0. MS (FAB) *m/z* (%): 591.2 (M^+ + 1, 36), 590.2 (M^+, 64), 289.1 (22), 261.1 (27). Anal. calcd. for $C_{36}H_{30}Fe_2O$ (590.3): C 73.25, H 5.12; found: C 73.19, H 5.08.

1-(4′-Ferrocenyl)benzoyl-2-(3″-methoxyl-4″-methoxyl-methoxyl)phenylcyclopropane (4i)

Brown-red solid. IR (KBr, cm^{-1}) ν: 1658 (C=O). ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.55 (m, 1H, CH), 1.92 (m, 1H, CH), 2.69 (m, 1H, CH_2), 2.87 (m, 1H, CH_2), 3.55 (s, 3H, OCH_3), 3.91 (s, 3H, OCH_3), 4.06 (s, 5H, cp-ring), 4.43 (s, 2H, cp-ring), 4.74 (s, 2H, cp-ring), 5.24 (s, 2H, OCH_2O), 6.73 (d, *J* = 8.4 Hz, 1H, C_6H_3), 6.80 (s, 1H, C_6H_3), 7.12 (d, *J* = 8.4 Hz, 1H, C_6H_3), 7.56 (d, *J* = 8.2 Hz, 2H, C_6H_4), 7.95 (d, *J* = 8.2 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 197.7, 149.9, 145.3, 145.2, 135.1, 128.3, 125.7, 118.0, 116.9, 110.8, 95.7, 83.2, 69.8, 66.9, 56.1, 55.9, 29.6, 29.1, 18.7. MS (FAB) *m/z* (%): 497.3 (M^+ + 1, 14), 496.3 (M^+, 39), 288.8 (11), 261.1 (28). Anal. calcd. for $C_{29}H_{28}FeO_4$ (496.4): C 70.17, H 5.69; found: C 70.07, H 5.71.

1-(4′-Ferrocenyl)benzoyl-2-(2″-furyl)cyclopropane (4j)

Brown-red crystals, mp 78–80 °C. IR (KBr, cm^{-1}) ν: 1661 (C=O). ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.66 (m, 1H, CH), 1.94 (m, 1H, CH), 2.57 (m, 1H, CH_2), 3.12 (m, 1H, CH_2), 4.03 (s, 5H, cp-ring), 4.43 (s, 2H, cp-ring), 4.86 (s, 2H, cp-ring), 5.61 (s, *J* = 1.8 Hz, 1H, furyl), 6.26 (d, *J* = 3.6 Hz, 1H, furyl), 6.36 (dd, *J* = 1.8 Hz, *J* = 3.6 Hz, 1H, furyl), 7.68 (d, *J* = 8.4 Hz, 2H, C_6H_4), 7.99 (d, *J* = 8.4 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 196.7, 154.2, 146.0, 141.7, 134.8, 128.6, 126.0, 110.8, 105.5, 70.1, 69.9, 67.1, 26.1, 22.1, 16.4. MS (FAB) *m/z* (%): 397.4 (M^+ + 1, 30), 396.4 (M^+, 65), 289.3 (11), 261.3 (19). Anal. calcd. for $C_{24}H_{20}FeO_2$ (396.3): C 72.74, H 5.09; found: C 72.66, H 5.12.

2-Ferrocenyl-1-(4′-ferrocenyl)benzoylcyclopropane (4k)

Brown-red crystals, mp 161 to 162 °C. IR (KBr, cm^{-1}) ν: 1644 (C=O). ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.32 (m, 1H, CH), 1.82 (m, 1H, CH), 2.40 (m, 1H, CH_2), 2.75 (m, 1H, CH_2), 4.03 (s, 5H, cp-ring), 4.11 (s, 4H, cp-ring), 4.18 (s, 5H, cp-ring), 4.40 (s, 2H, cp-ring), 4.72 (s, 2H, cp-ring), 7.54 (d, *J* = 8.2 Hz, 2H, C_6H_4), 7.94 (d, *J* = 8.2 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 197.8, 147.9, 128.6, 128.3, 125.8, 69.8, 69.1, 68.8, 66.9, 66.7, 29.7, 26.3, 13.7. MS (FAB) *m/z* (%): 515.2 (M^+ + 1, 39), 514.2 (M^+, 47), 328.9 (32), 289.2 (43). Anal. calcd. for $C_{30}H_{26}Fe_2O$ (514.2): C 70.07, H 5.10; found: C 69.97, H 5.08.

