2-Bromobenzoic acid (20 g, 0.1 mol) was dissolved in a mixture of $SOCl_2$ (300 mL) and toluene (500 mL) and refluxed under N_2 for 3 h. The solvent and extra $SOCl_2$ were then removed under reduced pressure distillation to give the acid chloride. The residue was then redissolved in CH_2Cl_2 (500 mL). To this solution, a solution of 2-naphthol (14.4 g) and triethylamine (15 g) in 250 mL CH_2Cl_2 was added dropwise and stirred at room temperature (rt) for several hours. After reaction, the mixture was first washed with water, then dried over $MgSO_4$. The solvent was evaporated to give a brown solid. Pure 2′-naphthyl-2-bromobenzoate was obtained upon recrystallization from toluene (~80%); mp 79 to 80 °C. ^{1}H NMR (250 MHz, $(CD_3)_2CO$) δ: 7.45–7.66 (m, 5H), 7.78–7.88 (m, 2H), 7.90–8.00 (m, 2H), 8.02 (d, 1H, J = 8.8 Hz), 8.06–8.16 (m, 1H). MS (CI) *m*/*z* (relative intensity): 327/329 (M + 1) (14/13), 183/185 (M – $C_{10}H_8O$) (100/99).

5*H*-Dibenzo[*c*,*f*]chromen-5-one (13)

2′-Naphthyl-2-bromobenzoate (5.0 g, 15 mmol), sodium acetate (2.5 g, 30 mmol), triphenylphosphane (2.4 g, 9 mmol), and palladium(II) acetate (0.10 g, 0.45 mmol) were dissolved in dry *N*,*N*′-dimethyl acetamide (180 mL) and heated to 120–130 °C for 24 h. After cooling to rt, CH_2Cl_2 (720 mL) was added. This solution was washed with 10% HCl three times. The organic layer was dried over $MgSO_4$ then the solvent was removed using a rotary evaporator. A mixture of **13** and its β-isomer (3:1 mixture, total 1.5 g, 6 mmol, 40%) was obtained after chromatography (silica gel, CH_2Cl_2). This mixture was separated by slow recrystallization from hexanes (the two isomers separated from the mother liquor at different times). Pure **13** was obtained after an additional recrystallization procedure (final yield 25%); mp 160–162 °C. IR (KBr, cm^{-1}) ν: 3040 (w, C-H aromatic), 1710 (s, C=O), 1605, 1590 (m, C=C), 1500 (m), 1458 (m), 1300 (s), 1270 (s), 1210 (s), 1110 (s), 1065 (s), 805 (s), 780 (m), 740 (s). ^{1}H NMR (250 MHz, $(CD_3)_2CO$) δ: 7.50 (d, 1H, J = 7.9 Hz), 7.60 (ddd, 1H, J = 8, 8, 1 Hz), 7.73 (ddd, 2H, J = 8, 8, 1 Hz), 7.98–8.14 (m, 3H), 8.41 (dd, 1H, J = 8, 1 Hz), 8.75 (d, 1H, J = 8 Hz), 8.85 (d, 1H, J = 8 Hz). HR-MS (EI) calcd. for $C_{17}H_{10}O_2$: 246.0681; found: 246.0688. Chemical anal. calcd. for $C_{17}H_{10}O_2$ (%): C 82.91, H 4.09; found: C 82.80, H 4.08.

General procedure for $LiAlH_4$ reduction

A solution of the substrate in dry THF was added (under stirring, rt) dropwise into a round-bottomed flask charged with $LiAlH_4$ (excess) and a small amount of dry THF. After the addition was completed, the mixture was refluxed for

© 2005 NRC Canada

1 h. Then the mixture was cooled to rt and poured into a mixture of ice and 10% HCl. The corresponding biaryl methanol was obtained after standard extraction (Et_2O–CH_2Cl_2, 1:2), drying ($MgSO_4$), and evaporation (rotary evaporator) of the solvent. Pure product (**4**–**6**) was obtained after recrystallization from toluene (yield ≥90%).

2-[2′-(Hydroxymethyl)-1′-naphthyl]phenol (4)

According to the general procedure for $LiAlH_4$ reduction, 2.5 g of **12** gave 2.4 g of **4** (95%); mp 167 to 168 °C. ^{1}H NMR (360 MHz, CD_3CN) δ: 4.42 (s, 2H, CH_2), 6.99–7.11 (m, 3H), 7.30–7.42 (m, 3H), 7.47 (ddd, 1H, *J* = 7.4, 7.4, 1.5 Hz), 7.74 (d, 1H, *J* = 8.5 Hz), 7.91 (d, 1H, *J* = 8.1 Hz), 7.95 (d, 1H, *J* = 8.6 Hz); additional ^{1}H NMR peaks in $(CD_3)_2CO$: 4.20 (s, broad, 1H, exchangeable with D_2O, OH), 8.03 (s, broad, 1H, exchangeable with D_2O, ArOH). MS (CI) *m*/*z* (relative intensity): 233 (M – OH^-) (100). Chemical anal. calcd. for $C_{17}H_{14}O_2$ (%): C 81.58, H 5.64; found: C 81.54, H 5.54.

1-[2′-(Hydroxymethyl)phenyl]-2-naphthol (5)

According to the general procedure for $LiAlH_4$ reduction, 2.0 g of **13** gave 1.9 g of **5** (95%); mp 167 to 168 °C. ^{1}H NMR (360 MHz, CD_3CN) δ: 4.21 (AB quartet, 2H, *J* = 13.5 Hz, CH_2), 7.06–7.12 (m, 1H), 7.13–7.17 (dd, 1H, *J* = 9, 2 Hz), 7.22 (d, 1H, *J* = 8.8 Hz), 7.27–7.33 (m, 2H), 7.41 (ddd, 1H, *J* = 7.4, 7.4, 1.5 Hz), 7.49 (ddd, 1H, *J* = 7.4, 7.4, 1.5 Hz), 7.67 (d, 1H, *J* = 7.4 Hz), 7.80–7.86 (m, 2H); additional ^{1}H NMR peaks in $(CD_3)_2CO$: 4.10 (s, broad, 1H, exchangeable with D_2O, OH), 8.05 (s, broad, 1H, exchangeable with D_2O, ArOH). MS (CI) *m*/*z* (relative intensity): 233 (M – OH^-) (100). Chemical anal. calcd. for $C_{17}H_{14}O_2$ (%): C 81.58, H 5.64; found: C 81.50, H 5.56.

2-Hydroxy-2′-hydroxymethyl-1,1′-binaphthyl (6)

According to the general procedure for $LiAlH_4$ reduction, 3.0 g of **14** gave 2.8 g of **6** (95%); mp 172 to 173 °C. ^{1}H NMR (360 MHz, CD_3CN) δ: 4.30 (AB quartet, 2H, *J* = 13.3 Hz, CH_2), 6.82 (d, 1H, *J* = 8 Hz), 7.50 (d, 1H, *J* = 8 Hz), 7.19 (ddd, 1H, *J* = 7.6, 7.6, 1.4 Hz), 7.26 (ddd, 1H, *J* = 7.6, 7.6, 1.3 Hz), 7.30 (ddd, 1H, *J* = 7.6, 7.6, 1.3 Hz), 7.31 (d, 1H, *J* = 8.9 Hz), 7.46 (ddd, 1H, *J* = 7.6, 7.6, 1.3 Hz), 7.86 (d, 1H, *J* = 8.6 Hz), 7.90 (d, 1H, *J* ≈ 9 Hz), 7.94 (d, 1H, *J* = 9.0 Hz), 7.98 (d, 1H, *J* ≈ 9 Hz), 8.06 (d, 1H, *J* = 8.4 Hz); additional ^{1}H NMR peaks in $(CD_3)_2CO$: 4.10 (s, broad, 1H, exchangeable with D_2O, OH), 8.20 (s, broad, 1H, exchangeable with D_2O, ArOH). MS (CI) *m*/*z* (relative intensity): 283 (M – OH^-) (100). Chemical anal. calcd. for $C_{21}H_{16}O_2$ (%): C 83.98, H 5.37; found: C 83.54, H 5.24.

4-[4′-(Hydroxymethyl)phenyl]phenol (11)

According to the general procedure for $LiAlH_4$ reduction, 2.0 g of 4-(4′-hydroxyphenyl)benzoic acid (in 200 mL dry THF) gave 1.75 g (93%) of pure **11** after recrystallization from a mixture of toluene and hexanes; mp 205–208 °C. ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ: 4.18 (t, 1H, *J* = 5.5 Hz, exchangeable with D_2O, OH), 4.64 (d, 2H, *J* = 5.5 Hz, CH_2), 6.90–6.99 (m, 2H), 7.35–7.45 (m, 2H), 7.45–7.60 (m, 4H), 8.43 (s, 1H, exchangeable with D_2O, ArOH). MS (CI) *m*/*z* (relative intensity): 201 (M + 1) (61), 183 (M – OH) (100). Chemical anal. calcd. for $C_{13}H_{12}O_2$ (%): C 77.98, H 6.04; found: C 78.06, H 6.03.

2-Hydroxy-2′-methyl-1,1′-binaphthyl (32)

A sample of 10 mg chromene **21** (photocyclization product of **6**) was refluxed with $LiAlH_4$ in dry THF (ca. 10 mL) for 6 h. After reaction, the solution was then quenched with 5% HCl–ice and extracted with Et_2O (4 × 50 mL). The solvent was evaporated and the residue was purified on preparatory TLC (CH_2Cl_2). Recrystallization from toluene gave a white crystal, mp 163 to 164 °C. ^{1}H NMR (360 MHz, $(CD_3)_2CO$) δ: 2.14 (s, 3H, CH3), 6.85 (d, 1H, *J* ≈ 8 Hz), 7.13 (d, 1H, *J* ≈ 8 Hz), 7.16–7.31 (m, 3H), 7.35–7.43 (m, 2H), 7.55 (d, 1H, *J* = 8.5 Hz), 7.88–7.97 (m, 4H), 7.98 (s, 1H, exchangeable with D_2O, ArOH). ^{13}C NMR δ: 20.3 (CH_3), 119.2, 119.3, 123.7, 125.0, 125.7, 126.4, 126.7, 127.2, 128.6, 128.8, 129.0, 129.6, 129.8, 130.2, 132.4, 133.4, 134.3, 134.8, 136.6, 153.2. HR-MS (EI) calcd. for $C_{21}H_{16}O$: 284.1201; found: 284.1214.

4-(2′-Methylphenyl)anisole (17) and 3-(2′-methylphenyl)anisole

3-Bromoanisole (80 mmol) was dissolved in 100 mL of toluene followed by the addition of $Pd(PPh_3)_4$ (0.70 g). After all the catalyst was dissolved, a solution of boronic acid **16** (100 mmol in 200 mL of 95% ethanol) and a solution of K_2CO_3 (20 g in 100 mL of water) were subsequently added. The mixture was refluxed for 24 h, then worked up by addition of NaOH (10%, ca. 400 mL) followed by extraction into CH_2Cl_2 (3 × 400 mL). The organic layer was dried over $MgSO_4$ and the solvent evaporated to give the crude product as a colourless oil (~90%). This crude product was used directly in the next step without further purification. 3-(2′-Methylphenyl)anisole: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 2.20 (s, 3H, CH_3), 3.79 (s, 3H, OCH_3), 6.85–7.05 (m, 3H), 7.05–7.30 (m, 5H). MS (CI) *m*/*z* (relative intensity): 199 (M + 1) (100). In a similar manner, use of 4-bromoanisole gave 4-(2′-methylphenyl)anisole (**17**): ^{1}H NMR (90 MHz, $CDCl_3$) δ: 2.20 (s, 3H, CH_3), 3.79 (s, 3H, OCH_3), 6.80–7.00 (m, 2H), 7.05–7.35 (m, 6H). MS (CI) *m*/*z* (relative intensity): 199 (M + 1) (100).

4-[2′-(Bromomethyl)phenyl]anisole

To a solution of 16 g of 4-(2′-methylphenyl) anisole **17** (80 mmol) in 250 mL CCl_4, a slurry of 14.2 g of NBS (80 mmol) in 100 mL CCl_4 was added. Then 0.3 g of benzoperoxide was added. The mixture was refluxed for 10 h then allowed to cool to rt and filtered. Upon washing with H_2O (3 × 100 mL), drying over $MgSO_4$, and evaporation of the solvent (rotary evaporator), 20 g (~90%) of crude product was obtained. ^{1}H NMR (90 MHz, $CDCl_3$) δ: 3.79 (s, 3H, OCH_3), 4.35 (s, 2H, CH_2), 6.75–7.05 (m, 2H), 7.05–7.65 (m, 6H). The crude product was used in the next step without further purification.

3-[2′-(Bromomethyl)phenyl]anisole

To a solution of 9.7 g of 3-(2′-methylphenyl) anisole (49 mmol) in 800 mL CCl_4, a slurry of 9.0 g of NBS (50 mmol) in 200 mL CCl_4 was added. Then 0.5 g of benzoperoxide was added. The mixture was refluxed for 30 h and allowed to cool to rt and filtered. Upon washing

© 2005 NRC Canada

with H_2O (3 × 100 mL), drying over $MgSO_4$, and evaporation of the solvent (rotary evaporator), 20 g (~90%) of crude product was obtained. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.87 (s, 3H, OCH_3), 4.49 (s, 2H, CH_2), 6.85–7.10 (m, 3H), 7.20–7.45 (m, 4H), 7.50–7.59 (m, 1H). MS (CI) *m/z* (relative intensity): 277/279 (M + 1) (7/6), 197 (M – Br) (100). The crude product was used in the next step without further purification.

4-[2′-(Hydroxymethyl)phenyl]anisole (7) and 3-[2′-(hydroxymethyl)phenyl]anisole (9)

4-[2′-(Bromomethyl)phenyl]anisole (15 g) or 3-[2′-(bromomethyl)phenyl] anisole (15 g) was dissolved in 750 mL of acetone–H_2O (1:1, *v*/*v*) with 5.0 g of added $NaHCO_3$. The mixture was refluxed overnight. The solution was cooled to rt and extracted with CH_2Cl_2 (twice) then with diethyl ether (once). The extract was combined and dried over $MgSO_4$. Upon evaporation of the solvent, 11 g (90%) of crude product was obtained. Pure product was obtained after recrystallization from toluene–hexanes. 4-[2′-(Hydroxymethyl)phenyl]anisole (**7**): mp 77 to 78 °C. ^{1}H NMR (360 MHz, $(CD_3)_2CO$) δ: 4.17 (t, 1H, *J* = 5.5 Hz, exchangeable with D_2O, OH), 4.55 (d, 2H, *J* = 5.5 Hz, CH_2), 6.96–7.01 (m, 2H), 7.18–7.23 (m, 1H), 7.26–7.37 (m, 4H), 7.58–7.63 (m, 1H). MS (CI) *m/z* (relative intensity): 215 (M + 1) (23), 197 (M – OH) (100). Chemical anal. calcd. for $C_{14}H_{14}O_2$ (%): C 78.48, H 6.59; found: C 78.56, H 6.59. 3-[2′-(Hydroxymethyl)phenyl]anisole (**9**): mp 63 to 64 °C. ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ: 3.80 (s, 1H, OCH_3), 4.25 (t, 1H, *J* = 5.5 Hz, exchangeable with D_2O, OH), 4.65 (d, 2H, *J* = 5.5 Hz, CH_2), 6.85–7.00 (m, 3H), 7.15–7.45 (m, 4H), 7.55–7.66 (d, 1H, *J* = 8Hz). MS (CI) *m/z* (relative intensity): 197 (M – OH) (100). Chemical anal. calcd. for $C_{14}H_{14}O_2$ (%): C 78.48, H 6.59; found: C 78.31, H 6.46.

4-[2′-(Hydroxymethyl)phenyl]phenol (8) and 3-[2′-(hydroxymethyl)phenyl] phenol (10)

A solution of 10 g (36 mmol) 4-[2′-(hydroxymethyl)phenyl]anisole (**7**) or 3-[2′-(hydroxymethyl)phenyl]anisole (**9**) in 750 mL CH_2Cl_2 was added dropwise into a solution of BBr_3 (0.1 mol/L in CH_2Cl_2, 180 mL) at rt over 1 h. The solution was stirred for an additional 4 h. The reaction was quenched by addition of ca. 200 mL of water. The water layer was extracted with diethyl ether (3 × 150 mL). The combined organic extract was dried over $MgSO_4$ and the solvent evaporated to give an oily residue. This residue was dissolved in ca. 500 mL of acetone–H_2O (1:1, *v*/*v*) and refluxed overnight. The solution was cooled to rt and extracted with CH_2Cl_2 (twice) then with diethyl ether (once). The extract was combined and dried over $MgSO_4$. The crude product was obtained upon evaporation of the solvent. Pure product (6.0 g, 80%) was obtained after recrystallization from toluene. 4-[2′-(Hydroxymethyl)phenyl]phenol (**8**): mp 121 to 122 °C. ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ: 4.10 (t, 1H, *J* = 5.5 Hz, exchangeable with D_2O, OH), 4.55 (d, 2H, *J* = 5.5 Hz, CH_2), 6.83–6.93 (m, 2H), 7.12–7.35 (m, 5H), 7.53–7.62 (m, 1H), 8.45 (s, 1H, exchangeable with D_2O, ArOH). MS (CI) *m/z* (relative intensity): 183 (M – OH) (100). Chemical anal. calcd. for $C_{13}H_{12}O_2$ (%): C 77.98, H 6.04; found: C 78.03, H 6.15. 3-[2′-(Hydroxymethyl)phenyl]phenol (**10**): mp 96 to 97 °C. ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ: 4.10 (t, 1H, *J* = 5.5 Hz, exchangeable with D_2O, OH), 4.55 (d, 2H, *J* = 5.5 Hz, CH_2), 6.80–6.90 (m, 3H), 7.10–7.40 (m, 4H), 7.60 (d, 1H, *J* = 8 Hz), 8.40 (s, 1H, exchangeable with D_2O, ArOH). MS (CI) *m/z* (relative intensity): 183 (M – OH) (100). Chemical anal. calcd. for $C_{13}H_{12}O_2$ (%): C 77.98, H 6.04; found: C 78.19, H 6.02.

2-(2′-Methyl-1′-naphthyl)phenol (23) and 2-(2′-methylphenyl)phenol (30)

The corresponding biaryl alcohol (**4** or **1**, 50–100 mg) was photolyzed (254 nm) in 100 mL of 2-propanol in the presence of excess (~0.5 g) $NaBH_4$ for 2 h. Then 10% HCl (50–100 mL) was added, and the mixture was extracted with Et_2O–CH_2Cl_2 (1:2, 3 × 80 mL). Pure **23** or **30** were isolated by preparative TLC (CH_2Cl_2–hexanes, second component) as a colourless oil. 2-(2′-Methyl-1′-naphthyl)phenol (**23**): ^{1}H NMR (300 MHz, CD_3CN) δ: 2.18 (s, 3H, CH_3), 6.6 (s, 1H, exchangeable with D_2O, ArOH), 6.95–7.09 (m, 3H), 7.25–7.52 (m, 5H), 7.77–7.90 (m, 2H). MS (CI) *m/z* (relative intensity): 235 (M + 1) (100). 2-(2′-Methylphenyl)phenol (**30**): ^{1}H NMR (360 MHz, $(CD_3)_2CO$) δ: 2.16 (s, 3H, CH_3), 6.89 (ddd, 1H, *J* = 7.4, 7.4, 1.2 Hz), 6.95 (dd, 1H, *J* = 8.0, 1.2 Hz), 7.05 (dd, 1H, *J* = 7.4, 1.7 Hz), 7.11–7.25 (m, 5H), 8.15 (s, 1H, exchangeable with D_2O, ArOH). ^{13}C NMR δ: 20.1, 116.4, 120.3, 126.3, 128.0, 129.3, 129.8, 130.4, 130.9, 131.6, 137.6, 139.6, 155.1. HR-MS (EI) calcd. for $C_{13}H_{12}O$: 184.0888; found: 184.0893.

General procedure for the synthesis of 31, 33, and 34

A solution of the biaryl alcohol **5**, **7**, or **10** (1 equiv.) in CH_2Cl_2 (70 mL per 10 mmol) was added dropwise into a solution of BBr_3 (1.5 equiv., 0.15 mol/L in CH_2Cl_2) at rt over 1 h. The solution was stirred at rt for another 4 h. The reaction was then quenched by the addition of water. The water layer was extracted with diethyl ether (3 × 150 mL). The combined organic extract was dried over $MgSO_4$ and the solvent evaporated on the rotary evaporator to give an oily residue. This residue was dissolved in dry THF and the solution was added (under stirring, rt) dropwise into a round-bottomed flask charged with $LiAlH_4$ (excess) and a small amount of dry THF. After the addition was completed, the mixture was refluxed for 1 h. Then the mixture was cooled to rt and poured into a mixture of ice and 10% HCl. The corresponding biaryl methanol (crude product) was obtained after extraction (Et_2O–CH_2Cl_2, 1:2), drying ($MgSO_4$), and evaporation (rotary evaporator) of the solvent.

1-(2′-Methylphenyl)-2-naphthol (31)

5 (10 mg) was converted to **31** using the preceding general procedure. Pure **31** (8 mg) was obtained as a white solid after purification by preparatory TLC (CH_2Cl_2–hexanes, 1:1), mp 91 to 92 °C. ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ: 1.99 (s, 3H, CH_3), 7.10–7.20 (m, 2H), 7.25–7.40 (m, 6H), 7.80–7.87 (m, 2H), 7.95 (s, 1H, exchangeable with D_2O, ArOH). MS (CI) *m/z* (relative intensity): 235 (M + 1) (100).

4-(2′-Methylphenyl)phenol (33)

According to the preceding general procedure, 1.07 g of **7** gave 0.85 g (90%) of pure **33** as a white solid after recrystallization from toluene, mp 76 to 77 °C. ^{1}H NMR (360 MHz, DMSO-D_6) δ: 2.21 (s, 3H, CH_3), 6.78–6.84 (m,

© 2005 NRC Canada

2H), 7.09–7.15 (m, 2H), 7.11–7.16 (m, 1H), 7.16–7.22 (m, 2H), 7.22–7.26 (m, 1H), 9.55 (s, 1H, exchangeable with D_2O, ArOH). MS (CI) *m*/*z* (relative intensity): 185 (M + 1) (100).

3-(2′-Methylphenyl)phenol (34)

According to the preceding general procedure, 0.20 g of **10** gave 0.17 g (90%) of pure **34** as a colourless oil. ^{1}H NMR (360 MHz, $(CD_3)_2CO$) δ: 2.24 (s, 3H, CH_3), 6.74–6.87 (m, 3H), 7.14–7.30 (m, 5H), 8.20 (s, 1H, exchangeable with D_2O, ArOH). MS (CI) *m*/*z* (relative intensity): 185 (M + 1) (100).

General photolysis procedure

Preparative scale photolysis was carried out in a Rayonet RPR 100 photochemical reactor using 254 or 300 nm lamps. The reaction mixture was contained in a 100 or 200 mL quartz tube, which was cooled to ≈15 °C using a cold finger (tap water) and purged continuously during photolysis with a stream of argon via a stainless steel syringe needle. Microscale photolysis was carried out in a 3 mL quartz cuvette or in an NMR tube, and irradiated either in a Rayonet RPR 100 photochemical reactor (254 or 300 nm) or on an optical bench (280 nm) equipped with an Oriel 200 W Hg lamp and an Applied Photophysics monochromator. Solutions were purged with a stream of argon via a stainless steel syringe needle for 5 min and sealed before photolysis.

General workup procedure for photolysis in aqueous solution

After photolysis, satd. NaCl solution was added and the mixture was extracted three to five times with either CH_2Cl_2 or Et_2O. The combined organic extract was then dried over $MgSO_4$ and the solvent evaporated on the rotary evaporator.

Photolysis of 2-[2′-(hydroxymethyl)phenyl]phenol (1) in CH_3CN

A solution of **1** (50 mg) in CH_3CN (80 mL) was photolyzed (254 nm) in a quartz tube for 30 min using the general procedure. The solvent was then removed by rotary evaporation. The residue (80% conversion to chromene **3** by ^{1}H NMR) was chromatographed on preparative TLC (silica, hexanes–CH_2Cl_2, 2:1). The first band was collected to give pure 6*H*-benzo[*c*]chromene (**3**) as a colourless oil. ^{1}H NMR (300 MHz, CD_3CN) δ: 5.12 (s, 2H, CH_2), 6.96 (dd, 1H, *J* = 8, 1 Hz), 7.06 (ddd, 1H, *J* = 8, 8, 1 Hz), 7.18–7.44 (m, 4H), 7.76 (d, 1H, *J* = 8 Hz), 7.80 (dd, 1H, *J* = 8, 1 Hz). MS (CI) *m*/*z* (relative intensity): 183 (M + 1) (100).

Photolysis of 2-[2′-(hydroxymethyl)-1′-naphthyl]phenol (4) in aprotic solvent (100% CH_3CN or THF)

A solution of **4** (50 mg) in 100 mL of solvent was photolyzed (254 nm) in a quartz tube for 45 min using the general procedure. The solvent was then removed by rotary evaporation. The residue (>95% conversion to chromene **19** by ^{1}H NMR) was chromatographed on preparative TLC (silica, hexanes–CH_2Cl_2, 2:1). The first band was collected to give pure 6*H*-naphtho[2,1-*c*]chromene (**19**) as a colourless crystal after recrfystallization from CH_3CN; mp 96 to 97 °C (lit. value (16) mp 101 °C). ^{1}H NMR (360 MHz, $(CD_3)_2CO$) δ: 5.13 (s, 2H, CH_2), 7.12–7.23 (m, 2H), 7.33 (ddd, 1H, *J* = 7.9, 7.9, 1.5 Hz), 7.42 (d, 1H, *J* = 8.3 Hz), 7.52 (ddd, 1H, *J* = 7.4, 7.4, 1.4 Hz), 7.58 (ddd, 1H, *J* = 7.6, 7.6, 1.6 Hz), 7.87 (d, 1H, *J* = 8.2 Hz), 7.94–7.98 (m, 1H), 8.05–8.09 (m, 1H), 8.56–8.61 (m, 1H). HR-MS (EI) calcd. for $C_{17}H_{12}O$: 232.0888; found: 232.0892.

For analytical runs (in CH_3CN), the preceding solution was sampled at set irradiation times and injected into the GC to determine the conversion. The GC retention times (t_r) were 12.8 min for **19** and 13.1 min for **4**.

Photolysis of 2-[2′-(hydroxymethyl)-1′-naphthyl]phenol (4) in H_2O–H_3CN (1:1)

A solutionof **4** (50 mg) in 100 mL of solvent was photolyzed (254 nm) in a quartz tube for 45 min using the general procedure. After photolysis, the solution was worked using the general procedure (CH_2Cl_2–Et_2O (2:1), 3 × 150 mL). GC and ^{1}H NMR showed that this sample contained ca. 60% of **19** and ca. 40% of **4**. No side products were detectable. Analytical runs were carried out as described previously, using GC analysis.

Photolysis of 2-[2′-(hydroxymethyl)-1′-naphthyl]phenol (4) in 100% CH_3OH

A solution of **4** (50 mg) in CH_3OH (100 mL) was photolyzed (254 nm) in a quartz tube for 5–45 min using the general procedure. The solvent was then removed by rotary evaporation. The residue (maximum yield, 75% of methyl ether **22** and 25% chromene **19** by ^{1}H NMR) was chromatographed on preparative TLC (silica, CH_2Cl_2). The second band was collected to give pure **22** as a colourless oil. ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ: 3.24 (s, 3H, OCH_3), 4.35 (AB quartet, 2H, *J* = 12.5 Hz, CH_2), 6.95–7.15 (m, 3H), 7.30–7.55 (m, 4H), 6.69 (d, 1H, *J* = 8.4 Hz), 7.87–7.96 (m, 2H), 8.20 (s, 1H, exchangeable with D_2O, ArOH).

Photolysis of 6H-naphtho[2,1-c]chromene (19) in 100% CH_3CN or THF

A solution of 20 mg of **19** in 60 mL of CH_3CN (or THF) was photolyzed (254 nm) in a quartz tube for 30 min using the general procedure. The solvent was then removed by rotary evaporation. ^{1}H NMR of the residue was identical to that of the starting material **19**.

Photolysis of 6H-naphtho[2,1-c]chromene (19) in H_2O–CH_3CN (1:1)

A solution of 20 mg of **19** in 60 mL of H_2O–CH_3CN (1:1) was photolyzed (254 nm) in a quartz tube for 30 min using the general procedure then worked up using the general procedure (CH_2Cl_2, 3 × 100 mL). The residue contained 60% of **19** and 40% of **4** as determined by ^{1}H NMR.

Photolysis of 6H-naphtho[2,1-c]chromene (19) in H_2O–CH_3OH (1:1)

According to the general procedure for microscale photolysis, a solution (3.0 mL, 2.14×10^{-4} mol/L) of **19** in H_2O–CH_3OH (1:1) was photolyzed in the Rayonet (254 nm) in 30 s intervals. Between each irradiation period, the UV spectrum of the solution was taken. When the UV spectrum of the solution remained unchanged (after a total of five irradiations), the composition of this solution was determined by UV photospectrophotometry by the absorbance of the so-

© 2005 NRC Canada

lution at 337 nm (for **19**, $\varepsilon_{337} = 1.04 \times 10^4$, $\varepsilon_{283} = 3.57 \times 10^3$) and the absorbance increases at 283 nm (for **22** and **4**, $\varepsilon_{283} = 9.23 \times 10^3$), as 8% of **19** and 92% of the ring-opening product **22** + **4**. The solutions for several runs were collected and extracted with CH_2Cl_2 (5 × 5 mL). The combined extracts were dried over $MgSO_4$ and evaporated. ^{1}H NMR of the residue showed that alcohol **4** and methyl ether **22** were formed in a 1:3 ratio, corresponding to a photostationary ratio of 8:23:69 of **19**:**4**:**22**.

Photolysis of 6H-naphtho[2,1-c]chromene (19) in 100% CH_3OH

According to the general procedure for microscale photolysis, a solution (3.0 mL, 1.25×10^{-4} mol/L) of **19** in CH_3OH was photolyzed in the Rayonet (254 nm) in 15 s intervals. Between each irradiation, the UV spectrum of the solution was taken. After 10 irradiations, the UV spectrum remained unchanged. The composition of this solution contained 24% of **19** and 76% of the ring-opening product **22** as determined by the method described previously using UV spectrophotometry. In another attempt, ca. 3 mg of **19** was dissolved in 3 mL of CH_3OH and photolyzed for 5 min. After the photolysis, the solvent was evaporated. ^{1}H NMR of the residue indicated that methyl ether **22** (50%) was the only product.

Photolysis of 1-[2′-(hydroxymethyl)phenyl]-2-naphthol (5) in H_2O–CH_3CN (1:1)

A solution of **5** (50 mg) in 100 mL H_2O–CH_3CN (1:1) was photolyzed (254 nm) in a quartz tube for 90 min and then worked up (CH_2Cl_2–Et_2O (2:1), 3 × 150 mL) using the general procedure. The ^{1}H NMR of the residue showed that 5*H*-dibenzo[*c*, *f*]chromene (**20**) was obtained in 60% yield (with 40% starting material left). Prolonged photolysis (>10 h) could raise the conversion to ca. 90% with decomposition of the product (ca. 10%). Pure **20** was isolated as a white solid by preparative TLC (silica gel, CH_2Cl_2–hexanes (1:1), first band collected). This solid was recrystallized from CH_3CN, mp 55 to 56 °C. ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ: 5.09 (s, 2H, CH_2), 7.25 (d, 1H, *J* = 8 Hz), 7.35–7.54 (m, 4H), 7.59 (dd, 1H, *J* = 8, 8 Hz), 7.85 (d, 1H, *J* = 9 Hz), 7.93 (d, 1H, *J* = 8 Hz), 8.03 (d, 1H, *J* = 8 Hz), 8.55 (d, 1H, *J* = 9 Hz). HR-MS (EI) calcd. for $C_{17}H_{12}O$: 232.0888; found: 232.0893. Chemical anal. calcd. for $C_{17}H_{12}O$ (%): C 87.91, H 5.21; found: C 87.58, H 5.16.

Analytical runs were carried out in a 3 mL quartz cuvette using the general procedure for microscale photolysis, and the yield of **20** was determined by the absorbance increases of the solution at 350 nm ($\varepsilon_{350} = 7.952$).

Photolysis of 1-[2′-(hydroxymethyl)phenyl]-2-naphthol (5) in 100% CH_3CN or THF

Using the general procedure for microscale photolysis, 3 to approximately 4 mg of **5** was dissolved in 3 mL of solvent and photolyzed in the Rayonet reactor for 10–15 min. After photolysis, the solvent was evaporated. ^{1}H NMR of the residue indicated that **20** was obtained in 10%–20% yield. Due to the low efficiency of this reaction, the conversion was kept low in these experiments to avoid significant decomposition of the reactants.

Photolysis of 1-[2′-(hydroxymethyl)phenyl]-2-naphthol (5) in 100% CH_3OH

Using the general procedure, a sample of ca. 3 mg of **5** in 3 mL of CH_3OH was irradiated in the Rayonet reactor for 15 min then solvent was evaporated. The ^{1}H NMR (300 MHz, $CDCl_3$) of the residue showed a singlet at δ 5.07 corresponding to the formation of **20** (10%). In addition, there was a weak, but sharp, singlet at δ 3.23 (OCH_3) and an AB quartet centred at 4.12 ppm ($J \approx -11$ Hz, CH_2), suggesting the formation of traces of the corresponding methyl ether product (<1%).

Photolysis of 5H-dibenzo[c,f]chromene (20) in H_2O–CH_3OH (1:1)

Using the general procedure for microscale photolysis, a sample of ~2 mg of **20** was dissolved in 3 mL of H_2O–CH_3OH (1:1) and photolyzed in the Rayonet reactor for 30 min and then worked up according to the general procedure. The ^{1}H NMR (300 MHz, $CDCl_3$) of the residue showed that the methyl ether product was obtained in ≈1% yield.

Photolysis of 2-hydroxy-2′-hydroxymethyl-1,1′-binaphthyl (6) in H_2O–CH_3CN (1:1), 100% CH_3CN, or 100% THF

A solution of **6** (50 mg) in 100 mL of solvent was photolyzed (254 nm) in a quartz tube for 30 min, then worked up (CH_2Cl_2–Et_2O (2:1), 3 × 150 mL) using the general procedure (aqueous) or solvent evaporated rotary (nonaqueous). The residue (contained ~90% of **21** by ^{1}H NMR) was chromatographed on preparative TLC (silica, hexanes–CH_2Cl_2, 2:1). The first band was collected to give a white solid, which was recrystallized from CH_3CN to give pure 4*H*-benzo[*f*]naphtho[2,1-*c*]chromene (**21**), mp 176–178 °C. ^{1}H NMR (360 MHz, $(CD_3)_2CO$) δ: 4.99 (d, 1H, *J* = –12.9 Hz, CH_2), 5.36 (d, 1H, *J* = –12.9 Hz, CH_2), 7.30–7.46 (m, 4H), 7.51 (ddd, 1H, *J* = 7.5, 7.5, 1.2 Hz), 7.60–7.67 (m, 3H), 7.93–8.03 (m, 4H). HR-MS (EI) calcd. for $C_{21}H_{14}O$: 282.1045; found: 282.1032. Chemical anal. calcd. for $C_{21}H_{14}O$ (%): C 89.34, H 5.00; found: C 88.97, H 4.84. When photolyzed in neat THF or CH_3CN using the preceding procedure, the reaction also gave the same product, but the efficiency is significantly lower (by ca. 30%–50%).

