Alkylcobalt carbonyls. Part XIV.[1] Generation of chiral conformations by centers of chirality in organocobalt complexes[2]

Claudia Zucchi, Davide Turrini, Roland Boese, Lajos Bencze, Robert Kurdi, Luciano Caglioti, and Gyula Pályi

Abstract: $R^1OC(O)CH_2Co(CO)_3PR^2_3$ complexes (**3**), (R^1 = **S**-EtOC(O)CH(CH_3), R^2 = Ph, **a**; R^1 = (1**S**,2**R**,5**S**)-2-isopropyl-5-methylcyclohexyl, R^2 = Ph, **b**; R^1 = (1**R**,2**S**,5**R**)-2-isopropyl-5-methylcyclohexyl, R^2 = Ph, **c**; R^1 = isopropyl, R^2_3 = Ph_2{(1**S**,2**S**,5**R**)-2-isopropyl-5-methylcyclohexyl}, **d**) were prepared and characterized by analyses including IR, ^{1}H-, ^{13}C{^{1}H}-, and ^{31}P{^{1}H} NMR spectra as well as by X-ray diffraction structure determination. Principles of self-organization of chiral conformations were deduced from the structural data.

Key words: alkylcobalt carbonyls, cooperative phenomena, intramolecular, chirality, conformations.

Résumé : On a préparé les complexes $R^1OC(O)CH_2Co(CO)_3PR^2_3$ (**3**) (R^1 = **S**-EtOC(O)CH(CH_3), R^2 = Ph, **a**; R^1 = (1**S**,2**R**,5**S**)-2-isopropyl-5-méthylcyclohexyl, R^2 = Ph, **b**; R^1 = (1**R**,2**S**,5**R**)-2-isopropyl-5-méthylcyclohexyl, R^2 = Ph, **c**; R^1 = isopropyl et R^2_3 = Ph_2{(1**S**,2**S**,5**R**)-2-isopropyl-5-méthylcyclohexyl}, **d**) et on les a caractérisés par des analyses, incluant l'IR, la spectroscopie RMN du ^{1}H, ^{13}C{^{1}H} et du ^{31}P{^{1}H} ainsi que la diffraction des rayons X. On a déduit les principes de l'autoorganisation des conformations chirales à partir des données de structure.

Mots clés : carbonyles d'alkylcobalt, phénomène coopératif, intramoléculaire, chiralité, conformations.

[Traduit par la Rédaction]

Introduction

Alkyl- and acylcobalt carbonyls are key intermediates of C—C bond couplings involving CO (carbonylations). The interest in these compounds goes back more than a half century into the already legendary times of Roelen, Reppe, Hieber, and Heck (2–5). Beyond practical reasons relevant to great industrial processes, these compounds and their transformations represent highly interesting preparative and theoretical challenges, met by scientists such as Cotton, Markó, and Hoffman in the 1960s and 1970s (6–9). The fact that these intermediates remain not only interesting, but also *actual in the 21st century* is in great part due to the exceptionally rich, many-sided contribution of Howard Alper (10, 11), inventor and very successful practitioner of the combination of phase-transfer catalysis with transition-metal catalysis (PTC–TM).

One of the open questions of the chemistry of alkyl- and acylcobalt carbonyls is the "fine structure" of intramolecular interactions leading to the development of chiral and (or) diastereomeric conformations, which are primarily responsible for the transfer of chiral information from one ligand ("auxiliary") to the other ("substrate"). We prepared and analyzed a number of relevant alkylcobalt carbonyls in the last decade from this viewpoint (1, 12, 13), studying mostly chiral interactions among achiral fragments of these molecules. The results of these studies and some observations with molecules containing a center of chirality either in racemic (12*e*) or in enantiopure (12*a*, 12*d*, 12*g*) form indicated that a systematic study, based on X-ray structure deter-

Scheme 1.

minations, will provide additional elements for completing the picture of the intramolecular transfer of chirality. We present here detailed analysis of four alkylcobalt carbonyl complexes of this kind.

Experimental

All operations were performed according to the standard Schlenk techniques (14).

Starting materials were of commercial origin, with the exception of *S*-2-bromoacetoxypropionic acid ethyl ester (15), the bromoacetate of *d*-menthol ((1**S**,2**R**,5**S**)-2-isopropyl-5-methylcyclohexanol) and l-(*o*)-menthol ((1**R**,2**S**,5**R**)-2-isopropyl-5-methylcyclo-hexanol) (16), as well as of dicobalt octacarbonyl (17), which were prepared according to published procedures.

IR spectra were recorded with a Bruker FT-IR IFS 113 V spectrometer, ^{1}H-, ^{13}C{^{1}H}-, and ^{31}P{^{1}H} NMR spectra were recorded with Bruker DPX-200 and AMX-400 instruments.

The X-ray diffraction experiments were performed using a Siemens P4 X-ray four circle diffractometer with Mo Kα radiation at room temperature (r.t.). The SHELXTL-Plus program and SGI IRIS Indigo computer were used for calculations. Atomic scattering factors were taken from SHELXTL and the literature (18), as well as the correction for anomalous dispersion (19).

The alkylcobalt tricarbonyl *tert*–phosphine complexes **3a**–**3d** were prepared according to variants of the procedures described in a published method (20) (Scheme 1): (1) using ion metathesis; (2) ligand-promoted carbonylation; and (3) thermal decarbonylation steps in a one-pot mode.

Preparation of (S)-EtOC(O)C(H)(CH$_3$)OC(O)CH$_2$Co(CO)$_3$PPh$_3$ (3)

A solution of Na[Co(CO)$_4$] (2.00 mmol, prepared by Na–Hg reduction of $Co_2(CO)_8$, 342 mg, 1.00 mmol) in 30 mL of dry Et_2O was filtered into a 100 mL Schlenk vessel, under an Ar atmosphere. This solution was cooled to –30 °C, and then, while stirred *S*-2-bromoacetoxypropionic acid ethyl ester (478 mg, 2.00 mmol) was added at once. Immediately after this, the formation of a white precipitate (NaBr) started and the (originally colorless) solution turned gradually yellow then brown. The stirring was continued for 2 h at –30 °C and then the reaction mixture was left to warm to room temperature (r.t.). At r.t., the stirring was continued for an additional 1 h. After this period, a liquid sample was taken for spectroscopic analysis. The IR ν(CO) spectrum showed the

complete disappearance of the strong, broad band of $[Co(CO)_4]^-$ at ~1900 cm^{-1} and the emergence of a new band system compatible with an $XCo(CO)_4$ type complex (1, 7, 11, 12, 20, 21). This complex was characterized as $R^1OC(O)CH_2Co(CO)_4$ (R^1 = EtOC(O)CH(CH_3)-) (**1a**) on the basis of its IR and NMR spectra (Table 1). Complex **1** was not isolated.

The reaction mixture was then filtered and to the filtrate, with stirring at r.t. and under an Ar atmosphere, $P(C_6H_5)_3$ (525 mg, 2.00 mmol) was added in one portion. The stirring was then continued for an additional 8 h, and after 2 h the color of the brown solution turned gradually light yellow and gas evolution (CO) was observed. After this period, a sample was taken, which was analyzed by IR spectroscopy, conducted in the CO stretching range (2200–1600 cm^{-1}). The only detectable metal carbonyl species showed a ν(CO) band system characteristic for an $XCo(CO)_3L$ type complex (12, 20–22), and it was attributed[4] to $R^1OC(O)CH_2Co(CO)_3PPh_3$ (**3a**). Then the reaction mixture was filtered and the solvent was evaporated at r.t. under reduced pressure. The crude product (673 mg, 60.9%) was then recrystallized from diethyl ether – *n*-hexane (liquid diffusion) providing light yellow crystals (473 mg, 42.8%). Complexes **3b**–**3d** were prepared similarly. The products **3** were characterized by elemental analyses (Table 2), IR, ^1H-, $^{13}C\{^1H\}$-, and $^{31}P\{^1H\}$ NMR (Table 3), and X-ray diffraction (Tables 4 and 5).[5]

Results and discussion

In the mononuclear series, complexes of the $ROC(O)CH_2Co(CO)_3PPh_3$ (**3**) type, with R = achiral alkyl

(12*f*, 12*h*, 12*i*), (racemic) *sec*-butyl (12*e*) and glucosyl groups (12*g*) were studied previously. The particular self-organization of these complexes is due to the concerted rotation of more groups around some single bonds, which opens relatively low activation energy paths (12*i*). As a consequence of this situation, transmission of chiral information though the achiral fragments of these molecules was observed. These (thermal) processes are *reversible* and *free of errors*, therefore always yielding racemates. The cooperation of the forces governing these self-organization processes results in concerted intramolecular displacements, very similar to movements in mechanical clockworks (Scheme 2). Experience with the (*R*,*S*)*s*-Bu (12*e*) and glucosyl (12*g*) derivatives indicated that the study of complexes with centers of chirality in the molecule may lead to interesting new effects (not necessarily the "expected" ones). This experience was the basis of the selection of the structures investigated in the present work: thus, compounds with (*i*) a flexible ester "alkyl" group with polar fragments and one center of chirality (**3a**); (*ii*) flexible apolar (not too bulky) alkyl groups with more (three) stereogenic units (**3b**, **3c**); and (*iii*) a (configurationally) chiral group in the phosphine ligand (**3d**), were chosen.

The preparative access to these molecules was developed on the basis of earlier experience with similar compounds (12, 20), using a one-pot variant, without isolation or detailed characterization of intermediates **1** and **2**. High yields of complexes **3** were obtained without attempt at optimization of the yield. No cobalt carbonyl species other than complexes **3** were detected after rxns. [1]–[3] were completed (Scheme 1). Spectroscopic analysis of the reaction mixture during the reaction and immediately after did not reveal isomers (equatorial?) other than the ones later characterized in the end-products **3a**–**3d** (cf. refs. 1, 7, 20, 21). X-ray crystal and molecular structure determination was performed for all **3a**–**3d** complexes.

The overall molecular structures of complexes **3** show a trigonal bipyramidal array with the non-carbonyl ligands in axial (trans) positions and the carbonyls in a slightly bent equatorial plane, turning its concave face toward the alkyl ligand. This picture is similar to the geometry of several other $XCo(CO)_3L$ type complexes (1, 12, 20–22). The preferential development of the trans-(bis-axial)-trigonal bipyramidal geometry in complexes **3** is a fortunate circumstance for the analysis of the mechanisms of the interaction of the conformations of ligands in the two opposite positions on the metal.

The crystal lattices of complexes **3a** and **3d** contain only one conformer of the complex (both are $P2_12_12_1$ phases), while **3b** and **3c** both form a $P2_1$ phase, with two independent molecules (each) in these lattices. All complexes contain four molecules in the elementary cell.

A comparison of the behavior of complexes **3a** and **3d** with that of the **3**, R = achiral alkyl (12*h*) (*R*,*S*)*s*-Bu (12*e*) and glucosyl (12*g*) derivatives, gives a strong indication for the supposition that the "racemates" of the conformational

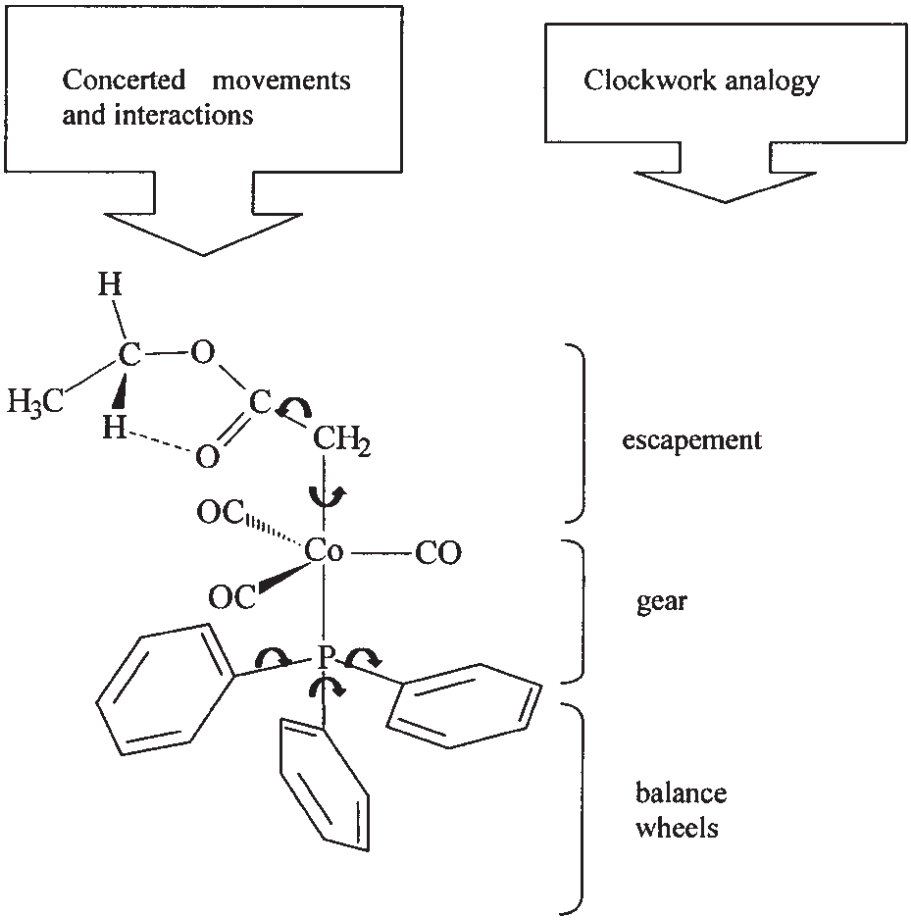
isomers of the ester and phosphine groups are "resolved" by the introduction of permanent centers of chirality into the ligands. This, however, *does not lead necessarily* to the formation of only one isomer (conformer). If the steric conditions permit, additional (diastereomeric) forms develop, as in the case of the two menthylester derivatives **3b** and **3c**. The loss of helicity in the phosphine ligand at the glucosyl derivative (12*g*) as well as the development of the two diastereomers (each) in the menthylester complexes **3b** and **3c** indicates that the presence of more centers of configurational chirality does not necessarily promote the formation of the "most chiral" product. This is a problem that one encounters in preparative (empirical) attempts in terms of observing the more or less "efficiency" of additives used for the induction of chirality.



The individual features of the structural details of complexes **3a**–**3d** require some comments.

The structure of complex **3a** (Fig. 1) is primarily characterized by the remarkable nonequivalence of the (ligand) carbonyl angles OC-Co-CO: 125.8°, 118.0°, 115.5°. The broadest of these angles is certainly due to the bulkiness of the organic ligand, which is organized in a very particular manner. First of all, it is to be noted that in this long, flexible organic ligand, with six σ bonds that could generate several new conformers, *only one conformer* develops in the $P2_12_12_1$ phase. This conformer is characterized by a very symmetric orientation with respect to the rest of the molecule, as it can be seen through the dihedral angle between the main axis of the "lactic acid" fragment and the anti-CO ligand: –178.3° (almost a straight line!). The other interesting feature is the short (ester) carbonyl-O vs. α-(alkyl)C distance (C10-O8, 269.4 pm) indicative for the formation of the C(sp^3)H vs. > C=O hydrogen bond, similarly as has been found with other derivatives **3** with (ester)-α-CH groups (12*e*, 12*g*, 12*h*). The H bridging generates a *new center of chirality* on C10 (Fig. 1). It is a highly interesting feature of this structure that the new center of chirality on C10 is generated only in one enantiomeric form ("**R**"). The phosphine ligand in complex **3a** shows only one helical conformation (**M**), where the phenyl ring orientations are somewhat different from those observed at the achiral alkyl (12*h*) and *s*-Bu (12*e*) derivatives. The difference is mostly in the orientation of the C16–C21 ring, which is more "steep" than usual. This can be caused by an additional H-bridge interaction between the C17 and O8 atoms (C17—O8 distance 269 pm, C17-H17-O8 angle 152.2°), which may be one of the factors contributing to the stabilization of the astonishingly selective organization of the conformation in the ester fragment of complex **3a**. An additional "through-space" intramolecular interaction can be identified between the C5 and the Co atoms. This "enforced" interaction (distance 293.9 pm) renders the C5 atom tetracoordinated, with four different substituents (Co, O5, O6, C4) and, therefore, generates a new center of chirality on this atom. Since in the $P2_12_12_1$ phase, the C5,O5,O6 carboxyl group turns only its si face towards the Co atom, the new center of chirality will be (with quantitative enantioselectivity) of **S** configuration. This kind of intramolecular interaction (23) was detected by X-ray structural studies in some analogous molecules (12, 20*a*) as well as analyzed by MO calculations (23*c*, 23*f*) that showed that a considerable electron density transfer occurs between the C5,O5,O6 and the Co atoms. These particular interactions lead to a dramatic diminution of the number of "statistically" possible conformers. Regarding only **P** and **M** for the PPh_3 ligand, si or re (turned towards Co) for the C5-centered ester group, as well as **R** or **S** for the C10 atom, this gives eight combinations and *only one* (12.5%) in 100% enantiomeric yield, gets realized under the influence of the permanent **S** configuration on C6 with the aid of the supramolecular forces.

The considerations described earlier in this paper on the structure of complex **3a** are reflecting the situation in the condensed $P2_12_12_1$ phase. Since most of the reactions where alkylcobalt carbonyls are important intermediates are displayed in solution or vapor phase (9), we made an attempt at exploring whether the highly interesting structural features observed in the crystalline phase are to be taken into account in the solution and (or) gas phase. The results are not conclusive: (*a*) the IR ν(CO) frequencies of both "organic" carbonyl groups observed in apolar solvents (Table 3) are compatible with C-H···O and =O···C interactions; (*b*) the

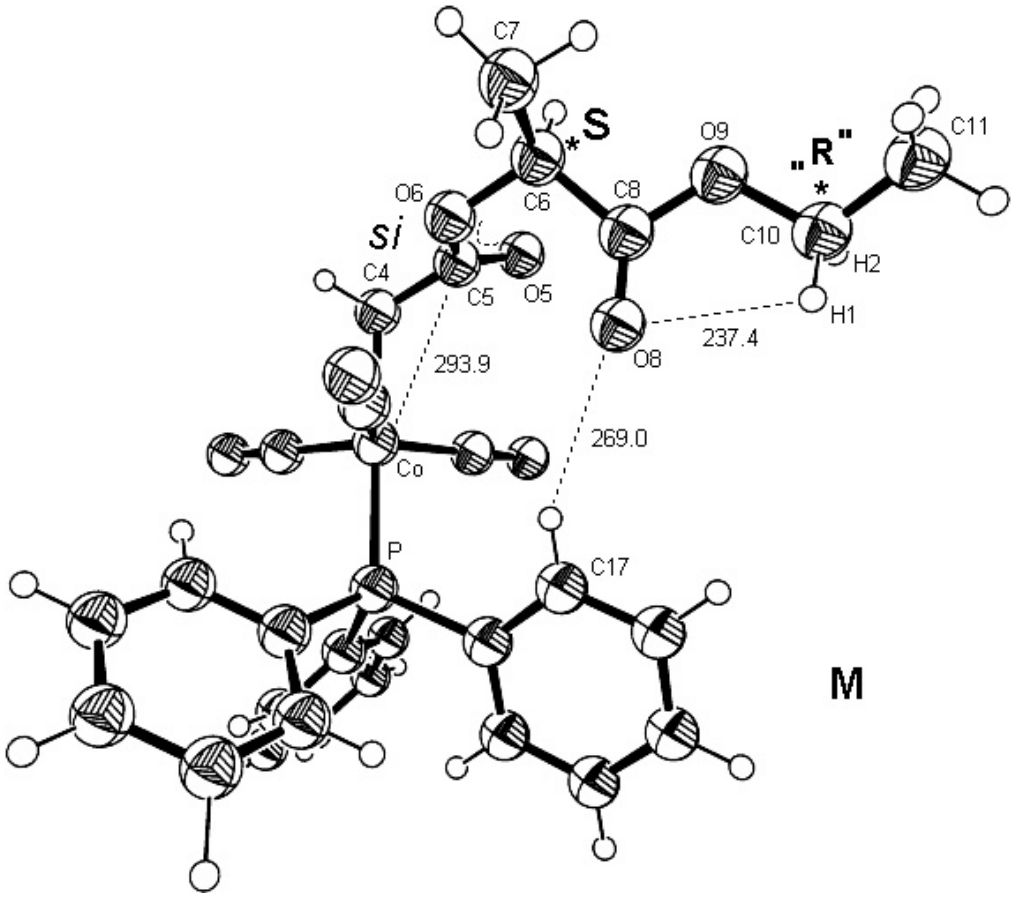
Scheme 2.

ABX type signal observed (in acetone-d_6) for the CH_2 group directly bonded to the Co atom in the ^{1}H NMR spectrum may represent an additional proof for the "survival" of the chiral conformation detected in the crystalline phase, but because of a center of chirality on C6 this may (even: should) have (also) intrinsic reasons; (*c*) the ^{1}H NMR spectrum of protons on C10 and the ^{13}C NMR signal of the coordinated carbonyls are indicating free rotation (at least on the NMR timescale at r.t.).

The X-ray structure of the menthylester complexes **3b** and **3c** provided an entirely new and highly interesting picture. This is characterized by the fact that both compounds (in the $P2_1$ phase) appear as pairs of diastereomers, each of which are characterized by the different orientations of the 5-methyl group (farther from ↑ or closer to ↓ the Co atom, or ↑↓: the 5-Me group of the menthyl fragment lies in or farther away from the equatorial plane) as well as by *enantiomeric configurations* developing in the rest of the molecules (Fig. 2). The four combinations found experimentally in the crystalline phase are **L**↑*re***P**, **L**↓*si***M**, and **D**↓*re***P**, **D**↑*si***M**, while the other 12 combinations are completely lacking. This is the first instance when diastereomer pairs are found to form the unit cells of compounds **3**.



One of the most interesting features of these structures is the fact that *each of the enantiomers appear separately in different crystals*: e.g., the chiral **L**↑*re***P** molecule is in the elementary cell of **3c** while its enantiomer **D**↑*si***M** is in the lattice of complex **3b**.

Both complexes **3b** and **3c** develop H bonding between the alkyl-α-H atom and the O sp^2 atom of the carboxyl group. The five-membered, H-bonded, nonplanar rings thus formed show enantiomeric configurations characterized by exactly the same bond lengths and angles and equal dihedral angles (with opposite signs) as shown in Fig. 3 and Table 6. Since the C6 atom in the menthyl group is already chiral, the H bonding does not generate a new center of chirality as it was observed at the "outer" ester group of complex **3a** (this work) as well as at the ethyl and *n*-propylester derivatives in earlier studies (12*h*, 12*i*). It is worth noting that the distances and angles around the C-H···O bridge show an *excellent agreement among the enantiomers in different crystals* (Table 6).

The "enforced" vicinity of the carboxylic C5 and the Co, i.e., the Co···C5 (O5,O6) coordination reproduces the C5—Co distances rather efficiently (**3b** 296.2 pm, **3c** 296.9 pm). This effect generates new centers of chirality on C5 (*si*→**S** and *re*→**R**) and on the Co atom. The chiral perturbation of the metal atom is reflected also in the low-energy CD bands of complexes **3c** and **3d** (12*a*). The ABX type signal of the α-CH_2 groups in the ^{1}H NMR spectra of these complexes provide important hints at the survival of the supramolecular effects also in the solution phase.

Fig. 1. Thermal ellipsoids are shown at the 90% probability level for the X-ray crystal structure of complex **3a**.

Compound **3d** was synthesized to test the effect of a chiral organic rest in the phosphine ligand. The X-ray structure of complex **3d** shows a bis-axial tbp overall geometry, which is similar to the previous complexes **3a**–**3c** (see also refs. 12*c*–12*j*, 21*b*–12*e*, 22). In the chiral $P2_12_12_1$ phase, the elementary cells contain four *identical* chiral molecules **3d** (Fig. 4). These are characterized by the following structural features: (*a*) the autosolvation-type (23) interaction between the carboxyl-C sp^2 atom and the Co seems to be justified again by the relatively short C5—Co distance (295.1 pm). The carboxyl group is turned with its re side towards the Co atom, and acquires **R** configuration by its interaction with the metal; (*b*) the bulky neo-menthyl group has heavily distorted the structure of the phosphine ligand, especially the arrangement of the two phenyl blades with their corresponding torsion angles of –72.5° and –12.6°. The helicity is nearly collapsed, but it is still possible to assign the **P** configuration and the average of the corresponding dihedral angles is about the ideal value (–46.5°). This *re***P** configuration is the "diastereomer" of the triphenyl phosphine analogue (12*c*) (*si***P**, *re***M**, Fig. 4); (*c*) one of the (O)C-Co-C(O) angles opens up to 123.6° to accommodate a bulky menthyl group, and capitalizing on the occasion, the ester group also organizes itself into this segment, eclipsing with the menthyl group. The two isopropyl groups are found in surprisingly close vicinity to each other; (*d*) the chiral alkyl (neomenthyl) group introduced into the phosphine ligand is inducing the inversion of the coordinated ester fragment from si to re and achieving a 100% enantioselection with respect to the possible stereoisomers; (*e*) similarly to other esters containing an α-CH unit (**3b** and **3c**, refs. 12*e*, 12*i*), H bonding between the C7 and O5 atoms can be identified; (*f*) the fundamental difference between the conformations of complexes **3b** and **3c** vs. complex **3d** is rooted in the difference between the rotational freedoms of the (otherwise very similar) organic groups bearing central chirality in **3b** and **3c** with respect to **3d**.

Most of our earlier studies on the mechanism of the intramolecular transfer of chiral information concerned the recognition and self-organization of conformationally invertible stereogenic units. The origin and the major driving force of these phenomena are the new co-ordination type of the prochiral ester group of the compounds **3** that may be influenced significantly by the structure of the corresponding alkoxide group. The stereoselectivity of the self-organization of these compounds may be fundamentally enhanced by the introduction of a permanent configurational chirality in the alkoxide group. The behavior of compound **3a**, as well as of (**R**, **S**)*s*-BuOC(O)CH_2Co$(CO)_3PPh_3$ (12*e*), shows clearly that *only one center of configurational chirality is sufficient* to generate the lowest possible number (one) of chiral conformations. Some sort of the combined effect of the various structural characteristics is transferred from the ester group to the trans axial ligand determining its energetically most favorable helical configuration. Due to this combined steric effect, more centers of chirality, as in the case of compounds

Fig. 4. Comparison of the structures of complexes **3d** and *i*-PrOC(O)$CH_2Co(CO)_3PPh_3$ (12*c*).

3b and **3c**, do not necessarily lead to the development of "more chiral" conformations. Even more, under certain conditions (e.g., steric repulsion) may produce "less chiral" states, as was recently observed with the glucose ester derived analogue of complexes **3** (12*g*). Now, this time we demonstrate that introducing a chiral hydrocarbon group into one of the distant trans axial positions, the chiral induction is efficiently channeled through the molecule to the other axial ligand.

The result is convincing: the intramolecular transmission of the chiral information is a two-way process and provides an easily accessible model of the transition state and for the mechanism of chiral phosphine induced, metal-catalyzed asymmetric syntheses.

The results described in this paper and in some previous reports (12) seem to support our initial hopes that a systematic study of the development of chiral conformations in transition-metal complexes might produce some useful principles for the "engineering" of sufficient systems for enantioselective catalysis. We believe, in this respect, it is not enough to develop chiral ligands, but it is also necessary to study the active complex(es) of the catalytic cycle. Our groups are working on the analysis of additional suitable models in this respect.

Synthesis and reactivity of the macrobicyclic complexes (1,5,8,12-tetraaza-17-oxabicyclo[10.5.2]-nonadecane)cobalt(III) perchlorate ($[Co(L_1)(ClO_4)](ClO_4)_2$), [(chloro(1,4,8,11-tetraaza-17-oxabicyclo-[9.5.3]nonadecane)cobalt(III) perchlorate ($[Co(L_2)(Cl)](ClO_4)_2$), (4,8-dimethyl-1,4,8,11-tetraaza-17-oxabicyclo[9.5.3]nonadecane)cobalt(III) perchlorate ($[Co(L_3)(ClO_4)](ClO_4)_2$), and (5,8-dimethyl-1,5,8,12-tetraaza-17-oxabicyclo[10.5.2]nonadecane)cobalt(III) perchlorate ($[Co(L_4)(ClO_4)](ClO_4)_2$) — Crystal structure of the L_2 complex[1]

Theo Rodopoulos, Koji Ishihara, Mary Rodopoulos, M.J. Zaworotko, M. Maeder, and A. McAuley

Abstract: The potentially penta-coordinating ligands L_2 and L_3 have been synthesized by reaction of the 10-membered macrocycle 1,5-diaza-8-oxacyclodecane with either 1,9-dichloro-3,7-diazanonane-2,8-dione, and subsequent reduction of the diamide (**3**), or with 1,9-dichloro-3,7-(dimethyl)diazanonane-2,8-dione and reduction (L_3). A similar procedure is outlined for the dimethylated macrobicycle (L_4), based on the corresponding nine-membered 1,4-diaza-7-oxacyclononane. The Co(III) complexes of these ligands and of 1,5,8,12-tetraaza-17-oxabicyclo[10.5.2]nonadecane (L_1) have been prepared. Spectrophotometric determinations on the L_1 complex ion confirm the presence of two hydrogen ion related equilibria, one of which ($pK = 2.2 \pm 0.2$) is associated with the proposed replacement of the apical ether oxygen by a water molecule that is bound to the metal centre and hydrogen bonded to the ether. The species derived from L_1 and L_2 exhibit remarkable kinetic stability. Studies on the anation of the $[Co(L_1)(H_2O)](ClO_4)_3$ with chloride ions in acidic media are consistent with the reaction of both the proton-related complex and the $[Co(L_1)(H_2O)]^{3+}$ ion. Whilst complex ions containing two secondary NH groups maintain the metal–ion coordination in strongly acidic media, corresponding species with ligands containing all four tertiary amine sites are subject to attack by protons leading to a relatively facile demetallation of the complexes. The latter finding is supported by kinetic studies and mass spectrometric fragmentation patterns of the ions.

Key words: cobalt(III), macrobicycle, hydrolysis, anation, spectroscopic analysis.

Résumé : Les ligands L_2 et L_3 qui pourraient donner lieu à une pentacoordination ont été synthétisés en faisant appel à la réaction du macrocycle à dix chaînons 1,5-diaza-8-oxacyclodécane avec la 1,9-dichloro-3,7-diazanonane-2,8-dione

et réduction subséquente du diamide cyclique (**3**) ou avec la 1,9-dichloro-3,7-(diméthyl)diazanonane-2,8-dione suivie d'une réduction (L_3). On décrit une méthode semblable pour le macrobicycle diméthylé (L_4) qui est basée sur le composé à neuf chaînons 1,4-diaza-7-oxacyclononane. On a préparé les complexes du cobalt(III) avec ces ligands et avec le 1,5,8,12-tétraaza-17-oxabicyclo[10.5.2]nonadécane (L_1). Des déterminations spectrophotométriques sur le complexe L_1 confirment la présence de deux équilibres apparentés des ions hydrogènes, dont l'un (pK = 2,2 ± 0,2) est associé au remplacement proposé de l'oxygène de l'éther apical par une molécule d'eau qui est liée au centre métallique et relié à l'éther par une liaison hydrogène. Les espèces qui dérivent des ligands L_1 et L_2 présentent une stabilité cinétique remarquable. Des études d'anation du $[Co(L_1)(H_2O)](ClO_4)_3$ avec des ions chlorures en milieu acide sont en accord avec une réaction du complexe lié par un proton et l'ion $[Co(L_1)(H_2O)]^{3+}$. Alors que les ions complexes comportant deux groupes NH secondaires maintiennent la coordination métal–ion en milieu fortement acide, les espèces correspondantes comportant des ligands sur chacun des quatre sites amines tertiaires sont sujettes à des attaques par des protons ce qui conduit à une démétallation relativement facile des complexes. Cette dernière observation est supportée par des études cinétiques et par les patrons de fragmentation en spectrométrie de masse des ions.

Mots clés : cobalt(III), macrobicycle, hydrolyse, anation, analyse spectroscopique.

[Traduit par la Rédaction]

Introduction

The synthesis of novel macrocyclic and polymacrocyclic ligands and the significant thermodynamic and kinetic stability imparted by them upon metal ion complexation has been a feature of interest for over two decades (1–5). Such species are now found in a variety of chemistries from competitive anion binding sites (6), multimacrocyclic luminescent arrays (7), and polynuclear complexes of pendant-arm ligands with unusual spin states (8). Reports from previous investigations from this laboratory have described macrobicyclic systems involving five-coordinate Cu(II) complexes (9) and six-coordinate Ni(II) (10, 11) species of L_1 and L_2, where, in the latter, the d^8 ion, being octahedral, exhibits a single substitution site. Such species exhibit extraordinary kinetic stability, with no detectable decomposition over days even in strongly acidic (4 mol/L) media. In addition, spectroscopic observations are consistent with the formation of nickel(III) species of sufficient lifetimes to permit kinetic measurements not only of redox reactions (12), but also, in some instances, the Ni(III) ions formed are sufficiently stable kinetically to permit rate studies of substitution by chloride (13). Hydrogen-ion dependences in these investigations are consistent with an unusually strongly acidic proton-related equilibrium associated with the ether linkage (13, 14). In this paper, we present the results of comparable studies of analogous cobalt(III) complexes where the d^6 ion imparts much greater kinetic stability than the nickel(III) ion, providing an opportunity to examine not only kinetic features, but also to spectroscopically identify species involved in the various proton-related equilibria. Included are kinetic observations involving a tetra-*N*-substituted macrobicycle where the stability in acidic media is diminished owing to protonation at the *N*-methyl tertiary amines competing with the complexation at the metal centre.

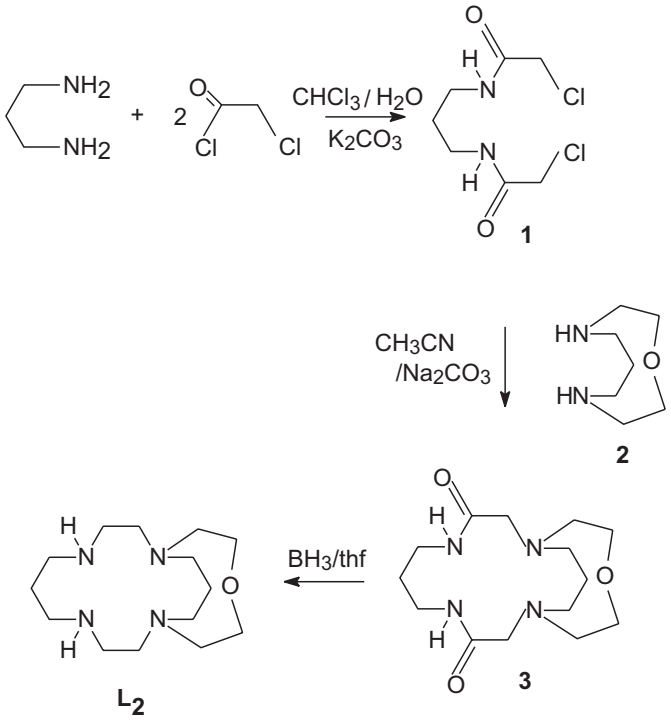
Experimental

The literature method was used to prepare 17-oxa-1,5,8,12-tetraazabicyclo[10.5.2]nonadecane (L_1) (11). The ligands 17-oxa-1,4,8,11-tetraazabicyclo[9.5.3]nonadecane (L_2), 4,8-dimethyl-1,4,8,11-tetraaza-17-oxabicyclo[9.5.3]nonadecane (L_3), and 5,8-dimethyl-1,5,8,12-tetraaza-17-oxabicyclo-[10.5.2]nonadecane (L_4) were synthesized as indicated in the following. Acetonitrile (Caledon) was fractionally distilled from CaH_2 and stored under nitrogen. Water, with a specific resistance of >15 MΩ cm was prepared using a MilliQ-Reagent system. $Co(ClO_4)_2{\cdot}6H_2O$ was synthesized from $CoCO_3{\cdot}xH_2O$ (Aldrich) through reaction with the stoichiometric amount of $HClO_4$. The perchlorate salt was recrystallized three times from water, dried under high vacuum for 48 h at room temperature, and stored over $CaSO_4$ in a desiccator. Ethanol (Commercial Alcohols, 100%), activated charcoal (Sigma, 250–350 mesh), $HClO_4$ (Allied Chemicals, 70% assay), HCl (Anachemia, 36.5%–38.0% assay), $NaClO_4{\cdot}H_2O$ (Fisher Scientific), NaOH (BDH), PbO_2 (BDH), D_2O (Cambridge Isotope Laboratories), and CD_3CN (Cambridge Isotope Laboratories) were all used as purchased. Mass spectra were recorded on a Kratos Concept mass spectrometer in the LSI-MS mode. The matrix employed in all cases was *m*-nitrobenzyl alcohol. Bruker WM-250 and AC-300 NMR spectrometers were used to record the ^1H and ^{13}C NMR spectra. ^{13}C NMR chemical shifts are referenced to the residual methyl carbon in incompletely deuterated CD_3CN (δ (CH_3CN) = 1.30 ppm) and ^1H NMR chemical shifts to the residual protons in incompletely deuterated D_2O (δ (H_2O) = 4.70 ppm). Elemental analyses were performed by Canadian Microanalytical Services, Vancouver, British Columbia, Canada.

Synthesis

(1,5,8,12-Tetraaza-17-oxabicyclo[10.5.2]nonadecane)cobalt(III) perchlorate ($[Co(L_1)(ClO_4)](ClO_4)_2$)

Ligand L_1 (0.299 g, 1.106 mmol) was dissolved in dry, distilled acetonitrile (30 cm^3) and an equivalent of cobalt(II) perchlorate hexahydrate (0.405 g, 1.106 mmol) was added with stirring. The solution was acidified to approximately pH 3 with $HClO_4$ and an excess of lead(II) oxide (0.400 g, 1.672 mmol) added. Upon bubbling the mixture with air overnight, a maroon solution was obtained. The mixture was centrifuged and the excess solid lead(II) oxide filtered leaving the maroon-coloured solution. Concentration of the filtrate to approximately 10 cm^3 and cooling in an ice bath resulted in the precipitation of a red solid. Crystallization of the complex was achieved by redissolution of the solid in the minimum amount of acetonitrile and allowing the solution to



© 2005 NRC Canada

evaporate slowly. Yield: 0.165 g (24%). ^{13}C NMR (D_2O): 75.7 (-*C*H_2-O-), 61.4, 58.0, 55.3, 53.2, 46.9 (-*C*H_2-N-), 24.45 (-C-*C*H_2-C-). Anal. calcd. for $[Co(C_{14}H_{30}N_4O)(ClO_4)](ClO_4)_2$ (%): C 26.79, H 4.82, N 8.93; found: C 26.77, H 4.87, N 9.54.

17-Oxa-1,4,8,11-tetraazabicyclo[9.5.3]nonadecane (L_2)

The synthesis was carried out as shown in Scheme 1.

Scheme 1.

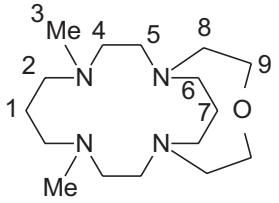
1,9-Dichloro-3,7-diaza-nonane-2,8 dione (1)

Propylenediamine (4.88 g, 0.0567 mol) was added under constant stirring to a mixture of $CHCl_3$ (69 mL) and H_2O (34 mL) and cooled in an ice bath. A mixture of chloroacetyl chloride (13.9 mL, 0.172 mol) in $CHCl_3$ (86 mL) and K_2CO_3 (22.36 g, 0.162 mol) in water (860 mL) were added simultaneously under a nitrogen atmosphere over a 1 h period. The reaction mixture was stirred at room temperature for a further 2 h. The $CHCl_3$ layer was separated, washed with water (2 × 100 mL), and dried over $MgSO_4$. Removal of solvent yielded a colourless oil that was dried in vacuo overnight. Upon addition of CCl_4 and cooling overnight, a white solid precipitated. Filtration and concentration of the solution followed by a further addition of CCl_4 afforded a second crop of material. The diamide (**1**) was dried under vacuum. Yield: 9.01 g, 70%. The material was used as such. ^{1}H NMR (D_2O): 7.2 (N-*H*), 4.1 (-C*H*$_2$-C(O)-), 3.4 (C*H*$_2$-NH), 1.8 (-C-C*H*$_2$-C-). ^{13}C NMR ($CDCl_3$): 170.1 (-*C*=O), 42.7 (*C*H_2-NH), 37.4 (-*C*H_2-C(O)-), 27.9 (-C-*C*H_2-C-). ^{13}C NMR (D_2O): 169.7 (-*C*=O), 42.2 (*C*H_2-NH), 37.0 (-*C*H_2-C(O)-), 27.5 (-C-*C*H_2-C-).

Cyclization with the free macrocycle, 1,5-diaza-8-oxacyclodecane (**2**), was carried out in basic acetonitrile. Doubly distilled acetonitrile (2.5 L) was placed in a 5 L four-necked flask fitted with a stirring attachment and a condenser and two septa for syringes. A stream of N_2 was attached and Na_2CO_3 (2.402 g, 22.66 mmol, 3.16 equiv.) was added to the bulk CH_3CN. The macrocycle **2** (1.036 g, 7.183 mmol) was dissolved in 200 mL of dry CH_3CN. Diamide **1** showed limited solubility in acetonitrile and only 0.408 g (1.797 mmol) was dissolved in 50 mL of solvent. The CH_3CN–Na_2CO_3 solution was heated to reflux and 50 mL each of the reactant solutions **1** and **2** were added slowly (four portions) over a period of 40 h. Reflux was continued for another 24 h. After filtration of the Na_2CO_3, the acetonitrile was removed in vacuo leaving a yellow, quasi-crystalline solid. Dissolution in $CHCl_3$ removed the residual amounts of diamide impurity yielding a yellow crystalline solid **3**. Yield: 2.07 g, 96%. ^{13}C NMR ($CDCl_3$): 174.8 (-*C*=O), 66.7 (*C*H_2-O-), 62.1, 57.4, 55.9 (*C*H_2-N), 37.4 (-*C*H_2-CH$_2$-NH-), 29.8, 27.7 (-C-*C*H_2-C-). MS: 299 $(M + 1)^+$.

The fully saturated macrocycle (**L_2**) was prepared by addition of a solution of BH_3·THF (100 mL) to a solution of **3** (1.002 g, 3.358 mmol) in dry THF (30 mL) and refluxing for 24 h. After cooling to room temperature, excess borane was destroyed with water. Upon removal of the solvent under vacuum, the white solid formed was treated with 6 mol/L HCl and refluxed for 3 h. Upon cooling, basification with KOH pellets to pH 14 and extraction with $CHCl_3$, the solution was dried, filtered, and the solvent removed, yielding a slightly yellow oil. Yield: 0.742 g, 82%. ^{13}C NMR ($CDCl_3$): 73.6 (-*C*H_2-O), 58.5, 58.1, 56.9 (*C*H_2-N), 47.8, 47.3 (-*C*H_2-*C*H_2-NH-), 28.2, 28.1 (-C-*C*H_2-C-).

[(Chloro)(1,4,8,11-tetraaza-17-oxabicyclo[9.5.3]nonadecane)cobalt(III)] perchlorate ([Co(L_2)(Cl)](ClO_4)$_2$)



An aqueous solution of cobalt(II) perchlorate hexahydrate (0.134 g, 0.366 mmol) was added to a refluxing ethanol–H_2O (4:1, 30 cm^3) solution of the ligand L_2 (0.099 g, 0.366 mmol). The resulting solution turned green almost instantaneously. A catalytic amount of activated charcoal was then added and the solution refluxed for 2 h. After cooling, air was bubbled through the mixture for several hours yielding a purplish-red solution. The charcoal was filtered off and the solvent removed under reduced pressure. An aqueous solution of the crude complex was purified by passage down a Dowex 50W-x8 (50–100 mesh) exchange column. The complex was eluted with 6 mol/L HCl and the eluate evaporated to dryness, leaving a green solid, which was recrystallized from a hot aq. 0.2 mol/L $NaClO_4$ (10 cm^3) solution, collected, washed with ethanol and diethyl ether, and air dried. Yield: 0.082 g, 40%. ^{13}C NMR (D_2O): 82.4 (-*C*H_2-O-), 67.4, 58.7, 58.0, 52.7, 50.1 (-*C*H_2-N-), 27.8, 24.0 (-C-*C*H_2-C-). Anal. calcd. for $[Co(C_{14}H_{30}N_4O)(Cl)](ClO_4)_2$·$H_2O$ (%): C 28.91, H 5.54, N 9.63; found: C 28.94, H 5.24, N 9.64.

Neutralizing an aqueous solution of the monochloride complex with 0.1 mol/L NaOH solution resulted in a colour change from green to orange-red. Leaving the solution open to the atmosphere to allow the solvent to evaporate slowly yielded the purple perchlorate complex, $[Co(L_2)(ClO_4)](ClO_4)_2$, which was filtered out, washed with ethanol, and air dried.

4,8-Dimethyl-1,4,8,11-tetraaza-17-oxabicyclo[9.5.3]nonadecane (L_3)

The ligand, with no ionizable protons, was prepared in a manner similar to that shown for L_2 (Scheme 1, vide supra). *N*,*N*′-Dimethylpropylenediamine (5 g, 0.0489 mol) was added

© 2005 NRC Canada

L3

under constant stirring to a mixture of $CHCl_3$ (69 mL) and H_2O (34 mL) and cooled in an ice bath. A mixture of chloroacetyl chloride (22.11 g, 0.1957 mol) in $CHCl_3$ (86 mL) and K_2CO_3 (22.36 g, 0.162 mol) in water (860 mL) was added simultaneously under a nitrogen atmosphere over a 1 h period. The reaction mixture was stirred at room temperature for a further 2 h. The $CHCl_3$ layer was separated, washed with water (2 × 100 mL), and dried over $MgSO_4$. Removal of the solvent yielded a colourless oil that was dried in vacuo overnight. Upon addition of CCl_4 and cooling overnight, a white solid precipitated. Filtration and concentration of the filtrate followed by a further addition of CCl_4 afforded a second crop of material. The diamide **4** was washed with ethanol and dried. Yield: 9.5 g, 76%. The NMR spectrum showed the presence of several isomers. ^{13}C NMR ($CDCl_3$): 166.2, 166.7 (-*C*=O), 45.7, 45.6 (*C*H_2-NMe), 41.0, 41.4, 41.6 (-*C*H_2-C(O)-), 24.3, 26.6 (-C-*C*H_2-C-).

To a solution of the bis(chloro)diamide **4** (1.718 g, 6.73 mmol), in dry distilled CH_3CN (200 mL), was added sodium iodide (5.548 g, 37.01 mmol). The macrocycle **2** (0.971 g, 6.73 mmol) was dissolved in dry distilled CH_3CN (200 mL) and solutions of the reagents **4** and **2** were added very slowly (over a 24 h period) under N_2 in 50 mL batches to a refluxing solution of dry distilled acetonitrile (2.5 L) containing Na_2CO_3 (9.415 g, 88.83 mmol). Heating of the mixture, now orange coloured, was continued for a further 10 h, and the mixture was cooled overnight. Filtration under nitrogen, removal of the solvent, and addition of $CHCl_3$ (250 mL) yielded an orange solution and an off-white solid. After washing with water and further addition of $CHCl_3$, the solution was dried (Na_2SO_4), filtered, and the solvent removed yielding an orange-brown oil that was dried under high vacuum overnight. The cyclised diamide, 4,8-dimethyl-1,4,8,11-tetraaza-17-oxabicyclo[9.5.3]nonadecane-2,9-dione (**5**), solidified as a yellow, crispy honeycomb that was quite hygroscopic. Yield: 2.0 g, 90%. MS: 327 $(M + 1)^+$.

The crude diamide **5** (2.5 g, 10.46 mmol) was transferred to a 1 L flask using dry, freshly distilled THF (170 mL). After addition of the BH_3·THF complex (340 mL, 1 mol/L), the solution was refluxed for 24 h and cooled to room temperature. The solution was cooled in ice water to quench the remaining borane. Evaporation to dryness in vacuo gave a cream-coloured solid to which was added 6 mol/L HCl (140 mL), and this solution was heated to reflux for 3 h. Cooling in ice followed by the addition of KOH pellets to pH ~ 14 and extraction with $CHCl_3$, and filtration, gave a pale-yellow solution of the macrobicycle $\mathbf{L_3}$. Upon drying under high vacuum, a yellow oil formed. The product after work-up (1.944 g, 85%) was observed to be a mixture. Purification was achieved by preparation of the corresponding copper(II) complex[3] (0.642 g) followed by decomplexation of the metal ion by use of Na_2S (9). The final yield of $\mathbf{L_3}$ was 0.426 g (21% from macrocycle **2**). ^{13}C NMR ($CDCl_3$): 72.1 (*C*H_2-O), 56.6, 56.2, 56.0, 55.5, 54.7 (*C*H_2-N), 43.2 (N-*C*H_3), 26.6, 25.8 (CH_2-*C*H_2-CH_2). MS: 298 (M^+), 299 $(M + 1)^+$, 327 $(M + 29)^+$.

4,8-Dimethyl-1,4,8,11-tetraaza-17-oxabicyclo[9.5.3]nonadecane-cobalt(III) perchlorate ($[Co(L_3)(ClO_4)](ClO_4)_2$)

The ligand $\mathbf{L_3}$ (0.132 g, 0.442 mmol) was dissolved in an ethanol–water mixture (48 mL : 12 mL) and heated to reflux. An aqueous solution of $Co(ClO_4)_2$·$6H_2O$ (0.162 g, 0.442 mmol) was added and the solution turned a yellow-green colour. Several grams of activated charcoal were introduced and the solution was refluxed for 2 h. Air bubbling of the cooled solution (5 h) followed by filtration yielded a pink-red solution. After removal of the residual ethanol and addition of 1 drop of concd. $HClO_4$, the solution was left to crystallize at 4 °C overnight. The crystals were washed with ethanol, ether, and air dried. Yield: 0.106 g, 37%. ^{13}C NMR (D_2O): 66.9 (*C*H_2-O), 60.9, 55.0, 54.6, 52.3, 51.7 (*C*H_2-N), 39.0 (N-*C*H_3), 19.7 (CH_2-*C*H_2-CH_2). It appears that there is overlap of the methylene peaks, since only eight and not nine signals were observed. MS (negative ion): 654.05 $([Co(L_3)(ClO_4)](ClO_4)_2]^-$. UV–vis ($\lambda_{max}$, nm): 232 ($\varepsilon$ = 5380 $(mol/L)^{-1}$ cm^{-1}) and 516 (ε = 17 $(mol/L)^{-1}$ cm^{-1}).

The isomeric macrobicyclic ligand, 5,8-dimethyl-1,5,8,12-tetraaza-17-oxabicyclo[10.5.2]nonadecane ($\mathbf{L_4}$), was prepared[4] in a manner similar to that outlined previously using *N*,*N*′-dimethylethylenediamine and 3-chloropropionyl chloride as initial reactants. Further reaction of the resultant bis(chloro)diamide with the macrocycle 1,4-diaza-7-oxacyclononane yielded the bicyclic diamide that upon reduction, as described previously, yielded ligand L_4. For the Co(III) complex $[Co(L_4)(Cl)](ClO_4)_2$ calcd. (%): C 32.48, H 5.79, N 9.47; found: C 32.87, H 5.84, N 9.57. UV–vis (λ_{max}, nm): 461 (ε = 16 $(mol/L)^{-1}$ cm^{-1}).

Caution! Transition-metal perchlorates are known to be hazardous and must be treated with care, especially in the presence of organic solvents.

Crystallography

$[Co(L_2)(Cl)](ClO_4)_2$

X-ray quality crystals were grown by slow evaporation of an aqueous solution containing the complex and $NaClO_4$. The experimental parameters for the complex are listed in Table 1.

A crystal of dimensions 0.10 mm × 0.15 mm × 0.40 mm was mounted in a glass Lindemann tube and optically centred in an Enraf-Nonius CAD-4 diffractometer employing graphite-monochromated MoKα radiation. The unit cell was refined by using 24 reflections in the 2θ range 25°–33°. The diffraction data were collected using the ω/2θ scan mode. A total of 3554 reflections were collected. The structure solution and refinement were completed using the PC version of

the NRCVAX system (15–18). Of the 3432 unique reflections observed, 1740 reflections with $I_{net} > 3.00\sigma(I_{net})$ were included in the final least-squares refinement for 61 atoms and 280 parameters. Absorption corrections were made and all non-hydrogen atoms were refined anisotropically. Min and max transmission factors were estimated to be 0.839 and 0.999, respectively. All hydrogen atoms were placed in calculated positions ($D_{C\text{-}H}$ = 1.08 Å), and were given isotropic thermal parameters based upon the atom to which they were bonded. The refinement converged with a max shift to estimated standard deviation (esd) of 0.009 in the final cycle, and a maximum peak of 0.640 e Å^{-3} at an $R(F_0)$ value of 0.062 (R_w = 0.061).

UV–vis (pK_a measurements)

UV–vis spectra were recorded on a Varian Cary 5 spectrophotometer. Small increments of NaOH solutions (varying concentrations) were added with a Gilson Pipetman P200 micropipette to approximately 1 mol/L $HClO_4$ solutions of the cobalt(III) complexes in quartz UV–vis cuvettes. The pH of the solutions was measured after each addition of base with a Fisher glass electrode connected to a Fisher Scientific Accumet pH meter 915 followed by the immediate recording of their UV–vis spectra. Measurements were made over the pH range 0.5–10.

Fig. 1. ORTEP diagram of the $[Co(L_2)(Cl)]^{2+}$ ion with 25% thermal ellipsoids.

Kinetic studies

Anation reactions of $[Co(L_1)(H_2O)](ClO_4)_3$ with chloride ions under pseudo-first-order conditions were followed at 25–40 °C using a Shimadzu UV-160A spectrophotometer at 240 nm. The rates of anation were determined by reaction with a series of LiCl solutions ranging in concentrations of 50–400 molar excess. The experiments were carried out at eight different $HClO_4$ concentrations between 0.11 and 0.96 mol/L (I = 1.0 mol/L, $LiClO_4$). Prior to mixing, the solutions were pre-equilibrated at the required temperature and were controlled to within ±0.1 °C. A minimum of three kinetic runs was collected for each pair of solutions, prior to signal averaging with kinetic analysis by nonlinear, least-squares fitting methods.

Although metal–ion complexes of ligands L_1 and L_2 were shown to be kinetically stable, with no detectable decomposition in 1 mol/L media over a >24 h period, the complexes incorporating L_3 and L_4, if left overnight in 1 mol/L acidic media, exhibited complete decomposition. Studies on $[Co(L_3)(ClO_4)](ClO_4)_2$ were undertaken at 25 °C at 232 nm where the rates of absorbance decrease over a range of acidities confirmed the acid dependence.

Results

Molecular structure

An ORTEP of the structure of the $[Co(L_2)Cl]^{2+}$ ion is shown in Fig. 1. Collection details are provided in Table 1 and selected bond lengths and bond angles are provided in Table 2. Atomic coordinates are shown in Table S1.[5] The geometry at the cobalt metal centre is only slightly distorted from an ideal octahedron expected for a d^6 ion, with the L_2 ligand occupying five of the coordination sites and a chloride ion the sixth site. The macrobicyclic ligand L_2 can be

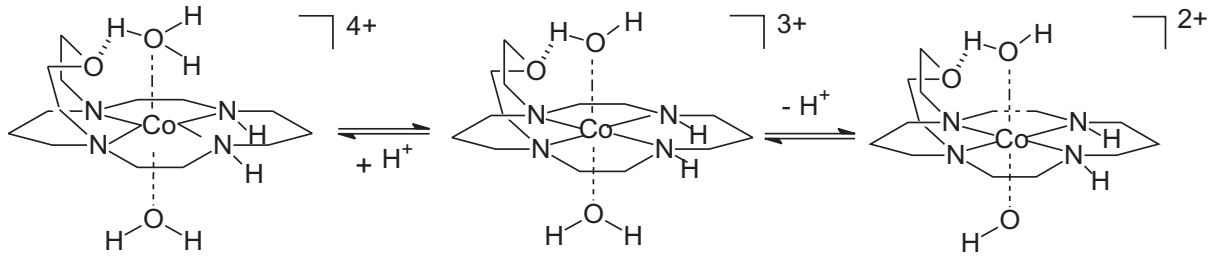
envisaged as the fusion of a 10-membered cyclodecane ring with a 14-membered cyclotetradecane ring. The cyclam ring in L_2 adopts a trans-III configuration according to the terminology of Bosnich et al. (19). Numerous studies have illustrated that for complexes of this type, the trans-III configuration is lowest in energy. In contrast to $[Co(L_2)(Cl)]^{2+}$, the trans-I configuration is adopted by ligands in the macrobicyclic ions $[Cu(L_1)]^{2+}$ and $[Ni(L_1)(ClO_4)]^{2+}$ and in the complexes of the analogous thioether ligand (1,5,8,12-tetraaza-17-thiabicyclo[10.5.2]nonadecane) (L_5) (10). Species such as $[Co(L_5)CH_3CN]^{3+}$ also incorporate nine-membered cyclononane and 14-membered cyclotetradecane rings. In effect, the only structural difference between L_2 and L_n, (where n = 1 or 5), other than the type of apical donor atom, is the placement of the five-membered apical bridge. The trans-III configuration results in a greater ability of the ether oxygen in the decane ring of L_2 to reach over and better encapsulate the axial site. The bond to the apical oxygen is quite strong with Co(1)—O(1) = 1.924(6) Å and is significantly shorter than the Co—S distance (2.206 Å) in $[Co(L_5)(CH_3CN)]^{3+}$,[6] which displays strain owing to the isomeric ligand structure. Furthermore, the Co(1)—Cl(1) bond length is 2.219(3) Å, which is similar to the Co—Cl distance (2.246 Å) observed in the crystal structure of $[Co(daptacn)(Cl)]^{2+}$ (20), where daptacn is the pentaaza ligand 1,4-di(3-aminopropyl)-1,4,7-triazacyclononane. In the latter complex ion, and in the corresponding system, 1,4,7-tri(3-aminopropyl)-1,4,7-triazacyclononane (21), there is a slight distinction between the Co—N(*tert*) and Co—N(*sec*) bond distances, with the former being slightly greater as expected owing to increased steric repulsion at the tertiary nitrogens. However, in contrast with the relatively more open species above, in the present complex, the distances are much more similar, probably owing to the constraints imposed by the macrobicyclic ligand.

Fig. 2. Spectra of the individual cobalt(III) ions. A = $[CoHL_1(OH_2)]^{4+}$; B = $[CoL_1(OH_2)]^{3+}$; C = $[CoL_1(OH)]^{2+}$.

Equilibrium studies



In the case of the ion $[Co(L_1)(ClO_4)]^{2+}$, spectra were measured over the pH range 0.872–9.92. The spectra showed the presence of more than one ion equilibrium (Figs. S1 and S2).[5] Measurements made at 10 nm intervals over the range 210–310 nm were analysed by a second-order global analysis procedure (22) developed to examine the existence of differing, but spectroscopically similar, species in titrations of this kind that result in an inability to reliably fit a reasonable model to the data. The EQUISPEC program (22) permits a number of titrations with differing initial concentrations of the equilibrium partners to be analysed simultaneously. The result is the determination of not only profiles for each reagent, but also the pK for each equilibrium observed. By use of the data shown in Fig. S1,[5] the absorption spectra of three species have been determined and are presented in Fig. 2. The concentration profiles and extent of agreement between observed and calculated spectra are presented in Figs. S3 and S4.[5] It was observed that there is no change in the UV–vis spectrum over 24 h under conditions of 1 mol/L $[H^+]$. Although there is maintenance of the Co–ether O linkage in the solid state, it is considered that in solution the bond dissociates and the presence of the lone pair on this oxygen provides a template for formation of a hydrogen bond as shown in Scheme 2. In increasingly basic conditions, there is loss of the protonated solvent and, at higher pH, the release of the proton from the trans aqua group with a significant change in the spectrum. The pK values associated with these equilibria are 2.2 ± 0.2 and 4.2 ± 0.2, respectively.

An alternative scheme could be envisaged in which there is retention of the Co—O (ether) bond and the site of the solvated H^+ interaction would be the remaining lone pair on

[6]K.R. Coulter. Unpublished observations.

Scheme 2.

the oxygen. It is not possible to exclude the latter, but the bond formation with the O atom to the Co(III) may be weak in this case.

The value for the first pK is higher than that (0.65) for the corresponding strongly oxidizing Ni(III) species (14). However, the second pK, not observed in the Ni(III) system owing to decomposition, is similar to that for other *trans* aquotetramminecobalt(III) species (23, 24).

Similar results on the cobalt(III) complex of the dimethylated ligand L_3 showed two spectroscopic changes, the first over the range pH 0.58–0.67, and a second more clearly defined change with pK ~ 1. For the corresponding complex of L_4, only a single pK ~1.05 is defined. In both cases, however, there is acid decomposition of the complexes owing to the protonation at the tertiary amines (vide infra).

Kinetic measurements

Anation reactions

Substitution reaction kinetics were investigated at 40 °C with chloride concentrations of approximately 50–400 times in excess halide. The rate data for the $[Co(L_1)(H_2O)]^{3+}$ reaction, obtained at 280 nm, are tabulated in Table S2.[5] In general, the scatter of individual values for k_{obs} was in the order of ±5%. The observed first-order rate constants (k_{obs}) vary linearly with chloride concentration. However, the intercepts and slope of each curve vary roughly inversely with $[H^+]$. No evidence was observed for a second substitution step in the anation.

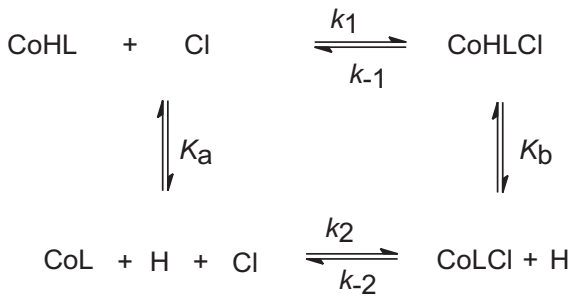
A mechanistic scheme that accounts for the observed acid dependence is described in Scheme 3, where (neglecting all charges) CoHL and CoL represent the complex ions $[CoL(OH_3)(OH_2)]^{4+}$ and $[CoL(OH_2)_2]^{3+}$, and CoHLCl and CoLCl, the corresponding chloro complexes.

The observed rate constant derived from this equilibrium set may be represented as:

$$[1] \qquad k_{obs} = (k_1[H^+] + k_2K_a)[Cl^-]/(K_a + [H^+]) + (k_{-1}[H^+] + k_{-2}K_b)/(K_b + [H^+])$$

As can be seen from eq. [1], approximate inverse proton dependences are predicted for both the intercepts and slopes of plots of k_{obs} vs. $[Cl^-]$ (eq. [1]). A plot of slope(K_a + $[H^+]$) vs. $[H^+]$ is shown in Fig. 3 and, using the K_a value (6.3 × 10^{-3} mol/L) obtained previously, the rate constants derived are k_1 = 0.053 ± 0.002 $(mol/L)^{-1}$ s^{-1} and k_2 = 3.8 ± 1.0 $(mol/L)^{-1}$ s^{-1}. However, the plots of intercepts (K_b + $[H^+]$) vs. $[H^+]$ show a slope of zero or are slightly negative

Scheme 3.



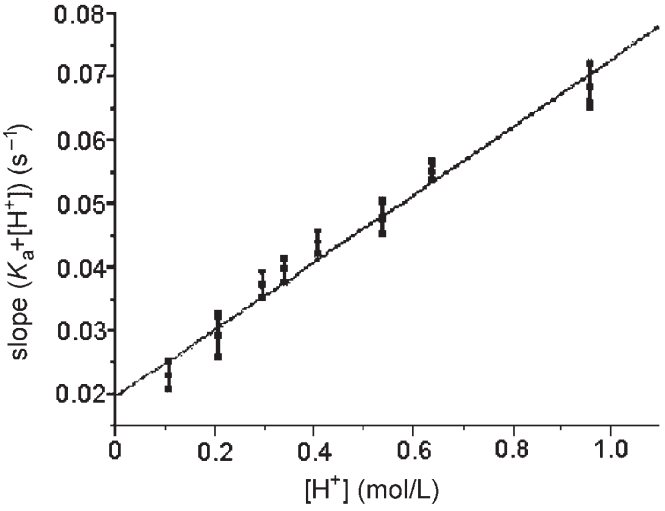


Fig. 3. Plot of slope (K_a + $[H^+]$) vs. $[H^+]$ (eq. [1]).

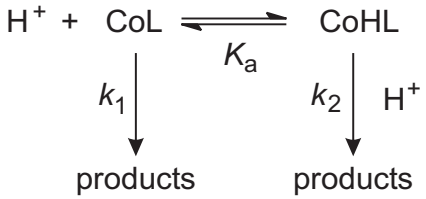
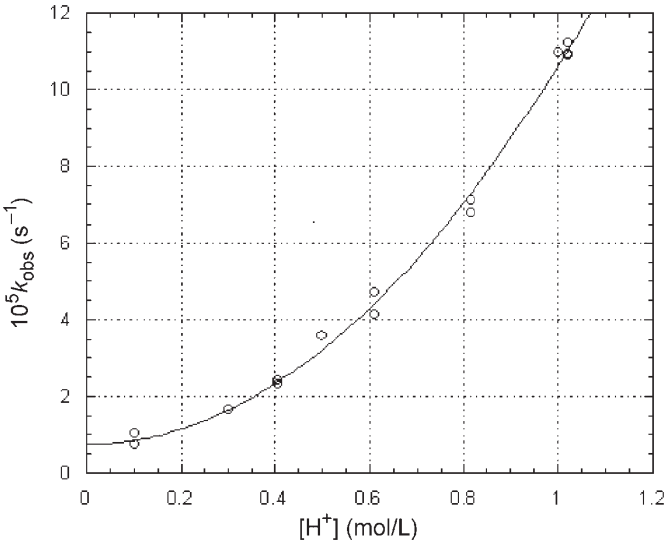


(k_{-1} not statistically discernible), with intercept $k_{-2}K_b$ = 10.4 ± 1.3 × 10^{-5} s^{-1}. Assuming K_a ~ K_b, then, at 40 °C, k_{-2} = 1.6 × 10^{-2} s^{-1} and K_2 = 230 ± 60 mol/L. Comparison with the analogous Ni(III) systems at 25 °C k_1 = 142 $(mol/L)^{-1}$ s^{-1} and k_2 = 1400 ± 300 $(mol/L)^{-1}$ s^{-1} (14) indicates, as expected, a significantly slower process for the d^6 ion.

Decomposition of $[Co(L_3)(ClO_4)](ClO_4)_2$ in acidic media

Although complexes of L_1 and L_2 appeared indefinitely stable, those incorporating the dimethylated ligands decomposed much more readily. Kinetic studies were made at 25 °C (I = 1.0 mol/L) over a range of acid concentrations using absorbance changes at 223 nm. The results are presented in Table S3[5] and are consistent with the reaction scheme (charges omitted):

© 2005 NRC Canada



for which the observed rate constant may be written in the form: $k_{obs}([H^+] + K_a) = k_1K_a + k_2[H^+]^2$. The data are presented in Fig. 4 and the individual rate constants (derived using the value of $K_a = 0.7$ derived spectroscopically) are consistent with the reaction not only of the neutral species, but also the protonated ion. The increased rate is attributed to protonation at the tertiary nitrogen atoms, leading to a reduction in the macrocyclic coordination and eventual release of the metal ion. A similar considerable increase in lability over the unsubstituted complex has been observed previously for the Ni(II) tetramethyl-cyclam ion (25).

Confirmation of the locus of reaction is provided by a comparison of the NMR spectra in neutral and acidic media. The ^{13}C NMR spectrum of $[Co(L_3)(ClO_4)](ClO_4)_2$ in D_2O–CD_3CN is highly symmetrical with only eight distinct lines exhibited (Table S4).[5] Thus, the complex in solution possesses a time-averaged C_2 axis of symmetry. Addition of a few drops of perchloric acid to the NMR tube containing such a solution (pH ~ 0) resulted in the initial precipitation of the purple complex. However, upon allowing the solution to stand overnight, dissolution occurred with loss of colour. The resultant spectrum reflects a high-symmetry species where significant chemical shifts are seen at atoms C5, C6, and C3 when compared to the Co(III) spectrum (at pH 7), and additional shifts compared to the free ligand noted at C9 and C1 were consistent with demetallation and protonation of the ligand. Bencini et al. (26) observed a similar downfield shift by the resonances of the carbon atoms adjacent to methyl centres upon protonation of the ligand 4,10-dimethyl-1,4,7,10-tetraazabicyclo[5.5.2]tetradecane.

Mass spectroscopy

Characterization by LSI-MS indentified both positively and negatively charged ions, providing informative similarities and differences. In the positive-ion spectra of $[Co(L_1)(ClO_4)](ClO_4)_2$, $[Co(L_2)(ClO_4)](ClO_4)_2$, and $[Co(L_3)(ClO_4)](ClO_4)_2$ (see Table S5)[5], there was no evidence for the pseudo-molecular ion $[M + H^+]^+$ where $M = [Co(L_n)(ClO_4)](ClO_4)_2$. The geometric isomers $[Co(L_n)(ClO_4)](ClO_4)_2$ ($n = 1$ or 2) gave almost identical positive-ion mass spectra with the highest ion observed at 428 ($[Co(L_n)(ClO_4)]^+$) owing to the inital loss of two outer-sphere perchlorate ions with the next highest ion at 328 being due to the subsequent loss of neutral $HClO_4$ ($[Co^{II}(H_{-1}L_n)]^+$). There is no evidence for any Co(III) fragments in either decay. In contrast, for the molecule $[Co(L_3)(ClO_4)](ClO_4)_2$, while a similar initial loss of two perchlorate ions to give a $[Co^{II}(L_3)(ClO_4)]^+$ fragment at 456 is observed, there is also a fragment at 355, $[Co(H_{-2}L_3)]^+$, in which the cobalt centre remains in the +3 oxidation state. Thus, in the same spectrum, there is evidence for cobalt in both the +2 and +3 oxidation states. The only other significant fragment observed at 299 is assignable to the protonated free ligand HL_3^+. No extrusion of the metal centre was observed in the positive-ion mode spectra of the cobalt(III) complexes with ligands L_1 or L_2.

Fig. 4. Rate constants for the decomposition of $[Co(III)(L_3))OH_2)]^{3+}$ in acidic media. Curve fit: $10^5k_1 = 1.1 \pm 0.11$ s^{-1}; $10^5k_2 = 9.9 \pm 0.2$ M^{-1} s^{-1}.

In the negative-ion spectra (Table S5),[5] there is strong evidence for the molecular ion $[M]^-$. This is the result of the reduction to Co(II) and maintenance of the outer sphere perchlorates. Again, the geometric isomers $[Co(L_1)(ClO_4)](ClO_4)_2$ and $[Co(L_2)(ClO_4)](ClO_4)_2$ gave almost identical mass spectra. Other than $[M]^-$, the only other significant fragment observed was at 526 due to the loss of neutral $HClO_4$. As seen in the positive-ion spectrum for $[Co(L_3)(ClO_4)](ClO_4)_2$, the negative-ion spectrum also exhibited fragments with removal of the metal ion. Ions at 597 and 497 correspond to $[(H_2L_3)(ClO_4)_3]^-$ and $[(HL_3)(ClO_4)_2]^-$, respectively. However, there is evidence for cobalt(I) as the fragment at 355 corresponds to $[Co(H_{-2}L_3)]^-$. The differences in mass spectra reflect the kinetic stabilities and reactivities of the methylated and non-methylated complexes. From Table S5,[5] it can be seen that $[Co(L_2)(ClO_4)](ClO_4)_2$ and the chloro-related complex$[Co(L_2)(Cl)](ClO_4)_2$ gave very similar negative-ion mass spectra when the loss of either $HClO_4$ or HCl from $[M]^-$ is taken into account.

In summary, the Co(III) complexes with ligands L_1 and L_2 are kinetically more stable than their Ni(III) analogues, but exhibit similar proton-related equilibria that are exhibited in the kinetic analysis. Whilst the species with secondary NH groups maintain macrocyclic coordination in acidic media, those incorporating all four tertiary nitrogens are subject to attack by protons leading to an unexpectedly ready demetallation of the complexes, a feature also observed in the mass spectroscopic fragmentation of the complexes.

Ruthenium catalyzed asymmetric hydrogenation of α- and β-keto esters in ionic liquids using chiral P-Phos ligand[1]

Kim Hung Lam, Lijin Xu, Lichun Feng, Jiwu Ruan, Qinghua Fan, and Albert S.C. Chan

Abstract: Chiral dipyridylphosphine ligand P-Phos was used in the Ru catalyzed asymmetric hydrogenation of α- and β-keto esters in room temperature ionic liquids (RTILs) with high conversions and good to excellent enantioselectivities. The catalyst was recycled by simple extraction and reused five times without loss of activity and enantioselectivity.

Key words: ruthenium, asymmetric hydrogenation, keto ester, ionic liquids, P-Phos.

Résumé : On a utilisé le ligand chiral dipyridylphosphine (P-Phos) dans l'hydrogénation asymétrique d'α- et de β-céto esters, catalysée par des complexes du ruthénium, à la température ambiante, dans des liquides ioniques, avec des degrés de conversion élevés et des énantiosélectivités allant de bonnes à excellentes. Le catalyseur peut être recyclé par simple extraction et peut être réutilisé jusqu'à cinq fois sans perte d'activité ou d'énantiosélectivité.

Mots clés : ruthénium, hydrogénation asymétrique, céto ester, liquides ioniques, P-Phos.

[Traduit par la Rédaction]

Introduction

Transition-metal-catalyzed asymmetric hydrogenation has become one of the most powerful tools for the preparation of optically active compounds in organic synthesis, and high activity and enantioselectivity have been observed using Rh, Ru, and Ir complexes with chiral phosphine, phosphite, or phosphoramidite as the ligand (1, 2). However, the industrial application of asymmetric hydrogenation has been hindered by the difficulty in the separation and recycling of the expensive chiral catalyst as well as the toxicity of the trace amounts of metal contaminants in the product. Immobilization of these catalysts offers an attractive solution to these problems (3). Recently, room temperature ionic liquids (RTILs) such as those based on imidazolium salts have attracted a great deal of interest because of their potential as a means to immobilize and to facilitate the recycling of transition-metal catalysts (4). A series of prochiral olefins, ketones, and imines have been successfully hydrogenated in ionic liquids, and the results were comparable to or even better than those obtained in common organic solvents (5–14). In most cases, the organic products could be easily separated via extraction with less polar solvents and the ionic liquid phase containing the active catalyst could be readily reused several times without significant loss of catalytic activity. However, recycling and reuse of the catalyst in ionic liquids has been problematic because of the leaching and (or) unstability of the catalyst. Recently, to overcome these obstacles, the attachment of the polar groups to the chiral phosphine ligands has been introduced (9–11). The synthesis of these modified ligands is tedious and much synthetic effort is required. It is highly desirable to develop efficient hydrogenation processes in ionic liquids with easily accessible ligands.

We have recently developed pyridyl-phosphine ligands, namely P-Phos and its derivatives, and have used them in transition-metal-catalyzed enantioselective hydrogenation of olefins and ketones to provide the desired products with high yields and excellent ees (15). In our pursuit of the immobilization and recycling of chiral catalysts in asymmetric hydrogenation (16), we have found that it is possible to replace the commonly used organic solvents with ionic liquids in the Ru-(P-Phos) catalyzed asymmetric hydrogenation of keto esters with retained enantioselectivity and catalytic activity. The use of ionic liquids allows easy isolation of the pure product and efficient recovery and reuse of the catalyst.

Results and discussion

The asymmetric catalytic hydrogenation of α-keto esters

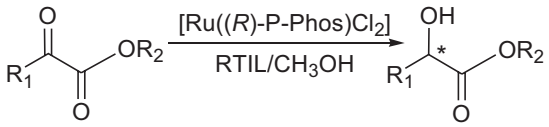
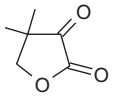
[b]The ee values (%) were determined by GC on a Cyclosil-B (J & W Scientific) 30 m × 0.25 mm × 0.25 μm column.
[c]The conversions were determined by ^{1}H NMR analysis.

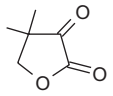
provides a convenient way to prepare chiral α-hydroxyl esters, and high enantioselectivities and conversions have been achieved in common organic solvents (1, 2). However, there is no report on the asymmetric hydrogenation of α-keto esters in ionic liquids. To determine whether the catalytic asymmetric hydrogenation of α-keto esters could occur in ionic liquids, we first examined the hydrogenation of methyl pyruvate in 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF_4]) and 1-butyl-3-methylimidazolium hexafluorophosphate ([bmim][PF_6]) using [Ru((*R*)-P-Phos)Cl_2] as the catalyst. For comparison, we also tested the catalytic performance of the extensively used chiral ligand BINAP in ionic liquids. Our results indicated that the hydrogenation in pure ionic liquids was very sluggish with very low conversions (5% and 10% in [bmim][BF_4] and [bmim][PF_6], respectively) after 20 h. In view of the significant co-solvent effect of alcohol in asymmetric hydrogenation in ionic liquids (4), we used an equal volume of MeOH as a co-solvent. As shown in Table 1, high enantioselectivities could be obtained with Ru-P-Phos in both [bmim][BF_4] and [bmim][PF_6] and the results were comparable to the ee values achieved in MeOH. The enantioselectivity was insensitive to the nature of the ionic liquids. However, the reaction in [bmim][PF_6] was slower, and only 73% conversion was achieved after 20 h while nearly complete conversion was observed in [bmim][BF_4]. In contrast, lower enantioselectivities were observed in Ru-BINAP catalyzed hydrogenation, though nearly complete conversions were attained in both ionic liquids. With the BINAP ligand, the enantioselectivity was quite dependent on the nature of the ionic liquids. As shown in Table 1, 81% ee was obtained in [bmim][BF_4] while only 55% enantioselectivity was obtained in [bmim][PF_6]. It was notable that P-Phos performed better than BINAP in ionic liquids, which may be related to the dipyridyl backbone of P-Phos.

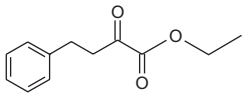
The hydrogenation was extended to other α-keto esters and low to high enantioselectivities were observed. Low enantioselectivities and conversions were observed in the hydrogenation of ketopantolactone in both ionic liquids (Table 2, entries 1 and 2). Moderate enantioselectivities and low conversions were obtained with ethyl 2-oxo-4-phenylbutyrate as a substrate (Table 2, entries 3 and 4). High ee values but low conversions were attained in the hydrogenation of methyl benzoylformate (Table 2, entries 5 and 6). The hydrogenation of ethyl benzoylformate only led to low conversions and low enantioselectivities (Table 2, entries 7 and 8).

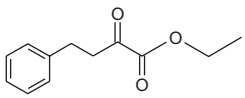


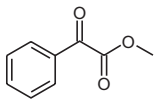
The asymmetric hydrogenation of β-keto esters has been previously studied in ionic liquids using modified BINAP ligands and the results are comparable to or better than those obtained in common organic solvents (9, 10). In this study, we examined the capability of [Ru((*R*)-P-Phos)Cl_2] in the asymmetric hydrogenation of β-keto esters in ionic liquids and the results are summarized in Table 3. The hydrogenation of methyl acetoacetate in a mixture of equal volumes of ionic liquid ([bmim][BF_4] or [bmim][PF_6]) and MeOH was first examined. After stirring at room temperature for 20 h, the reaction led to full conversion and higher than 99% ee. As shown in Table 3, the reaction was also conducted using (*R*)-BINAP as the ligand in both ionic liquids. Again, excellent conversions and enantioselectivites were achieved in both ionic liquids.

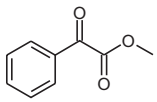


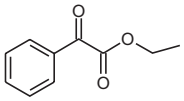


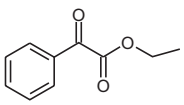












The results of the asymmetric hydrogenation of other β-keto esters are summarized in Table 4. High enantioselectivities (97%–99%) and high conversions (92% to >99%) were obtained for ethyl acetoacetate and *tert*-butyl acetoacetate (Table 4, entries 1–4). It should be pointed out that these results favorably compare with those obtained in common organic solvents. However, when R^1 was switched to other electronegative groups, both the enantioselectivity and the conversion declined (Table 4, entries 5–8). The Ru-P-Phos catalyst showed higher activity in [bmim][PF_6], but it gave better enantioselectivity in [bmim][BF_4].

The recyclability of the Ru-P-Phos catalyst in RTILs was explored using methyl acetoacetate as the model substrate.

[b]The ee values (%) were determined by GC on a Cyclosil-B (J & W Scientific) 30 m × 0.25 mm × 0.25 μm column.

[c]The conversions were determined by ^{1}H NMR analysis.

Upon completion of the reaction, the methanol was evaporated in vacuo, and the product was extracted with degassed hexane. The RTIL phase was washed twice with hexane. The combined extracts were used for analysis. The RTIL phase was recharged with methyl acetoacetate and MeOH, and then subjected to hydrogenation again under the same conditions. As shown in Table 5, the Ru-P-Phos could be reused and recycled in both ionic liquids, but the results differ considerably. In [bmim][BF_4]–MeOH, the level of enantioselectivity could be reasonably maintained for nine runs, but the activity deteriorated from the second run, and the subsequent runs led to a significant drop in activity. However, in

the case of [bmim][PF_6], good activity and excellent enantioselectivity were retained in the first five runs of the hydrogenation reactions.

Conclusion

We have developed an efficient Ru-P-Phos catalyst for the asymmetric hydrogenation of α- and β-keto esters in RTILs with high conversions and ee values up to >99%. The catalyst was recycled and reused with the reasonable retention of activity and enantioselectivity.

Experimental

General information

All manipulations with air-sensitive reagents were carried out under a dry nitrogen atmosphere using standard Schlenk techniques or in a nitrogen-filled MBRAUN Lab Master 130 glovebox. The hydrogenation reactions were performed in a stainless-steel autoclave from the Parr company.[bmim][BF_4] and [bmim][PF_6] were prepared according to the literature method (17). Following vacuum drying at 80 °C for 8 h, the ionic liquid was stored under nitrogen at ambient temperature. Optically pure P-Phos and [Ru((*R*)-P-Phos)Cl_2] were synthesized based on our previous reports (14). Other chemicals were purchased and were used as received. The solvents were dried prior to use via standard procedures. The ^{1}H NMR spectra were recorded on a Varian AS 500 spectrometer in ppm with reference to the TMS internal standard in $CDCl_3$.

Typical procedure for asymmetric hydrogenation

A mixture of [bmim][BF_4] (0.5 mL) and MeOH (0.5 mL) was added into a glass-lined stainless-steel autoclave containing methyl acetoacetate (26.7 mg, 0.23 mmol) and [Ru((*R*)-P-Phos)Cl_2] (18.8 mg, 0.023 mmol) in a drybox under a nitrogen atmosphere. After purging the autoclave with hydrogen gas several times, the final pressure of the hydrogen was adjusted to 1000 psi (1 psi = 6.894 757 kPa), and the reaction mixture was stirred at room temperature. After 20 h, the hydrogen gas was released, and the product was extracted with hexane and passed through a small column of silica gel. The organic volatiles were removed under reduced pressure to obtain the desired product. The conversion was then assessed based on the ^{1}H NMR analysis, while the ee value was determined by GLC using a chiral column.

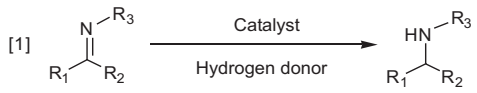
Efficient ruthenium catalyzed transfer hydrogenation of functionalized imines by isopropanol under controlled microwave heating[1]

Joseph S.M. Samec, Laetitia Mony, and Jan-E. Bäckvall

Abstract: Transfer hydrogenation of various functionalized imines by isopropanol catalyzed by $[Ru(CO)_2(Ph_4C_4CO)]_2$ (**3**) has been studied. The use of either an oil bath or controlled microwave heating in toluene led to an efficient procedure with high turnover frequencies and the product amines were obtained in high yields. An advantage with catalyst **3** over the conventional $[Ru_2(CO)_4(\mu\text{-}H)(Ph_4C_4COHOCC_4Ph_4)]$ (**1**) is the absence of an initiation period, which results in a faster reaction with **3** as compared to **1**.

Key words: transfer hydrogenation, ruthenium, imines, microwave.



Résumé : On a étudié la réaction de transfert d'hydrogène, catalysée par le $[Ru(CO)_2(Ph_4C_4CO)]_2$ (**3**), de l'isopropanol vers diverses imines fonctionnalisées. L'utilisation d'un bain d'huile ou d'un chauffage par micro-ondes contrôlé dans le toluène conduit à une méthode efficace impliquant des fréquences élevées de renouvellement et à des rendements élevés en amines. Par rapport au catalyseur conventionnel $[Ru_2(CO)_4(\mu\text{-}H)(Ph_4C_4COHOCC_4Ph_4)]$ (**1**), le catalyseur (**3**) ne présente pas de période d'initiation et il en résulte des vitesses de réaction plus rapides avec **3** par comparaison avec **1**.

Mots clés : hydrogénation par transfert, ruthénium, imines, micro-onde.

[Traduit par la Rédaction]

Introduction

The reduction of imines to amines is an important transformation in organic synthesis since amines are useful building blocks for pharmaceuticals and other biologically active compounds. In situ reduction of imines generated by the reaction of ketones with an amine (reductive amination) is a commonly used procedure (1). Although the latter protocol works fine in many systems with various reducing agents (2), it is often associated with low selectivity. Direct reduction of imines can be carried out with hydride reagents (3) or with catalytic hydrogenation (4). More recently, transfer hydrogenation has been reported as a viable alternative for reduction of imines (eq. [1]) (5). The advantage of the latter procedure is that the use of hydrogen gas is avoided and that, e.g., isopropanol can be used as the hydrogen source. The acetone thus produced is readily removed by distillation. The transfer hydrogenation protocol also shows a higher functional group tolerance compared to hydride reagents.

Several transition-metal complexes are known to catalyze the transformation in eq. [1] with isopropanol or formic acid as the hydrogen donor (6–8). Dimeric catalyst **1** (9) (Scheme 1), which has frequently been employed in various hydrogen transfer reactions (10, 11), was recently successfully used in our group for the transfer hydrogenation of imines (8). Catalyst **1** is in equilibrium with monomers **2** and **A** (Scheme 1). The monomer **2** is able to hydrogenate a hydrogen acceptor, e.g., an imine, whereas the monomer **A** can dehydrogenate a hydrogen donor, e.g., isopropanol. These processes interconvert **2** and **A**. We recently showed that the hydrogen transfer from **2** to a ketimine occurs in a stepwise manner (12).

The active monomers **2** and **A** involved in the catalytic hydrogen transfer of imines can also be generated from the dimeric catalyst **3** (13). In the present work we studied the use of catalyst precursor **3** in the hydrogen transfer of functionalized imines.

The use of microwaves to accelerate catalytic reactions has recently attracted attention (14, 15). With the employment of microwaves, the reaction times can be reduced considerably and this is of great use when a larger number of compounds are required (e.g., for screening). In this work we have used microwave heating to lower the catalyst load-

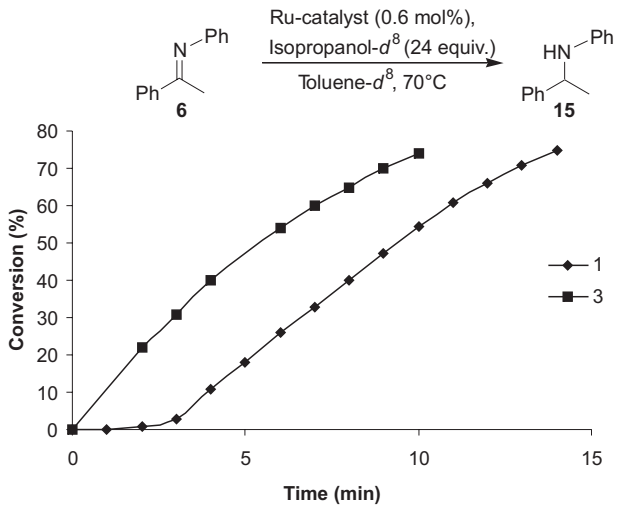
Scheme 1.

ing and reduce reaction times in the transfer hydrogenation of imines to amines with catalyst **3**.

Results and discussion



A few procedures for transfer hydrogenation of imines to amines have previously been reported in the literature (6–8). With the objective being to develop a more practical and useful procedure for ruthenium catalyzed transfer hydrogenation of imines by isopropanol, we decided to study the effects of catalyst precursor and temperature.

Choice of the catalyst precursor

Complexes **1** and **3** are catalyst precursors for the hydrogen donor **2** and hydrogen acceptor **A**. To compare **1** and **3** as catalyst precursors they were prepared according to a procedure described by Casey et al. (13). Tetraphenylcyclopentadienone and $Ru_3(CO)_{12}$ were refluxed in MeOH to give the Shvo dimer **1** or in heptane to give **3** (Scheme 2). The products were collected by filtration and recrystallized to give **1** and **3**, respectively, in high yields (~90%).

Initial experiments run in an oil bath at 110 °C revealed that catalyst **3** was more efficient than catalyst **1** in the transfer hydrogenation of imines and gave shorter reaction times. To obtain a more detailed comparison between the two catalyst precursors we studied their kinetics in the transfer hydrogenation of imine **6**. Thus, the transfer hydrogenation of imine **6** by isopropanol-d_8 in toluene-d_8 catalyzed by **1** or **3** was monitored by ^{1}H NMR at 70 °C.[3] The results are shown in Fig. 1. From these results, it is evident that catalyst precursor **1** has an initiation period of several minutes, whereas catalyst precursor **3** is active immediately and results in 23% conversion after 2 min. The time to reach 75% conversion was 14 and 10 min for **1** and **3**, respectively. During the first

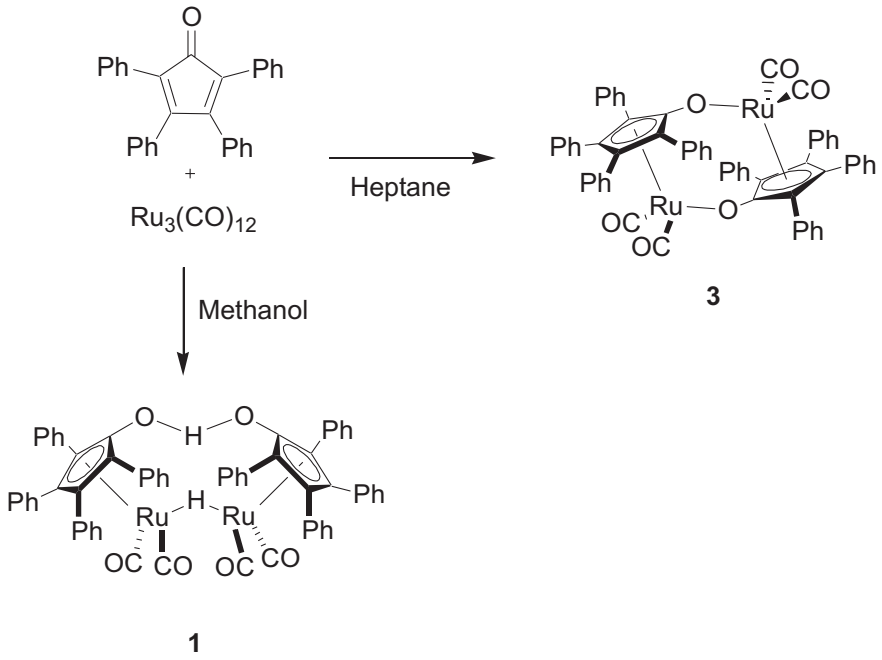


Fig. 1. Comparison between precatalysts **1** and **3** in the transfer hydrogenation of imine **6** in toluene-d_8 at 70 °C with isopropanol-d_8 using 0.6 mol% catalyst. The conversion was measured by ^{1}H NMR.

[3] Due to the low boiling point of isopropanol, the reactions were run at 70 °C to prevent overpressure in the NMR tube.

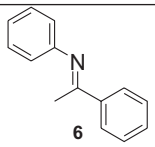
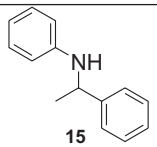
Scheme 2.

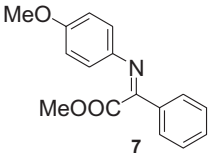
2 min, the turnover frequency (TOF) was <30 h^{-1} for **1** (<15 h^{-1} per ruthenium atom), whereas it was 1150 h^{-1} for **3** (575 h^{-1} per ruthenium atom). Because of the higher efficiency of **3** over **1**, the former catalyst was chosen for further studies.

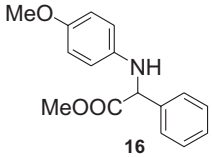
Transfer hydrogenation of imines under thermal heating

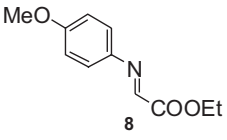
In our previously reported procedure for transfer hydrogenation of various imines by **1** using 24 equiv. of wet isopropanol in benzene at 70 °C, electron-deficient imines had long reaction times (8). For increased efficiency, it was desirable to shorten the reaction times and also to lower the catalyst loading. An increase in temperature would lead to shorter reaction times but it may also decrease the selectivity. With the aim to increase the efficiency of the reaction, the transfer hydrogenation of model substrate **6** by catalyst precursor **3** in isopropanol–toluene at 110 °C was studied. The increase in temperature led to an efficient transfer hydrogenation of **6** where the catalyst loading could be decreased 10 times compared to our previous study (8). This prompted us to study the electron-deficient imine **11**, which required 8 h at 70 °C in benzene. In the present system, imine **11** had reached full conversion within an hour with the same catalyst loading. The present system can also transfer hydrogenate the very electron-deficient imine **14** bearing a pyridyl group. To further extend this protocol and make it an attractive alternative in organic synthesis, we decided to study the transfer hydrogenation of imines having functional groups that make them difficult to reduce to amines. It was found that the present procedure tolerates various functional groups such as esters, amines, ethers, acetals, and olefins (Table 1, entries 2–5, 7, and 8). In conventional reductions using metal hydrides, the workup protocol includes tedious extractions in the presence of strong acids and (or) bases, which not only lowers the yield of the reactions, but also lowers the functional group tolerance. In the present procedure, the only workup is the removal of the solvents. The products are then readily purified by distillation giving the amines in high yield. For example, reduction of imines with either an ester or an acetal functionality, which may cause problems in metal hydride reductions (either during the reaction or in work up) proceeded smoothly with the present method (Table 1, entries 2, 3, and 7).

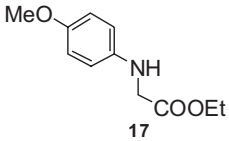


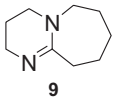


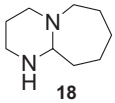


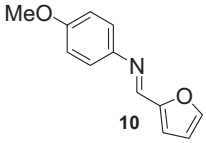


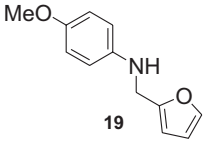


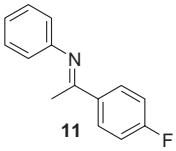


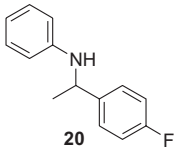


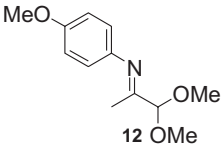


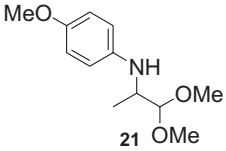


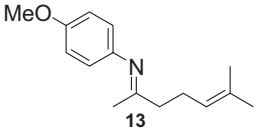


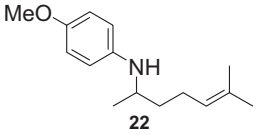


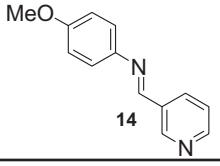


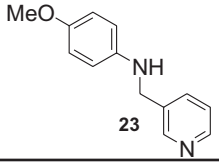












Transfer hydrogenation under controlled microwave heating

Recently, we showed that the hydrogen transfer from the active catalyst **2** to the imine is not concerted as previously proposed (13), but stepwise (12). In the latter study, we found that microwave irradiation was superior to conventional oil bath heating for the generation of the active species **2** from precursor **3** in a H_2 atmosphere (Scheme 3). Where conventional oil bath heating took several hours and with unsatisfactory results, the microwave-promoted generation of active species **2** was very efficient. Active species **2** can be generated in a minute at 180 °C using microwave irradiation, but with somewhat unreliable results. We found that decreasing the temperature to 120 °C and prolonging the reaction time to 20 min resulted in complete conversion of **3** to **2** with full reproducibility (12).

Initial attempts to perform transfer hydrogenation of imine **6** by precursor **3** in isopropanol and toluene with microwave irradiation gave unreliable results. For example, when imine **6** was run with low catalyst loading (0.03–0.06 mol%) at 110 °C, the results were difficult to reproduce. Increasing the catalyst loading slightly (to 0.1 mol%) gave a smooth transfer hydrogenation of imine **6** to amine **15** within 20 min (Table 2, entry 1). Next, it was of interest to find out if functionalized imines tolerate the transfer hydrogenation with microwave irradiation. We were pleased to find that employing microwave irradiation improved the reduction in most cases even though there were two exceptions: imines **6** and **7** (Table 2, entries 1 and 2) needed

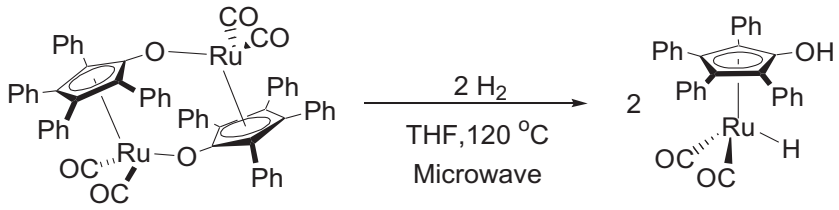
Table 1. Transfer hydrogenation of different amines by wet isopropanol in toluene using **3**.[a]



Entry	Imine	Amine	Catalyst loading (mol%)	Time (min)	Yield (%)[b]
1	 **6**	 **15**	0.03	90	93
2	 **7**	 **16**	0.06	60	93
3	 **8**	 **17**	0.06	60	95
4	 **9**	 **18**	0.3	60	>99[c]
5	 **10**	 **19**	0.3	150	97
6	 **11**	 **20**	1	60	>99[c]
7	 **12**	 **21**	3	60	95
8	 **13**	 **22**	3	60	96
9	 **14**	 **23**	3	240	96

[a]The reactions were carried out using imine (1.0 mmol), catalyst **3** (0.003–0.03 mmol), and isopropanol (24 mmol, 1.85 mL) in toluene (3.15 mL) at 110 °C. Full conversion was measured by ^{1}H NMR.
[b]Isolated yield unless otherwise noted.
[c]Yield determined by ^{1}H NMR.

higher catalyst loading in the microwave-assisted transfer hydrogenation than by conventional heating. Except for these examples, the general trend was shorter reaction times (10–20 min) and lower catalyst loading (0.1–0.5 mol%). For example, imine **10**, which needed 0.3 mol% of the catalyst and 150 min using oil bath heating, was finished within 20 min with only 0.1 mol% of the catalyst (Table 2, entry 4). This is an increase of >20 times in efficiency. Imines **12** and **13**, which needed 3 mol% of catalyst loading and 60 min with conventional oil bath heating, only needed 0.5 mol% of the catalyst and were over within 10 min in the microwave-assisted transfer hydrogenation (Table 2, entries 5 and 6). With these two imines, the efficiency is increased by a factor of 36 times. With microwave irradiation, the reaction time was reduced 12 times (from 240 to 20 min) for the electron-deficient imine **14** (Table 2, entry 7).

6	 **13**	 **22**	0.5	10	95
7	 **14**	 **23**	3	20	98

[a]The reactions were run using imine (0.3 mmol), **3** (0.0003–0.009 mmol), toluene (1.9 mL), isopropanol (1.1 mL) under microwave irradiation for 20 min (110 °C, 2 bar (1 bar = 100 kPa)).
[b]The yield was determined by ^{1}H NMR.

Conclusions

We have developed an efficient transfer hydrogenation protocol for imines. Imines bearing acid-or base-labile functional groups, not compatible with conventional metal hydride reduction, are readily reduced with low catalyst loading and short reaction times to give high yields of the corresponding amines. The use of controlled microwave ir-

© 2005 NRC Canada

radiation led to an efficient procedure where most imines were reduced in greater than 90% yield within 20 min employing 0.1–0.5 mol% of catalyst. This procedure should be a useful complement to existing methods for the reduction of imines to amines.

Experimental section

General methods

^{1}H (400 or 300 MHz) and ^{13}C (100 or 75 MHz) NMR spectra were recorded on a Varian Mercury spectrometer. Chemical shifts (δ) are reported in ppm, using residual solvent as the internal standard, and coupling constants (*J*) are given in Hz. Unless otherwise noted, all materials were obtained from commercial suppliers and used without further purification. Toluene was distilled from sodium benzophenone and isopropanol was distilled from CaO before use. All other chemicals were used as received. Short-path distillations were conducted in a Büchi glass oven B-580. Elemental analyses were performed by Analytische Laboratorien, Lindlar, Germany. Ruthenium complexes **1** and **3** were made according to literature procedures (13).

N-Phenyl-(1-phenylethylidene)amine (6)

This compound was made according to literature procedure (8).

N-(4-Methoxyphenylimino)phenylacetic acid methyl ester (7)

Anisidine (2.46 g, 20 mmol), methylphenyl glyoxylate (13 g, 80 mmol), activated molecular sieves (4 Å, 7 g), and toluene (10 mL) were added to a round-bottomed flask and stirred at room temperature overnight. The reaction mixture was filtered through Celite, the filtrate evaporated, and the crude product was precipitated from CH_2Cl_2–pentane. Yield: 3 g (50%) of yellow-brownish crystals. ^{1}H NMR (400 Hz, $CDCl_3$, 25 °C) δ: 3.69, (s, 3H, $COOCH_3$), 3.81 (s, 3H, OCH_3), 6.87–6.96 (m, 2H, aryl of *p*-methoxyphenyl), 6.97–7.01 (m, 2H, aryl of *p*-methoxyphenyl), 7.45–7.50 (m, 3H, phenyl), 7.84–7.86 (m, 2H, phenyl). ^{13}C NMR (100 Hz, $CDCl_3$, 25 °C) δ: 51.9 (CH_3 of ester), 55.4 (OCH_3), 114.2 (aryl of *p*-methoxyphenyl), 121.1 (aryl of *p*-methoxyphenyl), 127.8 (phenyl), 128.7 (phenyl), 131.5 (phenyl), 134.1 (phenyl), 143.1 (aryl of *p*-methoxyphenyl), 157.3 (aryl of *p*-methoxyphenyl), 159.1 (C=N), 166.1 (C=O).

Ethyl [*N*-(*p*-Methoxyphenyl)imino]acetate (8)

Anisidine (2.46 g, 20 mmol), ethyl glyoxalate (4 mL, 30 mmol), activated molecular sieves (4 Å, 7 g), and benzene (5 mL) were added to a round-bottomed flask and stirred at room temperature overnight. Spectral data were in accordance with those previously reported in the literature (16).

N-[1-(2-Furyl)methylidene]-*N*-(4-methoxyphenyl)amine (10)

Anisidine (2.46 g, 20 mmol), furfural (2.4 g, 25 mmol), activated molecular sieves (4 Å, 7 g), and benzene (5 mL) were added to a round-bottomed flask and stirred at room temperature overnight. The reaction mixture was filtered through Celite, the filtrate evaporated, and the crude product was precipitated from CH_2Cl_2–pentane to yield 2.6 g (55%) of white crystals. Spectral data were in accordance with those previously reported in the literature (17).

N-Phenyl-[1-(4-fluorophenyl)ethylidene]amine (11)

The title compound was made according to the literature procedure (8).

(2,2-Dimethoxy-1-methylethylidene)-(4-methoxyphenyl)-amine (12)

Anisidine (2.47 g, 20 mmol), dimethoxy acetone (3.94 g, 30 mmol), activated molecular sieves (4 Å, 7 g), and benzene (10 mL) were added to a round-bottomed flask and stirred at room temperature overnight. Yield: 4 g (90%) of a colorless oil. ^{1}H NMR (400 Hz, $CDCl_3$, 25 °C) δ: 1.83 (s, 3H, CH_3), 3.49 (s, 6H, OCH_3), 3.80 (s, 3H, OCH_3), 4.65 (s, 1H, CH), 6.72 (m, 2H, aryl of *p*-methoxyphenyl), 6.88 (m, 2H, aryl of *p*-methoxyphenyl). ^{13}C NMR (100 Hz, $CDCl_3$, 25 °C) δ: 13.9 (CH_3), 55.1 (OCH_3), 55.4 (OCH_3), 107.6 (CH), 114.2 (aryl of *p*-methoxyphenyl), 120.7 (aryl of *p*-methoxyphenyl), 142.9 (aryl of *p*-methoxyphenyl), 156.3 (C=N), 168.2 (aryl of *p*-methoxyphenyl). Elemental anal. calcd. for $C_{12}H_{17}NO_3$ (223.27) (%): C 64.55, H 7.68, N 6.28; found: C 64.32, H 7.56, N 6.41.

N-(6-Methyl-2-hept-5-enylidene)-4-anisidine (13)

Anisidine (2.47 g, 20 mmol), 6-methyl-5-hepten-2-one (3 mL, 20 mmol), activated molecular sieves (4 Å, 7 g), and benzene (10 mL) were added to a round-bottomed flask and stirred at room temperature overnight. Yield: 2.74 g (59%) of a yellow oil. Spectral data were in accordance with those previously reported in the literature (18).

N-(4-Methoxyphenyl)-*N*-[(*E*)-1-(3-pyridyl)methylidene]amine (14)

Anisidine (2.46 g, 20 mmol), 3-pyridinecarboxaldehyde (2.67 g, 25 mmol), activated molecular sieves (4 Å, 7 g), and benzene (5 mL) were added to a round-bottomed flask and stirred at room temperature overnight. The reaction mixture was filtered through Celite and the filtrate was evaporated. The starting material was removed by bulb-to-bulb distillation (120 °C, 1 mbar, 1 bar = 100 kPa) and the product was subsequently distilled (160 °C, 1 mbar). Yield: 3.8 g (90%) of yellow crystals. Spectral data were in accordance with those previously reported in the literature (17).

Screening catalysts

Catalyst **1** (1 mg, 1 μmol) or **3** (1 mg, 1 μmol) dissolved in toluene-d_8 (0.48 mL) was added to imine **6** (0.15 mmol) in a vial. The mixture was transferred to a NMR tube and isopropanol-d_8 (0.28 mL, 3.7 mmol) was added. The NMR tube was subsequently shaken and inserted into a prewarmed (70 °C) spectrometer. After initial locking and shimming (~2 min), acquisitions were acquired every minute. The reactions were followed by ^{1}H NMR to ~75% conversion following the appearance of the methyl group of the amine at δ 1.48 and the disappearance of the methyl group of the imine at δ 2.24.

General procedure for the transfer hydrogenation under thermal heating — *N*-Phenyl-1-phenylethylamine (15)

In a typical experiment, imine **6** (0.195 g, 1.0 mmol), catalyst **3** (0.33 mg, 0.3 μmol), toluene (3.15 mL), isopropanol (1.84 mL, 24.0 mmol), and water (42 μL, 1% w/w) were added to a 10 mL Schlenk tube and heated to 110 °C for 90 min. Solvents were evaporated in vacuo and the product was purified by distillation (250 °C, 0.5 mbar) to afford amine **15** (0.182 g, 93%). Spectral data were in accordance with those previously reported in the literature (19).

(4-Methoxyphenylamino)phenylacetic acid methyl ester (16)

The general procedure was followed by using imine **7** (1.9 mmol, 0.5 g), **3** (1.1 μmol, 1 mg), toluene (8 mL), and wet isopropanol (3.5 mL, 48.0 mmol). The product was distilled (250 °C, 0.5 mbar) to afford amine **16** (0.48 g, 93%). Spectral data were in accordance with those previously reported in the literature (20).

***N*-(4-Methoxyphenyl)glycine ethyl ester (17)**

The general procedure was followed by using imine **8** (0.21 g, 1.0 mmol) and **3** (0.65 mg, 0.6 μmol). The product was bulb-to-bulb distilled (200 °C, 0.5 mbar) to afford amine **17** (0.199 g, 95%). ^{1}H NMR (400 Hz, $CDCl_3$, 25 °C) δ: 1.27 (t, 3H, J = 7.1 Hz, CH_3), 3.74 (s, 3H, OCH_3), 3.86 (s, 2H, CH_2), 4.23 (q, 2H, J = 7.1 Hz, CH_2), 6.57–6.60 (m, 2H, aryl of *p*-methoxyphenyl), 6.77–6.81 (m, 2H, aryl of *p*-methoxyphenyl). ^{13}C NMR (100 Hz, $CDCl_3$, 25 °C) δ: 14.4 (CH_3), 47.0 (CH), 55.9 (OCH_3), 61.4 (OCH_3), 114.6 (aryl of *p*-methoxyphenyl), 115.1 (aryl of *p*-methoxyphenyl), 141.5 (aryl of *p*-methoxyphenyl), 152.8 (aryl of *p*-methoxyphenyl), 171.6 (C=O of ester).

Decahydropyrimido[1,2-α]azepine (18)

Imine **9** (0.3 mmol, 45 μL), **3** (0.92 μmol, 1 mg), toluene-d_8 (0.95 mL), and isopropanol-d_8 (0.55 mL, 7.2 mmol) were added to a 10 mL Schlenk tube and heated to 70 °C for 60 min. According to the ^{1}H NMR there was full conversion. The spectral data were in accordance with those previously reported in the literature (21).

Furan-2-ylmethyl(4-methoxyphenyl)amine (19)

The general procedure was followed using imine **10** (0.171 g, 1.0 mmol) and **3** (2.8 μmol, 3 mg). The product was bulb-to-bulb distilled (250 °C, 0.5 mbar) to afford amine **19** (0.167 g, 97%). The spectral data were in accordance with those previously reported in the literature (17).

***N*-Phenyl-1-(4-fluorophenyl)ethylamine (20)**

The general procedure was followed using imine **11** (64 mg, 0.3 mmol) and catalyst **3** (3.2 mg, 3 μmol), isopropanol (0.55 mL, 7.2 mmol), and 0.95 mL of toluene. After 1 h, the sample was cooled down and analyzed by ^{1}H NMR. Conversion was >99%. Spectral data were in accordance to those previously reported in the literature (8).

***N*-(2,2-Dimethoxy-1-methylethyl)-4-methoxyphenyl)amine (21)**

The general procedure was followed by using imine **12** (0.223 g, 1.0 mmol) and **3** (33 mg, 30 μmol). The product was bulb-to-bulb distilled (250 °C, 0.5 mbar) to afford amine **21** (0.202 g, 95%). ^{1}H NMR (400 Hz, $CDCl_3$, 25 °C) δ: 1.15 (d, 2H, J = 6.6 Hz, CH_3), 3.44 (s, 3H, OCH_3), 3.47 (s, OCH_3), 3.53–3.56 (m, 1H, CH), 3.74 (s, 3H, OCH_3 of *p*-methoxyphenyl), 4.27 (d, 1H, J = 3.8 Hz, acetal), 6.60–6.62 (m, 2H, aryl of *p*-methoxyphenyl), 6.76–6.78 (m, 2H, aryl of *p*-methoxyphenyl). ^{13}C NMR (100 Hz, $CDCl_3$, 25 °C) δ: 14.6 (CH_3), 51.6 (CH), 55.5 (OCH_3), 55.7 (OCH_3), 56.5 (OCH_3), 107.1 (CH), 114.9 (aryl of *p*-methoxyphenyl), 115.2 (aryl of *p*-methoxyphenyl), 141.3 (aryl of *p*-methoxyphenyl), 152.2 (aryl of *p*-methoxyphenyl). Elemental anal. calcd. for $C_{12}H_{19}NO_3$ (225.29) (%): C 63.97, H 8.50, N 6.22; found: C 63.74, H 8.39, N 6.35.

***N*-(6-Methyl-2-hept-6-enyl)-4-methoxyaniline (22)**

The general procedure was followed using imine **13** (0.136 g, 1.0 mmol) and **3** (22.5 mg, 20.8 μmol). The product was bulb-to-bulb distilled (250 °C, 0.5 mbar) to afford amine **22** (0.147 g, 96%). Spectral data were in accordance to those previously reported in the literature (18).

4-(Methoxyphenyl)pyridin-3-ylmethylamine (23)

The general procedure was followed using imine **14** (0.212 g, 1.0 mmol) and **3** (33 mg, 30 μmol). The product was bulb-to-bulb distilled (250 °C, 0.5 mbar) to afford amine **23** (205.9 mg, 96%). ^{1}H NMR (400 Hz, $CDCl_3$, 25 °C) δ: 3.74 (s, 3H, OCH_3 *p*-methoxyphenyl), 4.32 (s, 2H, CH_2), 6.58–6.61 (m, 2H, aryl of *p*-methoxyphenyl), 6.76–6.79 (m, 2H, aryl of *p*-methoxyphenyl), 7.26–7.29 (m, 1H, pyridyl), 7.71–7.73 (m, 1H, pyridyl), 8.51–8.52 (m, 1H, pyridyl), 8.62–8.63 (m, 1H, pyridyl). ^{13}C NMR (100 Hz, $CDCl_3$, 25 °C) δ: 46.7 (CH_2), 55.8 (OCH_3), 114.5 (aryl of *p*-methoxyphenyl), 114.9 (aryl of *p*-methoxyphenyl), 122.3 (pyridyl), 134.6 (pyridyl), 141.7 (aryl of *p*-methoxyphenyl), 148.5 (pyridyl), 149.0 (pyridyl), 154.9 (aryl of *p*-methoxyphenyl). Elemental anal. calcd. for $C_{13}H_{14}N_2O$ (214.27) (%): C 72.87, H 6.59, N 13.08; found: C 73.11, H 6.72, N 13.21.

General procedure for the transfer hydrogenation of imines under controlled microwave heating — *N*-Phenyl-1-phenylethylamine (15)

In a typical experiment, imine **6** (58.6 mg, 0.3 mmol), **3** (0.3 mg, 0.3 μmol), toluene (1.9 mL), isopropanol (1.1 mL), and water (25 μL, 1%) were charged into a Pyrex tube (5 mL) fitted with a screw cap with a silicone–teflon septum (Personal Chemistry AB, Uppsala, Sweden). The septum was closed and the vessel inserted into a microwave oven. The microwave was run for 20 min (110 °C, 2 bar). The solvents were evaporated, $CDCl_3$ (0.7 mL) was added, and the solution was transferred to an NMR tube and analyzed by ^{1}H NMR, which showed 98% yield integrating the doublet at δ 1.48 (CH_3) of the amine and the singlet at δ 2.24 (CH_3) of the imine.

Amines **16**–**23** were prepared from the corresponding imines (0.3 mmol) according to the general procedure for

© 2005 NRC Canada

transfer hydrogenation under microwave heating using **3** (0.3–9 μmol). The results are given in Table 2.[4]

β Elimination of a phosphonate group from an alkoxyl radical — Intramolecular acylation using acylphosphonate derivatives as carbonyl group acceptors[1]

Chang Ho Cho and Sunggak Kim

Abstract: The possibility of β elimination of a phosphonate group in radical reactions was studied. The facile β elimination of the phosphonate group from an alkoxyl radical was observed for the first time, whereas the β elimination of the phosphonate group from an aminyl and an alkyl radical did not occur. On the basis of our findings, the use of an acylphosphonate as a carbonyl group radical acceptor was investigated. Radical cyclization of the acylphosphonate in the presence of hexamethylditin in benzene at 300 nm for 2 h gave a cyclopentanone or a cyclohexanone derivative in good yield without the formation of a direct reduction product. The reaction can be carried out in the presence of a catalytic amount of hexamethylditin (0.2 equiv.) under similar conditions. In addition, an alkyl phosphonothiolformate group can act as an alkylthiocarbonyl group equivalent radical acceptor, providing ready access to a thiolactone synthesis.

Key words: radical, β elimination, acylation, cyclization, acylphosphonate.

Résumé : On a étudié la possibilité d'une élimination β d'un groupe phosphonate au cours de réactions radicalaires. On a observé pour la première fois une élimination β facile d'un groupe phosphonate à partir d'un radical alkoxyle alors qu'il ne se produit pas d'élimination β d'un groupe phosphonate à partir d'un radical aminyle ou d'un radical alkyle. Sur la base de ces observations, on a étudié l'utilisation d'un acylphosphonate comme groupe carbonyle accepteur de radical. La cyclisation radicalaire de l'acylphosphonate, en présence d'hexaméthyldiétain, dans le benzène, à 300 nm, pendant deux heures, conduit à la formation d'une cyclopentanone ou d'une cyclohexanone, avec un bon rendement, sans formation d'un produit de réduction directe. Il est possible d'effectuer la réaction dans des conditions semblables, en présence d'une quantité catalytique d'hexaméthyldiétain (0,2 équiv.). De plus, un groupe phosphonothiolformiate d'alkyle peut agir comme groupe alkylthiocarbonyle équivalent à l'accepteur radicalaire et fournir ainsi un accès facile à une synthèse de thiolactone.

Mots clés : radical, β élimination, acylation, cyclisation, acylphosphonate.

[Traduit par la Rédaction]

Introduction

The carbonyl group is one of the central functional groups in organic chemistry and can be readily prepared by treatment of carboxylic acid derivatives with organometallic compounds (1). However, the radical version of this conventional acylation reaction has not been successful to date because additions of alkyl radicals to C=O bonds are extremely difficult owing to the high π-bond strengths of C=O bonds (2, 3). Since β fragmentations of alkoxyl radicals are much faster than the additions of alkyl radicals to carbonyl groups, it is anticipated that carbonyl group derivatives cannot be used effectively as radical acceptors to achieve radical-mediated acylations. Thus, a limited number of carbonyl group radical acceptors has been utilized in intramolecular acylations and includes acyl sulfides, acyl selenides (4), and acylgermanes (5, 6). It is noteworthy that a mixed carboxylic phosphonic anhydride is a good radical acceptor in radical cyclizations but fails to function as the carbonyl group acceptor because the β fragmentation of the alkoxyl radical cleaves the carbon–carbon bond rather than the carbon–oxygen bond, as shown in Scheme 1 (7). In addition, several indirect approaches using a nitrile (8) and an oxime ether group have been developed (9, 10). In the case of intermolecular acylation, the use of carbonyl group derivatives as acceptors is uncommon and only several intermolecular radical carboxylations have been reported (11). We developed highly efficient indirect acylation approaches using sulfonyl oxime ethers (10). This indirect approach is at-

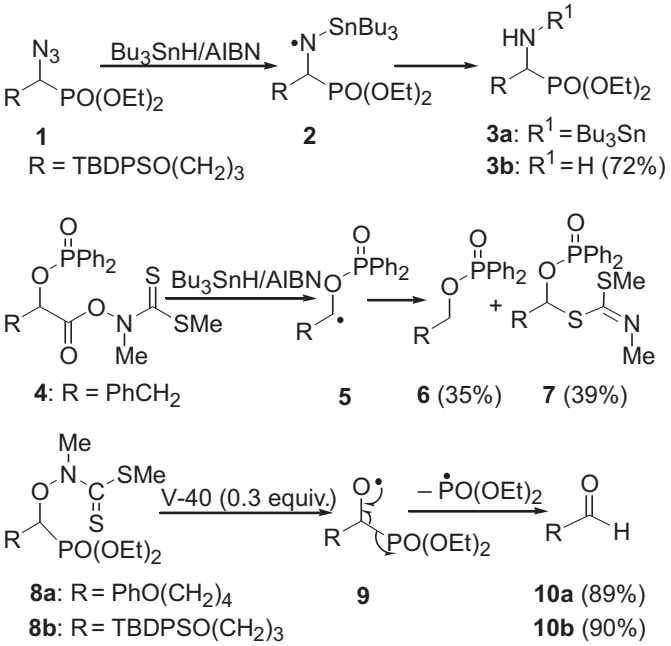
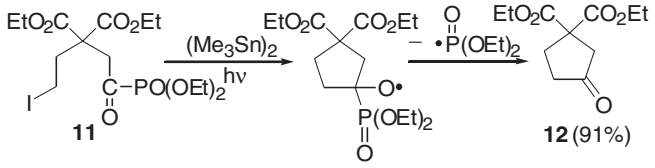
Scheme 1. Intramolecular acylation approach.

tractive since the carbonyl group can be easily generated by oxidative cleavage or by hydrolysis.



In connection with our continued interest on radical acylation, we have searched for other efficient carbonyl group radical acceptors and investigated the possibility of using a phosphonate as a leaving group in radical reactions (12).

Results and discussion

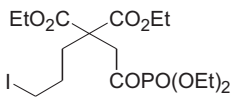


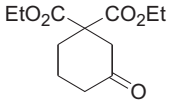
The β elimination of organophosphorous groups has not been well-studied and several reports have appeared only in recent years. The β elimination of a phosphinate group was observed during a rearomatization process (13). The β elimination of a diphenylphosphinoyl group has been known in radical allylation (14) and in tandem radical reactions involving cyclization and the subsequent β elimination of the diphenylphosphinoyl group (15).

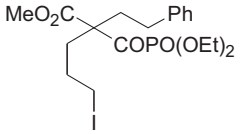
The ease of β elimination generally depends on the nature of the π bond formed and the strength of the σ bond broken. Thus, it is expected that the β elimination would be easier when the π bond formed is stronger (16). Based on this rationale, we initially studied the β elimination of a diethyl phosphonate group from an aminyl radical (Scheme 2). When azidophosphonate **1** was treated with Bu_3SnH–AIBN in refluxing benzene for 2 h (17), **3b** was isolated in 72% yield, clearly indicating that the β elimination of the phosphonate group from the aminyl radical in radical intermediate **2** did not occur, probably because of the relatively weak π-bond strength of C=N bonds. Thus, our attention was given next to the formation of a carbonyl bond as a result of the β elimination of the phosphonate group, and we studied the possibility of β elimination of the diethyl phosphonate group from the alkyl radical using thiohydroxamate ester **4** (18). Radical reaction of **4** with Bu_3SnH–AIBN in refluxing benzene for 4 h afforded a mixture of **6** and **7** roughly in an equal ratio without the β elimination of the phosphonate group. Apparently, the phosphorous–oxygen bond in radical intermediate **5** is strong and did not undergo cleavage. Thus, **5** reacted with Bu_3SnH and the starting thiohydroxamate ester **4** to afford a mixture of **6** and **7**, respectively. Finally, the β elimination of a phosphonate group from the alkoxyl radical was examined. As shown in Scheme 2, when **8a** was treated with V-40 (1,1′-azobis(cyclohexane-1-carbonitrile)) as initiator in chlorobenzene for 3 h (19), aldehyde **10a** was isolated in 89% yield. A similar result was obtained with **8b**. Evidently, the β elimination is energetically favorable because of the formation of a strong carbonyl bond along with cleavage of a relatively weak carbon–phosphorous bond.

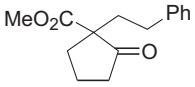
Scheme 2. β Elimination of a diethyl phosphonate group.

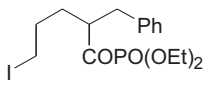
Scheme 3. Radical cyclization of an acylphosphonate.

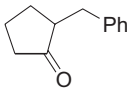


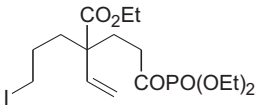


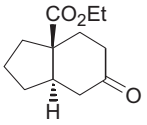


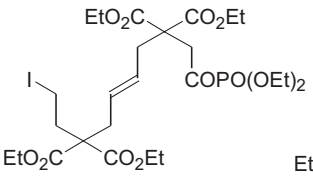


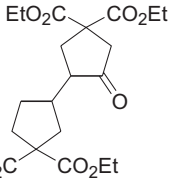


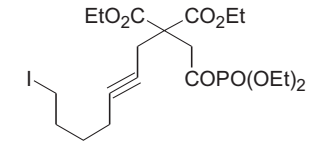


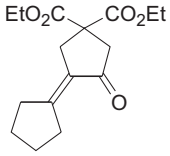












Based on our findings, we studied the feasibility of using an acylphosphonate as a carbonyl group radical acceptor in intramolecular radical acylations (Scheme 3) (12). Acyl and bis(acyl)phosphine oxides have been employed as photochemical sources of acyl radicals for use as initiators in polymerization reactions (20). Also, acylphosphonates were used as acylating agents of alcohols, amines, and enolates (21). Acyldiethylphosphonates were conveniently prepared by treatment of acid chlorides with triethyl phosphite in dichloromethane at room temperature and were quite stable to silica gel column chromatographic purification (22). Radical cyclization of acylphosphonate **11** in the presence of hexamethylditin at 300 nm (1.1 equiv.) for 2 h in benzene gave cyclopentanone **12** in 91% yield without the formation of the direct reduction product. The reaction can be carried out in the presence of a catalytic amount of hexamethylditin (0.2 equiv.) to afford **12** in 88% yield under similar conditions because the initially generated phosphonate radical reacts with an alkyl iodide to generate an alkyl radical. Thus, the remaining reactions were carried out in benzene using 0.2 equiv. of hexamethylditin at 300 nm for 3 to 4 h.

Table 1 summarizes the experimental results and illustrates the efficiency of the acylphosphonates as the carbonyl group radical acceptor. The reaction was normally clean, yielding the corresponding cyclopentanones and cyclohexanones in high yield. For most of the cases observed in this study, there was no indication of the presence of the direct reduction product and other side products. Tandem radical

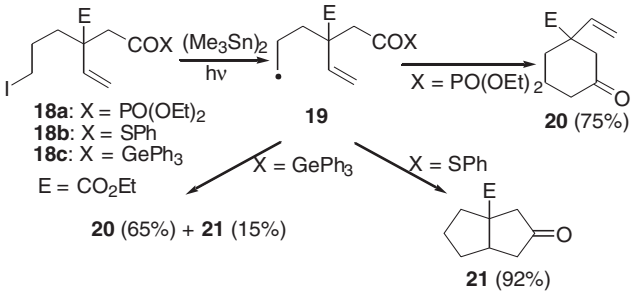
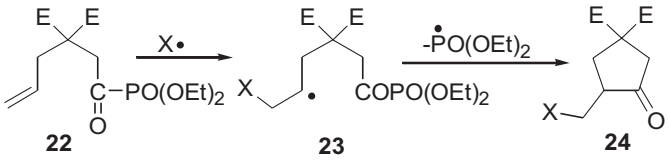
Table 1. Radical cyclization of acylphosphonates.[a]



Entry	Substrate	Product	Yield (%)[b]
1			71 (82)[c]
2			61
3			72
4			69
5			79[d]
6			77

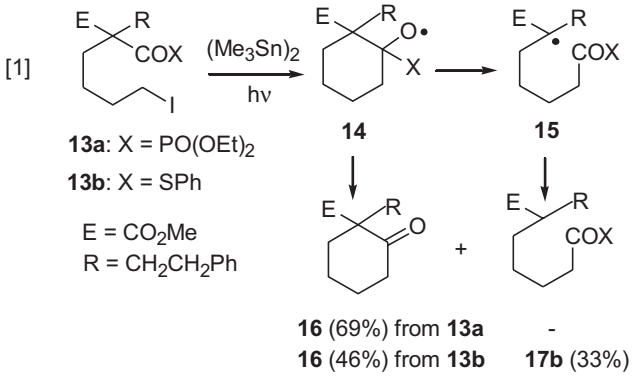
[a]The reaction was carried out with 0.2 equiv. of $(Me_3Sn)_2$ in benzene at 300 nm for 2 h.
[b]The yield was not optimized.
[c]$(Me_3Sn)_2$ (1.1 equiv.).
[d]Stereochemistry of starting material is *E* only. Diastereomeric mixture (1.2:1) of the product.



cyclizations worked equally well. Not only alkyl radicals but also alkenyl radicals reacted with acylphosphonates to give cyclopentanone derivatives (Table 1, entries 4–6).

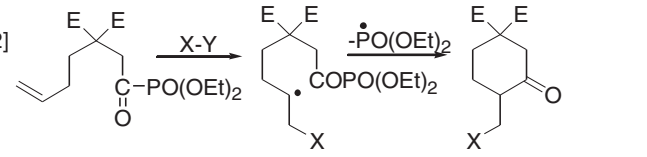
It is noteworthy that reaction of **13a** under similar conditions gave cyclohexanone **16** as a sole product, whereas **13b**, using a thioester as acceptor, gave a mixture of **16** and **17b** in 46% and 33% yield, respectively (4) (eq. [1]). Apparently, the latter is formed as a result of the formation of stable radical intermediate **15b** owing to the facile β fragmentation of the alkoxyl radical **14b**. The result obtained here clearly indicates that the β elimination of the phosphonate group in **9** is very fast and highly efficient. Even more exciting results were obtained with **18** (Scheme 4). When **18a** was treated with hexamethylditin (0.2 equiv.) at 300 nm for 2 h, gratifyingly, **20** was obtained exclusively, whereas **21** was reported to be a sole product from the radical reaction of acyl sulfide **18b** (4). Apparently, 6-exo ring closure to the acylphosphonate group is much faster than 5-exo ring closure to the C=C bond, whereas 5-exo ring closure to the C=C bond is much faster than 6-exo ring closure to the thioester group. To strengthen the efficiency of the acylphosphonate, a comparative experiment was also carried out with acylgermane **18c**. Irradiation of a benzene solution of **18c** in the presence of hexamethylditin (0.2 equiv.) at 300 nm for 3 h afforded a 65:15 mixture of **20** and **21**, indicating higher reactivity of the acylphosphonate relative to the acylgermane as the carbonyl group radical acceptor. Since an approximate rate constant for 5-exo cyclization of a primary alkyl radical to an acylgermane is known to be 7×10^6 s^{-1} (5*c*), the approximate rate constant for the same cyclization to the acylphosphonate would be 3×10^7 s^{-1}. Apparently, the acylphosphonate is regarded as the most reactive among previously reported carbonyl group acceptors.

Scheme 4. Comparative studies of an acyl sulfide, an acylgermane, and an acylphosphonate.



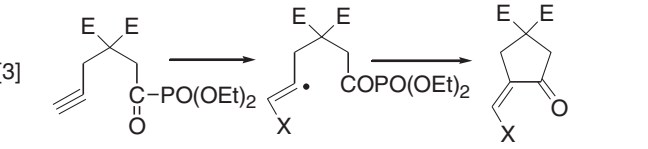
Scheme 5. Radical addition and cyclization of an acylphosphonate.

Based on the highly efficient and fast addition of the alkyl radical onto the acylphosphonate, we next studied sequential radical reactions involving intermolecular radical addition to the alkenyl and the alkynyl bond and subsequent cyclization (Scheme 5). This approach provides a ready access to β-functionalized cyclopentanones and cyclohexanones (23). Addition of a phenylsulfanyl radical and a phenylsulfonyl radical to an alkenyl group in **22** was followed by cyclization to afford cyclopentanone **24** along with the generation of the diethyl phosphonate radical for the chain propagation. Similarly, various electrophilic alkyl radicals from activated olefins bearing α-electron-withdrawing groups reacted smoothly with **22** to yield **24** in high yields. Appar-



[1]

© 2005 NRC Canada



ently, the fast addition of the alkyl radical to the acylphosphonate obviates the problem of the quenching of radical intermediate **23** by the alkyl iodide prior to the cyclization. The experimental results are summarized in Table 2. The present approach can be applied to the formation of cyclohexanone derivatives (eq. [2]). Treatment of **25** with ethyl iodoacetate and hexamethylditin (0.2 equiv.) in benzene at 300 nm for 5 h afforded **26a** in 86% yield. A similar result was obtained with iodomethyl phenyl sulfone under the same conditions. Furthermore, the present approach can be applied to alkynyl-acylphosphonate **27**. When **27** was reacted with thiophenol and phenylsulfonyl bromide in the presence of AIBN in refluxing benzene for 3 h, the desired products **28a** and **28b** were obtained in 86% and 90% yield, respectively (eq. [3]).

[2]

25 X-Y: $EtOOCCH_2I$, $PhSO_2CH_2I$ **26a**: X = CH_2COOEt (86%) **26b**: X = CH_2SO_2Ph (85%)

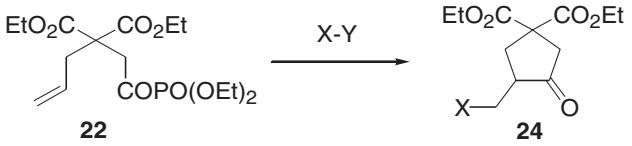
27 PhSH/AIBN **28a**: X = SPh: *E*/*Z* = 1:12, 86%

$PhSO_2Br$/AIBN **28b**: X = SO_2Ph: *E*/*Z* = 1:32, 90%

We next studied several interesting variations using a phosphonoformate and a phosphonothiolformate as radical acceptors to explore whether the present acylation could be further extended to the synthesis of lactone **31a** and thiolactone **31b**, respectively, via intermediate **30** (Scheme 6). Diethylphosphonoformate **29a** was prepared by the treatment of chloroformate **33a** with triethyl phosphite in dichloromethane at room temperature for 2 h (eq. [4]). **29a** was purified by passing it through a short column of silica gel. Similarly, diethylphosphonothiolformate **29b** was prepared from **32b** by a two-step procedure (24). Treatment of **32b** with diphosgene afforded **33b**, which was further treated with triethyl phosphite to give alkyl phosphonothiolformate **29b** in 75% yield.

[4]



32a: X = O **32b**: X = S **33** **29a** (83%) **29b** (75%)

Reaction of **29a** with phenylsulfonyl bromide in the presence of AIBN (0.2 equiv.) in benzene at 80 °C for 6 h did not afford lactone **35** but gave addition product **36a** in 84% yield (eq. [5]). When the reaction was carried out with ethyl iodoacetate and hexamethylditin at 300 nm, a similar result was obtained, yielding **36b** in 88% yield. It is evident that intermediate radical **34** underwent bromine and iodine atom transfer rather than cyclization. To enforce the cyclization of **36a**, the solution of **36a** was irradiated at 300 nm in the presence of hexamethylditin, but lactone **35** was not formed. The failure of the cyclization may be due to the unfavorable *E*-conformation of **34** and (or) the low reactivity of the alkoxycarbonyl group as a radical acceptor. Since the differences in energy are generally smaller for the *E* and *Z* conformations in thiol esters than for the corresponding carboxylic esters (25), radical cyclization of **29b** was studied. Irradiation of a benzene solution of **29b**, ethyl iodoacetate, and hexamethylditin (0.5 equiv.) at 300 nm for 3 h afforded a mixture of addition product **38** and thiolactone **39** in 15% and 42% yield, respectively (eq. [6]). Furthermore, reaction of **38** in the presence of hexamethylditin at 300 nm for 3 h gave thiolactone **39** in 88% yield. From the results obtained here, two features are noteworthy. The addition of an alkyl radical onto the phosphonothiolformate group occurred smoothly, and the diethyl phosphonate group was eliminated preferentially relative to the alkylthio group.

In conclusion, we have shown the facile β elimination of a phosphonate group from an alkoxyl radical and its application to intramolecular acylation approach, in which we demonstrated that the acylphosphonate was a highly efficient carbonyl group radical acceptor and more reactive than the previously known acyl sulfide and acylgermane. In addition, an alkyl phosphonothiolformate group can act as an

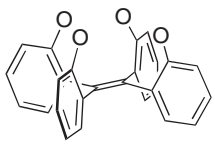
Coordination chemistry of the tetrakis(2-hydroxyphenyl)ethene support mimic — Polymetallic magnesium, aluminum, and titanium derivatives[1]

Udo H. Verkerk, Robert McDonald, and Jeffrey M. Stryker

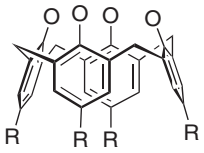
Abstract: The crystal structures of magnesium, aluminum, and titanium coordination complexes of the structurally preorganized tetrakis(2-hydroxyphenyl)ethene are reported. As a result of the absence of steric shielding and the conformational flexibility of the ligand, pseudo-dimeric complexes are formed instead of crown- or raft-like compounds. The unsubstituted tetrakis(2-hydroxyphenyl)ethene ligand thus emulates the complexation characteristics of the sterically open calix[4]arene system.

Key words: coordination chemistry, polymetallic, titanium complexes, magnesium complexes, aluminum complexes, tetrakis(2-hydroxyphenyl)ethene ligands, crystal structures.



Résumé : On a déterminé les structures cristallines de complexes de coordination de tétrakis(2-hydroxyphényl)éthène structuralement préorganisés avec du magnésium, de l'aluminium et du titane. En raison de l'absence de protection stérique et de flexibilité conformationnelle du ligand, il y a formation de complexes pseudodimères au lieu de composés en forme de couronnes ou de bateau. Le ligand non substitué tétrakis(2-hydroxyphényl)éthène émule donc les caractéristiques de complexation du système calix[4]arène stériquement ouvert.

Mots clés : chimie de coordination, polymétallique, complexes du titane, complexes du magnésium, complexes de l'aluminium, ligands tétrakis(2-hydroxyphényl)éthène, structures cristallines.



[Traduit par la Rédaction]

Introduction

The recently introduced tetrakis(2-hydroxyphenyl)ethene ligand **I** (1), a topologically unique analogue of calix[4]arene **II** (2), should by virtue of the constrained arrangement of four phenol groups be useful for modeling the coordination chemistry of an oxo surface. As reported for various calix[4]arenes (2*b*, 3), such an arrangement imposes unique reactivity on complexed metals (3) and could act as an additive (4) or model (3*c*) for heterogeneous supports as used in industrial polymerization catalysis (5). Here we report the crystal structures of magnesium, aluminum, and titanium complexes formed by coordination to tetrakis(2-hydroxyphenyl)ethene.

I

II

Results and discussion

Whereas the reaction of tetrakis(2-hydroxyphenyl)ethene (**1**) with Et_3Al in pentane yields the hydrocarbon soluble, crown-like compound **2**, the reaction of the tetraarylethene with Et_2AlCl generates a pentane insoluble precipitate, presumably the result of predominant intermolecular association (Scheme 1). The addition of THF as a stronger coordinating solvent discourages intermolecular coordination and improves the solubility, allowing isolation of tetrametallic aluminum complex **3** after crystallization from THF–toluene. Compound **3** shows, in the centrosymmetric crystal structure (Fig. 1), two pentacoordinate aluminum centers as part of a Al_2O_2 four-membered ring and two pentacoordinate ethylaluminum chloride fragments sandwiched in between two highly distorted tetraphenylethene ligands. The observed Al2—O4 bond length in the peripheral pentacoordinate fragment Al2 (Table 1) is within the range observed for alumi-

num phenoxides (lit. (6, 7) value 1.79–1.895 Å), as are the Al2—Cl (lit. (6) value 2.104–2.199 Å) and Al2—C3 (lit. (6) value 1.946–1.994 Å) bond lengths. The axial Al2—O bonds are considerably longer (avg. 2.045 Å). The varying bond angles O_{eq}-Al2-O_{eq} (see Supplementary information),[3] and the O5-Al2-O2′ bond angle of 160.64(16)° (Table 1) indicate a distorted trigonal bipyramidal geometry. These features are repeated in the pentacoordinate fragment around Al1, with longer O_{axial}—Al (avg. 1.909 Å) compared to the $O_{equatorial}$—Al (avg. 1.801 Å) bond lengths (see Table 1). The observed range of O4-Al1-O1, O2′, and O3 angles (78.19–93.70°, Table 1), and the O4-Al1-O3′ angle (169.21(16)°) again indicate a significantly distorted trigonal bipyramidal geometry.

Table 1. Key bond lengths (Å), angles (°), and dihedral angles (°) for aluminum complex **3**.

Bond lengths (Å)	
Al1—O1	1.741(4)
Al1—O3	1.860(3)
Al1—O4	1.923(3)
Al2—O4	1.844(4)
Al2—Cl	2.166(2)
Al1—O2′	1.802(4)
Al1—O3′	1.895(3)
Al2—O2′	2.080(4)
Al2—O5	2.010(4)
Al2—C3	1.959(6)
Bond angles (°)	
O1-Al1-O4	93.47(16)
O3-Al1-O4	93.70(15)
O2′-Al1-O4	78.19(15)
O4-Al1-O3′	169.21(16)
O5-Al2-O2	160.64(16)
Tetrakis(2-phenoxy)ethene ligand dihedral angles (°)	
C2-C1-C11-C16	135.9(5)
C11-C1-C2-C41	–14.4(8)
C21-C1-C2-C31	–24.4(7)

The tetrakis(2-phenoxy)ethene ligand itself is highly distorted in the crystal structure (Fig. 2), with three phenoxy groups coordinating to Al1 and the other phenoxy group coordinating to Al1′. One of the phenoxy groups (O1) coordinated to Al1 is angled in towards the plane of the ethene bond (dihedral angle C2-C1-C11-C16: 135.9°) to bring that group into an equatorial binding position. This position resembles one of the transition states for the rotational isomerization of the tetraarylethene aryl ring (8). Simultaneously, the geminal phenoxy O2 is rotated outward into a position that allows the bridging of Al1′ and Al2′. As a result, the double bond is twisted between 14° and 24° to accommodate the metal binding (Table 1).

It is of interest to compare the observed bonding with that of the previously reported aluminum-fused bis-*p*-*tert*-butylcalix[4]arene (7). This structure was obtained by the reaction of the corresponding calix[4]arene with the tertiary amine adduct of aluminum hydride, and shows a sandwich ligand arrangement around a Al_2O_2 core similar to the crystal structure reported here. The calix[4]arene ligands, however, are only slightly distorted, presumably a function of the markedly different topology inherent to the [4]cyclophane structure. In contrast to the tetrakis(2-hydroxyphenyl)ethene derived complex, one calix[4]arene ligand binds all four phenoxy groups to a single, distorted, pentacoordinate aluminum atom.

The reaction of tetrakis(2-hydroxyphenyl)ethene with methylmagnesium chloride is of interest because it may be possible to isolate discrete, raft-like, magnesium complexes

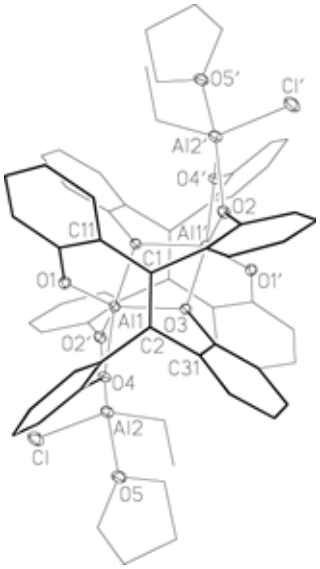
Fig. 2. Alternate view of compound **3** from "above" the tetrakis(2-phenoxy)ethane ligand showing the variation in twisting of the phenyl rings.



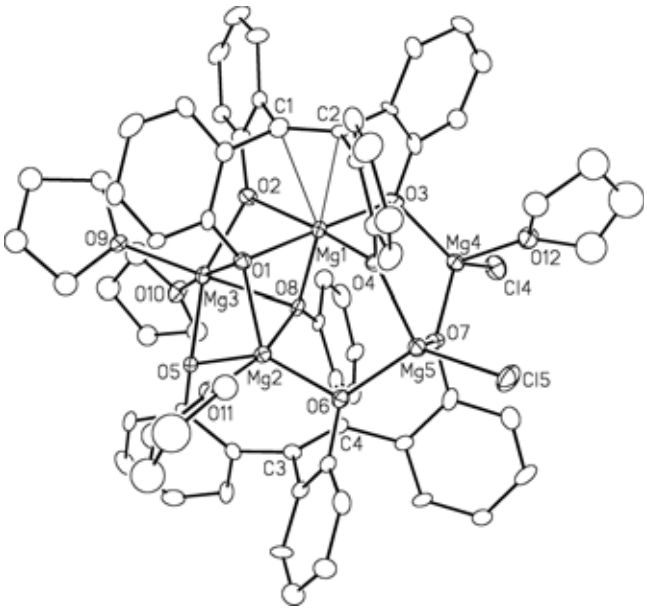


Fig. 3. Perspective view (ORTEP) of compound **4** showing the atom labeling scheme. Hydrogen atoms have been omitted for clarity. A weak interaction between Mg1 and the C1=C2 double bond is indicated by the thin Mg1-C1 and Mg1-C2 lines.

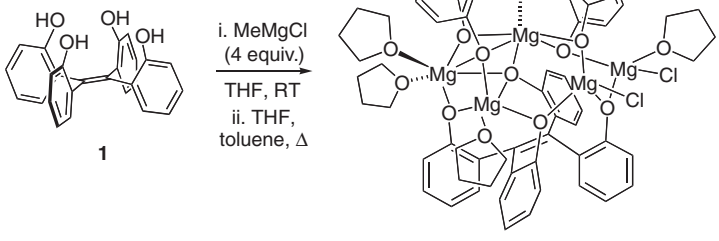

that could be used to introduce transition metals on the magnesium oxide like layer and study the catalytic behavior of such bimetallic heterogeneous catalyst models. However, even in the strongly coordinating solvent THF, the reaction between the Grignard reagent and tetrakis(2-hydroxyphenyl)ethene yields only sparingly soluble material, from which the unusual polymagnesiated complex **4** could be isolated by crystallization from hot THF – toluene (eq. [1]).

The crystal structure of compound **4** shows a sandwich of five magnesium atoms, with coordination numbers ranging from four to six, arrayed between two tetrakis(phenoxy)ethene molecules (Fig. 3). Such an arrangement minimizes intermolecular interactions and accommodates saturating the coordination demands of the magnesium cations; as a result, the cluster shows significant solubility. Unfortunately, the crystallographic analysis is hindered by the weak data set obtained and by the limited number of previously reported aryloxymagnesium solid-state structures (9).

In the crystal structure, Mg4 and Mg5 (Fig. 4) are four coordinate with a distorted tetrahedral geometry according to the wide range of O-Mg-Cl and O-Mg-O angles (see Supplementary information).[3] The observed Mg—O (avg. 1.97 Å), and Mg—Cl (avg. 2.27 Å) bond lengths are comparable to published bond lengths for Mg—μ-O (1.93–1.98 Å) and Mg—Cl (2.27 Å) in tetracoordinate magnesium structures (9). The Mg–THF coordination, Mg4—O12, with a bond length of 2.031(4) Å, also follows observations in the literature (9*e*). Pentacoordinate Mg2 has a distorted trigonal bipyramidal coordination with O_{eq}-Mg-O_{ax} angles ranging from 80.1° to 102.5°, and an O_{eq}-Mg-O_{eq} range of 90.6°–143.1° (see Supplementary information).[3] The Mg—O bond lengths are irregular, but more or less follow the behavior of metal alkoxides (9*e*): as the degree of bridging by an oxygen increases, so does the Mg—O bond length (Mg2—O1, Mg2—O8 > Mg2—O5, Mg2—O6; Table 2). Within the observed range, the Mg2—O8 bond length (2.241(12) Å) is much larger than the Mg2—O1 bond length (2.020(12) Å). This may be a ligand imposed effect or, possibly, a consequence of crystal packing forces. The observed Mg—O_{THF} bond length falls within the reported range of Mg–ether bonds (2.033–2.232 Å) (9*d*).

In the crystal structure, two hexacoordinate magnesium atoms are also present, Mg1 and Mg3 (Fig. 5), with a wide range of bond lengths (Mg—O: 1.973(12)–2.317(11) Å, lit. (9) value 2.0379–2.244 Å) and bond angles (O-Mg-O, cis: 77.6(4)°–106.7(5)°, lit. (9) value 78.4°–85.5°; see Supplementary information).[3] No π complexes of an olefin with Mg are known, but the data presented here do not support a definitive Mg–ethene interaction. First, the shortest Mg1—C

distance (2.514(17) Å) is well beyond the Mg—C bond distances observed for an alkyne complex (10*d*), although within the range of Mg—(π-C) bonds observed for magnesium-cyclopentadienyl interactions (10*a*–10*c*). Secondly, the position of the Mg relative to a plane defined by O1-O2-O3-O4 is 0.1 Å *further away* from the ethene bond.

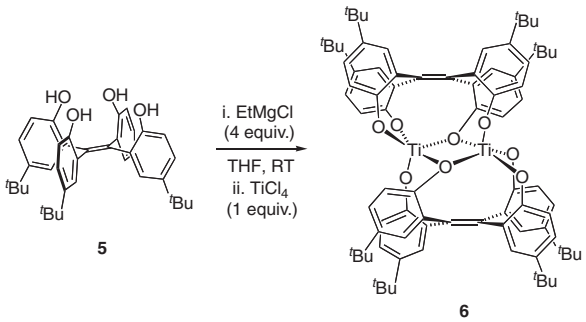

Fig. 5. Alternate view of compound **4**, omitting thermal ellipsoids for the carbon atoms, emphasizing the coordination environment for Mg1 and Mg3. A weak interaction between Mg1 and the C1, C2 double bond is indicated by dashed lines. The distance between Mg1 and the center of the C1, C2 double bond is 2.432 Å.

The tetraarylethene framework involved in bonding to Mg1 shows minimal distortion of the C1—C2 ethene bond, with phenyl ring – ethene bond dihedral angles ranging from 94° to 107° (Table 2) and Mg1—O bond lengths ranging from 1.973(12) to 2.120(11) Å (see Supplementary information).[3] The second tetraarylethene moiety centered around C3—C4 shows a distorted double bond and an irregular phenyl ring twist motif (Table 2). As observed for the aluminum compound, the metal coordination preferences appear to dictate the ligand geometry and binding.

The direct approach to forming Mg–Ti bimetallic procatalysts was attempted by using nonheterogeneous conditions for in situ generation of the magnesium salt of the more soluble ligand tetrakis(2-hydroxy-5-*tert*-butylphenyl)ethene (**5**) (1*a*). Thus, the magnesium salt was generated in THF, followed by the addition of $TiCl_4$ (eq. [2]). Unfortunately, crystallization did not result in isolation of a bimetallic Ti–Mg compound, producing instead a homobimetallic titanitum complex. The crystal structure of dititanium complex **6** is quite similar to the aluminum and magnesium sandwich complexes **3** and **4** (Fig. 6). Trapped

between two tetraarylethene units are two titanium atoms in a centrosymmetric arrangement. No coordinating solvent molecules or magnesium chloride fragments are present. The observed Ti—O bond lengths are within the expected range (lit. (11, 12) value 1.809–1.937 Å, Table 3), except for the Ti—O3′ bond length (2.122(4) Å), which is significantly longer. If four coordination is assumed, the Ti—O1, O2, O4′, and O3 bond lengths should be approximately the same, which is the case. However, the observed bond angles of O1-Ti-O3 (93.93°) and O2-Ti-O3 (128.11°) show significant deviations from true tetrahedral geometry. The deviation could be due to ligand-imposed restrictions on the O2-Ti-O3 angle, given that the O2 and O3 are positioned across the ethene bond, but this argument does not appear to apply to the O1-Ti-O3 angle. If instead a pentacoordinate titanium is assumed, the variation in the Ti—O_{axial} and Ti—$O_{equatorial}$ bond lengths become apparent, as well as the irregularity of O_{eq}-Ti-O_{eq} and O_{eq}-Ti-O_{ax} bond angles (see Table 3). On this basis, the metals in complex **6** may best be considered five-coordinate, albeit distorted. The dilemma with regard to coordination of the titanium atoms is similar to that reported for a *p-tert*-butylcalix[4]arene titanium complex (12). This structure, obtained from the reaction of $Ti(NMe_2)_4$ with *p-tert*-butylcalix[4]arene, shows two tetracoordinated titanium atoms between two calix[4]arene ligands. The authors opted for tetracoordination on the basis of a weak Ti—O bridging interaction (2.473 Å), a significantly longer bond than that observed for Ti—O3′ in complex **6** (2.122(4) Å) (Table 3).

The tetraarylethene framework also shows distortion in the planarity of the ethene bond, with a dihedral angle range of 7.6°–10.6°. Three of the phenyl ring – ethene bond dihedral angles fall in the range of 76°–88°, the fourth ring is significantly tilted towards the ethene bond plane with a dihedral angle of 37° (Table 3). A similar combination of a single phenyl ring and double bond torque is also observed in aluminum complex **3**.

Conclusion

In all cases reported here, ligand dimers surrounding a set of metal atoms rather than raft-like surface analogues are isolated. In this way, intermolecular interactions are minimized to produce the solubility required for crystallization. The tetrakis(2-aryloxy)ethene ligands incorporated in these structures show a surprising flexibility in both ethene bond torsion and aryl ring twist. Taken together, the limited solubility of the initially obtained metal–ligand complexes, the preferential formation of pseudo-dimeric products, and the pronounced deformation of the ligand geometry all suggest that modification of the ligand system (1*b*) is required to prevent indiscriminate ligand–metal interactions. The results of such ligand modifications on the ligand–metal coordination will be reported in forthcoming publications.

Experimental

Reagents and solvents

All solvents were distilled from appropriate drying agents under nitrogen. The tetrakis(2-hydroxyaryl)ethene ligands were prepared by published procedures (1).

General methods

All manipulations were carried out in oven-dried glassware, under a dry and oxygen-free nitrogen atmosphere using a Vacuum Atmospheres drybox. Spectroscopic and elemental analyses to establish the identity and purity of bulk samples were severely constrained by a combination of very

low solubility (complexes **3** and **4**) and systematic inconsistencies in the analytical data obtained from combustion elemental analyses. The latter may arise either from bulk heterogeneity or from incomplete combustion (presumably a consequence of metal oxide formation), difficulties common to the coordination complexes of highly electrophilic metals. To some extent, such problems mirror those identified in the coordination chemistry of the calix[4]arenes.

Tetraaluminum complex 3

To a stirred suspension of 37 mg (0.1 mmol) tetrakis(2-hydroxyphenyl)ethene in 10 mL pentane was added 245 mg (0.5 mmol) Et_2AlCl as a 25 wt% solution in toluene diluted in 5 mL pentane. A bright yellow suspension formed. No ethane formation was observed. After stirring overnight, the solvent was removed under vacuum and the remaining residue resuspended in pentane. After removal of the pentane by decanting, a solid was obtained that, after crystallization from toluene at –30 °C in a glovebox freezer, yielded crystals of insufficient quality and size. This material was redissolved in toluene with the addition of a small amount of THF, from which crystals of sufficient quality for X-ray diffraction were obtained at –30 °C.

Polymagnesium complex 4

A solution of 0.12 g (0.3 mmol) of tetrakis(2-hydroxyphenyl)ethene in 12 mL THF was added to 0.5 mL (1.2 mmol) of a rapidly stirred solution of 3 mol/L methylmagnesium chloride solution in Et_2O. After 12 h at room temperature, the solvents were removed under vacuum and the resulting solid resuspended in a small amount of THF. After removal of soluble by-products by decanting, the remaining solid was dissolved in a minimum of boiling THF. After addition of toluene, crystals of sufficient quality for an X-ray diffraction study were obtained by leaving the solution undisturbed at room temperature for several days.

© 2005 NRC Canada

Dititanium complex 6

A solution of 0.12 g (0.2 mmol) of tetrakis(2-hydroxy-5-*tert*-butyl-phenyl)ethene in 10 mL of THF was slowly added to a stirred THF solution (10 mL) of EtMgCl (70 mg, 0.8 mmol). After stirring for 1 h at room temperature, a solution of 65 mg (0.2 mmol) $TiCl_4$·2THF dissolved in 3 mL THF was added. After stirring for 12 h at room temperature, the solution was reduced in vacuo to 5 mL and 20 mL pentane was added. The precipitate obtained was isolated from the supernatant by decanting and washed with and additional 20 mL of pentane. The solid was extracted with 40 mL of toluene and the resulting deep red solution reduced in vacuo to 5 mL. Crystals of sufficient quality for an X-ray diffraction study were obtained after repeated recrystallizations from toluene at –30 °C.

X-ray crystallographic analysis

Crystals obtained as described were mounted on a glass fiber from a pool of Paratone-N and immediately placed under a cold nitrogen stream and mounted on the diffractometer. Diffraction data were collected on Siemens P4/RA (compound **3**) or Bruker P4/RA/SMART 1000 CCD (compounds **4** and **6**) using Mo Kα radiation (Table 4); details are reported as Supplementary information.[3] For compound **3**, unit cell parameters were obtained from least-squares refinement of 44 reflections with $22.0° < 2\theta < 24.8°$. Unit cell parameters for compounds **4** and **6** were obtained from least-squares refinement of 5270 and 3028 centered reflections, respectively. The data for compound **3** were semi-empirically corrected for absorption. The data for compounds **4** and **6** were absorption corrected using the SADABS procedure (15). The structures of compounds **3** and **6** were solved using the SHELXS-86 program (13), the refinement method was a full-matrix least-squares on F^2 using the program SHELXL-93 (14). For compound **3**, distances involving the methyl carbons of the inversion-disordered solvent toluene molecules were given fixed idealized values. For compound **6**, the methyl carbon positions of the disordered solvent toluene molecule were refined in idealized positions by fixing $d(C_{methyl}—C_{ipso})$ = 1.54 Å and $d(C_{methyl}\cdots C_{ortho})$ = 2.54 Å. The toluene ring carbons were refined as idealized hexagons with d(C—C) = 1.39 Å. For compound **4**, the structure solution program used was a DIRDIF-96 (16) and the refinement program SHELXL-93 (14). An idealized geometry was imposed upon the solvent THF. Full details of the crystal structure determinations are included as Supplementary information.[3]

Synthesis and conformational analysis of disaccharide analogues containing disulfide and selenosulfide functionalities in the interglycosidic linkages[1]

Nagasree Chakka, Blair D. Johnston, and B. Mario Pinto

Abstract: The synthesis of novel disaccharides containing disulfide (methyl-4-*S*-(β-D-galactopyranosyl-1′-thio)-4-thio-α-D-glucopyranoside (**1**)) and selenosulfide (methyl-4-*Se*-(β-D-galactopyranosyl-1′-thio)-4-seleno-α-D-glucopyranoside (**2**)) functionalities in the interglycosidic linkages is described. The synthetic strategy relied on the reaction of a β-glycosylthiosulfonate with a carbohydrate thiol or selenol nucleophile. The resulting protected β-dihetero-linked disaccharides were deprotected to give the target compounds. The conformational preferences of these dihetero analogues were inferred from NOESY experiments and line-broadening effects in variable-temperature NMR spectra, and are rationalized in terms of molecular orbital theory. Low-energy conformations of these compounds can populate regions of conformational space not usually occupied by β-linked disaccharides, and offer the possibility for presentation of novel ligand topographies.

Key words: disaccharides, disulfides, selenosulfides, interglycosidic linkages, conformations, MO explanation.

Résumé : On décrit la synthèse de nouveaux disaccharides comportant des fonctionnalités disulfure (4-*S*-(β-D-galactopyranosyl-1′-thio)-4-thio-α-D-glucopyranoside de méthyle (**1**)) et sélénosulfure (4-*Se*-(β-D-galactopyranosyl-1′-thio)-4-séléno-α-D-glucopyranoside de méthyle (**2**)) dans les liaisons interglycosidiques. La stratégie de synthèse se base sur la réaction d'un β-glycosylthiosulfonate avec un carbohydrate comportant un nucléophile thiol ou sélénol. Les disaccharides protégés à liaison β-dihétéro ont été déprotégés pour fournit les composés cibles. Les préférences conformationnelles de ces analogues dihétéro ont été déduites d'expériences « NEOSY » et d'effets d'élargissement de bande dans les spectres de RMN à température variable et elles sont rationalisées en fonction de la théorie des orbitales moléculaires. Les conformations de basse énergie de ces composés occuper des régions de l'espace conformationnel qui ne sont généralement pas occupés par des disaccharides à liaisons β et elles offrent la possibilité de présenter de nouvelles topographies pour les ligands.

Mots clés : disaccharides, disulfures, sélénosulfures, liaisons interglycosidiques, conformations, explication d'orbitales moléculaires.

Introduction

Carbohydrates and carbohydrate mimetics are essential tools for the investigation of a variety of biological functions that are mediated by carbohydrate recognition events (1, 2). Furthermore, some of these compounds are known to be therapeutic agents (3–7). It is therefore of interest to examine novel types of carbohydrate derivatives or mimetics to expand the collection of potential drug candidates. The next level of carbohydrate mimetic design should include the potential for presentation of different conformational families on the potential energy surface. Such an approach should provide access to an alternative selection of ligand topographies that might have advantages in drug design.

In general, the conformational preferences about glycosidic linkages in oligosaccharides can be described by the ϕ and ψ torsional angles, as shown in Fig. 1. Excursions about the ψ torsional angles in α- and β-glycosides are pronounced, and are dictated by the exact steric requirements about a particular glycosidic linkage (8). However, the preferences about the ϕ torsional angle are much more restricted by the endo- (9) and exo- (10) anomeric effect. Thus, the preferences in α-glycosides are largely restricted to a ϕ_H gauche+ conformation, whereas those in β-glycosides are re-

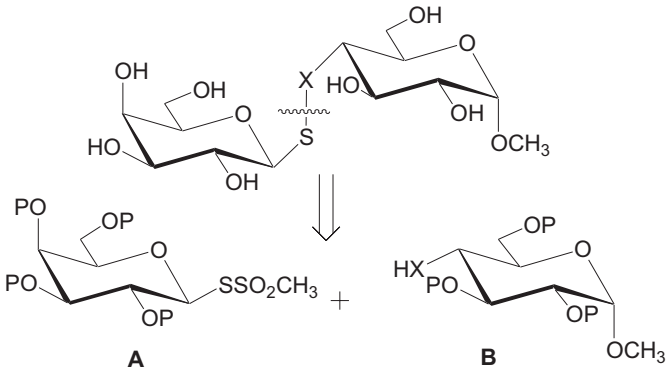
stricted to the ϕ_H gauche– conformation, dictated by the exo-anomeric effect (see structures *b* and *c* in Fig. 1), other conformations about the exocyclic C–O linkage being minimally populated (11).

Thus far, carbohydrate heteroanalogues have been used to advantage to gain access to alternative conformational preferences. For example, disaccharides containing 5-thio sugars, i.e., a sulfur atom in the ring, with different heteroatoms in the interglycosidic linkage, show population of conformations with different ϕ torsional angles (12), and thiooligosaccharides, i.e., those containing a sulfur atom in the interglycosidic linkage, e.g., thiocellobiose, show variations in both ϕ and ψ angles (13). Similarly, the pseudodisaccharide moiety in the tetrasaccharide dihydroglucoacarbose, containing a nitrogen atom in an α-glycosidic linkage, also displays variations in the ψ angle when free in solution (14). However, examples of β-glycosides containing ϕ angles that differ from the gauche conformation shown, e.g., a ϕ_H anti conformation (structure *d* in Fig. 1), have been elusive (15). It is worthy of note that the ϕ_H anti conformation will still permit operation of the exo-anomeric effect, i.e., the $n_Y \rightarrow \sigma^*_{C-X}$ stabilizing orbital interaction.



We were intrigued by the reported conformational preferences of oligosaccharides containing dihetero functionalities in the interglycosidic linkage, for example, those about the N–O glycosidic linkage in the naturally occurring calicheamycins (16), a family of enediyne antitumor antibiotics. These newly discovered compounds with unusual molecular structure have striking biological activity. This unusual N–O linkage has attracted the attention of several groups, and disaccharide mimics wherein two monosaccharide units are linked by a N—O bond have recently been reported (17–19). We propose here to investigate the corresponding compounds containing the S–S and S–Se functionalities in the glycosidic linkages.

Fraser et al. (20) have reported a variable-temperature NMR study of the effects of substitution on the barriers to rotation about the sulfur–sulfur bond in acyclic disulfides, and proposed that interconversion between the preferred ground-state enantiomeric +*g* and –*g* conformations proceeds by way of either syn or anti transition states (Fig. 2). A study of the influence of structure on the height of the interconversion barrier for a series of different R groups showed that the syn transition state, previously assumed to be less stable, was actually of lower energy than the anti transition state. The barrier to rotation about the S—S bond was found to increase from E_a = 7.0 to E_a = 9.4 kcal/mol with an increase in substituent size. The apparent steric rate retardation was explained in terms of a strong preference for the syn over the anti transition state. However, Jorgensen and Snyder (21) concluded on the basis of molecular mechanics calculations on dialkyl disulfides that rotation proceeds by way of an anti transition state. Although syn/anti

barriers for simple, uncongested disulfides (e.g., HSSH and CH_3SSCH_3) have been computed at various levels of sophistication (22), the anti energy maximum was always lower than the syn energy maximum. Our own previous study of restricted rotation in hindered dichalcogenides showed that diselenides and ditellurides exhibit similar conformational preferences to disulfides (23).

We chose to examine in detail the conformational preferences in β-linked disaccharides containing disulfide and selenosulfide moieties in the interglycosidic linkage and report herein that these compounds take up the nomal ϕ_H gauche+ conformation about the C-1′—S bond but exhibit restricted rotation about the S—X bond and preferentially populate either the (+*g*) or the (–*g*) conformation about this linkage. Szilágyi et al. (24) and Davis et al. (25) have separately reported the syntheses of symmetric, nonreducing di-

Scheme 2.

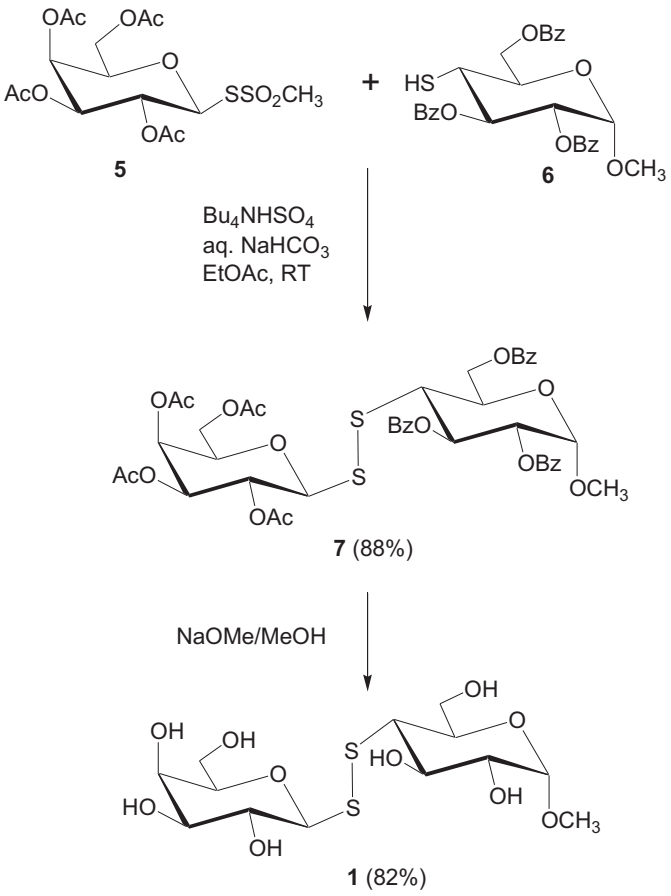
saccharides containing interglycosidic (1→1′) disulfide linkages; these compounds also display unusual conformational preferences. In addition, the syntheses of monosaccharides containing sulfenamide aglycons have been described recently (26).

Results and discussion

Synthesis

Retrosynthetic analysis of the target compounds showed that they could be synthesized by the coupling reaction of monosaccharide **A** (a glycosylthio donor) with a monosaccharide **B** containing an appropriate nucleophile at C-4 (Scheme 1).

The synthesis of the glycosyl donor **5** was first attempted by the reaction of acetobromogalactopyranose **3** with sodium thiomesylate **4** (27, 28) in ethanol, as described for the corresponding glucose derivative (29). No desired product was observed even after refluxing. A similar result was obtained when DMF was used as the solvent. However, the displacement reaction proceeded smoothly in acetonitrile at room temperature, to give thiomesylate **5** (Scheme 2).



The coupling reaction of thiomesylate **5** with thiol **6** (30) in the presence of a phase-transfer catalyst (tetrabutylammonium hydrogensulfate) and saturated aqueous sodium bicarbonate in EtOAc at room temperature gave the (1′→4) disulfide **7** in excellent yield (Scheme 3). Methanolysis then afforded the target disulfide **1**.

Analogously, the coupling reaction of thiomesylate **5** with selenol **8** (31) gave selenosulfide **9**, (4→4′) diselenide **10** being formed as an oxidative by-product. The target selenosulfide **2** was obtained by deprotection of compound **9** by methanolysis. Similarly, diselenide **11** was obtained by deprotection of (4→4′) diselenide **10** under Zemplén conditions (Scheme 4).

Conformational analysis

The conformational preferences of compounds **7** and **9** may be defined in terms of the φ, ψ, and ω angles shown in Fig. 3. These preferences were probed by means of ^{1}H NMR spectroscopy. The NOESY spectrum for each compound showed cross peaks for H-3/H-1′, H-3/H-5′, and OCH_3/H-5′, in addition to the cross peaks generally expected for the two monosaccharide units. COSY-type cross peaks for strongly coupled resonances could be distinguished from true NOESY correlations by their anti-phase character. The specific NOESY cross peaks suggest that the disaccharides have a preferred –gauche (–*g*) conformation about the ψ angle, although the ω angle could not be defined explicitly with the limited number of observed NOE cross peaks (Fig. 3). A more rigorous analysis by computational methods in the absence of experimental data did not seem warranted for the purposes of this study. Inspection of molecular models suggested that the observed NOEs would be consistent with a conformation in which the $C_1'SXC4$ (X = S, Se) torsion angle is about –60° (Fig. 3). Our assignment of conformational preferences is consistent with those reported by Szilágyi et al. (24) for 1→1′-linked disaccharides containing a disulfide moiety in the interglycosidic linkage.

Scheme 3.

The ^{1}H NMR spectra for compounds **7** and **9** in deuterated toluene showed broad resonances for H-1′, H-5′, H-6A′, and H-6B′ in ring **A**, suggesting that there is exchange on the NMR timescale between conformations in the intermediate exchange regime at room temperature. Heating the samples to about 350 K led to sharp NMR signals, as indicated in Fig. 4 for the case of **7**. As the temperature was lowered below room temperature, the spectra showed coalescence behaviour and eventually, below 200 K, resolution into resonances for two separate conformers at the slow-exchange limit. The ratio of the major conformer to the minor conformer was 3:1 based on integrations of the separate H-4

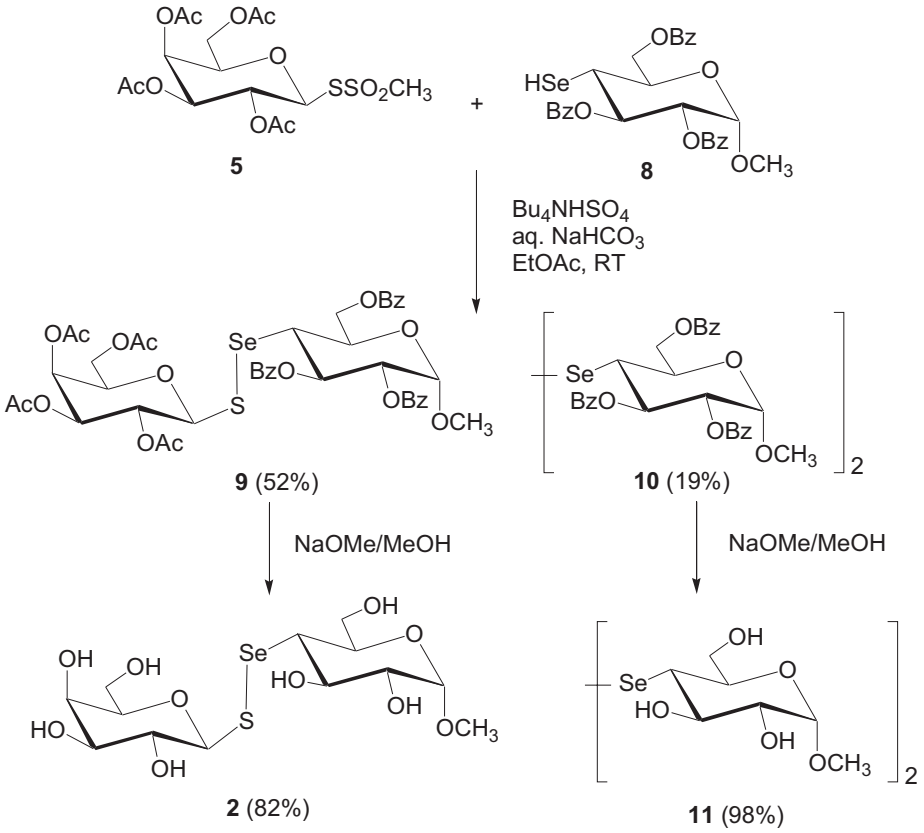
Scheme 4.



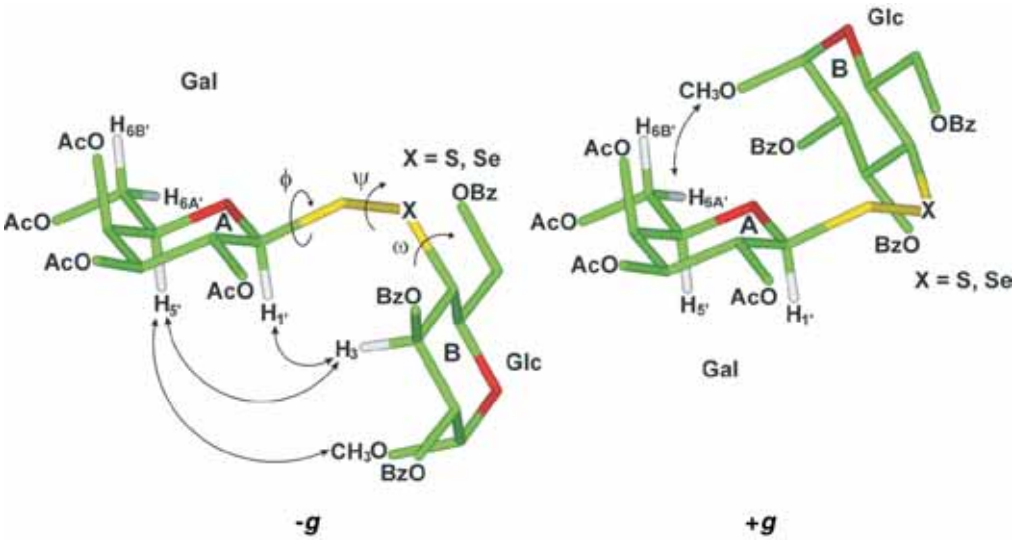


Fig. 3. Preferred conformations of compounds **7** and **9**.

resonances at δ 2.95 and δ 2.45 in the spectrum recorded at 193 K (Fig. 4). Based on these variable-temperature NMR results, we conclude that a second conformation, namely the +gauche (+*g*) conformation (Fig. 3) is also populated. Broadening of the H-1′ and H-5′ signals can then be accounted for by the proximity of ring **B** to ring **A**, in the (–*g*) conformation, where ring **B** is under ring **A**, and broadening of the H-6′ signal by the proximity of the two rings in the (+*g*) conformation, where ring **B** is above ring **A** (Fig. 3). The observations of weak OCH_3/H-6′ correlations in the NOESY spectra lend additional support to the importance of the (+*g*) conformation about the S—X bond in these compounds.

The NOESY spectra for target compounds **1** and **2** showed cross peaks for OCH_3 with the H-5′/H-6′ multiplet. However, the high degree of spectral overlap did not permit unambiguous assignment of the other signals. It seems reasonable that compounds **1** and **2** will have similar

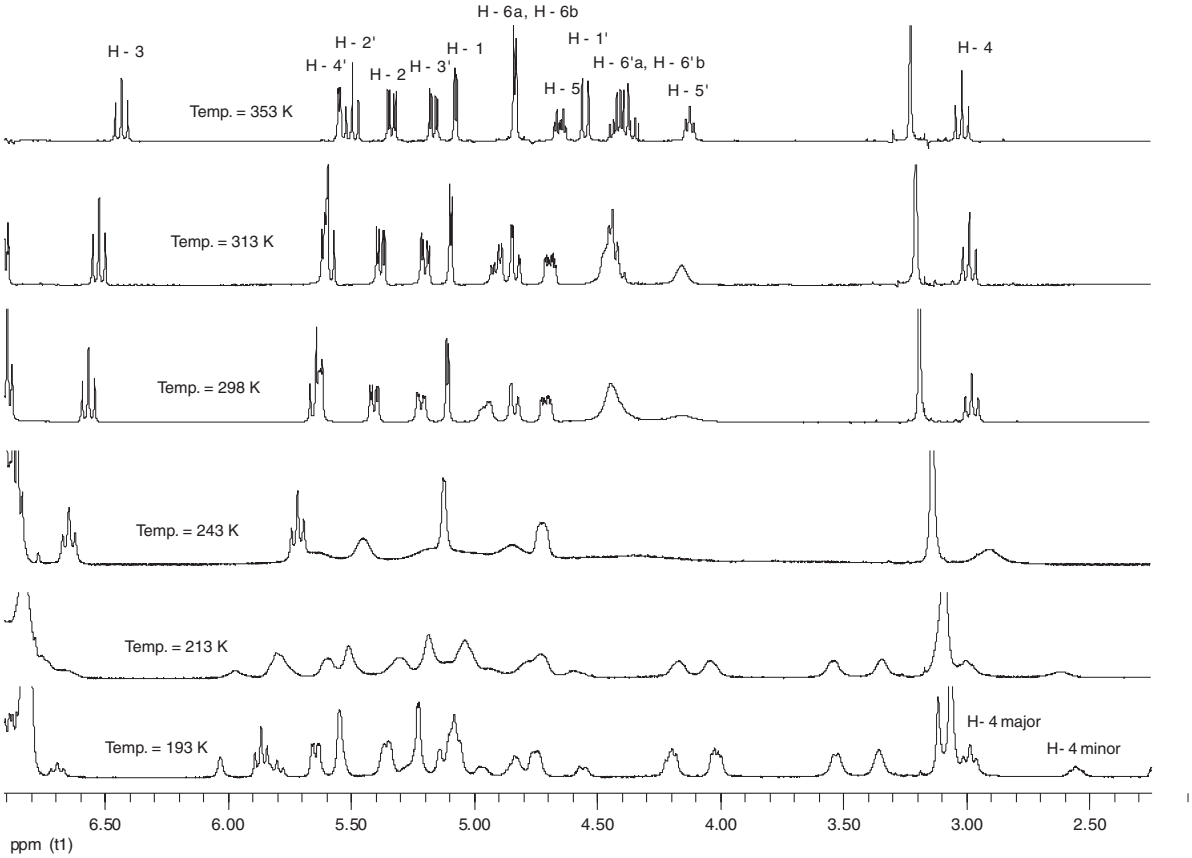
Fig. 4. Variable-temperature ^{1}H NMR spectra of compound **7** in toluene-d_8.



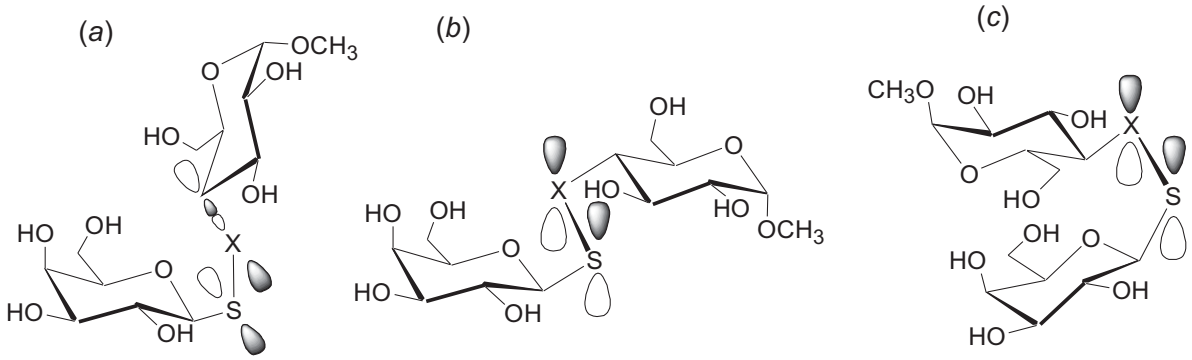


Fig. 5. Fragment molecular orbital interactions in compounds **1** and **2** (X = S, Se).

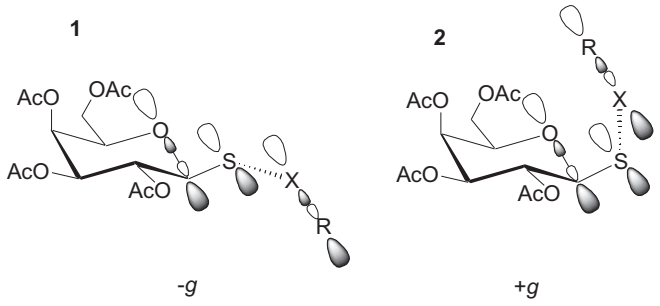
conformational preferences as their protected precursors. However, in these cases, no significant line-broadening effects were observed at room temperature, indicating that the barrier to rotation about the S—X (X = S, Se) bond is less than in the corresponding protected compounds.

The gauche conformational preferences about the S—S and S—Se bonds are consistent with arguments based on perturbational molecular orbital theory. Thus, an anti or syn preference is disfavored based on a 4e repulsive interaction between the 3*p* orbitals on the sulfur atom with either the S (3*p*) or Se (4*p*) orbital on the adjacent atom (Figs. 5*b*, 5*c*) (32). In contrast, the gauche conformations (e.g., Fig. 5*a*) permit a 2e stabilizing $n_S \rightarrow \sigma^*_{X-C}$ hyperconjugative interaction.



Interestingly, both (+*g*) and (–*g*) conformations also permit expression of the $n_S \rightarrow \sigma^*_{C1-O5\,Gal}$ exo-anomeric interaction (Fig. 6). These two conformations are therefore stabilized by both the exo-anomeric effect and the hyperconjugative interactions associated with the RS–SR′ and RS—SeR′ linkages (Fig. 6). Importantly, the (+*g*) conformation (Fig. 6*b*) places the glucose ring above the galactose ring in a manner similar to the elusive ϕ_H anti conformation in β-linked disaccharides while the (–*g*) conformation places the two sugar rings in a similar orientation to that observed for ordinary disaccharides.

Conclusions

Disaccharide analogues in which the interglycosidic linkage is either a disulfide or selenosulfide moiety have been

© 2005 NRC Canada

Fig. 6. Combined exo-anomeric $n_S \rightarrow \sigma^*_{C\text{-}1\text{-}O\text{-}5}$ and $n_S \rightarrow \sigma^*_{X\text{-}R}$ interactions (X = S, Se).

synthesized. The compounds display interesting conformational preferences, as determined by NOE spectroscopy and line-broadening effects. These preferences are consistent with the operation of the destabilizing and stabilizing orbital interactions associated with the RS–SR′ and RS–SeR′ linkages as well as with the stabilizing $n_S \rightarrow \sigma^*_{C\text{-}1'\text{–}O\text{-}5'}$ exo-anomeric orbital interaction. The conformational preferences suggest a means of expanding the repertoire of carbohydrate topographies for use as biological probes.

Experimental section

General

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Rudolph Research Autopol II automatic polarimeter. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker AMX-400 NMR spectrometer at 400.13 MHz and 100.6 MHz for proton and carbon, respectively. Chemical shifts are given in ppm downfield from TMS for those spectra measured in $CDCl_3$, CD_3OD, $(CH_3)_2CO$, or toluene-d_8 and from 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) for those spectra measured in D_2O. Chemical shifts and coupling constants were obtained from a first-order analysis of the spectra. All assignments were confirmed with the aid of two-dimensional ^{1}H/^{1}H (COSYDFPT), ^{1}H/^{13}C (INVBTP), ^{1}H (NOESYTP), and ^{1}H (MLEVTP) experiments using standard Bruker pulse programs. Processing of the spectra was performed with standard UXNMR (Bruker) and WINNMR software. Zero filling of the acquired data (512 t_1 values and 2 K data points in t_2) led to a final data matrix of 1 K × 1 K ($F_1 \times F_2$) data points. MALDI-TOF mass spectra were obtained for samples dispersed in a 2,5-dihydroxybenzoic acid matrix using a PerSeptive Biosystems Voyager-DE instrument. Analytical TLC was performed on aluminum plates precoated with Merck silica gel 60F-254 as the adsorbent. The developed plates were air-dried, exposed to UV light and (or) sprayed with a solution containing 1% $Ce(SO_4)_2$ and 1.5% molybdic acid in 10% aq. H_2SO_4 and heated. Compounds were purified by flash column chromatography on Kieselgel 60 (230–400 mesh). Solvents were distilled before use and were dried, as necessary. Solvents were evaporated under reduced pressure and below 50 °C.

2,3,4,6-Tetra-*O*-acetyl-β-D-galactopyranosyl methanethiosulfonate (5)

Acetobromogalactose **3** (1.00 g, 2.43 mmol) was added to a solution of sodium methanethiosulfonate **4** (0.38 g, 2.84 mmol) in acetonitrile (25 mL) at room temperature under nitrogen. The temperature was then slowly raised to 50–60 °C and the reaction mixture was stirred for 3 h until TLC showed completion of the reaction. The suspension was cooled and the solvent was removed. The residue was purified by chromatography on silica gel, (EtOAc–hexane, 7:12) to give the title compound as a white solid (0.95 g, 88%); mp 124–126 °C. $[\alpha]_D^{23}$ +3 (*c* 1.9, $CHCl_3$). ^{1}H NMR (400 MHz, acetone-d_6) δ: 5.50 (1H, dd, $J_{3,4}$ = 3.5 Hz, $J_{4,5}$ = 1.0 Hz, H-4), 5.47 (1H, d, $J_{1,2}$ = 10.4 Hz, H-1), 5.39 (1H, dd, $J_{2,3}$ = 9.9 Hz, H-3), 5.19 (1H, dd, H-2), 4.44 (1H, ddd, H-5), 4.22 (1H, dd, $J_{5,6a}$ = 4.4 Hz, $J_{6a,6b}$ = 11.6 Hz, H-6a), 4.13 (1H, dd, $J_{5,6b}$ = 8.0 Hz, H-6b), 3.56 (3H, s, SSO_2CH_3), 2.15–1.92 (12H, 4s, 4 × OAc). ^{13}C NMR (400 MHz, $CDCl_3$) δ: 170.17–169.69 (CO, 4 × OAc), 86.98 (C-1), 75.37 (C-5), 71.33 (C-3), 67.07 (C-4), 65.79 (C-2), 61.86 (C-6), 52.76 (SSO_2CH_3), 20.62–20.47 (Me, 4 × OAc). Anal. calcd. for $C_{15}H_{22}O_{11}S_2$: C 40.72, H 5.01; found: C 41.01, H 5.05.

Methyl 2,3,6-tri-*O*-benzoyl-4-*S*-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-galactopyranosyl-1′-thio)-4-thio-α-D-glucopyranoside (7)

To a mixture of thiosulfonate **5** (2.14 g, 4.8 mmol) and thiol **6** (2.75 g, 5.1 mmol) in EtOAc (58 mL) was added phase-transfer catalyst, tetrabutylammonium hydrogensulfate (2.16 g, 6.4 mmol), and saturated aqueous sodium hydrogencarbonate (13 mL). The reaction mixture was stirred at room temperature under nitrogen for 18 h and then diluted with EtOAc (100 mL). The organic layer was then washed with saturated sodium chloride solution (2 × 30 mL) followed by water (2 × 30 mL). The organic layer was dried over anhydrous sodium sulfate and evaporated. The crude product was purified by column chromatography (EtOAc–hexane, 1:2). The title compound **7** was obtained as an amorphous white solid (3.97 g, 88%). $[\alpha]_D^{23}$ –30.3 (*c* 3.5, $CHCl_3$). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.09–7.94 (6H, 3d, 3 × OBz ortho Hs), 7.64–7.34 (9H, m, 3 × OBz meta + para H), 6.23 (1H, dd, $J_{2,3}$ = 9.6 Hz, $J_{3,4}$ = 10.4 Hz, H-3), 5.50 (1H, d, $J_{3',4'}$ = 3.4 Hz, $J_{4',5'} \approx 0.0$ Hz, H-4′), 5.31 (1H, dd, $J_{1',2'}$ = 10.0 Hz, H-2′), 5.20 (1H, dd, $J_{1,2}$ = 3.6 Hz, H-2), 5.17 (1H, d, H-1), 5.13 (1H, dd, $J_{2',3'}$ = 10.1 Hz, H-3′), 4.82 (1H, broad dd, $J_{5,6a}$ = 4.0 Hz, $J_{6a,6b}$ = 12.1 Hz, H-6a), 4.73 (1H, dd, $J_{5,6b}$ = 2.1 Hz, H-6b), 4.53–4.51 (2H, m, H-1′, H-5), 4.44–4.27 (3H, m, H-5′, H-6a′, H-6b′), 3.48 (3H, s, OMe), 3.11 (1H, dd, $J_{4,5}$ = 10.4 Hz, H-4), 2.20–1.99 (12H, 4s, 4 × OAc). ^{13}C NMR (400 MHz, $CDCl_3$) δ: 170.38–169.42 (CO, 4 × OAc), 166.17–165.72 (CO, 3 × OBz), 133.29–128.36 (15C, Ph), 97.18 (C-1), 89.50 (br, C-1′), 74.51 (C-5′), 73.35 (C-2), 71.81 (C-3′), 69.62 (br, C-3), 67.58 (C-5), 66.87 (2C, C-2′, C-4′), 63.56 (C-6), 60.35 (C-6′), 55.67 (OMe), 47.91 (C-4), 20.72–20.56 (Me, 4 × OAc). Direct synthesis of unprotected α-amino acids via allylation of hydroxyglycine[1]

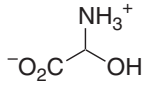
Masaharu Sugiura, Chieko Mori, Keiichi Hirano, and Shū Kobayashi

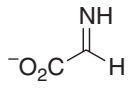
Abstract: Hydroxyglycine, the ammonia adduct of glyoxylic acid, was found to react with various allylboronates in the presence of triethylamine in methanol to give unprotected α-amino acids directly with high stereoselectivity. For instance, the reactions with (*E*)- and (*Z*)-crotylboronates afforded the corresponding anti- and syn-crotylated products (isoleucine and alloisoleucine after hydrogenation) with high diastereoselectivity, respectively. Interestingly, it was found that isomerization of the products (γ-adducts to α-adducts) occurred under the reaction conditions in some cases. Control experiments have suggested that the isomerization took place via 2-aza (or azonia) Cope rearrangement of imines derived from γ-adducts and glyoxylic acid.

Key words: hydroxyglycine, glyoxylic acid, allylboronates, α-amino acids, allylglycines, isoleucine, alloisoleucine, stereoselective reactions, isomerization, 2-aza (azonia) Cope rearrangement.



Résumé : On a trouvé que l'hydroxyglycine, le produit d'addition de l'ammoniac sur l'acide glyoxylique, réagit avec divers allylboronates, en présence de triéthylamine dans le méthanol, pour conduire directement à la formation d'acides α-aminés non protégés, avec une stéréosélectivité élevée. Par exemple, les réactions des (*E*)- et (*Z*)-crotylboronates conduisent respectivement aux produits anticrotylés et syncrotylés correspondants (isoleucine et alloisoleucine après hydrogénation) avec des diastéréosélectivités élevées. Fait intéressant, on a trouvé que, dans les conditions expérimentales et pour quelques cas, il se produit une isomérisation des produits (adduits γ en adduits α). Des expériences de contrôle ont suggéré que l'isomérisation se produit par un réarrangement 2-aza (ou azonia) de Cope des imines dérivées d'adduits γ et de l'acide glyoxylique.

Mots clés : hydroxyglycine, acide glyoxylique, allyboronates, acides α-aminés, allylglycines, isoleucine, alloisoleucine, réactions stéréosélectives, isomérisation, réarrangement 2-aza (ou azonia) de Cope.



[Traduit par la Rédaction]

Introduction

Hydroxyglycine (**1**), which is obtained as a zwitterionic solid under the isoelectronic conditions (pH ca. 6), is an equimolar adduct of glyoxylic acid and ammonia (1). It readily decomposes to glyoxylic acid in an aqueous media at pH < 6, while it oligomerizes via iminoacetate **2** (an assumed intermediate) at pH > 6. These compounds attracted us because we recently found that three-component reactions (α-aminoallylation) of glyoxylic acid (other aldehydes as well), ammonia, and allylboronates proceeded smoothly to afford allylglycines (homoallylic primary amines) in high yields (2). In these reactions, both **1** and **2** are supposed to serve as intermediates. However, despite their potential utility as intermediates for direct synthesis of *unprotected* α-amino acids, **1** and **2** have been barely utilized in organic synthesis (3). Herein, we report that nucleophilic addition of allylboronates to hydroxyglycine **1** provides an efficient, stereoselective route to unprotected allylglycines.

Results and discussion

Initial attempts were made for allylation of hydroxyglycine **1** with allylboronate **3a** (4*a*). First, the effect of varying solvents was investigated by simply mixing **1** and **3a** (1.2 equiv.) in a solvent at 0 °C to room temperature (rt) for 15–18 h (Table 1, entries 1–6). Protic solvents (ethanol, methanol, and water) were found to be effective (Table 1, entries 1–3), whereas less polar solvents (toluene, THF, and acetonitrile) were much inferior (Table 1, entries 4–6). The reaction mixtures were suspensions in these solvents except for in water because of the low solubility of **1**. Among the solvents tested, methanol gave the highest yield and chemoselectivity (amine **4a** vs. alcohol **5a**) (Table 1, entry 2). To improve the yield, further optimization of the conditions were performed choosing methanol as a solvent. A longer reaction time (72 h) or a higher temperature (50 °C) dramatically improved the yield (Table 1, entries 7 and 8). It is also

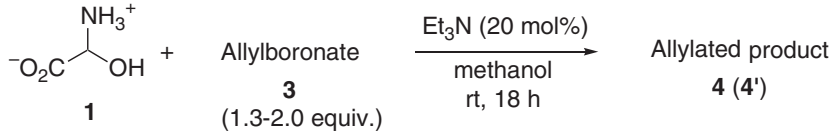
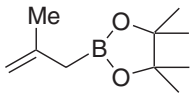
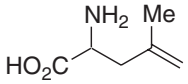
noteworthy that only allylated amine **4a** was obtained exclusively in these entries. Furthermore, a catalytic amount of triethylamine (20 mol%) was found to accelerate the reaction showing the highest yield and selectivity of **4a** (Table 1, entry 9). It is presumable that the base promotes formation of an active intermediate, iminoacetate **2** from **1**.

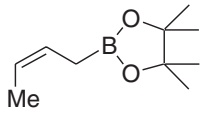
With the optimal conditions in hand, we then investigated reactions of **1** with various allylboronates **3** (4*b*–4*d*) (Table 2). Methallyboronate **3b** afforded the corresponding adduct **4b** in high yield (Table 2, entry 1). Triethylamine (1 equiv.) was used in this case to facilitate the desired reaction.[3] Significantly, (*Z*)-crotylboronate ((*Z*)-**3c**) provided syn-crotylated product (*syn*-**4c**) exclusively (>99% syn) along with a small amount of α-adduct (*Z*)-**4c′**, while anti-adduct (*anti*-**4c**) was obtained from (*E*)-crotylboronate ((*E*)-**3c**) in good yield with excellent selectivity (97% anti, Table 2, entries 2 and 3). In the later case, a very small amount of α-adduct **4c′** was yielded. Direct treatment of hydrogen (1 atm, 1 atm = 101.325 kPa) and Pd/C in the same pot successfully converted syn- and anti-adducts (*syn*- and *anti*-**4c**) to alloisoleucine (75%) and isoleucine (82%), respectively (Scheme 1). On the other hand, reactions of **1** with (*E*)-cinnamylboronate **3d** and cyclohexenylboronate **3e** provided **4d** and **4e**, respectively, in high yield with high diastereoselectivities (Table 2, entries 4 and 5). In the former case, 1 equiv. of triethylamine was effective to suppress formation of α-adduct **4d′**. Sterically more demanding prenylboronate **3f** also reacted with **1** in the presence of 2 equiv. of triethylamine to afford a mixture of the desired allylated product **4f** and α-adduct **4f′** (85:15) in high yield (Table 2, entry 6).

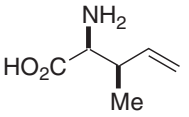


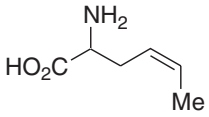
We were then interested in the mechanism of the formation of α-adduct **4′**. It was found that the formation of α-adduct **4′** became prominent when the reaction mixtures were concentrated with heating before purification. In the reaction of **1** with **3f**, for example, this manipulation led to only formation of **4f′**. In contrast, the formation of **4′** was suppressed to a large extent when the reaction mixture was directly purified by ion exchange resin (Dowex 50W-X2). Addition of a stoichiometric amount of triethylamine in allylations was also effective to suppress the formation of **4′** (vide supra). These observations indicated that some impurity involved in the reaction mixture promoted the isomerization on heating. We speculated that glyoxylic acid (or hydroxyglycine) formed an imine with allylated product **4**, which could undergo 2-aza (or azonia) Cope rearrangement leading to the isomerization (Scheme 2) (5, 6). To prove this hypothesis, purified *syn*- and *anti*-**4c** were treated with glyoxylic acid (0.1 equiv.) in D_2O at 50 °C (Fig. 1). Monitoring by ^{1}H NMR spectroscopy clearly showed gradual isomerization of *syn*- and *anti*-**4c** to α-adduct **4c′** (first order in [**4c**]; $t_{1/2}$ = 78 min for *syn*-**4c**, 34 min for *anti*-**4c**), whereas no isomerization was observed in the absence of glyoxylic acid.

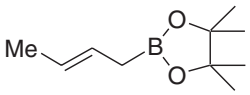


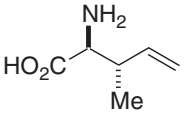


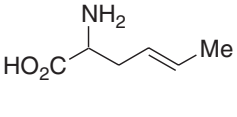


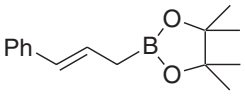


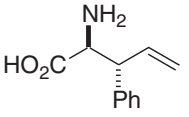


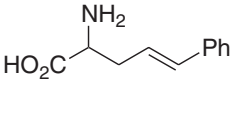


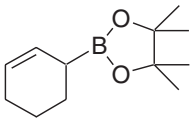


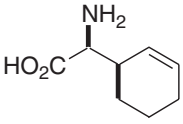


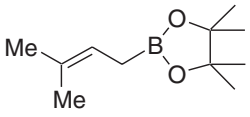


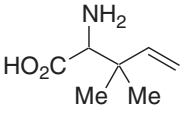


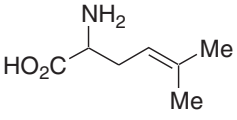












It should also be noted that (*Z*)-**4c′** was predominantly obtained from *syn*-**4c**, whereas *anti*-**4c** gave (*E*)-**4c′** with high selectivity (also see the Experimental section). Chair-like transition states **TS-*syn*** with the pseudo-axial methyl group[4] and **TS-*anti*** with the pseudo-equatorial methyl group could account for the observed stereochemical outcomes (Scheme 3). We also found that the rate of the isomerization of *anti*-**4c** to (*E*)-**4c′** was faster than that of *syn*-**4c** to (*Z*)-

[3] When a catalytic amount of triethylamine was used, an unidentified product was obtained along with **4b**. The ^{1}H and ^{13}C NMR spectra of this by-product suggested a Prins-type cyclization product. Further structural elucidation is now in progress.
[4] The preference of the equatorial CO_2H group might be ascribed to the acid–base interaction of the CO_2H group with the imino nitrogen.

[e]The reaction was conducted for 6 h.

4c′. This rate difference would be ascribed to the fact that **TS-*anti*** is more stable than **TS-*syn*** because of the number of pseudo-equatorial substituents. In addition, the higher isomerization tendency of **4f** could be explained by the mechanism via 2-aza (or azonia) Cope rearrangement in which the equilibrium favors release of the steric hindrance to the more stable trisubstituted alkene **4f′**.

In summary, we have demonstrated that hydroxyglycine (**1**), the ammonia adduct of glyoxylic acid, reacts with various allylboronates in the presence of a tertiary amine to give

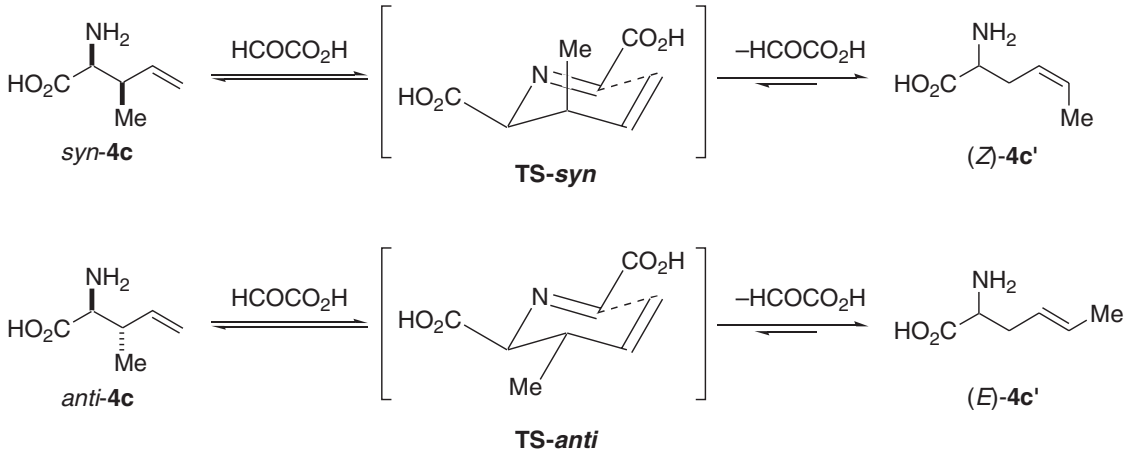
the corresponding unprotected α-amino acids directly. Reactions with γ-substituted allylboronates showed high diastereoselectivity, while isomerization of γ-adducts to α-adducts was accompanied to some extent. Further studies regarding its application to asymmetric synthesis are now in progress.



Experimental section

General methods

Melting points (mp) are uncorrected. ^{1}H and ^{13}C NMR spectra were recorded on JEOL ECX-400 or ECX-600 spectrometers in D_2O. 1,4-Dioxane served as the internal standard (δ 3.75 ppm for ^{1}H NMR and δ 67.19 ppm for ^{13}C NMR). High-resolution electrospray ionization mass spectra (HR-ESI-MS) were measured with a Bruker Daltonics BioTOF II mass spectrometer. Methanol was distilled from magnesium–iodine and stored over 3 Å MS. Purified water was employed for work-up and purification. All other solvents were purified based on standard procedures. Hydroxyglycine (**1**) (1) and allylboronates **3a**–**3f** (4) were prepared according to literature procedures.

Scheme 3. Chair-like transition state models for 2-aza Cope rearrangement.

General procedure for allylation of hydroxyglycine

Under an argon atmosphere, to a suspension of hydroxyglycine (**1**) (45.5 mg, 0.5 mmol) in dry methanol (2 mL), were added allylboronate **3** (1.2–2.0 equiv.) and triethylamine (0.1–2.0 equiv.) successively at ambient temperature. The mixture was stirred at that temperature for the indicated time, diluted with water, and charged on a cationic ion exchange resin column (Dowex 50W-X2, 50–100 mesh, H^+ form; ca. 5 g/wet) with water. After washing with a sufficient amount of water, α-amino acid **4** was eluted with 1.0 mol/L aqueous ammonia (fractions were checked by 0.1 wt% ninhydrine in acetone–water (4:1)), and concentrated to dryness.

Monitoring isomerization of 4c to 4c′ by ^{1}H NMR spectroscopy

A solution of *syn*- or *anti*-**4c** (7.7 mg, 0.06 mmol including a small amount of **4c′**) in deuterium oxide (0.6 mL) in a NMR sample tube was heated at 50 °C for 1 h and checked by ^{1}H NMR spectroscopy. No isomerization between **4c** and **4c′** was observed. Then, glyoxylic acid (0.1 equiv., 60 µL of a 0.1 mol/L solution in deuterated oxide) was added to the solution. The mixture was heated at 50 °C and monitored by ^{1}H NMR spectroscopy intermittently. Gradual changes of the **4c**:**4c′** ratio was observed as shown in Tables 3 and 4 (see also Fig. 1). Epimerization between *syn*- and *anti*-**4c** was not observed during the reaction.

Synthesis, structure determination, and hydroformylation activity of *N*-heterocyclic carbene complexes of rhodium[1]

Austin C. Chen, Daryl P. Allen, Cathleen M. Crudden, Ruiyao Wang, and Andreas Decken

Abstract: The effect of ancillary phosphine ligands on the structure and hydroformylation activity of Rh-*N*-heterocyclic carbene complexes of type [Rh(IMes)(PR_3)(CO)Cl] and [Rh(SIMes)(PR_3)(CO)Cl] is described. Very high selectivities for the branched isomer (>95:5) were obtained in the hydroformylation of vinylarenes in all cases except for R = OPh. The new complexes were characterized spectroscopically and by X-ray crystallography.

Key words: hydroformylation, rhodium, *N*-heterocyclic carbene, IMes.

Résumé : On décrit l'effet des ligands phosphines d'appoint sur la structure et l'activité d'hydroformylation de carbènes complexes Rh-*H*-hétérocyclique, du type [Rh(IMes)(PR_3)(CO)Cl] et [Rh(SIMes)(PR_3)(CO)Cl]. Dans tous les cas excepté celui où R = OPh, des sélectivités très élevées de l'isomère ramifié (>95 : 5) ont été obtenues lors de l'hydroformylation de vinylarènes. Les nouveaux complexes ont été caractérisés par spectroscopie et par diffraction des rayons X.

Mots clés : hydroformylation, rhodium, carbène *N*-hétérocyclique, IMes.

[Traduit par la Rédaction]

Introduction

The hydroformylation of alkenes is among the most important and well-studied catalytic reactions. First discovered in 1938 by Otto Roelen, the reaction adds the elements of hydrogen and carbon monoxide across carbon–carbon multiple bonds (1). Industrially, the hydroformylation reaction is employed for the production of 5–10 billion tons of aldehydes and alcohols yearly (2). The largest single product from this reaction is 2-ethylhexanol, a precursor to phthalate ester plasticizers (Scheme 1). For major industrial applications, the desired product in the hydroformylation of propene is the linear isomer (3).

The process is run commercially with homogeneous Rh catalysts in the presence of large excesses of phosphine, usually greater than 0.3 mol/L, which translates to 8%–50% of the total solution by weight. Such excesses of phosphine are required because under carbon monoxide pressure, the catalyst is in equilibrium with di- and tricarbonyl species that have a lower selectivity for the linear isomer (eq. [1]) (4). In addition, degradation of the phosphine occurs by oxidative addition of Rh into the P—C bond (5). Ultimately, this process leads to an erosion of selectivity because the degraded phosphines give lower selectivity, and more importantly, inactive Rh dimers can form that decrease the overall efficiency of the catalyst.

With vinylarenes as the substrates, the branched isomer is the target since the hydroformylated product can be converted into the corresponding 2-aryl propionic acid by a simple oxidation (eq. [2]) (6). High-branched selectivity can often be obtained depending on the choice of catalyst and ligand. Since the analgesic activity of 2-arylpropionic acids is ascribed solely to the S enantiomer, the asymmetric hydroformylation of vinylarenes has also been developed (7). However, ibuprofen, one of the largest volume nonsteroidal anti-inflammatory drugs (NSAIDs), is sold as a

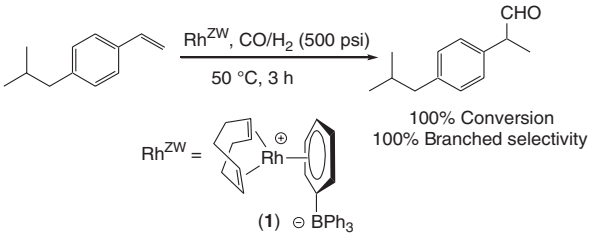
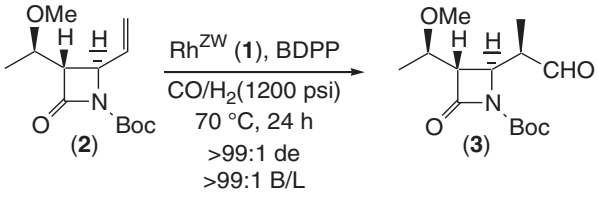


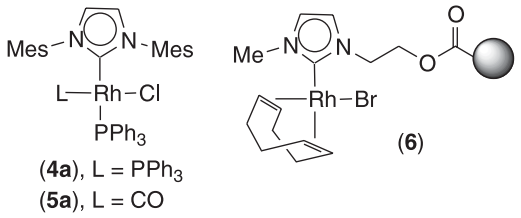
Scheme 1. Hydroformylation of propylene to produce commodity chemicals.



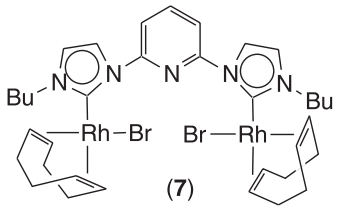
[2] 

racemate because of the presence of an inverting enzyme in the body that converts the inactive R enantiomer into the S (8). Naproxen, another large volume drug in this class, is sold in enantiomerically pure form, but the final step in the commercial process is a dynamic kinetic resolution (9). Therefore, an efficient, racemic hydroformylation that provides the branched isomer as the major product could be a viable method for the synthesis of ibuprofen or naproxen.

Several catalysts have been examined for the branched selective hydroformylation of vinylarenes, with one of the most effective being a zwitterionic catalyst (**1**) developed by Alper and Amer (10) (eq. [3]). This catalyst promotes the highly selective hydroformylation of vinylarenes at moderate pressures of carbon monoxide and hydrogen. In the hydroformylation of *p*-isobutylstyrene, the precursor to ibuprofen is obtained in 100% conversion after 3 h, with no detectable linear aldehyde.



[3] 

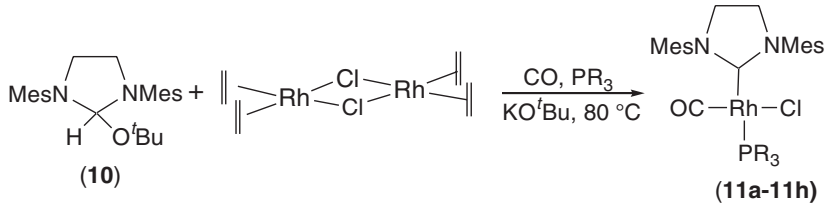


In addition to the hydroformylation of vinylarenes, a variety of functionalized alkenes react with high levels of selectivity using catalyst **1** (11). As shown in eq. [4], densely functionalized 4-vinyl β-lactam substrates such as **2** can be hydroformylated with high levels of regio- and stereocontrol using catalyst **1**. The product (**3**) can be easily elaborated into 1-methylcarbapenem antibiotics.

[4] 

Transition-metal complexes of *N*-heterocyclic carbenes (NHCs) have received considerable attention of late, particularly in coupling reactions (12, 13) and metathesis chemistry (14). Despite the importance of the hydroformylation reaction, and the significant number of Rh–NHC complexes that were prepared in the early 1980s by Lappert and co-workers (15), very little work has been done on the catalytic activity of NHC-ligated complexes in the hydroformylation reaction. This is somewhat remarkable since the professed strength of the metal–carbene bond (16) would prevent the type of dissociative equilibria that is problematic in Rh–phosphine complexes. Furthermore, breakdown of the carbene ligand is not anticipated to occur to the same extent as it occurs with phosphine complexes. However, it should be noted that examples have been reported in which carbene complexes breakdown under catalytic conditions (17).

Chart 1. *N*-Heterocyclic carbene-based hydroformylation catalysts.



In addition to our recent report of Rh–NHC catalysts **4a** and **5a** (Chart 1) for the hydroformylation of vinylarenes (18), we are aware of only two other published reports of NHC complexes that are catalytically active in the hydroformylation reaction. Weberskirch and co-workers (19) have described a Rh catalyst immobilized on a hydrophilic polymer (**6**) for the hydroformylation of 1-octene and Fernandez and co-workers (20) have prepared a bimetallic Rh carbene (**7**) that is active in the hydroformylation of styrene (Chart 1). A cobalt–carbene complex has been prepared by Van Rensburg et al. (21), but it showed no hydroformylation activity.

Results and discussion

The first complex that we examined in the hydroformylation of vinylarenes was **4a** ([ClRh(IMes)(PPh_3)$_2$]), a direct analog of Wilkinson's catalyst (**8**) ([ClRh(PPh_3)$_3$]), which was prepared in 87% yield by reaction between free IMes (**9**, 1,3-bis(2,4,6-trimethylphenyl)imidazol-2-ylidene) and **8** (eq. [5]). Since this species was highly air sensitive and somewhat difficult to handle, we employed its carbonyl derivative **5** ([ClRh(IMes)(CO)(PPh_3)]) in hydroformylation

[6] 

studies. This species was readily prepared by passing a stream of carbon monoxide through a solution of **4a**, providing **5a** in 88% yield.

The resulting lime-yellow complex (**5a**) was highly stable, and could be handled in air and even purified by silica gel chromatography. The ^{31}P NMR spectrum of **5a** contained one phosphine doublet at 31.7 ppm, with a ^{31}P–^{103}Rh coupling constant of 115 Hz, consistent with a phosphine ligand trans to the carbene ligand (22). X-ray quality crystals were obtained by slow diffusion of hexanes into a solution of **5a** in THF.[5]

Since Grubbs' catalyst is more active when prepared with the saturated carbene SIMes (1,3-dimesitylimidazolin-2-ylidene) than IMes itself, we attempted to prepare a Rh complex of this carbene using the in situ protocol described by Morgan and Grubbs (23). To generate the free carbene from *tert*-butanol adduct **10**, heating to 80 °C is required. Unfortunately, treatment of Wilkinson's catalyst (**8**) with **10** at this temperature gave none of the desired complex. Subsequent studies from our group have shown that complexes of the type $[ClRh(NHC)(PR_3)_2]$ have limited thermal stability, and thus it was likely that the desired complex was decomposing under the reaction conditions. However, when this reaction was carried out under an atmosphere of carbon monoxide, the desired carbene complex was isolated in 50% yield as bright yellow bricks (eq. [6]).