1-(4′-Ferrocenyl)benzoyl-2-propenylcyclopropane (4l)

Brown-red solid. IR (KBr, cm^{-1}) ν: 1658 (C=O). ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.13 (m, 1H, CH), 1.60 (m, 1H, CH), 1.75 (d, *J* = 6.6 Hz, 3H, CH_3), 2.13 (m, 1H, CH_2), 2.62 (m, 1H, CH_2), 4.05 (s, 5H, cp-ring), 4.41 (s, 2H, cp-ring), 4.74 (s, 2H, cp-ring), 5.19 (m, 1H, C=CH), 5.66 (m, 1H, C=CH), 7.53 (d, *J* = 7.8 Hz, 2H, C_6H_4), 7.91 (d, *J* = 7.8 Hz, 2H, C_6H_4). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 199.3, 145.1, 135.3, 131.4, 128.3, 126.2, 125.7, 69.9, 67.0, 29.3, 29.0, 26.4, 18.0. MS (FAB) *m/z* (%): 371.4 (M^+ + 1, 30), 370.4 (M^+, 70), 289.3 (9), 261.3 (28), 109 (70). Anal. calcd. for $C_{23}H_{22}FeO$ (370.3): C 74.61, H 5.99; found: C 74.50, H 5.61.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

J. Peter Guthrie 2003 Alfred Bader Award Lecture Predicting the rates of chemical reactions **1**

ARTICLES / ARTICLES

Evangelos Drougas and Agnie M. Kosmas Computational investigation of isomeric and conformeric structures of methyl iodoperoxide **9**

Xuesen Fan, Xueyuan Hu, Xinying Zhang, and Jianji Wang $InCl_3 \cdot 4H_2O$-promoted green preparation of xanthenedione derivatives in ionic liquids **16**

Alexandra S. Silchenko, Sergey A. Avilov, Alexandr S. Antonov, Anatoly I. Kalinovsky, Pavel S. Dmitrenok, Vladimir I. Kalinin, Valentin A. Stonik, Carl Woodward, and Peter D. Collin Glycosides from the sea cucumber *Cucumaria frondosa.* III. Structure of frondosides A_2-1, A_2-2, A_2-3, and A_2-6, four new minor monosulfated triterpene glycosides **21**

Yan Yang, Fengyun Wang, Fernande D. Rochon, and Margaret M. Kayser Synthesis of novel optically pure β-lactams **28**

Albert Y. Jin, Harold Kohn, Cécile Béguin, Shridhar V. Andurkar, James P. Stables, and Donald F. Weaver A quantitative structure–activity relationship study for α-substituted acetamido-*N*-benzylacetamide derivatives — A novel anticonvulsant drug class **37**

Jaakko I. Partanen, Pekka M. Juusola, and Virginie Verraes Re-evaluation of the second thermodynamic dissociation constants of α-alanine, valine, and leucine using potentiometric data measured for aqueous potassium chloride solutions at 298.15 K **46**

Ashraf A. Aly and Mohsen A.-M. Gomaa New cycloaddition of diarylazines with 1,2-dehydrobenzene, 1,1,2,2-tetracyanoethylene, and dibenzoylacetylene — Facile synthesis of acridinones, pyrazolidine, and pyridazine derivatives **57**

K.C. Majumdar, U.K. Kundu, U. Das, N.K. Jana, and B. Roy *N*-Iodosuccinimide — An effective reagent for regioselective heterocyclization of *o*-cyclohex-2′-enylanilines for the synthesis of hexahydrocarbazoles **63**