For analytical runs, two methods were used: (*i*) a solution of **6** was photolyzed in a quartz cuvette, and the formation of **21** was followed by UV spectrophotometry (absorbance at 360 nm, $\varepsilon = 1.04 \times 10^4$ $(mol/L)^{-1}$ cm^{-1}); (*ii*) ~5 mg of **6** was dissolved in 0.4 mL of CD_3CN and purged with Ar for 10 min then sealed in an NMR tube. This sample was irradiated in the Rayonet reactor (in the NMR tube, $\lambda_{ex} = 300$ nm) for a series of set times and the conversions were determined by ^{1}H NMR.

Photolysis of 2-hydroxy-2′-hydroxymethyl-1,1′-binaphthyl (6) in H_2O–CH_3OH (1:1) and 100% CH_3OH

A sample of **6** (20 mg) in 100 mL solvent was photolyzed in the Rayonet reactor for 20 min, then worked up using the method previously described. ^{1}H NMR of the residue showed ca. 15% yield of the methyl ether product and ca. 85% of **21**. The formation of the corresponding methyl ether product was inferred from the observation of the following three sets of characteristic ^{1}H NMR (300 MHz, $(CD_3)_2CO$) peaks δ: 3.19 (s, 3H, OCH_3), 4.23 (AB quartet, 2H, *J* = –13 Hz,

© 2005 NRC Canada

CH_2), and 6.88 (d, 1H, J = 8 Hz). No attempt was made to isolate this product.

Photolysis of 4H-benzo[f]naphtho[2,1-c]chromene (21) in CH_3CN–H_2O (1:1)

A solution of **21** (1.0×10^{-4} mol/L, in H_2O–CH_3CN (1:1)) was placed in a cuvette (3.0 mL) and irradiated at 254 or 300 nm. No changes were detectable by UV–vis spectrophotometry even on prolonged irradiation, indicating the lack of any conversion to the ring-opened product **6**. When this solution was photolyzed on the optical bench using 370 nm, the 360 nm band decreased and a new band at 280 nm grew in, suggesting the formation of **6**.

Photolysis of 4H-benzo[f]naphtho[2,1-c]chromene (21) in CH_3OH–H_2O (1:1)

A solution of **21** (1.0×10^{-4} mol/L in H_2O–CH_3OH (1:1), saturated) was placed in a cuvette (3.0 mL) and irradiated at 254 nm. As the photolysis proceeded, the 360 nm band decreased and a band at 280 nm grew in, suggesting the formation of **6** and (or) the methyl ether substitution product. The spectrum stopped changing at a state corresponding to 20% of chromene **21** and 80% ring-opened products (**6** + the methyl ether product).

Photolysis of 4H-benzo[f]naphtho[2,1-c]chromene (21) in 100% CH_3OH

A solution of **21** (ca. 5 mg in 3 mL CH_3OH) was photolyzed (254 nm) in a quartz cuvette for 5 min, then the solvent was removed by bubbling through the solution with a stream of air. The cuvette was then placed in a round-bottomed flask and left under vacuum for 1 h. ^{1}H NMR of the residue showed that the methyl ether substitution product was obtained in about 30% yield.

Photolysis of 4-[2′-(hydroxymethyl)phenyl]anisole (7) in CH_3OH–H_2O (1:1)

A solution of **7** (90 mg) in CH_3OH–H_2O (1:1, 100 mL) was photolyzed (254 nm) in a quartz tube for 10 min, then worked up (CH_2Cl_2, 3 × 150 mL) using the general procedure. The ^{1}H NMR of the residue showed two products, 4-[2′-(methoxymethyl)phenyl]anisole (**24**) (23%) and 4-(2′-methylphenyl)anisole (~3%). The residue was chromatographed on preparative TLC (silica, hexanes–CH_2Cl_2, 1:1) to give pure **24** as a colourless oil (second band collected). ^{1}H NMR (250 MHz, $(CD_3)_2CO$) δ: 3.28 (s, 3H, $ROCH_3$), 3.82 (s, 3H, $ArOCH_3$), 4.31 (s, 2H, CH_2), 6.95–7.03 (m, 2H), 7.18–7.39 (m, 5H), 7.47–7.53 (m, 1H).

Photolysis of 4-[2′-(hydroxymethyl)phenyl]anisole (7) in different pH

A solution of **7** (1.50 mL, 10 mg in 4.6 mL of CH_3OH) was added to each of the cuvettes charged with either 1.50 mL of H_2O or 0.05 mol/L H_2SO_4, respectively. These samples were irradiated in the Rayonet (254 nm) for 12 min and worked up according to the general procedure. The yields of methyl ether **24** at different pH is in the ratio of 1:1.1:1.2 (pH 7 : pH 1 : H_o = +0.04) as determined by ^{1}H NMR, indicating that the quantum yield increased slightly at low pH.

Photolysis of 4-[2′-(hydroxymethyl)phenyl]phenol (8) in H_2O–CH_3OH (1:1)

A solution of **8** (30 mg) in CH_3OH–H_2O (1:1, 60 mL) was irradiated in a quartz tube for 10 min, then worked up (CH_2Cl_2, 3 × 150 mL) using the general procedure. The ^{1}H NMR of the residue showed 60% yield of 4-[2′-(methoxymethyl)phenyl]phenol (**25**), which was isolated on preparative TLC (silica, CH_2Cl_2) as a colourless oil. ^{1}H NMR (250 MHz, $(CD_3)_2CO$) δ: 3.28 (s, 3H, OCH_3), 4.31 (s, 2H, CH_2), 6.87–6.95 (m, 2H), 7.15–7.35 (m, 5H), 7.45–7.51 (m, 1H), 8.60 (s, broad, exchangeable with D_2O, 1H, ArOH).

Photolysis of 4-[2′-(hydroxymethyl)phenyl]phenol (8) in the presence of ethyl vinyl ether

A solution of **8** (30 mg) in CH_3CN–H_2O (2:1, 100 mL) with 3.5 mL of ethyl vinyl ether added was irradiated in a quartz tube for 15 min according to the general procedure. After photolysis, the solution was worked up (CH_2Cl_2, 3 × 150 mL) using the preceding procedure. ^{1}H NMR showed that there was one major product, 3-[2′-(4″-hydroxyphenyl)phenyl]propanal (**26**), which was purified on preparative TLC (silica, CH_2Cl_2). ^{1}H NMR (300 MHz, $(CD_3)_2CO$) δ: 2.55–2.61 (m, 2H, CH_2), 2.88–2.94 (m, 2H, CH_2), 6.87–6.93 (m, 2H), 7.11–7.17 (m, 3H), 7.18–7.28 (m, 2H), 7.28–7.33 (m, 1H), 8.50 (s, 1H, exchangeable with D_2O, ArOH), 9.64 (t, 1H, J = 1.4 Hz, RCHO).

Photolysis of 4-[2′-(hydroxymethyl)phenyl]phenol (8) at different pH

A solution of **8** (1.50 mL, 9 mg in 4.6 mL of CH_3OH) was added to each of the cuvettes charged with either 1.50 mL of H_2O or 0.05 mol/L H_2SO_4, respectively. These samples were irradiated on the optical bench (280 nm) for 4.0 min, then worked up using the general procedure. The residues of all three samples contained (15 ± 1)% of **25** as determined by ^{1}H NMR, suggesting no pH dependence in this region.

Photolysis of 3-[2′-(hydroxymethyl)phenyl]phenol (10) in CH_3CN–H_2O (1:1)

A solution of **10** (50 mg) in CH_3CN–H_2O (1:1, 100 mL) was photolyzed (254 nm) in a quartz tube for 15 min, then worked up (CH_2Cl_2, 3 × 150 mL) using the general procedure. The ^{1}H NMR of the residue showed ~100% conversion to 3-hydroxyfluorene (**27**) and 1-hydroxyfluorene (**28**) in a ca. 10:1 ratio. The residue was chromatographed on preparative TLC to give a white solid (mixture of **27** and **28**). Recrystallization from toluene–hexanes gave pure **27**, mp 138 to 139 °C. ^{1}H NMR (360 MHz, $(CD_3)_2CO$) δ: 3.78 (s, 2H, CH_2), 6.80 (dd, 1H, J = 8.1, 2.4 Hz), 7.27 (ddd, 1H, J = 7.4, 7.4, 1.3 Hz), 7.30 (d, 1H, J = 2.4 Hz), 7.31–7.39 (m, 2H), 7.50–7.55 (m, 1H), 7.74–7.78 (m, 1H), 8.34 (s, 1H, exchangeable with D_2O, ArOH). MS (CI) m/z (relative intensity): 183 (M + 1) (100). Pure **28** was not isolated. ^{1}H NMR of **28** has CH_2 at δ 3.82 (s).

Photolysis of 3-[2′-(hydroxymethyl)phenyl]phenol (10) in CH_3OH–H_2O (1:1)

A solution of **10** (50 mg) in CH_3OH–H_2O (1:1, 100 mL) was photolyzed (254 nm) in a quartz tube for 15 min, then worked up (CH_2Cl_2, 3 × 150 mL) using the general procedure. The ^{1}H NMR of the residue showed two peaks at

© 2005 NRC Canada

δ 3.27 (OCH_3) and 4.32 ($ArCH_2OR$) with integrations in a 3:2 ratio, in addition to those corresponding to **27** and **28** (≥90%), suggesting the formation (5%–10%) of methyl ether **29**.

Photolysis of 4-[4′-(hydroxymethyl)phenyl]phenol (11) in CH_3OH–H_2O (1:1)

A solution of **11** (40 mg) in CH_3OH–H_2O (1:1, 100 mL) was photolyzed (254 nm) in a quartz tube for 8 min using the general procedure. The solution was then worked up (CH_2Cl_2, 3 × 150 mL) using the general procedure. The residue contained 16% of 4-[4′-(methoxymethyl)phenyl]phenol). Pure 4-[4′-(methoxymethyl)phenyl]phenol was isolated by preparative TLC (silica, hexanes–CH_2Cl_2 (1:1), first band collected) as a colourless oil. ^{1}H NMR (250 MHz, $(CD_3)_2CO$) δ: 3.33 (s, 3H, OCH_3), 4.43 (s, 2H, CH_2), 6.87–6.95 (m, 2H), 7.31–7.40 (m, 2H), 7.40–7.58 (m, 4H), 8.45 (s, 1H, exchangeable with D_2O, ArOH).

Laser flash photolysis

Experiments were carried out at the University of Victoria LFP Facility at 20 ± 2 °C. A Spectra-Physics GCR 12 YAG laser at 266 nm (<30 mJ) was used for excitation and signals were digitized with a Tektronix TDS 520 recorder. Samples of OD ≈ 0.3 at 266 nm were prepared and irradiated in quartz cells. Generally, flow solutions were used to avoid the accumulation of any photoproduct. Samples were continuously purged with a stream of N_2 or O_2.

Fluorescence lifetime measurements

All fluorescence lifetimes were measured on a PTI LS-1 instrument using the time-correlated single photon counting (SPC) technique (typically, using 10 000 counts). Samples were saturated with Ar and the absorbance at the excitation wavelength was adjusted to ~0.1. The lifetime was extracted from the SPC decay trace using the iterative reconvolution program that came with the instrument.

Steady-state fluorescence and fluorescence quantum yield measurements

All fluorescence spectra were recorded on a PTI A-1010 fluorimeter at rt. Samples were degassed by purging with argon gas prior to measurement. The concentrations of all samples were kept at $\leq 10^{-4}$ mol/L (OD ≈ 0.05). In determining the absolute fluorescence quantum yields, two secondary standards, naphthalene (in C_6H_{12}) and 2-aminopyridine (in 0.1 N H_2SO_4), were used.

Photocyclization quantum yields for 1, 4–6, and 10 in CH_3CN–H_2O (1:1)

The quantum yield for the chromene (or hydroxyfluorene) product formation was determined using UV spectrophotometry. Generally, a quartz cuvette containing 3.00 mL solution of the biaryl alcohol substrate was purged with Ar for ~5 min. and then irradiated for a set time (1~10 min) on the optical bench (λ_{ex} = 280 nm, slit 10 nm). The change of absorbance of the solution before and after irradiation (ΔA_λ) at the monitoring wavelength ($\lambda_{mon.}$) was measured. The quantum yield (Φ) was then calculated using the following equation:

$$\Phi = 3.00 \times 10^{-3} \times \Delta A/(\varepsilon_\lambda \times I \times \Delta t)$$

where ε_λ is the extinction coefficient of the product at $\lambda_{mon.}$, I is the light intensity determined using potassium ferrioxalate actinometry (10), and t is the time of irradiation. The initial concentration of the substrate was adjusted such that at 1% conversion, $\Delta A > 0.3$ and the absorbance of the solution at 280 nm >> 2 (typically, $>10^{-4}$ mol/L). The conversion was kept at ca. 1% for all runs. Finally, the sample was irradiated for a longer time to enhance the conversion to ~15% and the conversion rechecked by ^{1}H NMR. The results from ^{1}H NMR were consistent with that measured by UV spectrophotometry. The quantum yields of other solvents were measured relative to that obtained in CH_3CN–H_2O (1:1) using this method. The ε_λ at $\lambda_{mon.}$ are essentially independent of the solvents being studied. The λ_{max} and ε_λ data for all chromene products are summarized in Table 2.

General procedure for determination of photosolvolysis quantum yields for 7–8 and 11

A solution of the substrate (100 mL, typically 4.00 mmol/L in CH_3OH–H_2O (1:1)) and a sample of a reference compound were irradiated in the Rayonet reactor for a set time and worked up using the general procedure. The formation of the methyl ether products (15%–20% conversion) were determined by ^{1}H NMR and GC. The photomethanolysis of two reference compounds, 2,6-dimethoxybenzyl alcohol (Φ = 0.31) and 2-hydroxybenxyl alcohol (Φ = 0.24), were employed (17).

Time-resolved spectroscopic studies of the photochemistry of some diphenylgermylene (Ph_2Ge:) precursors[1]

Cameron R. Harrington, William J. Leigh, Bryan K. Chan, Peter P. Gaspar, and Dong Zhou

Abstract: The photochemistry of diphenylbis(trimethylsilyl)germane (**2a**) and 1,4-dihydro-5-methyl-1,2,3,4,9,9-hexaphenyl-1,4-germanonaphthalene (**11**) has been studied in solution by steady-state and laser flash photolysis methods with a view to detecting the transient germylene derivative diphenylgermylene (Ph_2Ge), which has previously been shown to be the major product of photolysis of **2a** and a closely related derivative of **11**. Steady-state trapping experiments confirm the formation of Ph_2Ge as the major germanium containing primary product in both cases; with **2a**, the results indicate that other transient species are also formed in minor yields, including phenyl(trimethylsilyl)germylene (Ph(TMS)Ge, ca. 6%) and diphenyl(trimethylsilyl)germyl radicals (Ph_2(TMS)Ge, ≥15%). Laser flash photolysis of **2a** in deoxygenated hexane solution yields a complex mixture of overlapping transient absorptions, which is shown to be comprised of Ph_2Ge, tetraphenyldigermene (**15**) and its oligomerization products, and another species with spectral characteristics similar to the Ph_2(TMS)Ge radical. The latter has been independently generated by hydrogen abstraction from diphenyl(trimethylsilyl)germane by *tert*-butoxyl radicals. Compound **11** extrudes Ph_2Ge more cleanly and efficiently upon photolysis in solution, yet laser flash photolysis affords excited triplet and triplet-derived species as the only detectable transient products; interpretation of the results for this compound is made difficult by its slow thermal decomposition to 5-methyl-1,2,3,4-tetraphenylnaphthalene. It is concluded that in spite of the fact that both **2a** and **11** afford Ph_2Ge in high yield upon photolysis, they are poor precursors for study of the species in solution by time-resolved UV–vis methods, owing to the formation of other, more strongly absorbing transient products than Ph_2Ge, whose lowest energy absorption is characteristically weak.

Key words: germylene, germyl radical, flash photolysis, disilylgermane, photochemistry.

Résumé : Afin d'essayer de détecter le dérivé germylène transitoire, diméthylgermylène (Ph_2Ge), qui avait été reconnu antérieurement comme le produit principal de la photolyse du produit **2a** et de son dérivé apparenté **11**, on a étudié la photochimie du diphénylbis(triméthylsilyl)germane (**2a**) et du 1,4-dihydro-5-méthyl-1,2,3,4,9,9-hexaphényl-1,4-germanonaphtalène (**11**) en solution, par les méthodes de l'état stationnaire et de la photolyse éclair au laser. Les expériences de piégeage de l'état stationnaire confirment dans les deux cas la formation du Ph_2Ge comme produit primaire principal contenant du germanium; avec le produit **2a**, les résultats indiquent que d'autres espèces transitoires se forment aussi, avec des rendements mineurs, dont les radicaux phényl(triméthylsilyl)germylène (Ph(TMS)Ge; rendement d'environ 6 %) et diphényl(triméthylsilyl)germyle (Ph_2(TMS)Ge; rendement supérieur à 15 %). La photolyse éclair au laser du composé **2a** en solution d'hexane désoxygéné mène à la formation d'un mélange complexe d'absorptions transitoires qui se superposent; il a été démontré qu'elles comprennent le Ph_2Ge, le tétraphényldigermène (**15**) et ses produits d'oligomérisation ainsi qu'une autre espèce de caractéristiques spectrales similaires au radical Ph_2(TMS)Ge. Ce dernier a été généré de manière indépendante par abstraction d'hydrogène par des radicaux *tert*-butoxyles à partir du diphényl(triméthylsilyl)germane. Par photolyse en solution, le composé **11** expulse le Ph_2Ge d'une façon beaucoup plus propre et plus efficace, toutefois la photolyse éclair au laser ne fournit comme produits transitoires détectables que le triplet excité et diverses espèces qui en dérivent; l'interprétation des résultats relatifs à ce composé est rendue difficile par sa décomposition thermique lente en 5-méthyl-1,2,3,4-tétraphénylnaphtalène. On en conclut que, même si la photolyse des composés **2a** et **11** mène dans les deux cas à la formation de Ph_2Ge avec un rendement élevé, ils sont de pauvres précurseurs pour l'étude de ces espèces en solution par des méthodes UV–vis résolues dans le temps en raison de la formation d'autres produits transitoires qui absorbent plus fortement que le Ph_2Ge dont la plus faible énergie d'absorption est normalement faible.

Introduction

Since the report nearly 20 years ago by Ando et al. (1) of the UV spectra of several simple, photochemically generated germylene derivatives in hydrocarbon matrixes at low temperature, there have been a number of studies published on the direct detection and study of reactive diarylgermylenes (2–10) and dialkylgermylenes (6, 11–15) in solution by laser flash photolysis techniques. Most of these studies employed Group 14 catenates as photochemical precursors to these "heavy carbene" analogues, such as **1**–**3** in the case of diphenylgermylene (Ph_2Ge). While steady-state trapping experiments showed that the germylene is the major transient photoproduct in each case, the results of laser photolysis experiments have been highly variable. For example, the UV–vis absorption max of Ph_2Ge has been reported to occur at various positions ranging from 445 to 630 nm, bracketing the value of λ_{max} = 466 nm originally reported by Ando et al. (1) in a 3-methylpentane matrix at 77 K using benzogermanorbornadiene derivative **4** and disilylgermane **2a** as germylene precursors. Thanks to the recent identification of a precursor that yields this reactive species *quantitatively* and in remarkably high quantum efficiency (**5**, eq. [1]), the UV spectrum of Ph_2Ge in hydrocarbon solvents at room temperature has now been conclusively established (9), as have quantitative details of its reactivity toward dimerization (9) and a number of representative metallylene scavengers such as amines, carboxylic acids, halocarbons, Group 14 hydrides, dienes, alkenes, and alkynes (10). In hexane solution at room temperature, diphenylgermylene exhibits λ_{max} = 500 nm (ϵ = 1650 ± 390 $(mol/L)^{-1}$ cm^{-1}) and dimerizes at close to the diffusion-controlled rate to yield the transient 1,1,2,2-tetraphenyldigermene ($Ph_2Ge{=}GePh_2$, λ_{max} = 440 nm, τ ~ 40 μs) (9). None of the UV spectra previously assigned to Ph_2Ge — including that reported by Ando et al. in 3-MP matrices at 77 K (1, 16, 17) — match the one reported more recently in solution using **5** as the precursor.

One of the compounds employed by Ando et al. for the photogeneration of Ph_2Ge — diphenylbis(trimethylsilyl)germane (**2a**) — has also been studied in fluid solution at room temperature by flash photolysis methods (2, 6). Photolysis of the compound in cyclohexane solution in the presence of 2,3-dimethyl-1,3-butadiene (DMB) was found to afford hexamethyldisilane (Si_2Me_6), trimethylphenylsilane ($PhSiMe_3$), and the diene trapping product **5** as the only detectable products (eq. [2]) (6), while laser flash photolysis of the compound afforded a transient that decayed over several hundred microseconds and exhibited λ_{max} = 445 nm (2), blue-shifted somewhat relative to the spectrum recorded for this compound in the earlier matrix experiments (1, 16). Absolute rate constants were determined for reaction of the species with various germylene scavengers, among them oxygen (1.02×10^8 $(mol/L)^{-1}$ s^{-1}), ethyldimethylsilane (k = 1.01×10^4 $(mol/L)^{-1}$ s^{-1}), 1-bromo-2-methylpropane (k = 6.36×10^5 $(mol/L)^{-1}$ s^{-1}), and 2,3-dimethyl-1,3-butadiene (2.75×10^4 $(mol/L)^{-1}$ s^{-1}) (2). Like the UV–vis spectrum, the reactivity of the transient toward the various germylene scavengers examined is in poor agreement with that reported much later for Ph_2Ge using **5** as the precursor (9). It is noteworthy that photolysis of the dimesityl analogue of **2a** (**6**) also affords the corresponding germylene (in this case dimesitylgermylene, Mes_2Ge) quite cleanly, as shown by the results of steady-state trapping experiments, matrix photolysis experiments (1, 16), and laser flash photolysis experiments in solution (7). In this case, the transient spectrum observed (and assigned to Mes_2Ge, λ_{max} ~ 550 nm) in solution (7) matches that obtained in matrix experiments (1, 16) or in solution from other precursors (7, 9) quite closely.

Recently, we reported a study of the photochemistry of 1,1,1-trimethyl-2,2,2-triphenylsilagermane (**7**) in solution by steady-state and laser flash photolysis methods (18). This compound also yields Ph_2Ge as the major germanium containing photoproduct in solution, but it also affords significant yields of the conjugated germene derived from 1,3-trimethylsilyl migration (**8**) and free radicals owing to triplet-derived Ge—Si bond homolysis (eq. [3]), as revealed by the results of steady-state trapping experiments. Only **8**

and triphenylgermyl radicals could be detected in laser flash photolysis experiments with the molecule, presumably because the absorption spectra of these transients are significantly more intense than that of Ph_2Ge, whose lowest energy (n,p) electronic transition is characteristically weak. Furthermore, the lowest energy absorption band in the UV–vis spectrum of **8** (λ_{max} ~ 475 nm) occurs at a similar position to the much weaker absorption band in the spectrum of the germylene (λ_{max} = 500 nm) under similar conditions. We speculated that an analogous mixture of products might well be expected from photolysis of **2a** under similar conditions, and that the transient spectroscopic behavior reported earlier for this compound might thus be better explained in terms of the corresponding germene (**9**) and (or) the diphenyl(trimethylsilyl)germyl radical (**10**) (18).

[3] $Ph_3GeSiMe_3$ (**7**) $\xrightarrow[\text{Hexane}]{h\nu}$ $Ph_2Ge:$ + $PhSiMe_3$ + $Ph_3Ge\bullet$ + $Me_3Si\bullet$

+ **8** ($GePh_2$, H, $SiMe_3$)

9 ($Ge(Ph)SiMe_3$, H, $SiMe_3$) **10** ($Ph_2GeSiMe_3\bullet$)

In the present paper, we report the results of a reinvestigation of the photochemistry of **2a** in solution by steady-state and laser flash photolysis methods, with a view to providing a secure identification of the transient species observed in the earlier work with this compound, and to see whether discrete evidence for the formation of free Ph_2Ge might be obtained. To aid in the interpretation of the results, germyl radical **10** has been generated by an independent route and its UV–vis spectrum and lifetime recorded under similar conditions to those employed for laser photolysis experiments with **2a**. We have also synthesized an analogue (**11**) of the benzogermanonorbornadiene derivative originally studied by Ando et al. (**4**), and have studied its photochemistry using similar methods. This compound differs from **4** only in the presence of a methyl group situated on the benzannelated ring, which was included so as to facilitate the determination of its purity and the identification of products from photochemical and (or) thermal decomposition, as compounds of this type are known to exhibit pronounced thermal lability under quite mild conditions (19–22).

Results and discussion

The photochemistry of $Ph_2Ge(SiMe_3)_2$ (2a)

The products of photolysis of **2a** in the presence of DMB (see eq. [2]) were originally identified, and their yields established, from a preparative-scale photolysis experiment carried to 64% conversion (6). Because secondary photolysis of **5** can be expected to lead to its preferential loss from the reaction mixture over such extended photolysis times, we began the present study with an examination of the product mixture at much lower conversions. Thus, a deoxygenated 0.05 mol/L solution of **2a** in cyclohexane-d_{12} containing 0.1 mol/L of the diene was irradiated with 254 nm light, monitoring the reaction periodically by (600 MHz) ^{1}H NMR spectroscopy over the 0%–16% conversion range. The NMR spectra of the photolysate showed discrete evidence for the formation of **5** and hexamethyldisilane (Si_2Me_6) in a ca. 1:1 ratio as the only detectable products. GC analysis of a similar photolysis in deoxygenated hexane solution (0.01 mol/L **2a**, 0.03 mol/L DMB) also showed **5** to be the major product of the reaction, but allowed the additional detection of $PhSiMe_3$ in minor amounts (≤6%), along with another minor product that eluted shortly before **2a**. The latter compound, which is formed in similar yield to $PhSiMe_3$, was tentatively identified as 3,4-dimethyl-1-phenyl-1-trimethylsilylgermacyclopent-3-ene (**12**) on the basis of GC–MS evidence. The results of these experiments are summarized in eq. [4].

[4] $Ph_2Ge(SiMe_3)_2$ (**2a**) + 0.03 mol/L $\xrightarrow[\text{Hexane}]{h\nu}$ **5** (89%) + Si_2Me_6 (0.94:1 relative to **5**)

+ **12** (6%) (Ph, Ge, $SiMe_3$) + $PhSiMe_3$ (1:1 relative to **12**)

Interestingly, photolysis of a 0.05 mol/L solution of **2a** in cyclohexane-d_{12} containing methanol (MeOH, 0.5 mol/L) afforded Si_2Me_6 and the Ph_2Ge insertion product **13** as the major products, but the latter was formed in only ca. 60% yield relative to consumed **2a** and in significantly lower yield than the coproduct of Ph_2Ge extrusion, Si_2Me_6. The 0–0.5 ppm region of the spectra also contained singlets attributable to three additional minor products, whose resonances integrated to 10:13:7; the total intensity of the three singlets owing to these products was ca. 30% relative to that of the singlet owing to Si_2Me_6. The most minor of these products was identified by ^{1}H NMR spectroscopy and GC as disilyldigermane **14**, by spiking the mixture with an authentic sample of the compound; the other two were not identified. The results of these experiments are summarized in eq. [5].

Taken together, these results indicate that while extrusion of Ph_2Ge is the dominant photoreaction of **2a**, accounting for ca. 60% of the photochemistry, other minor processes occur as well. One of these is assigned to the alternate germylene extrusion pathway, yielding Ph(TMS)Ge and

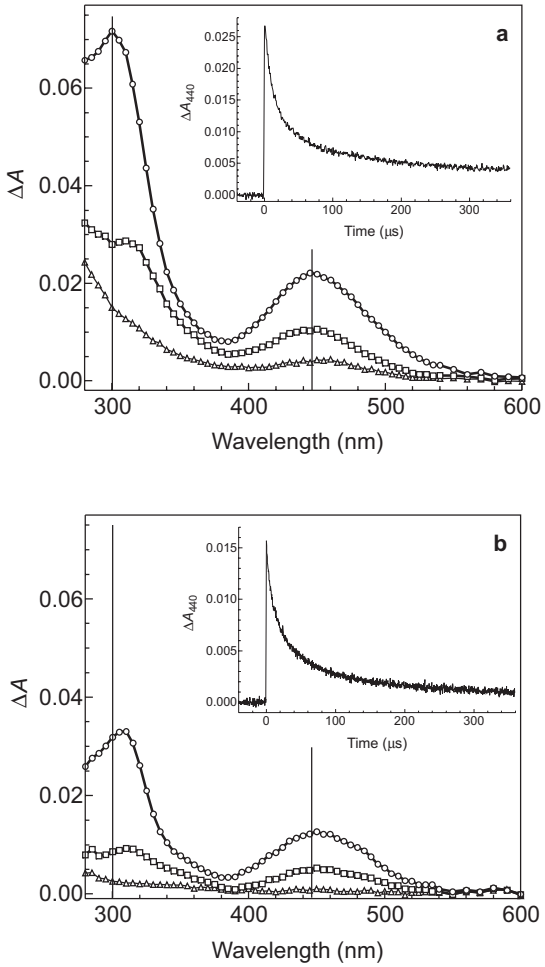
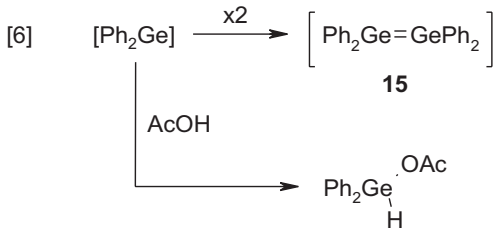
[5] $Ph_2Ge(SiMe_3)_2$ + MeOH $\xrightarrow[C_6D_{12}]{h\nu}$ $Ph_2GeH(OMe)$ + $Me_3SiPh_2Ge\text{-}GePh_2SiMe_3$ + other products + Si_2Me_6 (1.17:1 relative to **13**)



2a — 0.5 mol/L — **13** (60%) — **14** (8%) — 31%

$PhSiMe_3$ in about 6% chemical yield. Another is Si—Ge bond homolysis to yield the trimethylsilyl and diphenyl(trimethylsilyl)germyl radicals, as evidenced by the formation of minor amounts of digermane **14** in the photolysis in the presence of MeOH. This process constitutes at least 15% of the reactive excited-state decay processes of the molecule, based on the observed yield of **14** and the assumption that 50% of the Ph_2(TMS)Ge radicals produced will decay by recombination with trimethylsilyl radical, regenerating **2a**. Interestingly, **14** is not formed in the diene scavenging experiment, and the complete absence of additional $SiMe_3$ resonances in the NMR spectrum of this photolysis mixture indicates that the reason is *not* that the Ph_2(TMS)Ge radical is efficiently scavenged by the diene. A more likely mechanism by which the diene suppresses the formation of free radicals is triplet quenching, since it is known that the formation of radicals in the photolysis of aryldisilanes, arylgermasilanes, and aryldigermanes derives largely from the triplet state, and their formation can be quenched to at least some extent by added diene (18, 23, 24).

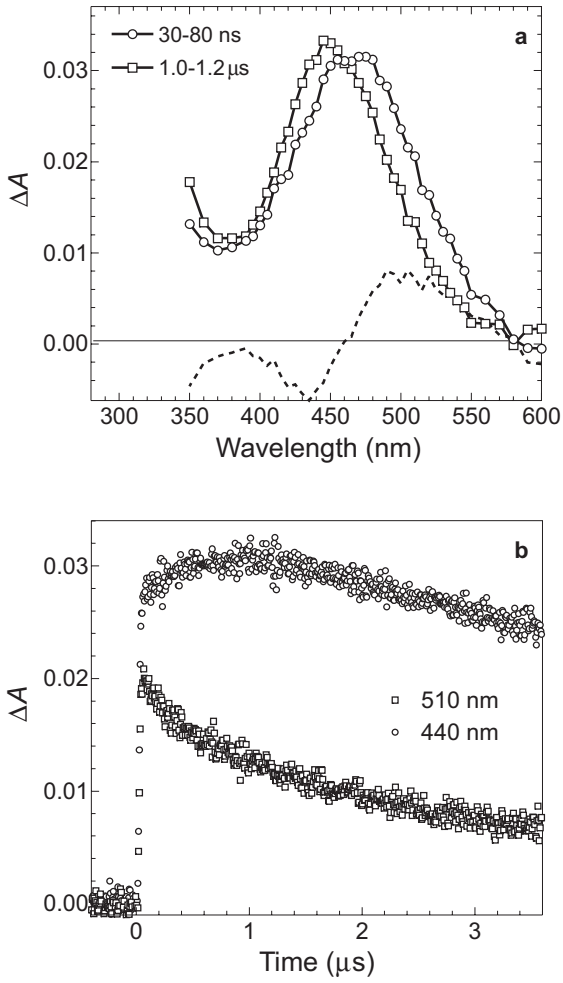
Laser flash photolysis experiments with **2a** employed flowed, deoxygenated 1.3×10^{-4} mol/L solutions of the compound in anhydrous hexane, and used the pulses from a KrF excimer laser (248 nm, ~25 ns, ~100 mJ) for excitation. As reported previously (2), laser photolysis of the compound affords strong transient absorptions throughout the 300–600 nm region of the spectrum, which decay over several hundred microseconds with complex kinetics. Figure 1 shows transient spectra recorded at selected time intervals over a ca. 350 μs time window after excitation in the absence and presence of 3 mmol/L acetic acid (AcOH). The spectra in the absence of acid were collected with a view to reproducing the originally reported conditions as closely as possible, while those in the presence of acid were intended to reveal those transient absorptions that remain behind when Ph_2Ge and its oligomerization products are removed from the mixture by trapping with AcOH, a potent germylene scavenger (9, 10). The main (gross) effects of the carboxylic acid are a marked reduction in the intensities of the signals observed throughout the spectrum, and simplification of the complex transient absorptions that arise below ca. 340 nm. In the absence of AcOH (Fig. 1*a*), the spectrum exhibits a band at λ_{max} = 300 nm during the earliest time window monitored, which evolves into a band with λ_{max} ~ 310 nm after ca. 25 μs; only the latter is evident in the region below 340 nm in the presence of the carboxylic acid (Fig. 1*b*). Addition of the acid also reduces the intensity of the long wavelength absorption band centered at λ_{max} ~ 445 nm, and markedly reduces the complexity of the transient decay profile at this wavelength, which decays with multiexponential kinetics in the absence of acid (see inset, Fig. 1*a*). In the presence of 3 mmol/L AcOH the long wavelength absorption decays with clean second-order kinetics (see inset, Fig. 1*b*) and a rate coefficient of $k_{decay}/\varepsilon = (7.4 \pm 0.2) \times 10^5$ cm^{-1} s^{-1} (r^2 = 0.987). The decay kinetics at 310 nm (not shown) are similar to those at 440 nm, suggesting that the two absorption bands in the spectrum of Fig. 1*b* belong to the same (as yet unidentified) transient species. It can thus be concluded that the early (0.64–2.56 μs) spectrum of Fig. 1*a* is the sum of the spectra of at least two transient species of which all but one is eliminated in the presence of 3 mmol/L AcOH.