To prepare a variety of carbene complexes from a common rhodium source, $[Rh(CH_2{=}CH_2)_2Cl]_2$ was examined as an alternative to Wilkinson's type complexes. Treatment of this species with **10** in the presence of 1 equiv. of phosphine and 1 atm of CO (1 atm = 101.325 kPa) gave the desired complex **11a** in 85% isolated yield (Table 1). This procedure was effective for a variety of different complexes **11a**–**11h** in moderate to good yield (eq. [7], Table 1). In those cases where decreased yield is observed, biscarbene and bisphosphine complexes were invariably observed. However, the high air and moisture stability of the complexes **11a**–**11h** permitted their facile separation from these species by column chromatography. After chromatographic purification, crystallization from dichloromethane–pentane mixtures provided X-ray quality crystals in all cases except for **11c** and **11d**. The crystal structures of complexes **11a** and **11b** and **11e**–**11h** are shown in Figs. 1–6, and the crystallographic data summarized in Tables 2–5.

As previously observed in the crystal structure of **5a**, complexes **11a**–**11h** are square-planar about rhodium, with the Cl and CO ligands in a trans orientation as would be expected. Table 4 describes the key bond lengths and angles,

[5]Note that the original crystal structure reported in ref. 18 was carried out at room temperature. For comparison's sake, we have performed a new crystal structure determination at –93 °C.

respectively, for carbene complexes **4a** (24), **5a**, and **11a**, along with data for the all phosphine derivatives **8** (25) and **12** ([ClRh(CO)(PPh_3)$_2$]) (26). All compounds are approximately square-planar around Rh, with the sums of the bond angles around Rh equaling approximately 360°. The most distorted is the IMes bisphosphine complex **4a**. In this case, the sum of the angles on the side of the phosphines (C_{NHC}-Rh-PPh_3 and Ph_3P-Rh-PPh_3) is 194.7(15)°, which is significantly greater than 180°. The chloro side of the molecule compensates for this with both angles being acute, and adding up to 165.9(15)°. Replacing the phosphine cis to the IMes with a CO ligand as in compound **5a** relieves the steric strain considerably such that the sum of the angles on the CO side of the molecule is very close to 180° (184.1(2)° in one molecule and 176.1(9)° in the other molecule in the crystal structure). SIMes derivative **11a** and phosphine carbonyl species **12** all have similar bond angles, but Wilkinson's catalyst **8** (25) is also significantly distorted. Thus, it is likely the presence of two *cis*-phosphines that leads to the distortion from ideal geometry.

The Rh–carbene bond length is similar in the SIMes, IMes, and CO derivatives, but interestingly the Rh—CO bond length is quite short in IMes complex **5a** (1.706(5) Å), especially compared with **11a** and **12** (26) at 1.8126(17) and 1.810(7) Å, respectively. However, in this case, the crystals were found to be disordered with 50% occupancy of the Cl and CO ligands,[6] and if one examines the other molecule in the crystal structure, the Rh—CO bond length is quite long at 1.828(7) Å. Thus, packing effects obviously cannot be ignored and the length of the Rh—CO bond should not be over interpreted.

The shortest Rh—P bond is found for **5a** at 2.2988(7) Å. The Rh—P bonds are shorter in all the carbene complexes compared with the phosphine complexes **8** and **12**, although the differences are not large. Rh—Cl bonds again show similarities among NHC complexes and bisphosphine complexes, being approximately 2.39 Å in the former and 2.37 Å in the latter.

Fig. 3. X-ray crystallographic structure of compound **11e** showing both independent molecules in the crystal structure.

In Table 5, the crystallographic data of other SIMes carbonyl derivatives are collected along with data for **5a**. All the complexes are square-planar, with little distortion as evidenced by the sum of the bond angles in many cases being close to 180°. The C(2)-Rh-P tensor is most linear for phosphite complex **11b** compared with all of the other complexes (179.19(4)°). With the exception of **5a** and **11e**, which are composed of two independent molecules in the crystal structure, the Rh—CO bond length is longest for **11b** (1.856(2) Å), which is reasonable since the phosphite ligand likely accepts some of the electron density from Rh, resulting in less backbonding to the CO ligand. The Rh—CO bond length is the shortest for complexes **11g** and **11h**, which have relatively bulky phosphine ligands (P(*o*-tolyl)$_3$ and PCy_3). Interestingly, the two orientations of the molecules in the crystal structures of **5a** and **11e** sport one very short (1.706(5) and 1.793(5) Å) and one very long (1.828(7)

[6] Note that this was the case in two separate crystal structure determinations on different batches of **5a**.

and 1.931(8) Å) Rh—CO bond. However, compound **11f**, which is also composed of two individual orientations, has relatively similar bond lengths: 1.8106(17) and 1.8075(17) Å.

The IR frequencies for key stretches in complexes **11a**–**11h** and **5a** are compiled in Table 6 (27). The carbonyl IR frequency for **12** ([ClRh(PPh_3)$_2$(CO)]) is 1980 cm^{-1} (27*c*), which is significantly higher than that of the SIMes derivative [ClRh(SIMes)(PPh_3)(CO)] **11a** (1954 cm^{-1}) and IMes derivative **5a** (1944 cm^{-1}). This implies that backbonding is more significant in the *N*-heterocyclic carbene complexes, which would be expected since carbenes are better donors than phosphines. Interestingly, the carbonyl stretch of IMes derivative **5a** is lower than that of the SIMes derivative, which is contrary to what would be expected since SIMes is believed to be a stronger donor than IMes, although the difference is small (28). Within the SIMes derivatives, the lowest stretch comes from the most electron-rich phosphine complex **11g** (PCy_3) at 1940 cm^{-1}), while the highest is for triphenylphosphite derivative **11b** (1976 cm^{-1}), consistent with the decreased back donation into the CO ligand for the phosphite derivative.

NMR data for the NHC–Rh complexes are also compiled in Table 6. As expected, the ^{31}P NMR spectra display a simple doublet from coupling to ^{103}Rh. The ^{13}C NMR data show little variation in the carbon monoxide resonance, even compared to **12**, where the CO resonates at 187.4 ppm (27*c*). However, there is a significant difference of 27.4 ppm between the NHC resonance for the carbon bound to Rh in the IMes derivative **5a** and the same carbon in SIMes complex **11a** (Table 6, entries 1 and 2). The IMes ligand resonates at 184.1 ppm, while the SIMes derivatives are all around 211 ppm. Although large, this difference tracks extremely well with the observed difference in the chemical shifts of the free carbenes, where SIMes is 24 ppm downfield of IMes (SIMes 243.8 ppm, IMes 219.7 ppm) (29). The position of the carbene carbon resonance is quite sensitive to electronics, as this carbon appears at 197.14 ppm in ClRh(IMes)(PPh_3)$_2$ (**4a**) and is shifted a remarkable 13 ppm

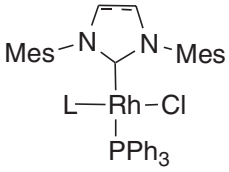
upfield by replacing one phosphine with a carbonyl ligand. Since the two downfield resonances in **5a** are very close to each other, a derivative of **5a** in which the carbene carbon was labeled with ^{13}C was prepared by treating ^{13}C-labeled **4a** with carbon monoxide.[7,8] This allowed us to assign the resonance at 184.1 ppm to the carbene carbon. As expected, both the NHC and CO resonances appeared as doublets of doublets because of the one-bond coupling to Rh and two-bond coupling to the phosphine.

Hydroformylation activity

Carbene complexes **4a** and **5a** were both examined in the hydroformylation of styrene as shown in Table 7. Wilkinson's catalyst itself (**8**) gives only 35% conversion after 19 h at 60 °C, with a poor branched to linear ratio of 87:13 (Table 7, entry 1). Replacing one phosphine with IMes (catalyst **4a**) results in significantly higher selectivity for the branched isomer (96:4), and approximately twice the conversion (Table 7, entry 2). The carbon monoxide derivative (**5a**) reacted with equally high selectivity, but to retain the activity, an equimolar amount of triphenyl phosphine was added (Table 7, entry 4). The reason for this is currently under investigation, but may have to do with the requirement for more than one phosphine on Rh in the key catalytic species, as in eq. [1]. Interestingly, compound **12** ([Rh(CO)-$PPh_3)_2$Cl]) displayed decreased regioselectivity and poor conversion, even in the presence of added phosphine (Table 7, entry 7), illustrating that the improved activity and selectivity are due to the carbene ligand. Under optimized conditions, a variety of vinylarenes were hydroformylated with complex **5a** in high yield and high selectivity (Table 7, entries 8–11).

The effect of varying the nature of the phosphine and the carbene was then examined as shown in Table 8 (31). On changing the catalyst from the unsaturated IMes derivative to the saturated SIMes catalyst, the turnover frequency doubled while the selectivity for the branched isomer stayed the same. Electron-donating substituents at the para position of the phosphine such as in compound **11c** (Table 8, entry 4) had little effect on the rate or the branched selectivity. Sterically hindered phosphines such as tricyclohexylphosphine and P(o–tolyl)$_3$ gave decreased selectivity for the branched isomer and decreased rates (Table 8, entries 8 and 9). The worst ligand in terms of rate and selectivity is triphenyl phosphite **11b** (Table 8, entry 3). Phenyl-dibenzophosphole also displayed decreased activity and somewhat diminished selectivity. In terms of rate, the best catalyst was

[7] This species was prepared for another project in collaboration with Jason Clyburne, starting with ^{13}C-labeled imidazolium chloride: C.M. Crudden, D.P. Allen, J.A.C. Clyburne, and T. Ramnial. Manuscript in preparation.



[8] In the case of the SIMes derivatives, the assignment was made based on the coupling constants to Rh and to the adjacent phosphine, which are very similar in magnitude to those reported for **12** ([ClRh($PPh_3)_2$CO]), δ 187.4 ppm, $^1J_{C\text{-}Rh}$ = 73 Hz, $^2J_{C\text{-}P}$ = 16 Hz (27).

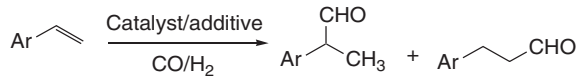
the trifuryl phosphine, although the regioselectivity was somewhat eroded.[9]

Several additives were examined for their effect on the reaction, with triethyl amine displaying the most dramatic effects. As shown in Table 9, the addition of triethyl amine increased the turnover frequencies for the hydroformylation by an order of magnitude in some cases, without any erosion in the branched to linear selectivity for most of the catalysts (compare to Table 8). Phosphite derivative **11b**, the phenyldibenzophosphole complex **11e**, and the two bulky phosphines **11g** and **11h** showed only marginal improvements upon the addition of triethylamine. It is likely that the accelerating effect of triethylamine is caused by removal of the chloride from the catalyst as HCl, a reaction that is accelerated by base (32). The reason that this effect is more dramatic with some of the catalysts is not clear yet, but may be due to the relative rates of reductive elimination of HCl. The catalysts that showed the lowest response to the addition of triethyl amine are also those with more electron-rich phosphines. These might be expected to undergo reductive elimination more slowly. It is possible that pretreament of the catalyst with triethylamine prior to the reaction would be a more effective strategy in these cases, an approach currently being investigated in our laboratories.



Interestingly, the hydroformylation of styrene with complex **11h** in the presence of triethylamine gave a considerable amount of the reduced alcohol along with the expected aldehyde. The ratio of alcohol to aldehyde was 63:37. This is the only time reduction was observed to accompany hydroformylation and is somewhat unusual since reducing ability is usually attributed to cobalt catalysts, not rhodium.

In conclusion, we have successfully prepared a variety of rhodium *N*-heterocyclic carbene complexes, which are capable of hydroformylating vinylarenes with high selectivity for the branched isomer. The IMes and SIMes complexes are more active than the corresponding all-phosphine derivatives, and SIMes-based catalysts appear to be twice as active as IMes derivatives. The addition of triethylamine causes an order of magnitude increase in rate, probably by promoting reductive elimination of HCl. Current work in our group is di-

[9]Note that in this case some decrease was observed in the turnover frequency with time so it is not clear how stable the catalyst is throughout the reaction conditions.

rected towards the de novo synthesis of a rhodium hydride carbene complex to obviate the need for the addition of NEt_3.

Experimental

General experimental

NMR spectra were recorded on an XL-200 (^{1}H at 200 MHz), a Varian Unity-400 (^{1}H at 400 MHz, ^{13}C at 100 MHz, ^{19}F at 376 MHz, and ^{31}P at 162 MHz), or a Bruker Avance 500 (^{1}H at 500 MHz, ^{13}C at 125 MHz) spectrometer in deuterated chloroform ($CDCl_3$) containing 0.03% TMS unless otherwise noted. ^{1}H NMR chemical shifts are reported in ppm relative to TMS (0.0 ppm) or $CHCl_3$ (7.26 ppm). ^{13}C NMR chemical shifts are reported in ppm relative to $CDCl_3$ (77.0 ppm). ^{19}F NMR chemical shifts are reported in ppm relative to the external standard $C_6H_5CF_3$ (–63.73 ppm). ^{31}P NMR chemical shifts are recorded in ppm relative to the external standard H_3PO_4 (0.0 ppm). Multiplicities are reported as broad (br), singlet (s), doublet (d), triplet (t), quartet (q), and multiplet (m),

© 2005 NRC Canada

along with integration (for ^{1}H NMR) and coupling constants (Hz). IR spectra were obtained with a Bruker IFS25 spectrometer as thin films on NaCl discs or as KBr pellets. Peaks are reported in cm^{-1} with relative intensities indicated (strong (s), medium (m), weak (w)). Mass spectra from UNB were recorded on a Kratos Concept 1H double-focusing mass spectrometer with 8 kV accelerating and 70 eV ionizing voltages. The spectrometer was calibrated against perfluorokerosene and has a resolution of 7000. Data are reported as *m*/*e* with intensities relative to the base peak. Mass spectra were recorded at Queen's University on an Applied Biosystems/MDS Sciex QSTAR XL Q-TOF mass spectrometer (Toronto, Ontario) equipped with an electrospray source. The sample was infused in a 1:1 mixture of CH_2Cl_2 and dried CH_3NO_2 at a flow rate of 6 μL/min. The spectrometer was internally calibrated and run in positive mode.

Solvents were dried and distilled under an inert atmosphere from the drying agents listed (33) — pentane, hexane, benzene, and toluene from sodium metal; acetonitrile, dichloromethane, and triethylamine from calcium hydride; diethyl ether and THF from sodium wire and benzophenone ketyl; DME from LAH; and acetone from $KMnO_4$. When necessary, solvents were purged of oxygen just prior to use by either flushing with argon or using repeated freeze–pump–thaw cycles.

With the exception of *p*-isobutylstyrene, which was prepared in three steps using a literature procedure (34), all other vinylarenes were purchased from commercial sources. Prior to use, they were distilled under a partial vacuum of argon and percolated through a column of dry, neutral alumina. *N*,*N*′-Bis(2,4,6-trimethylphenyl amino)ethane (35) and rhodium complexes $Rh(PPh_3)_3Cl$ (36) and $[Rh(C_2H_4)_2Cl]_2$ (37) were prepared according to literature procedures. Phosphine ligand Ph–DBP (38) was donated by Melanie Neil of Frank Bottomley's group. Triphenylphosphine was recrystallized from boiling ethanol and stored under argon. Technical grade chloromethyl methyl ether was distilled under argon and stored in a Schlenk flask.

Crystals of **5a** were grown by slow diffusion of hexane into a saturated solution of the complex in THF. A crystal of **5a** (colorless, plate-shaped, size 0.5 mm × 0.2 mm × 0.1 mm) was very quickly mounted on a glass fiber with grease. Data collection was performed at Queen's University on a Bruker SMART CCD 1000 X-ray diffractometer with graphite-monochromated Mo K radiation (λ = 0.710 73 Å), operating at 50 kV and 30 mA over 2θ ranges of 2.30°~56.62° at –93 °C controlled with a Crysostream Controller 700. No significant decay was observed during the data collection. Data were processed on a Pentium PC using the Bruker AXS Windows NT software package (version 5.10) (39). Neutral atom-scattering factors were taken from Cromer and Waber (40). The raw intensity data were converted (including corrections for scan speed, background, and Lorentz and polarization effects) to structure amplitudes and their esds using the program SAINT-Plus (39), which corrects for *L*p and decay. Empirical absorption corrections were applied using the program SADABS (41). The structure was solved and refined by using SHELXTL (39). The compound crystallized in the monoclinic space group $P2_1/c$, based on the systematic absences, *E* statistics, and successful refinement of the structure. The structure was solved by direct methods. Full-matrix least-square refinements minimizing the function $\Sigma w(F_o^2 - F_c^2)^2$ were applied to the compound. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were located gradually from the difference Fourier map and their contributions were included in the structure factor calculations.

Both Cl^- and CO have two positions (Cl(1A), C(22A), and O(1A) or Cl(1B), C(22B), and O(1B)) with 50% occupancy on each position. The two positions are not stereotically equal and, thus the two bonds Rh(1)—C(22A) and Rh(1)—C(22B) are of different lengths (1.828(7) and 1.706(5) Å, respectively). Convergence to final $R_1 = 0.0270$ and $wR_2 = 0.0553$ by using 8366 independent reflections and 589 parameters was achieved,[10] with the largest residual peak and hole to be 0.522 and –0.258 e/Å^3, respectively. Atomic coordinates, thermal parameters, and bond lengths and angles have been deposited as supporting information.[11]

Crystals of **11a**, **11b**, and **11e**–**11h** were grown by crystallization from a dichloromethane–pentane mixture. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold nitrogen stream of the goniometer. A hemisphere of data was collected at UNB on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and 10–40 s exposure times (**11a** 30 s exposure time, **11b** 20 s, **11e** 30 s, **11f** 40 s, **11g** 30 s, **11h** 10 s). The detector distance was 4 cm (**11a**–**11d** and **11f**–**11h**) or 5 cm (**11e**). The data were reduced (SAINT) (42) and corrected for absorption (SADABS) (41). The structures were solved by direct methods and refined by full-matrix least-squares on F^2(SHELXTL) (43). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically. Crystallographic data are summarized in Tables 2–4 and atomic coordinates, thermal parameters, and bond lengths and angles have been deposited as supporting information.[11]

Synthesis of catalysts

Chloro rhodium 1,3-bis(2,4,6-trimethylphenyl)imidazol-2-ylidene carbonyl triphenylphosphine (ClRh(IMes)(CO)(PPh$_3$), 5a)

In a 100 mL Schlenk flask, under an argon purge, was weighed catalyst **4a** (201.9 mg, 0.21 mmol). To the vessel was then added 25 mL of freshly deoxygenated THF. Through this yellow solution was bubbled a gentle stream of CO at ambient temperature for 2 h. The resulting homogeneous solution was then concentrated on the Schlenk line to afford a pale yellow foam. The foam was redissolved in a minimum amount of dichloromethane and triturated with

[10] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ ($w = 1/[\sigma^2(F_o^2) + (0.0266P)^2]$, where $P = [\max(F_o^2, 0) + 2F_c^2]/3$).

pentane (20 mL) under a vigorous argon purge. The resulting pentane suspension was then Schlenk filtered. The pale lime-yellow powder thus obtained was washed with additional pentane (3 × 10 mL) and dried under vacuum for 4 h. From this crude product, 129.9 mg (88% yield) of X-ray quality crystals of catalyst **5a** were grown (THF–hexane); mp 258–263 °C. IR (KBr pellet) ν: 2950 (m), 2884 (m), 1944 (s), 1680 (m), 1529 (s), 1475 (m), 1446 (m), 1355 (m), 1268 (s), 1188 (m), 1102 (s), 1080 (m), 845 (m), 788 (m), 691 (m). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.2–7.4 (m, 15H), 7.09 (s, 2H), 7.02 (s, br, 4H), 2.42 (s, 6H), 2.26 (s, br, 12H). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$) δ: 187.15 (dd, *J* = 77.8, 16.6 Hz), 184.14 (dd, *J* = 123.4, 47.5 Hz), 138.3, 136.3, 134.7 (d, *J* = 11.1 Hz), 134.4, 134.3 (d, *J* = 40.6 Hz), 129.4 (d, *J* = 1.3 Hz), 128.9, 127.5 (d, *J* = 9.6 Hz), 122.9 (d, *J* = 3.2 Hz), 21.3, 18.9 (br). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$) δ: 31.7 (d, *J* = 115 Hz). HR-TOF-MS *m/z*: 771.1180 $[M + K]^+$ calcd. for: 771.1167 ($C_{40}H_{39}N_2OPClRhK$); 697.1555 $[M - Cl]^+$, calcd. for: 697.1825 ($C_{40}H_{39}N_2OPRh$).

1,3-Dimesityl-4,5-dihydroimidazolium tetrafluoroborate (SIMesHBF$_4$, 13)

Into a 25 mL round-bottomed flask (RBF) were weighed *N*,*N*′-bis(2,4,6-trimethylphenylamino)ethane (3.91 g, 13 mmol) and ammonium tetrafluoroborate (1.36 g, 13 mmol). The resulting mixture was vigorously stirred in vacuo for 20 min. Then, the vessel was refilled with argon and triethylorthoformate (2.16 mL, 13 mmol) was added. After the attachment of an oven-dried reflux condenser, the reaction mixture was heated to 120 °C for 2 h. The resulting mixture, a white solid residue immersed in a dark oily liquid, was separated from its volatiles (ethanol and unreacted triethylorthoformate) in vacuo. The resulting residue was thoroughly triturated in 20 mL of dichloromethane and filtered. The insoluble ammonium tetrafluoroborate was washed with dichloromethane (2 × 5 mL) and the combined filtrate was then added slowly to 100 mL of rapidly swirled pentane. The pentane precipitated powder was thoroughly triturated and then harvested by filtration. The white powder was washed with pentane (3 × 25 mL) and dried in vacuo to yield 3.80 g (74% yield) of imidazolium salt **13** with spectroscopic properties consistent with those found in the literature (44).

Preparation of chloro rhodium 1,3-bis(2,4,6-trimethylphenyl)-4,5-dihydroimidazol-2-ylidene carbonyl triphenylphosphine (ClRh(SIMes)(CO)(PPh$_3$), 11a) from ClRh(PPh$_3$)$_3$

Into a 100 mL Schlenk flask was suspended the dihydroimidazolium salt **13** (0.278 g, 0.70 mmol) in 10 mL of deoxygenated THF. To this suspension was then added potassium *tert*-butoxide (0.70 mL of a 1.0 mol/L THF solution, 0.70 mmol) at room temperature, during which **13** dissolved to give a cloudy yellow solution. After 1 h of stirring, the reaction mixture was transferred via a cannula into another Schlenk flask containing a suspension of $Rh(PPh_3)_3Cl$ (0.463 g, 0.50 mmol) in deoxygenated benzene (20 mL). A stream of CO was then bubbled into the purple suspension for 15 min at room temperature before an oven-dried reflux condenser was attached. The flow of CO was stopped and the vessel was sealed. The resulting mixture was then heated to 80 °C for 1 h, at which point the reaction was complete as indicated by ^{31}P NMR. The volatiles were removed in vacuo and the resulting residue was triturated with pentane (150 mL). The bright yellow powder was then filtered, dissolved in dichloromethane (50 mL), and filtered through a bed of silica gel. The filtrate, when concentrated, revealed a yellow microcrystalline solid from which 0.18 g (50% yield) of X-ray quality crystals of **11a** were grown (dichloromethane–pentane).

Preparation of 11a (second route)

In a 100 mL Schlenk flask was prepared, as before, the protected carbene precursor **10** (0.70 mmol) in THF (10 mL) from the tetrafluoroborate salt **13** (0.276 g, 0.70 mmol) and potassium *tert*-butoxide (0.70 mL of a 1.0 mol/L THF solution, 0.70 mmol). Concurrently, in another Schlenk flask, was suspended $[Rh(C_2H_4)Cl]_2$ (0.097 g, 0.25 mmol) and triphenylphosphine (0.183 g, 0.70 mmol) in 20 mL of deoxygenated benzene. The resulting orange suspension was first stirred under a CO atmosphere for 15 min before the carbene precursor **10** was added via a cannula. Then, under a CO purge, an oven-dried reflux condenser was rapidly attached and the reaction mixture was heated to 80 °C for 2 h. After this period of reflux, the CO flow was stopped and the yellow homogeneous solution was allowed to cool to ambient temperature overnight. Concentration of the reaction mixture in vacuo followed by flash chromatography (silica gel, dichloromethane) afforded catalyst **11a** as a yellow microcrystalline solid from which 0.315 g (86% yield) of X-ray quality crystals were grown (dichloromethane–pentane); mp 228–232 °C. IR (NaCl) ν: 2958 (m), 1954 (s), 1684 (m), 1654 (m), 1538 (m), 1478 (m), 1434 (m), 1376 (m), 1266 (s), 1186 (m), 1090 (m), 1024 (m), 908 (m), 848 (m), 740 (m), 696 (m), 636 (m). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.18–7.34 (m, 15H), 7.01 (s, 4H), 4.06 (s, br, 2H), 4.00 (s, br, 2H), 2.55 (s, br, 6H), 2.45 (s, br, 6H), 2.41 (s, 6H). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$) δ: 211.50 (d, *J* = 115.9, 44.4 Hz), 187.25 (dd, *J* = 77.8, 17.1 Hz), 138.0 (br), 137.4, 136.8, 134.7 (d, *J* = 11.9 Hz), 134.2 (d, *J* = 40.6 Hz), 129.4 (br), 129.2, 128.9 (br), 127.5 (d, *J* = 9.6 Hz), 51.39, 51.36, 21.2, 19.6 (br), 18.5 (br). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$) δ: 31.2 (d, *J* = 114.5 Hz). HR-TOF-MS *m/z*: 773.1337 $[M + K]^+$, calcd. for: 773.1322 ($C_{40}H_{41}N_2OPClRhK$); 699.2011 $[M - Cl]^+$, calcd. for: 699.2028 ($C_{40}H_{41}N_2OPRh$).

Preparation of chloro rhodium 1,3-bis(2,4,6-trimethylphenyl)-4,5-dihydroimidazol-2-ylidene carbonyl triphenylphosphite (ClRh(SIMes)(CO)(P(OPh)$_3$), 11b)

*Preparation of catalyst **11b** (route two)*

Following the procedure outlined for the synthesis of catalyst **11a**, tetrafluoroborate salt **13** (0.28 g, 0.70 mmol), potassium *tert*-butoxide (0.70 mL of a 1.0 mol/L THF solution, 0.70 mmol), $[Rh(C_2H_4)Cl]_2$ (0.097 g, 0.25 mmol), and triphenylphosphite (0.22 g, 0.70 mmol) were reacted to give, after purification by way of chromatography (silica gel, pentane–dichloromethane (1:4)) and crystallization (dichloromethane–pentane), 0.30 g (77% yield) of complex **11b**. IR (NaCl) ν: 2916 (s), 1976 (s), 1588 (s), 1486 (s), 1450 (s), 1384 (m), 1296 (m), 1266 (s), 1222 (m), 1194 (s), 1164 (s), 1068 (m), 1024 (s), 966 (m), 908 (s), 856 (s), 776 (s), 732 (m), 688 (m), 622 (m). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.03–7.14 (m, 15H), 6.88 (s, 4H), 3.89 (s, br, 4H), 2.36 (s, 6H), 2.30 (s, br, 12H). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$) δ:

© 2005 NRC Canada

209.4 (dd, J = 180.9, 42.2 Hz), 184.5 (dd, J = 77.3, 19.9 Hz), 151.2 (d, J = 4.0 Hz), 137.3, 135.7, 129.8, 129.3 (br), 129.0, 128.6, 123.9, 121.1 (d, J = 5.5 Hz), 51.6 (br), 21.2, 19.3 (br). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$) δ: 122.2 (d, J = 196.0 Hz).

*Preparation of chloro rhodium 1,3-bis(2,4,6-trimethylphenyl)-4,5-dihydroimidazol-2-ylidene carbonyl tris(**p**-methoxyphenyl)phosphine (ClRh(SIMes)(CO)(P(**p**-MeOPh)$_3$), 11c)*

*Preparation of catalyst **11c** (route two)*

Following the procedure outlined for the synthesis of catalyst **11a**, tetrafluoroborate salt **13** (0.28 g, 0.70 mmol), potassium *tert*-butoxide (0.70 mL of a 1.0 mol/L THF solution, 0.70 mmol), $[Rh(C_2H_4)Cl]_2$ (0.097 g, 0.25 mmol), and tris(*p*-methoxy)phosphine (0.25 g, 0.70 mmol) were reacted to give, after purification by way of chromatography (silica gel, pentane–dichloromethane (1:5)) and crystallization (dichloromethane–pentane), 0.27 g (64% yield) of complex **11c**; mp 218–220 °C. IR (NaCl) ν: 2958 (s), 2916 (s), 1954 (s), 1596 (s), 1566 (s), 1500 (s), 1486 (s), 1434 (m), 1288 (m), 1252 (s), 1178 (s), 1098 (s), 1032 (s), 848 (m), 826 (s), 798 (s), 732 (s), 702 (m), 636 (m). ^1H NMR (400 MHz, $CDCl_3$) δ: 7.19 (m, 6H), 6.98 (s, 4H), 6.69 (m, 6H), 4.03 (s, br, 2H), 3.96 (s, br, 2H), 3.75 (s, 9H), 2.54 (s, br, 6H), 2.42 (s, br, 6H), 2.38 (s, 6H). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$) δ: 211.7 (d, J = 119.0, 40.3 Hz), 187.3 (dd, J = 79.4, 17.6 Hz), 160.2, 138.1 (br), 137.3, 136.5, 135.9 (d, J = 13.5 Hz), 129.4 (br), 128.9 (br), 126.0 (d, J = 44.7 Hz), 113.1 (d, J = 11.1 Hz), 55.0, 51.4, 51.3, 21.2, 19.6 (br), 18.4 (br). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$) δ: 26.7 (d, J = 111.6 Hz). tricyclohexylphosphine (0.20 g, 0.70 mmol) were reacted to give, after purification by way of column chromatography (silica gel, pentane–dichloromethane (1:2)) and crystallization (dichloromethane–pentane), 0.11 g (29% yield) of complex **11g**. IR (NaCl) ν: 2916 (s), 2854 (s), 1940 (s), 1478 (s), 1442 (s), 1376 (m), 1288 (m), 1258 (s), 1170 (m), 1002 (m), 892 (m), 848 (s), 740 (s), 636 (m). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.92 (s, 4H), 4.04 (s, br, 2H), 3.96 (s, br, 2H), 2.53 (s, 6H), 2.41 (s, 6H), 2.38 (s, 6H), 1.93 (dd, br, *J* = 21.6, 11.6 Hz, 3H), 1.61 (m, br, 12H), 1.23 (m, br, 6H), 1.10 (m, br, 12 H). ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$) δ: 213.8 (dd, *J* = 110.0, 49.0 Hz), 187.5 (dd, *J* = 75.0, 17.0 Hz), 138.0 (br), 137.2, 136.6, 135.6 (br), 129.1 (br), 128.6 (br), 51.2 (br), 33.0 (d, *J* = 19.9 Hz), 29.8, 27.6 (d, *J* = 9.6 Hz), 21.0, 19.5 (br), 18.6 (br). ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$) δ: 38.4 (d, *J* = 109.0 Hz).

Preparation of chloro rhodium 1,3-bis(2,4,6-trimethylphenyl)-4,5-dihydroimidazol-2-ylidene carbonyl tri-o-tolylphosphine (ClRh(SIMes)(CO)(P(o-tolyl)$_3$), 11h)

Following the procedure outlined for the synthesis of catalyst **11a**, tetrafluoroborate salt **13** (0.28 g, 0.70 mmol), potassium *tert*-butoxide (0.70 mL of a 1.0 mol/L THF solution, 0.70 mmol), $[Rh(C_2H_4)Cl]_2$ (0.097 g, 0.25 mmol), and tris(*o*-tolyl)phosphine (0.21 g, 0.70 mmol) were reacted to give, after purification by way of chromatography (silica gel, dichloromethane) and crystallization (dichloromethane–pentane), 0.12 g (31% yield) of complex **11h**. IR (NaCl) ν: 2906 (m), 1956 (s), 1584 (m), 1482 (s), 1438 (s), 1380 (m), 1262 (s), 1174 (m), 1130 (m), 1028 (m), 904 (s), 852 (s), 802 (m), 758 (s), 728 (s), 640 (m). ^{1}H NMR (400 MHz, CD_2Cl_2) δ: 7.24 (t, br, *J* = 7.2 Hz, 3H), 7.06 (s, br, 4H), 6.98 (m, br, 9H), 4.07 (s, br, 2H), 3.98 (s, br, 2H), 2.47 (s, br, 6H), 2.36 (s, br, 12H), 1.86 (s, br, 9H). ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$) δ: 211.6 (dd, *J* = 116.0, 46.0 Hz), 188.0 (dd, *J* = 85.0, 16.5 Hz), 143.4 (br), 138.5 (br), 138.1, 137.0, 136.5 (br), 131.7, 131.6, 130.1 (br), 129.8 (br), 129.3 (br), 125.4, 125.3, 51.8 (br), 23.4 (br), 21.4, 19.7 (br), 18.7 (br). ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$) δ: 26.0 (d, br, *J* = 90.0 Hz).

Representative hydroformylation experiment

Preparation of (±)-2-phenylpropanal

A glass liner was charged with catalyst **5a** (5.8 mg, 0.0079 mmol), triphenylphosphine (4.2 mg, 0.016 mmol), and dried benzene (5 mL). The resulting pale yellow solution was stirred under a static argon atmosphere for 10 min before the liner was inserted into the autoclave. To minimize liner movement and to facilitate heat transfer, benzene (3 mL) was also added between the liner and the autoclave's inner surface. Rapidly, the gauge and gauge block assemblies were attached to the autoclave. The system was filled and flushed three times with CO before it was finally pressurized to 500 psi (1 psi = 6.894 757 kPa). Then, the autoclave was charged with 500 psi of H_2, bringing the total pressure to 1000 psi. Finally, the autoclave was placed in the centre of an oil bath preheated to 60 °C on an efficient heater-stirrer. After 19 h, the autoclave was removed from the oil bath and cooled in an ice bath for 45 min. The excess gases were then discharged and the apparatus disassembled. The contents in the liner were transferred to a RBF and carefully concentrated in vacuo to approximately 0.5 mL in volume. The conversion was then determined by ^{1}H NMR with a known amount of hexamethylbenzene as the internal standard.

Acknowledgements

The Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged for support of this research in terms of equipment and operating grants to CMC, and postgraduate scholarships to ACC and DPA. The Canada Foundation for Innovation is also thanked for funding this research. UNB is thanked for providing Wiesner Awards to ACC and DPA, and for a Magee Third Century award to DPA. BioChem Pharma is also thanked for a scholarship to ACC.

Synthesis, thermal, electrochemical, and photophysical characterization of 1,5-bis(diarylamino)naphthalene derivatives as potential hole transport OLED materials[1]

Jingning Shan, Glenn P.A. Yap, and Darrin S. Richeson

Abstract: Novel 1,5-bis(diarylamino)naphthalene derivatives (**1**–**9**), which have potential as hole-transporting materials for electroluminescent devices, were obtained through palladium-catalyzed coupling of diarylamines and 1,5-dibromonaphthalene. The thermal, electrochemical, and photophysical properties of these compounds were examined and the effects of the *N*-aryl substituents on these properties were investigated. These materials possess glass transition temperatures (T_g) that range from 70–131 °C and these values are related to the identity of the aryl substituents. Cyclic voltammetric measurements demonstrated that these compounds possess two reversible oxidation processes and were further used to estimate the HOMO energy levels of these materials by comparison with the ferrocene/ferrocenium couple. The intramolecular charge mobility, as gauged by the difference between the two oxidation potentials, indicates that compounds **1**–**8** have a similar degree of delocalization as *meta*-diaminobenzene derivatives while that of **9** is similar to **TPD**. Compounds **1**–**9** emit in the blue-green region and optical absorption and emission data for these materials can be rationalized in terms of the electronic donating properties of the aryl substituents. This data when combined with the electrochemically determined HOMO energies allowed estimation of the LUMO energy levels.

Key words: hole transport materials, diaminonaphthalene, thermal analysis, palladium-catalyzed arylation.

Résumé : Faisant appel à un couplage catalysé par le palladium de diarylamines et de 1,5-dibromonaphtalène, on a préparé des 1,5-bis(diarylamino)naphtalènes (**1**–**9**), qui ont le potentiel de transporter des trous pour les appareils électroluminescents. On en a examiné les propriétés thermiques, électrochimiques et photophysiques et on a étudié les effets des substituants *N*-aryles sur ces propriétés. Ces matériaux possèdent des températures de transition de verre (T_g) qui s'étalent de 70 à 131 °C et on a pu établir une corrélation entre cette propriété et l'identité des substituants aryles. Des mesures de voltampérométrie cyclique démontrent que ces composés possèdent deux processus d'oxydations réversibles qui ont, de plus, été utilisées pour évaluer les niveaux d'énergie de l'orbitale moléculaire haute occupée de ces composés par comparaison avec le couple ferrocène/ferrocénium. La mobilité de la charge intramoléculaire, telle qu'évaluée par la différence entre les deux potentiels d'oxydation, indique que les composés **1**–**8** possèdent un degré de délocalisation semblable à celui des dérivés du *méta*-diaminobenzène alors que celle du composé **9** est semblable à celle du **TDP**. Les composés **1**–**9** émettent dans la région du bleu-vert et les données d'absorption et émission optique de ces composés peuvent être rationalisées en termes du caractère électrodonneur des substituants aryles. Lorsque ces données sont combinées avec les énergies de l'orbitale moléculaire haute occupée déterminée électrochimiquement, il est possible d'évaluer les niveaux d'énergie de l'orbitale moléculaire basse vacante.

Mots clés : matériaux pouvant transporter des trous, diaminonaphtalène, analyse thermique, arylation catalysée par le palladium.

[Traduit par la Rédaction]

Introduction

Polyaromatic amines have been essential components in molecular electroluminescent (EL) devices beginning with the first report of a two-layer organic light-emitting diode (OLED) (1, 2). Generally the amine assumes the role of the hole transport (HT) material in such devices (3, 4). Aromatic diamine derivatives and in particular *N*,*N*,*N*′,*N*′-tetraaryl-(1,1′-biphenyl)-4,4′-diamines remain synthetic targets for HT materials because of the ease with which they form

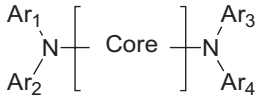
amorphous thin films, their high hole mobility, and suitable HOMO energy level (5–8).

Benchmark compounds in this field are represented by *N*,*N*′-diphenyl-*N*,*N*′-di(*m*-tolyl)benzidine (**TPD**) and *N*,*N*′-bis(1-naphthyl)-*N*,*N*′-diphenyl-benzidine (**NPD**). Establishing relationships between the molecular structure of these and related compounds and their physical characteristics such as oxidation potential (9, 10), solid-state structures (11, 12), reorganization energy upon charge transfer (13–15), and environmental stability is of considerable interest, as each of these properties will influence the hole transport performance of the compound in a device.

TPD



NPD

The hole transport in these materials has associated with it a reorganization energy (λ) that is related to the geometric rearrangments between the neutral and radical cation states (e.g., **TPD** and **TPD**$^+$). In the case of diamines with a biphenyl core such as **TPD** and **NPD**, the torsion angle between the two rings of the biphenyl bridges changes between the neutral and the cation radical and this has been ascribed to be the major barrier to electron exchange between these two species (13). Minimizing this reorganization term is one factor that may lead to improved hole mobility.

One of the chief failure modes for OLEDs is thermal instability in the molecular thin films, and in most devices, the HT component has the lowest thermal stability. Thermal stresses are inherent in device operation or can arise in the operating environment and can lead to significant expansion of the material or crystallization of the HT material. Furthermore, poor lifetimes for devices operated near room temperature have been attributed in part to thermal instabilities of the amorphous organic layers, which has been correlated with low glass transition temperatures (T_g) (2, 4, 16). For example, the T_g of tris(8-hydroxyquinolinato)aluminum (Alq), a common electron transport (ET) material, is 175 °C while those for **TPD** and **NPD** are reported to be 65 and 95 °C, respectively (17).

A major objective in developing new HT materials is the improvement of their thermal properties without sacrificing the advantageous properties exhibited by compounds such as **TPD** and **NPD**. A variety of approaches have been undertaken to improve the performance features of the HT component in EL devices, many of which center around core modifications to the generic diamine represented in Chart 1 (3, 6, 18–25). In addition to variation of the core structure, the aryl groups have been modified to produce symmetric (17–20) and asymmetric compounds (21, 24). Among the improved properties that have been observed in these examples are increased thermal stability and novel emission properties (20, 21, 26–29). Certainly, further development of related species could have significant device implications.

Chart 1.

Ar = aromatic groups

Herein we report our results for potential HT materials designed around the 1,5-diaminonaphthalene structure and an examination of the effects of variations of the aromatic substituents in these species. Only one example of an HT material designed around the naphthyl core has been reported and this compound displayed improved thermal properties as well as potential as a blue light-emitting material (30). In this case, the implementation of a fused aromatic core will remove the torsional freedom of the biphenyl core. In addition to characterizing the thermal behavior of these new diamines, we present their electronic spectra and electrochemical properties for comparison with **TPD**. Our synthetic methodology exploited the versatile and efficient palladium catalyzed amine arylation reactions pioneered by Buchwald and co-workers (31, 32) and Hartwig (33, 34).

Experimental section

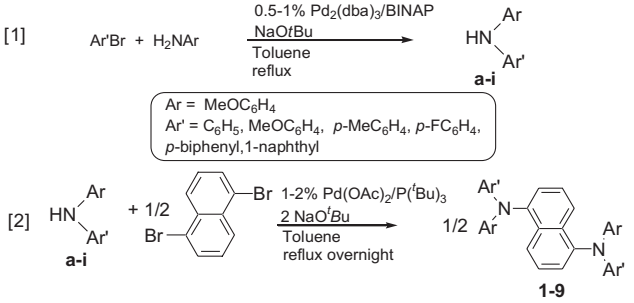
General information

All reactions were carried out under a nitrogen atmosphere using standard Schlenk techniques. Aryl amines, aryl bromides, diphenylamine, tris(dibenzylidineacetone)dipalladium ($Pd_2(dba)_3$), *rac*-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (BINAP), and sodium *tert*-butoxide were purchased from the Aldrich Chemical Company and used without further purification. Tri-*tert*-butylphosphine was purchased from Strem Chemicals. 1,5-Dibromonaphthalene was synthesized from 1,5-diaminonaphthalene according to literature procedures (35). Toluene was purified by passage through a column of activated alumina using an apparatus from Anhydrous Engineering. Dichloromethane was freshly distilled under nitrogen using CaH_2 as the dessicant.

Reactions were monitored using Silica gel 60 F_{254} TLC aluminum sheets by UV lamp and (or) GC–MS using a mass selective detector from Agilent GC systems 6890 series with an HP-5 capillary column (cross-linked 5% PH ME siloxane).

^{1}H NMR spectra were collected on a Varian Gemini-200 or a Bruker 300 MHz spectrometer using the residual protons of the deuterated solvent for reference. The overlapping ^{13}C peaks were identified through ^{13}C DEPT and ^{1}H^{13}C HMQC analysis on a Bruker 300 MHz spectrometer. Electron impact mass spectra (EI-MS) were recorded on a Kratos

© 2005 NRC Canada



Concept IIH instrument using electron ionization at 70 eV. High resolution mass spectra (HR-MS) were obtained at the University of Ottawa on a Kratos Concept IIH instrument using electron ionization at 70 eV, acceleration 8 KV, and resolution 7 000 – 10 000. The glass transition temperatures and melting points were measured using a TA 2010 differential scanning calorimeter (DSC) instrument. Heating rates of 5–20 °C/min were employed for these measurements. UV spectra were recorded in CH_2Cl_2 on a Varian Cary spectrophotometer. Steady-state fluorescence spectroscopy was carried out using a Photon Technology International version 1.2 X luminescence spectrometer with the same cuvette used for UV–vis spectra. Fluorescence quantum efficiency (Φ_f) of the compounds was determined by comparing with that of Coumarin-102 (Φ_f = 0.93 in ethanol) (36) in CH_2Cl_2 solution. Cyclic voltammograms (CV) were obtained using a Hokuto Denko HA501 potentiostat connected to a Hokuto Denko HB105 programmable function generator. A Nicolet 310 oscilloscope was used to follow the in situ CV scans. A freshly polished Pt wire and Pt plate were used as working and counter electrode, respectively. A silver wire was employed as pseudo-reference electrode. All solutions were prepared in millimolar concentrations in dry CH_2Cl_2, which was freshly distilled from CaH_2. Tetrabutyl ammonium hexafluorophosphate (TBAHFP) was used as the supporting electrolyte with a concentration of 0.1 mol/L. The electrochemical cell was degassed with nitrogen prior to analysis and was maintained under a nitrogen atmosphere during the potential scans. At the end of each set of CV scans, ferrocene (Cp_2Fe) was added to the solution and another potential scan was performed to provide the redox potential for the Cp_2Fe/Cp_2Fe^+ couple.

Compounds **a**–**h** were prepared via Pd catalyzed coupling of arylbromides and arylamines according to eq. [1] in Scheme 1. The general procedure for the synthesis of diarylamines followed that reported in the literature with details provided in the Electronic supplementary information (37, 38).[3]

General procedure for the synthesis of diaminonaphthalene derivatives

The general procedure for the synthesis of 1,5-diaminonaphthalene derivatives (**1**–**9**) according to eq. [2] in Scheme 1 was modified from the literature (39). In a drybox, a Schlenk flask was charged with toluene, 1,5-dibromonaphthalene, and 2.2 equiv. of the appropriate diarylamines (**a**–**i**). To this solution was added 1% to 2% $Pd(OAc)_2/P(t\text{-}Bu)_3$ (ligand/Pd = 1) and 2.8 equiv. of NaO-*t*-Bu. The reaction mixture changed from orange to dark black over the first few seconds. The flask was sealed, removed from the drybox, and was heated at 120 °C overnight. The reaction was then cooled to room temperature, filtered, and the residue was washed with ethylacetate and combined with the toluene. The solvents were then removed by vacuum evaporation and the residue was dissolved in $CHCl_3$. Column chromatography was used to purify the product using $CHCl_3$ as the eluent. Collection of the product was monitored by TLC and all fractions were combined at the end of the separation procedure. The solvents were removed under vacuum to yield pure compounds.

Scheme 1.

1,5-Bis(di-*p*-methoxyphenylamino)naphthalene (1)

Yield: 50%. ^{1}H NMR ($CDCl_3$) δ: 3.79 (s, 12H), 6.64–6.80 (m, 8H), 6.91 (d, 8H), 7.08–7.30 (m, 4H), 7.84 (d, 2H). ^{13}C NMR ($CDCl_3$) δ: 55.48, 114.41, 121.98, 123.44, 126.12, 126.25, 132.82, 142.98, 144.92, 154.54. *m*/*z*: 582 (M^+). HR-MS (*m*/*z*) calcd. for $C_{38}H_{34}N_2O_4$: 582.2519; found: 582.2530.

1,5-Bis(*p*-methoxyphenylphenylamino)naphthalene (2)

Yield: 75%. ^{1}H NMR ($CDCl_3$) δ: 3.76 (s, 6H), 6.7–6.9 (m, 9H), 7.0–7.4 (m, 13H), 7.87 (d, 2H). ^{13}C NMR ($CDCl_3$) δ: 55.46, 114.55, 119.84, 120.26, 122.43, 125.38, 126.56, 126.95, 128.93, 133.06, 141.55, 144.30, 149.5, 155.49. *m*/*z*: 522 (M^+). HR-MS (*m*/*z*) calcd. for $C_{36}H_{30}N_2O_2$: 522.2307; found: 522.2328.

1,5-Bis(*p*-methoxyphenyltolylamino)naphthalene (3)

Yield: 80%. ^{1}H NMR ($CDCl_3$) δ: 2.28 (s, 6H), 3.77 (s, 6H), 6.81 (t, 8H), 7.02 (t, 8H), 7.16–7.34 (m, 4H), 7.88 (d, 2H). ^{13}C NMR ($CDCl_3$) δ: 20.62, 55.46, 114.45, 120.77, 122.20, 124.59, 126.39, 126.58, 129.55, 130.11, 133.00, 142.18, 144.61, 147.05, 155.03. *m*/*z*: 550 (M^+). HR-MS (*m*/*z*) calcd. for $C_{38}H_{34}N_2O_2$: 550.2620; found: 550.2642.

1,5-Bis(*p*-methoxyphenyl-*p*-fluorophenylamino)naphthalene (4)

Yield: 78%. ^{1}H NMR ($CDCl_3$) δ: 3.76 (s, 6H), 6.72–7.32 (m, 20H), 7.82 (d, 2H). ^{13}C NMR ($CDCl_3$) δ: 55.48, 114.64, 115.63 ($J_{C\text{-}F}$ = 22.6 Hz), 122.15 ($J_{C\text{-}F}$ = 5.0 Hz), 122.22, 124.60, 126.49, 126.54, 132.84, 142.11, 144.59, 145.70, 155.33, 157.58 ($J_{C\text{-}F}$ = 240.2 Hz). *m*/*z*: 558 (M^+). HR-MS (*m*/*z*) calcd. for $C_{36}H_{28}F_2N_2O_2$: 558.2119; found: 558.2101.

1,5-Bis(*p*-methoxyphenyl-*p*-propylphenylamino)naphthalene (5)

Yield: 66%. ^{1}H NMR ($CDCl_3$) δ: 0.92 (t, 6H), 1.57 (m, 4H), 2.47 (t, 4H), 3.76 (s, 6H), 6.75–6.83 (m, 8H), 6.95–7.04 (M, 8H), 7.19–7.30 (m, 4H), 7.86 (d, 2H). ^{13}C NMR

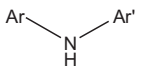
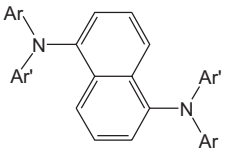
Structural determination for compounds 3 and 5

Single crystals were mounted on thin glass fibers using viscous oil and then cooled to the data collection temperature. Crystal data and details of the measurements are summarized in Table 1. Data were collected on a Bruker AX SMART 1 k CCD diffractometer using 0.3° ω scans at 0°, 90°, and 180° in ϕ. Unit-cell parameters were determined from 60 data frames collected at different sections of the Ewald sphere. Semi-empirical absorption corrections based on equivalent reflections were applied. The structures were solved by direct methods, completed with difference Fourier syntheses, and refined with full-matrix least-squares procedures based on F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were treated as idealized contributions. All scattering factors and anomalous dispersion factors are contained in the SHELXTL 5.1 program library (40).

Results and discussion





Synthesis of naphthalene diamines

Our strategy for preparing new aromatic amines possessing a naphthyl core (**1**–**9**) is outlined with eqs. [1] and [2] in Scheme 1. Diarylamines (**a**–**i**) were either first prepared via Pd catalyzed coupling of arylbromide and arylamine (**a**–**h**) (37, 38) or purchased (**i**). A $Pd(OAc)_2/P(t\text{-}Bu)_3$ catalyst system was then employed for the coupling reactions between 1,5-dibromonaphthalene and diarylamines (39). We also explored an alternative route based on the coupling of 1,5-diaminonaphthalene with aryl halides. This proved to be unsatisfactory and only led to products with a single arylation of each nitrogen center as the major products. The synthesis of a related diamine, 1,5-bis[*N*-(1-naphthyl)-*N*-phenyl]naphthalene diamine (**NND**) was recently reported via a modified Ullman condensation of 1,5-diiodonaphthalene and naphthylphenylamine, however, no details for this transformation were reported (30).

The naphthyl core diamines presented in Table 2 were isolated in good yields and were fully characterized by ^{1}H and ^{13}C NMR and HR-MS. The versatility of this method provides an avenue to invoke a wide range of amine substituent variation including electron-donating and electron-withdrawing groups. The molecular structures of two of these diamines, compounds **3** and **5**, were definitively established using single crystal X-ray diffraction analysis (Table 1). The structures of **3** and **5** are presented in Figs. 1 and 2, respectively, and selected bond distances and angles are provided in Ta-

ble 3. Both species display planar nitrogen centers with propeller-like arrangement of the three aromatic groups on each nitrogen. In **3**, the N—$C_{naphthyl}$ distance (N(1)—C(1) = 1.462(3) Å) is longer than the corresponding distances for the outer aryl groups (N(1)—C(18) = 1.416(6) Å and N(1)—C(11) = 1.449(6) Å). In contrast, although the longest N—C distance in compound **5** is to the naphthyl core, the C—N distances in this compound span a narrower range from 1.423(4) to 1.435(4) Å. These trends in C—N distance are opposite to those observed for **TPD** and for *N*,*N*′-diphenyl-*N*,*N*′-bis(2,4-dimethylphenyl)-(1,1′-biphenyl)-4,4′-diamine, where the N—$C_{biphenyl}$ distances are the shortest distances with values of 1.411(5) and 1.415(5) Å, respectively (7, 8). There are no unusual C—C bond lengths within the peripheral or core aryl groups.

Thermal properties

To be of practical consideration for OLED fabrication, the diamines **1**–**9** should form stable glasses. This general feature of materials for OLED construction avoids problems associated with grain boundaries in polycrystalline materials and provides for a high degree of uniformity within thin films. Associated with this amorphous state is a characteristic temperature (or temperature range) where the glassy and amorphous state of the material begins to soften and flow, which is referred to as the glass transition temperature (T_g). Above T_g, materials tend to crystallize generating grain boundaries and causing nonuniform thin films (17). The kinetics of the crystallization process will dictate whether or not a T_g is observed. Generally, large, globular, and rigid molecules or asymmetric molecules with high molecular masses and without strong intermolecular forces have high T_g values (17, 41). Such general features favor a high energy for the reorganization – molecular reorientation of the amorphous phase into a crystalline material. Strong intermolecular forces may favor organization of the molecules as they cool below their melting points, which, in turn, encourage crystallization at the expense of glass formation.

A typical DSC for the naphthalene diamines is shown in Fig. 3. The initial temperature scan of compound **3** shows a

crystalline phase transition (T_{tr} = 200 °C) and a melting point (T_m) at 249 °C. This sample was then allowed to cool to room temperature and heated a second time. This temperature scan displayed the glass transition (T_g) at 82 °C. Continuing to heat this sample revealed an exotherm at 103 °C, which was associated with crystallization. Finally, the sam-

ple was observed to melt at T_m. Similar DSC measurements allowed the determination of the T_g and T_m values of diamines **1–9** and these results are presented in Table 2. For comparison, the corresponding values for **TPD** are included in this table.

Figure 4 displays the DSC data for compound **6**. In the first run, compound **6** exhibits a coupled endothermic and exothermic phase transition prior to melting at 283 °C. This type of transition has been attributed to polymorphism of the crystalline materials (42). After the compound was flash cooled in liquid nitrogen to form the glassy state, the sample was subjected to a second heating cycle that allowed observation of the T_g (116 °C) and T_c (185 °C). Following this second run, the compound was allowed to cool under ambient conditions to room temperature, and a third heating cycle was initiated. This run was stopped prior to melting. The purpose of this heating cycle was to anneal the sample into a crystalline phase. The fourth heating cycle confirmed that **6** was again a crystalline sample in that no T_g was observed but T_m was clearly seen. The data presented in Fig. 4 demonstrates that the rate of sample cooling of **6** has no effect on the T_g values, but it will effect T_c. For example, T_c is observed at 185 °C for the compound cooled in the liquid nitrogen, while T_c is 200 °C for the compound cooled under ambient conditions.

As summarized in Table 4, compounds **1–9** possess melting points from 187–283 °C, which all exceed that of **TPD** at 175 °C. With the exception of **5**, diamines **1–9** have higher T_g values than **TPD** and in two cases surpass this value by more than 50 °C. We attribute the low T_g that was observed for **5** to the fact that it possesses a *n*-propyl group, a feature that makes it unique among these compounds and likely reduces the overall rigidity of this compound. The highest T_g values were observed for compounds **6** and **7**, which have extended aromatic substituents. The 4,4′-biphenyl and 1-naphthyl groups increase both the molecular weight and the rigidity of **6** and **7**. The remaining compounds have T_g values that fall within the narrow range of 70–83 °C. Compound **9** possesses N-substituents that are simple phenyl rings and it exhibited a slightly higher T_g of 83 °C compared with the substituted aromatic analogues. This suggests that there is little gain in thermal properties by using simple methoxy, methyl, or fluoro substituents on the aromatic groups in these systems.

Electrochemistry

In a simple OLED, emission arises from the recombination of electrons originating in the ET layer with holes that are transported in the HT material. This combination can occur in either of the two layers and for charge transfer across the ET/HT interface some degree of HOMO and (or) LUMO matching is required. Matching of the HOMO level of the

HT layer and that of the cathode is also important in EL device engineering. An electrochemical method based on cyclic voltammetry was used to estimate the HOMO energies of the naphthalene diamines **1**–**9** and to examine their electrochemical stability (43, 44).

Cyclic voltammetric scans were recorded under a N_2 atmosphere in CH_2Cl_2 solvent with a Ag wire pseudo-reference electrode and with TBAHFP as the supporting electrolyte. At the end of each set of scans, Cp_2Fe was added to the solution and another potential scan was performed that provided a reference potential for the Cp_2Fe/Cp_2Fe^+ couple as a calibration standard.

Over the positive potential scan range (0 to ~1.5 V), compounds **1**–**9** exhibited two reversible oxidation waves (examples are shown in Fig. 5). If the potential scan is extended to more positive potentials (~2 V), irreversible oxidation processes were also observed for all the compounds with the exception of **8**. The two reversible oxidation peaks in the CV

© 2005 NRC Canada

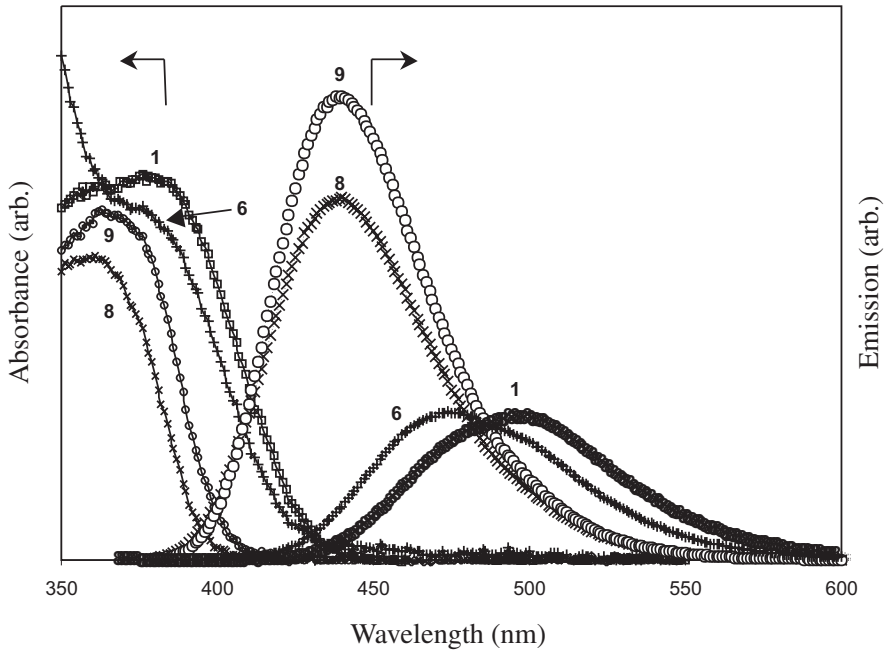
Fig. 5. CV scans of compounds **6**, **8**, and **9** at 100 mV/s in CH_2Cl_2 with 0.05 mol/L TBAHP under N_2. Five scans are shown.

curves can be ascribed to one-electron oxidation processes of the two amine centers. The first oxidation process corresponds to the HOMO energy level of the diamine and correlates directly to the energy required for hole generation and transport in the HT layer. The $E_{1/2}$ value of the diamine/diamine$^+$ couple relative to the $E_{1/2}$ value for the Cp_2Fe/Cp_2Fe^+ couple was used to estimate the HOMO energy levels for compounds **1**–**9**. The established value of the ferrocene HOMO energy level of 4.8 eV was added to the difference in the two oxidation potentials to obtain the diamine HOMO energy values and the results of these calculations are summarized in Table 4 (43, 44).

The extent of intramolecular charge mobility can be estimated by the difference between the first and second oxidation events for each of the diamines (ΔE_{oxid}). In the case of a large degree of charge delocalization, the first positive charge should have a pronounced effect on the second nitrogen center making it more difficult to oxidize and leading to a large difference in the two oxidation potentials. On the other hand, if the two charges are isolated from each other, only one oxidation couple would be observed. For example, **TPD** shows a potential gap of 220 mV indicating electronic communication between the two nitrogens after the first oxidation. Aromatic di- and triamines in which the N centers are bridged by a single phenyl group with a para or ortho disposition often exhibit even larger potential gaps in the range 330–530 mV (45–48). In contrast, the corresponding values for *meta*-diaminobenzene derivatives are smaller at 161–191 mV, presumably reflecting a low degree of conjugation between the two N centers (49). A similar lack of charge delocalization is observed for compounds **1**–**8**. Except for compound **9** (ΔE_{oxid} = 255 mV), the diaminonapthalene compounds **1**–**8** exhibit small ΔE_{oxid} values (121–169 mV).

The reproducibility of the voltammetric behavior over multiple potential scan cycles demonstrates the stability of these materials to the repeated redox steps they would experience in a device. When only the first two oxidation waves were scanned, compounds **1**–**9** showed reproducible CV behavior for at least five scan cycles as shown in the Fig. 5. With a wider potential range, compounds **1**–**7** continued to exhibit superimposible CV curves for at least five scan cycles. However, scanning of **8** and **9** over this wider potential range that included the third, irreversible oxidation process led to changes in the voltammograms. We attribute this instability to the deposition of the oxidized species onto the electrodes. In fact, during the CV scans for **9** a brown film was observed on the working Pt electrode, while for compound **8** a green precipitate was observed in the solution near the working electrode. These precipitates were not observed if the potential range did not extend beyond the second oxidation peak. The identity of these new species that are produced upon extensive oxidation of **8** and **9** has not been established, but the fact that this observation is associated with N-substitutents that do not have para substitution suggests that there may be a reaction of the oxidized species on the *N*-phenyl ring.

Electronic spectra



The naphthalene diamines **1**–**9** are white, yellow, or pale orange solids and they possess well-separated absorption and emission maxima with the later appearing in the blue to green region of the spectrum. The UV–vis absorption and emission spectra for these compounds is summarized in Table 4, and typical spectra for compounds **1**, **6**, **8**, and **9** are shown in Fig. 6. Except for compound **6**, these compounds exhibit a single λ_{max} in their absorption spectra. In the case of **6**, the value of λ_{max} was taken from the shoulder at 375 nm (Fig. 6). The HOMO–LUMO gap energy was also estimated from these spectra and is included in Table 4 (21, 22).

The absorption maximum for **TPD** at 350 nm has been assigned to an $n \rightarrow \pi^*$ electronic transition that is due to electron transfer from a nitrogen lone pair to the π^* orbital of the biphenyl group (41). We assign the λ_{max} absorption values for **1**–**9** as arising from a similar $n \rightarrow \pi^*$ electron transition with the π^* orbital residing on the naphthalene moiety. In the case of **6**, we propose that the rising absorption below 375 nm is a result of another $n \rightarrow \pi^*$ electron transition involving the nitrogen lone pair and the π^* orbital of the biphenyl group.

In comparison with compound **9**, all of the para-substituted phenyl compounds (**1**–**7**) exhibit a bathochromic shift in both absorption and emission, which can be ascribed to the electron-donating properties of the aromatic substituents. The electron-donating properties of the methoxy substituents appear to overwhelm the electron-withdrawing effects of the fluoro (**4**), phenyl (**6**), and naphthyl groups (**7**).

© 2005 NRC Canada

Fig. 6. UV–vis absorption (left) and emission (right) spectra for compounds **1** (□), **6** (+), **8** (×), and **9** (○).

As a result, compound **1** displays the largest red shift for emission and Stokes shift.

Generally, the HT materials in an OLED are not used as the source of emission. This is due to the fact the hole mobility is much faster than electron mobility, and as a result, the charge recombination usually occurs in the ET layer and this is where the emission arises. However, if the difference of HOMO energy levels between HT and ET is large enough and the difference in LUMO energy levels is small, holes will be blocked within the HT layer. As a result, emission could arise in the HT layer and there are recent reports of diamine-based HT materials functioning in the role of emitter hosts and as emission sources (20, 26, 29, 50). The emission properties of HT materials, both the emission wavelength (λ_{emi}) and quantum efficiency (Φ_f) provide important performance criteria for OLED fabrication. The values of Φ_f for diamines **1**–**9** were measured in CH_2Cl_2 relative to Coumarin 102 as a standard (36) and the results are presented Table 4.

Compounds **1**–**9** fall into two groups based on their Φ_f values. In particular, the Φ_f values for **8** and **9** are identical and more than twice those of the other diamines. Furthermore, **8** and **9** have identical values for their absorption and emission maxima. This phenomenon can be ascribed to the electron-donating properties of the substituents on the *N*-aryl groups. Since the transition is $n \rightarrow \pi^*$ in the diamines, the electron-rich amines that possess electron-donating groups at the para position of the aryl substituents (i.e., **1**–**7**) will display higher energies for the nonbonding HOMO electrons relative to those amines that do not have such groups (i.e., **8** and **9**). The result will be a reduced HOMO–LUMO gap and a smaller energy difference between the singlet and triplet states, which in turn allows for increased rate of intersystem crossing and a reduction in the Φ_f (51).

Estimates for the diamine LUMO energy levels were obtained by subtracting the HOMO energy values determined electrochemically from the HOMO–LUMO energy gap that was obtained from the absorption and emission spectra. With this method we can then compare the relative energy levels of the naphthyl core diamine compounds. From the data, we can see that meta-substituted **8** and unsubstituted **9** have the largest HOMO values, while all of the para-substituted compounds have similar HOMO values. These two groupings of HOMO energies are consistent with a HOMO that is predominantly the nonbonding electrons localized on the nitrogen centers. Furthermore, the very similar values of the LUMO energies for all of the compounds are also in harmony with a naphthalene core localized π^* orbital. The overall effects of the aryl substituents provides direction for orbital level tuning of these and related materials for the matching of the energy levels between the charge transport layers that is required for successful OLED fabrication.

Conclusions

Pd catalyzed coupling reactions have been used to synthesize a series of naphthyl core diamines with the general formula 1,5-$[Ar(Ar')N]_2C_{10}H_6$ (Ar = $MeOC_6H_4$; Ar′ = C_6H_5, $MeOC_6H_4$, *p*-MeC_6H_4, *p*-FC_6H_4, *p*-PhC_6H_4, 1-naphthyl) and the characterization of these species points to their potential as optoelectronic materials. We have examined the thermal, electrochemical, and photophysical properties of these materials. By varying the aryl groups, we have demonstrated the features that lead to the best thermal stability. All of these materials show enhanced glass forming ability and thermal stability compared to **TPD**. The relative HOMO and LUMO levels for these materials, important parameters for the design of efficient OLEDs, were assessed through electrochemical and spectroscopic measurements. Compounds **1**–**9** have the potential to function as hole transport materials and they emit in the blue to green color range. We are currently

© 2005 NRC Canada

investigating the transport properties of these materials and their use as HT materials in OLEDs.

Effect of charge and surface area on the cytotoxicity of cationic metallointercalation reagents[1]

Gavin L. Edwards, David St.C. Black, Glen B. Deacon, and Laurence P.G. Wakelin

Abstract: Reaction of a series of nitrogen donor ligands (1-phenylpyrazoles, 2-phenylpyridine, benzo[*h*]quinoline, 1-(2′-pyridyl)indole, 1-phenylindazole, and 2-phenylindazole) with palladium(II) and platinum(II) salts gave complexes where ortho-metallation had occurred resulting in bidentate binding to the metal centres through N and C atoms. These cyclometallated products were isolated as μ-chloro dimers. Subsequent treatment of these μ-chloro dimers with chelating diamines such as 1,2-ethanediamine converted them into 14 cationic (1+) complexes. Analogous coordination mixed ligand complexes (charge 2+) were prepared by reaction of dichloro(1,2-ethanediamine-*N*,*N*′)palladium(II) with aromatic diamines such as 2-(1′-pyrazolyl)pyridine, 2,2′-bipyridine, and 1,10-phenanthroline. The complexes exhibited growth inhibitory activity against L1210 mouse leukæmia cells in vitro over a wide concentration range; in general, the cyclometallated complexes were more active than the mixed ligand complexes, although one cyclometallated organoplatinum complex was less active than the mixed ligand analogue. Substitution around the periphery of the aromatic ligands also resulted in increased activity. One complex, derived from 1-(2′-pyridyl)indole, was tested in vivo and showed no significant antitumour inhibition against P388 leukæmia at doses below toxic levels.

Key words: anticancer, metallointercalator, cyclometallation, palladium, platinum, cytotoxicity.

Résumé : La réaction d'une série de ligands donneurs d'azote (1-phénylpyrazoles, 2-phénylpyridine, benzo[*h*]quinoléine, 1-(2′-pyridyl)indole, 1-phénylindazole et 2-phénylindazole) avec des sels de palladium(II) et de platine(II) conduit à la formation de complexes dans lesquels il s'est produit une ortho-métallation qui résulte en une liaison bidentate avec les centres métalliques par le biais des atomes de N et de C. On a isolé ces produits sous la forme de dimères μ-chloro et un traitement subséquent de ces dimères avec des diamines qui peuvent agir comme agent chélatant, telles l'éthane-1,2-diamine, a permis de les transformer en quatorze complexes cationiques (1+). On a préparé des complexes analogues avec des ligands à coordination mixte (charge 2+) en faisant réagir du dichloro(éthane-1,2-diamine-*N*,*N*′)palladium(II) avec des diamines aromatiques, telle la 2-(1′-pyrazolyl)pyridine, la 2,2′-bipyridine et la 1,10-phénanthroline. Dans des essais in vitro, ces complexes présentent, sur large plage de concentration, une activité inhibitrice de la croissance des cellules de la lignée L1210 de la leucémie de la souris; en général, les complexes cyclométallés sont plus actifs que les complexes de ligands mixtes, même si un complexe organique cyclométallé du platine est moins actif que l'analogue avec un ligand mixte. Une substitution autour de la périphérie des ligands aromatiques conduit aussi à une augmentation de l'activité. Un complexe, celui dérivé du 1-(2′-pyridyl)indole, a été évalué in vivo et, à des doses inférieures aux niveaux toxiques, il ne présente aucune activité d'inhibition antitumorale contre la leucémie P388.

Mots clés : anticancéreux, intercalation métallique, cyclométallation, palladium, platine, cytotoxicité.

Introduction

Cancer, as a group of diseases, ultimately kills one-quarter of the human population. The quest for new and effective chemotherapeutic agents to combat cancers has led to tremendous activity; however, until relatively recently, the use of heavy metals has attracted only sporadic interest. The serendipitous discovery by Rosenberg et al. (1) that *cis*-

diamminedichloroplatinum(II) (cisplatin) inhibited cell division in *Escherichia coli*, and the subsequent establishment that a range of platinum complexes inhibited the development of sarcoma 180 and leukæmia L1210 in mice (2), led not only to the introduction of cisplatin as a clinically efficacious agent against testicular and ovarian cancers in 1978 (3), but also to the rekindling of interest in metal-based therapies (4, 5). While the clinical effectiveness of cisplatin against human malignancies, both as a single agent and in combination therapy, has had a major impact on cancer treatment, its therapeutic usefulness has been offset by a range of toxic side effects. The combination of good activity, dose-limiting side effects, and the disadvantage that some tumours acquire resistance to the drug, has stimulated research into second and third generation platinum drugs (6, 7).

While the anticancer activity of cisplatin has been attributed to the formation of bifunctional adducts with DNA, especially guanine–guanine crosslinks (6), pioneering work initiated by Lippard and co-workers (8) utilized another aspect of the chemistry of platinum(II) — its ability to act as a square-planar template to impart planarity on ligands such as 2,2′-bipyridine (bpy). While these complexes would have been predicted to have negligible anticancer activity based on observations gleaned from cisplatin and its analogues, the synthesis of planar, kinetically inert metal complexes provided a new mechanism of action namely, intercalation. In particular, Lippard used platinum(II) as a framework to force the aromatic rings of ligands such as bpy and 2,2′:6′,2″-terpyridine (terpy) into a coplanar arrangement, providing a flat aromatic surface capable of intercalation into DNA. However, despite extensive studies on the interactions of these materials with isolated nucleic acids or synthetic polynucleotides (9, 10), until recently there have been relatively few reports of the biological activity of square-planar platinum(II) or palladium(II) metallointercalators (11, 12).

The work initiated by Lippard and co-workers (8) provided the basis for the design of a range of complexes as potential new anticancer agents. Based on the metallointercalation model, a potential intercalator (13) should incorporate a kinetically inert metal with square-planar geometry, and it should fix aromatic, multidentate ligands in a coplanar array. Central to our strategy was the use of bidentate, nonlabile cyclometallated ligands to stabilize the complex and suppress dissociation of the intercalating aromatic ligand from the metal centre in vivo. Analogous mixed ligand coordination compounds with nitrogen donor ligands would provide contrasts to determine the importance of intercalator charge. Most metal complexes with anticancer activity are based on platinum, and to date analogous palladium complexes have shown marginal in vivo activity at best. While some palladium complexes have shown promising activity in vitro (12) or in animal models (6), they have not made a successful transition to clinical usefulness; the poor activity could be attributed to the higher reactivity of palladium species towards ligand displacement reactions. In this study drugs were designed where covalent binding to DNA is not expected and, as the coordination chemistries of platinum(II) and palladium(II) are similar, both metals should provide suitable frameworks upon which to build intercalating complexes. In a following paper we report the activity of a range of monofunctional cyclometallated platinum(II) and palladium(II) complexes (14).

Results and discussion

Cyclometallation reactions

Reactions of nitrogen donor ligands such as 1-phenylpyrazole (Hpzph) (**1**) (15) and 2-phenylpyridine (Hpyph) (**2**) (16) with palladium(II) salts to give cyclometallated complexes (referred to herein as cyclopalladated complexes) have been well-documented. While we have previously shown that the cyclopalladation of these ligands occurs readily providing products **3** and **4** in near-quantitative yields (Table 1), the analogous reaction of **2** with a platinum(II) salt (cycloplatination) requires more forcing conditions and gives only a moderate (65%) yield of the μ-chloro dimer **5** (17) (Fig. 1). Although the dimeric complexes are insoluble or very sparingly soluble in most solvents, they dissolve with reaction in dimethyl sulfoxide. An examination of the ^{1}H NMR spectra recorded in ($^2H_6$)dimethyl sulfoxide ($(CD_3)_2SO$) indicated the loss of one aryl proton, in agreement with the cyclometallated structures. An alternative confirmation that cyclometallation had taken place was obtained in many cases by addition of one drop of ($^2H_5$)pyridine (py-d_5) to a suspension of the dimers in $CDCl_3$; the complexes dissolved with reaction to give monomers where loss of one proton was evident and shielding of the proton ortho to the site of metallation was observed as a result of its proximity to the pyridine ligand (Fig. 1) (17).

Variation of the aromatic ligand could provide increased surface area for the planar intercalator possibly resulting in enhanced DNA binding, and it was shown that 1-(2′-pyridyl)indole (Hpyin) (**6**), 1-phenylindazole (H-1phiz) (**7**), 2-phenylindazole (H-2phiz) (**8**) (18), and benzo[*h*]quinoline (Hbq) (**9**) (19) could be cyclopalladated with $Na_2[PdCl_4]$ in near-quantitative yields giving μ-chloro dimers **10**–**13** on heating of the reaction mixtures for up to 24 h (Table 1,

© 2005 NRC Canada

Fig. 1. Cyclometallation reaction and product of bridge cleavage with py-d_5.

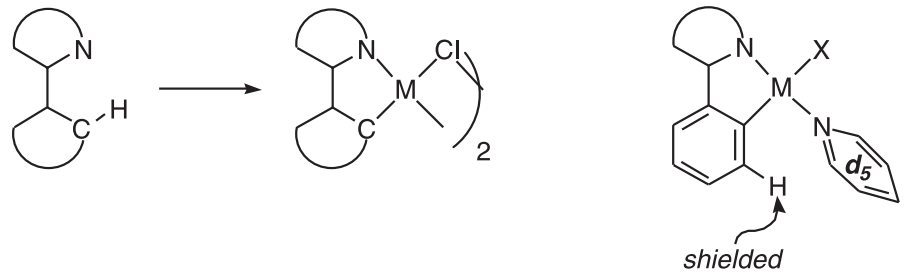

Fig. 2. Ligands and abbreviations with positions of metallation indicated.

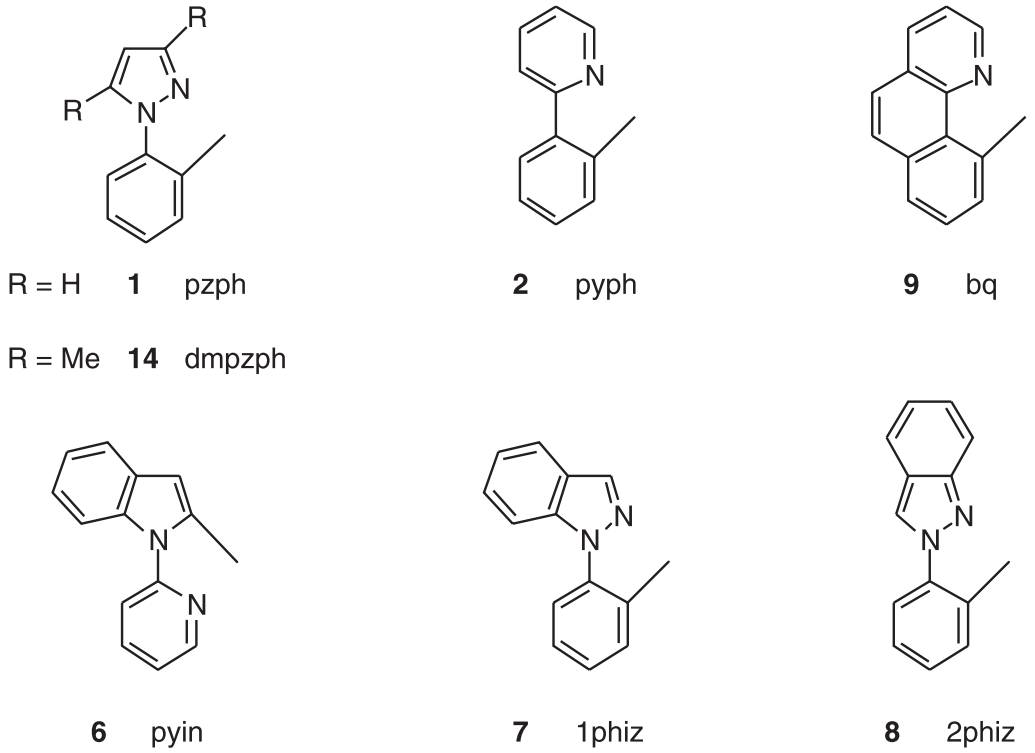

Fig. 2). Nonoyama and Nakajima (20) have recently reported the cyclometallation of **6** in moderate yield with palladium(II) acetate in boiling acetonitrile. Attempted cyclometallation of **6** with $Na_2[PdCl_4]$ at room temperature gave a mixture of the cyclometallated dimer **10** and a non-metallated coordination complex, as shown by a complex ^{1}H NMR spectrum in $(CD_3)_2SO$, where evidence for non-metallated ligand (indole H3 was noted as a doublet at δ 6.76 ppm, J = 3.5 Hz) was observed. A terminal ν(Pd–Cl) corresponding to the coordination complex was also observed at 343 cm^{-1} in the far-IR region, suggesting trans stereochemistry. No attempt was made to separate the mixture into its components. In several cases throughout this work, metathesis of the complexes with LiBr in acetone or dimethyl sulfoxide assisted interpretation of the far-IR spectra (17).

Cyclometallation of 3,5-dimethyl-1-phenylpyrazole (Hdmpzph) (**14**) using $K_2[PdCl_4]$ in boiling aqueous methanol gave a mixture of cyclometallated product **15** and coordination complex **16** (Fig. 3), at variance with earlier reports by Trofimenko and Vaughan (21) that cyclometallation was achieved quantitatively. Extended heating only increased the yield of the desired product **15** marginally. The products could be separated by extraction of coordination complex **16** into boiling dichloromethane. While the insoluble cyclometallated dimer **15** was contaminated with a small amount of palladium metal, it was of sufficient purity for further use. Analytically pure material could be obtained by precipitation of the dimer from a filtered solution of *N*,*N*-dimethylformamide (DMF) by the addition of methanol. Coordination complex **16** was identified as the cis stereoisomer by observation of two terminal ν(Pd–Cl) bands in the far-IR spectrum at 362 and 321 cm^{-1}; while approximately 10% of a second component was observed in the ^{1}H NMR spectrum, it was not determined whether this was due to a small amount of the trans isomer, or restricted rotation of the pyrazole ligands within the complex on the ^{1}H NMR timescale resulting in detection of syn and anti rotamers of complex **16**. All attempts to convert coordination complex **16** into cyclometallated dimer **15** were unsuccessful.

The ligand 1-methyl-3,5-diphenylpyrazole (**17**) is potentially able to form a five-membered chelate ring by metal-

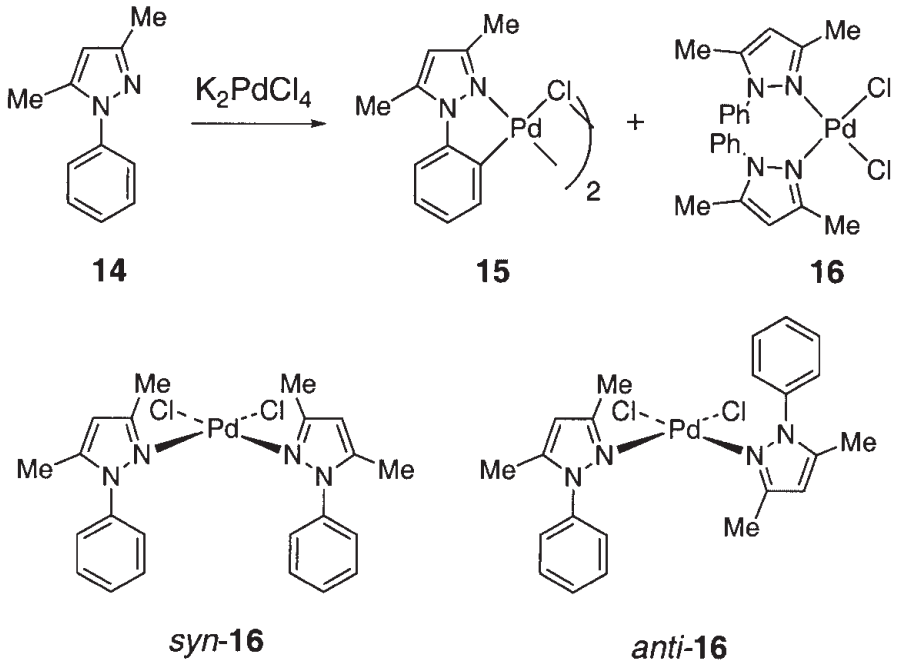

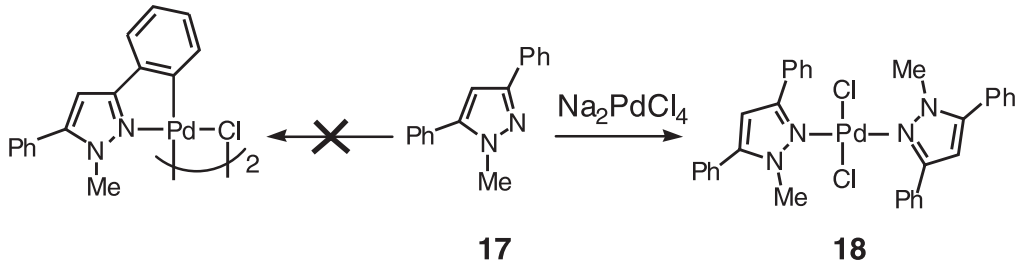

Fig. 4. Attempt to cyclometallate 1-methyl-3,5-diphenylpyrazole (**17**).

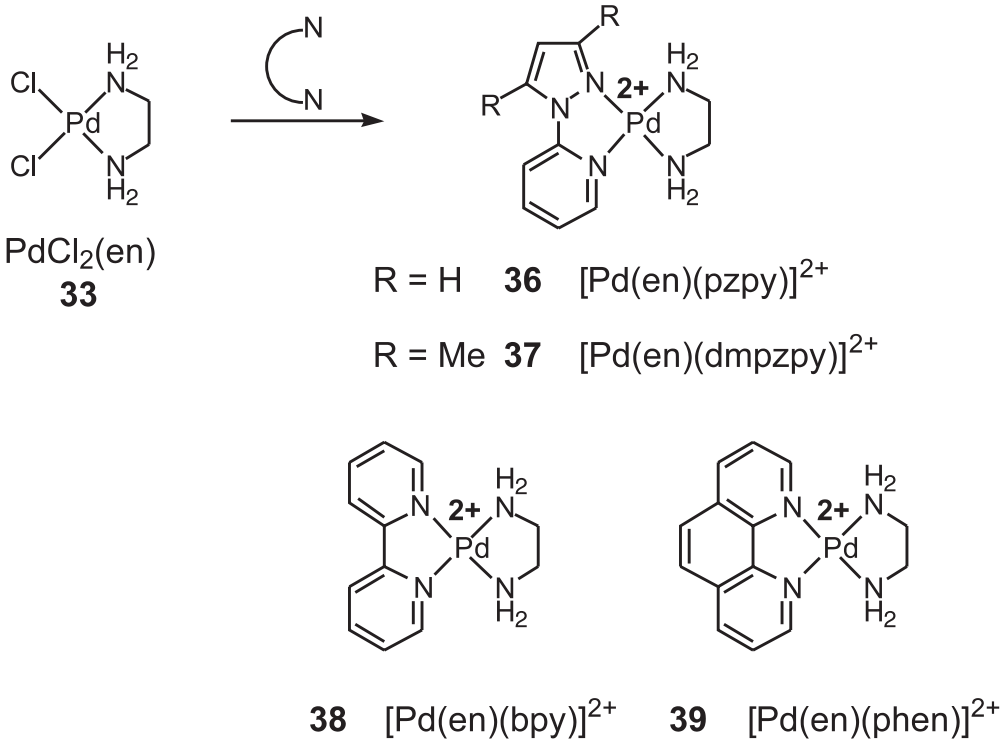
lation onto an ortho carbon of the 3-phenyl ring; this would provide an intercalator of comparable size but different geometry to other phenylpyrazoles (Fig. 4). Heating the ligand with $Na_2[PdCl_4]$ in methanol only gave the coordination complex $PdCl_2L_2$ (**18**) (22); a single ν(Pd–Cl) was observed in the far-IR spectrum at 349 cm^{-1} suggesting formation of the trans stereoisomer, and the ^1H NMR spectrum indicated that the product was a 15:1 mixture of two components, which Alonso et al. (22) have suggested results from restricted rotation about the Pd—N bonds. It is noteworthy that pyrazole **17** gives the trans stereoisomer **18**, whereas pyrazole **14** gives mainly the cis isomer **16**, despite both reaction mixtures being heated for comparable periods.

Preparation of cationic complexes



Addition of a bidentate diamine to the appropriate μ-chloro dimers gave the desired cationic complexes as water- and alcohol-soluble products (Table 2), which could be purified by precipitation of the complexes from alcoholic or aqueous alcoholic solution by the addition of ether. Diamine ligands chosen for study included 1,2-ethanediamine (en), 1,3-propanediamine (trimethylenediamine, tn), and *cis*- and *trans*-cyclohexanediamine (chxn). Biological and clinical studies of platinum complexes of chxn have been extensive (6, 7); in general, complexes of *trans*-chxn are more active than their *cis*-chxn analogues (6, 23), and complexes prepared from *R*,*R*-chxn are more active than those containing *S*,*S*-chxn (23). The oxalate-containing complex oxaliplatin ($Pt(C_2O_4)$(*R*,*R*-chxn)) in combination with 5-fluorouracil is emerging as a major therapy for colorectal cancer (24). In

Fig. 5. Mixed ligand complexes isolated as dichloride salts.

this study, complexes of *cis*- and racemic *trans*-chxn were prepared for biological testing.

Several of the complexes were isolated as hydrates; attempted drying at elevated temperature led to partial decomposition and drying at ambient temperature failed to remove the water of crystallization. In general, while the IR spectra of the complexes usually showed several absorptions of medium to strong intensity in the range 3000–3300 cm^{-1}, which could be attributed to the N–H stretching frequencies of the coordinated diamine ligands; absorptions at higher frequencies (3300–3500 cm^{-1}) were only observed for the hydrated complexes and were assigned to water of crystallization. Examination of the far-IR spectra of the complexes supported the assigned chelate structures as no strong absorptions between 240 and 360 cm^{-1}, which might be attributed to ν(M-Cl), were observed.

In the ^1H NMR spectra of the complexes, two distinct NH_2 signals were observed that can be attributed to a nonequivalence of the NH_2 groups as a result of the different trans carbon and nitrogen ligands. It is interesting that, for the platinum complex **26**, $^2J_{Pt,H}$ was only resolved in the signal for the downfield (6.15 ppm) NH_2 group; mere broadening of the other signal (5.44 ppm) was observed. The poly(methylene) bridges in the en and tn complexes were observed as broad signals. Coordination of chxn to a metal constrains the ligand to adopt specific conformations and, as a result, further resolution of the cyclohexyl amine protons was observed. The rigidity of the chelate ring constrains the protons on each nitrogen to lie in pseudoaxial and pseudoequatorial environments; as a result, up to four distinct exchangeable signals were observed for the chxn complexes.

The cyclometallation reaction gives complexes with anionic carbon σ-donor ligands and the overall charge on the resulting cationic complexes is therefore one less than the corresponding Pt(II) complexes $[Pt(en)(bpy)]^{2+}$ and $[Pt(en)(phen)]^{2+}$. A range of nonmetallated, cationic complexes analogous to these classical coordination compounds was also prepared to determine the relationship of intercalator charge to biological activity. Comparison of the activities of the palladium(II) complexes with those reported for the corresponding platinum(II) complexes could allow an assessment of the relationship between metal and activity.

Synthesis of the mixed complexes was achieved by reaction of $PdCl_2(en)$ **33** with the appropriate bidentate aromatic ligand (pyrazolylpyridines **34** and **35**, bpy, and phen) by an adaptation of the method of Watt and Carter (25); the mixed ligand complexes **36–39** (Fig. 5) were isolated in moderate to good yields. The alternative approach, where en was added to Pd complexes of the bidentate aromatic ligands, led to partial displacement of the ligand from the metal with $[Pd(en)_2]Cl_2$ being isolated instead. Some hydration of the mixed ligand complexes was evident from the microanalytical data, and this was confirmed by observation of ν(O-H) in the range 3300–3500 cm^{-1}, as described previously. The ^1H NMR spectra of the complexes were unremarkable; whereas two signals for the coordinated NH_2 groups were observed for the cyclometallated complexes, the symmetry or pseudosymmetry of the coordination complexes caused the NH_2 groups to be chemical-shift equivalent.

In vitro and in vivo testing

The complexes were subjected to an in vitro screen for growth inhibitory activity against the murine leukæmia cell line L1210. While these tests do not discriminate between cytotoxic and cytostatic activity, they provide valuable infor-

mation about whether the complexes can affect the rate at which cells grow and divide. The complexes (drugs) were dissolved in sterile water or ethanol (for the chxn complexes) and growth inhibition experiments were conducted for a 48 h period against L1210 cell cultures, providing drug concentrations that caused a 50% inhibition of cell growth (IC_{50}) (Table 3). For comparison, it should be noted that cisplatin has an IC_{50} of 0.9 μmol/L under similar conditions.

The cationic planar complexes reported in this study caused 50% growth inhibition over a wide range of concentrations. The cyclometallated complexes (formal charge 1+) generally were more active than the dipositive coordination analogues (compare **19** with **36**, **27** with **37**, and **22** with **38**), but it should be noted that the phenanthroline complex **39** had a similar IC_{50} value (13 μmol/L) to that of the benzo[*h*]quinolinyl complex **29** (16 μmol/L). Although a variation of the intercalator charge might influence the biological activity, especially in electrostatic stabilization of an initial drug–DNA complex, the relative stabilities of the organometallic drugs in the presence of a wide range of biological ligands could also explain the observed differences. As described above, in the preparation of the cationic complexes, addition of diamines to the cyclometallated μ-chloro dimers gave the desired products cleanly, whereas addition of en to palladium complexes of bidentate heterocyclic ligands resulted in at least partial displacement of the aromatic ligand. Thus, it is proposed that the presence of the palladium–carbon σ bond appears to increase the stability of the complexes, and therefore the cyclometallated complexes would be more likely to reach their biological target intact. It is possible that the increased stability of the phenanthroline complex with respect to displacement of the ligand from the metal centre meant that its stability was similar to that of the benzo[*h*]quinolinyl complex under biological conditions, hence its activity was likewise similar.

Table 4. Antitumour testing for complex **30** against P388 leukæmia.

In this study, a single organoplatinum cyclometallated complex $[Pt(pyph)(en)]^+$ (**26**) was prepared and its biological activity was measured (IC_{50} = 300 μmol/L); somewhat surprisingly it was almost an order of magnitude less active than $[Pt(en)(bpy)]^{2+}$ (IC_{50} = 33 μmol/L) (11). This suggests that there might be no firm correlation between platinum and palladium metallointercalators as the analogous organopalladium complex **22** $[Pd(pyph)(en)]^+$ (IC_{50} = 34 μmol/L) was *more* active than the coordination analogue **38** $[Pd(en)(bpy)]^{2+}$ (IC_{50} = 60 μmol/L).

Increased biological activity is observed with increased substitution on the planar organometallic ligand. Substitution with methyl groups or fusion of an extra benzene ring onto the planar aromatic structure, led to lower IC_{50} values. The methyl substituents may provide a steric barrier to dislodgement of an intercalated drug, accounting for the increased activity. The position of fusion of an extra aromatic ring did not seem to affect the activity greatly (compare: 1phiz **31** (18 μmol/L) and 2phiz **32** (17 μmol/L) complexes). Additional aromatic rings give a larger surface area to intercalate between the base pairs in a drug–DNA complex, and the extra aromatic ring could lead to a more stable complex as a result of an enhanced π-orbital overlap. The weakest drug–DNA complexes would be expected for complexes such as the 2-(2-pyridyl)phenyl and 1-(pyrazolyl)phenyl complexes, which have only two coplanar aromatic rings, and stronger drug–DNA adducts would be expected for larger cationic complexes. However, it is noteworthy that McFadyen et al. (11) found that a series of structurally related, cationic complexes exerted their biological activities in different ways, and it is possible that structurally similar complexes here might likewise be inhibiting cell growth by different mechanisms.

Variation of the diamine ligand also resulted in a change in biological activity. Increased bulk (chxn vs. en or tn) tended to give more active complexes, and a consistent effect was noted for the chxn complexes, where lower IC_{50} values for the *cis*-chxn complexes **20** and **24** than their trans analogues **21** and **25** were measured.

One of the more active complexes (the 1-(2-pyridyl)indolyl complex **30**) was selected for further study. Potential antitumour activity against P388 leukæmia in mice was evaluated over a range of dose levels up to a maximum tolerated dose, with results expressed (%T/C) as a ratio of mean survival times of treated animals (T) relative to control animals (C); significant antitumour activity requires %T/C values greater than 125%, and values of 0% indicate that no treated animals survived the drug regime at these dose levels. Results obtained in this screening (Table 4) indicated that the

© 2005 NRC Canada

metallointercalator showed no significant antitumour activity in vivo at doses below toxic levels.

Experimental

General procedure

Elemental analyses were performed by the Microanalytical Service, School of Chemistry, University of New South Wales. IR spectra were measured with a PerkinElmer 180 Grating IR spectrophotometer with a far-IR option, and refer to paraffin mulls of solids, measured between KBr plates (4200–380 cm^{-1}) and between polyethylene discs (550–100 cm^{-1}). Only absorptions of strong to medium intensity are reported herein. ^1H NMR spectra were recorded at 90 MHz (Bruker WH90 spectrometer), 200 MHz (Bruker AC200 spectrometer), or 300 MHz (Bruker AM300 spectrometer). Chemical shifts are reported in parts per million (ppm) downfield from tetramethylsilane (δ 0.00 ppm, referenced to $CHCl_3$ impurity in $CDCl_3$). Addition of one drop of py-d_5 to $CDCl_3$ suspensions of dimers **10**, **11**, **12**, **15**, and **18** converted the insoluble dimers into soluble monomeric complexes, which gave well-resolved spectra that integrated cleanly, providing excellent evidence for cyclometallation. Hbq (**9**), phen, bpy, *trans*-1,2-cyclohexanediamine (*trans*-chxn), en, and trimethylenediamine (tn) were obtained from the Aldrich Chemical Company and were recrystallized or distilled prior to use. *cis*-1,2-Cyclohexanediamine (*cis*-chxn) was separated from a mixture of isomers by the method of Saito and Kidani (26). 1-Phenylpyrazole (**1**) and **14** were prepared by the method of Finar and Hurlock (27). 1-(2′-Pyridyl)indole (**6**) was prepared by the method of Khan and Polya (28). 1-Phenyl-indazole (H-1phiz) (**7**) was prepared by the method of Pozharskii et al. (29), and **8** was prepared by the method of Cadogan and Mackie (30). 2-(1′-Pyrazolyl)pyridine (**34**) and 2-(3′,5′-dimethyl-1′-pyrazolyl)pyridine (**35**) were prepared by the general method of Khan and Pinto (31). Cyclopalladations of **1** to give **3** (15), of **2** to give **4** (16, 32), and of **9** to give **13** (19), and cycloplatination of **2** to give **5** (17), were carried out according to published procedures. Dichloro(1,2-ethanediamine-*N*,*N*′)palladium(II) ($PdCl_2$(en)) (**33**) was prepared by the method of McCormick et al. (33). Mixed ligand complex $[Pd(en)(phen)]Cl_2$ (**39**) (9) was prepared by the method described for complex **36** in the following section.

Preparations

Di-μ-chlorobis[1-(2′-pyridyl)indol-2-yl)-N′,C]dipalladium (10)

1-(2′-Pyridyl)indole (**6**) (1.50 g, 7.7 mmol) in methanol (20 mL) was added to a stirred solution of $Na_2[PdCl_4]$ (1.96 g, 6.7 mmol) in methanol (60 mL) under a nitrogen atmosphere. The mixture was heated under reflux for 24 h, and the resultant yellow precipitate was filtered off and washed successively with methanol and ether. A suspension of the crude product in dichloromethane (30 mL) was heated under reflux for 2 h, and then cooled to room temperature. The sparingly soluble solid was collected, washed with dichloromethane and then ether, and dried to give the μ-chloro dimer **10** as a yellow powder (2.16 g, 97%), mp 228–230 °C (dec.). A sample was recrystallized from DMF–methanol for microanalysis. IR (cm^{-1}): 1613, 1510, 1489, 1318, 1288, 1253, 1185, 745, 734, 418, 319 (Pd–Cl), 290, 240 (Pd–Cl). ^1H NMR (90 MHz, $CDCl_3$ – one drop of py-d_5) δ: 9.22 (dd, J = 5.9, 1.2 Hz, 1H, pyridyl H6), 7.91–7.07 (m, 6H, aryl), 6.89 (ddd, J = 7.4, 5.9, 1.4 Hz, 1H, pyridyl H5), 5.58 (d, J = 0.5 Hz, 1H, indolyl H3). Elemental anal. calcd. for $C_{26}H_{18}Cl_2N_4Pd_2$ (%): C 46.6, H 2.7, N 8.4; found: C 46.6, H 2.55, N 8.2.

Di-μ-chlorobis[2-(1′H-indazol-1′-yl)phenyl-N′,C]dipalladium (11)

The title compound **11** was prepared by a similar method to **10**, from **7** (0.62 g, 3.2 mmol) and $Na_2[PdCl_4]$ (0.75 g, 2.6 mmol), as a yellow powder (0.84 g, 99%), mp > 300 °C. A sample was recrystallized from DMF–methanol for microanalysis. IR (cm^{-1}): 1215, 1100, 836, 735, 722, 615, 421, 306 (Pd–Cl), 279, 230 (Pd–Cl). ^1H NMR (300 MHz, $CDCl_3$ – one drop of py-d_5) δ: 8.83 (s, 1H, indazolyl H3), 7.98 (dd, J = 8.7, 0.6 Hz, 1H, indazolyl H7), 7.79 (d, J = 8.1 Hz, 1H, aryl), 7.59 (ddd, J = 8.7, 7.1, 1.2 Hz, 1H, indazolyl H6), 7.54 (dd, J = 8.0, 1.0 Hz, 1H, aryl), 7.30 (t, J = 7.1 Hz, 1H, indazolyl H5), 7.17 (td, J = 7.7, 1.2 Hz, 1H, aryl), 6.80 (td, J = 7.6, 1.0 Hz, 1H, aryl), 6.33 (dd, J = 7.6, 1.1 Hz, 1H, phenyl H6). Elemental anal. calcd. for $C_{26}H_{18}Cl_2N_4Pd_2$ (%): C 46.6, H 2.7, N 8.4; found: C 46.5, H 2.5, N 8.45.

Di-μ-chlorobis[2-(2′H-indazol-2′-yl)phenyl-N′,C]dipalladium (12)

The title compound **12** was prepared by a similar method to **10**, from **8** (0.62 g, 3.2 mmol) and $Na_2[PdCl_4]$ (0.75 g, 2.6 mmol), as a yellow powder (0.83 g, 98%), mp > 300 °C (lit. value (18) mp > 300 °C). A sample was recrystallized from DMF–methanol for microanalysis. IR (cm^{-1}): 1627, 1519, 1489, 1352, 1071, 792, 784, 753, 745, 739, 437, 330 (Pd–Cl), 246 (Pd–Cl). ^1H NMR (300 MHz, $CDCl_3$ – one drop of py-d_5) δ: 9.01 (d, J = 8.9 Hz, 1H, indazolyl H7), 8.44 (s, 1H, indazolyl H3), 7.58 (d, J = 8.5 Hz, 1H, indazolyl H4), 7.34 (t, J = 7.4 Hz, 1H, aryl), 7.30 (dd, J = 7.9, 0.9 Hz, 1H, phenyl H3), 7.09 (t, J = 7.9 Hz, 1H, aryl), 7.03 (t, J = 7.5 Hz, 1H, aryl), 6.79 (t, J = 7.5 Hz, 1H, aryl), 6.08 (d, J = 7.6 Hz, 1H, phenyl H6). Elemental anal. calcd. for $C_{26}H_{18}Cl_2N_4Pd_2$ (%): C 46.6, H 2.7, N 8.4; found: C 46.5, H 2.7, N 8.4.

Di-μ-chlorobis[2-(3′,5′-dimethyl-1′-pyrazolyl)phenyl-N′,C]dipalladium (15)

A mixture of $K_2[PdCl_4]$ (1.50 g, 4.6 mmol) and **14** (1.00 g, 5.8 mmol) in aqueous dioxan (60 mL of 50% *v*/*v*) was stirred under a nitrogen atmosphere. A yellow precipitate separated and the mixture was stirred at room temperature for 18 h, and then heated under reflux for 36 h. The precipitate was filtered off, washed successively with methanol and ether, and dried. The product was suspended in dichloromethane (60 mL) and the suspension was heated under reflux for 6 h. The sparingly soluble solid was collected, washed with dichloromethane and ether, and dried to give the μ-chloro complex **15** as a yellow powder (0.65 g, 45% based on Pd), mp 337–339 °C (dec.). A sample was recrystallized from DMF–methanol for microanalysis. IR (cm^{-1}): 1552, 1443, 1438, 743, 738, 341 (Pd–Cl), 283, 265 (Pd–Cl). ^1H NMR (90 MHz, $(CD_3)_2SO$) δ: 7.64 (d br, J = 7.0 Hz, 1H, phenyl), 7.31–6.70 (m, 3H, phenyl), 6.21 (s, 1H,

© 2005 NRC Canada

pyrazolyl H4), 2.63 (s, 3H, Me), 2.33 (s, 3H, Me). Elemental anal. calcd. for $C_{22}H_{22}Cl_2N_4Pd_2$ (%): C 42.2, H 3.5, N 8.95; found: C 42.3, H 3.5, N 8.9.

The filtrate was evaporated to dryness and the residue was dissolved in dichloromethane and the solution filtered. On addition of hexane, dichlorobis(3,5-dimethyl-1-phenylpyrazole-N^2)palladium (**16**) separated as orange needles (0.98 g, 41% based on Pd), mp 315–317 °C (dec.) IR (cm^{-1}): 1595, 1555, 1503, 1418, 1399, 808, 764, 760, 696, 692, 565, 362 (Pd–Cl), 321 (Pd–Cl). ^{1}H NMR (90 MHz, $CDCl_3$) (major: minor components, 10:1) δ: 7.84–7.58 (m, 10H major + 10H minor, phenyl), 6.02 (s, 2H minor, H4′), 5.91 (s, 2H major, H4′), 3.05 (s, 6H minor, Me), 2.21 (s, 6H major, Me), 2.09 (s, 6H major, Me), 1.97 (s, 6H minor, Me). Elemental anal. calcd. for $C_{22}H_{24}Cl_2N_4Pd$ (%): C 50.6, H 4.6, N 10.7; found: C 50.7, H 4.6, N 10.7.

Dichlorobis(1-methyl-3,5-diphenylpyrazole-N^2)palladium (18)

1-Methyl-3,5-diphenylpyrazole (**17**) (0.22 g, 0.94 mmol) in methanol (10 mL) was added to a stirred solution of $Li_2[PdCl_4]$ (prepared from $PdCl_2$ (0.14 g, 0.79 mmol) and LiCl (0.20 g, 4.7 mmol)) in methanol (40 mL). A yellow solid separated, and the mixture was heated under reflux for 40 h under a nitrogen atmosphere. The product was filtered off and dissolved in dichloromethane, and the solution was filtered. On addition of hexane the palladium complex **18** separated as small yellow needles (0.19 g, 63%), mp 280–282 °C (dec.) (lit. value (22) mp 290–293 °C). IR (cm^{-1}): 3085, 1437, 1428, 1296, 838, 775, 766, 751, 703, 694, 681, 349 (Pd–Cl). ^{1}H NMR (300 MHz, $CDCl_3$) (major:minor components, 15:1) δ: 8.43–8.33 (m, 2H major + 2H minor, phenyl), 7.59–7.45 (m, 8H major + 8H minor, phenyl), 6.43 (s, 1H major + 1H minor, pyrazole H4), 4.80 (s, 3H minor, NMe), 4.36 (s, 3H major, NMe). Elemental anal. calcd. for $C_{32}H_{28}Cl_2N_4Pd$ (%): C 59.5, H 4.4, N 8.7; found: C 59.2, H 4.2, N 8.6.

(1,2-Ethanediamine-N,N′)[2-(1′-pyrazolyl)phenyl-N′,C]palladium(1+) chloride (19)

1,2-Ethanediamine (60 mg, 1.0 mmol) in chloroform (5 mL) was added to a stirred suspension of μ-chloro dimer **3** (0.233 g, 0.41 mmol) in chloroform (10 mL). A white powder slowly formed, and the mixture was stirred at room temperature for 12 h. The solid was filtered off, washed with chloroform, and dried. Recrystallization of the crude product from methanol–dichloromethane gave the title compound **19** as a white powder (0.166 g, 59%), mp 230 °C (dec.) (lit. value (15) mp 195 °C (dec.)). IR (cm^{-1}): 3295 (br), 3170 (br), 3105 (br), 1589, 1416, 1344, 1181, 1113, 1057, 1031, 755, 750, 612, 492, 406, 244, 192. ^{1}H NMR (300 MHz, $(CD_3)_2SO$) δ: 8.77 (d, J = 2.7 Hz, 1H, pyrazolyl H5), 7.95 (d, J = 2.2 Hz, 1H, pyrazolyl H3), 7.56 (d, J = 7.5 Hz, 1H, phenyl), 7.20–7.12 (m, 2H, phenyl), 7.00 (td, J = 7.4, 1.0 Hz, 1H, phenyl), 6.70 (t, J = 2.5 Hz, 1H, pyrazolyl H4), 5.40 (s br exch, 2H, NH_2), 4.59 (s br exch, 2H, NH_2), 2.71 (s br, C 4H, H_2CH_2). Elemental anal. calcd. for $C_{11}H_{15}ClN_4Pd$ (%): C 38.3, H 4.4, N 16.2; found: C 38.2, H 4.4, N 16.2.

(cis-1,2-Cyclohexanediamine-N,N′)[2-(1′-pyrazolyl)phenyl-N′,C]palladium(1+) chloride (20)

Freshly distilled *cis*-chxn (10 drops) was added to a stirred suspension of **3** (0.201 g, 0.35 mmol) in methanol (20 mL) and water (10 mL). The reaction mixture was warmed for 10 min and then stirred at room temperature overnight. Evaporation of the solvents gave a pale yellow solid that was recrystallized from methanol–ether to give the title compound **20** as fine colourless needles (0.183 g, 65%), mp 276–278 °C (dec.). IR (cm^{-1}): 3200, 3170 (br), 3135, 3095, 1600, 1511, 1412, 1210, 1093, 1070, 1059, 750, 741, 737, 364. ^{1}H NMR (300 MHz, $(CD_3)_2SO$) δ: 8.78 (d, J = 2.9 Hz, 1H, pyrazolyl H5), 7.93 (d, J = 2.2 Hz, 1H, pyrazolyl H3), 7.56 (dd, J = 7.8, 1.0 Hz, 1H, phenyl), 7.22 (dd, J = 7.5, 1.0 Hz, 1H, phenyl), 7.17 (td, J = 7.6, 1.0 Hz, 1H, phenyl), 7.00 (td, J = 7.4, 1.0 Hz, 1H, phenyl), 6.70 (t, J = 2.5 Hz, 1H, pyrazolyl H4), 5.59 (d br, J = 6 Hz, 1H, NH), 4.90 (dd br, J = 11, 7 Hz, 1H, NH), 4.82 (d br, J = 7 Hz, 1H, NH), 4.41 (dd br, J = 11, 7 Hz, 1H, NH), 3.04 (s br, 2H, C*H*NH_2), 1.78–1.57 (m, 6H, cyclohexyl), 1.32 (s br, 2H, cyclohexyl). Elemental anal. calcd. for $C_{15}H_{21}ClN_4Pd$ (%): C 45.1, H 5.3, N 14.0; found: C 44.9, H 5.4, N 14.0.

(trans-1,2-Cyclohexanediamine-N,N′)[2-(1′-pyrazolyl)phenyl-N′,C]palladium(1+) chloride (21)

Freshly distilled *trans*-chxn (15 drops) was added to a stirred, boiling suspension of μ-chloro dimer **3** (0.560 g, 0.95 mmol) in ethanol (70 mL) under a nitrogen atmosphere. The mixture was heated under reflux for 2 h, during which time the μ-chloro dimer dissolved. The resultant solution was filtered while hot, cooled to room temperature, and slowly diluted with ether to give the crude product. Recrystallization (twice) from ethanol–ether gave the title compound **21** as fine colourless needles (0.458 g, 67%), mp 287 to 288 °C (dec.). IR (cm^{-1}): 3195, 3150 (br), 3110, 3065, 1601, 1514, 1413, 1073, 1064, 1057, 755, 745, 738, 606, 363. ^{1}H NMR (300 MHz, $(CD_3)_2SO$) δ: 8.78 (d, J = 2.7 Hz, 1H, pyrazolyl H5), 7.96 (d, J = 2.2 Hz, 1H, pyrazolyl H3), 7.57 (dd, J = 7.3, 1.2 Hz, 1H, phenyl), 7.19–7.15 (m, 2H, phenyl), 7.01 (t, J = 7.3 Hz, 1H, phenyl), 6.70 (t, J = 2.5 Hz, 1H, pyrazolyl H4), 5.44 (d exch, J = 7 Hz, 1H, NH), 5.17 (t exch, J = 10.5 Hz, 1H, NH), 4.95 (d exch, J = 7 Hz, 1H, NH), 4.18 (t exch, J = 10.5 Hz, 1H, NH), 2.43–2.31 (m, 2H, C*H*NH_2), 1.99 (t, J = 14.7 Hz, 2H, cyclohexyl), 1.63 (d br, J = 7.6 Hz, 2H, cyclohexyl), 1.32 (sextet br, J = 10.7 Hz, 2H, cyclohexyl), 1.10 (t br, J = 10 Hz, 2H, cyclohexyl). Elemental anal. calcd. for $C_{15}H_{21}ClN_4Pd$ (%): C 45.1, H 5.3, N 14.0; found: C 45.0, H 5.3, N 13.8.

(1,2-Ethanediamine-N,N′)[2-(2′-pyridyl)phenyl-N′,C]palladium(1+) chloride (22)

This compound was prepared by the same method as complex **21** from the μ-chloro dimer **4** (0.258 g, 0.44 mmol) and 1,2-ethanediamine (0.06 g, 1.0 mmol) in methanol (10 mL). Recrystallization of the crude product from methanol–ether gave the title compound **22** as fine, pale yellow needles (0.263 g, 85%), mp 245 to 246 °C (dec.). IR (cm^{-1}): 3260 (br), 3185 (br), 3115 (br), 3090 (br), 1605, 1578, 1438, 1160, 1058, 753, 744, 341. ^{1}H NMR (300 MHz, $(CD_3)_2SO$) δ: 8.39 (d, J = 5.6 Hz, 1H, pyridyl H6), 8.10–8.06 (m, 2H, pyridyl), 7.74–7.72 (m, 1H, phenyl), 7.42–7.37 (m, 1H, aryl), 7.16–7.09 (m, 3H, aryl), 5.27 (s br exch, 2H, NH_2), 4.55 (s br exch, 2H, NH_2), 2.72 (m br, 4H, CH_2CH_2). Elemental anal. calcd. for $C_{13}H_{16}ClN_3Pd$ (%): C 43.8, H 4.5, N 11.8; found: C 43.9, H 4.6, N 11.8.

(1,3-Propanediamine*-N,N′*)[2-(2′-pyridyl)phenyl*-N′,C*]palladium(1+) chloride monohydrate (23)

This compound was prepared by the same method as complex **21** from **4** (0.217 g, 0.37 mmol) and 1,3-propanediamine (10 drops) in methanol (10 mL). Recrystallization of the crude product from methanol–ether gave the title compound **23** as pale yellow needles (0.224 g, 79%), mp 210 to 211 °C (dec.). IR (cm^{-1}): 3450 (br), 3365 (br), 3325 (br), 3240 (br), 3115 (br), 1607, 1582, 1433, 1191, 1150, 1037, 902, 755, 735. ^{1}H NMR (90 MHz, $(CD_3)_2SO$) δ: 8.41 (d, J = 5.6 Hz, 1H, pyridyl H6), 8.18–7.97 (m, 2H, aryl), 7.74–7.11 (m, 5H, aryl), 4.89 (s br exch, 2H, NH_2), 4.22 (s br exch, 2H, NH_2), 2.88–2.66 (m br, 4H, 2 × CH_2N), 1.76–1.55 (m, 2H, CH_2). Elemental anal. calcd. for $C_{14}H_{20}ClN_3OPd$ (%): C 43.3, H 5.2, N 10.8; found: C 43.3, H 5.1, N 10.8.

(*cis*-1,2-Cyclohexanediamine*-N,N′*)[2-(2′-pyridyl)phenyl*-N′,C*]palladium(1+) chloride (24)

This compound was prepared by the same method as complex **20** from **4** (0.357 g, 0.60 mmol) and *cis*-chxn (10 drops). Recrystallization of the crude product from ethanol–ether gave the title compound **24** as fine, pale yellow needles (0.308 g, 62%), mp 292 to 293 °C (dec.). IR (cm^{-1}): 3205 (br), 3175 (br), 3135, 3095 (br), 1602, 1578, 1434, 1093, 750, 730, 627, 407, 363. ^{1}H NMR (300 MHz, $(CD_3)_2SO$) δ: 8.36 (d br, J = 4.9 Hz, 1H, pyridyl H6), 8.08 (s br, 2H, aryl), 7.73 (d br, J = 6.9 Hz, 1H, aryl), 7.44–7.36 (m, 1H, aryl), 7.18–7.08 (m, 3H, aryl), 5.42 (s br exch, 1H, NH), 4.72–4.61 (m br exch, 2H, 2 × NH), 4.23 (s br exch, 1H, NH), 3.02 (s br, 2H, C*H*NH_2), 1.82–1.57 (m, 6H, cyclohexyl), 1.42–1.26 (m br, 2H, cyclohexyl). (1,2-Ethanediamine-*N,N′*)(2-(2′*H*-indazol-2′-yl)phenyl-*N′,C*)palladium(1+) chloride monohydrate (32)

This compound was prepared by the same method as complex **21** from the μ-chloro dimer **12** (0.120 g, 0.18 mmol) and 1,2-ethanediamine (10 drops) in methanol (10 mL). Recrystallization of the crude product from ethanol–ether gave the title compound **32** as fine, off-white needles (0.115 g, 78%), mp 271 to 272 °C (dec.). IR: 3460 (br), 3330 (br), 3245 (br), 3200, 3105 (br), 3070, 1929, 1520, 1444, 1282, 1056, 1050, 748, 729. ^1H NMR (300 MHz, $(CD_3)_2SO$) δ: 9.51 (s, 1H, indazolyl H3), 7.89 (d, *J* = 8.4 Hz, 1H, aryl), 7.87 (d, *J* = 7.7 Hz, 1H, aryl), 7.56–7.51 (m, 1H, aryl), 7.42 (d, *J* = 8.8 Hz, 1H, aryl), 7.30–7.25 (m, 2H, aryl), 7.22 (d, *J* = 7.2 Hz, 1H, aryl), 7.14 (t, *J* = 7.3 Hz, 1H, aryl), 5.54 (s br exch, 2H, NH_2), 5.00 (s br exch, 2H, NH_2), 2.75 (s br, 4H, CH_2CH_2). Elemental anal. calcd. for $C_{15}H_{19}ClN_4OPd$ (%): C 43.6, H 4.6, N 13.6; found: C 43.6, H 4.5, N 13.8.

(1,2-Ethanediamine-*N,N′*)[2-(1′-pyrazolyl)pyridine-*N,N′*]palladium(2+) dichloride dihydrate (36)

2-(1′-Pyrazolyl)pyridine (**34**) (0.37 g, 2.5 mmol) in methanol (40 mL) was added to a stirred suspension of $PdCl_2$(en) (0.60 g, 2.5 mmol) in water (50 mL) and the reaction mixture was heated under reflux for 24 h. During this time the orange solid dissolved to give a pale yellow solution. After being cooled to room temperature, the solution was filtered and the solvent removed. The crude product was dissolved in water (5 mL) and the solution was filtered and diluted with ethanol. On the addition of ether, the title compound **36** separated as fine, pale yellow needles (0.62 g, 59%), mp 328 °C (dec.). IR (cm^{-1}): 3420 (br), 3185, 3110, 3060, 1609, 1591, 1493, 1407, 1136, 1074, 1053, 784, 596. ^1H NMR (90 MHz, $(CD_3)_2SO$) δ: 8.62 (dd, *J* = 2.5, 0.5 Hz, 1H, pyrazolyl H5), 8.48 (dt, *J* = 4.9, 1.8 Hz, 1H, pyridyl H6), 8.03–7.94 (m, 2H, pyridyl H3 and H4), 7.83 (dd, *J* = 1.8, 0.5 Hz, 1H, pyrazolyl H3), 7.36 (ddd, *J* = 6.2, 4.9, 2.3 Hz, 1H, pyridyl H5), 6.58 (dd, *J* = 2.5, 1.8 Hz, 1H, pyrazolyl H4), 4.89 (s br exch, 4H, 2 × NH_2), 2.34 (s br, 4H, CH_2CH_2). Elemental anal. calcd. for $C_{10}H_{19}Cl_2N_5O_2Pd$ (%): C 28.7, H 4.6, N 16.7; found: C 28.5, H 4.4, N 17.1.

Heating a mixture of 1,2-ethanediamine (2.5 mL of a 0.03 g/mL solution in methanol, 1.2 mmol) and dichloro[2-(1′-pyrazolyl)pyridine-*N*,*N*′]palladium (34) (0.21 g, 0.7 mmol) in methanol (20 mL) and water (5 mL) gave, on addition of ether, a white solid that was identified as bis(1,2-ethanediamine-*N*,*N*′)palladium(2+) dichloride (35) (0.129 g, 69%), mp 245 °C (dec.). IR (cm^{-1}): 3195, 3150, 3060, 3020, 1606, 1599, 1318, 1274, 1136, 1126, 1058, 468, 370, 290. ^1H NMR (90 MHz, D_2O) δ: 2.75 (s br, 8H, CH_2CH_2).

[2-(3′,5′-Dimethyl-1′-pyrazolyl)pyridine-*N,N′*](1,2-ethanediamine-*N,N′*)palladium(2+) dichloride dihydrate (37)

This compound was prepared from 2-(3′,5′-dimethyl-1′-pyrazolyl)pyridine (**35**) (0.100 g, 0.58 mmol) in methanol (10 mL) and $PdCl_2$(en) (0.139 g, 0.59 mmol) in water (10 mL) as described for compound **36**. The crude product was dissolved in methanol–water (85% *v*/*v*) and ether was added slowly to give the title compound **37** as fine, pale yellow needles (0.182 g, 71%); mp 301 to 302 °C (dec.). IR (cm^{-1}): 3420 (br), 3370 (br), 3210, 3125, 3060, 1610, 1560, 1491, 1420, 1139, 1067, 1064, 773, 590. ^1H NMR (300 MHz, $(CD_3)_2SO$) δ: 8.44 (ddd, *J* = 4.9, 1.5, 0.8 Hz, 1H, pyridyl H6), 7.93 (ddd, *J* = 8.5, 7.1, 1.5 Hz, 1H, pyridyl H4), 7.79 (dd, *J* = 8.5, 0.9 Hz, 1H, pyridyl H3), 7.30 (ddd, *J* = 7.1, 4.9, 0.9 Hz, 1H, pyridyl H5), 6.11 (s, 1H, pyrazolyl H4), 4.89 (s br exch, 4H, 2 × NH_2), 2.57 (s, 3H, 5′-Me), 2.32 (s br, 4H, CH_2CH_2), 2.20 (s, 3H, 3′-Me). Elemental anal. calcd. for $C_{12}H_{23}Cl_2N_5O_2Pd$ (%): C 32.3, H 5.2, N 15.7; found: C 32.35, H 4.95, N 15.8.

(2,2′-Bipyridine-*N,N′*)(1,2-ethanediamine-*N,N′*)palladium(2+) dichloride sesquihydrate (38)

This compound was prepared from 2,2′-bipyridine (0.228 g, 1.5 mmol) in methanol (15 mL) and $PdCl_2$(en) (0.283 g, 1.2 mmol) in water (5 mL) as described for compound **36**. The crude product was dissolved in methanol and dichloromethane was added slowly to give the title compound **38** as small, pale yellow needles (0.388 g, 77%); mp > 270 °C (dec.). A sample was recrystallized from ethanol (95%) for microanalysis. IR (cm^{-1}): 3420 (br), 3150 (br), 3115, 3080, 3050, 3020, 1607, 1601, 1560, 1473, 1172, 770, 722, 580. ^1H NMR (300 MHz, $(CD_3)_2SO$) δ: 8.70 (d, *J* = 8.1 Hz, 2H, 2 × pyridyl H3), 8.53 (d, *J* = 5.6 Hz, 2H, 2 × pyridyl H6), 8.45 (t, *J* = 7.8 Hz, 2H, 2 × pyridyl H4), 7.89

(t, J = 6.6 Hz, 2H, 2 × pyridyl H5), 6.47 (s br exch, 4H, 2 × NH_2), 2.78 (s br, 4H, CH_2CH_2). Elemental anal. calcd. for $C_{12}H_{19}Cl_2N_4O_{1.5}Pd$ (%): C 34.3, H 4.55, N 13.3; found: C 34.25, H 4.3, N 13.3.

Growth inhibition of murine leukæmia L1210 cells in vitro (continuous exposure)

This procedure was adapted from the method of McFadyen et al. (11). Mouse lymphoid leukæmia L1210 cells in in vitro culture were grown on Minimum Essential Medium (Flow Laboratories, USA) supplemented with 15% foetal calf serum, glutamine (2 mmol/L), and gentamycin (2 mg/100 mL). Cells were incubated without agitation in a 5% O_2 – 10% CO_2 atmosphere at 37 °C and, under these conditions, the average doubling time was approximately 12 h. The drugs were dissolved in the appropriate sterile solvent (water or ethanol) and serial dilutions of the stock solution were made using the same solvent. Aliquots of the drug solutions (40 μL) were dispensed into 2 mL of medium containing approximately 5×10^4 cells/mL. Control cultures received the same volume of sterile solvent, and assays were conducted in duplicate for each drug concentration. After incubation at 37 °C for 48 h, cells were counted using a Coulter particle counter (Model ZM, Coulter Electronics Ltd., Luton, UK) with the lower (10) and upper (99) thresholds set to include all particles above 8 μm in diameter (the normal L1210 cell diameter is approximately 11 μm). Cell growth as a percentage of control cultures was plotted against drug concentration and the IC_{50} concentration (the concentration of drug required to effect 50% growth inhibition) was determined. Assays were repeated at least once and IC_{50} values quoted are the means of these determinations.

Antitumour testing was carried out by the method described by McFadyen et al. (11).

Acknowledgments

This work was initiated during the tenure of a grant from the Anti-Cancer Council of Victoria and was supported by the Australian Research Council. The authors would also like to thank Johnson Matthey Chemicals Ltd., UK, for the generous loan of platinum and palladium precursors. We would also like to thank Dr. Ian A.G. Roos for helpful discussions, and Virginia A. Leopold, Experimental Chemotherapy Unit, Cancer Institute, Melbourne, Victoria Australia, for assistance with the biological testing.

In vitro and in vivo studies of neutral cyclometallated complexes against murine leukæmias[1]

Gavin L. Edwards, David St.C. Black, Glen B. Deacon, and Laurence P.G. Wakelin

Abstract: Cyclometallated μ-halogeno dimers derived from nitrogen donor ligands (1-phenylpyrazoles, 2-phenylpyridine, and 1-(2′-pyridyl)indole) were treated with unidentate nitrogen and phosphorus donor ligands to give a series of neutral monomeric palladium(II) and platinum(II) complexes. An initial prescreen of the complexes against the mouse lymphoid leukæmia cell line L1210 indicated that the complexes exhibited growth inhibitory activity over a relatively wide concentration range. Two factors that gave rise to increased activity were steric hindrance about the metal centre resulting from hindered ligands such as 2,6-dimethylpyridine, or the presence of a phosphorus donor ligand. Little correlation between palladium and platinum complexes was noted. Four complexes were selected for further in vivo study and, while none of the palladium complexes showed more than marginal activity against P388 leukæmia at doses below toxic levels, one platinum complex with a hindered metal centre did display significant antitumour activity against this model.

Key words: cyclometallation, palladium, platinum, cytotoxicity, anticancer.

Résumé : Des dimères μ-halogéno cyclométallés dérivés de ligands donneurs d'azote (1-phénylpyrazoles, 2-phénylpyridine, 1-(2′-pyridyl)indole) ont été traités avec des ligands donneurs unidentates d'azote et de phosphore pour conduire à la formation d'une série de complexes monomères neutres du palladium(II) et du platine(II). Un préfiltrate de l'activité de ces complexes contre la lignée L1210 de cellules de leucémie lymphoïde de la souris ont montré qu'ils présentent une activité inhibitrice de la croissance sur une grande plage de concentration. Il y a deux facteurs qui provoquent une augmentation de l'activité, l'empêchement stérique autour du centre métallique résultant de la présence de ligands encombrés comme la 2,6-diméthylpyridine et la présence d'un ligand donneur de phosphore. On n'a pas noté de corrélation entre le palladium et le platine. Quatre complexes ont été sélectionnés pour des études in vivo ultérieures et, même si aucun des complexes du palladium n'a montré plus qu'une activité marginale contre la leucémie P388 à des doses inférieures aux degrés toxiques, un des complexes du platine avec un centre métallique encombré a présenté une activité antitumorale significative contre ce modèle.

Mots clés : cyclométallation, palladium, platine, cytotoxicité, anticancéreux.

Introduction

Throughout history heavy metals have been used as therapeutic agents (1); mercury was once used as a treatment for syphilis (2), and arsenic compounds have been used for over 2000 years (3). In modern times, heavy metals fell out of favour and until relatively recently they have been largely ignored as starting points for rational drug design. Rosenberg et al. (4) changed the face of modern chemotherapy with their observation of the antiproliferative activity of *cis*-diamminedichloroplatinum(II) (cisplatin) and their subsequent discovery of the anticancer properties of a range of

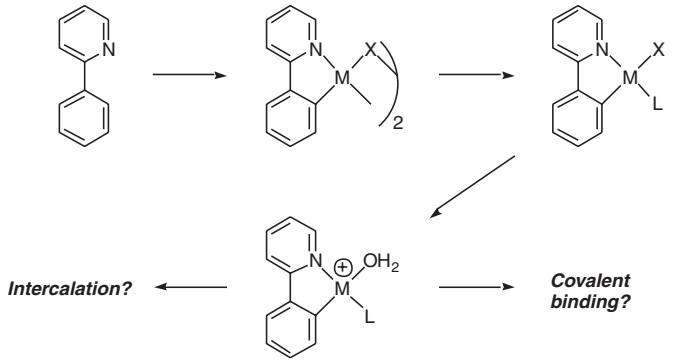
It is a pleasure to honour Howard Alper's very significant contributions both to chemistry and to the chemical profession.



There once was a Canuck called Howard,
Over other chemists he towered,
His group in fine fettle,
Used many a metal,
Leaving the science empowered.

platinum complexes (5), resulting in the introduction of cisplatin into the clinic in 1978 (6).

The development of second and third generation platinum drugs has followed in an attempt to broaden the spectrum of activity, overcome resistance, and obviate toxic side effects. Some general principles emerged as a guide to the design of new bioactive platinum containing therapeutics, and several useful platinum based anticancer drugs were developed as a result (6, 7). Active agents are neutral platinum(II) or (IV) complexes, normally containing two kinetically inert ligands that should be primary amines or ammonia, and also containing two labile anionic ligands in a cis configuration to enable bidentate binding to the heterocyclic bases of the target DNA (7). Complexes containing aromatic amines such as pyridine, monohalo complexes ("monofunctional" complexes), and those with trans stereochemistry, were generally inactive, although there have been some notable exceptions (7–9), and there remains significant scope for the development of more varied platinum containing structures (10) as drugs.

The formation of bifunctional lesions upon the binding of cisplatin to DNA has been linked to its activity, and studies on the relatively small number of monofunctional platinum complexes — those with a single labile ligand — have reinforced the notion that bifunctional binding is necessary for activity. Interesting exceptions are found in a new class of organoamidoplatinum(II) complexes that are monofunctional and have *trans*-amine ligands, yet possess excellent activity across in vitro, cellular, and animal studies (11). However, many monofunctional platinum complexes studied to date have been charged and therefore issues such as membrane permeability may influence the biological activity of these complexes adversely (7). As a part of a programme investigating nitrogen directed metallations (12, 13), we sought to develop a series of neutral cyclometallated complexes as potential monofunctional DNA binding agents (Fig. 1). Cyclometallation of ligands such as 2-phenylpyridine gives μ-halogeno dimers, which, upon cleavage with appropriate unidentate ligands, provide neutral monomeric complexes. These complexes could act as monofunctional DNA binding agents where, in the low chloride concentration of intracellular fluid, aquation would lead to a reactive cationic species. While the aquated complex could bind covalently to DNA, another possible interaction would be intercalation of the planar chromophore into the DNA double helix, in a similar manner to metallointercalation reagents studied by Lippard (14), Barton and co-workers (15), and others (16, 17). Recent reports on highly cytotoxic cyclometallated complexes by Kodaka and co-workers (18), Navarro-Ranninger and co-workers (19), and Ma and Che (20) have prompted us to publish our findings on a range of mononuclear platinum(II) and palladium(II) complexes that exhibit significant activity against murine leukæmia L1210 in vitro with a notable effect shown by complexes containing bulky ligands. This correlates with the recently discovered activity of the crowded complex *cis*-amminedichloro(2-methylpyridine)platinum(II) AMD473 (ZD0473) (21), which has progressed to phase III clinical trials (10). In the preceding paper (22), we have also reported our results on the synthesis and biological activity of a series of cationic metallointercalation complexes, many of which incorporate a cyclometallated chromophore.

Results and discussion

Synthesis of metal complexes

Preparation of the required ligands (Fig. 2) and the subsequent cyclometallation reactions to provide μ-chloro dimers **1** (23), **4** (12), **6** (24), **9** (22), and **10** (22) (Table 1) have been described previously. While the nature of the halide was of little importance for the cationic metallointercalators where the halide would merely act as a counterion, variation between coordinated chloride, bromide, and iodide could be crucial for increased activity in the series of neutral complexes, and therefore several μ-chloro dimers were converted to the corresponding bromo and iodo derivatives **2** (12), **3** (12), **5** (12), **7** (24), and **8** (12) (Table 1) by metathesis reactions with the appropriate lithium halide as described previously (12). The structures were confirmed by elemental analysis, far-IR, and ^{1}H NMR spectroscopy. ^{1}H NMR analy-

[a]Key to unidentate ligands: pyridine (py), perdeuteropyridine (py-d_5), β-lutidine (3,5-dimethylpyridine) (blut), α-lutidine (2,6-dimethylpyridine) (alut), 2-phenylpyridine (2phpy), dimethylsulfoxide coordinated through sulfur (*S*-dmso), α-picoline (2-methylpyridine) (pic).

sis of the dimers proved difficult because of their extremely low solubility in common solvents, and therefore the μ-halogeno dimers were converted to the monomers by the addition of a drop of ($^2H_5$)pyridine (py-d_5) to a suspension in $CDCl_3$ providing the monomeric complexes in solution; loss of one proton confirmed that cyclometallation had taken place, and observation of a single set of resonances demonstrated that metathesis was complete (12).

Synthesis of the monomeric complexes **11**–**36** (Table 2) was effected by treatment of a suspension of a μ-halogeno dimer in dichloromethane or acetone with a unidentate ligand (L) to give clear solutions; the products usually separated as microcrystalline solids upon the addition of hexane or pentane. The palladium dimers reacted quite rapidly; by comparison, cleavage of the platinum–halogen bridge appeared to be much slower. The complexes were stable at room temperature and the platinum complexes could be recrystallized from hot solvents, however attempts to recrystallize the analogous palladium complexes (where L = nitrogen donor ligands) at elevated temperatures led to dissociation of the ligand L and reformation of the μ-halogeno dimers. Thus, these palladium complexes were purified by dissolution in an appropriate solvent at room temperature and reprecipitation upon the addition of hexane or pentane. Far-IR and ^1H NMR spectroscopy as well as microanalysis established the identity and purity of our products. Any attempts to heat the palladium complexes — to speed drying, measure melting points, or volatilize the complexes for mass spectrometric analysis — led to quantitative loss of the unidentate ligand. This may explain the discrepancy between the observed (mp 155 °C (dec.)) and reported (24) (mp 200 °C (dec.)) melting points for compound **29**: a significant difference in the rate of heating could mean that a larger proportion of one sample may have degraded before reaching the melting (decomposition) point. Pérez et al. (25) have recently determined the activation energy for the decomposition of this class of complexes by this pathway as 90–100 kJ mol^{-1}.

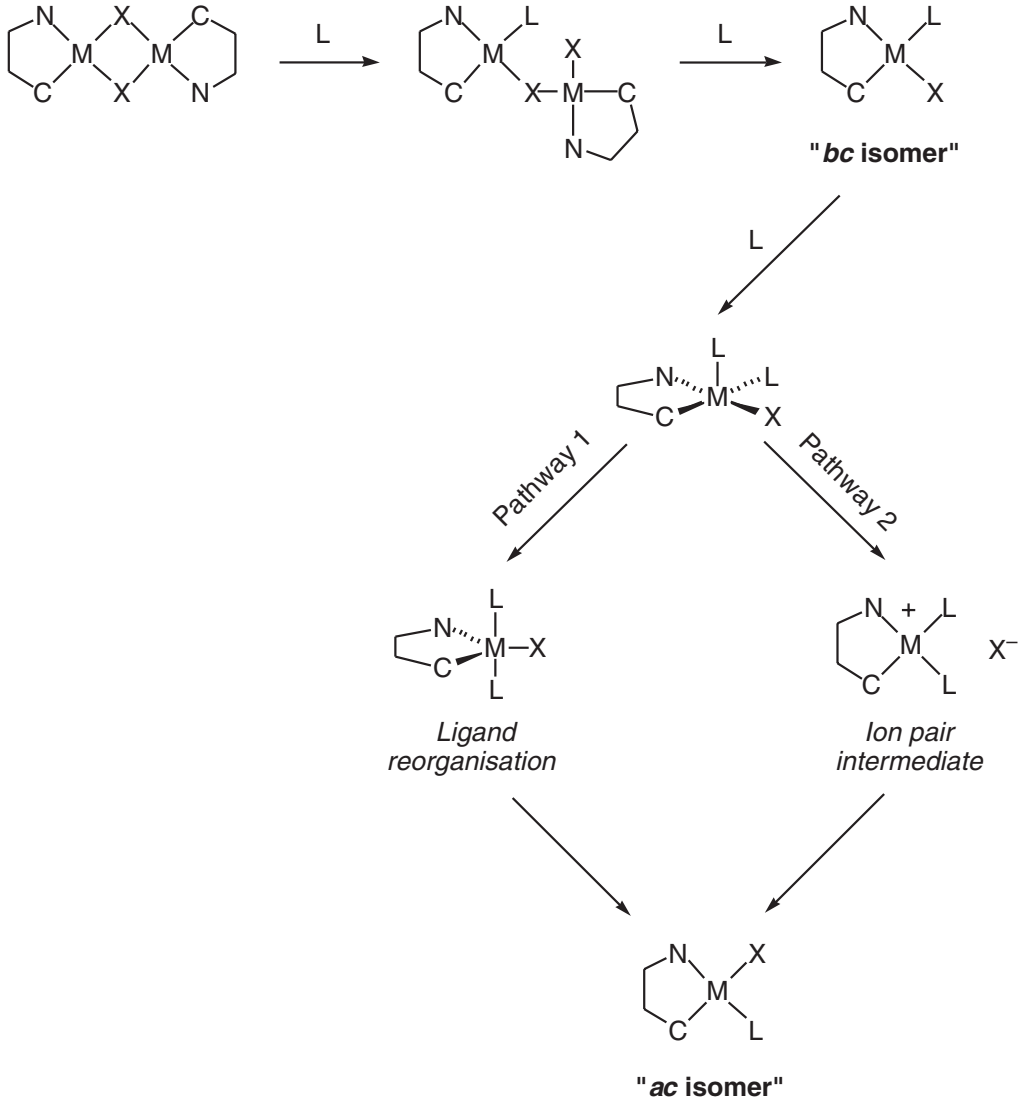

Fig. 3. Possible products of bridge cleavage.

While the bridge cleavage reactions can, in principle, produce two isomeric products (Fig. 3) — one, with the halogen

© 2005 NRC Canada

Fig. 4. Mechanism for isomerization of the *bc* isomer to the *ac* isomer (adapted from ref. 12).

ligand trans to the carbon donor (the *ac* isomer)[3] and the other with the unidentate ligand L trans to the carbon donor ligand (the *bc* isomer) — the palladium complexes and many of the platinum complexes were isolated as the *ac* isomers exclusively. In these reactions, the strong kinetic trans effect of the σ-carbon ligand means that the first bond in the bridge to be cleaved is that trans to the aryl substituent. Thus, the initial (kinetic) product from bridge cleavage should be the *bc* isomer (Fig. 4). Subsequent rearrangement of this kinetic product could occur either via formation of a five-coordinate transition state with accompanying ligand reorganisation (Pathway 1), or formal formation of a square-planar ion pair as an intermediate (Pathway 2). The subsequent conversion of this ionic intermediate to the neutral complex would be governed by the strong kinetic trans effect of the σ-carbon ligand, leading to selective cleavage of the C—L bond trans to the aryl group. In all cases, the palladium complexes are sufficiently reactive and only the thermodynamically favoured *ac* isomers are observed. Platinum(II) complexes are less labile and, if there is sufficient steric hindrance around the metal centre (2,6-dimethylpyridine ligands introduce hindrance above and below the metal), the kinetic *bc* product can be isolated. Other platinum complexes are isolated as the *ac* products. A fuller mechanistic discussion and supporting experimental evidence has been published previously (12).

In all cases, the structures and stereochemistry of the monomeric products were confirmed by spectroscopic analysis. Comparison between the far-IR spectra of analogous complexes below 300 cm^{-1} often allowed assignment of the palladium–halogen stretching frequencies and these values were used as a guide to the assignment of ν(Pd–X) for other neutral monomeric species. The relatively low frequencies observed for most ν(Pd–X) (for example, palladium–chlorine stretching frequencies were observed in the range 230 to ≈260 cm^{-1}, while ν(Pd–Br) was approximately 160 cm^{-1}, and ν(Pd–I) was in the range 120–140 cm^{-1}) (12) were indicative that the halogen ligand is trans to an σ-carbon donor

[3] The *ac*/*bc* nomenclature system was adopted in our previous report (12) to simplify the discussion of stereochemistry: all *ac* complexes have the halide trans to the carbon donor ligand and all *bc* complexes have the halide cis to the carbon donor ligand.

© 2005 NRC Canada

of strong trans influence (26); this confirmed that the complexes had *ac* stereochemistry. Structural assignments for the platinum complexes were discussed in the mechanistic report (12).

The ^{1}H NMR spectra of the complexes likewise confirmed the assigned structures, where several features were noteworthy. Coordination of unidentate pyridine ligands results in deshielding of the α-pyridyl protons (27) or the α substituents; for example, 2,6-dimethyl substituents move downfield by about 0.7 ppm on coordination. Presumably, this effect is a combination of the inductive nature of the metal as well as the through-space paramagnetic anisotropy of the metal atom (28). As described previously (12), strong shielding of the proton ortho to the site of metallation (H_{ortho}) was observed where L is a pyridine ligand, owing to the proximity of the proton to the adjacent orthogonal pyridine ring. Greater shielding with increased α substitution on the pyridine nucleus indicates that the α-methyl groups restrict rotation about the Pd—N bond and thus prevent rotation of the ring current associated with the unidentate ligand away from H_{ortho}. While ammine and primary amine ligands (complexes **16**–**18**) produced no noticeable effect on H_{ortho} (the proton ortho to the C—M bond), deshielding of the pyridyl H6 in the cyclometallated ligand of 2-pyridylphenyl complexes was observed, consistent with coordination to the metal and also with the through-space paramagnetic anisotropy of the adjacent halide ligand.

Palladium complexes **19**, **20**, and **36** containing triphenylphosphine and trimethyl phosphite ligands were more stable than those with nitrogen donor ligands. They could be recrystallized from hot solvents without reverting to the dimeric precursors, and mass spectra could also be measured. Numerous absorptions because of the triphenylphosphine ligand were observed in the far-IR spectra of complexes **19** and **26**; the most distinctive of these were several bands in the regions 400–460 cm^{-1} and 490–550 cm^{-1} (29). In the ^{1}H NMR spectra of the complexes, several ^{31}P–^{1}H and ^{195}Pt–^{1}H couplings were observed. In the triphenylphosphine complexes **19** and **26**, the phenyl protons H5 and H6 were both shielded by the ring currents of the adjacent P–Ph groups, confirming the *ac* stereochemistry. In the low-field region of the ^{1}H NMR spectrum of complex **26**, the signal owing to the pyridyl H6 proton is observed as a distorted triplet with fine coupling and ^{195}Pt satellites. Although exact coupling constants could not be assigned, it is apparent that $J_{5,6} \approx J_{P,H6} \approx$ 4.5–5.5 Hz. The estimated $J_{Pt,H6}$ of 27 Hz is lower than observed for other platinum complexes (27) as a result of the strong trans influence of the *trans*-phosphine ligand. Platinum-195 coupling to phenyl H6 (56 Hz) is comparable with literature values (24), and ^{31}P–^{1}H coupling to pyridyl H6 is also similar to published results (30).

In vitro and in vivo testing

Most metal complexes with anticancer activity are based on platinum; while the coordination chemistry of platinum(II) and palladium(II) are similar, many palladium complexes show moderate in vivo activity at best (7). Although some palladium complexes have shown promising activity in vitro (31) or in animal models (22), to date they have not made a successful transition to clinical trials (7). However, the possibility of covalent or intercalative mechanisms of action for this class of compounds suggested that the monofunctional palladium complexes were worthy of study.

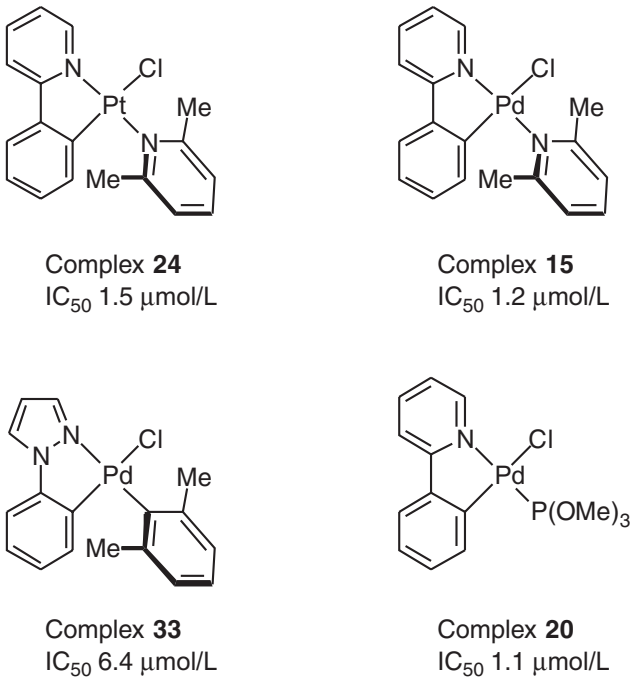
The complexes were subjected to an in vitro prescreen for growth inhibitory activity against the murine leukæmia cell line L1210, as described in the preceding paper (22). As the complexes are neutral, water proved to be an unsuitable solvent for preparation of stock solutions or for serial dilutions, and therefore ethanol, ethanol – dimethyl sulfoxide, or dimethyl sulfoxide were used. Serial dilutions of stock solutions were made using ethanol without precipitation. It is desirable that the complexes retain their structures in solution prior to the addition of the drug to the cell culture, and ^{1}H NMR spectroscopy was employed to examine the behaviour of selected complexes in solution. The spectrum of the 2,6-dimethylpyridine complex **15** in perdeuteromethanol was unchanged after the solution was allowed to stand at room temperature for 3 days, and the spectrum was well-resolved with the exception of a broadened signal corresponding to a single proton at low field that could be assigned as pyridyl H6 for the cyclometallated ligand. The observed broadening of this signal could result from weak axial association and exchange of CD_3OD ligands, or from reversible displacement of the chloride ligand; the chemical shift of this pyridyl H6 correlates with a coordinated ligand and therefore the cyclometallated ligand is essentially unaffected. The 2,6-dimethylpyridine ligand also remains complexed to the metal centre. The ^{1}H NMR spectra of monomeric py-d_5 complexes **11**–**13** in perdeuterodimethylsulfoxide ($(CD_3)_2SO$) were broadened by comparison with the spectra recorded in $CDCl_3$ (12), however the spectra of the three complexes in $(CD_3)_2SO$ were clearly different from one another, and the observation of signals at low field (above 9 ppm, pyridyl H6) and at high field (below 6.1 ppm, phenyl H6) indicates that a significant concentration of unchanged complex exists in solution and the clear differences indicated that the halogen had not been displaced.

The results of growth inhibition experiments against L1210 cells in vitro, expressed as drug concentrations that caused a 50% inhibition of cell growth (IC_{50}), are given in Table 2. For comparison, cisplatin has an IC_{50} of 0.9 μmol/L under similar conditions.

Antitumour screening of simple analogues of cisplatin ($Pt(NH_3)_2X_2$) has indicated that there is a strong relationship between the halide leaving group X and biological activity, where antitumour activity generally decreases with larger halogens (32). In this study, results for complexes **11**–**13** and **29**–**31** suggest that changing halogen has no significant effect on the biological activity of the organopalladium complexes in vitro. Either aquation of the labile palladium complexes (or displacement of the halogen by other ligands) occurs and therefore the drugs are converted to the same active intermediates, or reaction of the Pd—X bond is not crucial for activity. Two platinum complexes with *bc* stereochemistry were also evaluated and the bromo complex **28** was almost twice as active as the chloro complex **27**; while a definitive statement concerning trends cannot be made based on two results, it does appear as though the bulkier halides lead to more active complexes.

The unidentate ligand (L) is observed to play an important role in the biological activity of these drugs. Small amine ligands such as NH_3 (complex **16**), $MeNH_2$ (**17**), and *t*-

© 2005 NRC Canada



$BuNH_2$ (**18**), and unsubstituted pyridine ligands (**11** and **29**) cause 50% growth inhibition at similar concentrations. Use of pyridine (platinum complex **21**) or py-d_5 (**22**) has no significant effect on activity, suggesting that reaction of the coordinated unidentate ligand is not involved in the modes of action of the drugs. A pyridine ligand that is substituted away from the metal–nitrogen bond (the 3,5-dimethylpyridine ligand (blut), complex **14**) does not affect the biological activity compared to the unsubstituted analogue. However and notably, introduction of steric crowding around the metal ion with successive α substituents on the pyridine rings (compare complexes **29**, **32**, and **33**, or **11** and **15**) leads to greatly enhanced activity. The mechanism of action of this class of compounds is not clear, but the poor activity of free 2,6-dimethylpyridine (IC_{50} > 200 μmol/L) indicates that the enhanced biological activity is not due to the unidentate ligands following release from the metal. In fact, for good activity it appears as though the neutral ligand L must remain coordinated to the metal.

The introduction of α substituents on the unidentate pyridine ligands (L) gives increased steric hindrance around the metal, and interactions between the α-methyl groups and the bidentate organometallic ligand would cause the ligand L to lie approximately orthogonal to the coordination plane of the metal. These α-methyl substituents would hinder the formation of a trigonal bipyramidal intermediate, and therefore impede substitution by an associative mechanism. This effect is similar to that observed for the sterically hindered α-picoline platinum complex, AMD473 (ZD0473) (8, 21), however, in the case of the palladium complexes reported herein two α-methyl substituents are required before significant enhancement of activity is noted. Whether, in the case of drugs reported in this study, the enhanced activity with extra α substituents on L is due to slower displacement of the halide ligand (X) or of the unidentate ligand (L), is unclear.

Complexes with unidentate phosphorus donor ligands in general effect growth inhibition at relatively low concentrations with some complexes showing IC_{50} values approaching that of cisplatin. The phosphorus donor ligands L give stable complexes where L is not readily displaced, and the trimethyl phosphite ligands (complexes **20** and **36**) would introduce negligible steric hindrance around the metal and therefore $P(OCH_3)_3$ would not impede substitution at the metal centre by an associative mechanism. Thus, if the mechanism of action of these complexes is similar to that for the nitrogen donor ligands, then slow or negligible displacement of the unidentate ligand is indicated as an important event for activity. This can be achieved by either steric or coordinative stabilization of the complexes with respect to substitution. Another alternative is that the antiproliferative effects could arise from localized release of the phosphine/phosphite ligands within the cells; the lower activity observed for platinum complex **26** (IC_{50} = 10 μmol/L) compared to its palladium analogue **19** (IC_{50} = 1.8 μmol/L) could reflect the greater lability of the palladium complex and the faster release of bioactive phosphine ligands (33).

The nature of the cyclometallated ligand also appears to be crucial for activity. If an intercalative mode of binding is implicated in the mechanism of action, increased surface area should result in higher activity. Pyrazolylphenyl ligands gave complexes that generally caused growth inhibition at relatively high concentrations, but addition of methyl groups produced a more active drug (compare pzph complex **33** (IC_{50} = 6.4 μmol/L) with dmpzph complex **34** (IC_{50} = 3.0 μmol/L)). Likewise, fusion of an extra benzene ring (compare pyin complex **35** (IC_{50} = 7.7 μmol/L) with pzph complex **29** (IC_{50} = 52 μmol/L)) resulted in enhanced activity. These factors are consistent with an intercalative mechanism.

Fig. 5. Complexes selected for in vivo testing against P388 leukæmia (in vitro IC_{50} vs. L1210 given for comparison).

Insufficient platinum complexes have been prepared in this study for clear trends to become evident, however, a comparison of the *ac* (complexes **22**–**24**, for instance) and *bc* (**27** and **28**) complexes suggests that the thermodynamically favoured *ac* complexes are likely to be more active. Further work is needed to confirm this observation. Additionally, it is apparent that there is not necessarily any firm correlation between the palladium and the platinum complexes; in some cases, the platinum complexes are more active than the palladium analogues (compare **22** (Pt) with **11** (Pd)), while in others the palladium complex was more active (compare **26** (Pt) with **19** (Pd)), and the key 2,6-dimethylpyridine complexes (compare **24** (Pt) with **15** (Pd)) have similar activities.

Four of the more active complexes (Fig. 5) were selected for evaluation of potential antitumour activity against P388 leukæmia in mice. The drugs were tested over a range of dose levels with results expressed as a ratio of mean survival times of treated animals (T) relative to controls (C). Significant antitumour activity is indicated by a %T/C greater than 125%. A %T/C of 0% indicates that none of the treated animals survived as a result of the toxicity of the drug at that dose level. Results are shown in Tables 3*a* and 3*b*; the anticancer agent 5-fluorouracil (5-FU) is used for comparison. Platinum complex **24** showed significant activity (%T/C 138%) against P388 leukæmia at 80 mg/kg. Complex **15**, its

palladium analogue, demonstrated only marginal activity (%T/C 126%) at the highest dose level of 400 mg/kg despite showing almost identical activity against L1210 in vitro. Pyrazolylphenyl complex **33** achieved a %T/C of 120% at doses of 100 mg/kg before toxicity then became evident. Finally, trimethyl phosphite complex **20**, while being highly active in vitro, showed no antitumour activity in vivo, and was toxic at relatively low doses with no treated animals surviving doses of 16 mg/kg or higher. Among the palladium complexes chosen for study, only marginal antitumour activity was observed at best. The very high dose levels required to demonstrate activity, and the possibility that complexes such as **15** may be approaching limiting toxicity, indicated that further testing of those complexes was not warranted.

On the other hand, platinum complex **24** has steric bulk around the metal centre in a similar manner to the clinically active 2-methylpyridine containing complex AMD473 (21), and the results obtained in this study for this complex **24** are encouraging (%T/C 138% at 80 mg/kg). In light of Kodaka and co-workers' recent reports (18, 34) of the promising activity against a cisplatin resistant mouse sarcoma 180 cell line of platinum complex **23** previously prepared in our laboratories (12), extension into the platinum series focussing on systems with bulky ligands is being investigated further.

Experimental

General procedure

General experimental details, including instrumental specifications and in vitro and in vivo biological testing protocols, have been described previously (22). Mass spectra were obtained on a VG Micromass 7070F spectrometer at 70 eV, samples being introduced by direct evaporation. Where relevant, the listed value is the most intense peak (^{195}Pt, ^{231}(PtCl), ^{106}Pd, ^{143}(PdCl)) of a cluster with the correct isotope pattern. Cyclometallated dimers **1** (23), **2**–**5** (12), **6** and **7** (24), **8** (12), and **9** and **10** (22) were prepared by published procedures, and monomeric complexes **11**–**13**, **15**, **22**–**25**, **27**–**31**, and **33** were prepared by the procedures referred to in Table 2. Unidentate ligands (2-methylpyridine, 2-phenylpyridine, 2,6-dimethylpyridine, 3,5-dimethylpyridine, triphenylphosphine, and trimethyl phosphite) were obtained from the Aldrich Chemical Company and were recrystallized or distilled prior to use. ($^2H_5$)Pyridine (py-d_5) (Aldrich Gold Label) was used without further purification. Solvents and organic reagents were purified by established methods.

Preparations

General method

The appropriate unidentate ligand was added to a stirred suspension of the μ-halogeno dimer in dichloromethane or acetone. The mixture was stirred at room temperature until the reaction was complete (this was indicated when the solid had dissolved completely). Hexane or pentane was added to precipitate the crude product, which was filtered off and washed with hexane or pentane. The solid was dissolved in a polar solvent (dichloromethane or acetone) at room temperature, and the solution was filtered. Slow addition of hexane or pentane gave the monomeric complex as a microcrystalline solid, which was dried at room temperature.

a-*Chloro*-b-*(3″,5″-dimethylpyridine*-N″)-dc-*[2-(2′-pyridyl)-phenyl*-N′,C]*palladium (14)*

This compound was prepared from μ-chloro dimer **1** (0.359 g, 0.61 mmol) and 3,5-dimethylpyridine (10 drops) in acetone (15 mL). Recrystallization of the crude product from acetone–hexane at room temperature gave the title compound **14** as a pale yellow microcrystalline solid (0.399 g, 82%); mp 204 to 205 °C. IR (cm^{-1}): 1606, 1595, 1578, 1568, 1437, 1422, 1275, 1157, 857, 854, 790, 766, 756, 731,

699, 410, 323, 300, 238 ν(Pd–Cl). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.45 (d, J = 5.6 Hz, 1H, pyridyl H6′), 8.59 (s br, 2H, pyridyl H3″ and H5″), 7.90–6.85 (m, 7H, aryl), 6.18 (dd, J = 7.3, 1.5 Hz, 1H, phenyl H6), 2.35 (s, 6H, 2 × Me). Elemental anal. calcd. for $C_{18}H_{17}ClN_2Pd$ (%): C 53.6, H 4.25, N 6.95; found: C 54.0, H 4.3, N 6.8.

b-*Ammine*-a-*chloro*-dc-*[2-(2′-pyridyl)phenyl*-N′,C*]palladium (16)

A solution of anhydrous ammonia in methanol was added dropwise to a stirred suspension of **1** (0.116 g, 0.20 mmol) in dichloromethane (5 mL) until a colourless solution resulted. Hexane was added to give a white solid, which was filtered off and washed with hexane. The crude product gradually became yellow on standing in air. Recrystallization twice from dichloromethane–ether at room temperature gave the title compound **16** (35) as small, bright yellow needles (0.090 g, 73%); mp > 300 °C. IR (cm^{-1}): 3315 (br), 3210 (br), 3045, 3040, 1606, 1579, 1437, 1421, 1204, 1182, 1166, 1156, 1022, 738, 722, 404, 230 ν(Pd–Cl). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.05 (d, J = 5.0 Hz, 1H, pyridyl H6), 7.68–6.71 (m, 7H, aryl), 2.86 (s br, 3H, NH_3). Elemental anal. calcd. for $C_{11}H_{11}ClN_2Pd$ (%): C 42.2, H 3.5, N 8.95; found: C 42.3, H 3.5, N 8.8.

a-*Chloro*-b-*(methylamine)*-dc-*[2-(2′-pyridyl)phenyl*-N′,C*]-palladium (17)

This compound was prepared by the general method by the addition of anhydrous methylamine (as a solution in dichloromethane) to **1** (0.153 g, 0.26 mmol) in dichloromethane (2 mL). Recrystallization of the crude product from dichloromethane–hexane at room temperature gave the title compound **17** as fine yellow needles (0.139 g, 82%); mp 205 °C (dec.). IR (cm^{-1}): 3295 (br), 3220 (br), 3150, 1605, 1588, 1582, 1437, 1424, 1161, 1156, 1030, 748, 727, 406, 243 ν(Pd–Cl) or 215 ν(Pd–Cl) (either assignment possible). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.98 (dd, J = 5.7, 1.2 Hz, 1H, pyridyl H6), 7.62 (td, J = 7.8, 1.6 Hz, 1H, aryl), 7.36 (d, J = 8.0 Hz, 1H, pyridyl H3), 7.21–7.18 (m, 1H, aryl), 7.01–6.38 (m, 4H, aryl), 3.34 (m br exch, 2H, NH_2), 2.82 (t (s after exch), J = 6.6 Hz, 3H, Me). Elemental anal. calcd. for $C_{12}H_{13}ClN_2Pd$ (%): C 44.1, H 4.0, N 8.6; found: C 44.2, H 4.0, N 8.6.

b-*(*tert*-Butylamine)*-a-*chloro*-dc-*[2-(2′-pyridyl)phenyl*-N′,C*]-palladium (18)

This compound was prepared from **1** (0.255 g, 0.43 mmol) and *tert*-butylamine (10 drops) in dichloromethane (4 mL). Recrystallization of the crude product from dichloromethane–hexane at room temperature gave the title compound **18** as pale yellow microcrystals (0.256 g, 81%); mp > 290 °C. IR (cm^{-1}): 3275 (br), 3220 (br), 3140, 1606, 1588, 1578, 1439, 1426, 1160, 1149, 1030, 749, 733, 413, 227 ν(Pd–Cl). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 9.31 (dd, J = 5.7, 1.0 Hz, 1H, pyridyl H6), 7.74 (td, J = 7.8, 1.6 Hz, 1H, aryl), 7.54 (d, J = 7.9 Hz, 1H, pyridyl H3), 7.36 (dd, J = 7.2, 1.8 Hz, 1H, aryl), 7.09 (ddd, J = 7.4, 5.7, 1.3 Hz, 1H, pyridyl H5), 7.06–6.92 (m, 3H, aryl), 3.41 (s br exch, 2H, NH_2), 1.51 (s, 9H, CMe_3). Elemental anal. calcd. for $C_{15}H_{19}ClN_2Pd$ (%): C 48.8, H 5.2, N 7.6; found: C 48.7, H 5.1, N 7.4.

a-*Chloro*-dc-*[2-(2′-pyridyl)phenyl*-N′,C*]-b-*(triphenylphosphine)palladium (19)

This compound was prepared from **1** (0.156 g, 0.26 mmol) and triphenylphosphine (0.140 g, 0.53 mmol) in dichloromethane (16 mL). Recrystallization of the crude product from dichloromethane–hexane gave the title compound **19** (34) as small pale yellow prisms (0.242 g, 82%); mp 211–214 °C (dec.). IR (cm^{-1}): 1602, 1579, 1566, 1439, 1434, 1426, 1423, 1313, 1100, 1093, 1018, 750, 745, 731, 705, 695, 689, 628, 531, 513, 501, 498, 310, 244 ν(Pd–Cl). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 9.64 (dddd, J = 5.4, 1.0, 0.6 Hz, $J_{P,H}$ = 3.7 Hz, 1H, pyridyl H6), 7.86–7.73 (m, 8H, aryl), 7.52 (d, J = 7.9 Hz, 1H, aryl), 7.47–7.33 (m, 9H, aryl), 7.26–7.21 (m, 1H, aryl), 6.98–6.92 (m, 1H, aryl), 6.57–6.48 (m, 2H, H5 and H6). Elemental anal. calcd. for $C_{29}H_{23}ClNPPd$ (%): C 62.4, H 4.15, N 2.5; found: C 62.2, H 3.9, N 2.8.

a-*Chloro*-dc-*[2-(2′-pyridyl)phenyl*-N′,C*]-b-*(trimethyl phosphite)palladium (20)

This compound was prepared from **1** (0.116 g, 0.20 mmol) and trimethyl phosphite (0.049 g, 0.40 mmol) in dichloromethane (6 mL). Recrystallization of the crude product from cyclohexane gave the title compound **20** as fine, pale yellow needles (0.121 g, 74%), mp 139 to 140 °C. IR (cm^{-1}): 1604, 1578, 1436, 1427, 1012, 810, 801, 770, 764, 740, 544, 285, 238 ν(Pd–Cl). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 9.48 (dddd, J = 5.7, 1.0, 0.7 Hz, $J_{P,H}$ = 4.9 Hz, 1H, pyridyl H6), 7.85 (td, J = 7.7, 1.6 Hz, 1H, aryl), 7.74 (d, J = 8.2 Hz, 1H, pyridyl H3), 7.62 (td, J = 7.2, 1.5 Hz, 1H, aryl), 7.58 (d, J = 8.0 Hz, 1H, aryl), 7.28–7.09 (m, 3H, aryl), 3.89 (d, $J_{P,H}$ = 12.8 Hz, 9H, $P(OMe)_3$). Mass spectrum m/z (%): 421 (M^+, 1.1), 384 ($C_{14}H_{17}NO_3PPd^+$, 0.1), 369 ($C_{13}H_{14}NO_3PPd^+$, 0.2), 297 ($C_{11}H_8ClNPd^+$, 0.2), 278 ($C_{11}H_{10}NOPd^+$, 22), 260 ($C_{11}H_8NPd^+$, 2.3). Elemental anal. calcd. for $C_{14}H_{17}ClNO_3PPd$ (%): C 40.0, H 4.1, N 3.3; found: C 40.1, H 4.1, N 3.3.

a-*Chloro*-b-*(pyridine*-N″)-dc-*[2-(2′-pyridyl)phenyl*-N′,C*]-platinum (21)

This compound was prepared by the general method by the addition of pyridine (5 drops) to the μ-chloro dimer **4** (0.21 g, 0.27 mmol) in dichloromethane (15 mL). Recrystallization of the crude product from dichloromethane–pentane gave the title compound **21** as small yellow needles (0.25 g, 99%). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 9.70 (dd with satellites, J = 5.1, 1.6 Hz, $J_{Pt,H}$ = 39 Hz, 1H, pyridyl H6′), 9.01 (dt with satellites, J = 5.1, 1.4 Hz, $J_{Pt,H}$ = 46 Hz, 2H, pyridyl H2″ and H6″), 7.95–7.79 (m, 2H, aryl), 7.66 (d with satellites, J = 8 Hz, $J_{Pt,H}$ = 9 Hz, 1H, pyridyl H3′), 7.51–7.41 (m, 3H, aryl), 7.19–7.07 (m, 2H, aryl), 6.98 (td with unresolved satellites, J = 7.4, 1.4 Hz, 1H, phenyl H5), 6.36 (dd with satellites, J = 7.5, 0.9 Hz, $J_{Pt,H}$ = 48 Hz, 1H, phenyl H6). Mass spectrum (%): m/z 464 (M^+, 6), 428 ($C_{16}H_{13}N_2Pt^+$, 1), 385 ($C_{11}H_8ClNPt^+$, 8), 348 ($C_{11}H_7NPt^+$, 9), 321 ($C_{10}H_6Pt^+$, 2). This compound is the py analogue of py-d_5 complex **22** and full analytical data for **22** has been previously reported (12).

a-*Chloro*-dc-*[2-(2′-pyridyl)phenyl*-N′,C*]-b-*(triphenylphosphine)platinum (26)

This compound was prepared from **4** (0.232 g, 0.30 mmol) and triphenylphosphine (0.200 g, 0.76 mmol) in dichloromethane (50 mL). Recrystallization of the crude product

© 2005 NRC Canada

from dichloromethane–pentane gave the title compound **26** as yellow needles (0.195 g, 50%); mp 305–307 °C (dec.). IR (cm^{-1}): 1605, 1583, 1439, 1436, 1425, 1100, 1096, 750, 746, 731, 706, 702, 695, 690, 542, 519, 505, 300, 284 ν(Pt–Cl). ^1H NMR (300 MHz, $CDCl_3$) δ: 9.90–9.87 (m with satellites, $J_{Pt,H} \approx 27$ Hz, 1H, pyridyl H6), 7.89–7.76 (m, 8H, aryl), 7.52 (J = 7.8, 1.4 Hz, 1H, aryl), 7.46–7.33 (m, 9H, aryl), 7.29 (qt, J = 7.1, 6.0, 1.5 Hz, $J_{P,H}$ = 1.5 Hz, 1H, pyridyl H5), 6.95 (td, J = 7.5, 1.2 Hz, 1H, aryl), 6.67 (ddd with satellites, J = 7.9, 0.9 Hz, $J_{P,H}$ = 3.3 Hz, $J_{Pt,H}$ = 56 Hz, 1H, phenyl H6), 6.52 (td with unresolved satellites, J = 7.6, 1.4 Hz, 1H, phenyl H5). a-*Chloro*-b-*(2″,6″-dimethylpyridine*-N″)-dc-*[2-(3′,5′-dimethyl-1′-pyrazolyl)phenyl*-N′,C*]-palladium (34)

This compound was prepared from the μ-chloro dimer **9** (0.180 g, 0.29 mmol) and 2,6-dimethylpyridine (5 drops) in dichloromethane (10 mL). Recrystallization of the crude product from dichloromethane–hexane at room temperature gave the title compound **34** as fine, colourless needles (0.114 g, 47%); mp > 300 °C. IR (cm^{-1}): 1603, 1580, 1568, 1551, 1440, 1422, 1400, 1392, 1028, 795, 786, 761, 749, 299, 263 ν(Pd–Cl). ^1H NMR (90 MHz, $CDCl_3$) δ: 7.67 (J = 7.1 Hz, 1H, pyridyl H4), 7.26–7.17 (m, 3H, aryl), 7.03 (td, J = 7.5, 1.5 Hz, 1H, aryl), 6.66 (td, J = 7.4, 1.5 Hz, 1H, aryl), 5.98 (s, 1H, pyrazolyl H4), 5.70 (d, J = 7.6 Hz, 1H, phenyl H6), 3.20 (s, 6H, 2″- and 6″-Me), 2.76 (s, 3H, pyrazolyl Me), 2.64 (s, 3H, pyrazolyl Me). Elemental anal. calcd. for $C_{18}H_{20}ClN_3Pd$ (%): C 51.45, H 4.8, N 10.0; found: C 51.2, H 4.9, N 9.8.

a-*Chloro*-b-*[($^2H_5$)pyridine*-N″]-dc-*[1-(2′-pyridyl)indol-2-yl*-N′,C*]palladium (35)

This compound was prepared from the μ-chloro dimer **10** (0.281 g, 0.42 mmol) and ($^2H_5$)pyridine (10 drops) in dichloromethane (5 mL). The crude product was dissolved in dichloromethane and the resulting solution was filtered and diluted with ether. On addition of hexane, the title compound **35** separated as small yellow prisms (0.232 g, 66%); mp 236–238 °C (dec.). IR (cm^{-1}): 2290 ν(C–D), 1612, 1598, 1563, 1510, 1496, 1448, 1322, 1318, 1290, 1258, 1189, 1147, 1085, 777, 756, 742, 740, 728, 616, 538, 530, 304, 240 ν(Pd–Cl). ^1H NMR (300 MHz, $CDCl_3$) δ: 9.25 (dd, J = 5.7, 1.7 Hz, 1H, pyridyl H6), 7.86 (ddd, J = 8.5, 7.3, 1.7 Hz, 1H, aryl), 7.69–7.65 (m, 2H, aryl), 7.37–7.34 (m, 1H, aryl), 7.16 (td, J = 7.3, 1.6 Hz, 1H, aryl), 7.12 (td, J = 7.2, 1.2 Hz, 1H, aryl), 6.95 (ddd, J = 7.2, 5.7, 1.1 Hz, 1H, pyridyl H5), 5.61 (d, J = 0.7 Hz, 1H, indolyl H3). Elemental anal. calcd. for $C_{18}H_9(^2H_5)ClN_3Pd$ (%): C 51.6, H 3.5, N 10.0; found: C 51.2, H 3.2, N 9.7.

a-*Chloro*-dc-*[1-(2′-pyridyl)indol-2-yl*-N′,C*]-b-*(trimethyl phosphite)palladium (36)

This compound was prepared from **10** (0.209 g, 0.31 mmol) and trimethyl phosphite (0.087 g, 0.70 mmol) in dichloromethane (8 mL). Recrystallization of the crude product from cyclohexane gave the title compound **36** as lustrous yellow plates (0.222 g, 78%); mp 168 to 169 °C. IR (cm^{-1}): 1607, 1596, 1506, 1323, 1293, 1261, 1181, 1166, 1151, 1071, 1065, 1004, 826, 808, 768, 763, 746, 740, 730, 613, 546, 537, 274, 236 ν(Pd–Cl). ^1H NMR (300 MHz, $CDCl_3$) δ: 9.28 (dddd, J = 5.8, 1.7, 0.7 Hz, $J_{P,H}$ = 5.1 Hz, 1H, pyridyl H6), 7.94 (ddd, J = 8.6, 7.1, 1.8 Hz, 1H, aryl), 7.85 (dt, J = 7.5, 1.0 Hz, 1H, pyridyl H3), 7.76–7.73 (m, 1H, aryl), 7.53–7.50 (m, 1H, aryl), 7.23–7.14 (m, 2H, aryl), 7.08 (dddd, J = 7.1, 5.8, 1.3 Hz, $J_{P,H}$ = 2.0 Hz, 1H, pyridyl H5), 6.68 (d, $J_{P,H}$ = 2.3 Hz, 1H, indolyl H3), 3.93 (d, $J_{P,H}$ = 13.1 Hz, 9H, $P(OMe)_3$). Mass spectrum *m/z* (%): 460 (M^+, 7.5), 423 ($C_{16}H_{18}N_2O_3PPd^+$, 0.5), 408 ($C_{15}H_{15}N_2O_3PPd^+$, 0.4), 364 ($C_{14}H_{14}N_2O_3Pd^+$, 0.5), 336 ($C_{13}H_9ClN_2Pd^+$, 3.4), 317 ($C_{13}H_{11}N_2OPd^+$, 57), 299 ($C_{13}H_9N_2Pd^+$, 3). Elemental anal. calcd. for $C_{16}H_{18}ClN_2O_3PPd$ (%): C 41.85, H 3.95, N 6.1; found: C 41.9, H 4.0, N 6.3.

Synthesis of *N*-substituted isoindolinones via a palladium catalysed three-component carbonylation – amination – Michael addition cascade[1]

Ronald Grigg, Xinjie Gai, Tossapol Khamnaen, Shuleewan Rajviroongit, Visuvanathar Sridharan, Lixin Zhang, Simon Collard, and Ann Keep

Abstract: We herein describe a novel palladium catalysed three-component cascade process involving carbonylation of an aryl iodide to generate an acyl palladium(II) species that is intercepted by a primary aliphatic or aromatic amine, amide, or sulfonamide followed by intramolecular Michael addition to furnish *N*-substituted isoindolinones in good yield. Overall, the cascade results in the formation of one C—C and two C—N bonds, one ring and one stereocentre.

Key words: isoindolinone, palladium, cascade, amidation, sulfonamidation.

Résumé : On décrit un nouveau processus en cascade, à trois composants et catalysé par le palladium qui permet de procéder à la carbonylation d'un iodure d'aryle pour générer une espèce palladium(II) acyle qui peut être interceptée par une amine, un amide ou un sulfonamide primaire, aliphatique ou aromatique, suivie d'une addition intramoléculaire de Michael qui permet d'obtenir des isoindolinones *N*-substituées avec de bons rendements. La cascade globale conduit à la formation d'une liaison C—C et de deux liaisons C—N, d'un cycle et d'un stéréocentre.

Mots clés : isoindolinone, palladium, cascade, amidation, sulfonamidation.

Introduction

Nitrogen heterocycles containing isoindolinone skeletons have attracted much interest in recent years owing to their biological activity. *N*-Substituted isoindolinones of general structure **1** (Fig. 1) possess anxiolytic activity and are of interest as sedatives, hypnotics, and muscle relaxants (1). Typical examples are the anxiolytics pazinaclone (**2**), pagoclone (**3**) (Aventis/Pfizer, phase III clinical trials) (2), and the anxiolytic and anticonvulsant zopiclone (**4**) (3, 4). The isoindolinone moiety also features in anti-cancer drug candidates including protein kinase inhibitors.

Current syntheses of isoindolinones are often unsatisfactory because of severe reaction conditions (5–7), substituent restrictions (8–10), multi-step protocols, or even product purification difficulties (11–13). We earlier described a simple one-step process for the synthesis of *N*-substituted isoindolones (14) from *o*-phthalaldehyde that did not access 1(3)-substituted derivatives. Naming and numbering of isoindolones using ACD/I-Lab version 8.0 software results in interchange of the 1- and 3-positions depending upon the 1(3)-substituent. This simple protocol was subsequently extended by others (15, 16) for accessing more complex polysubstituted isoindolinones (17–22). Additionally, we have described a range of catalytic processes that exploit the versatility of carbon monoxide and allene as powerful relay switches in palladium catalysed cyclisation – anion capture cascades (23). Our ongoing interest in designing palladium catalysed atmospheric pressure carbonylation processes in a tactical combination with core reactions led us to explore combinations with Michael addition processes as a novel approach to isoindolinone derivatives (Scheme 1) (24). native catalytic approaches to isoindolinones involving inter- or intramolecular carbopalladation of imines have been reported by Cho et al. in a series of papers (25–30).

Results and discussion

Recently, we reported palladium catalysed three-component cascade allenylation – amination – Michael addition furnishing 4-methylene-tetrahydroisoquinolines and 4-methylene-tetrahydronaphthalenes (31), which utilized **5** as key substrates. We therefore initially selected **8a**–**8d** (Fig. 2) as the prototypical dual aryl iodide – Michael acceptors, but using carbon monoxide, instead of allene, to evaluate the novel Scheme 1 three-component cascade. Subsequently, the in-

vestigation was extended to the particular biologically important heterocyclic amides **8e**–**8j** (Fig. 2) as the electron-withdrawing group in the Michael acceptor. Compounds of type **8a**–**8j** could react with carbon monoxide (1 atm, 1 atm = 101.325 kPa) and a primary amine in the presence of palladium(0) to afford *N*-substituted isoindolinones via either path **a** or path **b** (Scheme 1). In path **a**, carbon monoxide insertion is followed by amination to give the amide **6**, which subsequently undergoes intramolecular Michael addition to afford *N*-substituted isoindolinones **7**. In path **b**, the order of events, beginning with an intermolecular Michael addition, is reversed.

Arylamine nucleophiles

Compounds **8a** and **8b** reacted with carbon monoxide, a primary aromatic or heteroaromatic amine, $Pd(OAc)_2$ (10 mol%) and PPh_3 (20 mol%) and Cs_2CO_3 in toluene at 90 °C over 24 h to afford isoindolinones **9**–**12** in good yield (Table 1, entries 1–4). The reactivity of aniline nucleophiles (Table 1, entries 1–3) with different para substituents showed that the more nucleophilic *p*-anisidine (Table 1, entry 2) afforded **10a** in 90% yield, whereas *p*-(trifluoromethyl)aniline (Table 1, entry 3), a weaker nucleophile, gave **11a** in 68% yield under the same reaction conditions. However, 2-aminothiazole required 48 h under the same reaction conditions for complete conversion to **12a** (73%) (Table 1, entry 4). In the cases of the use of 2- and 4-aminopyridines (Table 1, entries 5 and 6), a catalyst system comprising Pd_2dba_3 (2.5 mol%) and tris(2-furyl)phosphine (10 mol%) was utilized to provide the corresponding isoindolinones **13** and **14** in excellent yield, whilst bicyclic heteroaromatic amines in the presence of a modified catalyst system consisting of $Pd(PPh_3)_2Cl_2$ (2 mol%) and TFP (12 mol%) afforded isoindolinone **15e** (86%) (Table 1, entry 7). The pK_as of the nucleophiles (Table 1) fall into two groups. Those (Table 1, entries 1–3) involving protonation at the NH_2 group and those (Table 1, entries 4–8) involving protonation on sp^2 N centres in the heterocyclic rings. It is likely that in all cases, except perhaps entry 3, that the reactive nucleophiles are not the neutral species (vide infra).

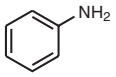
Note that for all isoindolones where the electron-withdrawing group (EWG) is CN or CO_2Me naming and (or) numbering is as shown by **9a** and **9b** (Table 1). When EWG is a ketone, amide, or 2-pyridyl, the numbering is as shown by **13e** (Table 1).

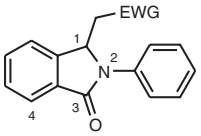
Aliphatic amine nucleophiles

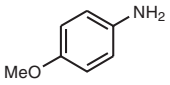
The cascade successfully incorporated primary aliphatic amines furnishing **16**–**21** (Table 2, entries 1–6). We briefly studied the diastereoselectivity of the Michael addition reaction with (*R*)-(+)-α-methylbenzylamine (Table 2, entries 7 and 8), which afforded a 1:1.75 and a 2:3 diastereomeric mixture of **22a** and **22b**, respectively. *S*-Alanine methyl ester similarly afforded **23a** as an 1:1 diastereomer mixture. In a case of **23a**, 2 mol equiv. of amine and increasing the reaction time to 48 h were required for complete conversion, probably owing to competitive self-condensation of the amino acid ester (diketopiperazine formation). Thus, under our standard conditions there is little inherent diastereoselectivity.

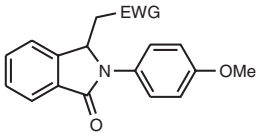
Unexpectedly, Michael acceptor **8**, where EWG = NO_2, failed to furnish the cascade product with benzylamine using the same catalyst system possibly owing to its instability under the reaction conditions.

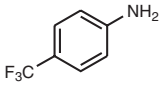
Amide and sulfonamide nucleophiles

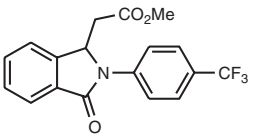


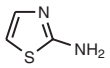


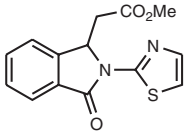


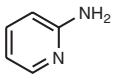


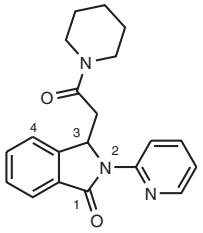


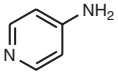


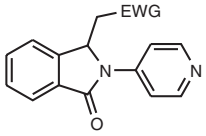


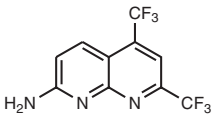


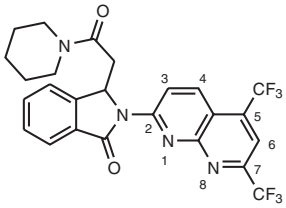












Amides and sulfonamides were also successfully used as nucleophiles in the above cascades (Table 3). When trifluoroacetamide was utilized as a nucleophile, hydrolysis occurred furnishing NH amide **25e** in good yield (Table 3, entry 2). This opens up a significant number of further synthetic opportunities.

2-Vinylpyridine as a Michael acceptor

It is well-known that 2-vinylpyridines can function as Michael acceptors (32) and this prompted the evaluation of **8k**

[b]Isolated yield.

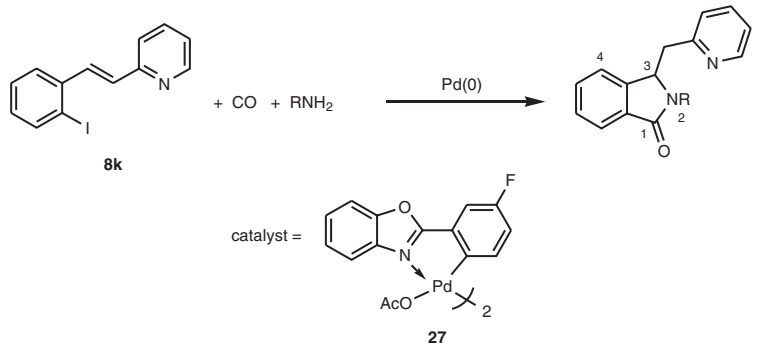
in our three-component cascade using alkyl-, aryl-, and heteroarylamines (Table 4). For these cascades, we used our cyclopalladated catalyst **27** (5 mol%), which is known to form Pd nanoparticles rapidly in the presence of carbon monoxide (33*a*). The corresponding isoinolinones **28–33** were obtained in good yield in all cases.

Mechanism

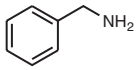
We have only very briefly probed the mechanism of the reaction. A control experiment in which carbon monoxide was omitted as the reagent and benzylamine used as the nucleophile was carried out, but no Michael adduct resulting from the reaction of **8a** with benzylamine was detected under the standard reaction conditions. Intermediates were detected in a study of a related reaction by our group (33*b*). It is inherently unlikely that with such a disparate collection of *N*-nucleophiles that the mechanism is identical in every case. Rather, one would expect that the reactive nucleophiles in the case of the aryl and heteroarylamines and the amides and sulfonamides are the *N*-deprotonated species, whilst in the case of the aliphatic amines the neutral species are involved. Our control experiment is supportive of path **a** rather than path **b** (Scheme 1), but clearly a more detailed study is indicated before drawing any firm conclusions.

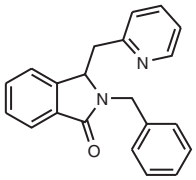
Summary

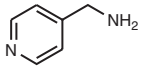
N-Substituted isoindolinones have been successfully synthesized via a novel palladium catalysed three-component carbonylation – amination – intramolecular Michael addition cascade process. The reaction tolerates a wide variety of *N*-nucleophiles and delivers a diverse range of isoindolinones. Overall, the cascade results in the formation of one C—C and two C—N bonds, one ring and one stereocentre.

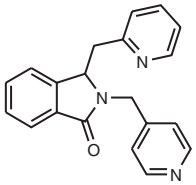


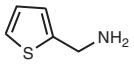
Experimental

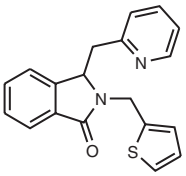


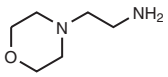


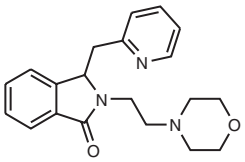


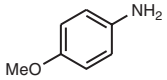


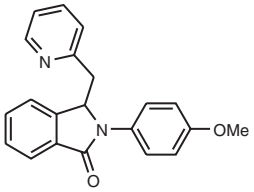


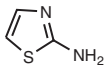


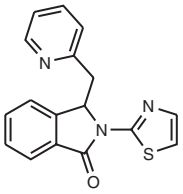












Melting points were determined on a Reichert hot-stage apparatus and are uncorrected. IR spectra were recorded on a Nicolet Magna FT-IR 560 spectrometer (to prepare samples for IR, a small amount of sample was dissolved in dichloromethane, transferred onto a germanium plate, and left to evaporate to provide a film). NMR spectra were recorded at 250 MHz on a Bruker AC 250 spectrometer, at 300 MHz on a Bruker DPX 300 spectrometer, and at 500 MHz on a Bruker DRX 500 spectrometer. Unless otherwise specified, deuteriochloroform was used as the solvent with tetramethylsilane (TMS) as the internal standard. Chemical shifts are given in parts per million (ppm, δ) downfield from TMS and the coupling constants are given in Hertz (Hz). The splitting patterns are designed as singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), and double doublet (dd). The mass spectral mode of ionization is EI unless otherwise stated. EI and FAB were obtained using a VG-Autospec operating at 70 eV. ES were obtained on a LCT Micromass (TOF). Accurate molecular weights were determined using perfluorotributylamine or polyethylenimine as an internal standard at Leeds University or from the EPSRC Swansea Mass Spectroscopy Service. Microanalyses were obtained using a Carlo Erba MOD 11016 elemental analyser. Flash column chromatography was performed using silica gel 60 (Merck 9385, 230–400 mesh).

Commercially available reagents and solvents were used without further purification. The term ether refers to diethyl

ether and petroleum ether refers to the fraction with a boiling point of 40–60 °C.

General procedure A

Michael acceptor **8** (1 mmol), *N*-nucleophile (1.2 mmol), $Pd(OAc)_2$ (0.022 g, 0.1 mmol), PPh_3 (0.052, 0.2 mmol), and Cs_2CO_3 (0.650 g, 2 mmol) were mixed in dry toluene (10 mL). Carbon monoxide was then introduced through a balloon and the mixture heated with stirring at 90 °C for 24 h, cooled to room temperature, filtered to remove inorganic materials, and concentrated in vacuo. The crude product was purified by flash column chromatography.

General procedure B

Michael acceptor **8** (0.5 mmol), *N*-nucleophile (0.6 mmol), $Pd(OAc)_2$ (0.011 g, 0.05 mmol), PPh_3 (0.026, 0.1 mmol), and Cs_2CO_3 (0.325 g, 1 mmol) were mixed in dry toluene (6 mL). Carbon monoxide was then introduced through a balloon and the mixture heated with stirring at 95 °C for 48 h. Work-up was as for general procedure A.

General procedure C

As for general procedure A, but with Pd_2dba_3 (0.024 g, 0.025 mmol) and TFP (0.025 g, 0.1 mmol) as the catalyst precursors and heating at 90 °C for 18 h.

General procedure D

As for general procedure A, but with $Pd(PPh)_3Cl_2$ (0.014 g, 0.02 mmol) and TFP (0.029 g, 0.12 mmol) as the catalyst precursors, dry dioxane as the solvent, and heating under reflux for 18 h.

General procedure E

As for general procedure A, but with precatalyst **27** (0.02 g, 0.025 mmol).

Methyl (3-oxo-2-phenyl-2,3-dihydro-1*H*-isoindol-1-yl)acetate (9a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and aniline (0.111 g, 1.2 mmol). Column chromatography of the crude product eluting with 3:7 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.208 g, 75%) as colourless needles, mp 121 to 122 °C. IR (cm^{-1}): 2951, 1736, 1697, 1649, 1597, 1498, 1456, 1379. ^1H NMR ($CDCl_3$, 250 MHz) δ: 2.50 (dd, 1H, *J* = 16.3, 8.5 Hz, C*H*HCO), 2.95 (dd, 1H, *J* = 16.3, 4.5 Hz, CH*H*CO), 3.64 (s, 3H, OMe), 5.60 (dd, 1H, *J* = 8.5, 4.5 Hz, NCH), 7.26 (m, 1H, ArH), 7.60–7.43 (m, 7H, ArH), 7.90 (d, 1H, *J* = 7.5 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 37.8, 52.4, 57.9, 123.0, 124.2, 124.6, 126.3, 129.3, 129.7, 132.2, 132.8, 136.8, 144.6, 167.2, 171.2. ES-MS *m*/*z* (%): 304 ([MNa^+], 100). Anal. calcd. for $C_{17}H_{15}NO_3$: C 72.60, H 5.40, N 5.00; found: C 72.55, H 5.40, N 4.85.

3-Oxo-2-phenyl-2,3-dihydro-1*H*-isoindol-1-yl)acetonitrile (9b)

Prepared according to general procedure B employing **8b** (0.255 g, 1 mmol) and aniline (0.111 g, 1.2 mmol), catalyst **27** (0.040 g, 0.05 mmol), and cesium carbonate (0.65 g, 2 mmol) in dry toluene (12 mL). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.16 g, 65%) as colourless needles, mp 183 to 184 °C. IR (cm^{-1}): 1683, 1496, 1391, 1214. ^1H NMR ($CDCl_3$, 250 MHz) δ: 2.69 (dd, 1H, *J* = 16.8, 7.2 Hz, C*H*HCN), 3.02 (dd, 1H, *J* = 16.8, 3.3 Hz, CH*H*CN), 5.35 (dd, 1H, *J* = 6.9, 3.3 Hz, NCH), 7.2–7.35 (m, 1H, ArH), 7.45–7.75 (m, 6H, ArH), 7.98 (dd, 1H, *J* = 7.2, 1.0 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 22.3, 55.9, 115.4, 115.8, 122.8, 124.4, 125.1, 127.1, 130.1, 130.3, 132.4, 133.3, 136.0, 142.1, 167.0. MS *m*/*z* (%): 248 ([M^+], 22), 208 (100), 77 (37). Anal. calcd. for $C_{16}H_{12}N_2O$: C 77.25, H 5.05, N 11.10; found: C 77.40, H 4.85, N 11.25.

Methyl [2-(4-methoxyphenyl)-3-oxo-2,3-dihydro-1*H*-isoindol-1-yl]acetate (10a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and *p*-anisidine (0.147 g, 1.2 mmol). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.279 g, 90%) as colourless needles, mp 97–99 °C. IR (cm^{-1}): 2952, 1735, 1694, 1613, 1512, 1467, 1438, 1386. ^1H NMR ($CDCl_3$, 250 MHz) δ: 2.50 (dd, 1H, *J* = 16.0, 8.5 Hz, C*H*HCO), 2.90 (dd, 1H, *J* = 16.0, 4.5 Hz, CH*H*CO), 3.62 (s, 3H, OMe), 3.83 (s, 3H, OMe), 5.50 (dd, 1H, *J* = 8.5, 4.5 Hz, NCH), 6.98 (d, 2H, *J* = 6.8 Hz, ArH), 7.43 (d, 2H, *J* = 6.8 Hz, ArH), 7.52–7.60 (m, 3H, ArH), 7.92 (d, 1H, *J* = 7.5 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 38.1, 52.4, 55.9, 58.5, 115.0, 122.9, 124.6, 126.5, 129.3, 129.5, 132.3, 132.6, 144.6, 158.3, 167.3, 171.3. ES-MS *m*/*z* (%): 334 ([MNa^+], 100). Anal. calcd. for $C_{18}H_{17}NO_3$: C 69.45, H 5.55, N 4.50; found: C 69.55, H 5.80, N 4.35.

[2-(Methoxyphenyl)-3-oxo-2,3-dihydro-1*H*-isoindol-1-yl)acetonitrile (10b)

Prepared according to general procedure B employing **8b** (0.13 g, 0.5 mmol) and *p*-anisidine (0.074 g, 0.6 mmol). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.11 g, 79%) as colourless needles, mp 197–199 °C. IR (cm^{-1}): 1695, 1513, 1387, 1248. ^1H NMR ($CDCl_3$, 250 MHz) δ: 2.67 (dd, 1H, *J* = 16.8, 7.2 Hz, C*H*HCN), 3.0 (dd, 1H, *J* = 16.8, 3.4 Hz, CH*H*CN), 3.84 (s, 3H, OMe), 5.25 (dd, 1H, *J* = 7.2, 3.3 Hz, NCH), 7.0, 7.39 (2 × d, 2 × 2H, *J* = 9.0 Hz, ArH), 7.3–7.5 (m, 3H, ArH), 7.97 (dd, 1H, *J* = 7.1, 1.3 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 22.4, 55.9, 57.6, 115.4, 115.9, 122.8, 125.0, 126.6, 128.6, 130.2, 132.4, 133.1, 142.2, 158.8, 167.0. ES-MS *m*/*z* (%): 301 ([MNa^+], 100). Anal. calcd. for $C_{17}H_{14}N_2O_2$: C 73.30, H 5.00, N 10.05; found: C 73.10, H 5.10, N 10.15.

Methyl {3-oxo-2-[4-(trifluoromethyl)phenyl]-2,3-dihydro-1*H*-isoindol-1-yl}acetate (11a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and *p*-(trifluoromethyl)aniline (0.193 g, 1.2 mmol). Column chromatography of the crude product eluting with 3:7 *v*/*v* ethyl acetate – pentane afforded the product (0.237 g, 68%) as colourless needles, mp 156–158 °C. IR (cm^{-1}): 2955, 1736, 1705, 1612, 1520, 1469, 1438, 1375. ^1H NMR ($CDCl_3$, 250 MHz) δ: 2.50 (dd, 1H, *J* = 16.3, 8.8 Hz, C*H*HCO), 2.98 (dd, 1H, *J* = 16.3, 3.8 Hz, CH*H*CO), 3.67 (s, 3H, OMe), 5.67 (dd, 1H, *J* = 8.8, 3.8 Hz, NCH), 7.52–7.80 (m, 7H, ArH), 7.93 (dd, 1H, *J* = 8.3,

7.5 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 38.1, 52.6, 57.4, 123.0, 123.1, 124.9, 126.7, 126.8, 126.9, 129.6, 129.7, 131.7, 133.3, 140.1, 144.4, 167.4, 171.0. FAB-MS *m/z* (%): 350 ([MH$^+$], 100). Anal. calcd. for $C_{18}H_{14}F_3NO_3$: C 61.85, H 4.05, N 4.00; found: C 61.65, H 4.00, N 4.05.

Methyl [3-oxo-2-(1,3-thiazol-2-yl)-2,3-dihydro-1*H*-isoindol-1-yl]acetate (12a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and 2-aminothiazole (0.120 g, 1.2 mmol). Column chromatography of the crude product eluting with 2:3 *v/v* ethyl acetate – pentane afforded the product (209 mg, 73%) as pale yellow needles, mp 150 to 151 °C. IR (cm^{-1}): 2951, 1733, 1706, 1616, 1595, 1505, 1466, 1437, 1411, 1369. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.85 (dd, 1H, *J* = 16.3, 8.8 Hz, C*H*HCO), 3.69 (s, 3H, OMe), 3.78 (dd, 1H, *J* = 16.3, 3.5 Hz, CH*H*CO), 5.78 (dd, 1H, *J* = 8.8, 3.5 Hz, NCH), 7.06 (d, 1H, *J* = 3.5 Hz, thiazolyl 5-H), 7.54 (d, 1H, *J* = 3.5 Hz, thiazolyl 4-H), 7.63–7.66 (m, 3H, ArH), 7.95 (dd, 1H, *J* = 7.5, 1.0 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 37.4, 52.4, 58.6, 114.2, 123.5, 124.9, 129.6, 130.4, 134.0, 138.3, 144.5, 157.4, 166.5, 171.1. ES-MS *m/z* (%): 311 ([MNa$^+$], 100). Anal. calcd. for $C_{14}H_{12}N_2O_3S$: C 58.30, H 4.20, N 9.70, S 11.10; found: C 58.35, H 4.35, N 9.80, S 10.95.

3-(2-Oxo-2-piperidin-1-ylethyl)-2-pyridin-2-ylisoindolin-1-one (13e)

Prepared according to general procedure D employing **8e** (0.341 g, 1.0 mmol) and 2-aminopyridine (0.113 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v/v* ethyl acetate – hexane afforded the product (0.288 g, 86%) as a pale yellow gum. IR (cm^{-1}): 2250, 1693, 1468, 1403, 1210, 1107, 1030, 960. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.42–1.61 (m, 6H, $CH_2CH_2CH_2CH_2CH_2$), 2.38 (dd, 1H, *J* = 15.2, 9.9 Hz, C*H*HCO), 3.34 (m, 2H, NCH_2), 3.55 (dd, 1H, *J* = 15.2, 3.0 Hz, CH*H*CO), 3.64 (m, 2H, NCH_2), 6.14 (dd, 1H, *J* = 9.9, 3.0 Hz, NCH), 7.07 (m, 1H, ArH), 7.50 (t, 1H, *J* = 7.3 Hz, ArH), 7.59 (t, 1H, *J* = 7.4 Hz, ArH), 7.77 (m, 2H, pyridyl H), 7.92 (d, 1H, *J* = 7.3 Hz, Ar 7-H), 8.43 (dd, 1H, *J* = 4.1, 0.8 Hz, pyridyl 4-H), 8.60 (d, 1H, *J* = 8.4 Hz, pyridyl 6-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 24.9, 26.0, 26.9, 37.9, 43.3, 47.0, 57.7, 115.9, 119.8, 124.4, 128.9, 131.9, 133.3, 138.3, 146.4, 148.2, 151.4, 168.2, 168.7. MS *m/z* (%): 336 ([MH$^+$], 100), 251 (68), 223 (20), 209 (71). Anal. calcd. for $C_{20}H_{21}N_3O_2$: C 71.60, H 6.30, N 12.50; found: C 71.80, H 6.30, N 12.45.

3-(2-Oxo-2-piperidin-1-ylethyl)-2-pyridin-4-ylisoindolin-1-one (14e)

Prepared according to general procedure D employing **8e** (0.341 g, 1.0 mmol) and 4-aminopyridine (0.113 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v/v* ethyl acetate – hexane afforded the product (0.308 g, 92%) as a colourless viscous oil. IR (cm^{-1}): 1701, 1656, 1504, 1454, 1380, 1210. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.42 (m, 2H, $CH_2CH_2CH_2CH_2CH_2$), 1.61 (m, 4H, $CH_2CH_2CH_2CH_2CH_2$), 2.49 (dd, 1H, *J* = 16.2, 9.7 Hz, C*H*HCO), 3.01 (dd, 1H, *J* = 16.2, 2.8 Hz, CH*H*CO), 3.14–3.28 (m, 2H, NCH_2), 3.58–3.75 (m, 2H, NCH_2), 5.96 (dd, 1H, *J* = 9.7, 2.7 Hz, NCH), 7.54 (dt, 1H, *J* = 7.2, 1.4 Hz, ArH), 7.60–7.69 (m, 2H, ArH), 7.77 (d, 2H, *J* = 4.8 Hz, pyridyl 3- and 5-H), 7.94 (dd, 1H, *J* = 7.5, 1.0 Hz, Ar 7-H), 8.64 (d, 2H, *J* = 4.8 Hz, pyridyl 2- and 6-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 24.7, 26.0, 26.8, 36.8, 43.5, 47.0, 57.1, 115.2, 123.9, 124.8, 129.4, 131.2, 133.7, 144.6, 145.9, 151.3, 167.7, 168.0. ES-MS *m/z* (%): 358 ([MNa$^+$], 100). Anal. calcd. for $C_{20}H_{21}N_3O_2$: C 71.6, H 6.3, N 12.5; found: C 71.3, H 6.35, N 12.75.

3-[2-(1,4-Dioxa-8-azaspiro[4,5]dec-8-yl)-2-oxoethyl]-2-pyridin-4-ylisoindolin-1-one (14f)

Prepared according to general procedure D employing **8f** (0.399 g, 1 mmol) and 4-aminopyridine (0.113 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v/v* ethyl acetate – hexane afforded the product (0.390 g, 99%) as a pale yellow gum. IR (cm^{-1}): 1701, 1656, 1504, 1454, 1380. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.55 (m, 2H, NCH_2CH_2), 1.73 (m, 2H, NCH_2CH_2), 2.50 (dd, 1H, *J* = 16.2, 9.8 Hz, C*H*HCO), 3.05 (dd, 1H, *J* = 16.2, 2.6 Hz, CH*H*CO), 3.27–3.40 (m, 2H, NCH_2CH_2), 3.69–3.77 (m, 2H, NCH_2CH_2), 3.94–4.01 (m, 4H, OCH_2CH_2O), 5.94 (dd, 1H, *J* = 9.8, 2.6 Hz, NCH), 7.52–7.60 (m, 1H, ArH), 7.62–7.66 (m, 2H, ArH), 7.76 (d, 2H, *J* = 6.2 Hz, pyridyl 3- and 5-H), 7.94 (d, 1H, *J* = 7.5 Hz, Ar 7-H), 8.65 (d, 2H, *J* = 6.2 Hz, pyridyl 2- and 6-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 32.2, 35.9, 36.8, 40.6, 43.9, 57.0, 64.9, 106.9, 115.2, 123.8, 124.8, 129.5, 131.2, 133.8, 144.5, 145.8, 151.4, 167.9, 168.0. MS *m/z* (%): 394 ([MNa$^+$], 100), 225 (23), 211 (32), 186 (44), 144 (82), 95 (69), 80 (51). Anal. calcd. for $C_{22}H_{23}N_3O_4$: C 67.20, H 5.90, N 10.70; found: C 67.00, H 5.90, N 10.80.

3-(2-Azepan-1-yl-2-oxoethyl)-2-pyridin-4-ylisoindolin-1-one (14g)

Prepared according to general procedure D employing **8g** (0.355 g, 1 mmol) and 4-aminopyridine (0.113 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v/v* ethyl acetate – hexane afforded the product (0.310 g, 89%) as a pale yellow gum. IR (cm^{-1}): 1701, 1656, 1504, 1454, 1380. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.21–1.50 (m, 6H, azepyl H), 1.71–1.83 (m, 2H, azepyl H), 2.47 (dd, 1H, *J* = 16.1, 9.6 Hz, C*H*HCO), 3.05 (dd, 1H, *J* = 16.1, 3.0 Hz, CH*H*CO), 3.14–3.32 (m, 2H, NCH_2), 3.50–3.58 and 3.67–3.76 (2 × m, 2 × 1H, NCH_2), 5.97 (dd, 1H, *J* = 9.6, 3.0 Hz, NCH), 7.51–7.67 (m, 3H, ArH), 7.78 (d, 2H, *J* = 4.8 Hz, pyridyl 3- and 5-H), 7.95 (d, 1H, *J* = 7.5 Hz, Ar 7-H), 8.64 (d, *J* = 4.8 Hz, pyridyl 2- and 6-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 27.2, 27.3, 27.9, 29.2, 37.2, 46.7, 48.2, 57.2, 115.2, 123.8, 124.8, 129.4, 131.2, 133.7, 144.6, 146.0, 151.3, 168.0, 169.2. MS *m/z* (%): 50 ([MH$^+$], 100), 273 (11), 159 (18), 142 (67), 120 (22), 95 (100), 80 (73). Anal. calcd. for $C_{21}H_{23}N_3O_2$: C 72.20, H 6.80, N 12.10; found: C 72.20, H 6.60, N 12.00.

3-[2-Oxo-2-(4-pyrimidin-2-ylpiperazin-1-yl)ethyl]-2-pyridin-4-ylisoindolin-1-one (14i)

Prepared according to general procedure D employing **8i** (0.420 g, 1 mmol) and 4-aminopyridine (0.113 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v/v* ethyl acetate – hexane afforded the product (0.363 g, 88%) as a pale brown gum. IR (cm^{-1}): 1701, 1656, 1504, 1454, 1380, 1210. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 2.55 (dd,

1H, *J* = 16.2, 9.0 Hz, C*H*HCO), 3.09 (dd, 1H, *J* = 16.2, 2.8 Hz, CH*H*CO), 3.70–3.93 (m, 6H, piperazyl H), 5.98 (dd, 1H, *J* = 9.0, 2.8 Hz, NCH), 6.56 (m, 2H, piperazyl H), 7.28–7.69 (m, 3H, ArH), 7.77 (d, 2H, *J* = 6.0 Hz, pyridyl 3- and 5-H), 7.96 (d, 1H, *J* = 7.4 Hz, Ar 7-H), 8.33 (m, 3H, pyrimidyl H), 8.65 (d, 2H, *J* = 6.0 Hz, pyridyl 2- and 6-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 37.0, 42.2, 43.8, 43.9, 45.6, 57.0, 111.1, 115.2, 123.8, 124.9, 129.5, 131.2, 133.8, 144.5, 145.7, 151.4, 161.7, 161.8, 167.9, 168.4. MS *m*/*z* (%): 415 ([MH$^+$], 98), 207 (50), 165 (100), 134 (18), 95 (78), 80 (51). Anal. calcd. for $C_{23}H_{22}N_6O_2$: C 66.65, H 5.35, N 20.30; found: C 66.70, H 5.45, N 20.60.

3-[2-Oxo-(2-aminopyrimidin-2-yl)ethyl]-2-pyridin-4-ylisoindolin-1-one (14j)

Prepared according to general procedure D employing **8j** (0.351 g, 1 mmol) and 4-aminopyridine (0.113 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v*/*v* ethyl acetate – hexane afforded the product (0.199 g, 58%) as a pale yellow gum. IR (cm^{-1}): 1699, 1651, 1500, 1455, 1379. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 2.46 (dd, 1H, *J* = 15.6, 9.5 Hz, C*H*HCO), 3.29 (dd, 1H, *J* = 15.6, 3.1 Hz, CH*H*CO), 5.87 (dd, 1H, *J* = 9.5, 3.1 Hz, NCH), 7.08 (d, 2H, *J* = 6.3 Hz, pyridyl 3- and 6-H), 7.52–7.64 (m, 3H, ArH), 7.75 (m, 3H, pyrimidyl H), 8.17 (d, 1H, *J* = 8.4 Hz, Ar 7-H), 8.45 (bs, 1H, NH), 8.63 (d, 2H, *J* = 6.3 Hz, pyridyl 2- and 6-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 0.9, 56.5, 114.6, 115.3, 120.8, 123.3, 125.1, 129.7, 132.2, 133.9, 139.1, 144.3, 145.0, 148.3, 151.1, 151.4, 167.6, 168.6. MS *m*/*z* (%): 345 ([MH$^+$], 6), 207 (22), 165 (17), 144 (23), 137 (48), 94 (78), 80 (38). Anal. calcd. for $C_{20}H_{16}N_4O_2$: C 69.80, H 4.70, N 16.30; found: C 69.50, H 4.75, N 16.10.

2-[5,7-Bis(trifluoromethyl)-1,8-naphthyridin-2-yl]-3-(2-oxo-2-piperidin-1-ylethyl)isoindolin-1-one (15e)

Prepared according to general procedure D employing **8e** (0.341 g, 1.0 mmol) and 7-amino-2,4-bis(trifluromethyl)-1,8-napthyridine (0.232 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v*/*v* ethyl acetate – hexane afforded the product (0.449 g, 86%) as a colourless, viscous oil. IR (cm^{-1}): 1710, 1650, 1505, 1445, 1382. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.49–1.69 (m, 6H, piperidyl H), 2.67 (dd, 1H, *J* = 14.5, 9.3 Hz, C*H*HCO), 3.57–3.71 (m, 4H, piperidyl H), 3.82 (dd, 1H, *J* = 14.5, 3.2 Hz, CH*H*CO), 6.15 (dd, 1H, *J* = 9.3, 3.2 Hz, NCH), 7.55 (t, 1H, *J* = 7.4 Hz, ArH), 7.68 (m, 1H, ArH), 7.74 (d, 1H, *J* = 7.6 Hz, ArH), 7.97 (d, 1H, *J* = 7.6 Hz, Ar 7-H), 8.00 (s, 1H, napthyridyl 6-H), 8.60 (d, 1H, *J* = 9.4 Hz, napthyridyl 3-H), 9.26 (d, 1H, *J* = 9.4 Hz, napthyridyl 4-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 24.9, 26.1, 26.9, 37.6, 43.4, 47.6, 58.2, 113.7, 119.7, 124.5, 125.0, 129.3, 130.9, 134.4, 135.4, 146.2, 155.3, 168.0, 169.1. ES-MS *m*/*z* (%): 421 ([MH$^+$], 100). Anal. calcd. for $C_{23}H_{21}ClN_4O_2$: C 65.65, H 5.05, Cl 8.40, N 13.30; found: C 65.60, H 5.20, Cl 8.25, N 13.05.

Methyl (2-benzyl-3-oxo-2,3-dihydro-1*H*-isoindol-1-yl)acetate (16a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and benzylamine (0.128 g, 1.2 mmol). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – pentane afforded the product (0.268 g, 91%) as colourless prisms, mp 92–94 °C. IR (cm^{-1}): 2951, 1736, 1690, 1617, 1495, 1469, 1435, 1408, 1360. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.85 (dd, 1H, *J* = 16.3, 7.3 Hz, C*H*HCO), 2.86 (dd, 1H, *J* = 16.3, 5.5 Hz, CH*H*CO), 3.63 (s, 3H, OMe), 4.43 (d, 1H, *J* = 15.5 Hz, NC*H*HPh), 4.83 (dd, 1H, *J* = 7.3, 5.5 Hz, NCH), 5.20 (d, 1H, *J* = 15.5 Hz, NCH*H*Ph), 7.25–7.31 (m, 5H, ArH), 7.40–7.54 (m, 3H, ArH), 7.95 (d, 1H, *J* = 7.5 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 37.8, 44.7, 52.4, 56.5, 122.8, 124.3, 128.0, 128.3, 129.0, 129.2, 132.1, 133.3, 137.4, 145.2, 168.8, 171.1. FAB-MS *m*/*z* (%): 296 ([MH$^+$], 100). Anal. calcd. for $C_{18}H_{17}NO_3$: C 73.20, H 5.80, N 4.75; found: C 73.00, H 5.85, N 4.60.

(2-Benzyl-3-oxo-2,3-dihydro-1*H*-isoindol-1-yl)acetonitrile (16b)

Prepared according to general procedure B employing **8b** (0.13 g, 0.5 mmol) and benzylamine (0.064 g, 0.6 mmol). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.09 g, 69%) as colourless needles, mp 104–106 °C. IR (cm^{-1}): 2248, 1689, 1469, 1405. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.72 (dd, 1H, *J* = 16.9, 6.6 Hz, C*H*HCO), 2.93 (dd, 1H, *J* = 16.9, 4.4 Hz, CH*H*CO), 4.42 (d, 1H, *J* = 15.4 Hz, NC*H*HPh), 4.56 (dd, 1H, *J* = 6.5, 4.4 Hz, NCH), 5.29 (d, 1H, *J* = 15.4 Hz, NCH*H*Ph), 7.29–7.35 (m, 5H, ArH), 7.56–7.61 (m, 3H, ArH), 7.95 (dd, 1H, *J* = 8.0, 1.5 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 22.1, 44.7, 55.3, 116.1, 122.7, 124.8, 128.4, 128.5, 129.5, 129.9, 132.1, 132.8, 136.6, 142.9, 168.6. MS *m*/*z* (%): 262 ([MH$^+$], 100), 222 (51), 91 (100). Anal. calcd. for $C_{17}H_{14}N_2O$: C 77.85, H 5.30, N 10.70; found: C 77.60, H 5.45, N 10.80.

2-Benzyl-3-(2-oxopropyl)isoindolin-1-one (16c)

Prepared according to general procedure B employing **8c** (0.15 g, 0.5 mmol) and benzylamine (0.064 g, 0.6 mmol). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.085 g, 61%) as colourless prisms, mp 87–89 °C. IR (cm^{-1}): 1717, 1687, 1469, 1408, 1362, 1160. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.50 (s, 3H, Me), 2.68 (dd, 1H, *J* = 17.8, 6.3 Hz, C*H*HCO), 2.89 (dd, 1H, *J* = 17.8, 5.9 Hz, CH*H*CO), 4.62, 4.89 (2 × d, 2 × 1H, *J* = 15.4 Hz, NCH_2Ph), 5.03 (dd, 1H, *J* = 6.3, 5.9 Hz, NCH), 7.25–7.30 (m, 5H, ArH), 7.35 (dd, 1H, *J* = 7.3, 0.7 Hz, ArH), 7.50 (m, 2H, ArH), 7.90 (dd, 1H, *J* = 7.5, 1.2 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 30.8, 45.2, 47.1, 55.9, 122.8, 124.3, 127.9, 128.3, 128.9, 129.1, 132.1, 132.3, 137.6, 145.9, 168.9, 206. ES-MS *m*/*z* (%): 280 ([MH$^+$], 100). Anal. calcd. for $C_{18}H_{17}NO_2$: C 77.40, H 6.10, N 5.00; found: C 77.30, H 6.15, N 4.95.