Y. Chiang, A.J. Kresge, V.A. Nikolaev, I. Onyido, and X. Zeng The 2-oxo-3,3,5,5-tetramethylcyclopentanecarboxylic acid keto–enol system in aqueous solution — Generation of the enol by flash photolytic Wolff rearrangement of 2-diazo-4,4,6,6-tetramethylcyclohexane-1,3-dione followed by hydration of the acylketene thus formed **68**

Author Index / Index des auteurs **AI-1**

February / Février

AWARD LECTURE / CONFÉRENCE D'HONNEUR

Laurence K. Thompson 2004 Alcan Award Lecture From dinuclear to triakontahexanuclear complexes — Adventures in supramolecular coordination chemistry **77**

ARTICLES / ARTICLES

Gennady V. Shustov, Melanie K. Chandler, and Saul Wolfe Stereoselective synthesis of multiply substituted [1,2]oxazinan-3-ones via ring-closing metathesis **93**

Pedro P. Corbi, Antonio C. Massabni, Andréia G. Moreira, Francisco J. Medrano, Miriam G. Jasiulionis, and Claudio M. Costa-Neto Synthesis, characterization, and biological activity of a new palladium(II) complex with deoxyalliin **104**

Iraj Mohammadpoor-Baltork and Mohammad Abdollahi-Alibeik Mild, efficient, and chemoselective dehydrogenation of 2-imidazolines, bis-imidazolines, and *N*-substituted-2-imidazolines with potassium permanganate supported on montmorillonite K-10 **110**

Iraj Mohammadpoor-Baltork, Hamid R. Memarian, and Kiumars Bahrami 3-Carboxypyridinium chlorochromate – aluminium chloride — An efficient and inexpensive reagent system for the selective oxidation of sulfides to sulfoxides and sulfones in solution and under microwave irradiation **115**

© 2005 NRC Canada

Miguel A. Zamora, Luis N. Santágata, Marcelo F. Masman, José A. Bombasaro, Mónica L. Freile, and Ricardo D. Enriz Conformational study of internally retrograde and quasi-retrograde molecules — An ab initio and DFT study **122**

Christian Laurence, Michel Berthelot, Karine Evain et Bertrand Illien Échelles pK_{HB} et enthalpique du pouvoir accepteur de liaison hydrogène de thioéthers, thiols et disulfures **138**

Mojtaba Bagheri, Najmedin Azizi, and Mohammad R. Saidi An intriguing effect of lithium perchlorate dispersed on silica gel in the bromination of aromatic compounds by *N*-bromosuccinimide **146**

M'hamed Chahma, Daniel J.T. Myles, and Robin G. Hicks Synthesis, characterization, and coordination chemistry of phosphines with ethylenedioxythiophene substituents **150**

Lill Kindahl, Lennart Kenne, and Corine Sandström ^{1}H NMR studies on the solution conformation of the [L-Ser^{10}] and [D-Ser^{10}] analogues of contulakin-G **156**

Xiao-Juan Liu, Ji-Kang Feng, Ai-Min Ren, Xin Zhou, and Hong Cheng Theoretical studies on the absorption and luminescent properties of a series of derivatives of 1,3-diphenyl-5-pyrene-2-yl-4,5-dihydro-1*H*-pyrazole **166**

Donald C. Craig, Ian G. Dance, Philip A.W. Dean, James M. Hook, Hilary A. Jenkins, Christopher W. Kirby, Marcia L. Scudder, and Umarani Rajalingam A synthetic, structural, and ^{113}Cd NMR study of cadmium complexes of 1,3-thiazolidine-2-thionate, including the structures of $Cd(C_3H_4NS_2)_2$, $(Cd(C_3H_4NS_2)_2(C_5H_5N)_3 \cdot C_5H_5N$, and $(Ph_4P)_2[I_2Cd(\mu\text{-}C_3H_4NS_2)_2CdI_2]$ **174**