AcOH is known to react with Ph_2Ge irreversibly, with a rate constant of 3.9×10^9 (mol/L)$^{-1}$ s^{-1} (9). Thus, a concentration of 3 mmol/L is sufficient to reduce the lifetime of Ph_2Ge to <100 ns and more or less completely suppress its dimerization to tetraphenyldigermene (**15**), the main mode of decay of the germylene in the absence of scavengers (see eq. [6]) (9). In the absence of scavengers, the concentration

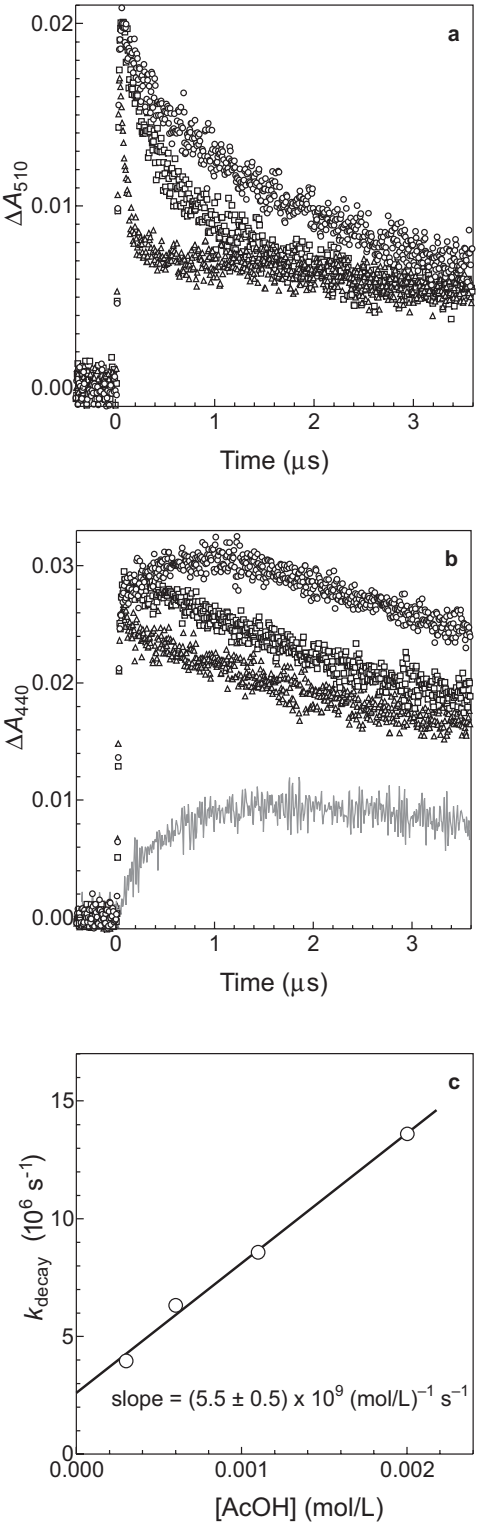
Fig. 1. Transient absorption spectra from laser flash photolysis of a flowed, deoxygenated solution of **2a** (1.3×10^{-4} mol/L) in anhydrous hexane containing (*a*) 0 mmol/L of AcOH and (*b*) 3 mmol/L AcOH, recorded under identical conditions, 0.64–2.56 μs (○), 24–39 μs (□), and 324–325 μs (△) after the pulse. Transient decay traces recorded at a monitoring wavelength of 440 nm are shown as inserts.

© 2005 NRC Canada



of **15** reaches a maximum in the first ca. 1 μs after the excitation pulse, and then decays over several tens of microseconds (9). We thus attribute that portion of the transient spectrum of Fig. 1*a* that is eliminated in the presence of AcOH to **15** (λ_{max} = 300, 440 nm (9)), formed by dimerization of Ph_2Ge, and its oligomerization product(s). The long wavelength absorption band in the spectrum of **15** is almost exactly coincident with that of the longer lived (nonquenchable) species that was erroneously identified as owing to Ph_2Ge in the original work (2).

Direct evidence for the formation of Ph_2Ge from **2a** was obtained by examination of the transient spectroscopic behavior over shorter timescales. Figure 2 shows transient spectra recorded at selected time intervals within ca. 1 μs after excitation, along with representative transient absorption profiles recorded at 510 and 440 nm. As can be seen from the data, the long wavelength absorption band in the transient spectrum from **2a** is centered at λ_{max} ~ 465 nm during the first ca. 100 ns after excitation, and appears to shift to λ_{max} ~ 445 nm (its position in the spectra of Fig. 1) during the next ~900 ns. Inspection of the transient absorption profile at 440 nm reveals a slight increase in signal strength at this wavelength over this early time period, indicative of the delayed formation of a species that is not present (or at least present in lower concentration) immediately after the ca. 25 ns laser pulse. Thus, the apparent shift in the position of the long wavelength transient absorption during the first microsecond after excitation can be understood as owing to the superposition of three distinct transient absorptions that each evolve differently over this timescale: one that decays almost completely (465 nm < λ_{max} < 550 nm), one that grows in (400 nm < λ_{max} < 460 nm), and one that is essentially nondecaying (λ_{max} ~ 445 nm, see Fig. 1*b*). This behavior is consistent with the initial formation of Ph_2Ge (λ_{max} = 500 nm (9)), which decays over 1 to 2 μs by dimerization to yield **15** (λ_{max} = 440 nm (9)). The timescale over which these changes occur correlates almost precisely with that found in our previous study of these species, generated by laser photolysis of **5** (9). The transient decay profiles shown in Fig. 2 bear only qualitative similarities to those previously obtained from **5** (9), however, owing to the presence of the third transient species, which absorbs relative strongly over the same range of the spectrum, and whose decay proceeds over a much longer timescale.



Inspection of the transient absorption profiles over the short timescale as AcOH is added to the solution provides somewhat clearer evidence for the presence of Ph_2Ge and its dimerization product in the transient mixture. Figures 3*a* and 3*b* show a series of decay profiles recorded at the two wavelengths in the presence of 0, 0.1, and 2.0 mmol/L of added carboxylic acid, demonstrating quite clearly that a significant portion of the signal at 510 nm is quenched by the reagent, concomitant with a reduction in the yield of a transient absorbing at 440 nm. Nonlinear least-squares analysis of the initial rapidly decaying portion of the 510 nm decay profiles at several AcOH concentrations as a single exponential decay (with the more slowly decaying residual absorption treated as nondecaying) afforded quite reasonable fits; the resulting pseudo-first-order decay rate constants (k_{decay}) are plotted in Fig. 3*c* vs. AcOH concentration. Linear least-squares analysis of these data according to eq. [7], where k_0 is the effective pseudo-first-order decay rate constant at [AcOH] = 0 and k_{AcOH} is the bimolecular rate constant for scavenging by the carboxylic acid, affords a slope of k_{AcOH} = (5.5 ± 0.5) × 10^9 $(mol/L)^{-1}$ s^{-1}, in excellent agreement with the value reported by us earlier for the O-H insertion reaction of Ph_2Ge with AcOH (k_{AcOH} = 3.9 × 10^9 $(mol/L)^{-1}$ s^{-1} (9)). Figure 3*b* also shows the result of subtracting the decay trace at 440 nm in the presence of 2.0 mmol/L AcOH (where formation of **15** should be more or less completely suppressed) from that recorded in the ab-

Fig. 2. (*a*) Transient absorption spectra from laser flash photolysis of a flowed, deoxygenated solution of **2a** (1.3 × 10^{-4} mol/L) in anhydrous hexane, 30–80 ns (○) and 1.0–1.2 μs (□) after the pulse. The dashed line is the difference between the early and late spectrum. (*b*) Transient absorption profiles recorded at 440 nm (○) and 510 nm (□).

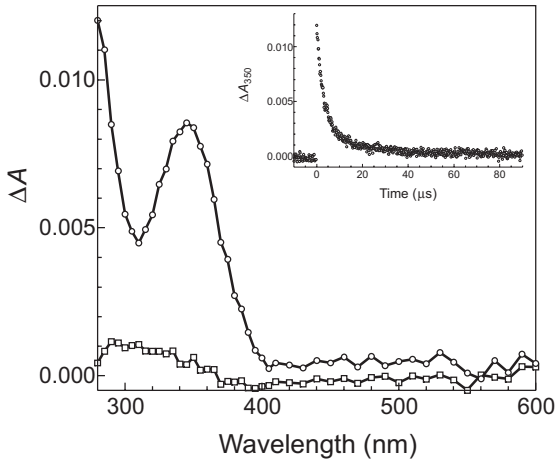
Fig. 3. Transient decay traces recorded with a deoxygenated anhydrous hexane solution of **2a** at (*a*) 510 nm and (*b*) 440 nm in the presence of 0 mmol/L AcOH (○), 0.1 mmol/L AcOH (□), and 2.0 mmol/L AcOH (△). The grey trace in (*b*) is the difference between the 0 and 2.0 mmol/L traces. (*c*) Plot of the rate constant for the initial rapid decay at 510 nm (k_{decay}) vs. [AcOH] over the 0.3–2.0 mmol/L concentration range.

sence of scavenger. This is also in good agreement with the growth–decay profile for **15** that is observed using **5** as the germylene precursor (9).

$$[7] \qquad k_{decay} = k_0 + k_Q[Q]$$



Addition of *n*-butyl amine ($BuNH_2$, 5.0 mmol/L) or MeOH (50 mmol/L) to the hexane solutions of **2a** had similar effects as AcOH on the overall transient behavior (Fig. 1), eliminating the absorptions owing to Ph_2Ge and its products and leaving behind the same long-lived transient species that is observed in the presence of AcOH. Like the carboxylic acid, both of these reagents are potent germylene scavengers, reacting with Ph_2Ge at close to the diffusion-controlled rate in both cases (9).[3] Addition of carbon tetrachloride (CCl_4), chloroform ($CHCl_3$), or oxygen (O_2) to hexane solutions of **2a** in hexane containing 50 mmol/L MeOH caused an increase in the decay rate of the surviving long-lived transient (monitored at 440 nm) in proportion to the concentration of added reagent, and plots of k_{decay} vs. [Q] according to eq. [7] were linear, with slopes of k_{CCl_4} = (7.3 ± 0.7) × 10^6 mol/L^{-1} s^{-1}, k_{CHCl_3} = (1.2 ± 0.1) × 10^4 mol/L^{-1} s^{-1} and k_{O_2} = (6.6 ± 0.8) × 10^7 mol/L^{-1} s^{-1} for CCl_4, $CHCl_3$, and O_2, respectively. The k_{O_2} value is in good agreement with that reported for this species in the original study (k_{O_2} = 1.02 × 10^8 mol/L^{-1} s^{-1}) (2). It is interesting to note that the transient exhibits similar (but two to three times greater) reactivity towards O_2 and CCl_4 as Ph_2Ge does under similar conditions (10), but exhibits ca. 20 times lower reactivity toward $CHCl_3$ (10).

Finally, we examined the flash photolysis behavior of **2a** in deoxygenated tetrahydrofuran (THF) solution, as Ph_2Ge and other reactive germylenes are known to form Lewis acid–base complexes with ethers, with substantially blue-shifted absorption maxima compared to those of the free species (16, 17); for example, generation of Ph_2Ge in a 2-methyltetrahydrofuran glass at 77 K leads to a species absorbing at λ_{max} = 325 nm, which was assigned to the germylene–ether complex (17). The transient spectra obtained by flash photolysis of **2a** in THF solution are similar to those of Fig. 1*b*, but exhibit a weak shoulder on the long wavelength edge of the rising 310 nm absorption, consistent with the presence of the Ph_2Ge-complex. The spectrum of the complex could be isolated by addition of 0.2 mol/L CCl_4 to the solution, which shortened the lifetime of the 310/445 nm transient absorptions to ca. 500 ns and left behind longer lived absorptions ($\tau \sim 2$ μs), centered at λ_{max} = 345 nm that decayed with second-order kinetics (see Fig. 4). The spectrum is in reasonably good agreement with that assigned to the Ph_2Ge–THF Lewis acid–base complex (eq. [8]) in the earlier matrix experiments (17). From the lifetime of the 310/445 nm species under these conditions, a rate constant of ca. 1 × 10^7 mol/L^{-1} s^{-1} can be estimated for its reaction with CCl_4, in good agreement with the value measured in hexane solution (vide supra). The extended lifetime of the Ph_2Ge–THF complex under these conditions presumably results from the fact that it is much less reactive toward CCl_4 than the free germylene, whose concentration is reduced by orders of magnitude relative to that in hexane solution owing to the solvent complexation equilibrium. The "stabilizing"

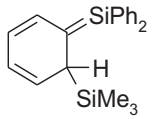
Fig. 4. Transient absorption spectra recorded by laser flash photolysis of a deoxygenated 1.3×10^{-4} mol/L solution of **2a** in THF containing 0.2 mol/L CCl_4, 0.6–2.1 μs (○) and 81–85 μs (□) after the (248 nm) laser pulse. The inset shows a transient decay profile recorded at 350 nm.

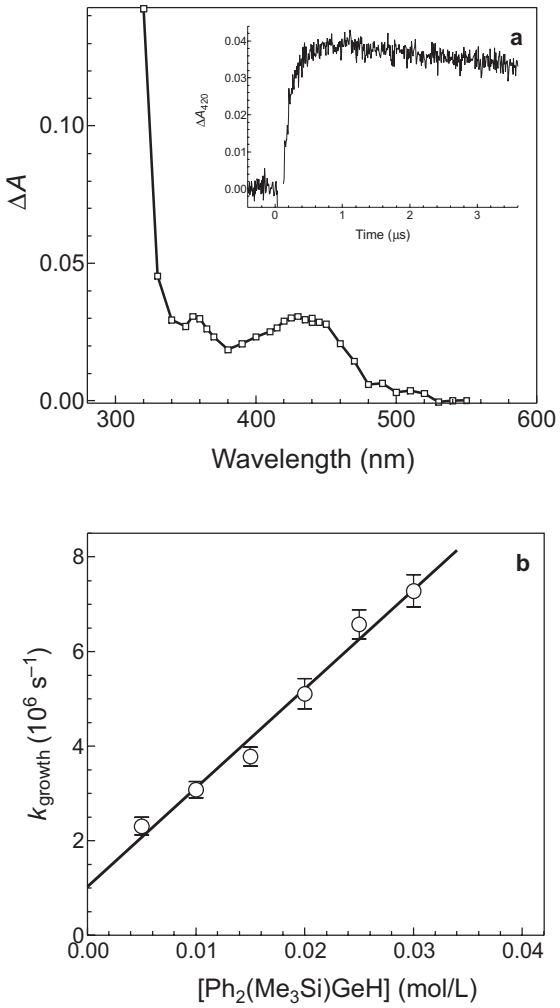


effect of ethers and other Lewis bases on reactive germylenes is well-recognized (25–28).

[8] $Ph_2Ge + O \rightleftharpoons Ph_2Ge^{-}-O^{+}$

The two most reasonable candidates for the 310/445 nm species of Fig. 1*b* are the diphenyl(trimethylsilyl)germyl radical (**10**), which our steady-state results indicate *is* formed upon photolysis of **2a** in significant yield, and the 1-germahexatriene derivative **9**, which would be derived from formal 1,3-trimethylsilyl migration into the ortho position of one of the phenyl groups in the excited singlet state of **2a**. While we have *no* evidence for the formation of **9** from steady-state photolysis experiments, we can nevertheless not easily discount the possibility that it is formed in minor yields and escaped detection in the product studies; trapping of germenes (and silenes) of this general structure by dienes and alcohols is known to afford more than a single product (18, 23, 29). Furthermore, photorearrangements of this type are common in arylgermasilanes (6, 18, 30) and aryldisilanes (31–33) in which the reaction was initially discovered (34). Germene **9** can be expected to be a much stronger absorber than Ph_2Ge, and exhibit similar reactivity to that actually observed for the 310/445 nm transient (18).

The rationale behind the latter statement is as follows. The rate constants for reaction of AcOH and MeOH with germene **8** (one of only two germenes of this type that have been studied (18)) are on the order of 4×10^5 mol/L^{-1} s^{-1} or less, three orders of magnitude lower than the homologous silene derivative (**16**) (18). The reactivity of **9** with nucleophiles can be expected to be significantly lower than that of **8** because of the presence of the trimethylsilyl substituent at Ge, based on analogies in transient silene chemistry; trimethylsilyl substitution at silicon in silenes reduces the reactivity of the Si=C bond by roughly a factor of 10 relative to a methyl substituent (35), which is similar to a phenyl group in its effects on Si=C reactivity (36, 37). Finally, like its silicon counterpart (**16**), germene **8** exhibits significantly higher reactivity toward O_2 and chlorocarbons than it does toward alcohols or other nucleophiles, owing to the radical-like nature of these reactions and the radical-stabilizing effect of the cyclohexadienyl substituent attached to the germenic carbon atom (18). These considerations suggest that the reactivity of the 310/445 nm transient species of Fig. 1*b* is not inconsistent with what might be expected for germene **9**. The only piece of data that argues *against* this assignment is the UV absorption maximum, which lies ca. 35 nm (1800 cm^{-1}) to the *blue* of that exhibited by germene **8** (18). In silenes, replacement of a methyl substituent at silicon with a trimethylsilyl group produces a ca. 4000 cm^{-1} red shift in the UV absorption maximum (35); this fact, coupled with the facts that replacement of one of the phenyl groups in **16** with a methyl group causes a ca. 2000 cm^{-1} blue shift in the absorption maximum (23) and silenes and germenes with the same substituents exhibit essentially identical UV–vis absorption maxima (18, 38), leads to the expectation that the absorption maximum of **9** should be quite similar to that of **8** (λ_{max} ~ 475 nm).



16

To address the other possible transient assignment, germyl radical **10**, we have independently generated the radical by hydrogen abstraction from the corresponding germyl hydride (**17**) by *tert*-butoxyl radicals (eq. [9]), generated by 308 nm laser flash photolysis of 5–30 mmol/L solutions of **17** in di-*tert*-butylperoxide (BOOB) – isooctane (1:4) solution, using a similar procedure to that used previously for the generation of triphenylgermyl and other Group 14 radicals (39, 40). Figure 5 shows the resulting transient absorption spectrum of the radical, a representative transient absorption profile illustrating its growth kinetics, and a plot of the pseudo-first-order rate constant for growth of the radical absorption vs. concentration of **17**, the slope of which is the absolute rate constant for hydrogen abstraction from **17** by *tert*-butoxyl radical. The value obtained, $k = (2.4 \pm 0.4) \times 10^8$ (mol/L)$^{-1}$ s^{-1}, is roughly twice higher than that for the analogous reaction of triphenylgermane (Ph_3GeH) (39),[4] which is the expected result on the basis of comparisons of the corresponding rate constants for hydrogen abstraction from tris(trimethylsilyl)germane and triethylgermane (41), and analogies taken from silicon radical chemistry (42). A possible alternate assignment of the transient product to the diphenylgermyl radical, which might be formed by trimethylsilyl transfer from **17** rather than the expected hydrogen abstraction to form **10**, can be ruled out on the basis of comparisons of the spectrum to that reported for the diphenylgermyl radical (λ_{max} = 325, 405 nm (39*b*)).[5] The authentic spectrum of radical **10**

[4] We also remeasured the rate constant for H abstraction from Ph_3GeH in the course of this work and obtained a value of $k = (1.2 \pm 0.1) \times 10^8$ (mol/L)$^{-1}$ s^{-1}, in excellent agreement with the previously reported value of 9×10^7 (mol/L)$^{-1}$ s^{-1} (39).
[5] We thank a referee for alerting us to this possible alternate assignment.

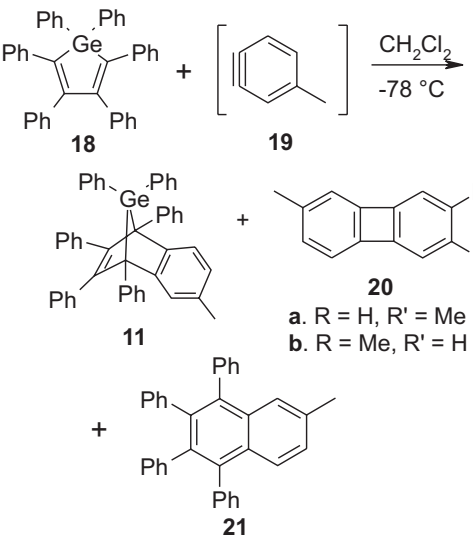
Fig. 5. (*a*) Transient absorption spectrum of the diphenyl(trimethylsilyl)germyl radical, recorded 3.7–3.9 μs after 308 nm laser photolysis of a 0.040 mol/L solution of $Ph_2Ge(H)SiMe_3$ (**17**) in BOOB–isooctane (1:4, *v*/*v*); the inset shows a typical growth profile of the radical, recorded at a monitoring wavelength of 420 nm. (*b*) Plot of k_{growth} at 420 nm vs. the concentration of added **17**. The solid line represents the linear least-squares fit of the data to eq. [6].

(Fig. 5*a*) agrees reasonably well with the spectrum of the 310/445 nm transient from photolysis of **2a** (Fig. 1*b*), although the match is not precise. We did not attempt to measure rate constants for reaction of authentic **10** with O_2 or with CCl_4 for comparison to those for the 310/445 nm transient, the latter because the germane precursor is unstable in the presence of the halocarbon and light.



[9] $Me_3Si(Ph)_2Ge{-}H + t\text{-}Bu{-}O\bullet \longrightarrow Me_3Si{-}(Ph)_2Ge\bullet + t\text{-}BuOH$

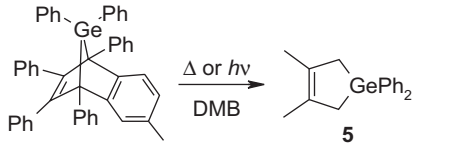
17 **10**

Table 1 lists the UV absorption maxima and absolute rate constants for reaction of triphenylgermyl radicals (germene **8**) and the 310/445 nm transient from flash photolysis of **2a**. As mentioned previously, the reactivity of the species is similar to that of **8** with the same reagents, significantly more so than it is to the reactivity of the triphenylgermyl radical. In fact, a significantly lower reactivity toward halocarbons and oxygen compared to triphenylgermyl is what one would expect of radical **10**, as the stabilizing effect of trimethylsilyl substitution on both germanium and (in particular) silicon centered radicals is well-known (41–43).

The photochemistry of 1,4-dihydro-5-methyl-1,2,3,4,9,9-hexaphenyl-1,4-germanonaphthalene (11)

Compound **11** was synthesized in ca. 80% yield by cycloaddition of 4-methylbenzyne (**19**) to hexaphenylgermole (**18**; see eq. [10]) in dichloromethane at –78 °C, by an analogous procedure to that reported for the synthesis of **4** (16). The reaction mixture also contained small amounts of the 4-methylbenzyne dimerization products **20** and 6-methyl-1,2,3,4-tetraphenylnaphthalene (**21**); small amounts of **18** are very likely present as well, although the compound could not be specifically detected in the NMR spectrum of the mixture. The amount of **21** in the sample increased slowly relative to **11** over a few hours, thus, the latter was isolated from the reaction mixture by cold (ca. –15 °C) radial chromatography, characterized on the basis of its ^1H and ^{13}C NMR and mass spectra (see the Experimental section), and stored in the dark at –78 °C. However, in spite of reasonable efforts, a sample of **11** containing less than ca. 5% **21** could not be obtained.

[10] 



To quantify the thermal lability of **11**, a 0.055 mol/L solution of the compound was prepared in deoxygenated cyclohexane-d_{12} containing 0.5 mol/L DMB and monitored over time at 23 °C by NMR spectroscopy. The mixture contained ca. 10% **21** at the beginning of the experiment, evidently formed by thermal decomposition of **11** subsequent to its initial purification. The NMR spectrum was measured at selected time intervals over the following 20 h, which revealed slow conversion of **11** to **21** and **5** (eq. [11]). A plot of log([**11**]/(mol/L)) vs. time was reasonably linear (r^2 = 0.9886; see Fig. 6) and linear least-squares analysis afforded a first-order rate constant of $(1.6 \pm 0.1) \times 10^{-5}$ s^{-1} for the decomposition of **11**, which yields **21** and Ph_2Ge, trapped as DMB adduct **5** at 23 °C. This corresponds to a half-life of

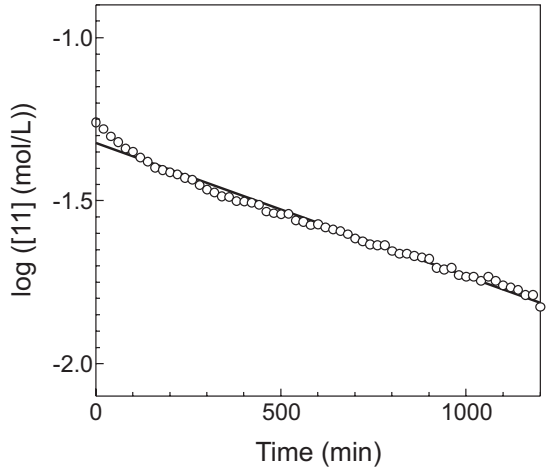
Table 1. Comparison of UV–vis absorption spectra and absolute rate constants for the reaction of the 310/445 nm transient from **2a**, triphenylgermyl radicals (Ph_3Ge), and germene **8** with halocarbons and O_2.

	310/445 nm Transient	Ph_3Ge	**8**
λ_{max} (hexane solution, nm)	310, 445	328, 405 (50)	475 (18)
k_{CCl_4} ((mol/L)$^{-1}$ s^{-1})	7.3×10^6	5.8×10^8 (3)	2.9×10^7 (18)
k_{CHCl_3} ((mol/L)$^{-1}$ s^{-1})	1.2×10^4	5.5×10^7 [6]	$<3\times10^6$ (18)
k_{O_2} ((mol/L)$^{-1}$ s^{-1})	6.6×10^7	3.8×10^9 (3)	9.6×10^7 (18)

ca. 12 h, or (put another way) a decomposition rate of ca. 6% per hour at 23 °C.

[11] 

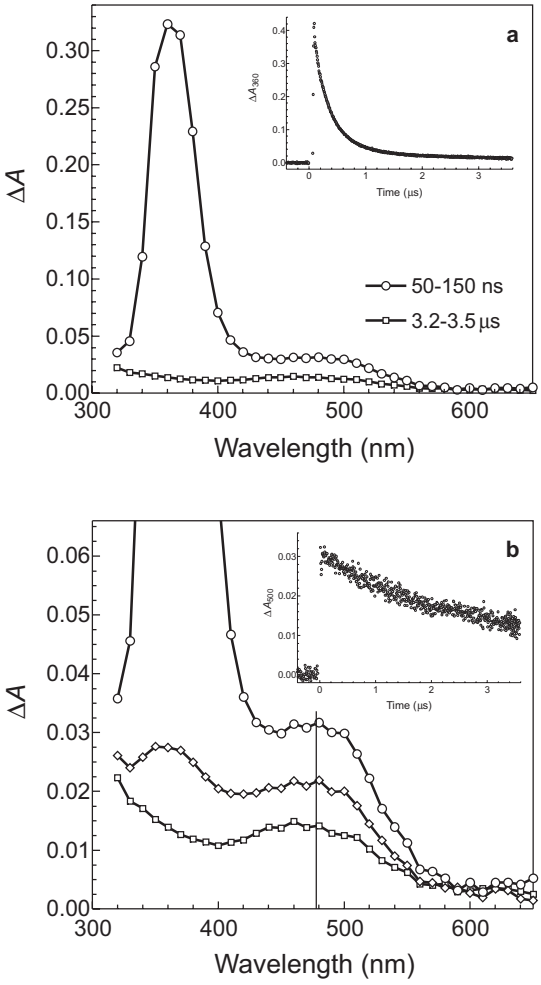


Steady-state photolysis of **11** was carried out on argon outgassed 0.05 mol/L solutions in cyclohexane-d_{12} containing 0.5 mol/L MeOH or DMB with 254 nm light, with the course of the photolyses periodically monitored by ^{1}H NMR spectroscopy; the samples of **11** each contained ca. 10% **21** at the beginning of the experiment. While irradiations and NMR analyses were all carried out at room temperature, the samples were otherwise stored at –78 °C to minimize thermal decomposition. Irradiation to ca. 50% conversion of **11** showed **21** and the corresponding Ph_2Ge trapping products (methoxygermane **13** or germacyclopentene **5**) to be the only detectable photolysis products. While no attempts were made to determine the quantum yield for Ph_2Ge extrusion from the compound, it was estimated to be of similar magnitude to that from **5** for which a value of $\Phi = 0.62$ has been reported (9). Görner et al. (44) reported a quantum yield of $\Phi = 0.4$ for the extrusion of Me_2Ge from the related compound **22** in deoxygenated methylcyclohexane solution.

22

Laser flash photolysis experiments were carried out with flowing, argon outgassed solutions of freshly chromatographed **11** (ca. 5×10^{-5} mol/L, containing ca. 5% **21**) in anhydrous hexane, again using the KrF excimer laser as excitation source. Figure 7 shows a series of transient absorption spectra recorded at various time intervals over the first

Fig. 6. The thermal decomposition of germanorbornadiene **11** in cyclohexane-d_{12} at 23 °C. The solid line represents the linear least-squares fit of the data, affording a first-order rate constant $k = (1.6 \pm 0.1) \times 10^{-5}$ s^{-1}, $r^2 = 0.9886$).



3.6 μs after the laser pulse. The results are consistent with the formation of at least three transient species. The shortest lived transient exhibits very strong absorptions centered at λ_{max} = 360 nm, is formed with the laser pulse, and decays with a lifetime of $\tau \sim 300$ ns. The second species is assigned to the weak shoulder on the 360 nm band in the 50–150 ns spectrum. Its apparent absorption maximum is ca. 480 nm (see the expanded spectra in Fig. 7*b*), which is clearly an underestimate caused by the substantial overlap with the 360 nm band. Nevertheless, the absorptions in the 460–540 nm region of the spectrum are at least five times more intense than would be expected if Ph_2Ge was the only contributor to the absorptions in this range, assuming the germylene is produced at an initial concentration of ca. 10 μmol/L, which is the maximum value we would expect under the conditions of our experiments. The third species is significantly longer lived than the other two and exhibits an apparent $\lambda_{max} \sim 460$ nm, too far to the red to be assigned to the expected germylene dimerization product (digermene **15**). While it is perhaps relevant to point out that the spectrum of this species is similar to that reported in the previous matrix photolysis of **4** (1), we have insufficient information to make a reliable assignment of the species. At no monitoring wavelength in the range studied was a growth in the transient signal discernible, although this is to be expected

Fig. 7. (*a*) Transient absorption spectra recorded by laser flash photolysis of a deoxygenated 5×10^{-5} mol/L solution of **11** in anhydrous hexane at 23 °C, 50–150 ns (○) and 3.2–3.5 μs (□) after the (248 nm) laser pulse; the inset shows a transient decay profile recorded at 360 nm. (*b*) An expanded plot of the spectra of (*a*) with a spectrum recorded 1.4–1.6 μs after the pulse included; the vertical line marks the apparent maximum of the long wavelength absorption band in the 50–150 ns spectrum.

considering the substantial overlap with the strongly absorbing species at 360 nm.

Similar experiments carried out on an O_2 saturated solution of **11** verified that Ph_2Ge and its oligomerization products contribute in only a very minor way, if at all, to the transient absorptions observed from flash photolysis of this compound. Under these conditions the transient at 500 nm exhibited a lifetime of ca. 75 ns, and decayed to a residual absorption level roughly 4% of that immediately present after the pulse. A quenching rate constant of $k_{O_2} \sim 9 \times 10^8$ $(mol/L)^{-1}$ s^{-1} can be estimated from the lifetime (using a value of $[O_2] = 0.015$ mol/L for the concentration of O_2 in O_2 saturated hexane), which is ca. 30 times higher than the rate constant reported by us recently for the reaction of Ph_2Ge with O_2 ($k_{O_2} \sim 2.7 \times 10^7$ $(mol/L)^{-1}$ s^{-1} (10)). The other major change noted upon saturation of the solution with O_2 was a change in the form of the decay of the 360 nm transient to biexponential kinetics, with roughly 65% of the absorptions decaying on a very fast timescale and the remaining ~35% exhibiting a lifetime similar to that observed in the absence of O_2. This behaviour suggests that the transient absorptions produced upon flash photolysis of **11** are dominated by triplet or triplet-derived species.

Our results for **11** are similar to those reported for the related compound **22** by Görner and co-workers (44), who assigned the transients observed upon 248 nm laser flash photolysis of the compound to the triplet state of 1,2,3,4-tetraphenylnaphthalene, the coproduct of Me_2Ge photoextrusion from this compound. They were similarly unable to obtain discrete evidence for the formation of a transient assignable to the germylene (44).

As was also reported in the earlier study of **22** (44), virtually identical transient spectroscopic behaviour was observed upon laser flash photolysis of (static) 1×10^{-5} mol/L solutions of the tetraphenylnaphthalene coproduct (**21**, in the present case) in both deoxygenated and oxygen saturated hexane solution, with the transient spectra and lifetimes at various wavelengths coinciding quite closely to those obtained using **11** under corresponding conditions. In this case, saturation of the solution with O_2 decreased the lifetime of the 500 nm transient absorptions to ca. 50 ns from which can be estimated a quenching rate constant of $k_{O_2} \sim 1.3 \times 10^9$ $(mol/L)^{-1}$ s^{-1}, in good agreement with that obtained in experiments using **11** as the precursor.

Görner and co-workers (44) explained their results for **22**, which were much more extensive than the present ones for **11** and involved purer samples (**22** is evidently significantly more stable thermally than **11** (19)), in terms of a mechanism in which the (1,2,3,4-tetraphenylnaphthalene) coproduct of Me_2Ge extrusion is formed in the excited singlet state, which then yields the triplet after intersystem crossing. The alternative possibility that the naphthalene triplet is directly produced along with (singlet) Me_2Ge from the triplet state of the precursor was ruled out on the basis of CIDNP experiments. Because our samples of **11** contained small amounts of the corresponding naphthalene derivative (**21**), we cannot ascertain to what extent the transient mixture produced in our experiments with the Ph_2Ge precursor is contaminated by cophotolysis of the impurity. Nevertheless, our results verify that the transient spectroscopic behaviour observed in flash photolysis experiments with compounds of this type is dominated by triplet and (or) triplet-derived species (for one reason or another), and that simple germylenes such as Ph_2Ge or Me_2Ge are impossible to detect reliably (if at all) in fluid solution from such precursors by time-resolved UV spectroscopic methods.