2-Benzyl-3-(2-oxo-2-phenylethyl)isoindolin-1-one (16d)

Prepared according to general procedure B employing **8d** (0.167 g, 0.5 mmol) and benzylamine (0.064 g, 0.6 mmol). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.12 g, 70%) as colourless prisms, mp 97 to 98 °C. IR (cm^{-1}): 1683, 1596, 1448, 1408, 1211, 988. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 3.14 (dd, 1H, *J* = 17.6, 7.2 Hz, C*H*HCO), 3.47 (dd, 1H, *J* = 17.6, 5.3 Hz, CH*H*CO), 4.53, 5.06 (2 × d, 2 × 1H, *J* = 15.3 Hz, NCH_2Ph), 5.24 (dd, 1H, *J* = 7.2, 5.3 Hz,

NCH), 7.15–7.25 (m, 5H, ArH), 7.35–7.50 (m, 6H, ArH), 7.56 (t, 1H, *J* = 7.0 Hz, ArH), 7.79 (dd, 2H, *J* = 8.1, 0.9 Hz, ArH), 7.91 (d, 1H, *J* = 8.5 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 42.5, 45.0, 56.3, 123.3, 124.3, 127.9, 128.4, 128.5, 128.8, 129.1, 132.1, 132.3, 134.0, 136.6, 137.5, 146.3, 168.9, 196.0. ES-MS *m*/*z* (%): 364 ([MNa$^+$], 100). Anal. calcd. for $C_{23}H_{19}NO_2$: C 80.90, H 5.55, N 4.10; found: C 80.70, H 5.60, N 4.10.

Methyl [3-oxo-2-(pyridin-4-ylmethyl)-2,3-dihydro-1*H*-isoindol-1-yl]acetate (17a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and *p*-(aminomethyl)pyridine (0.129 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.275 g, 93%) as pale yellow needles, mp 148 to 149 °C. IR (cm^{-1}): 2952, 1734, 1689, 1601, 1563, 1494, 1469, 1435, 1409, 1364. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.73 (dd, 2H, *J* = 6.3, 4.3 Hz, CH_2CO), 3.61 (s, 3H, OMe), 4.55 (d, 1H, *J* = 16.3 Hz, NC*H*HAr), 4.91 (t, 1H, *J* = 6.3 Hz, NCH), 5.08 (d, 1H, *J* = 16.3 Hz, NCH*H*Ar), 7.18 (d, 2H, *J* = 4.5 Hz, pyridyl 3- and 5-H), 7.28–7.59 (m, 3H, ArH), 7.90 (dd, 1H, *J* = 7.5, 1.0 Hz, Ar 4-H), 8.55 (d, 2H, *J* = 4.5 Hz, pyridyl 2- and 6-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 38.2, 44.1, 52.6, 57.0, 122.8, 122.9, 124.5, 129.3, 131.5, 132.7, 145.0, 146.4, 150.6, 169.1, 171.0. ES-MS *m*/*z* (%): 319 ([MNa$^+$], 100). Anal. calcd. for $C_{17}H_{16}N_2O_3$: C 68.90, H 5.45, N 9.45; found: C 68.75, H 5.40, N 9.45.

[3-Oxo-2-(pyridin-4-ylmethyl)-2,3-dihydro-1*H*-isoindol-1-yl]acetonitrile (17b)

Prepared according to general procedure A employing **8b** (0.255 g, 1 mmol) and 4-aminomethylpyridine (0.13 g, 1.2 mmol) and heating at 95 °C for 48 h. Column chromatography of the crude product eluting with 4:1 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.23 g, 88%) as colourless prisms, mp 147 to 148 °C. IR (cm^{-1}): 2251, 1690, 1602, 1469, 1406. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.80 (dd, 1H, *J* = 16.9, 5.9 Hz, C*H*HCN), 2.92 (dd, 1H, *J* = 16.9, 4.9 Hz, CH*H*CN), 4.52 (d, 1H, *J* = 16.2 Hz, NC*H*HAr), 4.64 (dd, 1H, *J* = 5.4, 4.9 Hz, NCH), 5.23 (d, 1H, *J* = 16.2 Hz, NCH*H*Ar), 7.23 (d, 2H, *J* = 5.0 Hz, pyridyl 3- and 5-H), 7.55–7.68 (m, 3H, ArH), 7.93 (dd, 1H, *J* = 8.2, 1.3 Hz, Ar 4-H), 8.57 (d, 2H, *J* = 5.0 Hz, pyridyl 2- and 6-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 22.4, 43.8, 55.8, 115.9, 122.8, 122.9, 124.9, 130.2, 131.5, 133.2, 142.8, 145.7, 150.8, 168.8. MS *m*/*z* (%): 263 ([M$^+$], 41), 223 (100), 92 (87). Anal. calcd. for $C_{16}H_{13}N_3O$: C 73.00, H 4.90, N 16.00; found: C 72.70, H 5.05, N 16.15.

Methyl [3-oxo-2-(thien-2-ylmethyl)-2,3-dihydro-1*H*-isoindol-1-yl]acetate (18a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and 2-(aminomethyl)thiophene (0.135 g, 1.2 mmol). Column chromatography of the crude product eluting with 3:7 *v*/*v* ethyl acetate – pentane afforded the product (0.261 g, 87%) as pale yellow needles, mp 148 to 149 °C. IR (cm^{-1}): 2950, 1734, 1690, 1617, 1500, 1469, 1436, 1406, 1366. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.69 (dd, 1H, *J* = 16.0, 6.8 Hz, C*H*HCO), 2.92 (dd, 1H, *J* = 16.0, 5.5 Hz, CH*H*CO), 3.66 (s, 3H, OMe), 4.58 (d, 1H, *J* = 16.0 Hz, NC*H*HAr), 4.92 (dd, 1H, *J* = 6.8, 5.5 Hz, NCH), 5.32 (d, 1H, *J* = 16.0 Hz, NCH*H*Ar), 6.91 (dd, 1H, *J* = 5.3, 3.5 Hz, thienyl 4-H), 7.01 (dd, 1H, *J* = 3.5, 1.3 Hz, thienyl 3-H), 7.18 (dd, 1H, *J* = 5.3, 1.3 Hz, thienyl 5-H), 7.41–7.51 (m, 3H, ArH), 7.83 (dd, 1H, *J* = 7.5, 1.0 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 37.7, 39.3, 52.5, 56.2, 122.9, 124.2, 126.0, 127.0, 127.3, 129.0, 131.9, 132.4, 139.9, 145.2, 168.4, 171.1. MS *m*/*z* (%): 301 ([M$^+$], 44), 228 (47), 97 (100). Anal. calcd. for $C_{16}H_{15}NO_3S$: C 63.75, H 5.00, N 4.65, S 10.65; found: C 63.50, H 4.90, N 4.80, S 10.60.

[3-Oxo-2-(thien-2-ylmethyl)-2,3-dihydro-1*H*-isoindol-1-yl]acetonitrile (18b)

Prepared according to general procedure A employing **8b** (0.255 g, 1 mmol) and 2-aminomethylthiophene (0.135 g, 1.2 mmol) and heating at 95 °C for 48 h. Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.22 g, 82%) as colourless needles, mp 129–131 °C. IR (cm^{-1}): 2251, 1690, 1469, 1405. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.82 (dd, 1H, *J* = 16.5, 6.5 Hz, C*H*HCN), 2.99 (dd, 1H, *J* = 16.9, 4.5 Hz, CH*H*CN), 4.55 (d, 1H, *J* = 15.8 Hz, NC*H*HAr), 4.67 (dd, 1H, *J* = 6.5, 4.5 Hz, NCH), 5.43 (d, 1H, *J* = 15.8 Hz, NCH*H*Ar), 6.96 (dd, 1H, *J* = 5.1, 3.5 Hz, thienyl 4-H), 7.07 (d, 1H, *J* = 3.5 Hz, thienyl 3-H), 7.25 (dd, 1H, *J* = 5.1, 1.2 Hz, thienyl 5-H), 7.55–7.65 (m, 3H, ArH), 7.91 (dd, 1H, *J* = 7.9, 1.3 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 22.2, 39.3, 55.1, 116.2, 122.8, 124.8, 126.6, 127.6, 129.9, 131.8, 132.9, 138.9, 142.9, 168.2. MS *m*/*z* (%): 268 ([M$^+$], 44), 228 (24), 97 (100). Anal. calcd. for $C_{15}H_{12}N_2OS$: C 67.10, H 4.50, N 10.50, S 11.90; found: C 66.90, H 4.50, N 10.60, S 11.90.

3-(2-Oxopropyl)-2-(thien-2-ylmethyl)isoindolin-1-one (18c)

Prepared according to general procedure A employing **8c** (0.272 g, 1 mmol) and 2-aminomethylthiophene (0.135 g, 1.2 mmol) and heating at 95 °C for 48 h. Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.095 g, 55%) as colourless prisms, mp 74–77 °C. IR (cm^{-1}): 1716, 1686, 1407, 1365. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.48 (s, 3H, Me), 2.76 (dd, 1H, *J* = 17.9, 6.4 Hz, C*H*HCO), 2.99 (dd, 1H, *J* = 17.9, 5.8 Hz, CH*H*CO), 5.03, 5.13 (2 × d, 2 × 1H, *J* = 15.6 Hz, NCH_2Ar), 5.11 (dd, 1H, *J* = 6.4, 5.8 Hz, NCH), 6.92 (dd, 1H, *J* = 5.0, 3.5 Hz, thienyl 4-H), 6.94 (dd, 1H, *J* = 3.5, 1.3 Hz, thienyl 5-H), 7.21 (dd, 1H, *J* = 5.0, 1.3 Hz, thienyl 3-H), 7.37 (dd, 1H, *J* = 7.1, 0.8 Hz, ArH), 7.46 (td, 1H, *J* = 6.9, 1.1 Hz, ArH), 7.53 (td, 1H, *J* = 7.5, 1.6 Hz, ArH), 7.86 (dd, 1H, *J* = 7.8, 1.2 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 30.9, 39.9, 47.2, 55.7, 122.9, 124.3, 126.0, 127.0, 127.2, 128.9, 121.9, 132.4, 140.2, 145.9, 168.6, 207.0. MS *m*/*z* (%): 285 ([M$^+$], 14), 227 (66), 146 (39), 131 (37), 97 (100), 43 (67). Anal. calcd. for $C_{16}H_{15}NO_2S{\cdot}0.25H_2O$: C 66.30, H 5.35, N 4.85; found: C 66.60, H 5.20, N 5.00.

3-(2-Oxo-2-phenylethyl)-2-(thien-2-ylmethyl)isoindolin-1-one (18d)

Prepared according to general procedure B employing **8d**

© 2005 NRC Canada

(0.167 g, 0.5 mmol) and 2-aminomethylthiophene (0.068 g, 0.6 mmol). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.095 g, 55%) as colourless prisms, mp 99 to 100 °C. IR (cm^{-1}): 1684, 1406, 1211, 987. ^1H NMR ($CDCl_3$, 250 MHz) δ: 3.24 (dd, 1H, *J* = 17.7, 6.8 Hz, C*H*HCO), 3.55 (dd, 1H, *J* = 17.7, 5.5 Hz, CH*H*CO), 4.68, 5.21 (2 × d, 2 × 1H, *J* = 15.6 Hz, NCH_2Ar), 5.33 (dd, 1H, *J* = 6.8, 5.5 Hz, NCH), 6.82 (dd, 1H, *J* = 5.1, 3.4 Hz, thienyl 4-H), 6.96 (d, 1H, *J* = 3.4 Hz, thienyl 5-H), 7.13 (d, 1H, *J* = 5.1 Hz, thienyl 3-H), 7.38–7.49 (m, 5H, ArH), 7.58 (t, 1H, *J* = 7.0 Hz, ArH), 7.85–7.89 (m, 3H, ArH). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 39.8, 42.7, 56.0, 123.3, 124.3, 126.0, 127.2, 127.2, 128.5, 128.9, 129.2, 132.0, 132.4, 134.2, 136.6, 140.0, 146.3, 168.6, 198.0. ES-MS *m*/*z* (%): 370 ([MNa^+], 100). Anal. calcd. for $C_{21}H_{17}NO_2S$: C 72.60, H 4.90, N 4.00, S 9.20; found: C 72.40, H 4.90, N 4.00, S 9.00.

Methyl (2-cyclopropyl-3-oxo-2,3-dihydro-1*H*-isoindol-1-yl)acetate (19a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and cyclopropylamine (0.206 mL, 3 mmol). Column chromatography of the crude product eluting with 1:1 *v*/*v* ethyl acetate – pentane afforded the product (0.181 g, 74%) as a pale yellow oil. IR (cm^{-1}): 2952, 1735, 1694, 1614, 1468, 1436, 1404, 1370. ^1H NMR ($CDCl_3$, 250 MHz) δ: 0.80–1.10 (m, 4H, 2 × cyclopropyl CH_2), 2.66 (m, 1H, cyclopropyl CH), 2.67 (dd, 1H, *J* = 15.6, 8.0 Hz, C*H*HCO), 3.11 (dd, 1H, *J* = 15.6, 5.0 Hz, CH*H*CO), 3.74 (s, 3H, OMe), 4.83 (dd, 1H, *J* = 8.0, 5.0 Hz, NCH), 7.43–7.53 (m, 3H, ArH), 7.8 (dd, 1H, *J* = 7.5, 6.8 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 5.3, 8.2, 23.3, 39.3, 52.5, 58.2, 122.8, 124.0, 129.0, 132.2, 132.6, 144.7, 169.3, 171.4. FAB-MS *m*/*z* (%): 246 ([MH^+], 100). Anal. calcd. for $C_{14}H_{15}NO_3$: C 68.55, H 6.15, N 5.70; found: C 68.30, H 6.40, N 5.50.

2-(Cyclopropyl)-3-oxo-2,3-dihydro-1*H*-isoindol-1-yl)acetonitrile (19b)

Prepared according to general procedure B employing **8b** (0.255 g, 1 mmol) and cyclopropylamine (0.206 mL, 3 mmol) and heating at 95 °C for 48 h. Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.11 g, 52%) as a pale yellow oil. IR (cm^{-1}): 2250, 1693, 1468, 1403, 1210, 1107, 1030, 960. ^1H NMR ($CDCl_3$, 250 MHz) δ: 0.81–1.18 (m, 4H, 2 × cyclopropyl CH_2), 2.70 (m, 1H, cyclopropyl CH), 2.89 (dd, 1H, *J* = 16.8, 7.2 Hz, C*H*HCN), 3.10 (dd, 1H, *J* = 16.8, 4.4 Hz, CH*H*CN), 4.63 (dd, 1H, *J* = 7.2, 4.4 Hz, NCH), 7.32–7.75 (m, 3H, ArH), 7.85 (dd, 1H, *J* = 7.3, 1.1 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 5.3, 8.3, 22.6, 23.3, 57.3, 116.3, 122.7, 124.5, 129.9, 132.6, 132.7, 142.5, 169.1. MS *m*/*z* (%): 212 ([M^+], 32), 172 (100), 128 (31), 102 (30), 89 (37), 77 (43), 41 (53). Anal. calcd. for $C_{13}H_{12}N_2O{\cdot}H_2O$: C 71.90, H 5.75, N 12.90; found: C 71.60, H 6.05, N 13.20.

Methyl {2-[(2-1*H*-indazol-3-yl)ethyl]-3-oxo-2,3-dihydro-1*H*-isoindol-1-yl}acetate (20a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and tryptamine (0.192 g, 1.2 mmol). Column chromatography of the crude product eluting with 1:1 *v*/*v* ethyl acetate – pentane afforded the product (0.241 g, 69%) as a yellow oil. IR (cm^{-1}): 3293, 2950, 1733, 1676, 1619, 1513, 1469, 1455, 1436, 1415, 1364. ^1H NMR ($CDCl_3$, 250 MHz) δ: 2.57 (dd, 1H, *J* = 16.3, 7.0 Hz, C*H*HCO), 2.80 (dd, 1H, *J* = 16.3, 5.5 Hz, CH*H*CO), 3.12 (m, 2H, NCH_2CH_2Ar), 3.64 (s, 3H, OMe), 4.29, 4.45 (2 × m, 2 × 1H, NCH_2CH_2Ar), 4.87 (dd, 1H, *J* = 7.0, 5.5 Hz, NCH), 6.98 (d, 1H, *J* = 2.3 Hz, ArH), 7.11–7.14 (m, 2H, ArH), 7.30–7.49 (m, 3H, ArH), 7.67 (m, 1H, ArH), 7.82 (d, 1H, *J* = 1.3 Hz, Ar 4-H), 8.78 (bs, 1H, NH). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 24.8, 37.7, 41.4, 52.6, 56.9, 111.9, 112.7, 119.0, 119.7, 122.3, 122.7, 122.8, 124.0, 127.7, 129.0, 132.2, 132.4, 136.8, 145.2, 168.8, 171.4. ES-MS *m*/*z* (%): 349 ([MH^+], 100). Anal. calcd. for $C_{21}H_{20}N_2O_3$: C 72.40, H 5.80, N 8.05; found: C 72.10, H 5.90, N 7.85.

2-[2-(3,4-Dimethoxyphenyl)ethyl]-3-(2-oxo-2-piperidin-1-ylethyl)isoindolin-1-one (21e)

Prepared according to general procedure D employing **8e** (0.341 g, 1 mmol) and 2-(3,4-dimethoxyphenyl)ethylamine (0.217 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v*/*v* ethyl acetate – hexane afforded the product (0.358 g, 85%) as a brown gum. IR (cm^{-1}): 1699, 1650, 1510, 1450, 1382, 1210. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.28–1.89 (m, 6H, piperidyl H), 2.44 (dd, 1H, *J* = 16.1, 7.1 Hz, C*H*HCO), 2.68 (dd, 1H, *J* = 16.1, 5.7 Hz, CH*H*CO), 2.94 (m, 2H), 3.23 (t, 2H, *J* = 5.5 Hz, NCH_2CH_2Ar), 3.40 (m, 1H, piperidyl H), 3.65 (t, 2H, *J* = 5.5 Hz, NCH_2CH_2Ar), 3.82, 3.84 (2 × s, 2 × 3H, 2 × OMe), 4.11 (m, 3H, piperidyl H), 5.19 (dd, 1H, *J* = 7.1, 5.7 Hz, NCH), 6.77–6.83 (m, 3H, ArH), 7.43–7.52 (m, 3H, ArH), 7.85 (d, 1H, *J* = 7.1 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 24.8, 26.0, 26.8, 34.4, 37.3, 43.3, 47.0, 56.2, 57.4, 111.5, 112.5, 121.3, 123.4, 123.7, 131.9, 132.4, 146.4, 147.9, 149.2, 168.2, 168.8. MS *m*/*z* (%): 423 ([MH^+], 100), 271 (5), 164 (40), 146 (6). HR-MS calcd. for $C_{25}H_{30}N_2O_4+H^+$: 423.2284; found: 423.2281.

2-[2-(3,4-Dimethoxyphenyl)ethyl]-3-[2-(4-methylpiperazin-1-yl)-2-oxoethyl]isoindolin-1-one (21h)

Prepared according to general procedure D employing **8h** (0.356 g, 1 mmol) and 2-(3,4-dimethoxyphenyl)ethylamine (0.217 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v*/*v* ethyl acetate – hexane afforded the product (0.419 g, 96%) as a brown gum. IR (cm^{-1}): 1708, 1656, 1500, 1444, 1382, 1200. ^1H NMR ($CDCl_3$, 300 MHz) δ: 2.29 (s, 3H, NMe), 2.30–2.40 (m, 6H, piperidyl H), 2.43 (dd, 1H, *J* = 16.2, 7.4 Hz, C*H*HCO), 2.69 (dd, 1H, *J* = 16.2, 5.5 Hz, CH*H*CO), 2.69 (m, 2H, NCH_2CH_2Ar), 3.28 (m, 2H, piperidyl H), 3.42 (m, 1H, piperidyl H), 3.67–3.88 (m, 2H, NCH_2CH_2Ar), 3.81, 3.84 (2 × s, 2 × 3H, 2 × OMe), 4.09 (m, 1H, piperidyl H), 5.15 (dd, 1H, *J* = 7.2, 5.5 Hz, NCH), 6.73–6.79 (m, 3H, ArH), 7.43–7.52 (m, 3H, ArH), 7.85 (d, 1H, *J* = 6.7 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 34.4, 37.1, 42.2, 43.4, 45.7, 46.3, 55.0, 55.3, 56.2, 56.3, 57.4, 111.6, 112.5, 121.3, 123.4, 123.9, 128.8, 131.9, 132.0, 132.4, 146.2, 147.9, 149.2, 168.5, 168.8. MS *m*/*z* (%): 438 ([MH^+], 100), 286 (3), 164 (32), 99(7). HR-MS calcd. for $C_{25}H_{31}N_3O_4+H^+$: 438.2393; found: 438.2393.

Methyl {3-oxo-2-[(1*R*)-1-phenylethyl]-2,3-dihydro-1*H*-isoindol-1-yl}acetate (22a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and (*R*)-(+)-α-methylbenzylamine (0.145 g, 1.2 mmol). Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – pentane afforded a 1:1.75 inseparable diastereomeric product mixture (0.217 g, 74% combined yield) as a pale yellow oil. IR (cm^{-1}): 2951, 1735, 1686, 1615, 1494, 1468, 1436, 1398. ^1H NMR spectra of both isomers were assigned from the mixture of diastereomers. Diastereomer 1 (minor): ^1H NMR ($CDCl_3$, 250 MHz) δ: 1.80 (d, 3H, *J* = 7.3 Hz, Me), 2.15 (dd, 1H, *J* = 16.8, 8.3 Hz, C*H*HCO), 2.55 (dd, 1H, *J* = 16.8, 4.3 Hz, CH*H*CO), 3.56 (s, 3H, OMe), 5.10 (dd, 1H, *J* = 8.3, 4.3 Hz, N*CH*CH_2), 5.73 (q, 1H, *J* = 7.3 Hz, N*CH*Me), 7.27–7.36 (m, 5H, ArH), 7.42–7.52 (m, 3H, ArH), 7.87 (dd, 1H, *J* = 8.0, 7.0 Hz, Ar 4-H). Diastereomer 2 (major): ^1H NMR ($CDCl_3$, 250 MHz) δ: 1.80 (d, 3H, *J* = 7.3 Hz, Me), 2.55 (dd, 1H, *J* = 16.3, 12.3 Hz, C*H*HCO), 2.97 (dd, 1H, *J* = 16.3, 4.0 Hz, CH*H*CO), 3.59 (s, 3H, OMe), 4.68 (dd, 1H, *J* = 12.3, 4.0 Hz, N*CH*CH_2), 5.54 (q, 1H, *J* = 7.3 Hz, N*CH*Me), 7.27–7.36 (m, 5H, ArH), 7.42–7.52 (m, 3H, ArH), 7.87 (dd, 1H, *J* = 8.0, 7.0 Hz, Ar 4-H). ES-MS (isomer mixture) *m*/*z* (%): 332 ([MNa^+], 100). Anal. calcd. for $C_{19}H_{19}NO_3$: C 73.75, H 6.20, N 4.55; found (isomer mixture): C 73.70, H 6.30, N 4.35.

{3-Oxo-2-[(1*R*)-1-phenylethyl]-2,3-dihydro-1*H*-isoindol-1-yl}acetonitrile (22b)

Prepared according to general procedure A employing **8b** (0.255 g, 1 mmol) and (*R*)-(+)-α-methylbenzylamine (0.145 g, 1.2 mmol) and heating at 95 °C for 48 h. Column chromatography of the crude product eluting with 2:3 *v*/*v* ethyl acetate – petroleum ether afforded a 2:3 separable diastereomeric mixture the product (0.212 g, 77% combined yield). Diastereomer 1 (major): colourless prisms, mp 89–94 °C. $[\alpha]_D$ +145.6 (0.71, $CHCl_3$). IR (cm^{-1}) ν: 1685, 1468, 1395, 1218. ^1H NMR ($CDCl_3$, 250 MHz) δ: 1.75 (d, 3H, *J* = 7.2 Hz, Me), 1.99 (dd, 1H, *J* = 16.8, 7.5 Hz, C*H*HCN), 2.51 (dd, 1H, *J* = 16.8, 3.5 Hz, CH*H*CN), 4.81 (dd, 1H, *J* = 7.5, 3.5 Hz, N*CH*CH_2), 5.83 (q, 1H, *J* = 7.2 Hz, N*CH*Me), 7.36–7.44 (m, 3H, ArH), 7.51 (m, 2H, ArH), 7.61 (m, 3H, ArH), 7.94 (d, 1H, *J* = 6.7 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 17.1, 23.4, 49.5, 54.3, 116.2, 122.6, 124.7, 127.7, 128.6, 129.4, 129.9, 132.1, 132.8, 140.7, 143.4, 168.9. MS *m*/*z* (%): 276 ([M^+], 49), 261 (27), 158 (48), 132 (53), 105 (100), 77 (72), 51 (32). HR-MS calcd. for $C_{18}H_{16}N_2O$: 277.1341; found: 277.1338. Anal. calcd. for $C_{18}H_{16}N_2O$: C 78.20, H 5.80, N 10.15; found: C 77.80, H 5.90, N 10.25. Diastereomer 2 (minor): colourless prisms, mp 123–127 °C. $[\alpha]_D$ +70 (0.86, $CHCl_3$). IR (cm^{-1}): 1685, 1468, 1395, 1218. ^1H NMR ($CDCl_3$, 250 MHz) δ: 1.82 (d, 3H, *J* = 7.2 Hz, Me), 2.76 (dd, 1H, *J* = 16.8, 6.5 Hz, C*H*HCN), 2.94 (dd, 1H, *J* = 16.8, 3.4 Hz, CH*H*CN), 4.36 (dd, 1H, *J* = 6.5, 3.4 Hz, N*CH*CH_2), 5.74 (q, 1H, *J* = 7.2 Hz, N*CH*Me), 7.34–7.40 (m, 5H, ArH), 7.48 (m, 1H, ArH), 7.56 (m, 1H, ArH), 7.91 (d, 1H, *J* = 6.6 Hz, Ar 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 18.8, 23.9, 51.2, 55.2, 115.9, 122.4, 124.6, 127.9, 128.6, 129.5, 129.9, 132.3, 132.7, 139.4, 143.0, 168.8. MS *m*/*z* (%): 276 ([M^+], 58), 261 (38), 158 (42), 132 (57), 105 (100), 77 (64). Anal. calcd. for $C_{18}H_{16}N_2O$: C 78.20, H 5.80, N 10.15; found: C 78.00, H 6.10, N 10.10.

Methyl (2*S*)-2-[(2-methoxy-2-oxoethyl)-3-oxo-1,3-dihydro-2*H*-isoindol-1-yl]propanoate (23a)

Prepared according to general procedure A employing **8a** (0.288 g, 1 mmol) and *S*-alanine methyl ester hydrochloride (0.279 g, 2 mmol) and heating at 90 °C for 48 h. Column chromatography of the crude product eluting with 3:2 *v*/*v* ethyl acetate – pentane afforded a 1:1 inseparable diastereomeric mixture of the product (0.185 g, 63%) as a yellow oil. IR (cm^{-1}): 2952, 1738, 1693, 1617, 1469, 1436, 1416, 1353. ^1H NMR spectra of both isomers were assigned from the mixture of diastereomers. Diastereomer 1: ^1H NMR ($CDCl_3$, 250 MHz) δ: 1.62 (d, *J* = 7.5 Hz, 3H, Me), 2.62 (m, 1H, C*H*HCO), 2.99 (m, 1H, CH*H*CO), 3.71 (s, 3H, OMe), 3.75 (s, 3H, OMe), 4.64 (m, 1H, N*CH*CH_2), 5.10 (m, 1H, NCH), 7.41–7.59 (m, 3H, ArH), 7.83 (m, 1H, Ar 4-H). Diastereomer 2: ^1H NMR ($CDCl_3$, 250 MHz) δ: 1.67 (d, *J* = 7.5 Hz, 3H, Me), 2.79 (m, 1H, C*H*HCO), 3.02 (m, 1H, CH*H*CO), 3.75 (s, 6H, 2 × OMe), 4.91 (m, 1H, N*CH*CH_2), 5.10 (m, 1H, NCH), 7.41–7.59 (m, 3H, ArH), 7.83 (m, 1H, Ar 4-H). ES-MS (isomer mixture) *m*/*z* (%): 314 ([MNa^+], 100). Anal. calcd. for $C_{15}H_{17}NO_5$: C 61.85, H 5.90, N 4.80; found (isomer mixture): C 62.15, H 6.05, N 4.70.

2-Acetyl-3-(2-oxo-2-piperidin-1-ylethyl)isoindolin-1-one (24e)

Prepared according to general procedure D employing **8e** (0.341 g, 1.0 mmol) and acetamide (0.072 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v*/*v* ethyl acetate – hexane afforded the product (0.186 g, 62%) as colourless prisms, mp 107–109 °C. IR (cm^{-1}): 2995, 1700, 1648, 1500, 1450, 1382. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.48–1.67 (m, 6H, piperidyl H), 2.44 (dd, 1H, *J* = 15.5, 9.7 Hz, C*H*HCO), 2.68 (s, 3H, Me), 3.31–3.38 (m, 2H, piperidyl H), 3.51 (dd, 1H, *J* = 15.5, 2.7 Hz, CH*H*CO), 3.53–3.67 (m, 2H, piperidyl H), 5.68 (dd, 1H, *J* = 9.7, 2.7 Hz, NCH), 7.50 (t, 1H, *J* = 7.4 Hz, ArH), 7.63 (dt, 1H, *J* = 7.7, 1.1 Hz, ArH), 7.74 (d, 1H, *J* = 7.7 Hz, ArH), 7.80 (d, 1H, *J* = 7.6 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 24.8, 26.0, 26.1, 37.6, 43.2, 46.9, 57.0, 124.9, 125.3, 129.3, 130.3, 134.8, 146.8, 167.9, 168.3, 171.6. ES-MS *m*/*z* (%): 301 ([MH^+], 100). Anal. calcd. for $C_{17}H_{20}N_2O_3$: C 68.00, H 6.70, N 9.35; found: C 68.30, H 6.55, N 9.40.

2-Acetyl-3-[2-(1,4-dioxa-8-azaspiro[4.5]dec-8-yl)-2-oxoethyl]isoindolin-1-one (24f)

Prepared according to general procedure D employing **8f** (0.399 g, 1 mmol) and acetamide (0.072 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v*/*v* ethyl acetate – hexane afforded the product (0.186 g, 52%) as colourless needles, mp 145–147 °C. IR (cm^{-1}): 2990, 1690, 1648, 1500, 1456, 1382. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.61–1.73 (m, 4H, 2 × NCH_2CH_2), 2.48 (dd, 1H, *J* = 15.6, 9.7 Hz, C*H*HCO), 2.68 (s, 3H), 3.47–3.51 (m, 4H, 2 × NCH_2CH_2), 3.54 (dd, 1H, *J* = 15.6, 2.7 Hz, CH*H*CO), 3.72–3.77 (m, 4H, 2 × OCH_2), 5.68 (dd, 1H, *J* = 9.7, 2.7 Hz,), 7.51 (dt, 1H, *J* = 7.4, 0.7 Hz, ArH), 7.64 (dt,

© 2005 NRC Canada

1H, *J* = 7.4, 1.2 Hz, ArH), 7.72 (d, 1H, *J* = 7.4 Hz, ArH), 7.90 (d, 1H, *J* = 7.6 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 35.2, 35.9, 37.5, 40.3, 43.9, 57.0, 64.9, 107.1, 124.8, 125.4, 129.4, 130.4, 134.8, 146.7, 168.0, 168.3, 171.6. ES-MS *m/z* (%): 359 ([MH$^+$], 100). Anal. calcd. for $C_{19}H_{22}N_2O_5$: C 63.70, H 6.20, N 7.80; found: C 63.50, H 6.25, N 7.65.

3-(2-Oxo-2-piperidin-1-ylethyl)isoindolin-1-one (25e)

Prepared according to general procedure D employing **8e** (0.341 g, 1.0 mmol) and 1,1,1-trifluoroacetamide (0.136 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v/v* ethyl acetate – hexane afforded the product (0.155 g, 60%) as a pale yellow gum. IR (cm^{-1}): 2991, 1700, 1648, 1498, 1445, 1382. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.43–1.66 (m, 6H, piperidyl H), 2.38 (dd, 1H, *J* = 16.5, 10.8 Hz, C*H*HCO), 3.06 (dd, 1H, *J* = 16.5, 2.9 Hz, CH*H*CO), 3.33 (m, 2H, piperidyl H), 3.44–3.69 (m, 2H, piperidyl H), 5.03 (dd, 1H, *J* = 10.8, 2.9 Hz, NCH), 7.02 (bs, 1H, NH), 7.42–7.52 (m, 2H, ArH), 7.57 (t, 1H, *J* = 7.2 Hz, ArH), 7.87 (d, 1H, *J* = 7.4 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 24.8, 25.9, 26.7, 37.4, 43.2, 46.8, 53.8, 122.7, 124.5, 128.8, 132.1, 132.4, 146.8, 168.6, 170.1. ES-MS *m/z* (%): 259 ([MH$^+$], 100). Anal. calcd. for $C_{15}H_{18}N_2O_2$: C 69.75, H 7.00, N 10.85; found: C 69.90, H 7.20, N 10.65.

3-(2-Oxo-2-piperidin-1ylethyl)-2-(phenylsulfonyl)isoindolin-1-one (26e)

Prepared according to general procedure D employing **8e** (0.341 g, 1 mmol) and benzenesulfonamide (0.188 g, 1.2 mmol). Column chromatography of the crude product eluting with 4:1 *v/v* ethyl acetate – hexane afforded the product (0.223 g, 56%) as colourless needles, mp 190–192 °C. IR (cm^{-1}): 2995, 1710, 1667, 1498, 1450, 1380. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.52–1.70 (m, 6H, piperidyl H), 2.69 (dd, 1H, *J* = 16.0, 9.9 Hz, C*H*HCO), 3.30–3.42 (m, 2H, piperidyl H), 3.57–3.72 (m, 2H, piperidyl H), 3.80 (dd, 1H, *J* = 16.0, 2.6 Hz, CH*H*CO), 5.81 (dd, 1H, *J* = 9.9, 2.6 Hz, NCH), 7.44 (t, 1H, *J* = 7.5 Hz, ArH), 7.50–7.65 (m, 5H, ArH), 7.70 (d, 1H, *J* = 7.8 Hz, ArH), 7.77 (d, 1H, *J* = 7.7 Hz, ArH), 8.12 (dd, 1H, *J* = 8.5, 1.3 Hz, Ar 7-H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 24.8, 26.0, 26.8, 39.8, 43.3, 47.0, 60.2, 124.9, 125.2, 128.6, 129.4, 129.5, 134.5, 134.8, 138.8, 147.1, 167.1, 167.7. ES-MS *m/z* (%): 399 ([MH$^+$], 100). Anal. calcd. for $C_{21}H_{22}N_2O_4$: C 63.30, H 5.60, N 6.90; found: C 63.25, H 5.60, N 6.90.

2-Benzyl-3-pyridin-2-ylmethylisoindolin-1-one (28)

Prepared according to general procedure E employing **8k** (0.15 g, 0.5 mmol) and benzylamine (0.064 g, 0.6 mmol). Column chromatography of the crude product eluting with 1:2 *v/v* ethyl acetate – petroleum ether afforded the product (0.10 g, 64%) as colourless prisms, mp 118 to 119 °C. IR (cm^{-1}): 1685, 1590, 1469, 1436. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 3.10 (dd, 1H, *J* = 14.0, 7.1 Hz, NCHC*H*HAr), 3.41 (dd, 1H, *J* = 14.0, 5.3 Hz, NCHCH*H*Ar), 4.37 (d, 1H, *J* = 15.3 Hz, NC*H*HPh), 5.00 (dd, 1H, *J* = 7.1, 5.3 Hz, NCH), 5.27 (d, 1H, *J* = 15.3 Hz, NCH*H*Ph), 6.81 (m, 1H, pyridyl 3-H), 6.97 (m, 1H, pyridyl 5-H), 7.15–7.30 (m, 6H, ArH), 7.40–7.50 (m, 3H, pyridyl 6-H and 2 × ArH), 7.85 (m, 1H, Ar 7-H), 8.53 (m, 1H, pyridyl 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 44.4, 44.8, 59.2, 122.4, 123.1, 124.2, 124.5, 127.8, 128.3, 128.6, 129.1, 131.7, 132.4, 136.7, 137.7, 145.6, 149.8, 157.0, 168.9. ES-MS *m/z* (%): 315 ([MH$^+$], 100). Anal. calcd. for $C_{21}H_{18}N_2O$: C 80.20, H 5.75, N 8.90; found: C 80.00, H 5.85, N 8.90.

2-Pyridin-4-ylmethyl-3-pyridin-2-ylmethylisoindolin-1-one (29)

Prepared according to general procedure E employing **8k** (0.15 g, 0.5 mmol) and 4-aminomethylpyridine (0.065 g, 0.6 mmol). Column chromatography of the crude product eluting with ethyl acetate afforded the product (0.11 g, 70%) as a colourless oil. IR (cm^{-1}): 1689, 1600, 1470, 1436, 1412. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 3.50 (dd, 1H, *J* = 14.2, 6.6 Hz, NCHC*H*HAr), 3.31 (dd, 1H, *J* = 14.2, 6.0 Hz, NCHCH*H*Ar), 4.45, 5.10 (2 × d, 2 × 1H, *J* = 16.0 Hz, NCH_2Ar), 5.14 (dd, 1H, *J* = 6.6, 6.0 Hz, NCH), 6.83 (m, 1H, pyridyl 3-H), 7.04 (m, 1H, pyridyl 5-H), 7.05 (d, 2H, *J* = 5.5 Hz, pyridyl 3′- and 5′-H), 7.18 (m, 1H, pyridyl 4-H), 7.44–7.45 (m, 3H, ArH), 7.88 (m, 1H, Ar 7-H), 8.48 (d, 2H, *J* = 5.5 Hz, pyridyl 2′- and 6′-H), 8.54 (m, 1H, pyridyl 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 41.7, 44.2, 59.7, 122.6, 122.9, 123.1, 124.3, 124.5, 128.8, 131.7, 132.1, 136.9, 145.7, 146.8, 149.9, 150.3, 156.7, 169.2. MS *m/z* (%): 316 ([MH$^+$], 100), 200 (48), 151 (91). HR-MS calcd. for $C_{20}H_{18}N_3O$+H$^+$: 316.1444; found: 316.1446.

3-Pyridin-2-ylmethyl-2-thiophen-2-ylmethylisoindolin-1-one (30)

Prepared according to general procedure E employing **8k** (0.15 g, 0.5 mmol) and 2-aminomethylthiophene (0.068 g, 0.6 mmol). Column chromatography of the crude product eluting with 1:2 *v/v* ethyl acetate – petroleum ether afforded the product (0.12 g, 74%) as colourless prisms, mp 124 to 125 °C. IR (cm^{-1}): 1688, 1591, 1469, 1436, 1408. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 3.21 (dd, 1H, *J* = 14.0, 6.9 Hz, NCHC*H*HAr), 3.45 (dd, 1H, *J* = 14.0, 5.4 Hz, NCHCH*H*Ar), 4.54, 5.38 (d, 1H, *J* = 15.7 Hz, NC*H*HAr), 5.10 (dd, 1H, *J* = 6.9, 5.4 Hz, NCH), 5.38 (d, 1H, *J* = 15.7 Hz, NCH*H*Ar), 6.86 (d, 1H, *J* = 7.7 Hz, thienyl 4-H), 6.89–6.95 (m, 2H, ArH), 7.00–7.05 (m, 1H, thienyl 3-H), 7.15–7.20 (m, 2H, ArH), 7.35–7.45 (m, 2H, ArH), 7.51 (dt, 1H, *J* = 7.7, 1.8 Hz, thienyl 5-H), 7.77–7.83 (m, 1H, Ar 7-H), 8.57 (d, 1H, *J* = 4.5 Hz, pyridyl 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 39.5, 41.4, 59.1, 122.5, 123.1, 124.2, 124.5, 125.8, 126.9, 127.2, 128.6, 131.8, 132.3, 136.8, 140.1, 145.6, 149.9, 157.0, 168.5. ES-MS *m/z* (%): 321 ([MH$^+$], 100). Anal. calcd. for $C_{19}H_{16}N_2OS$: C 71.20, H 5.05, N 8.75, S 10.00; found: C 71.10, H 5.15, N 8.65, S 9.80.

2-(2-Morpholin-4-ylethyl)-3-pyridin-2-ylmethylisoindolin-1-one (31)

Prepared according to general procedure E employing **8k** (0.15 g, 0.5 mmol) and 2-morpholin-4-ylethylamine (0.079 g, 0.6 mmol). Column chromatography of the crude product eluting with ethyl acetate afforded the product (0.11 g, 64%) as a colourless oil. IR (cm^{-1}): 1684, 1652, 1470, 1434, 1310, 1116, 861, 775. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.47 (t, 4H, *J* = 4.1 Hz, $NCH_2CH_2N(CH_2)_2$), 2.59 (t, 4H, *J* = 4.1 Hz,

© 2005 NRC Canada

$NCH_2CH_2N(CH_2)_2$), 3.05 (dd, 1H, J = 13.9, 7.5 Hz, NCHC*H*HAr), 3.29 (dt, 2H, J = 14.3, 6.3 Hz, $NCH_2CH_2N(CH_2)_2$), 3.47 (dd, 1H, J = 13.9, 5.2 Hz, NCHCH*H*Ar), 3.66 (t, 4H, J = 4.5 Hz, CH_2OCH_2), 4.17 (dt, 2H, J = 14.3, 6.7 Hz, $NCH_2CH_2N(CH_2)_2$), 5.32 (dd, 1H, J = 7.5, 5.2 Hz, NCH), 6.93–6.97 (m, 2H, ArH), 7.19 (dd, 1H, J = 7.1, 5.0 Hz, ArH), 7.38–7.45 (m, 2H, ArH), 7.57 (dt, 1H, J = 7.6, 1.9 Hz, ArH), 7.76–7.82 (m, 1H, Ar 7-H), 8.59 (d, 1H, J = 4.1 Hz, pyridyl 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 37.6, 41.5, 54.1, 57.2, 59.9, 67.4, 122.5, 122.9, 123.9, 124.6, 128.5, 131.5, 132.6, 136.8, 145.9, 149.9, 157.3, 168.7. ES-MS *m*/*z* (%): 338 ([MH^+], 100). HR-MS calcd. for $C_{20}H_{24}N_3O_2$+H^+: 338.1863; found: 338.1859.

2-(4-Methoxyphenyl)-3-pyridin-2-ylmethylisoindolin-1-one (32)

Prepared according to general procedure E employing **8k** (0.15 g, 0.5 mmol) and *p*-anisidine (0.074 g, 0.6 mmol). Column chromatography of the crude product eluting with 1:2 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.11 g, 67%) as colourless prisms, mp 127–129 °C. IR (cm^{-1}): 1685, 1512, 1472, 1457, 1387, 1247. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.83 (dd, 1H, J = 13.9, 8.6 Hz, C*H*HAr), 3.46 (dd, 1H, J = 13.9, 4.8 Hz, CH*H*Ar), 3.82 (s, 3H, OMe), 5.77 (dd, 1H, J = 8.6, 4.8 Hz, NCH), 6.85 (m, 2H, ArH), 6.95 (d, 2H, J = 9.0 Hz, ArH), 7.41 (m, 1H, ArH), 7.43–7.45 (m, 3H, ArH), 7.53 (d, 2H, J = 9.0 Hz, ArH), 7.90 (m, 1H, Ar 7-H), 8.55 (m, 1H, pyridyl 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 41.8, 55.9, 61.3, 114.8, 122.3, 123.2, 124.4, 124.9, 125.8, 128.8, 130.4, 131.9, 132.5, 136.7, 145.1, 149.9, 157.4, 157.8, 167.4. ES-MS *m*/*z* (%): 331 ([MH^+], 100). Anal. calcd. for $C_{21}H_{18}N_2O_2$: C 76.35, H 5.50, N 8.50; found: C 76.10, H 5.40, N 8.30.

3-Pyridin-2-ylmethyl-2-thiazol-2-ylisoindolin-1-one (33)

Prepared according to general procedure E employing **8k** (0.15 g, 0.5 mmol) and 2-aminothiazole (0.06 g, 0.6 mmol) and the reaction heated at 95 °C for 96 h. Column chromatography of the crude product eluting with 3:2 *v*/*v* ethyl acetate – petroleum ether afforded the product (0.11 g, 72%) as pale yellow prisms, mp 141 to 142 °C. IR (cm^{-1}): 1702, 1591, 1505, 1465, 1435, 1368, 1276, 1212, 1134. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 2.31 (dd, 1H, J = 13.5, 8.5 Hz, C*H*HAr), 3.20 (dd, 1H, J = 13.5, 3.4 Hz, CH*H*Ar), 5.01 (dd, 1H, J = 8.5, 3.4 Hz, NCH), 6.93 (d, 1H, J = 7.7 Hz, thiazolyl 5-H), 7.02 (d, 1H, J = 7.0 Hz, thiazolyl 4-H), 7.03–7.10 (m, 2H, ArH), 7.44–7.52 (m, 3H, ArH), 7.62 (d, 1H, J = 3.6 Hz, ArH), 7.85 (m, 1H, Ar 7-H), 8.50 (m, 1H, pyridyl 4-H). ^{13}C NMR ($CDCl_3$, 62.5 MHz) δ: 40.7, 61.9, 114.0, 122.3, 123.8, 124.6, 129.0, 130.4, 132.3, 136.6, 138.5, 145.7, 149.8, 156.9, 157.6, 166.7. ES-MS *m*/*z* (%): 308 ([MH^+], 100). Anal. calcd. for $C_{17}H_{13}N_3OS$: C 66.40, H 4.25, N 13.65, S 10.40; found: C 66.20, H 4.15, N 13.75, S 10.30.

Pauson–Khand reactions in water[1]

Marie E. Krafft, James A. Wright, and Llorente V.R. Boñaga

Abstract: We have investigated the cobalt mediated Pauson–Khand (PK) reaction in water. In the presence of detergents and surfactants, $Co_2(CO)_8$ and $Co_4(CO)_{12}$ are effective under aqueous-phase, thermal PK reactions. In a water–Triton®X-100 medium, $Co_4(CO)_{12}$ is catalytically active. Further, dicobalthexacarbonyl complexes of alkynes and enynes undergo effective cyclization under thermal (70 °C) and NMO-promoted conditions. The oxidative nature of the latter conditions inhibits the reductive PK reaction. In all protocols, moderate to excellent yields of the cycloadducts are obtained. Substrates that are prone to hydrolysis, such as acetals, highly activated carboxylic acid derivatives, and those bearing propargylic heteroatom groups are tolerated under appropriate conditions. Finally, the more challenging intermolecular cycloadditions can also be easily achieved under aqueous conditions.

Key words: alkyne, cycloaddition, green chemistry, Pauson–Khand reaction, water.

Résumé : On a étudié la réaction de Pauson–Khand (PK) catalysée par le cobalt et effectuée dans l'eau. En présence de détergents et d'agents de surface, le $Co_2(CO)_8$ et le $Co_4(CO)_{12}$ sont efficaces pour les réactions de PK thermiques, effectuées en phase aqueuse. Dans un milieu d'eau et de Triton®X-100, le $Co_4(CO)_{12}$ est catalytiquement actif. De plus, les complexes du dicobalthexacarbonyle des alcynes et des énynes subissent une cyclisation effective dans des conditions thermiques (70 °C) catalysées par NMO. Dans tous les protocoles et dans des conditions appropriées, des rendements allant de modérés à excellents ont été obtenus. Les substrats sujets à une hydrolyse, tels les acétals, les dérivés hautement activés d'acides carboxyliques et ceux portant des groupes propargyliques avec hétéroatomes sont tolérés. Enfin, dans des conditions aqueuses, il est possible de réaliser les cycloadditions intermoléculaires présentant les plus grands défis.

Mots clés : alcyne, cycloaddition, chimie verte, réaction de Pauson–Khand, eau.

[Traduit par la Rédaction]

Introduction

Organometallic reactions conducted in nonorganic solvents, such as water (1), ionic liquids (2), and supercritical fluids (3) have become increasingly more relevant (4); the Pauson–Khand (PK) and the PK-type reactions are no exception to this (5). These reactions are the widely studied approaches to cyclopentenones, which incorporate two unsaturated components with a carbonyl unit in a transition-metal-mediated [2 + 2 + 1] cycloaddition process (Scheme 1, eq. [1]). To date, this transformation can be derived from a reaction of alkynes with alkenes (5), allenes (6), or dienes (7), and can also be promoted by complexes of titanium, zirconium, molybdenum, tungsten, iron, ruthenium, rhodium, nickel, iridium and cobalt (5).

The use of water as an alternative solvent is most attractive for practical reasons. However, the poor solubility of the reactants, such as organic compounds and metal complexes, in water results in problems associated with phase separation and inefficient mixing of reactants (1*c*). Instability and reduced reactivity of reactants also pose a problem. The solubility issue has been addressed by taking advantage of the solubilizing properties of organic co-solvents and surfactants, and (or) employing hydrophilic ligand auxiliaries and heterogenous or homogeneous catalysts (1).

Relatively few studies have focused on aqueous-phase PK reactions. Quite understandably, this is owing to the presumed sensitivity of the cobalt carbonyl complexes toward water, such that early work concentrated only on supercritical fluids (3) and ionic liquids (8). Interestingly, water was used as additive in a $Co_2(CO)_8$-catalyzed thermal protocol in toluene (9), and was also found to accelerate the thermally promoted cyclizations of cobalt carbonyl complexes of enynes (10). In the context of green chemistry (4), Chung and co-workers first described the use of water as solvent in PK reactions promoted by colloidal cobalt nanoparticles, in the presence of sodium dodecyl sulfate (11). More recently, Kakiuchi and co-workers developed an effective $[RhCl(cod)]_2$-catalyzed PK-type reaction in water employing a water-soluble phosphine salt, triphenylphosphane-3,3′,3″-trisulfonic acid trisodium salt, in addition to 1,3-bis(diphenylphosphanyl)propane (12). Chung and co-workers also developed an asymmetric version of the $[RhCl(cod)]_2$-catalyzed PK-type reaction in aqueous media (13).

We describe in this report the first comprehensive studies on the cobalt-promoted PK reaction in water. The reactivity

of dicobalthexacarbonyl complexes of alkynes and enynes, as well as uncomplexed enynes, with $Co_2(CO)_8$ and $Co_4(CO)_{12}$ in water, and the effectiveness of surfactants and detergents were examined. The scope and limitations of these methods, in terms of substrate compatibility and reactivity, and reaction conditions (thermal and oxidative promotions) were also explored.

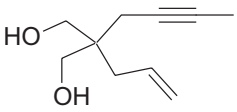
Results and discussion

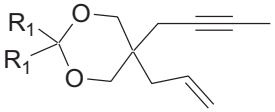
Reactivity of dodecacarbonyltetracobalt in water (14)

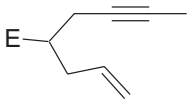
There has been a limited amount of exploration on the use of $Co_4(CO)_{12}$ in organometallic reactions despite its greater stability towards air oxidation than the congeneric $Co_2(CO)_8$ (15, 16). The dinuclear complex has been widely used in the Pauson–Khand (5) and Nicholas reactions (17), conversions of aziridine to β-lactams (18), 1-(1-alkynyl)cyclopropanols to cyclopentenones (19), enones to ketones (20), and in a tandem cycloaddition reaction (21). We discovered the reactivity of $Co_4(CO)_{12}$ in the PK reaction under mild reaction conditions and reported its mechanistic implications in the related reactivity of $Co_2(CO)_8$ (22, 23). Early studies demonstrated that $Co_4(CO)_{12}$ catalyzed the PK reaction under elevated temperatures and CO pressures to presumably favor the formation of $Co_2(CO)_8$, the accepted precatalyst of the reaction (23). We became interested in pursuing the synthetic potential of this cobalt cluster, and found that it can also induce a reductive PK reaction (eq. [2]) and reductive cyclization of specific types of enynes (24). These results further led us to examine its reactivity towards alkynes under aqueous conditions since the reactivity of $Co_4(CO)_{12}$ with alkynes in water was unknown. Additionally, $Co_4(CO)_{12}$ catalyzed PK reactions in aqueous media are significant from the practical standpoint. We reported the unprecedented reactivity of $Co_4(CO)_{12}$ with alkynes (22), and more importantly, its catalytic activity in water in the presence of additives that subsequently lead to the development of a mild and simple aqueous-phase $Co_4(CO)_{12}$ catalyzed PK reaction protocol (14).

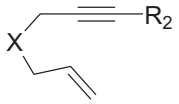
Stoichiometric amounts of $Co_4(CO)_{12}$ were used in our initial studies (eq. [1], Table 1, reaction condition I). Based on literature precedents we focused on surfactants and detergents as additives in our aqueous-phase PK reactions.[3] We found that the cationic micelle-forming surfactant cetyltrimethylammonium bromide (CTAB)[4] worked as a general surfactant for our aqueous reactions (vide infra). We were gratified to find that $Co_4(CO)_{12}$ is active in a water–CTAB media allowing enynes that typically undergo PK reactions conducted in organic solvents to smoothly undergo cyclization (Table 1, condition I). 1,6-Enynes bearing an internal alkyne and either a terminal alkene (Table 1, entries 1–3, 8 and 9) or a disubstituted alkene (Table 1, entries 13 and 14) easily underwent cyclization. A 1,7-enyne also uneventfully underwent the PK reaction (Table 1, entry 16). A particular exception, however, is evident in the unsuccessful cyclization of substrates bearing the hydrolyzable ester and amide groups (Table 1, entries 11 and 12). In contrast, substrates possessing heteroatoms in the tether proved to be stable to hydrogenolysis under these conditions (Table 1, entries 8 and 9 vs. 11 and 12).

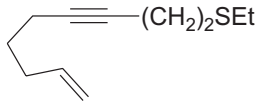
We next examined the corresponding reactions of enynes using catalytic amounts of $Co_4(CO)_{12}$, initially screening its catalytic activity in water or a water–alcohol mixture, with and without additives (Table 2). Cyclization of enyne **2** in water alone, using only 10% of $Co_4(CO)_{12}$, under a blanket of carbon monoxide is inefficient, providing only a modest yield of the cycloadduct **18** and unreacted **2** (Table 2, entry 1). Similar low efficiencies were observed in cyclizations conducted in water–alcohol and water–THF mixtures (Table 2, entries 2–4). Addition of triphenylphosphane-3,3,3-trisulfonic acid trisodium salt (TPPTS)[5] or cyclohexylamine (10, 25) to PK reactions in a water–methanol solvent system only resulted in the isolation of unreacted enyne as the major product after the reactions (Table 2, entries 5 and 6). Incomplete conversions were noted in aqueous reactions carried out with additives, such as TPPTS, tetrabutylammonium

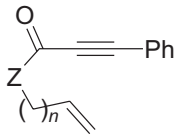


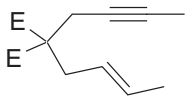


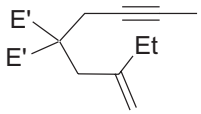


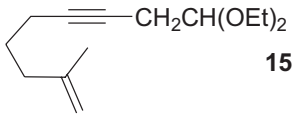


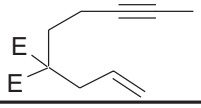












[3] Surfactants and detergents are amphiphiles (molecules carrying a hydrophilic headgroup and a hydrophobic tail) and are surface-active agents, which assemble in aqueous or nonpolar media. They aggregate to form supramolecular assemblies in a colloidal dimension, such as micelles, vesicles, and related species. Surfactants are adsorbed at the interfaces of aqueous and organic two-phase systems resulting in reduced interfacial tension. The very high polarity gradient between surface and core causes micelles to enclose organic species out of the surrounding aqueous phase. The encapsulation of reactants in micelles often enhances or inhibits the reaction rates (1*a*). "Detergent" is often used interchangeably with "surfactant"; detergent is a substance capable of cleaning, and contains, inter alia, surfactants (1*a*).

[4] CTAB: $[CH_3(CH_2)_{15}N(CH_3)_3][Br]$.

[5] TPPTS, with all three aromatic rings of triphenylphosphine sulfonated, is water-soluble. Metal compounds with this ligand are also water-soluble.

bromide, and Fisher detergent[3] (Table 2, entries 7–9). Ultimately, CTAB, Tween 40, and polyoxyethylene(10) isooctylcyclohexyl ether, Triton® X-100, all led to relatively efficient catalytic activity of $Co_4(CO)_{12}$ in PK reactions in water (Table 2, entries 10–13).

To explore the generality of the catalytic activity of $Co_4(CO)_{12}$, we surveyed the cyclizations of various enynes in water with the aid of Triton® X-100 (eq. [1], Table 1, condition II). Efficient cyclization was achieved with enynes that typically undergo PK reactions in organic solvents. Our studies focused on the behavior of substrates that are potentially unsuitable for aqueous conditions due to their proclivity to hydrolyze, and revealed noteworthy results. The acetal moieties in enynes **5** and **15** were stable in this aqueous medium. Reaction of the dicobalthexacarbonyl complex of **5** in water using Brij 35 or the anionic surfactant cetyltrimethylammonium hydrogen sulfate (CTAHS)[3] as additives led to cycloadducts with hydrolyzed acetal groups (vide infra). Successful cyclizations of **8** and **9** are also striking since hydrogenolysis of the heteroatom group in the propargylic position could potentially occur. In fact, this has been observed as a side reaction in PK reactions conducted even in organic solvents (26*a*, 26*e*). These types of substrates (**8** and **9**) underwent substantial hydrogenolysis (~50%) under $Co_4(CO)_{12}$ mediated cycloadditions in DME, even in the presence of only 20 equiv. of water (26*b*). Enyne **10**, which is devoid of substitution on the tether and thus lacking Thorpe–Ingold assistance in the cyclization, cleanly underwent PK reaction. Successful reaction of enynes **11** and **12** is particularly impressive since activated carboxylic acid derivatives can easily be hydrolyzed, and the chemical reactivity of electron-deficient alkynes is unpredictable in the PK reaction (27). It is worth nothing that the corresponding reactions of **11** and **12** using stoichiometric $Co_4(CO)_{12}$ in the water–CTAB medium failed (Table 1, condition I). We showed in our earlier work that cyclizations of substrates bearing alkynes substituted with electron-withdrawing groups, such as **11** and **12**, occur in low to modest yields in organic solvents (27). While the thermally promoted PK reaction of **11** (toluene, 70 °C, 3 days) gave a 15% yield of cycloadduct **27**, the NMO-promoted variant (CH_2Cl_2, rt) gave a 59% yield of **27** (cf. Table 1, entry 11) (27). Enynes **12** and **16**

© 2005 NRC Canada

also provide examples of successful PK reactions of 1,7-enynes providing the bicyclononenones. Substrates **14** and **15** bearing an internal alkyne and a disubstituted alkene smoothly cyclized, furnishing highly substituted bicyclooctenone adducts. These results illustrate the catalytic efficiency of $Co_4(CO)_{12}$ in promoting the PK reaction of various types of enynes in water, by taking advantage of the micellar properties of Triton®X-100 (Table 1, condition II).

We also addressed the issue of realizing a carbon-monoxide-free, $Co_4(CO)_{12}$ catalyzed PK reaction (12). However, a slight decrease in the yield of cycloadducts from reactions conducted under an argon atmosphere was noted. PK cyclization of enynes **2** and **3** in the water–Triton®X-100 medium using 20 mol% of $Co_4(CO)_{12}$ gave rise to 70% and 59% yields of bicyclooctenones **18** and **19**, respectively (cf. Table 1, condition II). Nevertheless, these results show the potential of the aqueous protocol in the absence of carbon monoxide and warrant further studies.

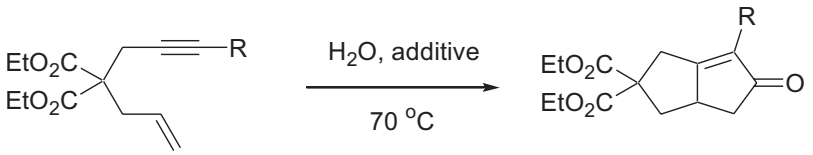
Reactivity of dicobalthexacarbonyl–alkyne complexes in water (28)

The ease with which dicobalthexacarbonyl complexed enynes undergo PK reactions in water was also studied. We prepared the dicobalthexacarbonyl complexes of several enynes and surveyed their thermal reactions in water with different additives (Table 3). Use of CTAB (Table 3, entries 4, 8, and 11) and Tween 40 (Table 3, entries 2 and 5) as additives with preformed enyne–$Co_2(CO)_6$ complexes resulted in consistently efficient aqueous PK reactions. PK cyclization of the cobalt carbonyl complex of **2** using tris[2-(2-methoxyethoxy)ethyl]amine (TDA-1)[6] and castor oil were a little inferior when compared to the use of CTAB as an additive (Table 3, entry 8 vs. 6 and 7). Use of the surfactants Brij 35 (Table 3, entry 9) and CTAHS (Table 3, entry 10) led to the hydrolysis of the acetal group. Under both conditions, reactions of the dicobalthexacarbonyl complex of acetal **5** provided the bishydroxyl bearing cycloadduct **20**, which is also derived from the reaction of diol **4**. We then examined the cyclization efficiencies of a series of dicobalthexacarbonyl complexed enynes in water using CTAB as the additive (eq. [1], Table 1, condition III). As expected, results showed a similar general trend as the reactions conducted according to conditions I and II (Table 1).

Reactivity of dicobalthexacarbonyl–alkyne complexes with NMO in water (29)

Using NMO as a reaction promoter, we also explored the cyclization efficiencies of enynes with internal alkynes and with various substitution patterns in the alkene component (eq. [1], Table 1, condition IV). As anticipated, these substrates underwent PK cyclizations efficiently resulting in good to excellent yields of PK reaction cycloadducts. Table 1 further shows that the yields in the NMO-promoted cyclizations are comparable to or better than the yields derived from the thermally promoted variant (70 °C, Table 1, condition III). In both cases, enynes that undergo PK reactions conducted in organic solvents also cyclized smoothly. 1,6-Enynes with a terminal alkene, and an alkyne component bearing alkyl (Table 1, entries 1, 2, 5, and 7) and aryl groups (Table 1, entries 3 and 8), underwent efficient cylization. Substitution on both alkene and alkyne moieties is well tolerated, e.g., Table 1, entry 1 vs. 13 (cf. entry 14). Groups prone to undergo hydrolysis, such as an acetal (Table 1, entry 5) and propargylic heteroatom groups (Table 1, entries 8 and 9), are stable under these aqueous conditions. However, the amide and ester moieties were hydrolyzed under these reaction conditions (Table 1, condition IV, entries 11 and 12, cf. conditions I and II). Cyclization of a 1,7 enyne occurred smoothly as well (Table 1, entry 16).

We further noted several interesting observations in the cyclizations of enyne **2** while probing the manner of preparation of the alkyne cobalt complex and the amount and source of NMO. The cobalt complex of enyne **2** can alternatively be prepared directly in the reaction media, i.e., by treatment of the enyne with $Co_2(CO)_8$ in the water-Triton®X-100 mixture. Synthesis of the cobalt enyne complex in this manner (1.5 h) and subsequent addition of crystalline NMO·H_2O (6 mol equiv.) gave 80% of adduct **18** after 6 h (cf. Table 1, entry 2, condition IV). Commercially available NMO (6 mol equiv., 50% in water) or only 3 mol equiv. of crystalline NMO·H_2O can also be used in the reaction, providing 68% and 76% of enone **18**, respectively (cf. Table 1, entry 2, condition IV).



Previously developed stoichiometric and catalytic thermal PK reaction procedures proceed efficiently under aqueous conditions, but are limited to enyne substrates bearing internal alkynes (vide supra). Enynes containing terminal alkynes gave rise to bicyclooctanones (eq. [2]), either as a side product (11) or the exclusive product (14, 28). These thermal conditions, either stoichiometric or catalytic in the cobalt carbonyl complex, are conducive to reductive PK reaction to give ketones (eq. [2]) (24). We proposed earlier that residual cobalt carbonyl complexes from PK reactions utilizing $Co_2(CO)_8$, $Co_4(CO)_{12}$, and enyne–$Co_2(CO)_6$ complexes may react with a proton source, such as aqueous and alcoholic solvents, to form $HCo(CO)_4$ (24*a*). A metal hydride transfer from the hydridocobalt complex can effect a 1,4-reduction of the enone generated in the PK reaction. We also found that unsubstituted bicyclooctenones, derived from 1,6-enynes with terminal alkynes (via eq. [1]), are prone to this secondary process. We became interested in the behavior of enynes bearing terminal alkynes towards PK reaction (eq. [1]) or reductive PK reaction (eq. [2]) in water, most importantly in the inhibition of the reductive PK reaction as a side reaction.

Results revealed that the reductive PK reaction was preferred in aqueous reactions using stoichiometric amounts of $Co_4(CO)_{12}$ leading to the favored formation of bicyclooctanones instead (eq. [2], Table 4). In our control experiments, we learned that thermal cyclization of an enyne bearing a terminal alkyne such as **33** primarily furnished bicyclooctanone **37**, along with the bicyclooctenone **35**, in water as the solvent (Table 4, entry 1). The nature of the additive, i.e., Triton®X-100 and CTAB (Table 4, entry 4 vs. 6) and quantity (Table 4, entries 2–5) did not prevent the occurrence of reductive PK reaction, i.e., the reaction depicted in eq. [1] is

[6] TDA-1 ($N(CH_2CH_2OCH_2CH_2OCH_3)_3$) is a very hydrophilic phase-transfer catalyst, which is most useful for solubilizing solid salts. It also forms complexes with some metal carbonyls (1*a*).

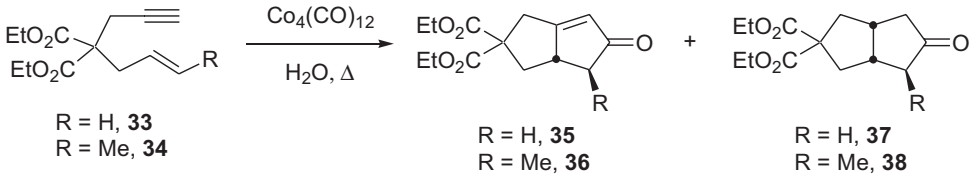
21

less favored than in eq. [2]. Understandably, the amount of the cobalt cluster affected the efficiency of cycloaddition and the extent of the reductive PK reaction (Table 4, entry 2 vs. 4 and 3 vs. 5) (24*a*).

Preformed dicobalthexacarbonyl complexes of substrates bearing a terminal alkyne behaved as expected under thermal conditions, undergoing inefficient PK reactions in water (28). Use of additives such as cyclodextrins β-CD and γ-CD (30), Triton®X-100, and Triton®X-100 (reduced form) did not significantly improve the reaction efficiency in water and in a water–methanol system. In these reactions, up to 10% of saturated bicyclooctanones was observed as a side product.[7]



We were however delighted to discover that when NMO was used as promoter, room-temperature cyclization of the dicobalthexacarbonyl enyne complex of **39** furnished 74% of the bicyclooctenone **40** (eq. [3]) (31). This result is particularly striking since the corresponding bicyclooctanone was not observed. In contrast, Me_3NO promoted cyclization of complex **39** in dichloromethane under an argon atmosphere (–78 °C to rt) furnished an 82% yield of a 4:1 mixture of bicyclooctenone **40** and the corresponding bicyclooctanone (31*b*). The oxidative nature and (or) the ambient temperature of these present reaction conditions have apparently prevented the occurrence of the reductive PK reaction. Further, NMO is water-soluble, thus is advantageous in promoting the PK reaction in water.

The behavior of various terminal alkynes in the NMO promoted PK reaction was examined to gain a sense of the scope and limitations of this important observation. Results indeed show that enynes with terminal alkynes generally underwent the PK reaction smoothly, providing good yields of enones (eq. [1], Table 5). Substitution on the alkene moiety

[7]We inadvertently overlooked the formation of by-products from reductive PK reaction in our preliminary communication (28).

7	**34**	Triton X®-100 (2)	2			46

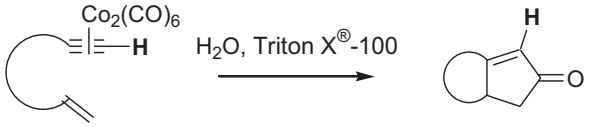
[a]Reactions were conducted at concentrations of 0.05 mol/L (relative to enyne) in water at 70 °C under a nitrogen atmosphere and were complete in 18 h.

(Table 5, entry 1 vs. 6) and a longer tether length (Table 5, entries 6 and 7) are tolerated. As a comparison, the thermal version was also conducted and showed the significant formation (up to 46%) of the reductive PK reaction adduct (Table 5, entries 2, 3 and 5).

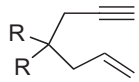
Cyclization of the dicobalthexacarbonyl complex of enyne **33** under various thermal conditions deserves comment. In a water – sodium dodecyl sulfate medium and using colloidal cobalt nanoparticles as the catalyst (20 atm CO (1 atm = 101.325 kPa), 130 °C), a significant amount of the bicyclooctanone (24%), in addition to enone **35** (71%), was observed (11). In the presence of either catalytic or stoichiometric amounts of $Co_4(CO)_{12}$, thermally promoted reaction of the complex of **33** in water with additives, such as Triton®X-100 and CTAB exclusively provided the corresponding bicyclooctanone (Table 4). It also gave 80% of bicyclooctanone **34**, when it was treated with an equivalent of $Co_2(CO)_8$ and 20 mol equiv. of water in refluxing DME (26*b*).

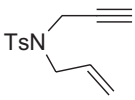
The room temperature, NMO promoted PK reaction proceeds efficiently in the water–Triton®X-100 medium (Table 1, condition IV), and is as efficient as the thermal reaction in the water–CTAB medium (Table 1, condition III). This procedure is particularly useful for the PK reactions of enynes bearing terminal alkynes because of the inhibition of further 1,4-reduction of the enone (cf. eq. [2]). Substrates that possess acetals prone to undergo hydrolysis are stable under these aqueous conditions.

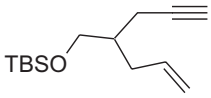
Intermolecular PK reactions in water

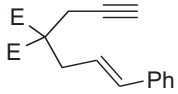


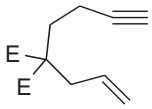
We were also interested in the application of several aqueous protocols to the intermolecular PK reaction (6) (Table 6). We felt that the challenging intermolecular nature of such reactions under aqueous conditions deserved study. Results showed that both strained and unstrained alkenes reacted with alkynes to provide good yields of PK reaction cycloadducts. The good results observed in the intermolecular PK cyclization of a less reactive alkene, such as 1-nonene, under three different sets of aqueous conditions is particularly worth emphasizing. As expected, the regiochemical outcomes parallel that observed in adducts generated from intermolecular reactions conducted in organic solvents (26*a*).

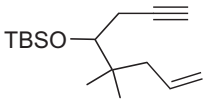












Summary and conclusions

We have studied the PK reaction under aqueous conditions, where we have focused on the (*a*) reactivity of $Co_2(CO)_8$ and $Co_4(CO)_{12}$ towards alkynes, (*b*) determination of optimal aqueous conditions, (*c*) compatibility of the PK reaction with various detergents and surfactants, and (*d*) stability of the substrates. In the presence of detergents and surfactants, such as Triton®X-100 and CTAB, PK reactions of enynes in water were efficiently promoted by $Co_2(CO)_8$ and $Co_4(CO)_{12}$ at 70 °C. A desirable catalytic protocol was developed using $Co_4(CO)_{12}$, which further delineated the unprecedented reactivity of the cobalt cluster under aqueous conditions. We have noted however that these thermal aqueous procedures were only suitable for enynes with internal alkynes. Enynes with terminal alkynes underwent the reductive PK reaction providing bicyclooctanones. Gratifyingly, this problem was avoided by promoting the aqueous PK reaction with NMO. Lastly, our studies have defined the type of enyne substrates that are compatible with water, and

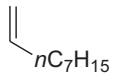
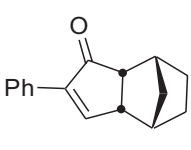
Experimental section

General procedure



$Co_4(CO)_{12}$ and $Co_2(CO)_8$ were purchased from Strem Chemicals Co. and used without further purification. Brij 35, *n*-Bu_4NBr, castor oil, β- and γ-CD, CTAB, CTAHS, $CyNH_2$, Fisher detergent, TDA-1, TPPTS, Triton®X-100, Triton® X-100 (reduced form), and Tween 40 were purchased from commercial suppliers and used as received. Distilled deionized water was used for these reactions. Base-washed glassware was also used.

Reaction condition I



To a round-bottomed flask containing enyne **1** (83 mg, 0.329 mmol) and $Co_4(CO)_{12}$ (188 mg, 0.329 mmol) was added CTAB (72 mg, 0.197 mmol) followed by water (4 mL). The reaction mixture was then placed under an atmosphere of nitrogen and heated at 70 °C for 18 h. Upon completion of the reaction, the mixture was filtered through paper on a Büchner funnel, extracted with ethyl acetate, dried over $MgSO_4$, and filtered through a short pad of Celite.

53

54

55

Subsequent concentration and purification by flash column chromatography (SiO_2, 25% EtOAc in hexanes) provided 75 mg of enone **17** (82% yield).

Reaction condition II

To a resealable tube containing enyne **3** (90 mg, 0.28 mmol), $Co_4(CO)_{12}$ (32 mg, 0.57 mmol, 20 mol%), and Triton®X-100 (91 mg, 0.14 mmol, 0.5 mol equiv.) was added water (1 mL). Carbon monoxide was then bubbled through the mixture (1 to 2 min), the tube was then sealed, and the reaction mixture was heated at 70 °C. Upon completion of the reaction (6–18 h), the mixture was filtered through a filter paper on a Büchner funnel, extracted with EtOAc, dried over $MgSO_4$, and filtered through a short pad of Celite. Subsequent concentration, followed by purification by flash column chromatography (SiO_2, 20% EtOAc in hexanes) provided 83 mg of enone **19** (85% yield).

Synthesis of dicobalthexacarbonyl complexes of alkynes and enynes

To a solution of enyne **3** (85 mg, 0.30 mmol) in CH_2Cl_2 (1 mL) was added $Co_2(CO)_8$ (114 mg, 0.332 mmol). The reaction mixture was then stirred at room temperature under N_2 for 1 h or until complex formation was complete. Concentration under reduced pressure provided the corresponding enyne–$Co_2(CO)_6$ complex in quantitative yield. These organocobalt complexes can alternatively be prepared by treating the enyne with $Co_2(CO)_8$ in a water–Triton®X-100 mixture. These complexes were then subjected immediately to reaction conditions III and IV.

Reaction condition III

To a round-bottomed flask containing the enyne–$Co_2(CO)_6$ complex of **2** (0.31 mmol) was added water (3 mL), followed by CTAB (67 mg, 0.18 mmol) and a small amount of Celite. The reaction mixture was then placed under an atmosphere of nitrogen and heated at 70 °C. Upon completion of the reaction (6–18 h), the mixture was filtered through a filter paper on a Büchner funnel, extracted with diethyl ether, and dried over $MgSO_4$. Subsequent concentration and purification by flash column chromatography (SiO_2, 25% EtOAc in hexanes) afforded 80 mg of enone **18** (85% yield). In some cases, a small amount of Celite was added into these reaction mixtures to facilitate stirring and to adsorb cobalt residues after the reaction. Insignificant differences in the yields were observed when Celite was not added to the reaction mixture.

Reaction condition IV

To a round-bottomed flask containing the enyne–$Co_2(CO)_6$ complex of **13** (0.285 mmol) was added Triton®X-100 (91 mg, 0.14 mmol), water (1 mL), and $NMO{\cdot}H_2O$ (235 mg, 1.7 mmol). The reaction mixture was then placed under an atmosphere of nitrogen and stirred at rt for 6 h. Upon completion of the reaction, the mixture was filtered through paper on a Büchner funnel, extracted with EtOAc, and dried over $MgSO_4$. Subsequent concentration and purifi-

© 2005 NRC Canada

cation by flash column chromatography (SiO_2, 25% EtOAc in hexanes) afforded 72 mg of enone **29** (86% yield).

The following compounds were previously reported and characterized: **3**, **13**, **19**, **29**, **42**, **44**, and **51**, (ref. 24); **2**, **9**, **10**, **18**, **25**, **26**, **33**, **35**, **47**–**49**, **52**, **53**, **56**, and **57** (ref. 25); **4**–**7**, **16**, **20**–**23**, **30**, and **32** (ref. 28); **11**, **12**, **27**, and **28** (ref. 27); **1** and **17** (ref. 32); **54** and **55** (ref. 33).

30. Cyclodextrins (CD) are cyclic oligosaccharides consisting of six (α-CD), seven (β-CD), and eight (γ-CD) glucopyranose units and possessing both hydrophilic and hydrophobic sites. The cyclodextrin cavity is slightly apolar so that when it is occupied by polar water molecules it can be energetically unfavorable. Because of this negative interaction, the water molecules can be substituted by the less polar molecules in a host–guest manner. The cyclodextrin molecule usually can trap one guest molecule so that it can theoretically improve the normally unfavorable environment that exists with a poorly soluble molecule and the aqueous solution. The reactivity of the trapped molecule can either decreased because of stabilization or be enhanced in other cases. For a background on cyclodextrins, see: J. Szejtli. Chem. Rev. **98**, 1743 (1998).

Surface organometallic chemistry — Carbonyl complexes of Re(I) with silanolates as models of silica anchored rhenium carbonyl species[1]

Giuseppe D'Alfonso, Claudia Dragonetti, Simona Galli, Elena Lucenti, Piero Macchi, Dominique Roberto, and Renato Ugo

Abstract: Reaction of Me_3SiONa with $[Re(CO)_5Cl]$ affords the new complex $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$, which could be generated via formation of $[Re(CO)_5OSiMe_3]$ followed by immediate reaction with Me_3SiO^-. Substitution of some CO ligands by phosphines significantly decreases the electrophilicity of the Re(I) center, and therefore hinders further attack by Me_3SiO^-. Thus, *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OTf]$ (OTf is the triflate anion) reacts with Me_3SiONa to give *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$, a molecular model of silica anchored $[Re(CO)_5OSi\equiv]$. However, substitution of only one CO by triphenylphosphine is not enough to avoid the formation of $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$. While *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ is stable towards hydrolysis, $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$ is readily hydrolyzed to $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]^-$, a molecular model of silica anchored $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSi\equiv)_2]^-$, whose structure has been determined by single crystal X-ray diffraction.

Key words: surface organometallic chemistry, rhenium, silica, silanolate, molecular model.

Résumé : La réaction de Me_3SiONa avec $[Re(CO)_5Cl]$ fournit le nouveau complexe $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$, probablement généré via la formation de $[Re(CO)_5OSiMe_3]$ suivie par une réaction immédiate avec Me_3SiO^-. La substitution de quelques CO par des phosphines diminue fortement l'électrophilicité du centre Re(I) et, par conséquent, empêche toute attaque ultérieure par Me_3SiO^-. Ainsi, *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OTf]$ (OTf est l'anion triflate) réagit avec Me_3SiONa pour donner *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$, modèle moléculaire de l'espèce ancrée à la silice $[Re(CO)_5OSi\equiv]$. Cependant la substitution d'un seul CO par la triphenylphosphine ne suffit pas à empêcher la formation de $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$. Alors que *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ est stable en présence d'eau, $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$ s'hydrolyse rapidement pour donner $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]^-$, modèle moléculaire de l'espèce ancrée à la silice $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSi\equiv)_2]^-$, dont la structure a été déterminée par diffraction des rayons X.

Mots clés : chimie organométallique de surface, rhénium, silice, silanolate, modèle moléculaire.

Introduction

Transition-metal carbonyls supported on silica are hybrid materials of interest as precursors of highly dispersed metals that may show improved or unusual catalytic properties (1). Although largely investigated in the last two decades (2), the surface organometallic chemistry between molecular metal carbonyl fragments and the surface sites is not always fully established. A recently developed way for a better understanding of the structure and reactivity of molecular metal carbonyl fragments bound to the silica surface is based on the structural and chemical characterization of metal carbonyl compounds bearing various silanolate ligands that mimic the functional groups of the silica surface. These models are a useful tool not only to understand the structural aspects of surface organometallic species, but also to clarify

the rather complex chemical behavior of metal carbonyl species anchored to silica (2). Many models of silica anchored carbonyl species of various noble metals (e.g., Rh (3), Os (2, 4),[3] and Ru (5)) have been synthesized, structurally characterized, and chemically investigated; however, in the case of the oxophilic metal Re, just anionic $[Re_2(CO)_6(\mu\text{-}OH)_x(\mu\text{-}OSiEt_3)_{3-x}]^-$ (x = 0, 1, or 2) (6) and neutral $[Re_2(CO)_8(\mu\text{-}H)(\mu\text{-}OSiR_2R')]$ (R = Et, Ph; R′ = Et, Ph, OH, or $OSiPh_2OH$) (7) species have been obtained and described only recently. Nevertheless, these few models cannot give a full understanding of the surface organometallic chemistry involving various rhenium carbonyl species anchored to silica. There is still a need for the synthesis and investigation of novel rhenium carbonyl species bearing silanolate ligands to fully clarify the complex surface chemistry occurring when rhenium carbonyl species such as $[Re_2(CO)_{10}]$ or $[Re(CO)_3(OH)]_4$ are chemically interacting with the silica surface. Indeed, this kind of surface organometallic chemistry is not yet well known, despite the industrial relevance of Re catalysts supported on inorganic oxides (8).

Recently, in fact, we reported that silica supported $[Re(CO)_3(OH)]_4$ is easily converted into $[Re_2(CO)_{10}]$ by reductive carbonylation under very mild conditions (1 atm CO, 1 atm = 101.325 kPa). This reaction does not occur in solution, suggesting that the silica surface plays a unique role via the formation of the surface anchored species $[Re(CO)_5OSi\equiv]$, which could also act as the intermediate in the silica mediated conversion under N_2 of $[Re_2(CO)_{10}]$ into $[Re(CO)_3(OH)]_4$ (9). Evidence for an intermediate chemically bound to the silica surface was based on IR studies and on its lack of extraction with solvents, together with its reactivity with HCl and $HReO_4$ to afford $[Re(CO)_5Cl]$ and $[Re(CO)_5OReO_3]$, respectively. This proposed surface species anchored via a Re—OSi bond to the surface is quite peculiar since carbonyl species of the type $[Re(CO)_5OR]$ have so far eluded isolation (9). Therefore, to produce additional evidence for its existence and to enlighthen its chemical behavior, we started an investigation on the synthesis and characterization of molecular models of this unusual silica anchored species.

Results and discussion

Attempts to prepare the molecular model of silica anchored $[Re(CO)_5OSi\equiv]$ by reaction of $[Re(CO)_5Cl]$ with Me_3SiONa invariably failed. The expected compound, $[Re(CO)_5OSiMe_3]$, was not obtained upon addition of Me_3SiONa to a solution of $[Re(CO)_5Cl]$ in dichloromethane (1:1 molar ratio), working under nitrogen at room temperature. Under these conditions, only some $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$ (ν(CO) = 2007 (s, br) and 1879 (vs, br) cm^{-1}) is quickly formed. With a 1.5:1 molar ratio Me_3SiONa:$[Re(CO)_5Cl]$, $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$ is quantitatively obtained (eq. [1]). Similarly, Et_3SiONa leads to the known anion $[Re_2(CO)_6(\mu\text{-}OSiEt_3)_3]^-$, previously prepared by reaction of an anisole solution of $[Re_2(CO)_6(\mu\text{-}OH)_3]^-$ with an excess of triethylsilanol at 200 °C (6).

$$[1]\qquad 2[Re(CO)_5Cl] + 3Me_3SiO^- \rightarrow [Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^- + 2Cl^- + 4CO$$

Reaction of $[Re(CO)_5Cl]$ with the anion Me_3SiO^- reasonably generates $[Re(CO)_5OSiMe_3]$ as a very reactive intermediate species, which could not be detected even by working under CO at 0 °C. This intermediate would be so reactive towards nucleophiles to react rapidly with the anion Me_3SiO^- affording, finally, by a double nucleophilic attack, $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$. Such an easy dimerization by silanolates bridging and concomitant loss of carbon monoxide, even under a CO atmosphere, suggests that the silanolate anion, as the alkoxide one (10), is an exceptionally good cis-labilizing ligand, which facilitates a further nucleophilic attack: the behavior of Me_3SiO^- towards $[Re(CO)_5Cl]$ is thus parallel to that of the structurally related alkoxide Me_3CO^- (11), despite its lower basicity. The quite high stability of the proposed silica anchored $[Re(CO)_5OSi\equiv]$ intermediate (9) can be due to the much lower nucleophilicity of surface silanols because the lack of dimerization cannot be attributed to the topological arrangement of surface silanols. In fact, we produced evidence for covalent anchoring of the dimer $[Re_2(CO)_6(\mu\text{-}OH)_3]^-$ to surface silanols (6).

It was thus clear that we could follow two strategies to obtain mononuclear Re(I) carbonyl silanolates: to decrease either the nucleophilic power of the silanolate anion or the electrophilic character of the Re(I) center. In this work we report on the results obtained by following the second option.

Substitution of some CO ligands of $[Re(CO)_5Cl]$ by phosphine ligands should decrease the electrophilicity of the Re(I) center and therefore hinder further nucleophilic attacks by Me_3SiO^- with formation of anionic dimeric species. Therefore, we treated *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)Cl]$ with a stoichiometric amount of Me_3SiONa, at room temperature in dichloromethane. No reaction took place because of the large increase of the electronic density on the Re(I) center, as it can be inferred from the IR spectrum. This effect obviously inhibits even the first nucleophilic attack by the trimethylsilanolate anion. However, it is well-known that in Re(I) carbonyl species the triflate anion is a much better leaving group than the chloride one. Thus, we studied the reaction of *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OTf]$ (OTf is the triflate anion), easily obtained by reaction of AgOTf with *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)Cl]$.

Addition of Me_3SiONa to a dichloromethane solution of *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OTf]$ slowly affords *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$. The reaction, which can be easily followed by IR and ^{31}P NMR spectroscopies (see the Experimental section), is complete in 2 days. Interestingly, although alkoxide complexes such as *fac*-$[Re(CO)_3(R'_2PCH_2CH_2PR'_2)OR]$ (R = Me, Et, or *i*-Pr; R′ = Et or Ph) were prepared by treatment of the triflate complex with the sodium salt of the appropriate primary or secondary alcohol (10, 12), it was reported that by reaction with the anion Me_3CO^-, structurally related to Me_3SiO^- but of increased nucleophilicity, the corresponding *tert*-butoxide complex was not isolated (10).

[3] E. Lucenti, F.J. Feher, and J.W. Ziller. Submitted for publication.

fac-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ reacts readily with HCl(aq) to give *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)Cl]$, a behavior that mimics the formation of $[Re(CO)_5Cl]$ by treatment of the proposed silica anchored $[Re(CO)_5OSi\equiv]$ species with HCl(aq). As a matter of fact, it was already reported that addition of gaseous HCl to the related alkoxide complex *fac*-$[Re(CO)_3(Et_2PCH_2CH_2PEt_2)OEt]$ results in a similar cleavage of the metal–oxygen bond with formation of the corresponding chloride (13).

It appears that the balance of the electron density on the rhenium atom is of paramount relevance for the stabilization of monomeric silanolate complexes. Indeed, by decreasing the electronic density on the rhenium center, such as when replacing a chelating diphosphine with one triphenylphosphine as in *cis*-$[Re(CO)_4(PPh_3)OTf]$, reaction with the anion Me_3SiO^- still gives $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$ with release of CO and even PPh_3, as evidenced by ^{29}Si and ^{31}P NMR spectroscopy, also when working at 0 °C (see the Experimental section). This latter result suggests that the coordination to rhenium of only one phosphorous donor atom is not sufficient to avoid aggregation by bridging silanolates when working in the normal range of temperatures between 0 and 25 °C.

It is worth pointing out that the Re-$OSiMe_3$ bond in *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ is quite stable to hydrolysis in the presence of water at room temperature, as in some other neutral rhenium silanolate models such as $[Re_2(CO)_8(\mu\text{-}H)(\mu\text{-}OSiR_2R')]$ (R = Et, Ph; R′ = Et, Ph, OH, or $OSiPh_2OH$) (7), but in sharp contrast with the fast hydrolysis of anionic species such as $[Re_2(CO)_6(\mu\text{-}OH)_x(\mu\text{-}OSiEt_3)_{3-x}]^-$ (x = 0, 1, or 2) (6). Indeed, addition of a stoichiometric amount of $[NEt_4]Cl$ to an acetonitrile solution of $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$, followed by evaporation of the solvent and extraction of the organometallic anion with dry dichloromethane, afforded $[NEt_4][Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$. However, by slow crystallization from dichloromethane–*n*-pentane at –20 °C, only crystals of the product of the first step of the hydrolysis (6), namely $[NEt_4][Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]$, were obtained because a partial hydrolysis arose even from very minor traces of water. The related complex $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiEt_3)_2]^-$ has already been characterized spectroscopically (6), but has never been structurally investigated, although it is of interest as a model of the silica anchored surface species $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSi\equiv)_2]^-$ proposed to be thermally formed by condensation of $[Re_2(CO)_6(\mu\text{-}OH)_3]^-$ with surface silanols (6).

The crystal structure of $[NEt_4][Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]$ (orthorhombic *Cmcm*) is composed by dimeric $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]^-$ anionic units (Fig. 1), lying about a crystallographic *m2m* position (C_{2v}), counterbalanced by disordered tetraethylamonium cations, lying on a 2/*m* symmetry operator. Crystallographic data as well as data collection and treatment details are gathered in Table 1. A synoptic collection of bond lengths and angles is reported in Table 2. To our knowledge, this is the first example of a $[Re_2(CO)_6(\mu\text{-}OH)_x(\mu\text{-}OR)_{3-x}]^-$ structure (x = 0, 1, or 2) in which R is a silyl group. Previous characterizations regarding both homo- and hetero-bridged dimers of this kind invariably involved alkoxy or aryloxy bridges (14). Moreover, among the known X-ray structures of hetero-bridged $[Re_2(CO)_6(\mu\text{-}OH)_x(\mu\text{-}OR)_{3-x}]^-$ complexes, a well-defined

Fig. 1. ORTEP representation (at 20% probability) of $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]^-$. The labels adopted for the structural description are depicted.

structure for the anionic dimer, as in the present case, was obtained only for the anion $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OPh)_2]^-$ (14*f*), heavy disorder affecting the alkoxy groups in all the other cases (14*a*, 14*e*).

Within each $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]^-$ dimer, the metal center, hexa-coordinated in distorted octahedral stereochemistry, is bound by three terminal carbonyl ligands, occupying facial positions, by two bridging -$OSiMe_3$ moieties and a bridging hydroxy group. The metal atom thus satisfies the valence bond electron rule without invoking a bonding metal···metal interaction, whose distance (3.111(1) Å) is anyway only slightly greater than that of 3.02 Å found in $[Re_2(CO)_{10}]$ (15), as occurs in other RO^- supported Re–Re dimers (see Table 2). Comparable Re—O(H) and Re—O(Si) bond distances (2.142(5) and 2.141(3) Å, respectively) find correspondence in similar Re-O(H)-Re and Re-O(Si)-Re bond angles (93.1(3)° and 93.2(2)°, respectively). Both independent carbonyl groups reveal almost normal features, with Re—C bond distances of 1.888(6) and 1.904(9) Å, C—O bond distances of 1.161(7) and 1.166(11) Å, and Re-C-O angles of 177.3(6)° and 176.9(9)°.

The steric hindrance of the trimethylsilanolate group seems not to induce significant molecular rearrangements: by inspecting Table 2, the major sterical effect seems to occur when PhO^- is acting as the bridge (see, in particular, the Re—O and Re···Re distances).

The dimeric $[Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]^-$ units pack to generate rows parallel to **a** which stack, staggered, along **b** with minor intermolecular interactions (Fig. 2). Consecutive stacks of rows are separated, along **c**, by the counterions.

Conclusions

Due to (*i*) the high cis-labilizing effect of the silanolate ligand, (*ii*) the lability of CO ligands in "$Re(CO)_5$" and

[b] $S(F^2) = [\Sigma w(F_o^2 - F_c^2)^2/(n-p)]^{1/2}$, where n is the number of reflections, p is the number of parameters, and $w = 1/[\sigma^2(F_o^2) + (0.019P)^2 + 1.88P]$ with $P = (F_o^2 + 2F_c^2)/3$.

[c] $R(F) = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR(F^2) = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{1/2}$.

"$Re(CO)_4$" moieties containing mutually trans carbonyls, and (*iii*) the strong tendency of $OSiR_3$ groups to function as bridging ligands (4*g*), the molecular model $[Re(CO)_5OSiMe_3]$ of the proposed surface species $[Re(CO)_5OSi\equiv]$ can not be obtained by reaction of $[Re(CO)_5Cl]$ with the trimethylsilanolate anion, despite the lower nucleophilicity of this latter compound when compared with alkoxy or aryloxy anions. The reaction product, under different reaction conditions, is invariably the bridged anion $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$, as it occurs with alkoxy anions (11).

Only substitution of CO groups with a chelating diphosphine to increase the electron density on the Re(I) complex enhances the stability of CO ligands and thus allows the preparation of neutral rhenium silanolate mononuclear species. Thus, the easy reaction of Me_3SiONa with *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OTf]$ provides a pathway to the novel complex *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$, characterized by an increased stability towards hydrolysis of a Re—OSi bond in sharp contrast with the easy hydrolysis of anionic species such as $[Re_2(CO)_6(\mu\text{-}OH)_x(\mu\text{-}OSiR_3)_{3-x}]^-$ (x = 0, 1, or 2; R = Me, Et) (6).

The increased stability of carbonyl ligands and the lower electrophilicity of the rhenium center, which is the origin of the stability of the monomeric silanolate complexes towards dimerization by further nucleophilic attack by the trimethylsiloxy anion, are quite dependent on the number of phosphorous donor atoms coordinated to the rhenium center. Whereas the complex *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ does not react with excess Me_3SiO^-, *cis*-$[Re(CO)_4(PPh_3)OSiMe_3]$, reasonably formed as intermediate species by reaction of *cis*-$[Re(CO)_4(PPh_3)OTf]$ with Me_3SiO^-, still shows a great lability of a cis carbonyl and even a phosphine ligand giving place to $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$.

In conclusion, this work has indirectly suggested that the relative stability of the proposed "$Re(CO)_5(OSi\equiv)$" species anchored to the silica surface may be due to the extremely low nucleophilicity of the silanols of the silica surface. Therefore, work is in progress to synthesize $[Re(CO)_5OSiR_3]$ species where R_3 better represents the tetrahedral oxygen sphere of silica silanols, which, being quite acidic, display a very low basicity either as such or even as silanolates.

Experimental section

General comments

$[Re(CO)_5Cl]$ and $[Re(CO)_4Cl]_2$ were prepared according to the literature, the first complex by reaction of $[Re_2(CO)_{10}]$ (commercially available from Acros Organics) with Cl_2 (16), the second by heating under reflux a heptane solution of $[Re(CO)_5Cl]$ (17). AgOTf and Me_3SiONa (1 mol/L solution in dichloromethane) were purchased from Sigma-Aldrich. Organic solvents were freshly distilled before use (Et_2O and THF from sodium/benzophenone; CH_2Cl_2 from CaH_2). All reactions were carried out under N_2 (dried by flowing over drierite) in anhydrous conditions. Products were characterized by IR and NMR (^1H, ^{29}Si, ^{31}P) spectroscopies, by mass spectrometry, and by elemental analyses, which were carried out at the Dipartimento di Chimica Inorganica, Metallorganica ed Analitica of the Università di Milano.

Synthesis of $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$

In a typical synthesis, a solution of Me_3SiONa in CH_2Cl_2 (0.65 mL of a 1 mol/L solution) was added to a solution of $[Re(CO)_5Cl]$ (150 mg, 0.415 mmol, molar ratio $[Re(CO)_5Cl]$:Me_3SiONa = 1:1.6) in freshly distilled anhydr. CH_2Cl_2 (35 mL) under N_2 in a 100 mL two-neck round bottomed flask equipped with a magnetic stirring bar. After 24 h under stirring at room temperature, a white precipitate was present and the reaction was complete as evidenced by IR spectroscopy of the solution, which showed that no $[Re(CO)_5Cl]$ (ν(CO) in CH_2Cl_2 = 2046 (m), 1985 (s) cm^{-1}) was left. Evaporation to dryness of the solvent afforded a white residue that was dissolved in freshly distilled anhydr. THF (5 mL). Anhydr. Et_2O was slowly added to the latter solution, at ca. –5 °C (ice and salt bath), to precipitate the NaCl formed during the reaction. The solution was then separated from the precipitate using a syringe. Evaporation of the solvent followed by washing with a few mL of anhydrous pentane afforded pure $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$ as a white powder (162 mg, 0.195 mmol, 94% yield). IR (in

CH_2Cl_2, cm^{-1}): ν(CO) 2007 (s, br), 1879 (vs, br). ^1H NMR (in CD_3CN, ppm) δ: 0.02. ^{29}Si NMR (in CD_3CN, ppm) δ: 0.59; the ^{29}Si NMR signal of Me_3SiONa in CD_3CN lies at –13.09 ppm. In the FAB$^-$ mass spectrum, the ion peak corresponding to $[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]^-$ lies at *m/e* = 807. Elemental anal. calcd.: C 21.67, H 3.25; found: C 21.79, H 3.41.

Synthesis of $Na[Re_2(CO)_6(\mu\text{-}OSiEt_3)_3]$

Synthesis of Et_3SiONa

An excess of metallic Na (3.82 g, 166 mmol, cut in small pieces) was added to a solution of Et_3SiOH (0.98 mmol, 0.15 mL, *d* = 0.846 g/mL) in anhydr. Et_2O (15 mL) under N_2. After stirring at room temperature for ca. 4 h no more gas was evolved, the solution was separated with a syringe and evaporated to dryness affording pure Et_3SiONa. ^1H NMR (in CD_3CN, ppm) δ: 0.36 (q, 2H, CH_2), 0.93 (t, 3H, CH_3). ^{29}Si NMR (in CD_3CN, ppm) δ: –3.19.

Synthesis of $Na[Re_2(CO)_6(\mu\text{-}OSiEt_3)_3]$

A solution of Et_3SiONa in anhydr. CH_2Cl_2 (6.5 mL of a 0.0981 mol/L solution) was added to a solution of $[Re(CO)_5Cl]$ (150 mg, 0.415 mmol, molar ratio $[Re(CO)_5Cl]$:Et_3SiONa = 1:1.5) in freshly distilled anhydr. CH_2Cl_2 (35 mL) under N_2 in a 100 mL two-neck round bottomed flask equipped with a magnetic stirring bar. After 24 h under stirring at room temperature, a white precipitate was present and the reaction was complete as evidenced by IR spectroscopy of the solution. Evaporation to dryness of the solvent afforded a white residue that was dissolved in freshly distilled anhydr. THF (5 mL). Anhydr. Et_2O was slowly added to the latter solution, at –5 °C, to precipitate the NaCl formed during the reaction. The solution was then separated from the precipitate using a syringe. Evaporation of the solvent followed by washing with a few mL of anhydrous pentane (to remove traces of $Et_3SiOSiEt_3$ and Et_3SiOH) afforded the known complex $Na[Re_2(CO)_6(\mu\text{-}OSiEt_3)_3]$ (6) as a white powder (188 mg, 0.197 mmol, 95% yield).

Synthesis of *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$

The new complex *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ was prepared from *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OTf]$ (12), easily obtained by the reaction of AgOTf with *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)Cl]$ (18) recovered in quantitative yield by refluxing under N_2 for 14 h a $CHCl_3$ solution of $[Re(CO)_4Cl]_2$ (0.154 mmol) with a stoichiometric amount of $PPh_2CH_2CH_2PPh_2$ (0.308 mmol).

Thus, addition of AgOTf (19.8 mg, 0.073 mmol) to a solution of *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)Cl]$ (54 mg, 0.077 mmol, IR (in CH_2Cl_2 cm^{-1}): ν(CO) 2034 (vs), 1954 (s), 1906 (s); ^{31}P NMR (in CD_2Cl_2, ppm) δ: 32.65) in anhydr. CH_2Cl_2 (10 mL) led to the precipitation of AgCl and the formation of *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OTf]$ as confirmed by IR and ^{31}P NMR spectroscopies (IR (in CH_2Cl_2, cm^{-1}): ν(CO) 2044 (vs), 1966 (s), 1919 (s); ^{31}P NMR (in CD_2Cl_2, ppm) δ: 38.68). After 2.5 h under stirring in the dark at room temperature, the reaction was complete, as evidenced by IR spectroscopy, and the solution containing *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OTf]$ was transferred with a syringe in a round-bottomed flask. Then Me_3SiONa (1 mol/L solution in CH_2Cl_2, 0.152 mmol, molar ratio Re:Me_3SiONa = 1:2) was added at 0 °C, and the resulting solution was stirred under nitrogen at room temperature for 48 h, evaporated to dryness, and the residue extracted with anhydrous pentane to give, after evaporation to dryness of the solvent, *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ in 75% yield (43.75 mg, 0.058 mmol). IR (in CH_2Cl_2, cm^{-1}): ν(CO) 2014 (vs), 1927 (s), 1873 (s). ^1H NMR (in CD_2Cl_2, ppm) δ: –0.61 (s, 9H, $OSiMe_3$), 2.43 (m, 2H, CH_2), 3.04 (m, 2H, CH_2), 7.21–7.83 (m, 20H, $2PPh_2$). ^{31}P NMR (in CD_2Cl_2, ppm) δ: 31.36. ^{29}Si NMR (in CD_2Cl_2, ppm) δ: 6.05. Mass spectrometry (EI, *m/e*): 758 (M = Molecular ion peak), 730 [M – CO], 702 [M – 2CO], 674 [M – 3CO]. Elemental anal. calcd.: C 50.71, H 4.35; found: C 50.32, H 4.30.

Reactivity of *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$

Addition, at room temperature, of a drop of aq. HCl to *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ (4 mg) dissolved in CH_2Cl_2 (5 mL) led to the immediate formation of *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)Cl]$ as confirmed by IR and ^{31}P NMR spectroscopies. On the contrary, no reaction occurred upon stirring a CH_2Cl_2 solution of *fac*-$[Re(CO)_3(Ph_2PCH_2CH_2PPh_2)OSiMe_3]$ in the presence of a few drops of water for ca. 48 h at room temperature.

Reactivity of *cis*-$[Re(CO)_4(PPh_3)OTf]$ with Me_3SiONa

Addition of AgOTf (20.6 mg, 0.084 mmol) to a solution of *cis*-$[Re(CO)_4(PPh_3)Cl]$ (19) (40 mg, 0.067 mmol; IR (in CH_2Cl_2, cm^{-1}): ν(CO) 2107 (m), 2005 (vs), 1947 (s); ^{31}P NMR (in CD_2Cl_2, ppm) δ: 4.28) in anhydr. CH_2Cl_2 (8 mL), at room temperature, led to the precipitation of AgCl and the formation of *cis*-$[Re(CO)_4(PPh_3)OTf]$ as confirmed by IR and ^{31}P NMR spectroscopies (IR (in CH_2Cl_2, cm^{-1}): ν(CO) 2117 (m), 2016 (vs), 1961 (s); ^{31}P NMR (in CD_2Cl_2, ppm) δ: 11.60). After 2.5 h under stirring in the dark at room temperature, the reaction was complete, as evidenced by IR spectroscopy, and the solution containing *cis*-$[Re(CO)_4(PPh_3)OTf]$ was filtered on Celite under nitrogen. Then Me_3SiONa (1 mol/L solution in CH_2Cl_2, 0.067 mL, 0.067 mmol, molar ratio Re:Me_3SiONa = 1:1) was added, leading to the precipitation of some product. After 1.5 h, evaporation of the solvent afforded a residue that contained $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$ and free PPh_3 as evidenced by ^{29}Si NMR (signal at δ 0.59 ppm) and ^{31}P NMR (signal at δ –4.91 ppm) spectroscopy (in CD_3CN).

Formation of $[NEt_4][Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]$

Addition of $[NEt_4]Cl$ (stoichiometric amount) to a solution of $Na[Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$ in acetonitrile, followed by evaporation of the solvent to dryness, extraction of the residue with CH_2Cl_2 and filtration, afforded a solution of $[NEt_4][Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]$ because of the presence of traces of water. Addition of pentane to this solution led, at –20 °C, to the formation of colorless crystals of $[NEt_4][Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]$ suitable for X-ray structure determination. IR (in CH_2Cl_2, cm^{-1}): ν(CO) 1995 (s, br), 1876 (vs, br). ^1H NMR (in CD_3CN, ppm) δ: 0.22 (s, 18H, $2Si(CH_3)_3$), 1.22 (t, *J* = 7.2 Hz, 12H, $4NCH_2CH_3$), 1.76 (s, 1H, O*H*), 3.18 (q, *J* = 7.2 Hz, 8H, $4NCH_2CH_3$). ^{29}Si

NMR (in CD_3CN, ppm) δ: 16.61; the ^{29}Si NMR signal of Me_3SiONa in CD_3CN lies at –13.09 ppm.

X-ray crystallography

A suitable colorless needle of $[NEt_4][Re_2(CO)_6(\mu\text{-}OH)(\mu\text{-}OSiMe_3)_2]$, obtained by slow crystallization of a CH_2Cl_2–pentane solution of $[NEt_4][Re_2(CO)_6(\mu\text{-}OSiMe_3)_3]$, was mounted in air on the glass fiber tip of a goniometer head. Data collection was performed on a Bruker Axs SMART CCD area-detector equipped with graphite-monochromatized Mo Kα radiation (λ = 0.710 73 Å), by applying the ω-scan method. 2500 frames were acquired with Δω = 0.3°, t = 25 s per frame, and sample–detector distance fixed at 3.45 cm. Data reduction within the hemisphere with 2θ < 61.2° afforded 26 963 reflections of which 2537 were unique. An empirical absorption correction was applied (20). The structure was solved by direct methods (21) and refined with full-matrix least-squares calculations on F^2 (22). Anisotropic temperature factors were assigned to all atoms but: (*i*) hydrogens, riding their parent atoms with an isotropic temperature factor arbitrarily chosen as 1.2 times that of the parent itself; and (*ii*) the nitrogen and carbon atoms of the tetraethylammonium cation. To properly describe the heavily disordered tetraethylammonium cation: (*i*) some of its carbon atoms have been "splitted" over two positions, with a fixed site occupation factor of 0.5; (*ii*) soft restraints have been imposed on its C—C bond distances (1.55 Å); (*iii*) all its carbon atoms have been given a common isotropic displacement parameter; and (*iv*) hydrogen atoms have not been assigned.[4]

Novel nitrogen containing chelating ligands from aziridines — Preparation, coordination studies, and catalytic application in the cyclopropanation of styrene[1]

Larissa B. Krasnova and Andrei K. Yudin

Abstract: Novel ligands have been synthesized by the reaction of readily available aziridines with appropriate nitrogen based nucleophiles under mild conditions. Complexes of different stoichiometry can be readily obtained upon reaction between these ligands and the corresponding copper salts. The enantiomerically pure form of one of the ligands was obtained and applied in the styrene cyclopropanation reaction, where the copper catalyst revealed unexpectedly high diastereoselectivity in comparison with the known systems.

Key words: ligands, aziridines, cyclopropanation, copper catalysts, metal complexes.

Résumé : On a effectué la synthèse de nouveaux ligands en procédant à la réaction, dans des conditions douces, d'aziridines facilement disponibles avec des nucléophiles appropriés à base d'azote. On peut facilement obtenir des complexes de stoechiométries différentes par réaction de ces ligands avec les sels de cuivre correspondants. On a pu obtenir la forme énantiomériquement pure d'un de ces ligands et on l'a appliquée à la réaction de cyclopropanation du styrène pour laquelle le catalyseur de cuivre conduit à une diastéréosélectivité aussi haute qu'inattendue par comparaison avec les systèmes connus.

Mots clés : ligands, aziridines, cyclopropanation, catalyseurs de cuivre, complexes métalliques.

[Traduit par la Rédaction]

Introduction

Cheleating ligands based on a rigid cyclohexyl backbone have been widely used in asymmetric catalysis (1). Among them is Trost's ligand for asymmetric palladium catalyzed allylic substitution (2), alkylation of β-ketoesters (3), and addition of alcohols to vinyl epoxides (4). The salen-type ligands, which have been extensively studied by Jacobsen, were successfully applied in the epoxidation of olefins (5), asymmetric sulfoxidation (6), hetero-Diels–Alder reaction (7), ene reaction (8), asymmetric ring opening of epoxides (9), and cyclopropanation (10). Recently, a new type of *P,N*-ligands containing a cyclohexyl backbone was developed in our lab and applied in the Suzuki coupling with sterically hindered substrates (11). The relative facility of the aziridine ring opening coupled with complete trans selectivity should also make cyclohexyl aziridine a convenient precursor towards cyclohexyl-backbone-containing ligands with an anti relationship between the two nitrogen containing functional groups. The present manuscript details our explorations in this area.

Results and discussion

Our recent interest in aziridine chemistry prompted us to explore simple aziridine building blocks as precursors to new nitrogen containing ligands. The 7-azabicyclo-[4.1.0]heptane was synthesized from cyclohexyl oxide using the Staudinger reaction (Scheme 1) (12). The resulting aziridine was opened with hydrazine hydrate. The product of the reaction was characterized by NMR and was submitted to the next step without purification. The reaction with 2,4-pentanedione led to the formation of racemic pyrazole **1**. The reaction between 7-azabicyclo[4.1.0]heptane and 5-phenyltetrazole occurred under mild conditions at pH 5 (Scheme 1) giving tetrazole **2** (13).

Several chiral acids were screened to resolve the ligand **2** in enantiomerically pure form. The best results were

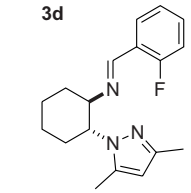
achieved with (*S*)-(–)-mandelic acid and (*S*)-(+)-camphorsulfonic acid. The enantiomeric purity was measured by ^{19}F NMR of the Mosher amide with (*R*)-(–)-MTPA.[3] The absolute stereochemistry of the amine was determined from the X-ray analysis of the diastereomeric salt obtained with (*S*)-(+)-mandelic acid. The amine **1** was resolved with D- or L-dibenzoyltartaric acid, however, we were not able to prove the absolute stereochemistry of enaniomerically pure **1**.

The corresponding imines of ligand precursor **1** were synthesized in good yields (Scheme 2). Different aromatic aldehydes were also used under similar reaction conditions to give the corresponding imines from aminotetrazole **2** (Scheme 3). The imines were synthesized in high yields. The amine **2** was found to be more stable than **1** and its derivatives and can be stored at room temperature without decomposition. In addition, tertiary amine **5** can be easily synthesized from **2** according to Scheme 4.



Scheme 4.

[3] The stereochemistry of the enantiomer obtained from the diastereomeric salt with (*S*)-(+)-10-camphorsulfonic acid was assigned to be opposite, since both enantiomers have different ^{19}F NMR signals in the Mosher amide with (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenyl acetic acid.

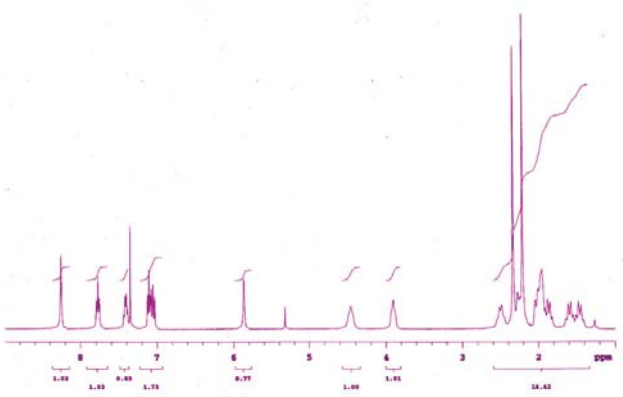
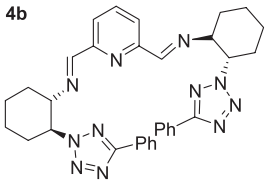
Fig. 1. ^{1}H NMR studies of Cu(I) coordination to ligand **3d**.

Shift of pyrazole and imine protons indicate coordination of Cu(I) to both pyrazole and imine functionalities.

Free ligand

Coordination to Cu(I)





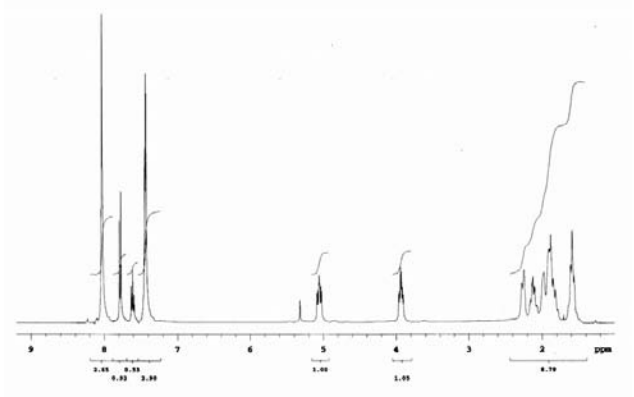


Fig. 2. ^{1}H NMR studies of Cu(I) coordination to ligand **4b**.

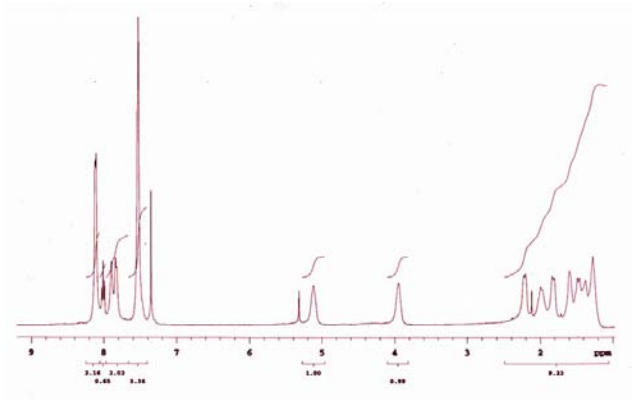

Shift of the pyridine para proton corresponds to the coordination of the metal to the pyridine ring.

Free ligand

Coordination to Cu(I)

We used ^{1}H NMR to evaluate the coordination ability of the newly synthesized ligands to transition metals. This allowed us to screen several complexes of different ligands with CuOTf·0.5C_6H_6. Coordination of the metal to the heterocycle moiety is known to induce a downfield shift of the aromatic proton signals (14). For example, ligand **3d** (Fig. 1) shows coordination to Cu(I) through the pyrazole and imine nitrogens. The imine proton shifts from 8.0 to 8.22 ppm, whereas the pyrazole proton shifts from 5.48 to 5.82 ppm. In addition, nonequivalent methyl protons of the pyrazole ring were observed in the spectrum of the Cu(I)/**3d** mixture. The other two examples did not reveal any copper coordination to the heterocycle moiety. Thus, comparison of the ^{1}H NMR of ligand **4b** with and without Cu(I) (Fig. 2) shows the downfield shift of the pyridine para proton (7.7–8.1 ppm) and corresponds to the copper coordination to the imine. This fact was also confirmed by the X-ray analysis of complex **6** (Fig. 3). No coordination between the tetrazole group and Cu(I) was observed. Importantly, the complex preserves the C_2 symmetry present in the starting material. On the other hand, mixing Cu(I) and ligand **5** showed coordination to the tertiary amine, whereas coordination to the tetrazole was not detected by ^{1}H NMR at all (Fig. 4).

No catalytic activity was observed when ligands **3a**–**3c** and **4a** were applied in asymmetric cyclopropanation according to the literature conditions (15). In light of these negative results, we were encouraged to obtain interesting data in the cyclopropanation using **4b** as the catalyst precursor (Scheme 5). The diastereoselectivity of the copper catalyzed cyclopropanation is known to mostly depend on the nature of the diazo compound ester group. The sterically bulky menthyl group usually gives the best trans:cis ratio. However, in the case of ligand **4b**, a 93:7 trans:cis ratio (determined by ^{1}H NMR) of the regioisomers was obtained even with a group as small as methyl. Unfortunately, the enantioselectivity was very low (<5%). In comparison, the background reaction without the ligand proceeds with a 57:43 trans:cis ratio. Under the same conditions, ligand **4c**

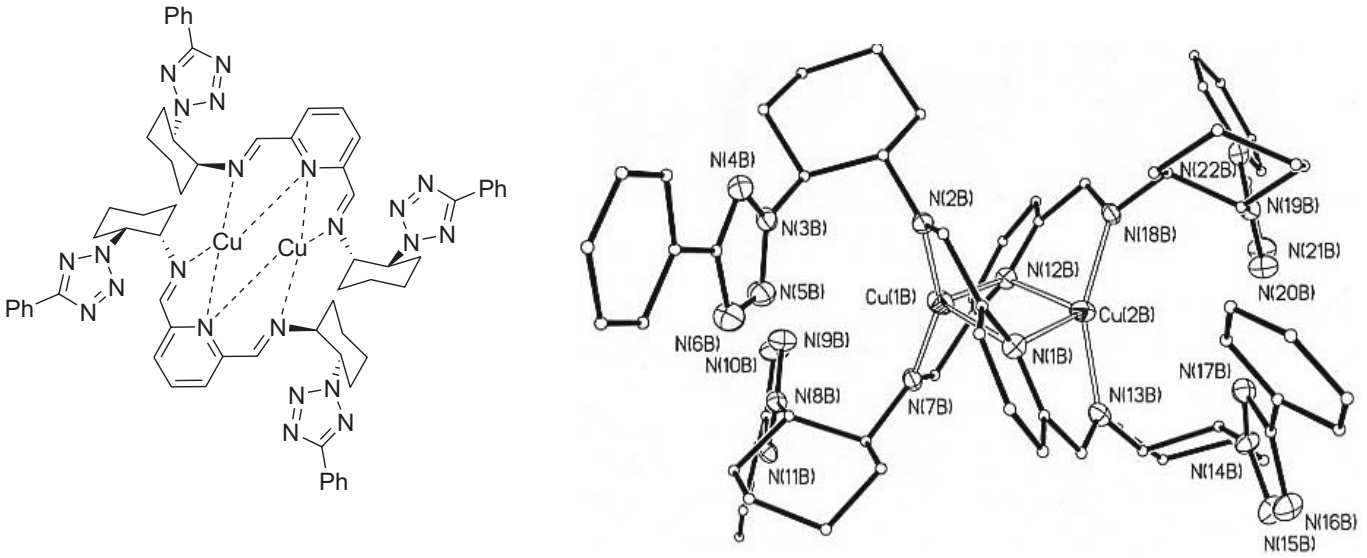
Fig. 3. X-ray structure of (*S*)-(*S*)-[2,6-di-*trans*-(5-phenyltetrazol-2-yl)cyclohexyl]pyridin-2-yl methylene-amine / Cu(I) complex (**6**).



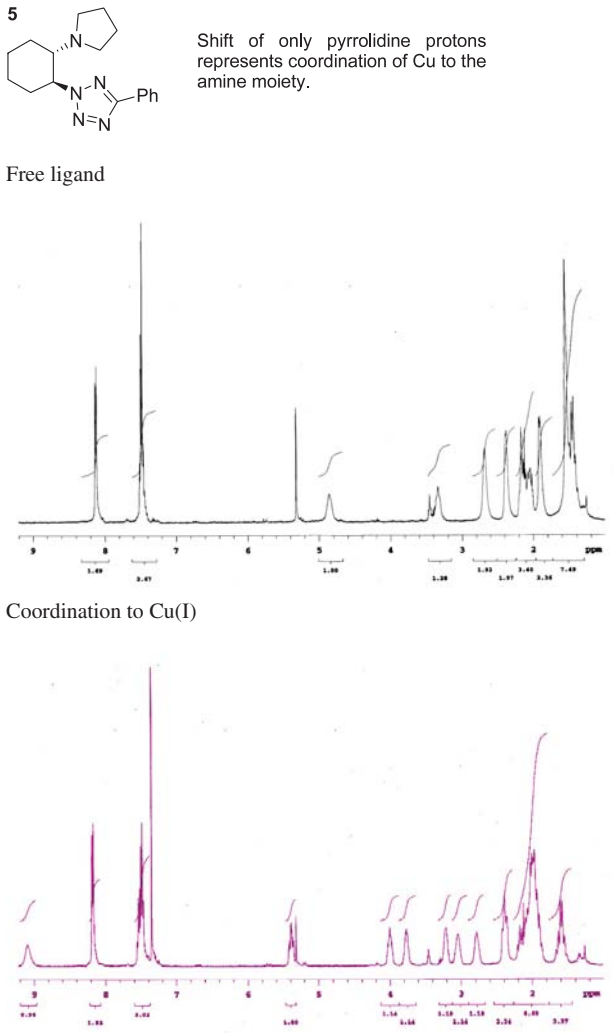


Fig. 4. ^{1}H NMR studies of Cu(I) coordination to ligand **5**.

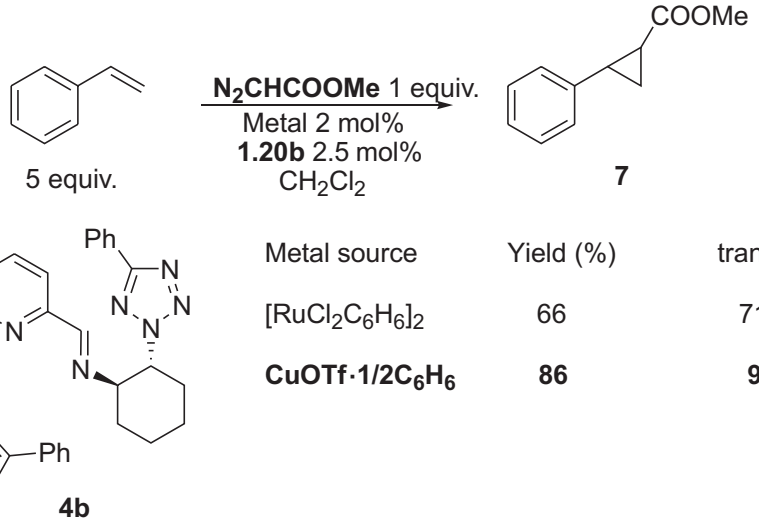
gave lower diastereoselectivity (trans:cis ratio, 73:27). These results demonstrate that ligand **4b** gives the highest reported diastereoselectivity in cyclopropanation among the ligands synthesized to date. Unexpectedly, ruthenium, which is known to show better results with the pybox system compared to copper, showed no diastereoselectivity in the case of ligand **4b**. In comparison, diastereoselectivity as well as enantioselectivity for the cyclopropanation of styrene catalyzed by Cu(I) with a pybox-type ligand was found to be low (16).



In summary, new *N*,*N*-ligands have been synthesized by the reaction of readily available cyclohexane based aziridines with appropriate nitrogen based nucleophiles under mild conditions. It was shown that Cu(I) coordinates to these ligands and, depending on modifications of the amino group, complexes of different stoichiometry can be obtained. The enantiomerically pure forms of one of the ligands were obtained and applied in the cyclopropanation reaction, where the copper catalyst revealed unexpectedly high diastereoselectivity in comparison with the ruthenium catalyst. The observed diastereoslectivity is superior to the known copper catalyzed cyclopropanation systems. The mechanistic basis for this observation is currently under scrutiny, along with attempts to find enantioselective systems in this new structural class.

Experimental section

Dichloromethane, ether, acetonitrile, toluene, and hexanes were purchased from Aldrich as "anhydrous". Tetrahydrofuran (THF) was dried over sodium benzophenone ketyl. Moisture-sensitive reactions were carried out using standard syringe–septum techniques under a nitrogen atmosphere. ^{1}H and ^{13}C NMR spectra were recorded on 300 or 400 MHz spectrometers. ^{1}H NMR spectra were referenced to residual $CHCl_3$ (δ 7.27 ppm), CH_2Cl_2 (δ 5.32 ppm), DMSO (δ 2.50 ppm), CH_3CN (δ 1.94 ppm), and benzene (δ 7.16 ppm); ^{13}C NMR spectra were referenced to $CDCl_3$ (δ 77.0 ppm), CD_2Cl_2 (δ 54.0 ppm), DMSO-d_6 (δ 99.5 ppm), CD_3CN (δ 118.7 ppm), and benzene-d_6 (δ 128.4 ppm).

7-Azabicyclo[4.1.0]heptane (12)

A mixture of cyclohexene oxide (31 mL, 306 mmol) and NaN_3 (50.4 g, 775 mmol) in H_2O–acetone (1:1, 320 mL) mixture was heated to reflux for 17 h (temperature of the oil bath was 75 °C). Acetone was removed under reduced pressure and the residue extracted with Et_2O (3 × 160 mL). The combined extracts were washed with H_2O (2 × 40 mL) and dried over $MgSO_4$. After filtration, removal of the solvent yielded the azido alcohol (~93%–96% yield) as a practically pure yellow oil, which was concentrated and used in the next step without further purification. ^{1}H NMR (benzene-d_6) δ: 0.72–1.12 (m, 4H), 1.20–1.34 (m, 2H), 1.59 (m, 1H), 1.74 (m, 1H), 2.23 (s, 1H), 2.79 (m, 1H), 3.10 (m, 1H). ^{13}C NMR (benzene-d_6) δ: 24.7, 25.0, 30.7, 34.2, 67.7, 74.3.

Triphenylphosphine (77.2 g, 294 mmol) was added within 30 min to a solution of azidocyclohexanol (41.7 g, 294 mmol) in THF (250 mL) while N_2 evolved from the reaction mixture. The reaction mixture was then refluxed for 16 to 17 h. Pentane (~1 L) was added to precipitate $Ph_3P{=}O$, and the white precipitate was filtered off and the solvent was removed on a rotary evaporator (water bath 30–45 °C). The THF was distilled off at 25 mmHg (1 mmHg = 133.322 4 Pa), and the residue was again distilled at 45 °C (oil bath temperature) under vacuum (1 mmHg), collecting aziridine in the receiving flask, which was placed in a dry ice – acetone bath. 7-Azabicyclo[4.1.0]heptane (20 g, 70% yield) was obtained as a colorless oil, which solidified upon cooling at –5 °C. Storage: over KOH; bp 50 °C / 1 mmHg. ^{1}H NMR ($CDCl_3$) δ: 1.19–1.37 (m, 6H), 1.81 (m, 6H), 2.17 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 20.0, 24.5, 29.3.

***trans*-2-(3,5-Dimethyl-pyrazole-1-yl)cyclohexylamine (1)**

$NH_2NH_2 \cdot H_2O$ (490 μL, 10 mmol) was added to the 1 mol% solution of NH_4Cl in 2 mL of H_2O and 1 mL (10 mmol) of aziridine. The reaction was stirred at room temperature for several hours (24 h) and turned from a white suspension to the colorless solution. Upon completion, the reaction mixture was treated with 25–50 mL of benzene, concentrated, and dried under high vacuum. *trans*-2-Hydrazinocyclohexylamine was obtained as a colorless oil and was used without further purification in the next step. ^{1}H NMR (DMSO-d_6) δ: 1.14 (m, 4H), 1.60 (s, 2H), 1.73 (m, 1H), 1.83 (m, 2H), 2.29 (dt, J = 4.2, 10.5 Hz, 1H), 2.65 (dt, J = 4.2, 10.5 Hz, 1H), 3.56 (m, 1H). ^{13}C NMR (DMSO-d_6) δ: 24.5, 29.1, 31.6, 53.4, 63.2, 67.5.

The crude *trans*-2-hydrazinocyclohexylamine was suspended in 20 mL of ethanol and at 0 °C, 1 mL (12 mmol) of 2,4-pentadione was added dropwise and the reaction was stirred for another 30 min and then concentrated. The residue was washed with 5 mL of 30% KOH, and the water layer was extracted with EtOAc (3 × 25 mL), which was washed with brine, dried over Na_2SO_4, concentrated, and dried under the high vacuum. The product can be further purified by Kugelrohr distillation. *trans*-2-(3,5-Dimethylpyrazol-1-yl)cyclohexylamine (1.25 g, 65% yield) was obtained as a beige solid; mp 120 °C / 1 mmHg. ^{1}H NMR ($CDCl_3$) δ: 1.25–1.46 (m, 4H), 1.60–2.05 (m, 6H), 2.23 (s, 3H), 2.25 (s, 3H), 3.40 (dt, J = 5.2, 10.8 Hz, 1H), 3.59 (dt, J = 5.2, 10.8 Hz, 1H), 5.77 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 11.3, 13.8, 24.8, 25.6, 32.2, 34.6, 53.8, 64.5, 104.6, 139.5, 147.8.

***trans*-2-(5-Phenyltetrazol-2-yl)cyclohexylamine (2)**

Aziridine (1.75 mL, 17 mmol) was added to the reaction mixture containing Bu_4NBF_4 (570 mg, 1.7 mmol) and 2.5 g (17 mmol) of tetrazole in 34 mL of buffered H_2O (AcONa–AcOH, pH 5) / ether mixture (1:1). The reaction was stirred for 5 to 6 h. Completion of the reaction was confirmed by TLC (hexane–EtOAc, 8:2). The reaction was quenched with 5% NaOH and extracted with EtOAc. Combined organic extracts were washed with brine, dried over $MgSO_4$, and concentrated. The product was purified by flash chromatography on silica gel (hexane–EtOAc, 6:4 with 3 vol% of Et_3N). *trans*-2-(5-Phenyltetrazol-2-yl)cyclohexylamine (2.96 g, 70% yield) was obtained as a white solid; mp 70–72 °C. ^{1}H NMR ($CDCl_3$) δ: 1.35–1.54 (m, 4H), 1.85–2.24 (m, 4H), 3.37 (dt, J = 4.5, 11.1 Hz, 1H), 4.47 (m, 1H), 7.43–8.15 (m, 5H). ^{13}C NMR ($CDCl_3$) δ: 25.0, 25.3, 32.5, 35.0, 54.1, 71.5, 126.8, 127.6, 128.9, 130.2, 164.8.

Resolution of *trans*-2-(3,5-dimethylpyrazol-1-yl)cyclohexylamine (1) with D-(+)-dibenzoyl tartaric acid

D-(+)-Dibenzoyltartaric acid (1.5 equiv.) was added to the

© 2005 NRC Canada

solution of amine in a minimum amount of CH_2Cl_2–MeOH (9:1). The reaction was heated to dissolve the acid and then cooled to room temperature. The precipitate was filtered off and recrystallized from CH_2Cl_2–MeOH. ^{1}H NMR (DMSO-d_6) δ: 1.29–1.80 (m, 8H), 2.10 (s, 3H), 2.18 (s, 3H), 2.59 (s, 4H), 3.58 (dt, J = 4.5, 10.2 Hz, 1H), 4.97 (dt, J = 4.5, 10.2 Hz, 1H), 5.73 (s, 1H), 7.49–8.00 (m, 10H).

The precipitate was hydrolyzed with KOH, and extracted with EtOAc, dried over Na_2SO_4, and concentrated to give 184 g (48% yield) of one of the enantiomers of *trans*-2-(3,5-dimethylpyrazol-1-yl)cyclohexylamine obtained as a white solid, with 99.9% ee determined from the ^{19}F NMR of the Mosher amide (–69.55 ppm signal).

General procedure for the resolution of *trans*-2-(5-phenyltetrazol-2-yl)cyclohexylamine (2)

Racemic *trans*-2-(5-phenyltetrazol-2-yl)cyclohexylamine (4.23 g, 17.4 mmol) was dissolved in 50 mL of 95% EtOH and reacted with 0.7 equiv. (12.2 mmol) of resolving acid. In the case of mandelic acid, the precipitate was dissolved in an additional 200 mL of ethanol. The hot, clear solution was then cooled down to room temperature and a crystalline precipitate was filtered off and recrystallized from ethanol. The precipitate was hydrolyzed with KOH and the water layer was extracted with EtOAc (3 × 50 mL), dried over Na_2SO_4, and concentrated.

(*R*)-(*R*)-*trans*-2-(5-Phenyltetrazol-2-yl)cyclohexylamine (2)

(*R*)-(*R*)-*trans*-2-(5-phenyltetrazol-2-yl)cyclohexylamine (490 mg, 70% yield) was obtained through the formation of a diastereomeric salt with (*S*)-(+)-mandelic acid, followed by hydrolysis. (*R*)-(*R*)-*trans*-2-(5-Phenyltetrazol-2-yl)cyclohexylamine was isolated as a white solid with 99.9% ee, determined from the ^{19}F NMR of the Mosher amide (–69.82 ppm). Absolute stereochemistry of the amine was determined from the X-ray analysis (see Supplementary notes)[4] of the diastereomeric salt with (*S*)-(+)-mandelic acid. A sample for X-ray analysis was obtained after recrystallization from ethanol; mp 204–205.5 °C. ^{1}H NMR (DMSO-d_6) δ: 1.42 (m, 2H), 1.68–2.20 (m, 5H), 3.39 (m, 1H), 4.70 (s, 1H), 4.81 (dt, J = 4.2, 11.7 Hz, 1H), 5.20 (br s, 1H), 7.18–8.08 (m, 10H). ^{13}C NMR (DMSO-d_6) δ: 23.7, 24.0, 31.9 (d, J = 78.9 Hz), 52.9, 67.0, 72.8, 126.0, 126.1, 126.4, 126.9, 127.3, 128.9, 130.1, 141.8, 163.5, 173.9.

(*S*)-(*S*)-*trans*-2-(5-Phenyltetrazol-2-yl)cyclohexylamine (2)

(*S*)-(*S*)-*trans*-2-(5-Phenyltetrazol-2-yl)cyclohexylamine (455 mg, 65% yield) was obtained through the formation of a diastereomeric salt with (*S*)-(+)-10-camphorsulfonic acid, followed by hydrolysis. (*S*)-(*S*)-*trans*-2-(5-Phenyltetrazol-2-yl)cyclohexylamine was isolated as a white solid with 99.9% ee, determined from the ^{19}F NMR of the Mosher amide (–70.07 ppm); mp 194 °C. ^{1}H NMR (DMSO-d_6) δ: 0.73 (s, 3H), 1.03 (s, 3H), 1.26 (m, 1H), 1.40–2.30 (m, 9H), 2.38 (d, J = 15 Hz, 1H), 2.66 (m, 1H), 2.88 (d, J = 15 Hz, 1H), 3.38 (s, 3H), 3.69 (m, 1H), 5.04 (dt, J = 3.9, 11.4 Hz, 1H), 7.57 (m, 2H), 8.08 (m, 3H). ^{13}C NMR (DMSO-d_6) δ: 19.6, 20.2, 22.9, 23.6, 24.1, 26.4, 29.5, 31.5, 42.2 (d, J = 44.4 Hz), 46.7, 47.1, 52.4, 58.2, 64.3, 126.5, 127.1, 129.3, 130.7, 164.4, 216.4.

General procedure for Mosher amide synthesis (17)

Oxalyl chloride (5 μL, 0.057 mmol) was added to a stock solution of (*R*)-(+)-MTPA (2.8 mg, 0.012 mmol) in DMF (0.95 μL, 0.012 mmol) / hexane (0.5 mL) at room temperature. A white precipitate formed immediately with evolution of gas. After 1 h, the mixture was filtered and concentrated in vacuo. A solution of amine (0.01 mmol), Et_3N (4 μL, 0.03 mmol), and DMAP (small crystals, ~1 mg) in $CDCl_3$ (100 μL) was added to the residue. After 1 h, ^{1}H NMR and ^{19}F NMR of the mixture revealed the conversion into the diastereomeric Mosher amide. *N*-[*trans*-2-(3,5-Dimethylpyrazol-1-yl)-cyclohexyl]-3,3,3-trifluoro-2-methoxy-2-phenylpropionamide: ^{19}F NMR ($CDCl_3$, ppm) δ: –65.5 or –69.5. 3,3,3-Trifluoro-2-methoxy-2-phenyl-*N*-[*trans*-2-(5-phenyltetrazol-2-yl)cyclohexyl]propionamide: ^{19}F NMR ($CDCl_3$, ppm) δ: –69.8 or –70.1.

General procedure for imine synthesis (18)

A solution of the amine (1 or 2 equiv. in case **4b**) and the appropriate aromatic aldehyde (1–1.2 equiv.) in EtOH (0.1 mol/L reaction mixture) was refluxed for 2 to 3 h. The solvent was removed and pentane was added to the resulting oil. If the imine does not crystallize after 24 h at –25 °C, it can be purified by column chromatography on silica gel (eluent: hexane–EtOAc, 6:4 with 5 vol% of Et_3N) followed by crystallization from pentane or hexane.

2,4-Di-(*tert*-butyl-6-{[*trans*-2-(3,5-dimethylpyrazol-1-yl)cyclohexylimino]methyl}phenol (3a)

2,4-Di-(*tert*-butyl-6-{[*trans*-2-(3,5-dimethylpyrazol-1-yl)cyclohexylimino]methyl}phenol (36.5 mg, 77% yield) was obtained as a yellow solid after recrystallization from pentane. ^{1}H NMR ($CDCl_3$) δ: 1.26 (s, 9H), 1.41 (s, 9H), 1.46–2.24 (m, 8H), 2.09 (s, 3H), 2.19 (s, 3H), 3.67 (dt, J = 4.5, 10.8 Hz, 1H), 3.97 (m, 1H), 5.53 (s, 1H), 6.80 (d, J = 2.7 Hz, 1H), 7.30 (d, J = 2.4 Hz, 1H), 7.76 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 11.3, 14.1, 24.5, 25.8, 29.8, 31.7, 31.8, 34.4, 35.3, 61.2, 72.1, 100.1, 104.4, 117.9, 126.0, 126.7, 136.3, 139.7, 147.3, 157.8, 163.0, 166.0.

2-{[*trans*-2-(3,5-Dimethylpyrazol-1-yl)cyclohexylimino]-methyl}phenol (3b)

2-{[*trans*-2-(3,5-Dimethylpyrazol-1-yl)cyclohexylimino]-methyl}phenol (2.65 g, 89% yield) was obtained as an orange solid. ^{1}H NMR ($CDCl_3$) δ: 1.40–2.00 (m, 8H), 2.07 (s, 3H), 2.20 (s, 3H), 3.95 (dt, J = 4.2, 9.9 Hz, 1H), 3.70 (m, 1H), 5.56 (s, 1H), 6.79–7.26 (m, 4H), 7.71 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 11.1, 13.8, 24.2, 25.5, 31.4, 33.8, 60.9, 72.1, 104.4, 117.0, 118.7, 118.9, 131.6, 132.3, 140.0, 147.7, 161.1, 165.4.

Benzylidene[*trans*-2-(3,5-dimethylpyrazol-1-yl)cyclohexyl]amide (3c)

Benzylidene[2-(3,5-dimethylpyrazol-1-yl)cyclohexyl]amide (1.69 g, 75% yield) was obtained as a yellow solid (purified by column chromatography and then recrystallized from pentane); mp 89 °C. ^{1}H NMR ($CDCl_3$) δ: 1.10–2.25 (m, 8H), 2.11 (s, 3H), 2.18 (s, 3H), 3.61 (dt, *J* = 4.5, 10.5 Hz, 1H), 4.02 (m, 1H), 5.50 (s, 1H), 7.32–7.50 (m, 5H), 7.64 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 11.5, 14.1, 24.5, 25.8, 31.4, 33.9, 60.9, 74.1, 103.9, 127.9, 128.4, 130.4, 136.4, 139.8, 147.0, 161.00.

[*trans*-2-(3,5-Dimethylpyrazol-1-yl)cyclohexyl]-(2-fluorobenzylidene)amine (3d)

[2-(3.5-Dimethylpyrazol-1-yl)cyclohexyl]-(2-fluorobenzylidene)amine (21 mg, 70% yield) was obtained as a beige solid; mp 74 °C. ^{1}H NMR ($CDCl_3$) δ: 1.40–2.40 (m, 8H), 2.16 (s, 3H), 2.21 (s, 3H), 3.70 (dt, *J* = 4.2, 10.5 Hz, 1H), 4.07 (m, 1H), 5.56 (s, 1H), 6.98–7.82 (m, 4H), 8.05 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 11.3, 13.8, 24.2, 25.6, 31.2, 33.7, 60.8, 74.4, 104.0, 115.9 (d, *J* = 84.3 Hz), 124.0, 124.3, 127.5, 132.1 (d, *J* = 34 Hz), 139.9, 147.5, 154.8, 164.0. ^{19}F NMR ($CDCl_3$) δ: –122.1 (dq, *J* = 5.7, 7.5 Hz).

(*S*)-(*S*)-2,4-Di-*tert*-butyl-6-{[*trans*-2-(5-phenyltetrazol-2-yl)cyclohexylimino]methyl}phenol (4a)

(*S*)-(*S*)-2,4-Di-*tert*-butyl-6-{[*trans*-2-(5-phenyltetrazol-2-yl)cyclohexylimino]methyl}phenol (210 mg, 95% yield) was obtained as a yellow solid after recrystallization from pentane. ^{1}H NMR ($CDCl_3$) δ: 1.18 (s, 9H), 1.28 (s, 9H), 1.48–2.34 (m, 8H), 3.91 (dt, *J* = 4.8, 10.8 Hz, 1H), 5.01 (m, 1H), 6.87 (d, *J* = 2.4 Hz, 1H), 7.30 (d, *J* = 2.4 Hz, 1H), 7.7.43–8.01 (m, 5H), 8.15 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 24.1, 24.8, 29.5, 29.6, 31.5, 31.6, 31.1, 34.2, 35.2, 68.0, 71.1, 117.7, 126.3, 127.1, 127.5, 129.0, 130.3, 136.8, 140.3, 158.0, 164.8, 166.9.

(*S*)-(*S*)-[2,6-Di-*trans*-(5-phenyltetrazol-2-yl)cyclohexyl]pyridin-2-yl methyleneamine (4b)

(*S*)-(*S*)-[2,6-Di-*trans*-(5-phenyltetrazol-2-yl)cyclohexyl]pyridin-2-yl methyleneamine (142 mg, 97% yield) was obtained as a beige solid after recrystallization from pentane. ^{1}H NMR ($CDCl_3$) δ: 1.50–2.30 (m, 8H), 3.92 (dt, *J* = 5.1, 9.9 Hz, 1H), 5.07 (m, 1H), 7.40 (m, 3H), 7.55 (t, *J* = 7.8 Hz, 0.5H), 7.77 (d, *J* = 7.8 Hz, 1H), 8.02 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 24.1, 25.1, 32.0, 33.7, 67.9, 72.2, 122.5, 126.8, 127.7, 128.7, 130.0, 136.8, 153.5, 162.2, 164.6.

(*S*)-(*S*)-[*trans*-2-(5-Phenyltetrazol-2-yl)cycloexyl]pyridin-2-yl methyleneamine (4c)

(*S*)-(*S*)-[*trans*-2-(5-Phenyltetrazol-2-yl)cyclohexyl]pyridin-2-yl methyleneamine (123 mg, 93% yield) was obtained as a pale brown solid. ^{1}H NMR ($CDCl_3$) δ: 1.50–2.30 (m, 8H), 4.00 (dt, *J* = 4.8, 10.2 Hz, 1H), 5.12 (m, 1H), 7.17–8.50 (m, 7H), 8.15 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 24.1, 25.0, 32.0, 33.6, 67.8, 72.1, 121.5, 124.8, 126.7, 127.5, 128.7, 130.0, 136.4, 149.1, 153.8, 162.4, 164.5.

5-Phenyl-2-((*R*)-(*R*)-*trans*-2-pyridin-1-ylcyclohexyl)-2*H*-tetrazole (5)

trans-2-(3,5-Dimethylpyrazol-1-yl)cyclohexylamine (100 mg, 0.411 mmol) 1,4-dibromobutane (54 μL, 0.452 mmol, 1.1 equiv.), and 68 mg (0.822 mmol, 2 equiv.) of $NaHCO_3$ in toluene (1 to 2 mL) were refluxed under N_2 with good stirring and Dean–Stark removal of water for 19–24 h (controlled by TLC). The reaction mixture was concentrated and purified by column chromatography (hexane with 5 vol% of Et_3N, then hexane–EtOAc, 6:4 with 5 vol% of Et_3N). 5-Phenyl-2-(*trans*-2-pyridin-1-ylcyclohexyl)-2*H*-tetrazole (230 mg, 77% yield) was obtained as a brown solid. ^{1}H NMR (CD_2Cl_2) δ: 1.30–2.10 (m, 6H), 1.92 (br s, 2H), 2.18 (br s, 2H), 2.39 (br s, 2H), 2.69 (br s, 2H), 3.36 (br s, 1H), 4.85 (br s, 1H), 7.40–8.20 (m, 5H). ^{13}C NMR (CD_2Cl_2) δ: 23.9, 24.8, 25.1, 25.3, 31.1, 31.8, 32.9, 47.7, 62.2, 66.1, 127.0, 128.2, 129.0, 130.1, 164.4.

General procedure for ^{1}H NMR studies

The ligand (0.02 mmol) in CD_2Cl_2 was mixed at room temperature with 0.02 mmol of $CuOTf{\cdot}0.5C_6H_6$, stirred at room temperature for 1 h, and filtered. In the case of **4b**, upon mixing in an 1:1 ratio (Cu^I/L), part of the metal complex did not dissolve. A sample of 1:2 ratio (Cu^I/L) was prepared, which showed the same ^{1}H NMR spectra as the first sample.

Cu^I coordination to 3d

^{1}H NMR (CD_2Cl_2) δ: 1.44–1.61 (m, 2H), 1.85–2.60 (m, 6H), 2.12 (s, 3H), 2.34 (s, 3H), 3.90 (br s, 1H), 4.45 (br s, 1H), 5.87 (s, 1H), 7.03–7.79 (m, 4H), 8.25 (s, 1H). ^{19}F NMR (CD_2Cl_2) δ: –122.1 (dq, *J* = 5.7, 7.5 Hz).

Cu^I coordination to 4b

The NMR sample gave red crystals of complex **1.23** after storage at room temperature for several days in an inert atmosphere upon slow addition of hexane. These sample crystals were further characterized by X-ray analysis. ^{1}H NMR (CD_2Cl_2) δ: 1.26–2.23 (m, 8H), 3.95 (br s, 1H), 5.11 (br s, 1H), 7.52 (br s, 3H), 7.85 (m, 1H), 8.01 (t, *J* = 8 Hz, 0.5H), 8.10 (m, 2H).

Cu^I coordination to 5

^{1}H NMR (CD_2Cl_2) δ: 1.50 (m, 2H), 1.86–2.20 (m, 8H), 2.39 (m, 2H), 2.78 (br s, 1H), 3.04 (br s, 1H), 3.77 (m, 1H), 4.00 (m, 1H), 5.39 (m, *J* = 4.4, 10.8 Hz, 1H), 7.50 (m, 3H), 8.17 (d, *J* = 7.2 Hz, 2H), 9.09 (br s, 1H).

General procedure for cyclopropanation

A flame-dried Schlenk flask was charged with metal precursor (2 mol%, 0.007 mol/L stock solution in CH_2Cl_2), ligand (4 mol%, 0.1 mol/L stock solution in CH_2Cl_2), and styrene (5 equiv.) and the reaction was stirred under an inert atmosphere at room temperature in approximately 1 mL of CH_2Cl_2. A solution of 1 mL (1 equiv., 1 mmol) of $N_2CHCOOMe$ in dichloromethane (1 mL) was added gradually over 8–10 h via a syringe pump and the reaction mixture was stirred for another 10–12 h. The reaction was concentrated and the product was purified by column chromatography (hexane, then hexane–EtOAc (8:2)).

2-Phenylcyclopropanecarboxylic acid methyl ester (7)

2-Phenylcyclopropanecarboxylic acid methyl ester was obtained as a colorless oil. Yield with $[RuCl_2C_6H_6]_2$ was

RAPID COMMUNICATION / COMMUNICATION RAPIDE

Anion effects in the formation of the active catalyst in the Ruhrchemie – Rhône-Poulenc aqueous biphasic hydroformylation process. Are there any?[1]

József Kovács, Ferenc Joó, and Carl D. Frohning

Abstract: The water soluble [Rh(OAc)(CO)(*m*tppms)$_2$] containing monosulfonated triphenylphosphine ligands was prepared for the first time and its hydrogenation was studied in aqueous solutions. In the presence of additional *m*tppms, the reaction yielded [RhH(CO)(*m*tppms)$_3$], a close analogue of [RhH(CO)(*m*tppts)$_3$], the immediate catalyst precursor in the Ruhrchemie – Rhône-Poulenc aqueous biphasic hydroformylation process. The extent of the [Rh(OAc)(CO)(*m*tppms)$_2$] → [RhH(CO)(*m*tppms)$_3$] transformation strongly depended on the solution pH, similar to the case of the hydrogenation of [RhCl(CO)(*m*tppms)$_2$] studied earlier. In this respect, $RhCl_3$·aq and $Rh(OAc)_3$·aq can be used equally well for the in situ preformation of [RhH(CO)(*m*tppts)$_3$], although the latter is the preferred choice in the industrial process.

Key words: rhodium, water-soluble, hydrides, sulfonated phosphines, biphasic.

Résumé : On a préparé pour la première fois les complexes [Rh(OAc)(CO)(*m*tppms)$_2$] qui sont solubles dans l'eau et qui contiennent des ligands triphénylphosphines monosulfonées et on a étudié leur hydrogénation dans des conditions aqueuses. En présence de *m*tppms additionnel, la réaction a conduit à la formation du [RhH(CO)(*m*tppms)$_3$], un analogue apparenté au [RhH(CO)(*m*tppts)$_3$], le précurseur immédiat du catalyseur utilisé dans le procédé d'hydroformylation biphasique aqueuse de la société Ruhrchemie – Rhône-Poulenc. Le degré de transformation de [Rh(OAc)(CO(*m*tppms)$_2$] → [RhH(CO)(*m*tppms)$_3$] dépend fortement du pH de la solution, ce qui est semblable à ce qui a été observé antérieurement dans le cas de l'hydrogénation du [RhCl(CO)(*m*tppms)$_2$]. À cet effet, le $RhCl_3$·aq et le $Rh(OAc)_3$·aq peuvent être utilisés aussi bien l'un que l'autre pour la préformation in situ du [RhH(CO)(*m*tppts)$_3$], même si le dernier est préféré dans le procédé industriel.

Mots clés : rhodium, soluble dans l'eau, hydrures, phosphines sulfonées, biphasique.

[Traduit par la Rédaction]

Introduction

The Ruhrchemie – Rhône-Poulenc process for the aqueous/organic biphasic hydroformylation of propene (1–3) was introduced into the industrial scene more than two decades ago. The key to the success of this process was the invention of an utterly hydrophilic, active, and stable catalyst [RhH(CO)(*m*tppts)$_3$] (*m*tppts = 3,3′,3″-phosphinetriylbenzenesulfonic acid, *meta*-trisulfonated triphenylphosphine) (4). In practice, the catalyst is *preformed* from suitable precursors, most commonly from hydrated rhodium(III) acetate and *m*tppts under synthesis gas pressure, and used without isolation (5). Under actual hydroformylation conditions, [RhH(CO)(*m*tppts)$_3$] is involved in various chemical equilib-

ria, leading to the formation of $[RhH(CO)_2(mtppts)_2]$, $[RhH(CO)_2(mtppts)]$, and $[RhH(CO)(mtppts)_2]$ (2–5). Of these compounds, $[RhH(CO)(mtppts)_2]$ is the active catalyst for the formation of linear products, and these equilibria have been studied in detail (6) to obtain optimum rate and selectivity performance of the in situ formed catalyst.

Despite the continuous research and development, a few questions with regard to the reaction mechanism still deserve scrutiny. One of these is the effect of pH on the rate of hydroformylation. It is known that an increase in pH from 5.5 to 7.5 brings about a 35% increase in the reaction rate of the hydroformylation of propene (1). A similar rate increase was observed in the reaction of octene-1 (7). Since the chemical reaction does not involve H^+ or OH^-, the answer may involve the pH-sensitivity of the formation and further equilibria of the catalytically active rhodium complexes.

Some time ago, it was shown that the hydrogenation of the related, water-soluble $[RhCl(CO)(mtppms)_2]$ complex (*m*tppms = (3-diphenylphosphino)benzenesulfonic acid, *meta*-monosulfonated triphenylphosphine) in aqueous solution was, indeed, governed by the pH (8). In the presence of excess *m*tppms and chloride, the hydrogenation of $[RhCl(CO)(mtppms)_2]$ to yield $[RhH(CO)(mtppms)_3]$ did not take place below pH 4.5 but reached 100% conversion at pH 10. Importantly, at basicities between pH 5 and 8, the conversion increased gradually with the gradual increase of pH, and that referred to a pH-dependent mobile equilibrium (eq. [1]).

$$[1] \quad [RhCl(CO)(mtppms)_2] + mtppms + H_2 = [RhH(CO)(mtppms)_3] + H^+ + Cl^-$$

Although the conditions of this model study and those of the industrial hydroformylation strongly differ, one may expect similar equilibria be involved in the pH dependence of the hydroformylation reaction. However, albeit hydrated $RhCl_3$ is a suitable starting material for the synthesis of $[RhH(CO)(mtppts)_3]$, industry prefers $Rh(OAc)_3$·aq ($OAc^- = CH_3COO^-$) for the preformation of the catalyst to avoid the presence of the strongly nucleophilic chloride (4, 5). On the contrary, the pH-static hydrogenations [8] were performed at constant ionic strength maintained by KCl. The question arose, therefore, whether it is justified to draw conclusions regarding the pH effects on the formation of $[RhH(CO)(mtppts)_3]$ based on studies of chloride-containing systems, or to put it another way, whether there is an effect of the anion of the precursor on the formation of this hydroformylation catalyst. In the following, we report the results of a pH-static hydrogenation study of $[Rh(OAc)(CO)(mtppms)_2]$ under chloride-free conditions.

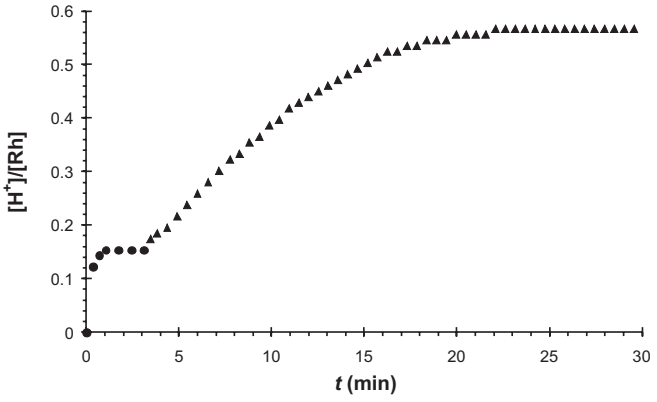
Experimental

All manipulations were done under an argon or nitrogen atmosphere. All solvents were purified by distillation and carefully deaerated before use.

IR spectra were recorded on a PerkinElmer Paragon 1000 PC FT-IR spectrometer in KBr discs. ^1H and ^{31}P NMR spectra were recorded on Bruker AV 360 equipment in D_2O or $(CD_3)_2SO$ (DMSO-d_6). Chemical shifts are referenced to residual solvent peaks further referenced to external 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) sodium salt (^1H) and 85% H_3PO_4 (^{31}P), respectively. Conditions of the pH-potentiometric measurements are described in detail in refs. 9 and 10.

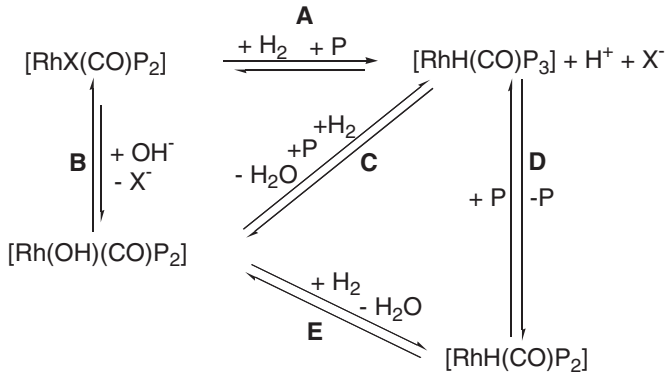
$RhCl_3$·aq was purchased from the Pressure Chemical Co. (Pittsburgh, Pennsylvania), D_2O and DMSO-d_6 from Cambridge Isotope Laboratories, and H_2, N_2, Ar, and CO from Linde (Hungary). Other reagents were obtained from Aldrich and used without further purification. *m*tppms (Na^+-salt) (11) and $[Rh(OAc)_2]_2$·2MeOH (12) were prepared as described in the literature.

$[Rh(OAc)(CO)(mtppms)_2]$ was prepared by a modification of the literature method (13) for the synthesis of $[Rh(OAc)(CO)(PPh_3)_2]$. To a suspension of 0.1 g (0.4 mmol Rh) $[Rh(OAc)_2]_2$·2MeOH in 10 mL ethanol was added 0.25 mL of 50% HBF_4 and the solution was stirred at 60 °C for 20 h. To the resulting green solution, a solution of 640 mg (1.6 mmol) *m*tppms and 545 mg (4 mmol) $NaOAc·3H_2O$ in 10 mL ethanol was added at room temperature and the mixture was refluxed for 3 h. An orange solid separated that was filtered and washed with ethanol. This raw product ($[Rh(OAc)(mtppms)_3]$ together with inorganic impurities, NaOAc, $NaBF_4$) can be directly used for further synthesis. It was suspended in 5 mL of fresh ethanol, and bubbled with CO at room temperature, upon which the color changed gradually to orange then to yellow with dissolution of the solid. The reaction with CO overnight gave a cream-coloured precipitate. The *complex* was filtered, washed with ethanol, and dried. Weight: 300 mg (67% overall yield). IR (cm^{-1}): 1978 ν(CO), 1399 ν_s(COO), 1579 ν_{as}(COO), 1038, 1195 ν(SO_3). ^1H NMR (360 MHz, DMSO-d_6, r.t., ppm) δ: 0.67 (s, CH_3COO), 6 to 7 (m, aromatic protons). ^{31}P NMR (360 MHz, DMSO-d_6, r.t., ppm) δ: 35.3 (d, ^1J(Rh-P) = 138 Hz). Anal. calcd. (%): C 47.28, H 3.97, S 6.47; found: C 46.30, H 4.07, S 6.49.



Results and discussion

$[Rh(OAc)(CO)(mtppms)_2]$ was synthesized for the first time by a modified procedure of Mitchell et al. (13) for the synthesis of $[Rh(OAc)(CO)(PPh_3)_2]$, based on the reaction of the green dirhodium(II) cation (Rh_2^{4+}) with *m*tppms) followed by carbonylation with CO. Replacement of PPh_3 with *m*tppms in the procedure described by Spencer (14) for the preparation of $[Rh(OAc)(PPh_3)_3]$ from $RhCl_3$·aq did not yield the expected acetatorhodium(I) complex, but afforded $[RhCl(mtppms)_3]$. The cream-coloured $[Rh(OAc)(CO)(mtppms)_2]$ dissolves well in water and in DMSO, but is only slightly soluble in ethanol and insoluble in apolar organic solvents. According to the IR and NMR spectra, it has a square-planar geometry with a monodentate acetato ligand (ν_{as}(COO) – ν_s(COO) = 180 cm^{-1}) (15) and with the phosphine ligands in the trans position.



Aqueous solutions of $[Rh(OAc)(CO)(mtppms)_2]$ react with H_2 and in the presence of excess *m*tppms yield the known $[RhH(CO)(mtppms)_3]$ (8, 16). This reaction was studied in a pH-static hydrogenation apparatus as described in detail for $[RhH(CO)(mtppms)_3]$ (8). Briefly, the pH of the deoxygenated solvent (0.1 mol/L $NaClO_4$ to maintain constant ionic strength) was set to a given value in the range $4 < pH < 10$ using $HClO_4$ or KOH, and a known amount of the complex was dissolved in it under an argon atmosphere. Fig. 1. Proton production upon dissolution (●) and subsequent hydrogenation (▲) of [Rh(OAc)(CO)(*m*tppms)$_2$]. [Rh] = 1.8 mmol/L, [*m*tppms] = 5.4 mmol/L, [$NaClO_4$] = 0.1 mol/L, pH = 7.0, $p(H_2)$ = 1 bar (1 bar = 100 kPa), T = room temperature.

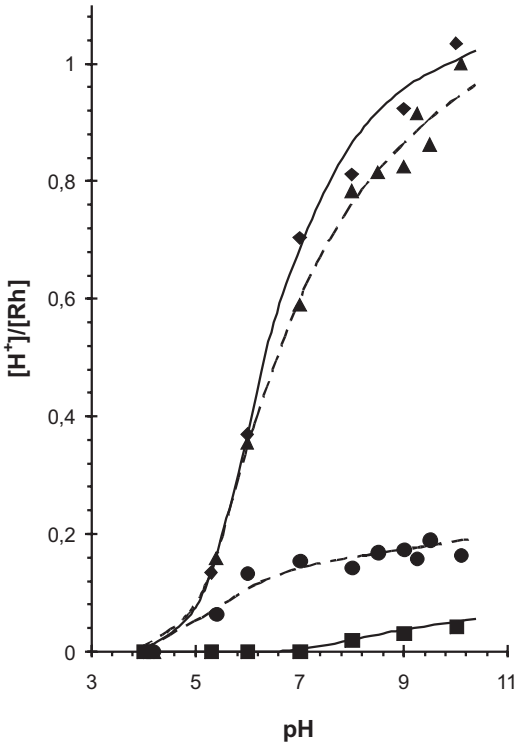

Scheme 1. Equilibria in solutions of [RhX(CO)P$_2$] (X = OAc$^-$ or Cl$^-$, P = *m*tppms) under H_2 in the presence of excess *m*tppms.

pending on the actual pH, hydrolysis of the complex to [Rh(OH)(CO)(*m*tppms)$_2$], the *m*tppts analog of which is described in ref. 17, occurred to a certain extent, resulting in proton release to the solution. However, the acid formed in this reaction was neutralized by KOH supplied by the autoburette and the pH remained constant; furthermore, the extent of hydrolysis could be calculated from the volume (amount) of KOH consumed. Figure 1 shows such a "titration curve" and the first "step" on the graph refers to the hydrolysis of the complex under an inert atmosphere (at the particular pH, i.e., 7.0 used in the experiment). Bubbling H_2 through the equilibrated solution resulted in further KOH consumption, indicating a heterolytic split of H_2 in its reaction with [Rh(OAc)(CO)(*m*tppms)$_2$] (and with [Rh(OH)(CO)(*m*tppms)$_2$] produced by the partial hydrolysis). This is the second step on Fig. 1. The reactions involved are shown on Scheme 1. Of particular interest is the fact that at this pH, the [H$^+$]/[Rh] ratio levels off at about 0.55 showing that only 55% (i.e., by far less than 100%) of all Rh reacted to yield [RhH(CO)(*m*tppms)$_3$].

Similar measurements were made at several pH values and the results are shown on Fig. 2. It is seen that [Rh(OAc)(CO)(*m*tppms)$_2$] does not react with H_2 below pH 4. However, the [H$^+$]/[Rh] ratio increases steadily with

Fig. 2. Proton production upon dissolution (●, ■) and subsequent hydrogenation (▲, ◆) of [Rh(OAc)(CO)(*m*tppms)$_2$] (●, ▲) and [RhCl(CO)(*m*tppms)$_2$] (■, ◆) at various pH. Conditions (●, ▲): [Rh] = 1.8 mmol/L, [*m*tppms] = 5.4 mmol/L, [$NaClO_4$] = 0.1 mol/L, $p(H_2)$ = 1 bar (1 bar = 100 kPa), T = room temperature; (■, ◆): [Rh] = 2.4 mmol/L, [*m*tppms] = 7.2 mmol/L, [$NaClO_4$] = 0.1 mol/L, $p(H_2)$ = 1 bar (1 bar = 100 kPa), T = 35 °C.

increasing pH showing that the reaction goes more and more extensively towards the formation of [RhH(CO)(*m*tppms)$_3$], reaching a practically complete conversion at pH 10. It is important to note that all reactions in Scheme 1 are reversible, and the pH-static hydrogenations reveal the extent to which [Rh(OAc)(CO)(*m*tppms)$_2$] (together with [Rh(OH)(CO)(*m*tppms)$_2$]) are converted to [RhH(CO)(*m*tppms)$_3$]. This extent is strongly pH dependent. Taking the closely similar chemical properties of *m*tppms and *m*tppts, we may assume that during the preformation of the catalyst in the Ruhrchemie – Rhône-Poulenc process [RhH(CO)(*m*tppts)$_3$] takes part in similar equilibria. Since [RhH(CO)(*m*tppts)$_3$] is the immediate precursor of the true hydroformylation catalysts (under syngas [RhH(CO)$_2$(*m*tppts)] and [RhH(CO)(*m*tppts)$_2$]), the actual proportion of rhodium that may enter the catalytic cycle(s) is strongly influenced by the pH, and this explains (at least in part) the higher catalytic activities observed at pH 7.5 vs. 5.5.

Data of the pH-static hydrogenation of [RhCl(CO)(*m*tppms)$_2$] are also shown in Fig. 2 for comparison. It can be concluded that there is no substantial effect of the anionic ligand (Cl$^-$ or OAc$^-$) on the pH dependence of the formation of [RhH(CO)(*m*tppms)$_3$]. In aqueous solutions, the heterolytic split of H_2 by transition metal complexes (such as shown by rxn. [1] and Scheme 1) is largely facilitated (18, 19) by the strong

© 2005 NRC Canada

hydration of the resulting H^+, $\Delta H^\circ_{hyd} = -1091$ kJ mol^{-1} (20), and the particular anion. It seems that the relatively small difference in the hydration ethalpies of Cl^- and OAc^-, –381 kJ mol^{-1} (20) and –334 kJ mol^{-1} (21), respectively, does not modify substantially the overall energy balance. The hydration enthalpy of OH^-, $\Delta H^\circ_{hyd} = -460$ kJ mol^{-1} (20), is higher than that of Cl^- and OAc^-; furthermore, formation of H_2O adds an additional driving force to reaction **E** (Scheme 1), so [Rh(OH)(CO)(*m*tppms)$_2$] is expected to react preferentially over [Rh(OAc)(CO)(*m*tppms)$_2$] and [RhCl(CO)(*m*tppms)$_2$]. Whether [RhH(CO)(*m*tppms)$_3$] (the resting state of the catalyst at high phosphine concentrations) is formed on path **A**, on path (**B** + **C**), or on path (**A** + **E** + **D**) is not known from these investigations, but its equilibrium concentration is pH-governed, independent of the way of formation. [Rh(CO)(OAc)(*m*tppms)$_2$] shows a somewhat higher tendency towards hydrolysis than [RhCl(CO)(*m*tppms)$_2$], although at room temperature, the extent of this hydrolysis does not exceed 20%.

Based on the above findings, it can be concluded that the pH of the aqueous phase has the same effect on the catalytic activity of Rh(I)-carbonyl-hydrides independent of the anion of the precursor being chloride or acetate. Nevertheless, the industrial preference for Rh(III)-acetate may be justified on other grounds, e.g., less corrosion or more favourable kinetics of the preformation of the catalyst. It is understood that the chemistry going on in the industrial hydroformylation reactor is far more complex than that described in this communication, and that the operational conditions of the Ruhrchemie – Rhône-Poulenc process for the aqueous/organic biphasic hydroformylation of propene (120 °C, 50 bar syngas (1 bar = 100 kPa)) are far from those of our measurements. This may influence the *positions* of the equilibria on Scheme 1, however, no other species were detected under pressure in case of the related *m*tppts complexes (6). Therefore, we think that the pH effects observed under more realistic hydroformylation conditions (1, 7) can also be related to the base-promoted formation of the actual hydroformylation catalysts, [RhH(CO)$_2$(*m*tppts)] and [RhH(CO)(*m*tppts)$_2$], as described previously.

RAPID COMMUNICATION / COMMUNICATION RAPIDE

Synthesis, characterization, and reactivity of the first hafnium alkyl complex stabilized by amidate ligands[1]

Robert K. Thomson, Brian O. Patrick, and Laurel L. Schafer

Abstract: A photo and thermally stable bis(amidate)–dibenzyl complex of Hf ($[^{DMP}(NO)^{Ph}]_2Hf(CH_2Ph)_2$(THF) (**2a**) was formed as a monosolvated THF adduct in near quantitative yield from $Hf(CH_2Ph)_4$ and *N*-2,6-dimethylphenyl(phenyl)amide (**1**). Isomerization between the THF-bound product and the THF-free product can be observed visually by the conversion from a red-orange product at low temperatures to a pale yellow product at high temperatures. Solid-state crystallographic characterization of the orange product confirmed its constitution as a monosolvated species. Kinetic parameters for the exchange of the THF moiety were determined from variable-temperature NMR experiments. The product of the hydrolysis of the Hf dibenzyl species by water was characterized by X-ray crystallography, and was found to be a rare tetrametallic Hf oxo cluster species (**3**).

Key words: hafnium, protonolysis, amidate, coordination chemistry, organometallic chemistry, exchange processes.

Résumé : Un complexe de bis(amidate)–dibenzyle de Hf ($[^{DMP}(NO)^{Ph}]_2Hf(CH_2Ph)_2$(THF) (**2a**) qui est stable à la lumière et à la chaleur a été formé comme adduit monosolvaté de THF avec un rendement presque quantitatif de $Hf(CH_2Ph)_4$ et *N*-2,6-dimethylphenyl(phenyl)amide (**1**). L'isomérisation entre le produit avec THF et le produit sans THF peut être observée visuellement par la conversion d'un produit rouge-orange aux températures basses en un produit jaune pâle aux températures élevées. La caractérisation cristallographique du produit orange à l'état solide a confirmé sa constitution comme l'espèce monosolvaté. Des paramètres cinétiques pour l'échange du THF ont été déterminés à partir d'expériences de RMN à la température variable. Le produit d'hydrolyse de l'espèce dibenzyle de Hf par l'eau a été caractérisé par cristallographie de rayons X et c'est une espèce rare d'agrégat oxotétramétallique de Hf (**3**).

Mots clés : hafnium, protonolyse, amidate, la chimie de coordination, la chimie organométallique, processus d'échange.

Introduction

Much of the recent research in Group 4 metal chemistry has involved the development of new non-cyclopentadienyl (Cp) ligands and the exploration of their reactivity (1). In recent reports from our research group, we have shown that amidate ligands are versatile ancillary ligands for Group 4 metals (2–4). The amide proligands are highly modifiable and are synthesized in a modular manner, making them attractive alternatives to Cp (Fig. 1). The amide proligands have a pK_a of approximately 15, which makes protonolysis a highly useful method of synthesizing metal complexes.

In particular, we have shown that the synthesis of bis(amidate)–bis(amido) complexes of Ti and Zr is facile and high yielding, and can be accomplished via protonolysis of commercially available tetrakisamido metal starting materials (2, 3). Since amidate ligands have been underexplored in early transition metal chemistry, there is a need to discover the general utility of these ligands to support reactive metal centers. To this end, here we report the first examples of stable bis(amidate)–dibenzyl complexes of Hf. The stability and coordination geometry of this new class of complexes has been established by X-ray crystallographic analysis as well as VT NMR spectroscopic investigations.

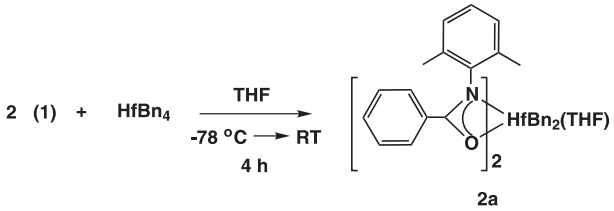
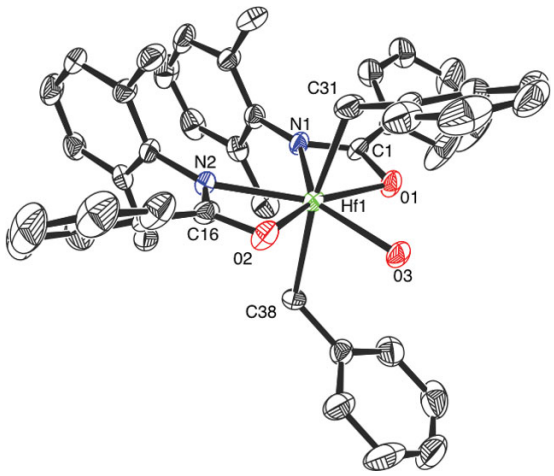
Fig. 1. Amide proligand set $[^{R'}(NO)^{R}]H$.



Results and discussion

Easily assembled modular ligand systems are important in expediting the discovery of catalyst systems for various organic transformations (5). Organic amides offer an easily modified scaffold for the study of ligand-based effects in their resultant transition metal complexes. A general synthetic scheme for the preparation of organic amides is shown in eq. [1]. Elimination of HCl upon reaction of an acid chloride and a primary amine results in the formation of the desired amide product in high yields (75%–95% yield). Purification of these proligands for use in metal chemistry can be accomplished by vacuum sublimation or recrystallization from an appropriate solvent. Proligand **1** (*N*-2,6-dimethylphenyl(phenyl)amide) was synthesized in excellent yield. Purification via recrystallization from $CHCl_3$ at –20 °C and

[1] 



subsequent drying while heating under vacuum overnight gave pure proligand **1** in 64% yield.

Protonolysis reactions have been utilized successfully in the synthesis of amidinate (6) and guanidinate (7) complexes of the Group 4 metals. Given the structural similarity of the amidate ligand motif, protonolysis was anticipated to be an efficient route into analogous amidate complexes. The protonolysis methodology used to form this bis(amidate)–bis(alkyl) Group 4 metal complex (**2a**) was facile and high yielding (eq. [2]). Freshly prepared and recrystallized $Hf(CH_2Ph)_4$ was combined with 2 equiv. of proligand **1** ($[^{DMP}(NO)^{Ph}]H$) in a darkened Schlenk flask, which was cooled to –78 °C before introduction of THF via cannula transfer. Warming to room temperature resulted in the for-

[2] 

mation of a bright red-orange solution, which was concentrated in vacuo to give a bright orange powder in 98% crude yield. Low temperatures utilized during this process were necessary to control the rate of reaction, as reaction at room temperature results in the formation of the desired product contaminated with a homoleptic side-product. In addition, the starting material ($Hf(CH_2Ph)_4$) is well-known to exhibit a high sensitivity towards ambient visible light, and the

Fig. 2. ORTEP depiction of the solid-state molecular structure of $[^{DMP}(NO)^{Ph}]_2Hf(CH_2Ph)_2(THF)$ (**2a**) (the THF ring at O3 has been omitted for clarity).

protonolysis of the Hf—C bonds proceeds very rapidly and exothermically because of the low pK_a of the organic amide proligands.

Purification of this complex in moderate yield can be achieved by recrystallization from a concentrated solution of **2a** in hexanes, giving orange single crystals. X-ray crystallographic analysis of this complex revealed that the bis(amidate)–dibenzyl species is monosolvated by THF in the solid state, as shown in Fig. 2. Selected bond lengths and angles are found in Table 1 and crystallographic details are located in Table 2.

The solid-state structure of **2a** exhibits pseudo-C_{2v} symmetry in a slightly distorted pentagonal bipyramidal geometry. This coordination geometry has been previously observed for seven-coordinate salen complexes of Hf (8), acetylacetonato complexes of Zr (9), and structurally related monothiocarbamate and dithiocarbamate complexes of Ti (10, 11). Both amidate ligands in **2a** are found in the equatorial plane, with the O atoms nearly trans to each other at 156°. A bound THF molecule occupies the final equatorial coordination site. The plane containing Hf and the N and O donor atoms is nearly perfectly planar, with the sum of the bond angles about the Hf center being 360.2°. In the axial positions, the two benzyl groups are located 169.8° apart. As expected, the Hf1—O3 bond length of the coordinated THF (2.236 Å) is significantly longer than the Hf1—O1 and Hf1—O2 bond lengths (2.161 and 2.174 Å, respectively). Bond lengths between the amidate N atoms and the Hf center are somewhat longer than the corresponding Hf – amidate O bond lengths (Hf1—N1 = 2.265 Å, Hf1—N2 = 2.258 Å), indicating that the amidate ligands are bound in an alkoxy-imine fashion (2). Unexpected elongation of the C—N bond in the ligand backbone is also observed; however, the steric bulk at the N of the amidate ligands precludes the formation of the anticipated shorter C—N bond. This ligand binding motif has been seen previously by our group for bis(amidate)-bis(amido) complexes of Ti and Zr (2, 4). There are some variations from expected bond lengths, which may be due to the unique π-stacking interactions present between the coplanar *N*-aryl rings of the amidate ligands, whose centroids are separated by approximately 3.6 Å. Intramolecular

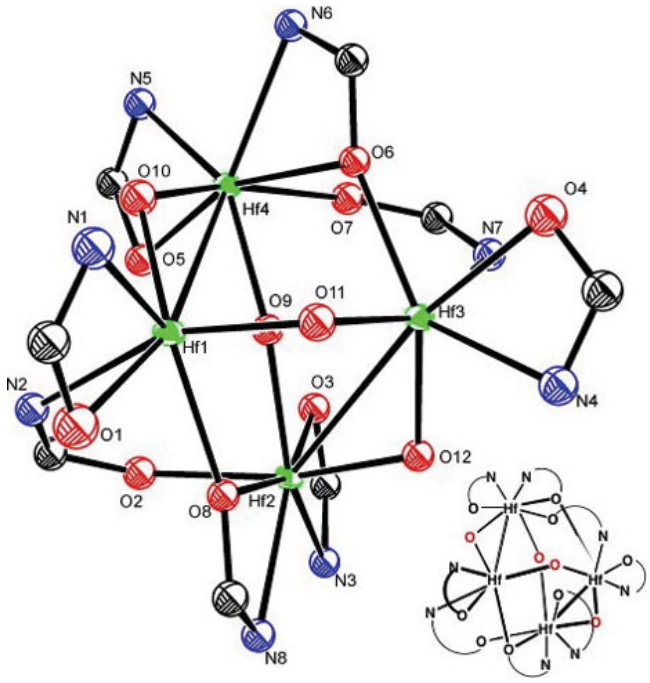
monometallic π-stacking interactions of this type are rare, but the phenyl ring separation of 3.6 Å is consistent with a previously reported π-stacking interaction in a Ti – late metal bimetallic species, in which the interactions ranged between 3.51 and 3.77 Å (12). In our case, the bulky 2,6-dimethylphenyl rings orient themselves in a cis fashion in the crystal structure and are stabilized by the π interaction between them. Furthermore, the difference between the two ligand C—O, C—N bond asymmetries may be due to the slight canting of the rings to one side, resulting in more steric crowding of the C16—N2 bond than the C1—N1 bond. These observations could also be due to crystal packing effects.

^{1}H and ^{13}C NMR spectra of the recrystallized orange product indicate that the solid state C_{2v} symmetry of this species is maintained in solution at room temperature. A single resonance is seen for the aryl methyl protons at δ 2.34 ppm, and the requisite singlet for the benzylic methylene protons is present at δ 2.55 ppm. Bound THF peaks are also present at δ 1.64 and 3.83 ppm. The ^{13}C NMR spectrum showed a broadened signal at δ 81.64 ppm, which was correlated to the broadened THF OCH_2CH_2 proton signal at δ 3.83 ppm in the ^{1}H NMR spectrum by ^{1}H^{13}C HMQC. Dissolution of the orange crystals of **2a** in C_6D_6 at room temperature immediately resulted in a light orange solution. Warming of the tube resulted in a color change to pale yellow, and cooling of the tube to temperatures at or below 0 °C was accompanied by a color change to a deep orange. Given these preliminary observations, we suspected that the THF solvated complex **2a** is stable in the solid state, but undergoes exchange to the unsolvated species **2b** in solution (eq. [3]).

Variable-temperature NMR experiments were performed on the orange product **2a** to verify the THF exchange process and to determine the activation energy ($\Delta G^{\ddagger}$) and the rate of exchange (k_{solv}). The two bound THF peaks are observed to broaden in response to decreased temperature. The peak at δ 3.59 ppm is observed to broaden and split into two peaks at δ 4.12 and 3.50 ppm that sharpen at –50 °C. The coalescence temperature for these two peaks, corresponding to bound and free THF, respectively, occurs at (–25 ± 5) °C. The rate constant for the THF exchange process was calculated to be (560 ± 110) s^{-1}, and the activation energy for this process was likewise found to be (47 ± 1.5) kJ mol^{-1}.[3] To verify that the yellow product observed at higher temperatures was desolvated, this compound was isolated as a powder by removing all solvent at elevated temperatures. The ^{1}H NMR spectrum of this compound does not show the presence of any THF. Independent synthesis of the yellow product in toluene yielded material that gave identical NMR spectroscopic data as seen in the aforementioned preparation of **2b**. Ongoing investigations are focused on complete structural characterization of this complex.



[3] 

Although complexes **2a** and **2b** are stable to ambient light and heat (prolonged heating at 80 °C resulted in slow decomposition), they are highly sensitive to moisture and can be hydrolyzed by the presence of trace amounts of H_2O. Slow hydrolysis of **2a** by reaction with adventitious water resulted in the formation of the novel tetrametallic-bridged oxo species shown in Fig. 3. Complex **3** exhibits C_2 symme-

[3] Determined by NMR methods as described in ref. 13.

Fig. 3. ORTEP representation of the solid-state molecular structure of $\{[^{DMP}(NO)^{Ph}]_2Hf(\mu\text{-}O)\}_4$ (**3**) (the aryl rings have been omitted for clarity).

try in the solid state, with two pairs of different bridging oxo ligands, depicted in Fig. 3. Selected bond lengths and angles are given in Table 3, and crystallographic data is located in Table 4. The C_2 axis is located along the vector joining O9 and O11. It can also be seen that half of the amidate ligands are bound η^2 to a single Hf center analogous to complex **2**, and the other half are bridging between two adjacent Hf atoms. This is the first example of these bulky amidate ligands adopting a bridging mode for Group 4 metals. Independent synthesis of the hydrolyzed product resulted in the formation of an insoluble white powder that has resisted recrystallization. EI-MS data of this species did not give a parent ion, however, monomeric fragments ($[^{DMP}(NO)^{Ph}]_2HfO$) and higher order fragments ($[^{DMP}(NO)^{Ph}]_3HfO$, $[^{DMP}(NO)^{Ph}]_3Hf_2O_3$), were observed, which supports the formation of a complex oligomeric structure. Due to the low solubility of this complex, full spectroscopic characterization was not possible; however, the formation of toluene was observed and interestingly, there was no evidence of free ligand in the soluble fraction. The lack of complete hydrolysis of the amidate ligands implies that the amidate–Hf bonding interactions are strong and can act as robust ancillary ligands during reactions at the metal center. We are currently taking advantage of this observed stability and are investigating a wide range of reactivity of complexes **2a** and **2b**.

Conclusion

The first amidate-stabilized Hf alkyl complex was synthesized and structurally and spectroscopically characterized. The bis(amidate)–dibenzyl Hf species (**2a**) is pentagonal bipyramidal in the solid state, with an interesting intramolecular π-stacking interaction stabilizing the complex. Monosolvation of **2a** was observed in the solid state, with

the bound THF being coordinatively labile. The rate constant for THF exchange (k_{solv}) is (560 ± 110) s^{-1}, and the activation energy ($\Delta G^{\ddagger}$) for this process is (47 ± 1.5) kJ mol^{-1}, as determined by variable-temperature NMR spectroscopic experiments. Hydrolysis of **2a** resulted in the formation of a unique tetrametallic Hf oxo cluster species, which was also crystallographically characterized. The amidate ligands in this complex survived the hydrolysis and remained bound to Hf in either a bidentate chelating mode or as a bridge between two Hf centers.

Experimental

General information

Unless otherwise stated, all reactions were carried out using standard Schlenk line and glovebox techniques, under an atmosphere of nitrogen. Tetrahydrofuran and hexanes were purified by passage through a column of activated alumina and degassed with nitrogen. C_6D_6 was degassed and dried over molecular sieves prior to use. d^8-Toluene was purified by distillation from Na, followed by degassing and storing over molecular sieves. 2,6-Dimethylaniline, benzoyl chloride, and benzylmagnesium chloride (1 mol/L in Et_2O) were purchased from Aldrich and used without further purification. $HfCl_4$ was purchased from Strem and used as received. $Hf(CH_2Ph)_4$ was synthesized according to literature procedures and purified by recrystallization at –30 °C in the dark prior to use (14). ^1H, ^{13}C, and HMQC NMR spectra were recorded on Bruker 300 MHz or 400 MHz Avance spectrometers at ambient temperature, and chemical shifts are given relative to residual solvent. Variable-temperature ^1H NMR experiments were performed on Bruker 300 MHz or 400 MHz Avance spectrometers equipped with cryoprobes. Mass spectra were recorded on a Kratos MS-50 spectrometer using an electron impact (70 eV) source. Elemental analysis and single crystal X-ray structure determinations were performed at the Department of Chemistry, University of British Columbia.[4]

$[^{DMP}(NO)^{Ph}]H$ (1)

Ligand preparation was performed on the benchtop with no further precautions. A solution of 11.5 mL (11.3 g, 92.8 mmol) of 2,6-dimethylaniline in 75 mL of CH_2Cl_2 was stirred at room temperature. To this solution was added 12.9 mL (9.40 g, 92.8 mmol) of NEt_3 via pipette over a period of 5 min. The resulting solution was allowed to stir for 1 h before cooling to –78 °C in a dry ice – isopropanol bath. Using an addition funnel, a solution of 8.25 mL (10.0 g, 71.4 mmol) of benzoyl chloride dissolved in 50 mL of CH_2Cl_2 was added dropwise to the amine solution. The resulting colorless solution was allowed to warm to room temperature over a period of 4 h. The product was washed with 1 mol/L HCl (3 × 20 mL), 1 mol/L NaOH (20 mL), and brine (20 mL). The organic fraction was dried over anhydr. $MgSO_4$, filtered, and the solvent was removed in vacuo, giving 14.6 g of the crude product as a white microcrystalline solid (91% yield). Recrystallization from $CHCl_3$ gave 10.3 g of the purified product (64% overall yield). The final product was dried by heating under vacuum overnight at 70 °C. ^1H NMR ($CDCl_3$, 25 °C, 400 MHz) δ: 2.31 (s, 6H, Ar-CH_3), 7.18–7.30 (m, 3H, Ar-*H*), 7.55 (m, 2H, Ar-*H*), 7.63–7.75 (m, 2H, Ar-*H* and N-*H*), 7.98 (d, 2H, Ar-*H*). ^{13}C NMR ($CDCl_3$, 25 °C, 100 MHz) δ: 18.35, 127.21, 127.25, 128.13, 128.58, 131.60, 133.98, 134.38, 135.57, 165.90. EI-MS *m*/*z* (%): 225 ([M^+], [$^{DMP}(NO)^{Ph}$]H, 40). Anal. calcd. for $C_{15}H_{15}NO$ (%): C 79.97, H 6.71, N 6.22; found: C 80.24, H 6.72, N 6.20.

$[^{DMP}(NO)^{Ph}]_2Hf(CH_2Ph)_2(THF)$ (2a)

In a foil-wrapped Schlenk flask, 3.50 g (6.45 mmol) of $Hf(CH_2Ph)_4$ and 2.90 g (12.90 mmol) of [$^{DMP}(NO)^{Ph}$]H (**1**) were weighed out together. The mixture of the two solids was cooled to –78 °C in a dry ice – isopropanol bath. To this mixture was added approximately 125 mL of THF via cannula while stirring vigorously. The solution was allowed to warm to room temperature while stirring overnight. Excess THF was removed from the bright red-orange solution in vacuo, resulting in the isolation of 5.60 g of the crude product as a vibrant orange solid (98% yield). The product was dissolved in approximately 150 mL of hexanes at room temperature and filtered through a fritted disk. A small amount of a pale yellow hexanes insoluble product **2b** (0.57 g, 11% yield) was collect on the frit, and the dark orange filtrate was collected and cooled to –30 °C overnight. Microcrystals of a red-orange product **2a** were obtained in 34% yield (1.96 g) in the first batch. Repeated concentration and crystallization of the mother liquor resulted in a combined yield of approximately 65% for **2a**. ^1H NMR (C_6D_6, 25 °C, 300 MHz) δ: 1.64 (m, 4H, O-(CH_2CH_2)$_2$), 2.34 (s, 12H, Ar-CH_3), 2.55 (s, 4H, Hf-CH_2Ph), 3.83 (t, 4H, O-(CH_2CH_2)$_2$), 7.05–7.15 (m, 12H total, Ar-*H*), 7.35–7.46 (m, 10H total, Ar-*H*), 7.85 (d, 4H, Ar-*H*). ^{13}C NMR (C_6D_6, 25 °C, 75 MHz) δ: 18.69, 25.75, 68.03, 81.64, 122.13, 126.03, 128.55, 128.68, 128.86, 129.08, 131.99, 132.33, 133.07, 142.07, 144.73, 179.56. EI-MS *m*/*z* (%): 719 (M^+ – THF – CH_2Ph, 100). Anal. calcd. for $C_{48}H_{50}N_2O_3Hf$ (%): C 65.41, H 5.72, N 3.18; found: C 65.15, H 6.00, N 3.54.[5]

Acknowledgments

Funding for this research was provided by the University of British Columbia (UBC) and by the Natural Sciences and Engineering Research Council of Canada (NSERC) in the

[4] Crystallographic data for compounds **2a** and **3** appear in Tables 2 and 4, respectively. All measurements were made on Rigaku/ADSC or Rigaku AFC7 CCD area detectors with graphite-monochromated Mo Kα radiation. The data were processed (15) and corrected for Lorentz and polarization effects. The structures were solved by direct methods (16) and expanded by using Fourier (17) techniques. All non-hydrogen atoms were refined with anisotropic thermal parameters. Neutral atom scattering factors and anomalous dispersion corrections were taken from the International Tables for X-ray Crystallography (18, 19). Structures are visualized as ORTEP-3 depictions (20).

PREFACE / PRÉFACE

It is a great honor and privilege to contribute the preface to this special issue honouring Professor Howard Alper of the University of Ottawa. Professor Alper is among the most influential scholars in the area of chemical science of our days. He has contributed in many ways to research, education, and also scientific administration, particularly in Canada.

Professor Alper has made a number of truly outstanding contributions to homogeneous catalysis based on organometallic chemistry. His accomplishments in the broad realm of catalytic chemistry are listed in a large number of first-rate journals, but his impact on organometallic chemistry using carbon monoxide, with associated mechanistic insights, is particularly noteworthy. Among his superb contributions, one of the most significant is the ring expansion of saturated heterocyclic compounds such as aziridines and epoxides to lactams or lactones, respectively. The efficient synthesis of chiral β-lactams from racemic aziridines in the presence of (–)- or (+)-menthol is remarkable. His synthesis of tetrahydroindolizidines from piperidines is also very unique. He also discovered the Pd catalyzed cycloaddition of carbodiimides and heterocycles leading to imidazoline and pyrimidine imines. Furthermore, Alper achieved a general chiral synthesis of five-membered heterocycles by the Pd·BINAP promoted reaction of racemic aziridines and heterocumulenes. In addition, he discovered a series of regio- and stereoselective hydrocarbonylations and hydrocarboxylations of olefinic substrates under mild conditions. The highly enantioselective synthesis of naproxen and ibuprofen, very important anti-inflammatory agents, highlights the utility of his original approach to chemistry. His discovery of the double and triple carbonylation of organic compounds catalyzed by transition metals and lanthanides was a great surprise to many in the community, including ourselves. Alper was also the first to recognize the utility of zwitterionic Rh complexes for the regioselective (branched or linear) hydroformylation of olefins including α,β-unsaturated esters, vinylsilanes, unsaturated sulfones, and sulfoxides. Using this method, allyl acetate can be converted to 1,4-butanediol monoacetate.

Throughout his career, Alper developed many new reactions in homogeneous, liquid–liquid two-layer, and heterogeneous phases. Some exciting results generated from the biphasic chemistry ongoing in Alper's labs include the development of excellent methods for the dechlorination of chloroarenes aided by Pd catalysts. He also found an attractive method for the Pd – clay-catalyzed synthesis of commercially important isocyanates from nitroarenes. More recently, Alper described the ability of recyclable Rh dendrimers bound to silica- or resin-based supports to hydroformylate olefins.

Many of these discoveries were totally unexpected prior to his work. I have admired his intuitive insights that are far beyond the precise "designing" of chemical reactions. Overall, his scientific work is characterized by simplicity and sufficient practicality. Accordingly, many of his new reactions are potentially of high value to the pharmaceutical, petrochemical, and commodity chemical sectors. In fact, he has 37 patents based on his original chemistry. Professor Alper is obviously among the world-leading figures in this impor-

Il s'agit d'un grand honneur et privilège pour moi de contribuer à la préface du présent numéro spécial dédié au professeur Howard Alper, de l'Université d'Ottawa. Le professeur Alper est un des plus influents savants de notre temps dans le domaine de la chimie. Il a foncièrement transformé la recherche, l'enseignement et l'administration scientifique, particulièrement au Canada.

Nous devons au professeur Alper des contributions véritablement marquantes à la catalyse homogène organométallique. Même si ses réalisations dans le vaste secteur de la chimie catalytique sont attestées dans d'innombrables revues savantes prestigieuses, ce sont ses travaux de chimie organométallique axés sur l'usage du monoxyde de carbone dans une optique mécaniste qui ont galvanisé sa réputation. Parmi ses superbes contributions, l'une des plus notables est l'expansion du cycle des composés hétérocycliques saturés, tels que les aziridines et les époxydes pour la synthèse de lactames et de lactones respectivement. La synthèse concluante de β-lactames chiraux à partir d'aziridines sous forme racémique en présence de (–)-menthol ou de (+)-menthol est remarquable. D'ailleurs, sa synthèse de tétrahydroindolizidines à partir de pipéridines ne laisse rien à désirer. M. Alper a aussi découvert la cycloaddition catalysée par Pd de carbodiimides et d'hétérocycles conduisant à la formation des imines imidazoline et pyrimidine. Par ailleurs, il est arrivé à réaliser une synthèse chirale générale d'hétérocycles à cinq chaînes par réaction induite par Pd·BINAP des hétérocumulènes et des aziridines sous forme racémique. Il a aussi découvert une série d'hydrocarbonylations et d'hydrocarboxylations régiosélectives et stéréosélectives de substrats oléfiniques dans des conditions douces. La synthèse fortement énantiosélective du naproxène et de l'ibuprofène, deux agents anti-inflammatoires réputés, avère les vastes répercussions de sa démarche scientifique dans le domaine de la chimie. Sa découverte de la double et triple carbonylation des composés organiques catalysée par les métaux de transition et les lanthanides en a surpris plus d'un dans la collectivité, nous y compris. M. Alper a aussi été le premier chercheur à reconnaître le rôle crucial de complexes Rh zwitterioniques dans l'hydroformylation régiosélective (ramifiée ou linéaire) des oléfines, notamment des esters α,β-insaturés, des vinylsilanes, des sulfones insaturés et des sulfoxydes. Grâce à cette méthode, l'acétate d'allyle peut être converti en monoacétate de butanediol-1,4.

Au fil de sa carrière, M. Alper a défini de nombreuses nouvelles réactions en phase homogène, en phase liquide–liquide bicouche et en phase hétérogène. Parmi les fascinants résultats issus de ses expériences sur les systèmes biphasés, on remarque l'élaboration de très efficaces méthodes de déchloration des chloroarènes à l'aide de catalyseurs Pd. M. Alper a aussi trouvé une élégante méthode de synthèse catalysée par Pd – argile des isocyanates, prisés sur le marché, à partir de nitroarènes. Plus récemment, il a décrit les qualités des dendrimères Rh recyclables liés aux supports de silice ou de résine en vue de l'hydroformylation des oléfines.

Nombre de ces découvertes étaient tout à fait inattendues avant ses travaux. J'admire sa démarche intuitive qui s'écarte de la simple « orchestration » de réactions chimiques. Dans l'ensemble, ses travaux sont fondés sur la sobriété et sur l'applicabilité. Voilà pourquoi nombre des réactions qu'il a concoctées sont économiquement prometteuses pour

© 2005 NRC Canada

tant scientific realm. His seminal accomplishments have been recognized with many national and international awards that include: the Alcan Award for Inorganic Chemistry (1986, CSC), the Alfred Bader Award (1990, CSC), the Commemorative Medal from the Canadian Government (1992), the E.W.R. Steacie Award (1993, CSC), the Urgel–Archambault Prize in physical sciences and engineering (1996), the Chemical Institute of Canada Medal (1997), the Bell Canada Forum Award (1998), the NSERC Excellence in Research Award (2000), the most prestigious Gerhard Herzberg Gold Medal for Science and Engineering (2000), the President's Award (2001), and the Montreal Medal (2003). In 2001, Alper received the National Merit Award for contributions to the Life Sciences. In addition, he was given the Le Sueur Memorial Award of the Society of Chemical Industry in the UK (2002), and the award of Officer, National Order of Merit by the President of the Republic of France (2002).

It should be mentioned that Professor Alper is an outstanding "ambassador" of chemistry; he has received countless invitations from significant international conferences and academic or industrial research institutes. As such, Alper has encouraged the younger generation worldwide by not only publishing excellent papers (over 470), but also giving beautiful oral presentations in a unique lecture style. In addition, many leading scientific journals have asked Alper to put his name on their editorial boards. Furthermore, he has been heavily involved in scientific and educational administration in Canada. Most importantly, he is currently Vice-Rector (President), Research, of the University of Ottawa, and a member of the Council of the Canadian Institute for Advanced Research. Alper was named the President of the Academy of Science of the Royal Society of Canada in 2001–2003, and awarded the title of an Officer of the Order of Canada in 1999. He was elected to the European Academy of Arts, Sciences, and Humanities (1996) and the Third World Academy of Sciences (2003).

The foregoing describes only a few of Professor Alper's seminal contributions to modern science and the academic community. He has served as a vigorous and dedicated leader in the Canadian chemical community. Alper's activities encompass various roles outside the purely scientific domain. I deeply respect him as a stellar scientist, an enthusiastic educator, and an effective administrator, and also believe that such overall professional service is equally respected by the rest of the scientific community.

I have personally known Howard Alper for three decades. He is a superb scientist and an extremely warm person. Last but not least, a clever woman always exists behind a great man. Howard could be successful only with the support of his thoughtful wife, Anne, whose devotion must be deeply appreciated. I wish the Alper family continued success, health, and happiness.

Ryoji Noyori

l'industrie pharmaceutique, pétrochimique et chimique. De fait, il détient trente-sept brevets fondés sur les processus chimiques qu'il a mis en lumière. Le professeur Alper est sans contredit une des figures de proue du domaine. Ses importantes contributions ont été consacrées par de nombreux prix nationaux et internationaux dont le Prix Alcan en chimie inorganique (1986, SCC), le prix Alfred Bader (1990, SCC), la Médaille commémorative du 125^{e} anniversaire du Canada (1992), la Bourse commémorative E.W.R. (1993, SCC), le prix Urgel-Archambault en sciences physiques, mathématiques et génie (1996), la Médaille de l'Institut de chimie du Canada (1997), le prix Forum Bell Canada (1998), le prix d'excellence en recherche du CRSNG (2000), la très prestigieuse Médaille d'or Gerhard Herzberg en sciences et en génie (2000), le prix du président (2001) et la Médaille de Montréal (2003). En 2001, M. Alper a reçu le prix du mérite national pour ses contributions aux sciences de la vie. De plus, il a été primé par la Society of Chemical Industry du Royaume-Uni, qui lui a remis le prix Le Sueur Memorial Award (2002) et par le Président de la République française, qui lui a conféré le grade d'officier de l'Ordre national du Mérite (2002).

Il importe de souligner que le professeur Alper est un excellent « ambassadeur de la chimie » et qu'il a été invité à d'innombrables grandes conférences internationales et à des instituts de recherche universitaires et industriels réputés. M. Alper a inspiré une nouvelle génération de chercheurs du monde entier non seulement en signant des communications qui ont fait école (plus de 470), mais aussi en donnant des exposés oraux lumineux, dans un style bien à lui. De plus, nombreuses sont les revues savantes renommées qui ont invité M. Alper à se joindre à leur comité de rédaction. M. Alper a également touché de près à l'administration de la science et de l'enseignement au Canada. Il est d'ailleurs vice-recteur (président) à la recherche à l'Université d'Ottawa et membre du conseil d'administration de l'Institut canadien de recherches avancées. M. Alper a été le président de l'Académie des sciences de la Société royale du Canada de 2001 à 2003 et, en 1999, a été fait officier de l'Ordre du Canada. Il a été nommé membre titulaire de l'Académie européenne des arts, des sciences et des lettres (1996) et de la Third World Academy of Sciences (2003).

Ce qui précède ne constitue que quelques bribes de l'immense contribution du professeur Arper à la science contemporaine et à la collectivité universitaire. Il a été un porte-parole ardent et passionné de la collectivité de la chimie canadienne. Témoin la diversité de ses activités, l'étendue de l'influence de M. Alper n'est pas circonscrite au domaine scientifique. Je le respecte profondément sous toutes ses incarnations, soit celles de scientifique hors pair, d'enseignant enthousiaste et d'administrateur efficace, et je suis convaincu que l'impeccabilité de son service est tout autant respecté par l'ensemble de la communauté scientifique.

Je côtoie Howard Alper depuis une trentaine d'années. C'est un homme de science doué et une personne on ne peut plus affable. Cela étant, derrière tout homme remarquable se trouve une femme avertie, et Howard doit une grande partie de son succès au soutien de son attentive conjointe, Anne, dont le dévouement doit être profondément apprécié. Je souhaite beaucoup de succès, de santé et de bonheur à la famille Alper pour les années à venir.

Ryoji Noyori

TRIBUTE / HOMMAGE

It is my great pleasure to serve as co-editor of this special issue dedicated to an extraordinarily special individual, Dr. Howard Alper, Professor of Chemistry and Vice-Rector of Research at the University of Ottawa. I know Professor Alper best as the superb mentor that he was to me while I was a graduate student in his lab in the mid-1990s. During this time, I was impressed not only by his scientific insight and creativity, by his understanding of the complex factors affecting the political funding of science and superb grasp of university and scientific administration, or even by his talent as a teacher and mentor, but by his outstanding ability to excel at all three of these areas: research, administration, and education, at the same time. In my interactions with chemists around the world, I have never met someone as gifted in all of these areas as Howard Alper.

His abilities as a researcher are well-known to anyone who reads the current literature, and are beautifully summarized by the accompanying preface to this issue written by Professor Ryoji Noyori, Nobel Laureate. I was delighted by Professor Noyori's offer to pen this preface, and was reminded of the first time I met him. While a Ph.D. student in Professor Alper's lab, I had the incredible opportunity to work in Japan in the labs of Professor Shinji Murai for 3 months. During this time, Professor Murai arranged for me to visit several universities, including the University of Nagoya where I presented my Ph.D. work at one of Professor Noyori's group meetings. At the end of my presentation, Professor Noyori asked the first question. It was memorable: "How does Dr. Alper have so many unique research ideas?". Although this was and is a difficult question, I think the answer lies in his unique way of looking at science, his broad interest in all areas of chemistry and science, and his willingness to take risks. Working in his group was truly a remarkable experience.

When embarking on this issue, it was my sincere hope that the contributions would reflect the respect Howard Alper has generated throughout the international chemistry community. A quick perusal of the titles and contributors show not only the large number of people who have been influenced by his character and his chemistry, but also the breadth of his interests in science. In addition to the multitude of articles on catalysis, both heterogeneous and homogeneous, this issue contains articles describing radical chemistry, photochemistry, total synthesis, conformational analysis, materials science, sugar chemistry, peptide synthesis, and enzymology. Articles have been submitted from around the globe, representing researchers at all stages of their careers, including emeritus professors, presidents of chemical societies, and assistant professors, again illustrating the remarkable influence that Howard Alper continues to have on all generations of scientists. It has been a pleasure to compile this issue as a tribute to Professor Howard Alper, scientist, scholar, and mentor.

Cathleen M. Crudden

J'ai l'immense plaisir d'être rédactrice adjointe de ce numéro spécial consacré à une personne extraordinaire, monsieur Howard Alper, Ph.D., professeur de chimie et vice-recteur à la recherche à l'Université d'Ottawa. Pour moi, le professeur Alper représente d'abord et avant tout l'excellent mentor qui m'a accueillie dans son laboratoire au milieu des années 1990, durant mes études supérieures. À l'époque, son intuition et sa créativité sur le plan scientifique m'impressionnaient vraiment, ainsi que sa compréhension des facteurs complexes se rapportant au financement politique de la science, sans oublier son incroyable maîtrise de l'administration universitaire et scientifique, ni son talent en enseignement et en encadrement. Toutefois, ce qui m'avait vraiment renversée, c'est son exceptionnelle capacité à exceller simultanément dans les domaines suivants : la recherche, l'administration et l'éducation. Jamais au cours de mes interactions avec des chimistes partout dans le monde n'ai-je rencontré quelqu'un d'aussi talentueux dans ces trois domaines que Howard Alper.

Ses talents de chercheur, bien connus de tous ceux qui consultent la documentation courante, sont résumés de brillante façon par la préface qui accompagne ce numéro et qui a été rédigée par le professeur Ryoji Noyori, récipiendaire du prix Nobel. Par ailleurs, j'ai été ravie d'apprendre que le professeur Noyori s'est offert pour rédiger la préface, et je me suis souvenue de ma première rencontre avec lui. Lors de mes études doctorales réalisées au laboratoire du professeur Alper, j'ai eu une occasion rêvée de travailler au Japon au sein des laboratoires du professeur Shinji Murai pour une période de trois mois. Durant ce temps, le professeur Murai m'a permis de visiter plusieurs universités, y compris l'Université de Nagoya où j'ai présenté mes travaux de recherche doctorale lors d'une réunion de groupe du professeur Noyori. À la fin de ma présentation, le professeur Noyori a posé une première question qui était tout à fait mémorable : « Comment fait-il [professeur Alper] pour avoir des idées de recherches aussi uniques? ». Et même si cette question est toujours aussi difficile à répondre aujourd'hui que lors de mon exposé, je crois que la réponse réside dans son approche unique à la science, son intérêt varié pour tout ce qui traite de la chimie et de la science et sa disposition à courir des risques. Mon séjour au sein de son équipe s'est avéré une expérience très enrichissante.

Lorsque j'ai entrepris ce projet, je souhaitais sincèrement que la teneur du texte témoigne de la solide réputation que M. Alper s'est forgée au sein de la collectivité internationale. Une lecture cursive des titres et des collaborateurs révèle non seulement la portée de son talent et de ses travaux de recherche auprès de nombreux chercheurs, mais aussi l'étendue de son intérêt pour la science. Outre le grand nombre d'articles sur la catalyse hétérogène et homogène, ce numéro renferme des articles sur la chimie radicalaire, la photochimie, la synthèse totale, l'analyse conformationnelle, la science des matériaux, la sucrochimie, la synthèse peptidique et l'enzymologie. Les articles proviennent de partout dans le monde et de chercheurs à diverses étapes de leur carrière, y compris des professeurs émérites, des présidents de sociétés chimiques et des professeurs adjoints. Cela témoigne, une fois de plus, de l'importante influence que M. Alper continue d'exercer auprès de toutes les générations de scientifiques. C'est donc avec plaisir que j'ai compilé ce numéro qui rend hommage au professeur Howard Alper — scientifique, savant et mentor.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2003 Alcan Award Lecture — Roles of the adjacent metals in the coupling of methylene groups promoted by heterobinuclear complexes of Group 8 and 9 metals

Martin Cowie

Abstract: The reactivities of the heterobinuclear complexes, $[MM'(CO)_4(dppm)_2][X]$ (MM′ = RhOs, RhRu, IrRu; dppm = μ-$Ph_2PCH_2PPh_2$; X^- = BF_4^-, $CF_3SO_3^-$) with diazomethane are reported. The RhOs species reacts to give three products of methylene-group incorporation, depending on the temperature; at –80 °C the methylene bridged product, $[RhOs(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$, is formed exclusively, at ambient temperature only $[RhOs(\eta^1\text{-}C_3H_5)(CH_3)(CO)_3(dppm)_2]$-[X], having the allyl group bound to Rh and the methyl group bound to Os, is obtained, while at intermediate temperatures $[RhOs(\eta^1{:}\eta^1\text{-}C_4H_8)(CO)_3(dppm)_2][X]$, having the butanediyl fragment chelating on Os, is generated. Based on labeling studies a mechanism is proposed rationalizing formation of the different products. Under the same range of conditions the Rh/Ru and Ir/Ru species yield only the methylene bridged products, $[MM'(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$ (MM′ = RhRu, IrRu). A rationalization for the different reactivities observed and a description of the roles of the different metals in coupling of the methylene groups are presented. Attempts to model key intermediates in the methylene coupling sequence promoted by the Rh/Os complexes, through coupling of methylene groups with ethylene or alkynes, are described.

Key words: heterobinuclear, rhodium/osmium, rhodium/ruthenium, iridium/ruthenium, methylene coupling, Fischer–Tropsch, alkyne insertions, bimetallic cooperativity.

Résumé : On a étudié les réactivités des complexes hétérobinucléaires $[MM'(CO)_4(dppm)_2][X]$ (MM′ = RhOs, RhRu, IrRu; dppm = μ-$Ph_2PCH_2PPh_2$; X^- = BF_4^-, $CF_3SO_3^-$) avec le diazométhane. Suivant la température de la réaction, les espèces RhOs réagissent pour donner trois produits d'incorporation du méthylène; à –80 °C, le seul produit formé est le composé à pont méthylène, le $[RhOs(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$, à la température ambiante, le seul produit obtenu est le $[RhOs(\eta^1\text{-}C_3H_5)(CH_3)(CO)_3(dppm)_2][X]$ dans lequel le groupe allyle est lié au Rh alors que le groupe méthyle est lié au Os; aux températures intermédiaires, il y a formation du produit $[RhOs(\eta^1{:}\eta^1\text{-}C_4H_8)(CO)_3(dppm)_2][X]$ dans lequel le fragment butanediyle est lié au Os. Sur la base d'études de marquage, on propose un mécanisme pour rationaliser la formation de chacun des produits. Sous diverses conditions, les espèces Rh/Ru et Ir/Ru ne conduisent qu'à la formation des produits comportant le pont méthylène, $[MM'(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$ (MM′ = RhRu, IrRu). On présente une rationalisation des différentes réactivités observées et une description des rôles des différents métaux dans le couplage des groupes méthylènes. On décrit aussi des essais de modélisation des intermédiaires clés dans la séquence de couplage du méthylène catalysé par les complexes Rh/Os et impliquant un couplage des groupes méthylènes avec l'éthylène ou des alcynes.

Mots clés : hétérobinucléaire, rhodium/osmium, rhodium/ruthénium, iridium/ruthénium, couplage de méthylène, Fischer–Tropsch, insertions d'alcynes, coopération bimétallique.

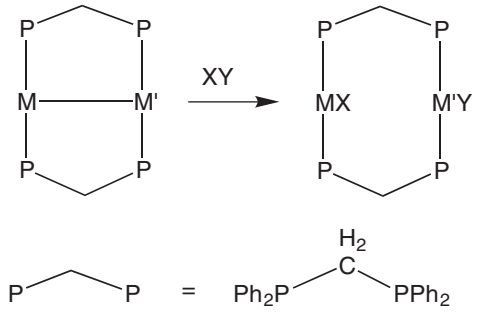
Background



I arrived at the University of Alberta in 1976, fresh from a postdoctoral position in the group of Jim Ibers at Northwestern University, where I had become interested in the organometallic chemistry of the late transition metals. In starting an independent research program, I looked to create a niche for myself in this fascinating area. At the time, the organo-

Chart 1.

metallic chemistry of complexes such as Wilkinson's catalyst (1) and Vaska's compound (2) was an active area of research so we decided to expand the scope of this chemistry by generating the binuclear analogues of these and related species on the assumption that the presence of the adjacent metals could give rise to significant reactivity differences compared to the mononuclear counterparts. We set out to establish whether adjacent metals could interact in a cooperative manner in the activation of organic substrates and to determine the roles of the adjacent metals in the activation process. Irrespective of how adjacent metals might cooperate in substrate activation, it certainly seemed that at a minimum the ability of substrates to bridge metals in multinuclear complexes should give rise to significant differences in reactivity compared to that of terminally bound substrates in mononuclear species.

At the time we started our work, there was already substantial interest in the chemistry of binuclear complexes (3). However, many of these complexes fragment into mononuclear species on reaction with substrates, removing any apparent advantage of having the metals initially bound together. It was immediately obvious that an appropriate bridging ligand was needed to hold the metals together, even upon cleavage of the metal–metal bond. I was fortunate at the time to be introduced to bis(diphenylphosphino)methane as a bridging ligand (commonly abbreviated as dppm) by Alan Sanger and Joel Mague, with whom I briefly collaborated (4). Dppm has an ideal bite and is flexible enough to bridge a wide range of metal–metal separations in the presence or absence of metal–metal bonds, as diagrammed in Chart 1 (ancillary ligands on M and M′ are not shown).

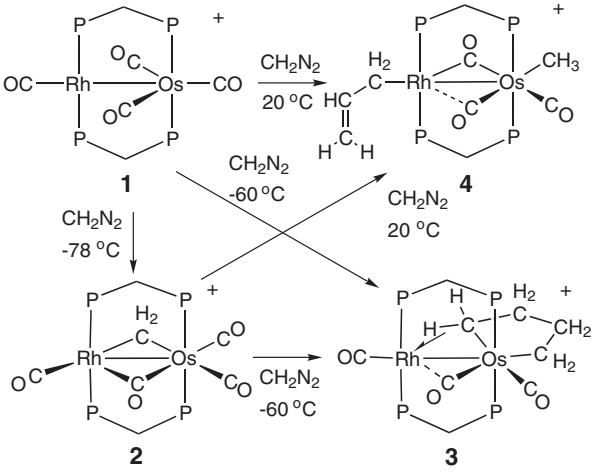
The study of dppm bridged complexes was an area of great interest and I found myself in the stimulating company of competitors such as Alan Balch (5), Richie Eisenberg (6), Bernard Shaw (7), Dick Puddephatt (8) (who at the time was still in Liverpool, but who was subsequently to move to London, Ontario), and Ray Haines, who studied diphosphines closely related to dppm (9). Other groups such as those of Selby Knox (10), Chuck Casey (11), Rowland Pettit (12), Luis Oro (13), and René Poilblanc (14) had similar goals related to binuclear reactivity, but did not routinely use diphosphines as bridging groups. In addition, there was substantial interest during this period in higher nuclearity clusters, which were being championed as links between classic coordination complexes and heterogeneous metal catalysts (15), and therefore could serve as valuable models for catalytic processes occurring on difficult-to-study metal surfaces. The relationship between metal surfaces and metal complexes was eloquently stated by Earl Muetterties (15*d*): "Surface chemistry is coordination chemistry. If the molecule or molecules in question are organic then the surface chemistry is organometallic chemistry".