Instructions to Authors **I-1**

Recommendations aux auteurs **R-1**

Notes for authors of papers presenting the results of X-ray crystal structure analyses **I-4**

Recommandations aux auteurs d'articles décrivant la détermination de structures par diffraction des rayons X **R-5**

March / Mars

AWARD LECTURE / CONFÉRENCE D'HONNEUR

X. Chris Le, Victor Pavski, and Hailin Wang 2002 W.A.E. McBryde Award Lecture — Affinity recognition, capillary electrophoresis, and laser-induced fluorescence polarization for ultrasensitive bioanalysis **185**

ARTICLES / ARTICLES

Victor X. Jin, Donal H. Macartney, and Erwin Buncel Kinetic and spectroscopic studies on α- and β-cyclodextrin rotaxanes with (μ-*N*,*N*′-bis(4-pyridinylmethylene)-α,ω-alkanediimine)bis[pentacyanoferrate(II)] threads **195**

N. Bhavani, S. Perumal, and R. Banureka Stereoselective synthesis and stereochemistry of *r*-2-alkoxycarbonyl-*c*-3-*o*-substituted phenyl-1,4-thiazane 1,1-dioxides **202**

Mohammad M. Khodaei, Ahmad R. Khosropour, and Mehdi Kookhazadeh A novel enamination of β-dicarbonyl compounds catalyzed by $Bi(TFA)_3$ immobilized on molten TBAB **209**

Woonphil Baik, Wanqiang Luan, Hyun Joo Lee, Cheol Hun Yoon, Sangho Koo, and Byeong Hyo Kim Efficient one-pot transformation of aminoarenes to haloarenes using halodimethylisulfonium halides generated in situ **213**

C. Jarne, S.T. Blanco, S. Avila, C. Berro, S. Otín, and I. Velasco Dew points of quaternary ethane + carbon dioxide + water + methanol mixtures — Measurement and modelling **220**

Murat Güney, Zeynep Çelik Ceylan, Arif Daştan, and Metin Balci Substituent effects of the cycloaddition reaction of 7-substituted 5*H*-benzocycloheptenes with singlet oxygen and the chemistry of the benzocycloheptene endoperoxides **227**

Mehrdad Bamdad, Saman Alavi, Bijan Najafi, and Ezat Keshavarzi Investigation of the density dependence of the shear relaxation time of dense fluids **236**

Alexandru C. Razus, Carmen Nitu, Claudia Pavel, Crinu-Anghel Ciuculescu, Valentin Cimpeanu, Corneliu Stanciu, and Philip P. Power Oxidation of 1-(4′-substituted phenyl)-2-(4-methylphenyl)diazene — Benzylic substitution vs. C–azo bond breaking **244**

A.S.A. Youssef, M.I. Marzouk, H.M.F. Madkour, A.M.A. El-Soll, and M.A. El-Hashash Synthesis of some heterocyclic systems of anticipated biological activities via 6-aryl-4-pyrazol-1-yl-pyridazin-3-one **251**

Surinderjit Singh, M.P.S. Ishar, Gajendra Singh, and Rajinder Singh Efficient, microwave-assisted intramolecular 1,3-dipolar cycloadditions of oximes and *N*-methylnitrones derived from *o*-alkenylmethoxy-acetophenones **260**

MINIREVIEW / MINISYNTHÈSE

Robert Franzén and Youjun Xu Review on green chemistry — Suzuki cross coupling in aqueous media **266**

RAPID COMMUNICATION / COMMUNICATION RAPIDE

Xiao-hua Cai, Hai-jun Yang, and Guo-lin Zhang Aromatization of 1,4-dihydropyridines with selenium dioxide **273**

Author Index / Index des auteurs **AI-1**

April / Avril

This issue commemorates the 40th anniversary of the publication of the first report of a dinitrogen complex, namely $[Ru(NH_3)_5N_2]^{2+}$ / Ce numéro souligne le 40e anniversaire de la parution du premier rapport faisant état d'un complexe diazoté, le $[Ru(NH_3)_5N_2]^{2+}$