Summary and conclusions

In spite of the indication from product studies that the direct photolyses of disilylgermane **2a** and benzogermanorbornadiene **11** afford Ph_2Ge in very high yields, they are clearly unsuitable as precursors of the germylene for study by time-resolved UV–vis spectroscopic methods in solution. In the case of **2a**, this is due to the competing formation of a second transient product, which, although it is formed in relatively low yield, absorbs strongly over the same spectral range as Ph_2Ge and its dimerization product (digermene **15**), and is much longer lived than the relatively weakly absorb-

© 2005 NRC Canada

ing germylene. The germylene and its dimer *can* be successfully detected in laser flash photolysis experiments with this compound, but their relatively weak absorptions are superimposed on a background of intense, relatively long-lived absorptions owing to the minor product. This makes them very easy to miss altogether, particularly when little or no independent information on their spectra and reactivities exists, as was the case in the original study. The UV–vis absorption spectrum of the species and its reactivity toward halocarbons and oxygen is broadly consistent with its assignment to the diphenyl(trimethylsilyl)germyl radical, which product studies show is formed in minor, but significant, yields upon photolysis of **2a**. Radical formation is suppressed in the presence of high concentrations of diene, suggesting that the Si—Ge bond homolysis process that is responsible for its formation is derived from the triplet state of the disilylgermane. The alternate assignment of the species to germene **9** cannot be ruled out.

Other factors frustrate attempts to detect the germylene and its dimer in laser flash photolysis experiments with the benzogermanorbornadiene derivative **11**, in spite of the fact that product studies indicate its photodecomposition to proceed cleanly and in relatively high quantum yield. One of these is the compound's rather low thermal stability, which makes it exceedingly difficult to purify to the level necessary for studies of this type; the major product of thermal decomposition (tetraphenylnaphthalene derivative **21**) absorbs strongly at the wavelength necessary to excite the germylene precursor, and its relatively efficiently populated triplet state absorbs very strongly over the same range as the germylene does. Earlier studies with a related compound (44) indicate that even when highly pure samples of the precursor can be obtained, the only transients detectable by time-resolved UV spectroscopic methods are derived from the excited triplet state of the aromatic coproduct. This is thought to be due to the fact that the photodecomposition reaction proceeds adiabatically, ultimately yielding the coproduct in its excited triplet state. In the present experiments with **11**, these two complicating factors combine to make the triplet state of tetraphenylnaphthalene **21** the dominant transient detectable upon laser flash photolysis of the compound in solution at ambient temperatures.

Experimental

^{1}H, ^{13}C, and ^{29}Si NMR spectra were recorded on Bruker AV 200 or AV 600 spectrometers in deuteriochloroform solution unless otherwise noted; ^{1}H and ^{13}C NMR spectra were referenced to the residual solvent proton and ^{13}C signals, respectively. High-resolution electron impact and atmospheric pressure chemical ionization (APCI) mass spectra and exact masses were determined on a Micromass TofSpec 2E (MALDI-TOF mass spectrometer) performed on a Micromass Ultima ESI/APCI triple quadrupole mass spectrometer. IR spectra were recorded on a BioRad FTS-40 FT IR spectrometer and are reported in wavenumbers (cm^{-1}). Gas chromatographic analyses were carried out using a Hewlett-Packard 5890 gas chromatograph equipped with a conventional heated injector, a flame ionization detector, a Hewlett-Packard 3396A integrator, and a SPB-5 capillary column (25 m, 0.25 μm, Supelco, Inc., Bellefonte, Pennsylvania), while GC–MS analyses were carried out using a Micromass GCT instrument interfaced to an Agilent 6890 Series GC system with a J & W DB-XLB 30 m column. Melting points were determined using a Mettler FP82 hot stage mounted on a polarizing microscope and are uncorrected. Radial chromatographic separations were carried out using a Chromatotron® (Harrison Research, Inc., Palo Alto, California) with silica gel 60 plates (4 mm thick) and with hexane as the eluant. Column chromatography was performed on a 30 mm × 600 mm column using silica gel (~100 g, acid washed, 230–400 mesh) (Silicycle). Steady-state photolyses were carried out in a Rayonet® photochemical reactor (Southern New England Ultraviolet Co., Branford, Connecticut) equipped with a merry-go-round apparatus and six RPR-2537 lamps (254 nm).

4-Methyl-2-nitroaniline (Sigma-Aldrich, St. Louis, Missouri), chlorotrimethylsilane (Gelest, Morrisville, Pennsylvania), *tert*-butyllithium (1.7 mol/L in pentane, Sigma-Aldrich), dimethylmalonate (Sigma-Aldrich), and lead tetraacetate (Sigma-Aldrich) were used as received from the suppliers. 2,3-Dimethyl-1,3-butadiene (Sigma-Aldrich) was purified before use by bulb-to-bulb distillation under vacuum. Tetrahydrofuran and hexanes (Caledon reagent grade, Georgetown, Ontario) were dried by passage through activated alumina under nitrogen using a Solv-Tek solvent purification system (Solv-Tek, Inc., Berryville, Virginia). Dichloromethane, methanol, acetone and pentane (all Caledon reagent grade) were used as received. Triethylamine (Sigma-Aldrich) was refluxed over solid KOH and distilled before use. 1,1,2,3,4,5-Hexaphenylgermole was prepared by the procedure of Ferman et al. (45).

Bis(trimethylsilyl)diphenylgermane (2a)

To a flame-dried 150 mL two-neck round-bottom flask equipped with a rubber septum, magnetic stirring bar, and nitrogen inlet was added anhydr. THF (30 mL) via a syringe. The solution was cooled to –40 °C ($MeCN–CO_2$ bath) and 5.2 g (22.8 mmol) of diphenylgermane was added by syringe dropwise through the septum. A solution of *tert*-butyllithium (1.7 mol/L in pentane, 32 mL, 54.4 mmol) was then added dropwise using a syringe in several portions over 10 min. The initial brilliant yellow reaction mixture because of the diphenylgermyl anion transformed to a dark red solution after the half-way point of the addition, signifying the presence of the diphenylgermyl dianion (Ph_2GeLi_2) (46). The solution was stirred at –40 °C for 25 min and then neat chlorotrimethylsilane (9 mL, 7.7 g, 71.3 mmol) was added dropwise via a syringe, causing a slight increase in temperature and the mixture to turn yellow and cloudy. The cooling bath was removed and the reaction mixture was stirred for 24 h, during which time a white precipitate formed. Saturated aqueous ammonium chloride was added slowly until the precipitate dissolved, diethyl ether (25 mL) was added, the layers were separated, and the aqueous portion was extracted with additional ether (3 × 25 mL). The combined ether extracts were washed with saturated brine (25 mL) and water (25 mL), dried over anhydrous magnesium sulphate, filtered, and the solvent was removed on the rotary evaporator. The resulting yellow oil was purified by vacuum distillation (6.7 g, 18.1 mmol, 79%, 110 °C (0.02 mmHg, 1 mmHg = 133.322 4 Pa)) and recrystallized at –40 °C sev-

1,1,2,2-Tetraphenyl-1,2-bis(trimethylsilyl)digermane (14)

To a flame-dried 25 mL one-neck round-bottom flask equipped with a septum and magnetic stirring bar, under nitrogen, was added 1,1,2,2-tetraphenyldigermane (0.51 g, 1.12 mmol) (47) in anhydr. THF (4 mL) via a syringe. The solution was cooled to –40 °C (MeCN–CO_2 bath) and *tert*-butyllithium (1.4 mL, 2.38 mmol) was added dropwise via a syringe in several portions over 10 min. The dark yellow reaction mixture was stirred for 40 min at –40 °C and chlorotrimethylsilane (0.4 mL, 3 mmol) was added dropwise via a syringe over 2 min, causing the mixture to turn colourless. The reaction mixture was warmed to ambient temperature and stirred for 1 h after which saturated aqueous ammonium chloride (2 mL) and distilled water (4 mL) were added slowly until the solution clarified. The work up consisted of dilution with diethyl ether (20 mL) and extraction of the aqueous layer with more ether (2 × 20 mL). The combined organic layers were washed with saturated brine (20 mL) and distilled water (20 mL), dried over magnesium sulphate, filtered, and the solvent was removed on the rotary evaporator. The resulting colourless solid (>95% pure by NMR) was identified as **14** (mp 212–214 °C) on the basis of the following spectroscopic data: IR (solid): 3066 (s), 2956 (m), 1580 (w), 1481 (m), 1429 (m), 1245 (s), 1046 (s), 833 (s). ^{1}H NMR (C_6D_6) δ: 0.14 (s, 18H), 7.11 (t, *J* = 7.2 Hz, 4H), 7.15 (t, *J* = 7.2 Hz, 8H) 7.64 (d, *J* = 7.8 Hz, 8H). ^{13}C NMR (C_6D_6) δ: 0.24, 128.3, 128.4, 136.5, 139.8. ^{29}Si NMR (C_6D_6) δ: –6.1. MS (EI) *m*/*z*: 602 (1), 601 (1), 600 (2), 599 (1), 598 (1.5), 587 (4), 585 (5), 583 (4), 529 (4), 527 (5), 525 (4), 451 (60), 450 (98), 448 (100), 446 (50), 301 (69), 299 (55), 297 (43), 151 (56), 149 (45), 147 (34). Exact mass calcd. for $C_{30}H_{38}Ge_2Si_2$: 602.0936; found: 602.0947.

Diphenyltrimethylsilylgermane (17)

To a 50 mL Schlenk tube connected to a vacuum line and equipped with a magnetic stirring bar was added diphenylgermane (1.18 g, 5.16 mmol) and freshly distilled THF (5 mL). The tube was cooled to –40 °C and *tert*-butyllithium in hexane (1.58 mol/L, 3.26 mL, 5.16 mmol)) was added over 5 min. The resulting yellow mixture was allowed to warm to –20 °C and then stirred for 20 min after which chlorotrimethylsilane (1 mL, freshly distilled from calcium hydride) was added via a syringe, causing the immediate formation of a colourless precipitate. The mixture was warmed to room temperature and stirred for 1 h after which the solvent and excess chlorosilane were removed under high vacuum. The residue was extracted with dry pentane; removal of the pentane under vacuum afforded a colourless liquid. The product was further purified by bulb-to-bulb distillation (twice) to yield a colourless solid (0.55 g, 1.83 mmol, 35%, mp 36.0–37.2 °C), which was identified as **17** on the basis of the following spectral data: IR (solid): 3068 (m), 2955 (s), 2915 (s), 1998 (s, Ge-H), 1483 (m), 1430 (m), 1246 (s), 1088 (m), 976 (w), 836 (s). ^{1}H NMR (C_6D_6) δ: 0.18 (s, 9H), 5.08 (s, 1H), 7.12–7.18 (m, 6H), 7.55–7.57 (m, 4H). ^{13}C NMR (C_6D_6) δ: –0.63, 128.5, 128.6, 135.8, 137.4. ^{29}Si NMR (C_6D_6) δ: –10.1. MS (EI) *m*/*z*: 299.7 (2), 229.9 (13), 228.9 (31), 227.9 (86), 227.0 (100), 226.0 (86), 225.0 (70), 224.1 (56), 223.1 (44), 198.1 (6), 197.1 (25), 195.2 (6), 154.1 (5) 153.1 (15), 152.1 (14), 151.1 (58), 150.1 (15), 149.1 (45), 148.1 (4), 147.1 (32), 136.2 (8), 135.2 (50).

1-Amino-5-methylbenzotriazole was prepared by a modification of the procedure of Campbell and Rees (48), starting from 4-methyl-2-nitronaniline and dimethyl malonate. The original synthetic work did not include NMR or MS data for the compound or its synthetic precursors, so these are listed in the following.

Dimethyl mesoxalate 4-methyl-2-nitrophenylhydrazone

Bronze-coloured crystals, mp 158–160 °C. IR (neat): 2991 (m), 1745 (s), 1725 (s), 1450 (w), 1368 (m), 1174 (m), 944 (w). ^{1}H NMR ($CDCl_3$) δ: 2.35 (s, 3H), 3.87 (s, 3H), 3.93 (s, 3H), 7.24 (d, *J* = 8.5 Hz, 1H), 7.91 (d, *J* = 8.5 Hz, 1H), 7.97 (s, 1H), 14.08 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 20.3, 52.5, 52.6, 117.1, 124.1, 127.2, 133.4, 134.4, 136.2, 136.9, 161.8, 163.2. MS (EI) *m*/*z*: 295 (2), 141 (5), 89 (6), 87 (20), 72 (100), 71 (99), 57 (85). Exact mass calcd. for $C_{12}H_{13}N_3O_6$: 295.0804; found: 295.0802.

Dimethyl mesoxalate 2-amino-4-methylphenylhydrazone

Orange granules, mp 128 to 129 °C. IR (neat): 3464 (m), 3311 (w), 2990 (w), 1745 (s), 1725 (s), 1680 (m), 1651 (m), 1530 (s), 1440 (m), 1360 (s), 1240 (s), 1200 (m), 800 (m). ^{1}H NMR ($CDCl_3$) δ: 2.22 (s, 3H), 3.80 (s, 3H), 3.86 (s, 3H), 5.0 (bs, 2H), 6.52 (d, *J* = 8.4 Hz, 1H), 6.54 (s, 1H), 6.90 (d, *J* = 8.4 Hz, 1H), 13.29 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 20.9, 51.8, 51.9, 112.8, 118.5, 119.0, 119.2, 124.4, 136.1, 137.0, 163.4, 164.4. MS (EI) *m*/*z* 265 (2), 263 (3), 205 (8), 177 (5), 159 (5), 146 (5), 133 (5), 120 (10), 119 (12), 91 (50), 85 (80), 84 (100), 71 (60), 49 (85). Exact mass calcd. for $C_{12}H_{15}N_3O_4$: 265.1063; found: 265.1067.

Dimethyl (5-methylbenzotriazol-1-yl)iminomalonate

Yellow powder, mp 115 to 116 °C. IR (neat): 2990 (w), 1745 (s), 1625 (m), 1430 (w), 1300 (m), 1240 (s), 1160 (m), 1030 (s), 812 (s). ^{1}H NMR ($CDCl_3$) δ: 2.51 (s, 3H), 3.99 (s, 3H), 4.02 (s, 3H), 5.1 (bs, 2H), 7.44 (d, *J* = 8.4 Hz, 1H), 7.73 (d, *J* = 8.4 Hz, 1H), 7.79 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 21.4, 53.5, 53.8, 110.2, 119.4, 130.2, 132.0, 136.2, 140.0, 145.3, 160.8, 162.5. MS (EI) *m*/*z*: 276 (2), 205 (4), 177 (6), 120 (5), 119 (7), 91 (15), 88 (28), 86 (95), 84 (100), 51 (70), 49 (99), 47 (55). Exact mass calcd. for $C_{12}H_{12}N_4O_4$: 276.0859; found: 276.0864.

1-Amino-5-methylbenzotriazole

Colourless needles, mp 91 to 92 °C (lit. value (48) mp 87 to 88 °C). IR (neat): 3295 (m), 3180 (m), 2990 (w), 1745

© 2005 NRC Canada

(m), 1725 (m), 1235 (m), 1150 (m), 1110 (m), 958 (s), 810 (s). ^{1}H NMR ($CDCl_3$) δ: 2.46 (s, 3H), 5.73 (s, 2H), 7.28 (d, J = 8.4 Hz, 1H), 7.47 (d, J = 8.4 Hz, 1H), 7.66 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 21.4, 109.3, 118.4, 129.9, 130.9, 134.1, 145.0. MS (EI) *m/z*: 148 (4), 133 (4), 120 (25), 119 (35), 92 (20), 91 (90), 86 (75), 84 (100), 77 (15), 65 (22), 51 (17), 50 (75). Exact mass calcd. for $C_7H_8N_4$: 148.0749; found: 148.0750.

1,4-Dihydro-5-methyl-1,2,3,4,9,9-hexaphenyl-1,4-germanonaphthalene (11)

1,4-Dihydro-5-methyl-1,2,3,4,9,9-hexaphenyl-1,4-germanonaphthalene (**11**) was prepared using the method of Ando et al. (17) for the synthesis of **4**. To a flame-dried 100 mL two-neck round-bottom flask equipped with an addition funnel and magnetic stir bar under N_2 was added anhydrous dichloromethane (30 mL) containing 1,1,2,3,4,5-hexaphenylgermole (2.00 g, 3.42 mmol) and 1-amino-5-methylbenzotriazole (0.53 g, 3.59 mmol). The resulting yellowish solution was cooled to –78 °C (*i*-PrOH–CO_2 bath) and a solution of lead tetraacetate (1.67 g, 3.77 mmol) in anhydrous dichloromethane (15 mL) added dropwise with stirring over 50 min. The resulting brown-tinged solution was allowed to warm gradually to room temperature over 1.5 h and then quenched with saturated aqueous sodium carbonate (20 mL). The organic layer was separated, dried with magnesium sulfate, filtered, and the solvent was removed on the rotary evaporator to yield a yellow oil. The oil was purified by radial chromatography in the freezer at –15 °C using precooled dichloromethane–pentane (1:3, *v/v*) as the eluant, which yielded three easily separable fractions. The first two fractions were identified as a 1:1 mixture of 3(3′)-dimethylbiphenylene and 3(4′)-dimethylbiphenylene (**20a** and **20b**, respectively, 0.05 g, 0.28 mmol) (49) and 6-methyl-1,2,3,4-tetraphenylnaphthalene (**21**) (0.35 g, 0.78 mmol) by comparison of their ^{1}H NMR spectra to the literature data. The third fraction (1.8 g, 2.67 mmol, 78%) consisted of a pale yellow powder that was identified as **11** on the basis of the following spectroscopic data: ^{1}H NMR ($CDCl_3$) δ: 2.34 (s, 3H), 6.62 (bs, 4H), 6.80 (d, J = 7.2 Hz, 2H), 6.90–6.96 (m, 7H), 7.07–7.13 (m, 12H), 7.19 (d, J = 7.2 Hz, 1H), 7.39 (d, J = 7.2 Hz, 2H), 7.39 (t, J = 7.2 Hz, 2H), 7.44 (t, J = 7.2 Hz, 1H), 7.75 (d, J = 7.2 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 21.5, 61.1, 64.4, 121.8, 122.9, 124.9, 125.5, 125.7, 127.1, 127.6, 128.0, 128.3, 129.7, 129.9, 130.0, 130.1, 131.5, 133.7, 135.0, 135.8, 136.1, 137.1, 138.0, 138.1, 138.3, 138.4, 145.1, 145.8, 146.2, 147.9. MS (APCI) *m/z*: 677.2 (20, ^{76}Ge, M + 1), 675.2 (100, ^{74}Ge, M + 1), 673.1 (60, ^{72}Ge, M + 1), 671.2 (45, ^{70}Ge, M + 1).

Steady-state photolysis experiments

Steady-state photolysis of a deoxygenated solution (ca. 0.75 mL) of **2a** (0.05 mol/L) in cyclohexane-d_{12} containing DMB (0.1 mol/L) was carried out in a quartz NMR tube, monitoring the reaction periodically by ^{1}H NMR spectroscopy over the 0%–16% conversion range. The NMR spectra of the photolysate showed the growth of peaks assignable to hexamethyldisilane (Si_2Me_6, δ 0.049) and **5** (δ: 1.78 (s, 6H) 1.97 (s, 4H), 7.20–7.24 (m, 6H), 7.40–7.43 (m, 4H)) on the basis of comparisons with the spectra of authentic samples; the relative intensities of the Si_2Me_6 singlet and the δ 1.78 ppm singlet owing to **5** averaged to 1.0:3.24, indicating a relative yield of 1:1.08. No other peaks were evident in the 0–0.3 ppm region of the spectrum, although it should be noted that the signal owing to $PhSiMe_3$ (δ 0.233) is almost coincident with that owing to **2a** (δ 0.228). In a second experiment, a deoxygenated hexane solution containing **2a** (0.01 mol/L) and DMB (0.03 mol/L) was photolyzed to ca. 60% conversion with periodic monitoring by GC. The product mixture contained (in order of increasing elution time) $PhSiMe_3$ (2.3%), **12** (2.5%), **5** (41%), and **2a** (50%); Si_2Me_6 elutes with the solvent under these conditions. The products were identified by GC–MS analysis; the product assigned to **12** exhibited the following mass spectrum: MS (EI) *m/z*: 308 (2, ^{76}Ge), 306 (8, ^{74}Ge), 304 (5, ^{72}Ge), 302 (3, ^{70}Ge), 291 (2), 289 (1), 287 (1), 226 (6), 224 (42), 222 (28), 220 (19), 156 (39), 154 (25), 152 (17), 151 (17), 149 (12), 147 (10), 136 (19), 135 (100), 73 (40), 45 (5).

Steady-state photolysis of a deoxygenated solution (ca. 0.75 mL) of **2a** (0.05 mol/L) in cyclohexane-d_{12} containing MeOH (0.5 mol/L) was carried out in a similar manner to that previously described for the DMB trapping experiment. The NMR spectra of the photolysate showed the growth of peaks assignable to Si_2Me_6 (δ 0.049), **13** (δ: 3.54 (s, 3H), 6.12 (s, 1H), 7.2–7.32 (m, 6H), 7.51–7.53 (m, 4H)), and **14** (δ: 0.027 (s, 18H), 7.15–7.19 (m, 12H), 7.36–7.40 (m, 8H)) on the basis of comparisons with the spectra of authentic samples, together with two additional Me_3Si containing species (δ 0.057 and 0.063), which were not identified; the relative intensities of the Si_2Me_6 singlet, the MeO singlet owing to **13** (δ 3.54), and the –$SiMe_3$ singlets owing to **14** (δ 0.027) and the two unidentified components were 1.00 : 0.139 ± 0.013 : 0.114 ± 0.020 : 0.103 ± 0.027 : 0.121 ± 0.006. This gives average relative yields of 1.0 : 0.84 ± 0.07 : 0.11 ± 0.02 : 0.20 ± 0.05 : 0.24 ± 0.02 for the five products, assuming that the singlets for the two unidentified components represent a single trimethylsilyl group each.

Steady-state photolyses (254 nm) of **11** were carried out in similar fashion, on argon outgassed 0.046 mol/L solutions of the compound in cyclohexane-d_{12} containing methanol (0.5 mol/L) and DMB (0.5 mol/L). The photolyses were taken to ca. 60% conversion and were monitored periodically by ^{1}H NMR spectroscopy. In both cases, the formation of the diphenylgermylene adduct (**5** and **13**, respectively) was accompanied by an equal yield of **21**; no other products could be detected in yields greater than ca. 3%. The identities of the products were verified by comparison of the spectra of the crude photolysis mixtures with those of authentic samples.

Thermolysis of benzogermanorbornadiene 11

The thermolysis of **11** was carried out with argon outgassed 0.046 mol/L solutions of the compound in cyclohexane-d_{12} containing DMB (0.5 mol/L). Thermal decomposition of **11** was monitored by 200 MHz ^{1}H NMR spectroscopy, measuring the relative intensities of the δ 2.28 singlet owing to **11** and the residual proton peak owing to the solvent, every 20 min over a 24 h period. The loss of **11** was accompanied by the formation of **21** (δ_{CH_3} 2.31) and **5**.

Laser flash photolysis experiments

Laser flash photolysis experiments with **2a**, **11**, and **21** employed the pulses from a Lambda Physik Compex 120

© 2005 NRC Canada

excimer laser filled with F_2–Kr–Ne mixtures (248 nm, ~25 ns, 100 ± 5 mJ) and a Luzchem Research mLFP-111 laser flash photolysis system, modified as previously described (9). Solutions were prepared at concentrations such that the absorbance at the excitation wavelength was between ca. 0.7 and 0.9, and were continuously flowed through a vacuum oven-dried, thermostatted 7 mm × 7 mm Suprasil flow cell connected to a calibrated 100 mL reservoir, fitted with a glass frit to allow bubbling of argon gas through the solution for at least 30 min prior to and then throughout the duration of each experiment; the entire apparatus was dried in a vacuum oven at 65–85 °C before use. Solution temperatures were measured with a Teflon-coated copper/constantan thermocouple directly inserted into the flow cell. Reagents were added directly to the reservoir by microliter syringe as aliquots of standard solutions. In experiments with those scavengers that absorb at the laser wavelength, the concentrations employed were kept low enough to ensure that the fraction of the excitation light absorbed by the scavenger never exceeded ca. 10%, to avoid complications in the kinetics owing to screening effects or the formation of potentially reactive species from cophotolysis of the scavenger. For experiments using oxygen as a scavenger, solutions of selected O_2–N_2 ratios were prepared by adding the appropriate volume of a nitrogen saturated solution of **1a** in hexane to an oxygen saturated hexane solution of the same concentration in **1a**.

Flash photolysis experiments with compound **17** and triphenylgermane were carried out using Professor J.C. Scaiano's system at the University of Ottawa and a Lumonics EX-530 excimer laser filled with Xe–HCl–Ne mixtures (308 nm, ~6 ns, 70 ± 5 mJ) for excitation. Signals from the monochromator/photomultiplier were captured by a Tektronix 2440 digitizer and transferred to a PowerMacintosh computer programmed in the LabVIEW 4.1 environment from National Instruments (Austin, Texas). Detailed descriptions of similar laser systems have been provided elsewhere (51). Argon outgassed solutions of **18** (5–30 mmol/L) in BOOB–isooctane (1:4, *v*/*v*) were contained in 7 mm × 7 mm (static) quartz cells. Experiments were carried out at room temperature (22 °C). Growth rate constants for radical absorptions were determined by biexponential nonlinear least-squares analysis of the growth–decay profiles, recorded at 420 nm in the case of **17** and 340 nm in the case of triphenylgermane.

Transient decay and growth rate constants were calculated by nonlinear least-squares analysis of the absorbance–time profiles using the PRISM 3.0 software package (GraphPad Software, Inc., San Diego, California) and the appropriate user-defined fitting equations, after importing the raw data from the Luzchem mLFP software. Rate constants were calculated by linear least-squares analysis of decay rate – concentration data (generally four to seven points) that spanned as large a range in transient decay rate as possible. Errors are quoted as twice the standard deviation obtained from the least-squares analyses.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support, Teck Cominco Metals Ltd. for a generous gift of germanium tetrachloride, the McMaster Regional Centre for Mass Spectrometry for mass spectra, J.C. Scaiano for the use of his laser photolysis system, and M. Chretien for technical assistance. PPG and DZ are grateful for financial support from the United States National Science Foundation under grants CHE-9981715 and CHE-0316124. BKC thanks the Reactive Intermediate Student Exchange (RISE) and NSERC for summer scholarships.

Kinetic isotope effect evidence for the concerted transfer of hydride and proton from hydroxycyclopentadienyl ruthenium hydride in solvents of different polarities and hydrogen bonding ability[1]

Charles P. Casey and Jeffrey B. Johnson

Abstract: The tolyl analogue of Shvo's hydroxycyclopentadienyl ruthenium hydride (**4**) efficiently transfers a hydride and proton to benzaldehyde or acetophenone to produce an alcohol. This reduction can be performed in toluene, methylene chloride, and THF. Reduction of benzaldehyde in toluene and methylene chloride occurs approximately 300 times faster than in THF at 0 °C. Reduction of acetophenone occurs between 75 and 150 times slower than benzaldehyde at 0 °C in each respective solvent. Despite the differences in rate, mechanistic studies have provided evidence for a similar concerted transfer of acidic and hydridic hydrogens in each solvent. Addition of water to THF led to further rate decrease coupled with an increase in the OH/D kinetic isotope effect and a decrease in the RuH/D kinetic isotope effect. Addition of excess alcohol to toluene or methylene chloride results in the significant retardation of the rate of reduction. The slower rate in THF and in the presence of alcohol is attributed to the stabilization of the ground state of ruthenium hydride **4** by hydrogen bonding and the additional energy required to break these bonds prior to carbonyl reduction.

Key words: ruthenium hydrogenation catalysis, hydrogenation mechanism, kinetic isotope effects, ligand–metal bifunctional catalysis.

Résumé : L'analogue tolyle du composé de Shvo, l'hydrure d'hydroxocyclopentadiényle ruthénium (**4**) permet d'effectuer un transfert efficace d'un hydrure et d'un proton vers le benzaldéhyde ou l'acétophénone pour conduire à la production d'un alcool. Cette réduction peut être effectuée dans le toluène, le chlorure de méthylène et le THF. À 0 °C, a réduction du benzaldéhyde dans le toluène et le chlorure de méthylène se produit environ 300 fois plus rapidement que dans le THF. À 0 °C, dans chacun des solvants respectifs, la réduction de l'acétophénone se produit entre 75 et 150 fois plus lentement que celle du benzaldéhyde. Malgré les différences dans les vitesses de réaction, les études de mécanismes ont fourni des données qui militent en faveur d'un transfert similaire d'atomes d'hydrogènes sous les formes de proton et d'hydrure dans chaque solvant. L'addition d'eau au THF conduit à une diminution encore plus grande de la vitesse de réaction couplée à une augmentation de l'effet isotopique cinétique OH/D et à une diminution de l'effet isotopique cinétique RuH/D. L'addition d'un excès d'alcool au toluène ou au chlorure de méthylène conduit à une diminution significative de la vitesse de réduction. La vitesse de réaction sensiblement plus faible dans le THF et en présence d'alcool est attribuée à la stabilisation de l'état fondamental de l'hydrure de ruthénium **4** par une liaison hydrogène et à l'énergie additionnelle requise pour briser ces liens avant la réduction du carbonyle.

Mots clés : catalyse d'hydrogénation par le ruthénium, mécanisme d'hydrogénation, effets isotopiques cinétiques, catalyse bifonctionnelle ligand–métal.

[Traduit par la Rédaction]

Introduction

The development of new catalysts over the past two decades has revolutionized hydrogenation chemistry. The emergence of ligand–metal bifunctional catalysts was initiated by Shvo's report of the hydroxycyclopentadienyl ruthenium hydride catalyst (**1**) (1) and followed by Noyori's development of the (BINAP)Ru(II)(diamine) (**2**) (2) and (arene)Ru(II)(diamine) (**3**) (3) catalysts (Fig. 1). These new species utilize electronically coupled acidic and hydridic hydrogens to catalyze the selective asymmetric reduction of ketones under mild conditions, using hydrogen or 2-

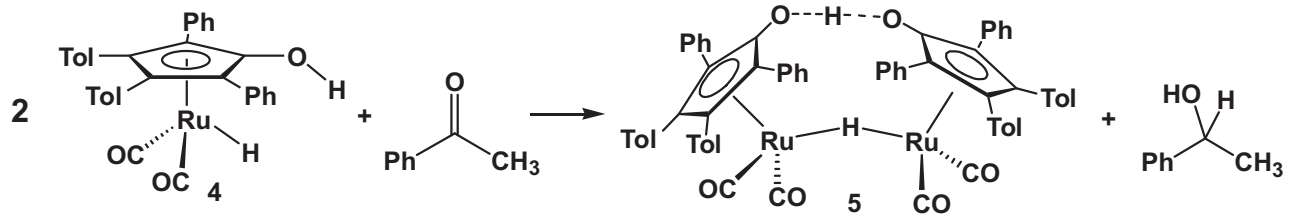
propanol as terminal reductants. These catalysts provide attractive alternatives to stoichiometric reducing agents such as $LiAlH_4$ and $NaBH_4$, and reduce ketones and aldehydes without the need for strongly acidic or basic conditions.

Several studies have been reported that provide mechanistic information about processes catalyzed by Shvo's ruthenium hydride complex. Utilizing the tolyl substituted analogue of Shvo's catalyst, our group has reported evidence consistent with a concerted transfer of the acidic and hydridic hydrogens from **4** to aldehydes (4). In this previous study, however, we could not conclusively exclude a two-step mechanism in which the activation barrier for proton transfer was of similar energy to that for hydride transfer. Here we report studies of ketone reduction performed in an effort to differentiate between these two mechanisms.

Our group has also reported studies of the reduction mechanisms of imines by the monomeric ruthenium hydride **4** (5), the method of hydrogen activation during catalysis (6), as well as a detailed report of the rates of each step within the overall catalytic cycle (Scheme 1).[3] Studies utilizing the Shvo catalyst have been reported in toluene, the solvent primarily used for catalytic reductions, as well as in THF and methylene chloride, solvents used for coupled oxidations, dynamic kinetic resolution, and other isomerization processes (7–9). To assess the validity of the assumption that these mechanisms remain similar in solvents of different natures, we initiated this study to establish the mechanism of aldehyde and ketone reduction by ruthenium hydride **4** in each of these solvents.

Results

Studies of the mechanism of aldehyde reduction in THF-d_8 by the active reducing agent in Shvo's system (ruthenium hydride **4**), have been previously reported by our group (4). These studies, however, were performed in the presence of a small amount of water. Although the role of water was once assumed to be of little consequence to the reaction mechanism, herein we present data that suggests that water slows reduction by stabilization of **4** by hydrogen bonding. The magnitude of each kinetic isotope effect is also dependent upon the concentration of water in solution. Additional data indicates that solvent polarity has little effect on the mechanism of hydrogen transfer, but hydrogen bonding solvents or additives retard reduction.



Reduction of acetophenone by 4 in dry toluene-d_8

Reduction of acetophenone by **4** in dry toluene-d_8 resulted in the clean formation of 1-phenylethanol and bridging ruthenium hydride **5** (Scheme 2). The rate of reduction was

[3] C.P. Casey and J.B. Johnson. Unpublished results.

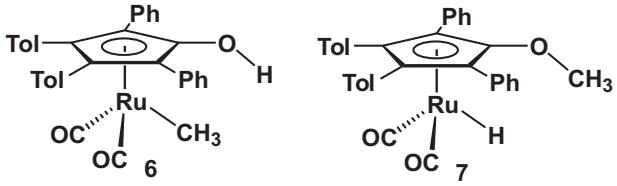
Scheme 2.

monitored by ^{1}H NMR spectroscopy at 6 °C under pseudo-first-order conditions, with a large excess of acetophenone (0.252 mol/L) over **4** (0.0134 mol/L). The first-order disappearance of resonances of **4** (δ 1.85 ($CpTolCH_3$) and –9.26 (RuH)) and the concurrent appearance of resonances consistent with diruthenium hydride **5** (δ 1.80 ($CpTolCH_3$)) and 1-phenylethanol (δ 0.70 (CH_3)) were monitored for at least three half-lives. A plot of concentration vs time was constructed, and the excellent fit to a first-order, nonlinear least-squares equation indicated that the reaction was first-order in ruthenium hydride. Linear dependence upon the concentration of acetophenone (0.185–0.252 mol/L) was observed. These experiments established a second-order rate law for the reduction of acetophenone by **4** (eq. [1]). The rate of ruthenium hydride disappearance is twice that of ketone reduction, as 1 equiv. reduces the ketone while a second traps the proposed unsaturated intermediate to form bridging diruthenium hydride **5**.

$$[1] \qquad -\mathrm{d[ket]}/\mathrm{d}t = -1/2\mathrm{d[\mathbf{4}]}/\mathrm{d}t = k[\mathbf{4}][\mathrm{ket}]$$



Nature of 4 in toluene

During reduction of acetophenone, the rate displays first-order dependence upon the concentration of **4**. Based upon pulsed gradient spin echo (PGSE) NMR spectroscopy studies (10), however, our group has previously determined that in the absence of hydrogen bonding species, **4** exists as a hydrogen bonded dimer in toluene (6). To test the state of aggregation of **4** in the presence of acetophenone in toluene, we utilized ruthenium methyl complex **6** as a model for **4**, as it has similar hydrogen bonding ability, but displays no reactivity with acetophenone at room temperature (Fig. 2).