Although it is unreasonable to expect binuclear complexes to be meaningful models for metal surfaces, they can, nonethe-less, yield valuable information on, and therefore can effectively model aspects of substrate coordination and activation at surfaces since many of the known ligand coordination modes occur in each. Furthermore, we felt that the lack of unnecessary complexity in two-metal systems made them ideal for establishing the intimate details of how adjacent metals were involved in cooperative substrate activation.

Our interests in dppm and related diphosphines, presumably like those of our closest competitors, derived from the similarities of dppm bridged complexes to the well-known mononuclear, late-metal phosphine complexes, such as those of Wilkinson and Vaska, that had played such a prominent role in studies of metal-promoted activation of small molecules (16). However, the importance of ^{31}P NMR spectroscopy in characterization of the dppm complexes was also a major reason for using this ligand. In this context, we have been extremely fortunate to have benefited greatly from the expertise in our Departmental NMR facility, supervised over most of my career, until his (early) retirement, by Tom Nakashima, and more recently by his replacement, Albin Otter.

Although our earlier work was concerned with the homobinuclear pairs of metals, Rh_2 (17) and Ir_2 (18), we eventually branched out into the mixed-metal combination, Rh/Ir (19), and realizing the potential richness of systems containing combinations of metals from different groups in the periodic table, it was not long afterwards that we began to experiment with a variety of metal combinations. Dave Antonelli, a former graduate student in my group, was instrumental in initiating this chemistry (20). It seemed clear that combining the unique properties of different metals could give rise to interesting variations in reactivity compared to either metal alone, thereby significantly extending the flexibility of the chemistry.

At this time, bimetallic catalysts were being extensively used, particularly in the petrochemical industry (21), in processes such as gasoline reforming (using Pt/Re or Pt/Ir catalysts), hydrocracking (using Ni/Mo or Ni/W), and hydrodesulfurization (using Co/Mo or Ni/Mo). This interest has continued, but in spite of their extensive use, little is understood about the roles of the different metals in these bimetallic catalysts. It seemed therefore that our interest in the reactivity of well-defined heterobinuclear complexes could shed light on the roles of adjacent metals in the activation of organic substrates.



One constant throughout most of our chemistry has been the use of either Rh or Ir as one of the two metals involved, thereby introducing a site of coordinative unsaturation into the complexes. This unsaturation is pivotal in endowing these species with remarkable reactivity, even at temperatures down to –80 °C.

Fischer–Tropsch chemistry

A process that had fascinated me for years is the Fischer–Tropsch (FT) reaction (22) in which synthesis gas ($CO + H_2$)

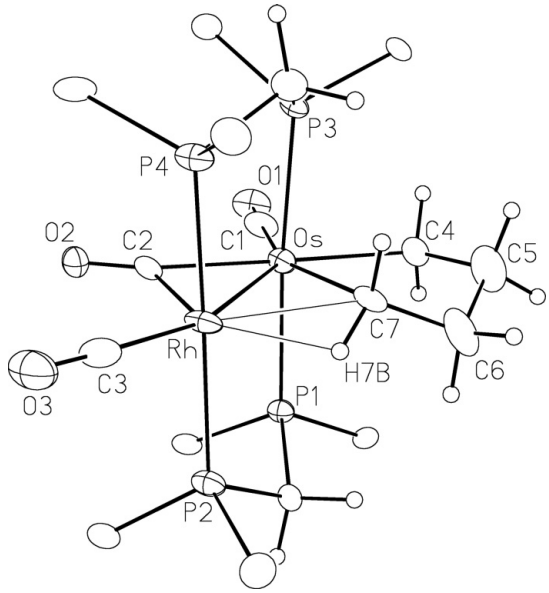
Scheme 1.

is converted, over a Group 8 or Group 9 metal catalyst, to mixtures of alkanes, alkenes, and oxygen containing products, as outlined in the (unbalanced) eq. [1].

$$[1] \quad CO + H_2 \xrightarrow{\text{catalyst}} C_nH_{2n+2} + C_nH_{2n} + \text{oxygenates} + H_2O$$



Although much remains to be learned about the mechanisms of carbon–carbon bond formation in this process, a number of proposals have been put forward, in which surface-bound methylenes play a prominent role (12*b*, 12*c*, 22*a*, 23–25). Furthermore, the observation that different metals catalyze the formation of different product distributions (26), suggested that *combinations* of metals may lead to interesting variations in product distributions. Work has been reported describing the use of the Ru/Co combination of metals as a FT catalyst (27).

Model systems

Realizing the importance of methylene fragments and the Group 8 and 9 metals in the FT process, we set out to investigate the reactivity of mixed Group 8/Group 9 metal complexes having bridging methylene groups in the aforementioned dppm bridged systems with the goal of investigating the roles of the different metals in carbon–carbon bond formation involving this C_1 fragment (28). At this time, a senior graduate student in my group, Brian Sterenberg, needing a break from writing his thesis on the organometallic chemistry of mixed Rh/Os and Rh/Ru complexes, chose to attempt the synthesis of the methylene bridged complex, $[RhOs(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$ (**2**; dppm = μ-$Ph_2PCH_2PPh_2$; X = BF_4, CF_3SO_3) by reacting one of his standard precursors, $[RhOs(CO)_4(dppm)_2][X]$ (**1**), with diazomethane at ambient temperature. Although he did not succeed in obtaining the targeted methylene bridged species, the product obtained, $[RhOs(\eta^1\text{-}CH_2CH{=}CH_2)(CH_3)(CO)_3(dppm)_2][X]$ (**4**), shown in Scheme 1, was far more interesting, having incorporated four methylene groups to give the allyl and methyl fragments, bound to the different metals.

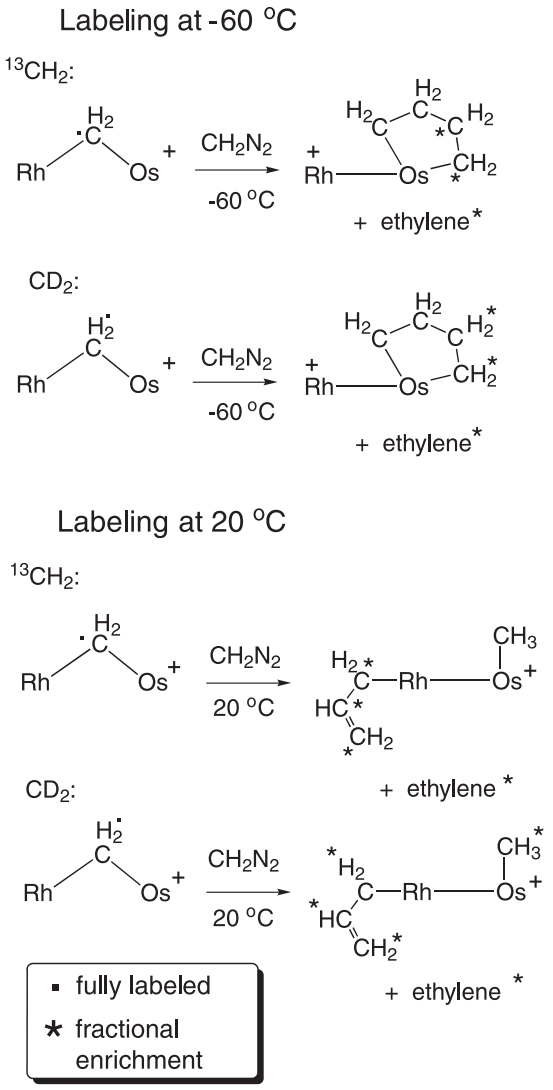
The generation of an allyl group from methylene groups was reminiscent of one step in the proposal by Peter Maitlis and co-workers (24) for chain growth in the FT process,

Fig. 1. Perspective view of $[RhOs(\eta^1{:}\eta^1\text{-}C_4H_8)(CO)_3(dppm)_2]^+$ (**3**). Only the ipso carbons of the dppm phenyl groups are shown.

through the coupling of surface-bound vinyl and methylene groups. Both Peter and I were interested in this parallel, and I spent several enjoyable weeks over two summers in Sheffield, as part of a NATO-sponsored collaboration, discussing our mutual interests in FT chemistry with Peter, Mike Turner, and their group members. In turn, Peter and Mike visited Edmonton on separate occasions to interact with my group. In England, Peter and his wife Marion were wonderful hosts, involving me in dinner parties, the theatre, and tours through the nearby countryside. Meanwhile, Mike and members of the Maitlis group ensured that I also sampled other cultural highlights of the UK, such as football, fish and chips, hill walking, and English bitter. I still can think of few greater pleasures than enjoying fish and chips over a pint of bitter in a country pub after a vigorous walk in the British hills (except maybe if the match of the day were also playing on the telly).

Shortly after Brian graduated and left the group, another graduate student, Steve Trepanier, took up the project and succeeded in obtaining the targeted methylene bridged $[RhOs(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$ (**2**) by carrying out the reaction of **1** with diazomethane at –78 °C. He discovered that this species was stable and could be readily isolated as long as the excess diazomethane was removed at –78 °C. However, warming a mixture of **2** and diazomethane above –78 °C resulted in further reactivity. Steve found that carrying out this reaction at ambient temperature generated the aforementioned compound **4**, whereas at intermediate temperatures around –40 to –60 °C, the butanediyl product $[RhOs(\eta^1{:}\eta^1\text{-}C_4H_8)(CO)_3(dppm)_2][X]$ (**3**), shown in Scheme 1 and Fig. 1, was obtained. The finding that compounds **3** and **4** could be obtained under the respective conditions from either **1** or **2** suggested that **2** was an intermediate in the formation of both products. However, the failure of **3** and **4** to interconvert, at ambient temperature or higher, indicated that these two species are derived from **2** by independent pathways (28, 29).

© 2005 NRC Canada



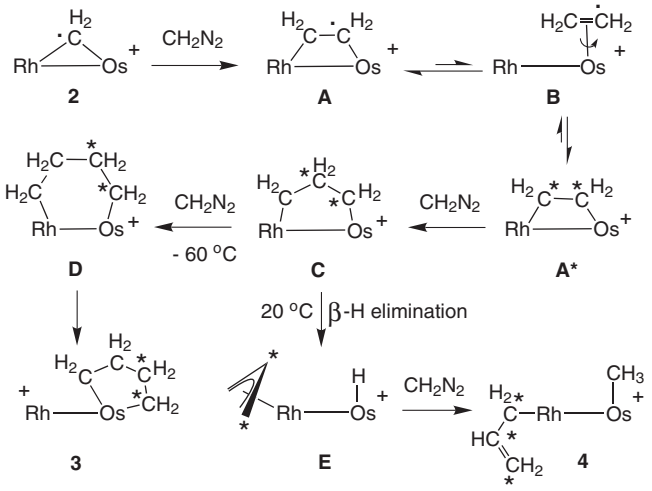
The selective transformation of diazomethane generated methylene groups into either C_3 and C_1 fragments (allyl/methyl groups) or a C_4 fragment (butanediyl group) depending on the temperature, together with ethylene in both cases, was unprecedented, and we were eager to learn more about this system. In particular, we wanted to resolve the roles of the metals in these methylene coupling reactions and to determine why termination at C_3 and C_4 species occurred, instead of generating longer C_n fragments. Furthermore, it was of interest to determine what products would be obtained using other metal combinations.

Mechanism of CH_2 incorporation

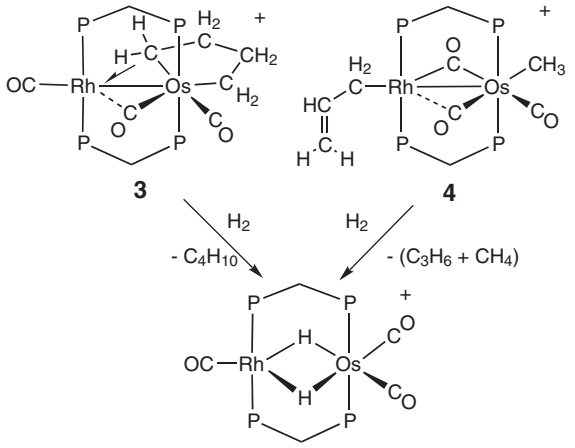
Valuable information about how methylene coupling occurred was obtained from labeling studies. Steve had subsequently prepared the $^{13}CH_2$ and the CD_2 labeled versions of **2**, and upon subsequent reaction with unlabeled diazomethane was able, using NMR spectroscopy, to track the distribution of the label through the final products. These experiments are summarized in Scheme 2 in which only the metals and hydrocarbyl groups are represented for simplicity. In the reaction carried out at between –40 and –60 °C, both the ^{13}C and the ^{2}H label occupied the two adjacent sites remote from Rh (as shown in this scheme), as well as appearing in ethylene that was also generated. However, for the allyl methyl product, the ^{13}C label appears in the three allyl carbons in a 1:2:1 intensity ratio, with no ^{13}C incorporation into the methyl ligand. In the experiments involving CD_2 labeled **2**, deuterium incorporation into all sites of the allyl and methyl groups occurred. As in the low-temperature experiment, ^{13}C and ^{2}H incorporation into free ethylene was also observed.

On the basis of these results, we suggested the mechanism of methylene incorporation outlined in Scheme 3 (in this scheme only the $^{13}CH_2$ label is tracked, and again, only the metals and hydrocarbyl groups are shown). In all cases, we propose that methylene insertion into the Rh—CH_2 bond of the bridging hydrocarbyl fragment occurs. Methylene insertion into the Rh—CH_2 bond of **2** is proposed to yield the ethylene bridged intermediate **A**, which at this stage would have the label (either ^{13}C or ^{2}H) solely in the CH_2 site adjacent to Os. Movement of a bridging ethylene group to a terminal, η^2-bound group (**B**) has been observed (30) and the well-documented, facile ethylene rotation (31) followed by regeneration of the ethylene bridged species would scramble the label over both CH_2 sites in **A***. Of course, some ethylene loss could occur from **B** accounting for the ethylene observed in these experiments, and the resulting Rh/Os containing product could regenerate compound **2** upon reaction with diazomethane. Subsequent methylene insertion into the Rh—CH_2 bond of **A*** would yield the propanediyl bridged intermediate **C** in which the label is evenly distributed between the two sites shown — the central site and the one adjacent to Os. At low temperatures, a fourth methylene group can react yielding the butanediyl bridged **D**, which can readily rearrange to the chelated product **3** by migration of the Rh bound methylene group to Os. This migration is presumably favoured by the relatively unstrained five-membered metallacycle that results, as opposed to the strained six-membered dimetallacycle of **D**. In this product,

Scheme 2.



the scrambling of the label over only the two sites remote from Rh is explained by the olefin rotation process occurring in intermediate **B**, and by selective methylene insertion into the Rh—CH_2 bond of the bridging hydrocarbyl unit. Based on our assumption of diazomethane activation at Rh and subsequent insertion of the resulting methylene group into the Rh—CH_2 bond of the bridging hydrocarbyl moiety, the isomerization of **D** to **3** in which there no longer is a Rh—CH_2 bond, explains our failure to obtain hydrocarbyl fragments longer than C_4. Presumably, the lifetime of **D** is too short to allow incorporation of a fifth methylene group.



Raising the temperature to near ambient is assumed to allow the activation of a C—H bond of the central CH_2 group in intermediate **C**, leading to an allyl hydride intermediate resembling **E**, which upon reaction with an additional diazomethane molecule can yield the allyl methyl product **4**. This process begins to appear at approximately –40 °C, at which temperature **4** is a very minor product, and becomes increasingly favoured over the methylene insertion step (**C** → **D**) as the temperature is increased, such that at ambient temperature, generation of **4** occurs essentially exclusively. In the

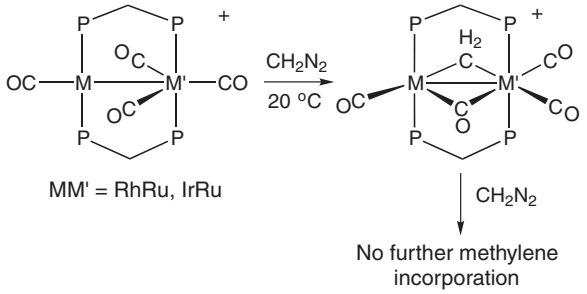


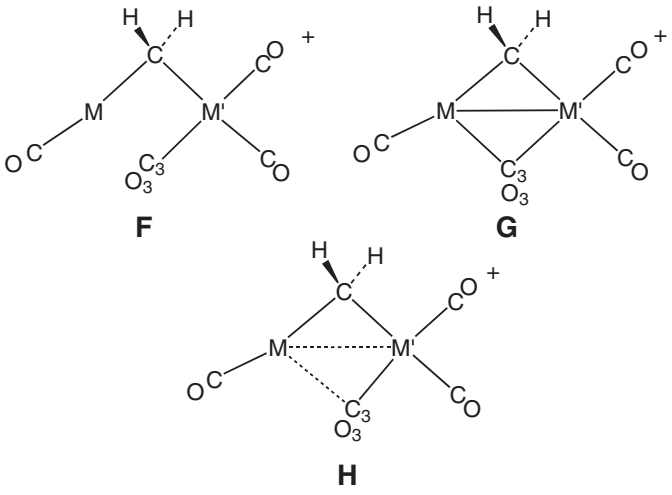
Scheme 3.

Scheme 4.

Scheme 5.

$^{13}CH_2$ labeled system the label becomes scrambled through the three positions of the allyl moiety in a 1:2:1 ratio, reflecting the equal probability of either end of the allyl unit coordinating to Rh, in the conversion of **E** to **4**, further diluting the label at both ends of this unit. We also note that slow exchange of both ends of the allyl ligand in **4** occurs in solution, representing another mechanism for scrambling of the terminal label. It is clear that the methyl group of **4** will contain no ^{13}C label since this group originates from an unlabeled methylene group. The observation of deuterium scrambling into this methyl group arises from the β-hydrogen elimination step, since the β position of intermediate **C** contains some deuterium from the previous scrambling process.

Hydrocarbons from hydrogenolysis



Both compounds **3** and **4** react slowly with H_2 yielding the respective products, *n*-butane or propene and methane, by hydrogenolysis of the metal–alkyl bonds, as shown in Scheme 4. In both cases, the metal-containing product is the known dihydride, $[RhOs(CO)_3(\mu\text{-}H)_2(dppm)_2][X]$, a species that can be readily converted into the precursor **1** upon addition of CO (32). This sequence allows us to construct a pseudo-catalytic cycle for the selective generation of butane or methane and propene (together with ethylene, produced in both cases) from diazomethane and hydrogen, fulfilling part of the FT sequence of conversion of methylene groups into different hydrocarbons.

Different metal combinations

The conversion of either **1** or **2** into the products **3** and **4** is accompanied by the loss of one carbonyl group, leading us to question the role of CO loss in the process and the stage at which this loss occurred. It seemed reasonable to expect that if CO loss is important in the methylene coupling process, the analogous Rh/Ru system should be more reactive owing to the greater lability of Ru compared to Os (33). Surprisingly, this has not proven to be the case. Bryan Rowsell, another graduate student in my group, established that the reaction of $[RhRu(CO)_4(dppm)_2][X]$ with diazomethane gave only the methylene bridged *tetracarbonyl* complex $[RhRu(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$(as shown in Scheme 5) even at ambient temperature (34). No carbonyl loss or further incorporation of methylene groups was observed under conditions similar to those investigated in the Rh/Os system. At the same time, Steve Trepanier and Maria Michela Dell'Anna, a visiting graduate student from Francesco Nobile's group in Bari, found that the Ir/Ru analogue also generated only the methylene bridged tetracarbonyl product (35). This contrast in reactivity compared to the Rh/Os system raised obvious questions about the lability of the carbonyl ligands in the series of compounds $[MM'(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$ (MM′ = RhRu (**5**), RhOs (**2**), IrRu (**6**)). Reflecting our crystallographic bias (originating in my previous associations with two very talented crystallographers, Mike Bennett, my Ph.D. supervisor, and Jim Ibers, my postdoctoral supervisor), we reasoned that a comparison of the solid-state structures of these three species might give clues about their reactivity differences. At the outset, three structural types could be envisioned as diagrammed in Chart 2 (dppm groups above and below the plane of the drawing are omitted for clarity). In one extreme (**F**), all carbonyls are terminally bound leaving the Group 9 metal (M) with a 16e configuration; this, in our view, was the ideal arrangement, allowing for incorporation of an additional diazomethane at the coordinatively unsaturated metal. In the other bonding extreme (**G**), one carbonyl bridges the metals leaving both metals coordinatively saturated, by virtue of this bridging carbonyl arrangement accompanied by the metal–metal

© 2005 NRC Canada

Chart 2.

bond. Also possible is the intermediate structure (**H**) in which one carbonyl is primarily bound to the Group 8 metal (M′) while involved in a weaker, semi-bridging interaction with Rh or Ir. For a species having one of the carbonyl bridged geometries to react with diazomethane at the Group 9 metal (as established in the previous labeling studies), displacement of the bridging carbonyl from this metal needs to occur, and it seems reasonable to expect that this could be more difficult in the case of the symmetrically bridged **G** in which binding to the Group 9 metal is strongest.

Structural comparisons and carbonyl lability

The structure of the Rh/Os member of this series (compound **2**) is diagrammed in Fig. 2, and a comparison of the key structural parameters of the three analogues is presented in Table 1. Referring to Chart 2, it is clear that the closer a compound resembles structure **G**, the shorter will be the metal–metal bond, the more symmetric will be the M-C(3)-O(3) and M′-C(3)-O(3) angles, and the more acute will be the C(5)-M-C(4) angle as the hybridization at M becomes perturbed by interaction with carbonyl C(3)O(3). Although it seems clear that a tendency towards extreme **G** should also be accompanied by a shortening of the M—C(3) distance, this is not observed in a comparison of these compounds for reasons that are not clear.

Superficially, all structures are similar, but a close comparison of the parameters given in Table 1 establishes that the Ir/Ru species (**6**) differs from the other two in having an essentially symmetrically bridged carbonyl, close to extreme **G**, while both the Rh/Os (**2**) and Rh/Ru (**5**) compounds have a geometry like **H** in which the bridging carbonyl tends significantly towards the semi-bridged geometry. A closer comparison of the structural parameters of compounds **2** and **5** indicates that **5** lies slightly closer to the symmetrically bridged extreme **G**. On the basis that the most reactive compound (**2**) appears to be least well-represented by extreme **G** and therefore presumably has the weakest interaction between M and C(3)O(3), we proposed that this carbonyl can be more easily displaced from this Group 9 metal upon

Fig. 2. Perspective view of $[RhOs(CO)_4(\mu\text{-}CH_2)(dppm)_2]^+$ (**2**). Only the ipso carbons of the dppm phenyl rings are shown.

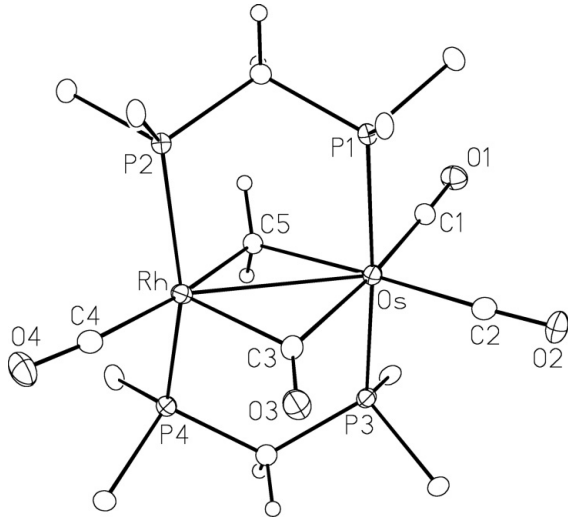


Table 1. Comparison of (*a*) bond lengths and (*b*) bond angles for the compounds $[MM'(CO)_4(\mu\text{-}CH_2)(dppm)_2][BF_4]$ (MM′ = RhOs, RhRu, IrRu).[a]

(*a*) Bond lengths (Å)			
MM′	RhOs[29]	RhRu[34]	IrRu[35]

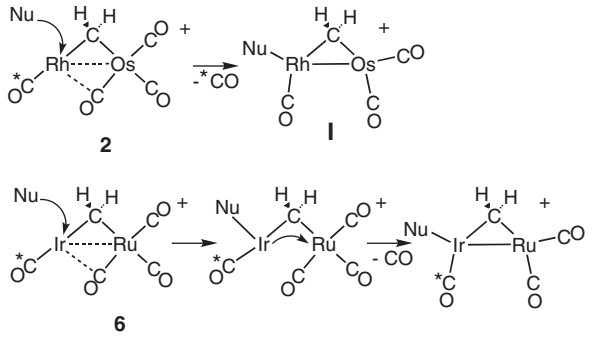
[b]M = Rh, Ir; M′ = Ru, Os.

nucleophilic attack by diazomethane at this metal, as shown in Scheme 6 (dppm groups omitted).

Support for these ideas about nucleophilic displacement of a carbonyl in the series of compounds **2**, **5**, and **6** was obtained in their reactions with trimethylphosphine. In all cases, reaction of these species with PMe_3 occurred readily, yielding the products $[MM'(PMe_3)(CO)_3(\mu\text{-}CH_2)(dppm)_2][X]$ (MM′ = RhOs, RhRu, IrRu), having a structure like that represented by **I** in Scheme 6 (Nu = PMe_3) and shown for the Ir/Ru species in Fig. 3. Furthermore, the rates of CO displacement at –25 °C at which these reactions could be conveniently monitored by NMR, was in the order: rate of **2** ≈ 30 × rate of **5** ≈ 36 × rate of **6**. These relative rates, under identical conditions, in an excess of PMe_3, are consistent with the structural trends noted above and with the argument that compound **2** having the weakest bridging carbonyl interaction with the Group 9 metal would react the fastest, while that having the strongest such interaction (**6**) would react the slowest.

© 2005 NRC Canada

Scheme 6.



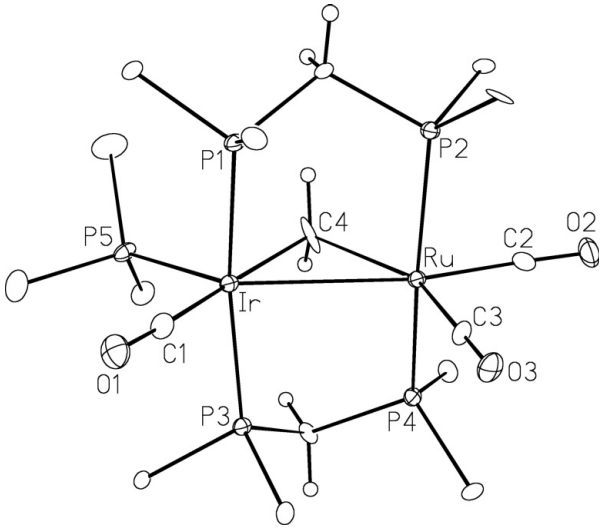


Fig. 3. Perspective view of $[IrRu(PMe_3)(CO)_3(dppm)_2]^+$. Only the ipso carbons of the dppm phenyl rings are shown.

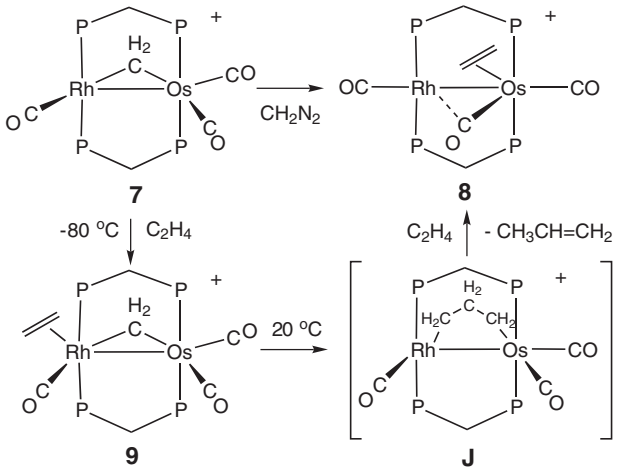
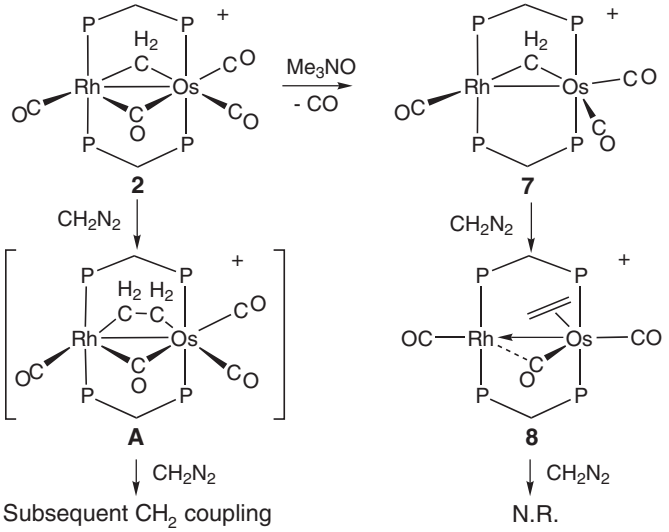


By selectively labeling the carbonyl bound to the Group 9 metal in compounds **2** and **6**, through reactions of the unlabeled precursors with ^{13}CO at –78 °C, we have been able to detect two subtly different mechanisms for carbonyl substitution by PMe_3. When the monolabeled **2** is reacted with PMe_3 at –78 °C, displacement of the labeled carbonyl occurs exclusively (see Scheme 6), indicating that for this metal combination, carbonyl substitution occurs solely at Rh. However, the Ir/Ru analogue (**6**) reacts in a binuclear fashion, with retention of the labeled CO on Ir and loss of an unlabeled Ru bound carbonyl. For the latter process, we can envision a mechanism in which nucleophilic attack at Ir is followed by dative bond formation, from Ir to Ru, which assists in displacing a carbonyl ligand from the latter. These different mechanisms can be rationalized based on the greater labilities of the second-row metals compared to their third-row congeners. As the reaction temperature is raised, carbonyl scrambling occurs in the Ir/Ru compound accompanied by some loss of labeled CO, indicating that other mechanisms become operable at higher temperatures. Unfortunately, we have not yet succeeded in selectively labeling the Rh/Ru analogue (**5**).

Carbonyl loss and methylene coupling

It seemed reasonable to assume that the reaction of **2** with diazomethane might parallel the PMe_3 reaction by loss of carbonyl to give an intermediate such as **I**, which might subsequently proceed through N_2 loss and coupling of the two methylene groups. This suggested to us that starting with the tricarbonyl analogue of **2**, namely $[RhOs(CO)_3(\mu\text{-}CH_2)(dppm)_2][X]$ (**7**), might yield either **3** or **4** under appropriate conditions, and that inducing CO loss from **5** and **6** in the presence of diazomethane might result in subsequent methylene incorporation in these species. We had presumed that the failures of **5** and **6** to react further with diazomethane had resulted because diazomethane was too weak a nucleophile to displace a carbonyl ligand in these species.

Scheme 7.



Surprisingly, Steve found that the reaction of **7** (generated by the reaction of **2** with 1 equiv. of Me_3NO) with diazomethane yielded neither **3** nor **4** over a wide temperature range, but instead yielded the ethylene adduct $[RhOs(\eta^2\text{-}C_2H_4)(CO)_3(dppm)_2]^+$ (**8**) as shown in Scheme 7. This product was shown by NMR techniques to have the ethylene group bound in an η^2 fashion to Os in a site adjacent to the bridging position between both metals (29). As such, compound **8** is similar to intermediate **B** in Scheme 3, which had been proposed as the species responsible for scrambling of the labels outlined in Scheme 2. It was puzzling therefore that the ethylene ligand in **8** did not move readily to the bridging site, resulting in subsequent methylene incorporation (as proposed in Scheme 3). Certainly, the failure of **8** to incorporate additional methylene groups is supportive of our earlier proposal that hydrocarbyl chain growth in this series arises by methylene insertion into the Rh—CH_2 bond of the *hydrocarbyl bridged* precursor.

The difference in the reactivity of the methylene bridged tetracarbonyl species **2** and its tricarbonyl analogue **7** with diazomethane is summarized in Scheme 8. Whereas the tetracarbonyl species gives rise to multiple methylene insertions yielding compounds **3** or **4**, the tricarbonyl species **7** yields only **8** with no further methylene incorporation occurring. Presumably, the additional carbonyl in intermediate **A** (of Schemes 3 and 8) is responsible for forcing the osmium bound ethylene in intermediate **B** (Scheme 3) back into the bridging site owing to steric congestion at Os. In the absence of this additional carbonyl, a terminally bound ethylene ligand, as observed in **8**, is favoured. In related chemistry, Jim Dennett, a postdoctoral fellow from Selby Knox's group, together with Steve Trepanier, have generated a series

© 2005 NRC Canada

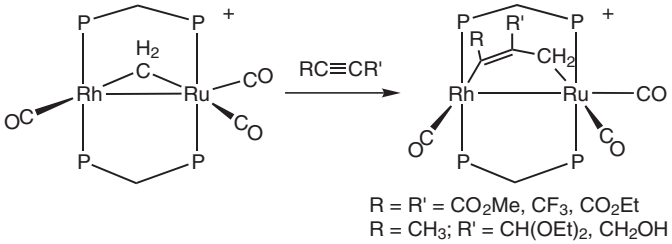
Scheme 8.

of mono- and bisethylene analogues of **8**, all of which have been shown to contain terminally bound ethylenes and are unreactive towards additional diazomethane (29). The failure of **8** to incorporate additional methylene groups suggests that carbonyl loss does not occur until *after* incorporation of the *third* methylene group, otherwise intermediate **A**, upon loss of a carbonyl, would yield the unreactive tricarbonyl species **8**.

As noted earlier, both the Ir/Ru and Rh/Ru analogues of **2** failed to incorporate additional methylene groups, presumably because the bridging carbonyl in these species was too strongly bound to the Group 9 metal to allow its displacement by diazomethane. Clearly, generation of the tricarbonyl analogues of these methylene bridged species, which is readily achieved by reaction of the tetracarbonyl precursors with Me_3NO, and their subsequent reaction with diazomethane was of interest to help establish the role of carbonyl loss in the methylene coupling sequence. In the case of $[IrRu(CO)_3(\mu\text{-}CH_2)(dppm)_2][X]$, analogous to **7**, Maria found that reaction with diazomethane yielded the ethylene adduct $[IrRu(CO)_3(\eta^2\text{-}C_2H_4)(\mu\text{-}CH_2)(dppm)_2][X]$ in which the ethylene ligand is bound to Ir, much like the structure proposed for compound **9**, shown in Scheme 7. However, labeling studies established that the metal-bound methylene group of the precursor was *not* incorporated into the ethylene ligand (35). Presumably, the strong Ir—CH_2 bond (36) of the precursor inhibits methylene insertion into this bond, and the ethylene is generated by a mechanism different from that proposed in Scheme 3 for the Rh/Os compound. In the case of the Rh/Ru analogue, Steve observed that reaction of $[RhRu(CO)_3(\mu\text{-}CH_2)(dppm)_2][X]$ with diazomethane at −40 °C yielded $[RhRu(CO)_3(\eta^2\text{-}C_2H_4)(dppm)_2][X]$, analogous to the Rh/Os product **8** (shown in Scheme 7); this ethylene adduct was also obtained at ambient temperature, but was contaminated by several unidentified products. Also observed in solution was free ethylene. Consistent with the expected weaker binding of ethylene to Ru than to Os (33), the Rh/Ru compound was found to be much less stable than **8**, surviving only a few hours in solution compared to several days for **8**.

The C_3 bridged intermediate

Looking back at our proposal for methylene coupling (shown in Scheme 3), it is clear that the pivotal intermediate in the production of either **3** or **4** is the propanediyl bridged intermediate **C**. This species either reacts with an additional diazomethane to give the butanediyl product **3** or undergoes β-H elimination and subsequent methylene incorporation to give the allyl methyl product **4**. We therefore were interested in learning more about this important C_3 bridged species.



In principle, another route to such a species is through ethylene insertion into the bridging methylene group of precursors such as **2** or **7**, as has been previously documented in related compounds (37). However, at ambient temperature, Jim and Steve found that neither reaction yielded the targeted product. Whereas **2** was unreactive towards ethylene, **7** reacted readily yielding the ethylene containing product **8** (as shown in Scheme 7) together with propene. At –80 °C, the ethylene adduct $[RhOs(\eta^2\text{-}C_2H_4)(CO)_3(\mu\text{-}CH_2)(dppm)_2]^+$ (**9**) was observed in which the ethylene ligand is assumed to be bound to Rh adjacent to the bridging CH_2 group. Although the lability of this ethylene ligand in **9** made unambiguous identification of the ethylene binding site impossible, the Ir/Ru analogue noted earlier, is much less labile and was clearly shown to have the geometry proposed for **9**, having the olefin bound to the Group 9 metal, adjacent to the bridging methylene ligand (35). Warming **9** to ambient temperature results in its transformation to **8** and propene, which we assume proceeds through ethylene insertion to yield the targeted propanediyl bridged intermediate **J**, which undergoes β-H elimination to yield an unobserved allyl hydride, which reductively eliminates propene. The putative "$[RhOs(CO)_3(dppm)_2]^+$" product would then react with an additional ethylene molecule to yield **8**.

Models for the C_3 bridged intermediate

Our failure to generate a propanediyl species was hardly surprising, given the proclivity of such species to undergo β-H elimination in the presence of coordinatively unsaturated late transition metals (12*a*, 12*f*, 38). We therefore considered the possibility of generating models for the C_3 bridged intermediates utilizing unsaturated substrates that would insert into the Rh—CH_2 bond of **2** or **7** to give products without hydrogen atoms in the β position of the resulting bridging hydrocarbyl group. One obvious substrate for achieving this is an internal alkyne, and the reactivities of several of these substrates with both Rh/Os and Rh/Ru series of compounds were investigated. Todd Graham, a former graduate student and at the time a postdoctoral fellow in my group, initiated the study on the Rh/Os compounds, which was completed by Amala Chokshi, while Bryan Rowsell looked at the Rh/Ru analogues. In both pairs of metal combinations, the tetracarbonyl precursors, $[RhM(CO)_4(\mu\text{-}CH_2)(dppm)_2][X]$ either failed to react with alkynes at ambient temperature or reacted very slowly. However, in the presence of trimethylamine oxide, the resulting loss of a carbonyl ligand to give $[RhM(CO)_3(\mu\text{-}CH_2)(dppm)_2][X]$, led to immediate reaction with the alkynes investigated. In the case of the Rh/Ru system, Bryan showed that reaction with RC≡CR′ (R = R′ = CO_2Me, CO_2Et, CF_3; R = CH_3, R′ = $CH(OEt)_2$, CH_2OH) yielded the products $[RhRu(CO)_3(\mu\text{-}\eta^1\text{:}\eta^1\text{-}RC{=}C(R')CH_2)$-

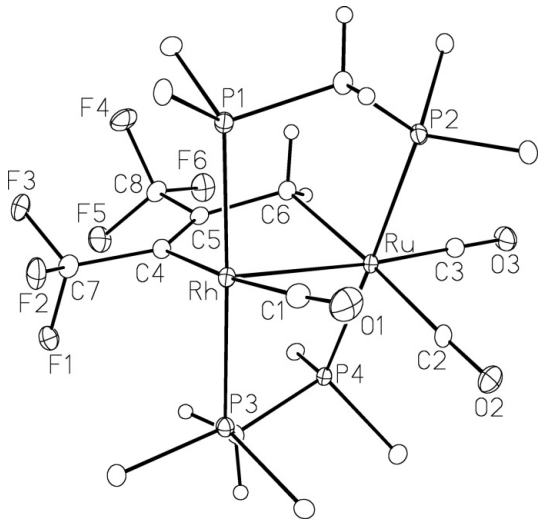
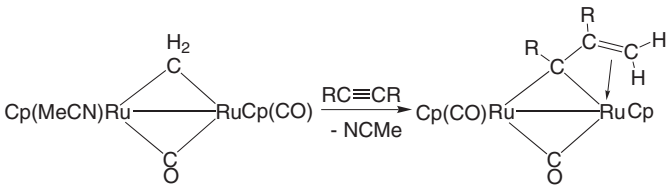
Scheme 9.



$(dppm)_2]^+$, as diagrammed in Scheme 9 (39). Todd and Amala demonstrated that the Rh/Os system reacted analogously with dimethyl acetylenedicarboxylate and hexafluorobutyne.[1] All products were found to have the targeted structure as diagrammed in Scheme 9 and shown in Fig. 4 for the hexafluorobutyne insertion product of Rh/Ru. These products are unsaturated analogues of the propanediyl bridged species (**C**) shown earlier.



Adjacent metals in hydrocarbyl group isomerization

Although these products of alkyne insertion were the targeted species, in some ways their structures were surprising. Previous alkyne insertions into bridging methylene groups had yielded the somewhat different bridging vinylcarbene products (40) as outlined for one example (40*f*) in Scheme 10. However, this η^1:η^3 coordination mode is closely related to the η^1:η^1 mode observed by us; whereas the former functions as a 4e donor, the latter is only a 2e donor. It seemed therefore that carbonyl loss from our compounds might induce a change in the hydrocarbyl group binding mode to alleviate the resulting electron deficiency, as suggested in Scheme 10. In the case of the Rh/Os compounds, $[RhOs(CO)_3(\mu\text{-}\eta^1\text{:}\eta^1\text{-}RC{=}C(R)CH_2)(dppm)_2][CF_3SO_3]$ (R = CO_2Me, CF_3), Amala discovered that carbonyl loss was merely accompanied by coordination of the triflate anion, leaving the hydrocarbyl binding mode unchanged. In the case of the Rh/Ru compound, $[RhRu(CO)_3(\mu\text{-}\eta^1\text{:}\eta^1\text{-}(CO_2Me)C{=}C(CO_2Me)CH_2)(dppm)_2][CF_3SO_3]$, the expected transformation (Scheme 11) to give **K** again did not occur. Instead, a related species resulted from a 1,3-hydrogen shift from the methylene group to the other end of the alkenyl group, accompanied by rotation of the vinylcarbene unit such that the carbon of the former methylene group ended up in the bridging position (as shown for **L**) (39). We propose that this occurs as diagrammed in Scheme 12 in which only the metals and the bridging hydrocarbyl groups are shown. First, C—H bond activation of the Ru bound methylene group yields a product such as **M**. We propose that carbon–hydrogen activation at the end remote from Rh is made possible by the twisting of the molecule about the Rh—Ru bond (as represented in Fig. 4). This twisting brings one of the methylene hydrogens into the vicinity of Rh, facilitating activation of this group. Reductive elimination of the hydride and vinyl fragment from Rh would yield the vinylcarbene complex **N**, which can yield the final product by rotation of the carbene moiety and subsequent coordination of the olefinic group at Ru.

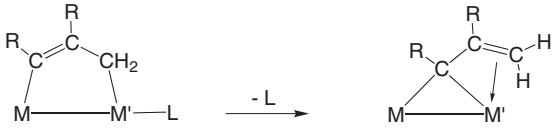


Fig. 4. Perspective view of $[RhRu(CO)_3(\mu\text{-}\eta^1\text{:}\eta^1\text{-}(CF_3)C{=}C(CF_3)CH_2)(dppm)_2]^+$. Only the ipso carbons of the dppm phenyl rings are shown.

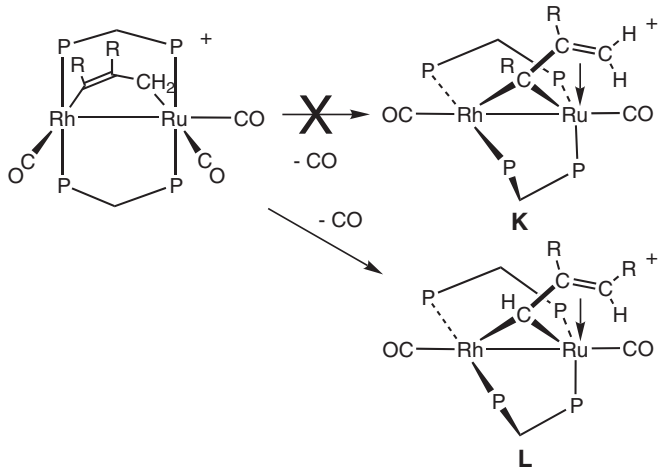
Scheme 10.

Compare 2e donor to 4e donor:



Although this isomerization of the hydrocarbyl fragment (demonstrated in Scheme 12) has no direct relevance to the methylene coupling sequence discussed throughout this paper, it certainly helps demonstrate how adjacent metals can work together to activate an organic fragment. The Ru bound methylene group is α to this metal, but is in a β position relative to the adjacent Rh centre, so facile β-H elimination can occur leading to subsequent rearrangements. This transformation also demonstrates the subtle reactivity differences that can be observed between otherwise similar pairs of metals. Therefore, carbonyl removal from the Rh/Os species results only in anion coordination, whereas the same initiation step in the Rh/Ru species leads to isomerization of the hydrocarbyl fragment. This reactivity difference is even more surprising when it is considered that the initial reactivity after carbonyl loss — either the initial C–H activation step in the Rh/Ru systems or anion coordination in the Rh/Os system — *occurs at Rh*. The subtle influence of an

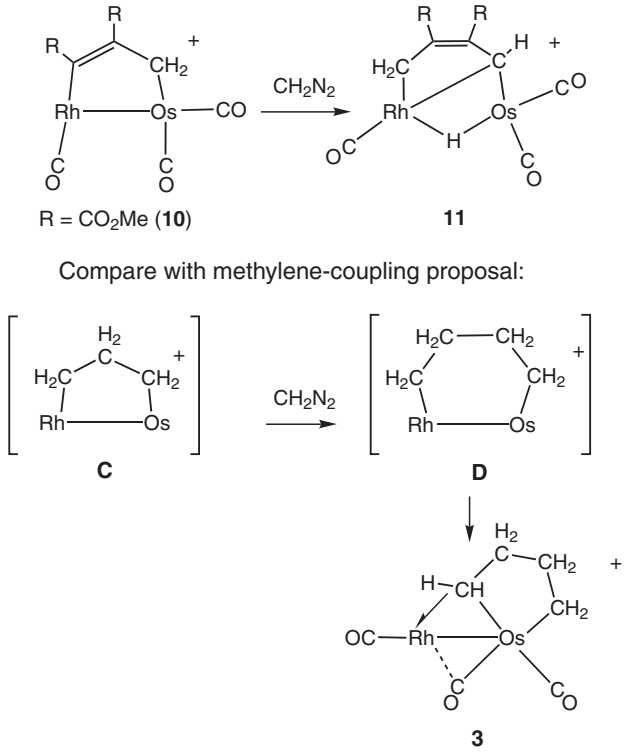
Scheme 11.

Scheme 12.



adjacent metal on the reactivity at another is an aspect that is currently not well understood.

C_3 to C_4 conversion

Irrespective of the isomerization discussed above, we were still interested in the use of species such as $[RhOs(CO)_3(\mu\text{-}\eta^1\text{:}\eta^1\text{-}RC{=}C(R)CH_2)(dppm)_2]^+$ (R = CO_2Me (**10**)), as models for the propanediyl bridged intermediates in methylene coupling reactions. Amala therefore sought to extend the above C_3 bridged fragment into C_4 or even higher fragments through reactions with diazomethane.[1] The reaction of compound **10** with diazomethane is summarized in Scheme 13 (dppm groups omitted). Significantly, this compound readily adds 1 equiv. of CH_2 to give the C_4 bridged product **11**, not unlike the C_3 to C_4 conversion proposed earlier in Scheme 3. Of some surprise is that methylene addition is accompanied by C–H cleavage of one of the methylene groups. Amala was able to establish by labeling studies that it is the original methylene group in **10** that undergoes C—H bond cleavage and not the newly added CH_2 group. The binding of both the methylene and methyne carbons to Rh is established by $^{13}C\{^1H\}$ NMR spectroscopy in which the

Scheme 13.

methylene carbon resonates at δ 70.3 showing 25 Hz coupling to Rh, while the methyne carbon appears at δ 118.3 with 16 Hz coupling to Rh. This C–H activation of a Group-8-bound methylene group by the adjacent Rh is reminiscent of the process noted earlier and shown in Scheme 12 for a related Rh/Ru complex.

In Scheme 13 is also shown a comparison with the transformation of a propanediyl group in **C** to the butanediyl product (**3**) through methylene incorporation. As shown, the immediate precursor of **3** is a butanediyl bridged species (**D**), having a structure that is not unlike that of **11**. It remains unclear why the butanediyl bridged intermediate **D** favours migration of the Rh bound end of the hydrocarbyl fragment to Os instead of the C–H activation process that yields **11**. It certainly seems clear that the putative unsaturated 2-butenediyl bridged intermediate immediately preceding **11** will experience a different strain within the dimetallacycle framework compared to that of the saturated analogue (**D**). This strain will influence, not only the tendency of the bridging group to migrate to Os to generate a more favourable five-membered ring, but also probably how close the C-H group to be activated can approach Rh. We assume here that a twisted structure as described above for the C_3 bridged species (see Fig. 4) will also be present in the C_4 bridged intermediates.

Recent results

James (Wiggy) Wigginton, a postdoctoral fellow also from Selby's group in Bristol, has recently followed up on Amala's studies in attempts to understand the subtle reactivity differences noted above for the two C_4 bridged species. He has generated a bridging "$CH_2CH_2C(R){=}CR$" group (R =

© 2005 NRC Canada

CO_2Me) by reacting the alkyne bridged complex, $[RhOs(CO)_3(\mu\text{-}RC{=}CR)(dppm)_2][X]$ (32), with 2 equiv. of diazomethane.[1] Interestingly, this species does not undergo C—H bond cleavage as diagrammed in Scheme 13 for the presumed precursor of **11**, which contains the isomeric "$CH_2C(R){=}C(R)CH_2$" fragment. Instead, it rearranges from the "C_4 bridged" structure to one in which the C_4 fragment is chelated to Os, analogous to the transformation of intermediate **D** to product **3**. The failure of a "$Rh(\mu\text{-}\eta^1{:}\eta^1\text{-}CH_2CH_2C(R){=}C(R))Os$" moiety to undergo C–H activation is certainly consistent with our proposal, described earlier, that it is a CH_2 group adjacent to either Ru or Os that is activated by Rh. Currently, we are continuing our attempts to further resolve the factors that influence the reactivity of these subtly different C_4 fragments.

In contrast to the above studies, Bryan Rowsell has established that the alkyne bridged Rh/Ru species, $[RhRu(CO)_3(\mu\text{-}RC{=}CR)(dppm)_2][X]$, appear not to give rise to CH_2 insertions into the metal–alkyne linkages (39), again demonstrating the strong tendency of the Rh/Os system to give rise to facile methylene insertions into the Rh—C bond of bridging hydrocarbyl fragments, while closely related systems containing other metal combinations are less reactive.

Wiggy and Amala have also demonstrated unusual differences in reactivity in the otherwise closely related alkyne bridged complexes, $[RhOs(CO)_3(\mu\text{-}\eta^1{:}\eta^1\text{-}RC{=}CR)(dppm)_2][X]$ (R = CO_2Me, CF_3). Whereas the first species (R = CO_2Me) reacts with diazomethane, as described previously, by the sequential insertions of *two* CH_2 groups into the Rh—alkyne bond, the second compound (R = CF_3) reacts with only a single equivalent of diazomethane to give the product of *apparent* CH_2 insertion into the *Os—alkyne* bond.[1] If this were the case, it would be the first example in our studies of preferential insertion into the Os—C bond in preference to insertion into Rh—C. However, we believe that the reaction occurs via alkyne loss at some stage followed by its insertion into the Rh—CH_2 bond of a bridging methylene group (as diagrammed earlier in Scheme 9). These observations again show that subtle changes to the system can give rise to significant reactivity differences. We need to obtain a better understanding of these effects and we are currently working towards this goal.

Concluding remarks

As noted in my introductory comments, one of our research goals has been to obtain a better understanding of the roles of adjacent metals in the activation of substrate molecules. I believe that the study presented herein achieves this goal in a number of important ways. First, we have established the importance of bridging hydrocarbyl groups in carbon–carbon bond formation while related terminally bound groups failed to lead to coupling of the hydrocarbyl fragments. The role of Rh in the Rh/Os and Rh/Ru compounds is clear; the coordinative unsaturation at this metal is pivotal in allowing initial substrate coordination at this metal followed by insertion into the adjacent Rh—C bond. Clearly, the lability of the Rh—C bond is also an important parameter, since upon substituting this metal by Ir a significantly lower tendency for insertions is observed.

The roles of the Group 8 metals in this chemistry are more subtle. In the methylene coupling sequence, we have observed the formation of C_3 and C_4 products only for the Rh/Os combination of metals. We propose that the strength of the Os–ethylene interaction seems necessary for enabling the ethylene to remain coordinated, rendering it susceptible to subsequent insertions. Although we have no direct comparison on the role played by the strength of ethylene binding upon the tendency to give increased hydrocarbyl chain length in the different metal combinations, since the Ir/Ru and Rh/Ru systems do not give chain growth under the same conditions as the Rh/Os system, we do note that the ethylene ligand in $[RhM(\eta^2\text{-}C_2H_4)(CO)_3(dppm)_2][X]$ (M = Ru, Os) is much more labile for Ru than for Os. Clearly, facile ethylene loss is not conducive to obtaining longer hydrocarbyl chain lengths.

We have also observed the subtle influence of the Group 8 metal in other ways. Although the chemistry reported is occurring primarily at Rh, the nature of this chemistry can change markedly upon changing the adjacent metal from Os to Ru. In the simple substitution reaction, for example, in which a PMe_3 group replaces a carbonyl on Rh, we might expect this to occur more readily with the Rh/Ru combination of metals (both being more labile than their third-row congeners). Instead, this combination is less labile than with Rh/Os. It is clear that in multinuclear systems, the influence of the adjacent metal, through interactions such as metal–metal bonds and involving bridging ligands, must also be considered in addition to the metal–ligand bond strengths.

An additional role of adjacent metals is observed in the facile activation of carbon–hydrogen bonds. We have observed a number of examples involving the activation of a C—H bond that is α to either Os or Ru by the adjacent Rh centre. In a metal–metal bonded binuclear species, a C—H bond that is α to one metal is β to the other, and facile torsion about the metal–metal bond seems capable of moving this C—H bond into a position that facilitates activation by the adjacent metal. Such an activation process is not possible in mononuclear systems.

As noted at several points throughout this paper, we still have a number of things to learn about the subtleties of binuclear reactivity. Nevertheless, our approach of methodically substituting the pairs of metals by their congeners appears to be useful in giving us a much improved understanding of the roles of these adjacent metals in the activation of organic substrates.

Acknowledgements

I have been fortunate in my career at the University of Alberta to have enjoyed the stimulating company of supportive colleagues such as John Bertie, Stan Brown, Bob Crawford, Bill Graham, Jeff Stryker, Rik Tykwinski, Rod Wasylishen, and (especially) Joe Takats, all of whom frequently advised me, particularly in matters related to organic chemistry or spectroscopy. I am also indebted to members of my research group over the years who were not only dedicated to the chemistry, but also helped create an enjoyable working environment. Only my diligence in checking purchase requisitions prevented one of them from owning a Porsche! In addition to the group members mentioned within this article,

Synthesis of fused pyrazolo-, isoxazolo-, pyrimido-, and pyridopyrimidines

Herojit S. Thokchom, Anita D. Nongmeikapam, and Warjeet S. Laitonjam

Abstract: A systematic study of the synthesis of the 5,7-diaryl-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thiones (**3**), 2-phenyl-5,7-bis(2′-methylphenyl)-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thiones (**4b**), 2(3*H*)-3-phenyl-5,7-diaryl-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thiones (**5**), 5,7-diaryl-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thiones (**7**), 3,5,7-triaryl-2,3-dihydro-4-oxo-isoxazalo[5,4-*d*]pyrimidin-6-thiones (**8**), 2-amino-6,8-diaryl-5-oxo-pyrimido[4,5-*d*]pyrimidin-7-thiones (**9**), 3,4-dihydro-2-amino-4-phenyl-6,8-diaryl-5-oxo-pyrimido[4,5-*d*]pyrimidin-7-thiones (**10**), 3-cyano-6,8-diaryl-2,5-dioxo-pyrido[2,3-*d*]pyrimidin-7-thiones (**11**) from the condensation products **1** and **2**, derived from 1,3-diaryl-2-thiobarbituric acids is described.

Key words: synthesis, fused, pyrazole, isoxazole, pyrimidines.

Résumé : On décrit une étude systématique de la synthèse des 5,7-diaryl-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thiones (**3**), 2-phényl-5,7-bis(2′-méthylphényl)-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thiones (**4b**), 2(3*H*)-3-phényl-5,7-diaryl-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thiones (**5**), 5,7-diaryl-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thiones (**7**), 3,5,7-triaryl-2,3-dihydro-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thiones (**8**), 2-amino-6,8-diaryl-5-oxo-pyrimido[4,5-*d*]pyrimidin-7-thiones (**9**), 3,4-dihydro-2-amino-4-phényl-6,8-diaryl-5-oxo-pyrimido[4,5-*d*]pyrimidin-7-thiones (**10**) et 3-cyano-6,8-diaryl-2,5-dioxo-pyrido[2,3-*d*]pyrimidin-7-thiones (**11**) à partir des produits de condensation **1** et **2** obtenus à partir des acides 1,3-diaryl-2-thiobarbituriques.

Mots clés : synthèse, condensé, pyrazole, isoxazole, pyrimides.

[Traduit par la Rédaction]

Introduction

Development of newer synthetic methods for the construction of fused heterocyclic rings of pyrimidine derivatives is a challenging task for synthetic organic chemists. It is well-known that pyrimidines either in isolated or in fused systems are associated with a number of biological activities. Moreover, the pyrimidine nucleus containing the thiouriedo linkage (-NH-C(S)-NH-) is pharmaceutically important because the development of medicines mainly arose from the heterocyclic compounds containing nitrogen and sulphur atoms (1, 2). It has been found that incorporation of various fused heterocycles into a pyrimidine nucleus enhances the biological activity (3, 4). In view of such wide applications, we have synthesized several derivatives of fused pyrimidines in maximum yields by using 1,3-diarylthiobarbituric acids. 1,3-Diarylthiobarbituric acids having an active methylene group can furnish several condensation products for easy cyclization to give various fused heterocyclic compounds of interest.

The 1,3-diarylthiobarbituric acids are among the simplest synthetic intermediates that can be easily prepared in a one-pot reaction by treating 1,3-diaryl thioureas with malonic acid in the presence of acetyl chloride. These intermediates have been extensively explored for five- and six-membered hetrocycles (5). The 1,3-diarylthiobarbituric acids undergo condensation with ethyl orthoformate and benzaldehyde to give the respective condensation products, namely, 5-ethoxymethylene-1,3-diaryl-2-thiobarbituric acids (**1**) and 5-phenylmethylene-1,3-diaryl-2-thiobarbituric acids (**2**), respectively (6). These condensation products possessing three electrophilic centers could undergo cyclocondensation with various binucleophiles to give various fused heterocycles of pyrimidine derivatives. In this paper, we report the synthesis of 4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thiones, 4-oxo-isoxazolo-[5,4-*d*]pyrimidin-6-thiones, 5-oxo-pyrimido[4,5-*d*]pyrimidin-7-thiones, and 5-oxo-pyrido[2,3-*d*]pyrimidin-7-thiones.

It is well-known that the fused heterocycles possessing the pyrazolo[3,4-*d*]pyrimidine nucleus serve as a class of compounds exhibiting a remarkable variety of biological activities (7–10). The pyrazolo[3,4-*d*]pyrimidine compounds have been found to show similar characteristics to purines, since they are isomeric structural purine analogues, which have resulted in several potent antagonists in biological systems (11, 12). It was also reported that the isoxazolo-pyrimidine derivatives exhibited antifungal, antibacterial, and many other important biological properties (13–15). The derivatives of pyrimido-pyrimidines are quite effective in the inhibition of cancer cell sickness (16), exhibition of diuretic activities (17), and also have central depressant analgesic and antiinflammatory activities (18).

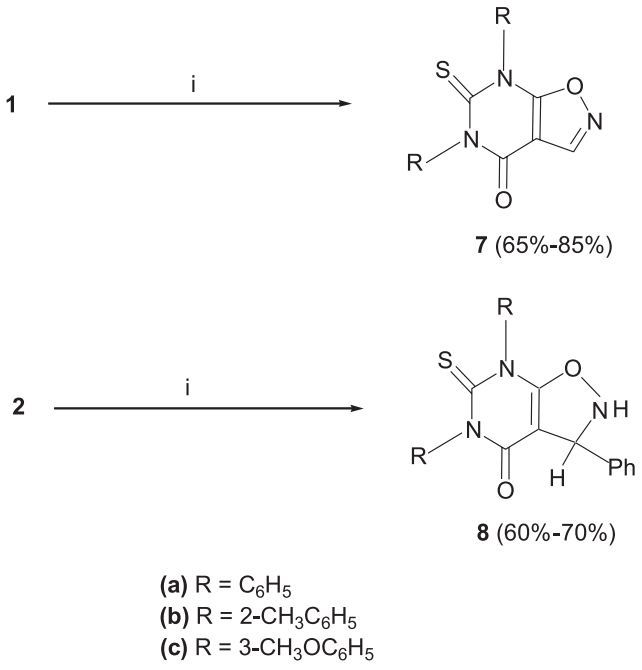
Results and discussion

A number of methods for the synthesis of pyrazolo-pyrimidines have been reported (19–24), but most of the methods involved a number of steps and yields were poor. In view of this, it was considered of interest to devise a convenient route for the synthesis of such compounds. Treatment of 5-ethoxymethylene-1,3-diaryl-2-thiobarbituric acids (**1**) with hydrazine hydrate in the presence of ethanol and acetic acid gave the corresponding pyrazolo[3,4-*d*]pyrimidin-6-thiones (**3**) in 65%–82% overall yields (Scheme 1). When **1b** was treated with phenyl hydrazine in ethanol and acetic acid, 2-phenyl-5,7-bis(2′-methylphenyl)-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thione (**4b**) was produced in 55% yield (Scheme 1). When 1,3-diaryl-5-phenyl-methylene-2-thiobarbituric acids (**2**) were refluxed with hydrazine hydrate in ethanol and acetic acid, the corresponding 2(3*H*)-3-phenyl-5,7-diaryl-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thiones (**5**) were obtained in 60%–75% overall yields (Scheme 1). It may be noted that **5** can be further oxidized to give the respective 3-oxo-pyrazolo-[3,4-*d*]pyrimidin-6-thiones (**6**).



Most of the methods for the preparation of the isoxazolo[5,4-*d*]pyrimidine system are initiated from the construction of an isoxazole ring first and followed by pyrimidine ring closure (25–27). As a part of our synthetic strategy, 1,3-diarylthiobarbituric acids were used as precursors for the synthesis of various isoxazolo[5,4-*d*]pyrimidines (28). The condensation products (**1** and **2**) on treatment with hydroxylamine hydrochloride in dehydrated alcohol and acetic acid gave the respective 5,7-diaryl-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thiones (**7**) in 65%–85% overall yields and 3,5,7-triaryl-2,3-dihydro-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thiones (**8**) in 60%–70% overall yields (Scheme 2).

In view of the various physiological properties, and in continuation of our work on fused pyrimidine systems, we also undertook the synthesis of substituted pyrimido[4,5-*d*]pyrimidines. In most cases, the pyrimido[4,5-*d*]pyrimidines were generally prepared from derivatives of enamines (29, 30). Various substituted 2-amino-6,8-diaryl-5-oxo-pyrimido[4,5-*d*]pyrimidin-7-thiones (**9**) in 55%–75% overall yields and 3,4-dihydro-2-amino-4-phenyl-6,8-diaryl-5-oxo-pyrimido[4,5-*d*]pyrimidin-7-thiones (**10**) in 62%–75% overall yields can be synthesized by reacting the respective compounds **1** and **2** with guanidine nitrate in the presence of sodium methoxide and methanol (Scheme 3).

Very few substituted pyrido[2,3-*d*]pyrimidines were syn-

Scheme 2. Reagents: (*i*) NH_2OH, EtOH, AcOH.

thesized from 6-aminouracils (31, 32). We report the synthesis of substituted 3-cyano-6,8-diaryl-2,5-dioxo-pyrido[2,3-*d*]pyrimidin-7-thiones (**11**) from the corresponding condensation product (**1**) derived from 1,3-diarylthiobarbituric acids (Scheme 4). Thus, we are reporting the synthesis of various fused heterocycles of pyrimidine derivatives from easily available starting materials, and most of the methods used by others are found to involve a number of steps and are of poor yields.

Experimental

Melting points were determined in open capillary tubes and are uncorrected. Infrared (IR) spectra were recorded on an ATI Mattson Genesis Series FT IR spectrometer. All samples were run as a thin film (produced by evaporation of a chloroform solution) on a sodium chloride plate. Absorption maxima were recorded in wavenumbers (cm^{-1}). ^1H NMR spectra were recorded on Varian Unity 500 (500 MHz), Bruker AC-300, and Varian XL (300 MHz) spectrometers. ^{13}C NMR spectra were recorded on Bruker AC-300 and Varian XL (75 MHz) spectrometers. Residual non-deuterated solvent was used as an internal reference and all chemical shifts (δ_H and δ_C) are quoted in parts per million (ppm) downfield from tetramethylsilane (TMS). All samples were run in deutero-chloroform ($CDCl_3$) as the solvent unless otherwise stated. Mass spectra were recorded on a Kratas Concept-IS mass spectrometer coupled to a Mach 3 data system, or on a Jeol-D 300 mass spectrometer.

5,7-Diphenyl-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thione (3a)

A mixture of **1a** (3.52 g, 0.01 mol), hydrazine hydrate (1 mL, 0.015 mol), ethanol (25 mL), and acetic acid (10 mL) was refluxed for 8 h. The reaction mixture was then concentrated, cooled, poured into ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. Flash chromatography (petroleum ether – EtOAc, 4:1) gave **3a** (2.56 g, 80%) as a white-grey solid, mp 261–263 °C. IR (ν_{max}, cm^{-1}): 3340, 1660. ^1H NMR (DMSO-d_6) δ: 5.00 (1H, br s, NH), 7.10–7.70 (10H, m, aromatic), 8.35 (1H, s, -CH=N-). MS (70 eV) *m*/*z* calcd. for $C_{17}H_{12}N_4OS$: 320.0750; found: 320.0734 (M^+).

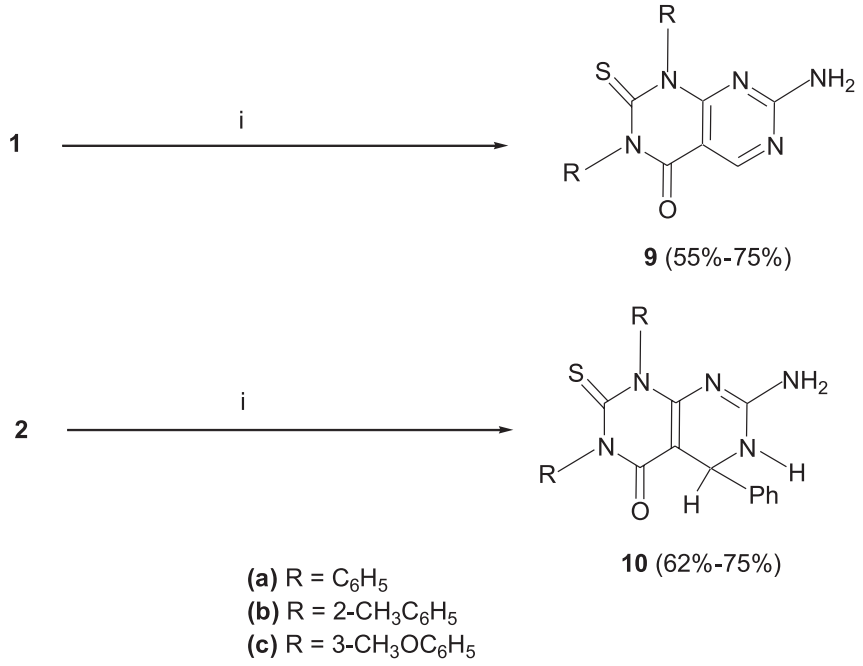
5,7-Di(2-methylphenyl)-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thione (3b)

A mixture of **1b** (3.80 g, 0.01 mol), hydrazine hydrate (1 mL, 0.015 mol), ethanol (25 mL), and acetic acid (10 mL) was refluxed for 9 h. The solution was worked up by pouring the concentrated residue onto ice water and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. The product was crystallized from ethanol to give **3b** (2.61 g, 75%) as a white solid, mp 282–284 °C. IR (ν_{max}, cm^{-1}): 3305, 1675. ^1H NMR (DMSO-d_6) δ: 2.08 (6H, s, 2 × CH_3), 5.35 (1H, br s, NH), 6.80–7.30 (8H, m, aromatic), 8.12 (1H, s, -CH=N-). MS (70 eV) *m*/*z* calcd. for $C_{19}H_{16}N_4OS$: 348.0970; found: 348.0960 (M^+).

5,7-Di(3-methoxyphenyl)-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thione (3c)

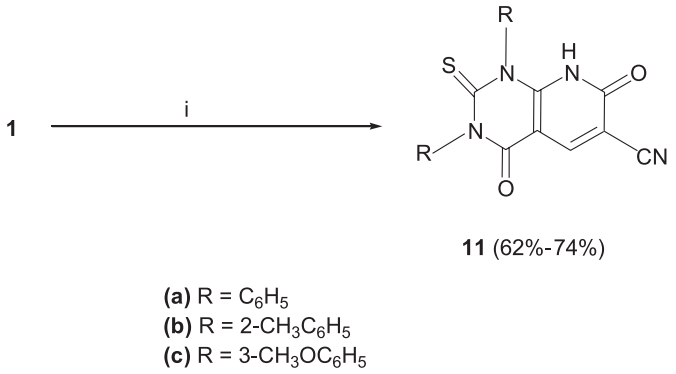
A mixture of **1c** (4.12 g, 0.01 mol), hydrazine hydrate (1 mL, 0.015 mol), ethanol (25 mL), and acetic acid (10 mL) was refluxed for 9 h. The reaction mixture was then concentrated, cooled, poured into ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. The product was crystallized from ethanol to give **3c** (3.12 g, 82%) as a white solid, mp 248–250 °C. IR (ν_{max}, cm^{-1}): 3310, 1680. ^1H NMR (DMSO-d_6) δ: 3.70 (6H, s, 2 × OCH_3), 4.75 (1H, br s, NH), 6.70–7.35 (8H, m, aromatic), 8.55 (1H, s, -CH=N-). MS (70 eV) *m*/*z* calcd. for $C_{19}H_{16}N_4O_3S$: 380.0603; found: 380.0607 (M^+).

5,7-Di(2-methylphenyl)-4-oxo-2-phenyl-pyrazolo[3,4-*d*]pyrimidin-6-thione (4b)



A mixture of **1b** (3.80 g, 0.01 mol), phenylhydrazine (1 mL, 0.015 mol), ethanol (25 mL), and acetic acid (10 mL) was refluxed for 6 h. The solution was worked up by pouring the concentrated residue into ice water and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. The product was crystallized from ethanol to give **4b** (2.32 g, 55%) as a white solid, mp 232–234 °C. IR (ν_{max}, cm^{-1}): 2950, 1660. ^1H NMR (DMSO-d_6) δ: 2.55 (6H, s, 2 × CH_3), 7.05–7.80 (13H, m, aromatic), 8.18 (1H, s, -CH=N-). MS (70 eV) *m*/*z* calcd. for $C_{25}H_{20}N_4OS$: 424.0707; found: 424.0716 (M^+).

2(3*H*)-3,5,7-Triphenyl-2(3*H*)-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thione (5a)



A mixture of **2a** (3.84 g, 0.01 mol), hydrazine hydrate (1 mL, 0.015 mol), ethanol (25 mL), and acetic acid (10 mL) was refluxed for 12 h. The reaction mixture was then concentrated, cooled, poured into ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. Flash chromatography (petroleum ether – EtOAc, 4:1) gave **5a** (2.58 g, 65%) as a white-grey solid, mp 212–214 °C. IR (ν_{max}, cm^{-1}): 3430, 3303, 1660. ^1H

NMR (DMSO-d_6) δ: 7.05 (1H, s, H-3), 7.15–7.80 (15H, m, aromatic), 10.02 (2H, m, 2 × NH). MS (70 eV) *m/z* calcd. for $C_{23}H_{18}N_4OS$: 398.0712; found: 398.0716 (M^+).

2(3*H*)-3-Phenyl-2(3*H*)-5,7-di(2-methylphenyl)-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thione (5b)

A mixture of **2b** (4.12 g, 0.01 mol), hydrazine hydrate (1 mL, 0.015 mol), ethanol (25 mL), and acetic acid (10 mL) was refluxed for 9 h. The reaction mixture was then concentrated, cooled, poured into ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. Flash chromatography (petroleum ether – EtOAc, 4:1) gave **5b** (2.08 g, 70%) as a white solid, mp 215–217 °C. IR (ν_{max}, cm^{-1}): 3400, 3300, 1680. ^1H NMR (DMSO-d_6) δ: 2.32 (6H, s, 2 × CH_3), 6.65 (1H, s, H-3), 6.80–7.60 (13H, m, aromatic), 9.38 (2H, m, 2 × NH). MS (70 eV) *m/z* calcd. for $C_{25}H_{22}N_4OS$: 426.0249; found: 426.0254 (M^+).

2(3*H*)-3-Phenyl-2(3*H*)-5,7-di(3-methoxyphenyl)-4-oxo-pyrazolo[3,4-*d*]pyrimidin-6-thione (5c)

A mixture of **2c** (4.44 g, 0.01 mol), hydrazine hydrate (1 mL, 0.015 mol), ethanol (25 mL), and acetic acid (10 mL) was refluxed for 11 h. The reaction mixture was then concentrated, cooled, poured into ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. The product was crystallized from ethanol to give **5c** (3.30 g, 72%) as a white solid, mp 235–237 °C. IR (ν_{max}, cm^{-1}): 3390, 3320, 1690. ^1H NMR (DMSO-d_6) δ: 3.30 (6H, s, 2 × OCH_3), 6.80 (1H, s, H-3), 6.95–7.80 (13H, m, aromatic), 9.68 (2H, m, 2 × NH). MS (70 eV) *m/z* calcd. for $C_{25}H_{22}N_4O_3S$: 458.0928; found: 458.0934 (M^+).

5,7-Diphenyl-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thione (7a)

A mixture of **1a** (3.52 g, 0.01 mol), absolute ethanol (50 mL), acetic acid (10 mL), and hydroxylamine hydrochloride (1.4 g, 0.02 mol) was refluxed for 8 h and excess ethanol was distilled off under reduced pressure. The residue was poured onto crushed ice, extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried (Na_2SO_4), and concentrated. Crystallization from ethanol gave **7a** (2.25g, 70%) as a white solid, mp 235 °C. IR (ν_{max}, cm^{-1}): 2980, 1670, 1210, 835, 725. ^1H NMR (DMSO-d_6) δ: 7.08–7.52 (10H, m, aromatic), 8.30 (1H, s, -CH=N-). MS (70 eV) *m/z* calcd. for $C_{17}H_{11}N_3O_2S$: 321.0762: found: 321.0754 (M^+).

5,7-Di(2-methylphenyl)-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thione (7b)

A mixture of **1b** (3.80 g, 0.01 mol), absolute ethanol (50 mL), acetic acid (10 mL), and hydroxylamine hydrochloride (1.4 g, 0.02 mol) was refluxed for 10 h. The solution was worked up by pouring the concentrated residue into ice water, and extracted with chloroform (3 × 100 mL),

washed with water (3 × 100 mL), dried, and concentrated. The product was crystallized from ethanol to give **7b** (2.27 g, 65%) as a white solid, mp 220–222 °C. IR (ν_{max}, cm^{-1}): 3100, 1690, 1220, 840, 785. ^1H NMR (DMSO-d_6) δ: 2.10 (6H, s, 2 × CH_3), 6.80–7.80 (8H, m, aromatic), 8.20 (1H, s, -CH=N-). MS (70 eV) *m/z* calcd. for $C_{19}H_{15}N_3O_2S$: 349.0578; found: 349.0583 (M^+).

5,7-Di(3-methoxyphenyl)-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thione (7c)

A mixture of **1c** (4.12 g, 0.01 mol), absolute ethanol (50 mL), acetic acid (10 mL), and hydroxylamine hydrochloride (1.4 g, 0.02 mol) was refluxed for 11 h. The residue was poured onto crushed ice, extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried (Na_2SO_4), and concentrated. Crystallization from ethanol gave **7c** (3.24 g, 85%) as a white solid, mp 215–217 °C. IR (ν_{max}, cm^{-1}): 2900, 1680, 1240, 845, 685. ^1H NMR (DMSO-d_6) δ: 3.75 (6H, s, 2 × OCH_3), 6.70–7.50 (8H, m, aromatic), 8.15 (1H, s, -CH=N-). MS (70 eV) *m/z* calcd. for $C_{19}H_{15}N_3O_4S$: 381.0250; found: 381.0254 (M^+).

3,5,7-Triphenyl-2,3-dihydro-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thione (8a)

A mixture of **2a** (3.84 g, 0.01 mol) and hydroxylamine hydrochloride (1.4 g, 0.02 mol) in absolute ethanol (50 mL) and acetic acid (10 mL) was refluxed for 12 h. The excess solvent was distilled off under reduced pressure and poured onto crushed ice, extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried (Na_2SO_4), and concentrated to give the crude product. Crystallization from chloroform–hexane gave **8a** (2.59 g, 65%) as a reddish-yellow solid, mp 195–198 °C. IR (ν_{max}, cm^{-1}): 3430, 2975, 1660, 1210, 838, 770. ^1H NMR (DMSO-d_6) δ: 6.50 (1H, s, -3CH), 6.80–7.70 (14H, m, aromatic), 10.40 (1H, s, NH). MS (70 eV) *m/z* calcd. for $C_{23}H_{17}N_3O_2S$: 399.0444; found: 399.0458 (M^+).

3-Phenyl-5,7-di(2-methylphenyl)-2,3-dihydro-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thione (8b)

A mixture of **2b** (4.12 g, 0.01 mol) and hydroxylamine hydrochloride (1.4 g, 0.02 mol) in absolute ethanol (50 mL) and acetic acid (10 mL) was refluxed for 10 h. The excess solvent was distilled off under reduced pressure and poured onto crushed ice, extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried (Na_2SO_4), and concentrated. The product was crystallized from ethanol to give **7b** (2.69 g, 63%) as a white solid, mp 205–207 °C. IR (ν_{max}, cm^{-1}): 3400, 2960, 1670, 1240, 845, 742. ^1H NMR (DMSO-d_6) δ: 2.20 (6H, s, 2 × CH_3), 6.65 (1H, s, H-3), 6.80–7.50 (13H, m, aromatic), 10.68 (1H, s, NH). MS (70 eV) *m/z* calcd. for $C_{25}H_{21}N_3O_2S$: 427.0800; found: 427.0803 (M^+).

3-Phenyl-5,7-di(3-methoxyphenyl)-2,3-dihydro-4-oxo-isoxazolo[5,4-*d*]pyrimidin-6-thione (8c)

A mixture of **2c** (4.44 g, 0.01 mol) and hydroxylamine hydrochloride (1.4 g, 0.02 mol) in absolute ethanol (50 mL) and acetic acid (10 mL) was refluxed for 15 h. The solution was worked up by pouring the concentrated residue onto ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. The product was crystallized from ethanol to give **7c** (3.58 g, 78%) as a white solid, mp 210–212 °C. IR (ν_{max}, cm^{-1}): 3390, 2980, 1680, 1240, 840, 785. ^1H NMR (DMSO-d_6) δ: 3.68 (6H, s, 2 × OCH_3), 6.30 (1H, s, H-3), 6.60–7.50 (13H, m, aromatic), 10.44 (1H, s, NH). MS (70 eV) *m/z* calcd. for $C_{25}H_{21}N_3O_4S$: 459.0342; found: 459.0347 (M^+).

2-Amino-6,8-diphenyl-5-oxo-pyrimido[4,5-*d*]pyrimidine-7-thione (9a)

The condensation product **1a** (3.52 g, 0.01 mol) in methanol (10 mL) was added to a well-stirred suspension of sodium methoxide (prepared by dissolving 0.92 g of sodium in 50 mL of methanol) and guanidine nitrate (2.57 g, 0.02 mol) and refluxed for 7 h. The solvent was removed under reduced pressure and the residue was poured onto crushed ice, extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried (Na_2SO_4), and concentrated to give the crude product. Crystallization from chloroform–hexane gave **9a** (2.50 g, 72%) as a reddish-yellow solid, mp 205–208 °C. IR (ν_{max}, cm^{-1}): 3380, 3320, 3200, 1650, 1580, 845. ^1H NMR (DMSO-d_6) δ: 5.24 (2H, br s, NH_2, exchangeable with D_2O), 7.10–7.80 (11H, m, aromatic and H-4). MS (70 eV) *m/z* calcd. for $C_{18}H_{13}N_5OS$: 347.0812; found: 347.0820 (M^+).

2-Amino-6,8-di(2-methyl)phenyl-5-oxo-pyrimido[4,5-*d*]pyrimidine-7-thione (9b)

The condensation product **1b** (3.80 g, 0.01 mol) in methanol (10 mL) was added to a well-stirred suspension of sodium methoxide (prepared by dissolving 0.92 g of sodium in 50 mL of methanol) and guanidine nitrate (2.57 g, 0.02 mol) and refluxed for 12 h. The solvent was removed under reduced pressure and the residue was poured onto crushed ice, extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried (Na_2SO_4), and concentrated to give the crude product. The product was crystallized from ethanol to give **9b** (2.21 g, 59%) as a yellowish solid, mp 196–198 °C. IR (ν_{max}, cm^{-1}): 3375, 3330, 3200, 1668, 1580, 804. ^1H NMR (DMSO-d_6) δ: 2.20 (6H, s, 2 × CH_3), 4.88 (2H, br s, NH_2, exchangeable with D_2O), 6.82–7.70 (9H, m, aromatic and H-4). MS (70 eV) *m/z* calcd. for $C_{20}H_{17}N_5OS$: 375.0528; found: 375.0543 (M^+).

2-Amino-6,8-di(2-methyl)phenyl-5-oxo-pyrimido[4,5-*d*]pyrimidine-7-thione (9c)

The condensation product **1c** (4.12 g, 0.01 mol) in methanol (10 mL) was added to a well-stirred suspension of sodium methoxide (prepared by dissolving 0.92 g of sodium in 50 mL of methanol) and guanidine nitrate (2.57 g, 0.02 mol) and refluxed for 8 h. The solution was worked up by pouring the concentrated residue into ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. The product was crystallized from ethanol to give **9c** (3.05 g, 75%) as a pale yellowish solid, mp 225–230 °C. IR (ν_{max}, cm^{-1}): 3382, 3325, 3210, 1655, 1585, 847. ^1H NMR (DMSO-d_6) δ: 3.76 (6H, s, 2 × OCH_3), 5.15 (2H, br s, NH_2, exchangeable with D_2O), 6.75–7.50 (9H, m, aromatic and H-4). MS (70 eV) *m/z* calcd. for $C_{20}H_{17}N_5O_3S$: 407.0829; found: 407.0834 (M^+).

3(4*H*)-2-Amino-4,6,8-triphenyl-5-oxo-pyrimido[4,5-*d*]pyrimidine-7-thiones (10a)

The condensation product **2a** (3.84 g, 0.01 mol) in methanol (10 mL) was added to a well-stirred suspension of sodium methoxide (prepared by dissolving 0.92 g of sodium in 50 mL of methanol) and guanidine nitrate (2.57 g, 0.02 mol) and refluxed for 7 h. The solvent was removed under reduced pressure and the residue was poured onto crushed ice, extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried (Na_2SO_4), and concentrated to give the crude product. The crude product was purified by flash chromatography (eluting with benzene–hexane, 1:2) and crystallized from chloroform–hexane to give **10a** (2.63 g, 62%) as a reddish-yellow solid, mp 215–218 °C. IR (ν_{max}, cm^{-1}): 3360, 3320, 3200, 1645, 1580, 824. ^1H NMR (DMSO-d_6) δ: 4.90 (2H, br s, NH_2, exchangeable with D_2O), 6.20 (1H, s, H-4), 6.80–7.60 (15H, m, aromatic). MS (70 eV) *m*/*z* calcd. for $C_{24}H_{19}N_5OS$: 425.0122; found: 425.0125 (M^+).

3(4*H*)-2-Amino-4-phenyl-6,8-di(2-methyl)phenyl-5-oxo-pyrimido[4,5-*d*]pyrimidine-7-thiones (10b)

The condensation product **2b** (4.12 g, 0.01 mol) in methanol (10 mL) was added to a well-stirred suspension of sodium methoxide (prepared by dissolving 0.92 g of sodium in 50 mL of methanol) and guanidine nitrate (2.57 g, 0.02 mol) and refluxed for 10 h. The reaction mixture was then concentrated, cooled, poured into ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. Flash chromatography (eluting with benzene–hexane, 1:2) and crystallization from chloroform–hexane gave **10b** (2.94 g, 65%) as a yellowish solid, mp 198–202 °C. IR (ν_{max}, cm^{-1}): 3385, 3330, 3205, 1655, 1570, 438. ^1H NMR (DMSO-d_6) δ: 2.30 (6H, s, 2 × CH_3), 4.85 (2H, br s, NH_2, exchangeable with D_2O), 6.25 (1H, s, H-4), 7.00–7.75 (13H, m, aromatic). MS (70 eV) *m*/*z* calcd. for $C_{26}H_{23}N_5OS$: 453.0639; found: 453.0642 (M^+).

3(4*H*)-2-Amino-4-phenyl-6,8-di(2-methyl)phenyl-5-oxo-pyrimido[4,5-*d*]pyrimidine-7-thiones (10c)

The condensation product **2c** (4.44 g, 0.01 mol) in methanol (10 mL) was added to a well-stirred suspension of sodium methoxide (prepared by dissolving 0.92 g of sodium in 50 mL of methanol) and guanidine nitrate (2.57 g, 0.02 mol) and refluxed for 6 h. The reaction mixture was then concentrated, cooled, poured into ice water, and extracted with chloroform (3 × 100 mL), washed with water (3 × 100 mL), dried, and concentrated. Flash chromatography (eluting with benzene–hexane, 1:2) and crystallization from chloroform–hexane gave **10c** (3.49 g, 72%) as a yellowish solid, mp 225–230 °C. IR (ν_{max}, cm^{-1}): 3375, 3330, 3200, 1650, 1580, 438. ^1H NMR (DMSO-d_6) δ: 3.70 (6H, s, 2 × CH_3), 4.93 (2H, br s, NH_2, exchangeable with D_2O), 6.30 (1H, s, H-4), 6.65–7.50 (13H, m, aromatic). MS (70 eV) *m*/*z* calcd. for $C_{26}H_{23}N_5O_3S$: 485.1018; found: 485.1023 (M^+).

3-Cyano-6,8-diphenyl-2,5-dioxo-pyrido[2,3-*d*]pyrimidin-7-thione (11a)

To a solution of sodium isopropoxide (prepared by dissolving sodium (0.46 g, 0.02 mol) in propan-2-ol (70 mL)), cyanoacetamide (1.68 g, 0.02 mol) was added and the reaction mixture was stirred for 10 min. Then, **1a** (3.52 g, 0.01 mol) was added and refluxed for 8 h. Evaporation of the solvent yielded an orange sodium salt of pyridone, which was dissolved in water (25 mL) and acidified with dilute HCl (8%) to give the crude product (**11a**). The product was crystallized from acetic acid to give **11a** (2.42 g, 65%) as an yellowish solid, mp 152–154 °C. IR (ν_{max}, cm^{-1}): 3333, 2194, 1686, 813. ^1H NMR (acetone-d_6) δ: 6.22 (1H, s, H-4), 6.85–7.58 (10H, m, aromatic), 8.83 (1H, br s, NH). M.S. (70 eV) *m*/*z* calcd. for $C_{20}H_{12}N_4O_2S$: 372.0716; found: 372.0710 (M^+).

3-Cyano-6,8-di(2-methylphenyl)-2,5-dioxo-pyrido[2,3-*d*]pyrimidin-7-thione (11b)

To a solution of sodium isopropoxide (prepared by dissolving sodium (0.46 g, 0.02 mol) in propan-2-ol (70 mL)), cyanoacetamide (1.68 g, 0.02 mol) was added and the reaction mixture was stirred for 10 min. Then, **1b** (3.80 g, 0.01 mol) was added and refluxed for 10 h. The solution was worked up by pouring the concentrated residue into ice water and acidified with dilute HCl (8%) to give the crude product. Crystallization from acetic acid afforded 3-cyano-6,8-di(2-methylphenyl)-2,5-dioxo-pyrido[2,3-*d*]pyrimidin-7-thione (**11b**, 2.96 g, 74%) as a yellow solid, mp 205–207 °C. IR (ν_{max}, cm^{-1}): 3346, 2210, 1684, 784. ^1H NMR (acetone-d_6) δ: 1.95 (3H, s, CH_3), 2.30 (3H, s, CH_3), 6.12 (1H, s, H-4), 6.65–7.95 (8H, m, aromatic), 8.78 (1H, br s, NH). MS (70 eV) *m*/*z* calcd. for $C_{22}H_{16}N_4O_2S$: 400.1012; found: 400.1015 (M^+).

3-Cyano-6,8-di(2-methylphenyl)-2,5-dioxo-pyrido[2,3-*d*]pyrimidin-7-thione (11c)

To a solution of sodium isopropoxide (prepared by dissolving sodium (0.46 g, 0.02 mol) in propan-2-ol (70 mL)), cyanoacetamide (1.68 g, 0.02 mol) was added and the reaction mixture was stirred for 10 min. Then, **1c** (4.12 g, 0.01 mol) was added and refluxed for 10 h. Evaporation of the solvent yielded an orange sodium salt of pyridone, which was dissolved in water (25 mL) and acidified with dilute HCl (8%) to give the crude product. Crystallization from acetic acid afforded 3-cyano-6,8-di(2-methylphenyl)-2,5-dioxo-pyrido[2,3-*d*]pyrimidin-7-thione (**11c**, 2.67 g, 62%) as a yellow solid, mp 186–188 °C. IR (ν_{max}, cm^{-1}): 3340, 2215, 1692, 811. ^1H NMR (acetone-d_6) δ: 3.62 (6H, s, 2 × OCH_3), 6.26 (1H, s, H-4), 6.95–7.45 (8H, m, aromatic), 8.92 (1H, br s, NH). MS (70 eV) *m*/*z* calcd. for $C_{22}H_{16}N_4O_4S$: 432.0970; found: 432.0959 (M^+).

Late metal salicylaldimine complexes derived from 5-aminosalicylic acid — Molecular structure of a zwitterionic mono Schiff base zinc complex

Tara A. Bourque, Megan E. Nelles, Teri J. Gullon, Christian N. Garon, Melissa K. Ringer, Lisa J. Leger, Jamie W. Mason, Susan L. Wheaton, Felix J. Baerlocher, Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott

Abstract: Condensation of salicylaldehyde (2-$HOC_6H_4C(O)H$) with 5-aminosalicylic acid (5-$H_2NC_6H_3$-2-(OH)-CO_2H) afforded the Schiff base 2-$HOC_6H_4C(H)=NC_6H_3$-2-(OH)-5-CO_2H (**a**). Similar reactivity with 5-bromosalicylaldehyde was also observed to give 5-Br-2-$HOC_6H_3C(H)=NC_6H_3$-2-(OH)-5-CO_2H (**b**). Reaction of these salicylaldehydes with Pd(II), Cu(II), and Zn(II) salts gave the corresponding bis(*N*-arylsalicylaldiminato)metal complexes (M = Pd (**1**), Cu (**2**), Zn (**3**)). The molecular structure of the Schiff base compound **a** has been confirmed by an X-ray diffraction study. Crystals of **a** were monoclinic, space group *P*2(1)/*c*, *a* = 7.0164(7) Å, *b* = 11.0088(11) Å, *c* = 14.8980(15) Å, β = 102.917(2)°, *Z* = 4. The molecular structure of a novel zwitterionic conformer of **3a** was also characterized by an X-ray diffraction study. Crystals of **4** were monoclinic, space group *P*2(1)/*c*, *a* = 9.5284(5) Å, *b* = 19.5335(11) Å, *c* = 8.6508(5) Å, β = 90.596(1)°, *Z* = 4. All new compounds have been tested for their antifungal activity against *Aspergillus niger* and *Aspergillus flavus*.

Key words: 5-aminosalicylic acid (5-ASA), antifungal, copper, palladium, salicylaldimines, Schiff base, zinc.

Résumé : La condensation du salicylaldéhyde (2-$HOC_6H_4C(O)H$) avec l'acide 5-aminosalicylique (5-$H_2NC_6H_3$-2-(OH)-CO_2H) conduit à la formation de la base de Schiff 2-$HOC_6H_4C(H)=NC_6H_3$-2-(OH)-5-CO_2H (**a**). On a observé une réactivité semblable avec le 5-bromosalicylaldéhyde qui conduit à la formation de la 5-Br-2-$HOC_6H_3C(H)=NC_6H_3$-2-(OH)-5-CO_2H (**b**). La réaction de ces salicylaldéhydes avec des sels de Pd(II), Cu(II) et Zn(II) conduit aux complexes correspondants bis(*N*-arylsalicylaldiminato)métal (M = Pd (**1**), Cu (**2**), Zn (**3**)). La structure moléculaire de la base de Schiff **a** a été confirmée par une étude de diffraction des électrons. Les cristaux de **a** sont monocliniques, groupe d'espace *P*2(1)/*c*, avec *a* = 7,0164(7) Å, *b* = 11,0088(11) Å et *c* = 14,8980(15) Å, β = 102,917(2)° et *Z* = 4. Faisant appel à la diffraction des rayons X, on a aussi caractérisé la structure moléculaire d'un nouveau conformère zwitterionique du composé **3a**. Les cristaux de **4** sont monocliniques, groupe d'espace *P*2(1)/*c*, avec *a* = 9,5284(5) Å, *b* = 19,5335(11) Å et *c* = 8,6508(5) Å, β = 90,596(1)° et *Z* = 4. L'activité fongicide des tous les nouveaux composés a été vérifiée contre *Aspergillus niger* et *Aspergillus flavus*.

Mots clés : acide 5-aminosalicylique (5-AAS), fongicide, cuivre, palladium, salicylaldimines, base de Schiff, zinc.

Introduction

Inflammatory bowel disease (IBD) is a serious disorder of the lower gastrointestinal tract where tissue damage and inflammation can impair the use of the bowel (1–13). Ulcerative colitis involves inflammation of the lining of the colon while Crohn's disease affects all layers of the intestinal wall. Both disorders are chronic, progressive diseases whose etiopathogenesis is not well understood. Current therapies for treating these disorders include glucocorticoids and 5-aminosalicylic acid (5-ASA, Fig. 1*a*) derivatives. Despite the well-documented benefits of 5-ASA in the treatment of IBD, its efficacy is limited due to side effects and allergic reactions associated with its mode of delivery. For example, sulfasalazine (Fig. 1*b*) was introduced over 60 years ago and has become the most widely prescribed agent for IBD, where the pharmacological action of this compound has been attributed to 5-ASA (14). When ingested orally, 88%

Fig. 1. (*a*) 5-ASA and (*b*) sulfasalazine.

of the sulfasalazine reaches the colon where it is degraded by azo reductases of the colonic microflora, into 5-ASA and sulfapyridine (8). All toxic effects associated with sulfasalazine are believed to arise from the sulfapyridine and, as a result, there has been a considerable amount of research focussed on designing new prodrugs of 5-ASA with less harmful side effects.

As part of our program designing metal complexes containing biologically active ligands, we have made Schiff base metal complexes derived from 5-ASA. As an initial screen of potential biological properties, we have examined all new complexes for their ability to act as antifungal agents.

Experimental

General

Reagents and solvents used were purchased from Aldrich Chemicals. $Pd(OAc)_2$ was purchased from Precious Metals Online Ltd. (Melbourne, Australia). NMR spectra were recorded on a JEOL JNM-GSX270 FT spectrometer or a Varian Mercury Plus 200 NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and referenced to residual solvent protons in deuterated solvent at 270 and 200 MHz, respectively. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 68 and 50 MHz, respectively, and are reported in ppm. Multiplicities are reported as singlet (s), doublet (d), triplet (t), multiplet (m), broad (br), and overlapping (ov). IR spectra were obtained using a Mattson Genesis II FT-IR spectrometer. Melting points were determined using a Mel-Temp apparatus and are uncorrected. Microanalyses for C, H, and N were carried out at Guelph Chemical Laboratories, Guelph, Ontario.

5-{[(1*E*)-(2-Hydroxyphenyl)methylene]amino}-2-hydroxybenzoic acid (a)

To an EtOH (10 mL) solution of 5-aminosalicylic acid (0.50 g, 3.26 mmol) was added an EtOH (5 mL) solution of salicylaldehyde (0.44 g, 3.60 mmol). The mixture was heated at reflux for 2 h to ensure completion, at which point a yellow precipitate was collected by suction filtration and washed with EtOH (3 × 5 mL) and Et_2O (3 × 10 mL). The yellow solid was then dried to afford **a** (0.63 g, 75%); mp 258–260 °C. IR (Nujol, cm^{-1}) ν: 1610 (C=N). Spectroscopic NMR data (in DMSO-d_6): ^{1}H NMR δ: 13.07 (br s, 1H, -O*H*), 8.98 (s, 1H, C(*H*)=N), 7.84 (d, *J* = 3 Hz, 1H, Ar), 7.67–7.64 (ov m, 2H, Ar), 7.39 (d of d, *J* = 8, 3 Hz, 1H, Ar), 7.06–6.94 (ov m, 3H, Ar). ^{13}C{^{1}H} NMR δ: 172.2, 162.2, 160.8, 160.7, 139.7, 133.4, 133.0, 129.1, 123.1, 119.8, 119.5, 118.6, 117.0, 114.1.

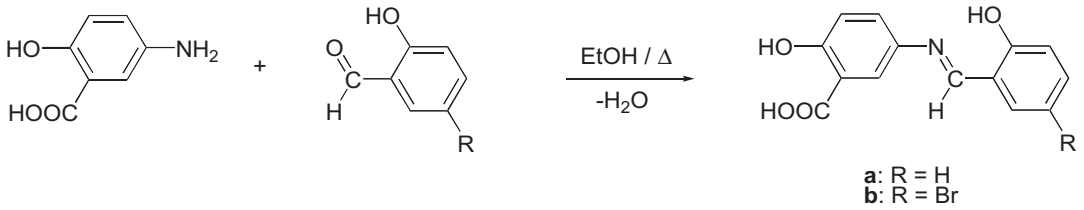
5-{[(1*E*)-(5-Bromo-2-hydroxyphenyl)methylene]amino}-2-hydroxybenzoic acid (b)

To an EtOH (10 mL) solution of 5-aminosalicylic acid (0.50 g, 3.26 mmol) was added an EtOH (5 mL) solution of 5-bromosalicylaldehyde (0.72 g, 3.58 mmol). The mixture was heated at reflux for 2 h to ensure completion, at which point a yellow precipitate was collected by suction filtration and washed with EtOH (3 × 5 mL) and Et_2O (3 × 10 mL). The pale yellow solid was then dried to afford **b** (0.93 g, 85%); mp 271 °C. IR (Nujol, cm^{-1}) ν: 1604 (C=N). Spectroscopic NMR data (in DMSO-d_6): ^{1}H NMR δ: 13.05 (br s, 1H, -O*H*), 8.94 (s, 1H, C(*H*)=N), 7.84–7.81 (ov m, 2H, Ar), 7.62 (d of d, *J* = 8, 3 Hz, 1H, Ar), 7.50 (d of d, *J* = 8, 3 Hz, 1H, Ar), 7.03 (d, *J* = 8 Hz, 1H, Ar), 6.90 (d, *J* = 8 Hz, 1H, Ar). ^{13}C{^{1}H} NMR δ: 172.2, 161.0, 160.9, 159.8, 139.8, 135.8, 134.6, 129.7, 123.3, 121.9, 119.6, 118.9, 114.2, 110.5.

Compound 1a

To an EtOH (50 mL) solution of palladium(II) acetate (0.20 g, 0.89 mmol) was added an EtOH (15 mL) solution of **a** (0.48 g, 1.87 mmol). The mixture was heated at reflux for 3 h at which point a yellow-green precipitate was collected by suction filtration and washed with cold EtOH (3 × 5 mL) and Et_2O (3 × 10 mL). The pale yellow solid was then dried to afford complex **1a** (0.47 g, 85%); mp 305 to 306 °C (decomposition). IR (Nujol, cm^{-1}) ν: 1608 (C=N). Spectroscopic NMR data (in DMSO-d_6): ^{1}H NMR δ: 8.11 (s, 2H, C(*H*)=N), 7.71 (d, *J* = 3 Hz, 2H, Ar), 7.47–7.43 (ov m, 4H, Ar), 7.17 (d of d, *J* = 8, 3 Hz, 2H, Ar), 6.99 (d, *J* = 8 Hz, 2H, Ar), 6.51 (t, *J* = 8 Hz, 2H, Ar), 6.03 (d, *J* = 8 Hz, 2H, Ar). ^{13}C{^{1}H} NMR δ: 172.1, 164.5, 164.4, 160.2, 140.8, 135.9, 135.7, 132.9, 126.2, 120.6, 120.1, 116.7, 115.4, 112.8. Anal. calcd. for $C_{28}H_{20}N_2O_8Pd$ (%): C 54.34, H 3.26, N 4.53; found: C 53.95, H 2.89, N 4.09.

Compound 1b



To an EtOH (40 mL) solution of palladium(II) acetate (0.15 g, 0.67 mmol) was added an EtOH (10 mL) solution of **b** (0.47 g, 1.40 mmol). The mixture was heated at reflux for 2 h at which point a yellow-green precipitate was collected by suction filtration and washed with cold EtOH (3 × 5 mL) and Et_2O (3 × 10 mL). The pale yellow solid was then dried to afford complex **1b** (0.47 g, 90%); mp 294 to 295 °C (decomposition). IR (Nujol, cm^{-1}) ν: 1603 (C=N). Spectroscopic NMR data (in DMSO-d_6): ^{1}H NMR δ: 8.09 (s, 2H, C(*H*)=N), 7.67 (d of d, *J* = 8, 3 Hz, 4H, Ar), 7.48 (d of d, *J* = 8, 3 Hz, 2H, Ar), 7.25 (d of d, *J* = 8, 3 Hz, 2H, Ar), 6.97 (d, *J* = 8 Hz, 2H, Ar), 5.93 (d, *J* = 8 Hz, 2H, Ar). ^{13}C{^{1}H} NMR δ: 172.2, 164.1, 163.4, 160.3, 140.6, 138.1, 137.2, 133.1, 126.2, 122.5, 122.4, 117.0, 112.7, 105.6. Anal. calcd. for $C_{28}H_{18}N_2Br_2O_8Pd$ (%): C 43.30, H 2.34, N 3.61; found: C 43.62, H 2.32, N 3.27.

Compound 2a

To an EtOH (50 mL) solution of copper(II) acetate (0.20 g, 1.10 mmol) was added an EtOH (15 mL) solution of **a** (0.59 g, 2.29 mmol). The mixture was heated at reflux for 3 h at which point a yellow-green precipitate was collected by suction filtration and washed with cold EtOH (3 × 5 mL) and Et_2O (3 × 10 mL). The pale yellow solid was then dried

to afford complex **2a** (0.60 g, 95%); mp 291 to 292 °C (decomposition). IR (Nujol, cm^{-1}) ν: 1608 (C=N). Anal. calcd. for $C_{28}H_{20}N_2CuO_8$ (%): C 58.38, H 3.51, N 4.86; found: C 57.74, H 3.32, N 4.75.

Compound 2b

To an EtOH (50 mL) solution of copper(II) acetate (0.20 g, 1.10 mmol) was added an EtOH (15 mL) solution of **b** (0.78 g, 2.32 mmol). The mixture was heated at reflux for 3 h at which point a yellow-green precipitate was collected by suction filtration and washed with cold EtOH (3 × 5 mL) and $CHCl_3$ (3 × 10 mL). The pale yellow solid was then dried to afford complex **2b** (0.52 g, 64%); mp 318–320 °C (decomposition). IR (Nujol, cm^{-1}) ν: 1610 (C=N). Anal. calcd. for $C_{28}H_{18}N_2Br_2CuO_8 \cdot 1.5CHCl_3$ (%): C 38.80, H 2.16, N 3.07; found: C 38.90, H 2.03, N 2.79.

Compound 3a

To an EtOH (50 mL) solution of zinc(II) acetate (0.20 g, 1.09 mmol) was added an EtOH (15 mL) solution of **a** (0.59 g, 2.29 mmol). The mixture was heated at reflux for 3 h at which point a yellow-green precipitate was collected by suction filtration and washed with cold EtOH (3 × 5 mL) and Et_2O (3 × 10 mL). The pale yellow solid was then dried to afford complex **3a** (0.60 g, 95%); mp 332–334 °C (decomposition). IR (Nujol, cm^{-1}) ν: 1608 (C=N). Spectroscopic NMR data (in DMSO-d_6): ^{1}H NMR δ: 13.36 (br s, 2H, -O*H*), 8.91 (s, 2H, C(*H*)=N), 7.79 (d, *J* = 3 Hz, 2H, Ar), 7.59 (d, *J* = 8 Hz, 2H, Ar), 7.44 (d of d, *J* = 8, 3 Hz, 2H, Ar), 7.33 (t, *J* = 8 Hz, 2H, Ar), 6.95–6.80 (ov m, 6H, Ar). ^{13}C{^{1}H} NMR δ: 173.6, 161.5, 161.1, 160.8, 139.1, 133.3, 133.0, 127.6, 123.7, 120.0, 119.6, 118.1, 117.6, 117.1. Anal. calcd. for $C_{28}H_{20}N_2O_8Zn$ (%): C 58.19, H 3.50, N 4.85; found: C 58.14, H 3.62, N 4.87.

Compound 3b

To an EtOH (50 mL) solution of zinc(II) acetate (0.20 g, 1.09 mmol) was added an EtOH (15 mL) solution of **b** (0.77 g, 2.29 mmol). The mixture was heated at reflux for 3 h at which point a yellow-green precipitate was collected by suction filtration and washed with cold EtOH (3 × 5 mL) and Et_2O (3 × 10 mL). The pale yellow solid was then dried to afford complex **3b** (0.64 g, 80%); mp 298–300 °C (decomposition). IR (Nujol, cm^{-1}) ν: 1601 (C=N). Spectroscopic NMR data (in DMSO-d_6): ^{1}H NMR δ: 13.33 (br s, 2H, -O*H*), 8.92 (s, 2H, C(*H*)=N), 7.81 (br m, 4H, Ar), 7.51–7.44 (ov m, 4H, Ar), 6.91–6.84 (ov m, 4H, Ar). ^{13}C{^{1}H} NMR δ: 173.1, 162.0, 159.9, 159.7, 138.4, 135.5, 134.5, 127.8, 123.6, 122.0, 119.6, 118.1, 118.0, 110.4. Anal. calcd. for $C_{28}H_{18}Br_2N_2O_8Zn$ (%): C 45.71, H 2.47, N 3.81; found: C 46.16, H 2.47, N 3.57.

X-ray crystallography

Crystals of **a** and **4** were grown from saturated EtOH and DMSO solutions, respectively, at 20 °C. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold stream of the goniometer. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and exposure times of 40 (**a**) and 30 s (**4**). The detector distances were 5 cm. The data were reduced (15) and corrected for absorption (16). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (17). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions and refined using a riding model (**a**) or located in Fourier difference maps and refined isotropically (**4**).

Antifungal testing

Compounds were tested for antifungal activity against pure cultures of *Aspergillus niger* and *Aspergillus flavus* supplied by Ward's Natural Science Ltd. (St. Catharines, Ontario). Cultures were maintained on Sabouraud dextrose agar. Six agar plugs (10 mm diameter) were cut from a 5–8 day old colony and homogenized in distilled, sterilized water (3 mL). From this suspension, 0.5 mL was transferred aseptically to a petri plate with Sabouraud dextrose agar (15 mL) and spread evenly over the entire surface. Each plate was provided with four evenly spaced paper disks (6 mm Fisherbrand P8 filter paper) containing the compound (100 μg). Each compound was applied to the disks as a solution (5 mg of compound per 1 mL of THF), where control disks were treated with neat THF (20 μL). Amphotericin B acted as a standard (100 μg) prepared in THF. Test plates with fungal homogenates were incubated at 20 °C for 48 h. Four replicate plates were used for each test. Antifungal activity was taken by the diameter of the clear zone surrounding the disk.

Results and discussion

Salicylaldimines

Schiff bases are remarkable compounds that have been utilized extensively in organic syntheses (18–24). For instance, a recent report describes a highly diastereo- and enantioselective asymmetric aldol reaction of glycinate Schiff bases with aldehydes (24). In this study, we have found that salicylaldehyde derivatives add to 5-aminosalicylic acid to give compounds having spectroscopic data consistent with the Schiff bases **a** and **b** (Scheme 1). As expected, a shift for the aldehyde proton from 10 to 9 ppm is observed in the ^{1}H NMR spectra and a resonance at ca. 160 ppm in the ^{13}C NMR spectra corresponds to the N=CH methine carbon. Likewise, formation of these compounds can be monitored

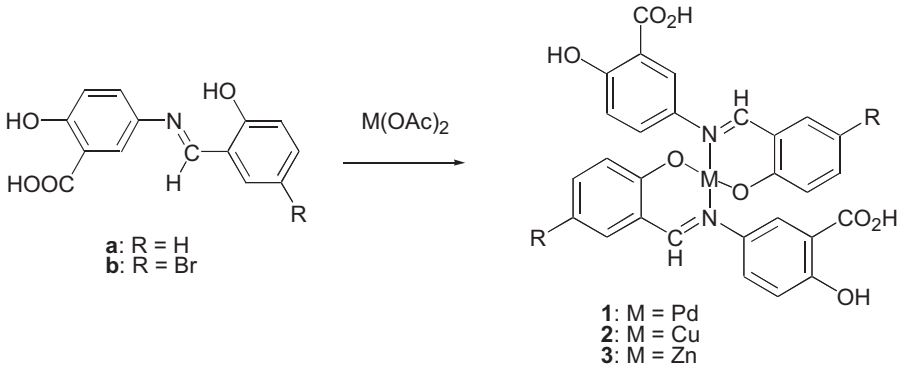
Fig. 2. Molecular structure of **a** with ellipsoids drawn at the 30% probability level. Hydrogen atoms omitted for clarity.

by the diagnostic C=N stretching band in the IR spectra at ca. 1620 cm^{-1} (20).



Compound **a** has also been characterized by a single crystal X-ray diffraction study, the molecular structure of which is shown in Fig. 2. Crystallographic data are provided in Table 1[3] and bond distances and angles are shown in Table 2. Structural features of **a** are similar to those reported recently for the hydroxy imide tautomer of sulfasalazine, 5-[4-[(2-pyridylideneamino)sulfonyl]phenyldiazenyl]salicylic acid (25). For instance, both molecules are almost planar as a result of extensive delocalization arising from an additional intramolecular interaction between the phenolic OH group on the 5-ASA fragment and the carboxylic acid C=O moiety (in **a**, O(8)-H(8)···O(1) = 1.622(2) Å). The imine C(10)—N(9) bond distance of 1.307(2) Å in **a** is comparable to bond lengths observed in other salicylaldimine derivatives (26). Although *N*-salicylaldimines are well-known to exist in tautomeric forms because of the intramolecular proton shift between the phenolic oxygen and the imine nitrogen (O-H···N ↔ O···H-N), no evidence for the other keto amine tautomer is present in the case of **a** (27).

Interestingly, lavendustin A, a structural derivative of compound **a**, has been reported to inhibit tyrosine kinase, an enzyme whose activity is often overexpressed in proliferative diseases (28). Compound **a** has also shown some inhibitory activity against tyrosine kinase (29). Likewise, the anti-inflammatory and antipyretic activities of Schiff bases derived from mesalazine and arylaldehydes have also been reported (30). These promising biological properties prompted

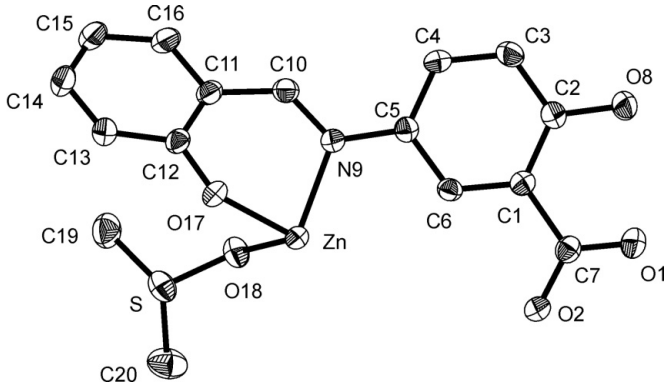
Scheme 2. Synthesis of metal Schiff base complexes **1**–**3**.

us to investigate the antifungal properties of late metal complexes containing these bioactive ligands.



Metal complexes

Schiff bases are ubiquitous in coordination chemistry and several reviews have recently been published outlining the practical aspects and challenges associated with these complexes (31–33). As part of our investigation into designing new chelating agents from biologically active compounds, we decided to examine the synthesis, reactivity, and antifungal properties of Schiff base Pd(II), Cu(II), and Zn(II) complexes derived from 5-ASA. Related Schiff base Pd(II) complexes derived from *S*-alkyldithiocarbazates have recently shown considerable antimicrobial activity against a number of pathogenic bacteria including methicillin-resistant *Staphylococcus aureus* (MRSA) and *Bacillus subtilis* (34). Copper and zinc Schiff base complexes have also shown considerable antibacterial and antifungal activity (35, 36).

We have found that addition of **a** and **b** to $M(OAc)_2$ (M = Pd, Cu, Zn) afforded bis(salicylaldiminato)metal(II) complexes (Scheme 2, **1**–**3**) in high to excellent yields (64%–95%). Complexes **1**–**3** have been characterized by a number of physical methods. For instance, elemental analyses for paramagnetic copper complexes **2** are consistent with bis-Schiff base formulation (37). The diagnostic C=N stretching band in the FT-IR spectra has shifted from ca. 1620 cm^{-1} to ca. 1595 cm^{-1} upon coordination to the metal centre (38). Multinuclear NMR spectroscopy was also used to characterize diamagnetic palladium and zinc complexes. For instance, a significant upfield shift in the ^1H NMR spectra is observed for the imine methine proton, from ca. 9 ppm to ca. 8 ppm, upon coordination of the ligand to the d^8 metal centre in complexes **1**. Coordination to the d^{10} zinc centres resulted in only minor shifts to ca. 8.9 ppm. More notable, however, is the absence of the broad OH stretch in the FT-IR spectra when the ligands are coordinated to the metals.

Interestingly, a zwitterionic conformer of complex **3a** has been characterized by an X-ray diffraction study, the molecular structure of which is shown in Fig. 3. Crystallographic data are given in Table 1, and bond distances and angles are listed in Table 3. Attempts to grow single crystals of **3a** in DMSO resulted in the loss of one Schiff base ligand, presumably via protonation by the carboxylic acid group of the 5-ASA moiety, to give the DMSO adduct **4** shown in Fig. 3. The solvent ligand is coordinated to the hard zinc via the oxygen atom of the DMSO. The remaining coordinated Schiff

Fig. 3. The molecular structure of **4** with ellipsoids drawn at the 30% probability level. Hydrogen atoms omitted for clarity.

base ligand must be behaving as a divalent anion to balance the Zn^{2+} cation. Indeed, the carboxylic carbon–oxygen bond lengths are roughly equivalent with C(7)—O(1) (1.254(3) Å) and C(7)—O(2) (1.261(3) Å), which is consistent with a deprotonated resonance structure (39). In comparison, the analogous distances in **a** are C(7)—O(1) (1.238(2) Å) and C(7)—O(2) (1.308(2) Å), where the single C(7)—O(2) bond is clearly defined as the benzylic oxygen. In related zinc 5-ASA complexes, coordination is believed to occur through the deprotonated carboxylate group (40).

Complex **4** exists as a self-assembled polymer consisting of dimeric units where two zinc atoms are connected asymmetrically by bridging Schiff base ligands via the phenolic oxygens (Fig. 4) (Zn—O(17) = 1.980(2) Å, Zn—O(17′) = 2.139(2) Å). The dimers form a 1D polymer via the carboxylic acid group (Zn—O(2) = 1.960(2) Å), and the distorted square pyramidal environment of Zn is completed by coordination of a DMSO molecule (Zn—O(18) = 2.130(2) Å) and the imine nitrogen (Zn—N(9) = 2.048(2) Å), the latter occupying the axial position.

Although zwitterionic zinc complexes are relatively well-known (41–48), Schiff base analogues are much less common. For instance, Zn(II) complexes of the type $ZnX_2(H_2salen)$ (X = Cl, Br, I, NO_3, SO_4) containing *N*,*N*′-ethylenebis(salicylideneimine) ligands have been reported previously (49). However, in these complexes the Schiff base ligand is bound to the metal centre through the negatively charged phenolic oxygens and not the nitrogen atoms. Related copper complexes containing only one tridentate Schiff base ligand have also been reported (50, 51). Complex **4** is

unique, however, in that it contains only one zwitterionic bidentate Schiff base ligand where the third coordination site is occupied by a solvent molecule.

Antifungal activity

As mentioned previously, the ability of metal Schiff base complexes to inhibit fungal growth is well-documented (34–

36). As a result, we have carried out initial antifungal studies on all new metal 5-ASA complexes described above (52). Unfortunately, only compounds **2b** and **3b** showed any appreciable activity against both *A. niger* and *A. flavus* (Table 4). It is interesting to note that the brominated derivatives showed slightly increased activities as compared to the parent Schiff base complexes and that copper and zinc complexes were more active than the analogous palladium complexes. Further work is needed, however, to fully understand the structural activity relationships in these complexes in an effort to design a more powerful antifungal agent.

Conclusion

We have prepared salicylaldimine compounds from 5-ASA and examined their ability to chelate to metals. Pd(II), Cu(II), and Zn(II) bis(*N*-arylsalicylaldiminato) complexes have been prepared in good to excellent yields. A novel zinc complex has been structurally characterized as a mono Schiff base DMSO adduct that forms a self-assembled polymer unit. The brominated complexes all showed moderate antifungal activity against both *A. niger* and *A. flavus*.

Triazene derivatives of (1,*x*)-diazacycloalkanes. Part IV.[1] Synthesis and characterization of 1-[2-aryl-1-diazenyl]-3-(3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinylmethyl)hexahydropyrimidines and 1-(5,5-dimethyl-3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinylmethyl)-5,5-dimethyl-3-[2-aryl-1-diazenyl]hexahydropyrimidines from the reaction of diazonium salts with mixtures of formaldehyde and 1,3-diaminopropanes

Shasta Moser, Ryan Church, M. Brad Peori, and Keith Vaughan

Abstract: Two new series of bistriazenes have been synthesized from a general reaction of diazonium salts with a mixture of a propanediamine and formaldehyde. Such reaction with 1,3-diaminopropane itself affords the 1-[2-aryl-1-diazenyl]-3-(3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinylmethyl)hexahydropyrimidines (**6**). 2,2-Dimethyl-1,3-diaminopropane reacts in an analogous manner to give the 1-(5,5-dimethyl-3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinylmethyl)-5,5-dimethyl-3-[2-aryl-1-diazenyl]hexahydropyrimidines (**7**). All new compounds have been characterized by IR and NMR spectroscopy, with elemental analysis or high resolution mass spectrometry of most of the new compounds. NMR assignments have been analyzed by a series of DEPT, COSY, and HSQC experiments. One example of each series has been unequivocally characterized by X-ray crystallography. The general conclusion of this study is that alkanediamines with three carbon atoms in the spacer link between the nitrogen atoms give rise to the linear bicyclic molecules of type **18**, in contrast to the case of ethylenediamine (spacer link has two carbon atoms), which affords cage-like molecules of type **17**.

Key words: bistriazene, hexahydropyrimidine, diazonium coupling, formaldehyde, diaminopropane, nuclear magnetic resonance.

Résumé : Deux nouvelles séries de bistriazènes ont été synthétisées par une réaction générale de sels de diazonium avec un mélange de propanediamine et de formaldéhyde. Une telle réaction avec le 1,3-diaminopropane conduit à la formation de 1-[2-aryldiazén-1-yl]-3-(3-[2-aryldiazén-1-yl]hexahydropyrimidin-1-ylméthyl)hexahydropyrimidines (**6**). Le 2,2-diméthyl-1,3-diaminopropane réagit d'une façon semblable pour conduire à la formation de 1-(5,5-diméthyl-3-[2-aryldiazén-1-yl]hexahydropyrimidin-1-ylméthyl)-5,5-diméthyl-3-[2-aryldiazén-1-yl]hexahydropyrimidines (**7**). Tous les nouveaux composés ont été caractérisés par spectroscopies IR et RMN, avec analyses élémentaires ou spectrométrie de masse à haute résolution pour la plupart des nouveaux composés. Les attributions RMN ont été analysées par une séries d'expériences DEPT, COSY et HSQC. Un exemple de chacune des séries a été caractérisé sans équivoque par diffraction des rayons X. La conclusion générale de cette étude est que les alcanediamines à trois atomes de carbones peuvent être utilisées comme lien pour créer un espace entre deux atomes d'azote avec la formation des molécules bicycliques linéaires de type **18**, par opposition aux produits résultant d'une insertion d'éthylènediamine (lien pour créer un espace de deux atomes de carbone) qui conduit à la formation de molécules en forme de cage du type **17**.

Mots clés : bistriazène, hexahydropyrimidine, couplage de diazonium, formaldéhyde, diaminopropane, résonance magnétique nucléaire.

Introduction

The term "bistriazene" has been coined to describe any molecule that contains two triazene units in the same molecule, with a link or spacer in between the triazene moieties. Recent progress in the synthesis of bistriazenes has been reviewed (1). The first encounter with bistriazenes in this laboratory was serendipitous. Reaction of a series of diazonium salts with mixtures of methylamine and formaldehyde was found to afford the novel hydroxymethyltriazenes (**1**) (2). A by-product of the synthesis of **1** was later found to be the bistriazene (**2**) (3); the bistriazene of type **2** is favoured by the presence of electron-donating groups in the aryl ring of the diazonium salt. Subsequent work found that the bistriazenes of type **3** (built around a central tetraazabicyclo[3.3.3]nonane cage) were produced from the analogous reaction of diazonium salts with ammonia–formaldehyde mixtures (4). This bridged bicyclic structure was also evident in the bistriazene products (**4**) synthesized by reaction of the diazonium salts with mixtures of ethylenediamine and formaldehyde (5). However, when the latter reaction was extended to the *trans*-1,2-diaminocyclohexane–formaldehyde–diazonium salt system, a different type of bistriazene with a linear bicyclic structure, rather than a bicyclic bridged structure, was formed. This structure is exemplified by compound **5**, which has been characterized by X-ray crystallography (6).

Thus, there seems to be a cross-over in behaviour of the alkanediamine going from ethylenediamine to cyclohexanediamine, and it is an intriguing question to see how other alkanediamines react under similar conditions. In the present study, we have explored these reactions with the next higher homologue of ethylenediamine, namely 1,3-diaminopropane, and also with 2,2-dimethyl-1,3-diaminopropane, which afford linear bicyclic molecules analogous to structure **5**. The products of these reactions are seen in structures **6** (**6a**–**6l**) and **7** (**7a**–**7l**), and they have been characterized by IR, ^{1}H and ^{13}C NMR spectroscopy, and elemental analysis or high resolution ESI mass spectrometry. One example of each series has been solved unequivocally by X-ray crystallography.

Experimental

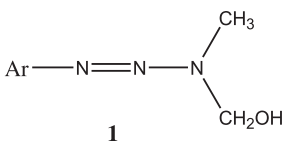
All reagents were reagent grade materials purchased from the Aldrich Chemical Co. Ltd., and were used without further purification. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. IR spectra were obtained using Nujol mulls on a PerkinElmer 299 spectrophotometer or with a Bruker Vector 22 spectrometer. ^{1}H and ^{13}C NMR spectra were obtained using either the Anasazi Instruments 60 MHz EFT spectrometer at Saint Mary's University, or the Bruker 250 MHz spectrophotometer at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University in Halifax, Nova Scotia. Chemical shifts were recorded in $CDCl_3$ or d_6-DMSO solutions at 20 °C, and are relative to TMS internal standard. The crystal structures were determined on a Nonius Kappa CCD diffractometer with graphite monochromated Mo Kα radiation (λ = 0.7107 Å). Elemental analyses were performed by the Canadian Microanalytical Service, Ltd., Delta, British Columbia.

Accurate mass measurements were performed at the Chemistry Department MS facility at UBC, Vancouver. ESI-MS was measured on a Water/Micromass LCT. The sample was dissolved in methanol or methanol–chloroform. The solution concentration was about 50~100 μmol/L. It was infused to LCT at a flow rate of 30 μL/min. For accurate mass measurement of $(M + H)^+$, either tetralysine KKKK or angiotensin III was used as the reference compound. The mass of $(M + H)^+$ from tetralysine was used as the lock mass.

Reaction of diazonium salts with mixtures of formaldehyde and a propanediamine

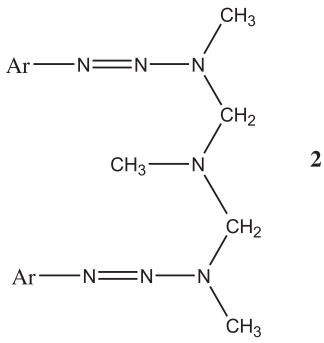
General procedure

Method A



The appropriate arylamine (0.010 mol) was dissolved in 40 mL of hydrochloric acid (3 mol/L) with heating if necessary to obtain a clear solution, and then this solution was cooled in an ice–salt bath. The arylamine hydrochloride solution was diazotized at 0–5 °C with a solution of sodium nitrite (0.011 mol) in water and the resulting mixture was stirred in the cold for 0.5 h, after which any insoluble impurities were removed by vacuum filtration. The mixture was brought to pH 7 using a saturated solution of sodium bicarbonate, at which point 37% aqueous formaldehyde solution (5 mL) was added. An appropriate amount of the diaminopropane (0.010 mol) was slowly added to the solution, which was allowed to stir in the cold for a further 0.5 h. Occasionally, a slight precipitate was evident during the period of the addition, but was not removed. The mixture was then adjusted to alkaline pH with additional saturated sodium bicarbonate solution, whereupon the product precipitated out of solution. Solid precipitates were isolated by vacuum filtration and purified by recrystallization from an appropriate solvent. Oils were recovered by extraction into dichloromethane (3 × 20 mL aliquots), dried over anhydrous $MgSO_4$, and rotoevaporated under vacuum.

Method B



The procedure of method A was followed exactly, with the exception of the amount of formaldehyde used; a 40:1 molar ratio of formaldehyde:arylamine was used, i.e., approx 32 mL of 37% aqueous formaldehyde was added at the appropriate time.

The application of method A or B with 1,3-diaminopropane gave the following compounds of series **6**: 1-[2-(*p*-cyanophenyl)-1-diazenyl]-3-(3-[2-(*p*-cyanophenyl)-1-diazenyl]-hexahydro-1-pyrimidinylmethyl)hexahydropyrimidine (**6a**): method B, 88% yield, mp 165 to 166 °C (EtOH). IR ν_{max} (cm^{-1}): 845, 2222 (CN). Anal. calcd. for $C_{23}H_{26}N_{10}$ (%): C 62.4, H 5.9, N 31.6; found: C 62.4, H 5.6, N 31.2. 1-[2-(*p*-Nitrophenyl)-1-diazenyl]-3-(3-[2-(*p*-nitrophenyl)-1-diazenyl]hexahydro-1-pyrimidinylmethyl)hexahydropyrimidine (**6b**): method B, 87% yield, mp 170–173 °C (toluene). IR ν_{max} (cm^{-1}): 850, 1378, 1510 (NO_2). ^{1}H NMR spectroscopic data for compounds **7** (**7a**–**7l**) are shown in Table 3; Table 4 is a list of the ^{13}C NMR spectroscopic data for these compounds. Proton and carbon labels relevant to these tables are shown in Fig. 2.

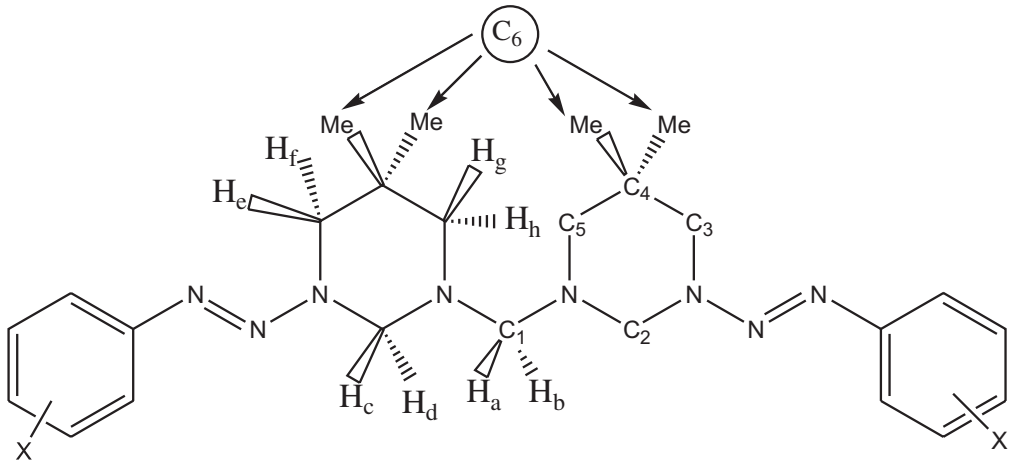
Results and discussion



Reaction of a mixture of 1,3-diaminopropane and formaldehyde with an arene diazonium salt afforded the new bistriazene series, the 1-[2-aryl-1-diazenyl]-3-(3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinylmethyl)hexahydropyrimidines (**6a**–**6l**), in moderate to excellent yields. It should be noted at the outset that there is a wide range of stability of the compounds in this series. Some of the compounds, notably **6d** and **6i**, started to decompose within a short time of being isolated, so that characterization of these products was restricted to immediate IR and NMR spectroscopic analysis. Several of the more stable products displayed a limited shelf life when stored for a couple of years; samples that were fine powders when fresh are now glass, such as **6c** and **6e**. Others like **6b**, **6f**, and **6g** show little, if any, sign of decay. Compound **6a**, which afforded an X-ray crystallographic structure, is somewhat fickle in this regard; a crude sample that was stored for over 2 years shows signs of glassiness, whereas two purified samples of the same compound show no sign of decomposition. It is possible that the stability of

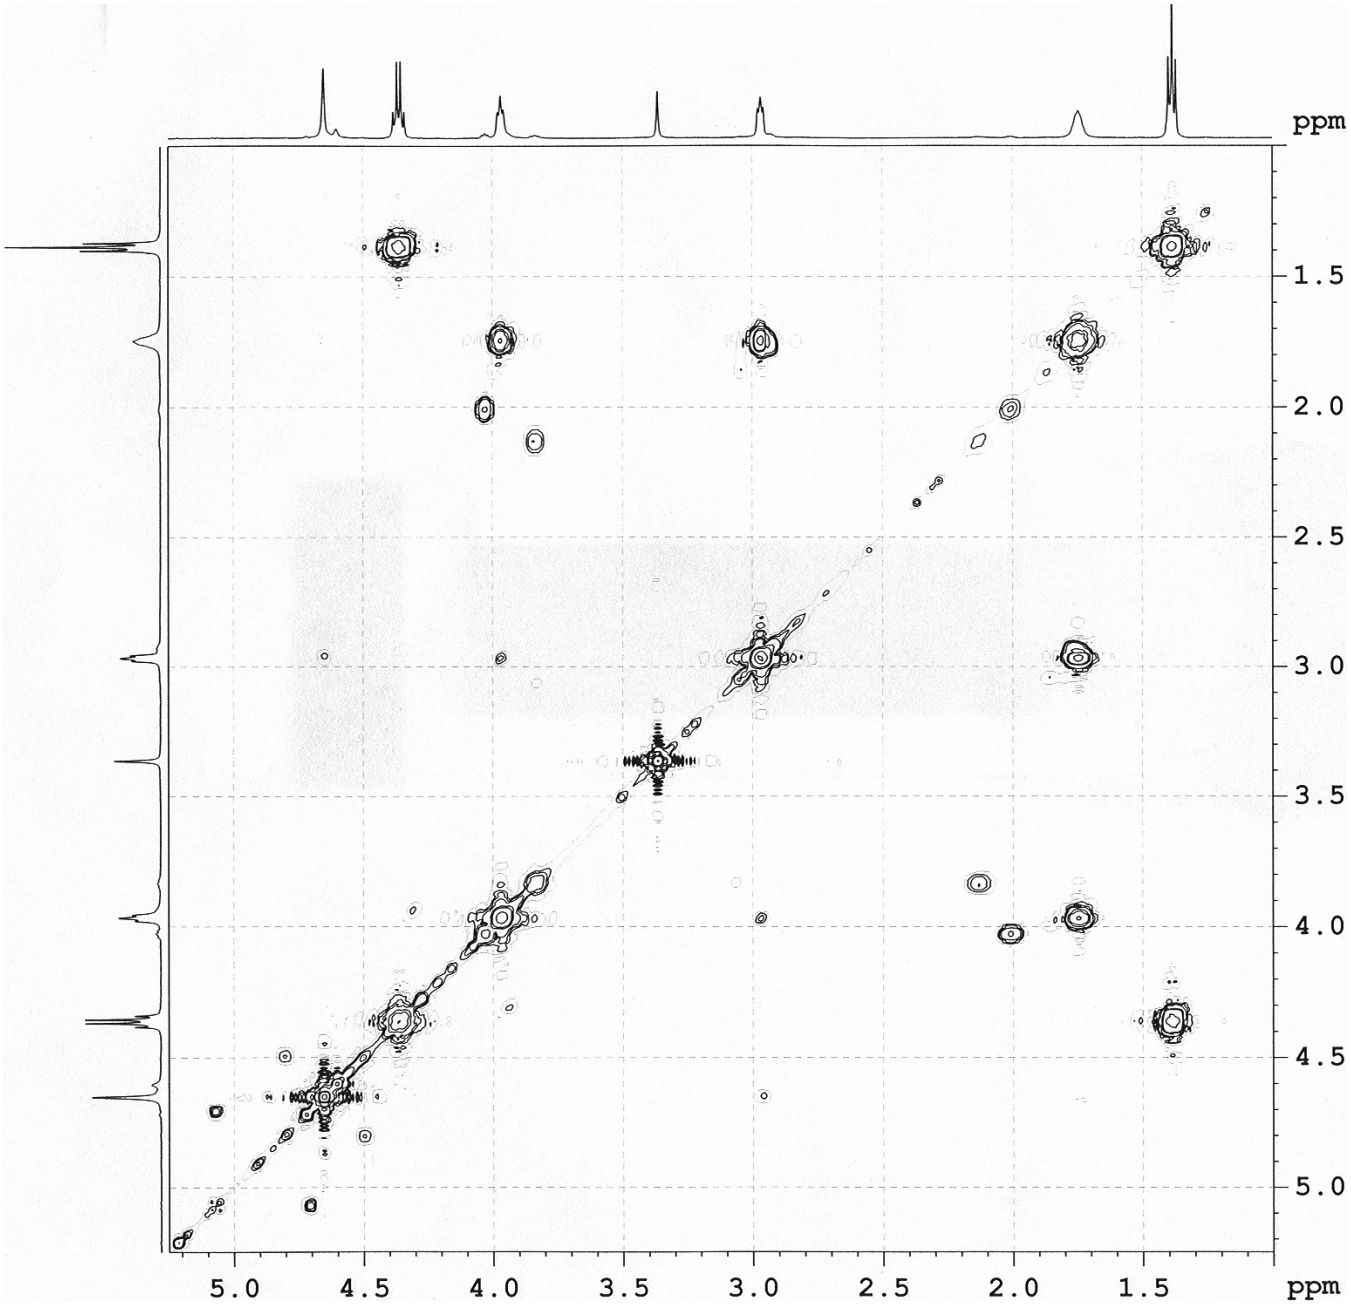
Fig. 2. Proton and carbon labels for the interpretation of the NMR spectra in Tables 3 and 4.



these bis(aryldiazenylhexahydropyrimidinyl)methanes is prolonged in the crystalline state compared to the amorphous state, but we have not undertaken a systematic study of this question.

In spite of these problems with handling and stability, there is no doubt that the structures of the products in series **6** are correct as described. An X-ray crystal structure of compound **6a** has been published recently (7). All compounds in series **6** have been characterized by ^{1}H NMR and, with the exception of compound **6f**, by ^{13}C NMR spectroscopy. **6f** was simply not sufficiently soluble to afford a ^{13}C spectrum. There is excellent correlation of chemical shifts throughout the series to reinforce the structural assignment. In the proton NMR spectra (Table 1), the central methylene protons (H_a and H_b), bridging the two heterocyclic rings, give rise to a singlet at ca. 3.3–3.4 ppm, with the exception of the signals in **6j** and **6k**, which appear as triplets. The small coupling constants associated with these triplets suggests that some long range coupling is responsible. A singlet methylene at ca. 4.6–4.7 ppm of twice the intensity arises from H_c and H_d attached to C-2 of the heterocyclic ring. The protons of the methylene groups H_g/H_h and H_i/H_j appear as broad triplets at ca. 4.0 and 3.0 ppm, respectively, with coupling constants around ca. 5 to 6 Hz, owing to vicinal coupling with the H_e/H_f protons of the central methylene group. The latter gives a broad signal at ca. 1.7 ppm, which is sometimes resolved into the expected pentuplet with a coupling constant of 5.5 Hz. The broadness of the signals in these spectra suggests that there is a dynamic equilibrium within the molecule, either arising from restricted rotation around the N—N bond in the triazene moieties (8) or from conformational equilibria in the heterocyclic rings. All compounds of series **6** give rise to the expected pattern of signals in the aromatic region and also show the appropriate

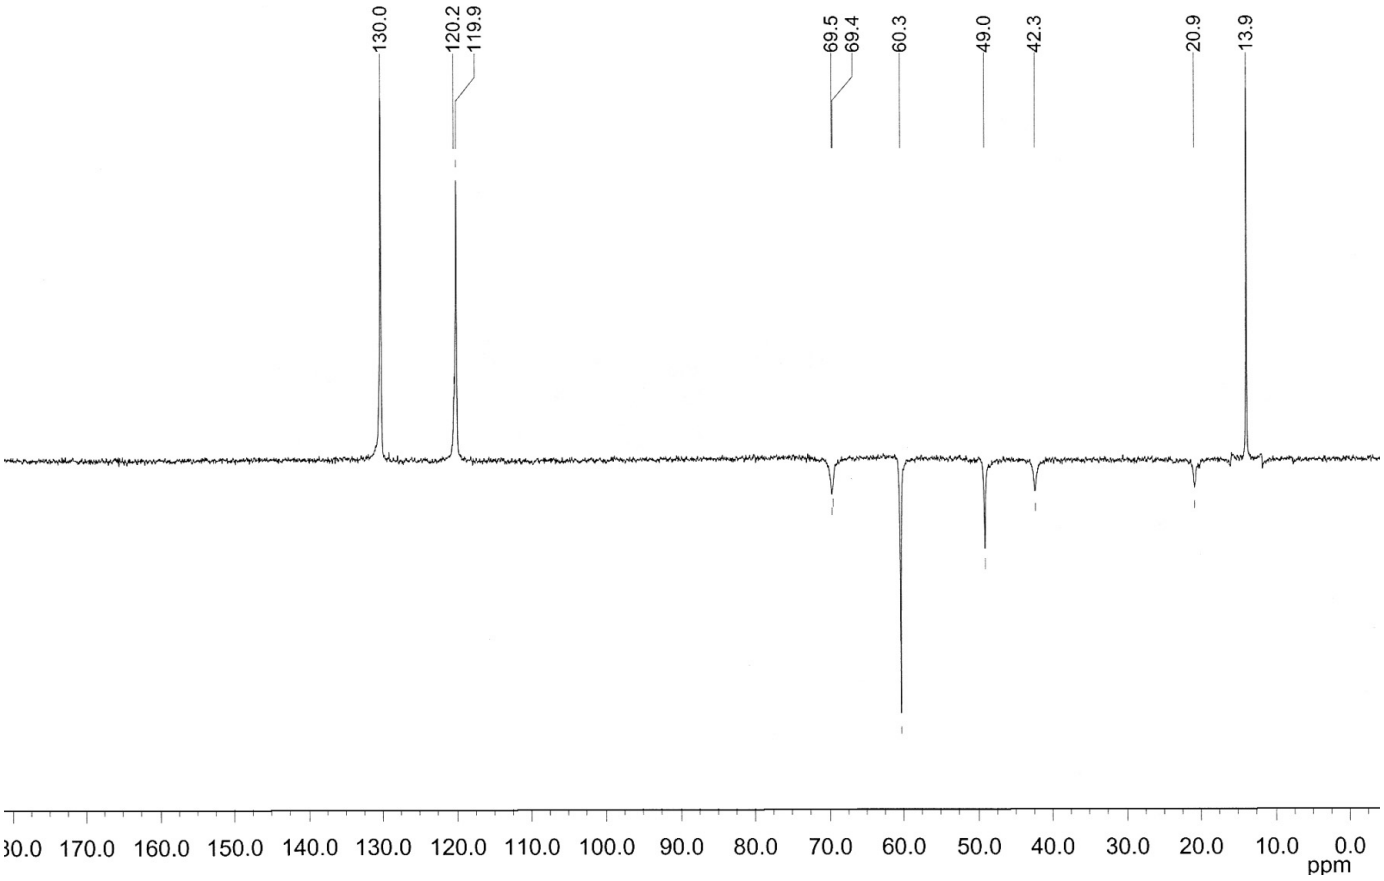
Fig. 3. COSY NMR spectrum of 1-[2-{*p*-ethoxycarbonylphenyl}-1-diazenyl]-3-(3-[2-{*p*-ethoxycarbonylphenyl}-1-diazenyl]hexahydro-1-pyrimidinylmethyl)hexahydropyrimidine (**6d**).

signals from the protons, if any, in the aryl substituent. The aryl substituents were also characterized by IR spectroscopic analysis.



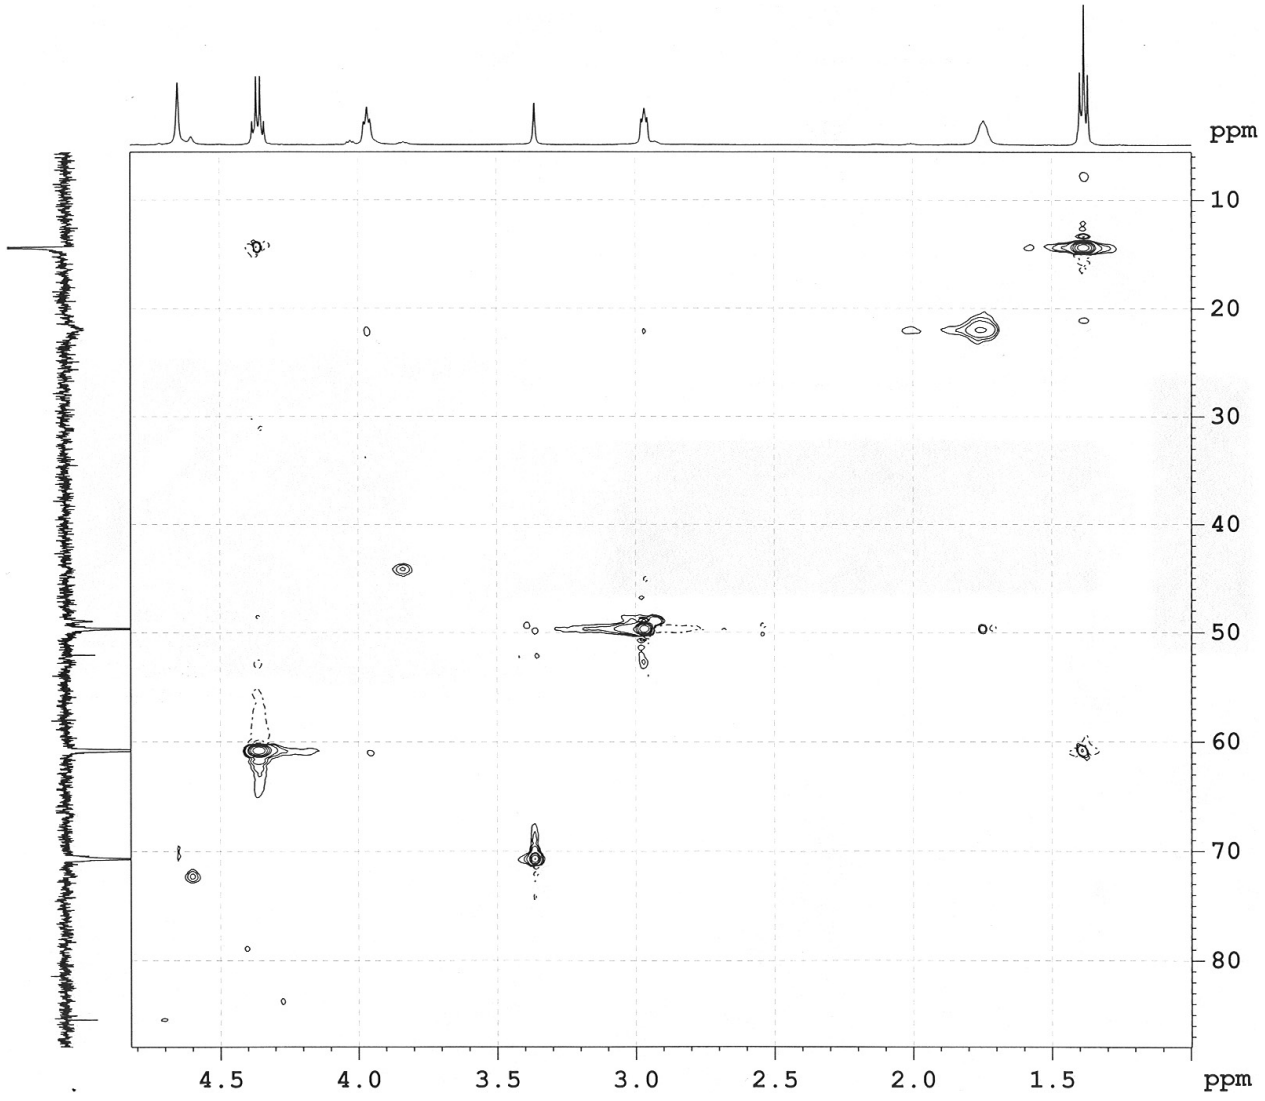
Correlation of proton NMR data and carbon NMR data was enhanced by a series of NMR experiments with the *p*-ethoxycarbonyl derivative (**6d**). Although this bistriazene was among the least stable of this series in the solid state, once it was taken up in solution in deuteriochloroform, it appeared to be reasonably stable in solution. A COSY spectrum of **6d** (Fig. 3) showed the coupling of the 1.39 and 4.36 ppm signals from the ethyl group. It also showed that the 1.75 ppm signal (assigned to H_e,H_f) is coupled both to the 2.97 ppm signal (H_i,H_j) and to the 3.97 ppm signal (H_g,H_h); there was no interaction between H_i,H_j and H_g,H_h evident in the COSY. As expected, the signals of the isolated methylene groups, H_a,H_b (3.36 ppm) and H_c,H_d (4.65 ppm) showed no interaction with other protons.

A DEPT 135 spectrum of **6d** (Fig. 4) showed first of all that the ethyl group assignments were correct with the methyl carbon at 14.3 ppm and the methylene carbon at 60.55 ppm. The DEPT spectrum also showed that the signals at 22.0, 45.0, 49.5, and 70.6 ppm arise from the methylene groups at C-4, C-3, C-5, and C-1 respectively. The signal of C-2 is not seen in the DEPT spectrum; this may be because the signal of this carbon is only barely seen in the fully decoupled ^{13}C spectrum of **6d**.

The dynamic equilibrium that causes the broadening of signals in the proton NMR spectra of **6** also caused the

© 2005 NRC Canada

Fig. 4. DEPT 135 spectrum of 1-[2-{*p*-ethoxycarbonylphenyl}-1-diazenyl]-3-(3-[2-{*p*-ethoxycarbonylphenyl}-1-diazenyl]hexahydro-1-pyrimidinylmethyl)hexahydropyrimidine (**6d**).



carbon-13 signals in the NMR to be significantly broadened. The assignment of the chemical shifts in the ^{13}C NMR spectra of these compounds was facilitated by the analysis of the HSQC spectrum of compound **6d** (Fig. 5), which firstly confirms the assignment of signals at 13.8 and 60.1 ppm to the ethyl group carbons in the ethoxycarbonyl substituent. The carbon signals at 21.7 (C-4), 44.6 (C-3), and 49.1 (C-5) ppm correlate with the proton signals at 1.75 (H_e,H_f), 3.97 (H_g,H_h), and 2.97 (H_i,H_j) ppm, respectively. The proton signal at 3.365 ppm, which integrates for 2H and is thereby assigned to H_a,H_b, correlates in the HSQC with the carbon signal at 70.5 ppm. The latter is therefore assigned to C-1. A weak, broad signal at 67.5 ppm in the carbon spectrum of **6d** also correlates with the proton signal at 3.365 ppm in the HSQC spectrum, suggesting that the higher field carbon signal arises from the presence of a minor isomer of **6d**. This hypothesis correlates with the general observation that the carbon signals of the compounds of series **6** are often extremely broadened because of the restricted rotation around the N—N bond in the triazene (8). The last feature of the HSQC spectrum of **6d** gives a clue to the chemical shift of the elusive carbon atom at C-2, since the proton peak at 4.65 ppm correlates with a weak carbon signal at 72.2 ppm, which is thereby assigned to C-2. Indeed, most of the compounds in series **6** do show a weak signal at ca. 72 ppm in the ^{13}C spectra.

Thus, it is possible to record and assign all of the carbon signals in these compounds (Table 2), with the exception of C-2 in compounds **6b** and **6e**. The aromatic carbon atoms give rise to the expected number of signals in the range 114–158 ppm, and the carbon atoms in the aryl substituents are all assigned. The bridging methylene carbon (C-1) is found at ca. 70 ppm, and the carbon atom at C-2 in the heterocyclic ring is universally weak in the range 71–73 ppm. The other carbons of the heterocyclic ring are found at ca. 49 to 50 ppm (C-5), ca. 44 to 45 ppm (C-3), and ca. 22 ppm (C-4). Intuitively, the lower field carbon signal at 50 ppm would be assigned to C-3 because of its proximity to the triazene moiety; however, the two-dimensional NMR spectra recorded with compound **6d** proved otherwise.

Extension of the foregoing reaction to the analogous reaction with 2,2-dimethyl-1,3-diaminopropane proved to be successful and afforded the new bistriazene series, the 1-(5,5-dimethyl-3-[2-aryl-1-diazenyl]hexahydro-1-pyrimidinylmethyl)-5,5-dimethyl-3-[2-aryl-1-diazenyl]hexahydropyrimidines (**7a**–**7l**). The compounds of series **7** displayed similar characteristics of instability as with series **6**, and the compounds of series **7** have been characterized in a parallel manner. An X-ray crystal structure of compound **7c** has been published (9), which verifies the linear bicyclic bistriazene structure for this compound and, by inference, the structures of the other compounds in this series. ^1H NMR results are listed in Table 3; the protons of the aromatic rings are as expected and the alkyl protons are all singlets. The vicinal coupling evident in series **6** is precluded by the intervention of the methyl groups attached to C-4. These methyl protons

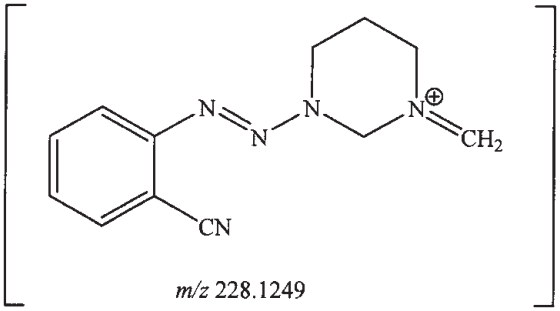

Fig. 5. HSQC spectrum of 1-[2-{*p*-ethoxycarbonylphenyl}-1-diazenyl]-3-(3-[2-{*p*-ethoxycarbonylphenyl}-1-diazenyl]hexahydro-1-pyrimidinylmethyl)hexahydropyrimidine (**6d**).

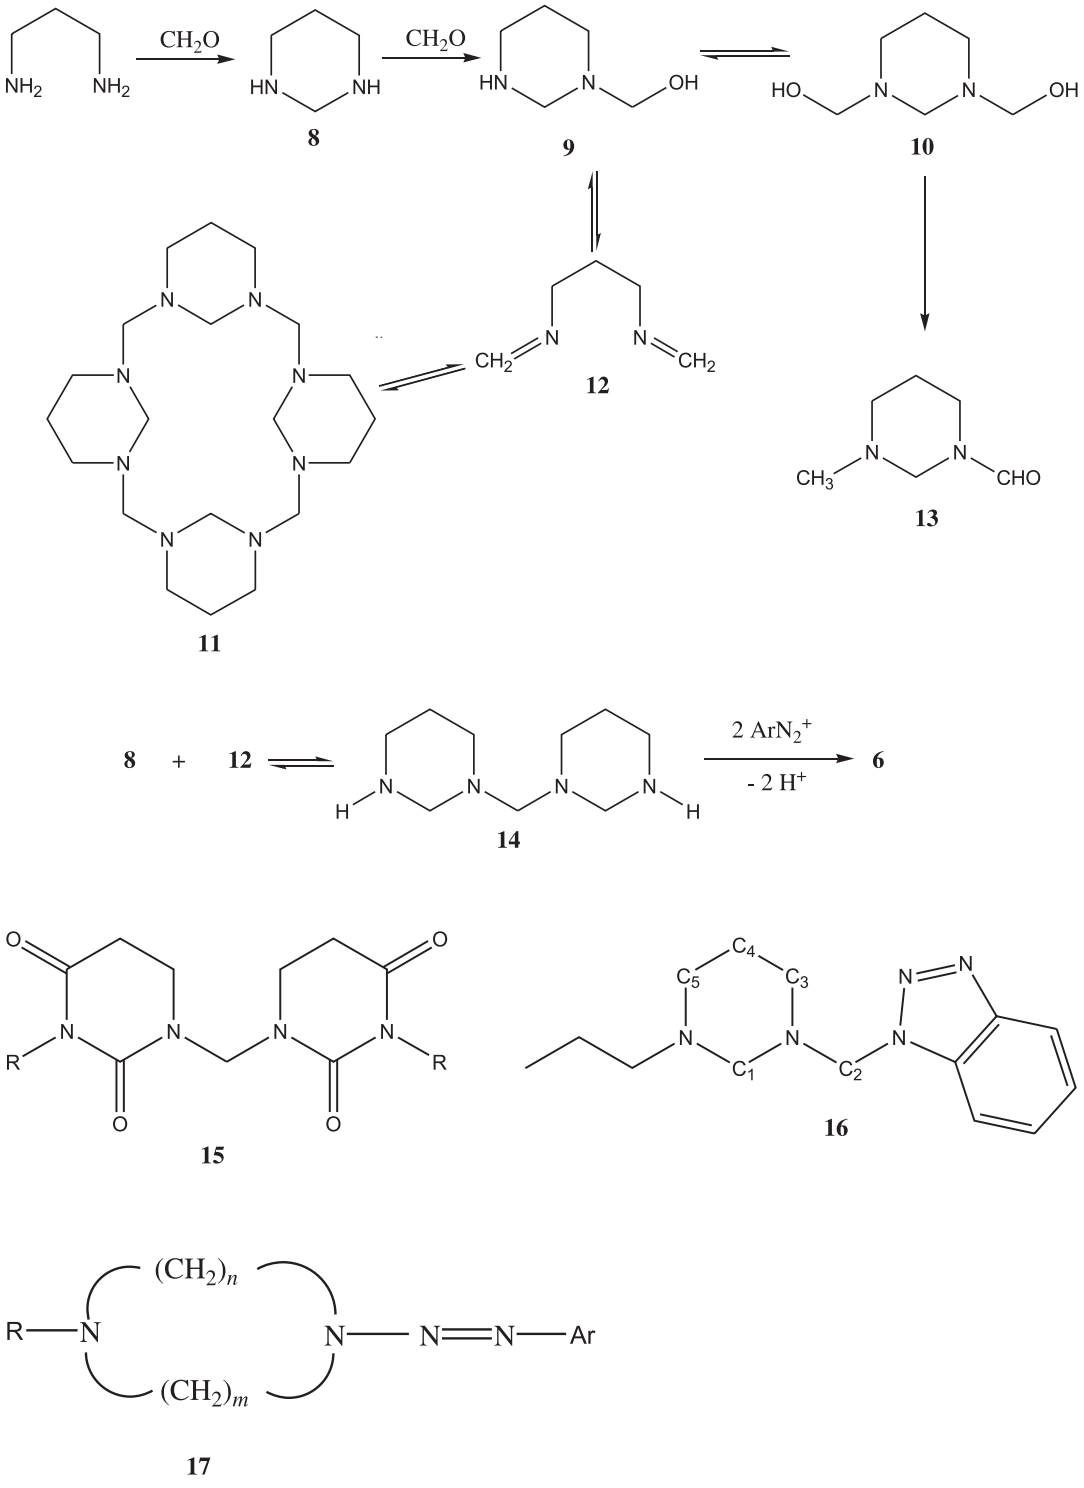
give rise to a 12 proton singlet at ca. 1 ppm. The chemical shifts of the methylene protons in compounds of series **7** are shifted a little upfield from the analogous protons in series **6**. An almost complete set of carbon-13 NMR data for the compounds of series **7** is listed in Table 4; the only signals not detected are those arising from C-1 and C-2 in compound **7f**.

The structures of the compounds in series **6** and **7** have been verified wherever possible by either elemental analysis or high resolution mass spectrometry. Only five of the 24 new compounds have *not* been analyzed in this way, owing to the stability problems described earlier. The *o*-cyano derivative (**6l**) did not show a molecular ion under EI or ESI mass spectrometry, but an accurate mass was obtained for the *m*/*z* 228 fragment shown in Fig. 6.

Fig. 6. Mass spectral fragment (*m*/*z* 228) identified in the ESI high resolution mass spectrum of compound **6l**.



Previous studies of the propanediamine–formaldehyde reaction

An important issue regarding the synthesis of compounds of series **6** and **7** is the question of the manner of their formation. Central to this question is the previously reported work relating to the reaction of 1,3-propanediamine and formaldehyde. There is a considerable body of work on the subject of the general reaction of alkanediamines with formaldehyde, but surprisingly no one has previously investigated what happens when a diazonium salt is introduced into the mixture. Scheme 1 illustrates the structures of various

© 2005 NRC Canada

Scheme 1.

molecules that have been implicated in the reaction of 1,3-propanediamine with formaldehyde; this scheme is mainly reproduced from Dale and Sigvartsen (10). Previous work by Krassig (11) was the first to suggest that the product of the reaction of formaldehyde with propanediamine is the tetrameric compound (**11**). Later work by Evans (12) confirmed this observation, which was then reinvestigated by Bagga et al. (13), who concluded that the reaction products were more complex. However, a complete picture of the chemistry involved did not appear until the pivotal work of Dale and Sigvartsen (10), who applied NMR spectroscopy to the analysis. Surprisingly, neither the monocyclic hexahydropyrimidine (**8**) or the dimeric molecule (**14**) have been observed. The tetrameric product (**11**) is a short-term prod-

© 2005 NRC Canada

uct, whereas after long reaction times, the extremely unlikely formamide derivative (**13**) becomes the exclusive product. Krassig and Evans failed to observe this stable end product, which is formed from intermediate **10** by a novel intramolecular hydride shift (10). Because the formation of **13** requires long reaction times, it is unlikely to feature in the formation of our products **6** (or **7**). In the formation of **6**, the diamine–formaldehyde mixture is reacted immediately with the diazonium salt, so our concern is more with what happens in the early phase of the diamine formaldehyde reaction.

The simplest explanation for our observations is that the dimeric hexahydropyrimidine (**14**), formed by reaction of **8** + **12**, is trapped out by reaction with the diazonium ion to afford the bistriazene **6**. Ironically, the dimeric species (**14**) is not considered as a possible product or an intermediate by any of the previous authors. The significance of our present work could be that we have demonstrated that the dimer (**14**) must be considered as a viable intermediate in the formation of the tetramer (**11**). This observation further exemplifies the importance of diazonium coupling as a tool for trapping otherwise unstable amines from solution and identifying them. Thus, the original formation of the hydroxymethyltriazenes (**1**) (2) essentially can be interpreted as diazonium "trapping" of the unstable carbinolamine, CH_3NHCH_2OH; likewise, the formation of the bistriazene (**2**) amounts to trapping the bis(methylaminomethyl)amine, $CH_3NHCH_2N(CH_3)CH_2NHCH_3$.

Compound **11** is reported to be thermally unstable (10). The decomposition of **11** has been studied by mass spectrometry, giving evidence for formation of the bisimine (**12**) and its precursor **9**, accompanied by a much weaker (M + 1) mass from the dimeric species **14**. Although the mechanism of the decomposition of **11** is not clearly delineated, these observations do provide a clue to the observation in the present work that the bistriazenes **6** and **7** are not universally thermally stable. The instability of compounds of types **6** and **7** is also evident from attempts to record mass spectra under electron ionization conditions; no molecular ions were observed under EI, in contrast to the ESI spectra that allowed us to obtain high resolution measurement of molecular ion mass.

In searching the literature for other model compounds of hexahydropyrimidines, only a few systems were found. Habermeier and Porret (14) reported the dihydrouracil derivatives (**15**), but provided little NMR data for comparison. Katritzky et al. (15), on the other hand, reported extensive NMR data for the hexahydropyrimidine (**16**), which was obtained by reaction of benzotriazole with a mixture of *N*-propyl-1,3-propanediamine and formaldehyde in aqueous methanol. The carbon-13 assignments in **16** are 22.8 (C-4), 51.3 (C-5), 56.4 (C-3), 66.9 (C-1), and 72.8 (C-2), which agrees well with the assignments in **6** in the present work.

Conclusion

It appears now that the interaction of a diazonium salt with a mixture of formaldehyde and an alkanediamine $[NH_2(CH_2)_nNH_2]$ gives rise to two distinct types of oligomer. Bistriazenes of types **3** and **4** are examples of the bridged bicyclic bistriazene, whereas the new compounds of series **6** and **7** exemplify the linear bicyclic bistriazene. Clearly, there is a cross-over in the molecular architecture going from ethylenediamine (two-carbon spacer) to propanediamine (three-carbon spacer). This type of cross-over was also observed in the transition from ethylenediamine to cyclohexanediamine in structure **5** (6).

This paper is part IV in a series that describes the synthesis of a variety of triazenes and bistriazenes that fit the general classification of 1-aryldiazenyl-(1,*x*)-diazacycloalkanes described by the general structure **17**, where $m = 1$ or 2 and $n = 2$, 3, 4, or 5. The new compounds of series **6** and **7** fit to the general structure **17** where $m = 1$ and $n = 3$. Previously, we reported new triazenes derived from piperazine (16, 17) ($m = n = 2$) and homopiperazine (18) ($m = 2$, $n = 3$). It is worth pointing out that the hexahydropyrimidine rings in **6** and **7** represent the isomeric heterocycle to the piperazine ring system.

In future papers in this series, we will report more examples of the linear bicyclic bistriazene derived from other diamines, such as 1,4-diaminobutane, 1,3-diaminopentane, and 2-methyl-1,2-diaminopropane. Evidently, the linear bicyclic bistriazene reported here in compounds of series **6** and **7** appears to be the normal type of molecular architecture in this field of chemistry.

Acknowledgements

The authors are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for a Discovery Grant to the principal author (KV) and to the Faculty of Graduate Studies and Research at Saint Mary's University for a Summer Research Award (2003) to Shasta Moser. Financial support, to Ryan Church, was provided by the Student Employment Experience Program (SEEP) at Saint Mary's University. We are also grateful to the Atlantic Region Magnetic Resonance Centre at Dalhousie University for providing NMR spectra; in particular, we would like to thank Dr. Bob Berno for assistance with the interpretation of the NMR spectral data.

Synthesis and preliminary bioactivity evaluation of new pregnane brassinosteroid-like compounds

Daniel G. Rivera and Francisco Coll

Abstract: Seven new pregnane compounds bearing some representative A- and B-ring brassinosteroid functions, as well as hydrogen bond donor and acceptor ones on the D ring, were efficiently synthesized. The obtained compounds did not show remarkable plant growth-promoting activity in the radish hypocotyl elongation and cotyledon expansion bioassays, however, introducing oxygen and amino functions on the D ring led to an enhancement of the bioactivity. The 16β-functionalized pregnane brassinosteroid-like compounds were slightly more active than the 16α-functionalized ones.

Key words: steroids, brassinosteroids, pregnane analogues.

Résumé : On a réalisé des synthèses efficaces de sept nouveaux dérivés du prégnane portant des fonctions représentatives des cycles A et B des brassinostéroïdes, ainsi que des fonctions pouvant donner ou accepter des liaisons hydrogènes sur le cycle D. Les composés obtenus ne présentent pas d'activité remarquable pour la promotion de la croissance dans des bioessais d'élongation de l'hypocotyle du radis et de l'expansion du cotylédon, toutefois l'introduction de fonctions oxygénées et aminées sur le cycle D conduit à une augmentation de leur bioactivité. Les composés du prégnane fonctionnalisés en 16β, de type brassinostéroïde, sont légèrement plus actifs que ceux fonctionnalisés en 16α.

Mots clés: stéroïdes, brassinostéroïdes, analogues du prégnane.

[Traduit par la Rédaction]

Introduction

Since their discovery (1), the brassinosteroids have commanded much interest in both the chemical and biological communities (2, 3) because of their extremely high plant growth-promoting activity and anti-stress effect (4). In view of their challenging steroidal structures and the presence of different stereochemical arrays of hydroxy groups, this class of plant hormones has also been the subject of elegant synthetic and biosynthetic studies (2, 3).

Nevertheless, the fascinating goal of achieving more synthetically accessible bioactive compounds continues to be a promising approach for improving the benefits of these hormones in agriculture. Thus, a highlight of this program has been the development of interesting analogues with drastic modifications either in the side chains or the ring system (3, 5–8), which has also facilitated the structure–activity relationship (SAR) studies and a thorough understanding of their mode of action (9–11).

Whereas brassinolide (**1**) is endowed with the unique feature of having a 6-oxo-7-oxa lactone function on ring B, a number of bioactive analogues bearing the 5α-hydroxyl group (e.g., **2**) have been reported and the effect of this function on the brassinosteroid-type activity is well documented (5, 12) (Fig. 1). Whilst this later function certainly does not bring out noteworthy improvements over the natural one from the biological point of view, its advantage is due to the greater synthetic accessibility starting from the readily available 5,6-epoxide derivatives (12, 13).

Additionally, despite the fact that most active natural and synthetic brassinosteroids are known to be those with campestane, ergostane, and stigmastane side chains, Kohout and co-workers have reported a set of analogues with androstane (14–16) and pregnane (17–19) side chains (e.g., **3**), some of them showing activity in the bean second internode bioassay.

Herein, we report the synthesis and a preliminary evaluation of the biological activity of seven pregnane brassinosteroid-like compounds. In connection with ongoing projects towards the development of brassinosteroid analogues, our approach was to exploit the great accessibility of the 2α,3α,5α-trihydroxy-6-oxo functionality and to introduce a variety of functions on ring D of the pregnane skeleton. The potential advantages of this approach should be realized in the further possible construction of the natural brassinosteroid side chain from 20-oxo derivatives (20), thereby achieving a striking array of structural features not found in any natural or synthetic brassinosteroid.

Results and discussion

The scope of our strategy is focused on the influence in the activity of modified D rings bearing either hydrogen

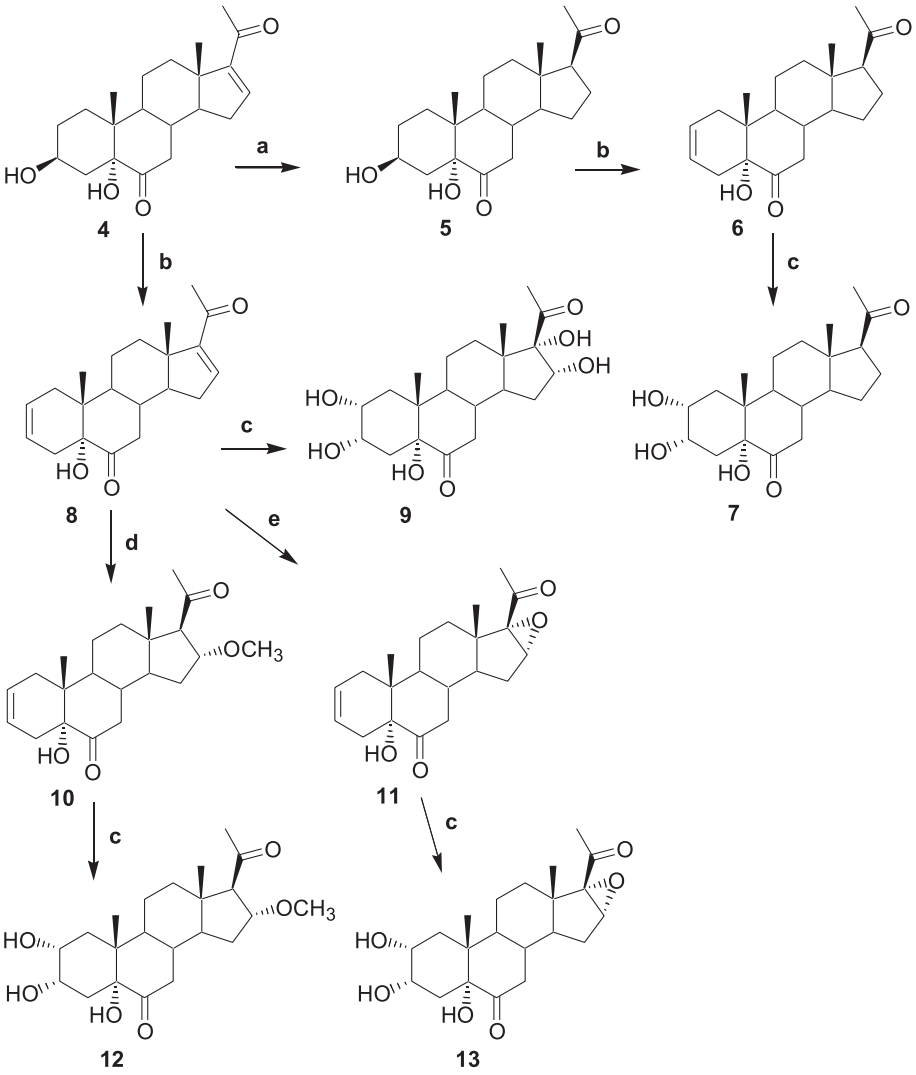
bond acceptors or donors. With a view toward achieving this goal, an efficient plan, which could generate A- and B-ring brassinosteroid functionalities, as well as functional and stereochemical diversity on ring D, was chosen. Moreover, encouraged by the fact that D-ring functionalized brassinosteroid analogues have not been studied, mainly because this ring is not recognized as one of the subsites of interaction in the brassinosteroid-receptor complex (11), we envisioned not only generating a set of brassinosteroid-like pregnanes, but also establishing the starting point of a more promising strategy towards D-ring functionalized brassinosteroid analogues.

Our approach for functionalizing rings A and B took advantage of the simple synthetic pathway to achieve the 5α-hydroxy-6-oxo functionality from the Δ^5 double bond via the acid-catalyzed epoxide opening (13). The attainment of the key Δ^2 double bond was accomplished by selective tosylation of the 3β-OH group and subsequent dehydrotosylation (without previous purification) to afford the precursor Δ^2-5α-hydroxy-6-oxo system. Additionally, we did not detect the formation of the 2β,3β-diol functionality by using the common osmium tetroxide – *N*-methylmorpholine *N*-oxide (NMO) procedure, which had been previously described in the osmium-catalyzed asymmetric dihydroxylation of both the Δ^2-5α-hydroxy-6-oxo and Δ^{22} systems on stigmastane analogues (12).

Scheme 1 summarizes the initial pathway to synthesize the target brassinosteroid-like compounds. Ketol **4** was obtained following a reported procedure (13) and represents the starting material of our synthetic route. The D-ring unfunctionalized analogue **7** was synthesized by a conventional procedure, which involved the reduction of the conjugated Δ^{16}-olefin by catalytic hydrogenation and the previously described method for functionalizing ring A in 46% yield from ketol **4**. The emphasized importance of this analogue is beyond its synthesis, since it is certainly necessary for SAR studies. Alternatively, the pentahydroxylated analogue **9** was obtained in good yield through the simultaneous Δ^2- and Δ^{16}-dihydroxylation processes, though several equivalents of NMO and noncatalytic amounts of OsO_4 as well as long reaction times were required because of the deactivation of the Δ^{16} double bond.

At this stage, we planned an efficient route, which avoided the use of protecting groups, and consisted of first introducing the D-ring functions and performing the Δ^2-dihydroxylation as the last step. The conjugated character of the Δ^{16} double bond allowed us to achieve this goal since precursors **10** and **11** were successfully obtained by treatment of intermediate **8** with NaOMe–MeOH and H_2O_2–NaOH–MeOH, respectively. Final dihydroxylation led to the desired analogues **12** and **13**.

As can be noted, this initial synthetic planning allowed us to only access one of the faces of ring D, since the expected stereoselectivity was achieved in the introduction of epoxy, methoxy, and hydroxy functions giving an α configuration for substituents at C-16 and C-17. Clearly, to achieve stereochemical diversity on ring D, it was critical to implement reactions that could enable us to obtain 16β-substituted pregnanes. With the 16,17-epoxide previously obtained, the oxirane ring opening was the first attempt to introduce different functionalities. However, in our hands, this system was extremely sensitive, even to mild acidic and basic conditions. Finally, this task was accomplished efficiently by performing the successful Mitsunobu reaction (21) for the epimerization of the 16α-hydroxy function, also making it possible to access nonoxygenated functions previously introduced at different sites of the steroidal moiety (22).



Two examples, highlighted in Scheme 2, illustrate the possibility of conveniently functionalizing the β face of ring D. Ketol **4** was initially tosylated and subsequently submitted to the Δ^{16}-dihydroxylation procedure affording the tosylate **14** in excellent overall yield. Further dehydrotosylation and selective protection of the secondary 16α-OH group with *tert*-butyldimethylsilyl (TBDMS) ether (23) gave the key intermediate **15**. The established Δ^2-dihydroxylation procedure and isopropylidene protection of the resulting diol succeeded in obtaining the acetonide **16** by using the 2,2-dimethoxypropane – pyridinium *p*-toluenesulfonate (PPTS) system without affecting the silicon protecting group (24). Selective removal of the TBDMS group (23) by using tetrabutylammonium fluoride (TBFA) gave the acetonide **17** in 33% overall yield, representing an advanced intermediate on the synthetic pathway towards the 16β-functionalized derivatives.

Epimerization of C-16 was accomplished by using the known DIAD–Ph_3P–HCO_2H system and subsequent cleavage of the 16β-formyloxy group, following a protocol already applied to a sort of equatorial hydroxyl at different sites of the steroidal moiety (5, 13, 25, 26). Final removal of the isopropylidene ketal led to the target compound **21** in 61% yield from **17**.

We were also attracted to introducing amine functions on ring D, since nitrogen-containing-brassinosteroid analogues have been previously tested and included in the currently ac-

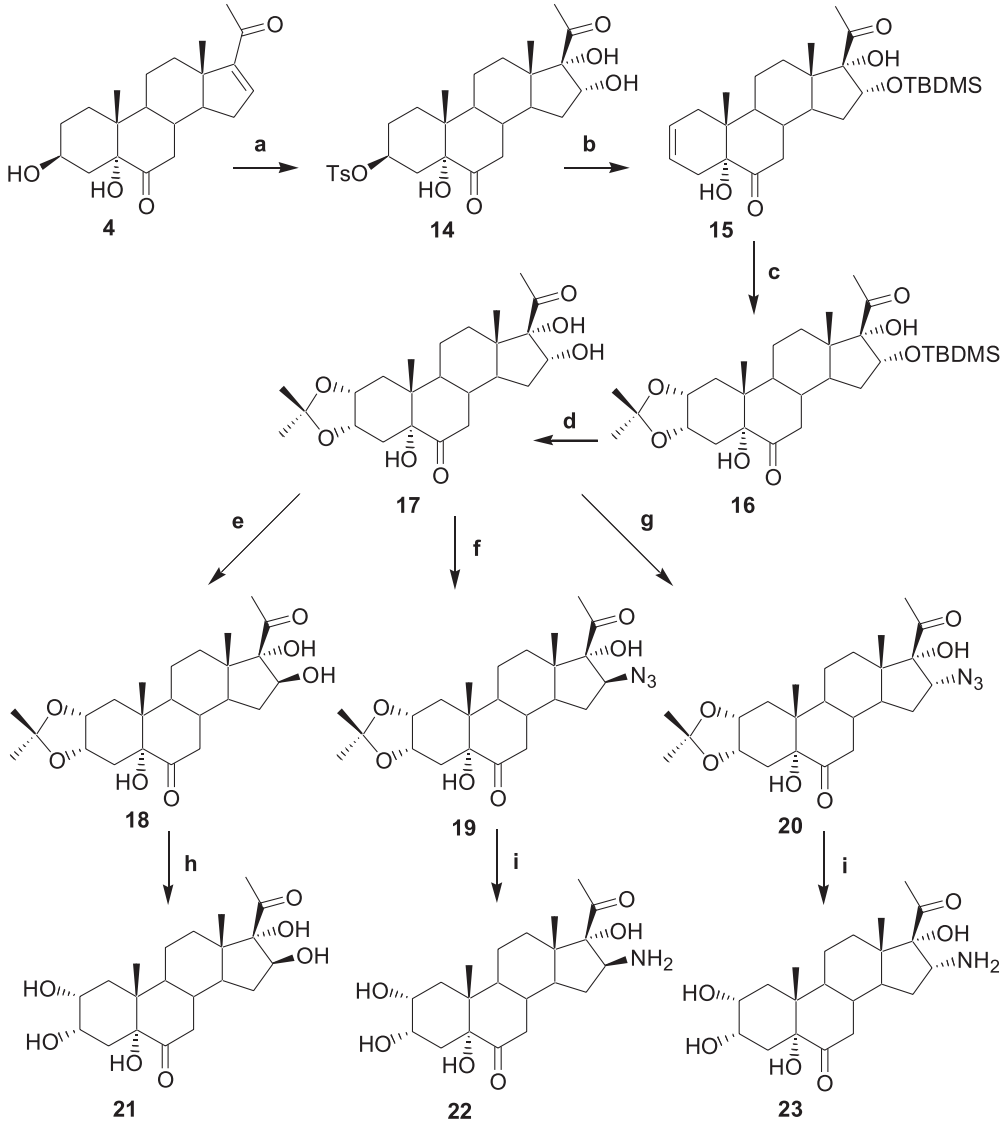
Scheme 1. Reagents and conditions: (*a*) 10% Pd(C), MeOH; (*b*) (*i*) TsCl, Py, (*ii*) LiBr, Li_2CO_3, DMF; (*c*) OsO_4, NMO, THF–*t*-BuOH–H_2O; (*d*) NaOMe, MeOH; (*e*) NaOH, H_2O_2, MeOH, 0 °C.



cepted SAR studies (11, 27, 28). Thus, a simple mesylation of the 16α-OH group followed by azide displacement afforded the intermediate **19**, which upon reduction of the azide group and subsequent deprotection of the 2α,3α-diol functionality led to the final 16β amino derivative **22** in 46% yield from **17**.

Evidently, synthetically challenging is the introduction of the 16α amino group from the function 16α,17α-diol of compound **17**. However, having previously established the value of the Mitsunobu reaction to access the β face of ring D, the replacement of the 16α-OH group by azide with the net retention of configuration was fulfilled by utilizing methanesulfonic acid as the acidic–nucleophilic component of the Mitsunobu reaction and consecutive azide displacement of the resulting 16β mesylate (23). The isopropylidene removal procedure used for achieving the epimer **22** similarly succeeded affording the final 16α amino derivative **23** in 36% yield from **17**. Of particular interest is the the prospect of introducing a variety of functions on ring D of pregnane brassinosteroid-like compounds. Whilst these could not be considered as brassinosteroid analogues since they lack the classical side-chain functionalities, the planning strategy used in the present work was intended to serve as the opening issue for accessing D-ring-functionalized brassinosteroid analogues. Moreover, considering that these additional D-ring functions could somehow present a high influence on the final active conformation of the hormone, the present approach might have a further outstanding impact on the present way of focussing the SAR studies.

The ^1H and ^{13}C NMR assignments of the obtained compounds were achieved by a combination of 1D and 2D experiments. The ^1H NMR features of the 2α,3α-diol functionality are usually the easiest to be assigned from the H-2 and H-3 coupling patterns even in the presence of the 5α-OH. Additionally, the stereochemistry of the functionalized carbons was unequivocally demonstrated by performing 1D NOE difference experiments, in which the enhancements on H-16, H-2, and H-3 upon irradiation of the two β-angular methyl groups CH_3-18 and CH_3-19 confirmed the α stereochemistry of the functions at these positions. The β stereochemistry of the functions at C-16 on compounds **21** and **22** was similarly demonstrated because of the lack of

enhancement on H-16 upon irradiation of CH_3-18. Interestingly, the coupling pattern of H-16 in the 16α-functionalized pregnanes showed the lack of coupling with one of the C-15 protons, suggesting a dihedral angle near 90° between H-16β and H-15α.

The growth-promoting activity was evaluated using the radish (*Raphanus sativus* L.) hypocotyl elongation and cotyledon expansion bioassays (29). Thus, the bioactivities were assessed in terms of increments of hypocotyl length or cotyledon weight with respect to the untreated control plants referred to as 100%.

As should be expected from the fact that these compounds lack the brassinosteroid functionalities in the side chain, the results of plant growth-promoting activity in the radish bioassays are far away from being considered as remarkable. However, analysis of Table 1 highlights some tendencies that might be seen as promising. Thus, all D-ring functionalized compounds were more active than the D-ring unfunctionalized pregnane **7**. Compound **22**, bearing the function 16β,17α-diol, was found to be the most active in the hypocotyl elongation bioassay.

Interestingly, the presence of hydroxy functions provoked a higher bioactivity than for epoxy and methoxy, which is in agreement with the classical behavior in bioassays reported for these functions at different sites of the steroidal moiety or the side chain. Furthermore, similar results were found in a comparison between hydroxy and amino groups at the same position, since the 16,17-dihydroxy derivatives **9** and **21** clearly were more active than the 16-amino-17-hydroxy ones (**22**, **23**). In both series of analogues, the epimerization of the function at C-16 provoked a moderate enhancement of activity either in the hypocotyl elongation or cotyledon ex-

pansion bioassays. As can be noted, the general tendency was that the tested compounds elicited higher activity in the hypocotyl elongation bioassay than in the cotyledon expansion one, with the only exception being the epoxy derivative **13**.

Conclusions

Seven new pregnane brassinosteroid-like compounds were efficiently synthesized and their plant growth-promoting activities evaluated. Either the introduction of oxygen or amino functions on ring D led to an increment in the bioactivity in the radish bioassays. Further experiments to compare the biological activity of the reported compounds with that of natural brassinosteroids are required.

Experimental

Chemistry

Melting points were determined on a Stuart Scientific apparatus and are uncorrected. IR spectra were obtained on a Nicolet 205 FT-IR spectrometer. ^{1}H NMR and ^{13}C NMR were recorded on a Bruker ACF-250 spectrometer at 250.13 and 62.9 MHz, respectively, using TMS as the internal standard. Two dimensional spectra: ^{1}H–^{1}H correlation spectroscopy (COSY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple bond correlation (HMBC) were measured for the final compounds on a Varian INOVA-500 spectrometer operating at 499.81 MHz using the standard pulse sequences given by the manufacturer. Elemental analyses were performed with a Leco CHNS-932 instrument. Reactions were monitored by thin-layer chromatography (TLC) on precoated plates with silica gel (Merck) and spots were visualized with a 0.01 g/mL solution of vanillin in perchloric acid and subsequent heating. Flash column chromatography was performed on silica gel 60 (Merck, >230 mesh). "Usual work-up" refers to dilution with water, extraction with an organic solvent, washing the extract consecutively with 5% HCl and (or) 5% $NaHCO_3$ and brine, drying over anhydr. Na_2SO_4, and removal of the solvent under reduced pressure. The solvents were purified and dried according to recommended procedures.

3β,5-Dihydroxy-5α-pregna-6,20-dione (5)

Pd/C 10% (210 mg) was added to a solution of **4** (1.5 g, 4.3 mmol) in 80 mL of MeOH. The mixture was treated successively with hydrogen and vacuum and finally stirred under a hydrogen atmosphere for 24 h. The reaction was monitored on TLC by the absence of UV absorption. The suspended catalyst was filtered off and the resulting solution was evaporated under reduced pressure to give the ketol **5** (1.44 g, 96%); mp (MeOH) 192–195 °C. IR (KBr, cm^{-1}): 3547, 3445, 1705, 1702, 1080, 1039. ^{1}H NMR ($CDCl_3$) δ: 0.59 (s, 3H, H-18), 0.80 (s, 3H, H-19), 2.03 (s, 3H, H-21), 2.50 (t, 1H, J = 8.9 Hz, H-17α), 3.87 (br m, 1H, H-3α). ^{13}C NMR ($CDCl_3$) δ: 29.7 (C-1), 29.7 (C-2), 66.6 (C-3), 35.2 (C-4), 79.8 (C-5), 213.9 (C-6), 41.4 (C-7), 37.1 (C-8), 44.0 (C-9), 42.2 (C-10), 21.2 (C-11), 38.6 (C-12), 13.7 (C-13), 56.2 (C-14), 23.9 (C-15), 22.5 (C-16), 63.3 (C-17), 13.2 (C-18), 13.7 (C-19), 210.1 (C-20), 31.3 (C-21). Anal. calcd. for $C_{21}H_{32}O_4$: C 72.4, H 9.3; found: C 72.7, H 9.6.

5-Hydroxy-5α-pregn-2-ene-6,20-dione (6)

Tosyl chloride (1.14 g, 6 mmol) was added to a solution of ketol **5** (1.4 g, 4.0 mmol) in 50 mL of pyridine and the reaction was stirred at room temperature in the dark for 24 h. After completion as indicated by TLC, the mixture was poured into 300 mL of 10% $NaHCO_3$ and the resulting suspension was stirred for another hour and filtered under reduced pressure. The obtained tosylate was dried and dissolved in 60 mL of anhydr. DMF. Li_2CO_3 (2.2 g) and LiBr (2.5 g) were added to this solution and the resulting mixture was refluxed under a nitrogen atmosphere for 2 h, poured slowly with stirring into 300 mL of 10% HCl, and filtered under reduced pressure. The solid was washed with water, dried, and recrystallized from acetone to give the olefin **6** (1.17 g, 88%); mp (acetone) 156 to 157 °C. IR (KBr, cm^{-1}): 3550, 3020, 1705, 1702, 1086, 1048. ^{1}H NMR ($CDCl_3$) δ: 0.56 (s, 3H, H-18), 0.66 (s, 3H, H-19), 1.97 (dd, 1H, J = 12.8, 4.2 Hz, H-7β), 2.04 (s, 3H, H-21), 2.50 (t, 1H, J = 8.9 Hz, H-17α), 2.75 (t, 1H, J = 12.6 Hz, H-7α), 5.60 (m, 2H, H-3 + H-2). ^{13}C NMR ($CDCl_3$) δ: 30.0 (C-1), 125.2 (C-2), 122.4 (C-3), 34.5 (C-4), 77.7 (C-5), 211.0 (C-6), 42.2 (C-7), 36.7 (C-8), 44.9 (C-9), 42.2 (C-10), 20.7 (C-11), 38.6 (C-12), 43.7 (C-13), 56.2 (C-14), 23.9 (C-15), 22.5 (C-16), 63.3 (C-17), 13.2 (C-18), 13.7 (C-19), 210.1 (C-20), 31.3 (C-21). Anal. calcd. for $C_{21}H_{30}O_3$: C 76.3, H 9.15; found: C 76.5, H 9.1.

2α,3α,5-Trihydroxy-5α-pregnane-6,20-dione (7)

General dihydroxylation procedure

NMO (1.05 g, 9.0 mmol) and a solution of OsO_4 in *t*-BuOH (9 mL, 12.5 mg/mL) were added to a solution of **6** (1.0 g, 3.0 mmol) in 60 mL of the solvent mixture THF–*t*-BuOH–H_2O (10:10:1). The reaction was stirred under a nitrogen atmosphere at room temperature for 16 h and then treated with 50 mL of a saturated solution of Na_2SO_3. The mixture was stirred for an additional hour and concentrated to half volume. The usual work-up (AcOEt) yielded a product that was purified by flash column chromatography ($CHCl_3$–MeOH, 10:1) to give the triol **7** (884 mg, 81%); mp (heptane–acetone) 205 to 206 °C. IR (KBr, cm^{-1}): 3477, 3420, 3335, 1715, 1697, 1121, 1080, 1034. ^1H NMR ($CDCl_3$) δ: 0.56 (s, 3H, H-18), 0.73 (s, 3H, H-19), 1.97 (dd, 1H, *J* = 12.9, 4.6 Hz, H-7β), 2.04 (s, 3H, H-21), 2.50 (t, 1H, *J* = 8.9 Hz, H-17α), 2.69 (t, 1H, *J* = 12.5 Hz, H-7α), 3.78–3.84 (br m, 1H, H-2β), 4.12 (m, 1H, H-3β). ^{13}C NMR ($CDCl_3$) δ: 30.1 (C-1), 67.4 (C-2), 69.5 (C-3), 34.1 (C-4), 79.3 (C-5), 211.0 (C-6), 41.2 (C-7), 36.9 (C-8), 44.2 (C-9), 45.2 (C-10), 21.0 (C-11), 38.5 (C-12), 44.5 (C-13), 56.2 (C-14), 24.0 (C-15), 22.7 (C-16), 63.3 (C-17), 13.3 (C-18), 14.6 (C-19), 209.8 (C-20), 31.4 (C-21). Anal. calcd. for $C_{21}H_{32}O_5$: C 69.2, H 8.85; found: C 69.1, H 8.9.

5-Hydroxy-5α-pregna-2,16-diene-6,20-dione (8)

Ketol **4** (6.0 g, 17.4 mmol) was submitted to tosylation (TsCl, 3.30 g, 26.1 mmol) and subsequent dehydrotosylation (Li_2CO_3 (6.8 g), LiBr (7.2 g)) in a similar way as described in the synthesis of **6** to furnish the olefin **8** (5.32 g, 80%); mp (acetone) 157 to 158 °C. IR (KBr, cm^{-1}): 3550, 3020, 1707, 1660, 1583, 1060, 1029. ^1H NMR ($CDCl_3$) δ: 0.86 (s, 3H, H-18), 0.72 (s, 3H, H-19), 2.25 (s, 3H, H-21), 2.32 (dd, 1H, *J* = 12.6, 4.5 Hz, H-7β), 2.79 (t, 1H, *J* = 12.8 Hz, H-7α), 5.63 (m, 2H, H-3 + H-2), 6.68 (dd, 1H, *J* = 3.4, 1.8 Hz, H-16). ^{13}C NMR ($CDCl_3$) δ: 30.1 (C-1), 125.4 (C-2), 122.3 (C-3), 34.3 (C-4), 78.0 (C-5), 210.7 (C-6), 42.4 (C-7), 35.6 (C-8), 45.5 (C-9), 42.4 (C-10), 20.7 (C-11), 46.5 (C-13), 56.1 (C-14), 31.9 (C-15), 143.9 (C-16), 155.0 (C-17), 15.7 (C-18), 14.4 (C-19), 196.6 (C-20), 27.0 (C-21). 5-Hydroxy-16α-methoxy-5α-pregn-2-ene-6,20-dione (10)

A freshly prepared solution of sodium (1.24 g, 54 mmol) in 30 mL of dry MeOH was added to a solution of the enone **8** (2.0 g, 5.4 mmol) in 100 mL of MeOH. The reaction mixture was stirred for 8 h under a nitrogen atmosphere, after which time TLC analysis (hexane–EtOAc, 3:1) revealed that some starting material had not been consumed. The solvent was removed under reduced preasure and the usual work-up (Et_2O) yielded a product, which was purified by flash column chromatography (hexane–EtOAc, 4:1) to furnish **10** (1.5 g, 70%); mp (acetone) 158–160 °C. IR (KBr, cm^{-1}): 3335, 3020, 1705, 1702, 1224, 1086, 1048. ^1H NMR ($CDCl_3$) δ: 0.57 (s, 3H, H-18), 0.66 (s, 3H, H-19), 2.15 (s, 3H, H-21), 2.54 (d, 1H, *J* = 6.3 Hz, H-17α), 2.75 (t, 1H, *J* = 12.5 Hz, H-7α), 4.00 (br s, 1H, OH), 3.16 (s, 3H, OCH_3), 4.29 (t, 1H, *J* = 6.5 Hz, H-16β), 5.60 (m, 2H, H-3 + H-2). ^{13}C NMR ($CDCl_3$) δ: 30.0 (C-1), 125.2 (C-2), 122.4 (C-3), 34.5 (C-4), 77.7 (C-5), 211.0 (C-6), 42.2 (C-7), 36.7 (C-8), 44.9 (C-9), 42.2 (C-10), 20.7 (C-11), 38.6 (C-12), 44.7 (C-13), 54.0 (C-14), 31.5 (C-15), 81.2 (C-16), 71.2 (C-17), 14.4 (C-18), 14.5 (C-19), 207.9 (C-20), 31.6 (C-21), 57.2 (OCH_3). Anal. calcd. for $C_{22}H_{32}O_4$: C 73.3, H 8.95; found: C 73.2, H 8.8.

2α,3α,5-Trihydroxy-16α-methoxy-5α-pregna-6,20-dione (12)

Olefin **10** (600 mg, 1.7 mmol) was treated following the general dihydroxylation procedure (NMO (596 mg, 5.1 mmol), OsO_4–*t*-BuOH (5 mL, 12.5 mg/mL)). Purification by flash column chromatography ($CHCl_3$–MeOH, 9:1) gave the triol **12** (470 mg, 72%); mp (heptane–acetone) 222–224 °C. IR (KBr, cm^{-1}): 3547, 3447, 3416, 3335, 1705, 1698, 1245, 1121, 1086. ^1H NMR ($CDCl_3$) δ: 0.56 (s, 3H, H-18), 0.72 (s, 3H, H-19), 2.15 (s, 3H, H-21), 2.54 (d, 1H, *J* = 6.3 Hz, H-17α), 2.73 (t, 1H, *J* = 12.5 Hz, H-7α), 3.17 (s, 3H, OCH_3), 3.74–3.81 (br m, 1H, H-2β), 4.09 (m, 1H, H-3β), 4.17 (br s, 1H, OH), 4.29 (t, 1H, *J* = 6.5 Hz, H-16β). ^{13}C NMR ($CDCl_3$) δ: 30.2 (C-1), 67.4 (C-2), 69.5 (C-3), 34.1 (C-4), 79.3 (C-5), 210.9 (C-6), 41.0 (C-7), 36.4 (C-8), 44.2 (C-9), 45.2 (C-10), 20.7 (C-11), 38.6 (C-12), 44.8 (C-13), 53.9 (C-14), 31.4 (C-15), 81.1 (C-16), 71.1 (C-17), 14.5 (C-18), 14.6 (C-19), 208.3 (C-20), 31.5 (C-21), 57.1 (OCH_3). Anal. calcd. for $C_{22}H_{34}O_6$: C 67.0, H 8.7; found: C 66.85, H 8.8.

16α,17α-Epoxy-5-hydroxy-5α-pregn-2-ene-6,20-dione (11)

A solution of enone **8** (2.0 g, 6 mmol) in 180 mL of MeOH was cooled to 0 °C and treated successively with 12 mL of 30% H_2O_2 and 4 mL of cold, aqueous 4 mol/L NaOH. The mixture was stirred and kept at 0–5 °C for 24 h. The reaction was monitored on TLC by the absence of UV absorption. The usual work-up (Et_2O) yielded a white crude solid, which was purified by flash column chromatography (hexane–EtOAc, 5:1) to give the epoxide **11** (1.5 g, 72%); mp (acetone) 158 to 159 °C. IR (KBr, cm^{-1}): 3550, 3020, 1705, 1700, 1092, 1036. ^1H NMR ($CDCl_3$) δ: 0.95 (s, 3H, H-18), 0.66 (s, 3H, H-19), 2.06 (s, 3H, H-21), 2.75 (t, 1H, *J* = 12.6 Hz, H-7α), 3.77 (d, 1H, *J* = 2.5 Hz, H-16β), 5.60 (m, 2H, H-3 + H-2). ^{13}C NMR ($CDCl_3$) δ: 30.0 (C-1), 125.2 (C-2), 122.4 (C-3), 34.5 (C-4), 77.7 (C-5), 211.0 (C-6), 42.2 (C-7), 36.7 (C-8), 44.9 (C-9), 42.2 (C-10), 20.7 (C-11), 38.6 (C-12), 41.6 (C-13), 44.8 (C-14), 27.3 (C-15), 60.4 (C-16), 70.8 (C-17), 15.3 (C-18), 14.0 (C-19), 205.1 (C-20), 25.9

(C-21). Anal. calcd. for $C_{21}H_{28}O_4$: C 73.2, H 8.2; found: C 73.1, H 8.3.

16α,17α-Epoxy-2α,3α,5-trihydroxy-5α-pregna-6,20-dione (13)

Olefin **11** (860 mg, 2.5 mmol) was treated following the general dihydroxylation procedure (NMO (978 mg, 7.5 mmol), OsO_4–*t*-BuOH (7 mL, 12.5 mg/mL)). Purification by flash column chromatography ($CHCl_3$–MeOH, 10:1) gave the epoxytriol **13** (766 mg, 81%); mp (heptane–acetone) 213–215 °C. IR (KBr, cm^{-1}): 3477, 3420, 3335, 1700, 1697, 1121, 1080, 1034. ^{1}H NMR ($CDCl_3$) δ: 0.95 (s, 3H, H-18), 0.73 (s, 3H, H-19), 2.06 (s, 3H, H-21), 2.70 (t, 1H, *J* = 12.5 Hz, H-7α), 3.77 (d, 1H, *J* = 2.5 Hz, H-16β), 3.78–3.84 (br m, 1H, H-2β), 4.12 (m, 1H, H-3β). ^{13}C NMR ($CDCl_3$) δ: 30.1 (C-1), 67.4 (C-2), 69.5 (C-3), 34.1 (C-4), 79.3 (C-5), 211.0 (C-6), 41.2 (C-7), 36.9 (C-8), 44.2 (C-9), 45.2 (C-10), 21.0 (C-11), 38.5 (C-12), 41.6 (C-13), 44.8 (C-14), 27.3 (C-15), 60.5 (C-16), 70.6 (C-17), 15.3 (C-18), 14.0 (C-19), 205.0 (C-20), 25.8 (C-21). Anal. calcd. for $C_{21}H_{30}O_6$: C 66.65, H 8.0; found: C 66.6, H 8.05.

5,16α,17α-Trihydroxy-3β-tosyloxy-5α-pregna-6,20-dione (14)

Tosyl chloride (6.6 g, 34.6 mmol) was added to a solution of ketol **4** (8.0 g, 23.1 mmol) in 120 mL of pyridine and the reaction was stirred at room temperature in the dark for 24 h. After completion as indicated by TLC, the mixture was poured into 500 mL of 10% $NaHCO_3$, stirred for another hour, and filtered under reduced pressure. The resulting tosylate was treated following the general dihydroxylation procedure (NMO (7.7 g, 66 mmol), OsO_4–*t*-BuOH (40 mL, 12.5 mg/mL)) for 48 h. Purification by flash column chromatography ($CHCl_3$–MeOH, 8:1) afforded the triol **14** (9.38 g, 76%); mp (AcOEt) 219 °C (decomp). IR (KBr, cm^{-1}): 3419, 3402, 1695, 1702, 1360, 1175, 1119, 1104. ^{1}H NMR ($CDCl_3$) δ: 0.70 (s, 3H, H-18), 0.76 (s, 3H, H-19), 2.05 (s, 3H, H-21), 2.41 (s, 3H, CH_3-Ts), 2.70 (t, 1H, *J* = 12.4 Hz, H-7α), 4.51 (d, 1H, *J* = 7.1 Hz, H-16β), 4.84 (br m, 1H, H-3α), 7.75 (d, 2H, *J* = 8.3 Hz, Ts), 7.30 (d, 2H, *J* = 8.5 Hz, Ts). ^{13}C NMR ($CDCl_3$) δ: 24.8 (C-1), 25.4 (C-2), 75.6.6 (C-3), 35.7 (C-4), 79.4 (C-5), 212.6 (C-6), 41.9 (C-7), 36.8 (C-8), 42.09 (C-9), 43.8 (C-10), 21.3 (C-11), 39.2 (C-12), 47.0 (C-13), 48.9 (C-14), 27.9 (C-15), 74.1 (C-16), 77.2 (C-17), 16.5 (C-18), 16.9 (C-19), 216.5 (C-20), 29.7 (C-21), 21.3 (*C*H_3-Ts), 134.2, 127.5, 129.8, 144.6 (6C-Ts). Anal. calcd. for $C_{28}H_{38}O_8S$: C 62.9, H 7.2, S 6.00; found: C 63.1, H 7.2, S 6.2.

*16α-(*tert*-Butyldimethylsilyloxy)-5,17α-dihydroxy-5α-pregn-2-ene-6,20-dione (15)*

Li_2CO_3 (12.0 g) and LiBr (14.5 g) were added to a solution of tosylate **14** (9.3 g, 17.5 mmol) in 100 mL of anhydr. DMF. The reaction mixture was refluxed under a nitrogen atmosphere for 2 h and followed by TLC until completion, then poured slowly with stirring into 600 mL of cool water, and filtered under reduced pressure. The resulting solid was washed with water, dried and dissolved in 80 mL of anhydr. DMF. TBDMSCl (2.6 g, 17.5 mmol) and imidazole (1.8 g, 26 mmol) were added to the solution and the reaction mixture was stirred under a nitrogen atmosphere for 3 h. The usual work-up ($CHCl_3$) yielded a product that was purified by flash column chromatography (hexane–AcOEt, 3:1) to give the olefin **15** (6.6 g, 79%); mp (acetone) 171–173 °C. IR (KBr, cm^{-1}): 3481, 3382, 3020, 1698, 1702, 1163, 1086, 1048. ^{1}H NMR ($CDCl_3$) δ: 0.07 (s, 3H, (CH_3)$_2$Si), 0.09 (s, 3H, (CH_3)$_2$Si), 0.69 (s, 3H, H-18), 0.66 (s, 3H, H-19), 0.92 (s, 9H, (CH_3)$_3$CSi), 2.05 (s, 3H, H-21), 4.56 (d, 1H, *J* = 7.0 Hz, H-16β), 5.63 (m, 2H, H-3 + H-2). ^{13}C NMR ($CDCl_3$) δ: 30.1 (C-1), 125.1 (C-2), 122.4 (C-3), 34.5 (C-4), 77.9 (C-5), 211.6 (C-6), 42.2 (C-7), 36.6 (C-8), 44.7 (C-9), 42.0 (C-10), 20.7 (C-11), 38.9 (C-12), 43.7 (C-13), 49.2 (C-14), 27.0 (C-15), 75.2 (C-16), 77.4 (C-17), 13.1 (C-18), 13.7 (C-19), 210.3 (C-20), 31.3 (C-21), 26.1 ((*C*H_3)$_3$CSi), 18.3 ((CH$_3$)$_3$*C*Si), –2.9 ((*C*H_3)$_2$Si). *16α-(*tert*-Butyldimethylsilyloxy)-5,17α-dihydroxy-2α,3α-isopropylidenedioxy-5α-pregna-6,20-dione (16)*

Olefin **15** (6.5 g, 13.6 mmol) was treated following the general dihydroxylation procedure (NMO (4.6 g, 39 mmol), OsO_4–*t*-BuOH (30 mL, 12.5 mg/mL)) until completion as indicated by TLC (minor impurities were also detectable). The usual work-up (AcOEt) afforded a product that was dried, dissolved in anhydr. DMF (150 mL), and treated with PPTS (0.8 g) and 2,2-dimethoxypropane (30 mL). Activated K_2CO_3 (500 mg) was added to the solution after 24 h, and the mixture was stirred overnight at room temperature. The usual work-up (CH_2Cl_2) yielded a product that was purified by flash column chromatography (hexane–AcOEt, 2:1) to give the colorless syrup **16** (4.93 g, 61%); mp (MeOH) 206–209 °C. IR (KBr, cm^{-1}): 3461, 1703, 1699, 1116, 1089, 1056, 1041. ^{1}H NMR ($CDCl_3$) δ: 0.08 (s, 3H, (CH_3)$_2$Si), 0.09 (s, 3H, (CH_3)$_2$Si), 0.67 (s, 3H, H-18), 0.75 (s, 3H, H-19), 0.90 (s, 9H, (CH_3)$_3$CSi), 1.47 (s, 3H, CH_3-ketal), 1.34 (s, 3H, CH_3-ketal), 2.05 (s, 3H, H-21), 4.08–4.15 (br m, 1H, H-2β), 4.31 (m, 1H, H-3β), 4.56 (d, 1H, *J* = 7.0 Hz, H-16β). ^{13}C NMR ($CDCl_3$) δ: 28.2 (C-1), 73.7 (C-2), 74.3 (C-3), 33.8 (C-4), 79.5 (C-5), 211.8 (C-6), 41.0 (C-7), 36.4 (C-8), 44.2 (C-9), 45.2 (C-10), 20.7 (C-11), 38.6 (C-12), 43.7 (C-13), 49.2 (C-14), 27.2 (C-15), 75.2 (C-16), 77.4 (C-17), 13.1 (C-18), 14.2 (C-19), 210.3 (C-20), 31.3 (C-21), 26.0 ((*C*H_3)$_3$CSi), 18.3 ((CH$_3$)$_3$*C*Si), –2.9 ((*C*H_3)$_2$Si), 108.2 (O-C-O), 26.9 + 28.4 (*C*H_3 ketal). Anal. calcd. for $C_{31}H_{54}O_7Si$: C 55.7, H 9.6, Si 4.95; found: C 55.8, H 9.7, Si 5.1.

5,16α,17α-Trihydroxy-2α,3α-isopropylidenedioxy-5α-pregna-6,20-dione (17)

TBAF (3 mL, 1 mol/L in THF) was added to a solution of acetonide **16** (4.9 g, 8.9 mmol) in anhydr. THF (100 mL). The reaction mixture was stirred under a nitrogen atmosphere for 6 h and then concentrated. The usual work-up (Et_2O) yielded the crude product in quantitative yield, which was recrystallized from MeOH to furnish the acetonide **17** (3.49 g, 90%); mp (MeOH) 211 to 212 °C. IR (KBr, cm^{-1}): 3414, 3339, 1700, 1697, 1205, 1142, 1118. ^{1}H NMR ($CDCl_3$) δ: 0.69 (s, 3H, H-18), 0.74 (s, 3H, H-19), 1.48 (s, 3H, CH_3-ketal), 1.34 (s, 3H, CH_3-ketal), 2.07 (s, 3H, H-21), 2.72 (t, 1H, *J* = 12.4 Hz, H-7α), 4.08–4.15 (br m, 1H, H-2β), 4.31 (m, 1H, H-3β), 4.50 (d, 1H, *J* = 7.3 Hz, H-16β). ^{13}C NMR ($CDCl_3$) δ: 28.4 (C-1), 73.6 (C-2), 74.0 (C-3), 33.8 (C-4), 79.4 (C-5), 211.7 (C-6), 41.0 (C-7), 36.4 (C-8), 44.2 (C-9), 45.2 (C-10), 20.5 (C-11), 34.5 (C-12), 47.0 (C-13), 48.9 (C-14), 27.9 (C-15), 74.1 (C-16), 77.2 (C-17), 16.5 (C-18),

5,16β,17α-Trihydroxy-2α,3α-isopropylidenedioxy-5α-pregna-6,20-dione (18)

To a stirred solution of triol **17** (700 mg, 1.6 mmol), formic acid (300 μL), and triphenylphosphine (635 mg, 2.49 mmol) in THF (50 mL) was added dropwise a solution of DIAD (570 μL, 2.94 mmol) in 7 mL of THF. The reaction mixture was stirred at room temperature for 24 h, after which time TLC analysis revealed that all the starting material had been consumed. Then the volatiles were evaporated off under reduced pressure and the resultant crude was dissolved in 80 mL of a saturated solution of $NaHCO_3$ in MeOH–H_2O (4:1) and stirred for 1 h at room temperature. The usual work-up (Et_2O) yielded a crude product, which was purified by flash column chromatography (hexane–AcOEt, 3:1) to give the triol **18** (497 mg, 71%); mp (EtOH) 215 to 216 °C. IR (KBr, cm^{-1}): 3459, 3401, 3346, 1700, 1696, 1204, 1145, 1074. ^{1}H NMR ($CDCl_3$) δ: 0.77 (s, 3H, H-18), 0.74 (s, 3H, H-19), 1.47 (s, 3H, CH_3-ketal), 1.34 (s, 3H, CH_3-ketal), 2.09 (s, 3H, H-21), 4.09–4.16 (br m, 1H, H-2β), 4.32 (m, 1H, H-3β), 4.41 (dd, 1H, J = 8.1, 5.9 Hz, H-16α). ^{13}C NMR ($CDCl_3$) δ: 28.5 (C-1), 73.6 (C-2), 74.0 (C-3), 33.7 (C-4), 79.4 (C-5), 211.8 (C-6), 41.0 (C-7), 36.4 (C-8), 44.2 (C-9), 45.2 (C-10), 20.5 (C-11), 34.5 (C-12), 46.1 (C-13), 53.0 (C-14), 28.1 (C-15), 73.7 (C-16), 77.0 (C-17), 15.1 (C-18), 14.5 (C-19), 216.2 (C-20), 29.7 (C-21). Anal. calcd. for $C_{24}H_{36}O_7$: C 66.0, H 8.3; found: C 66.2, H 8.4.

2α,3α,5,16β,17α-Pentahydroxy-5α-pregna-6,20-dione (21)

Acetic acid (2 mL) was added to a solution of **18** (400 mg, 0.9 mmol) in 20 mL of the solvent mixture MeOH–H_2O (5:1) and the reaction mixture was refluxed for 1 h. The usual work-up (AcOEt) yielded a white product, which was recrystallized from AcOEt to afford the pure pentaol **21** (282 mg, 86%); mp (AcOEt) 241 to 242 °C. IR (KBr, cm^{-1}): 3447, 3421, 3329, 3301, 1701, 1697, 1240, 1162, 1186, 1048. ^{1}H NMR ($CDCl_3$) δ: 0.78 (s, 3H, H-18), 0.72 (s, 3H, H-19), 2.09 (s, 3H, H-21), 2.70 (t, 1H, J = 12.5 Hz, H-7α), 3.78–3.84 (br m, 1H, H-2β), 4.11 (m, 1H, H-3β), 4.41 (dd, 1H, J = 8.0, 5.9 Hz, H-16α). ^{13}C NMR ($CDCl_3$) δ: 30.1 (C-1), 67.4 (C-2), 69.5 (C-3), 34.1 (C-4), 79.3 (C-5), 211.0 (C-6), 41.2 (C-7), 36.9 (C-8), 44.2 (C-9), 45.2 (C-10), 21.0 (C-11), 34.5 (C-12), 46.1 (C-13), 53.4 (C-14), 28.2 (C-15), 73.8 (C-16), 77.1 (C-17), 15.0 (C-18), 14.5 (C-19), 216.2 (C-20), 29.7 (C-21). Anal. calcd. for $C_{21}H_{32}O_5$: C 63.6, H 8.1; found: C 63.5, H 8.2.

16β-Azido-5,17α-dihydroxy-2α,3α-isopropylidenedioxy-5α-pregna-6,20-dione (19)

Mesyl chloride (0.558 g, 4.9 mmol) was added dropwise to a stirred solution of acetonide **17** (1.44 g, 3.3 mmol) in dry CH_2Cl_2 (50 mL) and Et_3N (1.0 mL, 7.3 mmol) at 0 °C under a nitrogen atmosphere. The resulting suspension was stirred at this temperature for 1 h, allowed to reach room temperature, and then poured into 200 mL of 10% $NaHCO_3$. The usual work-up (CH_2Cl_2) yielded a product, which was carefully dried and dissolved in DMPU (50 mL). NaN_3 (322 mg, 4.95 mmol) was added and the resulting mixture was stirred vigorously under an argon atmosphere at 50 °C for 48 h. TLC analysis of a mini work-up revealed the formation of two products, one being the more polar and the major steroidal product. The usual work-up (EtOAc) yielded a crude product, which was purified by flash column chromatography (hexane–AcOEt, 3:1) to afford, by collection of the more hydrophilic fractions, the azide **19** (1.1 g, 73%); mp (MeOH) 207–210 °C. IR (KBr, cm^{-1}): 3335, 3322, 2091, 1702, 1698, 1168, 1110. ^{1}H NMR ($CDCl_3$) δ: 0.78 (s, 3H, H-18), 0.74 (s, 3H, H-19), 1.49 (s, 3H, CH_3-ketal), 1.34 (s, 3H, CH_3-ketal), 2.08 (s, 3H, H-21), 4.08–4.15 (br m, 1H, H-2β), 4.24 (dd, 1H, J = 8.1, 5.7 Hz, H-16α), 4.32 (m, 1H, H-3β). ^{13}C NMR ($CDCl_3$) δ: 28.5 (C-1), 73.6 (C-2), 74.1 (C-3), 33.6 (C-4), 79.5 (C-5), 212.0 (C-6), 41.0 (C-7), 36.4 (C-8), 44.1 (C-9), 45.2 (C-10), 20.5 (C-11), 34.5 (C-12), 46.1 (C-13), 53.1 (C-14), 28.0 (C-15), 68.1 (C-16), 76.5 (C-17), 15.0 (C-18), 14.6 (C-19), 216.1 (C-20), 29.8 (C-21). Anal. calcd. for $C_{24}H_{35}O_6N_3$: C 62.5, H 7.6, N 9.1; found: C 62.3, H 7.5, N 9.2.