ARTICLES / ARTICLES

G.J. Leigh Bert Allen and the first complex of dinitrogen **277**

Jennifer Scott, Sandro Gambarotta, and Ilia Korobkov Ligand-assisted reduction of Co(II) to Co(I) and subsequent coordination of dinitrogen **279**

Jaime A. Pool and Paul J. Chirik The importance of cyclopentadienyl substituent effects in group 4 metallocene dinitrogen chemistry **286**

Patrick L. Holland Low-coordinate iron complexes as synthetic models of nitrogenase **296**

John-Paul F. Cherry, Paula L. Diaconescu, and Christopher C. Cummins Portability of the RNNMo(3+) core — Application to the synthesis of dinitrogen-derived trialkoxymolybdenum organodiazenido complexes **302**

Chaoyang Yue, Michel L. Trudeau, and David Antonelli Mesoporous tantalum oxide photocatalysts for Schrauzer-type conversion of dinitrogen to ammonia **308**

Bruce A. MacKay, Samuel A. Johnson, Brian O. Patrick, and Michael D. Fryzuk Functionalization and cleavage of coordinated dinitrogen via hydroboration using primary and secondary boranes **315**

Jason D. Masuda and Douglas W. Stephan Synthesis and structure of a (NacNac)rhodium terminal dinitrogen complex **324**

Rory Waterman and Gregory L. Hillhouse Synthesis and structure of a terminal dinitrogen complex of nickel **328**

Cora E. MacBeth, Seth B. Harkins, and Jonas C. Peters Synthesis and characterization of cationic iron complexes supported by the neutral ligands $NP^{i\text{-}Pr}_3$, $NArP^{i\text{-}Pr}_3$, and $NS^{t\text{-}Bu}_3$ **332**

Dmitry V. Yandulov and Richard R. Schrock Synthesis of tungsten complexes that contain hexaisopropylterphenyl-substituted triamidoamine ligands, and reactions relevant to the reduction of dinitrogen to ammonia **341**

Masanobu Hidai and Yasushi Mizobe Research inspired by the chemistry of nitrogenase — Novel metal complexes and their reactivity toward dinitrogen, nitriles, and alkynes **358**

William J. Evans and David S. Lee Early developments in lanthanide-based dinitrogen reduction chemistry **375**

Gerald C. Stephan, Gerhard Peters, Nicolai Lehnert, Carsten M. Habeck, Christian Näther, and F. Tuczek Bonding, activation, and protonation of dinitrogen on a molybdenum pentaphosphine complex — Comparison to *trans*-bis(dinitrogen) and -nitrile – dinitrogen complexes with tetraphosphine coordination **385**

Author Index / Index des auteurs **AI-1**

May / Mai

AWARD LECTURE / CONFÉRENCE D'HONNEUR

Cassie Ho, Dinah M. Soolaman, and Hua-Zhong Yu 2004 Fred Beamish Award Lecture — Analytical – materials chemistry on old CDs — Beyond self-assembly **403**

ARTICLES / ARTICLES

Arun A. Narine and Peter D. Wilson Synthesis and evaluation of 7-hydroxyindan-1-one-derived chiral auxiliaries **413**

Karin Liltorp, Peter Westh, and Yoshikata Koga Thermodynamic properties of water in the water-poor region of binary water + alcohol mixtures **420**

Emily Hollink, Pingrong Wei, and Douglas W. Stephan Homoleptic magnesium bis-phosphinimide derivatives **430**

Sangram Bagh and Matthew F. Paige Construction and application of a single-molecule fluorescence microscope **435**

Arkadiusz Klys, Malgorzata Dawid, and John Warkentin Synthesis and spectra of aldehyde- and ketone-*O*-(2,5-dihydro-2-methoxy-5,5-dimethyl-1,3,4-oxadiazol-2-yl)oximes — Thermal sources of some methoxy(oximino)carbenes **443**