In the absence of hydrogen bonding species, PGSE studies indicate that ruthenium methyl complex **6** (9.2 mg, 0.0157 mol/L)[4] has a diffusion constant ($D = 2.09 \times 10^{-11}$ m^2 s^{-1}) similar to that of **5** ($D = 1.98 \times 10^{-11}$ m^2 s^{-1}). This is consistent with **6** being a dimer in toluene, as is **4**. Upon addition of a 15-fold excess of acetophenone (0.229 mol/L), PGSE studies of **6** indicate a larger diffusion constant ($D = 3.40 \times 10^{-11}$ m^2 s^{-1}), similar to that observed for methoxy ruthenium complex **7** (6) ($D = 3.65 \times 10^{-11}$ m^2 s^{-1}). This indicates that in the presence of excess acetophenone, **6** is monomeric, most likely hydrogen bound to acetophenone. Further information is provided in the Supporting information.[5]

The rate of reduction of acetophenone by **4** was monitored at temperatures between –6 and 17 °C. The second-order rate constants $k = 6.67 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1} at –6 °C, $k = 12.2 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1} at 0 °C, $k = 16.2 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1} at 6 °C, $k = 30.5 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1} at 12 °C, and $k = 43.4 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1} at 17 °C allowed the determination of the activation parameters $\Delta H^{\ddagger} = 12.5 \pm 1.1$ kcal mol^{-1} (1 cal = 4.184 J) and $\Delta S^{\ddagger} = -21.4 \pm 3.5$ eu.

Fig. 2. Ruthenium models used in PGSE studies.

The kinetic deuterium isotope effects for this reaction in toluene were determined by measuring the rate of reduction of acetophenone with **4** and its isotopomers (**4-RuHOD**, **4-RuDOH**, and **4-RuDOD**) at 6 °C. These rate constants, $k_{RuHOH} = (15.5 \pm 0.6) \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}, $k_{RuHOD} = (13.5 \pm 0.1) \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}, $k_{RuDOH} = (4.74 \pm 0.12) \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}, and $k_{RuDOD} = (4.16 \pm 0.16) \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}, yielded the kinetic isotope effects provided in Table 1.

Kinetic study of the reduction of benzaldehyde by 4 in toluene-d_8

Kinetic study of the reduction of benzaldehyde by **4** in toluene-d_8 was performed in a similar manner to that described for the reduction of acetophenone. The reduction of benzaldehyde followed second-order kinetics and cleanly yielded benzyl alcohol and **5**. While reduction of acetophenone by **4** was monitored at 6 °C, the reduction of benzaldehyde by **4** was much faster and required lower temperatures (–26 to –49 °C) to obtain convenient rates. Activation parameters for benzaldehyde reduction were $\Delta H^{\ddagger} = 13.0 \pm 1.8$ kcal mol^{-1} and $\Delta S^{\ddagger} = -11.0 \pm 5.1$ eu. Kinetic isotope effects were determined at –37 °C and are reported in Table 1.

Reduction of benzaldehyde by 4 in toluene-d_8 in the presence of ethanol

To assess the effect of the presence of excess ethanol on the rate of reduction, the reduction of benzaldehyde by **4** was performed in toluene containing excess EtOH at –37 °C and monitored by ^{1}H NMR spectroscopy. In the presence of between 0.05 and 0.10 mol/L of EtOH, the rate was independent of ethanol concentration, and displayed first-order

[4] Concentration reported assuming a monomeric nature of each species tested.

dependence upon **4** and benzaldehyde. The rate constant at –37 °C ($k = 5.6 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}) is approximately 3 times slower than the rate constant under completely water and alcohol free conditions ($k = 17.7 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}).

The reduction of benzaldehyde by 4 in CD_2Cl_2

The reduction of benzaldehyde by **4** in CD_2Cl_2 also followed second-order kinetics in cleanly forming benzyl alcohol and **5**. Reduction of benzaldehyde between –30 and –47 °C resulted in activation parameters of $\Delta H^{\ddagger} = 11.9 \pm 1.0$ kcal mol^{-1} and $\Delta S^{\ddagger} = -15.6 \pm 3.2$ eu. Use of the isotopomers of **4** at –36 °C provided kinetic deuterium isotope effects (Table 1).

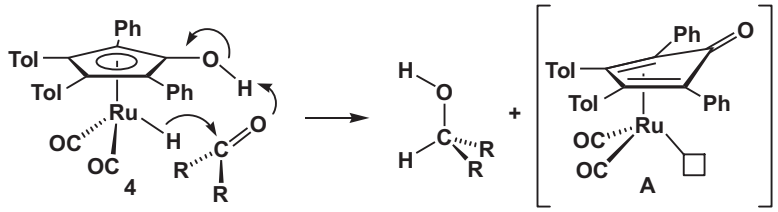
Kinetic study of acetophenone reduction by 4 in CD_2Cl_2

Kinetic study of acetophenone reduction by **4** in CD_2Cl_2 was performed between –6 and 17 °C. The reduction occurs with a second-order rate law. Activation parameters were $\Delta H^{\ddagger} = 10.8 \pm 1.2$ kcal mol^{-1} and $\Delta S^{\ddagger} = -28.8 \pm 3.8$ eu. Reduction by the isotopomers of **4** at 3 °C provided deuterium kinetic isotope effects (Table 1).

The reduction of benzaldehyde by 4 in dry THF-d_8

The reduction of benzaldehyde by **4** in dry THF-d_8 resulted in the clean formation of benzyl alcohol and **5** in a second-order process. Significantly slower benzaldehyde reduction required temperatures approximately 50 °C higher than those used for reduction in toluene-d_8 and CD_2Cl_2. Activation parameters were determined between 10 and 34 °C: $\Delta H^{\ddagger} = 11.2 \pm 0.9$ kcal mol^{-1} and $\Delta S^{\ddagger} = -28.9 \pm 2.6$ eu (Table 2).[6]

Reduction of benzaldehyde by the isotopomers of 4 under completely dry conditions



Reduction of benzaldehyde by the isotopomers of **4** under completely dry conditions in THF-d_8 at 22 °C was followed by ^{1}H NMR spectroscopy. The resulting second-order rate constants, $k_{RuHOH} = (15.02 \pm 0.29) \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}, $k_{RuHOD} = (11.56 \pm 0.13) \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1}, $k_{RuDOH} =$

[6] Activation parameters for this process in the presence of 0.1 mol/L of H_2O or D_2O ($\Delta H^{\ddagger} = 12.0 \pm 1.5$ kcal mol^{-1} and $\Delta S^{\ddagger} = -28 \pm 5$ eu) were previously reported in ref. 4.

[7] Similar kinetic isotope effects were obtained in the presence of 0.1 mol/L of water. See ref. 4.

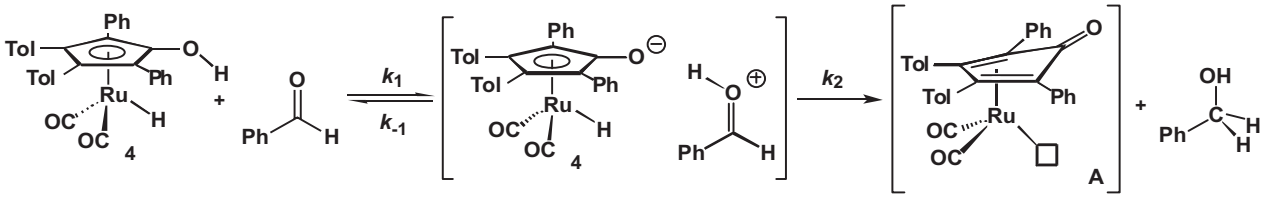
Scheme 3.

Scheme 4.



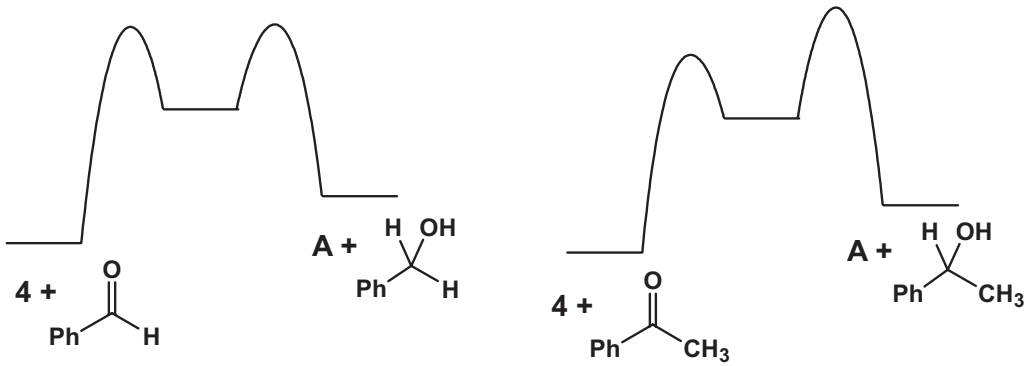


Fig. 3. Relative activation barriers expected for a stepwise hydrogen transfer mechanism to benzaldehyde and acetophenone with proton transfer preceding hydride transfer.

(5.78 ± 0.17) × 10^{-3} (mol/L)$^{-1}$ s^{-1}, and k_{RuDOD} = (4.45 ± 0.28) × 10^{-3} (mol/L)$^{-1}$ s^{-1} were obtained and used to determine the kinetic isotope effects given in Table 3.

Reduction of benzaldehyde by 4 in the presence of 0.079 mol/L of H_2O or D_2O

Reduction of benzaldehyde by **4** in the presence of 0.079 mol/L of H_2O or D_2O in THF-d_8 was followed by ^1H NMR spectroscopy at 22 °C. H_2O was added to the solutions of isotopomers **4-RuHOH** and **4-RuDOH**, while D_2O was added to **4-RuHOD** and **4-RuDOD** providing samples containing 0.079 mol/L of water. The second-order rate constants obtained from these reactions, k_{RuHOH} = (10.62 ± 0.21) × 10^{-3} (mol/L)$^{-1}$ s^{-1}, k_{RuHOD} = (4.60 ± 0.31) × 10^{-3} (mol/L)$^{-1}$ s^{-1}, k_{RuDOH} = (6.52 ± 0.92) × 10^{-3} (mol/L)$^{-1}$ s^{-1}, and k_{RuDOD} = (3.03 ± 0.21) × 10^{-3} (mol/L^{-1} s^{-1}, provided kinetic isotope effects (Table 3)).

Reduction of benzaldehyde by 4 in the presence of 0.120 mol/L of H_2O or D_2O

Reduction of benzaldehyde by **4** in the presence of 0.120 mol/L of H_2O or D_2O in THF-d_8 was performed at 22 °C and monitored by ^1H NMR spectroscopy. Solutions of **4-RuHOH** and **4-RuDOH** contained H_2O, while solutions of **4-RuHOD** and **4-RuDOD** contained D_2O. Second-order rate constants were independently obtained for the reduction of benzaldehyde with each of these isotopomers, k_{RuHOH} = (10.03 ± 0.72) × 10^{-3} (mol/L)$^{-1}$ s^{-1}, k_{RuHOD} = (3.35 ± 0.32) × 10^{-3} (mol/L)$^{-1}$ s^{-1}, k_{RuDOH} = (7.55 ± 0.30) × 10^{-3} (mol/L)$^{-1}$ s^{-1}, and k_{RuDOD} = (2.36 ± 0.52) × 10^{-3} (mol/L)$^{-1}$ s^{-1}. The rate constants for each isotopomer were compared to determine the isotope effects (Table 3).

Reduction of acetophenone by 4 under dry conditions

Reduction of acetophenone by **4** under dry conditions in THF was approximately 80 times slower than reduction of benzaldehyde at comparable temperatures. The formation of 1-phenylethanol and **5** occurred with second-order kinetics. Reduction of acetophenone between 51 and 73 °C yielded activation parameters $\Delta H^{\ddagger}$ = 17.5 ± 1.2 kcal mol^{-1} and $\Delta S^{\ddagger}$ = –15.8 ± 4.0 eu and reduction with the isotopomers of **4** at 67 °C provided kinetic deuterium isotope effects (Table 1).

Discussion

In our initial study of the mechanism of hydrogen transfer from **4** to benzaldehyde, we could not conclusively differentiate between a concerted transfer of hydride and proton (Scheme 3) and a stepwise mechanism in which the two steps have similar barriers ($k_{-1} \approx k_2$, Scheme 4). In a concerted mechanism, isotope effects are observed upon labeling either the acidic or the hydridic hydrogen, and the

Predicted two-step	3.02	3.41	2.85	2.32	2.90	2.65

doubly labeled isotope effect is the product of the individual isotope effects. In a stepwise mechanism with two similar barriers, isotope effects would also be observed upon labeling of either the acidic or hydridic proton. The doubly labeled isotope effect, however, is predicted to be smaller in magnitude than the product of the individual isotope effects.

In our initial study of the reduction of benzaldehyde, the doubly labeled isotope effect was within error of both the product of the individual isotope effects and the isotope effect predicted for a stepwise mechanism with similar barriers. In an effort to differentiate between these mechanisms, we determined the isotope effects on the reduction of acetophenone. For a two-step mechanism, the more basic nature of the acetophenone oxygen would be expected to lower the barrier for protonation of the carbonyl oxygen; the less electrophilic nature of the carbonyl carbon of acetophenone would be expected to raise the barrier for hydride addition to the carbonyl carbon (Fig. 3).[8] If hydrogen transfer occurs through a stepwise mechanism, elimination (or a decrease) in the OH/OD isotope effect and an increase in the RuH/RuD isotope effect would be expected. In addition, the doubly labeled isotope effect is expected to be substantially less than the product of the individual isotope effects. For a concerted mechanism, isotope effects similar to those seen for benzaldehyde are expected and the doubly labeled isotope effect would be equal to the product of the individual isotope effects.

The observation of similar kinetic isotope effects for both benzaldehyde and acetophenone reduction in the same solvents (Table 1) is consistent with a one-step simultaneous transfer of proton and hydride to the carbonyl group. If a two-step mechanism were operative, then significantly smaller OH/OD isotope effects would be expected for acetophenone reduction compared to benzaldehyde reduction. The product of the individual isotope effects for both acetophenone and benzaldehyde reduction in all three solvents is within error of the doubly labeled isotope effects (Table 4). Furthermore, the isotope effects observed upon labeling RuH or OH are independent of the isotopic identity of the other site. Each of these observations is consistent with the concerted rate-limiting transfer of a proton and hydride to the carbonyl.

For a two-step process, the doubly labeled isotope effect can also be predicted from the individually observed isotope effects. Although the exact magnitude of the isotope effects on the first and second steps varies significantly with the relative rates of the two steps, the isotope effects predicted upon labeling of the hydride, the proton, or both sites are independent of this rate difference. In all cases, the isotope effect predicted for the doubly labeled material is less than the product of the isotope effects observed upon individual labeling.[9] Overall, the observed doubly labeled isotope effect studies are consistent with a concerted transfer mechanism and provide additional support for the simultaneous transfer of proton and hydride to aldehydes and ketones.

Relative reactivity of benzaldehyde and acetophenone

Benzaldehyde was reduced much more rapidly than acetophenone in all the solvents studied. To conveniently measure rates, reactions of acetophenone were run at temperatures ~40 °C higher than benzaldehyde. The rate differences extrapolated to 0 °C were 150 in THF, 101 in CH_2Cl_2, and 75 in toluene.

Hydrogen bonding to 4 decreases reduction rate

The rate of reduction of benzaldehyde showed little dependence on solvent polarity. In going from toluene ($\varepsilon = 2.4$) to CH_2Cl_2 ($\varepsilon = 9.1$) at –45 °C, the rate decreased by 25%. Similarly, the rate of reduction of acetophenone decreased by 45% in going from toluene to CH_2Cl_2. However, the rate of reduction was dramatically slower in the hydrogen bonding solvent THF ($\varepsilon = 7.8$). For benzaldehyde, extrapolation of rate constants to 0 °C indicates that reduction occurs 300 times slower in THF than toluene. Similarly, acetophenone is reduced 600 times slower in THF than toluene.

The rate of reduction decreased greatly upon the addition of alcohol to toluene and decreased slightly upon the addition of water to THF. Addition of 0.05 mol/L of EtOH to toluene resulted in a threefold decrease in the rate of benzaldehyde reduction. Addition of 0.079 mol/L of H_2O to THF resulted in a 30% decrease in the rate of benzaldehyde reduction.

The slower reductions in THF are attributed to hydrogen bonding of THF to the acidic hydrogen of the hydroxycyclopentadienyl ligand of **4**. These hydrogen bonds provide additional stability to the complex, and must be broken, or at least altered, prior to reaction with benzaldehyde. The result is a slightly higher barrier to reaction, and slower benzaldehyde reduction. In contrast, **4** is already hydrogen bonded to a carbonyl oxygen of the substrate in toluene. Similarly, addition of alcohol to toluene results in hydrogen bonding to **4** that must be replaced by hydrogen bonding to the carbonyl group in the transition state. In THF, addition of water leads

[8] The products are placed at a higher energy level than the starting materials because of the instability of proposed unsaturated species **A**. DFT calculations are consistent with these results. See ref. 6.

[9] For a more thorough discussion on the prediction of kinetic isotope effects and determination of kinetic isotope effects on each step in a two-step mechanism, see the Supplementary material.[5]

© 2005 NRC Canada

to somewhat stronger hydrogen bonding of water to **4** than of THF to **4** that must be replaced in the transition state.

Despite the retardation of the reaction rate observed upon addition of ethanol to toluene in the catalytic reactions described in the previous section, no retardation was observed during the course of stoichiometric reduction. This may result from the relatively low ultimate concentration of alcohol, or from competition for hydrogen bonding with the carbonyl species.

Addition of water to THF alters isotope effects

The presence of water also results in significant alteration of the magnitude of the individual isotope effects for the reduction of benzaldehyde in THF. As the concentration of water increases, both individual isotope effects change: the OH/OD isotope effect increases with water concentration, while the RuH/RuD isotope effect decreases. The doubly labeled isotope effect also increases with higher concentrations of water (Table 3).

Deuterium labeling of the hydroxyl proton displayed an isotope effect of 1.30 in THF in the absence of water. Addition of 0.079 mol/L of water (H_2O and D_2O, respectively) led to an increase in the isotope effect to 2.22, and addition of 0.120 mol/L of water led to a further increase to 3.10. Deuterium substitution of ruthenium hydride results in an isotope effect of 2.60 in the absence of water. Addition of water (0.079 mol/L) led to the decrease of this isotope effect to 1.57, and addition of more water (0.120 mol/L) resulted in a further decrease to 1.36.

DFT calculations of the transition state for reduction of $H_2C{=}O$ by (η^5-C_5H_4OH)$Ru(CO)_2H$ indicate an early transition state with only moderate proton transfer from the CpOH to the carbonyl oxygen and moderate hydride transfer from Ru to the carbonyl carbon (5*b*). The increase in OH/OD isotope effect upon addition of water suggests more extensive proton transfer to the carbonyl oxygen at the transition state. Similarly, the decrease in the RuH/RuD isotope effect upon addition of water suggests less extensive transfer of hydride to the carbonyl carbon at the transition state. This is consistent with water stabilizing proton transfer in the transition state.

Conclusion

These studies provide detailed mechanistic evidence that the reduction of ketones and aldehydes occurs through a concerted transfer of the acidic and hydridic hydrogens from the tolyl analogue of Shvo's hydroxycyclopentadienyl ruthenium hydride **4** in toluene, methylene chloride, and THF. In each case, hydrogen transfer is the rate-limiting step of the reaction. The rate of carbonyl compound reduction is much faster in non-hydrogen bonding solvents. Use of the hydrogen bonding solvent THF results in slower reduction rates, in addition to a larger isotope effect on labeling of the acidic proton. These changes are presumably due to stabilization of **4** via hydrogen bonding to the acidic hydrogen.

Experimental

General

All syntheses and sample preparations were prepared following Schlenk techniques or in a nitrogen atmosphere glovebox. Toluene-d_8 and THF-d_8 were distilled from a sodium benzophenone solution immediately prior to use. CD_2Cl_2 was dried over CaH_2 and distilled prior to use. Other solvents were dried and deoxygenated with activated alumina and Q5 purification columns (11). Benzaldehyde and acetophenone were distilled prior to use. NMR spectra were recorded on a 360 MHz spectrometer, and are referenced to residual protons in the deuterated solvent. The temperature of the NMR probe was determined before and after each run with a calibrated internal thermocouple. Ruthenium hydride **4** and isotopomers were prepared according to literature procedure (5).

General kinetic procedure

The general kinetic procedure will be illustrated with a specific example. A standard THF solution of **5** (0.30 mL, 0.007 09 mol/L, prepared in a nitrogen glovebox from 20.2 mg of **5** and 2.5 mL of THF) was prepared in a resealable NMR tube. The sample was degassed by three freeze–pump–thaw cycles. Upon cooling the sample to –196 °C, 1 atm of H_2 was added (1 atm = 101.325 kPa). The sample was then heated at 80 °C to ensure complete conversion to **4-RuHOH**. The solvent was evaporated under low pressure, and the remaining solid was dissolved in 0.25 mL of toluene-d_8 in a nitrogen atmosphere glove box. The sample was cooled to –78 °C and benzaldehyde (100 µL, 0.0492 mmol, 20 equiv.) was added from a 100 µL gas-tight syringe. The NMR tube was resealed, inserted into an NMR spin collar, shaken for ~3 s, and inserted into an NMR spectrometer precooled to –37 °C. The disappearance of **4** and the appearance of benzyl alcohol and ruthenium dimer **5** were followed by ^{1}H NMR spectroscopy for over three half-lives.

[2,5-Ph_2-3,4-Tol_2(η^5-C_4COH)]$Ru(CO)_2CH_3$ (6)

A THF solution of [2,5-Ph_2-3,4-Tol_2(η^5-C_4COH)]Ru-$(CO)_2$Cl (106 mg, 0.175 mmol) and excess CH_3MgBr was refluxed under nitrogen for 4 h and then neutralized with 1.5 mL of 5% HCl (aq). This mixture was extracted with toluene. Evaporation of the toluene extract under vacuum gave **6** as a deep maroon solid (88 mg, 0.150 mmol, 86% yield). IR (CH_2Cl_2, cm^{-1}): 1946, 2008. ^{1}H NMR (toluene-d_8, 360 MHz) δ: 0.82 (s, $RuCH_3$), 1.89 (s, 6H, CpTolCH_3), 4.29 (s, OH), 6.63 (d, ^3J = 8.2 Hz, 4H, aromatics), 6.9–7.2 (m, 10H, aromatics), 7.43 (d, ^3J = 8.2 Hz, 4H, aromatics). ^{13}C{^{1}H} NMR (toluene-d_8, 90 MHz) δ: –15.6 ($RuCH_3$), 21.3 (CpTolCH_3), 88.6 (C3,4 of Cp), 104.2 (C2,5 of Cp), 137.8 (C1 of Cp), 125–137 (eight resonances, aromatics), 203.8 (CO).

Photochemical generation and ^{1}H NMR detection of alkyl allene oxides in solution[1]

Leah E. Breen, Norman P. Schepp, and C.-H. Edmund Tan

Abstract: Irradiation of substituted 5-alkyl-4,5-epoxyvalerophenones leads to the formation of alkyl allene oxides that, in some cases, are sufficiently long-lived to be detected at room temperature by ^{1}H NMR spectroscopy. Absolute lifetime measurements show that the size of the alkyl group has a significant influence on the reactivity of the allene oxide, with *tert*-butyl allene oxide having a lifetime of 24 h in CD_3CN at room temperature that is considerably longer than the 1.5 h lifetime of the ethyl allene oxide. The allene oxides react rapidly with water to give α-hydroxyketones. The mechanism involves nucleophilic attack to the epoxide carbon to give an enol, which can also be detected as an intermediate by ^{1}H NMR spectroscopy.

Key words: allene oxides, mechanisms, absolute reactivity, kinetics, photochemistry.

Résumé : L'irradiation de 5-alkyl-4,5-époxyvalérophénones substituées conduit à la formation d'oxydes d'alkyle et d'allène qui, dans certains cas, ont des temps de vie suffisamment longs pour qu'on puisse les détecter, à la température ambiante, par spectroscopie RMN du ^{1}H. Des mesures de temps de vie absolus montrent que la taille du groupe alkyle joue un rôle important sur la réactivité de l'oxyde d'allène; le temps de vie de l'oxyde de *tert*-butyle et d'allène, dans le CD_3CN et à la température ambiante, est de 24 h ce qui est beaucoup plus long que celui de l'oxyde d'éthyle et d'allène qui n'est que d'une heure et demie. Les oxydes d'allène réagissent rapidement avec l'eau pour conduire à la formation d'α-hydroxycétones. Le mécanisme implique une attaque nucléophile du carbone de d'époxyde pour conduire à un énol qu'on peut aussi détecter comme intermédiaire par spectroscopie RMN du ^{1}H.

Mots clés : oxydes d'allène, mécanismes, réactivité absolue, cinétique, photochimie.

[Traduit par la Rédaction]

Introduction

Allene oxides (1–3) have been studied by theoretical and experimental chemists for several decades. Much of the original interest in these compounds came from their close relationship with cyclopropanones, which are structural isomers of allene oxides (4–9). More recently, they have been implicated as intermediates in the conversion of fatty acids to cyclopentenones and α-ketols in some plants and marine organisms (10, 11), and have also been used as intermediates in synthetic organic chemistry (11–20).

While allene oxides are generally considered to be reactive species, some are sufficiently stable to be isolated (21–24). This has allowed for the spectroscopic analysis of some allene oxides, and has also led to qualitative conclusions concerning the effect of structure on allene oxide stability (1). The chemistry of allene oxides that are too unstable to be isolated has also been examined through the analysis of products from reactions in which the allene oxides are present as undetected, transient intermediates (1, 2). These studies have shown that the reactions of allene oxides are dominated by rearrangement to cyclopropanones and addition of nucleophiles to give α substituted ketones.

Some absolute rate constants for the reactions of allene oxides in solution have been measured (25–27), but this remains one area of allene oxide chemistry that has not yet been extensively examined. Quantitative data concerning the effect of structure, solvent, and other parameters on the reactivity of allene oxides can be readily obtained from absolute reactivity measurements, and this information can lead to mechanistic details that are often difficult to determine from product-based studies. In the present work, we describe results concerning the absolute reactivity of some monoalkyl substituted allene oxides. A key feature of this work is the use of a photochemical method to rapidly generate these allene oxides. As a result, more reactive and previously undetected allene oxides could be examined directly by ^{1}H NMR spectroscopy.

Results and discussion

The photochemical method used to generate the allene oxides in this work is based on the Norrish type II reaction of substituted 4,5-epoxyvalerophenones **1** (eq. [1]). With these substrates, excitation was expected to lead to efficient triplet formation followed by rapid intramolecular hydrogen transfer to generate a 1,4-biradical that fragments to give the desired allene oxide **2**, together with acetophenone.

 doi: 10.1139/V05-139 © 2005 NRC Canada

[1]

1a R = $(CH_3)_3C$
1b R = $(CH_3)_2CH$
1c R = CH_3CH_2
1d R = H

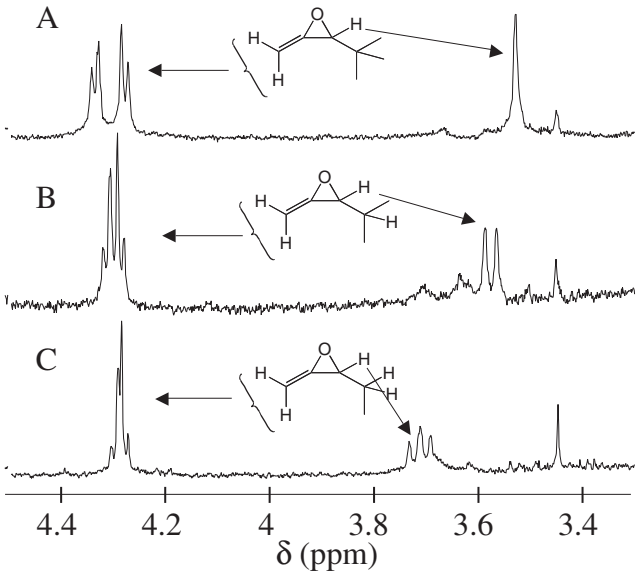
2a R = $(CH_3)_3C$
2b R = $(CH_3)_2CH$
2c R = CH_3CH_2
2d R = H

Initial experiments were carried out using the precursor **1a** (R = $(CH_3)_3C$), which would give the *tert*-butyl allene oxide **2a** that has been isolated by other methods and fully characterized by NMR spectroscopy (23, 28). ^{1}H NMR analysis showed that irradiation of **1a** (ca. 20% depletion) in CD_3CN at room temperature led to the formation of prominent new signals[3] including doublets at 4.34 ppm (J = 3.2 Hz) and 4.28 ppm (J = 3.2 Hz) and a singlet at 3.53 ppm (Fig. 1A), as well as a singlet at 2.60 ppm. The signals at 4.34, 4.28, and 3.53 ppm are the same as those previously assigned to the *tert*-butyl allene oxide (23, 28), with the doublets being assigned to the vinyl protons, and the singlet at 3.50 ppm to the epoxide proton; the signal at 2.60 ppm corresponds to the methyl protons of acetophenone. Thus, the NMR spectra obtained after irradiation clearly showed that fragmentation leading to allene oxide formation as shown in eq. [1] is occurring.

The same method was applied to the generation of other allene oxides with less bulky groups at the epoxide carbon that have until now eluded direct detection. For precursor **1b** (R = $(CH_3)_2CH$), the NMR spectrum after irradiation in CD_3CN showed the formation of overlapping doublets at 4.30 ppm and a doublet at 3.57 ppm (Fig. 1B). The signals at 4.30 and 3.57 ppm are similar to those observed for the *tert*-butyl allene oxide, which is consistent with the assignment of these signals to the isopropyl allene oxide **2b**. Furthermore, the signal at 3.57 ppm is now a doublet, rather then the singlet that appears for the *tert*-butyl allene oxide, as expected for the isopropyl **2b** allene oxide in which the epoxide proton is located adjacent to the CH of the isopropyl moiety. For precursor **1c** (R = CH_3CH_2), irradiation led to the formation of new peaks at 4.29 and 3.71 ppm (Fig. 1C). Again, these chemical shifts and the nature of the splitting are consistent with the assignment of these new peaks to the ethyl allene oxide **2c**.

Irradiation of precursor **1d** in CD_3CN led to no detectable amounts of the parent allene oxide **2d**. A signal at 2.60 ppm owing to the formation of acetophenone was observed, which suggests that allene oxide formation as outlined in eq. [1] had occurred. Thus, our inability to detect allene oxide **2d** is likely due to its high reactivity. To further establish that **2d** was indeed generated, irradiation of **1d** was carried out with 5% D_2O in acetonitrile. Under these conditions, a prominent singlet at 4.01 ppm and triplet at 2.09 ppm were observed. These signals correspond to 1-*d*-3-deuteroxy-2-propanone (29), which is the expected product upon addition of D_2O to allene oxide **2d**. Thus, the parent allene oxide is generated upon irradiation of **1d**, but even in dry acetonitrile it is too short-lived to be detected under our reaction conditions. Since our experimental conditions involved 5 min of irradiation followed by ca. 3 min to acquire the initial ^{1}H NMR spectrum, the lifetime of the parent allene oxide must be less 8 min in neat CD_3CN at room temperature.

Fig. 1. ^{1}H NMR spectra obtained 4 min after irradiation of precursors (A) **1a**, (B) **1b**, and (C) **1c** in CD_3CN at room temperature.



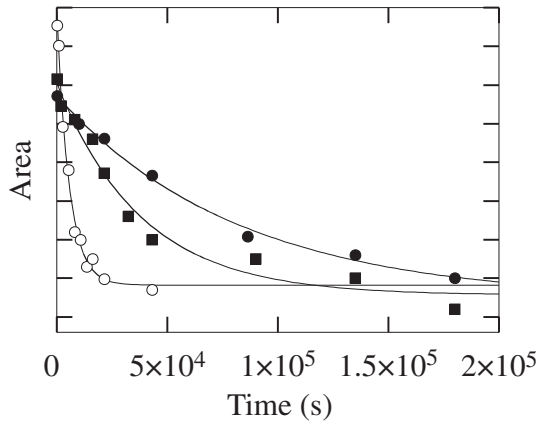


Fig. 2. Integrated area of the vinyl protons of the *tert*-butyl (●), isopropyl (■), and ethyl (○) allene oxides in CD_3CN at 25 °C measured as a function of time after irradiation of the corresponding precursors. The solid lines represent the line-of-best-fit calculated using a first-order rate expression.

Not surprisingly, the allene oxides **2a**–**2c** in neat CD_3CN at room temperature also were not stable, as illustrated by the decrease in the integrated areas of the ^{1}H NMR signals of the vinyl protons as a function of time in Fig. 2. These data can in principle be used to determine the absolute reactivity of the allene oxides; however, given the difficulties in measuring accurate values for the integrated areas, the data were not sufficiently good to distinguish between a first-order decay or a second-order decay of the allene oxides. Nonetheless, the data clearly show a substantial difference in the reactivity of the allene oxides as a function of the size of

[3] Other weak resonances owing to unidentified by-products were also evident in the ^{1}H NMR spectrum.

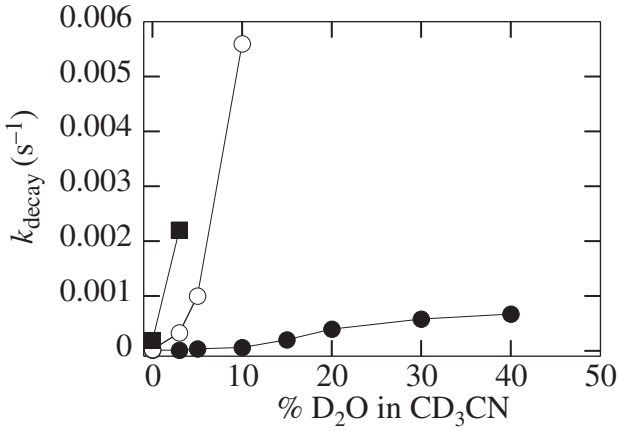
Table 1. First-order rate constants for the decay of allene oxides **2a**–**2d** in CD_3CN (25 °C).