16β-Amino-2α,3α,5,17α-tetrahydroxy-5α-pregna-6,20-dione (22)

Lindlar catalyst (200 mg) was added to a solution of azide **19** (1.0 g, 2.1 mmol) in 60 mL of absolute EtOH. The mixture was treated successively with hydrogen and vacuum and finally stirred under a hydrogen atmosphere for 36 h, when TLC analysis revealed that all the azide had been consumed. The catalyst was removed by filtration and the resulting solution was evaporated under reduced pressure to give the corresponding amine, which was dissolved in 60 mL of the solvent mixture MeOH–H_2O (5:1). Acetic acid (4 mL) was added and the reaction mixture was refluxed for 1 h. The solvent was concentrated until half volume and partitioned between 10% NaOH (200 mL) and EtOAc (300 mL). The aqueous layer was extracted successively with EtOAc (3 × 100 mL), dried over anhydr. Na_2SO_4, and concentrated under reduced pressure. Recrystallization from EtOAc gave the pure amine **22** (522 mg, 63%); mp (EtOAc) 227–230 °C. IR (KBr, cm^{-1}): 3428, 3391, 3326, 3311, 1700, 1204, 1158, 1116. ^{1}H NMR ($CDCl_3$) δ: 0.78 (s, 3H, H-18), 0.73 (s, 3H, H-19), 2.10 (s, 3H, H-21), 3.74–3.81 (br m, 1H, H-2β), 4.09 (m, 1H, H-3β), 4.17 (br s, 1H, OH), 4.33 (dd, 1H, J = 7.9, 5.9 Hz, H-16α). ^{13}C NMR ($CDCl_3$) δ: 30.2 (C-1), 67.4 (C-2), 69.5 (C-3), 34.1 (C-4), 79.3 (C-5), 210.9 (C-6), 41.0 (C-7), 36.4 (C-8), 44.2 (C-9), 45.2 (C-10), 20.7 (C-11), 35.3 (C-12), 46.1 (C-13), 53.2 (C-14), 28.2 (C-15), 73.8 (C-16), 76.9 (C-17), 15.1 (C-18), 14.5 (C-19), 216.2 (C-20), 29.8 (C-21). Anal. calcd. for $C_{21}H_{33}O_6N$: C 63.8, H 8.4, N 3.5; found: C 63.7, H 8.3, N 3.65.

16α-Azido-5,17α-dihydroxy-2α,3α-isopropylidenedioxy-5α-pregna-6,20-dione (20)

Methanesulfonic acid (570 μL, 8.8 mmol) was added to a stirred solution of acetonide **17** (1.74 g, 4.0 mmol) and triphenylphosphine (3.14 g, 12.0 mmol) in dry THF (120 mL). The temperature was raised to 40 °C and a solution of DIAD (2.33 mL, 12 mmol) in 15 mL of THF was added dropwise over a 10 min period under an argon atmosphere. The reaction mixture was stirred vigorously for 24 h at 40 °C under an argon atmosphere, and then the volatiles were evaporated off under reduced pressure. The crude product was purified by flash column chromatography to give a pure product, which was analyzed by ^{1}H NMR confirming the structure of the mesylate. This later was submitted to

© 2005 NRC Canada

azide displacement as described for the synthesis of **19**. Purification by flash column chromatography yielded the azide **20** (1.12 g, 61%); mp (MeOH) 205 to 206 °C. IR (KBr, cm^{-1}): 3368, 3312, 2091, 1701, 1162, 1130, 1058. ^1H NMR ($CDCl_3$) δ: 0.70 (s, 3H, H-18), 0.74 (s, 3H, H-19), 1.48 (s, 3H, CH_3-ketal), 1.34 (s, 3H, CH_3-ketal), 2.06 (s, 3H, H-21), 2.70 (t, 1H, J = 12.5 Hz, H-7α), 4.08–4.15 (br m, 1H, H-2β), 4.28 (d, 1H, J = 7.1 Hz, H-16β), 4.32 (m, 1H, H-3β). ^{13}C NMR ($CDCl_3$) δ: 28.5 (C-1), 73.6 (C-2), 74.1 (C-3), 33.8 (C-4), 79.6 (C-5), 211.9 (C-6), 41.0 (C-7), 36.4 (C-8), 44.2 (C-9), 45.2 (C-10), 20.5 (C-11), 34.5 (C-12), 47.1 (C-13), 48.9 (C-14), 27.7 (C-15), 67.9 (C-16), 76.3 (C-17), 16.4 (C-18), 14.7 (C-19), 216.3 (C-20), 29.8 (C-21). Anal. calcd. for $C_{24}H_{35}O_6N_3$: C 62.5, H 7.6, N 9.1; found: C 62.1, H 7.5, N 9.05.

16α-Amino-2α,3α,5,17α-tetrahydroxy-5α-pregna-6,20-dione (23)

Azide **20** (800 mg, 1.73 mmol) was treated as described in the synthesis of the amine **22**. Recrystallization from EtOAc gave the pure amine **23** (403 mg, 59%); mp (EtOAc) 229 to 230 °C. IR (KBr, cm^{-1}): 3345, 3428, 3419, 1701, 1697, 1240, 1162, 1048. ^1H NMR (CD_3OD) δ: 0.769 (s, 3H, H-18), 0.73 (s, 3H, H-19), 2.06 (s, 3H, H-21), 2.72 (t, 1H, J = 12.4 Hz, H-7α), 3.74–3.82 (br m, 1H, H-2β), 4.09 (m, 1H, H-3β), 4.39 (d, 1H, J = 7.1 Hz, H-16β). ^{13}C NMR (CD_3OD) δ: 30.5 (C-1), 66.7 (C-2), 69.3 (C-3), 33.4 (C-4), 79.4 (C-5), 211.6 (C-6), 40.2 (C-7), 35.5 (C-8), 43.2 (C-9), 44.6 (C-10), 19.5 (C-11), 34.5 (C-12), 47.0 (C-13), 48.9 (C-14), 27.9 (C-15), 73.4 (C-16), 77.0 (C-17), 16.5 (C-18), 14.5 (C-19), 216.5 (C-20), 29.8 (C-21). Anal. calcd. for $C_{21}H_{33}O_6N$: C 63.8, H 8.4, N 3.5; found: C 63.9, H 8.6, N 3.6.

Biological activity

Radish seeds (*R. sativus* L.) were germinated over wet cotton in the dark at 25 °C for 72 h. The hypocotyls (cut to 1 cm long) and the cotyledons were placed in independent plates (diameter 11 cm) over filter paper (diameter 9 cm), and 5 mL of the ethanol–water solutions containing the targets pregnane-brassinosteroid-like compounds (concentrations: 0.1–0.001 ppm) were applied over the filter paper. For control experiments, cotyledons and hypocotyls were treated with 5 mL of distilled water. After 72 h, the lengths of the hypocotyls were measured, the cotyledons were weighted, and the averages of these magnitudes were calculated. Each experiment at one concentration consisted of three different plates containing 10 hypocotyls or cotyledons per plate. Statistical analysis of the data was carried out to establish significant differences with respect to control utilizing the Duncan test as implemented in the STATGRAPHICS program.

Acknowledgments

We are grateful to Dr. Carlos. S. Pérez from the University of Havana, and Dr. Andrea Porzel from the Institute of Plant Biochemistry, Halle (Saale) Germany, for the spectroscopic measures. We also gratefully acknowledge Ing. Deysma C. Herrera for experimental assistance.

One-step synthesis of Sb_2O_3 broom-like belts with controllable morphology

Qingrui Zhao, Xuanjun Zhang, Qing Yang, and Yi Xie

Abstract: A direct and simple surfactant- and template-free route has been developed for the controlled synthesis of Sb_2O_3 belt-like microstructures. By adjusting the reactant ratio between $SbCl_3$ and urea under solvothermal reaction conditions, broom-like belts and rods of Sb_2O_3 have been successfully prepared. X-ray powder diffraction (XRD), scanning electron microscopy (SEM), high-resolution transmission electron microscopy (HR-TEM), and X-ray photoelectron spectroscopy (XPS) has been used to characterize the phases and morphologies of the as-prepared products. A possible formation mechanism is also discussed.

Key words: antimony trioxide, solvothermal synthesis, broom-like belts.

Résumé : Une méthode simple et directe n'impliquant aucun gabarit ou agent de surface a été développée pour la synthèse contrôlée de microstructures de Sb_2O_3 en forme de ceinture. La réaction du $SbCl_3$ et de l'urée, dans des conditions solvothermiques et en ajustant le rapport des réactifs, permet de préparer avec succès des tiges et des ceintures de Sb_2O_3 en forme de balais. On a fait appel à la diffraction des rayons X par des poudres, à la microscopie électronique à balayage et la microscopie électronique en transmission à haute résolution et à la spectroscopie photoélectronique des rayons X pour caractériser les phases et les morphologies des produits tels que préparés. On discute aussi du mécanisme possible de leur formation.

Mots clés : trioxyde d'antimoine, synthèse solvothermique, ceintures en forme de balais.

[Traduit par la Rédaction]

Introduction

Recently, compounds with interesting morphologies and specific structures, especially one-dimensional (1D) nano- and microstructures, have drawn an increasing amount of attention since the discovery of carbon nanotubes (1). The unique physical and chemical properties of 1D materials have been well documented and are proposed for a wide range of potential applications in the fabrication of electroluminescent devices (2, 3), photovoltaic devices (4), and light-emitting diodes (5, 6). Consequently, considerable effort has been devoted to the synthesis of various 1D tubes and wires over the past decade. More recently nano- and microscale belts, which are distinctively different from wires and tubes, have been the subjects of intensive research since they have shown promise as new kinds of building blocks that can be integrated into electronic devices. At present, several strategies have been developed for the growth of nano- or submicroscaled belts through different growth mechanisms. These strategies include evaporation of the source compounds via a vapor–solid (VS) or vapor–liquid–solid (VLS) process (7, 8), a complex, surfactant-assisted hydrothermal route to ferromagnetic nickel nanobelts (9), and the organogel template-directed synthesis of helical titanium dioxide nanoribbons (10).

Among published reports, general strategies for the synthesis of belt-like materials involve high-temperature, template- or catalyst-based methods, and complicated processes in which impurities may be introduced. In this paper, we report a low-temperature, simple solution synthetic method to produce large-scale, single-crystalline Sb_2O_3 belts without using any catalysts or templates. This synthetic strategy will provide an effective approach to the development of 1D structures.

Sb_2O_3, which possesses many distinctive properties, has been widely used as an effective catalyst in photochemistry, either individually or combined with other oxides, and is employed as a highly efficient flame retardant (11). Recently, several groups have prepared 1D nanostructures of Sb_2O_3, such as Sb_2O_3 fibrils and tubules synthesized via a VS route (12) and nanorods via a surfactant-assisted solvothermal process (13). Additionally, with the help of a microemulsion system composed of sodium bis(2-ethylhexyl)-sulfosuccinate (AOT), water, and toluene (14) or carbon nanotube templates (15), Sb_2O_3 nanorods were also prepared. To date, there have been very few reports on the large-scale synthesis of Sb_2O_3 on a micrometer scale. In this paper, we report for the first time a facile and simple surfactant- and template-free solution route to prepare Sb_2O_3 belts with a micrometer size.

Experimental section

Synthesis of Sb_2O_3 broom-like belts

A total of 1 mmol $SbCl_3$ and 4 mmol of urea were dissolved in a 10 mL water–ethanol solution (1:1, *v*/*v*). The mixture was then transferred into a 15 mL Teflon-lined autoclave. The autoclave was maintained at 160 °C for 12 h and then cooled to room temperature. The light yellow powders formed were collected, washed sequentially several times with distilled water and ethanol, and then dried in vacuum at 50 °C for 6 h.

Characterization of the products

The phase of the products was determined by X-ray powder diffraction (XRD) using a Japan Rigaku D/max γA X-ray diffractometer with graphite-monochromatized Cu Kα radiation (λ = 1.541 78 Å). The scan rate of 0.05°/s was applied to record the patterns in the 2θ range of 10°~70°. The morphology and size of the as-prepared products were observed by scanning electron microscopy (SEM), performed using an X-650 scanning electron microanalyzer. High-resolution transmission electron microscopy (HR-TEM) images and selected area electron diffractions were taken using a JEOL-2010 high-resolution electron microscope with an accelerating voltage of 200 kV. X-ray photoelectron spectroscopy (XPS) was performed using an ESCALAB MKII with Mg Kα ($h\nu$ = 1253.6 eV) as the excitation source. The binding energies obtained in the XPS spectral analysis were corrected for specimen charging by referencing the C1s peak to 284.60 eV.

Results and discussion

The product was firstly characterized using XRD and a typical diffraction pattern is shown in Fig. 1. From the XRD pattern, all reflection peaks could be readily indexed to the orthorhombic phase of Sb_2O_3, with calculated lattice constants of a = 4.910 Å, b = 12.348 Å, and c = 5.329 Å, which were in good agreement with the values of the Joint Committee for Powder Diffraction Studies (JCPDS) file (No. 11-689), and no obvious impurities could be detected in the obtained pattern.

The morphology of the as-prepared product was examined using SEM. Figure 2 shows images of the Sb_2O_3 structure at different magnifications. A low-magnification image (Fig. 2*a*) displays a panorama of as-prepared belts, indicating that the Sb_2O_3 belts cluster form in a high yield, and the proportion of free-standing belts in the whole sample is under 10%. Some belts grow from the original core and extend toward different directions. Figure 2*b* reveals that the Sb_2O_3 belts are fairly straight with lengths of approximately several micrometers. The surfaces of the belts are clean with regular edges and the belts appear to have generally uniform widths over their entire length. The high-magnification images (Figs. 2*c* and 2*d*) give further details about the morphological features of the belts. From the top view (Fig. 2*c*), we can see many uniform Sb_2O_3 belts, with widths of about 3–7 μm extending in different directions, all issuing from a common center. More detail about the belts can be found in a partially magnified image (Fig. 2*d*) in which one can see that a small belt can be split from a thicker belt as indicated by the arrowhead and that the typical thickness of the products can vary from 300 to 400 nm. HR-TEM images of an individual belt (Figs. 3*a* and 3*b*) provide further insight into the fine structure of these products. The selected area electron diffraction (SAED) pattern was recorded with the electron beam perpendicular to the surface of an individual belt, as shown in Fig. 3*a*. Through careful analysis of the diffraction pattern, the spots could be readily indexed, as marked in the figure, and the [100] zone axis of the belts could be identified by diffraction of orthorhombic Sb_2O_3. These results mean that the wide surface and the narrow side surface of the belt correspond to the (010) and (100) planes, respec-

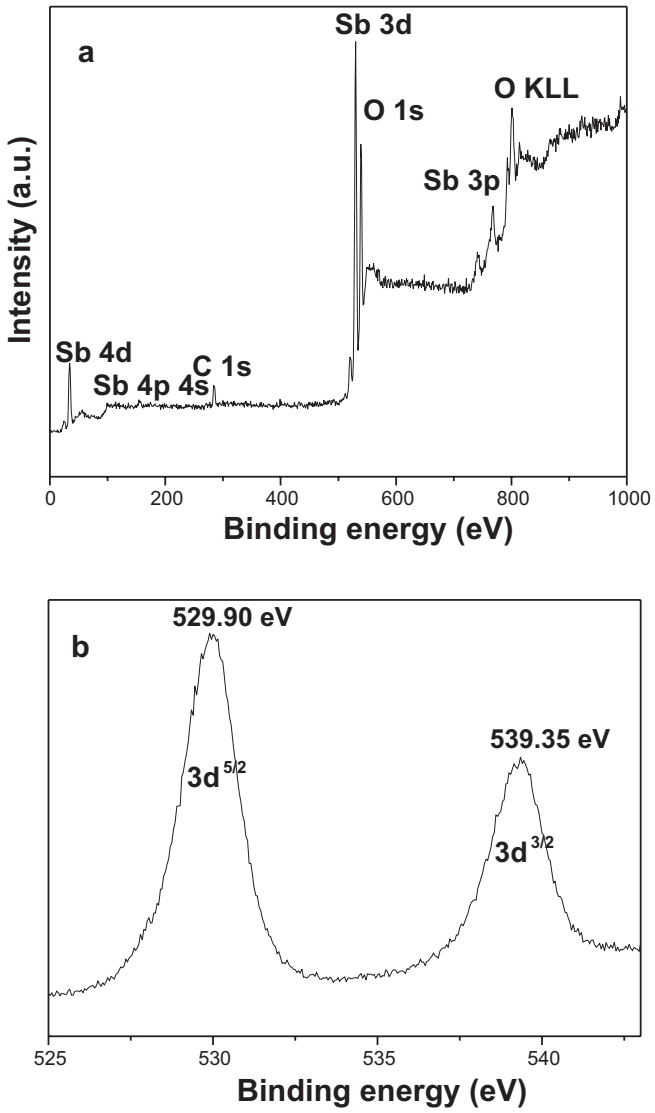
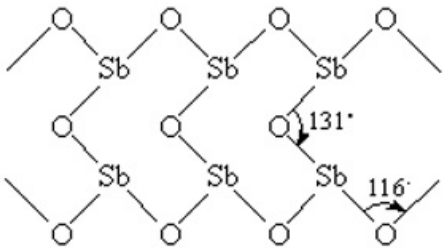
Fig. 3. (*a*) HR-TEM image of an individual belt and a SAED pattern (inset) of the belt. (*b*) HR-TEM image of high quality Sb_2O_3 belts projected along the [100] zone axis.

tively. The growth of the long axis is along the [001] direction. This conclusion is supported by our subsequent HR-TEM investigation, and the image obtained is shown in Fig. 3*b*. The identified fringe spacing of 1.235 nm corresponds well with the separation between neighboring (010) lattices. We employed SAED and HR-TEM to characterize different belts, as well as different parts of the same belt. All results confirm that the belts grow along the [001] direction.



To further characterize the product, XPS was carried out to investigate the surface composition and chemical state of the broom-like Sb_2O_3 belts. Typical high-resolution spectra of Sb_2O_3 are shown in Fig. 4. Since the position of the Sb $3d^{5/2}$ binding energy is superimposed over that of the O 2p binding energy, the Sb $3d^{3/2}$ binding energy was used for characterization. Figure 3*b* shows that the strong peak centered at 539.35 eV corresponds to the Sb $3d^{3/2}$ binding energy and this coincides with the value reported in the literature (16). No obvious impurities (besides trace adsorbent O_2) could be detected in the samples. Quantification gave an atomic ratio of Sb to O elements of 0.736 based on the areas of the Sb and O peaks, respectively, including adsorbent O_2 consistent with the given stoichiometric ratio within experimental error. The valence state of the Sb ions in the product is confirmed as Sb^{3+} rather than Sb^{5+}. On the basis of the above characterizations of the XRD pattern and XPS, the as-synthesized products are pure-phase Sb_2O_3.

The whole reaction process can be formulated as follows:



$$[1] \quad 2SbCl_3 + 3CO(NH_2)_2 + 6H_2O \longrightarrow Sb_2O_3 + 3CO_2 + 6NH_4Cl$$

To understand the observed behavior of Sb_2O_3, it is necessary to investigate its unusual crystal structure, as shown in Scheme 1. Sb_2O_3 forms in the orthorhombic system with space group *Pccn*. It has infinite double chains of corner sharing SbO_6 octahedra in a unit cell with a strong covalent bond of Sb—O and each double chain is held to the next chain only by weak Van der Waals forces. Orthorhombic structured Sb_2O_3 has a pseudo-two-dimensional structure, which is seldom found in oxides (17). This kind of molecular structure can confine and promote one-dimensional growth along one particular axis, as has been demonstrated for tungsten (18) and molybdenum trioxide nanobelts (19). In addition, one-dimensional growth occurs because the orthorhombic lattice is intrinsically anisotropic and has a unique (001) axis (20, 21). Sb and O atoms are bound in infinite pseudo-two-dimensional hexagonal sheets along the [001] direction. It is the large difference in lattice parameters between *b* and *a* and *c* in the orthorhombic Sb_2O_3 that leads to the notably different growth rates in different directions and belts with a large width-to-length ratio form come into being. It is the inherent chain type of Sb_2O_3 that could demonstrate the structure that tends to exhibit belt-like growth along the [001] direction (22, 23).

Fig. **5.** SEM image of Sb_2O_3 broom-like belts at 9 h.

For a better understanding of the synthesis of Sb_2O_3 belts, we performed several experiments in which intermediates were collected at different times. In this experiment, the products with the reaction time of 3 h were removed and checked with SEM. It was found that the products were mainly slabs that exhibited nonuniform roughness. Prolonging the reaction time resulted in slabs that kept on growing along the preferred growth direction until at 9 h small Sb_2O_3 belts could be obtained in combination with some short rods, which had not been able to evolve into complete belts (Fig. 5). During the growth course from rods to belts, owing to the different growth rates at different sites, tip slipping occurred, which eventually resulted in bundle broom-like belts.

It was also found that many factors, such as temperature and molar ratio of $SbCl_3$ to urea, had a profound influence on the morphology of the product. The suitable temperature and reaction time provided a greater possibility for nucleation and growth of belt-like crystals. For example, if the reaction temperature was decreased to 80 °C, the decomposition of urea was very slow, and as a result, the nucleation and growth rate of the crystals were also very slow and the major products were solids with irregular shapes. The influence of the molar ratio between $SbCl_3$ and urea, which is a prerequisite for controlling the synthesis of Sb_2O_3 with different product morphologies, has also been investigated in some detail. If the molar ratio between $SbCl_3$ and urea was decreased to 1:1, rough irregular flakes (Fig. 6) were formed. However, when the molar ratio between $SbCl_3$ and urea was changed to 1:3 or 1:5, minor belts of Sb_2O_3 were also produced in addition to the existence of irregular particles. However, if the ratio of $SbCl_3$ to urea was increased to 1:10, short rods (Fig. 7) were formed as the final product. Therefore, it is worth pointing out that a molar ratio of 1:4 between $SbCl_3$ and urea is the optimal experimental condition to produce broom-like belts of Sb_2O_3.

Summary

In summary, broom-like belts and rods of Sb_2O_3 were successfully synthesized from $SbCl_3$ and urea via a simple mild process. If the molar ratio of $SbCl_3$ to urea is 1:4, the main products are broom-like belts of Sb_2O_3. Changing the molar ratio of $SbCl_3$ to urea to 1:10 results in the transformation of the broom-like belts to rods. Sb_2O_3 with both these morphologies may have applications in many areas. The influence of reaction temperature and reaction time on the formation of different morphologies was also investigated in detail. This synthesis route provides a simple method for preparing broom-like belts of Sb_2O_3, which could offer new opportunities for technological applications.

Study of the nitration of di-*n*-octylcrown-6 calix[4]arene using LC–MS, NMR, and molecular modelling

C.K. Jankowski, M.-R. Van Calsteren, N. Aychet, J.F. Dozol, C. Moulin, and C. Lamouroux

Abstract: The selective HNO_3 nitration of di-*n*-octylcrown-6 calix[4]arene using different conditions, studied with LC–MS and NMR (^1H and ^{13}C) spectroscopic techniques, lead to the identification of most of the expected nitro derivative isomeric compounds. The formation of these isomers under acidic and radiolytic conditions is discussed with the help of molecular modelling.

Key words: calix crown compounds, nitration of calixarenes, NMR of isomeric nitrocalixarenes, LC–ESI-MS.

Résumé : La nitration sélective au HNO_3 du di-*n*-octylcouronne-6 calix[4]arène dans différentes conditions, étudiée par des techniques spectroscopiques de LC–MS et de RMN (^1H et ^{13}C), conduisent à l'identification de la plupart des isomères de dérivés nitro attendus. La formation de ces isomères dans des conditions acides et radiolytiques est discutée avec l'aide de la modélisation moléculaire.

Mots clés : composés calix couronne, nitration de calixarènes, RMN des nitrocalixarènes isomères, LC–ESI-MS.

Introduction

The calixarene crown compounds have their notoriety as efficient and selective extractants of several cations, for example, cesium in the presence of sodium (1) within the nuclear spent fuel reprocessing framework. Nitric acid slurries contaminated with radioactive material could be treated with calix[4]arenes derivatives in order to extract or to retain some of the radioactive cations (2).

The calix[4]arene crown-6 compounds have an exceptional capacity to bind (complex) Cs^+ cations, in particular ^{137}Cs or ^{135}Cs. Unfortunately, during this process, the aromatic ring of the calixarenes could be nitrated via the acid-catalysed or radiolytic (probably assisted by radiolysis) processes. This can decrease their extractant ability, in particular by hindering crown access to the cations, and lead to a deterioration in the performance of a calix[4]arene crown-6 based device (diaphragm) (3).

In this study, we would like to report on the nitration of di-*n*-octyl calix[4]arene crown-6 (oct-MC-6 or as used in this paper c0o0) (4)[2,3]. This compound was found to be a promising cesium extractant, combining fair stability under industrial radiolysis conditions, conformational homogeneity (1,3-alternate conformation only), and as a result of that, lipophilic octyl chains are in a preferred anti position to the crown orientation (5) (Figs. 1 and 2).

Under uncontrolled nitration conditions, such as those used during the reprocessing of nuclear fuel, several nitrations can take place. First, the nitric phase is strongly acidic and this leads to the aromatic S_E substitution of one or more of the calix[4]arene crown-6 aromatic rings. It is then foreseeable that up to eight isomeric nitrocalix[4]arene crown-6 compounds having from one to four NO_2 groups placed in the electronically favoured para position (para to the electrodonating crown or octyloxy substituents) can be obtained. Some of these isomers can also be obtained from the radical $NO_2\cdot$ reaction with the aromatic ring. Nitration of an oct-MC-6 from the crown side in particular could block access to this cavity for the Cs^+ cation and subsequently reduce the extractant capacity of the entire system.

The nitration of the benzylic methylene of the crown ether or of the octyl chain methylenes could be considered less probable and more related to the radical nitration.

These two nitrations, S_E or radical, were observed in our previous studies of a nuclear fuel solvent reprocessing cycle (tributylphosphate, TBP) (6).

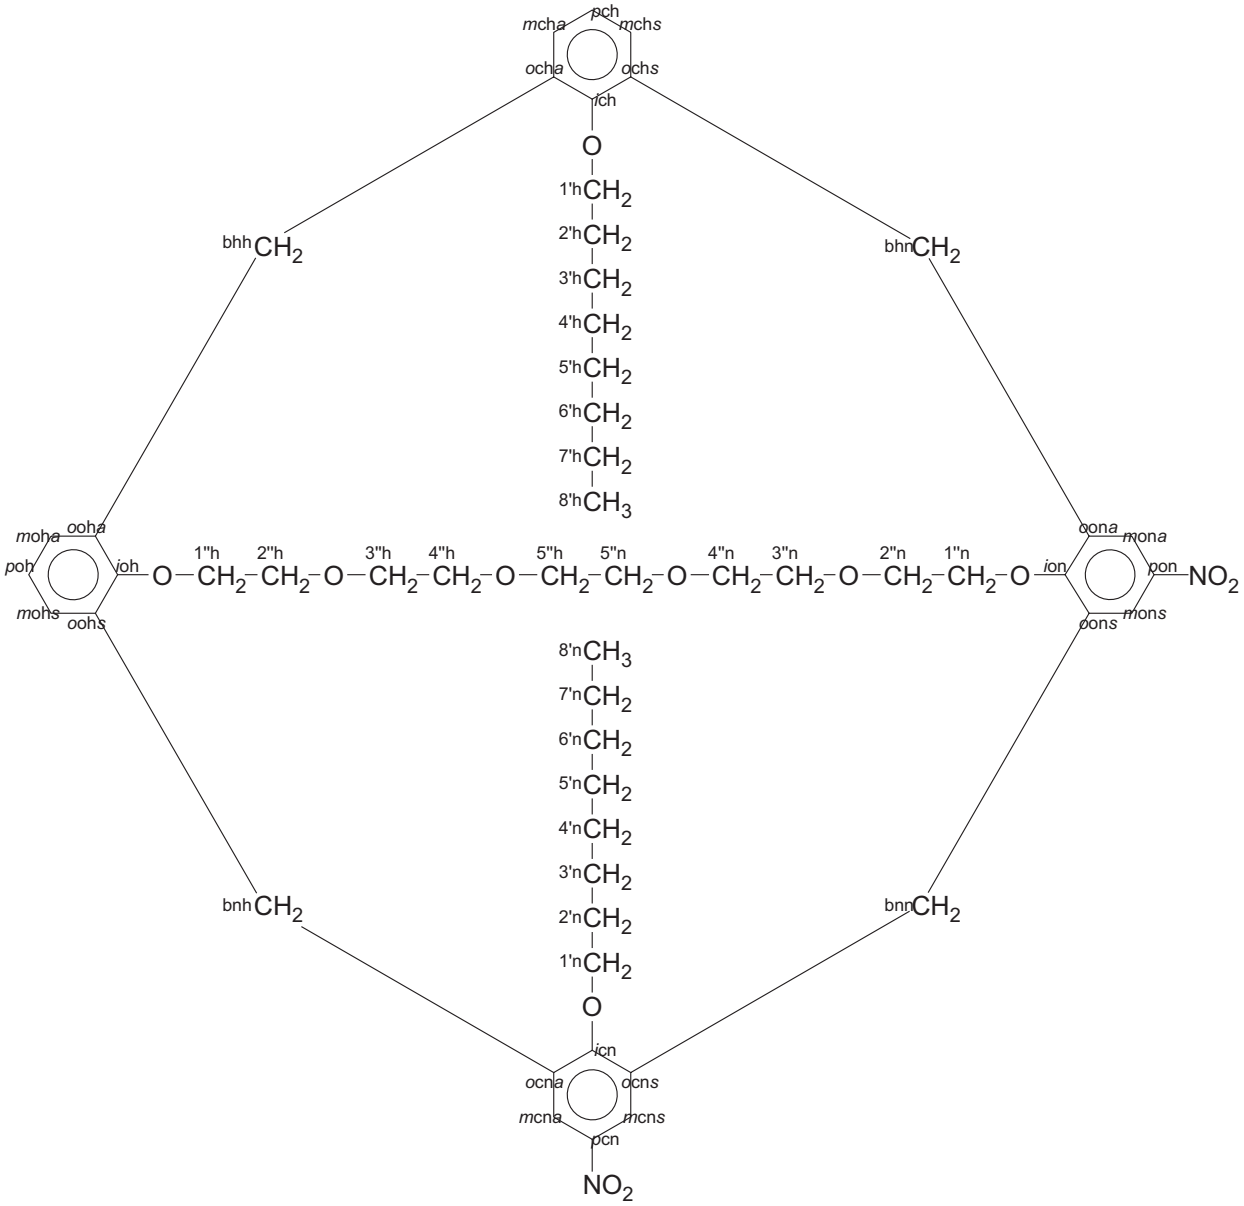
First row: oct-MC-6 (c0o0); Second row left to right: (NO_2)-oct-MC-6 (c0o1), $(NO_2)_2$-oct-MC-6 (c1o1), $(NO_2)_2$-oct-MC-6 (c0o2), $(NO_2)_3$-oct-MC-6 (c1o2), $(NO_2)_4$-oct-MC-6 (c2o2); Third row left to right: (NO_2)-oct-MC-6 (c1o0), $(NO_2)_2$-oct-MC-6 (c2o0), $(NO_2)_3$-oct-MC-6 (c2o1).

Although most similar calix[4]arene crown compounds when tested under radiolysis displayed good stability of the skeleton structure, several substitution reactions were also observed (7). During these studies, it was necessary to develop selective nitration methodology. For di-isopropyl-MC-6 and biscrown BC-6 calix[4]arenes, several nitro isomers were prepared and the structures were identified using electrospray ionization mass spectrometry (ESI-MS) (8).

In this study, while pursuing the search for selective synthesis of different nitro-oct-MC-6, a detailed study of these complex molecules with a complete assignment of their spectra was performed (Tables 1–6) by high-resolution NMR (^{1}H and ^{13}C). We also report on LC–MS use for this identification together with ESI-MS (Table 7). Finally, some mechanistic hypotheses for the formation of specific isomers were advanced with the help of molecular modelling (Table 8).

Synthesis



There are many methods of pernitration of activated aromatic rings. The calix[4]arene crown compounds, which formally are phenol ethers, fully maintain this capacity and react easily, despite some solubility problems showed by the parent polyphenol substrates (9). The selective nitration of similarly activated aromatic rings is a more sensitive reaction. The usual methodology applied to obtain some specific undernitrated isomers is to use the low-temperature nitration with formation of the S_E postulated intermediate NO_2^+ cation stabilized by an acetate or trifluoroacetate anion. The second approach is the use of nitrates. The most common approach, however, remains the undernitration of the substrate followed sometimes by very tedious separation of the resulting isomers. The nitration of calix[4]arene crowns under several conditions were successfully attempted by our group (8) by using seven different methods of nitration leading to the identification of almost all the possible isomeric nitro isomers of di-isopropyl calix[4]arene crown-6 and calix[4]arene biscrown-6 (Fig. 1).

The calix[4]arene studied in this paper has two *n*-octyl chains and one crown; both substituents of the calix[4]arene ring have a similar activating effect on the nitration of the molecule fixed in the 1,3-alternate conformation.

Access to specific isomers of nitro-oct-MC-6 is possible with the use of our previous methodology of low-temperature nitration. There are eight different polynitrated oct-MC-6 compounds in total: two isomeric mononitro-oct-MC-6, one with the NO_2 on the crown side (c1o0) and one on the *n*-octyl side (c0o1) of the molecule; three dinitro –

Fig. 2. Nomenclature used to report NMR data taking as an example the trans $(NO_2)_2$-oct-MC-6 (c1o1) molecule.

two cis, one with two NO_2 on the crown side (c2o0) and the other with two NO_2 on the *n*-octyl side (c0o2), and one *trans*-dinitro-oct-MC-6 having one NO_2 group on each side of the molecule (c1o1); two trinitro-oct-MC-6 (c2o1 and c1o2); and finally, one tetranitro-oct-MC-6 (c2o2).

The most challenging synthetic problem was the synthesis of specific mononitro and dinitro compounds.

The use of nitric acid at low temperature with acetic anhydride or trifluoroacetic anhydride leads to the discrete synthesis of two resulting mononitro isomers. In a second successful synthesis, we obtained two dinitro-oct-MC-6 of a total of three possible, by modification and strict control of the reaction conditions. The trinitro-oct-MC-6 was obtained as a secondary nitration product in several attempts; however, its specific synthesis from the dinitro-oct-MC-6 of known geometry was achieved only after rigorous identification of the starting dinitro-oct-MC-6 structure as c2o0. In total, six specific nitro-oct-MC-6 were synthesized and their structures established.

During this work, it was necessary to develop a reliable and fast method of identification of nitro-oct-MC-6 derivatives. This was done first by using the fast ESI-MS method on the Cs^+ spiked solution of oct-MC-6 (10–12); we have tried to cross compare the results using LC and LC–MS techniques.

In general, the more rigorous but slower method using LC needs specific standards to give a quantitative picture of the reaction. The LC method offers the possiblity of determining specific isomers.

Both techniques (MS and LC) are complementary in the synthetic framework and were constantly used in this study. However, despite all these important qualities, they do not completely identify the structure of isomeric nitro-oct-MC-6; this could only be done by the use of NMR.

Liquid chromatography study of nitration of oct-MC-6

The determination of postreaction mixtures of oct-MC-6 was done using a C18 or TSK-GEL Super-ODS column. Using several samples from different nitration trials, we prepared a reconstructed mixture with some spiking with pure synthetic isomers (13, 14). We were then able to identify up to six isomeric nitro-oct-MC-6 from the spent fuel samples and to separate up to seven of the eight possible isomers of the nitration reactions (Table 7). The only missing isomer, polynitro-oct-MC-6, seems to be one of the three dinitro compounds, although there was a small peak in the LC within the expected retention time area corresponding to its presence.

The detection of isomeric nitro-oct-MC-6 followed the logical trend of retention times as presented in Figs. 3–5 and Table 7. The detection of these derivatives varied according to the wavelength used. However, using the appropriate analytical grade synthetic standards, such as the starting oct-

MC-6 or one of the dinitro isomers $(NO_2)_2$-oct-MC-6, the mixture constituents could be quantified.

Assuming that the starting oct-MC-6 has a relative retention time of 1.00, all polynitro-oct-MC-6 derivatives followed in order; for example, mono-, di-, tri-, and finally tetranitro compounds. This detection was based on several crude nitration mixture analyses and in particular on those coming from the real-life nuclear cycle of fuel reprocessing. In this manner, we were able, for instance, to identify that only one mononitro-oct-MC-6 of two possible (Fig. 3) and one dinitro-oct-MC-6 (Fig. 4) of three isomers were present in these slurries (with trace quantities of the other isomers at an equal nitration level). Because both mononitro-oct-MC-6 were synthesized, we were able to identify which of the two was a result of radiolysis.

Curiously, in several of the synthetic mixtures obtained as a result of temperature variation during nitration, we were able to identify and confirm most of the missing or difficult to synthesize in larger quantity isomers, using the other analytical tool MS. This method is also a very reliable way to

quantify the mixtures using the synthetic mononitro-oct-MC-6 (c1o0) isomer as a standard.

Finally, we could compare the LC method to the very efficient and fast evaluation of all oct-MC-6 derivatives using the ESI-MS technique. This comparison was necessary in order to validate and eventually extend the previous claim that the Cs^+ cationization of the crown-6 component of these compounds can be used for this purpose. When the Cs^+ solution is added to the mixture, one can quantify the nitro compounds within this narrow family with a certainty of ±3%–5% (8).

ESI-MS identification of postreaction mixtures

The obvious advantage of ESI over the other techniques remains its speed and the possibility to analyse many samples in a relatively short time using a very simple procedure.

This method, used and developed in our previous studies, is based on cationization by Cs^+ of the crown cavity. In a way, the principle of nuclear fuel reprocessing is used here in the opposite way — the Cs^+ cation is added to the solution and ESI spectra were run on such mixtures, allowing identification of the starting material as well as all the polynitrated oct-MC-6 according to their characteristic *m*/*z* ratios. This technique, however, cannot be used for the identification of isomers, since all isomers having the same mass are present as the same *m*/*z* ion. Examples of typical spectra are presented in Figs. 3 and 4 for mononitro and dinitro isomers, respectively. The presence of other oct-MC-6 cations was also detected, in particular Na^+ cationization for higher nitration level isomers, and to some extent its protonation was also observed (Fig. 5).

In particular, the ion current variation corresponding to *m*/*z* 1053 $[(NO_2)_4$-oct-MC-6 + $Na]^+$, *m*/*z* 963 $[(NO_2)_2$-oct-

Note: See Experimental for details. 1 cal = 4.184 J.
[a]c crown side, o octyl side; for example, c0o0 means no NO_2 group on any of two sites of the calixarene.

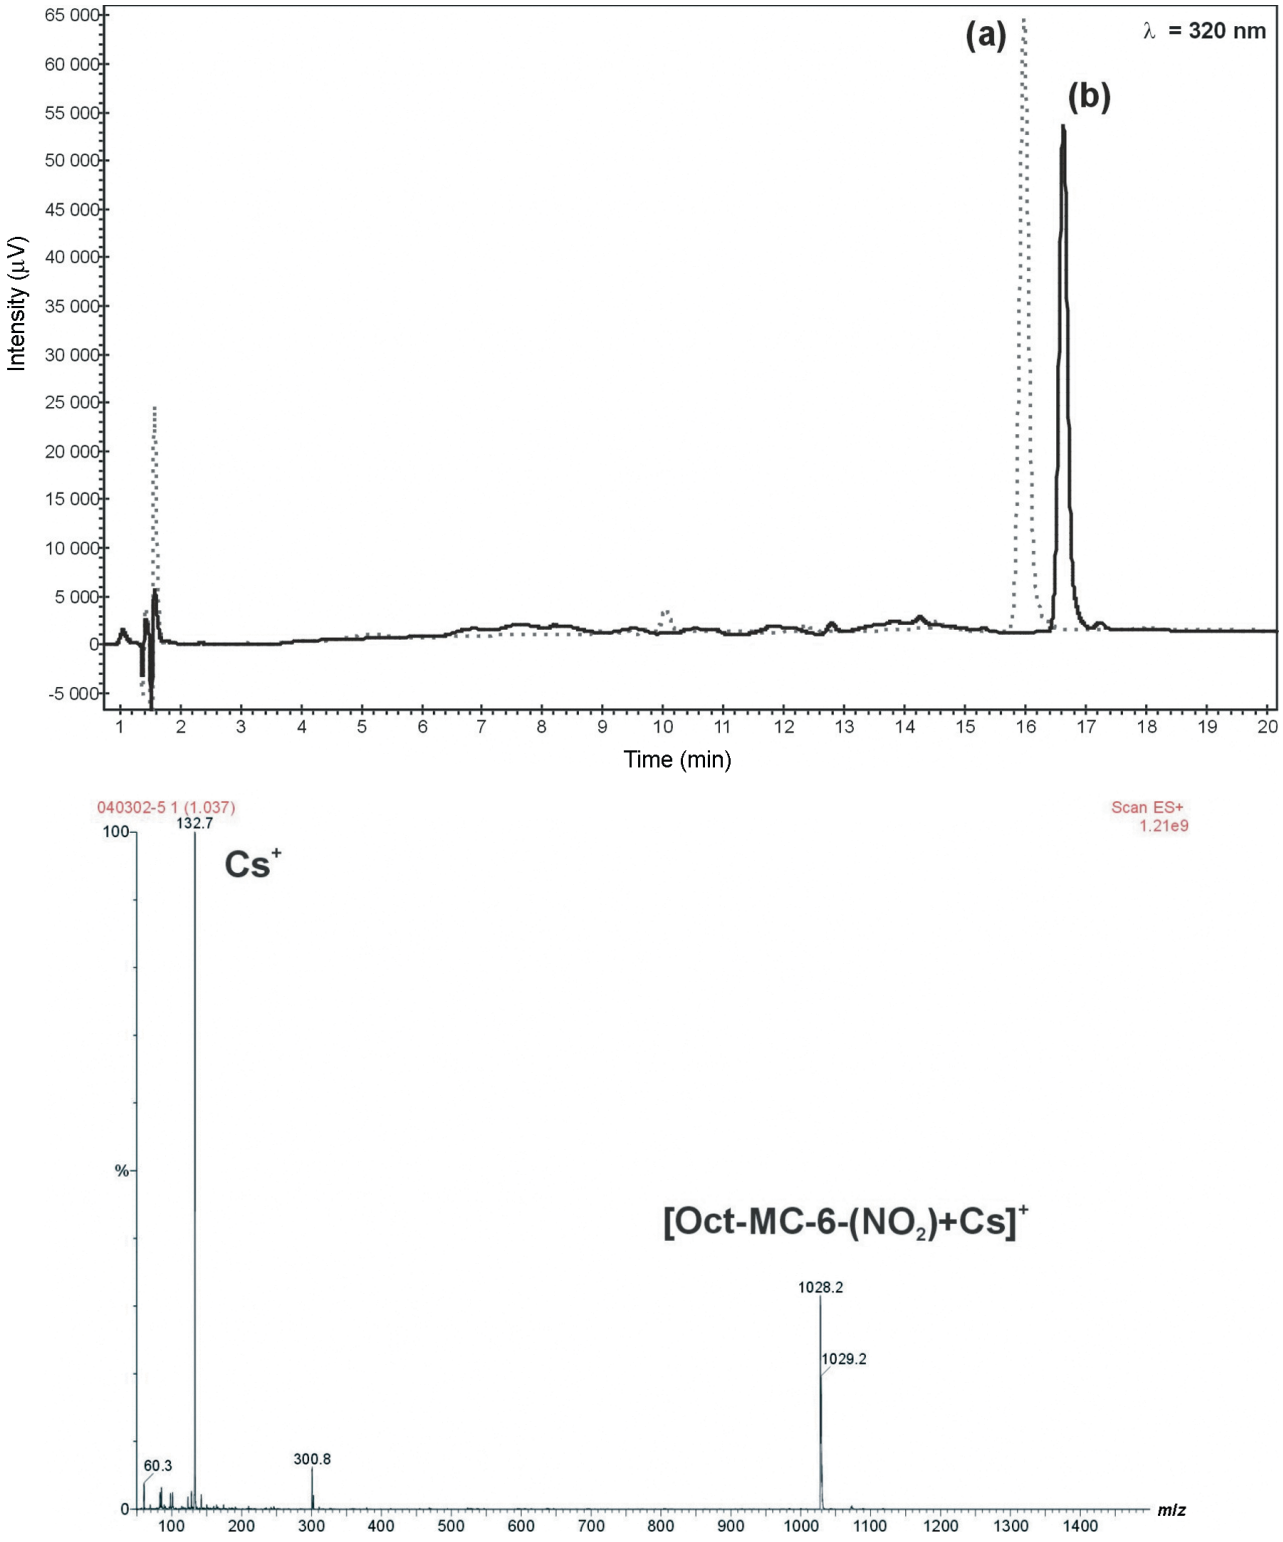
MC-6 + Na]$^+$, *m*/*z* 918 [(NO_2)-oct-MC-6 + Na]$^+$, and *m*/*z* 873 [oct-MC-6 + Na]$^+$ ions show that the elution order corresponds to the polarity of the compounds under the given chromatographic conditions. In such a way, the predominant mononitro isomer (NO_2)-oct-MC-6 (c1o0) was established as the main product formed in the slurries under radiolysis (also see the Supporting information).

Molecular modelling

Molecular modelling of all isomeric polynitro-oct-MC-6 was performed using the HyperChem 6 program. These calculations (Table 8) seem to indicate that if the NO_2 group is placed on the crown side, the calculated energy was lower than in the case when this group is placed on the octyloxy side. This trend was also preserved for polynitration in this family as well as for the Cs^+ cation inclusion complexes.

From the calculations, it could also be deduced that in the 1,3-alternate conformation all nitro-oct-MC-6 have the octyl chains oriented to the exterior of the molecule as well as, as already observed (4, 8, 15), the crown was not symmetrical and was bent toward one of the two aromatic rings. The Cs^+-crown complexes were found to be somewhat more stable when compared to the compounds without cations. When the nitration took place from the crown side, the products were less stable; this was also observed for the calculated Cs^+ complexes.

Modelling of the calix[4]arene crown system of the oct-MC-6 compounds was also done assuming that the 1,3-alternate conformation was replaced in the whole series by the partial cone conformation. This conformation was obtained by rotating one of the two benzene rings bearing the octyloxy substituent by 180°. In these cases, the calculated energies were situated at ca. 2 kcal/mol higher for the whole series of nitro-oct-MC-6 compounds.



Molecular modelling was attempted to provide a mechanistic hypothesis for the formation of specific isomers according to particular mechanistic pathways. The synthesis of polynitro-oct-MC-6 was done using typical kinetically controlled S_E reaction conditions with the formation of a NO_2^+ cation intermediate, under fuel reprocessing procedures, but contact with the radioactive material could also involve the formation of a radical $NO_2\cdot$ that could subsequently result in many different nitrations. Finally, the highly acidic nitric slurries could also produce their own S_E nitration conditions. The fact that for mononitro derivatives, the lower calculated energy was found for the crown side isomer (c1o0) could indicate that this isomer is obtained from the radical rather than the S_E pathway.

NMR studies of the nitro-oct-MC-6 calixarenes

The assignment of all resolved ^1H and ^{13}C NMR signals was made using several high-resolution 2D experiments, in particular COSY, NOESY, ROESY, HETCOR, HSQC, CHORTLE, and HMBC (16–26). In the following section, we would like to comment on these interpretations, highlighting the most interesting features, and to conclude with

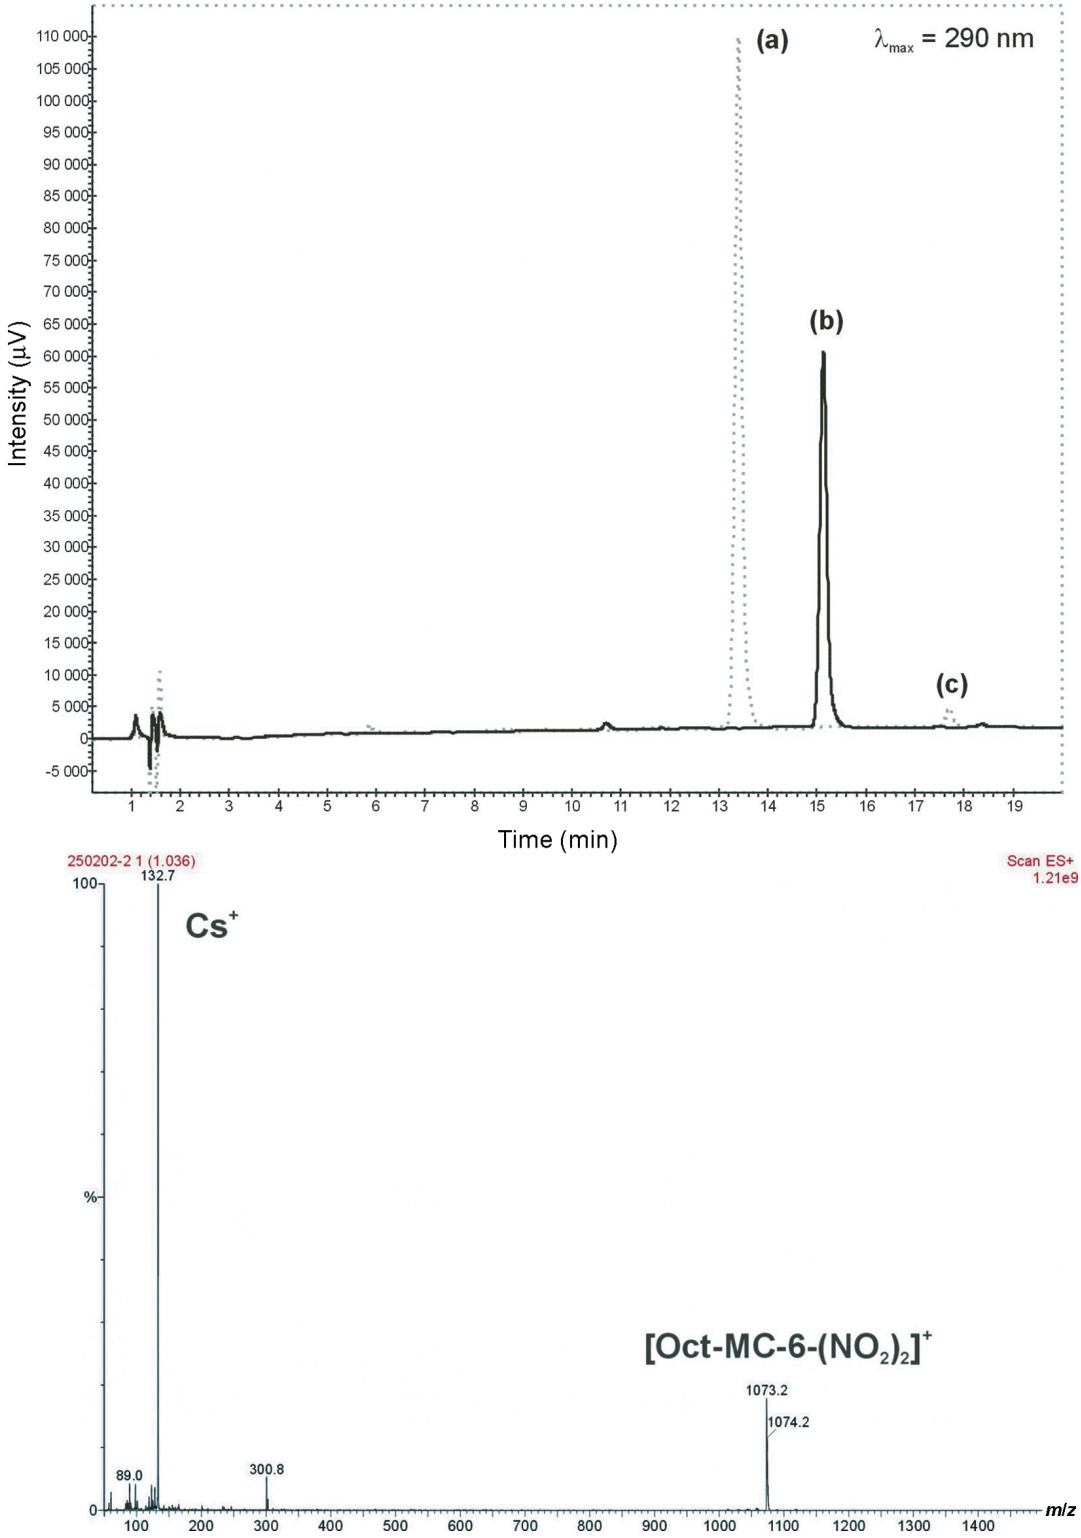
Fig. 3. Comparison of $[M + Cs]^+$ ion chromatogram for (NO_2)-oct-MC-6. (*a*) c0o1 (dotted line); (*b*) c1o0 (solid line).

some conformational observations (detailed spectra interpretation Tables 1–6, Fig. 2).

The molecules were considered as a collection of building blocks roughly corresponding to spectral regions: aromatic, interarylic benzyl methylene, crown, and octyl chain.



The starting oct-MC-6 (c0o0) compound was first used as a basis in determining the skeleton proton and carbon signals and was then considered as a reference when several nitro groups were added in a regiospecific way.

Nomenclature

Figure 2 displays the structure of the unsymmetrical

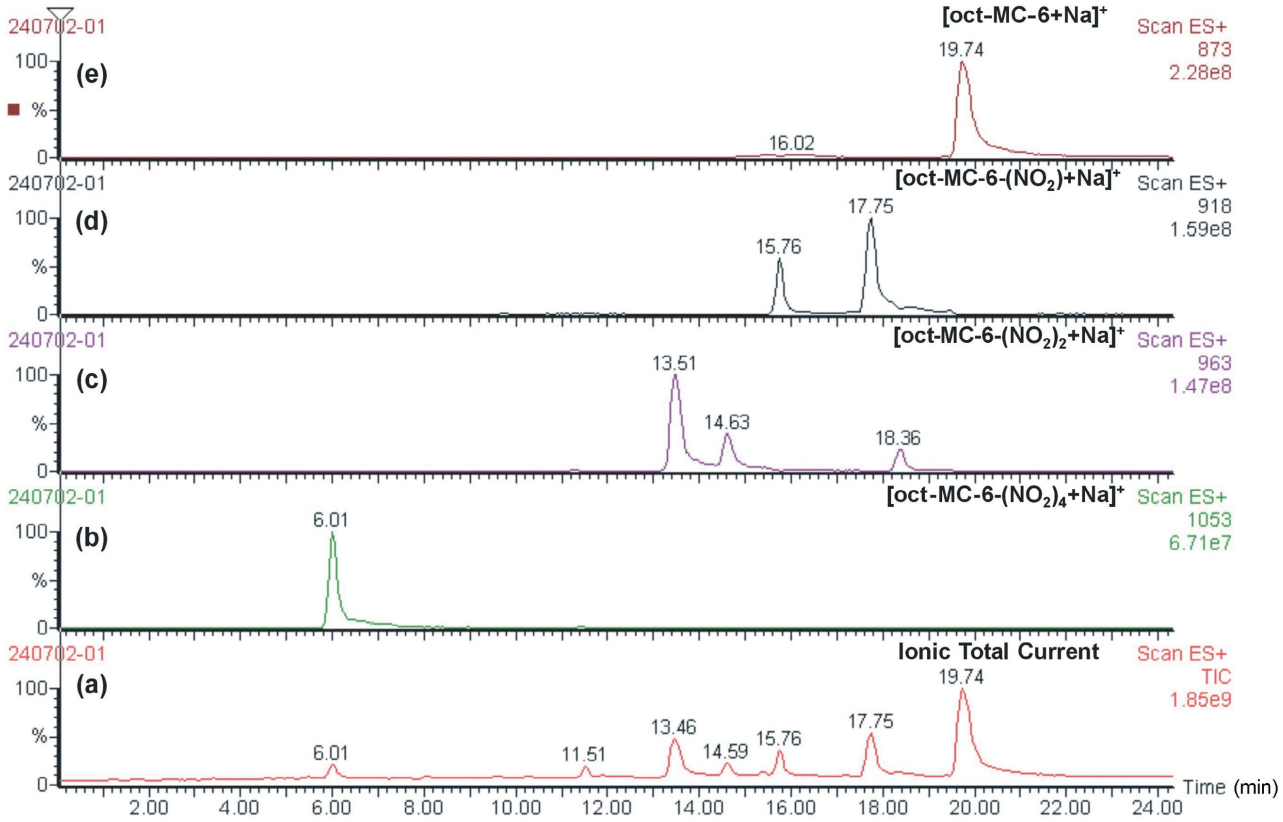
Fig. 4. $(NO_2)_2$-oct-MC-6 Cs^+ detection ESI (M, *m*/*z* 1073). LC profiles shown: (*a*) $(NO_2)_2$-oct-MC-6 (c1o1) (dotted line); (*b*) $(NO_2)_2$-oct-MC-6 (c2o0) (solid line); (*c*) $(NO_2)_2$-oct-MC-6 (c0o2) (dashed - traces line).



dinitro derivative $(NO_2)_2$-oct-MC-6 (c1o1), the least symmetrical of the nitrocalixarenes studied, which is used to explain the nomenclature used in this paper.

Aromatic carbons are labelled *i*, *o*, *m*, and *p* for ipso, ortho, meta, and para, respectively. The side is identified by c or o depending on whether it is crown or octyl, respectively. Then, h or n is used to identify the hydrogen or nitro substituent in the para position. Finally, *a* or *s* is used to identify whether the side is anti or syn towards an adjacent nitro substituted ring. The benzylic methylenes are labelled b followed by two letters, h or n, describing the hydrogen or nitro substituent on the adjacent aryl rings on the crown and

Fig. 5. LC–MS scan of the crude nitration of oct-MC-6. The corresponding masses of 1053 (tetranitro), 963 (dinitro), 918 (mononitro), and 873 (starting product) refer to $[M + Na]^+$ ions.

octyl sides, in that order. The octyl chain carbons are labelled 1′–8′ with h or n for the hydrogen or nitro substituent on the adjacent aromatic ring. For the crown part of the molecule, 1″–5″ are used, counting the carbons only. Again h or n represents the hydrogen or nitro substituent in the para position of the attached aryl ring.

c0o0

In the aromatic area of the proton spectrum of the parent oct-MC-6 (c0o0), we identified two spin systems of the AA′X type each composed of two meta and one para protons. The nOe effect enabled identification of the interaction between meta protons and 1′ or 1″ and 2″ protons, as well as a small interaction between *p*c and 5″, which led to the precise identification of the orientation of this aryl side toward the calixarene ring. The same system is also a primary indication of the number of nitro groups introduced on the molecule aryl rings. The benzylic methylene signal of this molecule displayed long-range coupling as well as nOe to the meta protons of the aromatic rings. The crown protons displayed two spin systems, one with full averaging corresponding to 1″ and 2″ protons, the other corresponding to 3″ and 4″ protons with only partial averaging despite some ambiguities in geminal coupling interpretation, and one singlet for two methylenes at the centre of the crown system. This observation confirmed a certain conformational flexibility of the crown, especially close to the centre. The chain protons on carbons 1′ and 2′ were assigned from their mutual coupling, H-3′ and H-6′ with the help of ^{13}C correlations, and finally the end protons on C-7′ and C-8′ from coupling to each other. Some minor discrepancies in the interpretation of the spectra of methylene proton signals by Casnati et al. (27) were corrected (Table 1).

Protonated carbons were assigned with the help of proton correlations and quarternary carbons (ipso and ortho) from long-range couplings. The distinction between carbons from the octyl or the crown sides was also made using long-range couplings. There were no problems with the assignment of the remaining methylene, crown, and chain carbons.

From the three possible isomeric dinitrocalixarene compounds, two were successfully isolated and obtained in pure form, enabling detailed interpretation of their NMR spectra (Tables 3 and 5).

c2o0

The first $(NO_2)_2$-oct-MC-6 (c2o0), having two nitro groups on the crown side (Table 3) and displaying a higher symmetry, showed in the aromatic area of its ^1H NMR spectrum one spin system of the AA′X type for the para unsubstituted aryl rings, and one singlet for two meta protons for the remaining nitro-bearing aryl ring protons. The side of substitution was unambiguously identified by nOe between given meta protons and 1′ or 1″ and 2″ protons. The interaryl methylene protons displayed a pair of geminal doublets (4H each) with some small long-range couplings and nOe to the above-mentioned meta aryl protons. The crown system ap-

© 2005 NRC Canada

peared as expected, with one singlet for four middle methylene protons and two spin systems, one with full averaging for 1″ and 2″ protons, the other ambiguous for 3″ and 4″ protons. The chain protons were assigned as in the previous case, that is H-1′ and H-2′ from mutual coupling, the second pair H-7′ and H-8′ from mutual coupling, H-3′ from its coupling to H-2′ and from ^{13}C, and H-6′ with the help of the ^{13}C correlation.

The ^{13}C spectrum was assigned according to our previous methodology: the quaternary carbons from long-range couplings, the ipso carbons from their connectivity to either 1′ octyl or 1″ crown protons. The benzylic, crown, and chain proton assignments were simplified using the same approach.

The spectra of two mononitrated oct-MC-6 isomers, one from the crown side and the second with NO_2 on the octyl chain side of the calixarene, were also assigned (Tables 2 and 4).

c1o0

First, the proton spectrum of the mononitro isomer (NO_2)-oct-MC-6 (c1o0) with the nitro group on the crown side accordingly showed two spin systems of the AA′X and ABX type (twice the integration), as well as one singlet for the remaining meta protons. The side of substitution by the NO_2 radical was identified with the help of the nOe effect between meta protons and 1′h, 1′n, or 1″ (1 of 2) and 2″ (Table 2). The methylene protons displayed one singlet (4H) and one pair of geminal doublets (2H each) with the usual long-range couplings and nOe to meta protons. The crown protons were present as two spin systems, one with no averaging corresponding to the 1″ and 2″ protons, one ambiguous for the 3″ and 4″ protons, plus one singlet for the middle two vicinal methylenes. For the chain protons, similarly to the previous compound, the pairs H-1′h and H-2′h as well as H-1′n and H-2′n were assigned from coupling to each other, then equivalent pairs of protons on C-7′ and C-8′ were assigned from their coupling to each other, whereas protons on C-3′ and C-6′ were assigned from their heterocorrelation to ^{13}C. There was a nOe effect observed between protons H-1′h and H-2′h.

In the ^{13}C spectrum, all aromatic carbons were assigned either from their proton partners for tertiary carbons or from long-range couplings for quaternary carbons. The connectivity of the ipso carbons to 1′h, 1′n, or 1″ (2 of 2) protons were observed. The methylene, crown, and chain carbons could generally be assigned without ambiguity with the help of the proton assignments as well as from long-range couplings and known chemical shifts.

c2o1

The structure of the last nitro derivative of oct-MC-6 (c2o1), the one with three nitro groups (Table 6), was assigned as the one having two nitro on the crown and one nitro on the octyl chain sides. Some important features used during the assignment of this one of two possible isomers were the following.

The aromatic region displayed one spin system of the AA′X type containing two meta and one para protons, one spin system of the AB type comprised of two meta protons (twice the integration), and one singlet for two meta protons. The crown or octyl side was identified by nOe between meta protons and 1′, 1″h and 2″h, or 1″n and 2″n. The interarylic methylene protons showed up as two pairs of geminal doublets. Again, long-range couplings and nOe were observed to nearby meta protons. For the crown portion of the molecule, four spin systems were present, two for 1″ and 2″ on each side were fully averaged, two for 3″ and 4″ on each side were ambiguous, and one singlet for 5″h/n. The chain protons were identified as described previously.

The ^{13}C spectrum was assigned as above, that is the protonated carbons from correlations to protons and the quaternary carbons from long-range correlations. There were connectivities between ipso carbons and 1′, 1″h, or 1″n. For the crown portion of the molecule, 3″ and 4″ on each side were ambiguous, and the 5″h and 5″n signals were not equivalent.

c1o1

The last dinitro-oct-MC-6 (c1o1) structure was established as the one having one nitro group on both sides of the molecule, one on the crown and one on the octyl chain sides (Table 5).

The aromatic region of the proton spectrum showed two spin systems of the ABX type containing two meta and one para protons and two spin systems of the AB type containing two meta protons. The side of substitution for each was identified by nOe between their meta protons and 1′h, 1′n, 1″h, or 1″n (1 of 2) and 2″n. Another nOe was observed between *p*ch and 5″h/n. The methylene protons appeared as two singlets (2H each) and two pairs of geminal doublets (1H each). Long-range couplings and nOe to meta proton were again observed. Four spin systems and one singlet corresponding to crown protons were found, as for the previous molecule. For the chain protons, 1′h and 2′h, 1′n and 2′n, as well as 7′h/n and 8′h/n, were assigned from their mutual coupling, whereas 3′h, 3′n, and 6′h/n were assigned from ^{13}C.

The ^{13}C spectrum was assigned as previously. In the aromatic region, para carbons on the NO_2 side were not resolved. In the crown region, 3″ and 4″ on each side were ambiguous, whereas the 5″h and 5″n signals were not equivalent.

c0o1

The second mononitro derivative (NO_2)-oct-MC-6 (c0o1) (Table 4), isolated in smaller yield, is the one with the nitro group on the octyl chain side.

The aromatic region of the ^1H NMR spectrum showed two spin systems of two meta and one para protons, one of the AA′X type, the other of the ABX type (twice the integration), and a singlet for two meta protons. The side was identified by nOe between the meta protons and 1′ or 1″h, 1″n, 2″h, and 2″n. There was also a nOe between *p*c and 5″h/n. The interarylic methylenes showed up as one singlet (4H) and a pair of geminal doublets (2H each). Long-range couplings and nOe to meta protons were again present. The crown protons appeared as three spin systems (1″h and 2″h resolved; 3″ and 4″ on each side ambiguous), a singlet with 1″n and 2″n superimposed, and a singlet for 5″h/n. The chain protons were assigned as previously.

Carbon signals were assigned as above. Connections showed up on the HMBC spectrum between ipso carbons

© 2005 NRC Canada

and 1″h and 1″n. Signals for 5″h and 5″n were not equivalent.

It is clear then that the structural difference between the two mononitro derivatives of oct-MC-6 was fully reflected by NMR, especially nOe and long-range.

Since the six compounds formed a family with zero, one, or two nitro groups on the crown side and zero or one nitro group on the octyl side, it was possible to extract substitution effects from the data.

In ^{1}H, *m*cs were shifted by 0.921 ± 0.013 ppm (N = 6) and *m*os by 0.962 ± 0.002 ppm (N = 4) with adjacent NO_2 substitution. On neighbouring rings, *m*as were always shifted more downfield (0.03–0.06 ppm) than the corresponding mss (0.00–0.03 ppm). Protons at position 5″ were shifted upfield by 0.071 ± 0.001 ppm (N = 2) with one NO_2 and by 0.158 ± 0.010 ppm (N = 2) with two NO_2s on the crown side.

In ^{13}C, *i*cs were shifted by 5.73 ± 0.05 ppm (N = 4), *i*os by 5.30 ± 0.03 ppm (N = 3), *o*cs by 1.4–2.2 ppm, and *o*os by 1.38 ± 0.12 ppm (N = 4) with para NO_2 substitution; *m*cs were shifted upfield by –4.64 ± 0.19 ppm (N = 6) and *m*os by –4.31 ± 0.01 ppm (N = 4) with adjacent para NO_2 substitution; *p*s were shifted by 19.8 ppm upon NO_2 substitution. On neighbouring rings, *i*cs were shifted downfield (0.2–0.3 ppm), *i*os upfield (–0.2 to –0.1 ppm), *o*as downfield (0.1–0.5 ppm), *o*css upfield (–1.5 to –1.0 ppm), and *o*oss upfield by –1.51 ± 0.09 ppm (N = 6); *m*cas were shifted more downfield (0.7–0.9 ppm) than the corresponding *m*css (0.10 ± 0.00 ppm (N = 4)); *m*oas were shifted downfield (0.5–0.7 ppm), *m*oss upfield (–0.4 to –0.2 ppm) and *p*s downfield (0.1–0.5 ppm). Finally, 1′′ signals were shifted by 1.3–1.4 ppm upon para NO_2 substitution on the attached ring.

The spectra of the last and least interesting polynitro derivative of oct-MC-6, the tetranitro one, $(NO_2)_4$-oct-MC-6 (c2o2), were also recorded but did not reveal any peculiarities, generally confirming the already assigned signals in the expected places (see Experimental).

Conclusion

In this study, we showed that the synthesis of specifically nitrated nitro-oct-MC-6 was possible. Specifically, the mononitration of this compound was successfully accomplished as was the production of several di- and tetranitro derivatives and, following a two-step procedure, trinitro derivatives were also obtained. The separation on a column was the key step in purification of these compounds. Refinement of the separation technique (HPLC) as well as full multidimensional NMR characterization of six of the compounds in this series was achieved. In addition, molecular modelling was used in order to rationalize the obtainment of one of two isomers of the mononitro-oct-MC-6 (c1o0) under radiolytic-mimetic conditions as being the result of radical NO_2 nitration.

All these derivatives will be used as viable standards for the quantitation of degradation products of calixarenes as well as for the evaluation of their capacity of extraction, particularly of Cs^+, during procedures for the retreatment of spent nuclear fuel.

These structure identifications meant that one of three nitro derivatives of the double nitration of oct-MC-6, the one with nitro groups on the octyl chain side, although formed and detected by LC, was present in a very small quantity in the original radiolysis mixture. Only one of the trinitro derivatives was also present in a very small quantity in a laboratory simulated *cold* nitration mixture and was formed to complete this NMR study by the mononitration at low temperature of the symmetrical dinitro isomer of the oct-MC-6 (c2o0) having both nitro groups on the crown side.

Only after the synthesis of this last standard, by the method mentioned in the previous sentence, was it possible to positively detect at least one of two trisubstituted oct-MC-6 (c1o2 or c2o1) in the LC. It also seems that the one with the lower retention time (of 8 or 10 min) corresponds to the trinitro isomer previously described (c2o1) while the second trinitro isomer (c1o2) was probably observed at ca. 10 or 12 min in two LC runs of these two mixtures (resulting from the radiolytic hot and cold synthetic cycles, respectively).

In the future, we would like to try this kind of synthesis under the newer microwave-assisted technology; the first results seem to be promising, especially from a perspective of synthesis of the other missing nitro-oct-MC-6 isomers.

Experimental

HPLC

A Bio-Tek series 525 LC system with a high-pressure binary pump, an autosampler, and a diode array detector (DAD), equipped with a 4.6 mm × 10 mm TSK-GEL Super-ODS (TosoHaas) column, 3 μm particle size, was used for the separations. The flow rate was 0.8 mL/min and the column was thermostatted at 40 °C (chosen after optimization tests between 20 and 80 °C). The injection volume was 20 μL. The DAD and ESI-MS detectors were connected in series. The column effluent was split after the DAD since the flow rate introduced into the mass spectrometer was optimum at 50 μL/min.

ESI-MS

Identification of the synthetic products was accomplished using a Quattro II triple-quadrupole mass spectrometer (Micromass, Manchester, UK) equipped with an ESI source and Mass Lynx software version 3.5. The instrumental operating parameters were as follows: capillary voltage 3.5 kV and source temperature 80 °C. Nitrogen was used as the bath and nebulization gas, and the pressure in the analyser was 3.5×10^5 mbar (1 bar = 100 kPa). The high voltage lens (counter electrode) was maintained at 600 V. The electron multiplier was fixed at 700 V. The source parameters, especially the cone voltage, were optimized at the beginning of the experiments by direct infusion of a test mixture containing $(NO_2)_x$-oct-MC-6 (with x = 0, 1, 2, 4), in that order, to obtain the best signal sensitivity, and were kept constant during all the LC–MS experiments; the cone voltage value was finally fixed at 45 V. Spectra were recorded in continuum mode by scanning the quadrupole between m/z 50–1500 with a scan time cycle of 2.1 s.

In parallel, the chromatograms were recorded at various wavelengths: at 200 nm to observe the maximum number of peaks, and at 270, 290, and 320 nm, corresponding to the maximum absorption wavelengths of oct-MC-6 (c0o0),

© 2005 NRC Canada

$(NO_2)_2$-oct-MC-6 (c2o0), and (NO_2)-oct-MC-6 (c1o0), respectively.

Selective nitration of oct-MC-6

Mononitration

A solution of 0.5 g of oct-MC-6 (c0o0) (Acros Chemicals) in 25 mL of acetic anhydride was treated with fumic nitric acid (1 equiv., 24.6 μL) in acetic anhydride (2.5 mL) and acetic acid (2.5 mL) for 45 min at –20 °C. The mixture was allowed to stand overnight, then was carefully neutralized, and purified on a SiO2 63/200 μm column with cyclohexane – ethyl acetate (8:2 or 7:3). The yield of mononitro isomers was 34%. The unreacted starting material was recovered. Two isomeric (NO_2)-oct-MC-6 were separated on similar columns.

Dinitration

Similarly, 0.5 g of oct-MC-6 (c0o0) in 25 mL of acetic anhydride was treated with 2.2 equiv. (54 μL) of nitric acid in 12.5 mL of acetic anhydride and 12.5 mL of acetic acid at –20 °C for 15 min, then for one more hour at room temperature. The yield of dinitration mixture was 54%.

Trinitration

Pure $(NO_2)_2$-oct-MC-6 (c2o0) (0.11 g) in 5 mL of acetic anhydride was treated as in the case of mononitration. $(NO_2)_3$-oct-MC-6 (c2o1) was obtained in a 12% yield.

Tetranitration

Oct-MC-6 (c0o0) (200 mg) in 10 mL of methylene chloride was treated for 5 min with 80 equiv. of fuming nitric acid in acetic anhydride (1 mL). The worst yield of pure $(NO_2)_4$-oct-MC-6 (c202) was 81%.

Molecular modelling

Molecular modelling calculations were performed with HyperChem 6 using Mm+ (Université de Moncton – U de M) in gas-phase and in solvent box (ethanol) modes. The minimization of energy was performed using the technique described in the HyperChem instruction manual and as in ref. 28. In a first phase, 1600 Polak–Ribiere iterations were applied. A small incremental energy was applied in a second phase (0.001 ps for a total of 1 ps, 370 K) for selected insertion models only. All calculated complex structures (1:1, 2:1, and 1:2 stoichiometry) and energy data are available upon request from CKJ (U de M).

$(NO_2)_4$-oct-MC-6 (c2o2) (as reference)

Yield: ≥81%, mp 184 °C. ESI-MS *m/z*: 1053.4 $[M + Na]^+$, 1163.3 $[M + Cs]^+$.

NMR

The samples were dissolved in $CDCl_3$, and TMS was used as an internal standard. High-resolution ^1H and ^{13}C NMR spectra were acquired at 25 °C on a Chemagnetics Infinity 300 spectrometer using 5 mm Nalorac probes: either *z*-gradient $^1H\{^{109}Ag–^{31}P\}$ or $^{13}C/^1H$.

A combination of 1D and 2D high-resolution NMR experiments were used to assign the ^1H and ^{13}C spectra as completely as possible. Connectivities between protons were obtained using 2D gradient-selected COSY (16). The 2D phase-sensitive NOESY (17) and ROESY (18) experiments were performed with a mixing time of 300–400 ms. The 1D ^{13}C NMR spectra were recorded with WALTZ proton decoupling (19). The multiplicity of the carbon signals was established using the 1D APT experiment (20) with an evolution time of 6.8–7.0 ms or the DEPT experiment (21) with a reading pulse of 135° and an evolution time of 3.4–3.5 ms. The 2D HETCOR (22) was performed using evolution times of 3.45 and 2.3 ms for $1/(2J_{CH})$ and $1/(3J_{CH})$, respectively. The 2D gradient-selected phase-sensitive HSQC (23) spectra were acquired with a 1.7 ms evolution time and MPF9 (24) carbon decoupling during acquisition. A higher precision in the proton dimension was obtained from the CHORTLE experiment (25) run with four increments for cosine and sine subspectra: 0.4, 1.0, 2.4, and 3.2 ms. The 2D gradient-selected magnitude HMBC (26) was run without carbon decoupling with one-bond and long-range evolution times of 3.4–3.5 and 72–83 ms, respectively.

Accurate ^1H chemical shifts and coupling constants were obtained by spectral simulation using the gNMR program from IvorySoft.

Supporting information

All other detailed spectral material is available on request from Christopher K. Jankowski (Canada).

The following LC and NMR partial spectra of compounds are available as supporting information:

LC: Fig. 6. Comparison of irradiated and synthetic samples: (*a*) Synthetic sample as per Fig. 4 (two peaks at 17.67 and 15.67 min) corresponding to mononitro (dotted line); (*b*) scan of mononitro 918 $[M + Na]^+$ of (*a*); (*c*) irradiated sample (an interesting feature is the presence of the more abundant mononitro isomer at 17.5 min but less abundant at 15.68 min); (*d*) scan of mononitro 918 $[M + Na]^+$ of (*c*).

Figure 7. LC of reconstituted mixture of all $(NO_2)_x$-oct-MC-6 isomers: (*a*) $(NO_2)_4$-oct-MC-6 (c2o2); (*b*) $(NO_2)_3$-oct-MC-6 (c2o1); (*c*) $(NO_2)_2$-oct-MC-6 (c2o0); (*d*) $(NO_2)_2$-oct-MC-6 (c1o1); (*e*) (NO_2)-oct-MC-6 (c0o1); (*f*) (NO_2)-oct-MC-6 (c1o0); (*g*) oct-MC-6 (c0o0, starting) at 18.2 traces of $(NO_2)_2$-oct-MC-6 (c0o2).

Spectroscopy and electrochemistry of new 6,6′-disubstituted-4,4′-bipyrimidine molybdenum(0) and tungsten(0) tetracarbonyl complexes

Elena Ioachim and Garry S. Hanan

Abstract: A new family of tetracarbonyl molybdenum(0) and tungsten(0) complexes based on new 6,6′-disubstituted-4,4′-bipyrimidine ligands was synthesized and characterized. The visible region of the absorption spectrum of each complex is dominated by a metal-to-ligand charge transfer band significantly lower in energy than the corresponding transition in 2,2′-bipyridine tetracarbonyl metal complexes. The 6,6′-substituents create a larger π-electronic system in the substituted bipyrimidines and are consequently better π acceptors than even the parent 4,4′-bipyrimidine. The absorption bands are shifted bathochromically with a decrease in solvent polarity.

Key words: molybdenum and tungsten, nitrogen ligands, tetracarbonyl metal complexes, absorption spectroscopy, electrochemistry.

Résumé : Une nouvelle famille de complexes de type tétracarbonyle de molybdène(0) et tungstène(0), à base des 4,4′-bipyrimidine substituées dans les positions-6,6′, a été synthétisée et caractérisée. Le spectre d'absorption dans la région du visible de chaque composé indique un déplacement vers le rouge pour la bande de transfert de charge métal-ligand comparé à celui du complexe tétracarbonyle de 2,2′-bipyridine. Ceci démontre une meilleure délocalisation du système π-électronique dans la bipyrimidine substituée qui rend ces ligands des meilleurs accepteurs π. Cette bande d'absorption est déplacée bathochromiquement avec la diminution de la polarité du solvant.

Mots clés : molybdenum et tungsten, ligands azotés, complexes métal-tétracarbonyle, spectroscopie d'absorption, électrochimie.

Introduction

Polypyridyl complexes of d^6 metal ions have been extensively studied over the last two decades owing to their fascinating spectroscopic, redox, and excited-state properties (1, 2). For example, α-diimine complexes of Ru(II) and Os(II) have been proposed as photosensitizers in the conversion of solar energy to chemical energy (3, 4) and have been successfully applied to the photolysis of water (5, 6). Re(I) complexes of type [(α-diimine)$Re(CO)_3$] represent another promising class of d^6 metal ion that are used in the photoreduction of CO_2 (7, 8), where the Re(I) complexes may act as both photosensitizer and homogenous catalyst.

Another class of compounds, the tetracarbonyl-diimine complexes of group 6 transitions metals (Cr, Mo, W) of type $M(CO)_4L$, also provide a unique combination of an electron-rich d^6 metal atom, stabilized by four CO ligands, and an electron-accepting diazine ligand. The growth in interest for these compounds stems not only from their role as starting materials for different classes of complexes, but also from their interesting spectroscopic properties. Thus, excitation of the metal-to-ligand charge transfer (MLCT) state can lead to CO dissociation (9), which can be used as the first step in photocatalytic cycles and photoinitiated redox processes (10).

The structural simplicity of this type of complex also makes them suitable for experimental and theoretical investigations of their MLCT transitions. It has been demonstrated that the relative position of the MLCT excited state is dependent on solvent polarity, as well as on the nature of the π-acceptor ligand (11, 12). The effect of the solvent on the electronic absorption spectra of transition-metal complexes is well recognized, and a correlation between the solvent parameters and electronic properties of this type of complex has been established (13). In addition, extensive modifications of the coordinating heterocyclic ligands can tune the ground- and excited-state properties of these complexes. Substitution on the pyridine ring (14) and replacement of the CH group by N, with the formation of a bidiazine ligand that possesses a more π-electron-deficient system (15), represent different strategies in which the photophysical properties of metal carbonyl complexes may be influenced.

In the bidiazine series (Chart 1), 4,4′-bipyrimidine (bpm) is the ligand with the lowest-lying π* orbitals, which leads to its metal complexes having the lowest energy MLCT excited states. Although this property would be favourable for the development of new red-emitting species for use in organic light-emitting diodes (16) or as biomarkers (17), no systematic study of substituted bpm complexes has been presented, even though considerable research has been done on 2,2′-bipyrimidine metal complexes (15, 18). Suitable substituents in the 6,6′ positions of bpm may yield bpm-type metal complexes that display favourable electrochemical and

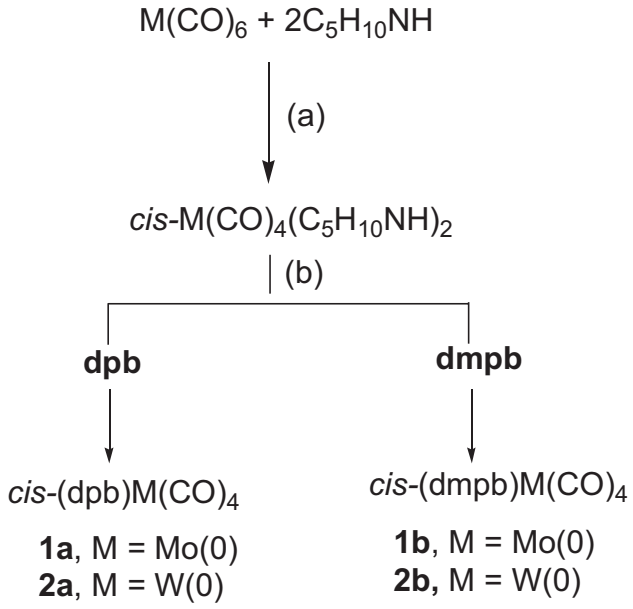
photophysical properties based on even lower lying π* orbitals. In this paper, we report on the synthesis of a novel series of Mo(0) and W(0) complexes of type (*N*-*N*)$M(CO)_4$ (Chart 2), where M = Mo or W, and *N*-*N* = 6,6′-diphenyl-4,4′-bipyrimidine (dpb) (**a**) or 6,6′-bis(*p*-methoxyphenyl)-4,4′-bipyrimidine (dmpb) (**b**). The investigation of their electrochemical and spectroscopic properties will verify whether or not they are suitable candidates for incorporation into photoactive d^6 metal systems.



Results and discussion

Synthesis

The new (*N*-*N*)$M(CO)_4$ complexes, where M = Mo or W, were obtained via substitution reactions, as outlined in Scheme 1.

In step (*a*), the piperidine metal carbonyls were prepared in good yield by refluxing the corresponding metal hexacarbonyl complexes with a large excess of piperidine, following a previously established method (19). The *cis*-(*N*-*N*)$M(CO)_4$ compounds of Mo and W were prepared in step (*b*) in moderate yield by treating *cis*-$M(CO)_4(pip)_2$ with the appropriate bidiazine ligands in dichloromethane for 20 min at reflux. The formation of complex **1b** was monitored by recording the ^1H NMR spectra every 5 min for 1 h. During this period, new peaks, corresponding to the coordinated ligand, appeared and intensified. After about 40 min, these newly formed peaks started to lose their intensity and the original peaks for the starting material reappeared. This observation suggests that a longer reaction time leads to decomposition of the complexes. The precipitate that formed after cooling the reaction mixture overnight was recrystallized from hexane and further purified by column chromatography on silica gel in order to purify the product. Attempts to use alumina as the support for the column chromatography failed as a result of the decomposition of the compounds during the purification process.

Scheme 1. Synthesis of (*N*-*N*)$M(CO)_4$ complexes. Reagents and conditions: (*a*) toluene, 4 h, yield: 56%–64%; (*b*) 1 equiv. *N*-*N*, CH_2Cl_2, reflux 20 min, yield: 46%–71%.

NMR spectroscopy

All of the compounds were characterized by ^1H and ^{13}C NMR spectroscopy. The 400 MHZ ^1H NMR data for the Mo(0) and W(0) complexes are displayed in Table 1 and are compared with the free ligands. The numbering scheme for the ligands is presented in Chart 2. The ^1H NMR spectra show that the signal of the H_2 proton of the pyrimidine ring is deshielded with respect to the signal of the free ligand (Table 1), as well as those of the phenyl substituents of the pyrimidine rings. The protons $H_{3',5'}$ of complexes **1b** and **2b** do not follow this trend, indeed, the opposite trend is observed, these protons being slightly more shielded when compared to the free ligand. The second proton of the pyrimidine ring, H_5, is shifted to higher field in all of the complexes when compared to the free ligand. To coordinate to the metal ions, the N atoms must move from a trans to a cis geometry about the pyrimidine–pyrimidine bond. This has the effect of diminishing the deshielding effect caused by the trans arrangement of the N atoms about the interannular bond (20), which leads to an upfield shift in the H_5 protons of the complexes.

Mass spectrometry

Even though the structures of the tetracarbonyl metal complexes have been confirmed by NMR spectroscopy, their matrix-assisted laser desorption–ionization (MALDI) and electron impact (EI) mass spectrometry analyses only displayed the signal corresponding to the free ligand. A possible explanation could be the low stability of these compounds under the conditions used for MALDI and EI mass spectrometry, which leads to the decomposition of the complexes. Even the milder electrospray ionization (ES) technique leads to their decomposition. Typically ES-MS requires the addition of acid to neutral complexes to generate cations. The ES-MS technique in combination with Ag^+ labeling, however, proved to be a convenient tool for the mass spectrometric characterization of this novel series of complexes. It has been demonstrated that this method is a convenient way to generate positively charged species that are sensitive to acid (21). The signals detected in the MS spectra of the complexes corresponded to the masses of the Ag^+ complexes as calculated from the chemical composition of the complexes and Ag^+. The MS spectra also contained one intense peak attributed to the ion with one less CO ligand. This fact supports the low stability of the tetracarbonyl complexes under MS conditions.

IR spectroscopy

All of the complexes that were synthesized in this study were characterized by vibrational spectroscopy in KBr. The energies for the vibrational bands are given in wavenumbers and are listed in Table 2, while the IR spectra of complexes **1a** and **1b** are illustrated in Fig. 1 for comparison. In their IR spectra, the tetracarbonyl metal complexes display four carbonyl stretching bands. The energy of these bands is shifted to slightly higher energy with the increase in π-acceptor ability of the bidiazine ligand as the better back-donation from metal to bidiazine diminishes the charge density on the metal center, which in turn diminishes the back-donation to the carbonyl groups. However, these differences in the series of bidiazine complexes are relatively small. The metal ion also has a slight effect on the energies of ν(CO), albeit a small one. The ν(CO) energies are similar to those found for Mo(bpm)(CO)$_4$ and W(bpm)(CO)$_4$ (Table 2) (15).

Electronic absorption spectra

The electronic absorption spectral data of complexes **1a** and **1b** and **2a** and **2b** in three different solvents are summarized in Table 3 and are compared to their unsubstituted bpm analogues.

The absorption spectra in the UV region display characteristic ligand-centered π–π* transitions. In the visible region, the absorption spectra of the bidiazine tetracarbonyl complexes consist of two bands. The band at lower energy has been assigned to a metal-to-ligand charge transfer d(M) → π*(bidiazine) MLCT transition. The next higher-energy band near 400 nm is also attributed to a MLCT transition, from the HOMO orbital localized on the metal center to the second SLUMO orbital of the bidiazine, by analogy with similar bidiazine-based complexes (15). In any particular solvent, the nature of the substituent on the bipyrimidine influences the position of the lowest MLCT band. Figure 2 shows the absorption spectra of (dpb)W(CO)$_4$ and

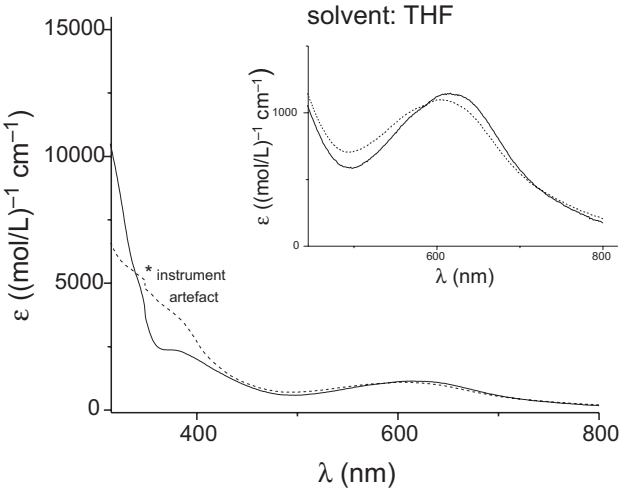

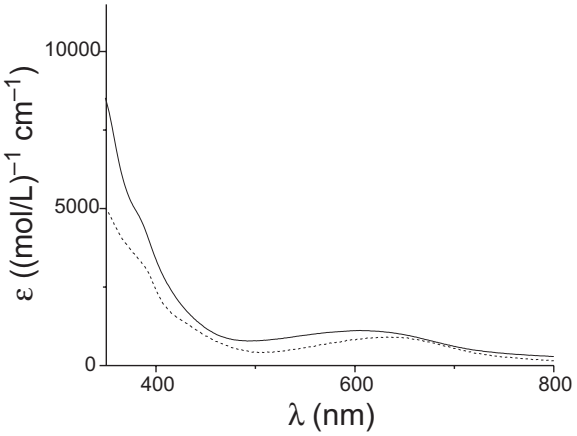

Fig. 3. Absorption spectra of (dmbp)$Mo(CO)_4$ (solid line) and (dmbp)$W(CO)_4$ (dashed line) in toluene.

(dmpb)$W(CO)_4$ in THF at room temperature. The presence of the methoxy donor group destabilizes the empty π^* orbitals of the dmpb ligand and gives rise to absorption at higher energy when compared to the dpb ligand. However, for both ligands, the corresponding Mo and W complexes present MLCT absorption bands at lower energy than the parent complexes with unsubstituted 4,4′-bipyrimidine (Table 3), for which MLCT transitions were observed at 579 nm for (bpm)$Mo(CO)_4$ and 607 nm for (bpm)$W(CO)_4$ in THF (15). This in accordance with the more extended π conjugation of the 6,6′-disubstituted-4,4′-bpm ligands and has the effect of lowering the MLCT energy in the newly prepared complexes. The planarity of the aryl substituent was demonstrated in the solid state for a tricarbonyl Re(I) complex of ligand **b**.[2] The *p*-methoxyphenyl rings were twisted with dihedral angles of 4.0° and 5.2° around the aryl-pyrimidine bond.

For a given *N-N* bidiazine ligand and solvent, the energy of the MLCT absorption follows the order Mo > W, as can be seen from the data listed in Table 3. This is exemplified in Fig. 3 for tetracarbonyls of Mo and W, with dmpb as the bidiazine ligand in toluene.

The MLCT absorption band is very sensitive to the nature of the solvent. All of the (*N-N*)$M(CO)_4$ complexes present a negative solvatochromism, translated by a shift of the MLCT absorption band to higher energy as the solvent polarity increases. The same trend has been observed for other $M(CO)_4$(α-diimine) related complexes (22, 23) and has been explained in terms of dipole moment changes between the ground and excited states (22, 24). The tetracarbonyl metal complexes are more polar in the ground state than in the excited state. Hence, the more polar solvents allow an enhanced stabilization of the ground state, which in turn leads to an increase in the transition energy. The results of correlating MLCT energies with solvent polarity are shown in Fig. 4 for the (dpb)$Mo(CO)_4$ complex in three different solvents for which the solvent parameter (E^*_{MLCT}) is included in parentheses in Table 3. The MLCT band is shifted to lower energy in going from tetrahydrofuran to toluene, along with the decrease in solvent polarity.

Electrochemistry

The electrochemical properties of the newly prepared complexes have been studied by cyclic voltammetry in acetonitrile solutions. The redox potentials are collected in Table 4 along with the corresponding redox potentials of the tetracarbonyl Mo and W complexes of bpm.

Note: From cyclic voltammetry in acetonitrile (0.1 mol/L in tetrabutylammonium perchlorate). Potentials are in volts vs. SCE, recorded at room temperature at a sweep rate of 500 mV/s. The difference between cathodic and anodic peak potentials (mV) is given in parentheses.

[a]Irreversible (irr); potential is given for the cathodic wave.

[b]In DMF solution, adjusted to acetonitrile as per ref. 15.

All of the complexes display one oxidation and two reduction processes in the potential region from +1.50 to –2.00 V. The oxidation is associated with a metal-centered process M(0) → M(I) and has proved to be irreversible in all cases, owing to the known lability of the complexes in the M(I) state with a 17-electron configuration (25). Indeed, the $Mo(CO)_4$ and $W(CO)_4$ complexes of the parent 4,4′-bipyrimidine, 3,3′-bipyridazine, 2,2′-bipyrimidine, and 2,2′-bipyrazine are also irreversible (15). The increase in π-acceptor properties of the bidiazine makes the abstraction of the electron from the metal center more difficult, and consequently, the oxidation occurs at more positive potentials for complexes **1a** and **2a** as compared to **1b** and **2b** and to the reference compounds $Mo(CO)_4$bpm and $W(CO)_4$bpm. The donating methoxyphenyl substituents of complexes **1b** and **2b** destabilize the metal-based orbitals, which facilitates the oxidation of the metal centres. The two reversible or quasi-reversible reduction waves observed in the cyclic voltammograms of all of the complexes are bidiazine centered. The reduction potentials depend on the nature of the bidiazine ligand, while the metal has just a slight influence on the reduction potentials. In the case of complexes **1b** and **2b**, the slight negative shift of the first reduction potential is due to electron donation by the methoxy groups to the bpm ligand, which raises the π* level of the coordinating diazine.

Conclusion

A number of tetracarbonyl bidiazine based complexes of Mo and W have been synthesized and characterized, and their electrochemical and photophysical properties have been investigated. It has been shown that acceptor ligands with low-lying π* levels can be used to red shift the energy of the lowest MLCT bands. (*N-N*)$M(CO)_4$ complexes show a negative solvatochromism, with a shift to lower energy of the MLCT absorption in nonpolar solvents. Electrochemical data was used to identify the lowest energy ligand acceptor. This study confirms that this new family of substituted bidiazine ligands has exceptional π-accepting properties, which bodes well for their incorporation into other transition-metal complexes. Further studies with metal carbonyls, such as the luminescent $Re(CO)_3Cl$ (α-diimine) type, and other metal complexes, such as the luminescent $M(\alpha\text{-diimine})_3^{2+}$ type, are underway and will be discussed in due course.

Experimental

Materials

All substituted bipyrimidine ligands were available in our laboratory from a previous study (26). $M(CO)_4(pip)_2$ (M = Mo or W) were synthesized according to a literature procedure (19). All metal complexes were purified by column chromatography on Kiesegel 60 (230–400 mesh) silica gel. Tetrabutylammonium hexafluorophosphate was purchased from Aldrich and purified by recrystallization from toluene–methanol. All of the solvents used for photophysical and electrochemical experiments were of spectroscopic grade. Elemental analyses were performed by Laboratoire d'Analyse Elementaire de l'Université de Montréal (Montreal, Quebec).

Instrumentation

NMR spectra were recorded in $CDCl_3$ at room temperature (rt) on a Bruker AV400 spectrometer at 400 MHz for ^{1}H NMR and at 100 MHz for ^{13}C NMR. Chemical shifts are reported in parts per million (ppm) relative to residual solvent protons (7.26 ppm for chloroform-*d*) and carbon resonance of the solvent. Routine absorption spectra were measured in deaerated tetrahydrofuran, chloroform, and toluene solutions at rt on a Cary 500i UV–vis–NIR spectrophotometer. The IR spectra were recorded as solid KBr discs on a Bio-Rad IR spectrophotometer. Electrochemistry data were collected in deaerated acetonitrile with 0.1 mol/L Bu_4NPF_6 on a BAS CV–50W voltammetric analyzer. Redox potentials were corrected by internal reference ferrocene (395 mV for acetonitrile vs. SCE).

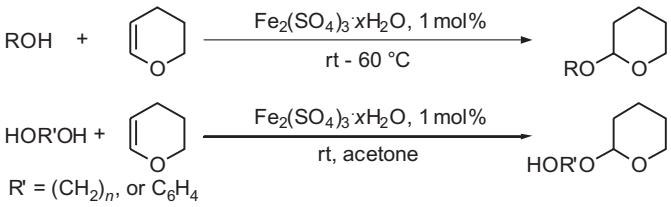
Convenient tetrahydropyranylation of alcohols and phenols by catalytic ferric sulfate hydrate ($Fe_2(SO_4)_3 \cdot xH_2O$)

Lingjun Li, Lizhi Zhu, Xinying Zhang, Guisheng Zhang, and Guirong Qu

Abstract: Ferric sulfate hydrate ($Fe_2(SO_4)_3 \cdot xH_2O$) is found to be an efficient heterogeneous catalyst for the tetrahydropyranylation of alcohols and phenols at ambient or near ambient temperature. In addition, selective monotetrahydropyranylation of symmetrical diols is achieved under similar conditions. The deprotection of THP ether and direct transformation of THP ether to the corresponding acetate by $Fe_2(SO_4)_3 \cdot xH_2O$ is also studied. The simplicity of manipulation, mild conditions, reusable catalyst, good selectivity, and environment benign characters make this method a good alternative way for the THP protection of alcohols.

Key words: tetrahydropyranylation, selective monotetrahydropyranylation, ferric sulfate hydrate, green chemistry.



Résumé : On a trouvé que l'hydrate du sulfate ferrique [$Fe_2(SO_4)_3 \cdot xH_2O$] est un catalyseur hétérogène efficace pour la tétrahydropyranylation des alcools et des phénols à la température ambiante. De plus, dans les mêmes conditions, on peut obtenir une monotétrahydropyranylation des diols symétriques. On a aussi étudié la réaction de déprotection des éthers THP et la transformation des éthers THP en acétate correspondant à l'aide de $Fe_2(SO_4)_3 \cdot xH_2O$. La simplicité de la manipulation, les conditions douces, la possibilité de réutiliser le catalyseur, la bonne sélectivité et les caractères bénins pour l'environnement font de cette méthode une bonne méthode alternative pour la protection des alcools.

Mots clés : tétrahydropyranylation, monotétrahydropyranylation sélective, hydrate du sulfate ferrique, chimie verte.

[Traduit par la Rédaction]

The protection of hydroxyl groups is a common event in multistep organic syntheses. Among various available methods, tetrahydropyranylation is one of the most frequently employed strategies because of THP ether's stability against a wide range of strong nucleophilic or basic reagents (1). A variety of protonic acid catalysts as well as Lewis acid catalysts have been developed for tetrahydropyranylation of alcohols and phenols, such as acidic clay (1), PTSA (2), DDQ (3), $BF_3 \cdot OEt_2$ (4), triphenylphosphine hydrobromide (5), $[Ru(CH_3)_3 \cdot (triphos)](Otf)_3$ (6), I_2 (7), ionic liquid (8), LiOTf (9), $In(OTf)_3$ (10), polyaniline salt (11), and heteropolyacids (12). However, these methods require large amounts of catalysts, harsh acidic conditions, organic solvent, or solid supports, which finally result in the generation of toxic waste. Meanwhile, the selective protection of one of two identical hydroxyl groups in a symmetrical molecule is relatively limited. Previously, the selective monotetrahydropyranylation was achieved through control of the volume of solvents and usage of metallic sulfates supported on silica gel (13). Recently, I_2 under microwave-assisted (14), ionic liquid ([CnMIM][$AlCl_4$]) (15), and LiOTf in $ClCH_2CH_2Cl$ at reflux (9) have been reported for this transformation. Unfortunately, those methods do not agree with the rule of green chemistry, and involve the problems of tedious work-up procedures and expensive reagents and equipment.

Scheme 1.

In our efforts to develop clean methods for functional group transformations, it was found that $Fe_2(SO_4)_3 \cdot xH_2O$ is an efficient, operationally simple (16), and reusable catalyst for esterification and preparation of acylals (17). Herein, we disclose a mild, efficient, and fairly clean protocol for tetrahydropyranylation of a variety of alcohols and phenols using 3,4-dihydro-2*H*-pyran in the presence of a catalytic amount of $Fe_2(SO_4)_3 \cdot xH_2O$ under solvent-free conditions. Selective monotetrahydropyranylation of symmetrical diols was achieved in similar conditions (Scheme 1). The deprotection of THF ether and the direct transformation of THP

[d]Excess DHP was used to dissolve the solid alcohol.
[e]Acetone was added to dissolve the solid alcohol.

ether to the corresponding acetate by $Fe_2(SO_4)_3{\cdot}xH_2O$ were also studied.

After a mixture of benzyl alcohol (10.0 mmol), 3,4-dihydro-2*H*-pyran (DHP, 1.1 mL, 12.0 mmol), and $Fe_2(SO_4)_3{\cdot}xH_2O$ (0.05 g, 0.1 mmol)[2] was stirred at ambient temperature for 1 h, the desired product, benzyl THP ether (2.21 g in 95% yield), was isolated through a short silica gel column. As shown in Table 1, with a catalytic amount of $Fe_2(SO_4)_3{\cdot}xH_2O$, a wide range of alcohols, including primary, secondary, tertiary, benzylic, and allylic alcohols as well as phenol and naphthol, undergo tetrahydropyranylation in good to excellent yields. Tetrahydropyranylation of primary alcohols was achieved at room temperature (rt) smoothly in excellent yields (Table 1, entries 1–4).[3] Secondary alcohols were protected as their THP ethers under increased temperature (Table 1, entries 5–7) with good yields. However, under these conditions without the addition of $Fe_2(SO_4)_3{\cdot}xH_2O$, no THP ether formation was observed. Carbon–carbon double bonds successfully survived the protection conditions (Table 1, entries 4 and 7). In addition, protection of a bulky molecule like diphenylmethanol (Table 1, entry 5) was achieved at 60 °C in good yield. *tert*-Butyl alcohol, which is an acid-sensitive alcohol, also undergoes tetrahydropyranylation smoothly and no dehydration was observed (Table 1, entry 8). Tetrahydropyranylation of phenolic hydroxyl groups (Table 1, entries 9–11) was

[2] $Fe_2(SO_4)_3{\cdot}xH_2O$ used in the experiments was purchased from the Beijing Chemical Factory (A.R. grade). The moles of $Fe_2(SO_4)_3{\cdot}xH_2O$ are calculated based on the formula: $M_{Fe_2(SO_4)_3{\cdot}xH_2O} = 0.5 \times (W_{Fe_2(SO_4)_3{\cdot}xH_2O} \times Fe(III)\%/55.8)$.

[3] The general procedure for tetrahydropyranylation and reuse of catalyst: benzyl alcohol (10.0 mmol), DHP (1.1 mL, 12.0 mmol), and $Fe_2(SO_4)_3{\cdot}xH_2O$ (0.05 g, 0.1 mmol) were stirred at rt. The progress of the reaction was monitored by TLC. At completion, the catalyst was moved by filtration and washed with dry acetone for further use. The filtrate was concentrated and the crude product was purified through silica gel column chromatography (petroleum ether – acetone, 125:1 *v*/*v*) to give benzyl THP ether (2.21 g, 95% yield). The product was identified by GC–MS and ^{1}H NMR and the spectroscopic data are comparable with the literature data.

2		65	80
3		60	72[b]

[a]Isolated yield of monoTHP ether; all products were identified by IR, ^{1}H NMR, and MS.
[b]BisTHP ether (12%) was also obtained.

achieved in good yields rather than forming a complex with Fe(III) or being oxidized by Fe(III). In general, 1 mol% of $Fe_2(SO_4)_3 \cdot xH_2O$ is enough for a fairly high yield. However, with 0.4 mol% of $Fe_2(SO_4)_3 \cdot xH_2O$, the same yield was also achieved under a longer reaction period (Table 1, entry 2).

The deprotection of the THP ether by $Fe_2(SO_4)_3 \cdot xH_2O$ was then explored. It was found that the deprotection of THP ether with the presence of a catalytic amount of $Fe_2(SO_4)_3 \cdot xH_2O$ was realized successfully. For example, the THP ether (1.0 mmol) of the compounds in Table 1 (entries 1, 5, 6, 8, and 10) were treated in anhydr. MeOH (3.0 mL) with 10 mol% of $Fe_2(SO_4)_3 \cdot xH_2O$ under reflux. Once the reaction was completed (indicated by TLC), the corresponding alcohols were finally isolated in 95%, 85%, 90%, 80%, and 90% yield, respectively. Therefore, a new reagent for both THP protection and deprotection was found, which will enrich the toolbox for organic chemists.

Meanwhile, selective monotetrahydropyranylation of symmetrical diols was studied under similar reaction conditions.[4] The reaction was carried out by stirring diol (5.0 mmol), DHP (0.45 mL, 5.0 mmol), and hydrated ferric sulfate (0.025 g, 0.05 mmol) in the presence of dry acetone (1.5 mL) and the process was monitored by TLC. After completion, symmetrical diols were selectively protected as their corresponding monotetrahydropyranylated products in good yields (Table 2). It is worth noting that hydroquinone (Table 2, entry 3) was selectively protected to give the monotetrahydropyranylation product in 72% yield (along with 12% of the diprotected product), which has seldom been achieved in the literature so far.

The effects of acetone and reaction time on the yield of monoprotected diol were then investigated by taking ethylene glycol as the model substrate. As shown in Fig. 1, at the primary stage, the reaction mainly gave the monoprotected product. Even when the yield of monoether reached 82% (Fig. 1, curve 1), the yield of diprotected diol was still lower than 10% (Fig. 1, curve 3). However, the yield of diprotected product increased remarkably after this stage, which implied that optimization of the reaction time (55 min under standard reaction conditions) leads to a maximum amount of monotetrahydropyranylation output. On the other hand, it

Fig. 1. Yield vs. reaction time. Ethylene glycol (5.0 mmol), DHP (0.45 mL, 5.0 mmol), and $Fe_2(SO_4)_3 \cdot xH_2O$ (0.05 mmol) were stirred at room temperature in the presence of acetone (1.5 mL). MonoTHP ether (■), bisTHP ether (●), monoTHP ether (▲) without the addition of acetone.

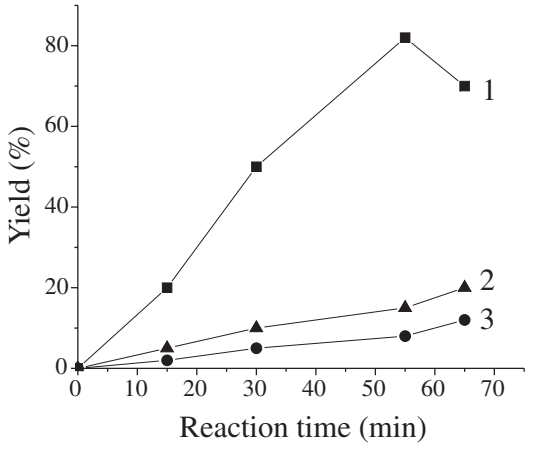

Table 3. The reusability of $Fe_2(SO_4)_3 \cdot xH_2O$ catalyzed tetrahydropyranylation.

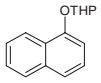
Round	Substrate	Catalyst recovered (g)	Reaction time (min)	Yield (%)[a]
1	$C_6H_5CH_2OH$	0.025	60	95
2	$C_6H_5CH_2OH$	0.024	80	92
3	$C_6H_5CH_2OH$	0.022	110	92
4	$C_6H_5CH_2OH$	0.021	150	89

[a]Isolated yield; all the products were identified by ^{1}H NMR.

was found that the presence of a small amount of acetone facilitated the reaction procedure significantly (Fig. 1, curve 1). In fact, acetone is very helpful in making the two reagents (ethylene glycol and DHP) into a homogeneous mixture, which helps the reaction proceed more smoothly than in a heterogeneous state (Fig. 1, curve 2).



In the view of green chemistry, efficient recovery and reuse of the catalyst are highly preferred. In our process, $Fe_2(SO_4)_3 \cdot xH_2O$ was easily recovered from the reaction mixture by filtration and subsequent washing with dry acetone. The recovered catalysts were ready to be used for the next reaction cycle. For example, benzyl alcohol was protected as its THP ether by using the recovered catalyst and the yields were not significantly decreased even after three recovery cycles (Table 3). However, an increased reaction period is necessary to achieve comparable yields.

On the other hand, the development of new methods for direct transformation from one protecting group to another has been gaining importance in recent years. However, the available method for direct transformation of THP ether to the corresponding acetate is very limited (18). Two reported

[4]Typical procedure for the monotetrahydropyranylation of symmetrical diols: ethylene glycol (5.0 mmol) and DHP (0.45 mL, 5.0 mmol) in dry acetone (1.5 mL) were stirred for several minutes. Then, $Fe_2(SO_4)_3 \cdot xH_2O$ (0.025 g, 0.05 mmol) was added. After 55 min, the reaction was terminated by filtration. The filtrate was concentrated and purified through silica gel column chromatography (2:1 petroleum ether – EtOAc) to give the monoTHP product (0.60 g, 82% yield). The product was identified by GC–MS and ^{1}H NMR and the spectroscopic data are comparable with the literature data.

Table 4. On-pot conversion of THP ether to acetate.

Entry	Substrate	Time (h)	Product	Yield (%)[a]
1		3		75
2		3		82
3		1.5		80
4		2		78
5		2		77

[a]Isolated yields.

methods for this conversion utilized either harsh conditions (AcOH/AcCl) or an expensive catalyst ($TiCl_4/Ac_2O$ in anhydrous dichloromethane). In our research, we found that $Fe_2(SO_4)_3{\cdot}xH_2O$ is a good catalyst for this transformation. As shown in Table 4, the THP ethers (1 mmol) were successfully converted to the acetates in the presence of Ac_2O (2.0 equiv.) and $Fe_2(SO_4)_3{\cdot}xH_2O$ (10 mol%) in refluxing 1,2-dichloroethane (15 mL).

It was also found that the transformation was very slow at rt under solvent-free conditions. Under reflux (large excess of Ac_2O), a complex mixture was observed and no significant amount of acetate was detected. However, in refluxing $ClCH_2CH_2Cl$ the reaction processed very well. Corresponding acetates were isolated after a short reaction period. Compared with the reported methods, this protocol is much milder and the catalyst is cheaper. It is worth noting that this protocol allowed a one-pot conversion of an acid-labile protecting group to a base-labile protecting group.

In conclusion, the present method is an efficient and practical method for the tetrahydropyranylation of alcohols and phenols as well as the monotetrahydropyranylation of symmetrical diols. In addition, a practical and mild protocol is developed for direct transformation of THP ethers to their corresponding acetates. The simplicity of manipulation, mild conditions, reusable catalyst, good selectivity, and environment benign characters will make this method a good alternative way for the THP protection of alcohols. Currently, further investigations of ferric sulfate hydrate as an efficient green catalyst are underway.

Characterization and identification of disintegrins in *Crotalus horridus* venom by liquid chromatography and tandem matrix-assisted laser desorption ionization – quadrupole ion trap time-of-flight (MALDI-QIT-TOF) mass spectrometry

Jacob A. Galán, Elda E. Sánchez, Sajid Bashir, and John C. Pérez

Abstract: Two disintegrins were purified from the venom of *Crotalus horridus* by multiple-dimension liquid chromatography (MDLC) (specifically C18 reverse phase (RP) high-performance liquid chromatography followed by size exclusion chromatography (SEC), and anion exchange chromatography (SCX)). Both disintegrins were subjected to mass spectrometry to determine their intact molecular mass, the number of disulfide linkages, and protein sequence, respectively. These disintegrins were named horrdistatin 1 (nominal mass, 7231 Da) and horrdistatin 2 (nominal mass, 7451 Da), and had IC_{50} (inhibitory concentrations) of 12.5 and 16.2 nmol/L (at 50%), respectively. For sequence confirmation from the C-terminal end, both disintegrins were derivatized using chemical-assisted fragmentation (CAF) and subsequently *unzipped* via collision-induced dissociation (CID) by matrix-assisted laser desorption – ionization – quadrupole ion trap time-of-flight (MALDI-QIT-TOF) mass spectrometry.

Key words: disintegrins, mass spectrometry, snake venom, Timber rattlesnake, *Crotalus horridus*.

Résumé : Deux désintégrines ont été extraites et purifiées à partir du venin de *Crotalus horridus* en faisant appel à la chromatographie liquide multidimensionnelle (CLMD) [particulièrement à la chromatographie liquide à haute performance à phase inversée (PI) C18 suivie d'une chromatographie par exclusion de taille (CET) et une chromatographie d'échange ionique (CXI)]. Les deux désintégrines ont été soumises à la spectrométrie de masse pour déterminer respectivement leur masse moléculaire intacte, le nombre de liaisons disulfures et la séquence des protéines. Ces désintégrines qui ont été dénommées respectivement horridistatine 1 (masse nominale de 7231 Da) et horridistatine 2 (masse nominale 7451 Da) présentent des concentrations inhibitrices à 50 % (IC_{50}) de 12,5 et 16,2 nmol/L. Pour confirmer la séquence à partir de l'extrémité C-terminale, on a préparé les dérivés des deux désintégrines en faisant appel à la fragmentation chimiquement assistée (FCA) et ceux-ci ont été soumis à un fractionnement par le biais d'une dissociation induite par une collision (DIC) par spectrométrie de masse à piège ionique quadripolaire avec désorption–ionisation au laser assisté d'une matrice (MALDI-QIT-TOF).

Mots clés : désintégrines, spectrométrie de masse, venin de serpent, serpent à sonnette des bois, *Crotalus horridus*.

[Traduit par la Rédaction]

Introduction

Crotalus horridus (Timber rattlesnake) is found in the central and northeastern United States. Herpetologists differ in opinion of whether the southern specimen consists of a separate subspecies, *Crotalus h. atricaudatus* (canebrake rattlesnake), or if instead it is a color variant because of geographical location (1). Due to the geographical locations of the specimens used in this study, the Natural Toxins Research Center had initially obtained them as *C. h. atricaudatus*. However, for practical purposes, the scientific name of *C. horridus* will be used.

In 1967, it was first discovered that *C. horridus* contained extremely lethal venom (2). However, prior to this discovery, *C. horridus* venom was not considered to be exceptionally toxic. The LD_{50} (lethal dose killing 50% of a population) for the venom of *C. horridus* ranged from 0.29 to 6.6 mg/kg body weight (2–4). Researchers have isolated a "canebrake toxin" from *C. horridus*, which is a two-component neurotoxin (5). Canebrake toxin is relatively homologous to phospholipase A (PLA) complex in the neurotoxins of crotoxin and Mojave toxin found in the venom of *Crotalus durissus terrificus* and *Crotalus scutulatus scutulatus*, respectively (5). *Crotalus horridus* venom is a complex mixture with the majority of molecules having pIs less than 6 (6). To date, *C. horridus* venom has been reported to have hemorrhagic,

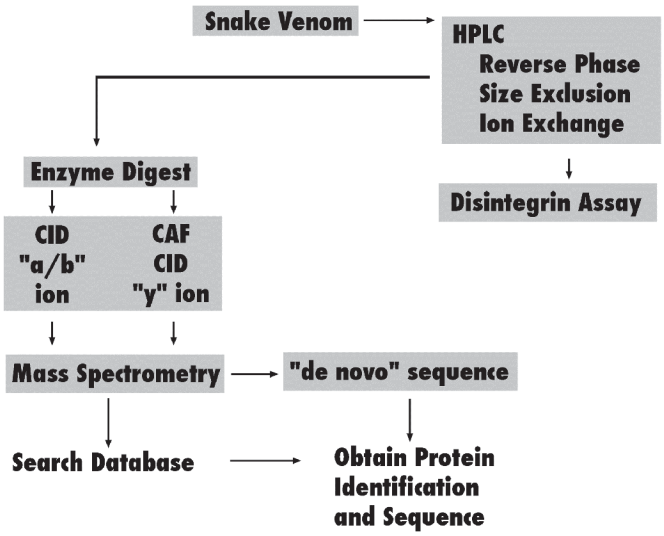
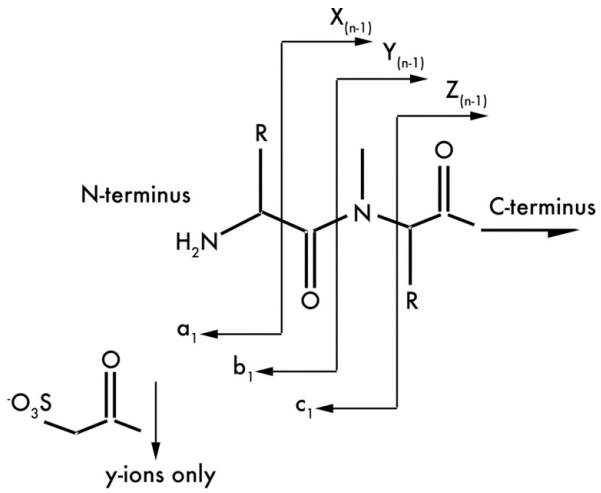
neurotoxic, myotoxic, and thrombin-like enzymes along with other proteolytic enzymes that are used in the capture and digestion of prey (4, 6–10). These snakes, like many other Viperidae species, exhibit geographical variation with respect to venom composition and lethality (11, 12).



Hemorrhagins and disintegrins are only two types of many components found in snake venom that affect hemostasis and cell adhesion (13). Many disintegrins are found in snake venom as single components that are proteolytically cleaved from the class PII of snake venom metalloprotease (SVMP) or found attached to metalloproteases (*a d*isintegrin *a*nd *m*etalloprotease, ADAM) (14, 15). The first disintegrin to be discovered, trigramin, was isolated from the venom of *Trimeresurus gramineus* (16). Trigramin blocks platelet aggregation and binding of ^{125}I-fibrinogen to ADP-stimulated platelets. Trigramin also blocks the binding of the human von Willebrand factor (vWF) to the $\alpha_{IIb}\beta_3$ complex in thrombin-activated platelets (16).

Disintegrins are naturally occurring proteins many of which have been isolated from snake venom. They are low molecular weight molecules ranging from 4–21 kDa. Many disintegrins possess an "RGD loop" found at the tip of a flexible hairpin loop (17), and can be recognized by their polypeptide length and number of disulfide bonds (18). Disintegrins and disintegrin-like proteins can be categorized into five groups. Examples of the short group are eristostatin, echistatin, and ocellatusin, which have 49–51 amino acid residues along with four disulfide bonds (19, 20). The medium-sized group that includes crotatroxin, kistrin, and flavoridin has approximately 70 amino acid residues and has six disulfide bonds (21, 22). The longest group has about 84 amino acid residues and seven disulfide bonds, which include bilitoxin-1, bitistatin, bothrostatin, and salmosin3 (23). Catrocollastatin and jararhagin are two examples belonging to a fourth group, which contains approximately 100 amino acid residues with eight disulfide bonds and have a disintegrin domain of PIII-SVMP (14, 15, 24). The homo- and heterodimeric disintegrins make up a fifth group, which contains approximately 67 amino acid residues and 10 cysteines that form four intrachain disulfides and two interchain linkages (24). Today there are over 90 disintegrins that have been isolated and characterized (23). Many isolated disintegrins show homology with one another, particularly in the cysteine arrangement. Because of their affinity to bind integrins on platelets and many other cells, disintegrins could be useful therapeutic agents in thrombosis, cancer, diabetes militius, angiogenesis, and inflammation (25–29).



There are many snakes containing different disintegrins in their venoms (23) and Duvernoy's gland secretions (30); and hence, a need for rapid isolation and characterization is essential. Multiple-dimension liquid chromatography along with mass spectrometry is a powerful tool in allowing the separation and identification of complex protein mixtures such as those found in snake venom (31).

The aim of this study was to isolate, characterize, and determine the sequences of two closely related disintegrins using MDLC and mass spectrometry. The isolated disintegrin proteins were de novo sequenced using mass spectrometry (32). We have attempted to utilize collision-induced dissociation (33) and chemical derivatization (34) to obtain the unique primary sequence of the disintegrins (35–37). The generic scheme is illustrated in Scheme 1 whilst the specific fragmentation types and derivatization is shown in Scheme 2. This is the first report of the isolation of disintegrins from *C. horridus* venom and the subsequent de novo sequencing.

Experimental

Specimen

The *C. horridus* (Avid No. 011-522-004) and *C. horridus* (Avid No. 010-782-102) specimens were obtained in Tennessee and Texas, respectively. These snakes are currently housed at the Natural Toxins Research Center (NTRC) at Texas A&M University-Kingsville, Kingsville, Texas. The Avid No. is a nine digit code given to individual snakes at the NTRC. Additional information pertaining to this snake can be queried using the Avid No. on the NTRC's snake database found at http://ntrc.tamuk.edu (6).

Venom collection

Venom was extracted by allowing the snakes to bite into a parafilm stretched over a disposable plastic container. The venom samples were clarified by centrifugation (500 × g for 10 min), filtered through a 0.45 μm filter, and frozen at –90 °C until lyophilized. Venom samples were collected from the individual snakes and were fractionated and analyzed individually.

Reverse-phase chromatography C18

A total of 5 mg of venom sample was fractionated by reverse-phase high-performance liquid chromatography (HPLC). Venom was injected into a Grace Vydac® reverse phase C18 (250 mm × 4.6 mm) column. Fractions were eluted using 0.1% TFA and 80% acetonitrile in 20% of a 0.1% TFA gradient over 60 min with a flow rate of 1 mL/min. A 2487 detector was used to monitor absorbances at 280 nm. Millennium software v.4 was used to control the 1525 binary HPLC pumps and store the data. Fractions were stored at –90 °C. Protein concentrations were determined by standard methods at 280 nm. The venom fractions from both specimens were tested for inhibition of platelet aggregation. Only specimen No. 011-522-004 contained a fraction that inhibited platelet aggregation and was further purified.

Size exclusion chromatography

Fractions collected from reverse-phase C18 chromatography inhibiting platelet aggregation were further fractionated by size exclusion HPLC. Two hundred and fifty micrograms of protein were injected into a Waters Protein-Pak™ 60 (7.8 mm × 300 mm) column. The buffer used was 0.02 mol/L sodium phosphate, pH 6.2 over 60 min with a flow rate of 0.5 mL/min, and proteins were detected at 280 nm using a 484 tunable detector. Millennium software v.4 was used to control the 510 pumps and store the data. The fractions were tested for inhibition of platelet aggregation.

Anion exchange chromatography

Fractions collected on size exclusion chromatography inhibiting platelet aggregation were further fractionated by anion exchange HPLC. Two hundred micrograms of protein were injected into a Waters Protein-Pak™ DEAE 5PW (7.5 mm × 7.5 mm) column. The buffer used was 0.02 mol/L Tris-HCl, pH 8.0 over 60 min with a flow rate of 1 mL/min, and proteins were detected at 280 nm using a 484 tunable detector. Millennium software v.4 was used to control the 510 pumps and store the data. The fractions were tested for inhibition of platelet aggregation.

Inhibition of platelet aggregation

A Chronolog™ whole blood lumi-aggregometer was used to monitor platelet aggregation, by impedance, when venom samples were added. Four hundred and fifty microliters of 10% citrated human blood were incubated to 37 °C at least 5 min prior to use with equal amounts of 0.15 mol/L saline solution. Ten microliters of venom fraction were incubated with the blood sample for 2 min. An electrode was inserted in the blood sample, and 1.5 min later, 10 μL of a 1 mmol/L adenosine diphosphate (ADP) solution was added to the blood sample to promote platelet aggregation. Per cent inhibition of platelet aggregation was calculated by the following equation: $[(C - E/C)] \times 100$, where C is the units of platelet aggregation (ohms) for the control and E is the unit of platelet aggregation (ohms) for the experimental fraction.

Characterization and identification of isolated proteins

Following isolation of disintegrin-like proteins from specimen No. 011-522-004, the samples were analyzed using the Axima-QIT™ MALDI-QIT-TOF (Shimadzu Biotech USA, Columbia, Maryland). The lyophilized proteins were resuspended in 20 μL of 25 mmol/L ammonium bicarbonate. From this stock approximately 2 μL were diluted in 10 μL of 0.1% TFA followed by a zip-tip (Millipore C4 zip-tip, Billerica, Massachussetts) clean up. Samples were then mass analyzed in high mass mode for both nonreduced and reduced forms. For the digest, the lyophilized protein was resuspended (1 mg) in 100 mmol/L ammonium hydrogen carbonate, pH 7.5, and digested with trypsin (1:50 $w_{enzyme}/w_{substrate}$) for 18 h at 37 °C (38, 39). The tryptic mixture was lyophilized and resuspended in 0.1% TFA and derivatized using a CAF labeling kit accordingly (40). Prior to digestion, half the sample (10 μL) was reduced using dithiothretol (DTT, Sigma, Louis, Missouri) and alkylated using idoacetamide (Sigma). The samples were then desalted using C18 micro zip-tips. Approximately 0.5 μL of protein, or digest, was mixed with 0.5 μL of 2,5-dihydroxybenzoic acid (DHB).

The QIT was used to store and fragment the MALDI generated ions, which were mass analyzed in the TOF reflectron in positive ion selection mode. The tryptic digest samples were calibrated using peptide standard P14R (m/z 1533.86), its fragments (m/z 1339.75, 1145.65, 951.44, 757.44) and angiotension 18–39 clip (m/z 2465.20). The MS–MS spectrum was externally calibrated using the fragments from P14R (PPPPPPPPPPPPPR, m/z 1533.86). The intact proteins were externally calibrated using a protein mixture consisting of insulin oxidized B chain (m/z 3494.65), insulin

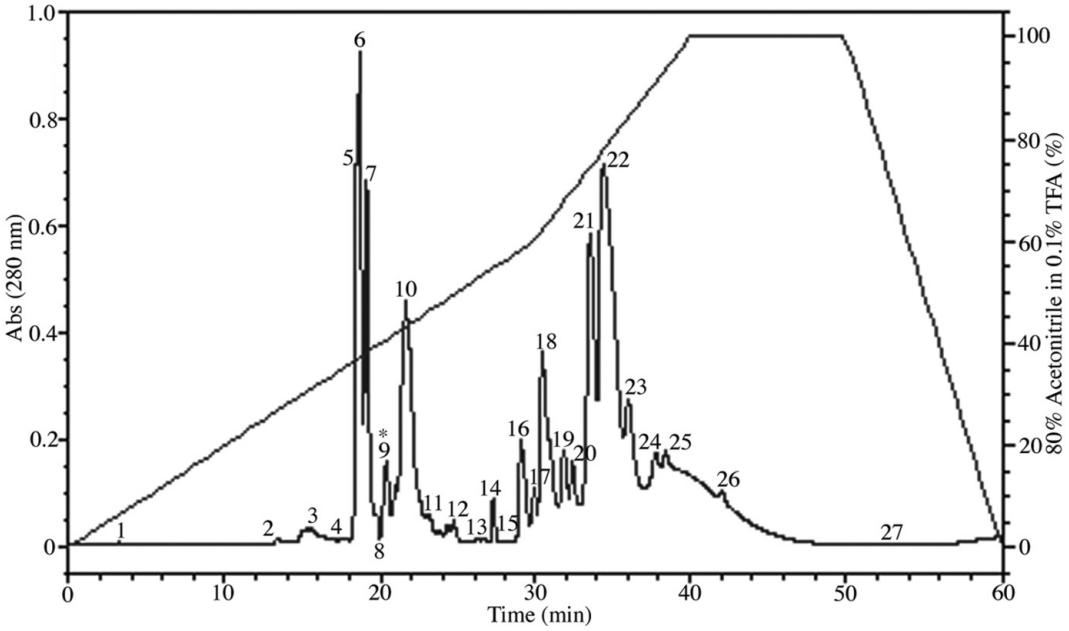
Fig. 2. Reverse phase C18 chromatography of *C. horridus* (No. 011-522-004) venom. A total of 5 mg of venom was injected into a Grace Vydac™ C18 column (4.6 mm × 150 mm). The venom was separated using 0.1% TFA with the eluting solvent of 80% acetonitrile in 0.1% TFA on a Waters HPLC system. The fractions were tested for inhibition of platelet aggregation. Fraction *9 contained disintegrin-like activity.



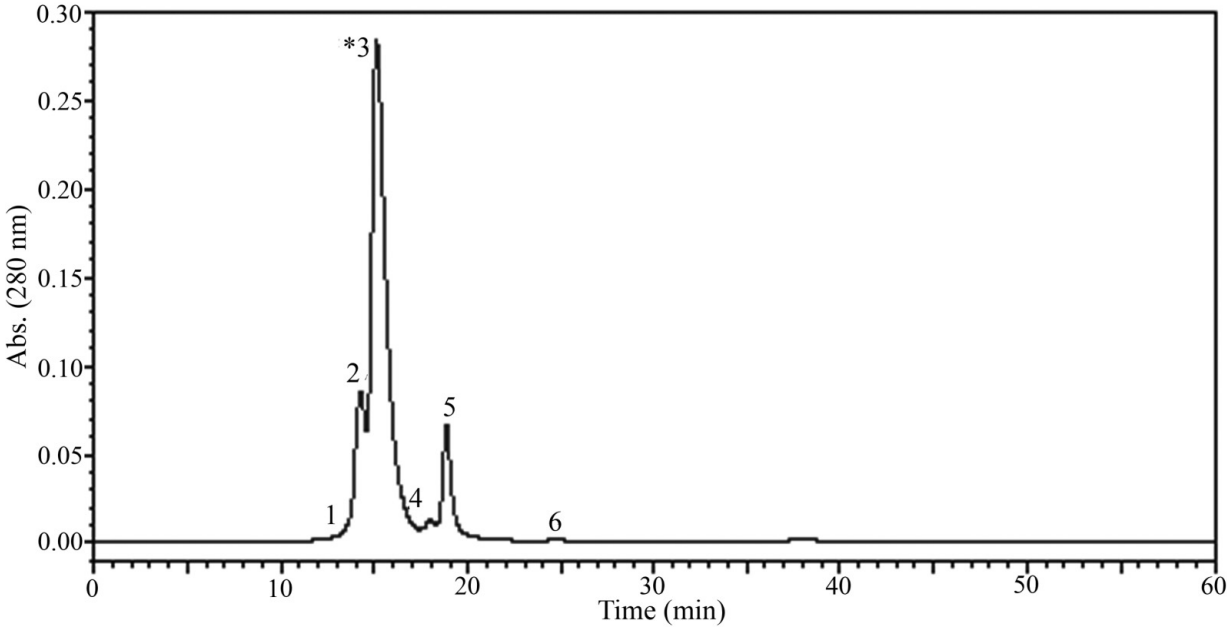


Fig. 3. Size exclusion chromatography of fraction 9 (Fig. 1). A total of 250 µg of fraction 9 was injected into a Waters ProteinPak™60 column (7.8 mm × 300 mm). The venom was separated using 0.02 mol/L sodium phosphate buffer (pH 6.2) on a Waters HPLC system. The fractions were tested for inhibition of platelet aggregation. Fraction *3 contained disintegrin-like activity.

(bovine, *m*/*z* 5730.61), and cytochrome C (equine, *m*/*z* 12 361.96). Argon was used as the collision gas for the generation of CID spectra and He was used as the cooling gas.

Database searching and amino acid sequence

The proteins digest masses-to-charge ratio's obtained from the matrix DHB were searched against a expressed sequence tag (EST) database for others (EST_{others}) at the National Center for Biotechnology Information, (NCBI, Bethesda, Maryland (http://www.ncbi.nlm.nih.gov/PMGifs/Genomes/others.html. The database can be downloaded from http://www.ncbi.nlm.nih.gov/dbEST/). The mascot and total ion scores obtained were search-parameter dependant and were stored within the data system. In the initial search, no enzyme specificity was used although carbamidomethyl (C) and (or) deamidation (NQ) were selected.

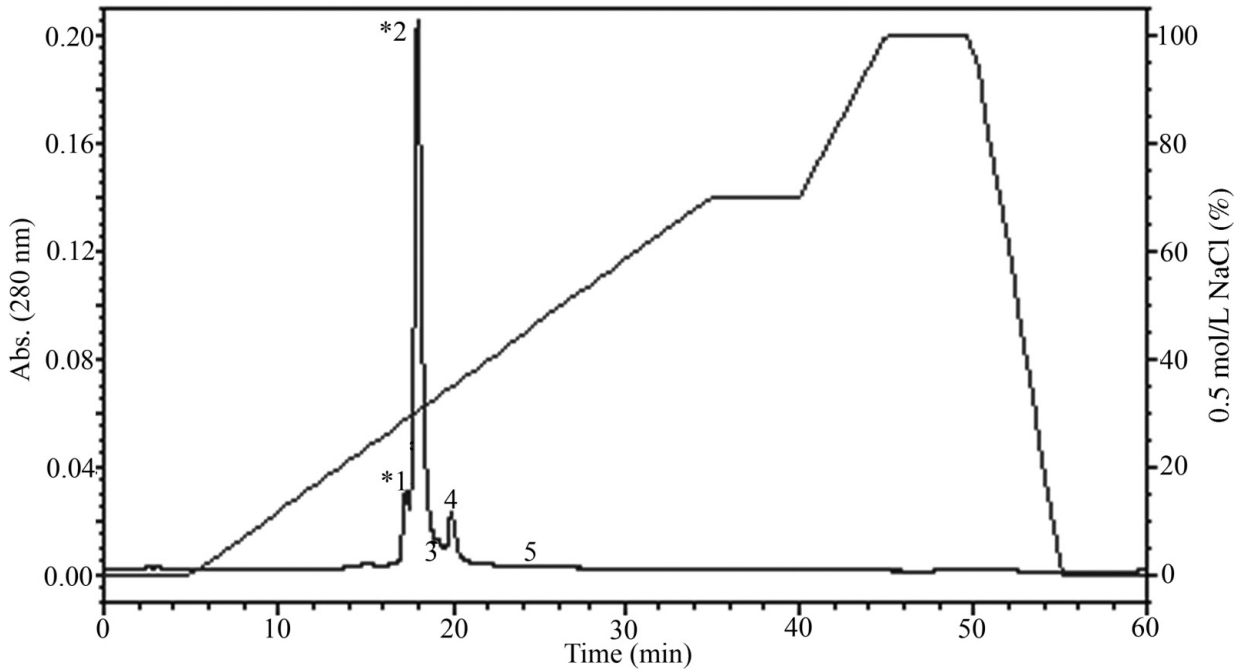
Fig. 4. Anion exchange chromatography of fraction 3 (Fig. 2). A total of 200 µg of protein was injected into a Waters Protein-Pak™ DEAE 5PW (7.5 mm × 7.5 mm) column. The venom was separated using 0.02 mol/L Tris-HCl buffer (pH 8.0) on a Waters HPLC system. The fractions were tested for inhibition of platelet aggregation. Fractions *1 and *2 contained disintegrin-like activity.



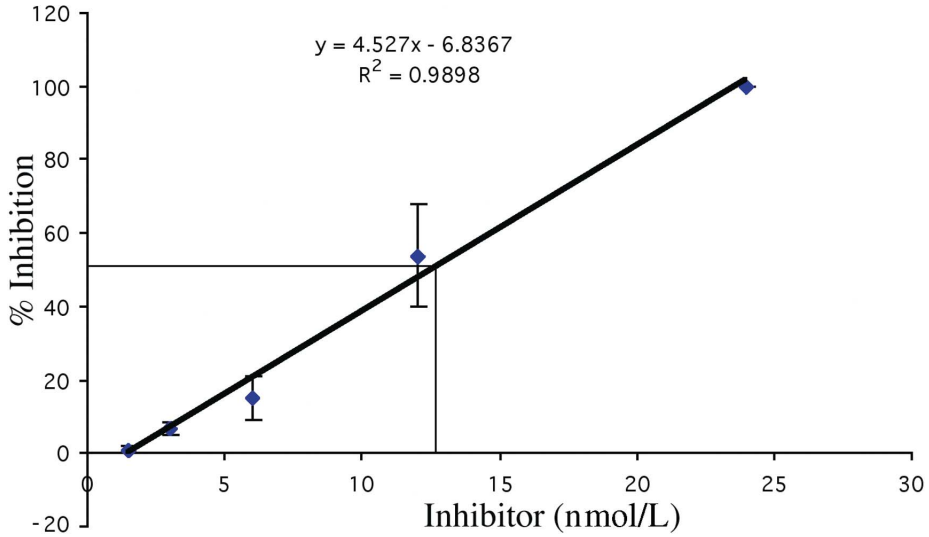


Fig. 5. The effects of horrdistatin 1 on ADP induced platelet aggregation. Various concentrations of horrdistatin 1 were preincubated with whole blood for 2 min at 37 °C prior to the addition of ADP (1 mmol/L). The IC_{50} was 12.5 nmol/L. Data was presented as the mean value of inhibition percentage to the control value. The values are in triplicate measurements and are representative of three independent experiments.

Results and discussion

In the present study, two disintegrins have been isolated and identified from the venom of one of the two Timber rattlesnakes tested. The venom of the Timber rattlesnake, like the Mojave rattlesnake, can exhibit intraspecific variation and have hemorrhagic, neurotoxic, and procoagulant enzymes (6–10). However, disintegrins have never been reported in the venom of the Timber rattlesnake. The two disintegrins isolated in this study share similar sequence homology and activity (22) with disintegrins found in the venom of other *Crotalus* species (Fig. 1).

The two disintegrins isolated by a three-step chromatography procedure (Figs. 2–4) were called horrdistatin 1 and horrdistatin 2. Both disintegrins had very similar IC_{50}s with regards to biological activity; the inhibition of ADP induced platelet aggregation. Horrdistatin 1 had an IC_{50} of 12.5 nmol/L and horrdistatin 2 had an IC_{50} of 16.2 nmol/L (Figs. 5 and 6). Following protein purification using the MDLC system, the samples were analyzed by MALDI-QIT-

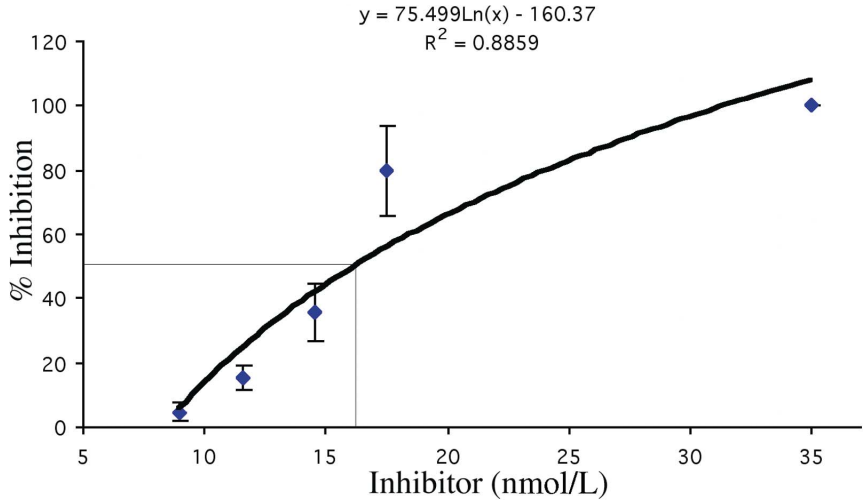
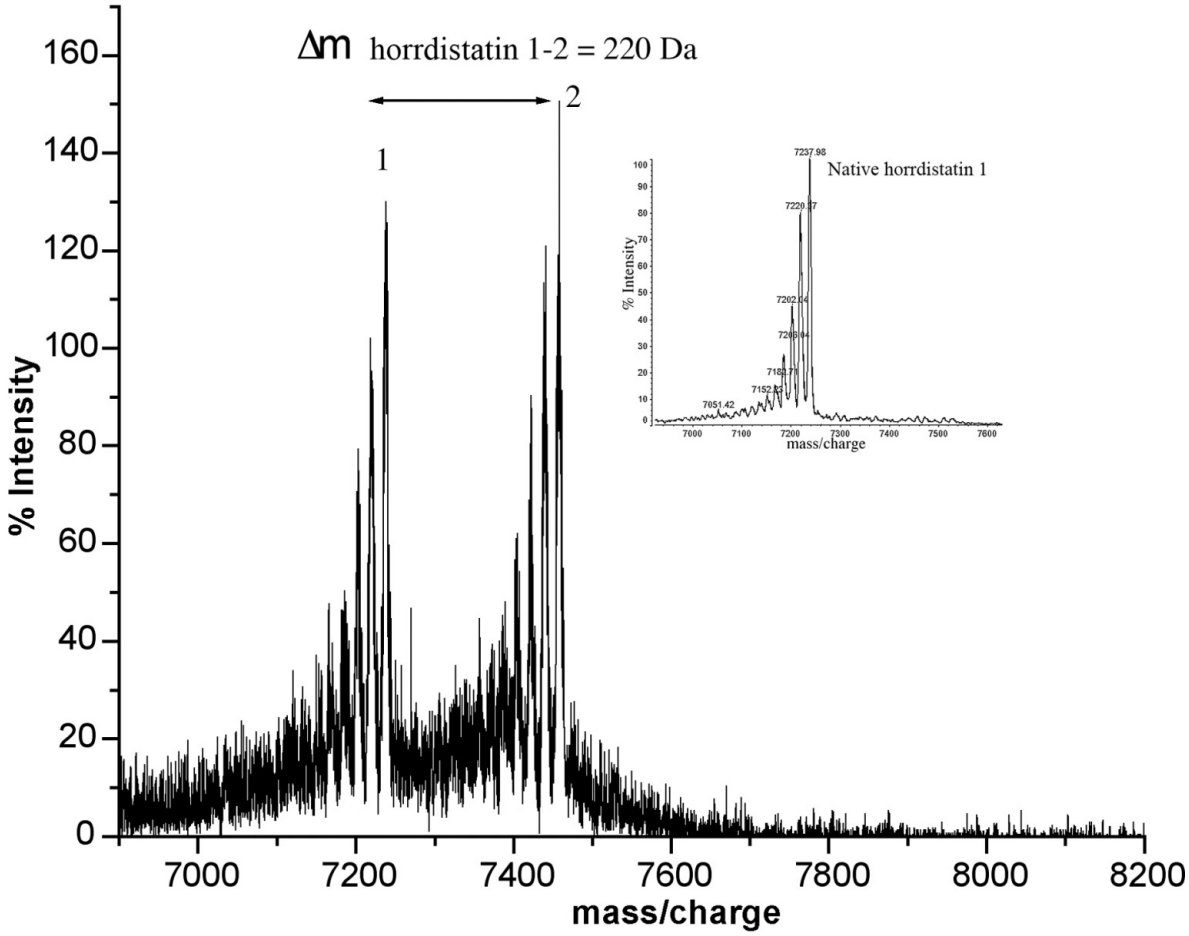
Fig. 6. The effects of horrdistatin 2 on ADP induced platelet aggregation. Various concentrations of horrdistatin 2 were preincubated with whole blood for 2 min at 37 °C prior to the addition of ADP (1 mmol/L). The IC_{50} was 16.2 nmol/L. Data was presented as the mean value of inhibition percentage to the control value. The values are in triplicate measurements and are representative of three independent experiments.





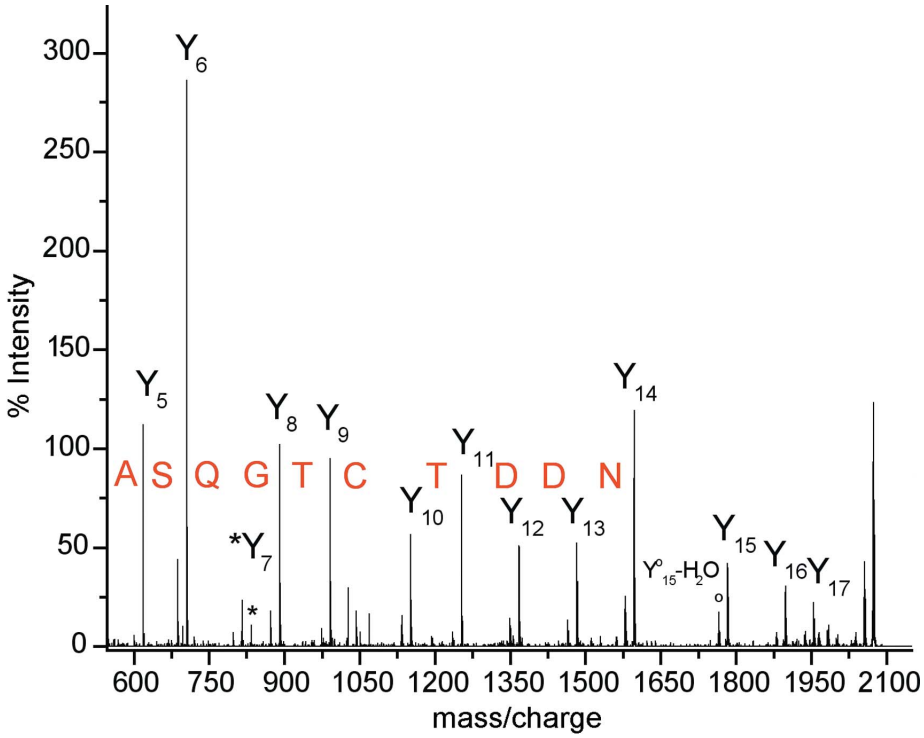


Fig. 7. MALDI-QIT-TOF mass spectrum of the isolated proteins horrdistatin 1 and 2. The samples were reduced and alkylated with DTT and iodoacetamide, respectively, and analyzed in positive mode. The insert is the corresponding mass spectrum for horrdistatin 1 (native). The mass difference between the native form and reduced form is an indicator of disulfide linkage. Note: $Exp_{measure-reduced}$ + H-H_2O = 7469 Da, calcd. 7550.4 Da, Δm = 0.6 Da, $\Delta m_{horrdistatin(nonreduced-reduced)}$ = 12 Da ~ six disulfide bonds.

Fig. 8. MALDI-CAF-CID spectrum of tryptic peptide ladder *m/z* 2090.72 from horrdistatin 1 from which the sequence could be determined. (The tryptic fragments from both proteins were compared; the common matched "paired" peptide fragments were used to generate the common sequence between the proteins, whilst the "unique" unmatched peptides were used to determine the differences between the proteins and also to confirm the assigned sequences). A tryptic fragment of *m/z* 2090.72 that could not be matched between the proteins was chemically derivatized to allow favored C-terminal fragmentation and subjected to CID fragmentation. The CAF-CID of unique peptide 2090.72 *m/z* and precursors of 1954.73 *m/z* generated "y"-type fragment ion, which were used to determine the amino acid differences between the two isolated proteins allowing the unique peptides to be "unzipped" allowing facile readout of the de novo sequence.

TOF. The nominal intact molecular mass for horrdistatin 1 was 7231 Da. The nominal intact molecular mass of horrdistatin 2 was 7469 Da with a true mass of 7451 Da (18 Da was due to hydration) resulting in a mass difference of 238 Da. A typical mass spectrum is shown in Fig. 7. Comparison of the nonreduced and reduced forms indicated a mass difference of 12 Da, revealing a high degree of disulfide cross-linking (~six disulfides), which was consistent with other known disintegrin proteins (Fig. 7).

The resulting mass sequence tags (MST) and initial peptide mass fingerprint (PMF) were jointly searched to obtain protein identities based upon sequence homology. This combined approach proved to be more successful than using PMF alone (32, 41). Almost 40% of the total protein sequence identified in this method, combined with CID, gave overall sequence coverage of 60% or more, allowing for unique identification. A CAF-CID spectrum representing horrdistatin 1 is shown in Fig. 8. Analysis of the tryptic digest in mid-mass mode between the two proteins indicated almost identical mass spectra, except horrdistatin 1 contained a fragment of mass-to-charge of 2239.88 Da that was absent from horrdistatin 2, which itself contained a tryptic fragment at mass-to-charge 2459.91 Da, which was absent in horrdistatin 1. The mass difference between these two unique tryptic fragments corresponds approximately to 220 Da, which was the mass difference between the native intact proteins (Fig. 7). The MS–MS search of the tryptic fragments (1954.74, 2036.86, and 2258.78 Da) from both proteins putatively indicated to be disintegrins similar to that of crotatroxin, a disintegrin from the Western Diamondback rattlesnake venom (Fig. 8). The difference in mass between the two proteins could be accounted for by consideration of the truncation of the former by two amino acids (deletion of the last two amino acids on the C terminus in horrdistatin 1 (Tyr-Gly)), which also accounts for the 220 Da difference in mass between the two proteins (Fig. 1). Additional MS–MS of the 2258.78 tryptic fragments indicates loss of Ala from the N terminal for both samples. The calculated mass of 7450.4 Da is in good agreement with the measured mass of 7469 Da (for the hydrated reduced form, where hydration is the inclusion of one water molecule).

Disintegrin proteins have been found in the venom of various snake species showing homology in their sequences, potencies, and their selective interactions with integrin receptors (42–45). The disintegrins, horrdistatin 1 and 2 have a high selectivity to the integrin $\alpha_{IIb}\beta_3$, which is responsible for the aggregation of platelets; and thus, could possibly have potential use in the treatment of myocardial infarctions and cerebrovascular accidents.

Role of the solvent in the oxidative process of a Hg electrode in the presence of thiopyrimidine derivatives

Souad Bakari, Marco Borsari, Maria Cannio, Giovanna Gavioli, Antonio Ranieri, Silvia Peressini, and Claudio Tavagnacco

Abstract: The electrochemical oxidation of a Hg electrode in the presence of thiopyrimidine derivatives has been investigated in a collection of organic solvents using voltammetric and polarographic techniques. Remarkable adsorption phenomena control the electrochemical process, which in all cases gives rise to a Hg(I) complex. The Laviron adsorption model is found to describe well the polarographic adsorption wave. Some correlations between adsorption parameters and solvent properties have also been observed and discussed.

Key words: polarography, voltammetry, thiopyrimidine, solvent effect, adsorption.

Résumé : On a étudié l'oxydation électrochimique d'une électrode de mercure en présence de dérivés thiopyrimidines dans divers solvants organiques, en faisant appel à des techniques polarographiques et voltampérométriques. Un phénomène remarquable d'adsorption contrôle le processus électrochimique qui, dans tous les cas donne lieu à un complexe Hg(I). On a trouvé que le modèle d'adsorption de Laviron décrit bien la vague d'adsorption polarographique. On a observé et on discute de quelques corrélations entre les paramètres d'adsorption et les propriétés du solvant.

Mots clés : polarographie, voltampérométrie, thiopyrimidine, effet de solvant, adsorption.

[Traduit par la Rédaction]

Introduction

Interest in the chemistry of thiopyrimidine derivatives arises from their involvement in some biological systems and from their potential use as anti-tumour and anti-thyroid agents (1–3). Studies have been reported concerning the electrochemistry of thiopyrimidines (4–14) in which particular attention has been focused on the reduction process in aqueous solutions. However, few data concerning the electrochemical oxidation in organic solvents are available. In dimethylformamide (DMF), adsorption phenomena are involved in the process, and the formation of a Hg(I) complex was observed (4). In this paper, polarographic and voltammetric methods have been used to characterize the electrochemical oxidation of a collection of thiopyrimidines (15, 16) on a Hg electrode in several solvents. Moreover, the role of the medium and the pyrimidine ring substituents on the adsorption processes has been emphasized. In fact, studies on electrosorption of organic molecules can provide fundamental information, which can be useful in clarifying the relation between the microstructure of the double layer in the presence of specific adsorption and the measured macro properties of the electrochemical system.

Results and discussion

The oxidative electrochemistry of a Hg electrode in the presence of 2-thiopyrimidines, 2-thiopyrimidine (**1**), 4,6-dimethyl-2-thiopyrimidine (**2**), 1,4,6-trimethyl-2-thiopyrimidine (**3**), and 4,6-dimethyl-1-phenyl-2-thiopyrimidine (**4**), has been investigated in several solvents (DMF, DMSO, acetonitrile (ACN), EtOH, and MeOH). The observed behaviour is found to be similar to that already reported for compounds **2** and **4** in DMF (4) and is found to be independent of the nature of the solvent.

In the cyclic voltammetry (CV) curves, in fact, at a concentration (c) of thiopyrimidine higher than a critical value independent of the solvent (c_m = 2.2 ± 0.2 × 10^{-4}, 2.0 ± 0.2 × 10^{-4}, 1.9 ± 0.2 × 10^{-4}, and 0.8 ± 0.1 × 10^{-4} mol/L for compounds **1**, **2**, **3**, and **4**, respectively), two anodic peaks (A_1,A_2) and their corresponding cathodic counterparts (C_1,C_2) are present (Fig. 1A-*ii*), while at $c < c_m$ only one pair of peaks (A_1,C_1) is observed (Fig. 1A-*i*). The A_1,C_1 couple shows the characteristics of an electrochemical signal corresponding to a reversible faradic process involving the adsorption of a species involved in the electron transfer (17, 18): the peak current (i_p) remains constant at $c > c_m$ (Fig. 2) and is proportional to the scan rate (v) (Fig. 3*a*). The A_2,C_2 peaks, however, show typical *diffusion* characteristics, corresponding to a faradic process involving a species that freely

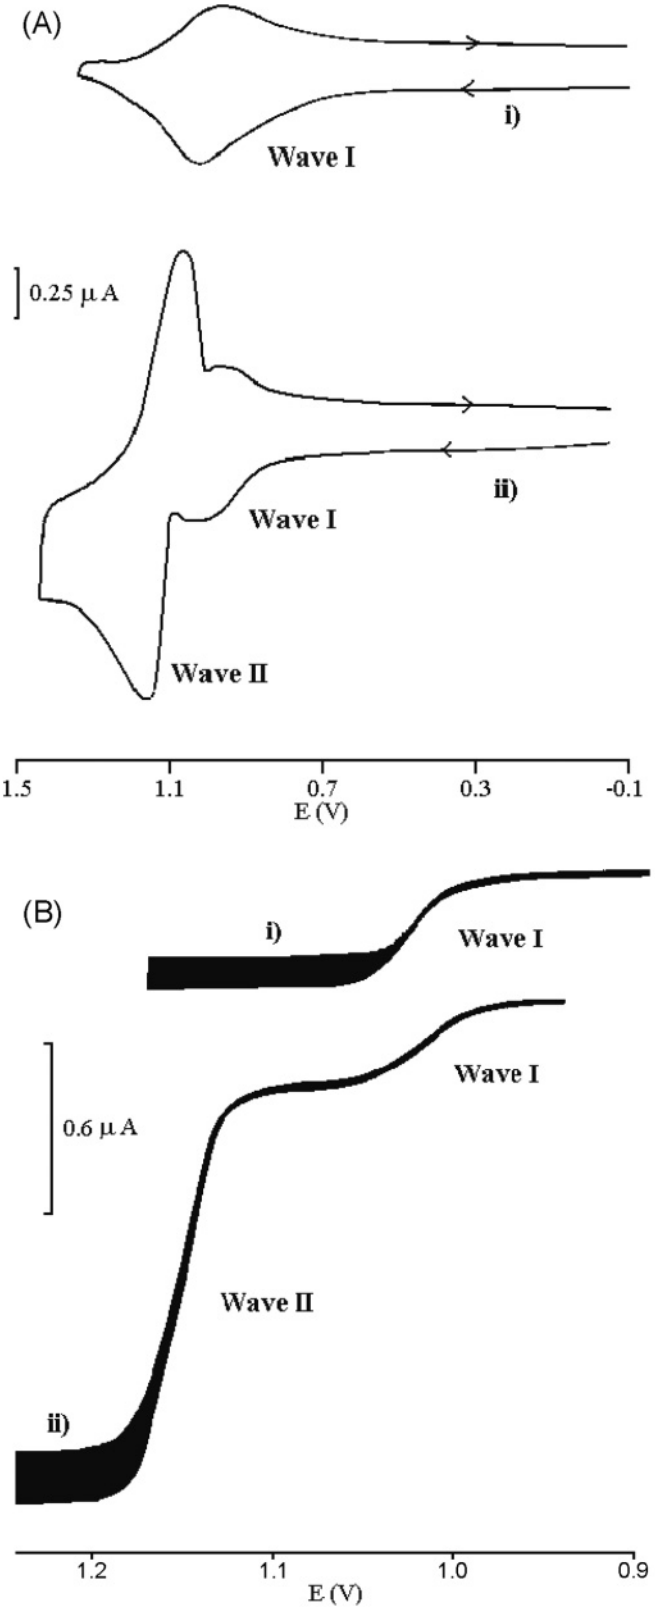
Fig. 1. Cyclic voltammogram (A) and polarographic curves (B) for (*i*) 2×10^{-4} and (*ii*) 5×10^{-4} mol/L solutions of 1,4,6-trimethyl-2-thiopyrimidine in ACN. Base electrolyte 0.1 mol/L TBAP, T = 25 °C, scan rate 0.05 V s^{-1}. Wave I – adsorption signal and wave II – diffusion-controlled signal. E values are referred to the reversible redox couple cobaltocene/cobaltocinium.



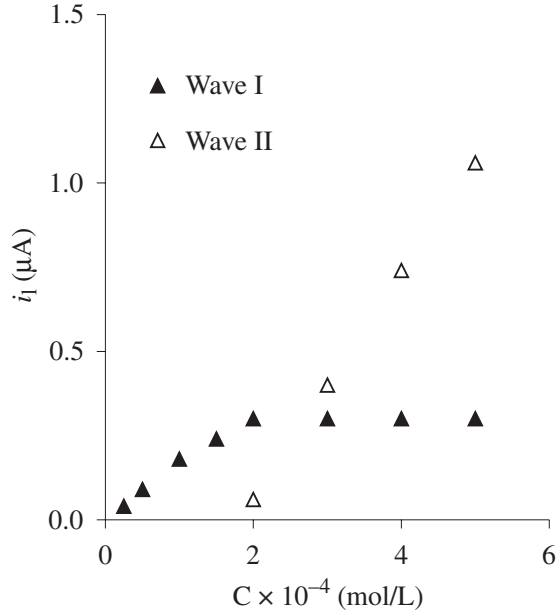


Fig. 2. Voltammetric anodic limiting current (i_l) vs. concentration (c) for 1,4,6-trimethyl-2-thiopyrimidine in ACN. Scan rate 0.05 V s^{-1}. Base electrolyte 0.1 mol/L TBAP, T = 25 °C.

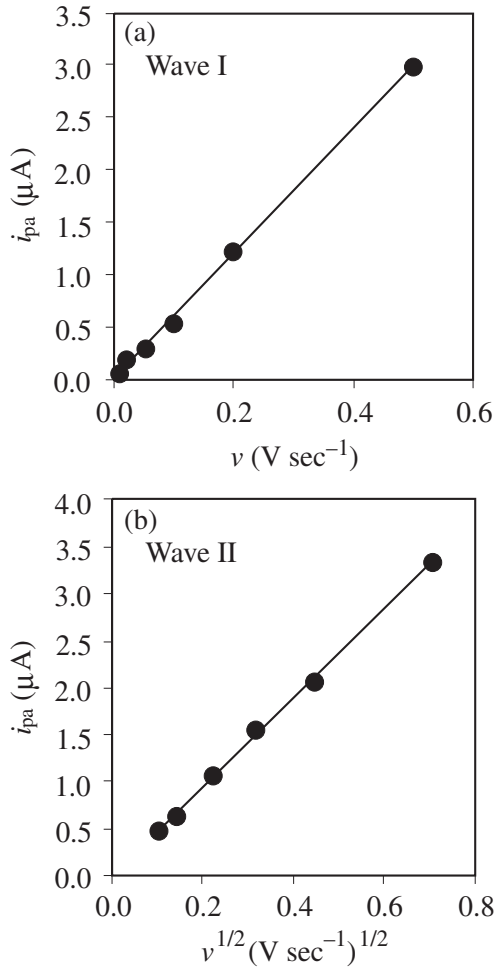
diffuses toward the electrode surface: i_p is proportional to c (Fig. 2) and $v^{1/2}$ (Fig. 3*b*), but no limiting value is observed.

The polarographic behaviour strongly resembles that found using voltammetric techniques (Fig. 1B): two oxidative waves occur at $c > c_m$ (wave I and II, c_m is the same as observed in the CV measurements, Fig. 1B-*ii*), while at $c < c_m$ only one wave (wave I) is present (Fig. 1B-*i*). Wave I is the adsorption wave (17, 19). In fact, at $c < c_m$ its limiting current (i_l) is proportional to c and $t_d^{1/6}$ (t_d = dropping time), while at $c > c_m$, i_l is independent of c and proportional to $t_d^{-1/3}$ (20). Wave II (the diffusion wave) is characterized by a more positive half-wave potential ($E_{1/2}$), and its i_l value is invariably found to be proportional to c and $t_d^{1/6}$ (20). Therefore, the voltammetric and polarographic results indicate the presence of a solely electrochemical process characterized by two signals corresponding to the oxidation product in two different states, one possibly arising from diffusion in solution and the second from adsorption on the mercury surface.

Coulometry at a constant potential value (CPO) has been performed at a potential value 50 mV more positive than peak A_2, and the number of electrons involved in the oxidative process, calculated by integration of the i vs. t curves, is found to be one in all of the solvents. The product of the CPO process was separated and identified (by elemental analysis, and IR and UV spectra) as $[Hg(L)]ClO_4$ (L = compounds **1**–**4**) for all solvents.



In the case of DMF, $[Hg(L)]^+$ is observed during electrolysis, but changes slowly in a mixture of Hg^{2+} into difficult to characterize complexes having a formula of $[Hg(L)_n](ClO_4)_2$ (n = 1–3). This can probably be attributed to the disproportionation of the Hg^+ complex to Hg^0 and Hg^{2+}, as is often observed for several Hg^+ compounds in DMF (21–24).

Therefore, the oxidation mechanism on the Hg electrode can be summarized as follows:

$$Hg + L = [Hg(L)]^+ + e^-$$

Fig. 3. (*a*) Plot of i_{pa} vs. v (scan rate) for wave I and (*b*) plot of i_{pa} vs. $v^{1/2}$ for wave II for a 5×10^{-4} mol/L solution of 1,4,6-trimethyl-2-thiopyrimidine in ACN. Base electrolyte 0.1 mol/L TBAP, T = 25 °C.

The observed behaviour of the CV and polarographic signals is apparently typical of reversible electrochemical processes involving a species electroactive both in solution and in adsorbed form (20). In our case, the product of the electrochemical process is the most strongly adsorbed. At low concentrations the single observed signal (a peak couple in CV) is due to an oxidative process involving dissolved thiopyrimidine, which forms a layer of adsorbed product on the electrode surface. At increasing thiopyrimidine concentrations, the current of this signal increases until a limiting value, corresponding to complete coverage of the electrode surface, is reached. Then an apparent diffusion signal appears and grows with respect to the adsorption signal, which remains constant. The diffusion signal is a result of the same faradic process as the adsorption one, but the product of the electrochemical process is not adsorbed but is free to diffuse in solution (20). The diffusion signal is characterized by a more positive potential value than the adsorption signal because adsorption of the oxidation product contributes to the free energy of the electrochemical reaction thereby making oxidation easier than in the case where the product freely diffuses (20). Such behaviour has been observed for a variety of thiols, thiourea derivatives, and thiobarbiturates (25–28), but while the origin of the first signal (adsorption) is invariably attributed to the formation of a Hg(I) compound adsorbed on the Hg surface, the origin of the second signal is not so clear. As a matter of fact, in our case it is limited by diffusion of the thiopyrimidine (at least in the concentration range examined) and gives a Hg(I) compound. Careful investigations concerning the oxidation of the Hg electrode in the presence of cysteine (26–28) in aqueous solution indicate the presence of two steps corresponding to the formation of Hg(I) and Hg(II) cysteine compounds, respectively. In particular, the first step is pH and concentration dependent, but in all cases, at concentrations higher than a critical value, it appears to involve two signals. The first one (*adsorption pre-wave*) exhibits a limited current value attributed to the inhibition effect of the adsorbed reaction product (cysteine mercurous thiolate). The second wave is attributed to the increased dissolution pressure of Hg under the adsorbed layer (26). The case of thiopyrimidine is probably not that different from cysteine, even if the presence of organic solvent renders the solubility of the Hg complex greater than that in aqueous solution, and this fact could affect the *compactness* of the adsorbed film. However, since the aim of this paper is to provide information on the characteristics of the first adsorption process on the Hg surface in the presence of different solvents, the nature of the second signal has not been investigated further.

As a matter of fact the thiopyrimidine derivatives (compounds **1**–**4**, r species) as well as the products of the oxidative process (Hg(I) complexes, p species) can be strongly adsorbed. For this reason, the polarographic adsorption wave I was analyzed in the different solvents according to the model proposed by Laviron introducing the mixed Frumkin isotherm (4, 19):

$$b_i c_i\ (0,t_d) = [\theta_i/n_i\ (1 - \theta_i - \theta_j)]\ \exp(-2a_i n_i \theta_i - 2a_{ij} n_{ij} \theta_{ij})$$

where i and j refer to the r and p species, θ is the coverage, b is the adsorption coefficient, n_i is the number of solvent molecules removed by one molecule of i, and a is the interaction parameter. The saturation value of the surface concentration of the p species ($\Gamma_{m,p}$) was determined from the polarographic adsorption current at $\theta = 1$ (17) (Table 1), while the $\Gamma_{m,r}$ for the r species was evaluated using the Korita equation (29) at $c = c_m$ (Table 1). Thus, according to Laviron (19) and Muller et al. (30–32), the following theoretical relationship between E and the current intensity (I) was used to analyze the adsorption wave:

$$E = E_{1/2} + (RT/\alpha nF)\{\ln[\Phi/2(I - \Phi)^2] + \sigma n_r G[4(\Phi - 1/2)]\}$$

where

$$\Phi = (I/I_l),\ \sigma = 0.74 D_r t_d^{1/2} c_r / \Gamma_{m,p}$$

$$G = a_{pr}(1 + 2\Gamma_{m,p}/\Gamma_{m,r}) - a_p - 2(\Gamma_{m,p}/\Gamma_{m,r})a_r$$

α is the electron transfer (ET) coefficient, F is Faraday's constant, D is the diffusion coefficient of species r, I_l is the limit current intensity, and G is the mixed Frumkin interaction parameter.

EtOH	4.16	8.66	3.65	2.25	3.18	2.75	1.19	0.83

Table 2. Mixed Frumkin interaction parameter values (*G*) in different solvents for the following compounds: 2-thiopyrimidine (**1**), 4,6-dimethyl-2-thiopyrimidine (**2**), 1,4,6-trimethyl-2-thiopyrimidine (**3**), and 4,6-dimethyl-1-phenyl-2-thiopyrimidine (**4**).

		G			
Solvent	$\varepsilon^{-1} \times 10^2$	**1**	**2**	**3**	**4**
DMF	2.61	–0.03	–0.29	–0.26	–0.15
DMSO	2.12	–0.02	–0.24	–0.21	–0.12
ACN	2.73	–0.04	–0.3	–0.27	–0.16
MeOH	3.03	–0.04	–0.34	–0.29	–0.17
EtOH	3.95	–0.05	–0.43	–0.4	–0.22

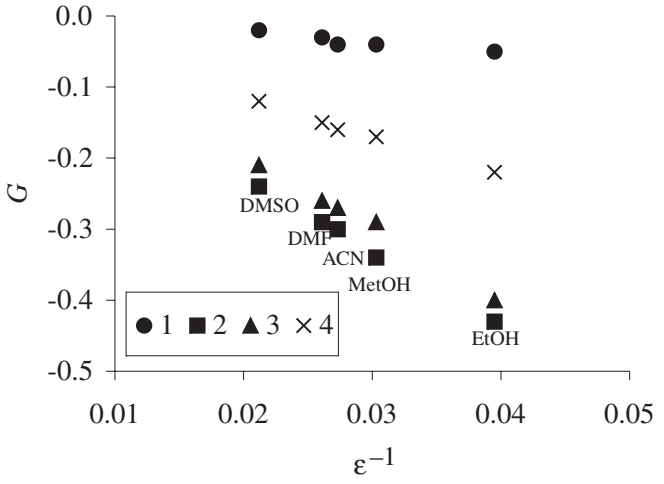
Note: ε = relative dielectric constant.

Therefore, a linear dependence of *E* vs. $\{\ln[I/(I_l - I)^2] + \sigma n_p G(I/I_l)\}$, i.e., *E* vs. *f*(*I*), is expected with a slope of $(RT/\alpha nF)$. The n_p value, evaluated according to Koppitz et al. (33), is found to be about 2 for all the compounds. The validity of Laviron's model is confirmed by the fact that plots of *E* vs. *f*(*I*) show a good linear shape using the *G* values reported in Table 2 (*G* = 0 corresponds to non interactive Langmuir behaviour).

The $\Gamma_{m,r}$ value can be used to evaluate the area occupied by one adsorbed molecule of each investigated thiopyrimidine on the Hg surface. The values obtained are nearly independent of the solvent and correspond to an area of 40 ± 2 Å^2 for **1**, 45 ± 2 Å^2 for **2**, 51 ± 2 Å^2 for **3**, and 135 ± 4 Å^2 for **4**. The calculated areas (Hyperchem program) for a flat orientation are 38, 41, 48, and 125 Å^2, respectively. As already proposed for **2** and **4** in DMF (4), these data suggest that all the compounds lie flat on the electrode, independent of the nature of the solvent.

A linear correlation can be observed to exist in plots of *G* vs. ε^{-1} (the dielectric constant) (Fig. 4). This kind of comparison could appear to be not completely justified on physical grounds, since *G* should be a corrective factor in the thermodynamic isotherm with respect to ideal behaviour; in spite of this, some information on the nature of the *real* behaviour of the system can be revealed by this type of procedure. *G* is somewhat directly related to the interaction energy among the adsorbed molecules, and its correlation with ε^{-1} suggests that its value is, at least partially, due to electrostatic potentials (34, 35). Since one of the adsorbed species (*r*) is neutral, the hypothesis that a partial charge could be localized on this once it is adsorbed as a result of its interaction with the Hg surface should be considered. It is also worthwhile noting that nonnegligible changes in electron density distribution have been observed when aromatic molecules are adsorbed in a planar disposition (34–36).

Fig. 4. Plot of *G* parameter vs. ε^{-1} for the compounds investigated in a collection of solvents.



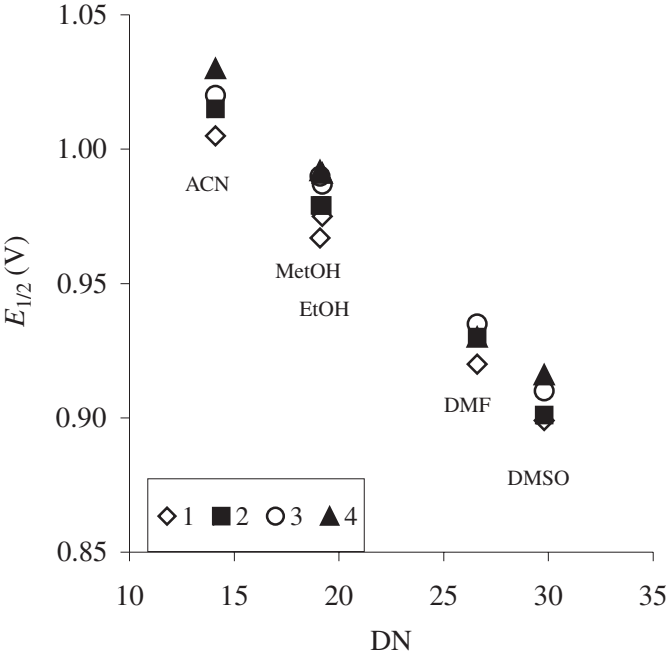


Fig. 5. Plot of $E_{1/2}$ vs. DN (donor number) for the investigated 2-thiopyrimidines in a collection of solvents. $E_{1/2}$ values are referred to the reversible redox couple cobaltocene/cobaltocinium. Base electrolyte 0.1 mol/L TBAP, *T* = 25 °C, thiopyrimidine concentration 5×10^{-4} mol/L.

Plots of $E_{1/2}$ vs. DN (donor number) for the investigated solvents show a rather good correlation for wave II (Fig. 5), while wave I appears to be almost independent of any change in DN value. This result is probably related to the nature of the electrochemical process. In fact, in an electron-transfer process the solvent interactions tend to stabilize the redox state corresponding to the form that carries the higher charge. In our case, the oxidized species, the Hg(I) complex, is the only charged form involved in the electrochemical process, and it should, therefore, interact more strongly with the solvent. Due to its positive charge, DN is the most appropriate and useful solvent index in this type of approach. Actually, the increase in DN value causes a shift in the $E_{1/2}$

© 2005 NRC Canada

values towards more negative values, according to the stabilization of the oxidized species. The low sensitivity of wave I to DN change is probably due to the relatively marginal role played by the solvent in the oxidative processes involving adsorbed species that are predominantly driven by the molecule–surface interaction.

The results indicate that the solvent characteristics affect the oxidation process of Hg in the presence of thiopyrimidines. Electrostatic repulsions among the adsorbed molecules appear to be modulated by the dielectric constant value of the solvent medium, while the disposition of the adsorbed molecules on the electrode surface is found to be independent of the nature of the solvent. The DN values play a certain role in determining the $E_{1/2}$ value and so induce a stabilization of the oxidation product.

Experimental section

All compounds were synthesized according to the literature methods (15, 16).

The electrochemical measurements were performed in dimethylformammide (DMF, Fluka), acetonitrile (ACN, Fluka), dimethylsulfoxide (DMSO, Fluka), ethanol (EtOH, Carlo Erba), and methanol (MetOH, Fluka) dried over 4 Å sieves and stored under Ar in dark bottles. Tetrabutylammonium perclorate (TBAP) (Fluka) was recrystallized from methanol and vacuum dried at 25 °C.

The concentrations of the investigated compounds ranged between 2×10^{-4} and 5×10^{-4} mol dm^{-3} in 0.1 mol dm^{-3} solutions of TBAP as the supporting electrolyte.

The polarographic and voltammetric measurements were carried out using a PAR 273 A Potenziostat–Galvanostat. The working electrode was a Metrohm 463 VA Hg stand, while a Pt ring and a $NaCl_{sat}$ calomel electrode were used as counter and reference electrode, respectively. Coulometric measurements, however, were performed using a Hg pool as the working electrode. All potentials were measured using the satd. aq. NaCl calomel electrode contained in a glass tube separated from the solution by a glass frit of medium porosity, which was located 1 mm from the tip of the working electrode to minimize the ohmic drop, and filled with the supporting electrolyte solution. To compare the results in different solvents, all the potential values were referred to the cobaltocene/cobaltocinium couple, as explicitly indicated. The measurements were all conducted at 25 ± 0.1 °C under an Ar atmosphere in a three-electrode thermostated jacket cell.

A mild and efficient procedure for the conversion of aromatic carboxylic esters to secondary amides

Revika Arora, Satya Paul, and Rajive Gupta

Abstract: A mild and efficient procedure has been developed for the conversion of aromatic carboxylic esters to secondary amides using reusable Zn dust with microwave heating in the presence of *N*,*N*-dimethylformamide or conventional heating by stirring in an oil bath using THF as solvent. Zn dust can be reused several times after simple washing with dil. HCl and distilled water.

Key words: aromatic carboxylic esters, aromatic primary amines, secondary amides, Zn dust, microwave activation.

Résumé : On a mis au point une méthode douce et efficace de transformer des esters d'acides carboxyliques aromatiques en amides secondaires en faisant appel à un catalyseur de Zn en poudre réutilisable, avec chauffage microonde en présence de *N*,*N*-diméthylformamide ou par chauffage conventionnel à l'aide d'un bain d'huile en utilisant du THF comme solvant. La poudre de Zn peut être réutilisée plusieurs fois après simple lavage avec de l'acide chlorhydrique dilué et de l'eau distillée.

Mots clés : esters d'acides carboxyliques aromatiques, amines primaires aromatiques, amides secondaires, poudre de Zn, activation par micro-ondes.

[Traduit par la Rédaction]

Introduction

The amide unit (1) is one of the most widely occurring functional groups as it represents a key feature in many biologically important natural and synthetic products. Numerous methods are available for the preparation of amides. These include ammonolysis of carboxylic acids and derivatives, thermal decomposition of ammonium salts of carboxylic acids, partial hydrolysis of cyanides, etc. The reaction of carboxylic acids with ammonia or amines to provide the corresponding amides is not a mild, efficient, and cost-effective method (2) as it requires the use of expensive reagents like DCC (3), Fe^{3+}-K10 montmorillonite clay (4), molecular sieves (5), silicon tetrachloride in pyridine (6), polymer-supported HOBT (7), chlorosulfonyl isocyanate (8), PCl_3 (9), etc. The other derivatives of carboxylic acids, particularly acyl halides, acid anhydrides and esters, are most commonly used. However, limitations are associated with the use of acyl halides and acid anhydrides and thus esters are preferred. Reactions of ammonia or amines with acyl halides are highly exothermic. Acid anhydrides, especially cyclic anhydrides, easily form imides with ammonia and primary amines.

Usually, reactions with esters require strongly basic catalysts and (or) high pressure. Although quite a number of methods are reported for the conversion of esters to amides (10), most of these have serious drawbacks with regard to toxicity of the reagent, particularly those involving tin compounds (10*b*, 10*c*), operational simplicity and efficiency. Thus, in recent times other approaches involving *N*-acylimidazoles (11), *N*-acylbenzotriazoles (12), and indium triiodide (13) have been demonstrated that also are not very simple and cost effective. Thus, there is a need to develop a simple, mild, cost-effective, and environment friendly procedure for the preparation of secondary amides. Some microwave-assisted synthesis of amides in the presence of strong bases has been reported (14–16).

In recent years, metal- or metal-salt-catalyzed reactions (17) are finding considerable attention because metals can be removed by simple filtration and be reused several times only by washing with suitable solvents. Among various metals, Zn dust (18) is attracting great attention because of its easy availability, inexpensiveness, and nontoxic nature. Recently, we have reported the use of reusable Zn powder for the Friedel–Crafts acylation (19), the Fries rearrangement (20), and the Williamson ether synthesis (21), and here we wish to report another successful application of Zn dust for the conversion of aromatic carboxylic esters to secondary amides by treatment with primary amines with microwave heating in the presence of *N*,*N*-dimethylformamide or conventional heating by stirring in an oil bath using THF as a solvent (Scheme 1).

Results and discussion

To demonstrate the applicability of this method, a series of secondary amides were prepared in good to excellent yields by taking various substituted methyl benzoates and aromatic primary amines using Zn dust with both microwave (MW) heating (70%–91%) or stirring in an oil bath at 70 °C using THF as the solvent (70%–84%).

Firstly, with MW heating, experimental conditions were carefully monitored to regulate the use of Zn dust, irradiation time, and power level to achieve the optimum conditions. The 1:1 ratio of an ester and amine was the most acceptable one, whereas 0.5 equiv. each of Zn dust and DMF were required to allow the reaction to proceed efficiently. The power level of 640 W was found to be the most acceptable as the low power level gave low yields along with prolonged reaction time, whereas, at a high power level, charring of the reaction mixture was observed. Further, the addition of DMF along with Zn dust in the ratio of 1:1 was very important as without DMF, the reaction did take place, but after 10 s of irradiation, the reaction became violent and charring of the reaction mixture was observed. So the role of DMF is possibly to make the reaction medium homogeneous and absorb some of the extra energy so that the reaction proceeds safely (every reaction was repeated four times to ensure that the reaction proceeds safely). Further, the amount of Zn dust to be used was examined. If a lesser amount of Zn dust was used, the product yield was low and with more amounts, the reaction became violent, which could burn the reaction mixture. The work-up procedure is simple, involving dilution with DMF and filtration followed by the addition of crushed ice.

With conventional heating (stirring in an oil bath), the optimum conditions selected are: for 5 mmol of an ester and amine each, 2.5 mmol of Zn dust, 10 mL of THF as the solvent, and 70 °C as the reaction temperature. When compared with MW heating, the yields of the products using oil-bath heating were lower and also the reaction times were longer (Table 1).

To see whether the formation of amides was catalyzed by commercially available Zn dust, the reaction of methyl benzoate (5 mmol) with aniline (5 mmol) was carried out in the absence of Zn dust with MW heating using DMF (2.5 mmol) or by stirring in an oil bath at 70 °C using THF (10 mL) as the solvent (product **3a**, Table 1). It was found that under conditions similar to those described for Zn dust, no reaction was observed on TLC (2 min under MW irradiation and 16 h in the case of oil-bath heating). Thus, Zn dust catalyzes the conversion of carboxylic esters into secondary amides.

Since the reactions were not carried out under an inert atmosphere and unpurified commercially available zinc dust was used, there may be a possibility of the formation of ZnO, which may catalyze the reaction. To see whether the reaction was catalyzed by Zn or ZnO, we carried out the reaction in the case of product **3a** using 0.5 equiv. of ZnO, instead of Zn dust, under the same conditions as described for the microwave and oil-bath heating experiments. It was found that we were not able to isolate the desired product after the final work-up (10 min under MW irradiation and 16 h using oil-bath heating). This observation clearly indicated that the formation of secondary amides was catalyzed by Zn dust.

The Zn powder can be reused six times after simple washing with diethyl ether and dilute HCl without much loss of activity, thus rendering the process more economical (Table 2).

To check the possibility of specific nonthermal MW effects for the Zn catalyzed conversion of aromatic carboxylic esters to secondary amides, we carried out the reaction of aniline with methyl benzoate (product **3a**, Table 1) using a preheated oil bath at 135 °C (temperature measured at the end of the reaction in the MW oven) for 2 min, keeping all other conditions identical as for the MW experiment. It was found that no reaction took place (TLC), although a yield of 60% was obtained when the reaction time was extended up to 12.5 h. This observation suggests that the effect of MW irradiation is not purely thermal. The results are summarized in Table 3.

Experimental

Melting points were determined on a Buchi melting point apparatus and are uncorrected. ^{1}H NMR spectra were obtained on a Bruker DPX-200 NMR spectrometer (200 MHz) in $CDCl_3$, with tetramethylsilane as the internal standard, and IR spectra were recorded using a KBr disc on a FT-Bruker Vector 22 spectrophotometer. The mass spectral data

was obtained on a JEOL JMS-D 300 spectrometer. The reactions were monitored by TLC. For the microwave irradiation experiments described in the following, a conventional (unmodified) household microwave oven equipped with a turntable was used (LG Little Chef MS 194 W operating at 2450 MHz having a maximum output of 800 W).

General procedure for the synthesis of secondary amides in the presence of Zn dust

Microwave heating approach

To a mixture of the aromatic carboxylic ester (5 mmol), the appropriate aromatic amine (5 mmol), and Zn dust (2.5 mmol) in a 50 mL borosil beaker, DMF (2.5 mmol) was added. The reaction mixture was mixed thoroughly with a glass rod (10 s) and then irradiated in a microwave oven for an appropriate time (Table 1) at 640 W. After cooling, DMF (5 mL) was added and the reaction mixture was filtered. To the filtrate, ice-cold water (100 mL) was added and the product extracted with ethyl acetate (3 × 15 mL). The combined extracts were washed with water and dried over anhydrous sodium sulfate. The product was obtained after the removal of the solvent under reduced pressure followed by crystallization from EtOAc – petroleum ether or by passing through a column of neutral alumina and elution with petroleum ether.

Oil-bath heating approach

To a mixture of the aromatic carboxylic ester (5 mmol), the appropriate aromatic amine (5 mmol), and Zn dust

(2.5 mmol) in a round-bottomed flask (50 mL), THF (10 mL) was added. The round-bottomed flask was fitted with a reflux condenser and the reaction mixture was stirred at 70 °C in an oil bath for an appropriate time (Table 1). After completion (monitored by TLC), the reaction mixture was cooled and filtered. The THF was removed under reduced pressure and the product was obtained by the same procedure as described for the MW experiment.

The structures of the products were confirmed by ^{1}H NMR, IR, mass spectral data, and by comparison with authentic samples.

Conclusion

In conclusion, we have developed an efficient procedure for the synthesis of secondary amides using Zn dust with MW heating in the presence of DMF or by stirring in an oil bath using THF as a solvent. The salient features of our method is that it is simple, rapid, economic, general, and environment friendly, and Zn dust can be reused several times without much loss of activity. This method could be a very efficient alternative to other existing methods.

Calmodulin antagonists: Structure of *N*-(6-aminohexyl)-5-chloro-1-naphthalenesulfonamide hydrochloride (W-7) and comparison with trifluoperazine (TFP) — Calmodulin binding

Andrew Hempel, Norman Camerman, Donald Mastropaolo, and Arthur Camerman

Abstract: The crystal structure of the title compound contains one *N*-(6-aminohexyl)-5-chloro-1-naphthalenesulfonamide hydrochloride molecule in the asymmetric unit. The molecule adopts an extended conformation with a linear hexyl group. Protonation occurs at the side chain terminal nitrogen atom. Hydrophobic packing and a three-dimensional hydrogen-bond network, involving all the hydrogen atoms capable of making hydrogen-bond contacts, stabilizes the crystal structure. Due to head-to-head and tail-to-tail arrangement of these hydrophobic molecules, an unusually long cell constant (b = 61.27 Å) characterizes the crystal structure. A stereochemical comparison with trifluoperazine suggests similar calmodulin binding mechanisms.

Key words: crystal structure, stereochemistry, W-7, calmodulin binding, TFP.

Résumé : La structure cristalline du composé mentionné dans le titre contient une molécule de chlorhydrate de *N*-(6-aminohexyl)-5-chloronaphtalène-1-sulfonamide par unité asymétrique. La molécule adopte une conformation étendue avec un groupe hexyle linéaire. La protonation se produit sur l'atome d'azote de la chaîne latérale. Un empilement hydrophobe et un réseau de liaisons hydrogènes tridimensionnel impliquant tous les atomes d'hydrogène capable de faire des contacts par liaisons hydrogène stabilise la structure. En raison de l'arrangement tête-à-tête et queue-à-queue de ces molécules hydrophobes, la structure cristalline est caractérisée par une constante de cellule particulièrement longue (b = 61,27 Å). Une comparaison stéréochimique avec la trifluopérazine suggère l'existence de mécanismes de fixation semblables à ceux de la calmoduline.

Mots clés : structure cristalline, stéréochimie, W-7, fixation de calmoduline, TFP.

[Traduit par la Rédaction]

Introduction

N-(6-Aminohexyl)-5-chloro-1-naphthalenesulfonamide (W-7) (Scheme 1) belongs to a group of vasodilating agents like sphingosine, W-5, and trifluoperazine (TFP), which were noted to relax blood vessels by inhibition of calmodulin-mediated processes involving actin and myosin (1, 2). Regarded as a calmodulin (CaM) antagonist, W-7 binds directly to the active, calcium saturated ($4Ca^{2+}$) form of CaM (3). Initiation of the smooth muscle contraction is associated with Ca^{2+} binding to CaM. W-7 and other calmodulin antagonists (sphingosine, trifluoperazine, calmidazolium) effectively block Ca^{2+} elevation through interaction with calmodulin-dependent processes (2). We have performed an X-ray analysis of W-7 to determine if there are stereochemical features shared by W-7 and the known calmodulin antagonist TFP that may be responsible for their apparent similar biological activity.

Experimental

The compound was synthesized at the Department of Pharmacology, Mie University School of Medicine, Edobashi, Japan, and made available to us by Professor H. Hidaka. Crystals of W-7 suitable for X-ray analysis were obtained by very slow crystallization from 95% ethanol. A crystal of dimensions 0.40 mm × 0.27 mm × 0.22 mm was used to obtain lattice parameters and X-ray intensities. Systematic absences visible on precession photographs taken with CuKα radiation were consistent with the space group *Pbca*. The cell parameters were determined from the least-squares refinement of the angular positions of 16 high angle

reflections with 40° ≤ 2Θ ≤ 60°. Intensity data were collected using a Θ ÷ 2Θ scan mode with Ni filtered CuKα radiation on a Picker FACS-1 four-circle diffractometer. The scan speed was 2°/min, and three standard reflections monitored every 100 reflections showed only random variations of 4% in intensity. A total of 3130 unique reflections within the range 3° ≤ 2Θ ≤ 130° were recorded, 1916 with $I > 2\sigma(I)$ were considered observed. The intensities were corrected for Lorentz and polarization factors and also for absorption from empirical data obtained using ϕ scan (4).

Solution and refinement of the structure

The structure was solved by direct methods and refined using SHELXS-97 and SHELXL-97 (5). The best solution E-map revealed all the atoms of the molecule heavier than hydrogen. The hydrogen atoms at N19 and N12 nitrogen atoms were found from a difference electron density map. The remaining hydrogen atoms were fitted geometrically and during the refinement were "riding" on host atoms. The final discrepancy index converged at *R* = 7.76% and *S* = 1.006 for the 1916 observed reflections. A final difference electron density map contained a featureless residual density of +0.49 and –0.48 e/Å^3. The highest residual density peaks and holes were located in the vicinity of chlorine and sulfur atoms. The data collection, solution, and refinement details are summarized in Table 1. The final positional parameters and equivalent isotropic temperature factors are listed in Table 2.

Discussion

The molecular structure of W-7 and the atom numbering is shown in Fig. 1. The naphthalene ring system is planar within experimental error, and bond distances and angles in the molecule do not differ significantly from expected values. The aminohexyl side chain adopts a fully extended conformation, roughly perpendicular to the naphthalene plane. A difference electron density calculation clearly showed three hydrogen atoms at N19, indicating it as the protonation site. A projection of the crystal structure-packing diagram is presented in Fig. 2. The molecules are arranged in a head-to-head and tail-to-tail manner along the *b* direction. Hydrogen bonds between the amino hydrogen atoms and the chloride ions and Van der Waals and stacking π interactions hold the molecules in the crystal. The chloronaphthalene rings are stacked perpendicular to the *a* axis direction, and the aminohexyl groups form parallel chains. All the hydrogen atoms capable of participating in hydrogen bonds are involved. The details of the hydrogen bond geometry are shown in Table 3. The chloride ions are hydrogen bonded to three N19 hydrogen atoms (H19A, H19B, and H19C) involving three different W-7 molecules, with very similar geometric parameters.

Binding of W-7 to calmodulin

Calmodulin is a small calcium binding protein with four Ca^{2+} binding sites, two in each C- and N-terminal domain. CaM antagonists like W-7, W-5, TFP, and sphingosine bind in hydrophobic patches of the protein, subsequently inhibiting CaM dependent processes of the activation of various intracellular enzymes (phosphodiesterase, myosine kinase, brain adenylate cyclase, Ca^{2+} ATPase, phosphorylase kinase). The CaM molecule was shown to possess two high-affinity apolar pockets, one of which is located in the N-terminal domain and the second, with an affinity of more than an order of magnitude higher, in the C-terminal region (6). Studies have shown that the affinity of pharmacological agents, known as calmodulin antagonists, is related to their hydrophobicity. Structure–activity relationship investigations also concluded that a positive charge at some distance from the phenothiazine moiety of TFP is essential when interacting with CaM (7). Comparative molecular modeling studies of TFP binding to calmodulin have shown the feasibility of the hydrophobic phenothiazine rings to stack against the residues in the hydrophobic cleft, while the positively charged piperazine ring nitrogen atom extends out to make contacts with negatively charged residues residing on the outer rim of the hydrophobic pocket (8).

Although chemically dissimilar to TFP, W-7 possesses certain structural features in common. The two molecules share a similar overall shape, both have hydrophobic ring systems, phenothiazine in TFP and chloronaphthalene in W-7, and the side chain of W-7 has an extended conformation, similar to that found in the crystal structure of TFP (9), with enough flexibility to adjust to the negatively charged acidic residues lining the outsides of the hydrophobic pocket of the protein. Another important feature common in both compounds is a positively charged nitrogen atom at some distance from the hydrophobic region. In W-7 the separation between the hydrophobic naphthalene moiety and the terminal positively charged atom N19 is similar to the distance from the hydrophobic phenothiazine ring to the positively charged side chain piperazine ring nitrogen in TFP, a feature that for TFP was shown to be important in binding to calmodulin (7). More recent molecular modeling studies of interactions between tamoxifen and some of its derivatives

Fig. 3. Stereoscopic comparison of stereochemistries of W-7 (large circles) and TFP (small circles) based on flexible fitting of the W-7 side chain.

with calmodulin also showed the importance, for binding, of similar structural features, i.e., a well-defined hydrophobic part and a side chain with the terminal atom capable of being protonated (10). Three crystal structure determinations of a Ca^{2+}–CaM–TFP complex have been reported: one (11) found only one TFP molecule bound to the protein in the C-terminal hydrophobic pocket, while the second (12) found four TFP molecules in the structure, the one with the highest occupancy in the same position in the C-terminal pocket but with a completely different orientation. The third determination (13) reported two TFP molecules in the complex, occupying the two best-defined sites of the four-TFP structure, but showing no evidence for TFP molecules in the other two sites. The forces responsible for binding TFP molecules to Ca^{2+}CaM are mainly hydrophobic and to a lesser degree electrostatic in nature, involving acidic side chains of CaM Glu residues and a positively charged nitrogen atom of the TFP side chain piperazine ring. Solution structure studies of a Ca^{2+}–CaM–W-7 complex determined by multidimensional NMR spectroscopy have been interpreted to indicate that the structure contains two W-7 molecules, one in each N- and C-terminal hydrophobic pocket (14). A postulated structure for W-7 in that complex has a position and ring orientation different from that of TFP, but that postulation was totally arbitrary.[3] Thus, resolution problems in the protein-inhibitor complexes result in conflicting evidence both on the numbers and positions of TFP (and, presumably, W-7) with respect to Ca^{2+}–CaM and in any relationships to W-7 binding to the protein.

A report on Ca^{2+}–CaM–W-7 solution structure studies using small-angle X-ray scattering and NMR shows that W-7 induces structural change in CaM resulting in a globular shape caused by an inter-domain compaction (15), similar to the situation observed in the Ca^{2+}–CaM–TFP crystal structure complexes (11, 12), again indicating similarities in the effects of TFP and W-7 binding to Ca^{2+}–CaM.

A flexible fitting of W-7 and TFP is presented in Fig. 3 and shows the main structural features (positively charged nitrogen atoms, chlorine atom and trifluoromethyl group, and overall stereochemistry) responsible for binding of TFP to overlap well with those of W-7. The positively charged nitrogen atom of W-7 overlaps with its counterpart in TFP, and the chlorine atom is in a very close proximity to the trifluoromethyl group of TFP. Hydrophobic rings of the two compounds also show a good overlap.

On the basis of the X-ray structure investigation of W-7 and the flexible fitting of the two substrates along with the arguments presented above, it is appropriate to conclude that the stereochemistry and the mechanism of binding of W-7 to calmodulin are likely to be similar to that of TFP.[4]

Catalyzed β scission of a carbenium ion — Mechanistic differences from varying catalyst basicity

Qingbin Li and Allan L.L. East

Abstract: The β-scission mechanism of physisorbed and chemisorbed pentenium ions, as catalyzed by $AlH_2(OH)_2^-$ and by $AlHCl_3^-$ anions, was investigated using density functional theory computations and explicit-contact modelling. A thorough search of intermediates was performed for each catalyst. On the aluminum chloride, β scission of an aliphatic, secondary carbenium ion featured chemisorbed and physisorbed ion intermediates, while on the aluminum hydroxide, β scission featured chemisorbed ions but physisorbed *neutral* species. The importance of this work is its demonstration of a qualitatively different mechanism, with qualitatively different intermediates, due only to the different basicity of the two catalysts.

Key words: C—C bond fission, β scission, carbenium ion, catalysis, mechanism.

Résumé : Faisant appel à la méthode de calculs de la théorie de la densité fonctionnelle et à la modélisation par contacts explicites, on a étudié le mécanisme de la scission β d'ions penténium physisorbés et chimisorbés, tel que catalysée par les anions $AlH_2(OH)_2^-$ et $AlHCl_3^-$. Pour chacun des catalyseurs, on a fait une étude approfondie des intermédiaires. Sur le chlorure d'aluminium, la scission β d'un ion carbénium secondaire et aliphatique implique des intermédiaires ioniques chimisorbés et physisorbés alors que sur l'hydroxyde d'aluminium, la scission β implique des ions chimisorbés, mais des espèces neutres physisorbées. L'importance de ce travail est de démontrer que, en raison seulement de différences dans les basicités des deux catalyseurs, que les réactions impliquent des mécanismes qualitativement différents avec des intermédiaires qualitativement différents.

Mots clés : fission d'une liaison C—C, scission β, ion carbénium, catalyse, mécanisme.

[Traduit par la Rédaction]

Introduction

Alkane cracking can be catalyzed by solid zeolites (aluminosilicates), chloroaluminate ionic liquids (1), and liquid superacids (2) such as $HF{\cdot}SbF_5$ and $HSO_3F{\cdot}SbF_5$ (having a great deal of ionic-liquid character). The cracking is generally performed by carbenium ions in a chain reaction (3), where the first step is hydride abstraction by a little carbenium ion to make a big carbenium ion, and the second step is β scission of the big carbenium ion, e.g.,

$$CHR_2\text{-}CH_2\text{-}C^+HR' \rightarrow C^+HR_2 + CH_2{=}CHR'$$

to create another little carbenium ion. The net result is cracking of the big alkane.

Upon closer scrutiny, the mechanism of the β-scission step must be different for different catalysts. From product distribution studies, several scientists (3–7) suggested that carbenium ion chemistry as observed in liquid superacids could be applied to the reactions on zeolites, although the product distributions were generally different. However, the direct comparison to liquid superacid chemistry was called into question by both experimental studies (8, 9) and theoretical computations (10, 11), which suggested that bound alkoxy groups (chemisorbed carbenium ions), rather than labile (physisorbed) carbenium ions, are the intermediates on zeolite surfaces (12, 13).

The success of those initial computations, combined with the belief that the differences may be due to large structural physical effects of the zeolite, pushed some computational chemists into invoking "large-scale" computational modelling in which the number of atoms in the calculation is maximized by invoking further computational approximations. Currently, however, this field is still in its infancy, limited in its accuracy by the approximations required to do large-scale modelling. A good example of this is the work of Demuth et al. (14), who modelled the isomerization of 2-pentene (actually, chemisorbed 2-pentenium ion to chemisorbed 2-methyl-1-butenium ion) in a ZSM-22 zeolite with a large-scale simulation, invoking periodic boundary conditions, the PW91 exchange functional, a plane-wave basis set, and approximate transition states. Their computations produced a physisorbed carbenium ion that would be observably stable, with barriers of 8 kcal mol^{-1} for chemisorption and 18 kcal mol^{-1} for proton transfer to the catalyst (1 cal = 4.184 J). This is in complete disagreement with in situ magic-angle-spinning nuclear magnetic resonance (MAS NMR) studies,

in which physisorbed nonaromatic carbenium ions have been eagerly searched for but never found (9, 15–22).

Despite the limitations on large-scale computational modelling, quantum chemical calculations are still a powerful tool in studying and understanding these molecular mechanisms. For example, the effect of the relative acidity or basicity of the catalyst upon the mechanism can be studied, without the need to invoke large-scale modelling. In 2003, our group published a theoretical study on an idealized Bronsted acid catalytic cycle for $C_6H_{14} \rightarrow C_3H_8 + C_3H_6$, using small cationic Bronsted acids in the computations (23). There we demonstrated that the existence of certain intermediates varied with the catalyst, simply because of the acidity of the catalyst. Here, we are going to show that varying catalyst basicity can change the catalyzed β-scission mechanism of $C_5H_{11}^+ \rightarrow C_2H_5^+ + C_3H_6$.

Modelling real systems is not a goal of this paper. If large-scale computational modelling of zeolites and ionic liquids could be achieved, and the results demonstrated a difference in mechanism, we would likely still be unable to state which aspect of the two catalysts is the most important one responsible for the mechanism change. Fundamental studies are required, and this is one of them. Also, we are certainly not suggesting that the change in relative basicity is the only reason for the mechanism change between zeolites and ionic liquids. We are simply providing the extremely important demonstration that relative catalyst basicity can be responsible for qualitative changes in the β-scission mechanism.

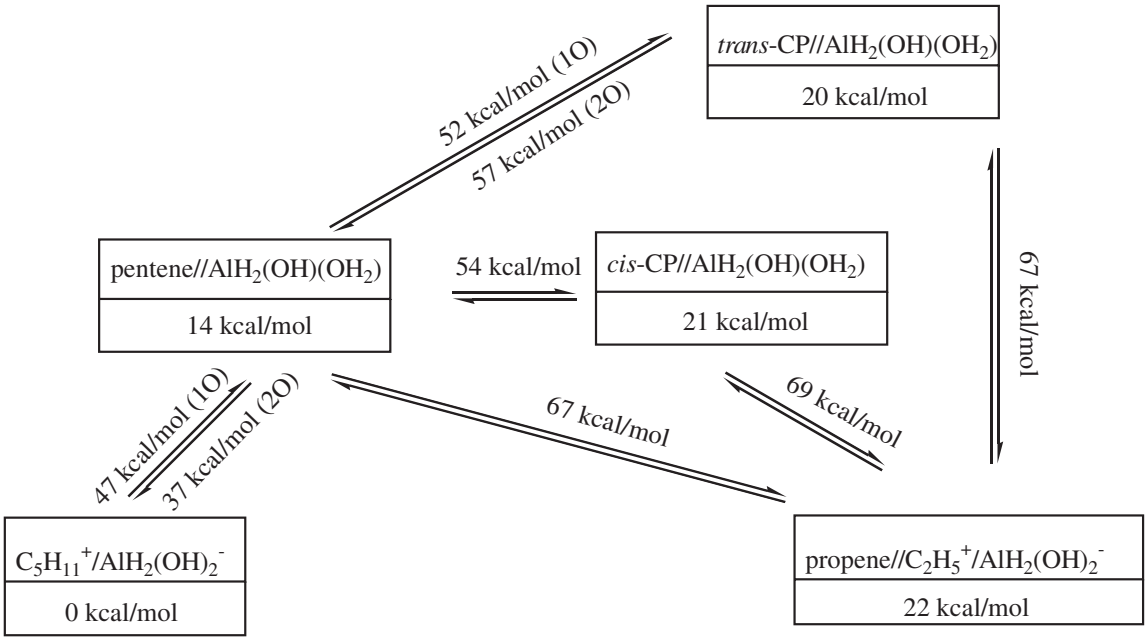
This paper is a computational chemistry study of the mechanisms, i.e., minimum energy pathways, used by the aluminum chloride $AlHCl_3^-$ and the aluminum hydroxide $AlH_2(OH)_2^-$ in performing the β scission of 2-pentenium ion into ethenium ion and propene. All the pathways start and end with covalently bound (chemisorbed) ion–catalyst complexes, as influenced by the β-scission study by Frash et al. (FKRS) (24). The initial purpose was to investigate the β scission with $AlHCl_3^-$ and compare these results to the results of FKRS who used $AlH_2(OH)_2^-$. However, it was soon discovered that the potential energy surface for the reaction on $AlH_2(OH)_2^-$ is even more complex than those reported by FKRS, and a direct comparison required a thorough investigation with one carbenium ion (2-pentenium ion), one level of theory (B3LYP/6-31G(d,p)), and the two catalyst fragments. We will compare our results with the other published computational studies of cationic β scission, which are the β-scission papers of FKRS (24) and Hay et al. (25), and the reverse β-scission (oligomerization) paper of Svelle et al. (26).

This paper is not addressed solely to those interested in the effects of varying the basicity of a catalyst. We hope it is also of interest to organic chemists interested in catalysis at the molecular level, and to surface scientists interested in the nature of physisorbed and chemisorbed states (27) on compound surfaces like metal oxides.

Methods, models, and terminology

All calculations used the semi-empirical density functional theory model called B3LYP (28, 29) with the 6-31G(d,p) orbital basis set (30). Molecular geometries and harmonic frequencies for intermediates and transition states were computed using analytic first and second derivative formulae, as are routine with most quantum chemistry codes. All reported results come from calculations with the GAUSSIAN 98 software suite (30) using the default numerical grid. In most cases, the PQS 3.0 software suite (31) was used to speed up transition-state searches because of its parallelism and because the Baker eigenvector-following algorithm (32) is not restricted to 50 variables, as it is in GAUSSIAN 98. However, because the default grid in PQS 3.0 is finer, the B3LYP energies between the two codes are not compatible, and final results were run with GAUSSIAN 98. The energies reported are not corrected for zero-point vibrational energies or thermal corrections, primarily to maintain focus on the underlying (and complicated) potential energy surface (PES).

Explicit-contact modelling was used with small catalysts. The catalysts are small for several reasons. First, this study required thorough searches of two tricky potential energy surfaces, so we wanted to compute real transition states in full-coordinate space (63 and 57 degrees of freedom, respectively), and properly verify each one by following the connections from these to the intermediates on either side; this cannot be done with larger catalyst models. Second, the 1998 FKRS study (24) with pentenium ion and $AlH_2(OH)_2^-$ was incomplete, and we wished to make use of the stationary points they had. Third, the $AlHCl_3^-$ catalyst was chosen from our exploratory ionic liquid calculations (33), which suggest that the active $Al_2Cl_7^-$ Lewis acid anion (34, 35) will create $AlHCl_3^-$ upon hydride abstraction from an alkane.



We will use the word chemisorbed to describe states in which there is a covalent bond between catalyst and reactant; this refers to states that have been variously called alkoxy, σ bonded, or alkyl silyl ether. We will use the word physisorbed to describe van der Waals neutral-pair complexes of catalyst and reactant, but also ion-pair (cation–anion, or sometimes called "zwitterionic") complexes. Some ion-pair complexes have an ionic bond strong enough to be considered chemisorbed, but in our systems the dissociation energies are much smaller because a proton transfer would occur if the molecular ions were pulled apart, resulting in neutral dissociated molecules. Although the concepts of chemisorbed and physisorbed states are taken from surface-science terminology (27), we think these states may prove to be pervasive in homogeneous as well as heterogeneous catalysis. We will use single and double slashes to denote chemisorbed and physisorbed complexes, respectively (e.g., $C_5H_{11}^+/AlHCl_3^-$ vs. $C_5H_{11}^+//AlHCl_3^-$). We will refer to the conversion from chemisorbed to physisorbed as ascension, and the opposite as descension, since the terms desorption and adsorption strictly refer to molecules leaving and approaching the surface.[2]

For most stationary points, there is more than one possible orientation of the reactant relative to the catalyst, and many possibilities were investigated. These possibilities are usually indistinguishable in energy on the scale of the reaction pathway, as will be demonstrated. Our atom-numbering con-

Scheme 1. Overview of the B3LYP/6-31G(d,p) potential energy surface for the β scission of 2-pentenium ion on the $AlH_2(OH)_2^-$ catalyst fragment. Notation: chemisorbed (/), physisorbed (//), dimethylcyclopropane (CP). Transition-state energies are listed as well, including two values in cases where two distinct paths were found for the same step in the mechanism.

vention will be to count the carbon atoms as C1, C2, C3, C4, and C5, such that the C2 atom is initially bound to the O1 or Cl1 atom of the catalyst in the chemisorbed state.

The transition states that were located had only one imaginary vibrational frequency corresponding to the desired reaction coordinate. Each transition state was validated by two verification minimizations (to locate the two relevant intermediates) from displaced geometries on either side of the transition state. The displaced geometries for these verification runs were obtained by identifying the key internal coordinates in the crucial normal mode via the animation of the imaginary frequency, and then displacing these coordinates in both directions (minus or plus 0.03 Å for bond lengths; minus or plus 3° for angles and dihedrals).

Finally, we define some abbreviations for the rest of the article: potential energy surface (PES), dimethylcyclopropane (CP), protonated dimethylcyclopropane (PCP) (the prevalent form of a poorly solvated or gas-phase 2-pentenium ion).

Results

$AlH_2(OH)_2^-$ catalyst

Scheme 1 shows an overview of the results for the β scission of a chemisorbed 2-pentenium ion on $AlH_2(OH)_2^-$, to form a chemisorbed ethenium ion and a physisorbed propene. The only first step we could find is ascension to a physisorbed, neutral 1-pentene. After ascension, the physisorbed 1-pentene was found to be able to produce the intended products via more than one path. The direct one is Bronsted acid catalyzed β scission; the indirect paths involve Bronsted acid catalyzed isomerization of physisorbed 1-pentene to physisorbed *cis*- or *trans*-CP, followed by Bronsted acid catalyzed fission of two simultaneous C—C bonds. FKRS had presented the transition state for only the second step of one of the indirect routes (24); we believe it is the step from *trans*-CP to products.

On this PES, all the physisorbed intermediate states are neutral-pair complexes. For the various transition states, there are varying degrees of charge separation between catalyst and reactant, as caused by proton transfer. Also, as FKRS had found (24), direct β scission from a chemisorbed state is not a minimum energy pathway on this PES. We now describe the various steps on this PES in more detail.

Ascension step

Figure 1 shows the 3D images of the stationary-point geometries for three different versions of the ascension of 2-pentenium to 1-pentene on $AlH_2(OH)_2^-$. Figure 2 has sketches of the transition states that demonstrate the bond rearrangement mechanism. Table 1 provides some geometric data for the nine structures of Fig. 1 using the atom numbering of Fig. 2.

All three transition states feature partial ascension of the pentenium cation, as well as partial proton transfer from it to the catalyst anion to avoid the creation of an ion pair. In the top row path, the transferring proton goes from C1 to O1 (the single oxygen pathway, Fig. 2*a*), while in the other two paths the proton goes from C1 to O2 (the two oxygen pathways, Fig. 2*b*), and all three paths result in the coordination of the newly formed OH bond of the catalyst to the pentene double bond. The involvement of the second oxygen atom lowers the barrier height from 47 to 37 kcal mol^{-1}.

The lower two paths in Fig. 1 only differ by the conformer of the hydrocarbon; the middle path produces a gauche alkene from an all-trans alkoxy species, while the bottom path in the figure produces a *cis*-alkene from a gauche alkoxy species. While the lower two pathways are isoenergetic with this model fragment, a truer zeolite surface would probably make gauche alkoxy forms more favoured

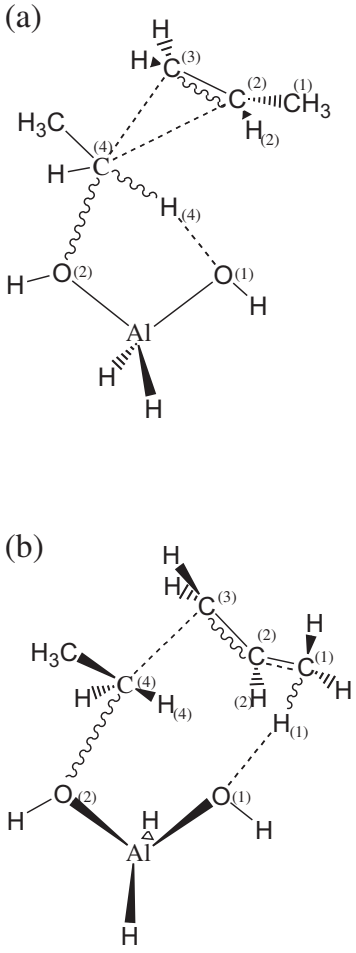
double-proton transfer step. The top two paths in the figure are single oxygen pathways (Fig. 4*a*) in which departing and incoming protons use the same oxygen atom, while the bottom path is a two oxygen pathway (Fig. 4*b*). All three paths result in a newly formed OH bond on the catalyst that coordinates to the region of the two tertiary carbons C2 and C4. Unlike in the ascension step, the two oxygen path has a higher barrier than the single oxygen paths in the cyclization step, although the difference here is smaller (43 vs. 38 kcal mol^{-1}).



The two upper paths in Fig. 3 only differ by the conformation; the top path forms *cis*-CP from a trans-gauche pentene, while the middle path forms *trans*-CP from all-gauche pentene. Since our two oxygen pathway produced *trans*-CP, this model fragment might also produce a two oxygen pathway that forms *cis*-CP.

Scission step

Figure 5 shows the 3D images of the stationary points for three different versions of the scission step that produces chemisorbed ethenium ion and physisorbed propene. Figure 6 has sketches of the transition states that demonstrate the bond rearrangement mechanism. Table 3 provides some geometric data for the nine structures of Fig. 5, using the atom numbering of Fig. 6.

All three paths involve a transition state in which a proton has transferred from a catalyst oxygen to the hydrocarbon, and the C4 atom has migrated in an S_N2-like fashion between C3 and a second catalyst oxygen (all two oxygen pathways). In the upper two versions in Fig. 5, products are

Fig. 6. Transition-state sketches for the scission (cracking) steps on $AlH_2(OH)_2^-$: (*a*) the dimethylcyclopropane pathways; (*b*) the pentene pathway. The dashed lines indicate bonds in the reactant, while the squiggly lines indicate bonds in the product.

created from CP (Fig. 6*a*), and all the action happens at the C4 atom; it sheds its bonds to C2 and C3 and creates bonds to the Bronsted proton and a catalyst oxygen. The bottom path creates the products directly from pentene (Fig. 6*b*) by transferring the catalytic proton to C1, and allowing the C4 atom to break its bond to C3 and form its bond to the catalyst. The three transition states are very isoenergetic, lying in a 69–72 kcal mol^{-1} range relative to the products.