David J. Berg, Chuanjian Zhou, Tosha Barclay, Xuening Fei, Shengyu Feng, Kevin A. Ogilvie, Robert A. Gossage, Brendan Twamley, and Mark Wood Lanthanide complexes of an oxazoline-phenoxide hybrid chelate **449**

Olivier Sigouin and André L. Beauchamp Oxo-rhenium(V) complexes with 8-hydroxyquinoline derivatives **460**

Vanessa Renée Little, Reid Tingley, and Keith Vaughan Triazene derivatives of (1,*x*)-diazacycloalkanes. Part III. Synthesis and characterization of a series of 1,4-di[2-aryl-1-diazenyl]piperazines **471**

Jason D. Masuda and Douglas W. Stephan Transition metal complexes of a sterically demanding diimine ligand **477**

Dongju Zhang, Xuebing Fu, Ruoxi Wang, and Chengbu Liu Theoretical study of the reaction of titanium ion with ethane — Structure, mechanism, and potential energy surface **485**

© 2005 NRC Canada

Christopher K. Jankowski, Sébastien Arseneau, Jérome Blu, Laurent Mauclaire, and Nicolas Aychet On the synthesis of new amphiphilic entities by the succinic coupling of β-cyclodextrins to calixarenes **493**

Purushottam Haldar and Bijan Das Viscosities of some tetraalkylammonium bromides in 2-ethoxyethanol at 308.15, 313.15, 318.15, and 323.15 K **499**

Najmodin Azizi and Mohammad R. Saidi Solid lithium perchlorate as a powerful catalyst for the synthesis of β-aminoalcohols under solvent-free conditions **505**

Jerzy J. Chruściel ^{29}Si NMR studies on the mechanism of dehydrocoupling of hydrosilanes with hydroxylic reagents in DMF — The role of DMF **508**

RAPID COMMUNICATION / COMMUNICATION RAPIDE

Keelara Abiraj, Gejjalagere R. Srinivasa, and D. Channe Gowda Palladium-catalyzed simple and efficient hydrogenative cleavage of azo compounds using recyclable polymer-supported formate **517**

Author Index / Index des auteurs **AI-1**

June/July / Juin/Juillet

This special issue is dedicated to Professor Howard Alper to honour his outstanding contributions to research in homogeneous catalysis / Ce numéro spécial est dédié au professeur Howard Alper en reconnaissance de ses contributions exceptionnelles dans le domaine de la catalyse homogène

ARTICLES / ARTICLES

Wai-Hung Cheung, Wing-Ping Yip, Wing-Yiu Yu, and Chi-Ming Che Oxidation of anisoles to *p*-benzoquinone monoketals catalyzed by a ruthenium complex of 1,4,7-trimethyl-1,4,7-triazacyclononane with *tert*-butyl hydroperoxide **521**

B.B. Kale, Jin-Ook Baeg, Jin S. Yoo, Sang Mi Lee, Chul Wee Lee, Sang-Jin Moon, and Hyunju Chang Synthesis of a novel photocatalyst, $ZnBiVO_4$, for the photodecomposition of H_2S **527**

André B. Charette and Jean-Emmanuel Bouchard Catalytic asymmetric synthesis of cyclopropylphosphonates — Catalysts' scope and reactivity **533**

Philippe Gaudreault, Christian Drouin, and Jean Lessard First examples of intramolecular addition of primary amidyl radicals to olefins **543**

Nathan D. Jones and Brian R. James Palladium(II) complexes of bis(phosphine)monooxide and bis(phosphine)monosulphide ligands bearing *o*-*N*,*N*-dimethylanilinyl substituents **546**

Bilal Baradie, Patricia H.M. Lai, and Molly S. Shoichet Synthesis and characterization of novel polysiloxane-grafted fluoropolymers **553**

Matthew D. Clay, Ditte Riber, and Alex G. Fallis Competing Diels–Alder intramolecular pathways from cross-conjugated trienes: Fused hydrindenones (bicyclo[4.3.0]nonenones) vs. bridged-ring (bicyclo[3.3.1]nonenones) adducts from a diene-transmissive precursor **559**