R	k_{decay} (s^{-1})
tert-Butyl (**2a**)	$(1.2\pm0.2) \times 10^{-5}$
Isopropyl (**2b**)	$(2.4\pm0.4) \times 10^{-5}$
Ethyl (**2c**)	$(1.9\pm0.2) \times 10^{-4}$
H (**2d**)	$>10^{-3}$

the alkyl group, with the isopropyl allene oxide **2b** being considerably more reactive than the *tert*-butyl allene oxide **2a**, and the ethyl allene oxide **2c** showing even greater reactivity. This order of reactivity as a function of the size of the alkyl group is nicely consistent with conclusions made previously (2, 24) that bulky groups directly attached to the epoxide ring serve to enhance the kinetic stability of allene oxides.



While the decay traces in Fig. 2 fit equally well to first- and second-order rate expressions, a measure of the differences in reactivity can be estimated by comparing rate constants obtained using a first-order fit (Table 1). These results show that the *tert*-butyl allene oxide **2a** and the isopropyl allene oxide decay slowly with rate constants of 1.2×10^{-5} and 2.4×10^{-5} s^{-1}, respectively, which differ only by a factor of two. On the other hand, the ethyl allene oxide **2c** decays about an order of magnitude more quickly with a rate constant of 1.9×10^{-4} s^{-1}. In addition, based on our inability to detect the parent allene oxide, we can estimate that it decays with a rate constant $>10^{-3}$ s^{-1}. The parent allene oxide therefore decays at least 10 times more rapidly than the ethyl derivative, and at least 100 times more rapidly than the bulky *tert*-butyl and isopropyl allene oxides.

The actual reaction of the allene oxides in neat CD_3CN remains unclear. One possibility is that the allene oxides rearrange to the substituted cyclopropanones. However, no ^1H NMR signals corresponding to cyclopropanones could be observed after complete decay of the allene oxides, nor could signals owing to the alkene that would be generated by rapid loss of CO from the cyclopropanone. In fact, no distinct signals were observed to grow as the allene oxides decayed, suggesting that the allene oxides may polymerize or react with solvent to give material difficult to characterize.

Allene oxides are well-known to react with nucleophiles to give α substituted ketones (2), but little is known about the absolute rate constants associated with this nucleophilic addition process. In the present work, the effect of adding D_2O was examined by monitoring the decay of the allene oxides signals in various D_2O–CD_3CN mixtures. Since D_2O was expected to add rapidly to the allene oxides, irradiation of the precursors was carried out in neat CD_3CN, and an ^1H NMR spectrum obtained to ensure that allene oxide formation had occurred. An appropriate amount of D_2O was then added, followed rapidly by the acquisition of a series of spectra. In this way, allene oxide decaying with rate constants less than 0.01 s^{-1} could readily be monitored.

In these experiments, the reduction in the intensity of the vinyl protons of the allene oxides as a function of time fit well to a first-order rate expression giving the pseudo-first-order rate constants that are plotted as a function of D_2O content in Fig. 3. These data clearly show that all three allene oxides decayed considerably more quickly upon the addition of water; however, the reactivity of the allene oxides toward D_2O was strongly dependent on the nature of the alkyl substituent. Thus, in the presence of the *tert*-butyl group, the rate constants for allene oxide decay hardly changed at low D_2O contents, and the *tert*-butyl allene oxide could still be easily observed in 40% D_2O where it decayed with a rate constant of 6.7×10^{-4} s^{-1}. This is in contrast to the results obtained with the isopropyl allene oxide whose decay increased dramatically even in the presence of small amounts of D_2O, and could no longer be observed at D_2O contents >10%. The ethyl allene oxide was even more reactive, with the rate constant for decay increasing 10-fold upon going from neat CD_3CN to 3% D_2O in CD_3CN. At higher D_2O contents, the ethyl allene oxide could no longer be observed.

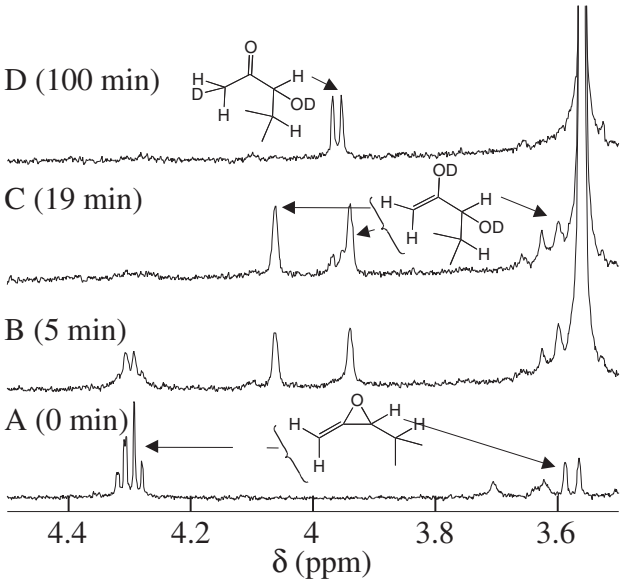


Fig. 3. Rate constants for the decay of the *tert*-butyl (●), isopropyl (○), and ethyl (■) allene oxides in CD_3CN as a function of D_2O content (25 °C).

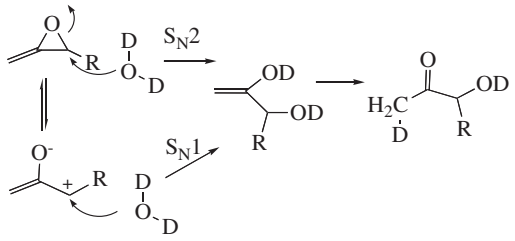

Nucleophilic addition of D_2O to the allene oxides was expected to lead to the formation of the corresponding α-hydroxyketone, and this material was indeed observed by ^1H NMR as the final stable product in the reaction of the allene oxides with D_2O. Two mechanisms for this nucleophilic addition can be envisioned: addition can occur via an S_N1-like mechanism characterized by initial breaking of the epoxide C—O bond followed by addition of the nucleophile, or via an S_N2-like mechanism where the nucleophile directly adds to the intact epoxide ring (eq. [2]). In both cases, the initial product is an enol that then tautomerizes to the more stable ketone form. The formation of the enol intermediate is supported by the sequence of ^1H NMR spectra in Fig. 4. Figure 4A shows the isopropyl allene oxide after irradiation in CD_3CN, but before the addition of D_2O. Five minutes after the addition of 10% D_2O, the allene oxide signals were reduced (Figs. 4B and 4C) and eventually replaced by resonances at 3.9 and 4.1 ppm that correspond to the expected (30) chemical shifts of the vinyl protons of the enol intermediate. A doublet at 3.65 ppm was also observed that can be assigned to the proton on the carbon bearing the hydroxy group of the enol. The enol signals were then replaced by a

[2]

doublet at 3.9 ppm (Fig. 4D), attributed to the proton at the α position of the expected α-hydroxyketone product[4] (29).

While formation of the enol intermediate is consistent with the mechanism shown in eq. [2], its observation was surprising given the high reactivity of most simple enols (31). Two factors may contribute to the unusually long lifetime. First, most absolute rate constant measures for the ketonization of enols have been measured in wholly aqueous solutions; in the 10% aqueous conditions used to observe the enol in Fig. 2B, the enol ketonization process may be somewhat slowed. In fact, in experiments carried out at higher water contents of 30%, the enol could no longer be observed, despite the more rapid disappearance of the allene oxide. Second, the α-hydroxy group may play a role in reducing the reactivity of the enol form by hydrogen bonding. Such hydrogen bonding may reduce the electron density at the enolic OH, thus reducing the overall electrophilicity and the rate constant for addition of a proton to the enolic carbon–carbon double bond.

The effect of structure on the absolute reactivity of the allene oxides with water can also provide some insight into the mechanism of the nucleophilic addition reaction. In particular, rate constants for addition of the nucleophile in the S_N2 mechanism should show a dependence on structure, while in the S_N1-like mechanism, little difference in reactivity upon going from *tert*-butyl to ethyl should be observed. As shown in Fig. 3, a fairly dramatic structural effect is observed, which leads to the conclusion that nucleophilic addition occurs via the S_N2 mechanism.

Conclusions

Our results clearly show that photogeneration of allene oxides by the Norrish type II fragmentation of 4-alkyl-4,5-epoxyvalerophenones leads to formation of simple alkyl substituted allene oxides. Since the allene oxides are generated rapidly, this method allows for the detection of allene oxides that had not previously been observed, and for absolute rate constants to be measured. The use of this photoreaction should be compatible with the generation of broader series of simple alkyl allene oxides, and also with the use of a fast reaction technique like flash photolysis to examine the reactivity of very short-lived allene oxides. Experiments to address those issues are currently under way.

Experimental

Preparation of precursors

Precursors **1a**–**1d** were prepared by addition of the enolate of acetophenone to the appropriate 1-bromo-2-alkene derivative to give the corresponding 1-phenyl-pent-4-en-1-one, followed by epoxidation using *m*-chloroperbenzoic acid. In general, the procedure involved the addition of 1 equiv. of lithium diisopropylamine to acetophenone (1.5 g) in dry THF (15 mL) under an argon atmosphere at –78 °C and stirring for 20 min. One equivalent of 1-bromo-4,4-dimethyl-2-pentene (32) (for **1a**), 1-bromo-4-methyl-2-pentene (33) (for **1b**), 1-bromo-2-pentene (33) (for **1c**), or 1-bromo-2-propene (Aldrich) (for **1d**) was then added, and the mixture allowed to warm up to room temperature over a period of 20 h. The solution was diluted with ether and washed with saturated aqueous ammonium chloride and sodium chloride. The organic layer was dried and the solvent removed under reduced pressure. The crude enone was purified by silica gel column chromatography using 50% dichloromethane in hexanes as the eluant.

Epoxidation was carried out by adding 1.5 equiv. of purified *m*-chloroperbenzoic acid to the enone in CH_2Cl_2. The mixture was stirred for 1.5 h at room temperature. After washing with 5% sodium hydroxide and evaporation of the solvent, the crude product was purified by silica gel column chromatography (20% ethyl acetate in hexanes).

Irradiation of precursors and determination of rate constants

About 10 mg of **1a**–**1d** were dissolved in 0.750 mL of CD_3CN (Aldrich) in a quartz cuvette (3 mm × 1 cm × 3 cm). The solution was bubbled with nitrogen for 10 min and then irradiated with 308 nm light (60 mJ/pulse, 8 ns pulse) from a Lambda-Physik excimer laser operating at 5 Hz for 5–10 min or with a high-pressure mercury lamp for 15–30 min. Immediately after irradiation, the solution was transferred to an NMR tube and the spectrum obtained using a Bruker AC-250 MHz spectrometer (probe temperature 25 °C). To obtain kinetic data, NMR spectra were obtained at specific time intervals after irradiation. The time intervals varied depending on the lifetime of the allene oxides, but generally six to ten spectra were obtained. The peak area or intensity corresponding to the vinyl protons of the allene oxides was measured in each spectrum (relative to a small amount of CH_2Cl_2 added as an internal standard). These areas or intensities were plotted as a function of time, and rate constants extracted by nonlinear least-squares fitting of the data to a first-order exponential equation.

For studies involving the addition of water, irradiation of the precursor was carried out in the same way in neat CD_3CN. The ^{1}H NMR spectrum was then obtained to ensure allene oxide formation had taken place. A desired amount of D_2O was then added, followed by the acquisition of further NMR spectra at appropriate time intervals. Rate constants were determined in the same way as described in the previous section for reaction in neat CD_3CN. In all cases, the ^{1}H NMR spectra of the final stable product matched closely the published spectra of the corresponding α-hydroxy ketones (29).

Bicyclo[3.2.0]hepta-1,3,6-triene — UV photoelectron spectroscopic and computational studies[1]

T. Bajorek and N.H. Werstiuk

Abstract: Pyrolysis of *N*,*N*-dimethylbicyclo[3.2.0]hepta-3,6-dien-1-amine oxide (**5**) at 120 °C in the source chamber of the UV photoelectron (PE) spectrometer yielded bicyclo[3.2.0]hepta-1,3,6-triene (**6**). The triene dimerizes to yield a mixture of two dimers in equal amounts. A PE spectrum of an authentic mixture of dimers was also recorded for the purpose of spectral subtraction. Pyrolysis of **5** also generates dimethylhydroxylamine (**7**), a spectrum of which was also recorded from an authentic sample. Spectral subtraction allowed the first two ionization potentials of triene **6** at 7.2 and 9.8 eV to be identified. The resultant PE spectrum was compared very favorably with a simulated spectrum obtained from DFT calculations. A QTAIM analysis and calculation of delocalization indexes showed that while homoconjugation between C4 and C6 is negligible there is a weak through-space interaction between the bridgehead carbon atom C1 and C6 of the four-membered ring.

Key words: bicyclo[3.2.0]hepta-1,3,6-triene, UV photoelectron spectroscopy, DFT calculations, QTAIM, delocalization indexes.

Résumé : La pyrolyse de l'oxyde de *N*,*N*-diméthylbicyclo[3.2.0]hepta-3,6-dién-1-amine (**5**) à 120 °C, dans la chambre source d'une spectromètre photoélectronique (PE) UV conduit à la formation de bicyclo[3.2.0]hepta-1,3,6-triène (**6**). Le trimère se dimérise pour conduire à un mélange de deux dimères qui se forment en quantités égales. On a aussi enregistré un spectre PE d'un mélange authentique des dimères afin de pouvoir procéder à une soustraction spectrale. La pyrolyse du composé **5** conduit aussi à la formation de diméthylhydroxylamine (**7**), dont on a aussi enregistré le spectre d'un échantillon authentique. La soustraction spectrale a permis d'identifier les deux premiers potentiels d'ionisation du triène **6** à 7,2 et 9,8 eV. Le spectre PE qui en résulte se compare favorablement avec le spectre simulé obtenu par des calculs basés sur la théorie de la densité fonctionnelle (TDF). Une analyse QTAIM et des calculs d'indices de délocalisation montrent qu'il existe une faible interaction à travers l'espace entre l'atome de carbone de pont C1 et le C6 du cycle à quatre chaînons, même si l'homoconjugaison entre les atomes C4 et C6 est négligeable.

Mots clés : bicyclo[3.2.0]hepta-1,3,6-triène, spectroscopie photoélectronique UV, théorie de la densité fonctionnelle (TDF), QTAIM, indices de délocalisation.

[Traduit par la Rédaction]

Introduction

Bicyclo[3.2.0]hepta-1,3,6-triene (**6**) has been implicated as a reactive intermediate on the C_7H_6 potential energy surface in a number of investigations both experimental (1–3) and computational (4, 5). Although it has not yet been explicitly identified and characterized, its existence was implicated by the isolation and characterization of its dimers (6–10) in solution. Recently, a highly substituted, stable silicon analogue of **6** has been reported with a silicon atom replacing C5 at the bridgehead position (11). Interest in the strained bicyclo[3.2.0]hepta-1,3,6-trienyl ring system remains high.

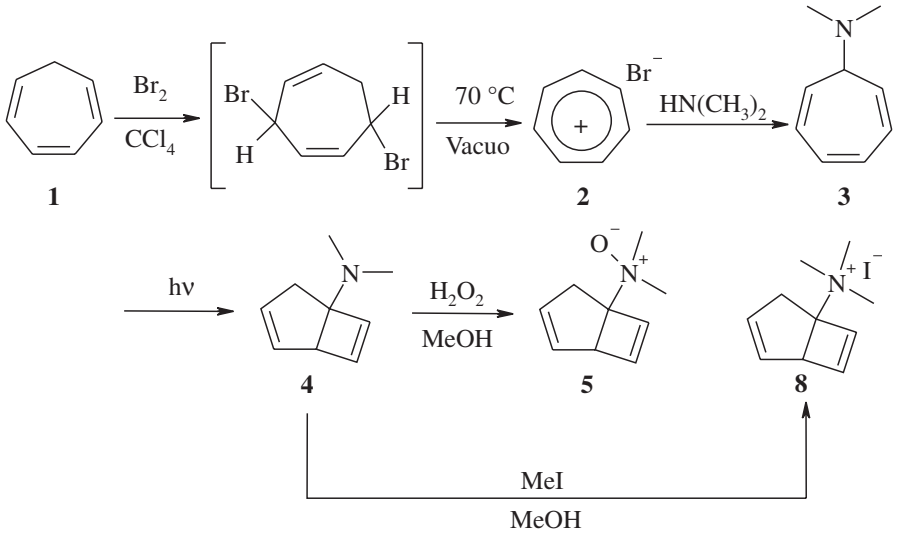
[2]Corresponding author (e-mail: werstiuk@mcmaster.ca).



In this paper, we report the first direct experimental evidence for the existence of transient **6** and its ultraviolet (UV) photoelectron spectrum. When combined with MO calculations, UV photoelectron spectroscopy yields information about the electronic structure and bonding of stable as well as transient species that is provided by no other experimental technique. We also undertook a computational study at B3LYP, B3PW91, MP2, and CCSD levels of theory, carried out a QTAIM analysis (12), and evaluated delocalization indexes with LI-DICALC (13, 14) to gain additional information on the bonding of **6** and document the results.

Photoelectron spectroscopic studies

Photoelectron (PE) spectra were recorded with our locally built UV PE spectrometer and calibrated with the 15.6 eV IP band of N_2 that is visible in all spectra (15). Linearity of the spectral scale was checked with the lowest IP bands of methyl iodide at 9.54 and 10.16 eV prior to the experiments. Our unique UV PE spectrometer – CW CO_2 laser apparatus (16) fitted with a heated probe allows us to use the laser as a

 doi: 10.1139/V05-145 © 2005 NRC Canada

Scheme 1.

directed heat source to produce a hot zone as short as 1 mm in length at the tip of a quartz tube positioned about 1 cm from the point of intersection with the ionization beam. We used this setup successfully to obtain PE spectra of short-lived, reactive species such as benzazete and *o*-benzyne (16), l-(2-thiaindane)ketene and benzocyclobutene-thione (17, 18), 1,2-cyclohexadiene (19), (dimethoxy)carbene (20), and *p*-substituted phenylketenes (21) through pyrolysis of suitable precursors. In this case, we used the heated probe to pyrolyze *N*,*N*-dimethylbicyclo[3.2.0]hepta-3,6-dien-1-amine oxide (**5**) contained in a small bottle-shaped quartz vessel located 1 cm from the ionizing beam.

Computational methods

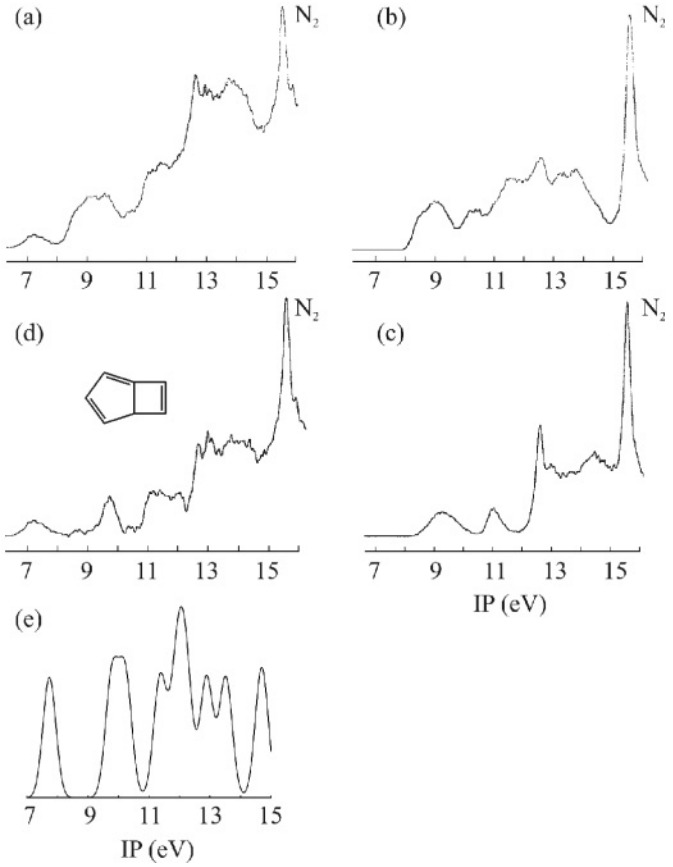
Interpretation of the PE spectrum of the transient was accomplished according to our recently developed (22) and successfully applied (23, 24) routine based on B3LYP (25) calculations. The structure of **6** was optimized at the B3LYP/6-31+G(d) level and used in a single-point calculation on its radical cation performed at the same level of theory. The PE spectrum of **6** was simulated with PESPEC (26). A Gaussian line broadening of 0.4 and a temperature of 300 K were used to simulate the partial PE spectrum with 10 MO energies (HOMO to HOMO-9). Equilbrium optimized geometries of **6** were obtained at the DFT and MP2 levels with GAUSSIAN 98 or GAUSSIAN 03 (27, 28), and frequency calculations were carried out to confirm that the geometries corresponded to minima. The uncorrected energies (E_{elec}) are included in a table as Supplementary information.[3] Wave functions were obtained at the B3LYP, B3PW91, MP2(FC), and CCSD levels. Displays of molecular geometries and molecular orbitals were generated using MOLEKEL (29, 30). QTAIM analyses were carried out with AIMALL (31) and the delocalization indexes were obtained with LI-DICALC (13, 14). The molecular graph of **6** and plots of the C1, C4, and C6 atomic basins were obtained with AIM 2000 (32).

Results and discussion

Synthesis of *N*-oxide 5

The precursor used to generate the transient bicyclo-[3.2.0]hepta-1,3,6-triene (**6**) was *N*,*N*-dimethylbicyclo-[3.2.0]hepta-3,6-dien-1-amine oxide (**5**), synthesized by the oxidation of *N*,*N*-dimethylbicyclo[3.2.0]hepta-3,6-dien-1-amine (**4**) with hydrogen peroxide in methanol. Amine **4** was synthesized according to Scheme 1.

Tropylium bromide (**2**) was synthesized using the procedure of Doering and Knox (33, 34). The bromination of cycloheptatriene (**1**) and subsequent pyrolysis under vacuum at 70 °C yielded tropylium bromide (**2**). Reaction of **2** with dimethylamine gave *N*,*N*-dimethylcyclohepta-1,3,5-trien-7-amine (**3**) (33). Photolysis of amine **3** with a medium pressure mercury arc lamp yielded *N*,*N*-dimethylbicyclo[3.2.0]-hepta-3,6-dien-1-amine (**4**) (35). Treatment of **4** with hydrogen peroxide in methanol gave *N*-oxide (**5**) (36). Alternatively, if amine **4** is treated with excess methyl iodide in ethanol the methiodide salt **8** is obtained (6). This salt was used to generate an authentic sample of a mixture of dimers of **6**.



Pyrolysis and PE spectroscopy

The *N*-oxide **5**, placed in a sample vessel and inserted into the tip of an electrically heated probe, was directly pyrolyzed at 120 °C in the source chamber of the spectrometer. The pyrolysis spectrum consists of two main IP bands as illustrated in Fig. 1*a*. The first IP band was observed at 7.2 eV, while the second, very broad IP band spanned the region between 8.5 and 10 eV. In the pyrolysis of **5**, two other products were generated in addition to triene **6**, namely dimethylhydroxylamine (**7**) and two isomers **9** formed by

dimerization of triene **6** (Scheme 2) (6). Selected experimental and calculated IPs of **6**, **7**, and **9** are listed in Table 1.

An authentic sample of the dimers was generated from the reaction of potassium *tert*-butoxide with methiodide salt **8** that yielded a 50:50 dimer mixture as reported by Bauld et al. (6). The composition of the dimer mixture was confirmed by GC–MS and showed two signals with identical intensities and areas. Both peaks showed a $M^{+\bullet}$ ion with *m/z* 180. The dimers were not separated because a mixture of the two dimers was needed for the PE spectroscopic experiments. Recently, Billups et al. (9) reported NMR assignments of the two dimers and concluded that the dimers can be represented by the two structures shown in Fig. 2.

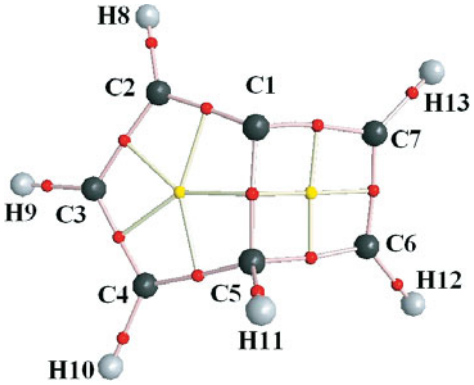
Fig. 3. Selected molecular orbitals of triene **6** (contour value 0.08) at the B3LYP/6-31+G(d) level.



π^- (HOMO) π (HOMO-1) π/σ (HOMO-2)

The photoelectron spectrum of the mixture of dimers shows a very broad IP band in the regions from 8 to 9.5 eV and 10 to 11 eV. That there is no IP band observed below 8 eV (Fig. 1*b*) in the spectrum of the mixture of dimers indicates that the PE spectrum obtained upon the pyrolysis of **5** contains IPs belonging to transient **6**. The photoelectron spectrum of dimethylhydroxylamine **7** was also recorded and revealed that there were no IP bands below 8 eV in its spectrum (Fig. 1*c*). The first broad IP band of **7** was observed in the region between 8 and 10 eV with a vertical ionization potential at 9.3 eV. The second band is narrower than the first and its vertical IP occurs at 11.06 eV. The PE spectra of **7** and the dimers were subtracted from the PE spectrum obtained upon the pyrolysis of **5**, to yield a spectrum showing IP bands at 7.2 and 9.7 eV (Fig. 1*d*). This spectrum is in excellent agreement with the simulated spectrum of bicyclo[3.2.0]hepta-1,3,6-triene (**6**) (Fig. 1*e*), which shows the first IP at 7.7 eV, the second and the third IP at 9.8 and 10.2 eV as a broad IP band that results from the overlap of the two IPs. The molecular orbitals associated with these ionizations are shown in Fig. 3.

The highest occupied molecular orbital (HOMO) is assigned as π^- because it is a π orbital with nodes between C2—C3 and C7—C1. The assignment of π^+ is less obvious; HOMO-1 also has π character, but perhaps HOMO-2, which is a mixed π/σ orbital, best fits the label. Given the nature of HOMO-2, the question arises as to whether or not C4 and

Fig. 4. Molecular graph of triene **6** at the CCSD/6-31+G(d)//MP2(FC)/6-31+G(d) level.

C6 of **6** are homoconjugated. To gain information on this point, we carried out a QTAIM analyses (12) and calculated delocalization indexes with LI-DICALC (13, 14).

QTAIM analysis

The molecular graph of **6** — along with the trajectories linking the (3,+1) ring critical points (yellow) to the (3,–1) bond critical points (red) — generated with AIM 2000 (32) from the wave function obtained at the CCSD/6-31+G(d)//MP2(FC)/6-31+G(d) level is displayed as Fig. 4. The atomic populations, obtained with AIMALL (31), and selected properties of bond and ring critical points, obtained with AIMALL or AIM 2000, are collected in Tables 2 and 3, respectively. It is seen that the carbon atoms bear a marginal negative charge and the hydrogens are slightly positive. The populations obtained at the B3PW91 and CCSD//MP2 levels are very similar. Tetracoordinate carbon C5 is the least negatively charged. As far as the values of ρ at the bond critical points are concerned, the values for the nominal double bonds C1—C2, C3—C4, and C6—C7 are 0.3219, 0.3224, and 0.3309, respectively, somewhat smaller than the value for ethene (0.3404) at the same level of theory. Based on a $\rho(\mathbf{r})_{bcp}$ value of 0.2312 and a laplacian of –0.4864, the C5—C6 bond surprisingly is the weakest of the single C—C bonds. Its distorted bond path is qualitatively in accord with this conclusion. The ellipticity ε ($\lambda_1/\lambda_2 - 1$) of the C1—C2 double bond (0.2786) is significantly smaller than the ellipticities of the other double bonds C3—C4 (0.3287) and C6—C7 (0.3624). Ethene exhibits a value of 0.3640 at the same level of theory with the negative curvatures λ_1 and λ_2 being –0.7295 and –0.5348, respectively. The values are –0.6702 and –0.5241 for the C1—C2 bond of **6** so the decrease in ellipticity is due to a decrease in λ_1 relative to ethene. The curvatures for the C6—C7 double bond are –0.7030 and –0.5140 so ε is 0.3674. The ring critical point of the four-membered ring exhibits a substantially larger value for ρ (0.0986) than the five-membered ring (0.0452).

Delocalization indexes

Using equations developed at the HF level to calculate localization indexes (LIs) and delocalization indexes (DIs) (13, 14), we recently extended the idea of Fermi correlation by expressing LIs and DIs in terms of natural molecular orbitals η_l with occupation numbers n_l, and obtained eqs. [1] (the Fermi hole density), [2], and [3] that allowed us to determine LIs and DIs for correlated wave functions (13, 14).

Table 2. QTAIM atom electron populations and charges of triene **6** at various levels of theory.

Atom	B3PW91/6-31+G(d)	CCSD//6-31+G(d)//MP2(FC)/6-31+G(d)

Total electrons (Charge)	48.0016 (–0.0016)	48.0004 (–0.0004)

[a]The atom electron population.
[b]The atomic charge in parentheses.

[1] $$h(\mathbf{r_1},\mathbf{r_2}) = \sum_l \sum_m n_l^{1/2} n_m^{1/2} [\eta_l^*(\mathbf{r_1})\eta_l(\mathbf{r_2})\eta_m^*(\mathbf{r_2})\eta_m(\mathbf{r_1})]/\rho(\mathbf{r_1})$$

[2] $$F(\Omega,\Omega) = \int_\Omega d\mathbf{r_1} \int_\Omega d\mathbf{r_2} \rho(\mathbf{r_1}) h(\mathbf{r_1},\mathbf{r_2}) = -\sum_{l,m} n_l^{1/2} n_m^{1/2} S_{l,m}^2(\Omega)$$

[3] $$F(\Omega,\Omega') = -\sum_{l,m} n_l^{1/2} n_m^{1/2} S_{l,m}(\Omega) S_{l,m}(\Omega')$$

The LI λ(A) and DI δ(A,B) are calculated from eqs. [4] and [5], respectively. We used νPΩ and Ω′ rather than A and B in the eqs. [4] and [5] to emphasize the fact that we are dealing with the physical spaces (the basins) of atoms A and B. The $S_{l,m}$ is obtained directly from the atomic overlap matrix for each Ω obtained from integration of the atomic basins with PROAIMV or PROMEGA of AIMALL (31).

[4] $$\lambda(A) = |F(\Omega,\Omega)|$$

[5] $$\delta(A,B) = 2|F(\Omega,\Omega')|$$

The occupation numbers n_l and n_m are available from the wave function file obtained with GAUSSIAN 98 or GAUSSIAN 03 calculations. The DIs are defined by eq. [5] from the integration of the density of the Fermi hole on two atomic basins Ω and Ω′, so Ω,Ω′ represents the extent to which the electrons in Ω basin are delocalized over the Ω′ basin and vice versa. Consequently, the sum of the LIs and the DIs/2 should equal the total number of electrons in the molecule. Though in strict sense, the density of the Fermi hole cannot be defined within the framework of the DFT theory, recent calculations have demonstrated that the DIs and LIs obtained from Kohn–Sham spin orbitals are similar to those computed with HF wave functions (37). As a result, any atomic population ($N(\Omega)$) can be partitioned into two

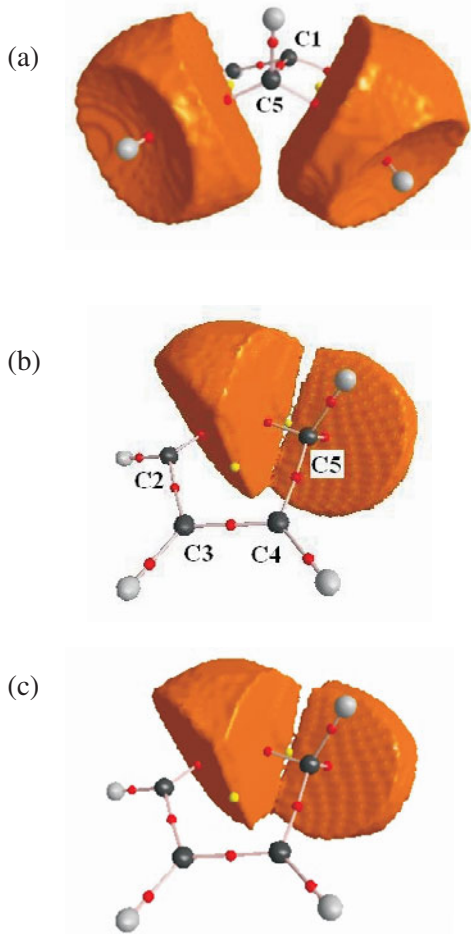
[a]This is the homoconjugative interaction.
[b]The values in italics were obtained at the B3PW91/6-31+G(d) level.
[c]All the DIs for C4 are: 0.0911 (C1), 0.0575 (C2), 1.3364 (C3), 0.8936 (C5), 0.0508 (C6), 0.0184 (C7), 0.0064 (H8), 0.0030 (H9), 0.8314 (H10), 0.0319 (H11), 0.0030 (H12), 0.0024 (H13); for C6: 0.1107 (C1) (at the B3LYP level 0.1448), 0.0505 (C2), 0.0187 (C3), 0.0508 (C4), 0.8112 (C5), 1.3755 (C7), 0.00234 (H8), 0.0017 (H9), 0.0015 (H10), 0.0308 (H11), 0.8243 (H12), 0338 (H13). The LIs for C4 and C6 are 4.4116 and 4.4212, respectively.
[d]% of pairs delocalized between a given basin Ω and another basin Ω′ is given by $[DI(\Omega,\Omega') \times 100]/\Sigma DI$.



components, one containing the delocalized electron population ($N_{DI}(\Omega)$), and another corresponding to the localized electronic charge at the HF (DFT), and correlated levels of theory and the % pair delocalization can be calculated. We have published a comparison of LIs and DIs obtained at the HF, DFT, and various correlated levels of theory and on the whole, inclusion of correlation tends to reduce the DIs relative to the HF and DFT levels. DIs obtained at the DFT level can be significantly overestimated. In this paper, we include the DIs between pairs of atoms of **6** along with % pair delocalization in each case. The data are collected in Table 4. For homonuclear molecules like ethane and ethene, the archetypal examples of molecules with single and double covalent bonds, the DIs should approach 1 and 2, an indication that one and two pairs of electrons are shared between two carbon atoms, respectively. The DIs for the C—C and C=C bonds of ethane and ethene at the CCSD/6-31+G(d)//MP2(FC)/6-31+G(d) level are 0.877 (Σ(LIs + DIs/2) = 18.0006) and 1.515 (Σ(LIs + DIs/2) = 18.0002), respectively. That DFT methods overestimate DIs is seen in the fact that at the B3PW91/6-31+G(d) level, the DIs are 1.029 and 1.931 for ethane and ethene, respectively. The same trend is seen in the data for **6** in Table 4. At the CCSD/6-31+G(d)//MP2(FC)/6-31+G(d) level, the DIs for the nominal double bonds of **6** are smaller than the DI of ethene. For the single bonds, the DIs are smaller than the DI of ethane except for C2—C3 where the value is 0.989 in keeping with the fact some double character is expected between C2 and C3. While Austen (38) has shown that DIs decrease when charge transfer occurs between atoms of diatomics, based on the electron populations (Table 2), there appears to no significant differential charge transfer between the carbon atoms of **6**. There is a significant difference between the populations of the hydrogens connected to C6 and C7 and the other hydrogens of **6** indicating that there is more charge transfer in these cases and the DIs for C6—H12 and C7—H3 are 0.8243 and 0.8256, respectively, somewhat smaller than the DIs for the other vinylic C—Hs: 0.8283 (C2—H8), 0.8285 (C3—H9), 0.8314 (C4—H10). Of particular importance in the case of **6** is the fact that the DI and the % pair delocalized between the C4—C6 basins — the potential homoconjugative interaction — are negligibly small at 0.051 and 1.52, respectively. That the homoconjgative interaction between C4 and C6 is negligible is also seen in the display of the C4 and C6 basins in Fig. 5*a* obtained with AIM 2000 with the B3LYP/6-31+G(d) wave function so a direct comparison can be made with the MOs displayed in Fig. 3. Even at the B3LYP/6-31+G(d) level in which DIs are overestimated, the basins are not close to each other at an isosurface contour value of 0.005. Moreover, even at a contour value of 0.001 (not shown) that is normally used to define van der Waals surfaces, the C4 and C6 basins are not close to each other. The zero-flux surfaces between the hydrogen and carbon basins are clearly see in Fig. 5*a*. The atomic basins obtained at the B3PW91/6-31+G(d) level (not shown) were not discernibly different from the B3LYP basins. Most interesting is the fact that there is a significant DI (0.1448 at B3LYP/6-31+G(d) and 0.1107 at CCSD/6-31+G(d)//MP2(FC)/6-31+G(d); see footnote *c* of Table 4) between C1 and C6. As seen in Figs. 5*b* and 5*c*, while it is not possible to visually discern differences in the displays, the wedge-shaped basins are in very close proximity in accord with the DIs being >0.1.