The two upper paths in Fig. 5 only differ by conformation; the top path starts with *cis*-CP, while the middle path starts with *trans*-CP. The three versions of the products appearing in Fig. 6 represent three different orientations of the ethyl and propene groups on the catalyst.

$AlHCl_3^-$ catalyst

Scheme 2 shows an overview of the results for the same β-scission reaction, but with $AlHCl_3^-$ as the catalyst. There are two significant differences between this PES and that from $AlH_2(OH)_2^-$ catalysis. One is the absence of minimum energy pathways involving physisorbed neutral-pair intermediates; instead, a barely stable ion-pair intermediate is seen (upper path in Scheme 2), involving a physisorbed, protonated *cis*-PCP. The second difference is that there is a

Scheme 2. Overview of the B3LYP/6-31G(d,p) potential energy surface for the β scission of 2-pentenium ion on the $AlHCl_3^-$ catalyst fragment. Notation: chemisorbed (/), physisorbed (//), protonated dimethylcyclopropane (PCP). Transition-state energies are listed as well.

direct one-step β-scission pathway from chemisorbed 2-pentenium ion. Several bombed searches suggest that a *flat*, *wide energy shelf* for PCP exists for both paths on the PES; PCP is barely stable in the upper pathway and not stable on the lower pathway.

The PES is also fairly flat in the region of neutral pair physisorbed intermediates. Here, the flat PES caused difficulties when using GAUSSIAN 98 frequency runs to verify stationary points because, in a few cases, a low-frequency mode had a frequency below the noise level of the normal mode diagonalization. This appears to be due to the coarse DFT numerical grid; when we switched to the "ultrafine" grid, we were able to definitively find four physisorbed intermediates (two ion pair and two neutral pair), and two transition states for conversion of these neutral-pair ones to ion-pair ones. In Scheme 2, the $PCP^+//AlHCl_3^-$ intermediate sits at 24 kcal mol^{-1}; the other three physisorbed minima are at 21 kcal mol^{-1} ($pentenium^+$), 21 kcal mol^{-1} (pentene), and 28 kcal mol^{-1} (CP), and the transition states are at 22 kcal mol^{-1} ($pentenium^+ \rightarrow$ pentene) and 30 kcal mol^{-1} ($PCP^+ \rightarrow$ CP). We are not presenting these results in Scheme 2 because: (*i*) no paths leading to β scission could be found from these minima; and (*ii*) they required the ultrafine grid.

In both β-scission pathways in Scheme 2, the hydrogens never leave their respective carbon partners. The C2—Cl1 and C3—C4 bonds are broken, and a C4—Cl3 bond is formed (both are two chlorine pathways). The presence of three chlorines in our catalyst model may prevent a *trans*-PCP intermediate from forming vis-à-vis the cis form.

Ascension step

We present only one path for the ascension of 2-pentenium ion on $AlHCl_3^-$; Fig. 7 shows the 3D images of its stationary-point geometries. Figure 8 has the sketch of the transition state demonstrating the "hydrogen bonds" between catalyst and reactant, and Table 4 provides some geometric data for the three structures of Fig. 7 using the atom numbering of Fig. 8.

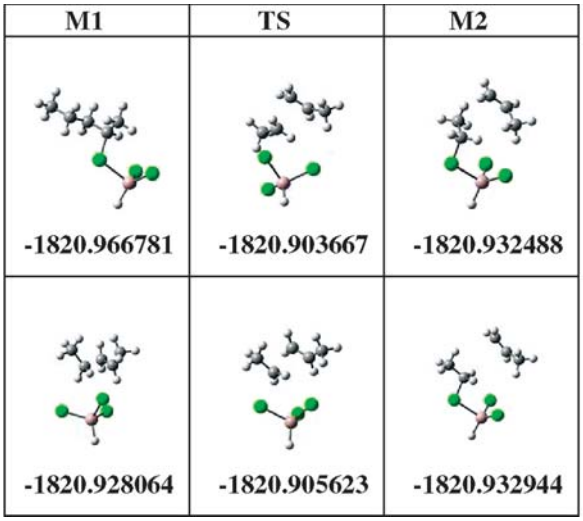
Fig. 7. B3LYP/6-31G(d,p) stationary points for the ascension step found on $AlHCl_3^-$.

The chemisorbed state has a C2—Cl1 distance of 1.9 Å. After ascension, the physisorbed pentenium ion has a structure that some scientists describe as an edge-protonated cyclopropane ring, where the C2, C3, C4, and H2 atoms lie nearly planar, and the C2-C3-C4 angle is acute (81°); we refer to it as PCP, to remind the reader of the analogous CP structure in the $AlH_2(OH)_2^-$ modelling. The resulting $C_5H_{11}^+$//$AlHCl_3^-$ intermediate features three H···Cl interactions in a stool-like structure in which the three catalyst chlorine atoms are coordinated with three different hydrogens near the C-C-C-H ring. These three H···Cl bond distances change from 3.8, 2.8, and 4.4 Å to 2.9, 2.5, and 2.8 Å in the transition state, and finish at 2.6, 2.5, and 2.8 Å in the stool-like structure, respectively. During this procedure, the C4—Cl3 bond distance also decreases from 4.7 to 3.6 Å, thus preparing for tight coordination in the scission step. The transition state for this endothermic step is extremely late, with the C2—Cl1 bond almost completely broken, and the closing of the C2 carbenium site to the C4 atom (actually to the C4—H2 bond) almost complete.

Fig. 8. Transition-state sketch for the ascension of pentenium ion on $AlHCl_3^-$. The dashed lines indicate coordination interactions between Cl and H in the stool-like structure of the ion-pair complex.



Scission step

We present two versions of the scission step that produce chemisorbed ethenium ion and physisorbed propene; Fig. 9 shows the 3D images of their stationary-point geometries. Figure 10 has the sketch of the transition states to demonstrate the bond rearrangement mechanism, and Table 4 provides some geometric data for the three structures of Fig. 9 using the atom numbering of Fig. 10.

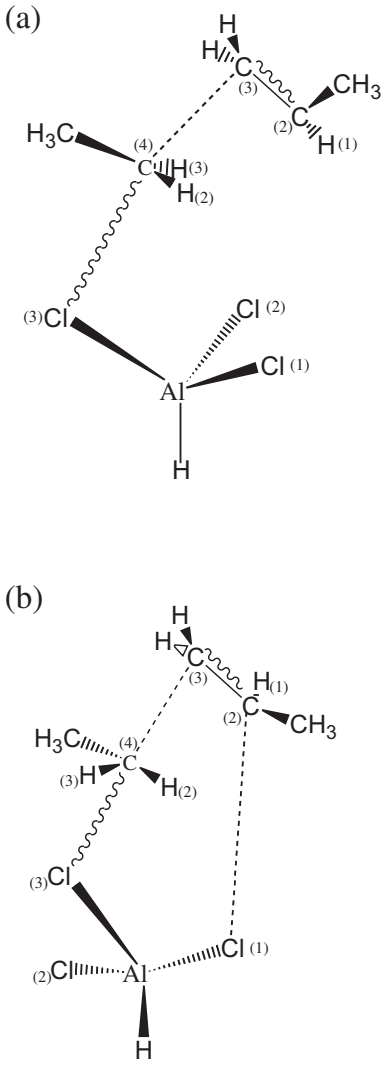
Fig. 9. B3LYP/6-31G(d,p) stationary points for two different scission (cracking) reactions on $AlHCl_3^-$. Top row: one-step β scission of chemisorbed pentenium ion. Bottom row: scission of physisorbed pentenium ion (also called protonated dimethylcyclopropane).



The top row of Fig. 9 shows the path for β scission directly from the chemisorbed pentenium ion, and the bottom row is the scission from the precariously stable PCP ion. Both go through very similar scission transition states in which the migrating C4 atom has moved to a spot roughly equidistant between the C3 atom it was leaving (2.4 Å) and the Cl3 atom it was approaching (2.6–2.7 Å). The C1—C2 bond changes from a single bond (1.41 Å) through the transition state (1.35 Å) to a double bond (1.33 Å). The products from these two scission-step versions differ in orientation of the ethyl and propene units relative to the catalyst, but are otherwise identical chemically.

Discussion

Visualizing and comparing the two catalyst mechanisms

The PES energetics are key to understanding the apparently dramatic qualitative differences in the β-scission mechanism on $AlHCl_3^-$ vs. $AlH_2(OH)_2^-$. To do this comparison, we chose to sketch approximate contour plots of the PES for both catalysts (Figs. 11 and 12), oriented in a common way that includes both neutral-pair and ion-pair physisorbed regions in both plots. The contours are approximate, based only on the 11 and six stationary points, respectively, of the lowest-energy paths between regions, but also guided by the nonexistence of other stationary points. For both these plots, the horizontal coordinate is a crude coordinate representing the general stepwise reaction path of ascension, isomerization, and β scission, and the vertical coordinate represents the ion-pair vs. neutral-pair nature of the physisorbed complexes (ion pair on the bottom, neutral pair on the top). The layout of this plot is rather arbitrary, but we have chosen to put the physisorbed pentene and 2-pentenium regions to the left of the CP and PCP ones because they require less geometrical rearrangement from the chemisorbed reactant state than the cyclopropanes would.

Fig. 10. Transition-state sketches for the scission (cracking) steps on $AlHCl_3^-$: (*a*) from a chemisorbed pentenium ion; (*b*) from a physisorbed protonated dimethylcyclopropane. The dashed lines indicate bonds in the reactant, while the squiggly lines indicate bonds in the product.

In Figure 11 ($AlH_2(OH)_2^-$ catalyst), although the intermediates are physisorbed neutral-pair complexes, the transitions states for the steps are more like ion-pair ones, causing the reaction paths to be curved in this plot. Without the catalyst, the steps would have much larger reaction barriers as indicated by the high walls blocking the direct routes on this plot. Each step proceeds via a significant (40–50 kcal mol^{-1}) energy barrier in the transition state before falling down into a well. This plot also helps to suggest that if the chemisorbed reactant has sufficient energy to overcome the first barrier, it might have sufficient excess energy and kinetic momentum to continue further down the channel towards complete β scission without having to fall down into either of the two potential wells for physisorbed neutral-pair intermediates.

In Fig. 12 ($AlHCl_3^-$ catalyst), the biggest difference relative to Fig. 11 is that the energies of the ion-pair intermediates (the lower half of the plot) have dropped significantly

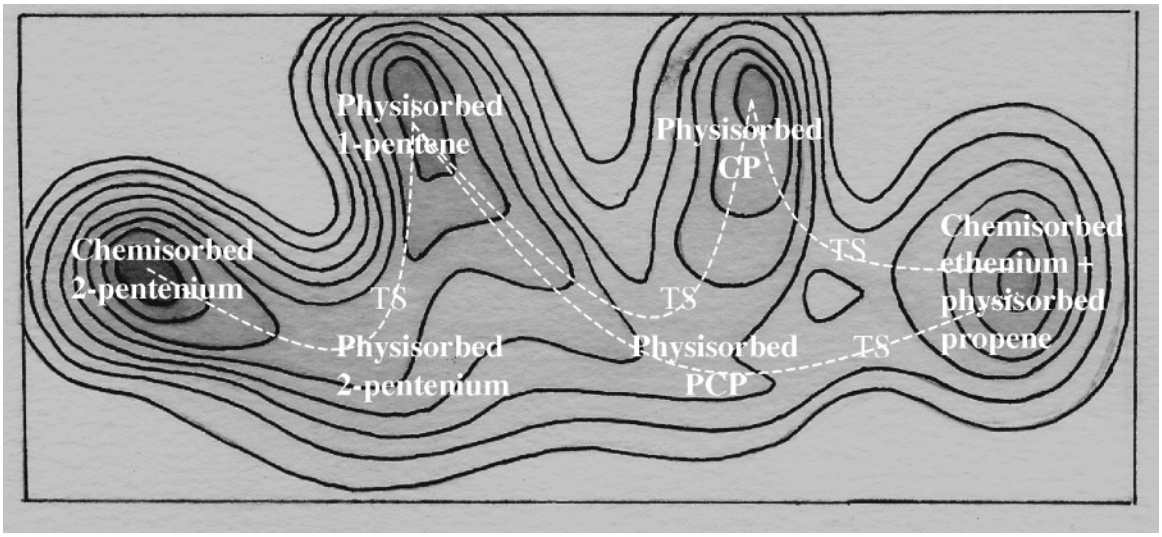
Fig. 11. Sketch of a plausible PES for β scission of the 2-pentenium ion on the $AlH_2(OH)_2^-$ catalyst, based on B3LYP/6-31G(d,p) stationary points. Each contour represents a rise of 10 kcal mol^{-1} from dark to light (1 cal = 4.184 J). The bottom half of the figure represents ion-pair complexes, such that a vertical rise to the top half represents proton transfer to the catalyst to obtain neutral-pair complexes. Note that all four transition states have a great deal of ion-pair character, as indicated by their location in the bottom half of the diagram.



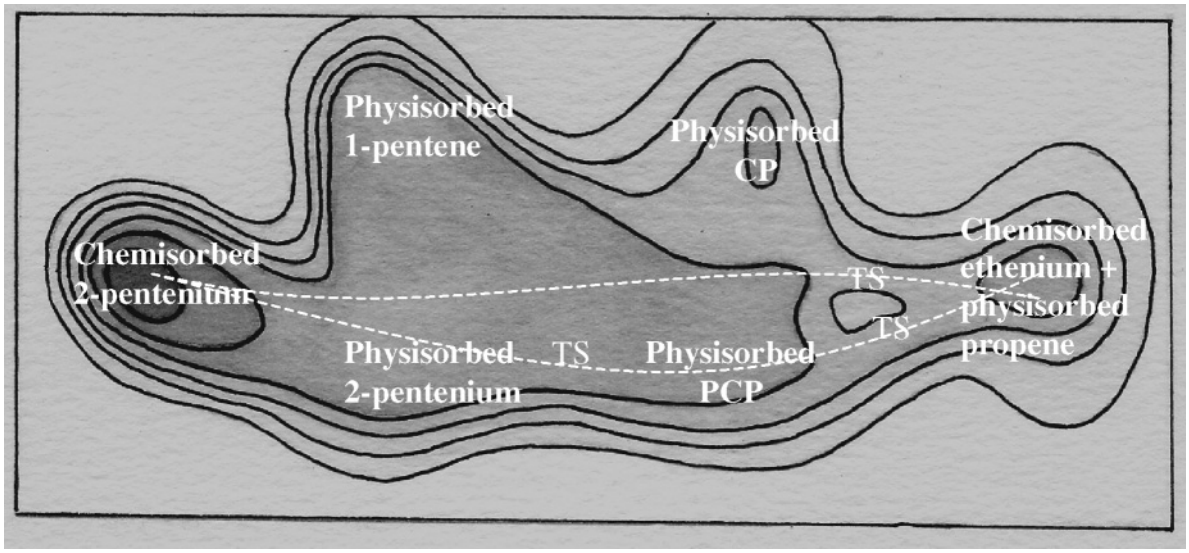


Fig. 12. Sketch of a plausible PES for β scission of the 2-pentenium ion on the $AlHCl_3^-$ catalyst, based on B3LYP/6-31G(d,p) stationary points. Each contour represents a rise of 10 kcal mol^{-1} from dark to light (1 cal = 4.184 J). The bottom half of the figure represents ion-pair complexes, such that a vertical rise to the top half represents proton transfer to the catalyst to obtain neutral-pair complexes. The minimum for the physisorbed ion-pair complex $PCP^+//AlHCl_3^-$ cannot be seen on this scale, owing to the flatness of the surface in the physisorbed regions.

relative to the neutral-pair intermediates, and so much so that the energies of ion-pair vs. neutral-pair structures have become competitive. The β-scission reaction proceeds along a wide, flat path before rising over a transition state late in the reaction.

We think these plots demonstrate that the qualitative differences between the two mechanisms are due to the lowering of the ion-pair regions of the PES relative to the neutral-pair ones, in substituting chloride for hydroxide on the catalyst. This lowering is due to the lowered proton affinity of the catalyst; we computed the proton affinities of our two catalysts with B3LYP/6-31G(d,p), and they are 338 kcal mol^{-1} for $AlH_2(OH)_2^-$ and 276 kcal mol^{-1} for $AlHCl_3^-$. For those concerned with the imbalance of the number of hydrides on each catalyst, this effect is minor; we calculated the proton affinity of $AlH_2Cl_2^-$ and obtained 285 kcal mol^{-1}. Hence, since the catalysts are virtually identical in size, the lower basicity (or proton affinity) of chlorine atoms vs. oxygen atoms is the cause of the mechanistic differences here. This demonstration of catalyst basicity effects on mecha-

© 2005 NRC Canada

nism meshes nicely with our earlier study on the protolysis of hexane (23), which demonstrated that catalyst acidity could cause qualitative differences in its mechanism.

Revisiting previous β-scission modelling work

Frash et al. (FKRS) (24) studied the β scission of chemisorbed 1-butenium and 2-pentenium ions on two model zeolite fragments, $AlH_2(OH)_2^-$ and $AlH_2(OSiH_3)_2^-$, using HF/6-31G(d) and B3LYP/6-31G(d) geometry optimizations. The B3LYP results with the $AlH_2(OH)_2^-$ fragment were the ones we took and greatly extended by adding five transition states to their one on this PES. FKRS stated that on this PES the "alkoxy" (chemisorbed) reactant first converts to a CP intermediate before performing the scission step; we have convinced ourselves that this is not correct, and that minimum energy ascension of the chemisorbed reactant leads formally to a physisorbed propene intermediate, which can then isomerize to CP or directly perform β scission itself. FKRS were likely misled by the 1-butenium PES for which they did find a transition state from the chemisorbed reactant directly to CP, but the difference may be due to the ability of 2-pentenium ion to lose a nearby methyl proton upon ascension, which 1-butenium ion cannot do. FKRS also expressed surprise that the B3LYP PES produced a two-step pathway, because their HF/6-31G(d) PES produced a one-step, direct β scission from chemisorbed 2-pentenium ion. Our Fig. 11 may help to understand the qualitative difference; it is conceivable that a different level of theory might produce a slight shift of the contours around 40 kcal mol^{-1} to produce a direct connection from chemisorbed reactant all the way to chemisorbed product. FKRS seemed to prefer the HF results over the B3LYP results, despite B3LYP being the higher level of theory; given that the difference may only be a subtle change in the PES, we suggest that the qualitative difference should not be worrisome, and that a proper description of the mechanism should include pathways connecting all four minima of Fig. 11 via carbenium ion paths.

Hay et al. (25) modelled the β-scission reaction of 2-pentenium ion with the zeolite fragment $AlH_2(OSiH_3)_2^-$, using HF/6-31G(d) optimized structures and B3LYP/6-31G(d) energies computed at the HF structures. They state the path as going from physisorbed pentene to chemisorbed 2-pentenium ion and then directly to products, in disagreement with our results. However, the direct β scission from the chemisorbed reactant does agree with the HF/6-31G(d) results of FKRS (24) with a different fragment model, and hence we merely comment that HF theory is being consistent in this matter, but that B3LYP optimizations present a different picture.

Svelle et al. (26) modelled the dimerization of linear alkenes with the zeolite fragment $Al(OH)(OSiH_3)_3^-$ (the active catalyst had an extra proton on an O atom between Al and a Si atom) using B3LYP/6-31G(d) optimizations and higher level single-point energies at these geometries. β Scission is the same reaction in the opposite direction. They refer to π and σ complexes, which in our language are physisorbed alkene and chemisorbed species, respectively. They refer to concerted vs. stepwise pathways; their stepwise hypothesis features a β-scission step between chemisorbed states, while the concerted hypothesis features a β-scission step between physisorbed states. However, despite showing figures of these hypotheses in their Results section, they admit to never finding chemi- to chemi-β-scission steps, as well as discovering some CP minima upon testing their transition states. Their results in fact agree with ours that β scission starts from various physisorbed states and not chemisorbed ones. Their finding of a β-scission step between two physisorbed states intrigued us, since we could not find such a step with our model system, so we tried some further calculations. We found that this step is unusually sensitive to the fragment model used: such a step exists for our pentene intermediate (1-pentene → propene + ethene) on the activated $Al(OH)(OSiH_3)_3^-$ fragment of Svelle et al., but not on activated $Al(OH)_4^-$ or $AlH_2(OH)_2^-$.

Chemisorbed or physisorbed reactants?

Conventional organic chemistry states that cationic β scission starts from a carbenium ion. After the initial computations of Kazansky and co-worker (10, 11), it has been assumed (12, 24) that this β scission (on a zeolite) starts with the carbenium ion in an alkoxy (chemisorbed) state. However, this is not necessarily true. Our thorough calculations with $AlH_2(OH)_2^-$ suggest that *physisorbed alkenes* can undergo β scission directly, without having to become chemisorbed ions (see Fig. 11). Furthermore, even though the β-scission step immediately results in a chemisorbed primary carbenium ion on $AlH_2(OH)_2^-$, Svelle et al. (26) with $Al(OH)(OSiH_3)_3^-$ found a β scission that resulted in physisorbed products. Hence, chemisorbed ions are not a requirement for the initial or final state in the cracking step. It might be better to think of the chemisorbed state as a "storage" state of alkenes or carbenium ions, rather than the active form of the reactant species.

Conclusions

At the B3LYP/6-31G(d,p) level of theory, catalyzed β scission of a secondary carbenium ion is qualitatively different on $AlHCl_3^-$ than it is on $AlH_2(OH)_2^-$, which is due only to the differing basicities of Cl and O atoms. On the $AlH_2(OH)_2^-$ catalyst, the stable physisorbed intermediates are neutral alkenes or alkylcyclopropanes (CP). On the less basic $AlHCl_3^-$ catalyst, however, the intermediates are protonated alkylcyclopropanes (PCP).

Although these chosen catalysts are not models of true ionic liquids or aluminosilicate zeolites, they happened to produce the same qualitative intermediates (ion pair vs. neutral pair) that are thought to exist in these two true systems.

With $AlHCl_3^-$, β scission can occur directly from the chemisorbed state, or occur via a barely stable ion-pair intermediate. With $AlH_2(OH)_2^-$, the scission step does not start from the chemisorbed state, but from physisorbed neutral-pair states, although trajectories with small excess energies and reaction momentum could achieve β scission from chemisorbed states.

Salicylaldimine dimers derived from 2-$H_2NC_6H_4Bpin$ (pin = 1,2-$O_2C_2Me_4$)

Jonathan D. Webb, Hanni A. Darwish, Haiwen Zhang, Susan L. Wheaton, Felix J. Baerlocher, Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott

Abstract: Condensation of salicylaldehyde (2-$HOC_6H_4C(O)H$) with 2-$H_2NC_6H_4Bpin$ (pin = 1,2-$O_2C_2Me_4$) afforded the macrocyclic dimer **1** with an OBOBO structural unit. Similar reactivity with substituted salicylaldehyde derivatives gave the corresponding Schiff bases **2**–**6**. Crystals of **1** were triclinic, space group *P*-1, a = 9.7915(4) Å, b = 10.8569(5) Å, c = 12.8445(6) Å, α = 102.067(1)°, β = 96.011(1)°, γ = 90.458(1)°, Z = 2. All new compounds have been tested for their antifungal activity against *Aspergillus niger* and *Aspergillus flavus*.

Key words: antifungal, boron, dehydration, heterocycles, Schiff bases.

Résumé : La condensation de l'aldéhyde salicylique (2-$HOC_6H_4C(O)H$) avec le 2-$H_2NC_6H_4Bpin$ (pin = 1,2-$O_2C_2Me_4$) conduit à la formation du dimère macrocyclique **1** qui comporte une unité structurale OBOBO. Une réactivité similaire avec des aldéhydes salicyliques substitués conduit aux bases de Schiff correspondantes, **2**–**6**. Les cristaux du composé **1** sont tricliniques, groupes d'espace *P*-1, a = 9,7915(4) Å, b = 10,8569(5) Å, c = 12,8445(6) Å, α = 102,067(1)°, β = 96,011(1)°, γ = 90,458(1)°, Z = 2. Tous les nouveaux composés ont été évalués pour leur activité antifongique contre l'*Aspergillus niger* et l'*Aspergillus flavus.*

Mots clés : antifongique, bore, déshydratation, hétérocycles, bases de Schiff.

Introduction

Compounds containing boronic acids [$RB(OH)_2$] or boronate esters [$RB(OR')_2$] have been used extensively as intermediates in Suzuki–Miyaura cross-coupling reactions for a variety of applications (1–11). Interest in these boron compounds also arises from their potent biological activities (12–26). For instance, aminoboronic acids are potent inhibitors of serine proteases, a diverse group of proteolytic enzymes responsible for the generation of most disease processes (13–18). The boronic acid containing inhibitor 2(*S*)-amino-6-boronohexanoic acid has also recently been shown to enhance erectile function in male rats (25). Likewise, simple aminoboronic acid derivatives are also being examined for application in boron neutron capture therapy, a binary form of cancer treatment that relies on delivering a compound containing boron-10 selectively to tumour tissues prior to irradiation by neutrons (26). With the wealth of medicinal properties associated with boron compounds, we decided to examine the reactivity of salicylaldehyde and the boronate ester aniline compound 2-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)phenylamine (2-$H_2NC_6H_4Bpin$ (pin = 1,2-$O_2C_2Me_4$)). Results of our study are presented herein.

Results and discussion

Salicylaldimines are versatile intermediates in organic synthesis and have been used to prepare numerous pharmacologically important compounds (27–33). For instance, Whiting and co-workers (27) have used imines containing boronate esters to make enantio-enriched γ-phenyl-γ-amino alcohols, and Höpfl and co-workers (33) have prepared air-stable cyclophane-type macrocycles from salicylideneaminoaryl alcohols and arylboronic acids. In this study, we found that addition of the ortho-substituted aniline derivative 2-$H_2NC_6H_4Bpin$ adds to salicylaldehyde in wet ethanol to give the Schiff base dimer **1** (Fig. 1). While the imine proton is observed in the ^{1}H NMR spectra at δ 8.47 ppm, the pinacol methyl groups are absent. The diagnostic C=N stretching band is observed in the FT-IR spectra at ca. 1620 cm^{-1}, and a broad peak at δ 3.7 ppm in the ^{11}B NMR spectra indicates that the boron atom is four coordinate (34, 35).

It is possible that the formation of **1** proceeds via initial formation of a Schiff base with subsequent cleavage of the pinacol group to give the corresponding boronic acid. This transient imine could then rapidly dehydrate to form the anhydride dimer **1**. Indeed, we have found that addition of water to the aldimine derived from salicylaldehyde and 2-$H_2NC_6H_4Bpin$ (prepared in dry THF) gave **1** as the only new

Fig. 1. Possible formation of Schiff base dimers.

boron containing product. Anhydride formation is also observed with substituted salicylaldehyde derivatives to give the corresponding heterocycles **2**–**6**, respectively, and similar reactivity has been reported previously for analogous Schiff bases derived from 2-aminophenol and 2-(4,4,5,5,-tetramethyl-[1,3,2]-dioxaborolan-2-yl)benzaldehyde (34). Interestingly, the reaction of 2-$H_2NC_6H_4$Bpin with 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde gave the corresponding aldimine **7** as the only new boron containing compound. It is possible that the increased steric bulk of the *tert*-butyl groups inhibits the formation of the dimer.

The molecular structure of **1** is shown in Fig. 2, crystallographic data are given in Table 1, and selected bond distances and angles are shown in Table 2. The two fragments form six-membered rings and are connected via a B-O-B bridge (B(1)-O(1)-B(2) = 111.50(12)°) with average B—O bond distances of 1.429(2) Å. The B-O-B angle, however, is somewhat smaller in **1** than that observed in a related heterocycle (B-O-B bond angle is 137(3)°) prepared through a condensation reaction between 2,4-pentanedione, 2-ethanolamine, and phenylboronic acid (Fig. 3) (36). In this latter example, the B-O-B fragment is part of a flexible seven-membered ring. Interestingly, the two phenolic B—O distances in **1** are slightly longer (1.475(2) and 1.473(2) Å) than the bridged B-O-B bonds (avg. 1.429(2) Å) (33, 37–45). Similar distances and angles have been reported for other O-B-O ring systems. For instance, a monomeric boronate compound derived from a salicylideneaminoaryl alcohol and 4-nitrophenylboronic acid has distances of 1.48(1) and 1.45(1) Å for the heterocyclic and terminal B—O bonds, respectively (33). The aldimine functionality in **1** is stabilized by N→B interactions with average B—N bonds of 1.619(2) Å, which is characteristic of strong coordination (33). Similar bond distances have been reported in related oxime, salen, and salicylaldehyde derivatives (46–59).

All new compounds were tested as potential antifungal agents against *Aspergillus niger* and *Aspergillus flavus* using Amphotericin B as a control. Although we recently reported that related N_2B heterocycles are potent antifungal agents (60), compounds **1**–**6** showed only negligible activity (Table 3). The starting aniline derivative 2-$H_2NC_6H_4$Bpin showed no activity. This result is also somewhat surprising, as the corresponding aldehydes, 2-formylphenyl boronic acid (2-$HC(O)C_6H_4B(OH)_2$), and its pincaolated derivative 2-$HC(O)C_6H_4$Bpin, displayed considerable fungitoxicity against both *A. niger* and *A. flavus* (61). Further work is therefore required to design more potent fungicidal compounds containing biologically active aminoboron groups.

Conclusion

Reactions of 2-$H_2NC_6H_4$Bpin with salicylaldehydes gave novel heterocyclic dimers containing six-membered rings with a B-O-B bridge. The aldimine functionality in these dimers is stabilized by intramolecular N→B interactions. These complexes showed only negligible antifungal activity against both *A. niger* and *A. flavus*.

Experimental

General

Reagents and solvents used were purchased from Aldrich Chemicals. 2-$H_2NC_6H_4$Bpin was synthesized by modification of an established procedure (62). NMR spectra were recorded on a JEOL JNM-GSX270 FT spectrometer or a Varian Mercury Plus 200 NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and referenced to residual solvent protons in deuterated solvent at 270 and 200 MHz, respectively. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 68 and 50 MHz, respectively, and are reported in ppm. ^{11}B NMR chemical shifts are reported in ppm and are referenced to BF_3·OEt_2 as an external standard at 87 MHz. Multiplicities are reported as singlet (s), doublet (d), triplet (t), multiplet (m), broad (br), and overlapping (ov). IR spectra were obtained using a Mattson Genesis II FT-IR spectrometer. Melting points were determined using a Mel-Temp apparatus and are uncorrected. Microanalyses for C, H, and N were carried out at Guelph Chemical Laboratories (Guelph, Ontario).

Compound 1

A solution of 2-$H_2NC_6H_4$Bpin (0.25 g, 1.14 mmol) in EtOH (3 mL) was added to a solution of salicylaldehyde (0.14 g, 1.14 mmol) in EtOH (3 mL) and the reaction was heated to reflux for 2 h. The reaction was stored at 5 °C, and after 18 h a precipitate was collected by suction filtration and was washed with cold EtOH (3 × 3 mL) to afford **1** (0.18 g, 75%) as a yellow solid; mp 362 to 363 °C. IR (Nujol, cm^{-1}) ν: 2931, 2870, 1620 (C=N), 1552, 1466, 1379, 1313, 1279, 1240, 1182, 1057, 1038, 987, 968, 926, 837, 764, 687, 573. Spectroscopic NMR data (in $CDCl_3$): ^{1}H δ: 8.47 (s, 2H, C*H*=N), 7.51 (t, *J* = 8 Hz, 2H, Ar), 7.43–7.40 (ov m, 4H, Ar), 7.21–7.12 (ov m, 6H, Ar), 7.04 (d, *J* = 8 Hz, 2H, Ar), 6.89 (t, *J* = 8 Hz, 2H, Ar). ^{13}C{^{1}H} δ: 160.4 (*C*=N), 154.1, 143.8, 142 (br, *C*-B), 137.8, 132.8, 132.1, 128.7, 128.6, 119.6, 118.9, 115.9, 115.6. ^{11}B{^{1}H} δ: 3.7 (br). Antifungal testing

Compounds were tested for antifungal activity against pure cultures of *A. niger* and *A. flavus* supplied by Ward's Natural Science Ltd. (St. Catharines, Ontario). Cultures were maintained on Sabouraud dextrose agar. Six agar plugs (10 mm diameter) were cut from a 5–8 day old colony and homogenized in distilled, sterilized water (3 mL). From this suspension, 0.5 mL was transferred aseptically to a Petri plate with Sabouraud dextrose agar (15 mL) and spread evenly over the entire surface. Each plate was provided with four evenly spaced paper disks (6 mm Fisherbrand P8 filter paper) containing the compound (200 μg). Each compound was applied to the disks as a solution (5 mg compound per 0.5 mL chloroform), where control disks were treated with neat chloroform (20 μL). Amphotericin B acted as a standard. Test plates with fungal homogenates were incubated at 20 °C for 48 h. Four replicate plates were used for each test. Antifungal activity was taken by the diameter of the clear zone surrounding the disk.

X-ray crystallography

Crystals of **1·2 EtOH** were grown from an EtOH solution at 5 °C. Single crystals were mounted using a glass fibre and Paratone-N oil and frozen in the cold stream of the goniometer. Data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and ϕ scans with a scan width of 0.3° and 40 s exposure times. The detector distance was 5 cm. The data were reduced (SAINT) (63) and corrected for absorption (SADABS) (64). The structure was solved by direct methods and refined by full-matrix least squares on F^2 (SHELXTL) (65). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically, with the exception of the hydrogens of one of the solvent molecules, which were included in calculated positions and refined using a riding model.[2]

One-pot conversion of β-aminocrotononitrile to secondary enaminonitriles including chiral ones — Application to synthesis

A. Chatterjee, M. Mishra, S.K. Dutta Chowdhury, and Kumar K. Mahalanabis

Abstract: A highly efficient one-pot conversion of β-aminocrotononitrile to secondary enaminonitriles including chiral ones is described. In contrast to β-aminocrotononitrile, some of these *N*-substituted β-enaminonitriles on reacting with acid chlorides show a unique preference for C-terminal selection allowing preparation of pyrazoles without separation of regioisomers. In addition, use of secondary enaminonitriles also provided access to pyrazoles that are not obtainable with primary enaminonitriles owing to an exclusive preference for *N*-terminal selection.

Key words: β-aminocrotononitrile, *N*-substituted enaminonitriles, regioselective, pyrazoles.

Résumé : On décrit une méthode unipot très efficace de conversion du β-aminocrotononitrile en énaminonitriles secondaires, y compris ceux de nature chirale. Contrairement à ce qui est observé avec le β-aminocrotononitrile, certains de ces β-énaminonitriles *N*-substitués réagissent avec les chlorures d'acides avec une préférence unique pour la position C-terminale, ce qui permet de préparer des pyrazoles sans avoir à séparer les régioisomères. De plus, l'utilisation d'énaminonitriles secondaires permet aussi d'accéder à des pyrazoles qui ne peuvent pas être obtenus à partir de l'énaminonitrile primaire en raison de la préférence exclusive pour la sélection *N*-terminale.

Mots clés : β-aminocrotononitrile, énaminonitriles *N*-substitués, régiosélective, pyrazoles.

[Traduit par la Rédaction]

Introduction

The chemistry of β-aminocrotononitrile is well-documented (1) and continues to remain an active area for further study. For some time now we have been engaged in systematic studies on the acylation reactions of β-aminocrotononitrile (**1**) with acid chlorides in the presence of an added organic base to evaluate preferences for regioselection (2–5) and to explore the utility of the derived products for synthesis of novel heterocyclic compounds (6–9). β-Acylenaminonitriles behave as masked 1,3-diketones and are considered to be useful intermediates (10) particularly in heterocyclic chemistry (11). Results reported from this laboratory on acylation reactions of primary enaminonitriles with acid chlorides although indicating a high degree of preference for terminal selection depending on the choice of acid chlorides used, nevertheless indicate that there is room to develop new routes to ensure exclusive acylation at the C-terminal particularly in those cases where either *N*-acylation occurred or a mixture of *C*- and *N*-acylated products were obtained. To realize this objective we decided to explore secondary enaminonitriles instead of **1** in our acylation study and to observe if there was any change in preference for terminal selection with regard to **1**. This contemplated study required preparation of a large number of secondary enaminonitriles in reasonably good yields under mild conditions. Several methods of preparation of *N*-substituted enaminonitriles are reported in the literature (12–17), but most of these employed indirect methods and thus are not suitable for a preparatory scale. Dedina et al. (16) reported three different procedures for the preparation of *N*-substituted-3-aminocrotononitrile: procedure A uses a solution of enaminonitrile and an amine in ethanol in an autoclave at 130–136 °C for 5–8 h. In procedure B, a solution of HCl (6 mol/L) in ethanol was added to a dioxane solution of enaminonitrile and amine and the mixture was heated for 5 to 6 h in a pressure tube at 120–140 °C. Procedure C involves heating a mixture of enaminonitrile and amine without any solvent. In our study we observed that the use of HCl or the absence of ethyl alcohol resulted in extensive polymerization of the enaminonitrile itself and the yield of the secondary enaminonitrile was poor. For example, we obtained *N*-phenyl-β-aminocrotononitrile (**2g**) in an 87% yield when the reaction was carried out in the presence of an alcohol, whereas in the case of procedure C as described by Dedina et al. (16) the yield of **2g** was reported to be only 37%.

Lack of a general approach, consistency in yields, and inadequacies of *N*-substituent variants leave significant room for improvement in the methodology for preparation of secondary enaminonitriles notwithstanding the extensive work done by Dedina et al. (16). Herein, we report a very simple,

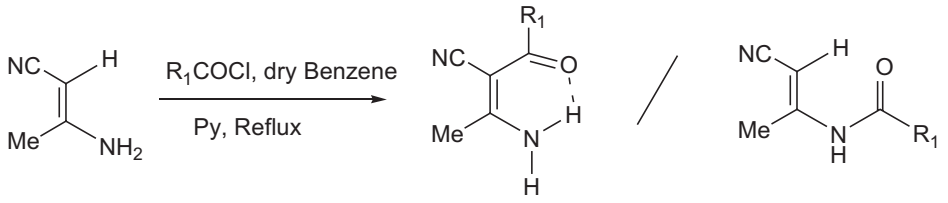
direct, and highly efficient general method for the one-pot preparation of secondary enaminonitriles **2a**–**2j** including the optically active ones **2k**–**2p** by reacting **1** with amines in refluxing dry ethyl alcohol (Scheme 1, Table 1). For the preparation of *N*-methyl-β-aminocrotononitrile (**2a**) and *N*-ethyl-β-aminocrotononitrile (**2b**), methyl ammonium chloride and ethyl ammonium chloride, respectively, were used in the presence of triethyl amine.



In the case of the optically active enaminonitriles **2k**–**2p**, the amino acids were first converted to their corresponding methyl ester hydrochlorides by treatment with thionyl chloride in refluxing dry methyl alcohol (18, 19). These ester hydrochlorides were then reacted with **1** in the presence of triethyl amine in refluxing ethyl alcohol. The amino acids used were (*S*)-(+)-alanine, (*S*)-(+)-leucine, (*S*)-(+)-valine, (*R*)-(+)-α-methylbenzyl amine, (*S*)-(–)-phenylalanine, and (*S*)-(–)-tyrosine. The homogeneity of the liquid products was checked by HPLC using a C-18 Bonda-pak column and a methanol–water (1:1) mixture as the mobile phase. The structures of these enaminonitriles are supported by consistent elemental and spectral analyses. Careful analysis of the ^{1}H NMR spectra of the isolated products is suggestive of the E conformation for the enaminonitriles (16). When compared with documented literature methods, the present procedure scores favorably in terms of simplicity, yields, choice of *N*-substituent variants, and purity of the products.

In our earlier investigations (5) on acylation of **1** we demonstrated that by choosing a suitable acid chloride it is possible to control the site of acylation to a large degree. β-Acylcyanoenaminonitriles thus obtained were easily converted to novel 5-substituted 1,2-azoles (8, 9). Although a high degree of success was achieved in terminal selection, there were examples where either a mixture of regioisomers or only *N*-acylated products were obtained. Since β-enaminones have proven to be valuable intermediates in the synthesis of a wide variety of heterocyclic compounds (20), we have initiated this study on the acylation reaction of secondary enaminonitriles to observe if there was any change in their preference for terminal selection when compared to primary enaminonitriles. Results obtained thus far indicate that *N*-substituted β-aminocrotononitriles show a strong preference for C-terminal selection when compared with the results obtained earlier for **1** (Scheme 2). Thus, *N*-benzyl-β-aminocrotononitrile (**2f**) on reaction with acid chlorides of benzoic acid, *o*-nitrobenzoic acid, *m*-nitrobenzoic acid, and thiophene-2-carboxylic acid afforded only *C*-acylated products in contrast to our earlier results with **1** whereby a mixture of regioisomers **3** and **4** (1:1) was obtained. The presence of compounds **3** and **4** in the reaction mixture was confirmed by ^{1}H NMR spectral analysis, and the pure regioisomers were obtained by column chromatography. A dramatic reversal of preference for site selection occurred when acylation of **2f** was carried out with isobutyryl chloride resulting in exclusive C-terminal selection. In an earlier experiment, treatment of **1** with isobutyryl chloride afforded only the *N*-acylated product, thereby precluding its use for the preparation of pyrazole (Scheme 2, Table 2). Such a strong preference by **2f** for C-terminal selection allowed us to synthesize pyrazoles that previously needed either separation of regioisomers or where the total lack of preference for C-terminal selection excluded their formation (Scheme 3, Table 3). Presently, we are working on the synthetic application of other secondary enaminonitriles including chiral ones.

Thus, easy access to secondary enaminonitriles provides a direct route for the synthesis of heterocycles that otherwise are not directly obtainable from acylation reactions of primary enaminonitriles. In addition, the availability of optically active secondary enaminonitriles is likely to provide

opportunities for their utilization as chiral auxiliaries towards the synthesis of chiral heterocycles.

Experimental

Melting points were determined in open capillaries. NMR spectra were recorded using a Brucker AC-300 and (or) Brucker Avance 400 MHz spectrometer. Elemental analyses were performed using a PerkinElmer 240C elemental analyzer, mass spectra were obtained with an Hitachi RMU 6L and JMS-Ax505H mass spectrometer, and GC–MS spectra were obtained using an Agilnet 6890N. Optical rotations were measured on a Jasco Dip 360 digital polarimeter. HPLC was carried out using a Water Corporation UV detector and version 2.1 Mellenium software. UV and IR spectra were obtained using Hitachi U-2000 and Hitachi 270–30 spectrometers, respectively.

5e	Isobutyryl	73 to 74	70

[a]Yields of isolated products.

β-Aminocrotononitrile and acid chlorides were prepared according to literature procedures in refs. 21 and 22, respectively.

General procedure

Preparation of N-substituted β-aminocrotononitriles

(*a*) A mixture of **1** (10 mmol), primary amine (10 mmol), and dry ethyl alcohol (40 mL) was refluxed for 2–5 h under dry conditions. Excess alcohol was distilled off

© 2005 NRC Canada

under reduced pressure, water was poured into the flask, and the contents were extracted with a suitable organic solvent. The organic layer was first washed with 2 N HCl, then with brine until neutral, it was then dried over anhydr. Na_2SO_4 and evaporated to dryness. Recrystallization of the crude product from a suitable solvent furnished the pure compound.

(*b*) A mixture of chiral amine (5 mmol), thionyl chloride (10 mmol), and dry methanol (15 mL) was refluxed for 2.5 h. Excess methanol and thionyl chloride were removed under reduced pressure and the residue was dried under vacuum. A solution of **1** (5 mmol) in dry ethyl alcohol (20 mL) was added to the residue with stirring at 0 °C followed by addition of triethylamine (5 mmol) in dry ethyl alcohol (5 mL). The reaction mixture was refluxed for 3 h. Following the usual work-up, purification of the crude product by column chromatography on silica gel (100–200 mesh) with 30% ethyl acetate – hexane as eluent afforded the product as a thick liquid.

Acylation reaction of *N*-benzyl-β-aminocrotononitrile with acid chlorides

The acid chloride (5 mmol) in dry benzene (10 mL) was added dropwise under ice cold conditions to a magnetically stirred solution of **2f** (5 mmol) in dry benzene (50 mL) and pyridine (15 mmol). Upon completion of the addition, stirring was continued for an additional 1 h at room temperature, and then refluxed for 3–5 h. The reaction mixture was then poured on ice water, acidified with HCl (2 N) followed by extraction with ethyl acetate (3 × 25 mL). The organic layer was then washed with a 5% $NaHCO_3$ solution followed by brine and then dried over anhydr. Na_2SO_4. Removal of the solvent afforded solid materials, which on crystallization furnished pure acylated products.

Preparation of pyrazoles

A mixture of α-cyanoenaminone (3 mmol) and phenyl hydrazine reagent (23) (9 mmol) was heated on a steam bath for 20–45 min, during which a yellow oily material separated. The reaction mixture was acidified with acetic acid (50%) followed by neutralization with solid $NaHCO_3$. It was then extracted with diethyl ether or ethyl acetate (3 × 20 mL). The organic layer was washed with brine and dried over anhydr. Na_2SO_4. The crude material obtained on removal of the solvent was purified by crystallization from a suitable solvent or by column chromatography (silica gel, 60–120 mesh, 5% ethyl acetate – petroleum ether).

Synthesis and structure of new trichloromethyl-β-diketones — 5-Trichloromethylisoxazole and 5-isoxazolecarboxylic acid derivatives

Marcos A.P. Martins, Sergio Brondani, Victor L. Leidens, Darlene C. Flores, Sidnei Moura, Nilo Zanatta, Manfredo Hörner, and Alex F.C. Flores

Abstract: An improved method for the synthesis of a new series of trichloromethyl-β-diketones including 1,1,1-trichloropentan-2,4-dione (**2a**), 1,1,1-trichloro-3-methylhexan-2,4-dione (**2b**), 4,4,4-trichloro-1-phenylbutan-1,3-dione (**2c**), 4,4,4-trichloro-2-methyl-1-phenylbutan-1,3-dione (**2d**), 2-trichloroacetylcyclohexanone (**2e**), 4-*tert*-butylcyclohexanone (**2f**), 4-*tert*-butylcycloheptanone (**2g**), and 4-*tert*-butylcyclooctanone (**2h**) is reported. A multinuclear NMR study showed that β-dicarbonyl compounds **2b** and **2d**–**2h** are predominantly in the keto form and **2a** and **2c** are in the enol form. The trichloromethyl-β-diketones react with hydroxylamine hydrochloride leading to three sets of isoxazole derivatives.

Key words: acetals, acylation, trichloromethyl-1,3-diketones, 2-trichloroacetylcycloalkanones, isoxazoles, cyclocondensation.

Résumé : On rapporte la mise au point d'une méthode améliorée de synthèse d'une nouvelle série de trichlorométhyl-β-dicétones, dont la 1,1,1-trichloropentan-2,4-dione (**2a**), la 1,1,1-trichloro-3-méthylhexan-2,4-dione (**2b**), la 4,4,4-trichloro-1-phénylbutan-1,3-dione (**2c**), la 4,4,4-trichloro-2-méthyl-1-phénylbutan-1,3-dione (**2d**) et les 2-trichloroacétylcyclohexanone (**2e**), 4-*tert*-butylcyclohexanone (**2f**), 4-*tert*-butylcycloheptanone (**2g**) et 4-*tert*-butylcyclooctanone (**2h**). Une étude de RMN multinucléaire a permis de montrer que les composés β-dicarbonylés **2b** et **2d**–**2h** existent principalement sous la forme dicétonique alors que les produits **2a** et **2c** existent sous la forme énolique. Les trichlorométhyl-β-dicétones réagissent avec le chlorhydrate d'hydroxylamine pour conduire à trois ensembles de dérivés isoxazoles.

Mots clés : acétals, acylation, trichlorométhyl-1,3-dicétones, 2-trichloroacétylcycloalkanones, isoxazoles, cyclocondensation.

[Traduit par la Rédaction]

Introduction

An ongoing research program enabled the development of a general acetal acylation method for the synthesis of trihalomethyl-1,3-dielectrophiles and demonstrated their usefulness for the preparation of heterocycles (1–4). The easy transformation of the trichloromethyl group attached to azoles into carboxyl groups led to devoting special attention to trichloromethyl-1,3-dielectrophiles (5–7).

Although trifluoromethyl-1,3-dicarbonyl compounds are well-known (8–16), the studies on trichloromethyl-1,3-dicarbonyl analogs are scarce (17–20). The most employed method to obtain trifluoromethyl-β-diketones is acylation of enol and enolates with perfluoralkanoates (8, 11, 16). The lack of literature and data on trichloromethyl-β-diketones is due to the acylation of enolates by Claisen condensation being limited in use to obtain perchloroalkyl-β-diketones. This is a result of the lability of the perchloroalkyl groups in basic medium (21, 22).

Continuing research focus in trichloromethyl substituted 1,3-dielectrophiles and their cyclocondensations with hydroxylamine hydrochloride prompted us to perform a systematic study of the dimethoxyacetals acylation with trichloroacetyl chloride. The aim of this investigation is to report the results of the synthesis of a series of the trichloromethyl-β-diketones prepared from the reaction of dimethoxy acetals with trichloroacetyl chloride. Also discussed are ^{1}H, ^{13}C, and ^{17}O NMR data for isolated β-dicarbonyl compounds and the influence of the trichloromethyl group on the keto–enol equilibrium. In addition, we report the cyclocondensation reactions of trichloromethyl-β-dicarbonyl compounds with hydroxylamine hydrochloride for the synthesis of isoxazole derivatives and the structural study of 4-alkyl substituted 4,5-dihydroisoxazoles. ^{1}H and ^{13}C NMR and X-ray data showed that cyclocondensation was enantioselective, only one pair of enantiomers was obtained for 4-alkyl substituted 4,5-dihydroisoxazoles.

Scheme 1.

i. $2Cl_3CCOCl$, 2Pyridine, $CHCl_3$, 0-50 °C, overnight (10-12 h), then H_2SO_4 (2 mol/L), 80 °C, 2 h.

Scheme 2.

i. $NH_2OH{\cdot}HCl$, MeOH, 40 °C, 5-8 h. *ii*. H_2SO_4 (98%), 25-30 °C, 5 h. *iii*. H_2SO_4 (85%), 75-100 °C, 8 h.

acetalization reaction of the respective ketones with trimethyl orthoformate in the presence of *p*-toluenesulfonic acid (23). The acylation of compounds **1a**–**1h** was carried out with trichloroacetyl chloride in chloroform in the presence of pyridine. The reaction was monitored by HPLC and the most satisfactory reaction time was found to be 12 h at 25–30 °C for **2a** and **2c** and 10 h at 50 °C for **2b** and **2d**–**2g**. After the acylation time had elapsed, 2 mol/L sulfuric acid was added and the mixture was stirred at 50 °C for 2 h. The trichloromethyl-β-diketones **2a**–**2h** were obtained with good yields (75%–95%) (Scheme 1). Compounds **2a**–**2c** are liquid and were purified by column chromatography with silica gel and hexane–chloroform (9:1) as the eluent. The crystalline **2d**–**2h** compounds were purified by crystallization from hexane. The yields and selected physical and spectral data for compounds **2a**–**2h** are reported in Table 1. We have the acetal acylation method as routine work for 1,1,1-trihalo-4-alkoxyalk-3-en-2-one synthesis (1–4), however, the posterior hydrolysis to the respective trichloromethyl-1,3-diketones closely with structural studies was the new contribution.

Isoxazole derivatives

The cyclization of **2a**–**2h** with hydroxylamine hydrochloride was carried out in methanol at 40 °C for 5–8 h. The products (5-hydroxy-5-trichloromethyl-4,5-dihydroisoxazoles, **3a**–**3h**) were obtained in good yields and they were dehydrated with concentrated sulfuric acid at 35 °C for 5 h to afford the corresponding 5-trichloromethylisoxazoles **4a**–**4h** in good yields (Scheme 2). However, when compounds **3a** and **3b** and **3e**–**3h** were heated at 75–100 °C for 12 h in an 85% sulfuric acid solution, respective 5-isoxazole carboxylic acids **5a** and **5b** and **5e**–**5h** were obtained with good yields. Under the same reaction conditions, compounds **3c** and **3d** were not converted to the respective carboxylic acids (6). We are able to demonstrate the effect of the substituents in the trichloromethyl hydrolysis to the carboxyl group. The 3-alkyl or 3,4-dialkyl substituted isoxazoles were suitable for conversion of the 5-trichloromethyl group to a carboxyl, however, the 3-phenyl substituted isoxazoles did not hydrolyse the 5-trichloromethyl group to a carboxyl even if a severely acidic medium was used.

Molecular structure

Trichloromethyl-β-diketones

For compounds **2a** and **2c** only one set of signals in the ^1H, ^{13}C, and ^{17}O NMR spectra was observed, which was assigned to an enol form (Tables 2 and 3). ^1H NMR spectra showed the signal of the enolic hydrogen at δ 13.0–14.0, and the chemical shifts for H-2 and C-2 are typical of vinyl moieties (δ 6.10–6.70 and δ 96.5–97.8, respectively) (see Tables 2 and 4). The IR spectra have a band at 1568–1595 cm^{-1} assigned to the absorption of the HO-C= group along with the band at 1593–1600 cm^{-1} attributed to the vibration of the C=O fragment from the trichloroacetyl group. ^{17}O NMR spectra for **2a** and **2c** showed two signals at δ 170 and δ 360,

[a]Calculated for the equilibrium at 298 K, as described in the Experimental.

characteristics for the push–pull conjugated keto–enol system (24, 25). Compounds 1,1,1-trichloropentan-2,4-dione (**2a**) and 4,4,4-trichloro-1-phenyl-butan-1,3-dione (**2c**) exhibited the same enolic trend as the fluorinated analogs 1,1,1-trifluoropentan-2,4-dione and 4,4,4-trifluoro-1-phenyl-butan-1,3-dione, respectively (26, 27) (Table 5).

The ^{1}H, ^{13}C, and ^{17}O NMR spectra for trichloromethyl-β-diketones **2b** and **2d**–**2h** showed that these compounds have an overall preference for the keto form. The chemical shift of H-2 is typical of the keto form for compounds **2b** and **2d**–**2h** at δ 4.35–5.48 (Table 2). For compounds **2e**–**2h**, the clear doublet of doublets signal and the coupling constants ($^3J_{HH}$) are consistent with pseudo-axial placement of H-2 (28). The $^{13}C\{^1H\}$ NMR spectrum for compounds **2b** and **2d**–**2h** showed only one set of peaks for each carbon. The signals in the range of δ 52–58 for C-2 confirmed the keto structure for compounds **2b** and **2d**–**2h** (Table 4). The IR spectra have a band at 1670–1713 cm^{-1} assigned to the absorption of the aromatic C=O (**2d**) and aliphatic C=O (**2b**, **2e**–**2h**) groups, along with the band at 1750–1765 cm^{-1} attributed to the vibration of the C=O fragment from the trichloroacetyl group. The ^{17}O NMR spectra for **2b** and **2d**–**2h** showed two near signals between δ 500–600, typical for nonconjugated carbonyl groups (29, 30). Therefore, the trichloroacetyl group in **2e**–**2h** strongly prefers a pseudo-equatorial position without conjugation.

The trichloromethyl-β-diketones with substituents at C-α (between the two carbonyls) prefer the keto form probably because of thermodynamic factors. Endocyclic or exocyclic enol forms increase molecular strain by planar placement of the bulky trichloroacetyl group. For these β-diketones, the keto–enol equilibrium on the NMR timescale is unlikely. Commonly simple 1,3-dicarbonyl compounds exhibit high concentrations of enol forms in solution, except if prohibitive structural factors are present. NMR data showed that 2-acetylcycloalkanones and 2-trifluoroacetylcycloalkanones are preferentially enol forms (31). These results showed that the trichloromethyl group on compounds **2b** and **2d**–**2h** (R^2 = alkyl) act like an anchor for the keto form. The ^{1}H and (or) ^{13}C NMR spectra of 2-trichloroacetylcyclohexanone (**2e**) were performed in different deuterated solvents (Table 3) without significant change to the spectral and (or) structural characteristics. The AM1 calculations performed showed that tautomer III of **2e** presents the lowest minimum energy. The calculated minimum energy values and relative % values for tautomer and (or) conformer concentrations are listed in the Table 4.

5-Hydroxy-5-trichloromethyl-4,5-dihydroisoxazoles

The nonequivalence for the diastereotopic hydrogens H-4a and H-4b is well-known for 5-hydroxy-5-trichloromethyl-4,5-dihydroisoxazoles **3a** and **3c** (19, 20). The 4,5-dihydroisoxazoles substituted on position 4 have two chiral centers, the C-4 and the C-5 of the isoxazole ring. However, the ^1H NMR spectra for **3b** and **3d** showed the signal of H-4 at δ 3.70–3.73 as quartets (^3J = 8.0 Hz), and for compounds **3e**–**3h** the ^1H NMR spectra showed the H-4 signals at δ 3.15–3.77 as a doublet of doublets; the coupling constant data is consistent with the pseudo-axial position of H-4 (28). The $^{13}C\{^1H\}$ NMR spectra for compound **3** also showed one set of signals for each carbon atom (see Experimental). The presence of one set of signals indicates only one pair of enantiomers (4*R*,5*R*/4*S*,5*S* or 4*R*,5*S*/4*S*,5*R*). The X-ray diffraction for the monocrystals showed the 4*S*,5*S* configuration for **3b** and **3h**. In these compounds, the alkyl group is cis to the OH group and the bulky CCl_3 group is cis to H-4. The crystal structures of 3-ethyl-4-methyl-5-hydroxy-5-trichloromethyl-4,5-dihydroisoxazole (**3b**) and 5-trichloromethyl-3,4-hexamethylene-5-hydroxy-4,5-dihydroisoxazole (**3h**) with the atomic numbering are displayed in Fig. 1. Previous structural analyses for X-ray diffraction performed on **3e** showed the 4*R*,5*R* configuration (32). X-ray diffraction enabled us to conclude that the synthetic procedure used always furnished a pair of diastereoisomers 4*R*,5*R*/4*S*,5*S* for compounds **3b** and **3d**–**3h**. The regiochemistry of these cyclocondensation reactions was discussed in ref. 32. The NMR and selected physical data from aromatic isoxazole derivatives **4** and **5** are shown in the Experimental.

Fig. 1. ORTEP plot with atom-labeling scheme of the structure of: (*a*) 5-trichloromethyl-3-ethyl-5-hydroxy-4-methyl-4,5-dihydroisoxazol (**3b**); and (*b*) 5-trichloromethyl-5-hydroxy-3,4-hexamethylene-4,5-dihydroisoxazole (**3h**). Displacement ellipsoids at the 30% level (see Experimental).

Conclusion

In summary, this work has presented a convenient one-pot method to obtain unusual trichloromethyl-β-diketones and we have demonstrated some important features of their molecular structure. This series of trichloromethyl-β-diketones were successfully used as precursors to obtain regiospecifically new 5-trichloromethylisoxazoles and 5-isoxazole carboxylic acids.

Experimental

Unless otherwise indicated, all common reagents and solvents were used as obtained from commercial suppliers without further purification. All melting points were taken on a Reichert-Thermovar melting point microscope and are uncorrected. The ^1H and ^{13}C NMR spectra were recorded on a Bruker DPX 400 (^1H at 400.13 MHz, ^{13}C at 100.62 MHz) with 5 mm sample tubes, at 300 K, in 0.02 mol/L in $CDCl_3$–

TMS, with a digital resolution of ±0.01 ppm. The ^{17}O NMR spectra were recorded at 54.26 MHz in 10 mm tubes, at 323 K, in 2 mol/L $CHCl_3$ solutions, with chemical shifts referenced to external H_2O (capillary coaxial tube). The spectra were recorded at natural abundance with a ring down eliminate (RIDE) sequence for suppression of acoustic ringing (31, 32). Mass spectra were registered in a HP 5973 MSD connected to a HP 6890 GC and interfaced by a Pentium PC. The GC was equipped with a split–splitless injector, autosampler, cross-linked HP-5 capillary column (30 m, 0.32 mm i.d.), and helium was used as the carrier gas. The dimethoxy ketals **1a**–**1h** were synthesized according to the literature (23) and purified by distillation.

Monocrystals of compounds **3b** and **3h** were grown from hexane. Diffraction data were collected at 293(2) K on an Enraf-Nonius CAD4 automatic four-circle diffractometer (MoKα, $2\theta_{max}$ = (3*b*), $2\theta_{max}$ = (3*h*)) (33). The structures were solved by direct methods and refined by full-matrix least-squares in anisotropic approximation. The basic crystallographic characteristics and the parameters of the refined crystal structures are cited in Table 6. Calculations were carried out using the programs ZORTEP and SHELXS-93 (34, 35).

MO calculations were performed using the Austin Model 1 (AM1) semiempirical method, implemented in the HyperChem 4.5 package (1995) (36). Geometries were completely optimized without fixing any parameter, thus bringing all geometric variables to their equilibrium values. The energy minimization protocol employs the Polak–Ribiere algorithm, which is a conjugated gradient method. Convergence to a local minimum was achieved when the energy gradient was <0.01 kcal mol^{-1} (1 cal = 4.184 J). The relative abundance of each species in equilibrium was calculated from the minimum energy associated with each compound employing the relationships: (1) $\Delta E = -RT \ln K$ (where ΔE stands for the standard energy difference between two given species, *R* is the molar gas constant expressed in units of kcal mol^{-1} K^{-1}, *T* is the absolute temperature in K, *K* is the corresponding equilibrium constant) and (2) [I] + [II] + [III] + [IV] = 100, where [I], [II], [III], and [IV] represent the percentage molar ratio of each tautomer and (or) conformer in equilibrium (Table 4). The calculations were performed using a Dell Precision 330 Pentium IV 1.4 GHz computer.

Trichloroacetylation of acetals 1a–1h

General procedure

To a stirred solution of dimethoxy acetal derivatives **1a**–**1h** (30 mmol) and pyridine (5.2 mL, 60 mmol) in chloroform (30 mL) kept at 0 °C, a solution of trichloroacetyl chloride (7.0 mL, 60 mmol) in chloroform (20 mL) was added dropwise. The mixture was stirred for 10–12 h at 25–50 °C. The mixture was quenched with a 2 mol/L sulfuric acid solution (30 mL) and stirred for 2 h at 80 °C. The organic layer was dried with sodium sulfate, the solvent was evaporated, and the products were obtained with high purity (see Table 1). The liquid compounds **2a**–**2c** were purified by column chromatography with Kieselgel 60 and hexane–chloroform (9:1) as the eluent. The crystalline compounds **2d**–**2h** were purified by recrystallization from hexane.

Synthesis of 5-trichloromethyl-4,5-dihydroisoxazoles 3a–3h

General procedure

To a stirred solution of trichloromethyl-β-diketones **2a**–**2h** (15 mmol) in methanol (5 mL), kept at 40 °C, was added

Synthesis of 5-trichloromethylisoxazoles 4a–4h

General procedure

A mixture of 5-trichloromethyl-4,5-dihydroisoxazoles **3a**–**3h** (5 mmol) and concentrated sulfuric acid (5–10 mL) was stirred at 25–30 °C for 5 h. The mixture was slowly poured into 50 mL of ice water and the solution was extracted with chloroform (3 × 30 mL). The combined organic fractions were washed with water, dried under anhydrous sodium sulfate, and the solvent removed under vacuum. The liquid compound **4a** was purified by distillation and the liquid **4b** was purified by column chromatography with Kieselgel 60 and hexane–chloroform (9:1) as the eluent. The crystalline compounds **4c** and **4d** were purified by crystallization from methanol and crystalline **4e**–**4h** were recrystallized from hexane. 5-Trichloromethylisoxazole compounds were fully characterized by spectroscopic methods. Data for **4a**: $C_5H_4Cl_3NO$, oil. ^{1}H NMR δ (mult., *J* Hz): 7.25 (H-4, s), 2.04 (Me-3, s). ^{13}C NMR δ: 160.0 (C-3), 168.5 (C-5), 104.4 (C-4), 84.8 (CCl_3). Anal. calcd.: C 29.96, H 2.01; found: C 30.0, H 2.00. **4b**: $C_7H_8Cl_3NO$, oil. ^{1}H NMR δ (mult., *J* Hz): 2.60 (CH_2, q, 7.4), 2.30 (Me-4, s), 1.1 (Me, t, 7.4). ^{13}C NMR δ: 160.8 (C-3), 159.3 (C-5), 105.1 (C-4), 84.0 (CCl_3). Anal. calcd.: C 36.79, H 3.53; found: C 37.0, H 3.50. **4c**: $C_{10}H_6Cl_3NO$, mp 80–84 °C, lit. value (37) mp 80 to 81 °C. ^{1}H NMR δ (mult., *J* Hz): 7.41 (H-4, s), 7.20–7.85 (Ph, m). ^{13}C NMR δ: 163.5 (C-3), 169.6 (C-5), 103.2 (C-4), 85.0 (CCl_3). Synthesis of 5-carboxyisoxazoles 5a and 5b and 5e–5h

General procedure

A mixture of 5-trichloromethyl-4,5-dihydroisoxazoles **3a**–**3h** (5 mmol) and a solution of 85% sulfuric acid (5–10 mL) was stirred at 75–100 °C for 5–10 h. The mixture was slowly poured into 20 mL of ice water; the product **5** was obtained in high purity by filtration from the cold aqueous solution and washed with water. The crystalline compounds **5a** and **5b** and **5e**–**5h** were purified by recrystallization from hexane–chloroform or hexane. 5-Carboxyisoxazole compounds were fully characterized by spectroscopic methods. **5a**: $C_5H_5NO_3$, mp 210 °C, lit. value (6) mp 208–210 °C. ^{1}H NMR δ: 7.0 (H-4), 2.3 (Me-3). ^{13}C NMR δ: 158.7 (COOH), 161.5 (C-3), 161.3 (C-5), 110.3 (C-4). Anal. calcd.: C 42.23, H 3.97; found: C 42.32, H 4.02. **5b**: $C_7H_9NO_3$, mp 210 °C. ^{1}H NMR δ: 7.0 (CH_2), 2.3 (Me-4), 1.0 (Me). ^{13}C NMR δ: 158.7 (COOH), 161.5 (C-3), 161.3 (C-5), 110.3 (C-4). Anal. calcd.: C 54.19, H 5.85; found: C 54.0, H 6.0. **5e**: $C_8H_9NO_3$, mp 128–130 °C, lit. value (38) mp 128–130 °C. ^{1}H NMR δ: 1.5–1.9 $(CH_2)_2$, 2.6–2.9 $(CH_2)_2$. ^{13}C NMR δ: 152.9 (COOH), 162.1 (C-3), 160.8 (C-5), 123.2 (C-4). Anal. calcd.: C 57.48, H 5.43; found: C 57.60, H 5.5. **5f**: $C_{12}H_{17}NO_3$, mp 191–196 °C. ^{1}H NMR δ: 1.35–3.2 $(CH_2)_2$. ^{13}C NMR δ: 152.9 (COOH), 162.5 (C-3), 161.6 (C-5), 124.8 (C-4). Anal. calcd.: C 64.55, H 7.67; found: C 64.5, H 7.8. **5g**: $C_9H_{11}NO_3$, mp 132–134 °C. ^{1}H NMR δ: 1.65–1.8 $(CH_2)_2$, 1.85 (CH_2), 2.8–3.0 $(CH_2)_2$. ^{13}C NMR δ: 152.8 (COOH), 167.2 (C-3), 161.6 (C-5), 128.5 (C-4). Anal. calcd.: C 57.48, H 5.43; found: C 57.60, H 5.5. **5h**: $C_{10}H_{13}NO_3$, mp 130–

Electron spin resonance analysis of the oxidation reactions of nitrone type spin traps with gold(III) ion

Akira Nakajima, Yuto Ueda, Nobuyuki Endoh, Kunihiko Tajima, and Keisuke Makino

Abstract: When cyclic nitrones, such as 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), 4-phenyl-5,5-dimethyl-1-pyrroline-*N*-oxide (PDMPO), and 3,3,5,5-tetramethyl-1-pyrroline-*N*-oxide (M4PO) were mixed with hydrogen tetrachloroaurate(III), DMPOX (5,5-dimethyl-1-pyrrolid-2-one-*N*-oxyl) type free radicals appeared with the precipitation of Au(0). The reaction did not proceed with noncyclic nitrones, such as *N-tert*-butyl-α-phenyl-nitrone (PBN) and α-(4-pyridyl-1-oxide)-*N-tert*-butyl-nitrone (POBN). The order of the $HAuCl_4$ decrease was DMPO > PDMPO > M4PO. The reaction was depressed by the addition of chloride or hydroxide ions. 1-Hydroxy-5,5-dimethyl-1-pyrrolid-2-one (HDMPN), the precursor of DMPOX, was also oxidized to DMPOX by $HAuCl_4$. Every step of the gold reduction from Au(III) to Au(0) can be used for the oxidation of HDMPN to DMPOX. Based on these and previous results, the reaction was assumed to proceed by the following scheme consisting of a ligand exchange interaction of $AuCl_4^-$ with $>N^+–O^-$ in DMPO, then nucleophilic addition of a water molecule to DMPO, then the stepwise intramolecular transfer of three electrons from DMPO to Au(III), and finally the precipitation of Au(0).

Key words: ESR, nitrone, spin traps, DMPO, DMPOX, gold(III) ion.

Résumé : Lorsque des nitrones cycliques, tels que 5,5-diméthyl-1-pyrroline-*N*-oxyde (DMPO), 4-phényl-5,5-diméthyl-1-pyrroline-*N*-oxyde (PDMPO), et 3,3,5,5-tétraméthyl-1-pyrroline-*N*-oxyde (M4PO) ont été mélangés avec du tétrachloroaurate(III) d'hydrogène, des radicaux libres de type DMPOX (5,5-diméthyl-1-pyrrolidine-2-one-*N*-oxyl) apparut avec la précipitation de Au(0). La réaction ne s'est pas produite avec les nitrones non cycliques, tels que *N-tert*-butyl-α-phényl-nitrone (PBN) et α-(4-pyridyle-1-oxyde)-*N-tert*-butyl-nitrone (POBN). L'ordre de la diminution de $HAuCl_4$ était DMPO > PDMPO > M4PO. La réaction a été abaissée par l'addition d'ions chlorure ou hydroxyde. 1-Hydroxy-5,5-diméthyl-1-pyrrolidine-2-one (HDMPN), le précurseur de DMPOX, a été aussi oxydé en DMPOX par $HAuCl_4$. Chaque étape de la réduction de l'or de Au(III) à Au(0) peut être utilisée pour l'oxydation de HDMPN en DMPOX. Basée sur ceux-ci ainsi que sur les résultats précédents, la réaction a été expliquée par la combinaison supposée se composant de l'interaction d'échange du ligand de $AuCl_4^-$ avec $>N^+–O^-$ dans DMPO, de l'addition nucléophilique d'une molécule d'eau à DMPO, du transfert intramoléculaire par étape de trois électrons de DMPO à Au(III), et de la precipitation de Au(0).

Mots clés : RPE, nitrone, piège à spin, DMPO, DMPOX, ion Au(III).

Introduction

Recently, various nitrones have been used as spin traps for short-lived free radicals, such as the hydroxyl radical, in biosystems (1). However, some of these are well-known to produce free radicals not only through radical reactions but also through ionic reactions. 5,5-Dimethyl-1-pyrroline-*N*-oxide (DMPO), one of the most popular nitrone type spin traps, was oxidized to 5,5-dimethyl-1-pyrrolid-2-one-*N*-oxyl (DMPOX) by various oxidants (2–11) or through oxidative bioreactions (12–17). Similar DMPOX-type radicals were also observed for 3,3,5,5-tetramethyl-1-pyrroline-*N*-oxide (M4PO) (9, 18, 19). Makino et al. (5) reported that DMPO was oxidized to DMPOX by Fe^{3+} ion through 2-hydroxy-5,5-dimethyl-1-pyrrolidinyloxy (DMPO-OH), 2-hydroxy-5,5-dimethyl-1-pyrrolid-2-one (HDMPO), and 1-hydroxy-

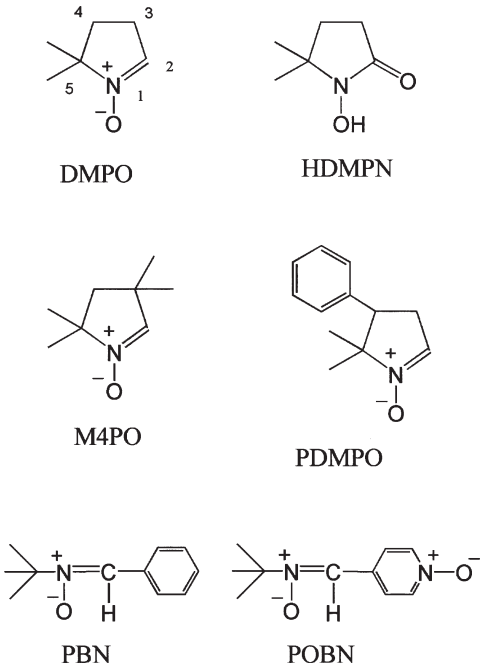
5,5-dimethyl-1-pyrrolid-2-one (HDMPN). Tajima and coworkers (18, 19) clarified in their electrochemical study that DMPO was oxidized to DMPOX by removal of three electrons. As the use of various nitrones for spin-trapping analysis has been increased recently, further information on specificities and kinetics of the DMPOX-type radical formation for various nitrones should become very important.

Various compounds containing sulfur, such as methionine (20), are well-known to reduce the Au(III) ion to Au(0). Recently, Zou et al. (21) found that Au(III) oxidized glycine through deamination and decarboxylation with formation of glyoxylic acid, ammonium ion, formic acid, carbon dioxide, and metallic gold. These results suggest that Au(III) is one of the best oxidants for various organic compounds, and can be applied for the analysis of DMPO oxidation.

The authors, therefore, examined the interaction between Au(III) and nitrone type spin traps, such as DMPO, and found the formation of DMPOX-type free radicals. In this study, some aspects and the mechanism of the nitrone oxidation reaction with Au(III) are discussed.

Experimental



Chemicals

Hydrogen tetrachloroaurate(III) ($HAuCl_4$) dihydrate and sodium dicyanoaurate(I) were obtained from Nacarai Tesque (Kyoto, Japan). DMPO, M4PO, *N-tert*-butyl-α-phenyl-nitrone (PBN), and α-(4-pyridyl-1-oxide)-*N-tert*-butyl-nitrone (POBN) were obtained from DOJINDO Ltd. (Kumamoto, Japan). During manufacture, a purity of more than 99% was obtained by repeated vacuum distillation and was checked by gas chromatography. 4-Phenyl-5,5-dimethyl-1-pyrroline-*N*-oxide (PDMPO) was obtained from Sigma-Aldrich Japan Inc. (Tokyo, Japan). HDMPN was prepared according to the method described by Bonnett et al. (22). Molecular structures of nitrones used in this study are shown in Fig. 1. All nitrones and the HDMPN used were examined by electron spin resonance (ESR) and no radical species were observed.

ESR measurements

Forty microliters of $HAuCl_4$ solution (1.25 mmol/L) and 40 μL of nitrone solution (1.25 mmol/L) were mixed at pH 4. After aspirating the mixture into a capillary tube, its ESR spectrum was immediately recorded using an X-band ESR spectrometer (JES TE-100, JEOL Ltd., Tokyo, controlled by a WIN-RAD ESR data analyzer, Radical Research Inc., Tokyo) under the following conditions: microwave power 5 mW; microwave frequency 9.42 GHz; magnetic field 335.3 mT; field amplitude ±5 mT; field modulation 100 kHz; modulation width 0.025~0.1 mT; sweep time 1 min; and the response time was 0.1 s. The solution pH was adjusted to the desired value with 0.1 N HNO_3 and 0.1 N NaOH solutions. To avoid the photochemical reduction of Au(III), the reaction was conducted under dark conditions. To determination the radical concentration, 60 μL of the sample solutions were aspirated into capillary tubes and their ESR spectra were recorded individually. The concentration of DMPOX-type radical was calibrated by using TEMPOL as a standard, following double integration of the observed ESR signal.

Fig. 1. Molecular structure of nitrone type spin traps and HDMPN, the precursor of DMPOX.

Gold determination

Total amounts of the Au(III) species in the reaction mixture were determined by spectrophotometry using Rhodamine B (23). The resulting amounts of Au(0) in the reaction mixture were determined as follows: the precipitate was dissolved in a solution of aqua regia (HNO_3–HCl mixture of 1:3) and then the concentration of gold in the solution was determined by using an ICP quantometer (Shimadzu ICPQ-1000II).

Results

Formation of aminoxyl radicals in nitrone–$HAuCl_4$ solutions

When solutions of cyclic nitrones (1.25 mmol/L), such as DMPO, PDMPO, and M4PO, were mixed with a $HAuCl_4$ solution (1.25 mmol/L) at pH 4, ESR signals with 9, 10, and 3 lines appeared, respectively (Fig. 2). The hyperfine coupling constants, that were estimated from computer simulations, are listed in Table 1. From these values, the radicals were identified as DMPOX (5, 7, 12, 13) and 3,3,5,5-tetramethyl-1-pyrrolid-2-one-*N*-oxyl (M4POX) (9). No β proton in M4POX gave the primary nitroxide triplet without any additional hyperfine splitting. Radical species that appeared in the PDMPO–Au(III) solution gave three hyperfine coupling constants at 0.71, 0.40, and 0.30 mT. Two of these, 0.71 and 0.40 mT, are identical to the a_N and a_{3H} of DMPOX. In PDMPO, the chiral C-4 atom, which can couple with one hydrogen atom and one phenyl group, will give rise to different hyperfine coupling constants for the two β protons, and they should appear at values of 0.40 and 0.30 mT. Therefore, the resultant radical can be assigned as a DMPOX-type radical, namely 4-phenyl-5,5-dimethyl-1-pyrrolid-2-one-*N*-oxyl (PDMPOX).

Fig. 2. ESR spectra of free radicals observed in the solution mixtures containing the following nitrones: (*a*) DMPO, (*b*) PDMPO, (*c*) M4PO, (*d*) PBN, and (*e*) POBN (1.25 mmol/L) and $HAuCl_4$ (1.25 mmol/L). The microwave frequency was 9.42 GHz.

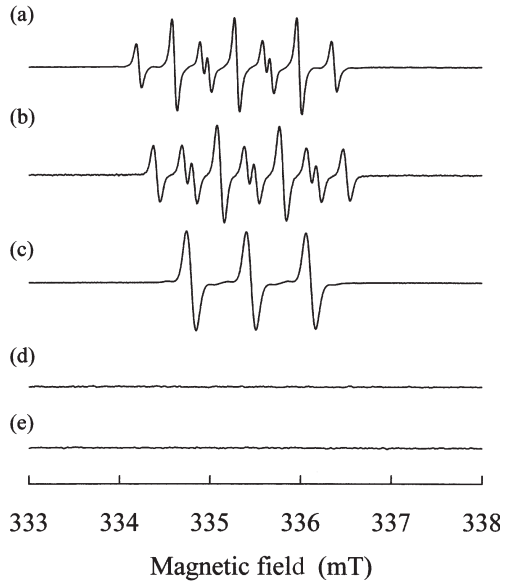

Table 1. Hyperfine coupling constants of free radicals observed in the reaction mixtures of hydrogen tetrachloroaurate(III) and cyclic nitrones, DMPO, PDMPO, and M4PO.

	Hyperfine coupling constant $A/g\beta$ (mT)	
Free radicals	a_N	a_{3H}[a]
DMPOX	0.71	0.40[b]
PDMPOX	0.71	0.40[c]
		0.30[c]
M4POX	0.67	

[a]The hyperfine coupling constant for protons combined with the C-3 atom in nitrone.
[b]Two protons combined with the C-3 atom are equivalent.
[c]Two protons combined with the C-3 atom are not equivalent to each other.

As the reaction proceeded, red-brown colored fine particles were deposited on the inner surface of the vessel. Deposited particles could be dissolved only in an aqua regia solution, and not in any other mineral acids. The resultant solution contained $AuCl_4^-$ species, which were identified by their absorbance at 322 nm (24) and by ICP quantometry. The deposited particles were thus deduced to be Au(0). These results indicate that Au(III) in the reaction mixture was reduced to Au(0) through the three-electron oxidation of nitrones to DMPOX-type free radicals. The reaction between DMPO and $HAuCl_4$ was conducted in N_2-bubbling water. No clear difference in any aspect of the reaction was observed in ordinal water. These results suggested that oxygen does not play an important role in the reaction.

In reaction mixtures of $HAuCl_4$ and noncyclic nitrones, such as PBN and POBN, no radical species, such as *N-tert*-butyl-α-phenyl-nitroxyl (PBNX) and α-(4-pyridyl-1-oxide)-*N-tert*-butyl nitroxyl (POBNX), were observed. These results indicated that the reaction proceeds only with cyclic nitrones, such as DMPO, PDMPO, and M4PO.

No ESR signal was observed for both neutral and acidic solutions of DMPO in the presence of excess amounts of sodium dicyanoaurate(I). The redox potentials are E[Au(III) – Au(0)] = +1.0, E[Au(III) – Au(I)] = +0.93, E[Au(I) – Au(0)] = +1.15 V for Cl^-, and E[Au(I) – Au(0)] = –0.61 V for CN^-. These values indicated that $Au(III)Cl_4^-$ is far more easily reduced to Au(0) than $Au(CN)_2^-$. Furthermore, CN^- in the dicyanaurate(I), being very stable under neutral conditions (β_2 = 11.23) (25), cannot be replaced with DMPO. Disproportionation of the Au(I) ion occurs only with difficulty (eq. [1]).

$$[1] \qquad 3[Au(I)L_2]^- \rightarrow [Au(III)L_4] + 2Au(0) + 2L$$

In the present system (20) disproportionation is not favourable since for L = CN^- the equilibrium constant of eq. [1] may be in the order of 10^{-25}. These results suggest that the oxidation of DMPO to DMPOX occurs only because of coupling with the three-electron reduction of Au(III) ion to Au(0).

Aspects of DMPOX-type radical formation in cyclic nitrone–$HAuCl_4$ solutions

Time course of radical formation

The time course of DMPOX-type radical formation was examined using mixtures of nitrones (1.25 mmol/L) and $HAuCl_4$ (1.25 mmol/L) at pH 4. The ESR signal intensities for all DMPOX-type radicals examined increased with time, and reached a maximum value within 20~30 min for DMPOX and PDMPOX, and more than 60 min for M4PO (Fig. 3). No other free radical species, except DMPOX-type ones, were observed for a period of 2 h after the reaction was started.

As shown in Fig. 3, the time course of DMPOX-type radical formation in these nitrones show lag phases in the first 5–10 min, which suggests complicated reaction processes. The decrease in Au(III) concentration in the reaction mixtures was fitted to eq. [2] and exhibited second-order reaction kinetics (Fig. 3),

$$[2] \qquad [Au(III)] = C/(Ckt + 1)$$

where C is the initial Au(III) concentration (1.25 mmol/L), t is time, and k is the equilibrium constant. The k values for each nitrone are listed in Table 2. As shown in Table 2, the relative order of magnitude in the rate for the initial stage of the reaction was PDMPO > DMPO >> M4PO, while for the final radical formation it was PDMPO ≥ DMPO > M4PO. In PDMPO, a weak inductive effect proceeds the reaction, while in M4PO, a couple of methyl groups at C-3 strongly hindered the reaction.

Effect of nitrone concentration

The effect of nitrone concentration on DMPOX-type radical formation was examined using a mixture of DMPO (0.5~5 mmol/L) and $HAuCl_4$ (1.25 mmol/L) at pH 3. As shown in Fig. 4, an unusual time dependency was observed for DMPOX radical formation. An anomalous increase in

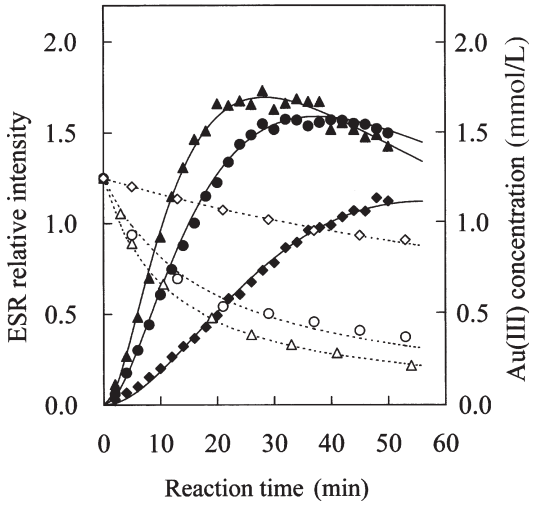
Closed circles are the ESR signal intensity in DMPO, closed triangles in PDMPO, and closed diamonds in M4PO solutions; open circles are the Au(III) concentration in DMPO, open triangles in PDMPO, and open diamonds in M4PO solutions. The solid lines indicate the best fitting curves using the least-squares method, while the dotted lines are those estimated using eq. [2]. Parallel experiments were conducted to determine the gold concentrations as described in the Experimental section.



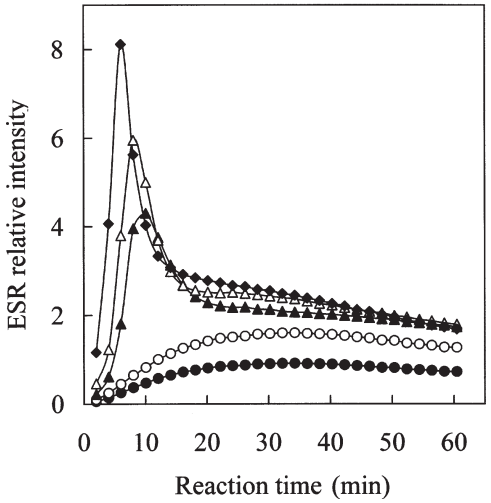


Table 2. Kinetic parameters for DMPOX-type radical formation.

Nitrone	k	Maximum amount of free radical (mmol/L)
DMPO	0.043	0.014
PDMPO	0.069	0.015
M4PO	0.0061	0.010

Note: [Au(III)] = $C/(Ckt + 1)$. The initial concentration of each nitrone was 1.25 mmol/L.

DMPOX was observed within the first 10 min of mixing DMPO (2.5~5 mmol/L) and $HAuCl_4$ (1.25 mmol/L). Twenty minutes after the reaction started, this time dependency slowed and settled down to match that of low DMPO concentrations (0.5 and 1.25 mmol/L). These results suggested that excess amounts of DMPO eliminated the DMPOX radical formed in the mixture. Thornalley et al. (14) reported a similar rapid decrease of DMPOX in *tert*-butyl hydroperoxide–methaemoglobin systems and suggested that DMPOX decomposed to various products such as 5,5-dimethyl-1-hydroxy-2-pyrrolidone (DMPOXH), 4-methyl-4-nitrosopentanoic acid (MNPA), 4-methyl-4-nitropentanoic acid (MNOPA), 4-methyl-4-nitrosobutane, and a radical species, *N*-(5,5-dimethyl-1-oxyl-pyrrolidine)-4-hydroylamino-4-methylpentane (DMPO–PNO) (26). In the present system, an ESR signal for DMPO–PNO with 18 lines characterized by a_{N1} = 1.43, a_H = 1.62, and a_{N2} = 0.42 mT was not observed under excess DMPO conditions. Furthermore, DMPOX decreased slower with small amounts of DMPO present than under excess DMPO conditions (Fig. 3). Other possibilities include the reduction of DMPOX to its hydroxyl amine or even dimerization of the DMPOX. Further precise experiments will be needed to clarify this situation. In this paper, low concentrations, such as 1.25 mmol/L of DMPO, where the anomalous increase was not observed within the first 10 min, will be adopted for the following experiments.

Fig. 4. Effect of DMPO concentration on DMPOX formation in mixtures of DMPO (0.5~5 mmol/L) and $HAuCl_4$ (1.25 mmol/L). Closed circles are 0.5 mmol/L, open circles are 1.25 mmol/L, closed triangles are 2.5 mmol/L, open triangles are 3.75 mmol/L, and closed diamonds are 5 mmol/L DMPO solutions. The solid lines indicate the best fitting curves using the least-squares method.

Effect of co-existing salts

Addition of sodium chloride to the reaction mixture markedly decreased the ESR signal intensities of DMPOX, PDMPOX, and M4POX, while no effect was observed when $NaNO_3$ was added (Fig. 5). The amount of $AuCl_4^-$ in the solutions, as depicted in Fig. 5, was calculated using the formation constants listed by Sillen and Martell (25). As shown in Fig. 5, formation of the stable complex anion, $AuCl_4^-$, suppressed the redox reaction.

Effect of solution pH

The ESR signal intensities of DMPOX-type radicals decreased below pH 1 and above pH 6 (Fig. 6) in DMPO, PDMPO, and M4PO. The ratios of chemical species, $AuCl_4^-$, $Au(OH)Cl_3^-$, $Au(OH)_2Cl_2^-$, $Au(OH)_3Cl^-$, and $Au(OH)_4^-$ calculated using the formation constants listed by Sillen and Martell (25), are also shown in Fig. 6. As shown in Fig. 6, as the ratios of $AuCl_4^-$ and $Au(OH)_4^-$ in the reaction mixture were increased, the ESR signal intensities decreased. Below pH 2, excess amounts of Cl^- stabilize the $AuCl_4^-$ ion, while above pH 7, excess amounts of OH^- stabilize the $Au(OH)_4^-$ ion. In the intermediate pH range, Cl^- ion in the complex ions were easily replaced with the OH^- ion. When DMPO exists in the solution, Cl^- ion in the complex ions were easily replaced with DMPO, in a manner similar to the reaction between thiomorpholin-3-one and $AuCl_4^-$ ion as proposed by De Filippo et al. (27). Complex formation between DMPO and the Au(III) ion will proceed via the redox reaction. These results suggest that the formation of stable com-

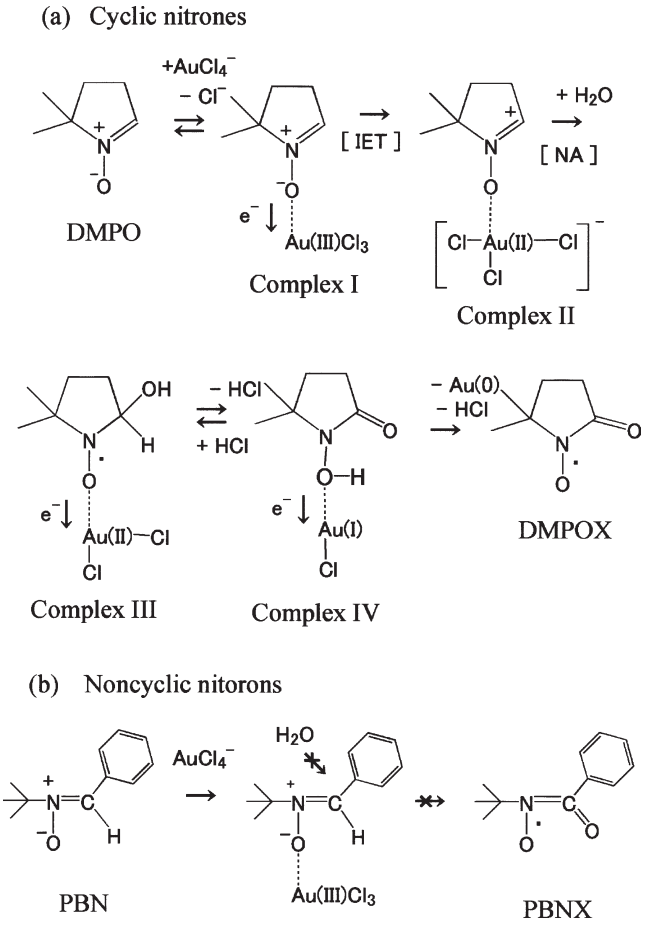
plex anions, such as $AuCl_4^-$ and $Au(OH)_4^-$, suppress the redox reaction.

Reaction of the DMPOX precursor with $HAuCl_4$

HDMPN, the precursor of DMPOX in the oxidation of DMPO by Fe^{3+} ion (5) and in the electrochemical oxidation of DMPO (18, 19), was also oxidized to DMPOX by the

Fig. 7. Time course of ESR relative intensities of DMPOX observed in the solution mixtures of $HAuCl_4$ and HDMPN. $HAuCl_4$ (1.25 mmol/L) was mixed with DMPO and HDMPN (1.25 mmol/L), respectively. Closed circles are the ESR signal intensity and open circles are the Au(III) concentration in the HDMPN–$HAuCl_4$ solution. The solid line indicates the best fitting curve using the least-squares method while the dotted line has been estimated using eq. [2]. The dashed line indicates the ESR intensity in the DMPO–$HAuCl_4$ solution. Parallel experiments were conducted to determine the gold concentrations as described in the Experimental section.



Au(III) ion. The ESR signal intensity of DMPOX in the 1:1 mixture of HDMPN and $HAuCl_4$ (1.25 mmol/L) was increased with the time course (Fig. 7). The time course of Au(III) reduction in the system was also well described by eq. [1], where $k = 0.028$ and the maximum amount of free radical was 0.012 mmol/L. Complexation between Au(III) and HDMPN is slower than that observed between Au(III) and DMPO. No precipitation of Au(0) was observed during the course of the reaction, which showed that the reduction step from Au(I) to Au(0) was not used for HDMPN oxidation in the 1:1 mixture. On the other hand, in the 3:1 mixture of HDMPN (1.25 mmol/L) and $HAuCl_4$ (0.417 mmol/L), DMPOX was formed with Au(0) precipitation, which indicated that the reduction step from Au(I) to Au(0) was coupled with HDMPN oxidation. Summarizing these results, it is proposed that the three-electron-reduction process from Au(III) to Au(0) can be coupled with the oxidation of DMPO to DMPOX.

A weak ESR signal for DMPOX was observed in a sodium dicyanoaurate(I)–HDMPN solution mixture under acidic conditions (pH 0.5), despite exhibiting no signal at neutral pH. There are two possible explanations for these results: first is the oxidation ability of Au(I) ions. Since dicyanoaurate(I) ion is very stable under neutral conditions (β_2 = 11.23) (25), HDMPN cannot form a complex with Au(I) if cyanide ions are present in the system. However, under acidic conditions, small amounts of CN^- in the dicyanoaurate(I) ion can be replaced with HDMPN, which causes transfer of an electron from Au(I) to HDMPN and DMPOX forms. Second is the disproportionation of the Au(I) ion (eq. [1]) (20). As discussed in the previous section, disproportionation is not favourable for the dicyanoaurate(I) ion

Fig. 8. Overall reaction of $HAuCl_4$ with cyclic nitrones such as (*a*) DMPO and noncyclic nitrones such as (*b*) PBN. The intramolecular electron transfer is abbreviated as IET and the nucleophilic addition as NA.

(20). These results, therefore, indicate the possibility that the reduction step from Au(I) to Au(0) was used for HDMPN oxidation.

Discussion

Cyclic nitrones, such as DMPO, PDMPO, and M4PO, were oxidized to DMPOX-type free radicals by the Au(III) ion with precipitation of Au(0). The reaction was greatly hindered by chloride ion, and was depressed in acidic and basic solutions. An assumed overall reaction scheme for the DMPO–$HAuCl_4$ system is shown in Fig. 8*a*. First, DMPO···Au(III)Cl_3 (complex I) is formed by the ligand exchange interaction between Cl^- and DMPO, in a manner similar to the formation of the Fe^{3+}–DMPO complex (5). This is followed by the intramolecular electron transfer from DMPO to Au(III)Cl_3 (complex II). The resultant complex II is then converted to complex III (DMPO-OH···Au(II)Cl_2) by the nucleophilic addition of a water molecule at the C-2 atom. The resultant complex III is converted to complex IV (HDMPN···Au(I)Cl) by the intramolecular electron transfer from DMPO-OH to Au(II)Cl_2 with the loss of HCl. Finally, complex IV is converted to DMPOX by the intramolecular electron transfer from HDMPN to Au(I)Cl and release of HCl and Au(0). Three electrons are, therefore, moved from DMPO to Au(III) through the reaction. When stable complex anions, such as $AuCl_4^-$ or $Au(OH)_4^-$ are formed by the addition of HCl, NaCl, or NaOH, the ligand exchange interaction in the first stage will be depressed. The rate of total Au(III) decrease corresponded to the increase in the ESR signal intensity of the resultant radical. Thus, the formation of complex I should be the rate-determining step in the reaction process. Two methyl groups at the C-3 atom in M4PO sterically hinder the addition of a water molecule to the C-2 atom, thereby causing the slower reaction rate. Similar kinetics for M4PO oxidation were found in the Fe^{3+}–M4PO system (27). The weak inductive effect of the 4-phenyl group in PDMPO will cause a slightly faster reaction rate than for DMPO.

In the reaction mixture of $HAuCl_4$ and noncyclic nitrones, such as PBN and POBN, no ESR signal was observed. Similar results were observed in the Fe^{3+}–PBN system and in the electrochemical redox reaction of PBN (19). These results suggest that steric hindrance of the phenyl group in PBN or the 4-pyridyl-1-oxide group in POBN inhibits the nucleophilic addition of a water molecule and chelation to the metal ion (Fig. 8*b*). Ozawa et al. (9) reported the formation of PBNX and POBNX by oxidation of PBN and POBN with the ClO_2 radical. They explained this reaction as the direct oxidation of the α-C atom in PBN and POBN by the ClO_2 radical, which is quite different from our scheme.

As discussed in the previous section, the results reported herein can be explained quite well by the proposed reaction mechanism shown in Fig. 8*a*. The reduced forms of DMPOX and HDMPN (18, 19) were also oxidized to DMPOX by reaction with 0.33 mol/L $HAuCl_4$, indicating that every step of the gold reduction, from Au(III) to Au(0), is coupled with oxidation of HDMPN and DMPO. These results suggested the possibility that HDMPN was the DMPOX precursor in our system. If the first step involved in the $HAuCl_4$–DMPO system is the ligand exchange interaction and the nucleophilic addition of a water molecule, then the reaction will proceed with a rate constant having a time dependency of $[1 - \exp(-0.043t)]$. Since the total Au(III) decrease should be caused by the ligand exchange interaction, the nucleophilic addition of a water molecule, the electron transfer, and complex III formation, then the increase in DMPOX formation should be a little bit faster than the total Au(III) decrease, namely $\exp(-0.070t)$. However, complexation between Au(III) and HDMPN is slower than that between Au(III) and DMPO. The decrease in Au(III) in the DMPO–$HAuCl_4$ solution is faster than that in the HDMPN–$HAuCl_4$ solution, while formation of DMPOX in the former solution is slower than in the latter solution. The amounts of radical formed in the system (0.014 mmol/L) (Table 2) are far smaller than the initial DMPO concentration (1.25 mmol/L), which means that the Au(III) decrease and the DMPOX formation are independent. The reaction process from DMPO to HDMPN is a little bit complicated, which causes slower DMPOX formation in the DMPO–$HAuCl_4$ solution than that in the HDMPN–$HAuCl_4$ solution.

Oxazoline chemistry. Part VIII. Synthesis and characterization of a new class of pincer ligands derived from the 2-(*o*-anilinyl)-2-oxazoline skeleton — Applications to the synthesis of group X transition metal catalysts[1]

Andreas Decken, Robert A. Gossage, and Paras N. Yadav

Abstract: The synthesis and characterization of a new and readily synthesized class of potentially anionic pincer ligands with C_1 point group symmetries is described. These materials can be made via amide coupling of a 2-(2′-anilinyl)-2-oxazoline unit with picolinic acid; the incorporation of enantiopure oxazoline fragments facilitates the construction of chiral C_1 pincers. Treatment of the free ligands with Pd metal sources leads to the formation of amido–Pd pincer complexes in good yield. One of these Pd complexes has been characterized by single crystal X-ray diffraction methods, which confirms the proposed tridentate binding mode of the ligand and the formation of an amido N—Pd bond. The metal complexes have been shown to be suitable precusors for catalytically active Pd species that are useful for C—C bond forming reactions, notably the Heck reaction under standard conditions.

Key words: oxazoline, 4,5-dihydro-2-oxazole, palladium, pincer ligand, amido, Heck reaction.

Résumé : On décrit la synthèse facile et la caractérisation d'une nouvelle classe de ligands anioniques à pinces ayant des groupes de symétrie ponctuelle C_1. Ces produits peuvent être obtenus par couplage d'amide d'une unité 2-(2′-anilinyl)-2-oxazoline avec de l'acide picolinique; l'incorporation de fragments oxazolines énantiopurs facilite la formation de ligands à pince de symétrie C_1. Le traitement des ligands libres avec des sources de palladium métallique conduit à la formation, avec de bons rendements, de complexes amido–Pd pincer. On a caractérisé un de ces complexes du Pd par diffraction des rayons X par un cristal unique et on a ainsi pu confirmer le mode de liaison tridentate du ligand et la formation d'une liaison N—Pd amido. On a montré que les complexes métalliques sont des précurseurs appropriés pour des espèces catalytiquement actives de Pd qui sont utiles dans les réactions de formation de liaisons C—C, particulièrement dans la réaction de Heck dans des conditions standards.

Mots clés : oxazoline, 4,5-dihydro-2-oxazole, palladium, ligand à pince, amido, réaction de Heck.

Introduction

In recent years, enantiopure (C_2 symmetric) bisoxazolines have become a popular and useful class of ligands for applications in asymmetric synthesis promoted by Lewis acids (1). Oxazolines have been shown to possess a rich transition-metal chemistry (2), and recently the oxazoline fragment has been incorporated into the design of the so-called "pincer" ligand framework. This has resulted in the accessibility of potentially anionic and C_2-symmetric pincers (3). Pincer ligands have been at the forefront of a number of areas of investigation within organometallic chemistry including dendrimer chemistry, molecular sensor technology, the study of unusual bonding motifs or metal oxidation states (e.g., Ni^{3+}), and metal-mediated catalysis (4). Despite these advances, there has been increasing interest in ligands of *lower* symmetry; this is due to the fact that in many cases superior enantioselective catalysis can be obtained from species containing such ligands (1*a*, 1*c*, 5). Herein, we report the facile syntheses of C_1-symmetric amide pincer ligands containing a chiral (or achiral) oxazoline group in addition to a secondary binding (pyridine) functionality. In addition, these amides (Fig. 1) are shown to readily deprotonate (to form anionic pincers) on reaction with Pd sources to form Pd–

Fig. 1. Synthetic methodologies for the production of **3**–**6**.

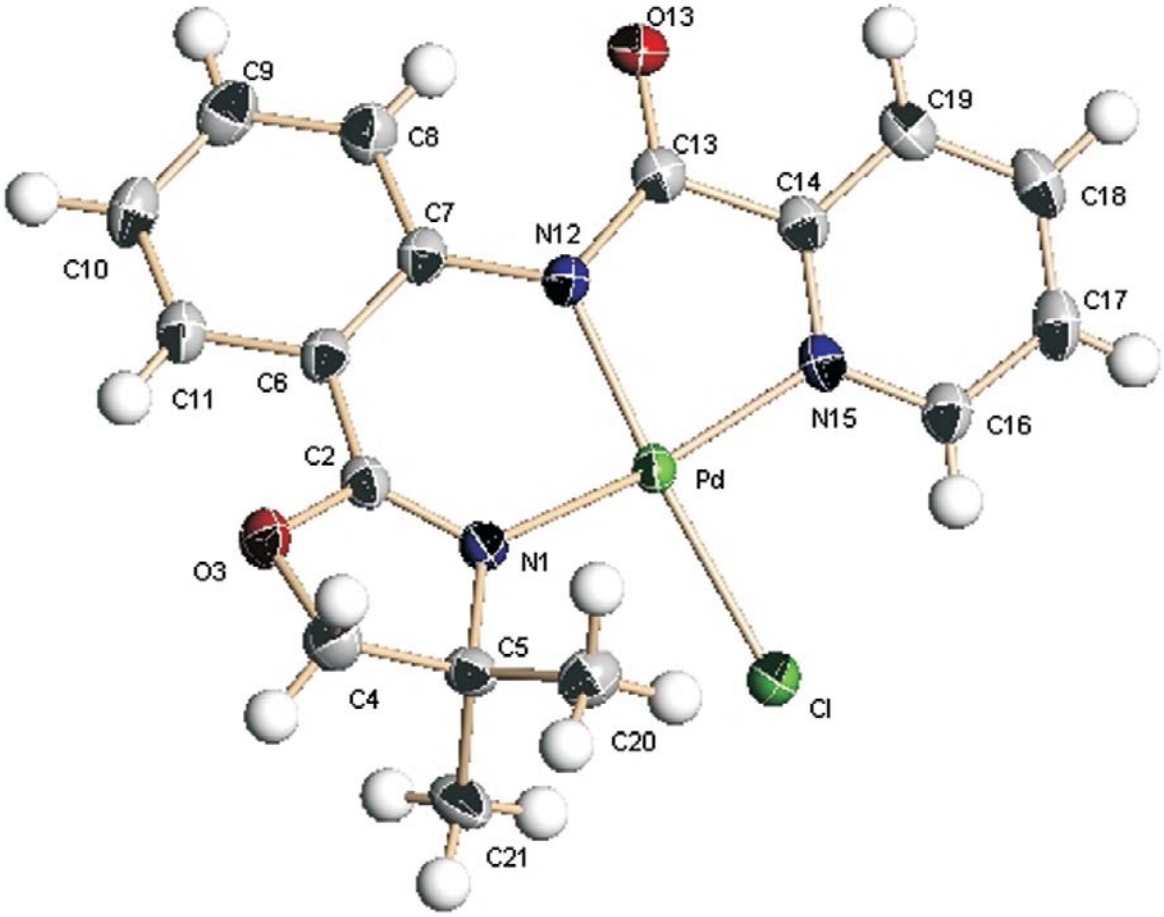
amido complexes; these metal derivatives are shown to be active catalysts for the Heck reaction under standard protocols.

Results and discussion

The synthesis of amide **3** (Fig. 1) was accomplished using the in situ produced ($SOCl_2$) acid chloride (6) derivative of picolinic acid (PA), followed by the low temperature addition of readily available 4,4-dimethyl-2-(*o*-anilinyl)-2-oxazoline (**1**, Fig. 1, eq. [1]) (7). Unfortunately, yields of chiral analogue **4** were found to be variable by the above methodology, but the desired product could be reproducibly synthesized using PA and **2** under DCC–DMAP protocols (Fig. 1, eq. [1], also see Experimental section). Both **3** and **4** can thus be easily produced in large quantities (>1 g). The air-stable nature of these materials makes them easier to handle than many of the sensitive "PCP" or "pincer carbene" ligands (1). Facile ligand "tuning" (8) can be readily envisioned because of the availability of a number of analogues of **1** and **2** (7).

Palladium complexes of deprotonated **3** or **4** are formed in good yield upon treatment of (MeOH) solutions of the ligands with stoichiometric Li_2PdCl_4. These reactions lead to the isolation of solid and air-stable brown-coloured complex **5** (82%) and yellow **6** (91%), respectively (Fig. 1, eq. [2]). ^{1}H NMR data on both materials, in combination with elemental analysis, IR data, and the diamagnetic nature of both complexes, strongly suggest the formation of 1:1 adducts of the ligand fragments with Pd^{2+}. Specifically, the disappearance of the ^{1}H NMR signal assigned to the amide N-*H* proton and loss of the corresponding IR stretching frequency assigned to this group, imply the formation of complexes of the general formula $[Pd(L\text{-}H)Cl]_x$ (L = **3** or **4**, respectively). To confirm the mononuclear nature of these species, a single crystal X-ray diffraction study was carried out on a sample of complex **5**. A molecular respresentation of this material is found in Fig. 2. Crystal data can be found in Table 1; Table 2 gives a list of selected bond lengths and angles for complex **5**.

The X-ray data confirm that **5** is a monopalladium complex incorporating deprotonated **3**; bond lengths and angles are typical for a formal Pd^{2+} metal centre (1, 9). Of note is the formal amido–Pd interaction in addition to the coordination of both the pyridine and the oxazoline groups forming five- and six-membered rings, respectively; the latter functionality binds through the N atom, as expected (2). Thus, a tridenate (κN, κN′, κN″) bonding motif is presented. The coordination geometry around the Pd atom is best described as distorted square-planar in nature. Therefore, ligands such as **3** do form pincer complexes and in excellent yields.



Several Pd pincer compounds are known to be active promoters of selective C—C bond formation (10). We have therefore performed some preliminary tests on complexes **5** and **6** as promoters of the Heck reaction under typical reaction conditions (9). Both complexes catalyse the regioselective coupling of iodobenzene with styrene to give high yields of *trans*-stilbene under standard protocols in the presence of base (NaOAc, see the Experimental section). Notably, these reactions were preformed *in open air* and hence these pincer catalysts appear to be highly robust (11) to the high temperature oxidizing conditions employed.

Conclusions

In conclusion, access to a new and readily synthesized class of potentially anionic pincer ligands has been realised. These compounds can be used to make catalytically active

Pd species for selective C—C bond forming reactions that can be used in the absence of inert atmosphere conditions. The investigation of other transition-metal complexes of these and related ligands, and their catalytic potentials, will be disclosed in due course.

Experimental section

General

All reactions were carried out using standard bench-top laboratory techniques using commercially available, reagent-grade solvents. ^{1}H NMR spectra were recorded from chloroform-*d* solutions at 300 MHz using a Bruker Avance 300 NMR spectrometer. Microanalyses were recorded at the analytical services department of the University of Windsor (Windsor, Ontario). IR spectra were obtained as Nujol muls using a PerkinElmer 683 IR spectrometer. Melting point data were obtained using a Mel-Temp II apparatus and reported values are uncorrected. Optical rotation measurements were made on a Bellingham + Stanley Ltd. model ADP220 polarimeter using a 1 dm path length optical cell.

Syntheses

Synthesis of 3

Thionyl chloride (5.6 g, 50 mmol) was added dropwise to a stirred and cold (0 °C) mixture of PA (6.15 g, 50 mmol) and Et_3N (7.6 g, 75 mmol) in 35 mL of CH_2Cl_2 (6). Stirring was continued for 30 min and then a suspension of **1** (7*a*) (9.5 g, 50 mmol) in 20 mL of CH_2Cl_2 was added (at 0 °C). The stirring was continued for a further 3 h as the mixture warmed to room temperature (RT); the reaction vessel was then left standing overnight. Neutralization by the addition of satd. aq. Na_2CO_3 was followed by isolation of the organic layer, which was subsequently washed with water (3 × 15 mL) and then evaporated in vacuo. The crude product thus obtained was purified by (flash) chromatography (SiO_2, 230–400 mesh) using hexanes – ethyl acetate (3:1, *v*/*v*) as the eluent (R_f = 0.50). The yellow solid *product* was thereafter isolated following solvent evaporation. Yield: 6.63 g (45%); mp 110 °C. IR (cm^{-1}): 3054 (w), 1670 (s), 1645 (s), 1583 (s), 1540 (s). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.51 (s, 6H), 4.12 (s, 2H), 7.15 (t, 1H, *J* = 7.9 Hz), 7.47–7.58 (m, 2H), 7.87–7.95 (m, 2H), 8.30 (d, 1H, *J* = 7.9 Hz), 8.69 (d, 1H, *J* = 4.5 Hz), 9.03 (d, 1H, *J* = 8.3 Hz). Anal. calcd. for $C_{17}H_{17}N_3O_2$ (%): C 69.14, H 5.80, N 14.23; found: C 70.03, H 5.82, N 14.57.

Synthesis of 4

In a round-bottomed flask containing chilled (10 °C) CH_2Cl_2 (160 mL) was added **2** (7*a*) (2.136 g, 11.2 mmol) and PA (1.674 g, 13.6 mmol). The mixture was stirred under an inert atmosphere for 25 min at 0 °C. To this mixture was added DMAP (0.412 g, 3.2 mmol) and DCC (3.492 g,

Catalysis

Heck coupling reactions of iodobenzene and styrene using 5 or 6[4]

Iodobenzene (25 mmol), styrene (30 mmol), *N*,*N*-dimethylformamide (25 mL), sodium acetate (30 mmol), and 0.5 mg (~1 μmol) of **5** or **6** were combined in a round-bottomed flask equipped with a reflux condenser (9). The mixture was heated, in open air, to 140–150 °C for 24 h. After cooling to RT, 0.1 L of dil. aq. HCl was added and the

[4] Nota bene: no attempt was made to optimize the reaction conditions.

organic components were extracted with ethyl acetate (3 × 100 mL). The organic layer was washed (brine) and dried (Na_2SO_4). After filtration, volatiles were removed (vacuo) and the product *trans*-stilbene (correct mp and ^{1}H NMR) was purified by flash column chromatography (hexanes–EtOAc, 9:1). Yield: 95% (using **5**); 89% (using **6**).

X-ray crystallography of complex 5[5]

Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold nitrogen stream of the goniometer. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and 10 s exposure times. The detector distance was 5 cm. The data were reduced (SAINT) (12) and corrected for absorption (SADABS) (13). The structure was solved by direct methods and refined by full-matrix least-squares on F^2 (SHELXTL) (14). Hydrogen atoms were included in calculated positions and refined using a riding model.

NOTE / NOTE

Induced structural changes of a supported planar bilayer after exposure to halothane — A real-time atomic force microscopy study

L.G. Shamrakov and D.T. Cramb

Abstract: Atomic force microscopy (AFM) was used to study the effect of the general anesthetic halothane on a supported DOPC phospholipid bilayer, under conditions of high anaesthetic loading. The presence of the anaesthetic in the lipid-induced restructuring of the supported bilayer, erosion of the bilayer from the mica surface, and the formation of lipid aggregates. Addition of halothane to lipid vesicles prior to adsorption on the mica surface inhibited the lysis of adsorbed vesicles and thus no planar bilayer formation was observed.

Key words: lipid bilayer restructuring, atomic force microscopy, halothane, anesthesis.

Résumé : On a fait appel à la microscopie des forces atomiques (MFA) pour étudier l'effet de l'anesthésique général, halothane sur une bicouche supportée de phospholipide DOPC, dans des conditions de charge élevée d'anesthésique. La présence de l'anesthésique dans le lipide induit une restructuration de la bicouche supportée, une érosion de la bicouche de la surface du mica et la formation d'agrégats de lipides. L'addition d'halothane aux vésicules de lipide avant l'adsorption sur la surface de mica inhibe la lyse des vésicules adsorbées et on ne peut alors observer de formation de bicouche planaire.

Mots clés : restructuration d'une bicouche de lipide, microscopie de forces atomiques, halothane, anesthésique.

[Traduit par la Rédaction]

Introduction

Although, general anaesthetics are known to have a direct interaction with biological cell membranes (1), the exact sequence of events leading to anesthetic action remains unknown at the molecular level. Presently, there is significant evidence that the targets of volatile anaesthetics are ligand-gated ion channels embedded in cell membranes (2). However, it has also been hypothesized that the interaction between anaesthetics and these ion channels occurs indirectly, via a change in the microenvironment of the phospholipid bilayer surrounding the ion channels (3). Regardless, since anaesthetic potency increases with lipophilicity, an understanding of the changes that occur within model biological membranes in the presence of anaesthetics will provide insight regarding anaesthetic mechanisms.

A supported 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) planar bilayer is often chosen as a model biological cell membrane, because its behavior is well-characterized and membrane mimetic (4). In addition, DOPC is stable in the form of a supported planar bilayer for a period of days (5, 6), allowing for long-term observations of interactions with anaesthetics.

The anaesthetic used in this study, halothane, is an amphiphilic molecule. Fluorescent studies have indicated that halothane resides predominantly in the headgroup region of a model DOPC bilayer (5). Moreover, using atomic force microscopy (AFM) we have recently shown that halothane likely has a heterogeneous lateral distribution in gel-phase 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) SPBs (6). Finally, molecular dynamic simulations revealed halothane is distributed unevenly across the membrane interior (7). It is of interest how this uneven distribution affects the stability of a supported planar bilayer. One would expect uneven distribution of halothane within a supported phospholipid bilayer to decrease line tension, resulting in destabilization, and possibly restructuring of the bilayer.

Supported planar bilayer restructuring after the addition of chitosan was previously observed by Fang and Chan (8). The presence of the protein chitosan within the bilayer induced growth clusters to form within the bilayer, and aggre-

 doi: 10.1139/V05-129 © 2005 NRC Canada

gation of lipids was observed. A decrease in bilayer line tension was cited as the cause of the changes. In addition, Fang and Chan reported an erosion of fragments of the lipid membrane from the mica surface.

In the present work, magnetic A/C mode (MAC) AFM was used to examine the effect of the presence of the general anaesthetic halothane on a mica-supported planar DOPC bilayer. The halothane-induced changes in a DOPC SPB were monitored over a 22 h period.

Methods

Materials

DOPC in chloroform solution was used without further purification (Avanti Polar-lipids Inc., Alabaster, Maine). Filtered (0.1 μm pore size) ultrapure water was used for the preparation of all solutions. Freshly cleaved ASTMV-2 quality, scratch-free ruby mica (Asheville-Schoonmaker Mica Co., Newport News, Virginia) was used as the SPB substrate for imaging.

Supported DOPC bilayer in water

A 0.7 mg/mL DOPC solution was prepared in ultrapure water using the method previously described (9). Briefly, an aliquot of DOPC suspended in chloroform was transferred into a dry vessel. The solution was then dried under a stream of nitrogen to remove the chloroform. The phospholipid was then resuspended in ultrapure water and stirred for 30 min. The solution was then sonicated and stirred for successive 10 min cycles at room temperature until it became clear (Branson 1200, Dansbury, Connecticut). The solution was then filtered (0.2 μm pore size) and sonicated for 10 min prior to deposition onto the mica substrate.

Supported planar bilayers were prepared via vesicle fusion (9). DOPC solution (75 μL, 0.7 mg/mL) was deposited on unmodified, freshly cleaved mica and incubated for 45 min. The surface was then gently rinsed with ultrapure water. All bilayers were imaged in ultrapure water at room temperature.

Supported DOPC bilayer containing halothane

Halothane (60 μL) was added to the AFM cell containing a previously imaged supported DOPC bilayer and incubated at room temperature for 30 min (creating a 10% *v*/*v* solution in ultrapure water). A series of exposure times were tested. Thirty minutes was the minimum time needed to observe change, and allows imaging of further changes in bilayer structure. The liquid above the bilayer was then gently removed from the cell with a pipette, and fresh ultrapure water was immediately added to prevent drying of the sample. Under these conditions the solution would be saturated with halothane (17.5 mmol/L).

AFM imaging conditions

All imaging was done using MAC mode AFM in which a magnetically coated probe, driven by an alternating magnetic field, oscillates near its resonant frequency. This technique was chosen as it has proven to be minimally invasive to supported planar bilayers in situ (9–11). Images were obtained using a Pico SPM microscope with an AFMS-165 scanner (Molecular Imaging Inc., Phoenix, Arizona) and magnetically coated type I Maclevers® (Molecular Imaging Inc.) were used. The cantilever used had a force constant of 0.6 N/m and the tip radius of curvature was quoted as being within the range of 5–10 nm. A standard MAC mode fluid cell (Molecular Imaging Inc.) was used in all experiments.

Results and discussion

To study the effect of halothane's presence on the supported phospholipid bilayer, it was first necessary to obtain a single planar supported bilayer via vesicle fusion on the mica surface. In the absence of halothane, a uniform supported planar DOPC bilayer was observed (Fig. 1A). Viscoelasticity analysis (9) was used to confirm the presence of a single supported bilayer (data not shown).

Next, halothane was added to a preformed SPB as described in the Methods section. The addition of halothane resulted in a restructuring of the supported DOPC bilayer. Images obtained 6 h and 45 min after halothane addition to the supported planar bilayer displayed large structures, which are presumably lipid aggregates (Fig. 1B). The largest aggregate observed had a height of 100 nm and was imaged at 7 h after halothane addition. It is uncertain whether this is the maximum size of aggregate, or whether they continue to increase in size indefinitely. Control experiments where halothane was added directly to the mica surface did not produce images comparable to those with a bilayer. Further control experiments were performed where the SPB was treated in the same way as for halothane addition, with the exception that an equivalent volume of water was injected. No changes in the SPB were observed under these conditions.

Although there is no evidence that these aggregates result from uncontrolled foreign substances acting upon the bilayer, viscoelasticity analysis should provide additional insight into the nature of the aggregates, possibly confirming that they are lipid-based. Viscoelasticity (i.e., phase) images provide information about a sample's ability to dissipate energy transferred from interactions with the AFM tip. Differences in viscoelasticity result from differences in phase, and thus viscoelasticity analysis can be used to distinguish samples that are different in lipid phase. For instance, the solid mica support can be distinguished from liquid- or gel-phase SPBs. Fig. 2A displays an aggregate of interest. Topography images indicate the presence of larger entities on the mica substrate (Fig. 1A). In the corresponding viscoelasticity (i.e., phase) image, areas of only two different viscoelasticities are evident. These two represent the bilayer and the mica support. There is no phase contrast between the large aggregates (identified by a circle in Fig. 1C) and the domain that surrounds them, suggesting that the aggregates are lipid based and possibly multilamellar. The formation of these lipid aggregates could result from erosion of the lipid from the mica support and restructuring of the lipids owing to a destabilizing effect of halothane on the supported bilayer. This destabilization would result from a decrease in line tension caused by uneven distribution of halothane within the bilayer.

Significantly, we were able to monitor the spontaneous formation of a lipid aggregate at times ranging from 4 h and 25 min to 5 h after initial halothane addition (Fig. 2). The

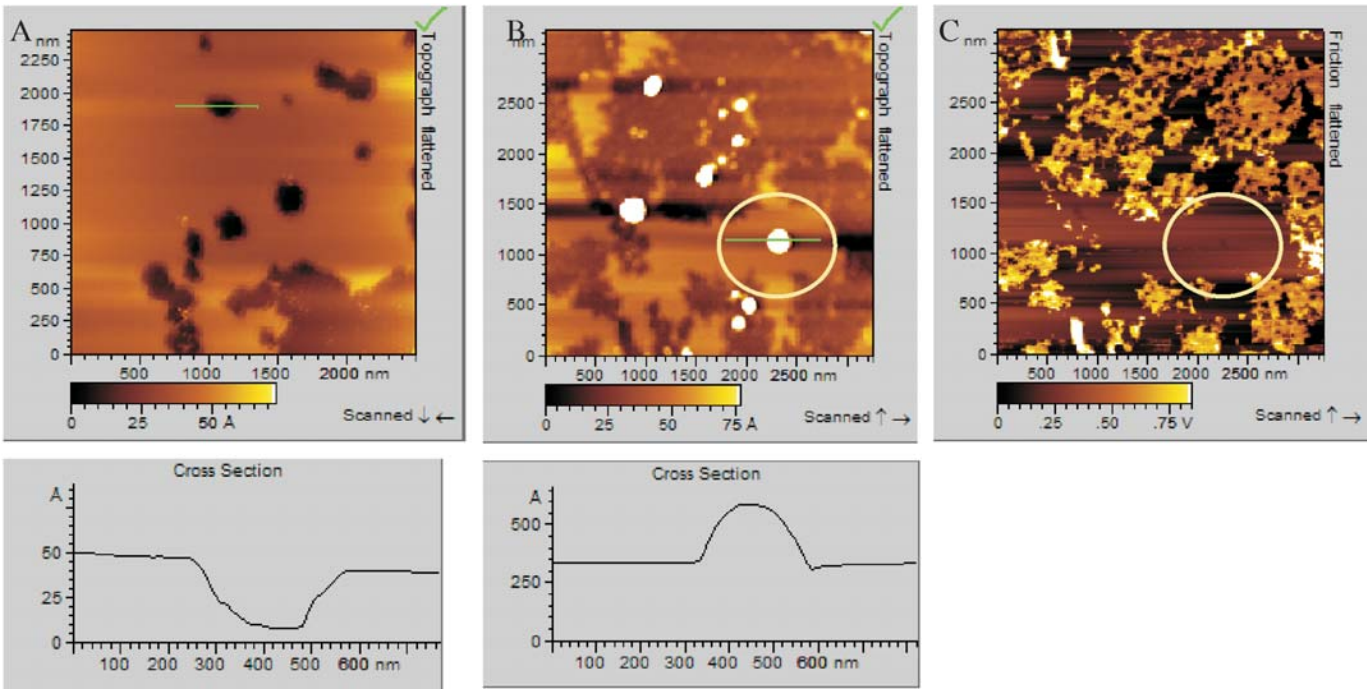
Fig. 1. Topography image of a supported planar DOPC phospholipids bilayer (A) prior to halothane addition, and (B) 6 h and 45 min after halothane addition. Panel C is a viscoelasticity (i.e., phase) image collected simultaneously with B. Large structures present in the topography image do not appear in the viscoelasticity image, indicating the structures are lipid based.



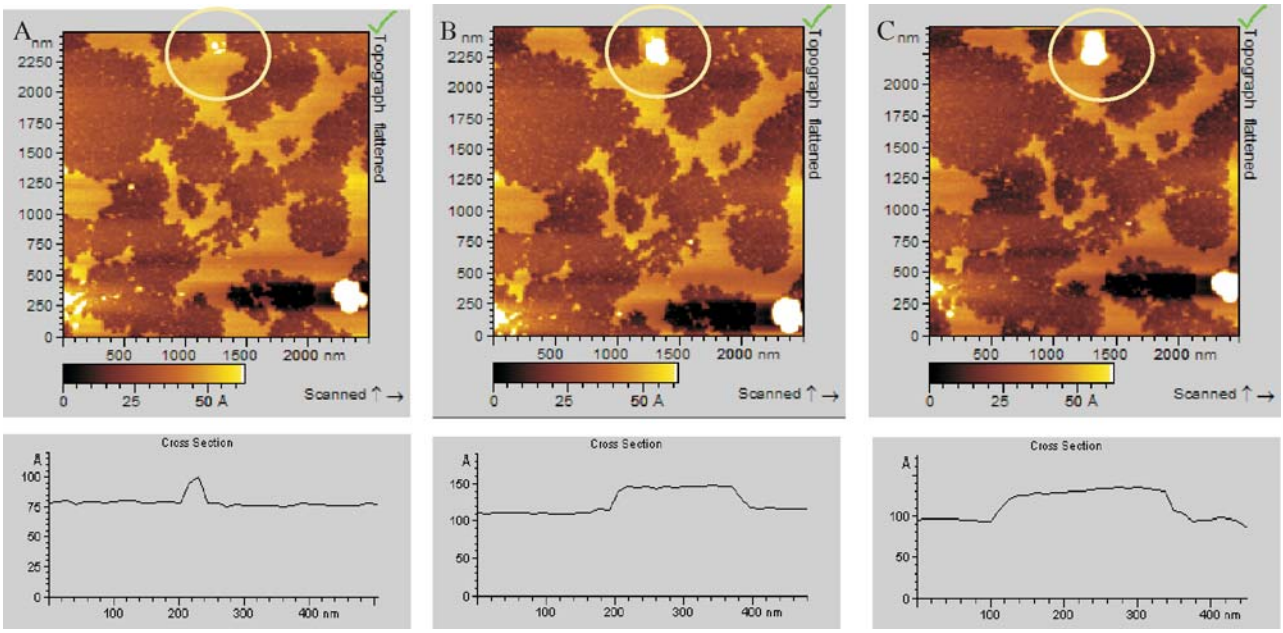


Fig. 2. DOPC supported planar bilayer (A) 4 h and 25 min after halothane addition, (B) 20 min after panel (A), (C) 35 min after panel (A). Cross-sections are taken of aggregate height relative to the supported planar bilayer.

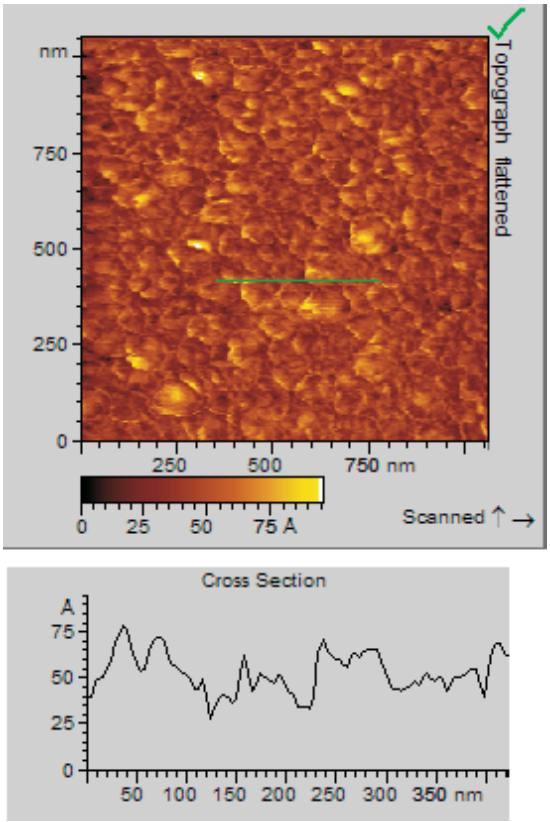

lipid aggregation observed is concluded to be solely because of the presence of halothane in the bilayer, as there is minimal perturbation of the system by the AFM probe during imaging. Moreover, a supported planar DOPC bilayer is stable in the absence of halothane over a period of up to days (6). The aggregate formation, observed after 4 h and 25 min, indicates halothane (at a high concentration regime) has a prolonged destabilizing effect on a supported phospholipid bilayer.

The results above suggest that in the presence of halothane a DOPC bilayer has a lower energy when curved rather than when planar. We postulate this is related to a ten-

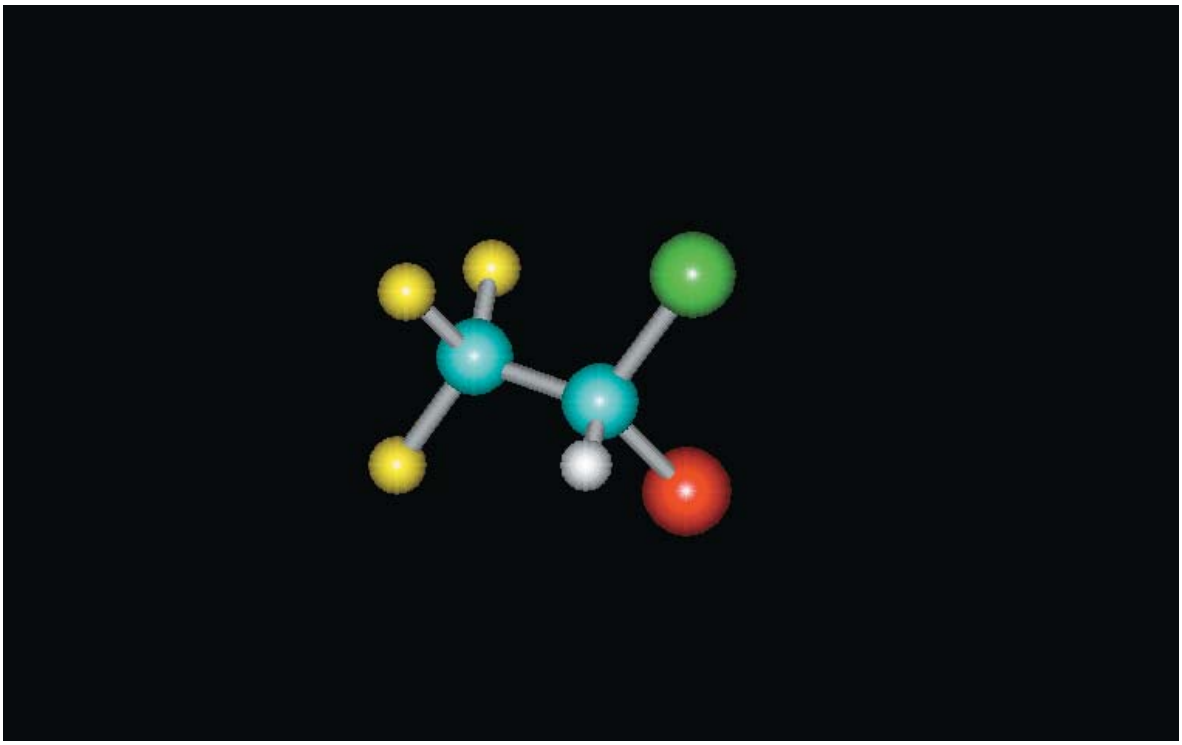
Fig. 3. Topography image of DOPC vesicles deposited on a mica surface. Halothane was added to the vesicle solution prior to surface deposition. Nonuniform curved structures are evident.

dency of halothane to reside in a region of the bilayer in which the space between head groups is increased. This is supported by the observation that halothane preferentially resides in a liquid-phase bilayer compared to a gel-phase bilayer (5). To test the hypothesis that a DOPC bilayer is more stable in a curved structure in the presence of halothane, halothane-containing DOPC vesicles were deposited onto the mica surface. This yielded no bilayer formation. Nonuniformly sized curved structures were observed adsorbed to mica. These are presumably nonlysed vesicles (Fig. 3).

Taken together, these observations are consistent with halothane's uneven bilayer distribution, which destabilizes the planar structure leading to an energetically favored curved configuration. The destabilization of the bilayer in the presence of the drug, attributed to a decrease in line tension, could be the consequence of many factors. First, the presence of halothane within the bilayer likely has a detergent effect, as its shape (Fig. 4) is much different from that of the cylindrical DOPC headgroup/tail unit. Thus, insertion of halothane may disrupt the packing of individual cylindrical headgroup/tail units within the bilayer. The molecular dynamics study of halothane in uneven distribution of halothane within the bilayer could further disrupt the stability of packed lipid units within a bilayer, therefore contributing to decreased line tension and inducing further restructuring. Since this behavior was not observed in previous studies at low halothane loading conditions (approximately 0.5 mmol/L halothane solution) (5), we postulate that the destabilization is concentration dependent. Furthermore, the anaesthetic interaction with the SPB may be co-operative. Initial aggregation of the SPB appears to enhance further restructuring locally, without affecting other regions of the bilayer (Fig. 2), likely owing to co-operative localization of halothane within the bilayer. It is possible that halothane absorbs initially near the edges of bilayer patches. However, change in the thickness of the bilayer edges were not observed either in this study or in our previous work (5). The possibility of halothane co-operativity in DOPC bilayers is consistent with our observation that halothane induces fusion between large unilamellar DOPC vesicles (12).

These results are comparable to those observed by Fang and Chan (8) in their lipid-restructuring study. They reported erosion of lipid fragments from a mica surface, and restructuring of an SPB in the presence of the protein chitosan. They cited decreased line tension as the cause of the induced restructuring, which is consistent with our postulation for the anaesthetic-induced SPB changes. Our results can also be compared with those of You et al. (13) where bilayer restructuring was observed induced by the peptide saposin C. Saposin C was found to induce two changes in a gel-phase bilayer. One was the formation of elevated patches and the other thinned domains. These differences were hypothesized to result from different local concentrations of the peptide, especially along the edges of bilayer patches.

An important property of supported DOPC bilayers for analysis is their stability over long periods of time. In the absence of the anaesthetic, vesicle deposition of DOPC consistently yields a supported bilayer that remains stable for imaging over a period of days, as was observed in this study. After addition of halothane to the supported planar bilayer, we observed a restructuring of the supported planar bilayer and the formation of lipid aggregates. Although AFM is typically used to study immobile biological samples, in this study, dynamic lipid aggregation was observed.



Thermodynamic theories suggest that the presence of anaesthetics within a bilayer may induce slight changes in lateral pressure that result in large conformational changes of embedded proteins (3). The lipid aggregation we observed in the present work could be due to pooling of halothane near the headgroup region. This, coupled with our fluorescence-based halothane distribution results (5), suggests that halothane may induce changes in lateral pressure gradients in phospholipid bilayers. Thus, in addition to direct anesthetic protein interactions, asymmetric anesthetic distribution may contribute to the mechanism of anesthesia. The question, then, is whether these two possible mechanisms compete or are synergistic.

Conclusion

DOPC vesicles were deposited onto a mica surface, both in the absence of the drug and after the addition of halothane. Height and viscoelasticity analysis indicate the lipid is stable in the form of a single planar bilayer in the absence of halothane. However, in the presence of the drug, a curved bilayer structure is favored. The addition of halothane to vesicles in solution followed by vesicle deposition did not yield the formation of a supported bilayer. How-

Fig. 4. Molecular model of halothane ($CF_3CHClBr$).

ever, adhesion of curved vesicles on the mica surface was observed. Together, these results indicate the destabilizing effect of halothane on a planar lipid bilayer at high anaesthetic loading regimes. To our knowledge, this is the first study to date of supported phospholipid bilayer restructuring induced by a general anaesthetic.

Physical organic chemistry in Canada 1900–2005[1]

Thomas T. Tidwell

Abstract: Some of the history of the development of physical organic chemistry in Canada from the 1920s is presented, including many of the individuals involved, and their major areas of interest.

Key words: history of physical organic chemistry in Canada, organic reaction mechanisms, free radicals, kinetics.

Résumé : Quelques faits marquants du développement de la chimie organique physique au Canada depuis les années 1920, y compris plusieurs des intervenants et leurs principaux domaines d'intérêt.

Mots clés : histoire de la chimie organique physique au Canada, mécanismes de réactions organiques, radicaux libres, cinétique.

[Traduit par la Rédaction]

The birth on Christmas day in 1900 of E.W.R. (Ned) Steacie was an event that had a far reaching effect for the development of physical organic chemistry in Canada and worldwide. Steacie was a physical chemist, but his research interests led him into the study of free radical reactions of organic molecules during a critical period for the development of this area (1, 2). At that time, about 1930, the appreciation of the role of reactive intermediates such as free radicals and carbocations was rapidly evolving. In a little more than a decade, marked by the appearance of Hammett's text *Physical organic chemistry* in 1940, and Steacie's monograph on free radical chemistry in 1946 (3*a*), there was a major improvement in understanding, and physical organic chemistry changed from a fringe activity to a comprehensive system that promised the power to explain all of organic chemistry, and to enable the rational design of reactions and prediction of chemical properties. Leaders in the field in the period 1945–1965 included E.D. Hughes and C.K. Ingold at University College, London, Paul Bartlett and Frank Westheimer at Harvard, Gardiner Swain at MIT, Saul Winstein and D.J. Cram at UCLA, J.D. Roberts and George Hammond at Caltech, and Cheves Walling and Ron Breslow at Columbia. Many of the physical organic chemists in Canada were to come from these groups.

This period from 1946 coincided with a tremendous growth in the university system in Canada, which included the development of strong research programs in chemistry all across the country, from Newfoundland to British Columbia, as well as at the excellent laboratories at the National Research Council in Ottawa. Physical organic chemistry was a glamorous field at the time, as it had become possible to gain a detailed understanding of what actually took place in organic reactions, including biological processes, and to understand what gave organic molecules their distinctive properties. Synthetic chemists, led by the example of R.B. Woodward at Harvard, also designed new reactions based on mechanistic principles, and so these were halcyon days for physical organic chemistry. Consequently, Canadian universities emphasized the field, and for the last half of the 20th century Canada had a disproportionate influence in this area worldwide. In contrast to the USA, research in physical organic chemistry in industrial laboratories was rather sparse. Exceptions include the spectacular early work on long-lived carbocations carried on by George Olah at the Dow labs in Sarnia around 1960, which was recognized by the award of the Nobel prize in Chemistry some 35 years later, and research in living free radical polymerization by Michael Georges at the Xerox laboratory in Missisauga.

Physical organic chemistry comes in many flavors, and rather than defining the purview of this area it will instead be illustrated by examples of the areas covered in Canada, and the people involved, some of whom may be surprised or even indignant at being placed in this group. Many of the practitioners of the subject, particularly in gas-phase chemistry, considered themselves as physical chemists, but nevertheless made major contributions to the understanding of organic reactions. The choice of topics and people to include is a personal choice, and while 123 individuals are named, others could have been included as well, and apologies are due to those who were left out. The individuals included were generally born before 1963, and many are now past the normal retirement age of 65. As a sign of the times women are scarce in this group, and it is encouraging that so many younger women are now discovering the satisfaction and excitement of the field. There is a younger generation born after 1962, with many new ideas, and augmented with many women, and the story they will write will partly derive from what has gone on before, but will include many things unimagined by the older generations. Perhaps they too, as they get older, will have some interest in their predecessors.

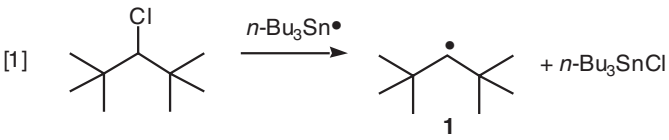
 doi: 10.1139/V05-178 © 2005 NRC Canada

The Supporting information[2] includes a list of individuals named, with some of their vital statistics, including their main position while working. It is impressive how many of these in earlier times received their undergraduate education and often Master's degrees in Canada, and then went elsewhere for the Ph.D., often at nearby universities such as Iowa State, Illinois, Chicago, and Wisconsin. There was a dearth of active Ph.D. granting institutions in Canada at that time, with McGill University in Montreal being the clear leader. A number of the pioneers in physical organic chemistry attended smaller schools in the Maritimes such as Mount Allison and Acadia Universities. The fledgling prairie universities in Saskatchewan, Alberta, and Manitoba also graduated many chemists who received graduate training elsewhere in the first half of the 20th century. In the growth years, many chemists were also hired from abroad, including many trained at the centers of the field in London and elsewhere in the UK, Los Angeles, and Cambridge, Massachusetts. Canada also exported many chemists who gained fame in chemistry in the USA.



Further information on 21 of the chemists named is available in special issues of the *Canadian Journal of Chemistry* dedicated to particular individuals, as listed in Appendix A. Other sources such as *Canadian Chemical News* and *Proceedings of the Royal Society of Canada* are cited in the Supporting information,[2] and the author would appreciate being informed of other sources that can be added.

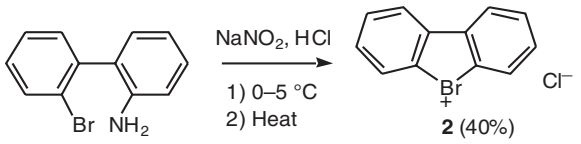
Special mention should be made of some of the organic chemists in Canada in the first half of the 20th century who taught and mentored many of those who became physical organic chemists. These include Charles F.H. Allen at McGill, George Wright at Toronto, Robert H. Clark at UBC, and Reuben Sandin at Alberta. These individuals carried on high-quality research, and also inspired future generations of chemists who made Canadian physical organic chemistry rank with the best in the world.

Free radical chemistry

E.W.R. (Ned) Steacie (1900–1962) received his Ph.D. from McGill University in 1926 for research carried out with Frederick Johnson on the solubility of gases in metals, and was also influenced by Otto Maass, an early leader in physical chemistry at McGill. Steacie took a teaching position there, and from about 1929 began the study of gas-phase kinetics of free radical reactions, particularly the pyrolysis of esters, ethers, and alkyl nitrites.

Steacie moved to the National Research Council in Ottawa in 1939 as Director of the Chemistry Division, which was greatly strengthened as a center of chemical research in Canada, particularly in free radical chemistry. Fred Lossing, also a McGill Ph.D. graduate, with Maass, joined the NRC in 1946, and developed a program in gas-phase ion chemstry studied by mass spectrometry. When hired at the NRC to set up a program in mass spectrometry he spent a year at McMaster University in the laboratory of Henry Thode to learn the field. In time his program attracted many co-workers who spread his knowledge and expertise around Canada and elsewhere, and his highly productive career was commemorated in 1990 (3*b*). An early collaborator was Keith Ingold, son of Christopher K. Ingold (1893–1970), who came as a postdoctoral fellow with Lossing in 1951. Keith has had a long career and distinguished career at the NRC, working in free radical chemistry. Included in his accomplishments are studies of hydrocarbon oxidations, "persistent radicals", such as the long-lived di-*tert*-butylmethyl radical (**1**, eq. [1]), the use of "free radical clocks", and free radicals in biological systems (4).

Many of Keith's co-workers at the NRC have also had successful careers in the study of free radicals or other reactive intermediates, including Tony Howard, David Griller, Dan Wayner (now Director General of the Steacie Institute at the NRC), J.C. (Tito) Scaiano, now Professor at the University of Ottawa, and Janusz Lusztyk (now Senior Advisor on Nanotechnology at the NRC). Many other Canadian chemists have been visitors or collaborators with the NRC labs, and the influence on the development of chemistry in Canada has been profound.



A notable event in physical organic chemistry in Canada was the General Discussion meeting "The reactivity of free radicals" of the Faraday Society of the UK, held in Toronto on 8 and 9 September 1952 (5*a*), with the participation of five future Nobel laureates (R.G.W. Norrish, George Porter, John Polanyi, Linus Pauling, and Gerhard Herzberg). A copy of the program for this meeting is included in the Supporting information,[2] including details of the dinner at the Royal York Hotel in Toronto. This was the first meeting of the Society to be held outside the UK, and it was rumored that initial plans to hold the meeting in the United States were canceled because of fears that certain delegates would not receive visas to the US, a problem that persists 50 years later.

Other prominent individuals involved in research on free radical chemistry in Canada include Ed Janzen (University of Guelph) on the development of spin labels, with a notable citation classic on the subject (5*b*), Jean Lessard (Sherbrooke) using electrochemistry to study radicals, and, Ross Barclay (Mount Allison), who moved from the study of crowded molecules to work on free radicals in biology, Dennis Tanner (Alberta) studied radical halogenation (5*c*), a field rife with controversy, while Nigel Bunce (Guelph) moved from free radical halogenation to prolific studies of organohalogen compounds in the environment. These individuals continued the tradition in organohalogen chemistry begun by Reuben Sandin at Alberta. Among his studies he reported in 1952 (5*d*) the isolation of the first stable bromonium ion, the crys-

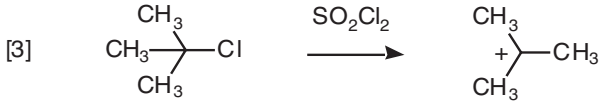
talline compound **2**, prepared by diazotization of 2-amino-2′-bromobiphenyl (eq. [2]).

[2] 

2 (40%)

Don Arnold, first at UWO and then at Dalhousie, emphasized photochemistry, including free radicals (5*e*), and his former collaborators include Jim Pincock (Dalhousie) and Willie Leigh (McMaster). At the University of Alberta, R.J. Crawford and Karl Kopecky generated free radicals from diazoalkanes (diazenes), as well as other reactive intermediates, while sulfur radicals were studied by Harry Gunning and Otto Strausz, who also studied carbenes and other reactive intermediates. Richard Hiatt at Brock University worked on peroxides, and at the University of British Columbia, Charles McDowell made early applications of electron spin resonance, while Richard Pincock studied radical generation, while Yuan Chow studied radicals at nearby Simon Fraser University.

Carbenes



Gerhard Herzberg at the NRC won the Nobel prize in Chemistry in 1971 for studies including carbene generation and structure. John Warkentin (McMaster) has worked in both free radical and carbene chemistry, and, Michael Liu (PEI) has carried on much of his extensive research on carbenes in a largely undergraduate institution.

Ionic reactions in solution

The study of ionic reactions in solution has been a major subject of interest in Canada, with origins that may be traced to several sources, including Keith Laidler at the University of Ottawa, a world renowned figure in the study of reaction kinetics and author of a prominent monograph *Chemical kinetics* (5*f*), as well as many other books. Another school of the study of reaction kinetics in solution was established by Ross Robertson at the NRC, who late in his career went to the University of Calgary. Others included John Scott at Memorial University in Newfoundland, James Hyne (Calgary), Alan Queen (Manitoba), and Ken Leffek (Dalhousie), all of whom came to Canada from the UK and worked with Robertson.

In 1921, Robert H. Clark at the University of British Columbia published a pioneering Canadian physical organic paper on the kinetics of sugar hydrolysis (5*g*), which was in the forefront of the field at the time. Later, he was a mentor of Ross Stewart at UBC, who received his Ph.D. at the University of Washington before returning to UBC. Early in his career Stewart was the Ph.D. supervisor of Keith Yates (5*h*), who became Professor at the University of Toronto, where he studied acid–base reactions, hydrolysis reactions, alkene brominations, computational chemistry, and much else, and whose students included James Pincock, Robert A. McClelland, Robert S. McDonald, Oswald S. Tee, and Robin Cox. Others at Toronto included Jerry Kresge with studies of enols, George Schmid studying additions of sulfenyl and selenyl halides as well as bromination, a topic also pursued by Stan Brown, first at the University of Alberta and later at Queen's University. Tom Tidwell at Toronto specialized in ketenes and electron-deficient carbocations, which were also pursued at York University by Ed Lee-Ruff. Don Lee (University of Regina) has studied the kinetics and mechanisms of oxidation reactions in solution.

Ron Gillespie (McMaster), though nominally an inorganic chemist, studied the protonation of organic compounds, and pioneered the use of highly ionizing solvents. These media were utilized by George Olah (6) in his renowned studies on the direct observation of carbocations in solution. In 1994, Olah was awarded the Nobel Prize for his work on carbocations for which the key first experiments on the *tert*-butyl cation (**3**, eq. [3]).were done in Sarnia. Ted Sorensen at Calgary also studied carbocations in highly acidic solutions by NMR, including important studies of long-lived hydride bridged cations. Jake Stothers (UWO) and Colin Fyfe (Guelph, later UBC) examined other reactive intermediates in solution by NMR, and Laurie Colebrook (Concordia) used NMR in conformational analysis.

[3] 

3

Isotope effects

Arthur Bourns (McMaster) specialized in studies of isotope effects, assisted by the mass spectrometry laboratory of Henry Thode, used to determine isotope ratios (7*a*). Later, he was diverted into an administrative career as President and Chancellor at McMaster, while his students Peter J. Smith (Saskatoon), and Ken Westaway (Laurentian) carried on in this field. Gerald Dunn was one of several Canadian chemists associated with Henry Gilman and others at Iowa State University and his work there included a study of isotope effects (7*b*), which he developed in his career at the University of Manitoba, where his students included John Warkentin (McMaster), Ed Janzen (Guelph), Robert S. McDonald (Mt. St. Vincent), and James Pincock (Dalhousie). Jerry Kresge (Toronto) made fundamental studies on isotope effects and utilized these in the elucidation mechanistic studies involving a variety of reactive intermediates.

Carbocations

Ron Childs (McMaster) who studied with Saul Winstein, continued carbocation studies and was later diverted into administration. Choi Chuk Lee (Saskatchewan) had worked with carbon isotopes at MIT with J.D. Roberts (8) and pursued similar studies of molecular rearrangements using isotopes. Alan Colter (Guelph), another Winstein student, studied solvolysis reactions and ion pairing. Ted Sorensen at the University of Calgary, as previously noted, studied stable ions by NMR. Bob McClelland (Toronto) carried out research on carbocations and later extended this work to nitrenium ions.

© 2005 NRC Canada

Carbanions and elimination reactions

Erwin Buncel began in peroxide chemistry with Alwyn Davies and as a postdoc with Joseph Bunnett became acquainted with azo compounds (9), a field he has pursued, along with work on carbanions. Tony Durst (Ottawa) studied substituent effects on carbanions, and Jake Stothers (UWO) studied these species by NMR. Duncan Hunter (UWO) and Pat Farrell (McGill University) studied elimination reactions, and the latter also examined the properties of solutions.

Bioorganic chemistry

Peter Guthrie (UWO) has made theoretical studies of mechanisms of fundamental reactions such as ester hydrolysis and related processes, while Stan Brown (Alberta, then Queen's) has studied amide hydrolysis, and Ron Kluger (Toronto) has studied enzyme mechanisms. Jik Chin, first at McGill and then at Toronto, has studied biological mechanisms and also organometallic chemistry, while John Bunting at Toronto worked on mechanisms of reactions of heterecocycles, and Bryan Jones (Toronto) studied enzyme models. Normand Voyer (Laval) studied ion channels, and Ossie Tee (Concordia) used cyclodextrins in hydrolysis reactions. Ray Lemieux (Ottawa, the NRC, and Alberta) had a diverse career including studies of conformational analysis and carbohydrate chemistry. Saul Wolfe examined enzyme mechanisms and penicillin chemistry at Queen's and later at Simon Fraser University, with diversions into computational chemistry. Jack Edward (McGill) studied amide hydrolysis, the acid–base properties of amino acids, and explosives. He and Ray Lemieux were responsible for a singularly Canadian invention, the "anomeric effect", widely known as the "Edwards–Lemieux effect". Pierre Deslongschamps (Sherbrooke) also achieved fame in this area, and Jean-Claude Richer (Montreal) studied stereochemistry in heterocyclic rings.

Silicon and germanium chemistry

Adrian Brook (Toronto) was a leader in studies of organosilicon chemistry and his student Kim Baines (UWO) extended these studies to organogermanium compounds. Willie Leigh (McMaster) has investigated silenes and germylenes and Michael Brook (McMaster) studied organosilicon chemistry for materials applications.

Molecular rearrangements, small ring compounds, and thermolysis reactions

Ed Warnhoff (UWO), Robert Fraser (Ottawa), and John Scheffer (UBC) studied rearrangements and molecular structures. At the University of Alberta, Karl Kopecky investigated dioxetanes and diazo compounds, Robert J. Crawford (Alberta) has studied small rings and pyrazolines, and David Darwish pursued the reactions of sulfur compounds. Persephone Cannone (Laval) examined cycloaddition reactions.

Photochemistry

Photochemistry has long been a major interest in Canada, and the Photochemistry Unit at the University of Western Ontario with Paul De Mayo and Don Arnold (who later moved to Dalhousie University) was a major centre for this research. Alan Weedon has continued this tradition, and several physical chemists have also participated. Others active in the area include Peter Yates and Jim Guillet (Toronto), James Pincock (Dalhousie), Denis Gravel (Montreal), Peter Wan (UVic), Ed Lee-Ruff (York U.), and Willie Leigh (McMaster). John Scheffer (UBC) studied photochemistry in the solid state. Tito Scaiano (Ottawa) has been a major contributor in this area, and he and his students, Cornelia Bohne (University of Victoria) and Monica Barra (University of Guelph) have brought a strong South American expertise to Canada.

Computational chemistry

Imre Csizmadia (Toronto) did much to popularize these methods among organic chemists and his students including Paul Mezey (Universty of Saskatchewan), Ray Poirier (Memorial University), and Alan Hopkinson (York University) have also played significant roles. Others active in this area are Russell Boyd (Dalhousie), Arvi Rauk (Calgary), Nick Westiuk (McMaster), Peter Guthrie (UWO) with his unique "no-barrier" theory, Saul Wolfe at Queen's University, later at Simon Fraser University in British Columbia, Dick Bader (McMaster), with his "atoms in molecules" approach, and Errol Lewars (Trent), who evolved from a background in synthetic organic chemistry.

Gas-phase reactions

The study of gas-phase reactions has followed the lead of Fred Lossing at the NRC in Ottawa, and has been carried on by Paul Kebarle (Alberta), Alex Harrison (Toronto), John Holmes (Ottawa), and Diethard Bohme (York). All of these have studied the reactions of organic ions in the gas phase. Carl Coffin at Dalhousie was a student of Maass who made important contributions, but his career was cut short.

Polymers and materials

In addition to individuals studying polymer chemistry there is growing interest in materials chemistry, as exemplified by the work of Bob Lemieux (Queen's University), Tom Fyles (University of Victoria), and Jim Wuest (University of Montreal). This area is expected to assume increasing importance.

Unusual molecules

Reg Mitchell (University of Victoria) for a long time was Canada's main representative in this area, as well as being a great popularizer of chemistry, and has been joined more recently by Graham Bodwell at Memorial University, Newfoundland. Satoru Masamune (Alberta) studied cyclobutadiene and other annulenes, in addition to his major interest in synthesis.

Physical organic minisymposium

Since 1973 physical organic chemistry in Canada has been nourished by the Ontario–Quebec Minisymposium on Physi-

© 2005 NRC Canada

cal Organic Chemistry (POMS), which has served as a forum for this field since its beginning at the instigation of Nick Werstiuk (McMaster), with promotion of the first meeting in Toronto by Keith Yates, Peter Yates, and others. This has included many active participants from the Maritimes, Western Canada, the US, and Europe, and has evolved over the years, reflecting the current state of the field.

Outlook

Physical organic chemistry has played a leading role in Canadian science for more than half a century, and has been a dynamic and developing enterprise. Many of the earlier problems examined by physical organic chemists have been solved and have been replaced by newer and different challenges. This has been an interdisciplinary field from the very beginning, with interests including biological, inorganic, and gas-phase reactions, polymerization, and theoretical chemistry. As the leading areas of chemical research have become increasingly decompartmentalized and the tools of physical organic chemistry have become increasingly pervasive, the boundaries of the field are now often difficult to recognize. Materials chemistry, nanotechnology, biological mechanisms, catalysis, and indeed the search for the origins of life are all physical organic chemistry in new garb. It may be expected that in a further 50 years the field will have evolved in still new directions, but the basic quest for the understanding of how things work will live on.

Acknowledgments

Thanks are due to John Andraos, Bob Crawford, Ossie Tee, John Warkentin, and many others for their assistance with this manuscript, and the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support.

Kinetics and mechanism of acid-catalyzed hydrolysis of the diazo functional groups of 1-diazo-2-indanone and 2-diazo-1-indanone in aqueous solution[1]

Yvonne Chiang, A. Jerry Kresge, Oleg Sadovski, Xiaofeng Zeng, and Yu Zhu

Abstract: Rates of hydrolysis of 1-diazo-2-indanone and 2-diazo-1-indanone were measured in dilute aqueous perchloric acid solutions using both H_2O and D_2O as the solvent, and rates of hydrolysis of the latter substrate were measured in dilute aqueous (H_2O only) formic acid buffer solutions as well. The data for 1-diazo-2-indanone gave the hydronium ion catalytic coefficient $k_H^+ = 5.7 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1} and the isotope effect $k_H^+/k_D^+ = 2.9$. The normal direction ($k_H/k_D > 1$) of this isotope effect was taken as evidence for a reaction mechanism involving rate-determining hydron transfer from the hydronium ion to the substrate's diazo carbon atom; followed by rapid displacement of diazo nitrogen by a water molecule, giving the observed 1-hydroxy-2-indanone product. The data for 2-diazo-1-indanone, on the other hand, gave a hydronium ion catalytic coefficient two orders of magnitude greater than the value for 1-diazo-2-indanone ($k_H^+ = 5.9 \times 10^{-1}$ (mol/L)$^{-1}$ s^{-1}), and an isotope effect near unity ($k_H^+/k_D^+ = 1.2$). It is argued that this isotope effect represents a situation in which diazo carbon hydronation and displacement of diazo nitrogen are each partly rate determining, a conclusion supported by incipient saturation of buffer catalysis in the formic acid buffer solutions. The 100-fold difference in hydronium ion catalytic coefficients for the two substrates is rationalized in terms of differing electron densities on the diazo carbon atoms.

Key words: diazo compound hydrolysis, solution kinetics, acid catalysis, solvent isotope effects, buffer catalysis saturation.

Résumé : On a mesuré les vitesses d'hydrolyse de la 1-diazoindan-2-one et 2-diazoindan-1-one en solutions aqueuses diluées d'acide perchlorique, en faisant appel tant au H_2O qu'au D_2O comme solvant; les vitesses d'hydrolyse du dernier substrat on aussi été mesurées dans des solutions aqueuses (uniquement avec du H_2O) de tampons à l'acide formique. Les données pour la 1-diazoindan-2-one permettent d'évaluer le coefficient catalytique de l'ion hydronium ($k_H^+ = 5{,}7 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}) et l'effet isotopique ($k_H^+/k_D^+ = 2{,}9$). On considère que la direction normale ($k_H/k_D > 1$) de cet effet isotopique est un indice en faveur d'un mécanisme réactionnel impliquant, dans l'étape cinétiquement déterminante, un transfert d'hydron de l'ion hydronium vers l'atome de carbone du diazo du substrat; celui-ci serait suivi d'un déplacement rapide de l'azote du diazo par une molécule d'eau qui conduirait à la formation du 1-hydroxydiazoindan-2-one qui a été observée. Par ailleurs, les données relatives à la 2-diazoindan-1-one indiquent que le coefficient catalytique de l'ion hydronium est de deux ordres de grandeur plus rapide que la valeur pour la 1-diazoindan-2-one ($k_H^+ = 5{,}9 \times 10^{-1}$ (mol/L)$^{-1}$ s^{-1}) et l'effet isotopique près de l'unité ($k_H^+/k_D^+ = 1{,}2$). On suggère que cet effet isotopique représente une situation dans laquelle l'hydronation du carbone du diazo et le déplacement de l'azote du diazo sont tous les deux partiellement cinétiquement importants; cette conclusion est supportée par la saturation induite de la catalyse par le tampon dans les solutions tampons d'acide formique. On rationalise le facteur de cent dans les coefficients catalytiques de l'ion hydronium pour les deux substrats en termes de densités électroniques différentes sur les atomes de carbone du diazo.

Mots clés : hydrolyse de composés diazo, cinétique en solution, catalyse acide, effets isotopiques du solvant, saturation de la catalyse par un tampon.

Introduction

The acid-catalyzed hydrolysis of aliphatic diazo compounds is a much-studied reaction that has played an important role in the development of modern ideas on acid–base catalysis (for reviews, see ref. 1). Diazo compounds are also synthetically useful materials: they can, for example, be transformed, via the Wolff rearrangement, into ketenes, which readily undergo a wide variety of useful reactions (2). The synthetic utility of diazo compounds, however, is limited by their facile acid-catalyzed hydrolysis, and information on the nature of this acid-catalyzed reaction, especially on how its rate depends on substrate structure, is consequently of practical value.

In the present paper, we report on an investigation of the acid-catalyzed hydrolysis in aqueous solution of 1-diazo-2-indanone (**1**) and 2-diazo-1-indanone (**2**).

1

2

Although these substances differ only in the relative placement of their diazo and carbonyl functional groups, they differ in reactivity by two orders of magnitude and hydrolyse by different reaction mechanisms.

Experimental section

Materials

1-Diazo-2-indanone

We prepared this substance by diazo group transfer from 4-acetamidobenzenesulfonyl azide (3) to 2-indanone under phase transfer conditions (4). In our hands, however, the yield of product was never greater than ca. 15%. In a typical procedure, 1.00 g (7.6 mmol) of 2-indanone, 2.00 g (8.3 mmol) of 4-acetamidobenzenesulfonyl azide, and 0.050 g of tetrabutylammonium bromide were dissolved in 120 mL of dichloromethane, and 9.0 mL of 1.0 mol/L aqueous sodium hydroxide was added. This mixture was stirred at 0 °C for 3 h and the layers were then separated. The water layer was extracted with two 30 mL portions of dichloromethane, and the combined organic layers were washed with water, dried with sodium sulfate, and the solvent was removed. The residue was purified by column chromatography (silica gel with hexanes–dichloromethane (1:1, *v*:*v*) eluent) and recrystallization from *n*-pentane. The product was a light orange-colored solid. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.24–7.34 (m, 2H), 7.09–7.17 (m, 2H), 3.55 (s, 2H). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 197.4, 131.2, 129.6, 128.3, 125.5, 125.0, 118.3, 68.4, 42.2. HR-MS calcd. for $C_9H_6N_2O$: 158.0480; found: 158.0483.

2-Diazo-1-indanone

This substance was prepared from the monotosylhydrazone of 1,2-indanedione, as described in the literature (5).

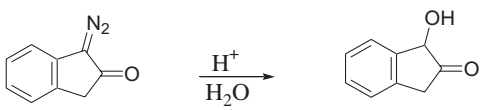
1-Hydroxy-2-indanone

This material was prepared by acid-catalyzed hydrolysis of 1-diazo-2-indanone. A mixture made by combining 50 mL of aqueous 0.04 mol/L perchloric acid with 50 mg of 1-diazo-2-indanone dissolved in 2 mL of acetonitrile was stirred at room temperature overnight and was then extracted with 50 mL of dichloromethane. The aqueous phase was neutralized with sodium hydroxide and then was extracted with dichloromethane three additional times. The combined extracts were dried over magnesium sulfate and the solvent was removed leaving a yellowish oil, which subsequently solidified. Two recrystallizations from dichloromethane–hexane gave a white product. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.6–7.7 (m, 1H), 7.38–7.26 (m, 3H), 5.17 (s, 1H), 3.68 (d, J = 22 Hz, 1H), 3.52 (d, J = 22 Hz, 1H), 3.0 (bs, 1H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 214.9, 139.3, 135.7, 129.2, 128.1, 125.2, 125.1, 75.2, 40.8.

2-Hydroxy-1-indanone

This substance was prepared by acid-catalyzed hydrolysis of 2-diazo-1-indanone, as described in the literature (6). The product was a white solid, mp 38 to 39 °C, whose ^{1}H NMR spectrum agreed with a published report (7).

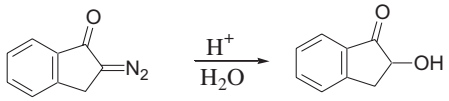
All other materials were best available commercial grades.



Kinetics

Rates of diazo compound hydrolysis were determined by monitoring the decrease of diazo absorption at λ = 260 nm for 1-diazo-2-indanone and λ = 320 nm for 2-diazo-1-indanone. Measurements were made using a Cary 2200 spectrometer, the temperature of whose cell compartment was controlled at 25.0 ± 0.05 °C. The data so obtained conformed to the first-order rate law well, and observed first-order rate constants were obtained by least-squares fitting of a single exponential function.

Results



Product analysis

The reaction of diazo carbonyl compounds with the hydronium ion, written here as H^+, in aqueous solution usually gives the corresponding hydroxy compounds as reaction products, as shown in eqs. [1] and [2] for the presently examined substrates. This was shown to be the case here for 1-diazo-2-indanone (**1**) by comparing the ^{1}H NMR spectrum of a spent reaction mixture formed in 0.04 mol/L $HClO_4$ solution with that of an authentic sample of 1-hydroxy-2-indanone (**3**). It was also shown to be the case for 2-diazo-1-indanone (**2**) by comparing the HPLC traces and UV spectra of spent reaction mixtures, formed in 0.001 mol/L $HClO_4$ solution as well as in a 0.2 mol/L formic acid buffer with a buffer ratio of $[HA]/[A^-]$ = 1, with those of authentic samples.

Kinetics for 1-diazo-2-indanone

Rates of hydrolysis of 1-diazo-2-indanone were measured in perchloric acid solutions, using both H_2O and D_2O as the solvent, over the concentration range [acid] = 0.04–0.1 mol/L. The ionic strength of these solutions was maintained at 0.10 mol/L by adding sodium perchlorate as required. The data so obtained are listed in Table S1[3] and are displayed in Fig. 1.

It may be seen that observed first-order rate constants increase linearly with increasing acid concentration. The data were therefore subjected to linear least-squares analysis. This produced the H_2O solution second-order rate constant $k_H^+ = (5.70 \pm 0.11) \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1} and a corresponding D_2O solution rate constant, which, in combination with the H_2O result, gave the solvent isotope effect $k_H^+/k_D^+ = 2.87 \pm 0.19$.

Kinetics for 2-diazo-1-indanone

Rates of hydrolysis of 2-diazo-1-indanone were also determined in perchloric acid solutions, again using both H_2O and D_2O as the solvent, over the concentration range [acid] = 0.01–0.1 mol/L at a constant ionic strength of 0.10 mol/L ($NaClO_4$). These data are listed in Table S2[3] and are displayed in Fig. 2. Once again, observed rate constants increased linearly with increasing acid concentration, and linear least-squares analysis gave the H_2O solution rate constant $k_H^+ = (5.88 \pm 0.11) \times 10^{-1}$ (mol/L)$^{-1}$ s^{-1} and the solvent isotope effect $k_H^+/k_D^+ = 1.18 \pm 0.03$.

Rates of hydrolysis of this substrate were also determined in a series of formic acid buffer solutions, all with the same constant stoichiometric buffer ratio ($[HA]_s/[A^-]_s = 1.3$) over the concentration range [buffer] = 0.003–0.3 mol/L, at a constant ionic strength of 0.10 ($NaClO_4$). These data are summarized in Table S3[3] and are displayed in Fig. 3. It may be seen that these observed first-order rate constants also increase with increasing buffer concentration, but not in a linear fashion. Their analysis is detailed in the following section.

Discussion

Perchloric acid solutions

The present results show that the hydrolysis of 1-diazo-2-indanone in perchloric acid solutions is an acid-catalyzed reaction and that it occurs with a substantial hydronium ion isotope effect in the normal direction ($k_H/k_D > 1$): $k_H^+/k_D^+ = 2.87$. This is classic evidence for slow hydron transfer from the hydronium ion to carbon (8), and it suggests that the reaction occurs by rate-determining hydronation of the substrate on its diazo carbon atom followed by more rapid replacement of nitrogen by the hydroxyl group of a water molecule, as shown in eq. [3].

Fig. 1. The relationship between hydronium ion concentration and the rate of hydrolysis of 1-diazo-2-indanone in H_2O (O) and D_2O (Δ) solutions of perchloric acid at 25 °C.

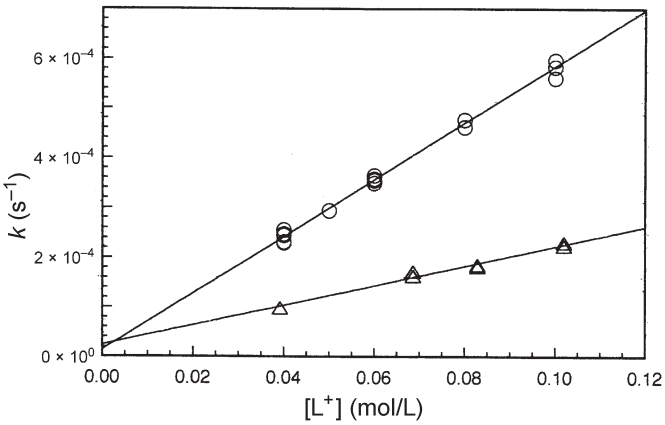

Fig. 2. The relationship between hydronium ion concentration and the rate of hydrolysis of 2-diazo-1-indanone in H_2O (O) and D_2O (Δ) solutions of perchloric acid at 25 °C.

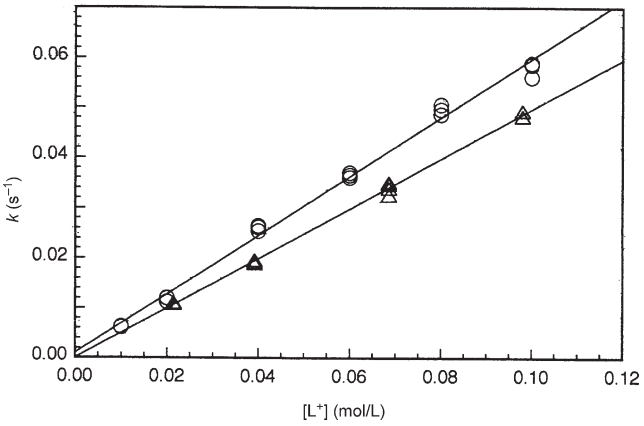

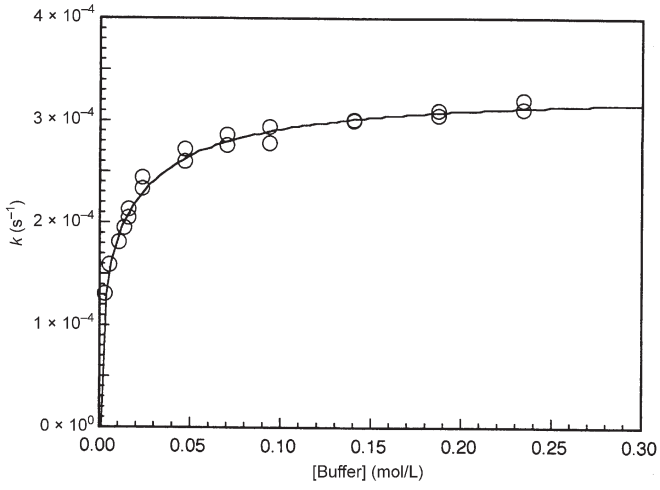

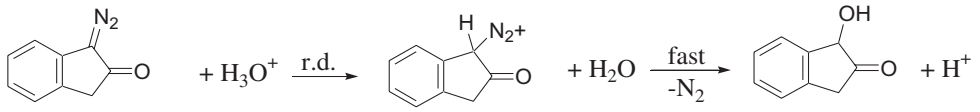

Fig. 3. The relationship between buffer concentration and the rate of hydrolysis of 2-diazo-1-indanone in aqueous (H_2O) formic acid buffer solutions at 25 °C.

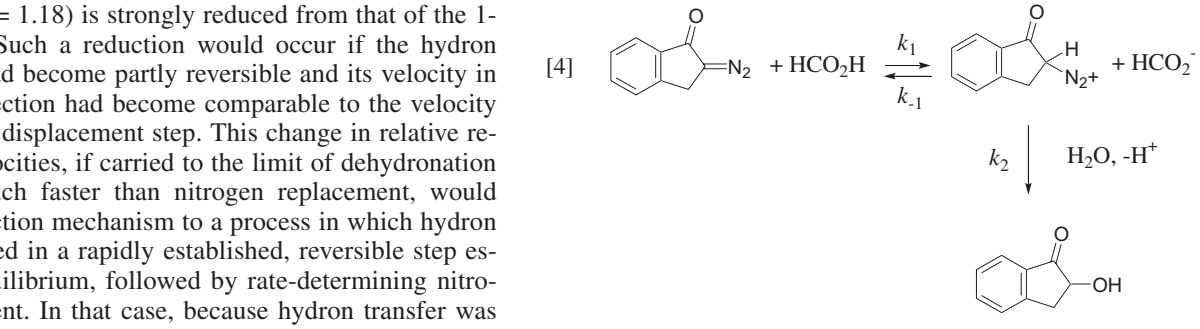
[3] 



Primary isotope effects on hydron transfer from the hydronium ion are accompanied by an inverse secondary component, contributed by tightening up of bonds to the two nontransferring hydrogen atoms of the hydronium ion unit (9). This reduces the magnitude of the overall effect considerably, and the present isotope effect is in fact a near-maximum value (10). This implies that hydronic motion makes up most of the reaction coordinate and that very little heavy atom participation contributes, as would have been the case if the hydrolysis reaction was a concerted process. The magnitude of the present isotope effect therefore implies that hydron transfer and nitrogen displacement take place in separate steps, as written in eq. [3].

The hydronium ion isotope effect on the hydrolysis of 2-diazo-1-indanone, on the other hand, is quite different: its value ($k_H^+/k_D^+ = 1.18$) is strongly reduced from that of the 1-diazo isomer. Such a reduction would occur if the hydron transfer step had become partly reversible and its velocity in the reverse direction had become comparable to the velocity of the nitrogen displacement step. This change in relative reaction step velocities, if carried to the limit of dehydronation being very much faster than nitrogen replacement, would change the reaction mechanism to a process in which hydron transfer occurred in a rapidly established, reversible step essentially at equilibrium, followed by rate-determining nitrogen displacement. In that case, because hydron transfer was no longer rate-determining, the solvent isotope effect would have no primary component. There would, however, be an equilibrium isotope effect on the hydron transfer step and, since the hydrogen–oxygen bonds of the water molecule product formed in this step are tighter than those of the reactant hydronium ion (9), this isotope effect would be inverse. An example of this kind of reaction is the hydrolysis of diazo acetaldehyde for which the hydronium ion isotope effect is $k_H^+/k_D^+ = 0.55$ (11). A situation intermediate between the limits of a rapidly reversible equilibrium hydron transfer and a rate-determining hydron transfer would be expected to have a hydronium isotope effect intermediate between the limits for these two mechanisms, i.e., a value near unity, as observed.

Hydron transfer could, of course, also take place to the carbonyl oxygen atom of a diazo compound producing an enediol intermediate, whose ketonization would give a hydroxy carbonyl product. Such a reaction, however, with hydronium ion as the hydron donor, would be a strongly uphill oxygen-to-oxygen hydron transfer, whose reverse would be a downhill encounter controlled process, much faster than the subsequent nitrogen displacement step. This would give a strongly inverse hydronium ion isotope effect. An example of such a reaction is the hydrolysis of 1,2-diphenyldiazoethanone for which an isotope effect of $k_H/k_D = 0.57$ has been reported (12), quite different from the isotope effects observed here. Oxygen protonation is also inconsistent with the fact that different hydroxycarbonyl products are formed from the hydrolysis of 1-diazo-2-indanone and 2-diazo-1-indanone (eqs. [1] and [2]), inasmuch as these diazo compounds would both give the same enediol intermediate whose ketonization would produce the same product for both substrates.

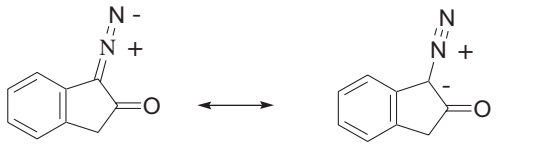
Formic acid buffer solutions

Further support for a two-step reaction mechanism with hydron transfer partly rate-determining for the hydrolysis of 2-diazo-1-indanone comes from the curved nature of the buffer dilution plot obtained from rate constants determined in formic acid buffer solutions. The buffer-catalyzed analog of this reaction mechanism is shown in eq. [4], and the rate law that applies to a combination of this route plus the hydronium ion reaction is given as eq. [5]. The concentration variables that appear in this rate law:

[4] 

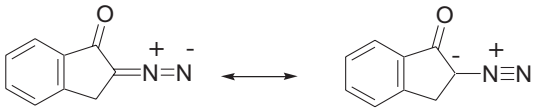
[5] $$k_{obs} = k_H^+[H^+] + k_1[HCO_2H]/\{1 + (k_{-1}/k_2)[HCO_2^-]\}$$

$[H^+]$, $[HCO_2H]$, and $[HCO_2^-]$ were evaluated for each buffer solution by calculation, using the concentration acidity constant for formic acid applicable at the ionic strength of the rate measurements, $Q_a = 2.80 \times 10^{-4}$ mol/L, based on $pK_a = 3.752$ for formic acid (13) and activity coefficients recommended by Bates (14). The results are listed in Table S3.[3] Least-squares analysis of the rate data using this rate law with $[H^+]$, $[HCO_2H]$, and $[HCO_2^-]$ as independent variables gave $k_H^+ = (4.43 \pm 0.18) \times 10^{-1}$ $(mol/L)^{-1}$ s^{-1}, $k_1 = (1.07 \pm 0.20) \times 10^{-2}$ $(mol/L)^{-1}$ s^{-1}, and $k_{-1}/k_2 = (8.64 \pm 1.53) \times 10^{-1}$ mol/L.



The line shown in Fig. 3 was drawn using these results. It may be seen that the data fit this model well. The value of k_H^+ obtained, moreover, is consistent with $k_H^+ = 5.88 \times 10^{-1}$ $(mol/L)^{-1}$ s^{-1} determined in perchloric acid solutions. The value of k_1, which is the rate constant for carbon protonation of the diazo compound by formic acid, is also a sensible result in that it is nearly two orders of magnitude less than k_H^+, the rate constant for the same hydronation reaction effected by the much more strongly acidic hydronium ion.

Relative reactivities



The present results show the hydronium ion catalyzed hydrolysis of 2-diazo-1-indanone to be two orders of magnitude faster than the same reaction of 1-diazo-2-indanone.

© 2005 NRC Canada

Although the mechanisms of these two reactions are not the same, they both involve hydron transfers, either rate-determining or partly rate-determining, to the diazo carbon atom. The rates of both reactions should therefore be influenced by the negative charge density on this carbon atom generated by electron delocalization from the diazo group, as shown by resonance structures **5** and **6**. With both substrates, this charge density is diminished by further delocalization into the adjacent carbonyl groups, and in the case of 1-diazo-2-indanone, it is diminished further by delocalization into the adjacent benzene ring. In the case of 2-diazo-1-indanone, however, the benzene ring is not adjacent to the diazo group, and such further delocalization is not possible. The negative charge density on the diazo carbon atom of 2-diazo-1-indanone is consequently greater than that on the diazo carbon atom of 1-diazo-2-indanone. This makes the diazo carbon atom of the 2-diazo isomer more basic, and more rapidly hydronated, than that of the 1-diazo isomer, as observed.

The art of discovery in biophysical organic chemistry[1]

Edward M. Kosower

Abstract: Observations made in the course of experiments on pyridinium salts led to important discoveries in physical organic chemistry. The way in which the discoveries were made is likened to art rather than goal-directed "cold logic". We can describe the art of discovery as an effort enhanced by practice and intuition to *recognize novelty* in a finding and *provide productive insight* into its nature. We shall present some examples, and describe what happened after finding an unexpected light absorption band, a surprising solvent effect on spectra, and an unexpectedly stable and beautiful small organic radical.

Key words: art of discovery, solvent polarity parameter, charge-transfer complex, stable free radical, solvent effect on spectra.

Résumé : Des observations faites au cours d' expériences sur des sels pyridiniques ont entraîné d'importantes découvertes dans le domaine de la chimie physique organique. La manière avec laquelle ces découvertes ont été faites semble plus proche de l'art que de la logique pure. On peut décrire l'art de la découverte comme un effort agrémenté par la pratique et par l'intuition à identifier les nouveautés et à donner un éclaircissement productif sur leur nature. Nous présentons ici quelques exemples tels qu'ils se sont manifestés à la suite de l'observation d'une bande d'absorption inattendue, d'un effet surprenant du solvant sur les spectres ainsi que d'un petit radical organique étonnement beau et stable.

Mots clés : art de la découverte, paramètre de polarité d'un solvant, complexe de transfert de charge, radical libre stable, effet de solvant sur un spectre.

One of the most difficult problems facing anyone is that of deciding what to do in life. One picks a direction or a profession on the basis of love for a subject, or out of admiration for an individual, or out of the desire to exploit skills that have been learned (such as playing an instrument, or carpentry, or being a salesperson or businessman). In my case, I was attracted to chemistry at about the age of 12 (in junior high school), and eventually, this was the subject that I studied and in which I made a career. A second difficult question is: What do you actually do within that career? If you are working for a company, problems are assigned to you. If you are a doctor, then problems generally present themselves in the form of patients. If you are a scientist, especially a research scientist, you must choose a problem yourself. It must be original (but still recognizable by others), it must be capable of yielding partial results even when the original question proves to be too difficult to answer, and it must be possible to carry out with means that are reasonably easy to acquire. Success comes as a result of hard work, a good knowledge of the literature, a good understanding of the science that you work in, paying attention to unexpected observations and last, but not least, luck! (remember Louis Pasteur's remark after the discovery of the scientific basis of vaccination that "chance favors the prepared mind"). I will describe in this article how my colleagues and I came to work on certain subjects. It is my hope that these examples will stimulate the reader to ask questions in a different way than that seen in a textbook.

Before we delve into my adventures in discovery, let us consider the meaning of the word, *art*. Of the several definitions that appear in dictionaries, three seem most relevant to our use of the word. These are: 1. Human effort to imitate, supplement, alter, or counteract the work of nature. 2. Skill that is attained by study, practice, or observation. 3. Skill arising from the exercise of intuitive faculties; and what about the word, *discovery*? The most interesting definition is: a productive insight (synonym: breakthrough, find). The art of discovery can be termed an effort enhanced by practice and intuition to *recognize novelty* in a finding and *provide productive insight* into its nature.

The unexpected absorption band

Once upon a time…(*many years ago*) I wanted to study biochemical mechanisms, and chose to spend a year in the laboratory of Frank Westheimer at Harvard University. Frank suggested that I look at the interaction of thiolate anions with pyridinium rings, to see if we could cast some light on the mechanism of action of nicotinamide adenine dinucleotide (NAD). Frank and Birgit Vennesland had just discovered that hydrogen was transferred directly from NADH to acetaldehyde, the first demonstration that a cofac-

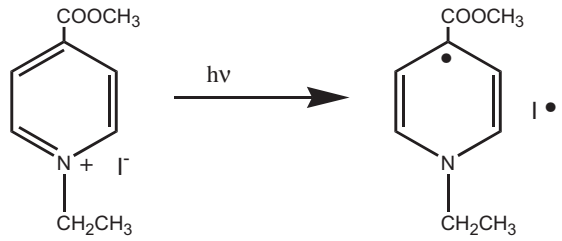
 doi: 10.1139/V05-120 © 2005 NRC Canada

tor and a substrate made direct contact at an enzyme "active site". In my early experiments with several pyridinium compounds, it appeared that rather basic conditions were required for the formation of thiolate anions, requiring knowledge of the interaction of pyridinium ions with hydroxide ion. I resolved to use the simplest pyridinium ion, the 1-methylpyridinium ion, as a reactant. To alkylate pyridine, there were three possibilities: methyl chloride (a gas), methyl bromide (a low boiling liquid, bp 3.6 °C), and methyl iodide (bp 42 °C). The iodide was the only practical choice, so I began with 1-methylpyridinium iodide as a model for the more complicated molecule, NAD. The reaction with hydroxide ion was expected to be slow, so I measured the spectrum of a reasonably high concentration of 1-methylpyridinium iodide (MP+I-). *The model MP^+I^- had a surprise for us: It absorbed light in an unexpected way, at a wavelength longer than expected. THIS WAS A DISCOVERY, in the recognition of novelty in the behavior of the iodide salt.*

1-Methylpyridinium iodide



1-Ethyl-4-methoxycarbonyl-pyridinium iodide

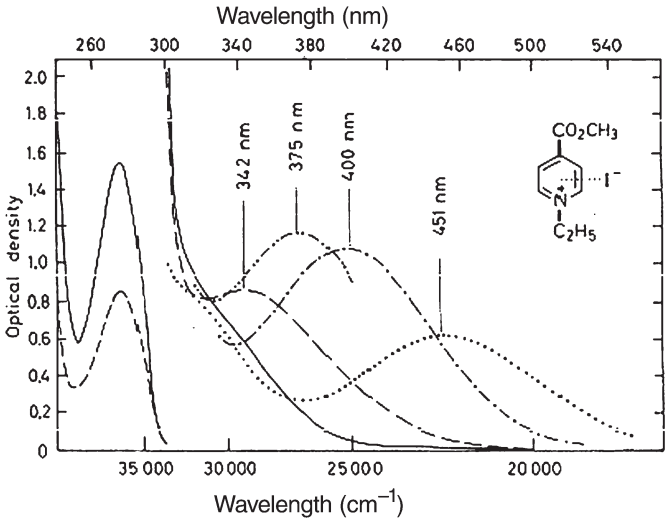
Since this discovery was to become the focus of a significant part of my research, it is worth exploring how we came to understand its true nature. At first, I thought that the iodide ion had added to the pyridinium ring (1). Sidney D. Ross, a chemist at Sprague Electric Company refereed the paper and later told me that he thought that charge-transfer complexes might be involved, but recommended its publication anyway. (Referees today would be less kind!). Of course, he was right, and we soon adopted his point of view after reading Mulliken's brilliant papers on charge-transfer complexes and examining the interaction of iodide ion with methyl substituted pyridinium rings. A methyl group should cause the equilibrium for addition at a given position to shift drastically towards dissociation; in fact, there is only a small shift, thus establishing the new absorption as that of a charge-transfer complex of the iodide ion with a pyridinium ring (2, 3). The interpretation of the charge-transfer character of the *novel* light absorption constituted the productive insight in the discovery. This was a significant development in the field of charge-transfer complexes, which are composed of two parts, an electron-rich molecule (a "donor") and an electron-deficient molecule (an "acceptor"). In such complexes, we may describe the light absorption as resulting in an electronic transition in which an electron jumps from an electron-rich molecule (the donor) to its partner in the complex, an electron-poor molecule (the acceptor). In our case, the donor is iodide ion and the acceptor is the 1-methylpyridinium ion. *Charge-transfer transitions* are rather common, and charge-transfer complexes ubiquitous. We shall see another example of such transitions shortly. A further lesson from the study was that dimers can behave differently from monomers, so that concentration dependence of any process or measurement should be carried out whenever possible.

A solvent surprise

Whenever you make a discovery, further questions are raised. What does one do next? We felt that we should learn more about the exciting new charge-transfer transitions, but were hindered by the fact that the absorption maxima were obscured by the pyridinium ion absorption. To move absorptions to longer wavelengths, we reasoned that extending the conjugation of the pyridinium ring would lead to a longer wavelength absorption. More accurately, if we increased the electron affinity of the acceptor we should expect a lower energy charge-transfer transition. To increase solubility, we replaced the 1-methyl group with a 1-ethyl group. The compound, 1-ethyl-4-methoxy-carbonylpyridinium iodide, had a beautiful orange color. To illustrate the power of a little understanding, we were not surprised by the color, thinking that indeed the charge-transfer transition would be more easily observed. A Swiss graduate student had made exactly the same compound some years before and assumed that the color meant that the compound was impure. He recrystallized the salt many times without changing the color. Since he was really trying to prepare the corresponding piperidine, he decided to hydrogenate the "impure" salt. The color disappeared, he obtained a pure piperidine and went on to have a successful career in the Swiss chemical industry. The charge-transfer absorption responsible for the color remained a mystery until we encountered it several years later.

There were hints in our initial work that solvent polarity had an influence on the position of the charge-transfer band. We then took 1-ethyl-4-methoxycarbonylpyridinium iodide and looked at its spectrum in a variety of solvents. We were astounded by the tremendous shifts in the position of the c-t band to longer wavelengths with decreasing solvent polarity. These are illustrated in Fig. 1. *THIS WAS ANOTHER DISCOVERY in the recognition of the novelty of the large solvent sensitivity of the charge-transfer transition.*

1-Ethyl-4-methoxycarbonyl-pyridinium iodide



1-Ethyl-4-methoxycarbonyl-pyridinyl radical iodine atom pair

Charge-transfer transition

What was the origin of this large change, essentially the largest ever found for a solvent effect on a spectrum? The basic explanation has to do with the Franck–Condon principle. The solvent molecules are organized around the ground-state donor–acceptor ion pair. The strength of the interaction between the ion pair and the solvent varies with the "polarity" of the solvent, the interaction being stronger for the more polar solvent. Light absorption occurs very rapidly,

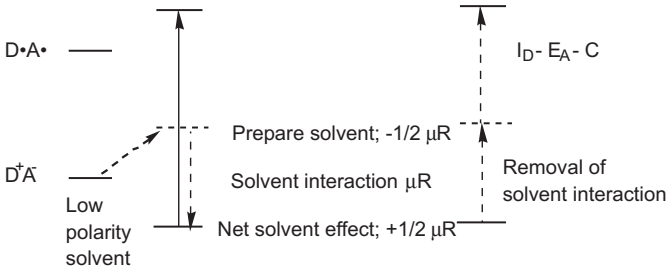
© 2005 NRC Canada

Fig. 1. The first charge-transfer band in the absorption spectra of 1-ethyl-4-methoxycarbonylpyridinium iodide in water (——), methanol (- - - -), 2-propanol (-·· –·· -), acetonitrile (–· –· –), and *cis*-1,2-dichloroethene (····) (adapted from refs. 8–10).

within a femtosecond or less. After light absorption, the solvent molecules are still organized as they were for the ground state, but now there is no ion pair. In fact, the organization represents a destabilization of the solvent structure. Roughly speaking, and reflecting an argument by Onsager about the reaction field in a solvent around a molecular dipole, the destabilization is similar to the stabilization of the ion pair by the solvent. We can thus expect a change in the electronic transition energy that is twice the ground-state stabilization, and consequently, a much larger change in the position of light absorption that might be expected for a "usual" solvent-sensitive light absorption such as that for an α,β-unsaturated carbonyl compound. These ideas are summarized in the diagram shown in Fig. 2. The interpretation was the productive insight into the novel solvent effect.

At this point, it became clear to me that such an electronic transition could be useful as a measure of "solvent polarity". I had earned my Ph.D. degree working with Professor Saul Winstein, who, together with Ernie Grunwald, had developed a solvent polarity parameter called *Y*-value, based on the rate of solvolysis of *tert*-butyl chloride in a given solvent. (Today, *Y*-values are based on the rate of solvolysis of adamantyl chloride and are still used to correlate rate constants of reactions). I therefore set out to correlate my solvent polarities with those of Winstein and Grunwald. I used solvent mixtures, methanol–water, ethanol–water, and acetone–water. I made up the mixtures rather randomly and plotted the results (*Y*-value against the transition energy, since these are both energies) as I measured them. I was disappointed at first to find a scatter of points, but as I proceeded, three straight lines emerged on the paper (like Botticelli's Venus arising from the sea). These straight lines converged at the *Y*-value for water, meaning that the spectroscopic parameter was also an effective measure of the polarity of the solvent (4) (Fig. 3)!! After the initial joy had subsided, colleagues in neighboring laboratories urged me to call them *K*-values. I resisted this suggestion, and chose *Z*-

Fig. 2. Energy diagram illustrating the stabilization of the ground state and the destabilization of the excited state for a charge-transfer transition in an ion-pair ground state. The Onsager model is also illustrated (R = reaction field, μ = molecular dipole).



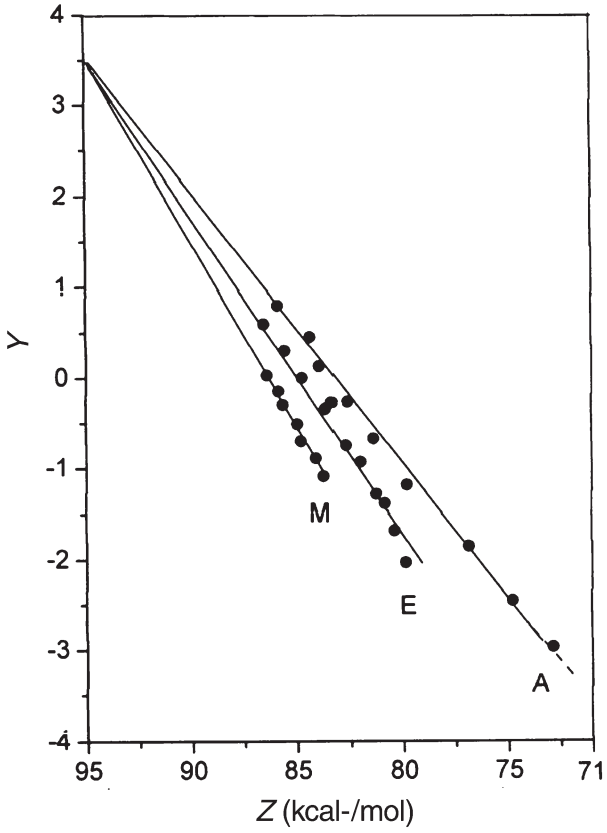


Fig. 3. *Z* vs. *Y* in methanol–water (M), ethanol–water (E), and acetone–water (A). The equations for the lines are Y_M = 0.416 76*Z* – 35.955, Y_E = 0.365 48*Z* – 30.962, and Y_A = 0.287 28*Z* – 23.936.

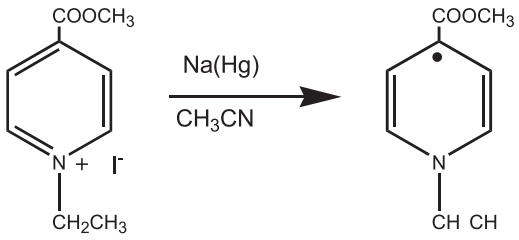

values because they came after *Y*. I then measured a substantial number of *Z*-values (the transition energy for the charge-transfer transition in kcal/mol, 1 cal = 4.184 J) and published the results in the *Journal of the American Chemical Society* (5), along with two other papers on the use of *Z*-values for correlating spectroscopic and kinetic data (6, 7). The paper became a citation classic (No. 47 on the JACS list of most-cited papers) with 1317 citations as of February, 2005).

Trying to gain some insight into the nature of the charge-transfer transition yielded a valuable new chemical resource, a quick and understandable way of measuring solvent polar-

© 2005 NRC Canada

ity. Formulating answers to the many questions raised by the discovery of *Z*-values led to a better understanding of the nature of such parameters. The compounds used to measure the parameter are molecular probes. What is a *probe*? An instrument used to search to the bottom of an object or a problem; also, as a verb, to scrutinize or examine thoroughly. What is a *molecular probe*? A molecular instrument used to scrutinize or examine thoroughly a molecular environment. A molecular probe provides information about the microscopic environment. In contrast, the dielectric constant represents a macroscopic summation or average of all the individual dipolar orientations within the measurement zone. In some cases, like those of *N*-alkylamides, the dielectric constant is high due to dipolar interactions between molecules, while the *Z*-value is relatively low because the microscopic polarity is modest. For a complete discussion of solvents and solvent parameters, the reader is referred to the excellent monograph by Reichardt (8); see also refs. 9 and 10. *Z*-values[2] have recently been used to evaluate the lack of preferential solvation of molecular probes or reactants in solvent mixtures (11).

Small radical is beautiful

1-Ethyl-4-methoxycarbonyl-pyridinium iodide

1-Ethyl-4-methoxycarbonyl-pyridinyl radical

Chemical reduction to radical

According to the theory of charge-transfer transitions, the excited state is formed by electron transfer from the donor to the acceptor. The acceptor pyridinium ring should accept electrons more easily, i.e., at lower excitation energies, as the electron-withdrawing power of the substituent increased. Another way to measure such a behavior is to examine the electrochemical reduction potentials. The potentials indeed fit the idea that the charge-transfer band moved to a longer wavelength with increasing electron affinity of the acceptor. More striking however was the observation that the pyridinyl radicals formed in electrochemical reduction seemed to be stable and colored (12). The prospect of studying small stable radicals was so attractive that E.J. Poziomek (who later went on to a distinguished career in a US Government laboratory) built a vacuum line and carried out the reductions that led to the discovery of the stable 1-ethyl-4-methoxycarbonylpyridinyl radical (13), allowing us to carry out many spectroscopic and kinetic studies (14). The orange 1-ethyl-4-methoxycarbonylpyridinium iodide melted to a scarlet liquid above 112 °C. In a most spectacular and colorful experiment, under high vacuum and in the presence of magnesium, a material distilled from the molten salt and condensed as a royal blue solid on a liquid nitrogen cooled condenser. That solid was shown to be the stable radical. The corresponding 1-methyl-4-cyanopyridinyl radical was shown to dimerize at a rate that could be detected electrochemically, and gave rise eventually to the 1,1′-dimethyl-4,4′-bipyridinium cation radical ("methylviologen") for which we discovered the dimeric complex and measured the ESR spectrum for the first time (15).

Again, asking simple questions about the charge-transfer band we *discovered* a whole new class of stable radicals. Recognizing the *novelty* of the apparent stability of pyridinyl radicals led to the productive insight that such stability might be exploited in a preparative procedure. Using a microsecond flash lamp developed by Lindqvist, we also showed that the pyridinyl radical was formed by the charge-transfer light absorption (16). Further information on pyridinyl radicals is summarized elsewhere (17).

Summary

The art of discovery has been the subject of a few serious studies and is clearly a form of serendipity for which a useful summary may be found on the Web (18). I have tried to give some insight into how one might proceed from an unexpected observation to a new development in science. The examples given are taken from my own early experience, and in most of my subsequent research, I have encountered the same general sequence of events. These would necessitate another article even longer than the present one. Our present research on surface-enhanced IR absorption on silver halide fibers belongs in the same category. If you would ask me what I might be doing a few years from now, I might honestly say that I don't know, but I am sure it will be interesting, exciting, and productive. I can add that enthusiasm and optimism is helpful in smoothing the way to discovery. You have read my story and I look forward to hearing yours!

Kinetics and mechanism of the oxidation of alcohols by tetrapropylammonium perruthenate[1]

W. David Chandler, Zhao Wang, and Donald G. Lee

Abstract: 2-Propanol is oxidized by tetrapropylammonium perruthenate (TPAP) in a reaction that is second order in TPAP and first order in 2-propanol. One of the products, believed to be ruthenium dioxide, is an effective catalyst for the reaction, making it an autocatalytic process. The rate of oxidation is relatively insensitive to the presence of substituents. Primary kinetic deuterium isotope effects are observed when either the hydroxyl or the α hydrogen is replaced by deuterium. The only product obtained from the oxidation of cyclobutanol is cyclobutanone, indicating that the reaction is a two-electron process. Tetrahydrofuran is oxidized at a rate that is several orders of magnitude slower than that observed for 2-propanol, suggesting that the reaction of TPAP with alcohols may be initiated by formation of perruthenate esters. A tentative mechanism consistent with these observations is proposed.

Key words: oxidation, alcohols, tetrapropylammonium perruthenate, reaction mechanism, autocatalysis.

Résumé : La réaction du propan-2-ol par le perruthénate de tétrapropylammonium (PTPA) est du deuxième ordre en PTPA et du premier ordre en propan-2-ol. Un des produits, qu'on suppose être le dioxyde de ruthénium, est un catalyseur efficace de la réaction qui la transforme en processus autocatalytique. La vitesse d'oxydation est pratiquement insensible à la présence de substituants. On observe des effets isotopiques cinétique du deutérium lorsqu'on remplace l'hydrogène de l'hydroxyle ou l'hydrogène en α par du deutérium. Le seul produit obtenu lors de l'oxydation du cyclobutanol est la cyclobutanone, ce qui indique que la réaction se produit par un processus à deux électrons. Le tétrahydrofurane est oxydé à une vitesse qui est de plusieurs ordres de grandeur plus faible que celui observé pour le propan-2-ol, ce qui suggère que la réaction du PTPA avec les alcools est peut-être initiée par la formation d'esters de l'acide perrhuténique. On propose un mécanisme qui est en accord avec les observations.

Mots clés : oxydation, alcools, perrhuténate de tétrapropylammonium, mécanisme de réaction, autocatalyse.

[Traduit par la Rédaction]

Introduction

The historical chemistry of tetrapropylammonium perruthenate (TPAP) has been reviewed (1–3). It is an excellent oxidant for the conversion of primary alcohols to aldehydes and secondary alcohols to ketones in nonaqueous solvents. The reaction is particularly fast, and good yields are usually obtained. Primary alcohols can be oxidized selectively in the presence of secondary alcohols (4) and 1,4- and 1,5-diols are converted to the corresponding five- and six-membered lactones (4, 5).

TPAP has also been used for the oxidation of sulfides to sulfones (6), secondary nitro compounds to ketones (7), and alkylboranes to the corresponding carbonyl compounds (8).

In addition to its use in solvents such as methylene chloride and acetonitrile, TPAP can be used effectively in ionic liquids (9).

Received 20 August 2004. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 5 October 2005.

[1]This article is part of a Special Issue dedicated to organic reaction mechanisms.

[2]Corresponding author (e-mail: dglee@uregina.ca).

Recent applications include the selective oxidation of a secondary alcohol that is part of a molecule that also contains a reactive ether functionality (10), the conversion of a primary alcohol to an aldehyde as a part of the asymmetric total synthesis of pironetin (11), the oxidation of 3-, 11-, 15-, 17-, and 20-hydroxy steroids to the corresponding ketones (12), and the preparation of a pyrrole from the corresponding α-aziridinyl alcohol (13).

TPAP can be used as a stoichiometric oxidant (14–18) or as a catalytic reagent in conjunction with a cooxidant such as *N*-methylmorpholine *N*-oxide (4–14).

Other than our previously published observation that its reactions with alcohols are autocatalytic (19), little is known about the mechanisms of TPAP oxidations. In an attempt to obtain a better understanding of the mechanism, a kinetic study of its reactions with aliphatic alcohols has been undertaken. Although autocatalytic reactions are not easily amenable to kinetic studies, sufficient experimental evidence has been obtained to propose a tentative reaction mechanism.

Experimental

Materials

Methylene chloride, used as the solvent in kinetic experiments, was purified by successive distillations from calcium hydride and tetrabutylammonium permanganate. The purified solvent was stored over molecular sieves.

 doi: 10.1139/V05-114 © 2005 NRC Canada

2-Propanol and the substituted 2-propanols were obtained commercially. They were distilled over calcium oxide and a middle fraction was collected and analyzed using gas chromatography. Purities of 99.9% or greater were obtained by this method. The observed boiling points were in agreement with published values (20). 2-Propanol-2-*d* and 2-propanol-O-*d* were prepared and purified as previously described (21).

Tetrahydrofuran, obtained from Aldrich, was purified by passage through a column of alumina to remove peroxide and fractionally distilled. A freshly purified sample with a boiling point of 64.0–64.2 °C was used in each experiment (22).

Tetrapropylammonium perruthenate, obtained from Aldrich, was dissolved in freshly purified methylene chloride, placed in a 10 mL brown bottle and used immediately in kinetic experiments. The concentration was determined spectrophotometrically from measurement of absorbances at 384 or 270 nm as described in the following.

Spectral studies

The UV–vis spectra of TPAP and its reduction product (RuO_2) have been reproduced in Fig. 1. It is apparent from these spectra that the greatest change in absorbance occurs at about 270 nm when TPAP is reduced by 2-propanol. Therefore, this wavelength is the most logical one to use for kinetic studies. However, before proceeding on that assumption, it was confirmed that the absorbances of both the reactant and the product are proportional to their concentrations at this wavelength. This was done by preparing the corresponding plots of absorbance vs. concentration, as in Figs. 2 and 3. From these plots it is apparent that both TPAP and RuO_2 obey Beer's Law at 270 nm.

Kinetic methods

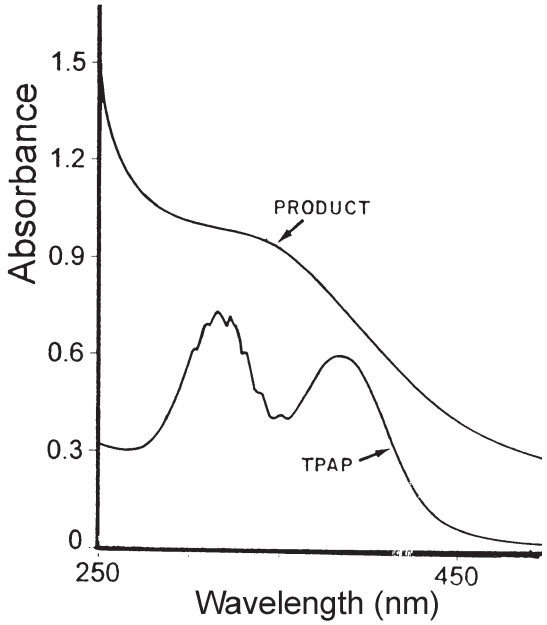
Determination of reaction rates was achieved by monitoring the increase in absorbance at 270 nm as the reaction progressed. Absorbance measurements were made using a Hewlett Packard 8450A spectrophotometer equipped with a thermostatted cell holder. Each experiment was repeated a minimum of five times and the average reported. The uncertainties noted are standard deviations.

The starting concentrations of the oxidant (TPAP) were between 1.57×10^{-4} and 4.11×10^{-4} mol/L. The concentration of the reductant (2-propanol) was at least 25 times greater in all experiments to ensure that pseudo-order conditions would pertain.

In a typical experiment, 10 mL of a freshly prepared solution of TPAP in methylene chloride was thermostatted at the required temperature in a water bath. An aliquot (2.00 mL) of this solution was then transferred to a cuvette and placed in the cell holder of the HP 8450A spectrophotometer, thermostatted at the same temperature. An excess of alcohol was added using a microliter syringe and the reaction rate was determined by monitoring absorbance changes at 270 nm. Usually, 99 absorbance readings were collected for each kinetic measurement.

A typical plot of absorbance against time is presented in Fig. 4. A sigmoidal plot of this type is typical of autocatalytic reactions. The rate, slow initially, increases dramatically as the product (catalyst) is formed, and then slows down again as the concentrations of reactants are diminished. The autocatalytic nature of the reaction can also be illustrated by plotting the rate (d*A*/d*t*) against time as in Fig. 5. It can be seen that the reaction rate passes through a maximum, giving a "bell-shaped" curve that is diagnostic for autocatalytic reactions (23).

Fig. 1. UV–vis spectrum of tetrapropylammonium perruthenate (TPAP) and its reduction product (RuO_2).



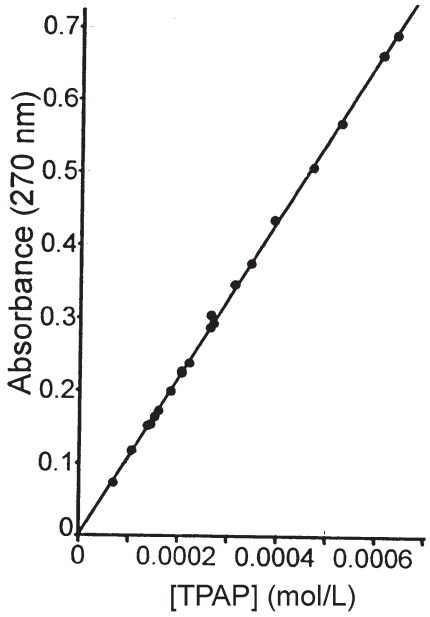


Fig. 2. Beer's Law plot for TPAP at 270 nm. Slope = 1084. Intercept = 0.0013. $r^2 = 0.999$.

Stability of the oxidant

Tetrapropylammonium perruthenate is slowly reduced by the solvent under the experimental conditions used in this study. The pseudo-first-order reaction rate (Fig. 6) is insignificant when compared to the rate at which TPAP is reduced by 2-propanol and shows no evidence of auto-

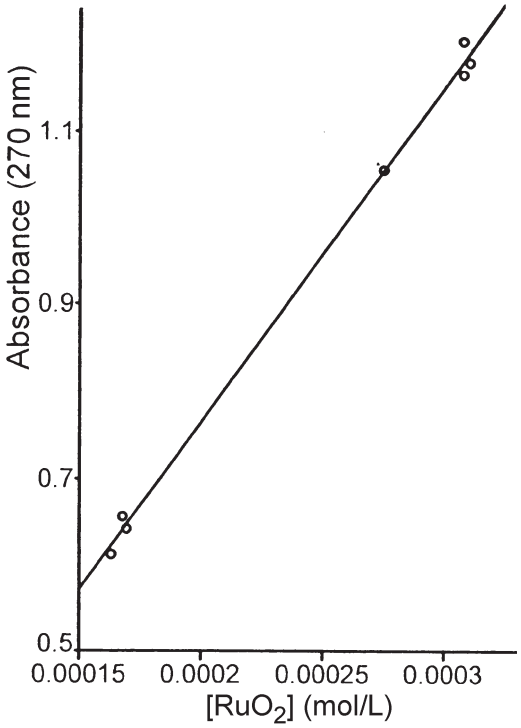

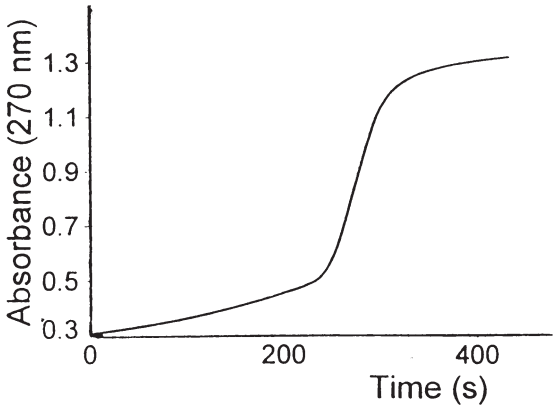

Fig. 4. Plot of the absorbance at 270 nm vs. time for the reduction of TPAP by 2-propanol.

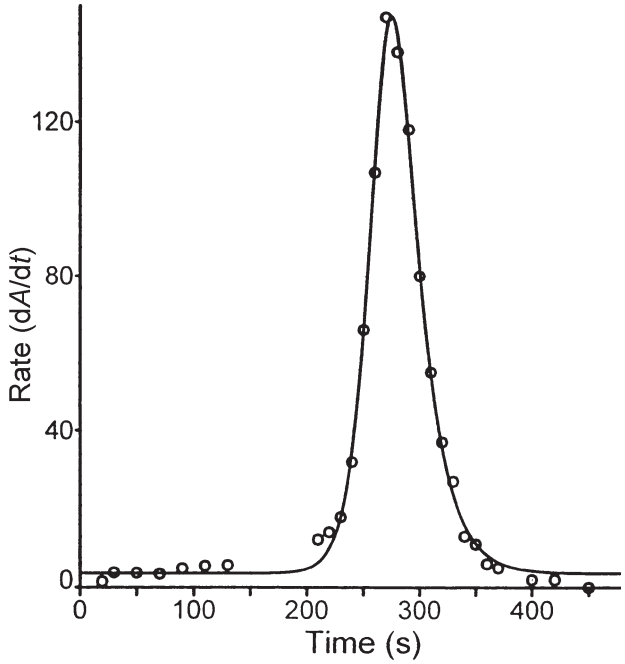
catalysis. Nevertheless, to minimize the potentially large effect of having a small amount of catalyst (RuO_2) present at the beginning of a kinetic experiment, freshly prepared solutions were always used.



Results

The rate law for the uncatalyzed reaction

The kinetics of an autocatalytic reaction can be analyzed by dividing the rate into two parts — one owing to the uncatalyzed portion of the reaction and one owing to the catalyzed portion, as in eq. [1].

$$[1] \qquad \text{Rate} = \text{Rate}_{\text{uncatalyzed}} + \text{Rate}_{\text{catalyzed}}$$

Fig. 5. Plot of the reaction rate for the reduction of TPAP by 2-propanol vs. time.

The rate of the uncatalyzed reaction was determined from a study of initial reaction rates. Since the catalyzed reaction is much faster than the uncatalyzed reaction, the rate of the autocatalyzed reaction was determined, as described in the following, from a study of the reaction after a significant amount of product had been formed.

At the start of the reaction no product (catalyst) is present and the observed reaction rate is due, therefore, only to the uncatalyzed reaction between tetrapropylammonium perruthenate ($QRuO_4$) and 2-propanol. Consequently, the rate law and rate constant for the uncatalyzed reaction were determined under initial reaction conditions. The general form of the expected rate law, as given in eq. [2], was simplified by using a great excess of 2-propanol. The resulting pseudo-order rate law is expressed in eqs. [3] and [4].

$$[2] \qquad (\mathrm{d}[RuO_2]/\mathrm{d}t)_i = k_u[QRuO_4]_i^m[\text{2-propanol}]^n$$

$$[3] \qquad (\mathrm{d}[RuO_2]/\mathrm{d}t)_i = k_u'[QRuO_4]_i^m$$

$$[4] \qquad k_u' = k_u[\text{2-propanol}]^n$$

Since the absorbance at 270 nm conforms to Beer's Law for both the reactant and the product, the rate law stated in eq. [3] can be expressed in terms of absorbances, as in eqs. [5] and [6].

$$[5] \qquad (\mathrm{d}A/\mathrm{d}t)_i = k_u'A_i^m(\varepsilon_{RuO_2}/\varepsilon_{QRuO_4}{}^m)$$

$$[6] \qquad \ln(\mathrm{d}A/\mathrm{d}t)_i = m\ln A_i + \ln k_u' + \ln(\varepsilon_{RuO_2} - \varepsilon_{QRuO_4}{}^m)$$

The initial reaction rates ($(\mathrm{d}A/\mathrm{d}t)_i$) were easily obtained from tangents to plots of absorbance vs. time at zero time. From a plot of $\ln(\mathrm{d}A/\mathrm{d}t)_i$ vs. $\ln(A_i)$, as in Fig. 7, the reaction was found to be second order with respect to $QRuO_4$. As described in the following, the order with respect to 2-propanol was subsequently found to be unity, resulting in the rate law given in eq. [7] for the uncatalyzed portion of the reaction.