Nitin T. Patil, Nirmal K. Pahadi, and Yoshinori Yamamoto Pd(0)–PhCOOH catalyzed addition of oxygen pronucleophiles to allenes and internal alkynes **569**

Prem Pal, Juliette Quartararo, Sharifah B. Abd Hamid, Eric G. Derouane, Jacques C. Védrine, Pieter C.M.M. Magusin, and Bruce G. Anderson A MAS NMR and DRIFT study of the Ga species in Ga/H-ZSM5 catalysts and their effect on propane ammoxidation **574**

Goverdhan Mehta and Senaiar S. Ramesh Polycyclitols — Novel conduritol and carbasugar hybrids as new glycosidase inhibitors **581**

Fenbao Zhang, Michael E. Broczkowski, Michael C. Jennings, and Richard J. Puddephatt Oxidative addition chemistry of dimethyl(dipyridyl ketone)platinum(II) **595**

Bruce H. Lipshutz, Bryan A. Frieman, John B. Unger, and Danielle M. Nihan Thermally accelerated asymmetric hydrosilylations using ligated copper hydride **606**

Olivier LeBel, Thierry Maris, Hugues Duval, and James D. Wuest A practical guide to arylbiguanides — Synthesis and structural characterization **615**

Christine L. Tennent and William D. Jones Kinetics and mechanism of dealkylation of coordinated isocyanide in $Fe(PMe_3)_2(t\text{-}BuNC)_3$ **626**

Laurent F. Groux, Francine Bélanger-Gariépy, and Davit Zargarian Phosphino-indenyl complexes of nickel(II) **634**

William J. Marshall and Vladimir V. Grushin Activation of chlorobenzene with Ni(0) *N*,*N*-chelates — A remarkably profound effect of a minuscule change in ligand structure **640**

Takanobu Sanji, Hiroyuki Ishiwata, Tomoyoshi Kaizuka, Masato Tanaka, Hideki Sakurai, Ritsuko Nagahata, and Kazuhiko Takeuchi An alternative convergent synthesis of silole-core dendrimers **646**

Michael P. Shaver, Samuel A. Johnson, and Michael D. Fryzuk Activation and cleavage of alkynes by the dinuclear tantalum complexes $([NPN]Ta)_2(\mu\text{-}H)_4$ and $([NPN]Ta)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}N_2)(\mu\text{-}H)_2$ (where NPN = $PhP(CH_2SiMe_2NPh)_2$) **652**

© 2005 NRC Canada

Natalie A. Wynberg, Lisa J. Leger, Maren L. Conrad, Christopher M. Vogels, Andreas Decken, Stephen J. Duffy, and Stephen A. Westcott Synthesis and catalysed hydroboration of styryl sulfonamides **661**

J.N. Behera and C.N.R. Rao Coordination polymers with Co(II) sulfate layers linked by alkanediamines of varying chain length **668**

Giuseppe Vasapollo and Giuseppe Mele Palladium-catalyzed asymmetric cyclocarbonylation of allyl naphthols **674**

Wen-Hua Chiou, Seung-Yub Lee, and Iwao Ojima Recent advances in cyclohydrocarbonylation reactions **681**

Lu Jiang and Tak Hang Chan Efficient synthesis of the nonamannoside residue of high mannose glycoproteins **693**

Abdelaziz Nait Ajjou and Jean-Louis Pinet Oppenauer-type oxidation of secondary alcohols catalyzed by homogeneous water-soluble complexes **702**

Takahide Fukuyama, Ryo Yamaura, and Ilhyong Ryu Synthesis of acetylenic ketones by a Pd-catalyzed carbonylative three-component coupling reaction in [bmim]PF_6 **711**

Akihiro Orita, Fangguo Ye, Govindarajulu Babu, Tomohiro Ikemoto, and Junzo Otera Double elimination protocol for the synthesis of arylene ethynylenes containing heteroaromatic rings **716**