Conclusions

The pyrolysis of *N*,*N*-dimethylbicyclo[3.2.0]hepta-3,6-dien-1-amine oxide (**5**) in the source of the PE spectrometer made it possible to record a PE spectrum that consists of IP bands corresponding to the transient bicyclo[3.2.0]hepta-

© 2005 NRC Canada

Fig. 5. Atomic basins of: (*a*) C4 and C6 (B3LYP/6-31+G(d)); (*b*) C1 and C6 (B3LYP/6-31+G(d)); and (*c*) (CCSD/6-31+G(d)//MP2(FC)/6-31+G(d)) at an isosurface contour value of 0.005.

1,3,6-triene (**6**). The initial pyrolysis spectrum was obscured by IPs corresponding to the dimers **9** of the triene and dimethylhydroxylamine **7**. Upon subtraction of the PE spectra of **9** and **7**, the IPs of the transient **6** were clearly exposed. The experimental and simulated PE spectra of **6** are in excellent agreement and illustrate the first direct experimental observation of the elusive bicyclo[3.2.0]hepta-1,3,6-triene (**6**). The molecular structure of **6** was studied with QTAIM and a comparison of delocalization indexes showed that there is no homoconjugation between C4 and C6. Nevertheless, a delocalization index >0.1 between C1 and C6 indicated the presence of a minor homoconjugative interaction between these atoms and this was corroborated by the fact that there is slight contact between the basins of these atoms. We expect that a combination of delocalization indexes and plots of atomic basins will be the method of choice for evaluating homoconjugation and delocalization, especially in reactive intermediates. We are currently studying delocalization in a variety of so-called nonclassical carbocations and carbenes and a range of carbanions using this approach.

Experimental

The PE spectra were recorded at pressures between 2 to 6×10^{-3} torr (1 torr = 133.322 4 Pa) on a locally built UV PE spectrometer and were calibrated with the IP band of N_2 that is visible at 15.6 eV in all spectra (15). Linearity of the spectral scale was checked with the lowest IP bands of methyl iodide at 9.54 and 10.16 eV prior to the experiments. *N*-oxide **5** was placed in a small bottle-shaped quartz sample tube that was inserted into the tip of the heated probe and pyrolyzed in the source of the spectrometer. The tip of the sample tube was located 1 cm from the ionizing beam. The sample was dried under source vacuum for at least 12 h and the temperature was raised until pyrolysis occurred (120 °C) and a suitable sample pressure was achieved. Spectra were obtained by collecting and averaging 20–30 scans. Spectra of the dimers and dimethylhydroxylamine were obtained using our external sample introduction system.

Interpretation of the PE spectrum of the transient was aided by the application of a recently developed (22) and successfully applied (23, 24) routine based on B3LYP calculations. The equilibrium optimized geometry of **6** was obtained at the B3LYP/6-31+G(d) level of theory and used in single-point calculations on the radical cation at the same level of theory. The simulated PE spectrum of **6** was obtained from the MO results using a Fortran program PESPEC (26). A Gaussian line broadening of 0.4 and a temperature of 300 K were used to simulate the partial PE spectrum with 10 MO energies (HOMO to HOMO-9). DFT, MP2, and CCSD calculations were carried out with GAUSSIAN 98 or GAUSSIAN 03 (27, 28). Displays of molecular geometries and molecular orbitals were generated using MOLEKEL (29, 30). QTAIM analyses were carried out with AIMALL (31) and the delocalization indexes were obtained with LI-DICALC (13, 14). The molecular graph of **6** and plots of the C1, C4, and C6 atomic basins were obtained with AIM 2000 (32). The grid-point file for **6** contained over 900 000 points calculated at a mesh size of 0.125, and the surfaces displayed in Fig. 5 were obtained by triangularization using the grid points of the 0.005 isosurface. This accounts for the relatively uneven appearance of the isosurfaces. To obtain smoother surfaces would have required long calculations and the generation larger than 100 MB in size.

Tropylium bromide (2) (33, 34)

A solution of 1,3,5-cycloheptatriene (24.2 g, 0.263 mol) in dichloromethane (200 mL) was placed in a round-bottomed flask cooled in a dry ice – acetone bath. A solution of bromine (15 mL) in dichloromethane (120 mL) was added dropwise. After the addition, the reaction was allowed to come to room temperature. Removal of solvent resulted in a dark brown oil, which was heated with stirring under vacuum in a round-bottomed flask fitted with a downward distillation apparatus at a temperature of 70 °C overnight. The dark solid residue was ground with mortar and pestle under dichloromethane and was filtered. Tropylium bromide was collected as a pale green solid.

N,*N*-Dimethylcyclohepta-1,3,5-trien-7-amine (3)

N,*N*-Dimethylcyclohepta-1,3,5-trien-7-amine was synthesized according to a procedure by Doering and Knox (33).

A solution of tropylium bromide (5.8 g) in 35 mL of distilled water was treated with 20% dimethylamine in water (40 mL). Immediately upon this addition a light brown oil separated. The solution was extracted with pentane (2 ×

© 2005 NRC Canada

20 mL). The combined organic extracts were dried with anhydr. $MgSO_4$. Filtration and removal of solvent resulted in 3.5 g of a yellow oil. Purity of the product was confirmed by NMR. ^{1}H NMR ($CDCl_3$) δ: 1.86 (t, 1H), 2.37 (s, 6H), 5.45 (m, 2H), 6.17 (m, 2H), 6.71 (m, 2H). ^{13}C ($CDCl_3$) δ: 43.2, 65.6, 122.8, 123.5, 130.6.

***N*,*N*-Dimethylbicyclo[3.2.0]hepta-3,6-dien-1-amine (4) (35)**

A solution of *N*,*N*-dimethylcyclohepta-1,3,5-trien-7-amine (2 g) in 1 L of hexanes (Omnisolve) was degassed for 1 h with nitrogen and photolyzed with a medium pressure mercury arc lamp for 6.5 h. The solution was then filtered to remove precipitated polymeric material and the solvent was removed using a rotary evaporator affording 1.6 g of the bicyclic amine. The product was checked by NMR and was used in PE spectroscopic experiments without further purification. ^{1}H NMR ($CDCl_3$) δ: 2.23–2.28 (m, 2H), 2.25 (s, 6H), 3.48 (m, 1H), 5.74 (m, 2H), 6.31 (br s, 2H).

***N*,*N*-Dimethylbicyclo[3.2.0]hepta-3,6-dien-1-amine oxide (5) (36)**

A solution of tertiary amine **4** (1 g) in 30 mL of methanol was treated with 30% hydrogen peroxide (2 g). The solution was stirred overnight at room temperature under nitrogen. Excess hydrogen peroxide was quenched with palladium on charcoal. The solution was filtered and the solvent was removed on a rotary evaporator. The sample was dried under vacuum to yield a tan solid. *N*-oxide **5** was identified by NMR in deuterated methanol. ^{1}H NMR (CD_3OD) δ: 3.33 (s, 3H), 3.36 (s, 3H), 3.95 (br s, 1H), 5.83 (br s, 2H), 6.26 (d, 2H), 6.55 (d, 2H).

Reactions of acetoxy(methylthio)carbene and *S*-methyl thiopyruvate[1]

Arkadiusz Klys, Wojciech Czardybon, John Warkentin, and Nick Henry Werstiuk

Abstract: Thermolysis of 2-acetoxy-5,5-dimethyl-2-methylthio-Δ^3-1,3,4-oxadiazoline in benzene at 110 °C afforded *S*-methyl 2-oxopropanethioate (*S*-methyl thiopyruvate) from 1,2-acyl migration in acetoxy(methylthio)carbene, as well as *S*,*S*-dimethyl 2-acetoxy-2-methylpropanebis(thioate) and *S*-methyl 2-acetoxy-2-(methylthio)butanethioate. The latter two, both composed of two carbene units, are derived from reaction of the first product with the carbene.

Key words: acetoxy(methylthio)carbene, carbene, *S*-methyl thiopyruvate, rearrangement.

Résumé : La thermolyse de la 2-acétoxy-5,5-diméthyl-2-méthylthio-Δ^3-1,3,4-oxadiazoline, dans le benzène à 110 °C, conduit à la formation du 2-oxopropanethioate de *S*-méthyle (thiopyruvate de *S*-méthyle) qui provient d'une migration 1,2 d'un groupe acyle dans l'acétoxy(méthylthio)carbène, ainsi que du 2-acétoxy-2-méthylpropanebis(thioate) de *S*,*S*-diméthyle et du 2-acétoxy-2-(méthylthio)butanethioate de *S*-méthyle. Ces deux derniers produits, qui sont formés de deux unités de carbène, dérivent de la réaction du premier produit avec le carbène.

Mots clés : acétoxy(méthylthio)carbène, carbène, thiopyruvate de *S*-méthyle, réarrangement.

Introduction

Recently, we reported the generation of acetoxy(methoxy)carbene (**2**) by thermolysis of 2-acetoxy-5,5-dimethyl-2-methoxy-Δ^3-1,3,4-oxadiazoline (**1**, Scheme 1) (1). Thermolysis of **1** is relatively complex, affording the carbene as well as 2-diazopropane as shown in the abbreviated Scheme 1. The carbene did not fragment to radicals, but it rearranged to methyl pyruvate (**3**) by acetyl migration from oxygen to the carbene carbon, a known process for other acetoxycarbenes (2–7).

We now report that thermolysis of **4** does not afford 2-diazopropane, but gives acetoxy(methylthio)carbene (**5**) under the same conditions. The latter also undergoes a 1,2-acyl shift, but the final products contained not only the rearrangement product (**6**), analogous to **3**, but also two additional compounds. In particular, **4** afforded **6** (the known propanethioic acid, 2-oxo-, *S*-methyl ester, also known as *S*-methyl thiopyruvate) and two additional compounds (**8** and **10**), each made up of two carbene units (Scheme 2).

The precursor of **5** was 2-acetoxy-5,5-dimethyl-2-methylthio-Δ^3-1,3,4-oxadiazoline (**4**) prepared from **9** according to Scheme 3.

Thermolysis of **4** in benzene gave **6**, **8**, and **10**. Formation of **6** probably occurs by concerted acetyl transfer from oxygen to the carbene carbon, as was found for other acyloxy carbenes (2–8). Formation of compounds **6** and **8** is most easily formulated in terms of zwitterionic intermediates (9) formed by reaction of **6** with **5** (Scheme 4).

The first formed *S*-methyl thiopyruvate (**6**) reacts with the carbene preferentially at the ketonic carbon, which must be more electrophilic than the thioester carbonyl carbon. Most likely, transfer of an acyl group occurs through a five-membered transition state to afford the solid **8**. Attack at the thioester carbonyl group, followed by an analogous transfer affords the liquid **10**.

The structure of **8** was confirmed by means of single crystal X-ray diffraction[4] and that of **10** was determined by NMR and mass spectrometry, with reference to the spectra of **8**, chemical shift tables, (10) and chemical shift predictions from the ChemDraw program. Good models for **8** were not found. Attack of dialkoxycarbenes on carbonyl groups has been observed (11), but we are not aware of analogous reactions of acetoxy(methylthio)carbene. Transfer of an acetyl group in zwitterionic intermediates such as **7** and **9** also appears to be unprecedented.

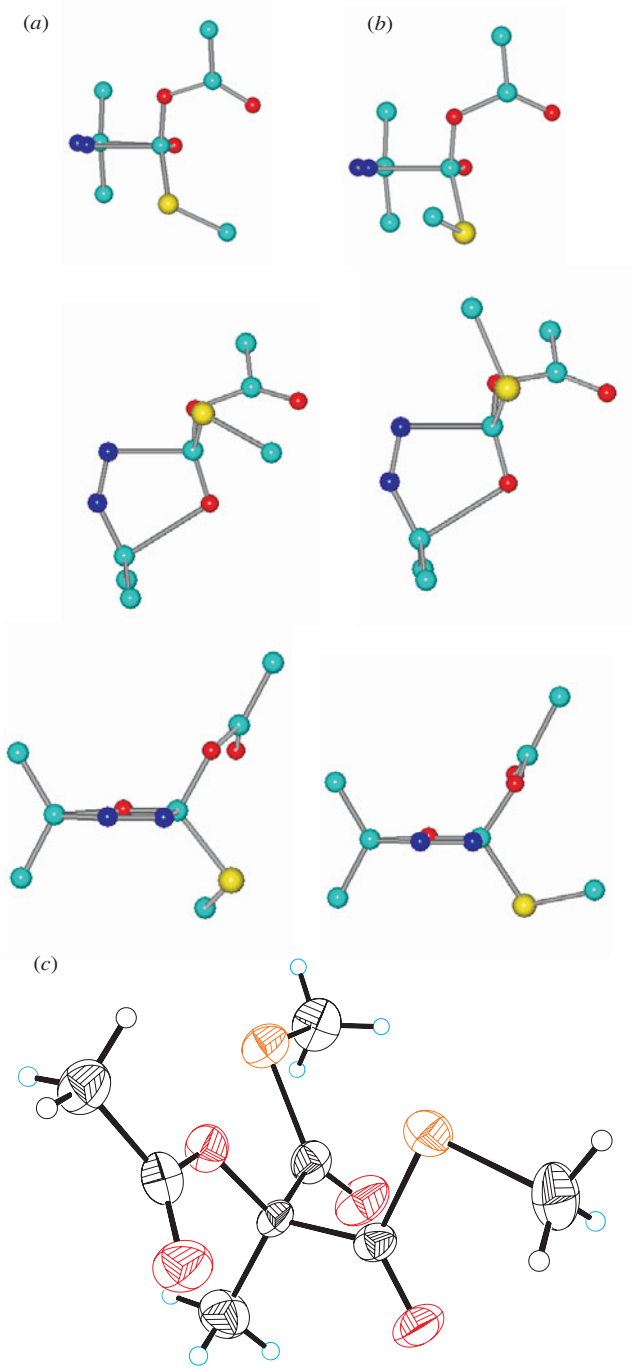
Scheme 1.

Scheme 2.

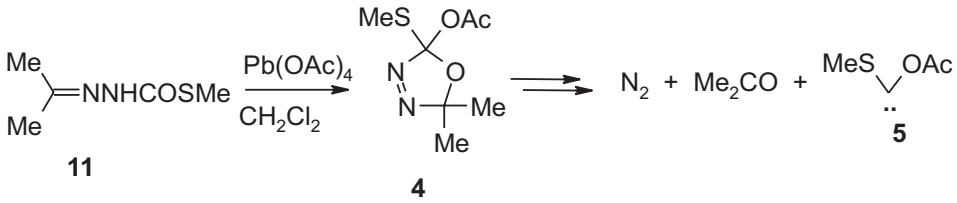
Although the zwitterions **7** and **9** are conjectural intermediates, there is some precedent for formation of persistent charge-separated structures from reactions of a nucleophilic carbene. Imidazol-2-ylidenes react with tetracoordinate silicon compounds (12), with stannylenes (13), and with a plumbylene (14), for example, to produce species that are zwitterions or resonance hybrids that have zwitterionic contributors. An imidazol-2-ylidene also attacks CS_2 to form an isolable zwitterion (15) (Scheme 5).



The reasons for the different thermolysis behaviours of **1** and **4** are not well understood but some potential causes of the differences were examined by means of computation. First, the free energy barriers to fragmentation of the two oxadiazolines might be different, either favouring fragmentation of **1** in the sense that affords 2-diazopropane (7) or favouring fragmentation of **4** in the sense that affords **5**. Either could account for the fact that **1** affords 2-diazopropane while **4** does not. To account for the fact that **4** affords **8** and **10** whereas **1** does not produce analogous 2:1 products, one could imagine that the reactivity of **5** toward **6** could be higher than that of **2** toward **3**.

Optimized equilibrium geometries and transition states were obtained at the Becke3PW91/6-31+G** (16*a*) level, which includes the three-parameter Becke–Perdew–Wang (Becke3PW91) exchange-correlation potential (16*b*) using either GAUSSIAN 98 (16*a*) or GAUSSIAN 03 (16*c*).

Computation of the free energy barriers for fragmentation of the oxadiazolines at 110 °C was carried out for both the gauche and antigauche conformations, where gauche and antigauche are defined in Fig. 1.



For **1**, the antigauche conformation is more favourable for diazopropane formation ($G^{\ddagger}$ = 24.6 kcal mol^{-1}, 1 cal = 4.184 J), while the gauche conformation is favoured for ylide formation ($G^{\ddagger}$ = 26.9 kcal mol^{-1}) (7). For **4**, the

Fig 1. Different views of the gauche and antigauche conformations of the transition state for formation of diazopropane from **4**, with hydrogen atoms omitted for clarity: (*a*) antigauche conformation; (*b*) gauche conformation. (*c*) ORTEP rendition of **8**.

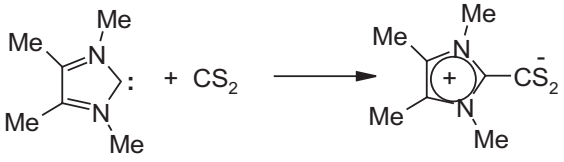

Scheme 3.

Scheme 4.

Scheme 5.

antigauche conformation is again favoured for diazopropane formation ($G^{\ddagger}_{\text{diazopropane}}$ = 20.2 kcal mol^{-1}), while the gauche conformation is slightly favoured for ylide formation (22.5 kcal mol^{-1}).

It is clear that the computations do not predict all of the experimental results, which indicate that **1** should fragment to 2-diazopropane at 110 °C (which it does) and that **4** should also do so (which it does not). However, the free energy differences for the two possible thermolysis paths open to **1** and **4** are only about 2 kcal mol^{-1}, which could easily be within the combined errors in the computations (Table 1).

Calculated free energies of activation for rearrangement (1,2-acyl migration) of the carbenes gave 16.6 and 13.1 kcal mol^{-1} for **2** and **5**, respectively. This result suggests that **5** probably rearranges more rapidly than **2**. As a reasonable explanation for the fact that **5** affords not only **6**, but also **8** and **10**, we suggest that **5** is significantly more reactive toward **6** than **2** is toward **3**. The methylthio group is poorer (compared to the methoxy group) at conjugative stabilization of both a carbene and a carbonyl group and that feature could make both **5** and **6** more reactive than their oxy counterparts (**2** and **3**). Ketoester **6** can be regarded as somewhat like an α-diketone rather than a simple α-ketoester, with a consequent increase in reactivity of both carbonyl groups toward nucleophiles.

Summary

Acetoxy(methylthio)carbene rearranges in benzene at 110 °C by 1,2-acyl migration to *S*-methyl thiopyruvate. The latter reacts with the carbene at both carbonyl groups to afford *S*,*S*-dimethyl 2-acetoxy-2-methylpropanebis(thioate) and *S*-methyl 2-acetoxy-2-(methylthio)butanethioate. Those products probably arise by acetyl group transfer, through five-membered transition states, in zwitterionic intermediates. Support for the formation of the carbene via cycloreversion of an oxadiazoline precursor to a carbonyl ylide, and rearrangement of the carbene by concerted acyl group transfer, was sought by means of computation.

Experimental

General

^{1}H NMR spectra were obtained from solutions in C_6D_6 or $CDCl_3$, with Bruker spectrometers operating at 200 or 600 MHz, unless otherwise indicated, and are referenced to the signal at 7.16 attributed to C_6HD_5 or to $CHCl_3$ at 7.26 ppm. ^{13}C NMR spectra, run at 50.9 or 150.9 MHz, in C_6D_6 or $CDCl_3$, are referenced to the center line of the solvent triplet at 128.1 or 77.2 ppm, respectively. Mass spectra were run with a Micromass/Waters GCT time-of-flight instrument. GC separations were performed with a 6 ft × 4.0 mm (1 ft = 0.0348 m) (internal) column containing 10% OV 101. The helium flow rate was 40 mL min^{-1} and the temperature program was 60 °C for 3 min, then 5 °C / min to 200 °C. IR spectra were taken with neat samples on a Bruker Tensor 27 FT IR instrument equipped with a Harrick ATR accessory and a ZnSe crystal.

Yields are calculated in the usual way, as 100 (mol product)/mol **4**, with the different stoichiometries involved in the formation of **6**, **8**, and **10** being taken into account. For example, 2 mol of **4** are required to make 1 mol of **8**. About 80% of the potential carbene units from **4** were accounted for by products **6**, **8**, and **10**.

2-Acetoxy-5,5 dimethyl-2-methylthio-Δ^3-1,3,4-oxadiazoline (4)

To a stirred solution of $Pb(OAc)_4$ (8.4 g) in CH_2Cl_2 at 0 °C was added hydrazone **11** (17) (2 g, 13.7 mmol). After 3 h the solution was filtered through Celite to remove $Pb(OAc)_2$ and the organic filtrate was washed with 100 mL of aq. (5%) $NaHCO_3$ before it was dried. Evaporation of the solvent left a yellow oil (1.9 g, 68%) that was a mixture of **4** and an acyclic isomer. Very fast chomatography on "old" neutral alumina (hydrated in an open beaker for 3 days) in a 15 cm × 3 cm column with hexane–EtOAc (95:5), collection of the first fraction, evaporation of the solvent immediately, and recrystallization from pentane at –20 °C gave 1.3 g (46%) of colorless crystalline **4**. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.56 (s, 3H), 1.65 (s, 3H), 2.13 (s, 3H), 2.41 (s, 3H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 13.55, 21.62, 23.35, 23.61, 125.72, 133.16, 166.98. MS (CI, NH_3) *m/z* calcd. for $C_7H_{13}N_2O_3S$: 205.0642 $(M + H)^+$; found: 205.0647.

Thermolysis of 4

Oxadiazoline **4** (204 mg, 1 mmol) in dry benzene (5 mL) was heated for 24 h at 110 °C. The solvent was then evaporated in vacuo and products **7** and **8** were separated by radial chromatography on a 2 mm silica plate with hexane–EtOAc (95:5). Product **6** was separated by GC with a 6 ft × 4.0 mm (internal) column containing 10% OV 101, which also separated **8** from **10**. The helium flow rate was 40 mL min^{-1} and the temperature program was 60 °C for 3 min, then 5 °C / min to 200 °C. The total yield of products was determined by analysis of the ^{1}H NMR spectrum of the crude product containing an internal standard. The same yields were calculated from GC data.

Propanethioic acid, 2-oxo-, *S*-methyl ester (6) (18)

Pale yellow oil. Yield: 14%. IR (cm^{-1}): 1722, 1670. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.35 (s, 3H), 2.43 (s, 3H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 11.42, 24.06, 191.86, 193.20.

S,*S*-Dimethyl 2-acetoxy-2-methylpropanebis(thioate) (8)

White solid. Yield: 25%. IR (cm^{-1}): 1753, 1697, 1663. Search for 2-diazopropane

Phenol generates the stable isopropyl phenyl ether (1) from 2-diazopropane. Thermolysis of oxadiazoline **4** (0.20 g, 0.98 mmol) in benzene (1 mL) in the presence of phenol (0.184 g, 1.96 mmol) and analysis of the crude reaction mixture by gas chromatography, with authentic ether as the reference in hand, showed at most a trace of the ether. Mass spectrometry of the same crude product and a careful search for *m/z* = 136.19 ($C_9H_{12}O$) failed to show any signal above noise. The detection limit by this method was estimated to be well below 1%.

Effect of modification of the electrophilic center on the α effect[1]

Ik-Hwan Um, Ji-Youn Lee, Sun-Young Bae, and Erwin Buncel

Abstract: We report on a nucleophilic study of esters R-C(=X)-Y-Ar in which the electrophilic center has been modified by replacing O by S in the leaving group or carbonyl center: 4-nitrophenyl acetate (**1**), *S*-4-nitrophenyl thioacetate (**2**), 4-nitrophenyl benzoate (**3**), and *O*-4-nitrophenyl thionobenzoate (**4**). The studies include O^- and S^- nucleophiles as well as α nucleophiles in H_2O at 25.0 ± 0.1 °C. The sulfur nucleophile (4-chlorothiophenoxide, 4-$ClPhS^-$) exhibits significant enhanced reactivity for the reactions with thiol and thione esters **2** and **4** compared with their oxygen analogues **1** and **3**. On the contrary, the common nucleophile OH^- is much less reactive towards **2** and **4** compared with **1** and **3**. The effect of changing both the electrophilic center and the nucleofugic center on the reactivity of the other oxygen nucleophiles is not so significant: 4-chlorophenoxide (4-$ClPhO^-$) is four to six times more reactive in the reactions with thiol and thione esters **2** and **4** compared with their oxygen analogues **1** and **3**. The α effects exhibited by butan-2,3-dione monoximate (Ox^-) and HOO^- are strongly dependent on the nature of the electrophilic center of the substrates, indicating that the difference in the ground-state solvation energy cannot be fully responsible for the α effect. Our results clearly emphasize the strong dependence of the α effect on the substrate structure, notably, the nature of the electrophilic center. The impact of change in the nucleofuge (**1**→**2**) and the electrophilic center (**3**→**4**) on reactivity indicates that α nucleophiles will need to be "purpose built" for decontamination and nucleophilic degradation of specific biocides.

Key words: α effect, nucleophilicity, nucleofuge effect, electrophilicity, polarizability.

Résumé : On a effectué une étude nucléophile des esters suivants, de formule générale R-C(=X)-Y-Ar, dans lesquels le centre électrophile a été modifié en remplaçant l'oxygène par un soufre dans le groupe partant ou dans le centre carbonyle: acétate de 4-nitrophényle (**1**), thioacétate de *S*-4-nitrophényle (**2**), benzoate de 4-nitrophényle (**3**) et thionobenzoate de *O*-4-nitrophényle (**4**). L'étude réalisée dans l'eau, à 25,0 ± 0,1 °C, inclut des nucléophiles O^- et S^- ainsi que des nucléophiles en α. Le nucléophile sulfuré (4-chlorothiophénolate, 4-$ClPhS^-$) présente une réactivité fortement accrue pour les réactions avec les esters thiolique et thionique **2** et **4** par comparaison avec leurs analogues oxygénés **1** et **3**. L'effet qui résulte d'un changement à la fois du centre électrophile et du centre nucléofuge sur la réactivité des autres d'oxygènes nucléophiles n'est pas aussi significatif: le 4-chlorophénolate (4-$ClPhO^-$) est de quatre à six fois plus réactif dans les réactions avec les esters thiolique et thionique **2** et **4** par comparaison avec leurs analogues oxygénés **1** et **3**. Les effets α présentés par le monoxoimate de la butane-2,3-dione (Ox^-) ou le HOO^- dépendent fortement de la nature du centre électrophile des substrats, ce qui indique que la différence dans l'énergie de solvatation de l'état fondamental n'est pas complètement responsable de l'effet α. Ces résultats mettent clairement en évidence la forte dépendance de l'effet α sur la structure du substrat, particulièrement, la nature du centre électrophile. L'impact d'un changement dans le centre nucléofuge (**1**→**2**) et le centre électrophile (**3**→**4**) sur la réactivité indique que les nucléophiles en α devront être synthétisés sur mesure pour la décontamination et la dégradation nucléophile de biocides spécifiques.

Mots clés : effet α, caractère nucléophile, effet nucléofuge, caractère électrophile, polarisabilité.

[Traduit par la Rédaction]

Introduction

Since α-effect nucleophiles exhibit abnormally enhanced nucleophilicity toward a variety of electrophilic centers (1), they can be used effectively for nucleophilic breakdown of neurotoxins, antidotes for nerve gases, cleanup of contaminated sites, etc. (2–5). A great deal of effort has been made to investigate the importance of determining factors that govern α nucleophilicity so as to design better decontaminants (1, 6–10).

Many factors have been suggested to influence the magnitude of the α effect. Dixon and Bruice (11) demonstrated

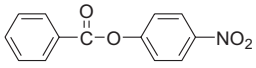
that the α effect increases as β_{nuc} increases, and it is also known that the α effect increases with increasing s character of the electrophilic center (i.e., $sp^3 < sp^2 < sp$) (12, 13), though some exceptions exist (14, 15).



We have recently shown that the α effect is significantly dependent on the nature of the solvent medium for reactions of 4-nitrophenyl acetate (**1**) with butan-2,3-dione monoximate (Ox^-) and 4-chlorophenoxide (4-ClPhO^-) as an α and its reference normal nucleophile, respectively, in DMSO–H_2O (8) and in MeCN–H_2O mixtures of varying compositions (9, 10). A bell-shaped profile has been obtained for the reactions performed in aq. DMSO (8) while in aq. MeCN, an increasing α effect was observed in the plot of the α effect vs. mol% of the organic solvent (9, 10). Interestingly, as well, the α effect has been found to be strongly dependent on the nature of the electrophilic center atom for the reactions of **1**, 4-nitrophenyl benzensulfonate, and diphenylphophinate with Ox^- and $ClPhO^-$ in DMSO–H_2O mixtures, i.e., the α effect decreases in the order C=O > SO_2 > P = O over the range of solvent composition (8*c*, 8*d*).

4: PNPTB

In a more systematic study, we have extended our study to the reactions of **1**–**4** in which both the electrophilic center and the nucleofugic center are modulated from oxygen to sulfur. Replacement of O by a polarizable S atom in the leaving group of **1**, or in the carbonyl bond of **3**, would increase the electrophilicity of the electrophilic center by increasing the polarizability without changing the structure (16–18). Besides, replacement of O by a polarizable S atom in the leaving group of **1** would increase its nucleofugality since thiol is more acidic than the corresponding alcohol by 2–4 pK_a units (16).

Equation [1] shows the overview of the reactions studied. Here, nucleophilic attack occurs at the electrophilic center (C=X). This center is modified by the attached group, R (CH_3 or C_6H_5), the nucleofuge, YAr (where Y = O or S), and the heteroatom, X (X = O or S). The kinetics of the nucleophilic substitution reactions of **1**–**4** have been examined using five different anionic nucleophiles, a sulfur centered nucleophile and four oxygen nucleophiles including two α-effect nucleophiles.

[1] 

R = CH_3 or C_6H_5

X = O or S, Y = O or S

Nu^- = 4-ClPhS^-, 4-ClPhO^-, Ox^-, HOO^-, HO^-

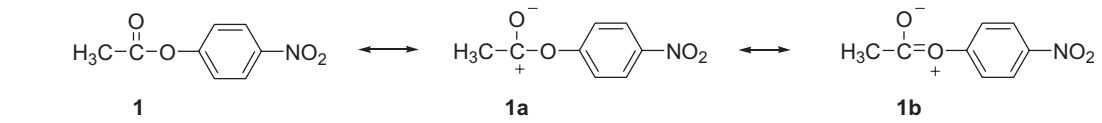
Table 1. Summary of second-order rate constants (k, $(mol/L)^{-1}$ s^{-1}) for the reactions of **1**–**4** with various anionic nucleophiles in H_2O at 25 °C.

Nu^-	pK_a (NuH)	**1**	**2**	**3**	**4**
4-ClPhS^-	7.50	0.143	42.7	0.025	342
4-ClPhO^-	9.38	0.685	2.53	0.260	1.53
Ox^-	9.42	65.8	61.0	23.0	48.9
HOO^-	11.7	3450	3460	1480	1570
HO^-	15.7	11.8	5.90	4.20	0.470

The systematic change in the environment of the electrophilic center has resulted in a significant effect on the reactivity of the anionic nucleophiles studied. We report the remarkable differential effects of changing the nucleofuge (**1**→**2**), the acyl group (**1**→**3**), and the electrophilic center (**3**→**4**) on reactivity of these nucleophiles.

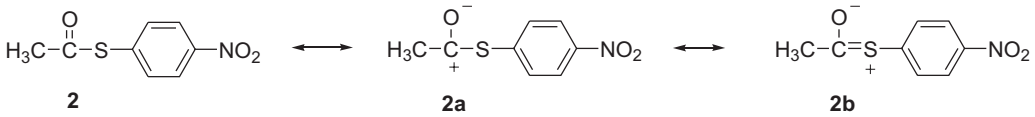
Results

Kinetic studies were performed spectrophotometrically under pseudo-first-order conditions with the nucleophile in excess. Pseudo-first-order rate constants (k_{obs}) were obtained from the equation, $\ln(A_\infty - A_t) = -k_{obs}t + c$. The correlation coefficients of the plots were usually higher than 0.9995. Generally, five different concentrations of nucleophile solutions were used to determine the second-order rate constant from the slope of the linear plot of k_{obs} vs. nucleophile concentration. It is estimated from replicate runs that the uncertainty in the rate constants is less than ±3%, except for the reactions with 4-ClPhS^- where rate constants have a larger uncertainty owing to oxidation to the disulfide. The second-order rate constants determined in this way are summarized in Table 1 and the kinetic conditions and results are given in the Supporting information.[4]



Discussion

Replacing O by S in the leaving group (1→2) — Nucleofuge effect



Replacement of the oxygen by a polarizable sulfur in the leaving group of **1** would result in an increase in nucleofugality of the leaving group as well as in the electrophilicity of the electrophilic center without changing its structure. This argument can be supported by the ^{13}C NMR chemical shifts of the carbonyl carbon and the C=O

1 **1a** **1b**

2 **2a** **2b**

stretching vibrations of thiol relative to the oxygen esters. Thiol esters exhibit 20–30 ppm downfield shifts relative to their oxygen analogues in the ^{13}C NMR spectra (17), while the C=O stretching vibration for thiol esters shifts to ca. 40–60 cm^{-1} lower frequencies than for the corresponding oxygen esters (18), indicating that the carbonyl carbon of thiol esters has greater partial positive charge and weaker double bond character than that of the corresponding oxygen esters (17, 18).