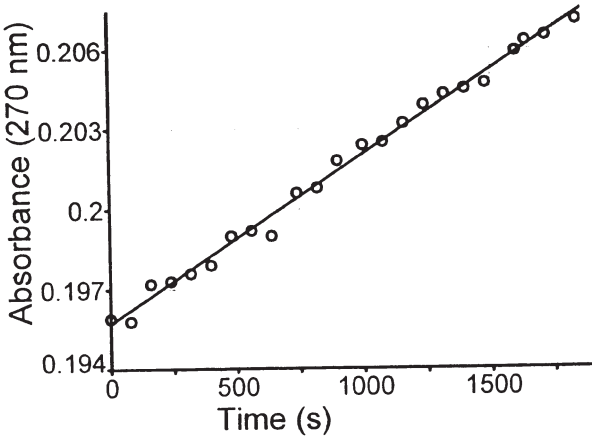
Fig. 6. Plot of the absorbance at 270 nm vs. time for the reduction of TPAP in a methylene chloride solution with no added 2-propanol. Slope = 0.196. Intercept = 6.3×10^{-6}. $r^2 = 0.993$.



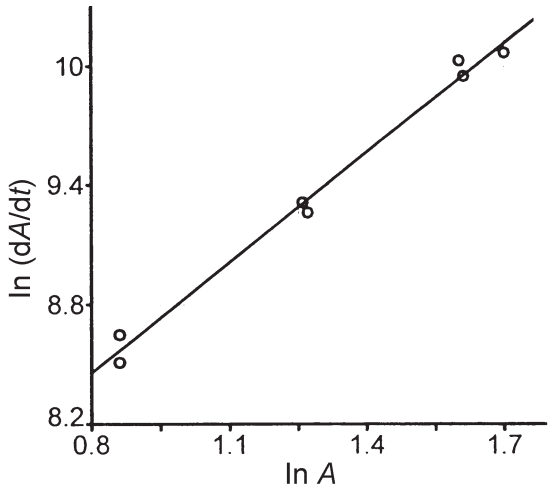


Fig. 7. Plot of the initial rates vs. initial absorbance for the reduction of TPAP by 2-propanol. Slope = 1.8 ± 0.1. Intercept = 6.98. $r^2 = 0.990$.

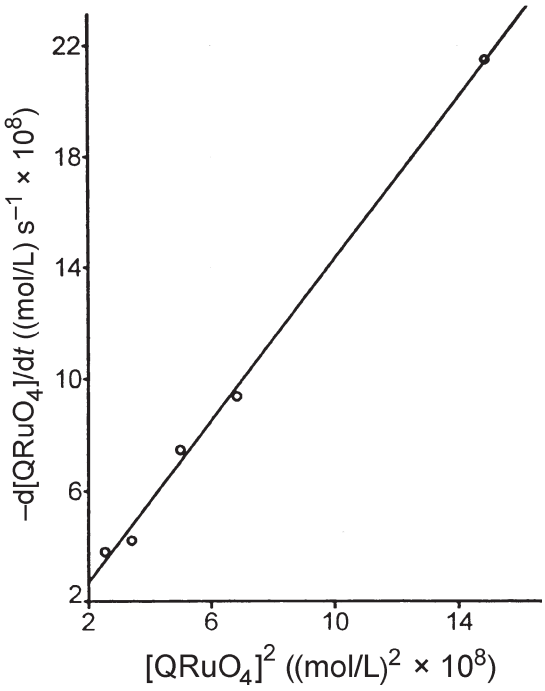
[7] $(\mathrm{d[RuO_2]}/\mathrm{d}t)_i = -(\mathrm{d[QRuO_4]}/\mathrm{d}t)_i = k_u[\mathrm{QRuO_4}]^2[\text{2-propanol}] = k_u'[\mathrm{QRuO_4}]^2$

The pseudo-second-order rate constants for this reaction (k_u') were then determined from plots of $-\mathrm{d[QRuO_4]}/\mathrm{d}t_i$ vs. $[\mathrm{QRuO_4}]^2$ as in Fig. 8.

Rate law for the catalyzed reaction



Rates for the catalyzed reaction were determined by taking tangents to the curve obtained from a plot of the absorbances against time after a significant amount of product (RuO_2) had formed. Under these conditions the contribution from the uncatalyzed reaction is negligible, as indicated from the data plotted in Figs. 4 and 5.

The general form of the rate law for the catalyzed portion of the reaction, given in eq. [8], can be simplified to eqs. [9] and [10] by using a large excess of 2-propanol.

[8] $-\mathrm{d[QRuO_4]}/\mathrm{d}t = k_c[\mathrm{QRuO_4}]^p[\mathrm{RuO_2}]^q[\text{2-propanol}]^r$

[9] $-\mathrm{d[QRuO_4]}/\mathrm{d}t = k_c'[\mathrm{QRuO_4}]^p[\mathrm{RuO_2}]^q$

Fig. 8. Plot for the determination of the rate constant (k_u'). Slope (k_u') = 1.45 ± 0.05. Intercept = 0.231. $r^2 = 0.997$.

[10] $k_c' = k_c[\text{2-propanol}]^r$

The concentrations of $QRuO_4$ and RuO_2 can be calculated at any point along a plot of absorbance vs. time (cf. Fig. 4) by use of eqs. [11] and [12] where A_i is the initial absorbance, A_f is the final absorbance, A_t is the absorbance at any time "t", and $\Delta\varepsilon$ is $(\varepsilon_{RuO_2} - \varepsilon_{QRuO_4})$ (24).

[11] $[\mathrm{QRuO_4}] = (A_f - A_t)/\Delta\varepsilon$

[12] $[\mathrm{RuO_2}] = (A_t - A_i)/\Delta\varepsilon$

A combination of eqs. [9] and [11] gives eqs. [13] and [14].

[13] $\mathrm{d}A_t/\mathrm{d}t = k_c'[\mathrm{QRuO_4}]^p[\mathrm{RuO_2}]^q\Delta\varepsilon$

[14] $\ln(\mathrm{d}A_t/\mathrm{d}t) = p\ln[\mathrm{QRuO_4}] + q\ln[\mathrm{RuO_2}] + \ln k_c' + \ln\Delta\varepsilon$

In a series of reactions with differing initial concentrations of $QRuO_4$, rates ($\mathrm{d}A_t/\mathrm{d}t$) were measured by taking tangents to the curves at points where the concentration of RuO_2 was constant. Under conditions of constant $[RuO_2]$, eq. [14] is reduced to eq. [15] where C is a constant. The order with respect to $[QRuO_4]$ obtained from a plot of $\ln(\mathrm{d}A_t/\mathrm{d}t)$ vs. $\ln[QRuO_4]$, as in Fig. 9, was observed to be two. Therefore, the catalyzed portion of the reaction is also second order with respect to the concentration of the oxidant.

[15] $\ln(\mathrm{d}A_t/\mathrm{d}t) = p\ln[\mathrm{QRuO_4}] + C$

Similarly, the apparent order with respect to the concentration of the catalyst (RuO_2) was determined from a series of rate measurements made at constant $QRuO_4$ concentration. Under those conditions, eq. [14] is simplified to eq. [16] where C' is a constant.

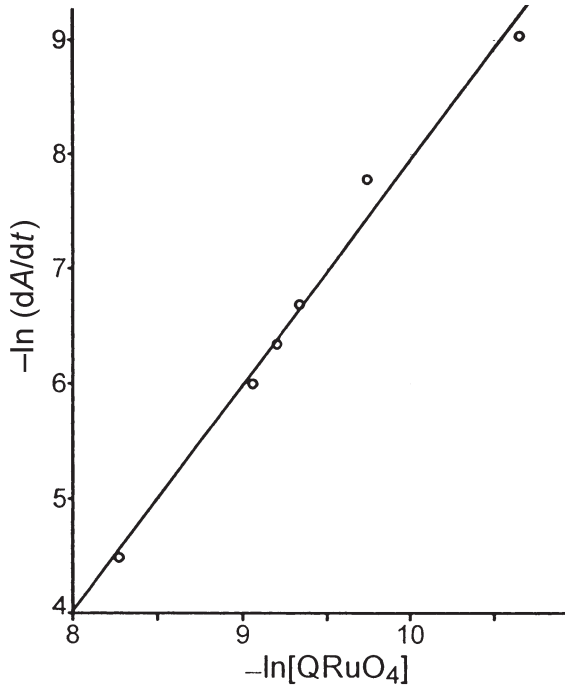
Fig. 9. Plot for determining the order of the catalytic reaction with respect to the oxidant. Slope (order) = 2.0 ± 0.1. Intercept = 11.7. r^2 = 0.986.



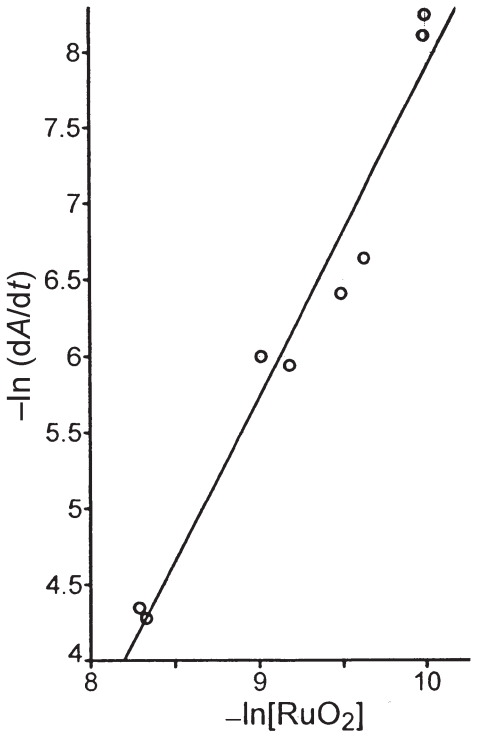


Fig. 10. Plot for determining the apparent order of the catalytic reaction with respect to the catalyst (RuO_2). Slope = 2.1 ± 0.3. Intercept = 13.7. r^2 = 0.957.

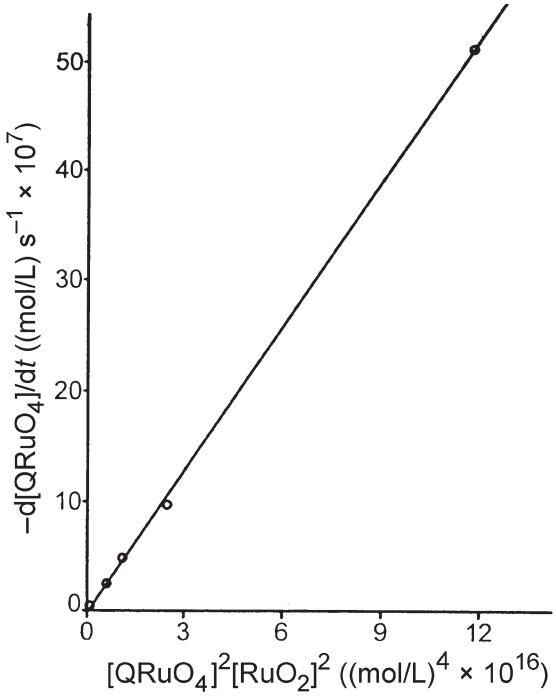
[16] $\ln(dA_t/dt) = q \ln[RuO_2] + C'$

The plot of eq. [16], in Fig. 10, indicates that the apparent order with respect to RuO_2 is about two. As described below, the order with respect to 2-propanol was subsequently found to be unity, resulting in the rate law given in eq. [17] for the catalyzed portion of the reaction.



[17] $-d[QRuO_4]/dt = k_c[QRuO_4]^2[RuO_2]^2[\text{2-propanol}]$

The pseudo-fourth-order rate constant (k_c') was then obtained from a plot of $-d[QRuO_4]/dt$ vs. $[QRuO_4]^2[RuO_2]^2$ as in Fig. 11.

The complete rate expression for the reaction determined from this analysis, therefore, is given by eq. [18].

[18] $-d[QRuO_4]/dt = ([QRuO_4]^2[\text{2-propanol}]) \times (k_u + k_c[RuO_2]^2)$

Fig. 11. Plot for the determination of the rate constant (k_c'). Slope = 4.34 ± 0.05. Intercept = 0.245. r^2 = 0.999.

Computer-assisted analysis of reaction rates

Obtaining rate constants for the reaction by use of the classical methods described in the previous section is time consuming and somewhat subject to personal biases. The use of computer-based models for the reaction can eliminate personal biases and greatly reduce the time required for analysis. Accordingly, software written in Turbo Pascal was developed to assist in the analysis of the raw time vs. absorbance data.

The computer program initially estimated pseudo-order rate constants (k_u' and k_c'), and then completed a least-squares regression using an analytic function derived from eq. [19].

[19] $-dA/dt = (k_u' + k_c'[RuO_2]^2)[QRuO_4]^2$

The variable parameters (k_u' and k_c') were then subjected to an iterative regression until the best correlation coefficient was obtained. In this way, it was possible to reproduce the experimental data very closely. The rate constants produced

Table 1. Comparison of rate constants obtained by graphical and computer-assisted analysis.

Rate constant	Graphical analysis[a]	Computer-assisted calculation[b]
k_u' ((mol/L)$^{-1}$ s^{-1})	1.46±0.05	1.57
k_u ((mol/L)$^{-2}$ s^{-1})	123±5	120
k_c'((mol/L)$^{-3}$ s^{-1} × 10^{-9})	4.21±0.05	4.79
k_c ((mol/L)$^{-4}$ s^{-1} × 10^{-9})	354±6	366

Note: Temp. = 25.0 ± 0.1 °C.
[a][2-Propanol] = 0.0119 mol/L.
[b][2-Propanol] = 0.0131 mol/L.

from this computer-assisted analysis compare satisfactorily with the results obtained from the classical analysis described previously. See the data for a typical example given in Table 1.

The data in Table 1 confirm that this approach gives consistent values for the rate constants, with somewhat greater uncertainly in the values for the catalytic rate constants. In an additional test of this approach, an attempt was made to fit the data to a simpler rate law that is first order in oxidant and catalyst, as in eq. [20].

$$[20] \quad -dA/dt = (k_u'' + k_c''[RuO_2])[QRuO_4]$$

The rate constants obtained using eq. [20] were less consistent and the correlation coefficients obtained were much lower than those for eq. [19]. All subsequently reported rate constants are those obtained from computer-assisted analysis of absorbance vs. time data.

From eq. [4], it can be seen that a plot of k_u' vs. [2-propanol] should be linear with a slope equal to k_u, and an intercept near zero, if the initial reaction rate is first order with respect to the concentration of 2-propanol. Similarly, it can be seen from eq. [10] that if the catalytic portion of the reaction is also first order with respect to the concentration of 2-propanol, a plot of k_c' vs. [2-propanol] should be linear with a slope equal to k_c and a zero intercept. The linearity of the two plots, presented in Figs. 12 and 13, confirms that the rate of this reaction is first order in the concentration of 2-propanol throughout.

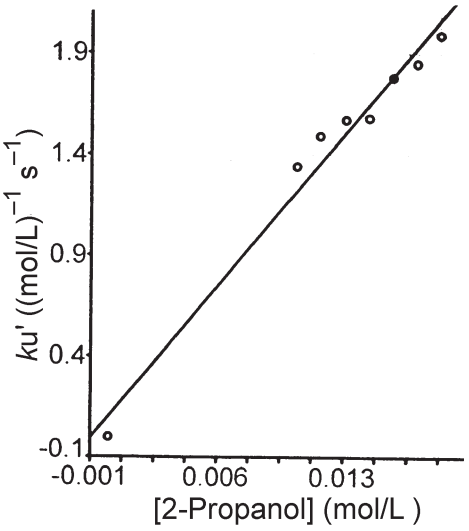
Isotope effects

Rate constants for the oxidation of 2-propanol-2-*d* and 2-propanol-O-*d* are compared with that of the non-deuterated compound in Table 2. The data indicate that primary kinetic isotope effects are observed for the oxidation of both 2-propanol-2-*d* and 2-propanol-O-*d*.

Substituent effects

Rate constants for the oxidation of 2-propanol and five-substituted 2-propanols were determined to test the sensitivity of the reaction to changes in the nature of the substituents (25). From the data in Table 3 and the corresponding Taft plots in Figs. 14 and 15, it is apparent the rate constants are rather insensitive to substituent effects. The ρ* value for the uncatalyzed reaction is 0.18 and ρ* for the catalytic reaction is –0.43.

Fig. 12. Plot for determining the rate constant (k_u) for the uncatalyzed portion of the reaction. Slope (k_u) = 107 ± 5. Intercept = 0.09. r^2 = 0.976.



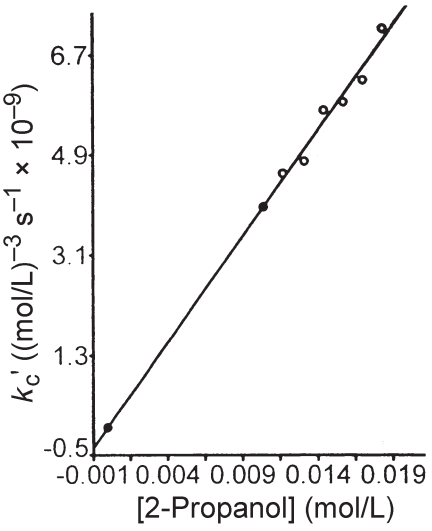


Fig. 13. Plot for determining the rate constant (k_c) for the catalytic portion of the reaction. Slope = (3.81 ± 0.06) × 10^{11}. Intercept = 0.005. r^2 = 0.994.

The oxidation of tetrahydrofuran by $QRuO_4$

When the oxidation of tetrahydrofuran (THF) was studied under similar conditions and with concentrations comparable to those used with 2-propanol in this study, the rates were found to be immeasurably slow. When the concentration of THF was drastically increased (6.14 mol/L), an autocatalytic reaction with a very long induction period was observed, as in Fig. 16.

The effect of moisture

The rate of oxidation of 2-propanol was found to be sensitive to the presence of moisture. When small amounts of water were added under typical reaction conditions, the autocatalytic nature of the absorbance vs. time plots was greatly diminished, as illustrated by the plots in Fig. 17.

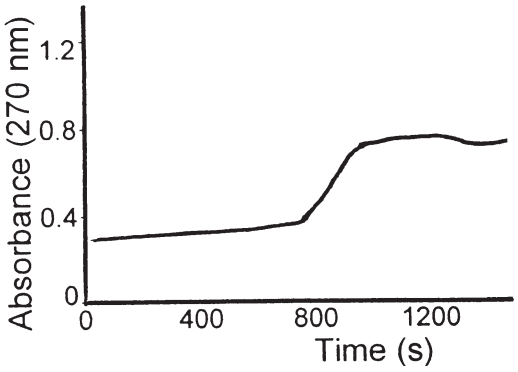
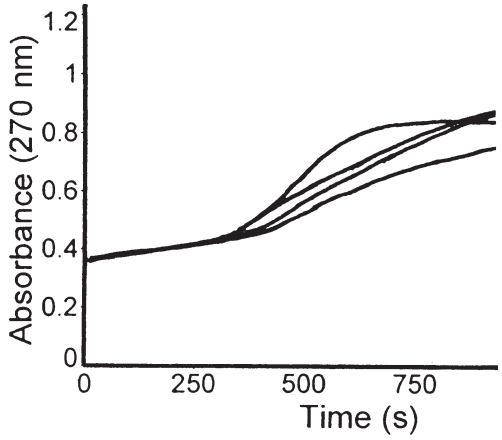
Consequently, precautions were taken to maintain anhydrous conditions at all times.



Demonstration of catalysis by the product (RuO_2)

The catalytic nature of the product of the reaction was also demonstrated in an experiment in which additional $QRuO_4$ was added after all of the oxidant initially present had been reduced by an excess of 2-propanol. As indicated by the plot in Fig. 18, the reaction resumed at an accelerated rate without an induction period. After 72 h, however, a fine black solid precipitated and the solution no longer exhibited autocatalysis.

The oxidation of cyclobutanol by $QRuO_4$



Tetrapropylammonium perruthenate (0.097 g, 0.29 mmol) was added to a 100 mL round-bottomed flask containing cyclobutanol (0.10 g, 1.4 mmol) in 50 mL of methylene

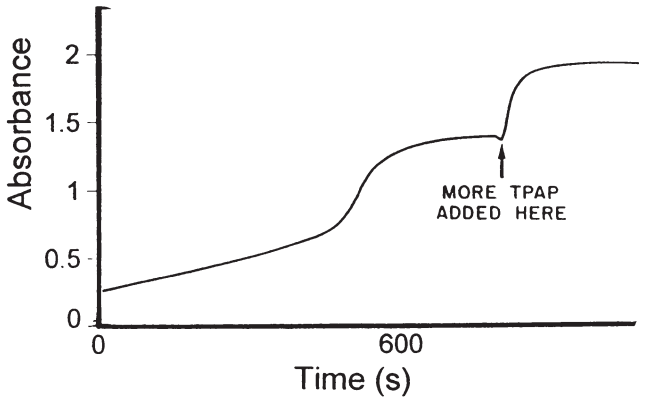
Fig. 17. Plots illustrating the effect of water on the reaction rates. The top plot was obtained in the absence of added water. The plots below it were obtained for reactions to which 0.5, 1.0, and 1.5 μL of water had been added, respectively.

chloride. The solution was stirred at room temperature until all of the oxidant had been reduced and a brown suspension of RuO_2 remained. After filtering to remove the RuO_2, a clear solution was obtained. Evaporation of the solvent left a product (0.096 g) that was determined by ^1H NMR to contain a nearly quantitative amount of cyclobutanone.

Discussion



Autocatalysis

The autocatalytic nature of the reaction between tetrapropylammonium perruthenate and 2-propanol is evident from the plots presented in Figs. 4 and 5. The rate of reaction is initially slow because no product (catalyst) is present. However, as the concentration of the product increases, the rate accelerates, with the result that product is produced more and more rapidly. This results in continuous rate increases until the concentration of $QRuO_4$ diminishes, causing the rate to decrease and, finally, to stop.

Although the identity of the product responsible for the autocatalytic nature of the reaction has not been unequivocally established, it is in all likelihood ruthenium dioxide. Evidence in support of this conclusion was obtained by demonstrating that the product from the reduction of ruthenium tetroxide in carbon tetrachloride also catalyzed the reaction between $QRuO_4$ and 2-propanol. When tetrapropylammonium perruthenate was added to a solution prepared by the reduction of RuO_4 with excess 2-propanol, a rapid reduction of $QRuO_4$ occurred without an induction period. Since ruthenium tetroxide is known to be reduced to ruthenium dioxide by alcohols, the observation that this product is also a catalyst for the reaction between $QRuO_4$ and 2-propanol is entirely consistent with the assumption that RuO_2 is responsible for the autocatalysis evident in Figs. 4 and 5 (26).

The catalytic nature of the product was further demonstrated by adding an aliquot of $QRuO_4$ in methylene chloride to a solution in which the reaction of $QRuO_4$ with an excess of 2-propanol had proceeded to completion. As indicated by the plot in Fig. 18, the added $QRuO_4$ was very rapidly reduced without an induction period.

Fig. 18. Plot illustrating the effect of adding additional TPAP after the initial reaction had stopped.

The reaction, therefore, is reminiscent of permanganate reductions in concentrated acid solution that are catalyzed by MnO_2, a product of the reaction (27). In such reactions, the product is a colloid that could act as a surface catalyst.

The observed decrease in catalytic activity in the presence of moisture (Fig. 17) is consistent with the possibility that RuO_2 acts as a surface catalyst whose active sites are blocked by adsorption of water. The observation that the reaction appears to be approximately second order with respect to the concentration of RuO_2 may be an artifact that is related in some way to the average size of the colloidal particles. Other possibilities involving a transition state that includes two molecules of $QRuO_4$, two molecules of RuO_2, and one molecule of 2-propanol are rather speculative (28).

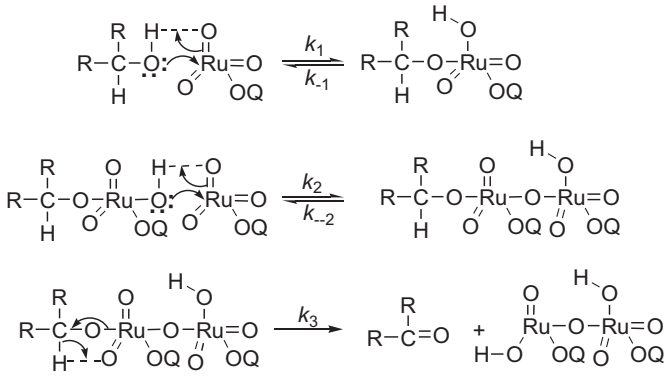
The reaction mechanism

Both the catalytic and noncatalytic portions of the reaction exhibit a similar rate law — first order in 2-propanol and second order in $QRuO_4$. Thus, the transition state must contain two perruthenate ions and a molecule of 2-propanol.

The presence of two perruthenate ions suggests a dimer, similar to those known for other high valent transition metal oxides such as chromate and manganate (29, 30). Two possibilities exist: dimerization of the RuO_4^- ions could take place prior to reaction with the alcohol, as in eqs. [21] and [22], or, an ion of perruthenate and alcohol could react before the second RuO_4^- ion becomes involved, as in eqs. [23] and [24]. Unfortunately, kinetic studies do not help to distinguish between these two possibilities.

[21] $2RuO_4^- \Leftrightarrow Ru_2O_8^{2-}$

[22] $Ru_2O_8^{2-} + ROH \rightarrow$ Products



[23] $RuO_4^- + ROH \Leftrightarrow RORuO_4H^-$

[24] $RORuO_4H^- + RuO_4^- \rightarrow$ Products

Regardless of the reaction sequence, it appears that 2-propanol must initially react by formation of an ester. Such a conclusion is consistent with the O-D isotope effect and with the observation that ethers are not readily oxidized by $QRuO_4$. Oxidants such as RuO_4 and MnO_4^- that react with alcohols by an initial cleavage of an α-C—H bond, oxidize alcohols and ethers at comparable rates because the α hydrogens of alcohols and ethers have similar chemical properties

© 2005 NRC Canada

Scheme 1.

(31, 32). However, the reactions of oxidants, such as chromic acid (H_2CrO_4), that are initiated by ester formation, proceed more rapidly when alcohols are the reductants (33).

The observation that cyclobutanol is oxidized to cyclobutanone indicates that the oxidative process is a two-electron transfer. Previous work has established that hydrogen atom transfer from cyclobutanol produces a free radical that opens very rapidly to give acyclic products (34–36). The oxidation of cyclobutanol to cyclobutanone, therefore, indicates that $QRuO_4$ is a two-electron oxidant.

In addition, the low sensitivity of the reaction to substituent changes displayed in the Taft plots (Figs. 14 and 15), suggests a cyclic process in which there is little charge built up on the α carbon in the transition state. A reaction sequence, consistent with these observations, is presented in Scheme 1.

The rate law derived from the reaction sequence in Scheme 1 is consistent with the observed isotope effects since the rate constants for O–D cleavage (k_1) and C–D cleavage (k_3) are both in the numerator of the derived rate law, as indicated in eq. [25].

$$[25] \quad \text{Rate} = (k_1k_2k_3[R_2CHOH][QRuO_4]^2)/(k_{-1}k_{-2} + k_{-1}k_3 + k_2k_3[QRuO_4])$$

Kinetic studies cannot be used to investigate reactions occurring after the transition state; however, the observed 1:1 stoichiometry allows some speculation with respect to the fate of the co-product ($H_2Ru_2O_8Q_2$). If this product (containing two ruthenium atoms, both with an average oxidation state of +6) was reduced to ruthenium(IV) by reaction with the solvent, the stoichiometry would be, $ROH:QRuO_4 = 1:2$. On the other had, if $H_2Ru_2O_8Q_2$ was reduced by 2 mol of 2-propanol, as in eq. [26], the stoichiometry would be, $ROH:QRuO_4 = 3:2$. Both of these possibilities, therefore, appear to be ruled out.

$$[26] \quad 2R_2CHOH + H_2Ru_2O_8Q_2 \rightarrow 2R_2CO + 2QRuO_4H_3$$

One possibility that results in a 1:1 stoichiometry is the suggestion that $H_2Ru_2O_8Q_2$ could dissociate into two different products, one with ruthenium in an oxidation state of +5 (H_2RuO_4Q) and the other, an oxidation state of +7 ($QRuO_4$), as in eq. [27]. Since a ruthenium(V) species would be expected to be very reactive, it would likely be reduced to ruthenium(IV) by reaction with the solvent. The overall result would be a 1:1 stoichiometry.

$$[27] \quad H_2Ru_2O_8Q_2 \rightarrow QRuO_4 + QRuO_4H_2$$

Conclusions

The reaction between alcohols and tetrapropylammonium perruthenate exhibits intense autocatalysis, making it an excellent reagent for synthetic purposes.

The product responsible for the autocatalytic nature of the reaction appears to be ruthenium dioxide.

The presence of moisture decreases the efficiency of the catalyst.

The rate law for the reaction under both noncatalytic and catalytic conditions is first order in the alcohol and second order in the oxidant.

The rate of reaction is much greater for 2-propanol than for THF, suggesting that the reaction involves formation of an intermediate ruthenate ester.

The oxidation of cyclobutanol to cyclobutanone by TPAP indicates that the reaction is a two-electron process.

Primary deuterium kinetic isotope effects are observed for the oxidation of both 2-propanol-2-*d* and 2-propanol-O-*d* by TPAP.

The impact of substituent effects on the reaction rates is not large.

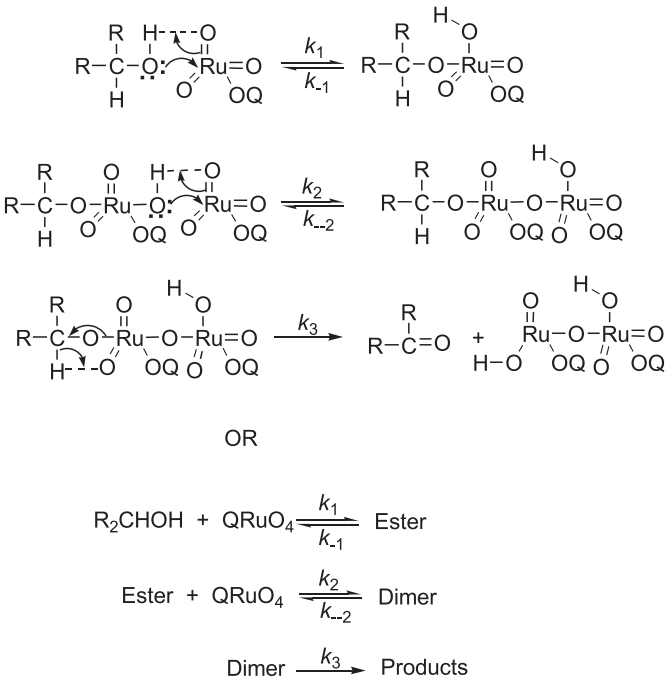
Appendix A

Derivation of eq. [A1] from Scheme A1.



$$[A1]\quad \text{Rate} = (k_1k_2k_3[R_2CHOH][QRuO_4]^2)/(k_{-1}k_{-2} + k_{-1}k_3 + k_2k_3[QRuO_4])$$

Apply the steady state approximation to the intermediates; i.e., to [Ester] and [Dimer].

$$d[\text{Ester}]/dt = k_1[R_2CHOH][QRuO_4] - k_{-1}[\text{Ester}] - k_2[\text{Ester}][QRuO_4] + k_{-2}[\text{Dimer}] = 0$$

$$d[\text{Dimer}]/dt = k_2[\text{Ester}][QRuO_4] - k_{-2}[\text{Dimer}] - k_3[\text{Dimer}] = 0$$

Scheme A1.

$$d[\text{Ester}]/dt + d[\text{Dimer}]/dt = k_1[R_2CHOH][QRuO_4] - k_3[\text{Dimer}] - k_{-1}[\text{Ester}] = 0$$

$$[\text{Ester}] = (k_1[R_2CHOH][QRuO_4] - k_3[\text{Dimer}])/k_{-1}$$

$$[\text{Dimer}] = (k_2[\text{Ester}][QRuO_4])/(k_{-2} + k_3)$$

$$[\text{Dimer}] = (k_1k_2[R_2CHOH][QRuO_4]^2 - k_2k_3[\text{Dimer}][QRuO_4])/(k_{-2} + k_3)(k_{-1})$$

$$[\text{Dimer}] = (k_1k_2[R_2CHOH][QRuO_4]^2)/(k_{-1}k_{-2} + k_{-1}k_3 + k_2k_3[QRuO_4])$$

$$\text{Rate} = k_3[\text{Dimer}] = (k_1k_2k_3[R_2CHOH][QRuO_4]^2)/(k_{-1}k_{-2} + k_{-1}k_3 + k_2k_3[QRuO_4])$$

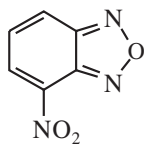
The remarkable effect of 7-amino substituents on the reactivity of 4-nitrobenzofurazans with nucleophiles[1]

Michael R. Crampton, Chukwuemeka Isanbor, and Thomas C. Willett

Abstract: The reactions of four 4-nitrobenzofurazans (**4a**–**4d**) substituted at the 7 position with (**a**) *N*-ethyl, (**b**) *N*-butyl, (**c**) piperidino, or (**d**) pyrrolidino groups have been examined with sulfite ions and with hydroxide ions in water–DMSO (80:20, *v*/*v*). Addition of sulfite at the 5 position gives σ adducts with equilibrium constants ca. 10^5 lower than that for the formation of the corresponding adduct from 4-nitrobenzofurazan. These reductions are attributed to the stabilization of the parent molecules **4a**–**4d** by conjugative interaction between the 4 and 7 substituents. In alkaline solution, **4a** and **4b** yield the conjugate bases while **4c** and **4d** suffer nucleophilic substitution to give 7-hydroxy-4-nitrobenzofurazan. Reactivity here is relatively high because of the iminium ion character of the substrates.

Key words: benzofurazans, σ adducts, nucleophilic reactivity, substitution.

Résumé : Opérant dans un milieu eau–DMSO (80:20, *v*/*v*), on a étudié les réactions des ions sulfites et des ions hydroxydes avec quatre 4-nitrobenzofurazanes (**4a**–**4d**) substitués en position 7 par (**a**) *N*-éthyle; (**b**) *N*-butyle; (**c**) pipéridino ou (**d**) des groupes pyrrolidino. L'addition de l'ion sulfite en position 5 conduit à des adduits σ dont les constantes d'équilibre sont 10^5 fois plus lentes que celles des formations des adduits correspondants à partir du 4-nitrobenzofurazane. On attribue ces réductions à la stabilisation des molécules parentes **4a**–**4d** par une interaction de conjugaison entre les substituants dans les positions 4 et 7. En solution alcaline, les composés **4a** et **4b** conduisent à la formation des bases conjuguées alors que les composés **4c** et **4d** subissent des réactions de substitution nucléophile qui conduisent à la formation de 7-hydroxy-4-nitrobenzofurazanes. Dans ces cas, la réactivité est relativement grande en raison du caractère d'ion iminium des substrats.



Mots clés : benzofurazanes, adduits σ, réactivité nucléophile, substitution.

[Traduit par la Rédaction]

Introduction

There is current interest in quantitatively measuring reactivity in nucleophile–electrophile combination reactions. Mayr and co-workers (1, 2) have investigated a wide-range of carbon–carbon bond forming reactions. There is also information available on the reactivities of both aromatic and heteroaromatic electron-deficient molecules with neutral and anionic nucleophiles (3, 4). Thus, Terrier, Buncel, and co-workers (5) were recently able to assign electrophilicity values (*E*) of –5.13 for 4,6-dinitrobenzofuroxan (DNBF), an excellent electrophile, and –13.10 for 1,3,5-trinitrobenzene (TNB), a weaker electrophile. These values were obtained in reactions with carbon nucleophiles in acetonitrile. The relative electrophilicities may be expected to show some dependence on the type of nucleophile and the solvent. Thus, the pK_a values (3) corresponding to the covalent reaction with water are 3.75 for DNBF and 13.43 of TNB, showing a rather larger difference than the *E* values.

In thermodynamic terms the stabilities of σ adducts formed by the reaction at the 5 position of 4-nitrobenzofurazan (**1**) are generally comparable with those of the corresponding σ adducts from TNB. However, there are significant differences depending on the nature of the nucleophile and the solvent. Thus, for the reaction with methoxide ions in methanol, values of equilibrium constants are 141 $dm^3\ mol^{-1}$ for **1** (6) and 23 $dm^3\ mol^{-1}$ for TNB (7). For reaction with aliphatic amines in dimethyl sulfoxide (DMSO), values of equilibrium constants are ca. 100 times lower for **1** than for TNB (8, 9). Interestingly, for reactions with sulfite ions (10) or hydroxide ions (11) in water, values are 10^3–10^4 times larger for **1** than for TNB. These differences may be largely due to the effects of solvation. Thus, **2** with a localized negative charge will be well-solvated by water, while **3** with a more delocalized charge will be stabilized by DMSO.

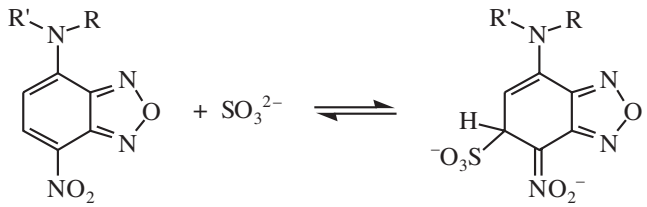
4d

Here, we are concerned with the reactivities of **1** and its 7-substituted derivatives in σ-adduct formation; in particular, the effect of an amino group or substituted amino group at the 7 position.

One source of interest in 4-nitrobenzofurazans is their potential to act as in vitro inhibitors of nucleic acid and protein biosynthesis in animal cells (12–15). Also, the fluorescence characteristics of 7-amino derivatives have been studied (16–18) and their use as fluorescent probes has been investigated (19).

Here, results are reported for the reaction of compounds **4a**–**4d** with sulfite and with hydroxide ions in largely aqueous media. There is evidence for strong conjugation between the groups at the 4 and 7 positions, which stabilizes the parent molecules.



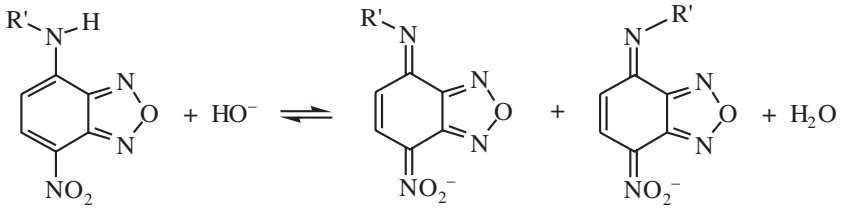
Results and discussion

Most measurements relate to a solvent system of water–DMSO (80:20, *v*/*v*). This system was chosen because of the low solubilities (<5×10^{-5} mol dm^{-3}) of **4b**–**4d** in water. The solubility of **4a** in water was higher, therefore, measurements were made both in water–DMSO (80:20) and in water, allowing a comparison of the solvent systems.

Reaction with sulfite

Spectroscopic results for the parent molecules in DMSO and for the products of the reaction with sulfite in water–DMSO (80:20) are in Table 1. The ^{1}H NMR spectra are consistent with sulfite addition at the 5 position to give **5** as shown in Scheme 1. H-5 shows a large shift to lower frequency (ca. δ 5.3) on adduct formation, while H-6 shows a smaller shift.

Scheme 1.



4 **5**

The coupling constant J_{56} is reduced from ca. 9 Hz in the parent to ca. 6 Hz, consistent with the change in hybridization at C-5. Since the shifts of H-5 and H-6 are similar, the assignments may be reversed. Due to the low solubility of **4d** and the low equilibrium constant for adduct formation, useful spectra could not be obtained for **5d**.

The spectra of the adducts were unchanged after several days and there was no evidence for sulfite attack at the 7 position. However, after a week, spectra of **4a** showed small bands at δ 8.42 and 6.08, characteristic of the anion of 7-

hydroxy-4-nitrobenzofurazan (**8**). Presumably in the sulfite solutions, which are weakly alkaline, hydrolysis occurs very slowly. The failure to observe sulfite attack at the 7 position of **4a**–**4d** is presumably steric in origin. It is known that in **1** itself, attack at the 5 position is followed by a slow isomerization to give the adduct at the 7 position.

Rate and equilibrium measurements for the formation of adducts **4a**–**4d** were made spectrophotometrically in solutions where the sulfite concentration was in large excess of the substrate concentration. In these conditions, a single, first-order process was observed, and rate constants were determined by the stopped-flow method.

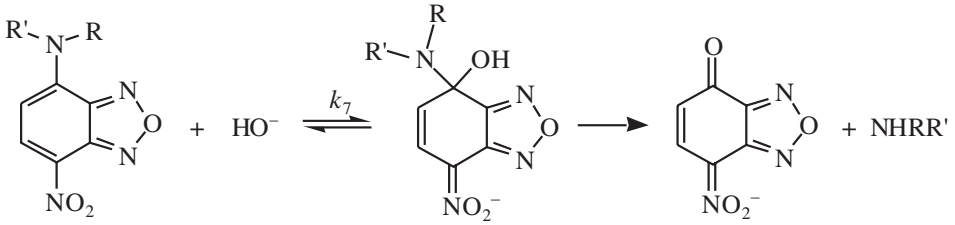
Plots of k_{obs} vs. sulfite concentration were linear with a positive intercept on the *y* axis, according to eq. [1], allowing the determination of values of k_5 and k_{-5}. Specific results for the reaction of **4c** are in Table 2. Values of the equilibrium constant K_5 calculated as k_5/k_{-5} were in excellent agreement with those determined using equilibrium absorbance values. Results are collected in Table 3. We will delay the detailed discussion, but note that the adducts formed from **4** have stabilities ca. 10^5 times lower than the corresponding adduct from 1.

$$[1] \qquad k_{obs} = k_5[SO_3^{2-}] + k_{-5}$$

Reaction with hydroxide

There is no spectroscopic evidence for σ-adduct formation from **4a**–**4d** and hydroxide ions in solutions containing up to 1 mol dm^{-3} hydroxide in water–DMSO (80:20, *v*/*v*). Hence, we may estimate that $K_5 < 0.1$ dm^3 mol^{-1}. This contrasts with the behaviour of **1** where the value (11) of the equilibrium constant for reaction with hydroxide at the 5 position is 2700 dm^3 mol^{-1}. However, this behaviour is not unexpected in light of the results with sulfite, which show that values of K_5 are many orders of magnitude lower for **4** than for **1**.

The ^{1}H NMR spectra of **4a** and **4b** in the presence of hydroxide are reported in Table 1 and indicate deprotonation to give the respective conjugate bases **6a** and **6b** as shown in Scheme 2.



Interestingly, the spectra in each case are compatible with the formation of two conformational isomers as indicated in the scheme. For **6a**, bands for H-5 and H-6 are observed at δ 7.62 and 6.42, J = 10.5 Hz, for the major isomer, and δ 7.50 and 6.20, J = 10.5 Hz, for the minor isomer. For **6a**, the ratio of isomers is 3:1 and for **6b** it is 4:1. Very slow displacement of the 7 substituents is observed so that after 1 week, bands are present due to the anion **8**.

Deprotonation of **4a** and **4b** is accompanied by changes in the UV–vis spectra. In the case of **4b**, λ_{max} is 484 nm in the parent and 392 nm in the anion. These changes were used to measure the pK_a values. An example calculation, in Table 4, yields a pK_a value of 10.15 ± 0.02 for **4b** in water–DMSO (80:20). Values for **4a** were 10.14 ± 0.05 in solvent (80:20) and 10.02 ± 0.02 in water.

In the presence of hydroxide, **4c** and **4d** were irreversibly converted to the anion (**8**) of 7-hydroxy-4-nitrobenzofurazan, which was identified from its ^{1}H NMR and UV–vis spectra (11). Kinetic measurements were made, at λ_{max} for the parent, with hydroxide concentrations in large excess and in the range 0.05–0.20 mol dm^{-3}. First-order kinetics were obtained, and plots of the rate constant vs. hydroxide concentration, which were linear with a zero intercept yielded values of the second-order rate constants. The reaction is likely (3, 4) to proceed by the addition–elimination mecha-

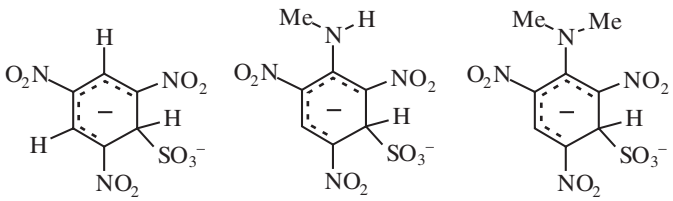
nism shown in Scheme 3. There was no evidence for the accumulation of the reaction intermediates **7c** and **7d** so that the measured second-order rate constants are likely to represent the values for k_7 for nucleophilic attack at the 7 position. Values obtained were 0.91 ± 0.05 dm^3 mol^{-1} s^{-1} for **4c** and 0.71 ± 0.04 dm^3 mol^{-1} s^{-1} for **4d**. These values may be compared to a value (11) of 0.2 ± 0.1 dm^3 mol^{-1} s^{-1} for hydroxide attack at the 7 position of **1**.

Comparisons

Our results provide evidence for a strong conjugation between the 4-nitro and 7-amino substituents as indicated in **9**. The UV–vis absorbance maxima in **4a**–**4d** are at 482–510 nm, showing a strong bathochromic shift relative to **1** where λ_{max} is 327 nm. A similar, but much weaker, conjugative effect has been noted in 7-methoxy-4-nitrobenzofurazan (**10**) where λ_{max} is 383 nm. It is interesting that in the ^{1}H NMR spectrum of **4d**, the pyrrolidino derivative, the two pairs of α-CH_2 hydrogens show discrete spin-coupled bands at δ 4.19 and 3.69, indicative of the double bond character in the carbon–nitrogen bond.

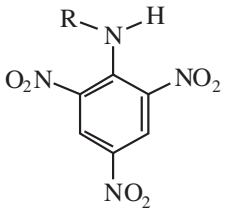


9

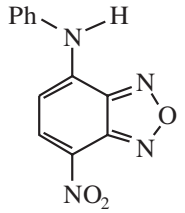
When comparing values of rate and equilibrium constants, it must be noted that here values generally refer to water–DMSO (80:20, *v*/*v*), corresponding to a mol fraction of 0.059 in DMSO. The comparisons with other compounds are generally made with results obtained in water. Nevertheless, the proportion of DMSO is small so that effects are likely to be small. Thus, the results in Table 3 for sulfite addition to **4a** indicate an increase in the value of K_5 by a factor of 2.5 on going from water to the mixed solvent. This is in line with other results showing increases in stability for the σ adducts as the proportion of DMSO in the solvent is increased (3, 4, 10).

One effect of the conjugative stabilization shown in **9** is to dramatically decrease values of equilibrium constants for σ-adduct formation at the 5 position. In the case of sulfite addition, the results in Table 3 show that values of K_5 are reduced by factors of ca. 10^5 relative to the value for the reaction of **1**. Values of k_5 are decreased and values of k_{-5} are increased. The overall effect is notably bigger for the pyrrolidino derivative (**4d**) than for the piperidino analogue (**4c**). Related differences between these amines have been reported previously (21–23) and may be attributed to the particular stability of the resonance form **9** in the pyrrolidino derivative.

It is of interest to contrast the effects of an amino substituted in the 4-nitrobenzofurazans with related effects in 1,3,5-trinitrobenzene derivatives. Thus, the values of the equilibrium constants for the formation of the sulfite adducts **10**, **11**, and **12** are (24) 250, 5.4 × 10^4, and 5.4 × 10^4 dm^3 mol^{-1}, respectively. Here, the effect of an *N*-methyl or *N*,*N*-dimethyl substituent is to enhance the stability of the adduct by a factor >100. It is likely that the difference in behaviour in the two systems is largely steric in origin. Hence, in the parent amino-trinitrobenzenes, it is not possible to achieve the degree of planarity required for strong conjugative interaction. The lower aromaticity in the benzofurazans relative to the benzene derivatives (4) may also favour conjugative interaction as shown in **9**.



σ-Adduct formation at the 5 position of **4** results in the loss of conjugation between the 4 and 7 substituents, and



10 **11** **12**

© 2005 NRC Canada

hence, is relatively disfavoured. However, ionization (Scheme 2) is not similarly disadvantaged. Thus, the pK_a values of ca. 10 found for **4a** and **4b** may be compared (3, 4, 25, 26) with corresponding values of ca. 13 for picramide and *N*-alkylpicramides (**13**). In a related fashion, the acidity in water–DMSO (20:80, *v*/*v*) of 7-anilino-4-nitrobenzofurazan (**14**, pK_a 7.68) has been found (27) to be higher than that of 2,4,6-trinitrodiphenylamine (pK_a 8.20).

13

14

The high reactivity of **4c** and **4d** towards hydrolysis (Scheme 3) may be attributed to the contribution of the resonance from **9** to the structure. This gives the carbon–nitrogen bond iminium ion character, hence explaining (28) the reactivity towards the attack of hydroxide. The values obtained for k_7 of ca. 1 dm^3 mol^{-1} s^{-1} may be compared (29) with values of 0.0031 and 0.015 dm^3 mol^{-1} s^{-1} for the corresponding attack of hydroxide on 1-piperidino- and 1-pyrrollidino-2,4,6-trinitrobenzene, respectively. It is interesting that in alkaline solutions, **4a** and **4b**, where anion formation predominates, are very slowly hydrolysed. This is likely to involve hydroxide attack on low concentrations of the parent molecules. As in previous work (10), there is no evidence for an attack of sulfite at the 7 position of 4-nitro-7 substituted benzofurazans, presumably owing to unfavourable steric interactions.

Experimental

Compounds **4a**–**4d** were prepared from 7-chloro-4-nitrobenzofurazan by reaction with 4 equiv. of the appropriate amine in DMSO. Mixtures were stirred for 5 h at room temperature and quenched in ice-cold dilute hydrochloric acid. The precipitates were filtered, washed with water and ethanol, and recrystallized from ethanol. ^{1}H NMR spectra are reported in Table 1, and indicated the absence of impurities. **4a**: mp 164 °C. MS (ES$^+$) *m*/*z* 209 corresponds to $C_8H_9N_4O_3$ (M + H$^+$). **4b**: mp 90 °C. MS (ES$^+$) *m*/*z* 237 corresponds to $C_{10}H_{13}N_4O_3$ (M + H$^+$). **4c**: mp 166 °C. MS (ES$^+$) *m*/*z* 249 corresponds to $C_{11}H_{13}N_4O_3$ (M + H$^+$). **4d**: mp 210 °C. MS (ES$^+$) *m*/*z* 235 corresponds to $C_{10}H_{11}N_4O_3$ (M + H$^+$).

Sulfite solutions were prepared from AnalaR sodium sulfite. To check that no depletion of sulfite concentration occurred because of hydrolysis when making kinetic and equilibrium measurements, measurements were also made in solutions buffered at pH 8.3 using mixtures of sodium sulfite and sodium hydrogen sulfite. The values of rate and equilibrium constants obtained were identical, within experimental error, to those obtained in unbuffered solutions with the same sulfite concentration. Solutions of known hydroxide concentration were made by dilution of AnalaR sodium hydroxide solution. The pH values of buffer solutions, borax or phosphate, were measured using a Jenway 3020 pH meter, calibrated using aqueous buffers. All other materials and solvents were the purest available commercial specimens.

^{1}H NMR spectra were measured using Bruker Ultrashield 400 MHz or Varian Inova 500 MHz spectrometers. Parent molecules were dissolved in [$^2H_6$]-DMSO. Measurements in solutions containing sodium sulfite or sodium deuteroxide were made in water–DMSO (80:20, *v*/*v*) using deuteriated solvents. Parent concentrations were in the range 0.005–0.01 mol dm^{-3} with the nucleophile concentration (ca. 0.1 mol dm^{-3}) in large excess. UV–vis spectra and kinetic measurements were made at 25 °C with a PerkinElmer Lambda 2 spectrophotometer, a Shimadzu UV-2101 PC spectrophotometer, or an Applied Photophysics SX-17 MV stopped-flow instrument. Reported rate constants are the mean of several determinations and are precise to ±5%.

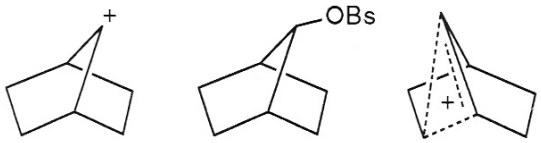
The fragmentation of 7-norbornyloxychlorocarbene — S_Ni-like transition states[1]

Robert A. Moss, Xiaolin Fu, and Ronald R. Sauers

Abstract: 7-Norbornyloxychlorocarbene (**15**) fragments mainly to 7-norbornyl chloride (**16**). A C-2 deuterated analog of **15** (*syn*-**15**-*d*) fragments to labeled chloride **16** with 78% retention and 22% inversion. When the deuterium label is replaced by a *syn*-*exo*-2-methyl group, the resultant carbene **22** fragments to *syn*- and *anti*-7-chloro-*exo*-2-methylnorbornane in a ratio of 1:1.1, corresponding to 48% retention and 52% inversion. Computational studies suggest that the fragmentations proceed via competitive S_Ni-like transition states that lead to either retention or inversion.

Key words: carbenes, carbocations, S_Ni reactions, stereochemistry.



Résumé : La fragmentation du 7-norbornyloxychlorocarbène (**15**) conduit principalement au chlorure de 7-norbornyle (**16**). La fragmentation d'un analogue du composé **15** deutéré en position C-2, le *syn*-**15**-*d*, conduit au chlorure **16** marqué avec 78 % de rétention et 22 % d'inversion. Quand on remplace le deutérium servant de marqueur par un groupe *syn*-*exo*-2-méthyle, le carbène **22** qui en résulte se fragmente en *syn*- et *anti*-7-chloro-*exo*-2-méthylnorbornanes dans un rapport de 1 : 1,1, ce qui correspond à 48 % de rétention et à 52 % d'inversion. Des études par calculs théoriques suggèrent que la fragmentation sur produit par le biais d'états de transition de type S_Ni qui sont en compétition et qui conduisent soit à une rétention soit à une inversion.

Mots clés : carbènes, carbocations, réactions S_Ni, stéréochimie.

[Traduit par la Rédaction]

Introduction

The 7-norbornyl cation **1** has long been a focus of organic reaction mechanism studies (1). Acetolysis of its tosylate precursor proceeded with $k = 8.4 \times 10^{-5}$ s^{-1} at 205 °C, extrapolated to 6.4×10^{-15} s^{-1} at 25 °C, with $\Delta H^* = 35.7$ kcal/mol (1 cal = 4.184 J) and $\Delta S^* = -3.5$ eu (2). This extraordinary lack of reactivity may, in part, be due to angle strain at C-7 (3), although this origin has been downgraded (1) in favor of an electronic origin suggested by Heilbronner, Hoffmann, and co-worker (4) who showed that for reasons of symmetry, the cation at C-7 cannot be stabilized by the ribbon orbitals of the σ skeleton of the underlying six-membered ring.

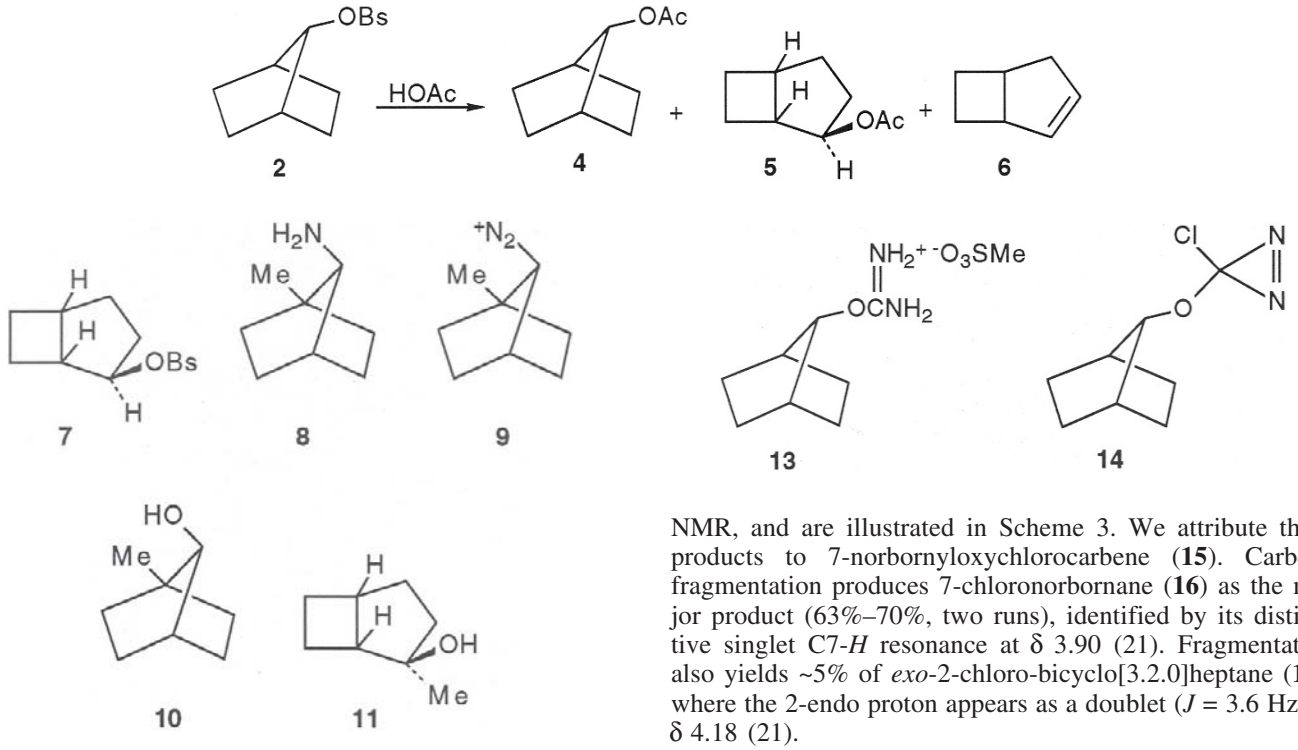
The solvolysis of 7-norbornyl brosylate (**2**) was depicted as passing through cation **3** by Winstein et al. (5*a*), who studied the stereochemistry and rearrangment attending the acetolysis of **2** at 205 °C. The products included 91% of unrearranged (5*a*) and 90% stereochemically retained (5*b*) acetate **4**, 7% of rearranged *exo*-2-bicyclo[3.2.0]heptyl acetate (**5**), and 2% of the related rearranged olefin **6** (see Scheme 1) (5).



To rationalize the stereoselectivity in the conversion of **2** to **5** (and in accord with the retention in the formation of **4**), cation **3** was suggested as the product-determining intermediate (5).

This postulate was strengthened by the finding that *exo*-2-bicyclo[3.2.0]heptyl brosylate (**7**) underwent acetolysis at 50 °C with anchimeric assistance, extensive rearrangement, and ion pair return to a mixture of 83% of rearranged brosylate **2**, 16% of rearranged acetate **4**, 1% of unrearranged acetate **5**, and a trace of alkene **6** (5*a*). Again, cation **3** was held to account for the course of the reaction.

Furthermore, aqueous nitrous acid deamination of the related (*S*)-1-methyl-7-norbornylamine (**8**), which proceeded via diazonium ion **9**, gave 1-methyl-7-norbornanol (**10**) with high sterochemical retention, as well as the *endo*-2-methyl-*exo*-2-bicyclo[3.2.0]heptanol rearrangement product **11** (6). A cation similar to the solvolysis intermediate was believed to be involved in this deamination reaction (6). More recently, the 7-norbornyl cation has been visualized in a cold SbF_5 matrix by IR spectroscopy, and its structure computed using high level ab initio methods (7, 8). Structures similar to **3** were presented for the 7-norbornyl cation. Our computed structure for this cation will be offered in Fig. 1.

Scheme 1.

We have found the fragmentation of alkoxychlorocarbenes (eq. [1]) to be a valuable, nonsolvolytic entry to several of the most interesting carbocations of organic chemistry (9). These fragmentations, which proceed in both polar (10) and hydrocarbon solvents (11), provide access to (inter alia) the 2-norbornyl cation (12), the 3-nortricyclyl and (or) 5-norbornen-2-yl cations (13), the menthyl and neomenthyl cations (14), and the bicyclo[3.1.0]hexyl cation (15). Here, we describe the application of carbene fragmentation methodology to the 7-norbornyl system. The results provide evidence for the operation of S_Ni-like reaction mechanisms.

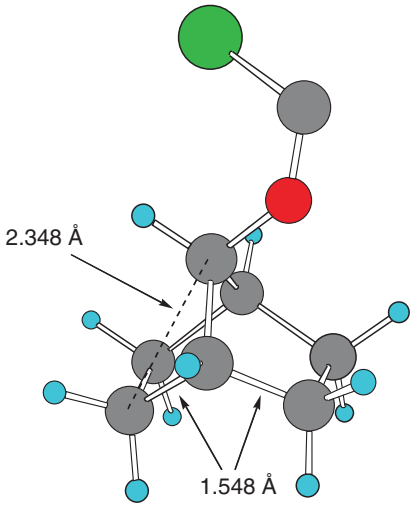
Results and discussion

7-Norbornyloxychlorocarbene and its products

7-Norbornanol (**12**) was prepared by the sequence of Scheme 2: norbornene was epoxidized with peracetic acid (16); the epoxide was opened to 2-*exo*-bromo-7-*syn*-hydroxynorbornane with HBr (17); and the bromohydrin was debrominated to **12** with a Zn–Cu couple in refluxing 95% ethanol (18). Norboranol **12** was converted to the isouronium mesylate **13** with cyanamide and methanesulfonic acid (19), and the salt was then oxidized to the carbene precursor 3-(7-norbornyloxy)-3-chlorodiazirine (**14**) with NaOCl in aq. DMSO (20). The diazirine was purified by chromatography over silica gel, and characterized by UV (λ_{max} 349 nm in pentane, 355 nm in 1,2-dichloroethane), IR (1541 cm^{-1}, film), and ^1H and ^{13}C NMR spectroscopy (see Experimental).

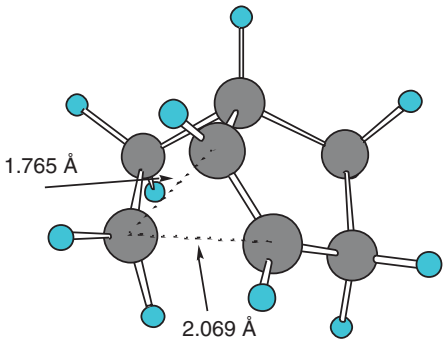
Diazirine **14** was dissolved in ~2 mL of $CDCl_3$ and irradiated for 1 h at 350 nm. The products were analyzed by NMR, and are illustrated in Scheme 3. We attribute these products to 7-norbornyloxychlorocarbene (**15**). Carbene fragmentation produces 7-chloronorbornane (**16**) as the major product (63%–70%, two runs), identified by its distinctive singlet C7-*H* resonance at δ 3.90 (21). Fragmentation also yields ~5% of *exo*-2-chloro-bicyclo[3.2.0]heptane (**17**), where the 2-endo proton appears as a doublet (J = 3.6 Hz) at δ 4.18 (21).

Trapping of carbene **15** by HCl affords ~14% of dichloride **18** (C7-*H* at δ 4.38, C*H*Cl_2 at δ 7.20), while trapping by adventitious water yields ~1.5% of formate **19** (C7-*H* at δ 4.85, OOC*H* at δ 8.05). There is ample precedent for the formation of these two carbene trapping products (22). As expected (22), generation of carbene **15** in $CDCl_3$ containing (deuterated) pyridine affords a product mixture in which dichloride **18** is suppressed because the pyridine scavenges HCl. Additionally, formate **19** is augmented when carbene **15** is generated in the presence of traces of added water.



One could formulate the fragmentation of **15** as proceeding via a [**3**$^+$$Cl^-$] ion pair in which return of chloride to C7 produces **16**, whereas chloride attack at C1 generates rearranged chloride **17**. This mechanism agrees with the solvolytic reactions of **2** (Scheme 1) (5) and **7** (5), as well as the deamination of **8** (6). In the following, however, we will suggest that the carbene fragmentation mechanism involves significant S_Ni character. This may also account for the absence of norbornanol, which could have been produced by trapping of the 7-norbornyl cation by traces of water.

Stereochemistry of fragmentation



To study the stereochemistry of the **15** → **16** conversion, we prepared deuterium labeled diazirine **14**. Thus, when the Zn–Cu reduction of the bromohydrin of Scheme 2 was carried out in refluxing EtOD, norbornanol **12** was obtained as a mixture of the **12**-*exo*-D and the **12**-*endo*-D isotopomers. Given that the chemical shifts of ^2H are comparable to those of ^1H (23), we can assign signals in the ^2H NMR spectrum by analogy to assignments in the ^1H NMR spectrum. In the latter, the exo and endo C2 and C3 protons of deuterated **12** at δ 1.78 and 1.49 (in $CDCl_3$) appear as multiplets with a total integral value of 3H. In the corresponding ^1H-decoupled

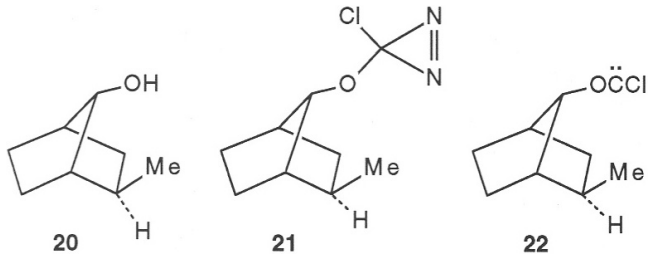
^{2}H NMR spectrum, the deuterons appear as singlets at δ 1.78 (*exo*-2-D) and δ 1.47 (*endo*-2-D) in a ratio of 1.5:1.

Alcohols **12**-*d* were converted to the deuterated diazirines **14**-*exo*-D (δ 1.22 for the ^{2}H in $CDCl_3$) and **14**-*endo*-D (δ 1.45), via the isouronium salts and NaOCl oxidation as above. Photolysis of the **14** isotopomers led, via carbene *syn*-**15**-*d*, to 68% of *syn*-**16**-*exo*-D and *syn*-**16**-*endo*-D (*retention* of configuration), together with *anti*-**16**-*exo*-D and *anti*-**16**-*endo*-D (*inversion*). The proton chemical shifts of **16** have been analyzed by Nash et al. (21*b*), who assign the C2-*exo*-H at δ 1.95, the C2-*endo*-H at δ 1.58, and the four C5 and C6 exo and endo protons at δ 1.29. We can therefore assign (23) the deuterium singlets that we observe in the ^{1}H-decoupled ^{2}H NMR spectrum of the reaction product mix-

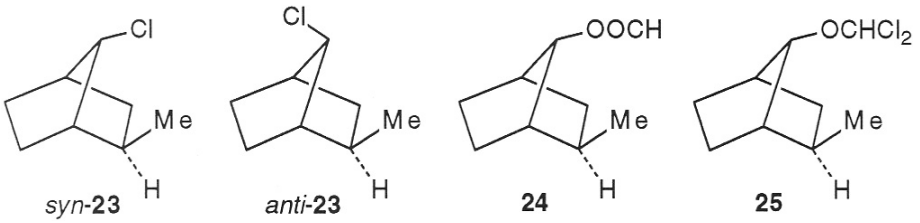
© 2005 NRC Canada



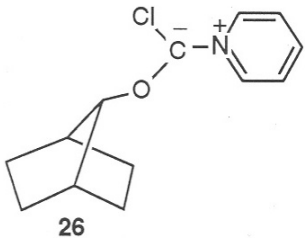
Scheme 3.

ture as *syn*-**16**-*exo*-D (δ 1.94), *syn*-**16**-endo-D (δ 1.59), and *anti*-**16**-*exo*-D plus *anti*-**16**-*endo*-D (both at δ 1.29). The syn/anti product ratio represents retention/inversion for the **15** → **16** conversion. From integration of the appropriate signals in the ^{2}H NMR spectrum, we find retention/inversion = 3.54:1. Therefore, the course of the **15** → **16** fragmentation in $CDCl_3$ is 78% (total) retention, or 56% *net* retention, i.e., there is 22% of inversion.

When D-labeled **15** fragmented in the presence of 3 mol/L *n*-$Bu_4N^+Cl^-$ in $CDCl_3$, ^{2}H NMR analysis gave the retention/inversion ratio of labeled **16** as 2.2 ± 0.3 (two experiments), corresponding to 69% (total) retention or 38% net retention. The small decrease in retention (increase in inversion) of the **15** → **16** conversion in the presence of added chloride may represent a minor incursion of a S_N2 component (chloride attack on carbene **15**) in competition with the normative "unimolecular" fragmentation of the carbene. An inverting attack of azide ion on 1-methyl-7-norbornyl triflate is known (6), as are S_N2 reactions of chloride ion and *primary* alkoxychlorocarbenes (24).



Further stereochemical information on the fragmentation reaction was provided by a methyl labeled analogue of carbene **15**. Thus, *syn*-2-*exo*-methyl-7-norbornanol (**20**) was obtained from the reaction of *exo*-norbornene oxide and methylmagnesium bromide (25). The alcohol was purified by chromatography over silica gel with pentane–ether (4:1), and characterized by ^{1}H and ^{13}C NMR spectroscopy. In the ^{1}H NMR spectrum of **20**, the characteristic C4 bridgehead proton appeared at δ 1.91 (reported at δ 1.97 (25)). Conversion of **20** to the isouronium methanesulfonate (19), followed by oxidation with NaOCl (20) gave diazirine **21** (IR: 1541 cm^{-1}; UV λ_{max}: 349, 366 nm in pentane). The diazirine was also characterized by NMR, as described in the Experimental.



Photolysis (λ > 320 nm) of **21** in $CDCl_3$ gave carbene **22**, which afforded the products shown in Scheme 4. The main products (two runs) were 38% to 39% of *syn*-7-chloro-*exo*-2-methylnorbornane (*syn*-**23**), 38% to 39% of *anti*-7-chloro-

© 2005 NRC Canada

Scheme 4.

exo-2-methylnorborane (*anti*-**23**), 0.8%–1.5% of formate **24**, and 14%–18% of dichloride **25**. There was also 2% to 3% of a product tentatively identified as a methylbicyclo[3.2.0]heptyl chloride, an analogue of **17**.

The identities of **24** and **25** follow from the NMR of their signature protons: for **24**, H7 at δ 4.85 and OOC*H* at δ 8.05; for **25**, H7 at δ 4.30 and C*H*Cl_2 at δ 7.20. Additionally, the yield of dichloride **25** is reduced from 14%–18% to just traces when the fragmentation of **22** occurs in the presence of pyridine.

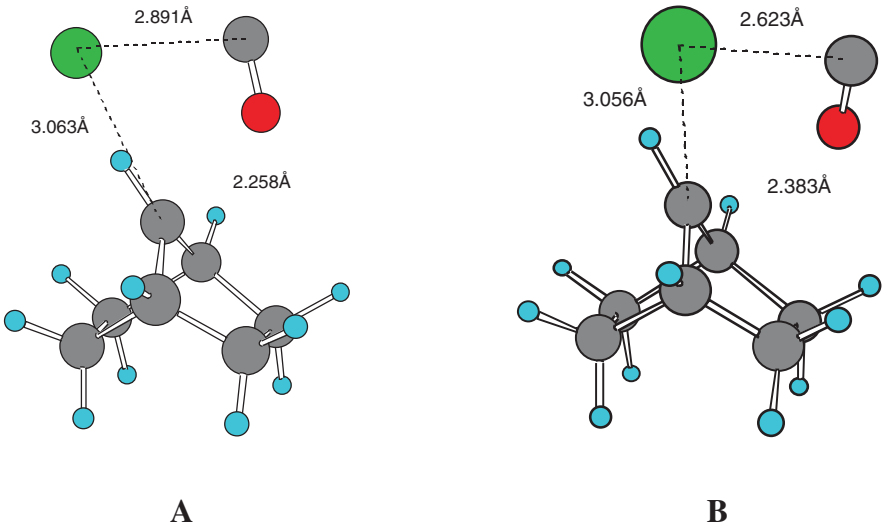
The identities of key products *syn*-**23** and *anti*-**23** were established by GC–MS (M^+ and $(M + 2)^+$ at *m/e* 144 and 146, respectively), as well as by ^1H and ^{13}C NMR, including various correlation experiments. In particular, the C7 protons of *syn*-**23** and *anti*-**23** appear at δ 3.82 and 4.02, respectively. NMR integration indicates that the two isomers were formed in approximately equal quantities. Capillary GC analysis gave an *anti*/*syn* ratio of 1.1, which increased to 2.4 when the fragmentation of **22** occurred in the presence of 3 mol/L tetrabutylammonium chloride (TBACl).

syn-**23** represents the fragmentation of carbene **22** with retention, while *anti*-**23** indicates inversion. The carbene fragments to chloride **23** with a roughly *equal* balance of retention and inversion. In comparison to the D-labeled carbene **15**, the inversion pathway here has significantly increased: retention/inversion is 3.5:1 for **15**, but 1:1.1 for **22**. The *syn*-*exo*-2-methyl group of **22** appears to hinder chloride return with retention to yield *syn*-**23**, relative to chloride return with inversion to give *anti*-**23**. Computational studies (below) provide a surprising mechanistic rationale.

Kinetics of fragmentation

Absolute rate constants for fragmentations of carbenes **15** and **22** were determined by laser flash photolysis (LFP) (24, 26) using the pyridine ylide method (27). LFP at 351 nm and 25 °C of diazirine **14** in 1,2-dichloroethane (DCE, $A_{351} = 2.1$) in the presence of pyridine produced an absorption assigned to ylide **26** at 424 nm. A correlation of the apparent rate constants for ylide formation (k_{obs}, 1.2–2.8 × 10^6 s^{-1}) vs. pyridine concentration (0.8–7.2 mol/L) was linear (nine points, $r = 0.995$) with a slope of 2.38 × 10^5 $(mol/L)^{-1}$ s^{-1}, equivalent to the rate constant for ylide formation (k_y). The *Y* intercept of 9.91 × 10^5 s^{-1} approximates k_{frag} for the fragmentation of carbene **15** to chlorides **16** and **17**, which constitute ~70% of the reaction products (see Scheme 3). A duplicate kinetics experiment gave similar results, leading to mean values for the rate constants ($k_y = 2.4 \pm 0.3 \times 10^5$ $(mol/L)^{-1}$ s^{-1} and $k_{frag} = 1.02 \pm 0.02 \times 10^6$ s^{-1}).

The latter rate constant is surprisingly high for the fragmentation of ROCCl where R is a *sec*-alkyl group; for example, k_{frag} for cyclopentyl-OCCl is 8.7 × 10^4 s^{-1} (12) and for cyclohexyl-OCCl it is 3.3 × 10^4 s^{-1} (14). Given the substantial kinetic difficulty in the solvolytic formation of the 7-norbornyl cation (2) and the instability of the cation (1, 4), the fast fragmentation of carbene **15** suggests that the transition state is early, and avoids the imposition of much positive charge on C7 of the norbornyl moiety. These ideas will be elaborated in the following.



We also studied the LFP of diazirine **14** in the presence of added TBACl. LFP of **14** in DCE with a constant concentration of pyridine and varying quantities (0.008–0.8 mol/L) of TBACl gave a linear correlation (eight points, $r = 0.992$) of k_{obs} for the formation of ylide **26** as a function of chloride concentration. The slope of this correlation can be taken as the second-order rate constant (k_2) for the quenching (or fragmentation) of carbene **15** induced by chloride ion (24, 27), although some of the observed rate enhancement may be due to a "simple" salt effect (also seen with TBA perchlorate). The observed k_2 for carbene **15** (2.4 × 10^6 $(mol/L)^{-1}$ s^{-1}) is very similar to the corresponding rate constant for the reaction of chloride with benzyloxychlorocarbene ($PhCH_2OCCl$), $k_2 = 2.2 \times 10^6$ $(mol/L)^{-1}$ s^{-1} in acetonitrile (24). We conclude that a minor S_N2 decomposition pathway operates for carbene **15** in the presence of an added nucelophile. This agrees with the modest increase in stereochemical inversion for the **15**-*d* → **16**-*d*, conversion with added TBACl (see the previous section).

The fragmentation of **15** was also studied as a function of temperature from –41 to 30 °C. A very good correlation of $\ln k_{frag}$ vs. $1/T$ was obtained (eight points, $r = 0.996$), from which E_a = 3.5 kcal/mol and $A = 4.7 \times 10^8$ s^{-1} ($\Delta S^* = -20$ eu). The low activation energy and strongly negative entropy of activation are fairly typical of ROCCl fragmentations. For example, 1-bicyclo[2.2.2]octyloxychlorocarbene in DCE fragments with E_a = 4.4 kcal/mol and $A = 2.8 \times 10^8$ s^{-1} ($\Delta S^* = -22$ eu) (28).

Finally, we examined the kinetics of fragmentation of carbene **22** using the same methodology applied to carbene **15**. For **22**, $k_{frag} = 7.0 \pm 0.1 \times 10^5$ s^{-1} in DCE, with E_a = 4.2 kcal/mol and $A = 1.8 \times 10^9$ s^{-1} ($\Delta S^* = -18$ eu). The fragmentation of **22** is kinetically comparable to that of carbene

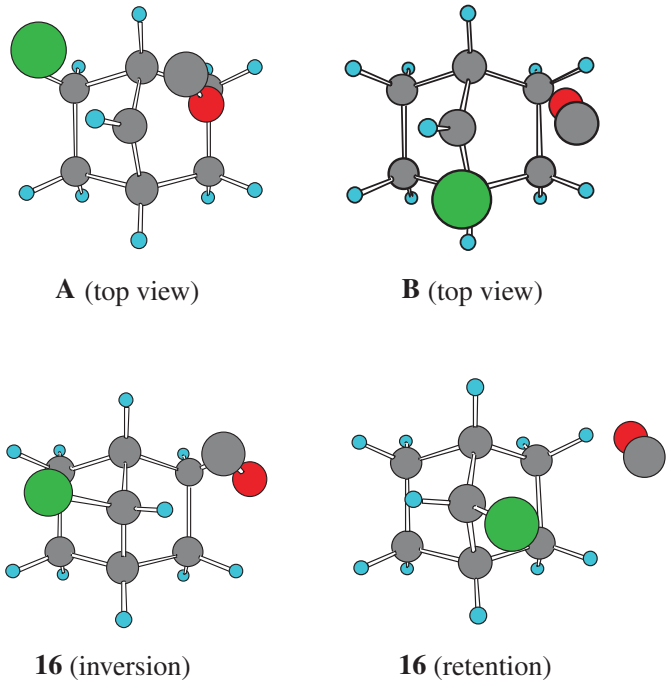
Fig. 2. B3LYP/6-31G(d) transition states for the (in vacuo) fragmentation of carbene **15** to chloride **16**. TS leading to **16** with inversion (**A**), TS leading to **16** with retention **(B**).

15, i.e., the *syn-exo*-2-methyl group of **22** does not induce a major kinetic perturbation.



Computational studies

We studied the fragmentation of carbene **15** with DFT methodology. All structures were fully optimized by analytical gradient methods using the GAUSSIAN 98 and GAUSSIAN 03 suites (29*a*), as well as density functional calculations at the 6-31G(d) level, with the exchange potentials of Becke and co-workers (29*a*, 29*b*) and the correlation functional of Lee and co-workers (29*a*, 29*c*).

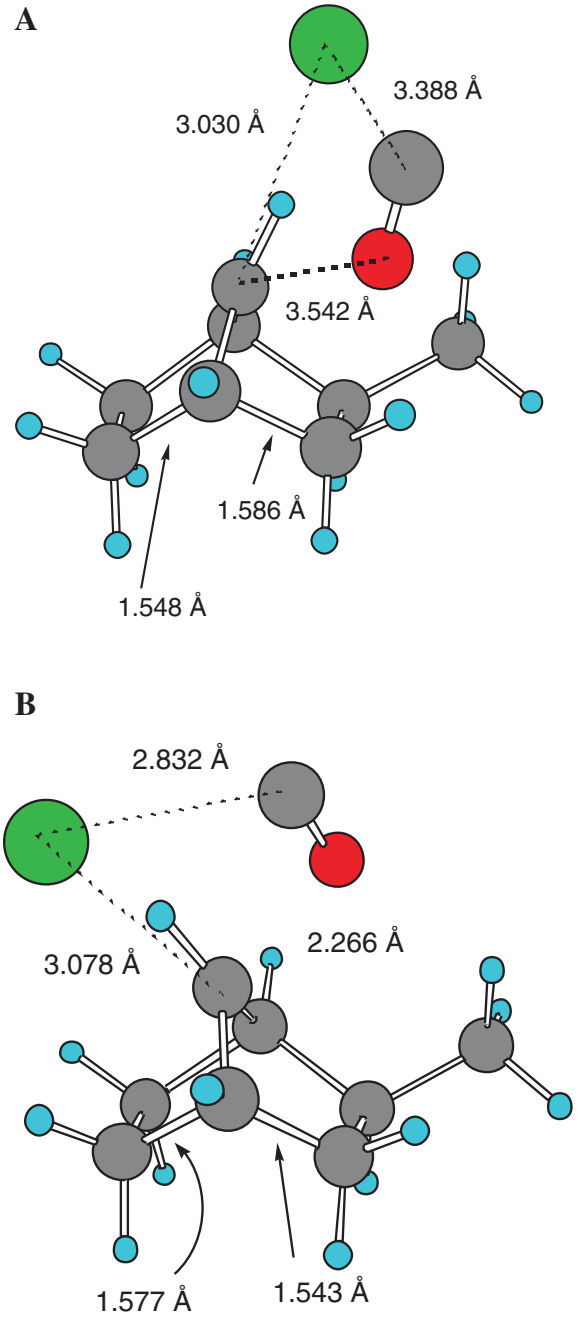
For the fragmentation of **15** to 7-chloronorbornane (**16**), we located not one, but *two* transition states (cf. Fig. 2, structures **A** and **B**). Transition state **A** (TS **A**) leads to chloride **16** with inversion, whereas TS **B** affords **16** with retention. Each TS was subjected to intrinsic reaction coordinate (IRC) calculations, which verified that they proceeded to chloride **16** in the forward direction and returned to carbene **15** in the reverse direction.

In Fig. 3, we present top views of TS **A** and **B** in which the contrasting skeletal symmetry and geometric relationships of the Cl and C7 atoms are apparent. The inverted and retained IRC end points (chloride **16**) are also illustrated. TS **A** and **B** are energetically comparable: in vacuum, their computed $\Delta H^{\ddagger}$ values (correlated for zero-point energy differences and thermal effects at 298.15 K) are 22.2 (inversion) and 23.3 (retention) kcal/mol. In simulated DCE, using the polarized contiuum model (PCM) (29*a*) and single-point calculations, the $\Delta H^{\ddagger}$ values decrease to 7.3 (inversion) and 7.9 (retention) kcal/mol. The key conclusion is that fragmentation of **15** to **16** should occur with a nearly equal probability of retention and inversion, in agreement with the experimental results for D-labeled **15**, which affords **16**-*d* with a retention/inversion ratio of 3.5:1. A reviewer suggested that the transition state regions for the conversions of **15** to **16** via TS **A** or **B** may be rather broad and flat so that the chloride might explore these regions as dictated by the transition-state geometries, leading to retention or inversion in least motion processes.

Fig. 3. Top views of TS **A** and **B** of Fig. 1 and end points of the IRC calculations on **A** and **B**, which afford chloride **16** with inversion or retention, respectively, relative to carbene **15**.

It is important to note that TS **A** and **B** *do not* evolve to ion pair minima; the lack of complete retention in the **15** → **16** conversion cannot be attributed to stereochemical randomization within an ion pair. When more stable cations can be formed, such as the 1-adamantyl or 3-homoadamantyl cations, IRC calculations indicate that the TS for ROCCl fragmentation gives [R^+Cl^-] ion pairs (10). However, this is not the case for TS **A** or **B**, which approximate those of a S_Ni reaction. A related TS was computationally indicated in the fragmentation of 1-norbornyloxychlorocarbene to 1-norbornyl chloride, where the high-energy 1-norbornyl cation was largely bypassed (10). S_Ni-like TS for the fragmen-

© 2005 NRC Canada



tation of certain secondary ROCCl have been suggested by Jones and co-workers (30), while Schleyer and co-workers have presented experimental and computational evidence for related processes in the fragmentation of alkyl chlorosulfites, a reaction analogous to the fragmentation of alkoxychlorocarbenes (31).

Previously, we suggested that the unexpectedly rapid fragmentation of carbene **15** implies that the TS is "early" and avoids the imposition of significant positive charge on C7. The computational studies support these ideas. Differences between computed ChelpG charges for TS **A** and **B** reveal that there are significant *decreases* in positive charge on C7 in both cases relatve to carbene **15**: –0.30 and –0.27, respectively. These changes are counterbalanced by corresponding increases in negative charge on the chlorine: 0.49 and 0.44, respectively. We interpret these findings to indicate that some positive charge leaks into the carbon framework as the transition states are generated. Related fragmentations that we have studied (e.g., cyclohexyl-OCCl) behave similarly. We conclude that the transition states are relatively early, i.e., between carbene **15** and the 7-norbornyl cation. Structural analyses (see the following) are also consistent with this conclusion.

In Fig. 1, we present the computed Cl—C2 (C3—C4) and C2—C7 (C3—C7) distances for carbene **15**, TS **A**, TS **B**, and the 7-norbornyl cation. Following the C2—C7 distance from carbene **15** (2.348 Å) to TS **A** (2.189 Å) or TS **B** (2.203 Å) and finally to cation **3** (1.765 Å), we observe that the TSs are indeed relatively early; the approach of C7 to C2, which enables the delocalization of positive change, covers only 0.14–0.16 Å in the TS compared to 0.58 Å in the fully developed cation. A similar conclusion emerges from consideration of the Cl—C2 distance, which lengthens as positive charge is delocalized. The expansion is 0.031 or 0.029 Å as carbene **15** goes to TS **A** or TS **B**, respectively, whereas the C1—C2 expansion between carbene **15** and cation **3** is 0.521 Å, about 17 times greater. The computed structure of cation **3** is "between" the 7-norbornyl cation and the (rearranged) 2-bicyclo[3.2.0]heptyl cation. The early TS **A** and **B** are consistent with the low activation energy observed (and computed) for the fragmentation, while the observed negative entropy of activation accords with the cyclic nature of the S_Ni-like TS (see the following).

We turn now to the *syn-exo*-2-methyl substituted carbene **22**. Computational studies at the B3LYP/G-31G(d) level reveal that the methyl group exerts a most subtle effect. For the fragmentation of **22** to chloride **23** we again locate two TSs; these appear in Fig. 4. IRC analysis of TS **B** in the forward direction reveals the formation of *anti*-**23** (i.e., **22** → **23** with inversion), whereas IRC analysis in the reverse direction confirms that TS **B** returns to carbene **22**. The behavior of TS **A**, however, is remarkable: IRC analysis in one direction leads to *anti*-**23** (inversion), while the opposite direction leads not to carbene **22**, but to *syn*-**23** (retention)! Thus, TS **A** bifurcates, leading to *both* products (32). Moreover, the computed activation enthalpy of TS **A** is lower than that of TS **B**, with ΔH^***A** = 18.9 (vacuum) or 3.0 (DCE) vs. ΔH^***B** = 20.8 (vacuum) or 6.0 (DCE), with all values in kcal/mol. Thus, in solution, TS **A** might be expected to dominate and to provide *syn*-**23** and *anti*-**23** in comparable quantities, as is indeed observed. That is, the "racemization"

Fig. 4. B3LYP/6-31G(d) computed transition states for the fragmentations of carbene **22** to *syn*-**23** and *anti*-**23** (see text for discussion).

observed in the fragmentation of carbene **22** to *syn*- and *anti*-**23** is attributable to bifurcation from a S_Ni-like TS (**A**). As in the fragmentation of carbene **15**, ion-pair minima are not detected and presumably cannot account for the inversion component of the reaction.

One caveat: the existence of TS **A** also suggests (32) that there should be a higher, as yet undetected, TS that leads in the forward direction to TS **A** and the reverse direction back to carbene **22**. We do not know the energy of this TS, but given that the experimental activation energies for the fragmentations of carbenes **15** and **22** are comparable at 3.5–

4.2 kcal/mol, ΔH^* for the unknown TS is probably between 4 and 6 kcal/mol (ΔH^* for TS **B** of Fig. 4).

Conclusion

7-Norbornyloxychlorocarbene (**15**) fragments mainly to 7-norbornyl chloride (**16**). An analog of **15** (*syn*-**15**-*d*), labeled with deuterium at C2, fragments to labeled chloride **16** with 78% retention and 22% inversion. When the deuterium label is replaced by a *syn-exo*-2-methyl group, the resulting carbene **22** fragments to *syn*- and *anti*-7-chloro-*exo*-2-methylnorbornane in a ratio of 1:1.1, i.e., with 48% retention and 52% inversion. Computational studies of carbenes **15** and **22** indicate that their fragmentation reactions proceed via S_Ni-like transition states rather than ion pairs. Loss of sterospecificity in the carbene to chloride transformations is due to competition between energetically similar S_Ni-like transition states, which undergo fragmentation with either retention or inversion.

Experimental

General

Pyridine (certified A.C.S. grade) was refluxed over CaH_2, distilled, and stored over 5 Å molecular sieves. Dichloroethane and pentane (HPLC grade) were stored over 5 Å molecular sieves and then used directly.

7-Norbornyloxyuronium methanesulfonate (13)

7-Norbornanol (**12**, Scheme 2), prepared by literature methods (16–18), was converted to the title compound **13** by reaction with cyanamide and methanesulfonic acid according to a literature procedure (19). The desired isouronium salt was obtained as an oil admixed with urea. ^{1}H NMR (400 MHz, DMSO-d_6) δ: 8.55 (s, 4H), 6.65 (br s, urea), 4.70 (s, 1H), 2.47 (s, 3H), 2.23 (s, 2H), 1.07–1.76 (m s, 8H). ^{13}C NMR (100 MHz, DMSO) δ: 161.8 (urea), 161.5, 86.2, 39.8, 38.2, 26.8, 26.5.

3-(7-Norbornyloxy)-3-chlorodiazirine (14)

Isuronium salt **13** was oxidized to diazirine **14** with NaOCl according to Graham's method (20): 1.0 g (4.0 mmol) of **13**, 5.0 g of LiCl in 50 mL of DMSO, and 50 mL of pentane were cooled at 20 °C and treated with 200 mL of 12% aq. NaOCl, saturated with NaCl, added in portions with vigorous shaking. Shaking was continued for 10 min at 15 °C after addition was complete. The reaction mixture was diluted with 100 mL of pentane, the aqueous phase was separated, the pentane phase was washed with 2 × 50 mL of cold brine, and dried over $CaCl_2$ at 0 °C. Diazirine **14** was purified by flash chromatography over silica gel eluted with pentane. The pentane eluate was concentrated by rotary evaporation to give 0.33 g (55%) of diazirine **14**. UV (λ_{max}, pentane, nm): 349, 366. IR (film, cm^{-1}): 1541. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.26 (s, 1H), 2.24 (s, 2H), 1.58 (m, 4H), 1.22 (d, J = 7.6 Hz, 4H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 85.6, 70.9, 38.6, 26.6, 26.0.

7-Norbornanol (*syn*-2-*exo*-D and *syn*-2-*endo*-D mixture)

2-*exo*-Bromo-7-*syn*-hydroxynorbornane (**17**) (24.4 g, 0.13 mol) was refluxed overnight in 200 mL of EtOD with a Zn–Cu couple prepared from 35.0 g (0.55 mol) of Zn dust (33). The cooled reaction mixture was diluted with 100 mL of D_2O and stirred at 25 °C for 2 h. The mixture was concentrated by rotary evaporation, diluted with 200 mL of water, and extracted with 4 × 100 mL of CH_2Cl_2. The combined extracts were dried over $MgSO_4$, and products **12**-*d* were purified by chromatography over silica gel, with elution by pentane–ether (2:1), to give 9.2 g (62%) of solid, mp 125–127 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.90 (s, 1H), 2.96 (s, 1H, OH), 1.88 (m, 2H), 1.78, 1.49 (m, 3H), 1.20, 1.10 (m, 4H). ^{2}H NMR (61.4 MHz, $CDCl_3$) δ: 1.78 (*exo*-2-D), 1.47 (*endo*-2-D). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 79.5 (C7), 40.2, 40.1 (Cl, C4), 26.8, 26.6 (C3, C5, C6), 26.5 (t, $J_{D\text{-}C}$ = 13.5 Hz, C2).

3-(7-Norbornyloxy)-3-chlorodiazirine (*syn*-2-*exo*-D and *syn*-2-*endo*-D mixture)

The D-labeled 7-norbornanol was converted to diazirine **14** as described previously for unlabeled 7-norbornanol. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.26 (s, 1H), 2.25 (m, 2H), 1.58 (m, 3H), 1.23 (m, 4H). ^{2}H NMR (61.4 MHz, $CDCl_3$) δ: 1.45 (*endo*-2-D), 1.22 (*exo*-2-D). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 85.6 (C7), 70.9 (quat. C), 38.6, 38.5 (C1, C4), 26.6, 26.0 (C3, C5, C6), 26.5 (t, $J_{D\text{-}C}$ = 12.2 Hz, C2).

2-*exo*-Methyl-*syn*-7-hydroxynorbornane (20)

This material was prepared in 21% yield as a colorless oil by the reaction of methylmagnesium bromide and *exo*-norbornene oxide (25). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.95 (s, 1H), 2.00 (s, 1H, OH), 1.91 (s, 1H), 1.70 (d, J = 2.4 Hz, 1H), 1.63–1.08 (m, 7H), 1.11 (d, J = 6.8 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 80.7, 46.4, 41.5, 37.0, 36.4, 27.8, 25.6, 22.4.

3-(*syn*-2-*exo*-Methyl-7-norbornyloxy)-3-chlorodiazirine (21)

2-Methyl-7-norbornanol (**20**) was converted to the isouronium salt (admixed with urea) by reaction with cyanamide and methansulfonic acid (19), and the oily isouronium salt was oxidized to diazirine **21** by Graham's procedure (20) as described previously for diazirine **14**. UV (λ_{max}, pentane, nm): 349, 366. IR (film, cm^{-1}): 1541. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 4.23 (s, 1H), 2.34 (s, 1H), 1.91, (s, 1H), 1.61–0.85 (m, 7H), 0.87 (d, J = 6.8 Hz, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 88.1, 66.0, 44.8, 39.5, 36.9, 36.4, 27.0, 25.0, 21.6.

Products

The characteristic resonances in the NMR spectra of products **16**–**19**, the **16**-*d* isotopomers, *syn*-**23**, *anti*-**23**, **24**, and **25** are described in the Results and discussion.

Photolysis

About 200 mg of prepared diazirines **14**, **14**-*d*, or **21** in 2 mL of $CDCl_3$ was placed in a small screw-cap vial or in a NMR tube and irradiated for 1 h with a focused Oriel UV lamp (with a uranium glass filter, λ > 320 nm) or with a Rayonet apparatus housing 350 nm lamps. The resulting NMR analyses are described in the Results and discussion section.

The structure, photochemical reactivity, and photophysical properties of adamantyl X-substituted aryl ethers and a comparison with the alkyl groups, methyl, *tert*-butyl, and allyl[1]

A.L. Pincock and J.A. Pincock

Abstract: The structure, photophysical properties, and photochemistry of the adamantyl aryl ethers **1** in both methanol and cyclohexane have been examined. UV absorption spectra, ^{13}C NMR chemical shifts, X-ray structures, and Gaussian calculations (B3LYP/6-31G(d)) indicate that these ethers adopt a 90° conformer in the ground state. In contrast, fluorescence spectra, excited singlet state lifetimes, and calculations (TDDFT) indicated a 0° conformer is preferred in the first excited singlet state S_1. Irradiation in either solvent results in the formation of adamantane and the corresponding phenol as the major products, both derived from radical intermediates generated by homolytic cleavage of the ether bond. The 4-cyano substituted ether **1j** was the only one to form the ion-derived product, 1-methoxyadamantane (16% yield), on irradiation in methanol. Rate constants of bond cleavage for these ethers from S_1 were estimated by two different methods by comparison with the unreactive anisoles **2**, but the effect of substituents was too small to determine structure–reactivity correlations. The temperature dependence of the quantum yields of the fluorescence of the unsubstituted, 4-methoxy and 4-cyano derivatives of **1** and **2** were also determined. These results indicated that the activated process for **1** was mainly bond cleavage for the 4-cyano substrate whereas for **2**, it was internal conversion and intersystem crossing.

Key words: aryl ether photochemistry, fluorescence, excited-state rate constants, excited-state temperature effects.

Résumé : On a étudié la structure, les propriétés photophysiques et la photochimie des oxydes d'adamantyle et d'aryles **1**, tant dans le méthanol que dans le cyclohexane. Les spectres d'absorption UV, les déplacements chimiques en RMN du ^{13}C, les structures obtenues par diffraction des rayons X et les calculs gaussiens (B3LPYP/6-31G(d)) indiquent que dans leur état fondement ces éthers adoptent un conformère à 90°. Par opposition, les spectres de fluorescence, les temps de vie de l'état singulet excité et les calculs (TDDFT) indiquent qu'un conformère à 0° est privilégié dans le premier état singulet excité, S_1. Les produits principaux d'une irradiation dans l'un ou l'autre des solvants sont l'adamantane et le phénol correspondant qui dérivent tous les deux d'intermédiaires radicalaires générés par un clivage homolytique de la liaison éther. L'irradiation dans le méthanol du dérivé **1j** portant un substituant 4-cyano est le seul à conduire à la formation du 1-méthoxyadamantane (rendement de 16 %), le produit dérivé de l'ion. On a utilisé deux méthodes différentes pour évaluer les constantes de vitesse de clivage de la liaison de ces éthers à partir de S_1 par comparaison avec des anisoles non réactifs (**2**); l'effet des substituants est toutefois trop faible pour déterminer des corrélations structure–activité. On a aussi établi la relation entre la température et le rendement quantique de fluorescence des dérivés des composés **1** et **2**, non substitués ou portant des substituants 4-méthoxy ou 4-cyano. Ces résultats indiquent que le processus activé pour le composé **1** est le clivage de la liaison pour le substrat 4-cyano alors que pour le composé **2** il s'agit de la conversion interne et d'un passage intersystème.

Mots clés : photochimie d'éthers aromatiques, fluorescence, constantes de vitesse d'états excités, effets de température sur l'état excité.

[Traduit par la Rédaction]

Introduction

The effect that substituents (X) on aromatic rings (Ar) have on the quantum yields and rate constants of bond cleavage reactions from photochemically generated excited singlet states of substrates of the general class ArY–Z, where the Y—Z bond is the reactive one, continue to attract interest. The objective is to develop excited state structure–reactivity relationships, like the Hammett equation, that are well-established for ground-state reactions. Related to this

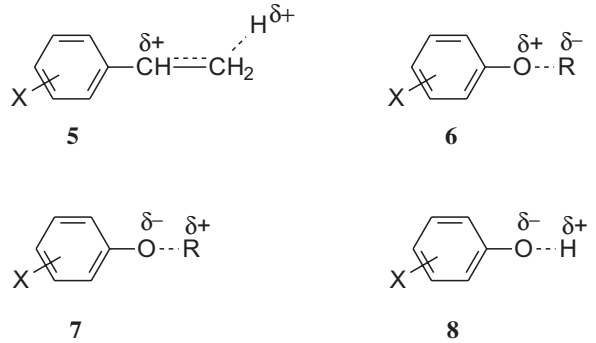
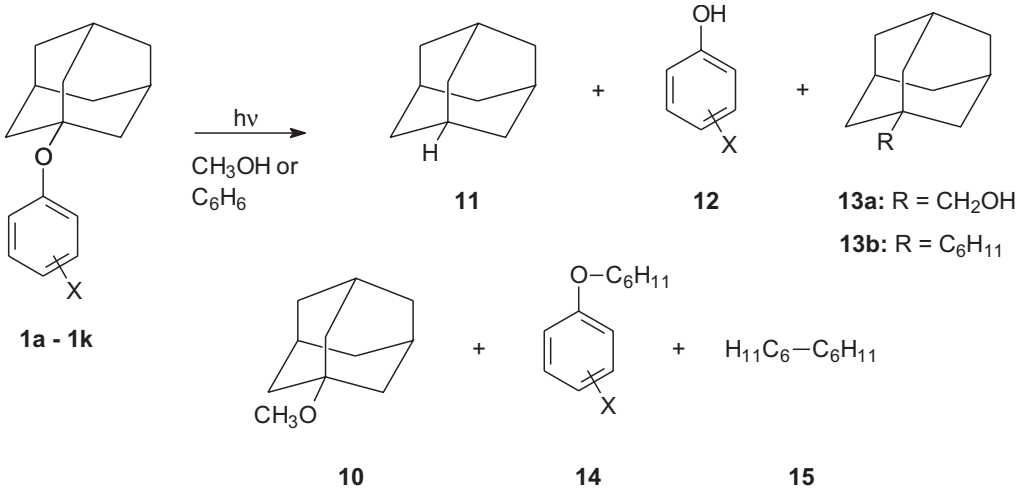


Scheme 1. Mechanism and products formed from the homolytic cleavage of alkyl aryl ethers and rate constants of reaction for S_1.

goal has been one of understanding, in the excited-state cases, the competition between the formation of the products derived from radical pairs (from homolytic cleavage of the Y—Z bond) and ion pairs (from heterolytic cleavage of the Y—Z or from rapid, exergonic redox electron transfer in the first formed radical pair). A general review of the mechanistic principles involved and a survey of the observed reactivity of the Z groups for arylmethyl cases (Y = CH_2) have been published (1).

We now summarize results for four series of the class of compounds ArO-C (**1**–**4**), i.e., phenolic ethers where Y = O and Z = C. New results will be given for the adamantyl aryl ethers **1**, in comparison with the anisoles **2**. Previously, we have reported on the photochemistry and photophysics of the *tert*-butyl (**3**) (2) and allyl ethers (**4**) (3). For these latter two cases, the products of photolysis in either methanol or cyclohexane were, in general, those expected from homolytic cleavage of the carbon–oxygen bond to form a radical pair followed by in-cage coupling (photo-Fries for **3**, photo-Claisen for **4**) or disproportionation (Scheme 1). For both, the reactions were shown to occur from the excited singlet state (S_1) by selective triplet quenching studies.

Rate constants k_r for the reaction from the excited singlet state for the *tert*-butyl compounds **3** were determined by the classic quantum yield (Φ_r) of the reaction method (eq. [1]) (2). The rate constants for S_1 of the reaction (k_r), fluorescence (k_f), internal conversion (k_{ic}), and intersystem crossing (k_{isc}) are shown in Scheme 1. The sum of these is k_t, the reciprocal of τ_s, the excited singlet state lifetime. Measurement of Φ_r by the disappearance of starting material and τ_s by fluorescence decay gives k_r. The rate constants obtained in this way gave a reasonable correlation with $\sigma^{h\nu}$ (4) and $\rho = -0.77$ ($r = 0.975$) for seven of the 10 compounds of set **3** studied where $\sigma^{h\nu}$ values were available. This correlation was surprising because the $\sigma^{h\nu}$ scale was developed from results for the photoprotonation of styrenes and phenylacetylenes, reactions that result in positive charge increases at the benzylic carbon in the rate-determining transition state, **5** for styrenes. A similar transition state (**6**) for the photo-Fries reaction of the *tert*-butyl ethers **3** seems less likely than one of opposite polarity (**7**). However, a very poor (nonexistent) correlation of the rate constants for **3** with the values of σ^{ex} (5–7), which are derived from the excited state pK_as of phenols **8**, was obtained.



$$[1] \qquad \Phi_r = \frac{k_r}{k_f + k_{ic} + k_{isc} + k_r} = \frac{k_r}{k_t} = k_r \tau_s$$

While studying the *tert*-butyl ethers **3** (2), we also examined the 4-cyano compound **1j** from the adamantyl derivatives. An interesting result was that on photolysis of **1j** in methanol, the ion-derived product 1-methoxyadamantane was obtained in 16% yield. This compound was synthesized

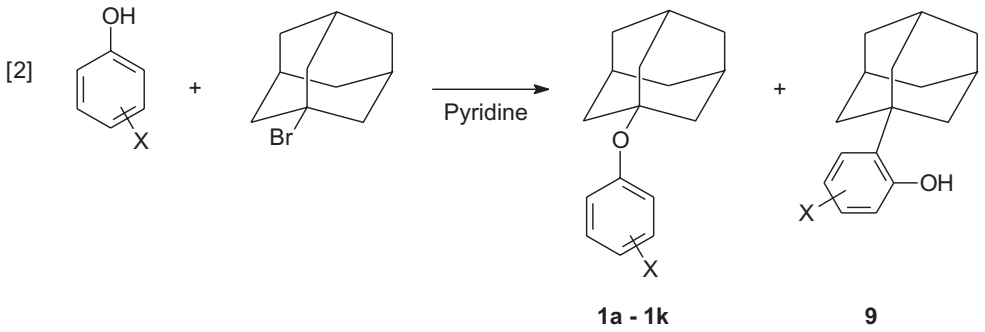
Scheme 2. Products of the photolysis of adamantyl ethers **1** in methanol and cyclohexane.

by reaction of the lithium salt of 1-adamantanol with 4-fluorobenzonitrile (8), a nucleophilic aromatic substitution reaction that relies on the electron-withdrawing nitrile group in the para position. This procedure was unsuccessful for 3-fluorobenzonitrile. Therefore, the other substituted derivatives of **1** were not previously studied.

We now report on the synthesis, photochemistry, photophysical properties, and excited-state rate constants for the complete set of the adamantyl ethers **1**. These compounds have an advantage that the fate of the non-aryl fragment of the ether cleavage reaction can be easily observed. This was not so for the very volatile fragments ($CH_3OC(CH_3)_3$, $CH_3OCH_2CH{=}CH_2$, etc.) expected from sets **3** and **4**.



Results and discussion

Synthesis of 1-adamantyl aryl ethers (1a–1k)

The ethers were synthesized by reaction of 1-bromoadamantane (by heating in pyridine) with the corresponding substituted phenols according to a method described previously (9) (eq. [2]). The reaction mixtures were not homogeneous. The reactions were usually monitored by GC-FID until the 1-bromoadamantane (the limiting reagent) had disappeared. The crude product always contained varying amounts of the isomeric (GC–MS) 1-adamantylphenol derivatives **9**, which were not characterized. However, because these isomers were possible products in the photochemistry of the ethers **1**, their GC retention times were useful. They could easily be removed by flash chromatography on silica gel and the ethers purified by crystallization. The yields after purification ranged from 20% to 35%. Characterization data are given in the Experimental section; ^{13}C NMR data, along with those of sets **2**, **3**, and **4**, which will be discussed in the following, are given in Table S1 (Supporting information).[3]

Photochemistry of 1-adamantyl aryl ethers 4a–4k in methanol and cyclohexane

The ethers **1** were photolyzed in either methanol or cyclohexane with 254 nm lamps in a Rayonet reactor at 25 °C. The reactions were reasonably efficient with little dependence on the substituent. For instance, for approximately 100 mg samples, 83% of the unsubstituted compound **1a** and 80% of the 4-methoxy compound **1b** in 100 mL of methanol had reacted after 30 min. The reactions were a factor of two to three times slower in cyclohexane. In both solvents in all cases, except for the 4-cyano compound **1j** in methanol, the products were those expected from the formation of radicals by homolytic cleavage of the C—O bond (Scheme 2). As reported previously (2), 16% of the methyl ether **10** was formed from **1j** in methanol indicating a minor intervention of a pathway involving ion pairs. In agreement with this observation, 4-cyanophenoxide has been used as a leaving group for the generation of diphenylmethyl cations (observable by nanosecond LFP) from diphenylmethyl ethers (10),

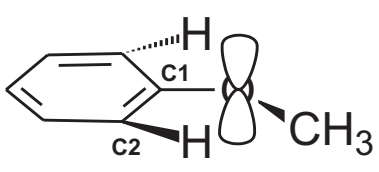
and in the pioneering study by Zimmerman and Somasekhara (11) on photochemically generated triphenylmethyl cations.

The major product from the adamantyl fragment of the ethers **1** for all substrates in both solvents was adamantane **11**, derived from the 1-adamantyl radical and accounting for 70%–90% of the mass balance. This is reasonable on the basis of the fact that hydrogen atom abstraction by the 1-adamantyl radical from both methanol and cyclohexane is somewhat more favourable than by the *tert*-butyl radical (C–H BDE = 99, 96, 99, and 96 kcal/mol for 1-adamantane, methanol, cyclohexane, and 2-methylpropane, respectively) (1 cal = 4.184 J) (12). The major product from the aryl fragment was the corresponding phenol **12**, but these gave very broad and tailing peaks in the GC traces that could not be reliably quantified. Photo-Fries products (GC–MS, 15% yield overall, presumably 2- and 4-(1-adamantyl)phenol) were only observed for **1a** in methanol. Low yields of products **13a**, **13b**, **14**, and **15** (Scheme 2) were also formed from the solvent-derived radicals.

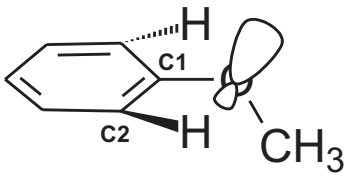
Geometry of aryl ethers 1–4 in the ground state

The geometry and rotational barriers for the methoxy group of anisole have been extensively studied by both experimental and computational methods. Two limiting structures have been considered: **16** with a C(H_3)-O-C1-C2 dihedral angle of $\Phi = 0°$ and **17** with the same angle equal to 90°. For **16**, an sp^2 hybridization model predicts conjugative overlap between the oxygen centered lone pair in a π orbital and the π system of the aromatic ring as indicated by the resonance structures **16a** and **16b**. For **17**, either an sp^2 or sp^3 hybridization model predicts a weaker interaction. Clearly, a vast body of experimental evidence demonstrates that the methoxy group in anisole is a π donor and therefore **16** must be the minimum energy structure on the rotational surface. A more difficult question to answer is the position of **17** on this surface.



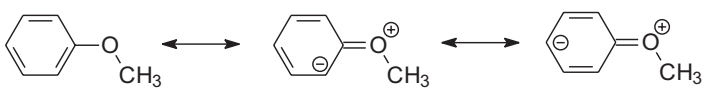
Most experimental studies have indicated a twofold rotational surface with **17** as a maximum at ~4 kcal/mol above **16** (13). Therefore, rotation between the two minima ($\Phi = 0°$ and 180°) would be rapid on the NMR timescale at room temperature. However, long-range C–H NMR coupling constants demonstrate that **17** is in a shallow minimum and therefore the rotational surface is fourfold (14). Calculations by ab initio methods have located this minimum with some basis sets but not with others (13). For instance, at the RHF/6-31G* level, **17** is 1.39 kcal/mol above **16**, and the transition state between the two (Φ = ~65°) is 1.59 kcal/mol above **16**. These same calculations give C-O-C1 bond angles of 119.8° and 115.5° for **16** and **17**, respectively. A conformational minimum similar to **16** has been found for allyl phenyl ether (**4a**: X–H) (15).

In terms of the photochemical reactivity of ethers **1**, **3**, and **4** (as discussed later, the anisoles are photochemically unreactive), **16** has the reactive C—O bond perpendicular to the π system of the aromatic chromophore whereas **17** has the same C—O bond parallel to it. Therefore, **17** should be more reactive. As discussed now, we have used a variety of probes to assess the conformational geometry of aryl ethers in the ground state and conclude that the tertiary alkyl derivatives **1** and **3**, in contrast to the anisoles **2** and the allyl ethers **4**, have preferred geometries analogous to **17**.



UV absorption spectra of ethers 1–4 in methanol and cyclohexane

The long wavelength absorption band λ_{max} (L_b transition) and molar absorptivity (ϵ) for the 1-adamantyl ethers **1a**–**1k**, and for comparison, the corresponding anisoles **2a**–**2k** in both methanol and cyclohexane as the solvent are reported in Table 1. Values for the *tert*-butyl ethers **3a**–**3i** in methanol and **3a**–**3c** in cyclohexane are also included. The L_b band for the anisoles has a significantly higher ϵ, and the λ_{max} tends to occur at longer wavelengths than the tertiary alkyl cases **1** and **3**. These trends are shown graphically in Fig. 1 for X = H, 4-OCH_3, and CN[4] in both methanol (left in each case) and cyclohexane (right in each case). The spectra for the corresponding allyl derivatives, which have been reported previously (3), are also included in these figures. The spectra for X = 4-CN and 4-CF_3 are not typical of those for the other substitutents because these electron-withdrawing groups interact strongly with the ether oxygen and shift the L_a band to longer wavelengths, partially obscuring the L_b band. The primary ethers (allyl (**4**) and methyl (**2**)) have very similar spectra that differ significantly (higher ϵ values, longer wavelengths) from those of the tertiary alkyl ethers **1** and **3**.



Similar observations have been made previously for anisoles that are sterically crowded by ortho substitution at C-2 and C-6 (16). For instance, the λ_{max} of the L_b band in

16 ($\Phi = 0^o$)

17 ($\Phi = 90^o$)

16a **16b**

[4] These three were chosen to span the complete range of electron-donating and electron-withdrawing abilities of all the substitutents studied.

[a]M is methanol, C is cyclohexane.
[b]Obtained from absorption spectra.
[c]Obtained from the overlap of the absorption and fluorescence spectra.
[d]Calculated from $E_{S_1} = 12.0 \times 10^4/\lambda_{0,0}$.
[e]Quantum yield of fluorescence relative to anisole in methanol (0.24) and cyclohexane (0.29), estimated error ±10%.
[f]Singlet lifetime by nanosecond single photon counting. The standard deviations of the fits to the experimental counts are <2%. No value indicates that the lifetime was less than 0.5 ns.
[g]The values of k_f(calcd) could not be obtained for X = 4-CF_3 and 4-CN because the L_a band was at a long enough wavelength so as to obscure the short wavelength portion of the L_b band, preventing the use of eq. [5].
[h]G. Kohler, G. Kittel, and N. Getoff. J. Photochem. **18**, 19 (1985).
[i]I.B. Berlman. Handbook of fluorescence spectra of aromatic molecules. Academic Press, New York. 1971. p. 139.

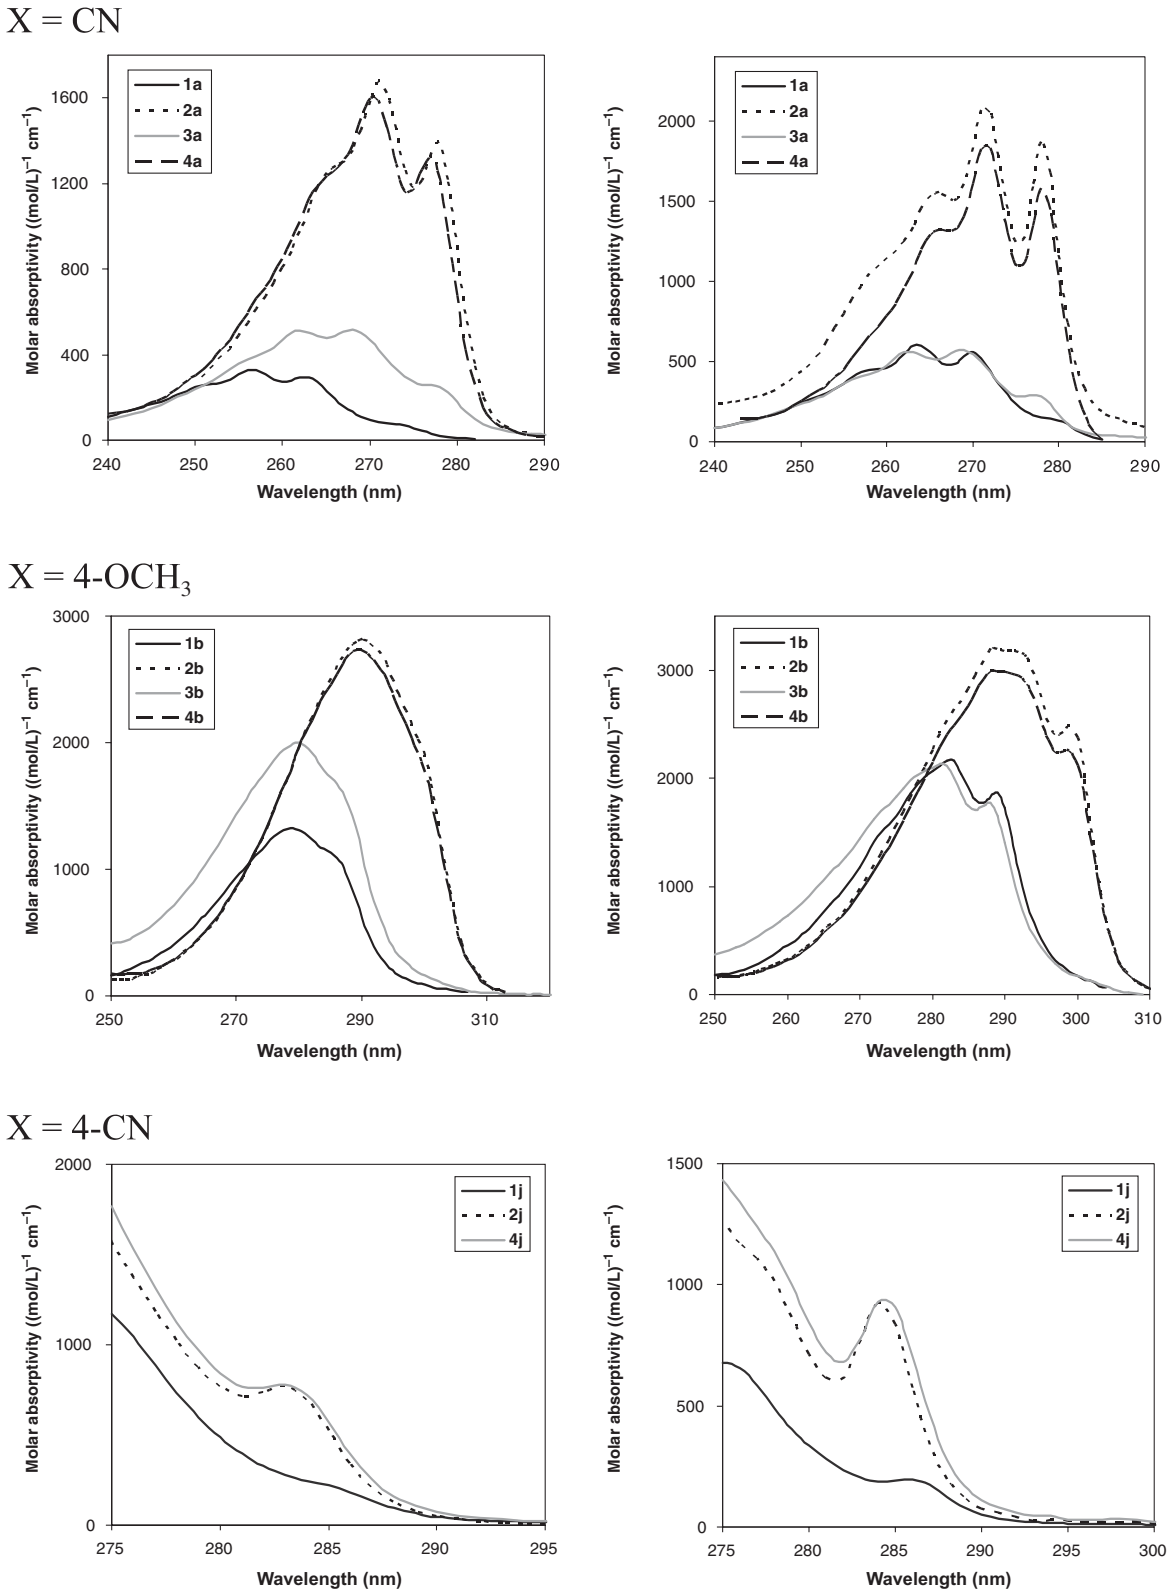
2,6-dimethylanisole shifts to shorter wavelengths (266 nm) and lower molar absorptivity (620 (mol/L)$^{-1}$ cm^{-1}) compared to anisole itself (269 nm, 2100 (mol/L)$^{-1}$ cm^{-1} (16); 271 nm, 1980 (mol/L)$^{-1}$ cm^{-1} (Table 1),[3] both in cyclohexane). The proposed explanation is that ortho substitution forces the methoxy group into the 90° geometry of **17**, reducing the importance of structures **16a** and **16b** that allow conjugation of the oxygen lone pair with the aryl ring.

^{13}C NMR spectra of ethers 1–4 in $CDCl_3$

Complete ^{13}C NMR spectral data for the adamantyl ethers **1** along with those for the anisoles **2**, *tert*-butyl ethers **3**, and the allyl ethers **4**, are given in Table S1 (Supporting information).[3] The anisole data were taken from the Aldrich compilation (17) and these values were confirmed for the para-substituted compounds by another literature source (18). The allyl ether data, which differ insignificantly from the anisole data, have been reported previously (3). Relative to the anisole derivatives, the ^{13}C chemical shifts at C-4 for both the adamantyl and *tert*-butyl derivatives have higher δ values (deshielded) by an average of 2.57 ± 0.52 ppm (11 compounds) and 2.97 ± 0.38 (nine compounds), respectively. Moreover, these changes vary around these averages in a random way over the range of X groups from electron-donating ones (CH_3O, CH_3) to electron-withdrawing ones (CF_3, CN) in either the meta or para position. Therefore, the contribution that resonance structure **16b** makes is not more important for a resonance electron-withdrawing group like CN.

For ortho-substituted anisoles, the same effect has been observed previously (19) with changes in ^{13}C δ values at C-4 relative to anisole of –0.3 ppm (2-methyl), +3.9 ppm (2,6-dimethyl), +7.2 ppm (2,6-diisopropyl), and +9.7 ppm (2,6-di-*tert*-butyl). These deshielding effects are a consequence of the lowering of the π-electron density at C-4 and reflect the decreasing importance of the resonance contributor **16b** as conformation **17** becomes more dominant. Therefore, the bulky *tert*-butyl and 1-adamantyl alkyl groups are providing a similar steric inhibition to a resonance interaction of the ether oxygen with the benzene ring as the case for two ortho methyl groups on the benzene ring. The effect that these bulky groups have at C-2 and C-6 is even larger (changes in δ values ranging from –10.5 to –11.5 ppm for the adamantyl ethers relative to the anisoles), but these changes probably reflect to some extent a direct steric interaction rather than only the importance of resonance effects.

Molecular orbital calculations



Two views of each of the two stable conformers for 1-adamantyl phenyl ether (**1a**: X = H) are shown in Figs. 2 and 3, the former corresponding to the 0° structure **16** and the latter to the 90° structure **17**. These were obtained as geometry optimized minima by GAUSSIAN 98 (20) at the B3LYP/6-31G(d) level of theory.[5] Similar calculations were performed for the para-substituted cases shown in Table 2 with OH replacing OCH_3 for computational convenience. Frequency analyses indicated that all were minima with all frequencies positive except for small negative values corresponding to methyl rotations for X = CH_3. The lowest energy positive frequencies (~35 cm^{-1} for **16** and ~15 cm^{-1} for **17**) correspond, by visualization in GaussView, to the rotation interconverting **16** and **17**.

After correction for zero point energy, the 90° conformer is calculated to be the more stable for all cases although the difference in energy between the two decreases systematically as the substituent changes from the resonance electron-donating 4-hydroxy group to the electron-withdrawing 4-cyano group. Clearly, this difference is dominated by the steric preference for the 90° geometry, which moves the ortho hydrogens on the benzene ring away from the adamantyl hydrogens. This steric crowding in the 0° structure is indicated by the large calculated O-C1(aryl)-C2(aryl) and C1(adamantyl)-O-C1(aryl) bond angles of 127.5° and 126.8°, respectively, at the ether functional group in contrast to 120.1° and 102.7° for the corresponding angles in the 90° structure. The energetic preference for the 90° conformer is decreased by conjugation of the oxygen lone pair of the ether with the substituent so that the 0° and 90° conformers are calculated to have almost identical stabilities for X = 4-CN. A related observation has been made previously for diphenyl ethers, monosubstituted on one of the two rings (21). The more stable conformer changes from that ring hav-

[5]The optimized geometries in C_1 symmetry have actual dihedral angles of 0.1° for the "0°" structure and 92.7° for the "90°" structure.

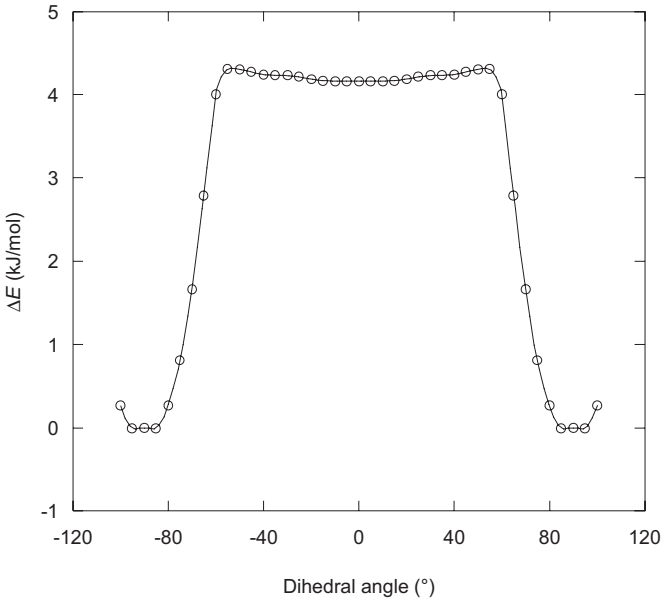
X-ray structures of adamantyl ethers 1b (X = 4-OCH$_3$) and 1h (X = 4-CF$_3$)

Suitable crystals were obtained for X-ray crystallograph structures[6] for these two compounds and that for **1b** is shown in Fig. 5. In both cases, a geometry similar to the 90° structure is preferred; the observed dihedral angles are 99° for **1b** and 107° for **1h**. These derivations from the symmetrical 90° structures are likely due to intermolecular crystal packing forces.

Geometry of the aryl ethers 1–4 in the excited singlet state

Information about the geometry of aryl ethers in the excited state can be obtained from fluorescence measurements using both excited singlet state lifetimes and steady-state spectra, and MO calculations. The conclusion is that the 0° structure is energetically preferred for S_1.



Excited singlet state lifetimes of ethers 1 and 2

The total rate of decay ($k_t = 1/\tau_s$) of the excited singlet state (τ_s from nanosecond single photon counting) along with the fluorescence quantum yields are reported in Table 1 in both methanol and cyclohexane solvents for the adamantyl **1** and methyl ethers **2**. The rate constants of fluorescence ($k_f = \Phi_f k_t$) are also given. Averaged over all substituted compounds, the ratios of $k_f(\mathbf{2})/k_f(\mathbf{1}) = 1.19 \pm 0.35$ and 1.26 ± 0.24 (10 compounds) in methanol and cyclohexane, respectively, are equal to unity, within experimental error. In fact, these ratios are improved to 1.02 ± 0.15 and $1.20 \pm$

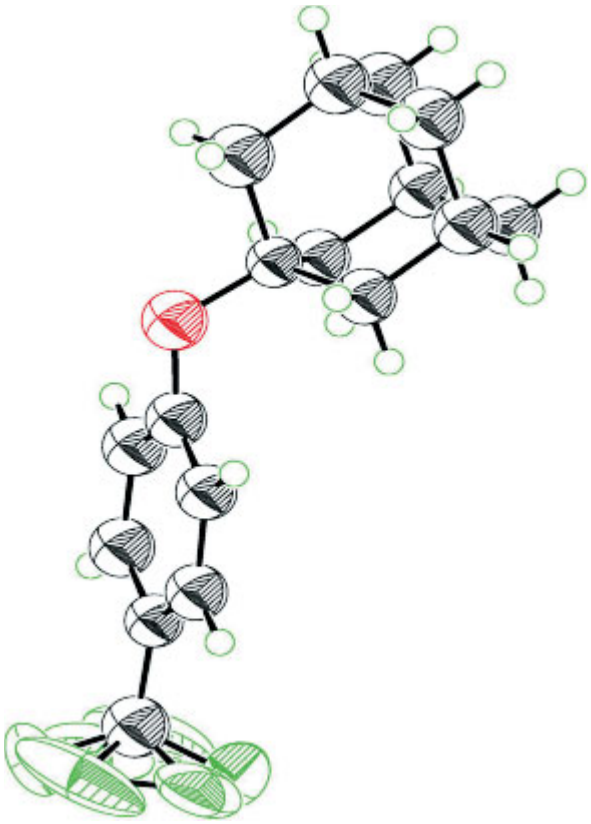
0.23, respectively, if the values for X = 3-CF_3, which seem unusually large, are not included in the two averages.

The general theoretical relationship (22, 23) between the radiative lifetime ($\tau_f = 1/k_f$) and the absorbance spectrum is given in eq. [3] where n is the refractive index of the solvent, υ_f is the expectation value for the frequency of the fluorescence spectrum, and the final term is the integrated absorbance spectrum. The constant gives k_f in units of s^{-1} if the frequency values are expressed in wavenumber (cm^{-1}), and molar absorptivity ϵ in the usual units ($(mol/L)^{-1}$ cm^{-1}). This equation is derived on the basis of the oscillator strength model and the important assumption that the excited singlet state and the ground state have similar geometries. It has been used successfully in the past for simple aromatic compounds like benzene, toluene, and *ortho*-xylene (24), and by us for the anisoles **2** and the allyl ethers **4** (3).



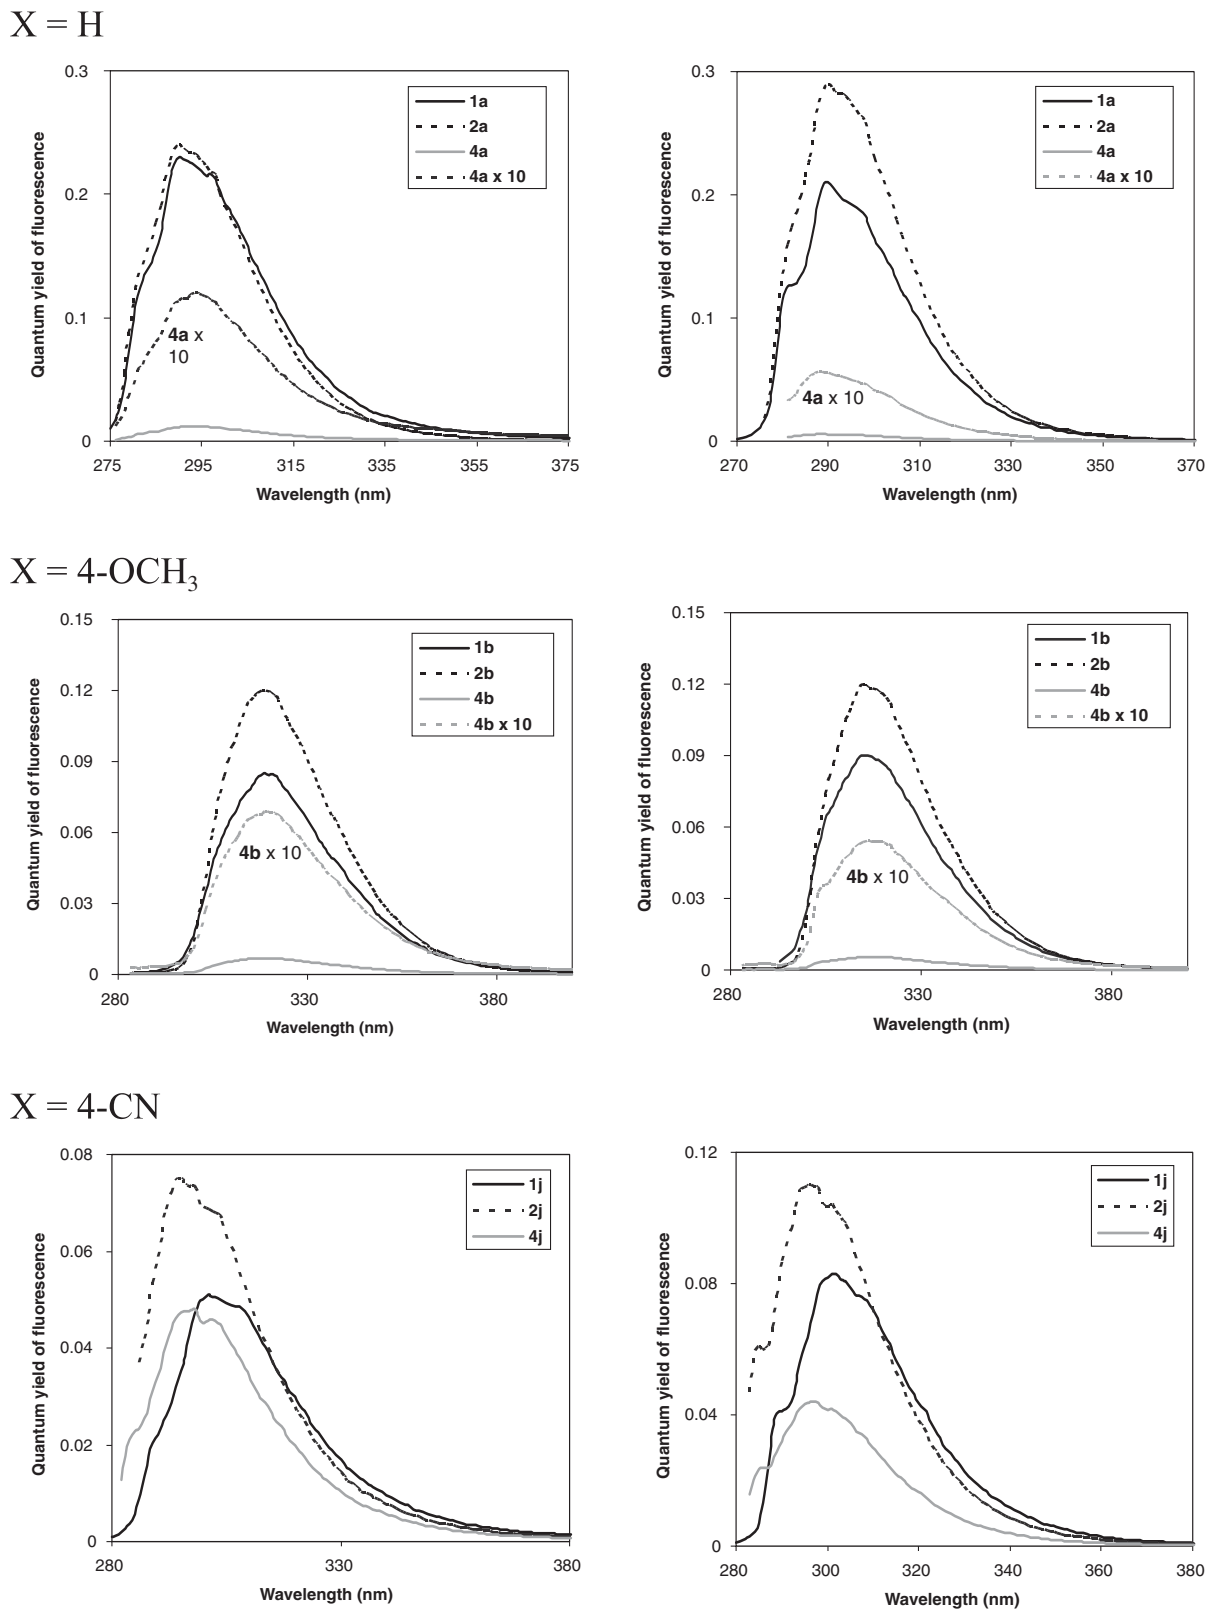
$$[3] \qquad k_f = 2.88 \times 10^{-9} n^2 < \overline{\nu}_f > \int \epsilon \ln \overline{\nu}$$

Equation [3] works very well for the anisoles **2** in both methanol and cyclohexane, $k_f(\text{exp})/k_f(\text{calcd}) = 1.05 \pm 0.10$ (seven compounds) and $k_f(\text{exp})/k_f(\text{calcd}) = 0.96 \pm 0.13$ (10 compounds), respectively. These values are in Table 1.

In contrast, as shown in Table 1, eq. [3] does not work as well for the adamantyl ethers **1**, with $k_f(\text{exp})/k_f(\text{calcd}) = 2.27 \pm 1.14$ (eight compounds) and $k_f(\text{exp})/k_f(\text{calcd}) = 1.98 \pm 0.83$ (eight compounds) in methanol and cyclohexane, respectively. The larger scatter and the average significantly greater than unity is a consequence of the decreases in ϵ for the adamantyl ethers. In general, the lower ϵ values decrease k_f(calcd) values and consequently increase ratios of $k_f(\text{exp})/k_f(\text{calcd})$. As discussed above, these lower values of ϵ for the adamantyl ethers **1** were ascribed to these ethers preferring the 90° geometry rather than the 0° geometry.

The similarity in the experimental k_f values for the anisoles **2** and the adamantyl ethers **1** suggest similar excited-state geometries for both. The good agreement among the k_f values obtained experimentally and from eq. [3] for the anisoles indicates that the ground-state and excited-state geometries are similar, presumably the 0° structure **16**. In contrast, for the adamantyl ethers, the experimental k_f values compare well with the anisoles, whereas those calculated from eq. [3] do not. This implies that the geometry of the adamantyl ethers changes on excitation from the 90° geometry in S_0 to the 0° geometry in S_1.

Fig. 5. X-ray crystal structure of **1h** (X = CF_3).



Fluorescence spectra of ethers 1 and 2

Values for the $\lambda_{0,0}$ (from the overlap of emission and excitation spectra), derived singlet state energies (E_{S1} (kJ/mol) = $[1.197 \times 10^5]/\lambda_{0,0}$ (nm)), and fluorescence quantum yields for the anisoles **2** and adamantyl ethers **1** are reported in Table 1. Sample fluorescence spectra for the ethers **1** and **2** with X = H, 4-OCH_3, and 4-CN[4] are shown in Fig. 6, for both methanol (left in each case) and cyclohexane (right in each case). The spectra for the corresponding allyl ethers **4** are also included.

Two features are obvious from the spectra. The first is the very similar wavelength dependence unrelated to the structural change in the alkyl group (from adamantyl to methyl to allyl) in the ether. The only significant exception, a shift to a longer wavelength of about 5 nm for the adamantyl ether, occurs when X = 4-CN in Fig. 6, a case where intramolecular charge transfer in the excited state may be important. Other than this case, the spectra imply that the excited-state geometries of the ethers **1**, **2**, and **4** are similar. This suggestion is reinforced by the similar values of E_{S1} obtained for the anisoles and the adamantyl ethers.

© 2005 NRC Canada

Fig. 6. Fluorescence spectra of the ethers **1**, **2**, and **4** for X = H, 4-OCH_3, and 4-CN in methanol (left) and cyclohexane (right).

The second feature of these spectra is the difference in quantum yields of fluorescence. In general, the adamantyl ethers **1** and the anisoles **2** have similar Φ_fs in either solvent, the adamantyl ether values being somewhat lower. In contrast, the allyl ethers **4** have significantly lower Φ_f values than both **1** and **2**. These decreases for compounds **4** reflect the very large increases in reactivity of the excited singlet state relative to the anisoles **2**. As will be described in the

© 2005 NRC Canada

following, according to eq. [4], the higher values of k_r for the allyl ethers result in higher values of k_t, and, consequently, lower values for $\Phi_f = k_f/k_t$, k_f being essentially constant for any given substituent X but independent of the alkyl group of the ether. The similar values of Φ_f for the adamantyl ethers and the anisoles indicate that the k_r values for the adamantyl compounds do not make a large contribution to the k_t of S_1.

[4] $$k_t = k_f + k_{ic} + k_{isc} + k_r$$

Molecular orbital calculations

Excitation energies to S_1 were calculated by TDDFT/6-31G1(d) (20) using vertical excitations from the optimized ground-state geometries calculated previously for both the $\Phi = 0°$ and 90° conformer, again for the substituents shown in Table 2. In all cases, as expected, the calculated oscillator strength was lower for the 90° than the 0° conformer. Moreover, also in agreement with the UV absorption spectra, the excitation energy was higher for the $\Phi = 90°$ geometry than for the 0° geometry. Combined with the ground-state energies, the relative energies for the excited singlet state ($\Delta E(S_1)$) in Table 1 can be calculated indicating that, for all substitutents, S_1 for the 0° conformer is more stable than S_1 for the 90° conformer. This observation supports the suggestion that excitation of compounds **1** from S_0 at $\Phi = 90°$ gives S_1 at 90°, which then relaxes by rapid rotation to give the more stable conformer S_1 at 0°. Fluorescence emission and reaction should then occur from the 0° conformer.

Rate constants of reaction (k_r) from the excited singlet state of the adamantyl ethers 1

The quantum yield method, as described by eq. [1], for obtaining rate constants for excited-state bond cleavage reactions has a major defect. In all cases where experiments have been designed to detect it, internal return of radical pair intermediates (k_{ir} in Scheme 1) has been observed (1). Therefore, the efficiency of product formation that a quantum yield measures does not give a reliable measure of k_r. In effect, k_{ir} is a form of internal conversion, although not occurring directly from S_1. A knowledge of the fraction of this internal return $[k_{ir}/(k_p + k_{ir})]$, which is undoubtably dependent on the substituent X, could be used to obtain correct values of k_r, but this fraction is a difficult number to obtain experimentally without a suitable probe. For instance, in the cases examined for the allyl ethers (**4a**–**4d**) in both methanol and cyclohexane, the importance of k_{ir} was demonstrated by the fact that the quantum yield method (eq. [1]) gave significantly lower values of k_r than the unreactive model method (eqs. [4] and [5]) (3), described in the following. With no suitable probe for the adamantyl ethers **1**, we decided not to measure quantum yields of reaction.

[5] $$k_t^M = k_f + k_{ic} + k_{isc}$$

The unreactive model method

For the allyl ethers **4**, we recently described an alternate method of measuring k_r for reactions of S_1 that relies on comparing a photochemically reactive compound with an unreactive one that has identical excited-state properties (3). We chose to compare compounds **4** with the anisoles **2**, which are, in comparison, photochemically inert. Either static (Φ_f) or dynamic (τ_s) measurements of fluorescence can be used although the latter is preferred because more reliable experimental values can be obtained. The assumption used is given in eqs. [4] and [5], where the changes in k_t of the reactive series only differ from those (k_t^M) of the model series **2** by k_r. Therefore, subtraction of experimentally determinable values ($k_t - k_t^M = k_r$) should reliably give k_r. Because these are exclusively properties of the excited singlet state, the k_r values obtained are independent of k_{ir}, the internal return process.

This method was applied quite successfully to obtain k_r values for the allyl ethers **4** in both cyclohexane and methanol (3). From absorbance spectra (λ_{max}, ϵ), fluorescence spectra ($\lambda_{0,0}$, E_{S1}), and calculated k_f values, good evidence was provided that the sets **2** and **4** have very similar excited-state properties for any given equivalently substituted pair in either methanol or cyclohexane. The resulting k_r values as a function of substituents spanned almost two orders of magnitude (10^8–10^{10} s^{-1}), and for some cases (3- and 4-methoxy and 3- and 4-methyl), were the dominant mode of decay of S_1. A plot of k_r in methanol vs. k_r in cyclohexane was linear and the slope (0.96) indicated a parallel substituent effect in the two solvents. This observation demonstrates that only radical pair intermediates are being generated, ion pairs not being possible in cyclohexane.

An examination of the k_t (adamantyl ethers **1**) and k_t^M (anisoles **2**) values in Table 1 indicates that the difference required to usefully apply eqs. [4] and [5] is hardly outside experimental error for most substitutents. Small positive values are obtained in most cases, although a few are actually negative. This observation quantitatively demonstrates that the adamantyl ethers have very small values of k_r, the rate constant of reaction, relative to the other modes of decay of the excited singlet state (k_{ic}, k_f, and k_{isc}). The only noticeable trend in the k_r values is towards higher values for those compounds **1j** and **1k** with cyano substitutents at C-3 and C-4, respectively, more so in methanol than in cyclohexane, but particularly for the 4-CN compound in methanol. This correctly accounts for the observation that the 4-cyano compound gives a significant yield of the ion-derived product **10** in methanol. Unfortunately, overall, the changes in k_r are too small to attempt a quantitative substituent effect correlation.

The temperature dependence of the fluorescence method

The effect of temperature on photochemical reactions has received far less attention than it deserves. However, recent studies from the laboratories of Lewis (activation barriers to E to Z isomerization in phenyl substituted alkenes) (25) and Zachariasse (thermally activated internal conversion in amino substitued aromatics) (26) have shown that the measurement of fluorescence quantum yields and lifetimes and intersystem crossing quantum yields over a wide temperature range provides a valuable tool to obtain rate constants for excited singlet state processes. Again, because the properties measured are exclusively those of S_1, the rate constants k_r obtained are independent of processes like k_{ir} or reaction from T_1. We have recently applied this approach to the phototransposition reactions of substituted benzenes (27).

The simplest assumption used is presented in eq. [6], which is the same as eq. [4] except that the reaction process k_r is considered to follow the Arrhenius expression. For

© 2005 NRC Canada

substituted benzenes, the S_0 to S_1 energy gap is large so that $k_{ic} \backsimeq 0$ ($k_{ic} \backsimeq 10^3$ s^{-1} for benzene with $E(S_1) = 444$ kJ/mol).[7] Because $S_1 \rightarrow T_1$ is an exergonic process and considered to be unactivated, the rate of intersystem crossing should be temperature independent. However, Zachariasse and coworkers (26) have clearly shown that for amino substituted aromatics, $S_1 \rightarrow T_n$ intersystem crossing can be an important process that will be activated. Therefore, the total rate of intersystem crossing should be expressed by eq. [7], where k^0_{isc} is the intersystem crossing rate constant at 0 K (temperature independent), and the Arrhenius activation term is for the activated k_{isc}. The activation parameters for this process are characterized by low values of $A_{isc} \backsimeq 10^8$ to 10^9 s^{-1} and $E_{a/isc} \backsimeq$ 4–6 kJ/mol.

$$[6] \qquad k_t = k_f + k_{ic} + k_{isc} + A \exp(-E_a/RT)$$

$$[7] \qquad k_{isc} = k^0_{isc} + A_{isc} \exp(-E_{a/isc}/RT)$$

Values for k_t as a function of temperature have normally been obtained by measuring S_1 lifetimes (τ_s), but this is a very time-consuming process. We have chosen a more rapid method using τ_s and Φ_f at 25 °C (Table 1) to obtain $k_f = \Phi_f/\tau_s$. Then measurement of relative fluorescence quantum yields over a wide temperature range (–25 to 65 °C in methanol and –25 to 95 °C in methylcyclohexane)[8] were done (see Experimental section), and $k_t(T) = \Phi_f(T)/\Phi_f(25\ °C)$ values obtained assuming k_f is constant, independent of temperature. In fact, although k^0_f (the superscript refers to the refractive index (n) of vacuum) is temperature independent, the usual experimental observation for solution measurements is given in eq. [8] where the refractive index of the solvent is temperature dependent. However, over the temperature range studied here, the change in n^2 for the two solvents used is insignificant. From literature values[9] of the variation in refractive index with temperature (28), the k_f values for anisole would only change from 3.1×10^{-7} to 3.3×10^{-7} s^{-1} from –25 to +65 °C in methanol, and from 3.5×10^{-7} to 3.9×10^{-7} s^{-1} from –25 to 95 °C in methylcyclohexane. These ranges do not exceed the estimated error of 10% in k_f (assuming an error of 10% in Φ_f), and consequently, were ignored.

$$[8] \qquad k_f = k^0_f n^2$$

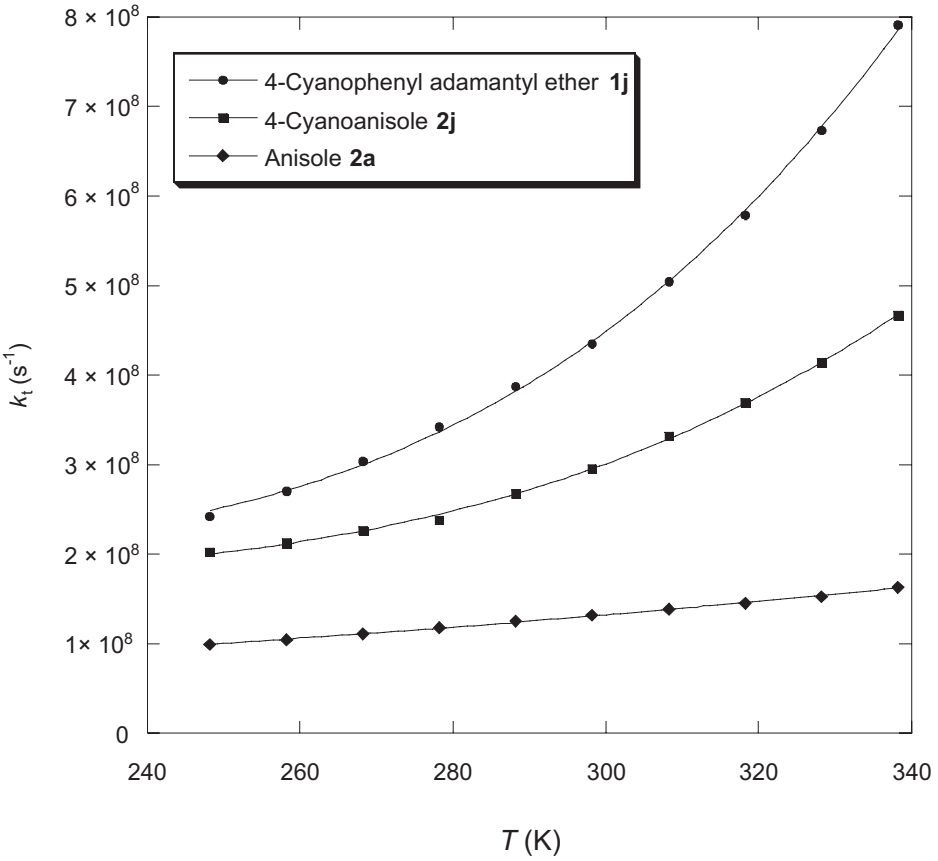
Plots of k_t vs. T are nonlinear and examples are shown in Fig. 7 for anisole, 4-cyanoanisole, and 4-cyanophenyl adamantyl ether (**1j**) in methanol. Other results are compiled in Table 3 for the adamantyl ethers **1** and the corresponding anisoles **2** for X = H, 4-OCH_3, and 4-CN.[4] Excellent fits of this data to eq. [6] were obtained ($r > 0.997$ in all cases) giving an intercept equal to $k_f + k_{isc}$ (assuming $k_{ic} = 0$) and Arrhenius A and E_a values. Using the independently determined experimental values of k_f gives k_{isc}. The consistency of the results is indicated by the similar values of k_{isc} obtained for any given pair of **1** and **2** with the same substituent and in either solvent.

Many of the compounds studied behave in a similar way to anisole in Fig. 7, with very little change in k_t as a function of temperature. As shown in Table 3, this results in low A values ($2.6–8.6 \times 10^9$ s^{-1}) that are characteristic of an activated intersystem crossing process and indicate that the dominant temperature-dependent process for these substrates even at room temperature is $k_{isc,}$ according to eq. [7]. This conclusion was also reached by a previous study on the temperature dependence of k_t (29), in 3-methylpentane and ethanol–methanol (1:1), although the A values ($\sim 2.5 \times 10^8$) reported are even lower than ours. The values of k_{isc} obtained by us for anisole at 25 °C of $(10.0 \pm 1.2) \times 10^{-7}$ s^{-1} (methanol) and $(9.1 \pm 0.9) \times 10^{-7}$ s^{-1} (methylcyclohexane) are in good agreement with literature values of 8.0×10^{-7} s^{-1} (cyclohexane) (30) and 9.4×10^{-7} s^{-1} (isooctane) (31), both obtained from directly measured Φ_{isc}/τ_s values. Moreover, the contribution that k_r makes to the total rate of decay of S_1 for anisole is small because $\Phi_f + \Phi_{isc} = 0.24 + 0.74$ (29) (Ermolaev's rule) in agreement with the observation that irradiation of anisoles does not result in product formation. Very likely, the dialkoxy compounds **2**, with low A and E_a values, also have $\Phi_f + \Phi_{isc} \backsimeq 1$, and therefore they have $\Phi_{isc} \backsimeq 0.9$ in both solvents, on the basis of $\Phi_f \backsimeq 0.1$ (Table 1).

As shown in Fig. 7, 4-cyanoanisole has a larger change in k_t as a function of temperature than does anisole even though both are photochemically unreactive in methanol. This suggests that both k_{isc} and k_r are contributing to the temperature dependence, but that the k_r process does not lead to products. As has been shown previously (26), to separate the activated k_{isc} and k_r rate constants reliably would require a combination of eqs. [6] and [7] and measurements over a much wider range of temperatures so that the process with lower A and E_a values (k_{isc}) would be dominant at low temperatures and k_r (higher A and E_a values) would be dominant at higher temperatures. Quantum yields of intersystem crossing as a function of temperature would also be required.

However, we have recently shown (27) that substituted aromatics undergo an activated process to form prefulvene biradicals. These intermediates (**18**–**20**), as in Scheme 3 for 4-methylbenzontrile (32), provide a pathway for both phototransposition reactions (ortho, meta, para) and also a pathway for k_{ir}, i.e., a chemical rather than photophysical route for internal conversion. We have also estimated (27) a quantum yield of $\Phi_r = 0.29$ for the formation of **18**, and measured a quantum yield of formation of the meta isomer of $\Phi_p = 0.025$ from the para one. Therefore, less than 10% of the intermediate **18** formed undergoes rearrangement to **19**. We suggest that formation of a prefulvene biradical is also the activated k_r process for 4-cyanoanisole. A similar activated internal conversion has been observed (26) for 4-cyanoaniline (and other aromatic amines in hydrocarbon solvents) with $E_a = 35$ kJ/mol and $A \backsimeq 5 \times 10^{12}$ s^{-1}. The authors noted that an activated, but undefined, geometric deformation in S_1 must be providing a pathway for S_1 to S_0 decay.

If this proposal is correct, then the difference in k_r between the anisoles and the adamantyl ethers obtained from the variable temperature studies reflects the increased reactivity of the adamantyl ethers because of C—O bond cleavage. This suggestion assumes that the activated k_{isc} and the



[7] See, in particular, the Introduction section of ref. 26.

[8] For the variable temperature studies, methylcyclohexane, rather than cyclohexane, was used as the solvent to expand the range of experimentally accessible temperatures.

[9] This reference gives values of $dn/dt = -0.000\ 39$/°C for methanol and $-0.000\ 55$/°C for cyclohexane.

other k_r processes (for instance, formation of the prefulvene biradical) are similar in rate for the equivalently substituted adamantyl ether and anisole. The difference in the temperature dependence between 4-cyanoanisole (**2j**) and adamantyl 4-cyanophenyl ether (**1j**) is clearly shown in Fig. 7, and the values of Δk_r (25 °C) in the last column of Table 2 support this suggestion. The values are larger in methanol than methylcyclohexane for all substrates studied, in agreement with the observation that the efficiency of photochemical conversion of the adamantyl ethers is greater in methanol. Moreover, both the substituted adamantyl ethers (4-OCH_3, 4-CN) react faster than the unsubstituted one. Most notable is the high k_r value for the 4-CN substrate in methanol, presumably as a result of the k_r process leading to ion pairs from S_1 and the resulting product 1-methoxyadamantane.

Conclusions

A variety of techniques have demonstrated that the adamantyl ethers **1** have a ground-state geometry with a dihedral angle of 90° that reduces conjugation of the ether oxygen with the aryl ring. Upon excitation to S_1, the geometry relaxes to a 0° conformer that increases the conjugation but decreases the overlap between the aromatic π system and the bond that breaks in the excited state. This observation provides an explanation for the low photochemical reactivity of these ethers and the lack of any large substituent effect on the rate constant of bond cleavage from S_1. For substrates that do not react, this technique provides a simple method of determining k_{isc} and Φ_{isc}. The method also allows a comparison between unreactive model compounds (the anisoles) and reactive substrates (the adamantyl ethers) so that the k_r process that leads to products or reactive intermediates can be separated from that which leads back to starting material (k_{ir}), a form of internal conversion.

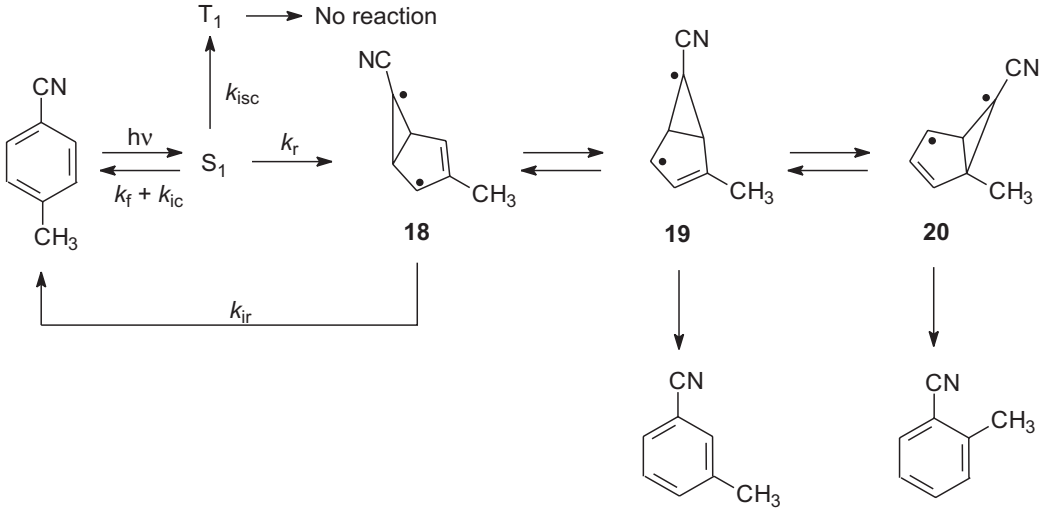
Note: Values in brackets are estimated errors: from fits to eq. [6] for A, E_a, and $(k_f + k_{isc})$; from ±10% for ϕ_f; from ±1% for τ_s; from accumulated errors for calculated quantities.

[a]Solvent: M (methanol), MC (methylcyclohexane).

[b]Arrhenius parameters from eq. [6].

[c]Intercept from eq. [6].

[d]$k_f = \phi_f k_t$.



[e]$(k_f + k_{isc}) - k_f$.

[f]$k_t = 1/\tau_s$ from nanosecond single photon counting at 25 °C.

[g]$k_r(25\ °C) = k_t(25\ °C) - (k_f + k_{isc})$.

[h]$k_r(\mathbf{1}) - k_r(\mathbf{2})$ at 25 °C.

Scheme 3. Mechanism for the phototransposition of *para*-methylbenzonitrile to the meta and ortho isomers and associated rate constants of reaction.

porting information)[3] were obtained on a Bruker AVANCE 500 MHz spectrometer with chemical shifts (δ) reported relative to the central line of $CDCl_3$ at 77.16 ppm. GC–MS analyses were performed on a PerkinElmer Autosystem XL instrument with a mass selective detector. The column used was a Supelco 30 m × 0.25 mm MDN-5S 5% phenyl methylsiloxane, film thickness 0.50 μm; temperature program: 60 °C for 1 min; 20 °C/min to 240 °C; 240 °C for 10 min. GC-FID analyses were done in a similar way except on a Supelco DB200 column. Mass spectral data are reported in units of mass over charge (m/z) for all values between 50 and the molecular ion if greater than 10% of the base peak. Intensities are reported as a percent of the base peak. HR-MS were obtained on a CEC 21-110 instrument with a resolution of 5–10 × 10^3. The solvents used for photochemical reactions and fluorescence measurements were used as received: methanol (EM, HPLC), cyclohexane (Aldrich, HPLC), and methylcyclohexane (Aldrich, spectrophotometric grade).

Preparation of the adamantyl aryl ethers 1a–1k

The ethers were synthesized by a modified literature method (9) from 1-bromoadamantane and the substituted phenol (Aldrich). In a typical procedure, a mixture of 8.40 g (75 mmol) of 4-fluorophenol and 3.24 g (15 mmol) of 1-bromoadamantane and 4.5 mL of pyridine was refluxed for 5 h. The reaction mixture was cooled, diluted with 50 mL of water – ethylene glycol (8:1), and extracted with 2 × 15 mL

© 2005 NRC Canada

of hexanes. The extract was washed with 5% NaOH (25 mL), water (2 × 25 mL), dried ($MgSO_4$), and the hexanes evaporated. The crude solid (2.26 g) was purified by flash chromatography using 2.5% ethyl acetate in hexanes to give 1.14 g (31%) of a colourless solid that was recrystallized from methanol.

Characterization of the adamantyl aryl ethers 1a–1k

^{1}H NMR spectra were not particularly diagnostic: the signals expected for the substituted benzene ring, the substituent for X = OCH_3 and CH_3, and the 1-adamantyl ring system (δ 2.17, 1.89, and 1.61, all broad singlets) were all present. ^{13}C NMR spectral data for the ethers **1**, along with those for **2**–**4** are reported in Table S1 (Supporting information).[3] Mass spectral data (GC–MS) were also not particularly diagnostic: a molecular ion (but not for X = 3-CF_3, 4-CF_3, 3-CN, and 4-CN) and $C_{10}H_{15}$, the adamantyl cation as the base peak (100) and its fragment ions at 107 (12), 93 (22), 79 (25), and 77 (13) were observed. Other characterization results: **1a** (X = H): mp 112 to 113 °C (lit. value (33) mp 99 to 100 °C). **1b** (X = 4-OCH_3): mp 48 to 49 °C (lit. value (33) mp 49–51 °C). **1c** (X = 3-OCH_3): mp 44–46 °C. HR-MS calcd. for $C_{17}H_{22}O_2$: 258.1620; found: 258.1628. **1d** (X = 4-CH_3): mp 53.5–54.0 °C (lit. value (33) mp 41–43 °C). **1e** (X = 3-CH_3): mp 69.0–70.0 °C. HR-MS calcd. for $C_{17}H_{22}O$: 246.1671; found: 246.1668. **1f** (X = 4-F): mp 110 to 111 °C. HR-MS calcd. for $C_{16}H_{19}OF$: 246.1420; found: 246.1423. **1g** (X = 3-F): mp 38 to 39 °C. HR-MS calcd. for $C_{16}H_{19}OF$: 246.1420; found: 246.1419. **1h** (X = 4-CF_3): mp 57.5–58.5 °C. **1j** (X = 4-CN): characterized previously (2). **1k** (X = 3-CN): mp 86 to 87 °C.

Irradiation of ethers

A solution of ~100 mg of the appropriate ether in 100 mL of methanol or cyclohexane was purged with nitrogen and then irradiated in a Rayonet photochemical reactor using 16 lamps (75 W, 254 nm). The temperature was kept at 25 °C by circulating water in an immersion tube. Reaction progress was monitored by GC.

Absorbance measurements

Absorbance spectra were recorded at 1 nm resolution using a Cary 100 UV–vis spectrometer thermostatted at 25 °C. Selected examples are shown in Fig. 1. The integrated spectra needed to obtain k_f values from eq. [3] were obtained by summing the 1 nm incremental areas (the absorbance values converted to ε by dividing by the molar concentration) over the complete absorption band. These areas are somewhat uncertain at the short wavelength end because of overlap with the long wavelength tail of the S_2 band so that the absorbance does not reach zero. The wavelength for the minimum in absorbance was used as the cut-off point for the S_1 band. For the 4-cyano and 4-trifluoromethyl derivatives of **1** and **2**, this overlap was too extensive to allow integration of the S_1 band and k_f values were not calculated.

Fluorescence measurements

All samples were degassed by three freeze–pump–thaw cycles and then thermostatted at 25 °C. The substituted anisoles used for comparison were all commercial samples (Aldrich) and were distilled before use. Fluorescence intensity measurements were done using a PTI-210M fluorescence spectrometer with dual model 101 monochromators, a 75 W Xenon lamp, and a model 814 photomultiplier detector. Corrected spectra were obtained. Selected examples are shown in Fig. 6. Fluorescence quantum yields were determined using solutions of matched absorbance by comparison with the known fluorescence quantum yield of 0.24 (30) for anisole in methanol and 0.29 (34) in cyclohexane. The expectation values necessary for calculating the k_f values from eq. [3] were obtained by summing the 1 nm incremental areas over the complete emission band. For temperature-dependent quantum yield measurements, a 1 cm cuvette was thermostatted with stirring in a cuvette holder equipped with a Quantum Northwest TLC 50 temperature controller, which allows relative fluorescence measurements at 10 °C intervals from –25 to 95 °C in methylcyclohexane and –25 to 60 °C in methanol over a 2 h time span. The stability of the lamp over this time period was normally confirmed by rerunning the fluorescence spectrum at 25 °C at the end.

Singlet lifetimes were measured at 25 °C by monitoring fluorescence decay using a PRA time-correlated, single-photon-counting apparatus with a hydrogen flash lamp of with a pulse width of about 1.8 ns.

Kinetics of glycoluril template-directed Claisen condensations — Effect of thionation of the glycoluril[1]

Karen Kam, Mohammad Rahimizadeh, Robert S. McDonald, Paul H.M. Harrison, Hao Chen, Stephen I. Jenkins, and Adrienne Pedrech

Abstract: Apparent rate constants for the *tert*-butoxide promoted Claisen-like condensation of a series of N^1-acetyl-N^6-aroyl-2,5-dithio-3,4,7,8-tetramethylglycolurils (**9a**–**9f**) to give N^1-(3′-aroyl-3′-oxopropionyl)-2,5-dithio-3,4,7,8-tetramethylglycolurils (**10a**–**10f**) were determined by UV spectroscopy. Overall rate accelerations of 3.5- to 18-fold were found relative to the corresponding reactions of the 2,5-dioxo compounds (**7a**–**7f**). Analysis of the Hammett plot for **9** and comparison with that for **7** shows that the key C—C bond-forming step, where the enolate of the acetyl group of the substrate attacks the aroyl carbonyl group, is accelerated by the thio substitution. For electron-withdrawing substituents in the aroyl group, the acceleration is sufficient to make this step nonrate limiting: the Hammett ρ value drops from approx. 1.5 for electron-donating groups to 0.27 for electron-withdrawing groups. Deuterium substitution in the acetyl group reduces the rate slightly, a result consistent with a slow but partially reversible first step in which substrate is deprotonated. A similar acceleration and isotope effect are found when diacetyl glycoluril (**2**) and diacetyl dithio glycoluril (**5**) are compared. The implications of these results are discussed.

Key words: glycoluril, Claisen condensation, kinetics, mechanism.

Résumé : Faisant appel à la spectroscopie UV, on a déterminé les constantes de vitesse apparente des condensations de type Claisen, catalysées par l'ion *tert*-butylate, d'une série de N^1-acétyl-N^6-aroyl-2,5-dithio-3,4,7,8-tétraméthylglycolurils (**9a**–**9f**) conduisant à la formation de N^1-(3′-aroyl-3′-oxopropionyl)-2,5-dithio-3,4,7,8-tétraméthylglycolurils (**10a**–**10f**). On a observé des vitesses globales qui étaient de 3,5 à 18 fois plus rapides que celles des réactions correspondantes avec les composés 2,5-dioxo (**7a**–**7f**). Une analyse de la courbe de Hammett pour les composés **9** et une comparaison avec celle des composés **7** montrent que l'étape clé de formation de la liaison C—C, dans laquelle l'énolate du groupe acétyle du substrat attaque le groupe carbonyle de l'aroyle est accélérée par la substitution thio. Pour les substituants électroaffinitaires du groupe aroyle, l'accélération est suffisante pour que cette étape ne soit plus l'étape cinétiquement déterminante: la valeur ρ de Hammett tombe d'une égale à environ 1,5 pour les groupes électrodonneurs à une valeur de 0,27 pour les groupes électroattracteurs. Une substitution du groupe acétyle par du deutérium réduit légèrement la vitesse, un résultat qui est en accord avec une première étape lente, mais partiellement réversible, dans laquelle le substrat est déprotoné. Une accélération et un effet isotopique semblable ont aussi été observés lorsqu'on a comparé le diacétylglycoluril (**2**) et diacétyldithioglycoluril (**5**). On discute des implications de ces résultats.

Mots clés : glycoluril, condensation de Claisen, cinétique, mécanisme.

[Traduit par la Rédaction]

Introduction

Auxiliaries are frequently pivotal in the design and execution of stereoselective syntheses (1). For example, the oxazolidinones developed by Evans allow highly diastereo- and enantioselective carbon–carbon bond forming reactions, as exemplified by their use in aldol condensations (1, 2). The sulfur congeners of these auxiliaries, the oxazolidinethiones and thiazolidinethiones (3), have also been studied, and have been found to exhibit altered properties compared with the oxygenated compounds; these include enhancement of the acidity of the protons of the *N*-acyl group, altered stereoselectivity, e.g., in aldol reactions (4), and enhanced ease of removal of the auxiliary after the desired aldol reac-

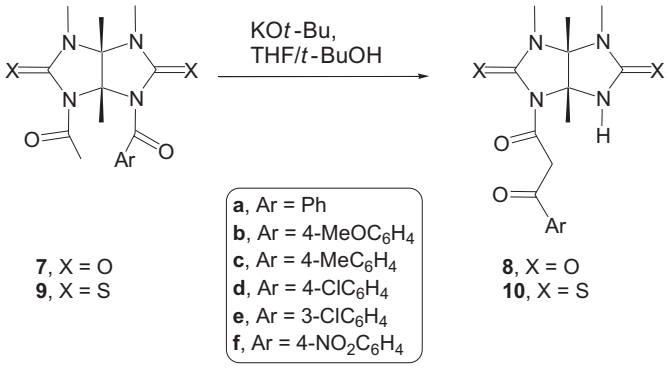
Scheme 1.



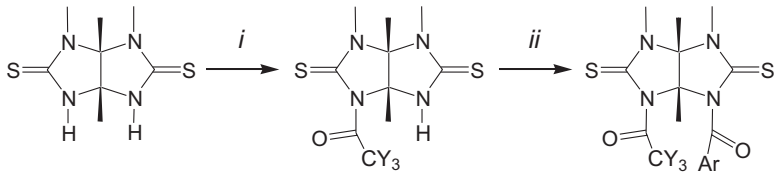
tion is complete (5). Although the effect of substitution of thiocarbonyl for carbonyl groups on nucleophilic substitution by non-carbon nucleophiles has been studied (6), there is little quantitative kinetic data on the extent to which sulfur substitution in auxiliaries influences the key C—C bond-forming chemistry, as results are generally determined as the overall outcome in preparative experiments.

As part of our on-going interest in biomimetic polyketide synthesis, we have developed glycolurils as auxiliaries to promote efficient intramolecular Claisen-like condensations (7). Thus, two sequential or concomitant acylations of 3,4,7,8-tetramethylglycoluril (**1**, Scheme 1) (8) at the N-1 and N-6 sites readily provide diacylglycolurils (e.g., **2**) in which the two acyl entities are held and oriented in proximity to each other. Deprotonation of one acyl moiety with an alkoxide base generates an enolate that is efficiently trapped by the other, electrophilic carbonyl group (9). After collapse of the resulting tetrahedral intermediate and workup, a β-ketoacylglycoluril (e.g., **3**) is generated in high yield (7, 9, 10). The glycoluril thus acts as a bifunctional analog of an Evans oxazolidinone, and the key condensation reaction is the intramolecular equivalent of the known intermolecular acylation of an Evans enolate by an acyl halide (11). In subsequent steps, a sequence of chemical reactions to modify the β-keto group can be effected; this process thus follows the order of events in fatty acid and polyketide biosynthesis (12). Finally, the resulting substituted acylglycoluril can undergo further rounds of acylations and intramolecular condensations (7), thus providing an iterative biomimetic approach to the synthesis of this class of natural products.

We have also described the preparation of thio substituted glycolurils in which one or both of the ureido oxygens has been substituted by sulfur (e.g., **4**) (13), and shown that the thioureido sites are more readily acylated than their ureido counterparts (e.g., conversion of **4** to **5**) (13, 14). The diacylthioglycolurils also rearranged in high yield to β-ketoacyl derivatives, e.g., **5** gives **6**. Although sulfur substitution qualitatively appeared to promote this condensation reaction, we sought a more quantitative way to determine the role of sulfur, and its impact on the various steps of this process.

Recently, we reported a detailed analysis of the condensation reaction using UV spectroscopy to monitor the kinetics of conversion of a series of acetyl aroyl glycolurils (e.g., **7a**–**7f**) into condensation products (e.g., **8a**–**8f**) (Scheme 2) (9). The results show that these reactions proceed cleanly, are first order in both substrate and base, are sensitive to aroyl substituents ($\rho = 1.5$ in a Hammett plot), and exhibit substantial primary kinetic isotope effects when the acetyl group is replaced by CD_3CO. The data were fully consistent with initial deprotonation of starting material at the acetyl group, followed by the proposed Claisen-like carbon–carbon bond formation step; both of these steps are partially rate-limiting, and later steps, including collapse of the ensuing tetrahedral intermediate, are fast. The enolate intermediate formed in the first step partitions between reprotonation by solvent (*t*-BuOH) and attack on the aroyl group; the extent of partitioning depends on the aroyl substituent.

Scheme 2.



The availability of a rapid kinetic assay to monitor and quantitate the condensation reaction opens up further explorations of this intriguing system. In the present work, we describe the use of this methodology to examine the role of thio substitution in the glycoluril, and present kinetic data for conversion of **9a**–**9f** into **10a**–**10f**, respectively, as well as for the analogous deuterated substrates. Rates for diacetyl glycoluril **2** and its sulfur analog **5** are also compared. The implications of these results for the mechanism of the intramolecular Claisen-like condensation, for the design of more efficient biomimetic systems, and for thionation in chiral auxiliaries in general, are discussed.

Results

Dithioglycoluril **4** was efficiently acetylated to give the monoacetyl compound **11a** as previously reported; **11b** was prepared similarly from [D_6]-acetic anhydride (Scheme 3) (13). The NH site in **11a** reacted readily with benzoyl chloride to give **9a**. Likewise, 4-methoxy-, 4-methyl-, 4-chloro-, 3-chloro-, and 4-nitrobenzoyl chlorides were reacted with

11a to afford **9b**–**9f**, respectively. The deuterated analogs, **12a**, **12e**, and **12f** were analogously prepared from **11b**.

Rates for rearrangement of **7a**, **9a**–**9f**, and deuterated analogues **12a**, **12e**, and **12f** were obtained as previously described (9). Briefly, each substrate was dissolved in anhydr. THF–*t*-BuOH (50:50), and placed in a sealed UV cuvette. After initiation of reaction with a fivefold or greater molar excess of a solution of base (KO-*t*-Bu) in the same solvent, absorbance at the λ_{max} of the enolate of the condensation product was monitored with time. Pseudo-first-order rate constants (k_{obs}) were determined by best fit, and converted to second-order rate constants (k_{app}) by dividing by base concentration. Slight variations in procedure were required when the rates were large: a lower substrate concentration and the minimal fivefold excess of base were used. In most of the experiments reported herein, and especially in these rapid cases, the reactions had progressed substantially by the time data collection started. Thus, only the last 20%–50% of the reaction progress could be monitored, and the absorbance changes were small, especially when the substrate concentration had been lowered. As a consequence of these effects, the individual kinetic runs had greater errors than those previously reported for the oxygen congeners. These problems were compensated for by performing three to five replicate analyses, and by repeating each measurement with new stock solutions at least once. It was found that the errors associated with curve fitting were small, and thus errors were determined by comparing results from different runs. The resulting average rate constants and errors are presented in Table 1.

Several controls were run during this study, as described previously. Thus, kinetic runs with **9a** and **9b** exhibited isosbestic points when the reaction was monitored in a sequence of rapid UV scans, as had been observed for **7a** (9). Compound **9d** was converted synthetically to condensation product **10d**. When treated with KO-*t*-Bu under similar conditions to those of the kinetics experiments, **10d** gave an essentially identical UV spectrum to that of the final solution at the end of a kinetics experiment with **9d**. This observation confirms that the process being monitored was indeed the expected condensation reaction, as discussed previously for **7a** (9). A plot of k_{obs} for **9a** vs. [Base] was linear, confirming that the reaction is first order in base concentration, as for **7a**. Regression of this plot gave k_{app} for **9a** of 180 ± 12 L mol^{-1} s^{-1}, in good agreement with the value obtained from curve fitting (161 ± 11 L mol^{-1} s^{-1}).

The values for k_{app} for compounds **9a**–**9f** and deuterated congeners thereof are shown in a Hammett plot (15) in Fig. 1, along with the previously reported data for **7a**–**7f** and their deuterated analogues. The results for **9a**–**9f** clearly show a substantial substituent effect, with an increase in rate from the electron-donating 4-methoxy to the withdrawing 4-nitro substituent of eightfold. However, unlike the plot for **7a**–**7f**, the Hammett plot for **9a**–**9f** is clearly nonlinear (r^2 = 0.744 for all data). A more satisfactory fit is obtained when the three data points at high σ are fit to a linear relationship, giving ρ = 0.27 ± 0.05 (r^2 = 0.967). Corresponding regression of the three points at low σ gives a positive value for ρ of 1.4 ± 0.5 (r^2 = 0.821), comparable to the previously reported values for **7a**–**7f** of 1.2–1.5 (9). However, the data may also be accomodated by a curved plot.

The isotope effect for substitution of three deuterons into the acetyl group(s) on the reaction rate constant k_{app} was next examined. Comparison of the rate constants for **9a** vs. **12a**, **9e** vs. **12e**, and **9f** vs. **12f** was made by performing a series of analyses, each of which was composed of five replicate runs; the k^H_{app}/k^D_{app} value obtained for the isotope effect on each of these overall reactions was 1.3 at 25 °C; these values compare with those obtained for **7a**, **7e**, and **7f** vs. their deuterated isotopomers of 1.6–2.6 (9). Overall, the results show a small, but consistent isotope effect in the dithioglycoluril condensations, which was reproduced in each independent analysis. It should be noted that in these experiments, at best only the latter 50% of the reaction progress could be monitored, owing to the high rates for reaction of the dithio analogues. Thus, potentially rapid exchange of deuterium with hydrogen from the *t*-BuOH solvent may mask any inherent isotope effect (see Discussion).

To further investigate the effect of thionation in the glycoluril, we also examined the kinetics for conversion of diacetyl glycolurils **2** and **5** to **3** and **6**, respectively (Scheme 1). In our previous work, we had used acetyl aroyl glycolurils (**7**) exclusively, reasoning that conjugation of the aroyl moiety in the enolate of products **8** would shift the UV absorption

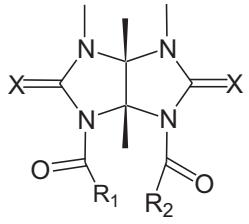
[f]Value defined for comparisons.



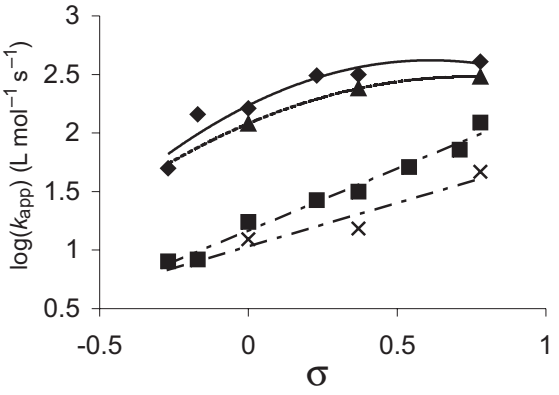


Fig. 1. Hammett plot showing the logarithm of the observed bimolecular rate constant ($\log k_{app}$) plotted against the substituent constant σ for the acetyl aroyl dithioglycoluril substrates **9a**–**9f** (◆) that were studied. Also presented are data for deuterated analogues **12a**, **12e**, and **12f** (▲). The corresponding data for the oxygenated analogues **7** from our previous study (9) are shown for comparison (■, and X for deuterated substrates). Trend lines are shown as an aid to interpretation.

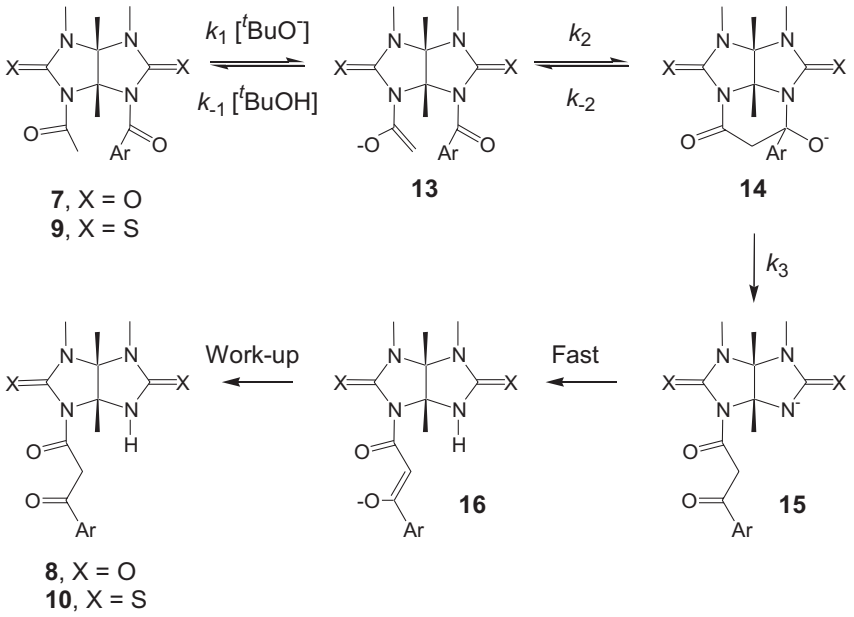
maxima of the product enolates to significantly higher wavelengths than those of the substrates. Indeed, we found that the aroyl groups permitted observation of the reactions in a region of the UV spectrum that was free from absorption owing to other species. However, we were intrigued by the possibility of extending the kinetics measurements to glycolurils bearing only aliphatic acyl groups, since these had been more widely used in our synthetic investigations.



In practice, we found that conversion of both **2** to **3** and **5** to **6** could be readily observed in kinetic runs under conditions otherwise identical to those for **7** and **9**, although λ_{max} for the product enolates was indeed shifted to a lower wavelength (300 nm), where some residual tail-end absorption from starting material was observed. Nonetheless, excellent reproducibility and good fits for the kinetic data were obtained. The rate constants for these reactions are given in Table 1 (entries 11 and 12). Although, as expected for the dramatic change from benzoyl to acetyl, the rate constants are quantitatively different between **2** and **7a** as well as between **5** and **9a**, the differences are remarkably small, suggesting no dramatic change in mechanism. Again, comparing **2** and **5**, thionation accelerates the reaction (17-fold), a result comparable with the effect on acetyl aroyl glycolurils. Further, substitution of CD_3 for CH_3 in both the acetyl groups of **5** slowed the reaction slightly ($k_{app}{}^{H}/k_{app}{}^{D} = 1.25$), a result similar to that observed in **9a** vs. **12a** (Table 1, entry 13).

Discussion

At the outset of this study, we had established that glycoluril **1** can be converted to a range of acetyl aroyl derivatives, and that these undergo efficient intramolecular

© 2005 NRC Canada

Scheme 4. Mechanism proposed for the intramolecular Claisen-like condensation of diacylglycolurils to give β-ketoacylglycolurils.

Claisen-like condensations induced by base, in almost quantitative yield. It had also been shown that the corresponding thio analogue **3** could be more efficiently acylated than **1**, and that a range of nonaromatic diacyldithioglycolurils can undergo the corresponding Claisen-like condensations. The present study shows that acetyl aroyl dithioglycolurils **9a**–**9f** are also readily prepared. That compound **9d** underwent preparative condensation to afford **10d** in reasonable yield (62%, unoptimized), along with the observation that each of **9a**–**9f** gave the enolate of products **10a**–**10f** in the kinetics experiments, shows that this reaction is applicable to the preparation of a range of 3-keto-3-aroylpropanoyl units; these in turn should be of use in synthesis, based on our application of the general methodology described earlier.

Although we had studied the influence of sulfur substitution for oxygen in the glycoluril on the regiochemistry of the condensation reaction, there was no quantitative data to indicate whether this substitution made the key condensation reaction more efficient. Since we had established a rapid method for measuring the reaction rates for conversion of **7** to **8**, and shown that the system obeys straightforward second-order kinetics, we thus set out to evaluate the influence of sulfur substitution on overall reaction rate, and to examine which individual step(s) of the mechanism is (are) influenced by this replacement.

The significantly enhanced overall rate of formation of each of the products **10a**–**10f** from **9a**–**9f** as compared with conversion of **7a**–**7f** to **8a**–**8f** clearly demonstrates that thionation in the glycoluril substantially accelerates the overall reaction (3.5- to 18-fold). A similar effect was found in comparing diacylglycolurils **2** and **5**, demonstrating that the magnitude of the effect appears to be general, and showing for the first time that an aroyl group was not required to observe the kinetics of the condensation reaction. Thus, sulfur substitution improves the overall efficiency of the condensation reaction, a result that was not apparent from the preparative work we had undertaken before. In conjunction with the benefits of thionation that had been shown previously, most notably the ease of acylation as shown here and elsewhere, these results indicate that thioglycolurils may be the auxiliary of choice when using this approach in synthesis.

While these results give the first quantitative measure of the influence of sulfur on the overall reaction rate, comparison of **7** and **9** alone reveals little about the mechanism by which the rate acceleration occurs, since the rates of several steps were comparable in **7a**–**7f**. In the previously proposed mechanism, the first step involved a partially rate-determining deprotonation (step 1, rate constant k_1, Scheme 4) of the diacylglycoluril. Subsequent intramolecular nucleophilic attack (step 2, rate constant k_2) of the ensuing enolate **13** onto the aroyl carbonyl carbon provides tetrahedral intermediate **14**. We previously reasoned that this step was also partly rate-determining, based on the observed positive ρ value in Hammett plots of **7a**–**7f**. However, step 3, the collapse of the tetrahedral intermediate to give **15**, could not be ruled out as a competing slow step. It was reasoned that proton transfer in **15** to give **16**, the species observed in every kinetic experiment, would be rapid.

The faster overall rate upon thionation potentially reflects an acceleration in any or all of the steps involved in the process because k_{app} may be a composite rate constant, depending on which step is influenced. Sulfur substitution might reasonably influence: (*i*) deprotonation, through enhanced kinetic or thermodynamic acidity of the acetyl group via accessibility of the base, enolate stability, or chelate effects, reflected in k_1; (*ii*) condensation, through either enhanced enolate nucleophilicity and (or) activation of the acyl acceptor moiety, either of which would impact k_2; (*iii*) enolate reprotonation, thus altering k_{-1}; or (*iv*) collapse of the tetrahedral intermediate through the enhanced leaving group ability of the thioureido nitrogen in **9** compared to the ureido group in **7**, as would be seen in alteration of k_3. To address the impact of thionation on these individual steps, we determined the rate as a function of aroyl substituent and of deuterium substitution in the acetyl moiety.

The results described here remain fully consistent with

© 2005 NRC Canada

this overall mechanistic scheme (Scheme 4). First-order kinetics in the reactant was observed for all compounds, and it was shown that the reaction of the typical representative **9a** was first order in base, as for **7a**. The rates are somewhat faster than for analogues **7**, but not dramatically altered, again suggesting no overwhelming mechanistic change.

However, the nonlinear Hammett plot for **9a**–**9f** clearly indicates a change in rate-determining step(s). Electron donation in the aroyl entity relative to phenyl decelerates the overall reaction, similar to the effect in **7**. This result is consistent with step 2 remaining at least partially rate-determining. However, with electron-withdrawing groups, there is little influence of substituent on the overall rate ($\sigma = 0.27$), a result consistent with step 2 becoming sufficiently fast with increasing electron withdrawal that it no longer influences the overall rate. Thus, thionation of the glycoluril accelerates step 2 in this regime, and does so to an extent greater than its effect on step 1. Mechanistically, this effect may be the result of either enhanced nucleophilicity of enolate **13** and (or) the enhanced carbonyl group electrophilicity at the aroyl moiety. Further experiments to distinguish these possibilities are now planned.

The observation of a small, but persistent isotope effect upon substitution of CD_3 for Me in the acetyl group in all three thio compounds examined, as well as in diacetyl glycoluril (**5a** vs. **5**) is consistent with step 1 being at least partially rate-determining, as previously proposed for **7**. For the compounds tested, it was not possible to determine from these results whether step 1 was solely the rate-limiting step, since this step may be partially reversible because of exchange with protonated solvent. The resulting gradual dilution of deuterium in the substrate may mask the true isotope effect, as noted previously for **7**. Nonetheless, if reprotonation were extremely fast compared to condensation, then no isotope effect would be expected, since **12** or **5a** would have exchanged completely in the period prior to commencement of measurement. That reprotonation can still compete with condensation in the thio analogues requires that both k_{-1} and k_2 are accelerated relative to the oxygen containing glycolurils.

Finally, it should be noted that the present results are not inconsistent with fast and reversible first and second steps, and a slow collapse of the tetrahedral intermediate in step 3. Although it seems unlikely that sulfur substitution *slows* step 3, further experiments are required to resolve this point.

Conclusions

From a practical standpoint, the results presented provide a rare quantitative measure of the influence of thionation in an auxiliary. Thus, the overall rate acceleration of approx. one order of magnitude, and the demonstration that this effect derives at least partially from acceleration of the key enolate–carbonyl condensation step have implications for the extent to which thionation in other systems such as oxazolidinones may influence the reactions of enolates. Clearly, thioglycoluril **4** is superior to **1** as an auxiliary from the perspective of rate acceleration of the key step of the reaction.

Taken together, the results are consistent with a mechanism for the Claisen-like condensation of acetyl aroyl dithio glycolurils **9a**–**9f** in which a slow (or competitively slow) first step gives enolate **13**. Reprotonation of **13** by *tert*-butanol solvent then competes with intramolecular carbon–carbon bond formation to give tetrahedral intermediate **14**. This quenching of the enolate results in gradual dilution of isotope in analogs **12** containing a trideuteroacetyl group, and masks the true isotope effect on step 1. The C—C bond-forming step is partially rate-determining when the aroyl moiety bears an electron-donating group, but is accelerated by electron-withdrawing groups to the point where it is no longer rate-determining. This effect is in contrast to oxygenated compounds **7**, where step 2 influences the rate even when a 4-nitro substituent is present. Thus, thionation of the glycoluril accelerates the overall condensation rate by accelerating the key condensation step, although it remains to be determined whether other steps are also influenced.

The present results provide a framework for further studies of this intriguing reaction through kinetics experiments. Thus, experiments with monothioglycolurils are underway, to examine the influence of sulfur on one or the other side of the glycoluril, while further experiments with diacyl glycolurils should allow competition experiments between acyl units, so that the mechanistic origins of the previously observed regioselectivities in these reactions can be established.

Experimental section

General

General conditions for preparation and characterization of the glycoluril derivatives were as previously described (9). UV spectroscopy was performed in quartz UV cells bearing a screw cap and septum on a Cary 500 spectrophotometer, with the temperature maintained at 25 °C as previously reported (9). The observation wavelengths used are given in Table 1. The procedures for data manipulation and determination of rate constants were unchanged from our prior work (9). Compound **11a** was prepared as described previously (13).

General procedure for preparation of acetyl aroyl dithioglycolurils 9a–9f

To a solution of **11a** in dichloromethane (15 mL/mmol) at 0 °C was added 2.5–3 equiv. Et_3N. The mixture was stirred for 5 min, then the aroyl chloride (2 to 3 equiv.) was added and stirring was continued for 2.5 h while warming to room temperature. The mixture was extracted three times with 5% HCl. The organic layer was dried over Na_2SO_4, filtered, and concentrated. The product was purified by recrystallization from CH_2Cl_2–hexanes, or by flash chromatography (EtOAc–hexanes, 30:70).

Acetyl benzoyl 2,5-dithioglycoluril (9a)

Compound **11a** (50 mg, 0.18 mmol) and benzoyl chloride (43 μL) gave 62 mg (92%) of **9a**, mp 242–244 °C. UV (THF–*t*-BuOH (50:50), λ_{max}, nm): 244 (ε = 27 000 (mol/L)$^{-1}$ cm^{-1}). IR ($CHCl_3$ cast, cm^{-1}): 2985, 2938 (C-H), 1712 (C=O), 1689 (C=O), 1485, 1402, 1368, 1350, 1333, 1306, 1270, 1240, 1111, 1101. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.26–7.55 (5H, m, Ar*H*), 3.38 (3H, s, N-CH_3), 3.25 (3H, s, N-CH_3), 2.70 (3H, s, O=C-CH_3), 2.05 (3H, s, CH_3), 1.71 (3H, s, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 179.9, 172.5, 170.3, 134.6, 133.3, 130.4 (2C), 128.3 (2C),

86.8, 86.2, 31.7, 30.8, 28.2, 23.4, 19.0, 16.5. EI-MS *m/z*: 376 [M^+], 246, 193, 142 (base). HR-MS calcd. for $C_{17}H_{20}N_4O_2S_2$: 376.1028; found: 376.1031.

Acetyl 4-methoxybenzoyl 2,5-dithioglycoluril (9b)

Compound **11a** (20 mg, 0.074 mmol) and 4-methoxybenzoyl chloride (38 mg) gave 12 mg (40%) of **9b**. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.72 (2H, d, *J* = 8 Hz, Ar*H*), 6.87 (2H, d, *J* = 8 Hz, Ar*H*), 3.83 (3H, s, O-CH_3), 3.35 (3H, s, N-CH_3), 3.24 (3H, s, N-CH_3), 2.67 (3H, s, O=C-CH_3), 2.01 (3H, s, CH_3), 1.68 (3H, s, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 180.1, 177.3, 172.4, 169.3, 163.9, 132.8, 127.1, 113.8, 86.7, 86.2, 55.4, 31.6, 30.8, 28.1, 18.9, 16.5.

Acetyl 4-methylbenzoyl 2,5-dithioglycoluril (9c)

Compound **11a** (175 mg, 0.65 mmol) and 4-methylbenzoyl chloride (200 mg) gave 231 mg (91%) of **9c**, mp 230–232 °C. UV (THF–*t*-BuOH (50:50), λ_{max}, nm): 250, 259 (ε = 4650, 4650 (mol/L)$^{-1}$ cm^{-1}). IR ($CHCl_3$ cast, cm^{-1}): 3021 (C-H), 1711 (C=O), 1217, 758. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.63 (2H, d, *J* = 8 Hz, Ar*H*), 7.18 (2H, d, *J* = 8 Hz, Ar*H*), 3.36 (3H, s, N-CH_3), 3.23 (3H, s, N-CH_3), 2.68 (3H, s, O=C-CH_3), 2.37 (3H, s, ArCH_3), 2.02 (3H, s, CH_3), 1.69 (3H, s, CH_3). EI-MS *m/z*: 390 [M^+], 260, 142, 119 (base), 91, 56, 43. HR-MS calcd. for $C_{18}H_{22}N_4O_2S_2$: 390.1184; found: 390.1176.

Acetyl 4-chlorobenzoyl 2,5-dithioglycoluril (9d)

Compound **11a** (175 mg, 0.65 mmol) and 4-chlorobenzoyl chloride (228 mg) gave 112 mg (42%) of **9d**, mp 170 to 171 °C. UV (THF–*t*-BuOH (50:50), λ_{max}, nm): 250, 261 (ε = 4100, 4100 (mol/L)$^{-1}$ cm^{-1}). IR ($CHCl_3$ cast, cm^{-1}): 3021 (C-H), 1716 (C=O), 1217, 759. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.66 (2H, d, *J* = 8 Hz, Ar*H*), 7.36 (2H, d, *J* = 8 Hz, Ar*H*), 3.38 (3H, s, N-CH_3), 3.24 (3H, s, N-CH_3), 2.73 (3H, s, O=C-CH_3), 2.04 (3H, s, CH_3), 1.72 (3H, s, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 179.7, 177.2, 172.5, 169.4, 139.7, 133.1, 131.7 (2C), 128.7 (2C), 86.7, 86.2, 31.8, 30.8, 28.2, 19.0, 16.6. EI-MS *m/z*: 410 [M^+], 280, 142, 43 (base). HR-MS calcd. for $C_{17}H_{19}{}^{35}ClN_4O_2S_2$: 410.0638; found: 410.0640.

Acetyl 3-chlorobenzoyl 2,5-dithioglycoluril (9e)

Compound **11a** (20 mg, 0.074 mmol) and 3-chlorobenzoyl chloride (39 mg) gave 27 mg (90%) of **9e**. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.70 (1H, m, Ar*H*), 7.55 (1H, m, Ar*H*), 7.48 (1H, m, Ar*H*), 7.31 (1H, t, *J* = 8 Hz, Ar*H*), 3.38 (3H, s, N-CH_3), 3.23 (3H, s, N-CH_3), 2.73 (3H, s, O=C-CH_3), 2.03 (3H, s, CH_3), 1.70 (3H, s, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 179.7, 177.4, 172.6, 169.2, 136.5, 134.4, 133.1, 130.3, 129.4, 128.4, 86.8, 86.2, 31.8, 30.8, 28.1, 19.1, 16.5. EI-S *m/z*: 410 [M^+], 267, 265, 224, 222, 156, 139 (base). HR-MS calcd. for $C_{17}H_{19}{}^{35}ClN_4O_2S_2$: 410.0638; found: 410.0645.

Acetyl 4-nitrobenzoyl 2,5-dithioglycoluril (9f)

Compound **11a** (20 mg, 0.074 mmol) and 4-nitrobenzoyl chloride (21 mg) gave 25 mg (80%) of **9f**. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.21 (2H, d, *J* = 9 Hz, Ar*H*), 7.81 (2H, d, *J* = 9 Hz, Ar*H*), 3.40 (3H, s, N-CH_3), 3.21 (3H, s, N-CH_3), 2.77 (3H, s, O=C-CH_3), 2.05 (3H, s, CH_3), 1.72 (3H, s, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 179.3, 177.4, 172.7, 168.8, 150.0, 140.2, 131.0, 123.3, 86.7, 86.3, 31.9, 30.8, 28.1, 19.1, 16.4. EI-MS *m/z*: 421 [M^+], 391, 314, 272, 142 (base). HR-MS calcd. for $C_{17}H_{19}N_5O_4S_2$: 421.0878; found: 421.0861.

[2-$^2H_3$]Acetyl-2,5-dithioglycoluril (11b)

To dithioglycoluril **4** (50 mg, 0.22 mmol) in THF (8 mL) was added *n*-BuLi (160 µL of 1.5 mol/L solution in hexanes), and the mixture was stirred for 15 min at room temperature before the addition of acetic anhydride-d_6 (42 µL, 0.44 mmol). After stirring for 1 h, the mixture was quenched with 1 mol/L $NaHSO_4$ (5 mL) and the THF removed on the rotary evaporator. The aqueous residue was extracted with CH_2Cl_2 (2 × 10 mL) and the organic extracts dried over Na_2SO_4. Purification by flash column chromatography (EtOAc–hexanes, 1:1) gave **11b** (28.6 mg, 47%) as a fine white powder. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.31 (3H, s, N-CH_3), 3.14 (3H, s, N-CH_3), 1.71 (3H, s, CH_3), 1.59 (3H, s, CH_3). EI-MS *m/z*: 275 [M^+], 143, 84 (base).

[2-$^2H_3$]Acetyl benzoyl 2,5-dithioglycoluril (12a)

Compound **11b** (25 mg, 0.091 mmol) and benzoyl chloride (24 µL) gave 26.3 mg (76%) of **12a**, as for **9a**. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.24–7.73 (5H, m, Ar*H*), 3.35 (3H, s, N-CH_3), 3.22 (3H, s, N-CH_3), 2.70 (missing, O=C-CH_3), 2.03 (3H, s, CH_3), 1.69 (3H, s, CH_3). EI-MS *m/z*: 379 [M^+], 246, 143, 105 (base).

[2-$^2H_3$]Acetyl 3-chlorobenzoyl 2,5-dithioglycoluril (12e)

Compound **11b** (20 mg, 0.073 mmol) and 3-chlorobenzoyl chloride (3 equiv.) gave 23 mg (76%) of **12e**, as for **9e**.

[2-$^2H_3$]Acetyl 4-nitrobenzoyl 2,5-dithioglycoluril (12f)

Compound **11b** (20 mg, 0.073 mmol) and 4-nitrobenzoyl chloride (3 equiv.) gave 27 mg (87%) of **12f**, as for **9f**.

4-Chlorobenzoylacetyl dithioglycoluril 10d from 9d

Compound **9d** (60.6 mg, 0.148 mmol) in THF (1.5 mL) was treated with potassium *tert*-butoxide (31.5 mg, 0.28 mmol). The mixture was stirred for 45 min, then quenched with 10% $NaHSO_4$ (3 mL), and extracted with CH_2Cl_2 (2 × 10 mL). The combined organic layers were washed (brine (2 × 10 mL) then water (10 mL)), dried (Na_2SO_4), filtered, and concentrated. Flash column chromatography (60% EtOAc–hexanes) gave 37.1 mg (62%) of **10d**, mp 70 °C dec. UV (THF–*t*-BuOH (50:50), λ_{max}, nm): 250, 330, 370 (sh) (ε = 37 000, 7530 (mol/L)$^{-1}$ cm^{-1}); when treated with excess KO-*t*-Bu: 353 nm (ε = 12 500 (mol/L)$^{-1}$ cm^{-1}). Ambident reactivity of phenoxyl radicals in DNA adduction

Richard A. Manderville

Abstract: Phenols are a class of compounds that can create beneficial effects in vivo owing to their antioxidant properties (through radical scavenging), or they can display hazardous effects owing to their pro-oxidant properties. The mechanism by which phenols act as pro-oxidants stems from their one-electron oxidation into reactive phenoxyl radicals by peroxidase enzymes or redox-active transition metals. In the presence of thiols and molecular oxygen, these reactive phenoxyl radicals stimulate an oxidative stress and cause oxidative damage to biomolecules, which is proposed to contribute to the occurrence of cancer in peroxidase rich tissues. Recent results from our laboratory show that certain phenoxyl radicals can also react directly with the C-8 site of deoxyguanosine to afford oxygen and carbon bonded adducts. This reactivity is consistent with the ambident (oxygen vs. C attachment) electrophilicity of phenoxyl radicals coupled with the susceptibility of the C-8 site of deoxyguanosine to radical attachment. Given that formation of covalent DNA adducts is regarded as the initiation event in the carcinogenic process, C-8 deoxyguanosine adducts of phenolic toxins are expected to contribute greatly to peroxidase driven toxic effects of phenolic xenobiotics. The focus of this review is the role of phenoxyl radicals in direct reactions with DNA and the use of Brown σ^+ values to predict their reactivity.

Key words: DNA adduction, phenoxyl radicals, chlorophenols, ochratoxin A, deoxyguanosine.

Résumé : Les phénols forment une classe de composés qui peuvent avoir des effets bénéfiques in vivo en raison de leurs propriétés antioxydantes (par le biais de leur capacité à piéger les radicaux) ou qui peuvent présenter des effets délétères en raison de leurs propriétés prooxydantes. Le mécanisme par lequel les phénols agissent comme prooxydants découle de leur oxydation, par un mécanisme impliquant un électron qui conduit aux radicaux réactifs phénoxyles, sous l'action des enzymes peroxydases ou des métaux de transition actifs en oxydoréduction. En présence de thiols ou d'oxygène moléculaire, ces radicaux phénoxyles stimulent un stress oxydant et provoquent des dommages oxydants aux biomolécules qui contribueraient, selon les théories actuelles, à l'apparition de cancers dans les tissus riches en peroxydases. Des résultats récents obtenus dans nos laboratoires montrent que certains radicaux phénoxyles peuvent aussi réagir directement avec le site C-8 de la désoxyguanosine pour conduire à la formation d'adduits liés par l'oxygène ou le carbone. Cette réactivité est en accord avec le caractère électrophile ambident (attachement à l'oxygène ou au carbone) des radicaux phénoxyles couplé à la susceptibilité du site C-8 de la désoxyguanosine à des attaques radicalaires. Se basant sur la théorie que la formation d'adduits covalents de l'ADN est considérée comme l'étape qui initie le processus cancérigène, on peut s'attendre à ce que les adduits de toxines phénoliques en C-8 de la désoxyguanosine contribueront fortement aux effets toxiques des xénobiotiques phénoliques activés par les peroxydases. L'objet principal de cette revue est le rôle des radicaux phénoxyles dans les réactions directes avec l'ADN et l'utilisation des valeurs σ^+ de Brown pour prédire leur réactivité.

Mots clés : adduits avec l'ADN, radicaux phénoxyles, chlorophénols, ochratoxine A, désoxyguanosine.

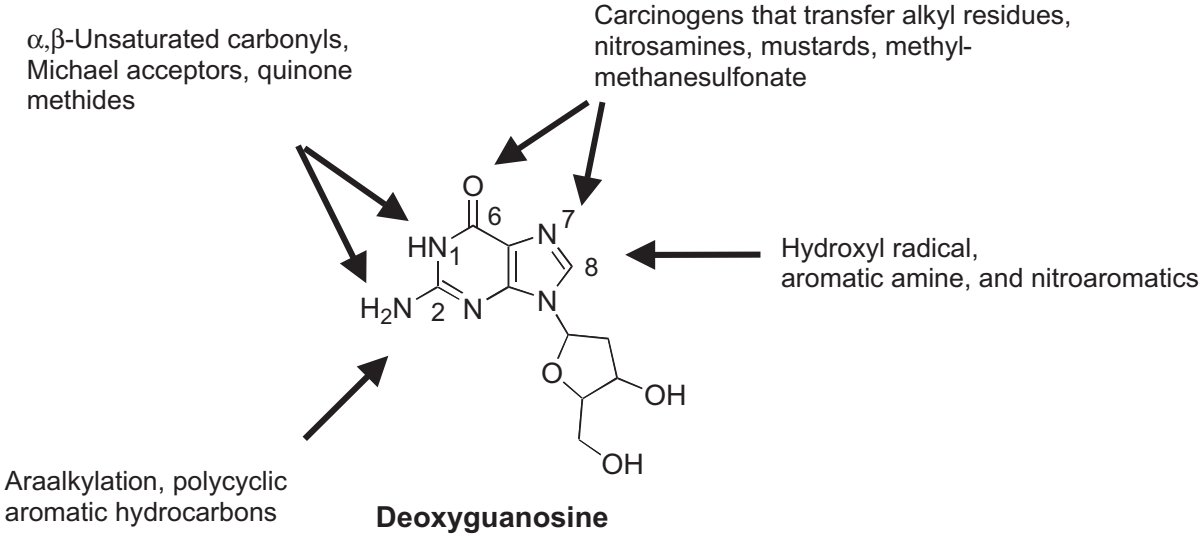
Introduction



Phenols are ubiquitous substances that possess a wide range of biological activities. Vitamin E and related phenols containing electron-releasing alkyl and methoxy groups possess antioxidant properties through radical scavenging that are beneficial to human health (1). However, certain phenols may also display deleterious pro-oxidant properties that are thought to contribute to aging and disease (2). This pro-oxidant activity is initiated through the one-electron (e) oxidation of phenols into reactive phenoxyl radical intermediates by enzymes with peroxidase activity and redox-active transition metals. These reactive intermediates then undergo a redox-cycling mechanism by hydrogen (H) atom abstraction of essential thiols, such as glutathione (GSH) and protein sulfhydryls, to yield thiyl radicals; this repeatedly generates the parent phenol as a substrate for peroxidase (3). The thiyl radicals react with GSH to generate a GSH disulfide anion radical that can reductively activate molecular oxygen (O_2), which in the presence of transition-metal complexes, can yield the hydroxyl radical that may damage lipids (4), proteins (5), and DNA (6). In addition to an oxidative stress mediated through the phenoxyl radical in vivo, direct covalent reactions of phenoxyl radicals with DNA to

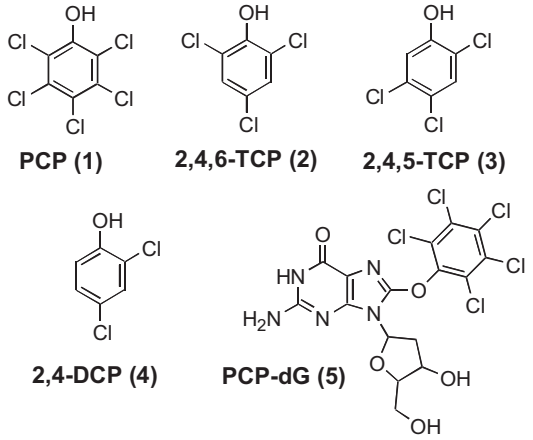
Fig. 1. Summary of the sites on deoxyguanosine that are modified by chemical carcinogens.

yield DNA adducts would contribute to peroxidase driven toxic effects of phenolic xenobiotics (3).

The formation of covalent DNA adducts in vivo is recognized as a common property of most potent carcinogens (7). Shown in Fig. 1 are the sites on deoxyguanosine (dG) that are modified by chemical carcinogens. Those that transfer alkyl residues (nitrosamines, mustards, and methyl-methanesulfonate) target the endocyclic N-7 atom and the exocyclic O-6 atom (7). Polycyclic aromatic hydrocarbons that undergo bioactivation to generate dihydrodiol epoxides and other agents that transfer an araalkyl group tend to target the exocyclic N-2 atom. This site is also modified by α,β-unsaturated carbonyls, Michael acceptors, and quinone methides (8, 9). While it is to be expected that these nucleophilic sites would be targeted by electrophiles, the C-8 site of dG is also a target site of many established carcinogens. For example, those that transfer an arylamine residue and include, aromatic amines, aminoazo dyes, nitroaromatics, and heterocyclic amines found in cooked fish and meats, are known to form nitrogen (N) bonded C-8–dG adducts as the major products (10). The hydroxyl radical also reacts at the C-8 site of dG to form 8-oxo-dG, which is the major oxidative lesion found in DNA, suggesting that the C-8 site of dG is susceptible to radical attack (6).

Recent findings from our work on DNA adduction by phenolic xenobiotics highlights their ability to react covalently with C-8–dG following activation by peroxidase enzymes or redox-active transition metals (11–13). Given that phenols are known to undergo peroxidase mediated oxidation into phenoxyl radicals (14), and C-8–dG adduct formation is in keeping with the susceptibility of C-8–dG to radical attachment, our studies suggest the intermediacy of the phenoxyl radical in covalent bond forming reactions with DNA. Due to their ambident (oxygen (O) vs. carbon (C) attachment) electrophilicity, O adducts and para and ortho C adducts can be formed. Correlation of phenoxyl radical reactivity is also possible due to the fact that remote substituent effects of phenoxyl radicals exhibit a linear correlation with Brown σ^+ constants because of the through-resonance between the electron-deficient phenoxyl radical and the ring substituent (15). The focus of this review is the role of phenoxyl radicals in direct reactions with DNA and the use of σ^+ values to predict reactivity, which is expected to dictate pro-oxidant vs. antioxidant behavior in biological systems.

Chlorophenol (CP) — O adduct formation

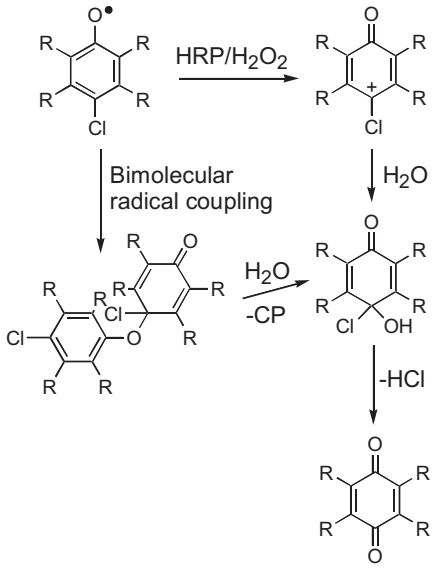


Chlorophenols (CPs) are toxic chemicals that are persistent in the environment. The Environmental Protection Agency (EPA) lists pentachlorophenol (PCP, **1**), 2,4,6-trichlorophenol (TCP, **2**), 2,4,5-TCP (**3**), and 2,4-dichlorophenol (DCP, **4**) as priority pollutants, and of these, **1** and **2** are classified as Group B2 (probable) carcinogens (16). CPs have found use in pesticides, disinfectants, wood preservatives, personal care formulations, and are substantial by-products of wood pulp bleaching with chlorine (17). Human exposure to CPs may occur through drinking water and food and they can be detected in the blood of a high percentage of the population (18). Case reports suggest an association between PCP (**1**) and Hodgkin's disease, soft tissue sarcoma, and acute leukemia (19). Oral animal studies have demonstrated that **1** is a liver carcinogen in mice (20); exposure of rats and mice to **2** resulted in increased incidences of leukemias and hepatocellular carcinomas (16).

It is believed that oxidative metabolism is necessary for CPs to exert their toxic effects. The metabolism of PCP in mammals has been studied extensively and, in general, it has been demonstrated that PCP undergoes cytochrome P450-mediated dechlorination to yield tetrachlorobenzoquinone (TCBQ) and (or) tetrachlorohydroquinone (TCHQ) metabolites (21). The formation of direct DNA adducts by the TCBQ metabolite of PCP has been reported in the liver of mice and rats following mulitiple doses of PCP (22). However, recent in vitro studies show that adduct levels ($36 \pm 9/10^5$ nucleotides) by 100 μmol/L PCP following activation by horseradish peroxidase (HRP) – H_2O_2 are 30-fold higher than levels induced by microsomes that contain cytochrome P450 and 10-fold higher than levels induced by 5 mmol/L TCBQ itself (23).