Ling Chen and Pierre Deslongchamps Studies towards the total synthesis of ouabagenin **728**

Sara Deledda, Elena Motti, and Marta Catellani Palladium-catalysed synthesis of nonsymmetrically disubstituted-1,1′-biphenyls from *o*-substituted aryl iodides through aryl coupling and delayed hydrogenolysis **741**

Samantha D. Drouin, Heather M. Foucault, Glenn P.A. Yap, and Deryn E. Fogg New pseudohalide ligands in Ru-catalyzed olefin metathesis — A robust, air-activated iminopyrrolato catalyst **748**

Naoto Chatani, Takeshi Uemura, Taku Asaumi, Yutaka Ie, Fumitoshi Kakiuchi, and Shinji Murai Rhodium-catalyzed C-H–CO–olefin coupling reactions — A chelation-assisted direct carbonylation at the ortho C—H bond in the benzene ring of 2-arylpyridines **755**

Aránzazu Orejón, Aída Castellanos, Pilar Salagre, Sergio Castillón, and Carmen Claver Oxidative carbonylation of aniline with new cobalt catalytic systems **764**

Yih-Huang Hsieh, Noham Weinberg, Kiyull Yang, Chan-Kyung Kim, Zheng Shi, and Saul Wolfe Hydration of the carbonyl group — Acetic acid catalysis in the co-operative mechanism **769**

Roman Goikhman, Tanya Karakuz, Linda J.W. Shimon, Gregory Leitus, and David Milstein Electron-rich siloxane–platinum complexes — Synthesis, structures, and reactivity **786**

James E. Dettwiler, Laurent Bélec, and William D. Lubell Synthesis and application of L-*N*-Boc-*N*-methyl-β-hydroxyvaline in the preparation of a depsipeptide **793**

Stephen Hanessian and Kiran Kumar Kothakonda Design and synthesis of oxazolidinone ketolide antibiotic segment mimetics **801**

Ivan J.B. Lin and Chandra Sekhar Vasam Review of gold(I) *N*-heterocyclic carbenes **812**

Hong Cao and Wen-Jing Xiao Microwave-accelerated, palladium-catalyzed carbonylative cyclization reactions of 2-iodophenol with alkynes — Rapid and efficient synthesis of chromen-2-one derivatives **826**

Arunachalampillai Athimoolam, Sandro Gambarotta, and Ilia Korobkov Preparation, characterization, and structure of two dipyrrolide thorium homoleptic complexes — Isolation of a dipyrrolide dipotassium salt with an inverted-sandwich type of structure **832**

Paul A. Wender, Nicole M. Deschamps, and Robert Sun Rh(I)-catalyzed cleavage of unactivated C—O bonds — Carbonylative rearrangement reactions of allenyl ethers to 2-carboalkoxy-1,3-dienes **838**

Stephen O. Ojwach, Mmboneni G. Tshivhase, Ilia A. Guzei, James Darkwa, and Selwyn F. Mapolie Furoyl and thiophene carbonyl linker pyrazolyl palladium(II) complexes — Synthesis, characterization, and evaluation as ethylene oligomerization catalysts **843**

Yvette M. Terblans, Johannes J. Huyser, Michelle Huyser, Michael J. Green, Desmond A. Young, and Mike S. Sibiya Aluminium triflate as catalyst for epoxide ring-opening and esterification reactions — Mechanistic aspects **854**

NOTE OF APPRECIATION / NOTE DE RECONNAISSANCE

The quality of the papers in this journal depends a great deal on the efforts of those who agree to act as critical readers of manuscripts. The editors gratefully acknowledge the following who helped us between 1 November 2004 and 31 October 2005:

La qualité des articles publiés dans notre revue dépend beaucoup de ceux qui acceptent de faire une lecture critique des manuscrits. Les directeurs scientifiques expriment leur reconnaissance aux personnes suivantes qui nous ont aidés, du 1er novembre 2004 au 31 octobre 2005 :

Abrahamson, H.