To gain insight into PCP-mediated DNA adduction, we examined the reaction of PCP (100 μmol/L) with DNA nu-

© 2005 NRC Canada

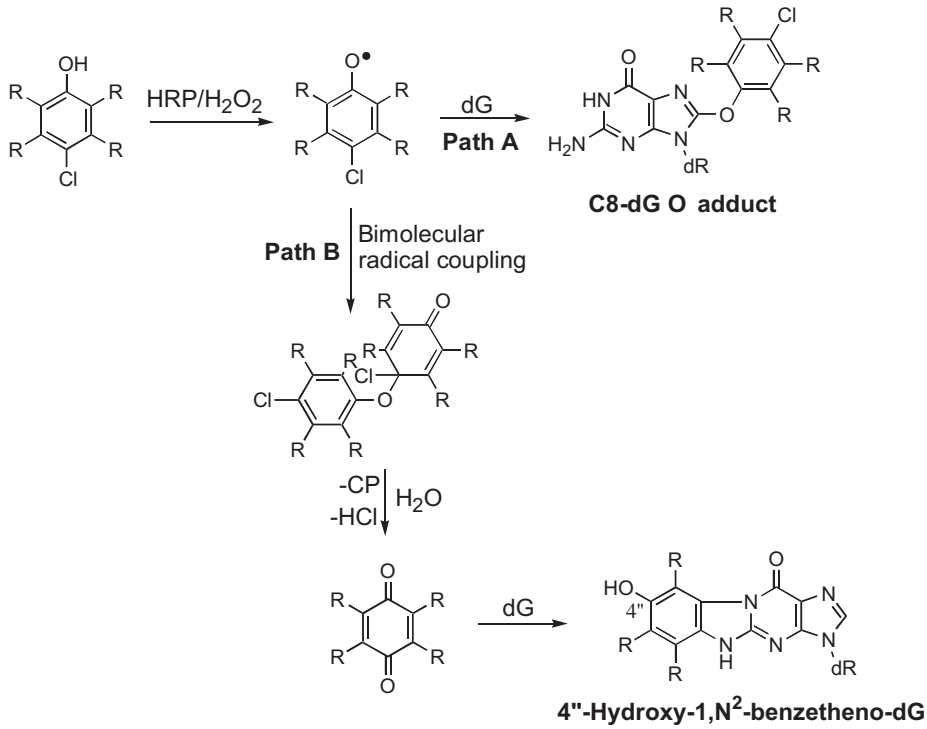


cleosides (2 mmol/L) using HRP–H_2O_2 as the oxidation catalyst and LC–MS (12). Interestingly, these conditions yielded a single DNA adduct that had the five chlorine isotope pattern of PCP and had a molecular ion at $[M - H]^-$ = 528, suggesting attachment of dG with loss of two protons (i.e., PCP(264) + dG(267) – 2H = 529). Isolation and NMR (^1H and ^{13}C) analysis confirmed C-8 attachment by the O site of PCP to yield the adduct PCP–dG (**5**).

Additional experiments were carried out to determine whether **5** could be formed by additional enzyme systems, and whether other DNA bases could react with **1** following HRP–H_2O_2 activation. These experiments showed the reaction to be absolutely specific for dG; no detectable adduct(s) was observed from HRP–H_2O_2 and **1** in the presence of dA, dC, or T. It was also found that the adduct **5** could be generated by treatment of PCP–dG with human myeloperoxidase. However, treatment of PCP–dG with rat liver microsomes that contain cytochrome P450 failed to yield **5** and instead an adduct with $[M - H]^-$ = 440 was detected that was found to co-elute with an adduct induced by reaction of dG with authentic TCBQ. That PCP is a substrate for myeloperoxidase is highly significant given that exposure to PCP has been linked to incidences of leukemia (19). As an analogy, it has been proposed that benzene, via its phenol metabolite, is a leukemogen owing to myeloperoxidase catalyzed oxidation of phenol into the phenolic radical that exhibits pro-oxidant properties (24).

An extension of our studies on HRP-mediated dG adduction by PCP (12) was conducted to include dG adduction by a greater range of CP toxins (**2**–**4**) and to determine whether the pentachlorophenoxyl radical reacts with an actual duplex DNA substrate to form **5** (25). In terms of HRP–H_2O_2 activation, the results with **1** suggested that other CPs (**2**–**4**) would similarly react with dG to yield C-8 O adducts. To test this hypothesis, CP–dG reactions were carried out using conditions analogous to the PCP–dG reaction and were analyzed by LC–MS. Here, it was expected that **2** and **3** would yield an O adduct with a molecular ion at $[M - H]^-$ = 460, while the O adduct from **4** would have a molecular ion at $[M - H]^-$ = 426. However, under conditions favourable for O adduct formation by **1**, the only other CP to yield detectable levels of O adduct was **3**. The major adduct detected for **2**–**4** had UV absorbances at ~275 and 334 nm with a molecular ion at $[M - H]^-$ = 390/392 with a single chlorine isotope. The UV spectrum of the major adduct was similar to

Scheme 1.



the spectrum reported for the dG adduct generated from 1,4-benzoquinone (BQ) – dG (26), suggesting that bioactivation by HRP–H_2O_2 for these CP substrates (100 µmol/L) yielded a BQ electrophile.

Insight into the intermediacy of a BQ electrophile in dG adduction by CP toxins was gleaned from the literature where the oxidation of halogenated phenols by peroxidase enzymes has been a subject of considerable interest and, in general, the predominant reaction product is a 1,4-BQ (27–31). Thus, as outlined in Scheme 1, the 1,4-BQ may arise by the elimination of HCl from a *gem*-chlorohydrin intermediate derived through HRP-catalyzed 1 e oxidation of a chlorophenoxyl radical to yield a carbocation intermediate that reacts with water. Alternatively, the *gem*-chlorohydrin could arise by hydrolysis of the ether formed by C-O coupling of two chlorophenoxyl radicals. In the case of peroxidase mediated oxidation of **1**, Kazunga et al. (31) presented evidence that the final quinone product (TCBQ) is an artifact of extraction and analytical methods and that the principal product is the ether 2,3,4,5,6-pentachloro-4-pentachlorophenoxy-2,5-cyclohexadienone formed by pentachlorophenoxyl radical coupling. This suggested a common mechanism for HRP–H_2O_2 mediated oxidation of a CP involving bimolecular radical coupling for 1,4-BQ formation. It also suggested the possibility that lowering the concentration of the CP to retard radical coupling would favour C-8-dG O adduct formation for **2**–**4**. Thus, the CP–dG reactions were repeated at 10 µmol/L CP and now all three CPs (**2**–**4**) generated the anticipated C-8–dG O adduct as the major lesion; for **3** the O adduct was the only observable adduct, while **2** and **4** still formed detectable levels of BQ adduct (25).

To determine whether a C-8–dG O adduct forms with a duplex DNA substrate, calf thymus DNA (1 mg/mL) was treated with PCP (100 µmol/L) in phosphate buffer (100 mmol/L, pH 7.4) at 37 °C for 24 h in the presence of HRP (Type VI, 25 units/mL) – H_2O_2 (1 mmol/L) (25). The reacted DNA was precipitated, enzymatically digested, and analyzed by LC–MS using an authentic sample of **5** for comparison. These studies showed that the major DNA le-

© 2005 NRC Canada

Scheme 2.

sion formed from PCP activation by HRP–H_2O_2 had an HPLC retention time, MS–MS fragmentation, and a parent ion identical to those of the authentic adduct standard **5**. This implied that the pentachlorophenoxyl radical reacted with the duplex DNA substrate to form the O bonded C-8 adduct **5** highlighting the in vitro relevance of C-8–dG adducts of phenolic toxins.

The results from these studies on CP-mediated DNA adduction by peroxidase activation allowed us to propose the mechanism summarized in Scheme 2. The reaction is initiated by the production of the chlorophenoxyl radical that may either react directly with dG to furnish the C-8–dG O adduct in an irreversible process (Path A) or self-couple to yield the 1,4-BQ electrophile that reacts with dG to give 4″-hydroxy-1,N^2-benzetheno-dG (Path B). Formation of the benzetheno–dG adduct in Path B may involve initial Schiff base formation from the exocyclic N-2 atom of dG and the carbonyl carbon of the BQ and subsequent nucleophilic attack of the endocyclic N-1 on the vinyl carbon. An alternative pathway, as originally proposed by Jowa et al. (32), would involve initial reaction of N-2 at the vinyl carbon of BQ followed by N-1 attachment to the carbonyl carbon atom to yield 3″-hydroxy-1,N^2-benzetheno-dG. However, the ^{1}H NMR chemical shifts and reaction chemistry for this family of cyclic adducts favour 4″-hydroxy-1,N^2-benzetheno-dG adduct assignment (25).

Differences in CP reactivity may be ascribed to differences in rate constant for the phenoxyl radical bimolecular self-reaction (Path B in Scheme 2). If the bimolecular self-reaction is favourable, then Path B competes effectively with Path A at 100 μmol/L CP substrate, while if the self-reaction is not favourable, then Path A dominates. Increased Cl substitution would be expected to inhibit the bimolecular self-reaction because of steric and (or) electronic repulsion. In this regard, the bimolecular self-reaction rate constant for the phenoxyl radical in H_2O is 2.6×10^9 $(mol/L)^{-1}$ s^{-1} (33) and it has a half-life of ~60 μs in CCl_4 (34). In contrast, the pentachlorophenoxyl radical has a half-life of 30–45 min in aqueous buffer, as determined from direct detection by EPR spectroscopy (28). Clearly Cl substitution increases phenoxyl radical lifetime and this factor would be expected to contribute to phenoxyl radical reactivity in a biological system by enabling the radical time to diffuse away from its site of formation and react with biopolymers.

Ochratoxin A (OTA) — C adduct formation

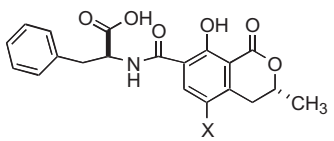
Ochratoxin A (OTA, **6**) is a mycotoxin produced by several species of *Aspergillus* and *Penicillium* fungi that structurally consists of a *para*-chlorophenolic group containing a dihydroisocoumarin moiety that is amide linked to L-phenylalanine (35). The growth of OTA-producing molds is not readily controlled in stored animal and human foods (36). The toxic effects of OTA include carcinogenicity, mutagenicity, and nephrotoxicity (35). Dietary feeding of OTA induces renal adenomas and carcinomas in male mice and rats (37), and for this reason, it has been classified as group 2B (possible carcinogenic to humans) by the International Agency for Research on Cancer (IARC) (38). The toxin is widespread in temperate areas such as Canada, Denmark, Norway, Germany, Sweden, and the United Kingdom (39). In North America, blood plasma samples collected from volunteers in 16 locations across Canada showed a range of 0.29–2.37 ng/mL with the highest mean concentration in Winnipeg, Manitoba (40). Canadian cancer statistics (2004) estimate 4300 new cases of kidney cancer in Canadians with prevalence in the male population (61%). The highest incidence rate of kidney cancer in males occurs in Manitoba, which correlates with individuals from Manitoba having the highest blood plasma levels of OTA (40). Given

© 2005 NRC Canada

that OTA is an established kidney carcinogen in male rodents (37), OTA may be a cause of kidney cancer in Canadian men.

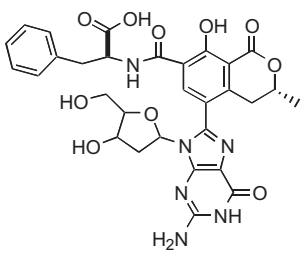
In Europe, OTA is implicated in a fatal kidney disease called Balkan endemic nephropathy (BEN) (41). BEN is a chronic tubulointerstitial nephropathy described in several rural regions of Bulgaria, Romania, and the former Yugoslavia. Of particular interest are the upper urinary tract tumors (UTT) seen in BEN patients at frequencies much higher than in individuals not suffering from the disease (41). A study of UTT in areas with BEN has demonstrated a direct correlation with OTA exposure (42). The UTT DNAs were studied by the ^{32}P postlabeling method for the presence of OTA-DNA adducts and identified for the first time were OTA-DNA adducts for UTT in patients with BEN that were absent in control tissues. This study provided impetus for the view that OTA-DNA adducts lead to UTT in patients suffering from BEN (42).

One hypothesis for the carcinogenicity of OTA is based on the toxin's genotoxic properties that follow from its biotransformation via an oxidative pathway (43). Because ^{32}P postlabeling studies have suggested a preference for OTA to specifically react with dG (44), we sought to characterize the OTA–dG covalent interaction (11). Initial efforts utilized the photochemistry of OTA to activate the toxin for reaction of dG. Photoirradiation of an OTA (100 μmol/L) – dG (50 mol equiv.) mixture for 2 min in 100 mmol/L phosphate buffer (pH 7.4) generated three major products, as evidenced by electrospray mass spectrometry (ES^-). Two of the products were assigned to the hydroquinone of OTA (OTHQ (**7**), $[M - H]^- = 384$) and the nonchlorinated analogue OTB (**8**) ($[M - H]^- = 368$). The third product also lacked the chlorine isotope pattern of OTA and had a parent ion at $[M - H]^- = 633$. Its MS–MS spectrum exhibited a prominent ion at *m/z* 517 (-deoxyribose (dR)) that was accompanied by ions at *m/z* 473 ($[M - dR - CO_2 - H]^-$) and 429 ($[M - dR - 2CO_2 - H]^-$), suggesting covalent attachment of dG to OTA with loss of HCl (i.e., OTA(403) – Cl(35) + dG(267) – H = 634) (11).



Isolation of the adduct with $[M - H]^- = 633$ and identification by two-dimensional NMR spectroscopy established the adduct structure as the C bonded C-8–dG adduct, OTA–dG (**9**). With the authentic sample of **9** in hand, it was then demonstrated that the same adduct could be formed by treatment of OTA–dG with redox-active transition metals (Fe and Cu) or HRP–H_2O_2 (11).

In collaboration with Dr. Annie Pfohl-Leszkowicz (Toulouse, France) we employed OTA–dG–3′-monophosphate (MP) as a cochromatographic standard for ^{32}P postlabeling studies and demonstrated that OTA–dG co-migrates with the major DNA lesion detected in diseased kidney tissue of rat and with one of four adducts detected in the kidney of the pig (13). The co-migration of OTA–dG with a spot observed by ^{32}P postlabeling emphasizes the biological significance of this compound.



Ambident reactivity of phenols in C-8–dG adduct formation

The isolation and identification of OTA–dG suggested involvement of the OTA phenoxyl radical in covalent bond formation. The toxin undergoes a 1 e oxidative process at ~0.8 V vs. the saturated calomel electrode (SCE) to form the phenoxyl radical (45), and structure–activity relationships implicate the OTA phenoxyl radical in OTA-mediated DNA damage (46). However, unlike CP toxins that favour O adduct formation at C-8–dG (12, 25), OTA favours C adduct formation (11). For OTA, O attachment must be disfavored due to steric (flanking carbonyl moieties) or electronic (delocalization of the OTA phenoxyl radical) factors. Binding of the phenolic O site to a transition metal would also be expected to preclude O attachment. In this regard, Ni(salens) that form phenoxyl radicals upon oxidation are reported to act like OTA and favour C adduct formation at the C-8 site of dG (47). For the amino acid tyrosine, theoretical calculations on DNA adduction by the tyrosyl radical predict ortho C adduct formation because delocalization of the radical favours C attachment and the para position is blocked (48).

In Scheme 3, pathways for ambident reactivity of *para*-chlorophenolic radicals at C-8 of dG are depicted. The O site of the phenolic radical (generated by peroxidase–H_2O_2) is shown reacting at C-8 to yield the N radical intermediate with the sp^3-bound C-8 atom; H atom abstraction (by a phenolic radical) would furnish the O adduct, i.e., **5**. In contrast, C attack would generate the corresponding quinoidal intermediate; homolytic loss of HCl would furnish the O radical that would require an H atom to give the C adduct, i.e., **9**. In the absence of steric factors, the electronic properties of the phenolic radical would be expected to dictate O vs. C adduct formation. Extensive radical delocalization would favour C adduct formation, while O attachment would be favoured for phenoxyl radicals with the unpaired electron localized on the oxygen atom. In this regard, it has been observed that remote substituent effects of phenoxyl radicals exhibit a linear correlation with Brown σ^+ constants because of the through-resonance between the electron-deficient phenoxyl radical and the ring substituent (15, 33). Table 1 gives pK_a values, standard reduction potentials (E°_{red}) for the phenoxyl radical / phenolate ion couples at pH 12, and σ^+ values that are available in the literature for CP substrates, phenol (PhOH), 4-MePhOH, and 4-MeOPhOH (33). A high value of σ^+ suggests that the radical is localized on the oxygen atom, while the negative value for 4-MeOPhOH (–0.78) suggests extensive radical stabilization by the 4-MeO substituent. Not surprisingly, the fully substituted analog PCP has the highest σ^+ value (1.1) and is predicted to be the most reactive O centered radical followed by **3** ($\sigma^+ = 0.61$), **2** ($\sigma^+ = 0.3$), and **4** ($\sigma^+ = 0.21$). Our data shows that the larger value of σ^+ for a CP gives a greater proportion of C-8–dG O adduct. In contrast, tyrosine would have a σ^+ value similar to 4-MePhOH (–0.31), which suggests extensive radical delocalization and is thus predicted to favour C adduct formation.

Conclusions

The studies previously discussed demonstrate the ability of phenoxyl radicals to react directly with DNA to yield C-8–dG O or C adducts, as a consequence of the ambident electrophilicity of phenoxyl radicals. Our work provides the first in vitro evidence for C-8–dG O adducts of phenolic toxins by demonstrating that PCP reacts directly with calf thymus DNA to give the O adduct **5** following activation by HRP–H_2O_2. For the natural product OTA, we have isolated and identified the C adduct **9** as the primary OTA–DNA adduct and ^{32}P postlabeling studies support its formation in kidney DNA isolated from pig and rat. Overall, these studies strengthen the hypothesis that direct reactions of phenoxyl radicals with DNA contribute to peroxidase driven toxic effects of phenolic xenobiotics. That physical organic studies have provided σ^+ constants for a wide range of phenols suggests the ability to develop quantitative structure–activity relations (QSAR) for DNA adduction by phenolic xenobiotics. It will be interesting to extend our current work and include a greater range of phenols to determine whether σ^+ values can predict C vs. O adduct formation and pro-oxidant vs. antioxidant behaviour. Current efforts are also focused on the chemical syntheses of C-8–dG adducts (O and C adducts) for site-specific incorporation into duplex DNA for biophysical measurements, NMR structural analysis, and biological testing.

Acceleration of the methanolysis of phosphate diesters promoted by $La(OTf)_3$ — The analysis of non-integer $^{s}_{s}$pH/rate profiles resulting from changes in metal ion speciation[1]

Graham T.T. Gibson, Alexei A. Neverov, Allen Chun-Tien Teng, and R.S. Brown

Abstract: In a previous publication (A.A. Neverov and R.S. Brown. Inorg. Chem. **40**, 3588 (2001)) we reported very effective catalysis of the methanolysis of some phosphate diesters (methyl *p*-nitrophenyl phosphate (**1**), bis(*p*-nitrophenyl) phosphate (**2**), and diphenyl phosphate (**3**)) promoted by La^{3+}, and noted a general observation that the plots of $\log k_{cat}$ vs. $^{s}_{s}$pH had non-integer gradients. In this report the origins of that behaviour are studied and analyzed through determination of the speciation of $La^{3+}(^{-}OCH_3)_n$, $(La^{3+})_2(^{-}OCH_3)_m$, $(La^{3+})_2$:phosphate:$(^{-}OCH_3)_y$ forms in solution as a function of $^{s}_{s}$pH. Potentiometric titrations of solutions of $La(OTf)_3$ in methanol at low ($<1 \times 10^{-4}$ mol/L) and high ($>1 \times 10^{-3}$ mol/L) concentration were analyzed through fits of the data to various models to provide speciation diagrams of the various La^{3+} forms in the absence of phosphate. Titrations of La^{3+} in the presence of diphenyl phosphate were also analyzed to provide speciation diagrams for phosphate bound forms. The kinetic data for the La^{3+} catalyzed methanolysis of **1** were analyzed through fitting the kinetic data at low and high $[La^{3+}]$ as a function of $^{s}_{s}$pH to a linear combination of the individual kinetic contributions of each species. Overall the data are best analyzed in the low $[La^{3+}]$ domain as resulting from methoxide attack on a transient complex of phosphate bound to $La^{3+}(^{-}OCH_3)_{0,1}$. In the high $[La^{3+}]$ domain the data fit two kinetically equivalent processes involving either a spontaneous decomposition of $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_{2,3,4,5}$ or external methoxide attack on $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_{1,2,3,4}$.

Key words: lanthanides, phosphate diester, methanolysis, kinetics, speciation, metal ion catalysis of methanolysis, DNA model methanolysis.

Résumé : Dans une publication antérieure (A.A. Neverov et R.S. Brown. Inorg. Chem. **40**, 3588 (2001)), nous avons rapporté une catalyse très efficace de la méthanolyse de quelques esters de l'acide phosphorique (phosphate de méthyle et de *p*-nitrophényle (**1**), phosphate de bis(*p*-nitrophényle) (**2**) et phosphate de diphényle (**3**)) sous l'influence du La^{3+} et nous avons noté que les gradients des courbes du $\log k_{cat}$ vs. $^{s}_{s}$pH n'étaient pas des nombres entiers. Dans ce travail, nous avons étudié ce comportement et l'avons analysé par une détermination de la spéciation des formes $La^{3+}(^{-}OCH_3)_n$, $(La^{3+})_2(^{-}OCH_3)_m$ et $(La^{3+})_2$:phosphate:$(^{-}OCH_3)_y$ en solution en fonction du $^{s}_{s}$pH. Afin de pouvoir obtenir des diagrammes de spéciation des diverses formes de La^{3+} en l'absence de phosphate, nous avons analysé les résultats de titrages potentiométriques de solutions de $La(OTf)_3$ dans le méthanol, à des concentrations basses ($<1 \times 10^{-4}$ mol/L) et élevées ($>1 \times 10^{-3}$ mol/L), en procédant à divers ajustements des données à divers modèles. Afin d'obtenir des diagrammes de spéciation des formes liées du phosphate, nous avons aussi analysé les données des titrages du La^{3+} en présence de phosphate de diphényle. Les données cinétiques pour la méthanolyse du **1** catalysée par le La^{3+} ont été analysées par le biais d'un ajustement des données à des concentrations faibles et élevées de La^{3+} en fonction de $^{s}_{s}$pH afin d'obtenir une combinaison linéaire des contributions cinétiques individuelles de chaque espèce. Dans l'ensemble, la meilleure façon d'expliquer les données dans le domaine de faible concentration de La^{3+} implique une attaque du méthanolate sur un phosphate intermédiaire lié à un $La^{3+}(^{-}OCH_3)_{0,1}$. Dans le domaine de concentration élevée de La^{3+}, les données peuvent être expliquées par deux processus cinétiquement équivalents impliquant soit une décomposition spontanée d'un complexe $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_{2,3,4,5}$ ou une attaque externe d'un méthanolate sur un complexe $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_{1,2,3,4}$.

Mots clés : lanthanides, diester de l'acide phosphorique, méthanolyse, cinétique, spéciation, catalyse par un ion métallique d'une méthanolyse, méthanolyse modèle de l'ADN.

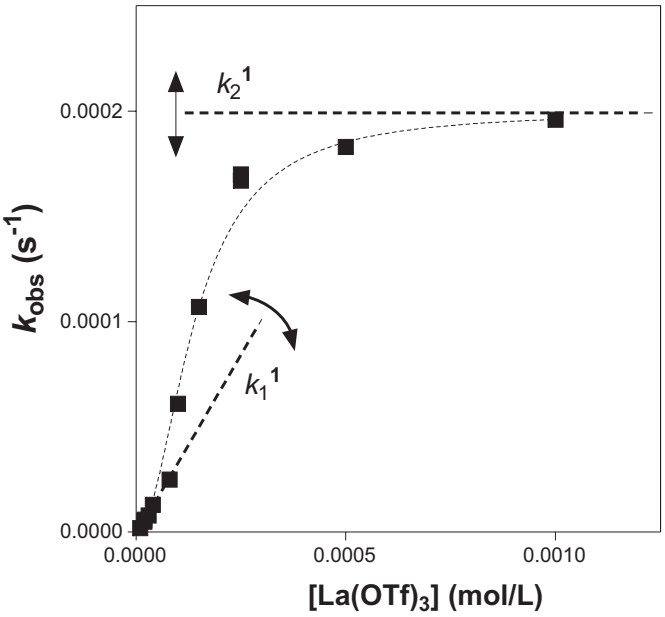
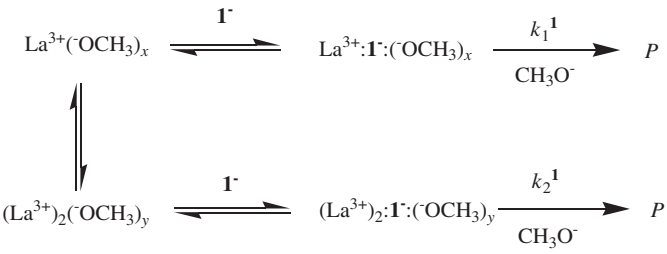
Introduction

Various studies from these labs have shown that La^{3+}, along with 1 equiv. of methoxide in methanol, is an extraordinarily active catalyst for the methanolysis of carboxylate esters (1), β-lactams (2), and a variety of phosphates and thiophosphates including phosphate di- and triesters (3). The phosphate diester linkage is biologically important because it is ideal for preserving genetic information in RNA and DNA because of its kinetic robustness toward hydrolysis. To facilitate what is otherwise a very slow hydrolytic process, Nature provides various metallo-enzymes (4) such as the RNAse from HIV reverse transcriptase (4*a*), 3′–5′ exonuclease from DNA polymerase I (4*b*), and P1 nuclease (4*c*) to cleave phosphate diesters so it is not surprising that a large number of studies have been reported concerning metal-ion-promoted hydrolysis of $(RO)(R'O)PO_2^-$ species (5).



1 $R_2O = OCH_3$, $R_1O = OC_6H_4NO_2$
2 $R_2O = R_1O = OC_6H_4NO_2$
3 $R_2O = R_1O = OC_6H_5$



4

Interestingly, metal-catalyzed alcoholysis of phosphate diesters is, to our knowledge, a scarcely investigated area although our own studies (3*a*) showed that the methanolyses of methyl *p*-nitrophenyl phosphate (**1**), bis(*p*-nitrophenyl) phosphate (**2**), and diphenyl phosphate (**3**) were accelerated by as much as 10^{10}-fold in the presence of La^{3+} compared to the background methoxide promoted reaction. Unfortunately, a comprehensive mathematical fit of the kinetic behaviour to a given mechanism that included all the species responsible for catalysis as a function of $^{s}_{s}$pH was not possible due to the complexity of the situation as revealed from kinetic plots of the observed pseudo-first-order rate constant (k_{obs}) for the methanolysis of **1** as a function of $[La^{3+}]$ at various $^{s}_{s}$pH values. Typically, the plots show (3*a*) two $^{s}_{s}$pH-dependent domains of interest, which are illustrated schematically in Fig. 1 (see Figs. 1S and 2S, Supplementary material, for the appearance of these plots at two different $^{s}_{s}$pH values).[3] On the basis of these plots, we rationalized the kinetic behaviour in terms of the simplified process given in Scheme 1, where monomeric and dimeric forms of La^{3+} associated with variable numbers of methoxides in a $^{s}_{s}$pH-dependent way were responsible for the catalysis.

Fig. 1. Plot of pseudo-first-order rate constants for the methanolysis of **1** (2×10^{-5} mol/L) vs. $[La(OTf)_3]$ at 25 °C; $^{s}_{s}$pH = 11.1 (0.02 mol/L triethylamine buffer). Based on data from ref. 3*a*. The values of $k_2^{\mathbf{1}}$ and $k_1^{\mathbf{1}}$ are taken as the limiting plateau value and initial gradient of the plots at given $^{s}_{s}$pH values; double-headed arrows show the direction of change of $k_2^{\mathbf{1}}$ and $k_1^{\mathbf{1}}$ as a function of $^{s}_{s}$pH.

Scheme 1.

At limiting low and high $[La^{3+}]$ we could define the $k_1^{\mathbf{1}}$ and $k_2^{\mathbf{1}}$ as the slope and plateau, respectively, of the k_{obs} vs. $[La^{3+}]$ plots at each $^{s}_{s}$pH, the values being reproduced in Table 1S of the Supplemental material.[3] Curiously, neither $k_1^{\mathbf{1}}$ nor $k_2^{\mathbf{1}}$ shows a unit linear dependence on $[^{-}OCH_3]$, the slopes being 0.35 and 0.5, respectively (3*a*): in the case of the $k_1^{\mathbf{1}}$ plot there is a serious downturn at the highest $^{s}_{s}$pH values.

Typically, log plots of rate constant vs. [lyate], [lyoxide], [catalyst], or $[M^{x+}]$ have integer gradients of 0, 1, or 2, which result from rate-limiting processes having zero-, first-, or second-order dependencies on the concentration of the species of interest. In some common cases such kinetic plots exhibit "saturation" behaviour, with a domain of unit slope evolving into a plateau of zero slope at higher concentration indicative of a substrate associated with the catalytic entity in a kinetically competent 1:1 complex. Non-integer kinetic

plots are far less common for ionic reactions[4] (6) although square root dependencies are often observed for reactions catalyzed by metal ions that dimerize to inactive forms such as was found in our recent study of the Zn^{2+} promoted methanolysis of *p*-nitrophenyl acetate and the phosphate triester paraoxon (7), or the Cu^{2+} catalyzed hydrolysis of *p*-nitrophenyl diethyl phosphate (8).

In cases where the speciation of a M^{x+} catalyst changes as a function of its concentration or as a function of pH, one can envision an alteration of the catalytic properties in such a way that the pH / log rate constant profiles can have non-integer gradients or exhibit irregular upward or downward curvature. This phenomenon is probably a general one, the recognition and incorporation of which will prove particularly applicable to studies of mono- and polymetal ion catalysis as a function of pH where the pH / log rate constant profiles do not vary in a regular way (9). Indeed, in a recent analysis of the La^{3+} promoted methanolysis of the β-lactam nitrocefin (**4**) we demonstrated (2) that the nonunit slope for the kinetic data as a function of ${}^{s}_{s}$pH could be accommodated by two kinetically equivalent mechanisms: methoxide attack on $La^{3+}{}_2(\mathbf{4}^-)(^-OCH_3)_n$, n = 0–2, or spontaneous decomposition of the forms $La^{3+}{}_2(\mathbf{4}^-)(^-OCH_3)_n$, n = 1–3.

In this report we analyze the previously obtained rate data for the La^{3+} catalyzed methanolysis of **1** (3*a*) in terms of models involving La^{3+} monomers and dimers with varying numbers of methoxides, the speciation of which depends upon [La^{3+}] concentration and the ${}^{s}_{s}$pH. The speciation of La^{3+} at low (<2 × 10^{-4} mol/L) and high (>1 × 10^{-3} mol/L) metal ion concentrations is computed through analysis of the potentiometric titration data using the program Hyperquad 2000 (10). At high concentrations of metal ion, where the kinetics are suggestive of the formation of $La^{3+}{}_2$ bound phosphate, we have conducted the titrations on solutions of La^{3+} with a fixed 2:1 La^{3+} : diphenyl phosphate ratio, analyzing these to determine the metal ion binding constants and speciation. Finally, we have analyzed the kinetic data in terms of the contributions of the various species present in solution to develop an internally consistent explanation of the shapes of the ${}^{s}_{s}$pH/rate profiles.

Experimental

Materials

Methanol (anhydrous, 99.8%), sodium methoxide (0.5 mol/L in MeOH), lanthanum trifluoromethanesulfonate (99.999%), bis(*p*-nitrophenyl) phosphate (**2**, 99%), and diphenyl phosphate (**3**, 99%) were all purchased from Aldrich and used without any further purification.

${}^{s}_{s}$pH Measurements

The $CH_3OH_2^+$ concentration was determined for kinetic and titration measurements using a Radiometer pHC4000-8 or an Accumet model 13-620-292 combination glass electrode calibrated with Fisher certified standard aqueous buffers (pH = 4.00 and 10.00) as described in our recent papers (11). Values of ${}^{s}_{s}$pH were calculated by subtracting a correction constant of –2.24 from the experimental meter reading (${}^{s}_{w}$pH). This method was described by Bates and co-workers (12*b*, 12*c*) for a molality scale (correction constant –2.34) and later by Bosch and co-workers (13) for a molar correction constant of –2.24 units.

${}^{s}_{s}p\mathit{K}_a$ Determination

The potentiometric titrations of $La(OTf)_3$ and diphenyl phosphate in methanol were performed using a Metrohm model 798 Titrino automatic titrator under anaerobic conditions (Ar) at 25.0 ± 0.1 °C. Methanolic $La(OTf)_3$ and diphenyl phosphate stock solutions (0.02 or 0.002 mol/L) were diluted to the required concentrations by adding anhydrous methanol. The total sample volume in all cases was 20.0 mL. Sodium methoxide titrant, prepared from stock 0.5 mol/L $NaOCH_3$ in a Sure Seal® bottle, was 0.021 or 0.0028 mol/L and was calibrated by titrating Fisher certified standard HCl in water, with the endpoint taken to be ${}^{w}_{w}$pH 7. After each titration the electrode was immersed in pH 4.00 aqueous buffer or a dilute aq. HCl solution for several minutes. The electrode was then rinsed with MeOH, dried with a tissue, and used for the next titration. The electrode was recalibrated often to ensure accurate readings.

The values of the species formation constants in methanol were calculated using the computer program Hyperquad 2000 (version 2.1 NT) (10), with the autoprotolysis constant of pure methanol taken to be $10^{-16.77}$ (13) at 25 °C. The formation constants for the species $La^{3+}{}_2(^-OMe)_n$ (n = 1–5) were determined from the analysis of the potentiometric titration of 1 × 10^{-3} mol/L $La(OTf)_3$. Two such titrations were analyzed separately and their respective species formation constants averaged; the resulting values were used as constants in the subsequent Hyperquad analysis of 2:1 $La(OTf)_3$:phosphate titrations. Similarly, formation constants for the species $La^{3+}(^-OMe)_n$ (n = 1–3) were determined from the analysis of the titration of 1 × 10^{-4} mol/L $La(OTf)_3$. Because the methanolysis of phosphates **1** and **2** in the presence of $La(OTf)_3$ is too fast to perform the titrations of these, **3** was used as a model for all three phosphates studied in the kinetics. The ${}^{s}_{s}p\mathit{K}_a$ of **3** was determined to be 3.47 ± 0.01 from the average result of the Hyperquad analysis of three separate titrations of 1 × 10^{-3} mol/L **3**, and this value was used in subsequent analyses as a constant. The formation constant for the species $La^{3+}{}_2$:$\mathbf{3}^-$, as a model for the species $La^{3+}{}_2$:$\mathbf{1}^-$, was computed from fitting as were other formation constants for species present in a solution of 2:1 La^{3+}:diphenyl phosphate.

Kinetic measurements

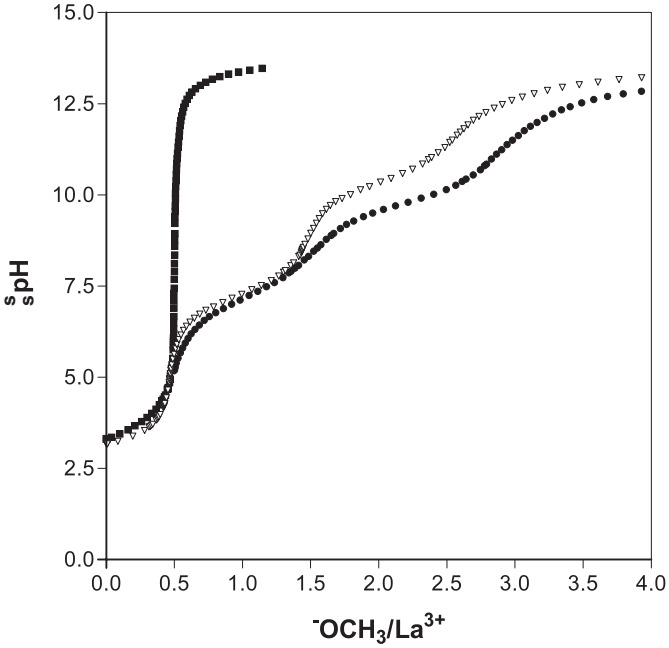
The rate of appearance of *p*-nitrophenol accompanying the methanolysis of **2** was followed by monitoring the increase in absorbance of buffered methanol solutions at 311 nm and 25.0 ± 0.1 °C with a Varian Cary 100 Bio UV–vis spectrophotometer. Its extinction coefficient at 311 nm was determined to be 10 878 ± 479 $(mol/L)^{-1}$ cm^{-1} by averaging the slopes of 17 independent plots of Abs. vs. added [*p*-nitrophenol] over 5 × 10^{-5} mol/L < [La^{3+}] < 1 × 10^{-3} mol/L and 2.5 × 10^{-5} mol/L < [*p*-nitrophenol] < 2.25 × 10^{-4} mol/L. Due to the slow rate of reaction at low [La^{3+}], all reactions

[4] Of course, the kinetics of free-radical-initiated chain reactions such as $H_2 + Br_2 \rightarrow 2HBr$, where the first step requires a dissociation of the Br_2 into 2Br radicals, are well-known to follow a square root dependence in [Br_2] (for a discussion of this mechanism see ref. 6).

© 2005 NRC Canada

in this study were followed to 10% completion and k_{obs} was determined in triplicate using the initial rates method. All reactions were performed at $^{s}_{s}$pH 9.21 ± 0.10 (measured after the kinetic run) using a methanol buffer solution of 1.75 × 10^{-2} mol/L *N*-ethylmorpholine ($^{s}_{s}pK_a$ = 8.60 (measured by half neutralization (3*a*)) partially neutralized with 70% $HClO_4$ (BDH). The solutions prepared in this way contain a small, but kinetically insignificant quantity (<0.1%) of water stemming from that present in the MeOH and what is derived from buffer neutralization. To avoid any chloride ion contamination from the glass electrode that might affect the metal ion reactions, the $^{s}_{s}$pH of the reaction solutions was always determined after kinetic measurements.

To investigate whether the kinetics in the low [La^{3+}] domain result from a 1:1 or a 2:2 La^{3+}:**2**$^{-}$ complex at a given $^{s}_{s}$pH (9.21), it was first necessary to establish the point of transition between the ascending and descending wings of the k_{obs} vs. [La^{3+}] plot (see Fig. 1S, Supplemental information).[3] This kinetic experiment was done using [**2**] = 5 × 10^{-5} mol/L and varying [La^{3+}] between 2.5 × 10^{-5} and 4 × 10^{-3} mol/L; the point of transition was determined to occur at 2 × 10^{-4} mol/L [La^{3+}]. To determine if the kinetically active species was a monomeric 1:1 La^{3+}:phosphate complex or a dimeric 2:2 La^{3+}:phosphate complex, [La^{3+}] and [total phosphate] were varied together such that [total phosphate] = [La^{3+}] = 2 × 10^{-4} to 1.2 × 10^{-3} mol/L. Phosphate **2** had poor solubility in the presence of La^{3+} at concentrations higher than 3 × 10^{-4} mol/L, and so its concentration was held constant at 2 × 10^{-4} mol/L in each case, and the far more soluble phosphate **3** was used make up the [total phosphate] throughout the rest of the concentration range.[5]



Electrospray MS

Mass spectra were determined in methanol using a Waters/Micromass ZQ (Manchester, UK) single quadrupole mass spectrometer equipped with an electospray source operating at cone voltages between 30 and 70 V. The solutions contained [**3**] = 2 × 10^{-4} mol/L, along with equimolar $La(OTf)_3$ and 4 × 10^{-4} mol/L Bu_4NOCH_3, the latter to create **3**$^{-}$ and add 1 equiv. of methoxide to the metal ion. Samples were infused at a flow rate of 10 μL/min; the spectrometer was externally calibrated and run in positive mode.

Results and discussion

The methodology for fitting the kinetic data as a function of varying [La^{3+}] and $^{s}_{s}$pH involves analyzing the speciation of the metal ion alone at low and high concentrations as a function of $^{s}_{s}$pH and then determining the speciation of the phosphate bound forms of the metal ion. All these data can be gleaned from potentiometric titrations under the appropriate conditions. Following analysis of the speciation, one can then fit the kinetic data (Table 1S, Supplemental material)[3] pertaining to k_1**[1]** (the second-order rate constant for La^{3+} promoted methanolysis of **1** at low [La^{3+}] as a function of $^{s}_{s}$pH) and k_2**[1]** (the plateaued pseudo-first-order rate constant for (La^{3+})$_2$:**1**$^{-}$ methanolysis as a function of $^{s}_{s}$pH) as a linear combination of the contribution of various kinetically active species.

Fig. 2. Potentiometric titration data for 0.001 mol/L $La(OTf)_3$ (●), 0.001 mol/L diphenyl phosphate (■), and a mixture of 0.001 mol/L $La(OTf)_3$ and 0.0005 mol/L diphenyl phosphate (▽) determined in methanol at 25 °C.

Titration analysis

High [La^{3+}] domain (>10^{-3} mol/L)

In the high [La^{3+}] domain of the k_{obs} vs. [La^{3+}] plots for methanolysis of **1** at each $^{s}_{s}$pH the saturation signifies that the active species comprise two metal ions and one phosphate substrate, the latter most likely bridging the two La^{3+} ions to employ double activation (3*a*, 3*b*). Depending on the $^{s}_{s}$pH, the active (La^{3+})$_2$:**1**$^{-}$ species are also proposed to contain a variable number of methoxides from zero to five (3*a*). The six (La^{3+})$_2$:**1**$^{-}$:($^{-}OCH_3$)$_{0-5}$ forms serve as a starting model to fit the potentiometric titration data for 2:1 La^{2+}:phosphate in methanol at 1 × 10^{-3} mol/L La^{3+}, a concentration within the k_2**[1]** domain. Since **1** is too reactive to survive titration in the presence of La^{3+}, the less reactive phosphate **3** was used in the present study as a structural model. While we recognize that the substitution of **3** for **1** might alter the phosphate binding constants and all formation constants for the associated methoxide containing species, the structural variations should not seriously alter the overall conclusions concerning stoichiometry and formation constants. The titration data for representative titrations of (La^{3+})$_2$:**3**$^{-}$, as well as La^{3+} alone and **3** alone for comparison are illustrated in Fig. 2. The formation constants for the background unbound (La^{3+})$_2$ with one to five methoxides were established first by Hyperquad fitting of a (La^{3+})$_2$($^{-}OCH_3$)$_{1-5}$ model to the titration data for 1 × 10^{-3} mol/L $La(OTf)_3$ in

[5] In previous work (ref. 3*b*) we showed that the effect of a second phosphate diester was to act as a bridge between the two La^{3+} ions to facilitate formation of catalytically active dimers, and that a nonreactive or less-reactive phosphate diester can be used to structurally maximize the formation of active (La^{3+})(reactive phosphate)(surrogate phosphate) dimers.

methanol. In Table 1 are presented the average of the log formation constants (log β or $\log {}^{s}_{s}K$) for three separate determinations that were used as constants for all subsequent analyses of the titrations in the presence of **3**. The ${}^{s}_{s}pK_a$ of **3** (3.47 ± 0.01) was also used as an experimentally determined constant, and the autoprotolysis constant for pure methanol ($10^{-16.77}$) (13) was included as the last constant for the fits. Table 1 shows the results for the formation constants of all the species used as the model in the Hyperquad fitting. The concentrations of the various $(La^{3+})_2$:**1**$^-$:$(^-OCH_3)_{0-5}$ species were subsequently computed as a function of ${}^{s}_{s}pH$ from these formation constants using HySS, another program in the Hyperquad 2000 suite. The speciation diagram shown in Fig. 3 was constructed using conditions relevant to the kinetics where [La^{3+}] = 2×10^{-3} mol/L and [**3**] = 2×10^{-5} mol/L. Also superimposed on Fig. 3 are the kinetic data for k_2**1** in units of s^{-1} from Table 1S[3] (3*a*) as a function of ${}^{s}_{s}pH$ to indicate possible species that may contribute to the rate constant. From the appearance of the latter plot, it is clear that no single species is responsible for the kinetic behaviour, and thus a more detailed analysis is required.

Low [La^{3+}] domain (<2 × 10^{-4} mol/L)

Due to the fact that the overall behaviour is a composite of two independent pathways, we analyze the k_{obs} vs. [La^{3+}] data at the limits of two concentration domains. In the low [La^{3+}] domain, the k_{obs} vs. [La^{3+}] plots for the La^{3+} catalyzed methanolysis of **1** show a linear increase corresponding to an apparent second-order process, with the gradient taken to be k_1**1** in units of $(mol/L)^{-1}\ s^{-1}$. The active form is believed to be a transiently formed La^{3+} bound phosphate, formulated preliminarily as La^{3+}:**1**$^-$:$(^-OCH_3)_n$, where the number of methoxides is zero to two depending on the ${}^{s}_{s}pH$. Since not all the substrate is bound in this region, the apparent second-order kinetics could also be accommodated by the process depicted in eq. [1], where k_1**1** = k_{cat}/K_B ($(mol/L)^{-1}\ s^{-1}$), where k_{cat} refers either to the spontaneous decomposition of La^{3+}:**1**$^-$:$(^-OCH_3)_n$ or to the second-order rate constant for the attack of external methoxide on La^{3+}:**1**$^-$:$(^-OCH_3)_{n-1}$.

Fig. 3. Speciation diagram for La^{3+}_2:**1**$^-$:$(^-OCH_3)_n$ forms as a function of ${}^{s}_{s}pH$ computed from the formation constants given in Table 1 for the titration of diphenyl phosphate (2×10^{-5} mol/L) and 2×10^{-3} mol/L La^{3+}. Captions of 2:1:*n* refer to La^{3+}_2:**1**$^-$:$(^-OCH_3)_n$ forms with a variable number of methoxides, (— — —) La^{3+}_2:**1**$^-$:$(^-OCH_3)_1$, (- - - - -) La^{3+}_2:**1**$^-$:$(^-OCH_3)_3$, (—·—·) La^{3+}_2:**1**$^-$:$(^-OCH_3)_4$. Data superimposed on the figure as (■) are first-order rate constants (k_2) for the La^{3+} catalyzed methanolysis of methyl (4-nitrophenyl) phosphate (**1**) from ref. 3*a*.

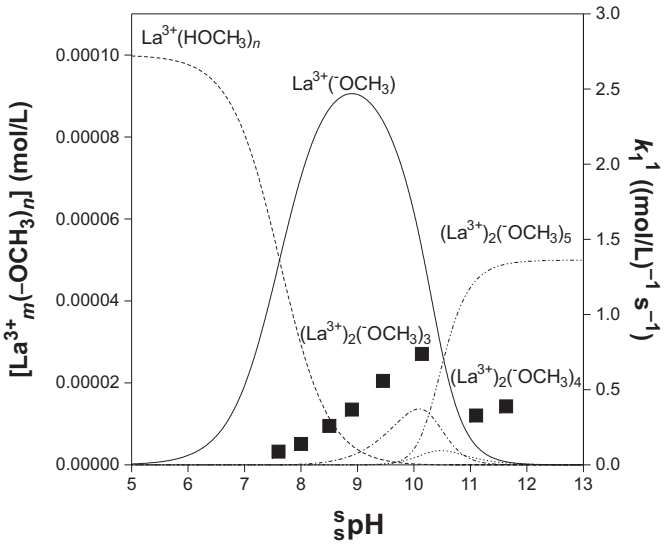
phosphate bridged dimer formulated as $(La^{3+})_2$:(phosphate^{-})$_2$:$(^{-}OCH_3)_m$ as was determined to be the case in the La^{3+} promoted methanolysis of 2-hydroxypropyl *p*-nitrophenyl phosphate (3*b*). To cast light on this question, two independent sets of experiments were performed. In the first, the electrospray mass spectrum of a methanol solution containing 2×10^{-4} mol/L of both $La^{3+}(^{-}OTf)_3$ and phosphate diester **3** (chosen because it is kinetically stable during the experimental measurement while **1** is not) displayed masses at *m*/*z* 419.12 and 451.15 indicative of La^{3+}:**3**$^{-}$:$(^{-}OCH_3)(HOCH_3)_{0,1}$, but no masses indicative of any dimeric forms. In the second set of experiments, the kinetics for methanolysis of **2** in the presence of equimolar La^{3+} were determined at an initial concentration corresponding to the point of transition (2×10^{-4} mol/L) between the low and high $[La^{3+}]$ domains observed in the k_{obs} vs. $[La^{3+}]$ plot for the methanolysis of **2**. This same trend and point of transition was previously observed in the methanolysis of **1** ((3*a*), see Fig. 1S, Supplemental material).[3] The kinetics of the methanolysis of **2** were then determined as a function of varying $[La^{3+}]$ concentration, but maintaining the $[La^{3+}]$:$[phosphate]_{total}$ ratio at 1.0. Under these conditions, one anticipates shifting a putative 2(La^{3+}:phosphate) $\rightleftharpoons$ (La^{3+}:phosphate)$_2$ equilibrium to the right so that if the dimeric species is active, an increase in observed rate constant, with possible saturation, will accompany the increase in [La^{3+}:phosphate]. This phenomenon was previously observed with the La^{3+} : 2-hydroxypropyl *p*-nitrophenyl phosphate system (3*b*). Above a concentration of 2×10^{-4} mol/L, the complex of phosphate **2** is poorly soluble in this medium so the additional phosphate concentration was made up with the more soluble **3**, but this change will not alter significantly the kinetic result since the observed reaction concerns the decomposition of **2** (2). The k_{obs} for methanolysis of **2** determined under these conditions is invariant to increasing $[La^{3+}]$ within experimental error ($k_{obs} = (2.43 \pm 0.12) \times 10^{-4}$ s^{-1}, Table 2S, Supplemental material)[3] as expected if the reactive species is the monomeric form La^{3+}:**2**: $(^{-}OCH_3)_n$.

Having established that La^{3+} monomers are active in the low $[La^{3+}]$ domain, we turned our attention to the analysis of the titration data in this concentration range. Shown in Fig. 3S, Supplementary material[3] is the titration curve for a 1×10^{-4} mol/L solution of $La(OTf)_3$ in methanol. The general appearance of this curve is quite different from the profile obtained at 1×10^{-3} mol/L (see Fig. 2) in that the first consumption of methoxide follows a regular titration profile consuming 1 equiv. of methoxide per La^{3+} followed by a much steeper profile for the consumption of additional methoxides. The steeper profile corresponding to the addition of more than 1 equiv. of $^{-}OCH_3$ per La^{3+} suggests that dimers or higher order aggregates are formed in that region. Therefore, for the low $[La^{3+}]$ titrations we analyzed the data in terms of a model comprising La^{3+}, $La^{3+}(^{-}OCH_3)_{0,1}$, and $(La^{3+})_2(^{-}OCH_3)_{3,4,5}$. The goodness-of-fit of this model to the titration profile up to ${}^{s}_{s}$pH 11 is shown in Fig. 3S,[3] and in Table 2 are presented the computed formation constants for all the species in this model. These were then used to compute the speciation diagram using HySS for the kinetically relevant conditions where $[La^{3+}] = 1 \times 10^{-4}$ mol/L. This speciation diagram is represented in Fig. 4 along with the overlaid kinetic data that refer to $k_1^{\mathbf{1}}$ in (mol/L)$^{-1}$ s^{-1} for the La^{3+} catalyzed methanolysis of **1** as a function of ${}^{s}_{s}$pH.

Kinetic analysis

High [La^{3+}] domain (>10^{-3} mol/L)



The fits of the titration data to the models previously described provide the concentration of all the participating species as a function of ${}^{s}_{s}$pH in the low and high $[La^{3+}]$ domains. In each domain we can fit the observed rate constants ($k_1^{\mathbf{1}}$ or $k_2^{\mathbf{1}}$) at the various ${}^{s}_{s}$pH values for the La^{3+} catalyzed methanolysis of **1** (3*a*) as linear combinations of the contributions of the individual species. For $k_2^{\mathbf{1}}$ vs. ${}^{s}_{s}$pH in the high $[La^{3+}]$ domain, the appropriate linear combination is given as eq. [2], where each of the $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_n$ species contributes its own first-order rate constant ($k_2^{2:\mathbf{1}:n}$) for reaction.

$$[2] \qquad k_2^{\mathbf{1}} = \sum_{n=1}^{5} k_2^{2:\mathbf{1}:n}[(La^{3+})_2:\mathbf{1}^{-}:(^{-}OCH_3)_n]/[\mathbf{1}]_{total}$$

This equation is appropriate for spontaneous breakdown of the substrate-bound species to methanolyzed product via an internal La^{3+} coordinated methoxide mechanism, the transition structure of which is not implied other than it probably contains a dual role for the metal ion as a Lewis acid and deliverer of nucleophilic methoxide. An alternative, and kinetically equivalent, mechanism requires external methoxide attack on the $(La^{3+})_2$:**1**$^{-}$ bound species having one less methoxide than in the internal methoxide model, the appropriate kinetic equation being shown as eq. [3] where

Fig. 4. Speciation diagram for La^{3+} species as a function of $^{s}_{s}$pH computed from the formation constants given in Table 2 for the titration of 1×10^{-4} mol/L La^{3+}. Data superimposed on the figure as (■) are second-order rate constants ($k_1^{\mathbf{1}}$) for the La^{3+} catalyzed methanolysis of methyl (4-nitrophenyl) phosphate (**1**) from ref. 3*a*.

$k'_2{}^{2:\mathbf{1}:n}$ is a second-order rate constant for methoxide attack on each species.

$$[3] \qquad k_2^{\mathbf{1}} = \sum_{n=0}^{4} k'_2{}^{2:\mathbf{1}:n}[(La^{3+})_2:\mathbf{1}^{-}:(^{-}OCH_3)_n][^{-}OCH_3]/[\mathbf{1}]_{total}$$

Given in Table 3 are the rate constants derived from fitting the $k_2^{\mathbf{1}}$ data to eqs. [2] and [3] with the results being displayed in Fig. 5, which includes the individual contributions for all species found to have activity. Their sum generates the overall best fit curve, which is remarkably good given the inherent assumptions of approximating the La^{3+}:**1**$^{-}$ stability constants through the use of **3**. Although the caption for Fig. 5 is specific for the internal methoxide model, the fit is obviously identical for the kinetically equivalent external methoxide model where the $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_n$ species responsible for catalysis have one less associated methoxide than in the internal model. The kinetically active forms for the internal methoxide process are $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_{2,3,4,5}$, while for the external methoxide process, the reaction is computed to proceed via methoxide attack on $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_{1,2,3,4}$.

There is nothing by way of argument that might allow one to prefer one or the other of the described two mechanisms. The computed rate constants for internal methoxide spontaneous decomposition of $(La^{3+})_2$:**1**$^{-}$:$(^{-}OCH_3)_{2,3,4,5}$ are 6.3×10^{-6}, 9.8×10^{-5}, 1.4×10^{-4}, and 1.3×10^{-3} s^{-1}, respectively, consistent with the expectation that the species having the highest basicity for its associated methoxide will react the fastest. For the external methoxide process, the computed second-order rate constants for methoxide on the bound forms with one to four associated methoxides are 1.5×10^4, 3.7×10^2, 2.5×10^2, and 3.3×10^1 $(mol/L)^{-1}$ s^{-1}, respectively, but are well below the limit of ~10^{10} $(mol/L)^{-1}$ s^{-1}, which would be appropriate for a diffusion-limited process involving reaction of an anion and a positively charged species (14). Nevertheless, the rate constants for the external methoxide model are considerably larger than the experimental second-order rate constant for methoxide attack on **1** alone of $(7.9 \pm 0.6) \times 10^{-7}$ $(mol/L)^{-1}$ s^{-1} at 25 °C (3*a*), indicating that complexation of **1** to the $(La^{3+})_2(^{-}OCH_3)_{1,2,3,4}$

Table 3. Computed $k'_2{}^{2:\mathbf{1}:n}$ or $k_2^{2:\mathbf{1}:n}$ rate constants for various species for the La^{3+} catalyzed methanolysis of **1** computed from fits of k_2 vs. $^{s}_{s}$pH data to eq. [2] and [1].

system provides a catalytic enhancement varying from 1.9×10^{10}-fold to 4×10^7-fold, with the least catalysis being observed for methoxide attack on the least positively charged complex.

Low [La^{3+}] domain

As stated previously, in the low [La^{3+}] domain the kinetics are linearly dependent on the metal ion. Thus, the preferred fitting procedure considers that the $k_1^{\mathbf{1}}$ rate constants at each $^{s}_{s}$pH can be described as a linear combination of second-order rate constants (equivalent to k_{cat}/K_B at each $^{s}_{s}$pH) for each of the contributing $(La^{3+})(^{-}OCH_3)_n$ species for the internal methoxide model. For the external methoxide model (eq. [4]), the rate constants are now third-order to accommodate the methoxide concentration that has been factored out.

At low [La^{3+}] the only monomeric species available in solution, as revealed by fits of the potentiometric curve, are $La^{3+}(^{-}OCH_3)_{0,1}$ and it immediately becomes clear that: (1) each species is required to provide a satisfactory fit to the kinetic $k_1^{\mathbf{1}}$ data; and (2) that an additional methoxide is required to explain the activity seen where $La^{3+}(^{-}OCH_3)_1$ is the dominant species to accommodate the increase in rate with $^{s}_{s}$pH. Thus, the internal methoxide mechanism is rendered unlikely because, if operative, the kinetic data would have to track the concentration behaviour of $La^{3+}(^{-}OCH_3)_1$ as a function of $^{s}_{s}$pH, which it does not: correspondingly, the external methoxide mechanism is favoured. Given in Table 4 are the best-fit rate constants from the application of eq. [4], which generate the species contributions to the overall fitted curve presented in Fig. 6 for $k_1^{\mathbf{1}}$ as a function of $^{s}_{s}$pH. The overall fit displayed in Fig. 6, while not as good as obtained for the $k_2^{\mathbf{1}}$ data vs. the $(La^{3+})_2$:$\mathbf{1}^{-}$:$(^{-}OCH_3)_n$ species, is still considered satisfactory in view of the inherent errors in determining the linear region of the k_{obs} vs. $^{s}_{s}$pH profile and the assumed speciation to fit the titration data. The computed constants of 3×10^8 and 5.1×10^6 $(mol/L)^{-2}$ s^{-1} refer to the apparent termolecular processes corresponding to CH_3O^{-} + $\mathbf{1}^{-}$ + $La^{3+}(^{-}OCH_3)_{0,1}$ respectively, the reduction by a factor of ~60-fold in rate constant between the two resulting from Lewis acidity differences attributable to the methoxide content of the respective complexes.

$$[4] \qquad k_1^{\mathbf{1}} = \sum_{n=0}^{1} k_1'^{1:n}[La^{3+}(^{-}OCH_3)_n][^{-}OCH_3]/[La^{3+}]_{total}$$

While the fitting provides the apparent third-order rate constant for the process involving CH_3O^{-} + $\mathbf{1}^{-}$ + $La^{3+}(^{-}OCH_3)_{0,1}$, it is difficult to envision any mechanism where there is not a preequilibrium binding of the substrate to the metal ion followed by attack of methoxide on that complex as in eq. [1]. On the basis of the experimental kinetic saturation plots of k_{obs} vs. [La^{3+}] (3*a*), we estimate the complex between an oppositely charged phosphate and metal ion to have a dissociation constant (K_{dis}) between 2×10^{-4} and 10^{-3} mol/L depending on the metal ion charge as controlled by the number of metal bound methoxides (n = 0, 1). Accordingly, one can calculate the second-order rate constant for methoxide attack on the transiently bound substrate as being between 6×10^4 and 3×10^5 $(mol/L)^{-1}$ s^{-1} in the case of the complex with n = 0, and 10^3 to 5×10^3 $(mol/L)^{-1}$ s^{-1} for the attack of methoxide on the complex with n = 1. Relative to the experimental second-order rate constant for methoxide attack on $\mathbf{1}^{-}$ alone of $(7.9 \pm 0.6) \times 10^{-7}$ $(mol/L)^{-1}$ s^{-1} at 25 °C (3*a*), coordination to $La^{3+}(^{-}OCH_3)_{0,1}$ provides a rate enhancement of at least 10^{11}- to 10^9-fold depending on the overall charge of the metal:substrate complex.

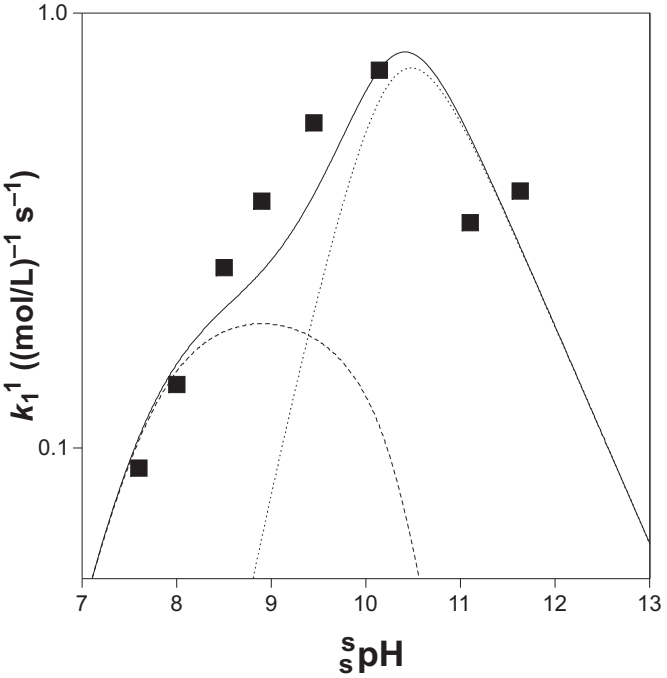

Table 4. Computed $k'^{1:n}_1$ or $k_1^{1:n}$ rate constants for various species for the La^{3+} catalyzed methanolysis of **1** computed from fits of $k_1^{\mathbf{1}}$ vs. $^{s}_{s}$pH data to eq. [4].

$[La^{3+}(^{-}OCH_3)_n]$	$k'^{1:n}_1$

Conclusions

In this paper we have presented a detailed analysis of the kinetic contributions of various La^{3+} species catalyzing the methanolysis of the phosphate diester **1** for which kinetic data were presented previously (3*a*), but only qualitatively analyzed within the framework of Scheme 1. By coupling the rate data to an analysis of the speciation of the La^{3+} containing complexes present in solution as a function of $^{s}_{s}$pH one can provide a simplified, but satisfactory, model to explain the kinetic behaviour in the high and low [La^{3+}] domains. We anticipate that such an approach will prove

© 2005 NRC Canada

beneficial to explain the origins of nonunit, or irregular dependencies of kinetic profiles of many other metal-ion-catalyzed reactions where the metal ion undergoes changes in speciation as a function of $^{s}_{s}$pH.

There is an interesting observation revealed by comparing these analyses with those previously reported for the La^{3+} promoted catalysis of the methanolysis of neutral substrates such as phosphate triesters (3*c*, 3*d*) and carboxylate esters (1). In those cases, the pH/rate profiles are bell-shaped or distorted bell-shaped and best accommodated by mechanisms involving a dual role for the metal ion as a Lewis acid and deliverer of a metal-coordinated methoxide on a transiently bound neutral substrate. However, in the present cases where there is stronger binding of the anionic phosphate to the metal ion to produce a thermodynamically more stable complex, the pH/rate profiles for both the La^{3+} monomer and dimer cases show gradual increases with non-integral slopes. The preferred analysis involves attack of external methoxide on the relatively stable complex where the main apparent role of the metal ion is to act as a Lewis acid or electrostatic stabilizer of the developing negative charge in the TS. While we offer no detailed explanation of the difference in behaviour between neutral and anionic substrates at this time, it must be related to a counterbalancing of the effects of coordination geometry, Lewis acid activation, relative nucleophilicity of metal-bound and external nucleophiles, and geometry of the activated complexes for each mode of catalysis.

Deuterium labeling as a test of intramolecular hydride mechanisms in the fragmentation of 2-(1-hydroxybenzyl)-N1′-methylthiamin[1]

Glenn Ikeda and Ronald Kluger

Abstract: 2-(1-Hydroxybenzyl)-N1′-methylthiamin (**1b**) is a model for the addition intermediate in the thiamin catalyzed benzoin condensation. However, N-alkylation alters the reactivity of the compound: instead of undergoing base-catalyzed formation of benzaldehyde and N1′-methylthiamin, it rapidly forms trimethyl amino pyrimidine (**2b**) and phenylthiazole ketone (**3**). The base-catalyzed fragmentation process is faster than the analogous enzymic reaction (in benzoylformate decarboxylase) under the same conditions. One possible mechanism for the rapid fragmentation is an internal hydride transfer from α-C2 to the methylene bridge between the heterocycles. To test the hydride mechanism we prepared α-C2-deuterated **1b** and conducted the fragmentation reaction in normal water. Spectroscopic analysis revealed that the trimethyl aminopyrimidine product does not contain any deuterium, ruling out a hydride transfer mechanism. This supports a mechanism for fragmentation that proceeds instead via a proton transfer from α-C2. Since protonation (and hence, deprotonation) of that site is part of the normal catalytic cycle of benzoylformate decarboxylase, the enzyme must divert the reaction from the lowest energy pathway since it would share a common intermediate with the fragmentation process.

Key words: thiamin, fragmentation, benzoylformate decarboxylase, proton transfer, hydride shift.

Résumé : La 2-(1-hydroxybenzyl)-N1′-méthylthiamine (**1b**) est un modèle pour l'intermédiaire d'addition dans la condensation de la benzoïne catalysée par la thiamine. Toutefois, la N-alkylation altère la réactivité du composé qui, au lieu de subir une réaction catalysée par les bases conduisant à la formation de benzaldéhyde et de N1′-méthylthiamine conduit à la formation rapide de triméthylaminopyrimidine (**2b**) et phénylthiazole cétone (**3**). Le processus de fragmentation catalysé par les bases est plus rapide que la réaction enzymatique analogue (en présence de décarboxylase de benzoylformate) dans les mêmes conditions. Un mécanisme possible pour la fragmentation rapide implique un transfert interne d'hydrure de la position α-C2 vers le pont méthylène entre les hétérocycles. Afin de tenter de confirmer ce mécanisme impliquant un hydrure, le composé **1b** deutéré en α-C2 a été préparé et soumis à une fragmentation dans de l'eau normale. Une analyse spectroscopique a révélé que le produit triméthyl aminopyrimidine ne contient pas de deutérium, ce qui élimine le mécanisme par transfert d'hydrure, mais qui supporte un mécanisme de fragmentation qui se produirait plutôt par le biais d'un transfert de proton à partir de α-C2. Puisque la protonation (et, par voie de conséquence, la déprotonation) de ce site fait partie du cycle catalytique normal de la décarboxylase du benzoylformate, l'enzyme doit faire dévier la réaction de la voie impliquant l'énergie minimale puisqu'il doit partager un intermédiaire commun avec le processus de fragmentation.

Mots clés : thiamine, fragmentation, décarboxylase de benzoylformate, transfert de proton, déplacement d'hydrure.

[Traduit par la Rédaction]

Introduction

The base-catalyzed addition of thiamin to benzaldehyde produces 2-(1-hydroxybenzyl)thiamin (HBnT, **1a**), following the mechanism deduced by Breslow (1, 2).

HBnT also resembles HBnT diphosphate, an intermediate on the pathway of benzoylformate decarboxylase (BFD) (3–5). In the enzymic system, ionization of the hydroxyl group facilitates the elimination of benzaldehyde. However, the major products from decomposition of HBnT in solution are an aminopyrimidine (AP, **2a**) and a phenylthiazole ketone (PTK, **3**) (6). These products were originally reported by Oka et al. for different conditions (7). Base-catalyzed fragmentation overwhelms elimination, being over 10^3 times faster at pH 7 (8). To observe fragmentation without competition from elimination, the N1′-methylated derivative of HBnT (MHBT, **1b**) was prepared, an analogue of the BFD intermediate with N1′ protonated on the enzyme (5).

The fragmentation pathway of HBnT is consistent with the first step being the loss of a proton from α-C2 to generate the delocalized conjugate base, which undergoes the fragmentation reaction as shown (Fig. 1, mechanism 1). The carbanion can also be accessed by decarboxylation (9, 10).

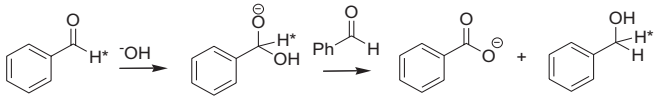

Fig. 1. Mechanisms and deuterium tracing in the fragmentation of HBnT.

An alternative pathway involves the kinetically equivalent oxyanion, obtained from rapid proton transfer from oxygen to carbon that may derive additional stabilization from the positively charged pyrimidine. Fragmentation then would result from an internal Cannizzaro-type reaction (11) involving a hydride shift from α-C2 (Fig. 1, mechanisms 2 and 3). If the hydride mechanism was responsible for the fragmentation, it might involve a manifold of intermediates that are clearly distinct from those formed in the enzymic process. In these mechanisms, the conjugate base of MHBT would react in analogy to the conjugate base of the hydrate of benzaldehyde (Fig. 2). The distinction of hydride and proton transfer mechanisms is reminiscent of the alternatives that were considered as possibilities in the normal catalytic process of glyoxylase I (12–14), which were resolved by the work of Jordan, Kozarich, and their co-workers (13, 14).

The hydride transfer mechanism must give a direct transfer to the acceptor site while a proton transfer mechanism leads to equilibration with the solvent. Thus, we produced the α-C2 deuterated analogue of MHBT (MHBT-*d*) by addition of thiamin addition to deuterobenzaldehyde, and then

Fig. 2. The hydroxide induced Cannizzaro reaction as a model for hydride transfer in MHBT.

conducted the reaction in normal water. The α-C2 carbon acid exchanges very slowly under the conditions of our studies of the fragmentation reaction, so loss of the deuteron will not occur prior to the fragmentation process. The hydride mechanisms require incorporation of the deuterium into the methyl or aryl groups of the pyrimidine product, and the relative rates assure us that this would be detected. Furthermore, proton–deuterium exchange does not occur into the products, so that any loss of deuterium comes from the initial reaction.

The proposed mechanism could potentially give C5′-deuterated AP from the fragmentation of MHBT-*d* in water if the aromatization step occurred with internal deuterium transfer. However, tautomerization would be subject to an

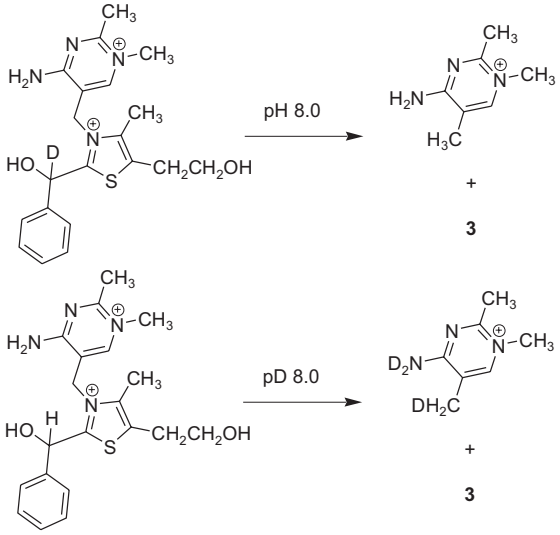
© 2005 NRC Canada

isotope effect and could be solvent-mediated. Therefore, only partial incorporation of deuterium into the C5′ hydrogen is possible in this mechanism.

In the case of BFD, a carbanion must be generated from loss of carbon dioxide from the intermediate generated by addition of thiamin diphosphate to benzoylformate. The same carbanion would be generated from the loss of a proton from the conjugate of thiamin diphosphate and benzaldehyde (HBnT diphosphate). If the fragmentation reaction occurs by a hydride shift mechanism, then this would compete with elimination of the TDP ylide in the enzyme reaction. The enzyme could promote formation of benzaldehyde by controlling the direction of elimination in formation of the carbonyl group, forming the aldehyde rather than the ketone.

Experimental section

The syntheses of MHBT and MHBT-*d* have been previously reported (8, 15). The bisperchlorate of MHBT-*d* (0.3 mmol) was dissolved in 10 mL of water at 25 °C. The solution acidity was maintained at pH 8.0 by addition of 0.1 mol/L potassium hydroxide by an automated burette. After 2 h, the reaction was stopped by addition of hydrochloric acid (1 mol/L) to give an acid concentration in the sample of 0.01 mol/L. The product was purified by extraction with two portions of dichloromethane. Lyophilization of the aqueous layer yielded a mixture of AP and potassium chloride (6–8).



A similar procedure was used for the reaction of MHBT in deuterium oxide. We converted pH meter readings to those for pD by adding 0.4 to the displayed results (16). Fully deuterated acid–base reagents were used. This produced the C5′-monodeuterated analog of AP. ^{1}H NMR (500 MHz, CD_3OD) δ: 8.0 (s, 1H), 3.8 (s, 3H), 2.6 (s, 3H), 2.1 (dt, 3H). EI-MS (high resolution) calcd. for $[N_7H_{10}DN_3]^+$: 138.1016; found: 138.1018.

Results and discussion

No deuterium incorporation occurs into AP from the fragmentation of MHBT-*d* in water (^{1}H NMR and EI-MS (high resolution) calcd. for $[N_7H_{11}N_3]^+$: 137.0953; found: 137.0953). As a control, AP was characterized from the fragmentation of MHBT in deuterium oxide. EI-MS indicates the incorporation of a single deuterium. The location of the deuteron was determined by ^{1}H NMR to be at the C5′ position, which is derived from the methylene bridge between the two heterocycles. The signal for the C5′-methyl group initially consisted of a doublet of triplets ($^2J_{H\text{-}D}$ = 2.1 Hz, $^4J_{H\text{-}H}$ = 0.9 Hz, CD_3OD) from coupling to the geminal deuteron and neighbouring C6′ proton. After confirming the latter assignment by ^{1}H–^{1}H COSY, signal decoupling produced the characteristic 1:1:1 triplet of the monodeuterated methyl group. As the protons of AP do not exchange in deuterium oxide, deuterium incorporation in water would have been detectable under these conditions.

Owing to the absence of deuterated AP products **4** and **5** from the fragmentation of MHBT-*d* in water, we can rule out hydride transfer mechanisms (Fig. 3). Deuterium would be scrambled into solvent from deprotonation of the weak carbon acid to generate the carbanion that is consistent with

Fig. 3. Summary of the results from the deuterium labeling experiments in water and deuterium oxide.

mechanism 1. Monodeuteration of AP from the fragmentation in deuterium oxide is also consistent with mechanism 1 in which C—N bond cleavage occurs with the ionization of C5′ followed by solvent-mediated protonation. Regiospecific deuterium incorporation demonstrates that the isotope comes from solvent and is not transferred internally. The fact that proton–deuterium exchange is not observed in AP indicates that the C5′ methyl group is only weakly acidic, which is consistent with the fragmentation being highly exothermic.

The evidence against an internal hydride transfer supports a mechanism involving the conjugate base at carbon (α-C2). If fragmentation involves the delocalized conjugate base of MHBT, C—N bond cleavage, oxidation of the hydroxyl, and protonation of the C5′ carbon must occur, in steps or in concert. The surprisingly low barrier associated with fragmentation (10^4 s^{-1}) (15) suggests that the transition state of the C—N cleavage process has special stabilization. We note that BFD avoids fragmentation of a similar carbanionic intermediate that is generated by decarboxylation of the addition intermediate from benzoylformate and thiamin diphosphate. The enzyme's normal catalytic route has a higher barrier (k_{cat} = 10^2 s^{-1}) than the fragmentation reaction (17). Since the enzyme-catalyzed reaction necessarily involves a carbanionic structure upon loss of carbon dioxide, the mechanism of fragmentation avoidance is clearly a result of the effects of the enzyme environment (10). The protein manifold of the active site must increase the barrier to fragmentation while lowering that for protonation since the analogous substrates readily undergo fragmentation in solution.

Hydrolysis of aryl hydrogen maleate esters mediated by cyclodextrins — Effect on the intramolecular catalysis[1]

Gabriel O. Andrés, O. Fernando Silva, and Rita H. de Rossi

Abstract: Kinetic studies of the hydrolysis of Z-aryl hydrogen maleates (Z = H, *p*-CH_3, *m*-CH_3, *p*-Cl, *m*-Cl) were carried out in the presence and absence of hydroxypropyl-β-cyclodextrin (HPCD) at variable pH from 1.00 to 3.00. The reaction involves the formation of maleic anhydride as an intermediate and the rate of its formation is strongly dependent on the pH. This is because the neighboring carboxylate group is a better catalyst than the carboxylic group. The rate constant for the formation of maleic anhydride decreases as the HPCD concentration increases in a nonlinear fashion. The results were interpreted in terms of the formation of a 1:1 inclusion complex of the esters with HPCD. The neutral (HA) and anionic (A) species of the substrate have different association constants (K_{CD}^{HA} and K_{CD}^{A}). In all cases studied, K_{CD}^{HA} is higher than K_{CD}^{A} for the same substrate. This difference is responsible for a decrease in the amount of the anionic substrate (reactive species) in the presence of HPCD, which results in a diminution of the observed rate constant. Besides, the rate constant for the reaction of the complexed substrate is smaller than that in the bulk solution indicating that the transition state of the cyclodextrin mediated reaction is less stabilized than the anionic substrate. The values of $\Delta\Delta G^{\ddagger}$ are almost independent of the substituent on the aryl ring and range within 0.48 and 1.05 kcal mol^{-1} (1 cal = 4.184 J). There is no correlation between K_{TS} and the association constant of the substrate indicating that the factors stabilizing the transition state are different from those that stabilize the substrate.

Key words: cyclodextrins, intramolecular catalysis, hydrolysis, inhibition.

Résumé : Opérant à des pH divers allant de 1,00 à 3,00, en présence et en absence de la hydroxypropyl-β-cyclodextrine (HPCD), on a réalisé une étude cinétique de l'hydrolyse de maléates acides de Z-aryle (Z = H, *p*-CH_3, *m*-CH_3, *p*-Cl et *m*-Cl). La réaction implique la formation d'anhydride comme intermédiaire et sa vitesse de formation dépend fortement du pH parce que le groupe carboxylate voisin est un meilleur catalyseur que le groupe carboxylique. La constante de vitesse pour la formation de l'anhydride maléique diminue d'une façon non-linéaire avec une augmentation de la concentration de HPCD. On interprète les résultats en fonction de la formation d'un complexe d'inclusion 1:1 des esters avec le HPCD. Les espèces neutre (HA) et anionique (A) du substrat ont des constantes d'association différentes, K_{CD}^{HA} et K_{CD}^{A}. Dans les cas étudiés, pour un même substrat, les valeurs de K_{CD}^{HA} sont supérieures à K_{CD}^{A}. En présence de HPCD, cette différence est responsable d'une diminution dans la quantité de substrat anionique (espèce réactive), ce qui conduit à la diminution observée de la constante de vitesse. De plus, la constante de vitesse pour la réaction du substrat complexé est plus faible que celle du substrat en solution ce qui indique que l'état de transition de la réaction catalysée par la cyclodextrine est moins stabilisé que celui du substrat anionique. Les valeurs de $\Delta\Delta G^{\ddagger}$ sont pratiquement indépendantes de la nature du substituant sur le noyau aromatique et elles se situent entre 0,48 et 1,05 kcal mol^{-1} (1 cal = 4,184 J). Il n'existe pas de corrélation entre K_{TS} et la constante d'association du substrat ce qui indique que les facteurs stabilisants l'état de transition sont différents de ceux qui stabilisent le substrat.

Mots clés : cyclodextrines, catalyse intramoléculaire, hydrolyse, inhibition.

[Traduit par la Rédaction]

Introduction

Intramolecular catalysis has been used as a model system because it gives important information about enzyme mechanisms (1–3). These reactions are very much dependent on the relative position of the reacting groups and the time that they remain at the proper distance for reaction (4).

Cyclodextrins (CD), which are cyclic oligomers of α-D-glucopyranose, have a well-defined cavity (5). They form inclusion complexes with a wide variety of species in aqueous

solution (6, 7), and this effect has resulted in multiple industrial applications (8, 9). As a result of the host–guest interaction between the organic substrate and the cyclodextrin, the rate of the reactions usually change and it can also be responsible for interesting changes in reaction mechanisms that are well-documented in the literature (10–12). CDs have been frequently used as microreactors that can catalyze or inhibit organic reactions by including the substrate in their cavity (13, 14).

CDs have also been derivatized to improve some desired property (7, 15), such as hydrophilicity or hydrophobicity (16, 17).

We are interested in the cyclodextrin effect on the intramolecular catalysis because inclusion in the cyclodextrin cavity may change the geometry of the substrate and therefore make intramolecular reaction more favorable (18) or more unfavorable (19) than the reaction of the free substrate.

In previous work, we studied the effect of CD on the hydrolysis of aryl hydrogen phthalate esters (20, 21). We suggested that the Z-aryl ring is included in the CD cavity, and the structure of the substrate is distorted making the intramolecular attack of the carboxylate on the carbonyl of the ester more difficult, and consequently, the rate of the intramolecular reaction decreases. In this paper we report the effect of cyclodextrins on the hydrolysis reaction of Z-aryl hydrogen maleate (**1**) where hydroxypropyl-β-cyclodextrin (HPCD) produces an important decrease in the rate of the anhydride formation, but the behavior is somewhat different from that found for aryl hydrogen phthalate esters indicating differences in the mechanism of the cyclodextrin mediated reaction.

Z = H, *p*-CH_3, *m*-CH_3, *p*-Cl, *m*-Cl

Results and discussion

Rate constants for the hydrolysis of Z-aryl hydrogen maleates (Z = *p*-CH_3, *m*-CH_3, H, *p*-Cl, *m*-Cl) and maleic anhydride were obtained by measuring the change in the absorbance at an appropriate wavelength with time. All the kinetics studies were carried out in water containing 3.85% *v*/*v* of acetonitrile (ACN) as the co-solvent and at 25 °C.

Maleic anhydride is an intermediate in the hydrolysis of monoaryl maleate esters (22, 23), therefore it is important to determine the effect of CD on its rate of hydrolysis to understand the effect of cyclodextrin on the hydrolysis of the esters. The reactions of maleic anhydride were studied at pH 2.00 and 3.00 at seven different concentrations of hydroxypropyl-β-cyclodextrin (HPCD) between 2.5 and 30 mmol/L. Only one kinetic process was observed in all cases and the rate constants were the same, within the experimental error, at both pH. The ratio between the rate constant at the highest HPCD concentration (30 mmol/L) and the rate constants without HPCD were 0.93 and 1.01 at pH 2.00 and 3.00, respectively (Supplementary material, Table D1).[3] We also studied the hydrolysis of maleic anhydride at the highest HPCD concentration with different concentrations of a potential competitor for the cyclodextrin cavity (11). The rate constants were not affected by compounds that are known to form inclusion complexes and the observed rate constants were always the same within experimental error (Table D2).[3]

Table 1. Rate constants for the formation of maleic anhydride in the hydrolysis of Z-aryl hydrogen maleates in the presence of different competitors and at constant HPCD concentration.

	p-CH_3[a]	H[b]

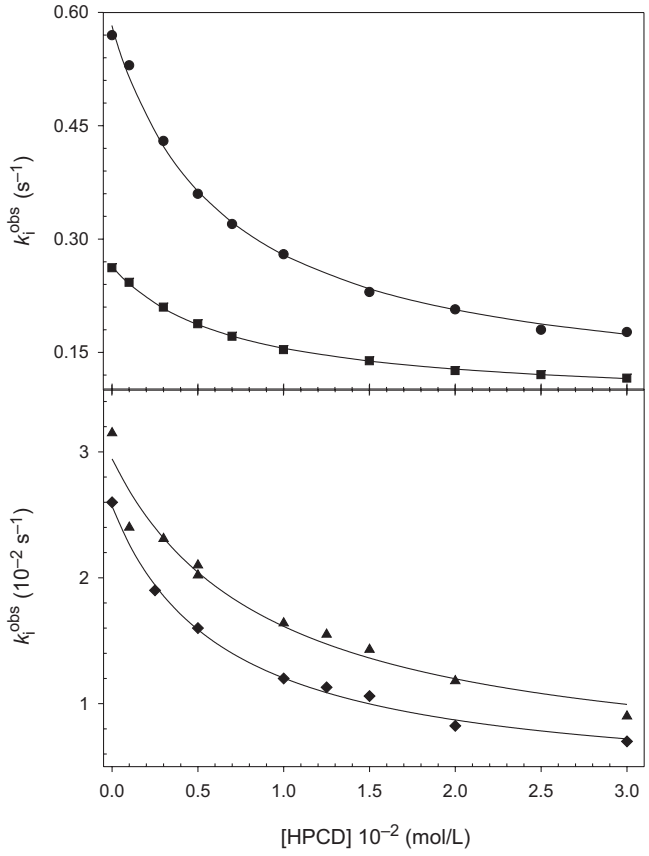
Note: Rate constants were obtained in a conventional spectrophotometer at pH 2.00, HPCD concentration 0.03 mol/L, ionic strength 0.5 mol/L, temperature 25 °C, acetonitrile 3.85%. The standard errors were obtained from at least two determinations.

[a]λ = 281 nm.

[b]λ = 271 nm.

The hydrolysis reaction of phenyl-, *p*-methylphenyl-, *m*-methylphenyl-, *p*-chlorophenyl-, and *m*-chlorophenyl hydrogen maleate was studied at pH 1.00, 2.00, 2.50, and 3.00 in the presence of a variable concentration of HPCD (Tables D3–D7).[3] Two kinetic processes were observed at some wavelengths, and they are associated with the formation and hydrolysis of maleic anhydride. To calculate the rate constants for the system we choose a wavelength where the anhydride did not absorb and the formation of Z-phenol is the only process measured. Under these conditions the data can be fitted by a single exponential equation and the rate constants calculated correspond to the formation of the maleic anhydride.



The addition of HPCD decreases the rate of formation of the anhydride, whereas γ-cyclodextrin did not show any effect and α-cyclodextrin showed a minor decrease in rate (Table D8),[3] therefore, the size of the cavity plays an important role on the inhibition observed.

We studied the effect of guests that may be included in the cyclodextrin cavity on the cyclodextrin retarded hydrolysis. At constant HPCD concentration (30 mmol/L) in the presence of cyclohexanol (25–100 mmol/L) and *tert*-butyl alcohol (100 mmol/L), the observed rate constants are higher than in the absence of the competitor (Table 1). The ratios between the rate constants for the hydrolysis in the presence of cyclohexanol at the higher concentration used

Fig. 1. Effect of HPCD concentration on the hydrolysis of aryl hydrogen maleates at pH 3. Solvent: water and 3.85% acetonitrile, temperature: 25.0 °C, ionic strength: 0.5 mol/L (NaCl as compensating electrolyte). The symbols for different plots of k_i^{obs} vs. HPCD concentration are: *m*-chlorophenyl hydrogen maleate (●), *p*-chlorophenyl hydrogen maleate (■), *m*-methylphenyl hydrogen maleate (▲), *p*-methylphenyl hydrogen maleate (◆).

(100 mmol/L) and the rate constant for the hydrolysis without the competitor are 3.86 and 2.84 by *p*-methyl- and phenyl hydrogen maleate, respectively. The ratios for the same substrates were 1.50 and 1.36 when the competitor was *tert*-butyl alcohol. The addition of a competitor that binds to the HPCD lowers the free host concentration, resulting in an increase in k_i^{obs} as result of a higher free substrate concentration. Cyclohexanol shows a greater effect than *tert*-butyl alcohol, consistent with the values of the corresponding association constants with β-cyclodextrin, which are 676 and 46 $(mol/L)^{-1}$, respectively (11). These results confirm that there is an effective inclusion complex between the substrate and HPCD because the size of the competitor should not affect any other kind of interaction responsible for the inhibition observed. On the other hand, the smaller effect observed for the phenyl hydrogen maleate is attributed to the smaller association constant in relation to *p*-methyl hydrogen maleate (see the following).

The plot of k_i^{obs} vs. HPCD concentration is nonlinear in all cases (Fig. 1 is representative), and the data were very well fitted by eq. [1]. All the parameters are pH dependent and the value of *c* decreases as the pH increases.

$$[1] \qquad k_i^{obs} = \frac{a + b[\text{HPCD}]}{1 + c[\text{HPCD}]}$$

Based of the results described in the previous section, we suggest the mechanism shown in Scheme 1. The neutral substrate and its anion associates with cyclodextrin with a different association constant. The observed rate constant for Scheme 1 is given by eq. [2].

$$[2] \qquad k_i^{obs} = \frac{k_i + k_{CD}K_{CD}^{A}[\text{HPCD}]}{1 + K_{app}[\text{HPCD}]} f_A$$

where k_i and k_{CD} are the rate constants of the free and complexed anionic substrate, respectively, K_{CD}^{A} is the association constant of the anion of the substrate with HPCD, and K_{app} is given by eq. [3]. It is the product of the association equilibrium constant of the anionic substrate and the fraction of the anion (f_A, eq. [4]) plus the product of the association equilibrium constant of the neutral substrate and the corresponding fraction ($f_{HA} = (1 - f_A)$).

$$[3] \qquad K_{app} = f_A K_{CD}^{A} + (1 - f_A)K_{CD}^{HA}$$

$$[4] \qquad f_A = \frac{K_a}{K_a + H^+}$$

Equation [2] is mathematically equivalent to eq. [1] with $a = k_i f_A$, $b = k_{CD}K_{CD}^{A}f_A$, and $c = K_{app}$. The rate and equilibrium constants obtained are shown in Table 2, which were calculated using eq. [2] to fit all the data obtained at various pH values. In Scheme 1, only the intramolecular reaction of the carboxylate group is considered because it is known that the reaction of the carboxylic acid does not compete with this (22, 23).

We had previously reported for monoaryl esters of phthalic acid that the ratio of association constants for the neutral (K_{CD}^{HA}) and anionic (K_{CD}^{A}) species (20) for the different substrates give values in a range of 6–10. In the case of the monoaryl hydrogen maleates, the difference between the two equilibrium constants is smaller; it amounts only to a factor of two to four (Table 2). Besides there is very small variation of K_{CD}^{HA} and K_{CD}^{A} among the various substrates, which contrasts with the results for monoaryl phthalate esters where there is a significant change in equilibrium constants with the substituents in the aryl ring (20).

The difference in equilibrium constant for the neutral and anionic substrates is important for the observed effect of HPCD because this difference drives the equilibrium toward the neutral species, which is much less reactive than the anionic species (23). Therefore, the absolute inhibition of the observed rate constant is stronger at low pH. For example, in the case of phenyl hydrogen maleate, the relative rates measured at 0 and 30 mmol/L concentrations were 5.1 and 2.7 at pH 1.00 and 3.00, respectively.

Included in Table 2 are the values of K_{TS}. These values have been calculated following the Kurz treatment (24), which was first applied for cyclodextrin mediated reactions by Tee and co-workers (25–27). It represents the hypothetical association equilibrium constant for the transition state for the reaction mediated by cyclodextrin and is defined as the ratio $k_{CD}K_{CD}^{A}/k_i$. The values of K_{TS} are in all cases smaller than the K_{CD}^{A} for the substrates, indicating that inclusion in the cyclodextrin cavity stabilizes the substrate more

than the transition state. In the last column of Table 2, the values of $\Delta\Delta G^{\ddagger}$ that are a measure of the differences in stabilization between substrate and transition state are collected. It is remarkable that the values are about the same for all the substrates, which again contrasts with the results of the aryl phthalate esters where there is a significant variation among the different esters; for instance, $\Delta\Delta G^{\ddagger}$ is 0.20 and 1.59 kcal/mol for the *p*-chloro and *m*-methyl derivative, respectively (20).

We conclude that in this case the orientation of the main complexes is as shown in Scheme 1, namely, with the maleic moiety pointing towards the primary hydroxyl side of the cavity. There are several examples in the literature where anionic compounds are oriented in that way. For instance, benzoate anion and 4-biphenyl carboxylate anion are axially included in the cavity of β-cyclodextrin with an orientation that locates the carboxylate group at the primary hydroxyl side (28) and the same type of orientation was demonstrated for the complex between β-cyclodextrin and β-naphthyloxyacetatate in the solid as well as in solution (29).

quires the carboxylate to be in the plane of the ring with the ester group approximately perpendicular. It is well-known that an appropriate geometry in the initial state is a critical factor for a reaction (30, 31). The inclusion of the substrate with the geometry shown in Scheme 1 probably decreases the degree of freedom of the carboxylate group to reach the appropriate geometry for reaction, and therefore, the transition state is destabilized compared to the reaction of the free substrate. It is also possible that the cyclodextrin makes some changes in the most stable conformation of the substrate, making it more difficult to reach the adequate position for intramolecular attack (32).

Conclusions

The intramolecular catalysis of hydrolysis of Z-aryl hydrogen maleate is affected by the presence of HPCD, where the size of the cavity plays an important role. The results presented here indicate that the inhibition of the intramolecular reaction as a result of inclusion in the cavity of the cyclodextrin is due to two main factors. One is the difference between the association constants for the neutral and anionic substrate that drive the equilibrium toward neutral species that is much less reactive than the anion. The second fact is steric restriction imposed for the inclusion in the substrate to reach the transition state, which is evident from a decrease in the stabilization of the transition state compared to the substrate.

From the similarities of the equilibrium constants for the substrates and also the similarities in the destabilization energy of the corresponding transition state we infer that the reactive complexes have the maleic moiety inside the cavity contrary to what was observed for aryl phthalate where inclusion of the aryl ring in the cavity was suggested.

Experimental

Materials

Maleic anhydride (Aldrich) and substituted phenols (Aldrich) were sublimed before use (33). HPCD (average degree of substitution 5.9, PM 1454) (Roquette) was a gift from Ferromet S.A. Argentina and was used without further purification.

The monoaryl esters were prepared from the maleic anhydride and the appropriate phenol by adapting the method described in the literature (34). The esters were characterized by ^{13}C and ^{1}H NMR and IR spectra; all this information along with melting points are summarized in Table 3. IR and NMR spectra were done on Nicolet 5SXC FT-IR (KBr pellets) and Bruker AC 200 (200 MHz) spectrometers, respectively. The purity of the products was also checked by comparing the UV–vis absorption spectrum of a solution containing the fully hydrolyzed esters with one at the same concentration prepared with maleic acid and the corresponding alcohol.

Aqueous solutions were made up from water purified in a Millipore apparatus. Acetonitrile Merck HPLC was dried on silica gel 10% *p*/*v* as described in the literature (33).

© 2005 NRC Canada

Kinetic procedures

The reactions were carried out in a stopped-flow Applied Photophysics SF 17MV apparatus (SF) with unequal mixing. The correspondent Z-aryl hydrogen maleate or the anhydride dissolved in dry acetonitrile was placed in the smaller syringe (0.1 mL). The large syringe (2.5 mL) was filled with a water solution containing all the other ingredients; the cyclodextrin concentration was varied between 0 and 30 mmol/L. The solutions of the substrate for the kinetic determinations were freshly prepared in dry acetonitrile in the appropriate concentration to get a final concentration of 2×10^{-4} mol/L. The total acetonitrile concentration was 3.85% *v*/*v*. When the rate was too slow for the stopped-flow apparatus the kinetic determinations were carried out in a thermostatted cell of a conventional spectrophotometer (Shimadzu UV2101) as described in previous work (21).

All reactions were run at 25.0 ± 0.1 °C and at constant ionic strength (0.5 mol/L) using NaCl as the compensating electrolyte. The pH measurements were carried out using a pH meter at controlled temperature and calibrated with buffers prepared according to the literature (35).

The observed rate constants were determined by measuring the change in absorbance at 250, 268, 271, 273.5, or 281 nm, depending on the substrate. In some of the experiments, the pH of the solution was checked after the reaction by measuring it in the discarded solution, and the change observed were always less than 0.03 pH units. The kinetic traces were fitted with one exponential equation using the software of the SF apparatus.

The aromatic character and resonance stabilization energies of substituted cyclopentadienyl and indenyl cations[1]

J.A. Pincock and A.W.H. Speed

Abstract: Calculations (B3LYP/6-31G(d)) have been used to assess the aromaticity of 5-X substituted indenyl (**4**) and cyclopentadienyl (**5**) cations with X = O^-, NH_2, OCH_3, CH_3, F, H, CN, and N_2^+. Two criteria were used, the aromatic stabilization energy (ASE), as determined by isodesmic reactions, and bond alternation, as determined from the Julg index (*A*) on the basis of carbon–carbon bond lengths. Substituent effects on the singlet state of the cyclopentadienyl cations resulted in significant decreases in antiaromatic character for electron-donating groups as indicated by larger *A* values (*A* = –0.25 for X = H and +0.26 for X = NH_2). These decreases paralleled increases in the C-2—C-3 bond length and good linear correlations were obtained between *A* vs. the C-2—C-3 bond length and *A* vs. the ASE. These effects were rationalized by the stabilization by the electron-donating groups of the positive charge at C-5 generated as a consequence of a Jahn–Teller distortion leading to a lowest energy singlet state with a HOMO of a_2 symmetry. In contrast, the lowest energy triplet state for each of the substituted cyclopentadienyl cations has little bond alternation (*A* > 0.9) and, by this criterion, is not significantly antiaromatic. The triplet state is more stable than the singlet state for the unsubstituted case and those with electron-withdrawing groups (ΔE_{ST} = –11.3 and –9.3 kcal/mol for X = H and CN, respectively) (1 cal = 4.184 J), but less stable for electron-donating groups (ΔE_{ST} = +15.0 kcal/mol for X = NH_2). For the indenyl cations **4**, the ASE values were almost independent of the substituent and the *A* values only decreased slightly for electron-donating groups. The *A* values also indicated that the indenyl cations could be divided into two moieties, an X-substituted pentadienyl cation with considerable delocalization and little bond alternation, and a 2,3-butadiene one with considerable bond alternation. This separation also placed the major portion of the positive charge on the pentadienyl part. The lack of symmetry in the substituted indenyl cations rationalizes the selective reactivity of the 5-methoxy-substituted cation at C-1. Finally, the resonance stabilization energies (RSE) of the substituted cations gave a linear correlation with the RSEs of 4-substituted benzylic cations.

Key words: indenyl cations, cyclopentadienyl cations, substituent effects, stabilization energies.

Résumé : On a fait appel à des calculs (B3LUP/6-31G(d)) pour évaluer l'aromaticité de cations indényles (**4**) et cyclopentadiényles (**5**) portant un substituant 5-X dans lesquels X = O^-, NH_2, OCH_3, CH_3, F, H, CN et N_2^+. On a utilisé deux critères, l'énergie de stabilisation aromatique (ESA) telle que déterminée par des réactions isodesmiques et l'alternance des liaisons telle que déterminée par l'indice de Julg (*A*) sur la base des longueurs des liaisons carbone–carbone. Les effets de substituants sur l'état singulet des cations cyclopentadiényles conduit à une diminution significative du caractère antiaromatique avec les groupes électrodonneurs, telle qu'indiquée par des valeurs plus élevées de *A* (*A* = –0,25 pour X = H et +0,26 pour X = NH_2). Ces diminutions sont accompagnées d'une augmentation parallèle de la longueur de la liaison C-2—C-3 et on a obtenu des bonnes corrélations linéaires entre la valeur de *A* en fonction de la longueur de la liaison C-2—C-3 et entre la valeur de *A* en fonction de ESA. On a rationalisé ces effets par la stabilisation par les groupes électrodonneurs de la charge positive en C-5 générée en conséquence d'une distorsion Jahn–Teller conduisant à un état singulet d'énergie le plus faible avec une orbitale moléculaire haute occupée de symétrie a_2. Par opposition, l'état triplet des cations cyclopentadiényles substitués ne présentent pas beaucoup d'alternance des liaisons et, par ce critère, ils ne sont pas très antiaromatiques. L'état triplet est plus stable que l'état singulet dans le cas du produit non substitué ou de ceux portant des groupes électroattracteurs (ΔE_{ST} = –11,3 et –9,3 kcal/mol respectivement pour X = H et CN) (1 cal = 4,184 J), mais plus stable pour les dérivés portant des groupes électrodonneurs (ΔE_{ST} = +15 kcal/mol pour X = NH_2). Pour les cations indényles **4**, les valeurs d'ESA sont presque indépendantes de la nature des substituants et les valeurs de *A* ne diminuent que légèrement avec les groupes électrodonneurs. Les valeurs de *A* indiquent aussi que les cations indényles peuvent être divisés en deux groupes, un cation pentadiényle substitué par un groupe X qui comporte beaucoup de délocalisation et peut d'alternance des liaisons et un buta-2,3-diène qui comporte beaucoup d'alternance de liaison. Ces divisions place aussi une portion importante de la charge positive

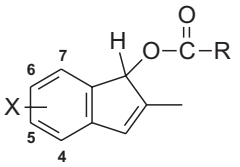
sur la partie pentadiényle. Le manque de symétrie dans les cations indényles substitués permet de rationaliser la réactivité sélective pour la position C-1 du cation substitué par un 5-méthoxy. Enfin les énergies de stabilisation de résonance (ESR) des cations substitués donnent une corrélation linéaire avec les valeurs de ESR des cations benzyliques substitués en position 4.

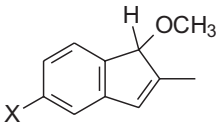
Mots clés : cations indényles, cations cyclopentadiényles, effets de substituant, énergies de stabilisation.

[Traduit par la Rédaction]



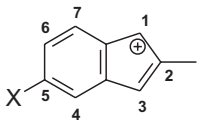
Introduction

We recently reported on the photochemistry of the indenyl esters, acetates (**1a**–**1c**) and pivalates (**2a**–**2c**), in both methanol and cyclohexane solvents (1). In cyclohexane, the products obtained were derived entirely from the radical pair intermediates expected from homolytic cleavage of the carbon–oxygen bond. In methanol, the methyl ethers **3a** and **3b** were obtained in significant yield (from 0% for **2a** to 100% for **1c**) as a consequence of the formation of ion-pair intermediates.

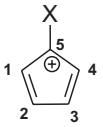


The mechanism of formation of ion-pair intermediates in photosolvolysis reactions has attracted considerable interest recently with two quite different pathways proposed. This topic has recently been reviewed (2). For arylmethyl esters, the first involves direct heterolytic cleavage of the carbon–oxygen bond from the excited singlet state (3). The second proposal is homolytic cleavage from the same excited state followed by rapid redox electron transfer converting the first-formed radical pair to the ion pair (4). For compound **1c**, we tentatively concluded that the former mechanism was the preferred one in contrast to most esters that seem to follow the latter pathway. Independent of the mechanism, the fact that products derived from indenyl cations are formed is certain, perhaps a consequence of the antiaromatic character of these $4n$ π cations, in agreement with Wan and co-workers' (5) proposal for 9-fluorenyl derivatives.

The observation that the 5-methoxy ether **3b** was obtained from either of the starting esters (5-methoxy **1b** or 6-methoxy **1c**) indicates that, as expected, a common indenyl cation **4** is obtained from both, as shown by the two resonance contributors **I-4c** and **II-4c** in Scheme 1. The fact that the methoxy substituted cation **4** reacts with methanol only at C-1 (as in **I**) and not C-1 (as in **II**) is a consequence of the change from C_{2v} symmetry for the unsubstituted indenyl cation **4f** to C_s symmetry by the addition of the methoxy group to C-5. Effectively, C-1 is para to the methoxy group and C-3 is meta in structure **1**–**4c**.



As the benzo analogue of the cyclopentadienyl cation, the indenyl cation has attracted considerable experimental and theoretical interest as a $4n$ antiaromatic ring system (6, 7). Unfortunately, experimental results for substituted cases are scarce. Recently, however, an alkyl (8) and a trifluoromethyl substituted cyclopentadienyl cation (9) and a trifluoromethyl substituted indenyl cation (10) have been the proposed intermediates generated in solvolysis reactions. Nevertheless, the effect that substitutents have on the charge distribution and aromaticity of these cations has not been explored in a systematic way. The limited number of literature results will be summarized in the appropriate context in the following.



1a: X = H, R = CH_3
1b: X = 5-CH_3O, R = CH_3
1c: X = 6-CH_3O, R = CH_3
2a: X = H, R = *t*-Bu
2b: X = 5-CH_3O, R = *t*-Bu
2c: X = 6-CH_3O, R = *t*-Bu

3a: X = H
3b: X = 5-CH_3O

4a: X = O^-
4b: X = NH_2
4c: X = OCH_3
4d: X = CH_3
4e: X = F
4f: X = H
4g: X = CN
4h: X = N_2^+

5a: X = O^-
5b: X = NH_2
5c: X = OCH_3
5d: X = CH_3
5e: X = F
5f: X = H
5g: X = CN
5h: X = N_2^+

We now report an ab initio molecular orbital study using GAUSSIAN 98 (11) for optimized geometries at the B3LYP/6-31G(d) computational level that probe these issues. This level was chosen so that the results could be conveniently compared with two other recent studies, one on the aromatic character of the unsubstituted cyclopentadienyl and indenyl cations by Jiao, Schleyer, Tidwell, and co-workers (12), and the other on the aromaticity of substituted benzyl cations by Morao and Hillier (13). Moreover, an isodesmic reaction analogous to eq. [1][3] gave calculated reaction energies, which, for our purposes, are independent of the level of theory: +36.28 kcal/mol (MP2(full)/6-31G(d)); +33.14 kcal/mol (MP4SDTQ/6-31G(d)//MP2(full)/6-31G(d)); +33.47 kcal/mol (B3LYP/6-31G(d)); +34.67 kcal/mol (B3LYP/6-31+G(d,p) (14) (1 cal = 4.184 J).

Although our interest in this topic was stimulated by our experimental observations on the photochemistry of the substituted indenyl esters **1** and **2**, we will first present results

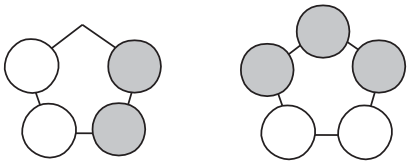
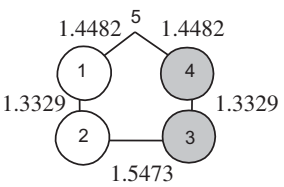
for the substituted cyclopentadienyl cations **5** that serve as a useful foundation for the more delocalized indenyl cations **4**.

Results and discussion



The cations examined (**4a**–**4h** and **5a**–**5h**) were chosen with a range of electron-donating and electron-withdrawing substitutents, as indicated by their Hammett σ^+ values shown in Table 1. Values of σ^+, rather than σ, were chosen on the basis of the direct resonance interaction of the substituent with the positive charge of the cation. The σ^+ values chosen are the same as those used by Morao and Hillier (13), taken from a recent review of Hammett substituent constants (15). The two charged substituents at the extremes, the oxy anion (**a**, X = O^-) and the diazonium cation (**h**, X = N_2^+), without a counter balancing cation for O^- or anion for N_2^+, are not accessible for experimentation, but serve as useful calculated values that reinforce the observed trends for the other, more usual, substitutents.

Aromatic stabilization energy (ASE) of the singlet state of the cyclopentadienyl cations 5



The cyclopentadienyl cation ($C_5H_5^+$) is often used as an introduction to the concept of antiaromaticity. However, as has been known for some time (14) and has been clearly explained in a recent high-level computational study (16), this species is not a single entity. In D_{5h} symmetry, two degenerate π HOMOs are predicted (nodal properties are sketched in **5-D_{5h}**, Fig. 1) and therefore the ground state should be a triplet, in agreement with experimental and computational studies (16). Two Jahn–Teller distortions give the singlet species **5-I** and **5-II** (bond lengths from RHF/6-31G(dp) calculations) C_{2v} geometries, both of which remove the degeneracy of these two orbitals (Fig. 1). In the first, **5-I**, the

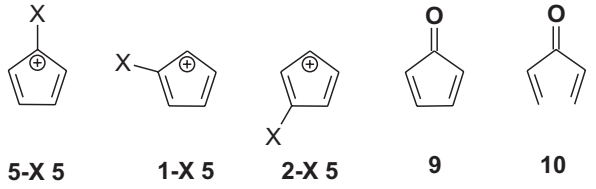
orbital of lower energy, now the HOMO, has a_2 symmetry, the stabilization resulting from lengthening the C-2—C-3[4] bond and decreasing the antibonding interaction. In the second, **5-II**, of b_2 symmetry, the stabilization results from equally increasing both the C-1—C-2 and C-3—C-4 bond lengths. These qualitative arguments have been developed some time ago and reinforced by HMO, MINDO, and ab initio STO-2G methods (17). These two singlet states have been described as a "… *cis*-butadiene moiety …and the other, a combination of an allyl cation and an ethylene…", respectively (12). Therefore, two closed-shell singlet states are possible. These two states are calculated to differ in energy by less than 1 kcal/mol and are higher in energy than the ground-state triplet by 3.4–11.6 kcal/mol, depending on the level of theory (16). At the RHF/6-31G** and CASSCF(4,5)/6-31G** levels of computation, the b_2 state has no imaginary frequencies, but the a_2 does have one of b_2 symmetry. In contrast, at the MP2/6-311G(2d,p) level, the a_2



[4] The cyclopentadienyl cations are numbered so that C-5 is on the C_2 axis and across the ring from the unique carbon–carbon bond (C-2—C-3) for each case. This numbering system then agrees with the IUPAC name for 1,3-cyclopentadiene.

© 2005 NRC Canada

state has no imaginary frequencies, but the b_2 one has one, again of b_2 symmetry. An open-shell singlet state is the least stable of all of the states, 11–17 kcal/mol above the triplet ground state (16).

The ASE of the singlet cyclopentadienyl cation **5f** has been previously assessed (12) by the isodesmic reaction in eq. [1] and we have reproduced their reported value of the reaction energy of +42.5 kcal/mol. The energy of **5f** obtained by us, using an input geometry with equal carbon–carbon bond lengths of 1.40 Å, resulted in a minimum energy structure (no imaginary frequencies) with symmetry analagous to **5-I** (bond lengths are in Table 1). Using the values reported in the Supporting information of the previous report (12) for each structure of eq. [1], gives a somewhat different value of +46.8 kcal/mol. The difference between the two values results from the reported value for **8** with X = H. In eq. [1], compounds **6** and **8** are shown so as to indicate the relationship of their bond connectivities to structures **5** and **7**. However, both structures **6** and **8** have conformational possibilities that must be considered. The Supporting information from that publication (12) states that the geometry used for **6** was "all-trans 1,4-pentadienyl ($C_5H_7^+$, C_{2v})", **6a** (Fig. 1) the energy of which we have reproduced. This W conformer is more stable by 3.60 kcal/mol than the sickle conformer **6b** (Fig. 1), and was used by us as the starting geometry for all of the 3-X substituted compounds **6**. We have also reproduced the energies reported for the unsubstituted structures **5** and **7** in eq. [1]. Compound **8** was described, again in the Supporting information of ref. 12, as "trans-1,4-pentadiene (C_5H_8, C_2)". We have found the minimum energy (–195.29777 au) conformer shown in **8a** (Fig. 1) that is more stable than that reported (–195.29087 au). We are not sure what the geometry of that higher energy structure corresponds to, but it was not the value that the authors used to calculate the reported reaction energy of eq. [1].

The situation for the substituted cyclopentadienyl cations **5** is complicated by the three possible positions (C-5, C-1, and C-2) for placing a substituent X on the cyclopentadienyl cation (**5-X 5**, **1-X 5**, and **2-X 5**). Naively, one might consider these three to be resonance contributors because the charge can be moved from one carbon to another using the usual curved-arrow notation. However, because of the unequal bond lengths in the ring this would create structures of differing geometry that cannot be resonance contributors. Therefore, each of these structures is a different species.

For the electron-donating groups, a geometry optimization with no constraints, puts the substituent at C-5 of the structure **5-I** (HOMO, a_2), independent of which carbon is substituted in the initial geometry. A similar minimum energy geometry has been found previously (MP2(full)/6-31G(d)) for the methyl **5d** and other monoalkyl derivatives (14). Therefore, only one minimum energy structure exists with the substituent placed so as to stabilize the high positive charge at C-5 (equal to +0.284)[5] in the parent cyclopentadienyl cation. This charge is largely a consequence of the fact that the HOMO of this ion has a node through this carbon. Significantly, lower charges are at C-1 = +0.147 and C-2 = +0.211.[5]

For the electron-withdrawing groups, structures of differing energy were obtained depending on the input geometry. For X = CN, two minima resulted, a 2-CN and a 5-CN structure. Both of these had C_s symmetry, but with bond lengths and HOMOs corresponding to, but slightly distorted from, the structure of a_2 symmetry, **5-I**. The 2-CN structure was more stable than the 5-CN one by 0.32 kcal/mol. For X = N_2^+, two C_s minima were also obtained: 5-N_2^+ with a HOMO of pseudo a_2 symmetry and 2-N_2^+ with bond lengths and a HOMO corresponding to the b_2 structure **5-II**. The latter structure is the more stable by 20.6 kcal/mol. For both of these electron-withdrawing substituents (CN and N_2^+), the more stable structure results when the substituent is not at the carbon atom of highest positive charge for the cyclopentadienyl cation itself, namely C-5. Computed values for bond lengths of all of the X-substituted cyclopentadienyl cations are in Table 1 and calculated values of the reaction energies, using the 5-substituted structures for **5** are in Table 2. Computed values for all compounds of eq. [1] are in Table S1[6] of the Supporting information.[7]

This isodesmic reaction predicts the effect of transferring a positive charge from the delocalized pentadienyl cation **6** to the delocalized, but antiaromatic, cyclopentadienyl cation **5**. The negatively charged O^- electron-donating group makes structures **5** and **6** the neutral molecules **9** and **10**, respectively, and the positively charged N_2^+ makes them dications. The process of eq. [1] is endergonic, as expected, but is clearly significantly dependent on the substituent X, becoming less disfavoured for electron-donating substituents. For comparison, a very recent computational study of cyclopentadienyl derivatives, including **5a = 9**, indicates that it is slightly antiaromatic on the basis of a negative value (–11.16) for the magnetic susceptibility enhancement and positive values of 8.83 and 5.64 kcal/mol from the energies

[5] All charges given are from Mulliken population analysis with hydrogens summed into the heavy atoms.
[6] As described in the footnote of this Table, structures **7** and **8** (X = O^-), and **8** (X = N_2^+) are not bound, and therefore the reaction energy for these substituents could not be calculated.

of two different reactions (18). Therefore, electron-donating substituents considerably decrease the antiaromatic character of the cyclopentadienyl cation. As will be described in the following, this effect parallels bond alternation effects.

Singlet–triplet splitting (ΔE_{ST}) for the cyclopentadienyl cations 5

The fact that the singlet state of the cyclopentadienyl cations is becoming less antiaromatic (more aromatic) as the electron-donating ability of the substituent increases parallels the ordering of the singlet–triplet splitting. As shown by the ΔE_{ST} values in Table 3, the triplet state (**5T**) is more stable than the singlet by 11.3 kcal/mol for the unsubstituted compound **5f**. In contrast, for the amino substituted case **5b**, the singlet is more stable by 15.0 kcal/mol. A ΔE_{ST} value of 17.9 kcal/mol (CISD at SCF geometries, 3-21G basis set) with very similar bond lengths (C-1—C-2 = C-3—C-4 = 1.447 Å, C-2—C-3 = 1.381 Å, C-4—C-5 = C-5—C-2 = 1.442 Å, see Table 3 for our values for **5T**) has been obtained previously for **5b** (19). As expected, the ΔE_{ST} splitting is very much the largest (23.3 kcal/mol) for the neutral molecule **5a** = **9**.

This substituent effect on the ΔE_{ST} for the cyclopentadienyl cations is analogous to that for carbenes. At the descriptive MO level, a linear carbene has two degenerate nonbonding p orbitals and is a ground-state triplet. Decreasing the bond angle splits the degeneracy and stabilizes the in-plane p orbital as it gains s character. The ground state can then be a closed-shell singlet and the empty π orbital stabilized by electron-donating groups like amino. Suitably substituted carbenes become stable, isolable molecules. These concepts for carbenes have attracted considerable experimental and theoretical interest (20, 21).

Bond alternation in the cyclopentadienyl cations 5 — The Julg index

A number of properties have been used to assess the aromatic character of cyclic conjugated π systems, one of them being geometry (bond length equalization for aromatic systems and bond length alternation for antiaromatic ones). Lee and Wright (16) have argued that "…whether a cyclic compound exhibits aromatic character or not maybe seen most simply by looking at geometry" and "…bearing in mind that the concept of aromaticity has limited chemical use, a definition based on geometry, which is very quick to use, seems most practicable." Although most chemists, including us, would disagree with the first point of the second quote, the second point of that quote is certainly valid. The Julg parameter (*A*), a commonly used index, is given by eq. [2] where *n* is the number of bonds, r_i is any individual bond length, and r_{avg} is the average of all the bond lengths (22). For benzene, with all C—C bonds of equal length, all values of $r = r_{avg}$,

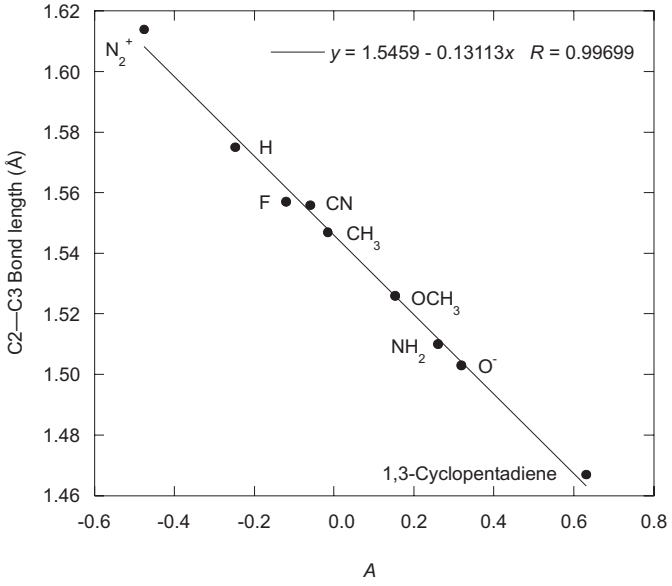
Fig. 2. Plot of *A* (Julg index) vs. the C-2—C-3 bond length (Å) for the cyclopentadienyl cations **5**. The substituent is at C-5 in all cases.



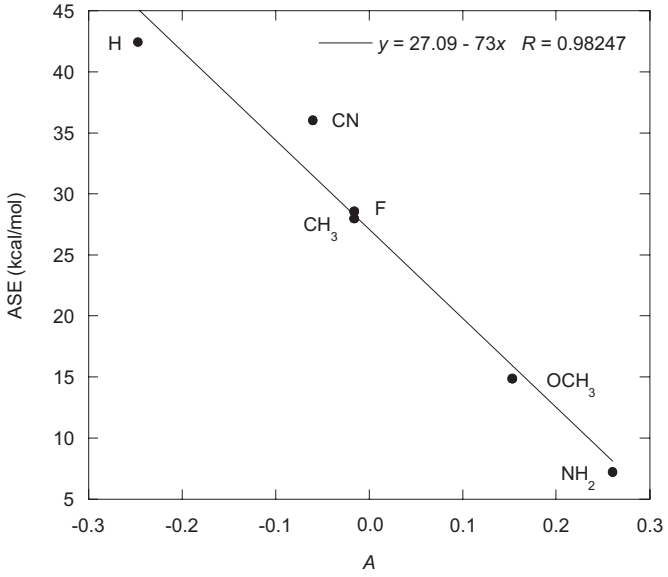


Fig. 3. Plot of *A* (Julg index) vs. the reaction energy (kcal/mol) for eq. [1], the ASE for the cyclopentadienyl cations **5**. The substituent is at C-5 in all cases.

and therefore the second term in eq. [2] equals zero leading to $A = 1$. The scaling factor of 225 is used to force $A = 0$ for Kekulé benzene (1,3,5-cyclohexatriene), a model chosen with alternating C—C bond lengths of 1.33 and 1.52 Å. Therefore, the aromatic cyclopentadienyl anion (12), with all bonds of equal length (1.413 Å, B3LYP/6-31G(d)), also has $A = 1.0$. The butadiene fragment in 1,3-cyclopentadiene (**7**) has $A = 0.618$ (C-1—C-2 = C-3—C-4 = 1.349 Å and C-2—C-3 = 1.470 Å, B3LYP/6-31G(d)) indicative of a greater bond alternation than for the cyclopentadienyl anion.

$$[2] \qquad A = 1 - (225/n)\Sigma[(r_{avg} - r_i)/r_{avg}]^2$$

As a consequence of its antiaromatic character, the singlet state of the cyclopentadienyl cation has considerable bond alteration. The Julg index for this cation has been calculated previously ($A = -0.084$, C-1–C-2 = C-3—C-4 = 1.255 Å, C-2—C-3 = 1.565 Å, MP2(FC)/6-31G(d)) using the carbon string from C-1 to C-4, but omitting the C-4—C-5 and C-5—C-1 bonds (23). In essence, this value reveals the effect that creating a cyclic π system has on the *A* value for a "normal" 1,3-butadiene unit by adding C-5. An even lower value of $A = -0.25$ (C-1—C-2 = C-3—C-4 = 1.350 Å, C-2—C-3 = 1.575 Å, and C-4—C-5 = C-5—C-1 = 1.450 Å in C_{2v} symmetry) is obtained by us using B3LYP/6-31G(d). The major contributor to this low (and negative) value is the long bond length for C-2—C-3.

The *A* values (omitting the C-5—C-1 and C-4—C-5 bonds as in the literature examples), along with the bond lengths, for the singlet state of the 5-X substituted cyclopentadienyl cations are given in Table 1. Similar bond lengths (C-1—C-2 = C-3—C-4 = 1.348 Å, C-2—C-3 = 1.515 Å, C-4—C-5 = C-5—C-1 = 1.489 Å (STO/3-21G) (19) and 1.36, 1.51, and 1.52 Å, respectively, (STO/2G) (17)) for the amino compound **5b** have been reported previously. The *A* values increase from a low of –0.48 for X = N_2^+ to a high of 0.32 for X = O^-, indicating an increase in bond equalization and a decrease in antiaromatic character for electron-donating groups. This increase in *A* is largely determined by the decrease in the C-2—C-3 bond length from a maximum of 1.614 Å for N_2^+ to a minimum of 1.503 Å for O^- compared to the C-1—C-2 and C-3—C-4 bond lengths that average 1.348 ± 0.006 Å over the whole set of X groups. In fact, a very good linear correlation exists between *A* and the C-2—C-3 bond length, including 1,3-cyclopentadiene (Fig. 2). Moreover, a similar linear correlation exists between *A* and the reaction energy for the isodesmic reaction (eq. [1], Fig. 3). The structural conclusion is that electron-donating substituents at C-5 reduce the antiaromatic character of the cyclopentadienyl cation by selectively interacting with the positive charge at C-5. The remaining four carbons become more like a normal butadiene fragment with considerably less bond alteration.

In contrast, the triplet states of the cyclopentadienyl cations have *A* values that are above 0.9[8] (Table 3) indicating that their geometries do not deviate significantly from the D_{5h} symmetry of the unsubstituted case. Therefore, by the bond length criterion, they are not significantly antiaromatic. This makes qualitative sense because the orbitals of **5-I** and **5-II** (Fig. 1) are now both singly occupied in contrast to the singlet state with **5-I** doubly occupied. The opposing symmetry (a_2 vs. b_2) of these two orbitals means that each is bonding where the other is antibonding. The overall result is little bond alternation.

Bond alternation for the singlet states of the indenyl cations 4

The unsubstituted indenyl cation **4f** has a singlet ground state with C_{2v} symmetry, which, unlike the cyclopentadienyl cation, is a consequence of the fusion of the benzene ring to

[8] The exception ($A = 0.79$) is for X = O^-, the neutral cyclopentadienone **9**.

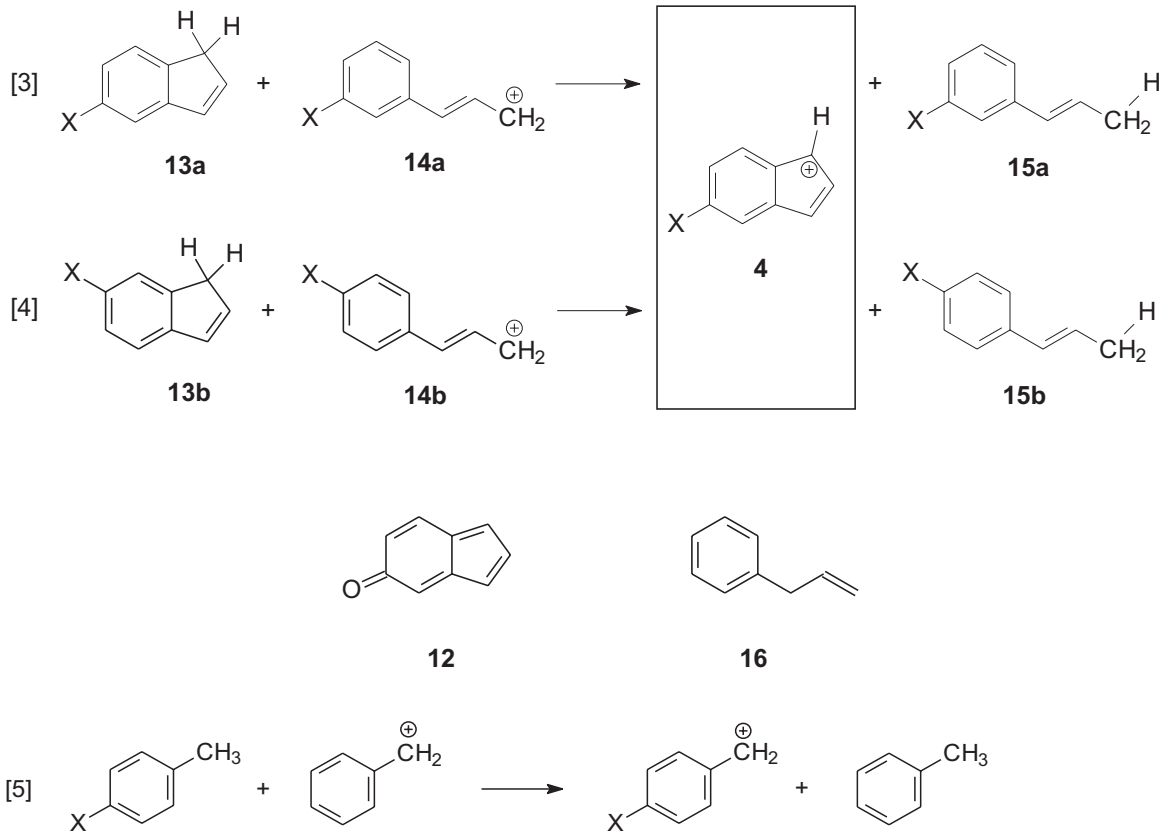
[a] A_{cp} is for the cyclopentadienyl part of the indenyl cations using the C-1—C-8, C-8—C-9, and C-9—C-3 bond lengths.

the cyclopentadienyl one rather than the Jahn–Teller distortion of the cyclopentadienyl cation. The π HOMO **4-II** has b_2 symmetry resembling **5-II** for the cyclopentadienyl part and the π LUMO **4-I** has a_2 symmetry resembling **5-I** (nodal properties are sketched in Fig. 1). Therefore, the bond lengths in this state are longest between C-1—C-8 = C-3—C-9 = 1.457 Å[9] (antibonding interaction) and shorter between C-1—C-2 = C-2—C-3 = 1.400 Å and C-8—C-9 = 1.424 Å. However, the bond alternation in the cyclopentadienyl fragment (A_{cp} = 0.97 (Table 4), for the C-1–C-8–C-9–C-3 string, again omitting C-2, the carbon on the C_2 axis), is very small. The b_2 symmetry also results in a very low charge[5] at C-2 = 0.090 and higher ones at C-1 = C-3 = 0.171, in contrast to the cyclopentadienyl cation, which has the highest charge at C-5, the atom on the C-2 axis. Breaking the C_{2v} symmetry by adding an X group at C-5 is therefore expected to have a significant effect on the geometry and charge distribution in the substituted indenyl cations because, for instance, an electron-donating X group is now directly conjugated to the carbon C-1 with the highest positive charge. The electron-donating groups shorten the C-1—C-8 bond and lengthen the C-9—C-3 one giving more bond alternation as in resonance structure **11d** (Fig. 1), the extreme being the neutral molecule **12**. As a consequence, the A_{cp} values (Table 4) are significantly smaller (0.77 for X = NH_2) for the cations with electron-donating groups than for the unsubstituted cation itself.

The total Julg indices for cations **4**, given in Table 4 as A(Total), were calculated in the usual way using the bond lengths around the periphery and do not include the C-8—C-9 bond. The bond lengths used for the unsubstituted compound **4f** were identical to those previously obtained at the same level of theory (12). Worth noting is the fact that the average calculated bond length in compounds **4** is essentially independent of X with an r_{av} = 1.417 ± 0.003 Å, not significantly different from the value of 1.407 ± 0.007 Å for the aromatic indenyl anion (12).



The alternation in the bond lengths for the indenyl cation itself **4f** gives A(Total) = 0.89, less than 1, as expected for an antiaromatic cation but not nearly as low a value as that calculated for the cyclopentadienyl cation (A = –0.25). For the substituted indenyl cations **4**, a trend towards lower values is observed for electron-donating substituents, reaching A = 0.62 for **4a** for X = O^-. A more revealing aspect of the bond alternation is obtained by dividing A(Total) into the two strings, that is A_1 = (C-1–C-8–C-7–C-6–C-5) and A_2 = (C-2–C-3–C-9–C-4). As shown in **11d** for X = methoxy, this separates the indenyl cation into two fragments, an X-terminally substituted pentadienyl cation and a neutral 1,3-butadiene. These A_1 and A_2 values are in Table 4. For the indenyl cation itself, this division makes little difference (A(Total) = 0.89, A_1 = 0.85, and A_2 = 0.87) as expected by its symmetry. However, for the cases substituted with electron-donating groups, $A_1 > A_2$. Most noticeably, for the strong electron-donating groups, the A_2 values are quite low (0.49 for X = NH_2 and 0.46 for X = OCH_3). This four carbon string is analogous to butadiene, but has, for these cases, even stronger bond alternation than butadiene itself (A = 0.63 using the experimental bond lengths of 1.349 Å (C-1—C-2) and 1.467 Å (C-2—C-3)). In contrast, the A_1 values are high (approaching 1.0 for X = NH_2, CH_3, and F) indicating extensive delocalization and bond equalization through this string of atoms. This observation reinforces the high asymmetry induced in indenyl cations by the electron-donating substituents and provides an explanation for their selective reaction at C-1 with nucleophiles.

Aromatic stabilization energy (ASE) of the singlet state of the indenyl cations 4

As for the cyclopentadienyl cations **5**, the ASE of **4** can be defined by an isodesmic reaction model. We have used two isodesmic reactions (eqs. [3] and [4]), again calculating ASE from reaction energies at optimized geometries for each molecule. This model reaction has been used previously (12) for calculations of the ASE of the indenyl cation itself where eqs. [3] and [4] are identical, and a value of ΔE = +20.3 kcal/mol, using B3LYP/6-31G(d), is reported. The concept of this isodesmic reaction is that the positive charge is transferred from a conjugated allyl-aromatic system **14** to an antiaromatic cation **4**. Table 1 of the Supporting information of ref. 12 states that **14** is the "1-phenylallyl cation, ($C_9H_9^+$, C_s)" whose calculated energy we have reproduced, as well as the energies for **4** and **13**, both with X = H. However, the last structure in eqs. [3] and [4] is named as "3-phenylpropene (C_9H_{10}, C_s)" (**16**), which is isomeric with our 1-phenylpropene (**15**, X = H). As expected, using **15**, which is stabilized by conjugation of the alkene with the aryl ring, a lower value of the calculated reaction energy (ΔE = +13.3 kcal/mol) is obtained. The conjugated connection of the alkene with the aryl ring between **13** and

[9] The numbering of atoms, shown in **4-II**, is that same as that in indene.

© 2005 NRC Canada

15 seems to be a more chemically reasonable isodesmic reaction than that between **13** and **16**, and was therefore used by us.

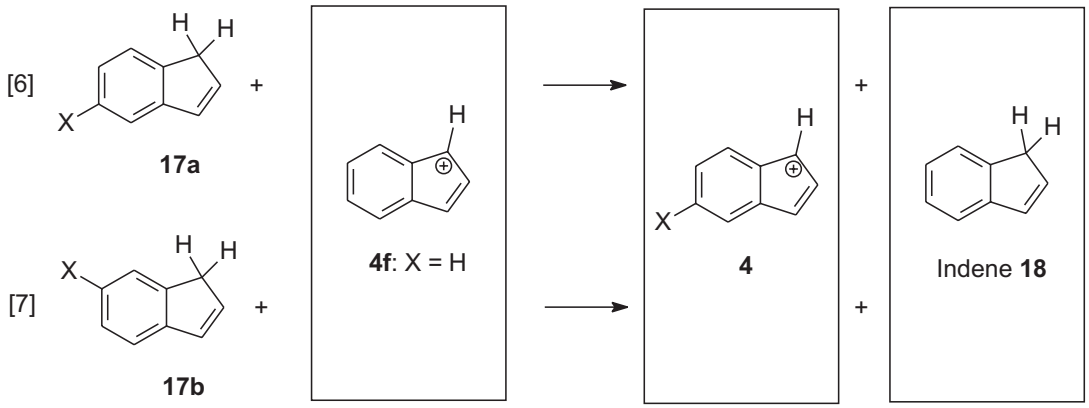
However, a complication arises using eqs. [3] and [4], which are identical only for X = H, the unsubstituted case. For the others, the substituent can be at two possible positions. As discussed previously (see Scheme 1), this change has no effect on the stability of **4**, but will change the energy of each of the other species as they are isomeric in the two equations. These changes are small for the uncharged species (**13a** vs. **13b** and **15a** vs. **15b**), but significant for the charged ones (**14a** vs. **14b**). For instance, the differences in energy between **13a** and **13b** and **15a** and **15b** for X = OCH_3 are only 0.2 and 0.1 kcal/mol, respectively, whereas the difference between **14a** and **14b** for X = OCH_3 is 10.1 kcal/mol, and, as expected, leading to stabilization of the isomer with the electron-donating substituent conjugated (para) to the positive charge in **14b**. The conclusion is that the X group has an effect on the relative stability of **14a** and **14b** that is positionally dependent and therefore different from that on **4** where it is always strongly conjugated. This clearly demonstrates that this isodesmic reaction, used for X = H, is only a suitable choice for assessing substituent effects on the ASE of **4** if the X group is conjugated with the positive charge on both sides of the isodesmic reaction, as in eq. [4].

Calculated values for both isodesmic reactions (eqs. [3] and [4]) as a function of X are given in Table 2. Electronic energies (optimized geometries) for each molecule in both equations are given in the Supporting information[7] (Table S2). For the para cases (**14b**, eq. [4]), the substituent effect is small, essentially negligible for the uncharged cases, indicating that the ASE of the indenyl cation is substituent independent, paralleling its effect on the stability of the propenyl cations **14b**.

Resonance stabilizing energy (RSE) of the singlet state of the indenyl cations 4

Recently, a computational study at a similar level of theory as used here has been published on the effect that substituents have on the relative stability of para-substituted benzyl cations (13). The isodesmic reaction (eq. [5]) was used. The concept here is that RSEs can be calculated for the effect of the substituent relative to the unsubstituted case. The reported values for the calculated reaction energies of eq. [5] are in Table 2. We have applied the analogous eqs. [6] and [7] for the RSEs of the indenyl cations **4**. The advantages that this pair of equations have over the pair from eqs. [3] and [4] are twofold. First, the charged species **4f** on the left-hand side has no substituent and, second, the substituent effect is constant for both the charged species **4** and the uncharged indene **17** on the right-hand side. The only differences in energy are between **17a** and **17b**, which, because they are neutral species, are small. Calculated electronic energies for all structures of eqs. [6] and [7] are in Table S3 of the Supporting information[7] and calculated reaction energies are given in Table 2. As expected, the values obtained are very similar for both substituent positions, and therefore should give a reliable estimate of the RSEs of the indenyl cations **4**.

© 2005 NRC Canada



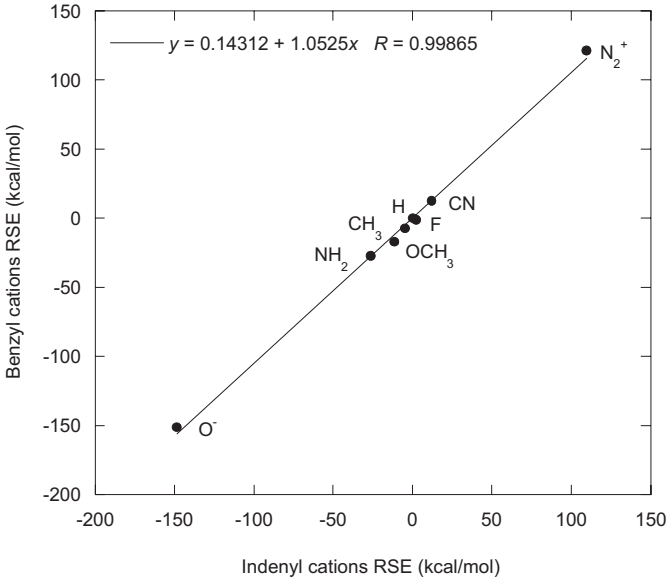


Fig. 4. Plot of the resonance stabilization energy (RSE) of the indenyl cations **4** from eq. [6] vs. the RSE of the benzyl cations from eq. [5].

A plot of the calculated RSEs of the indenyl catons **4** from the reaction energies of eq. [6] vs. those for the benzyl cations of eq. [5] is linear (Fig. 4) with a slope of 1.05. Therefore, substituent effects in reactions that generate indenyl cations should parallel those that generate benzyl or indanyl cations. To our knowledge, only one experimental report on the substituent effects for the generation of indenyl cations is available (24). The rate constants for solvolysis of the 3,5-dinitrobenzoate esters of 1-indenol, 5-methyl-1-indenol, and 5-methoxy-1-indenol gave linear Hammett plots vs. σ^+ with $\rho^+ = -6.0$ (80% aqueous acetone, 80 °C) and $\rho^+ = -5.4$ (2,2,2-trifluoroethanol, 21 °C). These values are very similar to those obtained for the corresponding indanol derivatives: $\rho^+ = -5.3$ (80% aqueous acetone, 21 °C) and $\rho^+ = -5.6$ (2,2,2-trifluoroethanol, 21 °C). Therefore, delocalization of charge in the indenyl cation seems to be unchanged by any antiaromatic effects.

Charge distribution in the indenyl cations 4

Our initial expectation was that the lack of symmetry in the substituted indenyl cations **4** and the resulting lack of symmetry in the charge distribution would rationalize the increased electrophilicity at C-1 relative to C-3 in **4c** with X = OCH_3. In fact, preliminary PM3 calculations indicated this was the case with charges $Q1$ at C-1 = +0.44 and $Q3$ at C-3 = +0.25.[4] However, the higher level Gaussian calculations were not in agreement with this suggestion: the charges at C-1 and C-3 in **4c** equal to +0.102 and +0.112, respectively. These values, along with those calculated for the other substitutents, are given in Table 4. In fact, independent of the substituent, the positive charge is slightly higher at C-3 than at C-1.

However, as the Julg indices indicated and on the basis of the negative σ^+ values, the substituents at the top of Table 4 are expected to strongly delocalize the charge by direct resonance interaction as in contributors **11** (X = OCH_3). Therefore, a more reasonable estimate of the charge distribution in cations **4** should be provided by examining the sum of the charges in the two carbon strings that were used above for the Julg indices: Q(1–5) for C-1–C-8–C-7–C-6–C-5 as shown in **11a** compared to Q(2–4) for the string C-2–C-3–C-9–C-4. The ratios of charges (Q(1–5)/Q(2–4)) in these two strings as a function of substituent are shown in Table 4. These ratios approach a value of three for the strong electron-donating groups indicating that a much larger portion of the positive charge is on the C-1 to C-5 string.[10] This observation correctly rationalizes the observed reactivity of **4c** at C-1 with the nucleophile methanol in the photosolvolysis reactions.

Singlet–triplet splitting (ΔE_{ST}) and bond alternation in the triplet state of the indenyl cations 4

The triplet states of the indenyl cations **5** were all less stable than the corresponding singlet states, as expected for a system without degenerate HOMOs. The ΔE_{ST} values (Table 5) are essentially independent of the substituent with an average of 9.3 ± 0.6 kcal/mol (omitting the values for the charged substituents, which are somewhat higher), 15.3 kcal/mol for O^-, and 14.7 kcal/mol for N_2^+. Moreover, all the A values are high, above 0.9 and approaching 1.0. Therefore, by the bond alternation criterion, the triplet state

[10]Values for **4a** (X = O^-) and **4h** (X = N_2^+) do not follow the trends for the other substituents because the net charge is zero and +2, respectively, for these structures in contrast to +1 for the other cases.

Table 5. Calculated Julg indices (A) and singlet–triplet splittings (ΔE_{ST}) values for the triplet state (**4T**) of the indenyl cations.

Cmpd.	X	A_{cp}	A(Total)	A_1(C-1—C-5)	A_2(C-2—C-4)	r_{av}	ΔE_{ST} (kcal/mol)
4a	O^-	0.97	0.89	0.87	0.93	1.420	15.3
4b	NH_2	0.99	0.93	0.92	0.94	1.413	10.4
4c	OCH_3	0.97	0.95	0.92	0.96	1.413	7.7
4d	CH_3	0.94	0.96	0.94	0.96	1.412	9.1
4e	F	0.94	0.97	0.96	0.98	1.410	9.3
4f	H	0.93	1.00	0.97	0.99	1.411	10.0
4g	CN	0.94	0.96	0.94	0.98	1.413	9.5
4h	N_2^+	0.95	0.95	0.96	0.99	1.416	14.7

of the indenyl cations, as is the case for the cyclopentadienyl cations, are not antiaromatic.

Conclusions

The initial question that led to these computations has been answered. The regiochemistry of the reaction of the 5-methoxyindenyl cation **4c** at C-1, as opposed to C-3, with nucleophiles is a consequence of its lack of symmetry. This cation, along with those others that are substituted with electron-donating groups, can be divided into two parts: a highly delocalized pentadienyl cation and a more localized neutral 1,3-butadiene unit. Bond alternation determinations (Julg index values, A) and substituent effects on resonance stabilization energies that parallel those for benzyl cations support this explanation. This observation emphasizes that substituent effects on resonance stabilization energies and aromatic stabilization energies are not necessarily related.

In addition, substituent effects for cyclopentadienyl cations demonstrated that the antiaromatic character, as determined by an isodesmic reaction, decreased significantly with electron-donating groups. This decrease coincided with a decrease in the bond alternation (again from Julg A values), particularly by the decrease in the C-2—C-3 bond length, as indicated by the correlations in Figs. 2 and 3.

Finally, the singlet–triplet splitting (ΔE_{ST}) for the cyclopentadienyl and indenyl cations were quite different. For the cyclopentadienyl cations, the more stable state changed from the triplet to the singlet for electron-donating groups, whereas the splitting favoured the singlet state independent of the substituent for the indenyl cations. In addition, by the bond alternation criterion, neither the cyclopentadienyl nor the indenyl cations are significantly antiaromatic in the triplet state.

All of these effects agreed qualitatively with the energies and symmetries of the HOMOs and LUMOs (shown in Fig. 1) for the two cations.

An ab initio study of 1,5-suprafacial shifts in 5-substituted 1,3-cyclopentadienes[1,2]

Cory C. Pye and Raymond A. Poirier

Abstract: A computational study of the degenerate 1,5-suprafacial migration of the 5-substituted cyclopentadienes is presented. The substituents considered are the Group 14–17 elements of the second through fifth periods, saturated by hydrogens as needed to fulfill normal valence requirements. The geometry of most transition states are remarkably similar in the carbon framework. The activation barrier to migration was shown to correlate well with a dimensionless "stretching" parameter, especially at the MP2 level.

Key words: 5-substituted 1,3-cyclopentadiene, 1,2-haptotropic shift, 1,5-suprafacial shift, ab initio, transition states.

Résumé : On présente une étude théorique de la migration-1,5 suprafaciale de cyclopentadiènes substitués en position 5. Les substituants considérés les éléments 14 à 17 des périodes deux à cinq, saturés par la quantité appropriée d'atomes d'hydrogène pour satisfaire leurs valences normales. Il est remarquable que la géométrie de la plupart des états de transition est très semblable à celle du squelette carboné. On a montré qu'il existe une bonne corrélation entre la barrière d'activation à la migration et un paramètre d'élongation sans dimension, particulièrement au niveau MP2.

Mots clés : cyclopenta-1,3-diène substitué en position 5, migration-1,2 haptotropique, migration-1,5 suprafaciale, ab initio, états de transition.

[Traduit par la Rédaction]

Introduction

5-Substituted cyclopentadienes are of interest as prototypical rigid systems for the investigation of facial selectivity in the Diels–Alder reaction, as previously discussed (1). In some cases, 5-substituted cyclopentadienes can undergo a degenerate 1,5-suprafacial shift as shown in Fig. 1. This process has been described in many ways, for example, as a hydrogen, metal, or carousel migration; as a prototropic, metallotropic, walk, intramolecular, (1,5)-sigmatropic, circumambulatory rearrangement; as fluxional behavior; and as stereochemical nonrigidity, to name a few. The process has been demonstrated and the activation barrier measured for many substituents, as shown in Table 1. The following quotation from Larrabee's 1974 review (8) provides a snapshot of both the situation 30 years ago, and also an accurate forecast of the situation today: "…it is not yet possible to predict the type of bonding a new structure will exhibit. It may ultimately be possible to make such predictions from large-scale numerical computations. Such bonding descriptions are to be considered incomplete if they do not include a description of the remarkable property found in many σ-bonded organometallic compounds: their fluxional behavior." Even today, the topic remains of much interest, as shown in two recent reviews (9, 10).

Method

Calculations were performed using MUNGAUSS (11), GAUSSIAN 92 (12), or GAUSSIAN 98 (13), utilizing the STO-3G (14), 3-21G (15), 6-31G(d) (16), and 6-31+G(d) (17) basis sets. Huzinaga's basis sets for Ge-Br (4333/433/4) and Sn-I (43333/4333/44), decontracted to {21} in the sp-valence region and polarization functions added, were used in conjunction with the 6-31G(d) basis set (18). Cartesian (6) d functions were used throughout except for STO-3G. Diffuse function exponents were previously presented (1). For brevity, the results and discussion using the STO-3G and 3-21G basis sets are presented in the supplementary material (19).[4]

The MP2 and higher level calculations (20) utilize the frozen core approximation. Default optimization specifications were normally used. For 6-31G(d) and higher, a frequency calculation was performed at the same level and the resulting Hessian used in the following optimization. Z-matrix coordinates constrained to the appropriate symmetry

PH_2	131.0±7.5	^{1}H-VT NMR	-$CpMe_5$ (7)
PMe_2	96.2±2.1	^{1}H-VT NMR	-$CpMe_5$ (7)

were used as required to speed up the optimizations. If symmetry constraints led to a transition state instead of a minimum, this would show up as the presence of one or more imaginary frequencies not belonging to the totally symmetric irreducible representation. The Hessian was evaluated at the first geometry for the first level in a series to aid geometry convergence. Molden was used to render the molecular structures (21).

In all tables, bond lengths are given in Å and angles in °. A general trend noticed is that d-polarization functions added to heteroatoms of the second row tend to shorten bonds to adjacent atoms, whereas, when added to heteroatoms of the third and fourth row, they tend to increase bond lengths to adjacent atoms. This was already noted and rationalized (1).

Results and discussion

Geometries

We discuss the geometry of only the transition states (hereafter abbreviated TS). As the cyclopentadienes themselves have been already discussed (1), we refer readers to the figures, tables, and discussion therein. For purposes of naming, the substituent is assumed to be migrating from C5 to C4.

Cyclopentadiene

The structure of the cyclopentadiene TS is shown in Fig. 2. Like the corresponding cyclopentadiene, the structure of the TS for the 1,5-suprafacial hydrogen shift changes little with basis set, with the angular range being about the same, but the bond range being larger (0.03 Å), predominantly about the reaction centers. The 6-31G(d,p) structure differed from the 6-31G(d) one only in the last reported figure, except for the parameters about the reaction centers, which varied in the next to last figure. The structures shown

are between the single and double bond lengths of cyclopentadiene, as expected. One surprising feature is the shortening of the C—C bond bisected by the migrating carbon (by over 0.03 Å at the Hartree–Fock level), but this may be related to the lengthening of the migrating C—H bond by over 0.21 Å, making the reactant carbons more sp^2-like. The bond lengths of the hydrogens attached to the reacting carbons decrease by about 0.015 Å to be very close to the usual sp^2 values. The C-C-C angles are within 2° of the idealized 108° of the cyclopentadienyl anion, and the nonmigrating hydrogens are very nearly planar. The migrating H-C-C angle becomes smaller in the TS by a few degrees.

Halocyclopentadienes

The geometries of the 1,5-suprafacial halogen shift TSs are given in Tables 3 and S6.[4] The addition of diffuse function and of correlation has very little effect on the bond angles, except when the associated bonds change significantly.

Adding diffuse functions tends to shorten the carbon–halogen distance slightly, except for the fluoride, where it lengthens it by about 0.05 Å. Adding correlation significantly shortens the carbon–halogen distance by around 0.10 Å, except for the fluoride, where it increases by 0.01 Å. This demonstrates the extreme importance of diffuse functions for fluorine, and of correlation in these TSs.

The TSs are all remarkably similar in the carbon framework for all halogens, with the only major difference being in the X—C length. We can define a dimensionless measure of the stretching in the TS as

$$[1] \qquad \xi = \frac{r_{\text{transition state}} - r_{\text{reactant}}}{r_{\text{reactant}}}$$

where r is the X—C length at a particular point on the PES. The closer this value is to zero, the less "stretched" the TS is. There is no trend seen in $r_{\text{transition state}} - r_{\text{reactant}}$. As one proceeds from fluorine to iodine, ξ decreases (Table 4), demonstrating that the molecule, on a relative scale, does not need to stretch as much to reach the TS.

Chalcocyclopentadienes

For the 1,5-suprafacial chalcogen shift, one must consider which reactant and product molecules the TS is meant to connect. For the antiperiplanar case, it is clear that the "antiperiplanar" TS should connect them as this involves the least torsional motion of the OH. For the synclinal reactants and products, the situation is not as clearcut. For the alcohol,

and for all HF/STO-3G calculations, the C_s symmetric app conformation is a TS, whereas it is a second-order saddle point for other cases. Here, the TS between the synclinal structures is also synclinal. The geometries of the 1,5-suprafacial chalcogen shift TS are given in Table S7 and S8.[4] The basis set trends are similar to those of the halogens, and the TS are similar in the carbon framework. The main difference between the app and spp/sc TSs are the bond lengths and angles involving the migrating group. A pronounced asymmetry develops for the synclinal TSs. The asymmetric TS is lower in energy for the selenium and tellurium cases, and it is also less stretched. For the asymmetrical transition states, the average of the two X—C distances was used to define ξ. Similar trends with ξ were also noticed as a function of period number.

Pnictocyclopentadienes

The geometries of the 1,5-suprafacial pnictogen shift transition states are given in Tables S9 and S10.[4] It appears that the app TSs are reasonable except for the amine, which is, along with all of the spp structures, a second-order saddle point. The app TSs connect the app conformers in the reactant and product. The sc TSs are higher in energy than the app TS where they exist, and are more stretched. For the amine, only one transition state exists that is C_s symmetric and the amine hydrogens are in the symmetry plane (i.e., the nitrogen undergoes an inversion). The C—N distance is much shorter here than in the app conformer. Basis set trends are similar to those of the halogens, with the amine being atypical, like fluorine. The carbon framework of the transition states are remarkably similar, except for the amine. If using the app conformer to define ξ, a similar downward trend is noted. The sc transition states have larger H-X-H and X-C4-C3 angles.

Group 14 cyclopentadienes

The geometries of the 1,2-suprafacial Group 14 shift transition states are given in Table S11.[4] The carbon skeleton is remarkably similar in all four TSs. ξ decreases with increasing atomic number.

Activation energies

The activation barriers for group migration are shown in Tables S12,[4] 5, and 6. Taking the CCSD(T) values as the most accurate, the Hartree–Fock barriers are seen to be too high, whereas the MP2 barriers are too low. Generally, there is little difference between the MP3 and MP4SDQ barriers (3 kJ/mol), and between the QCISD(T) and CCSD(T) barriers (1 kJ/mol), except for first-row substituents. The energy ordering from highest to lowest is HF >> MP4SDQ > MP3 > QCISD(T), CCSD(T) > MP4 > MP2, with the MP3,MP4SDQ and MP2,MP4 pairs occasionally interchanging.

The activation barrier always decreases upon going down a group, but the trend across a row is not always clear. Plots of the activation barrier vs. the stretching parameter are shown in Figs. 3 and 4. Although there is some scatter in the

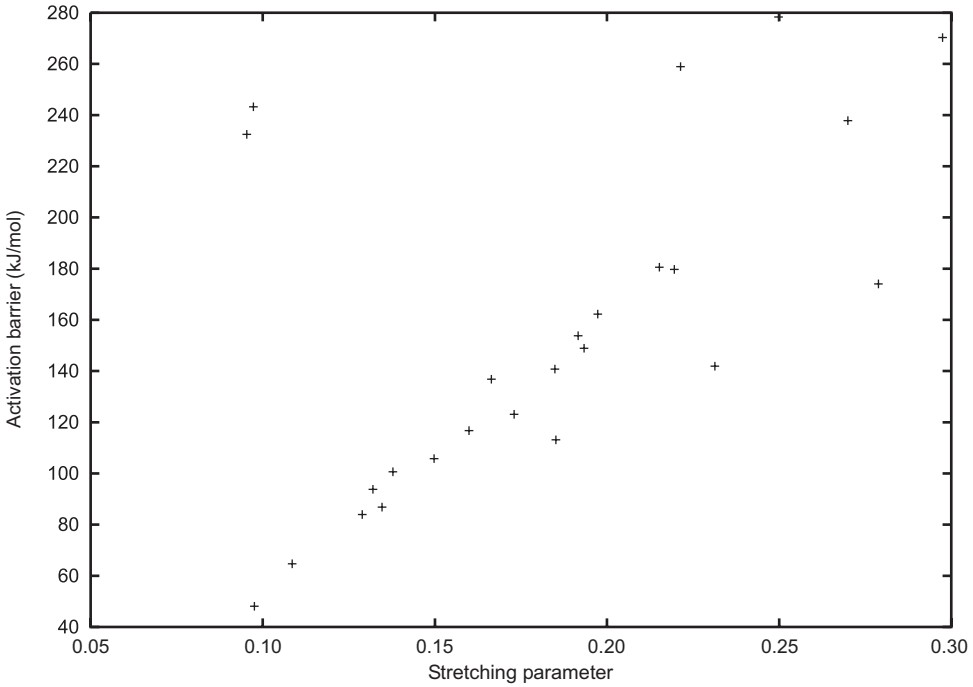
Fig. 3. Electronic activation barrier vs. stretching parameter (HF/6-31G(d)).



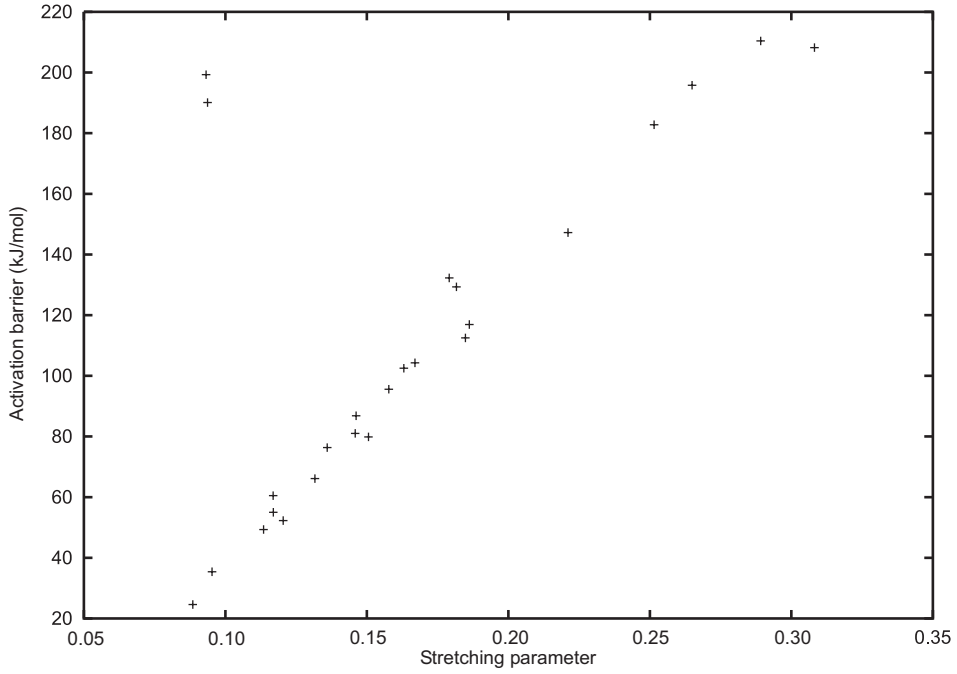


Fig. 4. Electronic activation barrier vs. stretching parameter (MP2/6-31+G(d)).

Hartree–Fock plots, the MP2 activation energies correlate very well with the stretching parameter. The amine is an outlier, as might be expected because of the inversion.

For cyclopentadiene itself, our barriers (kJ/mol) compare well with previous literature, for example, 162.3 (HF/6-31G(d)), 119.7 (MP2/6-31G(d)), and 110.2 (MP2/6-31G(d) + HF/ZPE+therm) (23). Bachrach (23) did not use the frozen core approximation, which accounts for the slight difference in his MP2 result. Our HF/6-31G(d,p) result is 156.63, which shows that polarization functions on hydrogen make a modest contribution (–5.7 kJ/mol) to lowering the activation barrier at the Hartree–Fock level. It is not anticipated that this would lower the barriers when other groups are migrating. Jiao and Schleyer (24) obtained the electronic barriers of 119.7 (MP2/6-31G(d)), 107.5 (MP2/6-311G(d,p)//MP2/6-31G(d)), 124.3 (QCISD(T)/6-311G(d,p)//MP2/6-31G(d)), and 122.2 (MP4/6-311G(d,p)//MP2/6-31G(d)), with MP2/6-31G(d) thermal correction of –5.9. The ZPE and thermal correction tends to cancel the RT correction term needed to obtain the activation energy. The larger 6-311G(d,p) basis

© 2005 NRC Canada

set seems to reduce the barrier by about 10 kJ/mol. B3LYP/6-31G(d) + ZPE calculations place the barrier at 113 kJ/mol (25). To facilitate comparison with our previous paper, and because it is not uniformly defined for the heavier elements, we do not use this larger 6-311G(d,p) basis set. Even at these sophisticated levels, the barrier still has not converged on a reasonable value, although tunnelling effects can account for part of the discrepancy.

The effect of zero-point energy (ZPE) corrections (MP2/6-31+G(d)) is largest for the smaller atoms, whereas the non-ZPE thermal corrections are largest for the largest atoms. In any account, the effects decrease the barrier by less than 10 kJ/mol for hydrogen. For the first-row elements, the barriers are decreased by 5–8 kJ/mol, and for the other elements, typically less than 5 kJ/mol.

From the experimental data presented in Table 1, it seems that methyl substitution has a small effect (5 kJ/mol) on the activation barrier of the migrating group IV atoms. We can thus compare our calculated values with the methyl substituted experimental values. Our best values (electronic) are, for the most part, slightly too high, and the thermal corrections partially correct for this.

The majority of previous work on the (non-hydrogen) shift concerned the application of semiempirical techniques. Dewar (27) found that the barrier of methyl migration in 5-methylcyclopentadiene using MINDO/3 was 194.3 kJ/mol. Cuthbertson and Glidewell (28) examined 5-silylcyclopentadiene using MNDO and found the barrier to be 99.1 kJ/mol. Schoeller (29, 30) predicted the MNDO barrier for the cyclopentadienylphosphane to be 170.3 kJ/mol and stated that the amine prefers inversion over retention of configuration, as we have already noted. MNDO clearly overestimates the barrier, whereas MINDO/3 gives very good results. Most recently, density functional calculations give the barrier (B3LYP/6-311+G(d,p)) as 85.8 and 98.7 kJ/mol for the app and sc isomers of the phosphine, and 63.6 and 75.7 kJ/mol for the app and sc isomers of the arsine. The inversion transition state for the phosphine and arsine was shown to be a higher order saddle point (31). These barriers are lower than ours and are probably more reliable because of the higher quality basis set used.

Conclusions

The structures of the transition states of the 1,5-suprafacial shift of the substituent in 5-substituted cyclopentadienes are, with the exception of the migrating group, very similar. A dimensionless stretching parameter is defined and is shown to correlate well with the activation barrier to this migration, especially at the MP2 level. Our best barriers are estimated to be about 10 kJ/mol too high.

Solvolysis and ring closure of quinone methides photogenerated from biaryl systems[1]

Yijian Shi and Peter Wan

Abstract: A variety of biaryl quinone methides have been photogenerated with a range of efficiencies from biaryl precursors **4**–**6** and **8**, **10**, and **11**, all having hydroxyl and hydroxymethyl substituents on alternate rings. These novel biaryl quinone methides, which cannot be readily generated via thermal chemistry, are trapped by added nucleophiles such as MeOH and ethanolamine; two that cannot undergo electrocyclic ring closure (from **8** and **11**) are readily observable by nanosecond laser photolysis, with long wavelength maxima (λ_{max}) of 600 and 520 nm, respectively. Photogenerated *o*,*o*′-biaryl quinone methides undergo electrocyclic ring closure to give the corresponding chromene (pyran) products in high yield. Since the precursor biaryl alcohols have highly twisted structures in the ground state (dihedral angle of up to 90° by molecular mechanics calculations), a significant twisting motion to planarity is required to achieve reaction. Using steady-state fluorescence studies, we present evidence to suggest that the mechanism of quinone methide formation may occur via one of the following mechanisms: (*i*) dissociation of the proton from ArOH that precedes twisting; or (*ii*) ArOH dissociation and twisting taking place either simultaneously or in quick succession.

Key words: biaryl quinone methide, photosolvolysis, photodeprotonation, photocyclization.

Résumé : Un certain nombre de biaryl quinone méthides diverses a été photogénéré avec des efficacités variables à partir des précurseurs biarylés **4**–**6**, **8**, **10** et **11** qui portent tous des substituants hydroxyle et hydroxyméthyle sur les autres cycles. Ces nouveaux biaryl quinone méthides, qui ne peuvent pas être générés facilement par le biais de la chimie thermique, peuvent être piégés par l'addition de nucléophiles tel que le méthanol et l'éthanolamine; deux d'entre eux qui ne peuvent pas subir des fermetures électrocycliques de cycles (obtenus à partir de **8** et **11**) peuvent facilement être observés par photolyse laser nanoseconde avec des longueurs d'onde maximales (λ_{max}) de 600 et 520 nm respectivement. Les *o*,*o*′-biaryl quinone méthides photogénérées subissent des fermetures électrocycliques de cycle conduisant à la formation des chromènes (pyran) correspondants, avec des rendements élevés. Puisque les structures de chaque alcool précurseur biarylé sont de nature fortement déformée à l'état fondamental (angle dièdre allant jusqu'à 90° sur la base de calculs de mécanique moléculaire), la réaction ne peut se faire qu'à la suite d'un mouvement de déformation important pour atteindre un état planaire. Faisant appel à des études de fluorescence en état stationnaire, on a obtenu des données qui permettent de suggérer que le mécanisme de formation de la quinoneméthide peut impliquer l'une des voies suivantes: (*i*) une dissociation de proton à partir du ArOH qui précède la déformation ou (*ii*) une dissociation du ArOH et une déformation qui se produisent soit de façon simultanée soit en succession rapide.

Mots clés : biaryl quinone méthide, photosolvolyse, photodéprotonation, photocyclisation.

Introduction

The moderate to highly twisted ground-state structures of biaryls (as measured by the dihedral angle between the two phenyl rings) are known, in general, to become more planar when electronically excited. This twisting motion towards planarity inherent in many biaryls on the excited-state surface has been generally rationalized by Zimmerman and Crumrine (1) and Imamura and Hoffmann (2), by noting that the coefficients of the two carbons joining the two aryl rings in the LUMO have the same sign, whereas they have opposite signs in the HOMO. Thus, population of the LUMO on electronic excitation causes an increase in the π-bond strength joining the two aryl groups, hence, a twisting motion to a more planar structure. This phenomenon has been utilized only on a limited basis to design or induce new photochemistry: most of the photochemical reactions reported for biphenyls do not appear to explicitly require a twisting motion to planarity (3). Interest in the photocontrol of supramolecular assemblies (4) and our wish to explore the mechanistic details and scope of quinone methide photogeneration from biaryl systems prompted us to investigate in detail the generality of photocyclization reactions reported by us over several years (5). For example, twisted 2-(2′-hydroxyphenyl)benzyl alcohol (**1**) (dihedral angle of 68°) is efficiently converted (in aq. CH_3CN) to the essentially planar

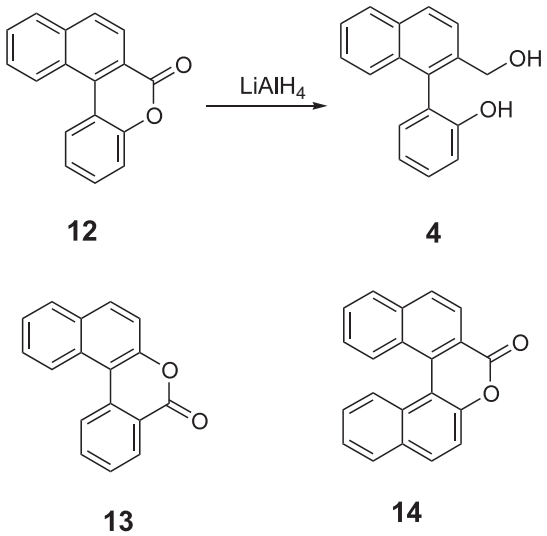
Scheme 1.

5*H*-dibenzo[*b*,*d*]pyran (**3**) (dihedral angle of 24°) via the proposed *o*,*o*′-biphenyl quinone methide *syn*-**2** with high quantum efficiency (Φ up to 0.5 at pH > 11) (Scheme 1) (5). The anti conformer (*anti*-**2**) is presumably also formed but is converted back to substrate **1** by nucleophilic attack by H_2O.

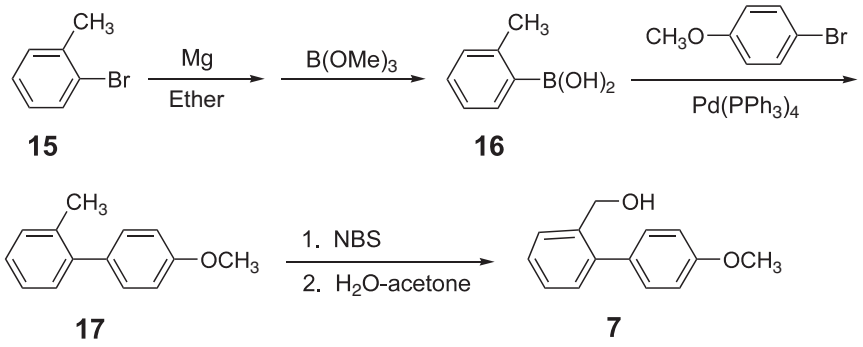
The incorporation of a naphthalene ring will, in general, make such biaryls more twisted than biphenyls owing to higher steric congestion induced by the naphthalene ring. For this reason, we decided to examine the photochemistry of naphthalene incorporated biaryls **4**–**6**, to test whether the photocyclization can occur for these more sterically congested systems. Biphenyl derivatives **7**–**11** were also studied to examine the photochemistry of those systems that cannot undergo photocyclization, but that contain the appropriate hydroxy and hydroxymethyl substituents to enable it to potentially generate the appropriate biphenyl quinone methide intermediate. We show that photocyclization takes place even for the highly sterically congested binaphthyl **6** and that biphenyl quinone methide intermediates are detectable by nanosecond laser flash photolysis only when the cyclization pathway is not available. In addition, photolysis of *m*-hydroxy substituted biphenyl **10** gave rise to a formally non-Kekulé biphenyl quinone methide.



Results and discussion

Materials

Biaryl alcohols **4**–**6** were readily made via $LiAlH_4$ reduction of the corresponding lactones **12**–**14** (e.g., eq. [1]), all known except for lactone **13**, which was made by adapting the procedure reported for **12** and **14** involving use of palladium(II) acetate mediated intramolecular coupling of aryl bromides (6). Biphenyl alcohols **8** and **10** were made by BBr_3 demethylation of methoxybiphenyls **7** and **9**, respectively, which in turn were readily made using palladium(0) mediated Suzuki coupling (7, 8) of the appropriate aryl bromide and arylboronic acid, followed by functional group modification, as shown in Scheme 2 for the synthesis of **7**, which starts from 2-bromotoluene (**15**). Biphenyl alcohol **11** was made by $LiAlH_4$ reduction of commercially available 4-hydroxy-4′-biphenylcarboxylic acid.



Many *o*,*o*′-disubstituted biphenyls are found in the syn geometry (as shown by *syn*-**18**) as opposed to the *anti* geometry (as shown by *anti*-**18**) with respect to the two *o*-substituents in the solid state (even in the absence of any

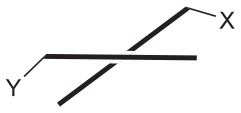

Scheme 2.

intramolecular hydrogen bonding), although the general reason for this remains unclear (9). We have shown that the crystal structure of **1** and its α,α-dimethyl derivative also take on the syn conformation, although for these alcohols intramolecular H bonding may play a role in favouring such a geometry (5*a*). With respect to the other biaryls studied in this work, we anticipate that their diaryl dihedral angles to be quite large, with also a preference for syn geometry. Molecular mechanics calculations (Chem 3D) of **4**–**11** confirm this; indeed the dihedral angles found for **4**–**6** were close to 90°.[2] Although these biaryls are expected to have highly twisted geometries, their solution structures may be different. Roberts (9) has shown there is close agreement between the dihedral angles of biphenyls observed in X-ray crystallography and those deduced from ^{13}C NMR studies. Thus, there is strong reason to believe that all biaryls **4**–**11** have highly twisted structures in solution. Moreover, if the preference for syn geometry observed and (or) predicted in the crystal for *o*,*o*′-disubstituted biaryls is also applicable in solution, then these molecules are also structurally optimized (in solution) to produce *syn* QMs (e.g., *syn*-**2**), which have the correct geometry for electrocyclic ring closure.

Product studies

Photolysis (254 or 300 nm) of **4**–**6** in 100% CH_3CN cleanly gave the corresponding ring closure chromene (pyran) products, as shown in Scheme 3 for **4** (correspondingly, **5** gave **20** and **6** gave **21**, Table 1), although with different quantum yields. These ring closure reactions can be conveniently followed by UV–vis spectrophotometry as all the chromene products show a red-shifted strong absorption band. Figure 1 shows the UV–vis spectral changes observed on photolysis of **4** in 100% CH_3CN, which gave chromene **19** quantitatively after sufficient photolysis. Note the presence of vibrational fine structure in the absorption of the photoproduct **19**, which is consistent with its more rigid structure (less torsional flexibility). The presence of isosbestic points throughout the conversion indicates a very clean reaction. The spectral traces for the analogous photochemical conversion of **6** to **21** have been published previously (5*c*) and show the same qualitative features.

The dihedral angle for chromene **21** is a point of interest since this would be the most sterically hindered of all the chromene products. A dihedral angle of 30° was calculated using molecular mechanics (Chem 3D). Thus, the photochemical conversion of **6** to **21** requires a substantial twisting motion, from about 90° to about 30°. Similar twisting motions are required for the conversions of **4** and **5** to the corresponding chromenes.

Photolysis (λ_{ex} = 254 nm) of **4** in H_2O–CH_3CN (1:1, *v*/*v*) results in a photostationary state containing 56% of the chromene product **19** and 44% of alcohol **4** (Fig. 2). Prolonged photolysis does not change this product to starting material ratio. The photostationary state composition was confirmed by exhaustive photolysis of a solution of **19** under the same conditions, which regenerated **4** and gave a photostationary state containing 60% of chromene **19** and 40% of alcohol **4**. Photolysis of **5** (or **6**) under identical conditions resulted in a photostationary state containing >95% chromene product **20** (or **21**) and <5% alcohol starting material.

Photolysis of **4** in neat CH_3OH gave a photostationary state containing approximately 24% of chromene **19** and 76% of the methyl ether product **22**. Prolonged photolysis, however, gave rise to a small amount (~10%) of unidentified side products, owing to the secondary photodecomposition of methyl ether **22**. The reversibility of this reaction was demonstrated by photolysis of chromene **19** in neat CH_3OH, which gave a photostationary state containing 21% of **19** and 79% of **22**. In H_2O–CH_3OH (1:1), photolysis of **19** resulted in a photostationary state containing **19**, **22**, and **4** in a ratio of 8:69:23. When the concentrations of CH_3OH and H_2O are taken into account, the relative rates of CH_3OH and H_2O ad-

[2] Unpublished X-ray analyses (A. MacKinnon, J.A.K. Howard, Y. Shi, and P. Wan) of some single crystals of these compounds confirm the expected large dihedral angles in the solid state. In addition, syn geometry was observed in all of **4**–**6**.

dition is approximately 7:1 in favor of CH_3OH. Photolysis of **5** and **6** in the presence of CH_3OH also resulted in the formation of the corresponding methyl ether products accompanied with a reduced yield for the corresponding chromene product. In the presence of $NaBH_4$ (~0.5 mol/L), photolysis of **4** (in 2-propanol or aq. CH_3CN) gave the reduction product **23** and **19** (Scheme 3). Photolysis of **1** and **6** also gave similar reduction products.

Photolysis of the biphenyl alcohols **7** and **8** in H_2O–CH_3OH (1:1) gave the corresponding methyl ether substitution products **24** and **25** (Scheme 4). In the presence of ethyl vinyl ether (~0.4 mol/L), photolysis (254 nm, 15 min) of **8** in aq. CH_3CN (H_2O–CH_3CN, 1:2) gave aldehyde **26** in high yield (>60%). In this reaction, ethyl vinyl ether simply functions as a nucleophile (β-vinyl carbon of ethyl vinyl ether) followed by hydrolysis. No evidence for [4+2] cycloaddition products was observed. Although less efficient, photolysis of **11** under similar conditions also resulted in the formation of the corresponding methyl ether product from CH_3OH, but no aldehyde product was observable in the presence of ethyl vinyl ether.

It was previously observed (5*a*) that when the phenolic OH group of the parent compound **1** was replaced with a methoxy group, photolysis of the substrate in aqueous methanol does not result in the corresponding methyl ether substitution product. This is also true for 3-[2′-

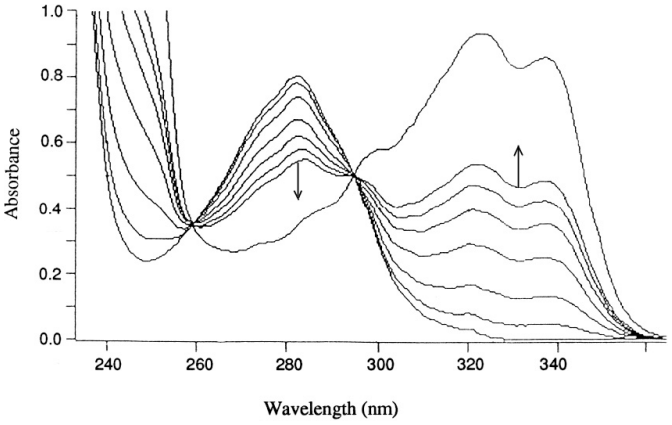
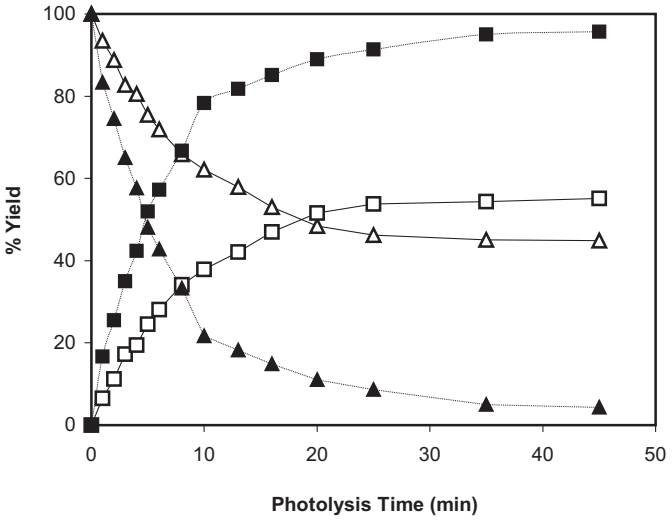
Fig. 1. UV–vis spectral traces showing the smooth conversion of **4** to chromene **19** in 100% CH_3CN (λ_{ex} = 254 nm; each trace represents about 10–20 s photolysis, except for the last trace, which was obtained after extended photolysis, >10 min). The final spectrum obtained is essentially identical to that of pure chromene **19**.





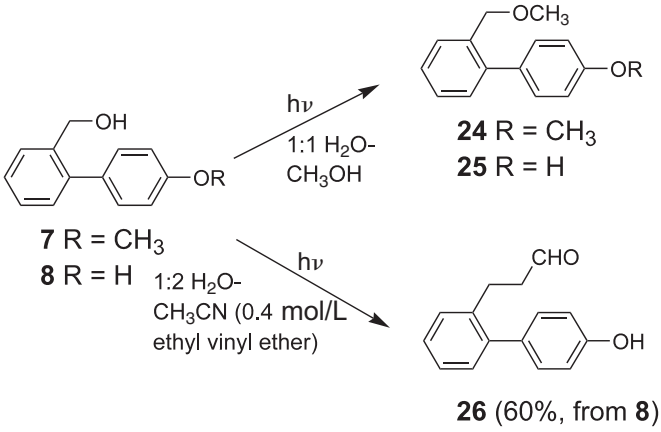


Fig. 2. Plot of % **4** (triangles) and % **19** (squares) vs. photolysis time in 100% CH_3CN (filled) and in CH_3CN–H_2O (1:1) (unfilled).

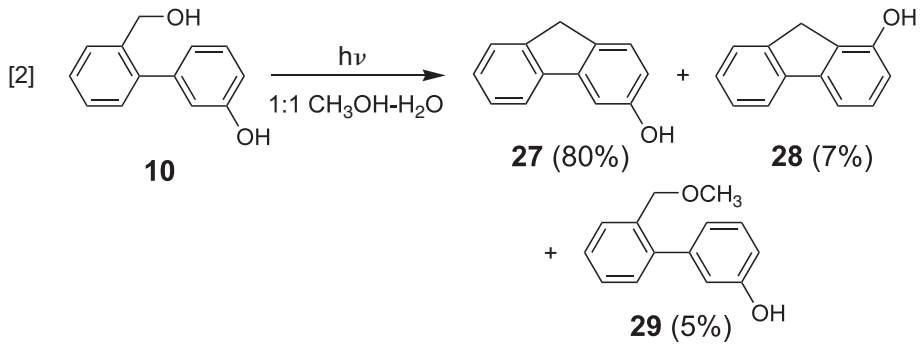
(hydroxymethyl)phenyl]anisole (**9**), where prolonged irradiation of **9** in CH_3OH–H_2O (1:1) did not give any product, and the starting material was completely recovered.



Scheme 4.

Interestingly, irradiation of **10** in CH_3CN–H_2O (1:1) resulted in a major product 3-hydroxyfluorene (**27**) and a minor product in approximately a 10:1 ratio. The minor product had the same molecular weight as **27** and its ^1H NMR spectrum showed only absorption at the aromatic region and a singlet at δ 3.82 ppm, corresponding to Ar-CH_2-Ar. This minor product is consistent with 1-hydroxyfluorene (**28**) (eq. [2]). In CH_3OH–H_2O (1:1), photolysis of **10** gave an additional minor product. The ^1H NMR spectrum of the product mixture is consistent with the formation of the substitution product methyl ether **29** (eq. [2]). The ring closure reaction (to give **27** and **28**) can also be monitored by UV spectrophotometry. Since the absorption spectrum of **27** is red shifted by about 20 nm relative to the starting material (**10**), as the reaction proceeds, a structured new band corresponding to **27** in the 300–320 nm region grows in with photolysis.

Product quantum yields

Product quantum yields for the photocyclization of biaryl alcohols **4–6** and for the photosovolysis/photocyclization of **7–11** were measured using potassium ferrioxalate actinometry (10) (λ_{ex} = 280 nm) as the standard, and UV–vis and (or) ^1H NMR to monitor for reaction progress. Photocyclization product quantum yields for **4–6** are summarized in Table 1. Large solvent dependence was observed in the photocyclization quantum yields. Although H_2O was previously observed to enhance the photocyclization of the parent compound **1** (5*a*), the water effect on the photocyclization of **4** was the opposite. Added H_2O (when the H_2O content ≥10%) noticeably decreased the quantum yield. In contrast

[a]Measured in neat CH_3CN. The lifetime of the corresponding phenolate or naphtholate (in 0.01 mol/L NaOH) quoted in brackets.

[b]Determined in neat CH_3CN using naphthalene and 2-aminopyridine as the standard. The number in brackets was determined in H_2O–CH_3CN (1:1).

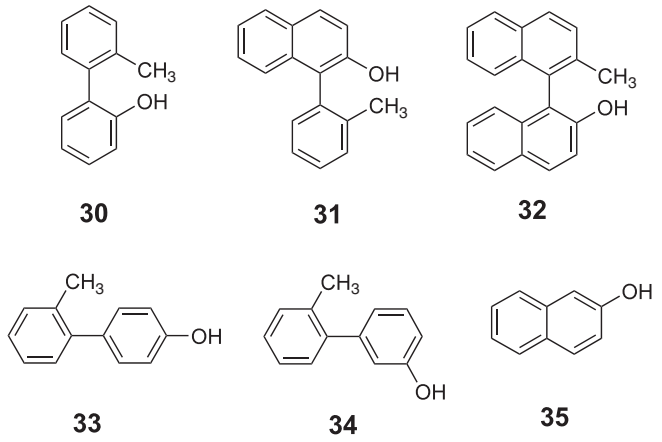
[c]Natural fluorescence rate constant as defined by $k_f^0 = \Phi_f/\tau_f$.

[d]$\Delta\nu$ is the Stokes shift and w is the spectral width (at half height), as defined by Berlman (11, 13).

[e]Due to stronger emission from the phenolate ion, Φ_f in aqueous solution was calculated from the Φ_f of **34** in neat CH_3CN and the relative fluorescence intensity in the two solvents.

to **4**, the quantum yield for **6** and **5** showed an initial increase with added water and a decrease at higher water contents. The quantum yield for **5** was also much smaller than those of **4** and **6**. Biaryl alcohol **6** is expected to be most sterically congested system, whereas **4** and **5** are expected to be similar in this respect; therefore, the explanation for the observed quantum yield difference probably lies in an electronic factor that we do not currently understand.

The quantum yield for the photocyclization (to the fluorene ring system) of **10** in CH_3CN–H_2O (1:1) (eq. [2]) was 0.17 (for the formation of both **27** and **28**). There was significant variations in measured quantum yields for the photosolvolysis of the remaining biphenyl alcohols **7**, **8**, and **11**. Photolysis of **8** in H_2O–CH_3OH (1:1) gave **25** with Φ = 0.23, while photolysis of **11** under identical conditions gave the corresponding methyl ether in much lower quantum yield (Φ = 0.026). Substitution of the phenol OH with an OCH_3 group significantly lowers the reactivity of these substrates. For example, the quantum yield (Φ = 0.075) for photolysis of **7** to give **24** is only one-third of that for photolysis of **8** to give **25**. Indeed, there was no methyl ether product (or ring closure product) observable in the photolysis of **9**. In general, the product quantum yields measured previously were unaffected in the pH 1–7 region (slight increases of up to about 10% was observed on lower acidity beyond pH 1). In the pH > 9 region, the compounds were more reactive as indicated by enhanced loss of the substrate, but quantification was problematic because of the formation of more side products as a result of direct excitation of the phenolate.



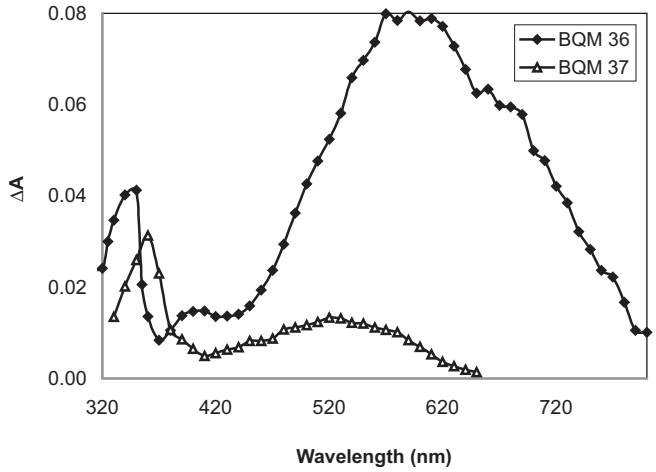
Fluorescence measurements

It is well-known that biphenyl and many of its derivatives have large geometry changes upon electronic excitation (11). When compared with more rigidly planar (in both ground and electronically excited states) molecules such as fluorene and anthracene, these molecules have larger energy differences (thus, a larger Stokes shift) between the Frank–Condon and the fluorescent state. For example, biphenyl and phenyl naphthalenes have significantly larger Stokes shifts (3000–3200 cm^{-1}) than fluorene (1430 cm^{-1}) and 1,2-benzofluorene (1400 cm^{-1}) (in cyclohexane) (11). Thus, excited-state twisting of biaryls can be qualitatively related to the Stokes shift values determined from fluorescence emission spectra (11, 12). In addition, transitions from a more planar initial state (S_0 or S_1) tend to give narrower as opposed to broad spectra (12). Thus, both Stokes shift ($\Delta\nu$) and spectral width (w) of the fluorescence emission band provide useful information with respect to geometry changes associated with the excited state.

Due to highly efficient photocyclization via S_1, some of the biaryl alcohols studied were only weakly fluorescent. Therefore, the fluorescence behavior of a series of model compounds (**7**, **9**, **23**, **27**, and **30**–**35**) that are either nonreactive or reacted only with low quantum efficiency were also studied. The fluorescence spectral properties ($\Delta\nu$, w), fluorescence quantum yields, and the fluorescence lifetimes for some of these compounds are also tabulated in Table 2.

As shown in Table 2, the Stokes shifts ($\Delta\nu$) for all the "loose" biphenyl systems in neat CH_3CN are approximately 3300 ± 300 cm^{-1}, which is significantly larger than that of the

© 2005 NRC Canada

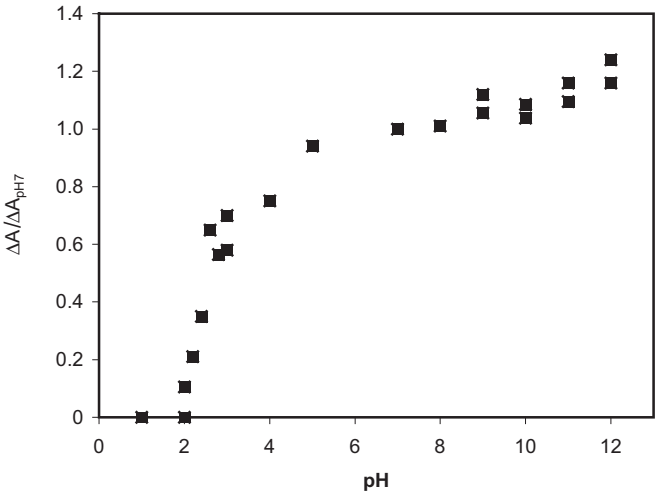


"rigid" biphenyl molecule **27** (1705 cm^{-1}). The spectral width (w) of all the *o*-substituted biphenyl derivatives ($w \approx 1750$–2000 cm^{-1}) is significantly larger than analogs not bearing a substituent at the *o*-position (**11**, $w = 1574$ cm^{-1}) and the rigid compound **27** ($w = 1411$ cm^{-1}). The spectral width of **11** is only slightly larger than that of **27**. This phenomenon is a result of the increased steric repulsion owing to *o*-substitution that results in a less rigid and less planar S_1 in these molecules. A similar trend was also observed in 0.01 N NaOH(aq) solutions, where the emitting species are the corresponding phenolate ions. For example, the Stokes shift and spectral width of **34** ($\Delta\nu = 6238$ cm^{-1}, $w = 2402$ cm^{-1}, model of **10**) and **30** ($\Delta\nu = 5590$ cm^{-1}, $w = 2138$ cm^{-1}, model of **1**) are larger than those of the rigid molecule **27** ($\Delta\nu = 4235$ cm^{-1}, $w = 2063$ cm^{-1}). Thus, it can be concluded that both the neutral and the phenolate ion forms of these biphenyl systems can twist to the more planar geometry upon electronic excitation.

In contrast to the biphenyl systems, biaryls with one or two naphthalene rings (**4**–**6** and their model compounds, bottom half of Table 2) *do not* show large Stokes shifts in neat CH_3CN. The fluorescence spectra of these molecules in neat CH_3CN resemble that of 2-naphthol (**35**) or 2-(hydroxymethyl)naphthalene. The Stokes shifts (~1750 ± 80 cm^{-1}, Table 2) of these compounds are also similar to (or only slightly greater than) that of **35**, but significantly smaller than that of 1-phenylnaphthalene (3200 cm^{-1}) (11), which suggests that these molecules are just as twisted in the S_1 state as in the ground state. The spectral width for these molecules, except for **4**, is also small (~1400–1500 cm^{-1}) indicating rigid S_1 states.

In aqueous solution, neither **4** nor **6** showed any detectable fluorescence emission owing to the very efficient photochemical cyclization from S_1. Thus, model compounds **23** and **32** provided valuable information. In CH_3CN–H_2O (1:1), both of these compounds only gave *one markedly red-shifted* emission band centered at ~560 nm. These emission bands are *identical* to the emission spectra of the corresponding phenolate and (or) naphtholate ions obtained by using 0.01 mol/L NaOH–CH_3CN (1:1) as the solvent. The absence of the emission from the neutral species of **23** and **32** at pH 7 suggests rapid excited-state proton transfer (ESPT) to the solvent. In 0.01 mol/L NaOH–CH_3CN (1:1), the Stokes shift and spectral width ($\Delta\nu = 6865$ cm^{-1}, $w = 2264$ cm^{-1}) of **32** and that of **23** ($\Delta\nu \approx 7800$ cm^{-1}, this emission is too weak for w to be measured accurately) are much larger than the naphtholate ion of **35** ($\Delta\nu = 3034$ cm^{-1}, $w = 1583$ cm^{-1}, Table 2). These extraordinary large Stokes shifts are consistent with large geometry changes in S_1 for the *deprotonated* forms of **32** and **23**. Thus, it seems reasonable that the deprotonated forms of **4** and **6** also twist to the planar (or more planar) geometry in the excited state. The lack of any observable emission from these compounds is due to an inherently efficient cyclization reaction that takes places from this more planar state.

Fig. 3. Transient spectra of biaryl quinone methides **36** and **37** obtained from nanosecond LFP of **8** and **11**, respectively, in 100% H_2O.



In contrast, **5** and its model compound **31** show strong emissions (at nearly equal intensity) from both the neutral 2-naphthol moiety ($\lambda_{max} \approx 360$ nm) and the naphtholate ion ($\lambda_{max} \approx 425$ nm) in H_2O. In 0.01 mol/L NaOH–CH_3CN (1:1), only the emission of the naphtholate ion was observable, but the spectral properties (Stokes shift, spectral width, and λ_{max}) of this emission closely resemble those of 2-naphthol **35** (the 2-naphtholate ion). It is concluded that **5**, even in its deprotonated form, can not twist to the planar geometry efficiently in S_1, which is required for the ring closure reaction. This is consistent with its low quantum efficiency observed for the ring closure reaction (Table 1).

Laser flash photolysis

Nanosecond laser flash photolysis (LFP) (266 nm, Nd:YAG laser, ≤20 mJ) of **8** in aq. CH_3CN gave a strong and very broad transient absorption spectrum with the major band at ~600 nm (Fig. 3). Although the transient spectrum was broad (450–800 nm), the decay at all wavelengths (including the weak band at 350 nm) was single exponential and had identical rates. It was also observed that the water content of the solvent affected the intensity as well as the decay rate of this transient. In neat CH_3CN, this transient was not observed; in neat H_2O, the intensity of the spectrum was ca. threefold larger than that in CH_3CN–H_2O (1:1). This indicated that H_2O was necessary for the formation of this transient. The λ_{max} of the transient was red shifted with increasing solvent polarity (575 nm in CH_3CN–H_2O (1:1) to 600 nm in neat H_2O). The shape of the spectrum was independent of pH; photolysis of **8** in pH 2.5, 7, and 12 gave essentially the same spectrum, although the intensity varied. The decay rate was not affected by O_2 but showed strong

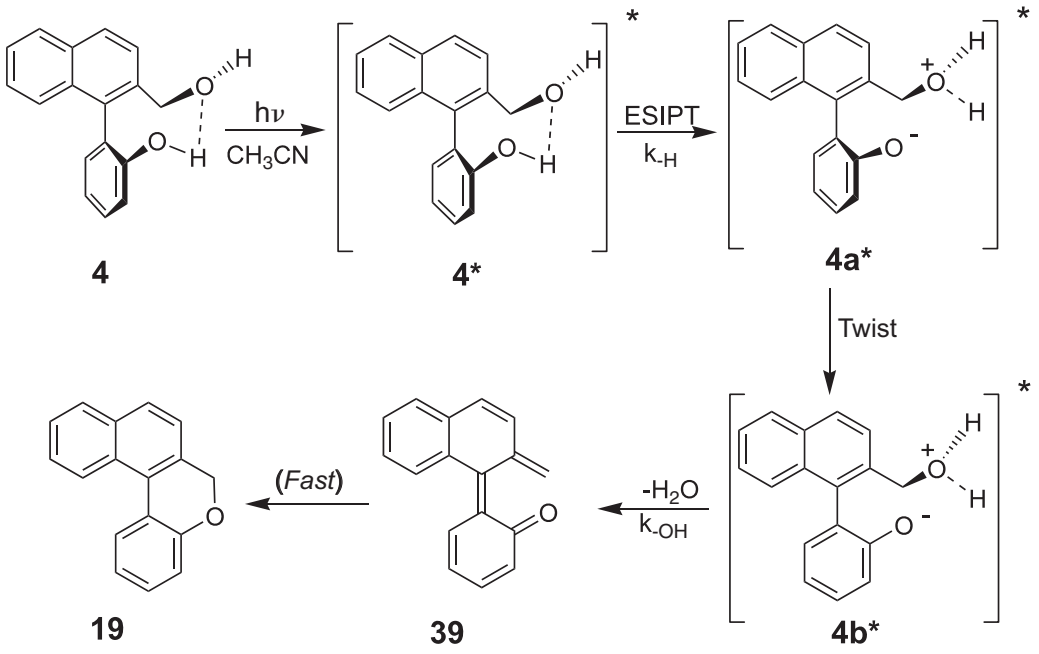
Fig. 4. pH Dependence for photogeneration of biaryl quinone methide **36** as observed by LFP of **8** (errors are ±10% of quoted value).

solvent and pH dependence. In the CH_3CN–H_2O mixed solvent system, the decay rate increased by ca. three orders of magnitude when the water content changed from 10%–100% H_2O. A plot of the logarithm of the decay rate vs. the molarity of H_2O was essentially linear. The transient could be efficiently quenched by H^+. In pH 4–12, there was essentially no pH effect on the decay rate constant (k_{obs}), although it was slightly affected by added electrolytes (in neat H_2O and 0.01 mol/L NaOH, $k_{obs} = 2.0 \times 10^6$ s^{-1}; in pH 4 and 7 buffered solutions, $k_{obs} = 2.5 \times 10^6$ s^{-1}). However, the decay rate increased dramatically at lower pH (pH 2 to 3), suggesting quenching by H^+. In this pH region, the observable transient intensity also decreased significantly with pH while the fluorescence intensity increased considerably. Due to interference from fluorescence emission and weaker transient absorption, it was not possible to measure the decay rate accurately at low pH. It was estimated that k_{obs} ~10^7 s^{-1} at pH 3 and ~10^8 s^{-1} at pH 2, corresponding to a quenching rate constant (by H^+) of $k_q \approx 10^{10}$ s^{-1} (mol/L)$^{-1}$. The transient was also quenchable by added nucleophiles such as ethanolamine ($k_q = 3.6 \times 10^6$ s^{-1} (mol/L)$^{-1}$).

We thus assigned this transient spectrum to biaryl quinone methide (BQM) **36**. The broad and structureless absorption spectrum is consistent with a ground state that is not rigidly planar. The fact that irradiation of **8** in 0.01 mol/L NaOH gave exactly the same transient spectrum as in pH 7, indicates that this same transient can be generated by irradiation of the corresponding phenolate ion of **8**. The relative quantum efficiency for generating this transient from the neutral form of **8** vs. its deprotonated form (the phenolate ion) is shown in Fig. 4 in which the ΔA at 600 nm at different pH values was measured immediately after each laser pulse, and the ratio $\Delta A/\Delta A_{pH7}$ was plotted against the pH of the solvent. When the energy of the laser pulse and the absorbance of the solution at the excitation wavelength were kept constant, the ratio $\Delta A/\Delta A_{pH7}$ is a direct measure of the relative quantum yield for formation of BQM **36** at this pH (relative to pH 7). It is expected that such a plot would show two transitions, one at pH ≈ 2–4 (corresponding to the pK_a* of the excited-state phenol) and the other at pH ≈ 10 (corresponding to the pK_a of the ground state). This is in fact revealed in Fig. 4. The first titration between pH 2–4 is clearly evident while the second at pH 10–12 is less marked. The modest increase in efficiency upon excitation of the phenolate might be due to the already high yield of the phenolate ion on adiabatic deprotonation from the phenol.

Although product studies showed that the photolysis of **7** in H_2O–CH_3OH (1:1) also gave the corresponding methyl ether product in reasonable yield, LFP of **7** did not produce any observable transient species assignable to quinone methides or carbocations. This seems reasonable since there is no simple mechanism for photogenerating quinone methides from the methoxy compound. Moreover, the anticipated carbocation intermediate responsible for the observed photosolvolysis would be of the benzylic kind and would be too short-lived in aqueous solution to be detectable by nanosecond LFP.

Laser flash photolysis of **11** in aq. CH_3CN also gave a transient absorption spectrum with two major bands at 360 and 525 nm (Fig. 3). Its decay rate in 100% (pH 7) H_2O ($k_{obs} = 1.50 \times 10^4$ s^{-1}) is less than that observed for **36**. The transient is quenched by H^+ and added nucleophiles and thus can be assigned to BQM **37**. A Stern–Volmer plot using $H_2NCH_2CH_2OH$ as a quencher gave $k_q = 2.61 \times 10^5$ s^{-1} (mol/L)$^{-1}$, which is significantly smaller than that observed for **36**. The fact that the spectral width of **37** is narrower than that of **36** is consistent with its more rigid ground state (less steric repulsion at the *o*-position). Unlike **36**, the phenolate ion of **11** gives rise to BQM **37** much more efficiently than the neutral molecule; the relative quantum yield for the photogeneration of **37** is 3.5 times higher at pH 12 than at pH 7.



Burnham and Schuster (14) have studied the photochemistry of **6** and **21**. They suggested that the photocyclization of **6** to **21** proceeded via a BQM intermediate (viz., **38**). They also suggested that BQM **38** was observable by nanosecond laser flash photolysis in cyclohexane with a lifetime of 5 μs. However, using nanosecond LFP, we have not been able to detect any transient species in the 450–700 nm region assignable to the BQM for any of **1**, **4**–**6**, and **10** in aq. CH_3CN. We conclude that in aq. CH_3CN any BQM intermediate from these substrates is too short-lived to be detectable on the nanosecond timescale, i.e., electrocyclic ring closure from intermediates such as **39**, to give two new aromatic rings in **19** (Scheme 5) would be expected to be very fast ($k >> 10^9$ s^{-1}).

Reaction mechanisms

We begin our mechanistic discussion for the most reactive compound that undergoes photocyclization, viz., **4** (Scheme 5). The quantum yield for the photocyclization of **4** is high in aprotic solvents such as CH_3CN ($\Phi = 0.3$) and THF ($\Phi = 0.4$). Since a small amount of added H_2O does not change the quantum yield dramatically (Table 1), the reaction cannot be ascribed by a mechanism mediated by traces of residual water or other protic solvent impurities. Although the molecules may be intermolecularly H bonded in the crystalline state, such intermolecular H bonding is not likely in dilute solution in a polar solvent such as CH_3CN. Thus, the reaction in aprotic solvent is most likely via an excited-state intramolecular proton transfer (ESIPT) mechanism, as

© 2005 NRC Canada

Scheme 5.

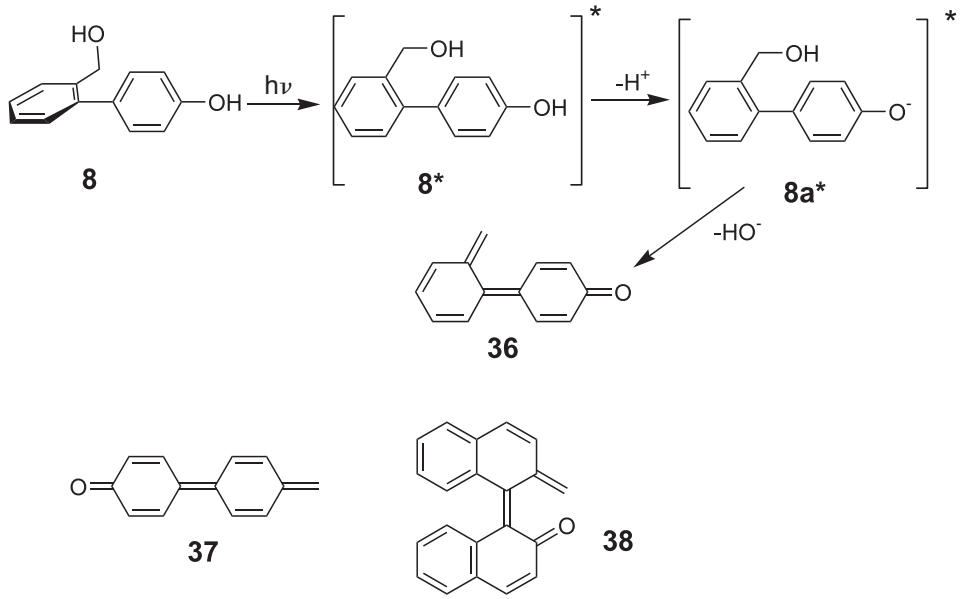
shown in Scheme 5, in which the ArOH proton is first transferred to the $ArCH_2OH$ oxygen atom of the same molecule via an intramolecular H bond to give **4a***. This is followed by twisting to the planar geometry to give **4b***, followed by the loss of a molecule of H_2O to give the BQM intermediate **39**, which subsequently undergoes electrocyclization in a fast reaction ($k >> 10^9$ s^{-1}) to give the chromene product **19**. This mechanism is supported by the Stokes shift data observed in the fluorescence measurements, which indicated that the neutral forms of **4** and **6** do not twist to the planar geometry, but their deprotonated forms do.

Since the product quantum yield for **4** is also much higher than its analogs (**1**, **5**, and **6**) in aprotic solvents, a faster ESIPT rate could be responsible for this. More insights on this aspect are obtained from the fluorescence quantum yield and fluorescence lifetime studies (Table 2). The kinetic expression for fluorescence quantum yield (Φ_f) is the ratio of the natural fluorescence rate constant (k_f^0) to the sum of the rates for all possible deactivation pathways, given by eq. [3],

$$[3] \qquad \Phi_f = k_f^0/(k_f^0 + \Sigma k_d + \Sigma k_r)$$

where Σk_d represents the sum of nonradiative deactivation rates such as the rate of internal conversion (k_{ic}) and the rate of intersystem crossing (k_{isc}); Σk_r represents the sum of all possible chemical reactions of S_1. According to the proposed mechanism (Scheme 5), Σk_r in this case is the ESIPT rate k_{-H}. For the model compound **23**, Σk_r is zero in neat CH_3CN. If we assume that **4** and **23** have similar k_f^0 and Σk_d values, then k_{-H} can be estimated by eq. [4]:

$$[4] \qquad k_{-H} = (k_f^{\,0} + \Sigma k_d)\left[\frac{(\Phi_f)_{mdl}}{(\Phi_f)_{rec}} - 1\right]$$



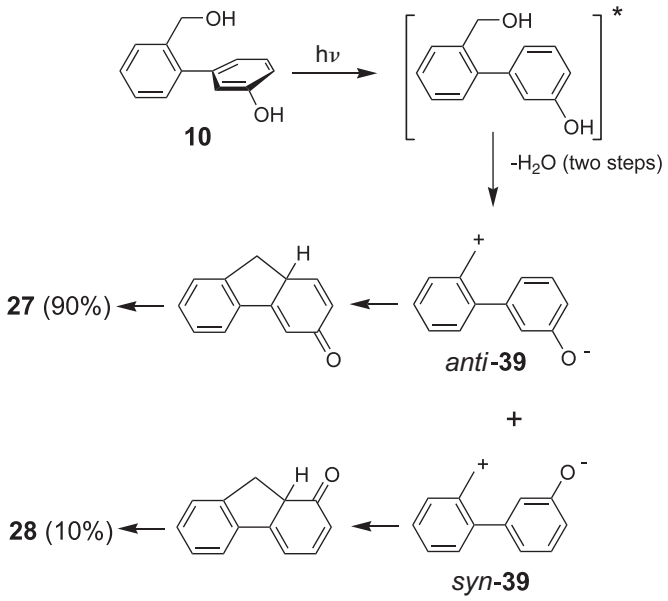
where the rec subscript refers to the reactive compound (i.e., **4**–**6**) and mdl to the corresponding model compound (i.e., **23**, **31**, and **32**); ($k_f^0 + \Sigma k_d$) is the reciprocal of the fluorescence lifetime (τ_f, Table 2) of the model compound. The ESIPT rate k_{-H} estimated for **4** using this method is 2×10^9 s^{-1}, which is nearly two orders of magnitude larger than those for **5** (2×10^7 s^{-1}) and **6** (3×10^7 s^{-1}).

Addition of H_2O to CH_3CN can change the mechanism for photocyclization. It was observed that upon the addition of water (0–2.5 mol/L), the fluorescence intensity of **31** (model of **5**) increased by 11% while both **32** and **23** showed significant fluorescence quenching (fluorescence intensity decreased by 41% and 53%, respectively), suggesting that **23** (or **4**) and **32** (or **6**) undergo efficient ESPT to water. Thus, the increase in cyclization quantum yield with added water (Table 2) can be rationalized as being due to the operation of a more efficient cyclization pathway in water, viz., ESPT to water to generate the phenolate or napththolate ion, followed by twisting to a more planar state and the loss of hydroxide ion. However, when the water content is sufficiently high, the quantum yield for cyclization decreases owing to the competition of nucleophilic attack on the quinone methide by water itself, which leads back to the starting material (i.e., **39** to **4**). In the case of **5**, where the cyclization quantum yield is intrinsically lower, other effects appear to dominate when water is added, making the fluorescence emission stronger at low water content than in pure CH_3CN.

In 0.01 mol/L NaOH, if we also assume that the reactive species has similar k_f^0 and Σk_d values as its model compound, k_{-OH} for **5** (its naphtholate ion) can be estimated from the fluorescence lifetime of **5** (τ_f = 10.8 ns) and that of its model compound **31** (τ_f = 15.0 ns), i.e., $k_{-OH} = (1/10.8 - 1/15) \times 10^9 = 2.6 \times 10^7$ s^{-1}, which is in the same order of magnitude as the natural fluorescence rate constant (k_f^0) for these types of molecules. This also explains the fact that **5** has a strong fluorescence emission in aq. 0.01 mol/L NaOH solution and a lower reaction quantum yield. In contrast, **6** showed complete fluorescence quenching in this medium,

© 2005 NRC Canada

Scheme 6.



although its model compound **32** does show reasonably strong fluorescence emission. This suggests that k_{-OH} for **6** is much larger than k_f^0, i.e., $k_{-OH} >> 10^7 s^{-1}$. It is therefore clear that the low quantum efficiency observed for the photocyclization of **5** is due to *both* a smaller k_{-H} and a smaller k_{-OH}.

LFP and product studies indicate that the efficiencies for the photogeneration of BQMs **36** and **37** are significantly different, which suggests that **8** and **11** have significantly different reactivities (different deprotonation rate k_{-H} and (or) dehydroxylation rate k_{-OH}). Fluorescence quenching experiments on these systems reveal some interesting insights on these processes. It can be easily seen from Table 2 that significant fluorescence quenching effect is only observable for the biphenyl system bearing both the phenolic and the benzylic OH (and also at the right positions), i.e., **8** and **10**. Φ_f of **8** decreased by a factor of five and that of **10** decreased by a factor of 3.5 when the solvent was changed from neat CH_3CN to H_2O–CH_3CN (1:1), suggesting very large k_{-H} and (or) k_{-OH} for these molecules. When either the CH_2OH moiety (of $ArCH_2OH$) is replaced by CH_3 or the phenolic OH is replaced by an OCH_3, there is either no fluorescence quenching or only a minor quenching effect. In addition, no fluorescence emission from the phenolate ions of **8** and **10** could be detected, although model compounds **33** and **34** did show strong fluorescence emission from their respective phenolate ions. These observations suggest that the deprotonation and dehydroxylation processes in **8** and **10** are unusually fast and may actually be concerted, although it is shown as a step-wise process in Scheme 6. Note that in this mechanism, the twisting about the biphenyl ring system takes place without the need for deprotonation of the phenol, consistent with the fluorescence results.

Although results from product studies indicate that the photolysis of **10** (Scheme 7) should proceed via BQM **39**, LFP studies showed no detectable transients longer than a few ca. 10 ns. This is consistent with the expectation since benzylic-type carbocations **39** should be shorter lived than a few nanoseconds (15). Assuming the presence of BQM **39**

Scheme 7.

intermediates, the working mechanism for the reaction is shown in Scheme 7. The isolation of fluorene products **27** and **28** is consistent with the formation of the zwitterionic BQMs *anti*-**39** and *syn*-**39**. The quantum yield for formation of these intermediates is quite high (Φ = 0.17, vide supra) and indicates that there is substantial charge transfer (electronic communication) between the *o* and *m* positions on *different* rings in the biphenyl system. Note that there is little to no electronic communication between such positions in the ground-state molecule, so the previous finding could be used to design systems where electronic communication can be switched on by photoactivation.

Summary

The main conclusion from this work is that a variety of

© 2005 NRC Canada

biaryl quinone methides (extended analogs of simple benzenoid quinone methides) are readily photogenerable from the corresponding hydroxymethyl substituted phenols (or equivalent compounds) in aqueous solution. Indeed, it would appear that at least for the biphenyl quinone methide series, all isomeric biphenyl quinone methides are photogenerable in aqueous solution, albeit with differing quantum efficiencies. The lifetimes of these quinone methides will range from subnanoseconds to as long as a few milliseconds. Two driving forces have been identified as being responsible for this kind of chemistry: (*i*) the tendency for twisted ground-state biaryls to twist to a more planar geometry in the excited state; and (*ii*) a large degree of charge transfer (to the other ring) inherent in the excited-state phenolate ion.

Experimental section

Instrumentation

^{1}H NMR spectra were recorded on a Bruker WM-250 (250 MHz), AMX (360 MHz), or AC-300 (300 MHz) instrument in $CDCl_3$ or $(CD_3)_2CO$, unless otherwise noted. IR spectra were recorded on a PerkinElmer 283 instrument. UV–vis spectra were measured on a Cary 5 instrument. Mass spectra were obtained on a Finnigan 3300 instrument (CI). High-resolution mass spectra (HR-MS) were obtained on a Kratos Concept H (EI) instrument. Melting points were determined on a Koefler hot stage microscope (uncorrected). Fluorescence spectra were obtained on a Photon Technology International (PTI) A-1010 fluorimeter. Fluorescence lifetimes were determined on a PTI LS-1 instrument in lifetime mode. Gas chromatography was performed on a Varian 3700 instrument with a Hewlett Packard 3390A integrator, with a column temperature of 100–250 °C (initial 100 °C, rate 10 °C/min, final 250 °C). Measurements of pH was carried out on a Corning pH meter 140. Preparative photolyses were carried out using a Rayonet RPR 100 photochemical reactor using 254 or 300 nm lamps. An Oriel 200 W Hg light source and an Applied Photophysis monochromator on an optical bench were employed in small scale photolysis and in product quantum yield determinations.

Common laboratory reagents

Dichloromethane (ACS reagent grade) was distilled before use. Anhydrous THF was obtained by distillation from potassium metal. Anhydrous diethyl ether and dimethyl acetamide were purchased from the Aldrich Chemical Co. and used as received. Other solvents (ACS reagent grade) used for synthetic purposes were used without further purification. Deuterated solvents, D_2O, $CDCl_3$, $(CD_3)_2CO$, CD_3CN, and DMSO-d_6, were purchased from the Cambridge Isotope Laboratory containing 99.9% D. Standard buffer solutions used for fluorescence and LFP studies were purchased from the Fisher Scientific Co. Solvents used for fluorescence studies, CH_3CN (HPLC grade), 95% CH_3CH_2OH, and C_6H_{12} (spectral grade), were checked for spurious emission before use. Anhydrous CH_3CN used for fluorescence studies was distilled over CaH_2 and used immediately. Preparative TLC was carried out on 20 cm × 20 cm silica gel GF Uniplates (Analtech).

Materials

The following compounds were purchased from Aldrich: naphthalene (recrystallized from 95% CH_3CH_2OH), 2-aminopyridine (99.9%, used as secondary standards for fluorescence quantum yield experiments), 2-naphthol (**35**) (recrystallized from 95% EtOH), BBr_3 (1 mol/L in CH_2Cl_2), 2-bromobenzoic acid, 3-bromoanisole, 4-bromoanisole, 2-bromotoluene (**15**), and 4-(4′-hydroxyphenyl)benzoic acid. Biphenyl **1** was synthesized according to a previous method (5*a*). Lactones **12** and **14** were synthesized from known procedures (6).

2′-Naphthyl-2-bromobenzoate