Thus, one can suggest that the contribution of resonance structures **1b** and **2a** is more important than **2b** and **1a**, respectively. This is also in accord with the fact that overlap between 2p and 3p orbitals is weaker than between 2p orbitals. Accordingly, the thiol ester **2** would exhibit enhanced electrophilicity compared to its oxygen analogue **1**. Furthermore, the fact that 4-nitrothiophenoxide (pK_a = 4.54) is less basic than 4-nitrophenoxide (pK_a = 7.14) (16) by 2.6 pK_a units in H_2O is in accord with the proposal that the former is a better nucleofuge. Thus, one might expect **2** should be more reactive than **1**. The following results interestingly reflect on these expectations.

Sulfur vs. oxygen nucleophiles

Our results show that the thiol ester **2** is ca. 300 times more reactive than its oxygen analogue **1** toward the sulfur nucleophile 4-ClPhS$^-$. As shown in Table 1, the rate constant for the reaction of 4-ClPhS$^-$ increases from 0.143 to 42.7 $(mol/L)^{-1}$ s^{-1} as the substrate is changed from **1** to **2**. On the contrary, **2** is less reactive than **1** in reaction with OH$^-$ by a factor of 2: the rate constant for the reaction of OH$^-$ decreases from 11.8 to 5.90 $(mol/L)^{-1}$ s^{-1} as the substrate changes from **1** to **2**. The decrease in the reactivity of OH$^-$ on changing the substrate from **1** to **2** is unexpected on the basis of the argument given in the previous section.

One might suggest that the nature of the rate-determining step (RDS) is responsible for the absence of the predicted nucleofuge effect for the reactions with OH$^-$, since an enhanced nucleofugality would be ineffective for reactions in which the leaving-group departure occurs after the RDS. Now, previous work suggests that alkaline hydrolysis of aryl acetates proceeds through an addition intermediate in which its formation is the RDS (19). Accordingly, one can expect that the nucleofuge effect would be absent for reactions of OH$^-$ with **1** and **2**. Contrastingly, the reactions of **1** and **2** with 4-ClPhS$^-$ have been reported to proceed through an addition intermediate but with a different RDS, i.e., breakdown of the intermediate for the reaction with **1** and its formation for the reaction with **2** (16). Thus, one might attribute the differential nucleofuge effect shown by 4-ClPhS$^-$ and OH$^-$ to the difference in their RDS. However, this argument cannot explain why in the reaction with OH$^-$ **2** is less reactive than **1**.

The differential nucleofuge effect shown by 4-ClPhS$^-$ and OH$^-$ in their reactions with **1** and **2** is in accord with the hard and soft acids and bases principle (HASB) (20): 4-ClPhS$^-$ is known to be highly soft while OH$^-$ is a hard base. Accordingly, basicity of the two nucleophiles does not govern their nucleophilicity, since the polarizable 4-ClPhS$^-$ is seven times more reactive than the charge localized OH$^-$ toward the polarizable thiol ester **2**, although 4-ClPhS$^-$ is less basic than OH$^-$ by 8.2 pK_a units (21).

Hydroxide vs. aryloxide nucleophiles

Table 1 demonstrates that the thiol ester **2** is more reactive than its oxygen analogue **1** toward 4-ClPhO$^-$ by a factor of 4: the rate constant for the reaction with 4-ClPhO$^-$ increases from 0.685 to 2.53 $(mol/L)^{-1}$ s^{-1} as the substrate is changed from **1** to **2**. Thus, 4-ClPhO$^-$, though an oxygen nucleophile, exerts higher reactivity toward the polarizable thiol ester **2** than toward its oxygen analogue **1**. This contrasts to the result obtained for the reaction with OH$^-$. Previous work suggests that the reactions of **1** and **2** with 4-ClPhO$^-$ proceed through an addition intermediate in which leaving-group departure occurs after the RDS (16, 22). It follows that the rate enhancement shown by 4-ClPhO$^-$ on changing the substrate from **1** to **2** is not due to a nucleofuge effect.

The negative charge on the oxygen atom of 4-ClPhO$^-$ can be delocalized on the phenyl ring by resonance as shown in the following. In agreement with this, the charge density of the oxygen atom of 4-ClPhO$^-$ has been calculated to be –0.777 at the MP2/6-31+G* level. It would seem reasonable to suggest that the difference in charge density between the oxygen atoms of OH$^-$ and 4-ClPhO$^-$ is responsible for the differential nucleofuge effect shown by OH$^-$ and 4-ClPhO$^-$ for the reactions with **1** and **2**. However, one can find from Table 1 that OH$^-$ is 17 times more reactive than 4-ClPhO$^-$ for the reaction with **1**, but only 2.3 times more reactive for the reaction with **2**, although the former is more basic than the latter by 6.3 pK_a units. Clearly, the rate constant ratio (k^{OH^-}/k^{ClPhO^-} = 2.3) for the reaction of **2** with OH$^-$ and 4-ClPhO$^-$ is unexpectedly small if one considers the large difference in the basicity of the two nucleophiles.

The α effect — Oximate vs. chlorophenoxide nucleophiles

Ox$^-$ exhibits only a slight decrease in its reactivity for the reaction with the thiol ester **2** compared to its oxygen ester **1**,

© 2005 NRC Canada

the rate constant decreasing from 65.8 to 61.0 $(mol/L)^{-1}$ s^{-1}. This small decrease in reactivity for Ox^- on changing the substrate contrasts to the result obtained for the reactions of 4-$ClPhO^-$.

The negative charge of the nucleophilic oxygen atom of Ox^- can be delocalized by resonance as shown in the folllowing, but it resides on the two electronegative oxygen atoms. In fact, the charge density on the nucleophilic oxygen and the carbonyl oxygen atoms has been calculated to be –0.565 and –0.670, respectively on the MP2/6-31+G* level. This could be one possible reason why Ox^- and 4-$ClPhO^-$ exhibit a contrasting nucleofuge effect.

As an α-effect nucleophile, Ox^- exhibits higher reactivity for the reactions with **1** and **2** than its reference normal nucleophile (4-$ClPhO^-$) of equal pK_a (8). As shown in Table 2, the α effect ($k^{Ox^-}/k^{4\text{-}ClPO^-}$) decreases from 96 to 24 as the substrate changes from **1** to **2**, indicating that the magnitude of the α effect is highly dependent on the nature of the substrates.

The α effect — HOO^- vs. OH^-

HOO^- exhibits nearly the same reactivity for the reactions with **1** and **2**: the rate constants shown in Table 1 are 3450 and 3460 $(mol/L)^{-1}$ s^{-1} for the reactions with **1** and **2**, respectively. This is an interesting result, since 4-$ClPhS^-$ exhibits a rate increase of 300, while OH^- results in a rate decrease of 2 on changing the substrate from **1** to **2**.

Although HOO^- is less basic than OH^- by 4 pK_a units, these two nucleophiles have often been employed as an α and the reference normal nucleophiles owing to the similarity of their structures (1). The magnitude of the α effect is larger for the reaction with the thiol ester **2** than for that with the oxygen analogue **1**. As shown in Table 2, the α effect shown by HOO^- (k^{HOO^-}/k^{HO^-}) increases from 290 to 590 as the substrate changes from **1** to **2**. The substrate-dependent α effect is also seen for the Ox^- system, but the α effect exhibited by Ox^- is smaller for the reaction with the thiol ester **2** ($k^{Ox^-}/k^{4\text{-}ClPO^-}$ = 24) than with the oxygen analogue **1** ($k^{Ox^-}/k^{4\text{-}ClPO^-}$ = 96), which is in agreement with the HASB principle.

Replacing O by S at the electrophilic center (3→4) — The heteroatom effect

It is generally considered that a C=S bond is more polarizable than a C=O bond, on the grounds that the overlap between the 2p and 3p orbitals in a C=S bond is not as strong as that between the 2p orbitals in a C=O bond, indicating that the contribution of **4a** is more significant than that of **3a**. ^{13}C NMR spectra for substrates **3** and **4** are in agreement with this argument. The chemical shifts for the carbon atoms of the C=O and C=S bonds in **3** and **4** are 163.8 and 209.8 ppm, respectively. Such a large downfield shift (46 ppm) suggests that the carbon atom of the C=S bond in **4** has greater positive charge than that of the C=O bond in **3**, consistent with the previous proposal that the contribution of **4a** outweighs that of **3a**. In turn, **4** is expected to be more electrophilic and more reactive than **3**.

Table 2. Summary of the α-effect shown by HOO^- and Ox^- for the reactions of **1**–**4** in H_2O at 25 °C.

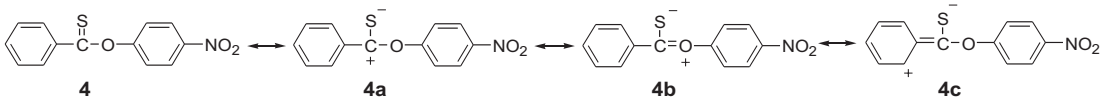
Substrate	k^{HOO^-}/k^{HO^-}	$k^{Ox^-}/k^{4\text{-}ClPhO^-}$
PNPA (**1**)	290	96
PNPTA (**2**)	590	24
PNPB (**3**)	350	88
PNPTB (**4**)	3300	32

Sulfur vs. oxygen nucleophiles

Our results show a striking major effect of changing the heteroatom X from O to S for the reactions of **3** and **4** with the sulfur nucleophile, 4-$ClPhS^-$. The rate constant (Table 1) for the reactions of 4-$ClPhS^-$ increases from 0.025 to 342 $(mol/L)^{-1}$ s^{-1} as the heteroatom X changes from O to S (**3**→**4**). Thus, the rate enhancement on changing the substrate from **3** to **4** for the reaction with 4-$ClPhS^-$ is 14 000, which is greater than for the reactions of **1** and **2** with 4-$ClPhS^-$ ($k^{4\text{-}ClPhS^-}$(**2**)/$k^{4\text{-}ClPhS^-}$(**1**) = 300).

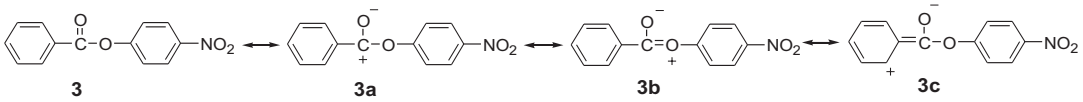
On the contrary, the rate constant for the reaction of OH^- decreases from 4.20 to 0.470 $(mol/L)^{-1}$ s^{-1} on changing the heteroatom X from O to S. Thus, the thione ester **4** is nine times less reactive than its oxygen analogue **3** for the reaction with OH^-.

Such a rate retardation is quite unexpected, since **4** would be expected to be more reactive than **3**. This indicates that the reactivity of OH^- is exceedingly low toward the polarizable thione ester **4**.



It is also noted that 4-$ClPhS^-$ is 180 times less reactive than OH^- in the reaction with **3**, but 730 times more reactive than OH^- in the reactions with **4**, although the former nucleophile is 8.2 pK_a units less basic than the latter. Thus, basicity alone cannot determine the nucleophilicity for the reaction with polarizable electrophiles.

Hydroxide vs. aryloxide nucleophiles



4-$ClPhO^-$ exhibits a rate enhancement of 6 on changing the heteroatom X from O to S (Table 1). Unexpectedly, while an oxygen nucleophile, 4-$ClPhO^-$ is more reactive in the reaction with the thione ester **4** than with the oxygen analogue **3**. The rate constant ratio ($k^{OH^-}/k^{4\text{-}ClPhO^-}$) decreases as the substrate changes from **3** to **4**, i.e., $k^{OH^-}/k^{4\text{-}ClPhO^-}$ = 16 and 0.3, for the reactions with **3** and **4**, respectively. Interestingly, although it is much more basic, OH^- is three times less reactive than 4-$ClPhO^-$ in the reaction with **4**.

The α effect — The oximate α nucleophile

Table 1 shows that Ox^- exhibits a rate enhancement by a factor of 2 on changing the substrate from **3** to **4**. The rate enhancement shown by Ox^- is smaller than that by 4-$ClPhO^-$ on changing substrates from **3** to **4**. Accordingly, the α effect decreases from 88 to 32 as the substrate changes

© 2005 NRC Canada

from the oxygen ester **3** to its sulfur analogue **4**. A similar result is obtained for the reactions with **1** and **2** as mentioned in the preceding section, i.e., the α effect exhibited by Ox^- is larger for the oxygen ester **1** than for its sulfur analogue **2**.

We have recently shown that the magnitude of the α effect is dependent on the nature of the electrophilic center for the series **1**, 4-nitrophenyl diphenylphosphinate and benzensulfonate, with Ox^- and 4-$ClPhO^-$ (8). The α effect ($k^{Ox^-}/k^{4\text{-}ClPhO^-}$) was found to decrease as the electrophilic center is changed from C=O to SO_2 and P=O (8*d*).

Calorimetric measurements have shown that Ox^- is ca. 4 kcal/mol (1 cal = 4.184 J) less solvated than 4-$ClPhO^-$ in H_2O (8*b*), indicating that a solvation effect could be responsible for the α effect shown by Ox^-, at least in part. In fact, we have recently shown that the magnitude of the α effect for the reaction of **2** with Ox^- and 4-$ClPhO^-$ is linearly proportional to the solvation energy difference between the α-effect nucleophile Ox^- and the normal nucleophile 4-$ClPhO^-$ in DMSO–H_2O mixtures of varying compositions (22). However, the substrate-dependent α effect found in the present and previous systems suggests that a solvation effect cannot be solely responsible for the origin of the α effect (8–10, 22).

The α effect — HOO^- vs. OH^-

The reactivity of HOO^- has been found to be independent of the nature of the electrophilc center in the present study. As shown in Table 1, HOO^- exhibits nearly the same second-order rate constant on changing the substrate from **3** to **4** or from **1** to **2**. This is interesting since the structurally similar OH^- exhibits significant rate retardation on changing the nature of the electrophilic center, from **3** to **4** or from **1** to **2**. Accordingly, HOO^- exhibits substrate-dependent α effects, i.e., k^{HOO^-}/k^{HO^-} increases from 290 to 590 and from 350 to 3300 as the substrate is changed from **1** to **2** and **3** to **4**, respectively. The α effect shown by HOO^- is larger for the reactions with thiol and thione esters **2** and **4** than for the corresponding oxygen esters **1** and **3**. Interestingly, this contrasts with the result obtained for Ox^-, which exhibits smaller α effects for the reactions with thiol and thione esters **2** and **4**.

OH^- has often been found to exhibit a negative deviation from Brønsted-type plots for various nuclephilic substitution reactions, which Jencks et al. (23) attributed to abnormal solvation. In fact, OH^- has been shown to be 12, 32, and 38 kcal/mol more solvated than HOO^-, PhO^-, and PhS^-, respectively, in H_2O (24). Thus, one might similarly attribute the unusually low reactivity of OH^- in this system to a solvation effect, at least in part. This would be consistent with the finding that OH^- exhibits nearly the same reactivity as HOO^- in gas-phase reactions with methyl formate (25). However, if the GS solvation effect were mainly responsible for the α effect shown by HOO^- in this study, then the α effect should have remained nearly constant irrespective of the nature of the substrate. In fact, the α effect has been shown to be significantly dependent on the nature of the electrophilic center. Thus, the ground-state (GS) solvation effect cannot be solely responsible for the α effect shown by HOO^-. This is consistent with our recent conclusion that TS stabilization is also a contributing factor responsible for the α effect (1, 8, 9).

Acyl group effect — Acetate vs. benzoate (1→3)

We have recently shown that the contribution of the resonance structure **3c**, which is not possible for **1**, is likely responsible for the decrease in reactivity of aryl benzoates in nucleophilic substitution reactions with various amines and anionic nucleophiles such as OH^-, N_3^-, and CN^- (26–28). Thus, replacement of the methyl group in **1** by a phenyl group would cause a rate retardation owing to stabilization of the GS in **3** by resonance (**3c**) and (or) enhanced steric hindrance.

As shown in Table 1, the acetate ester **1** is two to seven times more reactive than the benzoate ester **3** toward all the nucleophiles investigated in this study. Steric hindrance appears to be more significant for the reaction with the large 4-$ClPhS^-$ since the rate constant ratio for the reactions of **1** and **3** is much larger for the reactions with 4-$ClPhS^-$ than for those with the other oxygen nucleophiles, e.g., $k(\mathbf{1})/k(\mathbf{3})$ = 2 to 3 for the reactions with HOO^-, Ox^-, and 4-$ClPhO^-$, but $k(\mathbf{1})/k(\mathbf{3})$ = 7 for the reactions with the large sulfur nucleophile (4-$ClPhS^-$).

Conclusions

The present study has allowed us to conclude the following: (1) the sulfur nucleophile (4-$ClPhS^-$) exhibits significantly enhanced reactivity for the reactions with the thiol and thione esters **2** and **4** compared to their oxygen analogues **1** and **3**, respectively; (2) on the contrary, the common oxygen nucleophile OH^- is much less reactive in the reactions with the sulfur containing substrates **2** and **4**; (3) the strong solvation of OH^- in H_2O cannot be solely responsible for the unusually low reactivity shown by OH^- in the reactions with thiol and thione esters **2** and **4**; (4) the α effects shown by Ox^- and HOO^- are strongly dependent on the nature of the electrophilic center of the substrates, indicating that the difference in the GS solvation energy cannot be fully responsible for the α effect; (5) our results clearly emphasize the strong dependence of the α effect on the substrate structure, notably, the nature of the electrophilic center. The impact of change in the nucleofuge (**1**→**2**) and heteroatom X (**3**→**4**) on reactivity indicates that α nucleophiles will need to be "purpose built" for decontamination and nucleophilic degradation of specific biocides.

Experimental section

Materials

Substrates **1**–**4** have been readily prepared by reaction of the corresponding acid chloride with 4-nitrophenol or 4-nitrothiophenol in the presence of triethylamine in anhydrous ether. Their purity was checked by melting points and

© 2005 NRC Canada

spectroscopic data such as IR and NMR spectra. Other materials were of the highest quality available and were generally recrystallized before use. Glass-distilled water was further boiled and cooled under nitrogen just before use.

Kinetics

Kinetic studies were performed using a Scinco S-3100 PDA UV–vis spectrophotometer for slow reactions ($t_{1/2} \geq 10$ s) or an Applied Photophysics SX-17MV stopped-flow spectrophotometer for fast reactions ($t_{1/2} < 10$ s) equipped with a constant-temperature circulating bath. The reactions were followed by monitoring the appearance of 4-nitrophenoxide (or 4-nitrothiophenoxide for the reaction of **2**). Each reaction was monitored up to 10 half-lives.

Typically, a reaction was initiated by adding 5 μL of a ca. 0.01 mol/L solution of substrates in MeCN by a gas-tight syringe to a 10 mm quartz UV cell containing 2.50 mL of a thermostatted reaction mixture made of an aliquot of nucleophile solution. The stock solutions (ca. 0.2 mol/L) of 4-ClPhO$^-$, Ox$^-$, and HOO$^-$ were prepared by dissolving 2 equiv. of 4-ClPhOH, OxH, and HOOH and 1 equiv. of standardized NaOH solution to keep the pH constant by making self-buffered solutions. However, owing to the low solubility of 4-ClPhSH in water, the concentration of 4-ClPhS$^-$ stock solution was prepared by mixing ca. 0.011 mol/L of 4-ClPhSH and 0.010 mol/L of NaOH. The kinetic conditions and results are summarized in the Supporting information.[4] Other detailed kinetic methods were reported previously (8*b*, 8*c*).

Product analysis

One of the reaction products, 4-nitrophenoxide (or 4-nitrothiophenoxide for the reactions of substrate **2**), was determined quantitatively by measuring the optical density using a UV–vis spectrophotometer in all cases. Other products (e.g., *S*-4-chlorophenyl thioacetate, *S*-4-chlorophenyl thiobenzoate, and 4-chlorophenyl dithiobenzoate for the reactions of substrates **1**–**4** with 4-chlorothiophenoxide, respectively) were analyzed by a GC technique. The quantitative analysis was performed using the authentic samples by a Varian 3800 Model GC with a DB 624 column (30 m × 0.32 mm × 1.8 μm) for *S*-4-chlorophenyl acetate (retention time 13.50 min at the injector temperature of 250 °C, the column temperature starting at 50 °C and increased by 15 °C/min) and with a DB 5 column (30 m × 0.32 mm × 0.25 μm) for *S*-4-chlorophenyl thiobenzoate and 4-chlorophenyl dithiobenzoate (retention time 11.23 and 10.43 min, respectively, at the injector temperature of 250 °C, the column temperature starting at 50 °C and increased by 20 °C/min).

Computational studies of the properties of phenyloxenium ions — A comparison with phenylnitrenium and phenylcarbenium ions[1]

Stephen A. Glover and Michael Novak

Abstract: Properties of phenyloxenium ion **13a**, phenylnitrenium ion **14a**, and their 4-methyl and 4-phenyl analogues have been studied at the HF/6-31G* and pBP/DN*//HF/6-31G* levels to explain differences in their relative ease of formation and their stabilities. The phenyloxenium ions **13** are ground-state singlets but S_0–T_1 gaps are smaller than those of the corresponding nitrenium ions. The S_0 states are stabilized by donor methyl and phenyl substituents in both classes of ions, but phenyloxenium ion has much greater charge localization on the ring, primarily at the 4 position. Evidence for this difference stems from ground-state HF/6-31G*geometries, dipole moments, and vibrational frequencies. Nitrenium ions exhibit some quinoidal character, but the calculated C—N bond lengths are longer than those of their 4-hydroxy-2,5-cyclohexadienone imine hydration products **17** and the symmetric C-N stretching frequencies are ca. 60–100 cm^{-1} less than those of **17**. However, the C—O bond lengths and stretching frequencies of the phenyloxenium ions are slightly shorter and greater, respectively, than those of their 4-hydroxy-2,5-cyclohexadienone hydration products (**16**). The oxenium ions are best described by their 4-oxo-2,5-cyclohexadienyl carbenium resonance structures. Accordingly, a 4-phenyl group stabilizes the phenyloxenium ion more than the phenylnitrenium ion leading to a planar geometry and considerably more charge in the distal ring, thus accounting for regioselectivities of azide reactions. Isodesmic comparisons of the energy difference between phenyloxenium and phenylnitrenium ions and their neutral hydration products explains their relative stabilities under aqueous conditions; whereas 4-biphenylyloxenium ion **13c** has a lifetime in water of 12 ns as opposed to the corresponding nitrenium ion **14c** (300 ns), the 4-methylphenyloxenium ion **13b** is less stable to hydration by 18.7 kcal mol^{-1} (1 cal = 4.184 J) and cannot be observed under the conditions used to generate **13c**.

Key words: oxenium ions, nitrenium ions, computational chemistry, nucleophilic addition, singlet state properties.

Résumé : Les propriétés de l'ion phényloxénium **13a**, de l'ion phénylnitrénium **14a** et de leurs analogues 4-méthyl- et 4-phényl- ont été étudiées aux niveaux HF/6-31G* et pBP/DN*//HF/6-31G* pour tenter d'expliquer les différences dans leurs facilités relatives de formation dans leurs stabilités. Les ions phényloxénium **13** sont des singulets à l'état fondamental, toutefois les écarts S_0–T_1 sont plus faibles que ceux des ions nitrénium correspondants. Dans les deux classes d'ions, les états S_0 sont stabilités par les substituants donneurs méthyle et phényle; toutefois, la délocalisation de la charge sur le cycle est beaucoup plus grande avec l'ion phényloxénium, particulièrement vers la position 4. Les bases pour ces différences sont tirées des géométries HF/6-31G* de l'état fondamental, des moments dipolaires et des fréquences de vibration. Les ions nitrénium exhibent un caractère quinoïdal, mais les longueurs calculées des liaisons C—N sont supérieures à celle de leur produit d'hydratation, l'imine de la 4-hydroxycyclohexa-2,5-diénone (**17**) et les fréquences d'élongation symétrique du C-N sont de 60 à 100 cm^{-1} inférieures à celle du composé **17**. Toutefois, les longueurs des liaisons C—O et les fréquences d'élongation des ions phényloxénium ne sont respectivement que faiblement plus courtes et plus longues que celles de leur produit d'hydratation, la 4-hydroxycyclohexa-2,5-diénone (**16**). La meilleure façon de décrire les ions oxénium correspond aux structures de résonance du carbénium 4-oxocyclohexa-2,5-diényle. En conséquence, un groupe 4-phényle stabilise plus un ion phényloxénium que l'ion phénylnitrénium conduisant à une géométrie planaire et beaucoup plus de charge dans le noyau distal, ce qui expliquerait les régiosélectivités des réactions avec l'ion azoture. Des comparaisons isodesmiques des différences d'énergie entre les ions phényloxénium et phénylnitrénium et leurs produits neutres d'hydratation explique leurs stabilités relatives dans des conditions aqueuses; alors que le temps de vie de l'ion 4-biphényloxénium **13c** dans l'eau est de 12 ns par rapport à 300 ns pour celui de l'ion nitrénium correspondant **14c**, l'ion 4-méthylphényloxénium **13b** est moins stable à l'hydratation par 18,7 kcal mol^{-1} (1 cal = 4,184 J) et il ne peut pas être observé dans les conditions utilisées pour générer le composé **13c**.

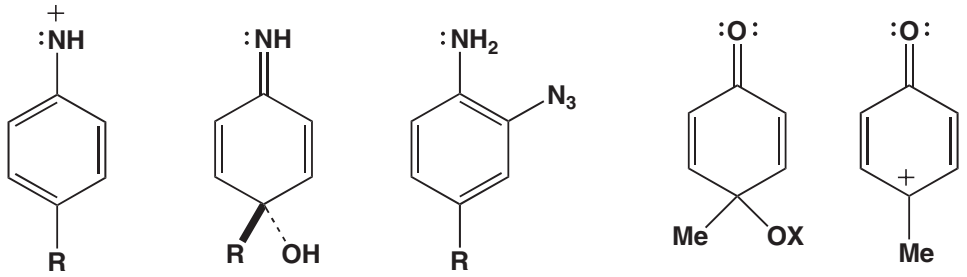
Introduction

Arylnitrenium ions **2**, which are widely accepted to be the intermediates derived from metabolites of carcinogenic aromatic amines, have been studied extensively. As a result, factors affecting their stability, their lifetimes under aqueous conditions and their reactivity with a range of inorganic and biological nucleophiles have been the subject of many investigations (1–15). Undoubtedly, these ions are strongly delocalized and they can best be regarded as 4-imino-2,5-cyclohexadienyl carbocations, although they do retain some electrophilic reactivity at nitrogen (4–7, 11, 15–25). Delocalization leads to predominant reaction on the aryl ring with attendant disruption of aromaticity. The intrinsic barrier resulting from this loss of aromaticity leads to long lifetimes in aqueous solution, which in certain instances accounts for elevated carcinogenic behaviour. The lifetimes of 4-biphenylylnitrenium ion (300 ns at 30 °C) and its bridged counterpart, 2-fluorenylnitrenium ion (30 μs at 20 °C) derived from mutagenic and carcinogenic arylamines, are longer in aqueous solution than those of nitrenium ions derived from noncarcinogenic arylamines (4, 13, 16, 18, 26).



1 **2**

The oxygen counterparts of arylnitrenium ions (aryloxenium ions **1**), have, on the other hand, received relatively little attention. They have been proposed to explain the products of the synthetically useful electrochemical and chemical oxidations of phenols (27–33), and the copper-catalysed generation of commercially useful polymers such as poly(2,6-dimethyl-1,4-phenylene oxide) (34, 35). Reactions on both the aryl substituent (28, 29, 31, 32) as well as upon oxygen (30, 33) have been ascribed to the electrophilic behaviour of these species, but the regiochemistry of reactions of purported examples of **1** generated from different sources is confusing; surprisingly, little is known of the reactivity and selectivity of these species, or even whether they have actually been generated in the cases in which they have been invoked. The possible formation of **1** with electron-deficient aryl groups is particularly intriguing (29). Compounding this, there is the possible involvement of triplet ions. A recent report has described a relatively unreactive, hindered form of **1** but this long-lived (0.55 μs) species provides little insight into the reactions of more transient members of this class of ions (36).

We recently described the solvolysis of the 4-acetoxy-4-phenyl-2,5-cyclohexadienone (**3**) and showed that, in neutral, acidic, and basic aqueous media, it solvolyses to 4-biphenylyloxenium ion **4** (37, 38). This ion has a lifetime in water at 30 °C of 12 ns, considerably longer than the analogous 1-(4-biphenylyl)ethyl and 4-phenylcumyl carbenium ions (0.1 and 0.5 ns, respectively) (39, 40), but more than an order of magnitude shorter than that of 4-biphenylylnitrenium ion **8a** (13). Water reacts at the 4 position giving the 4-phenylquinol **5**, but in the competition reactions with azide, from which its lifetime was determined, both the 2- and the 4′-azidobiphenols (**6** and **7**) were formed in a 4.7:1 ratio (Scheme 1) (37).

In similar competition reactions, 4-biphenylylnitrenium ion **8a** afforded the 4-hydroxy-4-phenyl-2,5-cyclohexadienone imine (**9a**) and only the 2-azidobiphenylamine (**10a**) (4). Thus, apart from their differences in lifetimes, 4-biphenylyloxenium and 4-biphenylylnitrenium ions differ in the regiochemistry of azide addition. The isolation of appreciable quantities of the 4′-regioisomer signals significantly greater delocalization of positive charge in the oxenium ion (37). In addition, substituents influence the stabilities of nitrenium ions and oxenium ions to a different extent. While 4-methylnitrenium ion **8b** has been detected from solvolysis of *N*-(4-methylphenyl)-*O*-pivaloyl hydroxylamine (lifetime of 0.8 ns in aqueous acetonitrile at 20 °C) and reacts with water and azide giving **9b** and **10b** (16, 17), we were not able to observe 4-methylphenyloxenium ion **12** from solvolysis of **11a** under any conditions. While the 4-methylquinol **11b** is formed, it does so through normal ester hydrolysis; in aqueous conditions and with 10 atom% ^{18}O water there is little or no incorporation of ^{18}O into the 4-hydroxyl of the product **11b** that is formed upon solvolysis of **11a**. However, there is full incorporation into **5** upon solvolysis of **3** (38). Relative to the phenylnitrenium ion, either the phenyloxenium ion is

Scheme 1.

stabilized far more weakly by a 4-methyl substituent or, alternatively, a 4-phenyl group can provide extra stabilization.

4-Biphenylyloxenium ion generated in this manner appears to react as a singlet species, but, as with nitrenium ions, oxenium ions can be both singlet and triplets. For the simplest form (HO^+), the triplet is lower in energy by 54 kcal mol^{-1} (1 cal = 4.184 J) (41), but electron-donating substituents are expected to stabilize the singlet state more than the triplet state. An earlier MNDO study indicated that singlet states of phenylnitrenium ion and *N*-formylphenylnitrenium ion were lower than the triplet states by about 20 kcal mol^{-1} (42). At the UHF/6-31G* level, singlet phenyloxenium ion is computed to be more stable than its triplet form by only 4 kcal mol^{-1} (34), but Li et al. (43) demonstrated that for both phenylnitrenium ion and phenyloxenium ion the computed energy difference was strongly dependent upon the size of the basis set and, particularly, on the inclusion of correlation energy. However, their calculations utilized HF/STO-3G optimized geometries. Using density functional theory, Cramer and co-workers (25, 44) have calculated singlet states of arylnitrenium ions to be significantly more stable than the triplets (by between 13 and 28 kcal mol^{-1}), and the gap is greatest with electron-donor groups at the 4 position.

In this study, we have compared the influence of 4-methyl and 4-phenyl substituents upon S_0–T_1 energies of phenyloxenium and phenylnitrenium ions and singlet ground-state properties of these, and their carbenium analogues, with a view to understanding the differences in their lifetimes and reactivities.

Methods

Geometries were optimized up to the HF/6-31G* (closed shell) and UHF/6-31G* (triplets) levels and these were used to compute energies, including correlation energies, at the density functional level (pBP/DN*//HF/6-31G*) using the Spartan suite of programs (45, 46). Energies at the pBP/DN*//HF/6-31G* level were on average 1 to 2 kcal mol^{-1} higher than those obtained from full optimization at the pBP/DN* level. Energies of orthogonal conformations of biphenylyl ions were obtained by constraining the inter-ring dihedral angles at 90° and fully optimizing the remaining structural parameters. HF/6-31G* geometries differed only marginally and systematically from those obtained by full DFT analysis and hence were used for comparative purposes. Gas-phase vibrational frequencies were determined using HF/6-31G* optimized geometries and corrected according to the HF/6-31G* scaling factor (0.8953) published by Scott and Radom (47). Trends in these were mirrored in vibrational frequencies of the pBP/DN* fully optimized structures where calculated. The pBP/DN* DFT method was benchmarked against higher level DFT methods by comparing singlet–triplet energies for unsubstituted, 4-chlorophenyl and 4-methylphenyl ions with previously published data. Singlet–triplet splittings were obtained at the pBP/DN*//HF/6-31G* level and, where practical, at the pBP/DN* level.

Isodesmic rxns. [1]–[3] were used to evaluate the relative hydration energies of 4-methylphenyloxenium ion **13b** and 4-biphenylyloxenium ion **13c** relative to the parent phenyloxenium ion **13a** as well as the relative stabilities of 4-methylphenylnitrenium ion **14b** and 4-biphenylylnitrenium ion **14c** relative to the parent phenylnitrenium ions **14a**. Relative hydration energies of phenyloxenium ion **13a** and phenylnitrenium ion **14a**, 4-methylphenyloxenium ion **13b** and 4-methylphenylnitrenium ion **14b**, and 4-biphenylyloxenium ion **13c** and 4-biphenylylnitrenium ion **14c** were determined likewise.

Isodesmic reactions were carried out using: (*i*) HF/6-31G* energies without electron correlation; (*ii*) pBP/DN*//HF/6-31G* with electron correlation and including ZPEs; (*iii*) pBP/DN*//HF/6-31G* with electron correlation, including ZPEs and free energies at 298.15 °C. A comparison of isodesmic reaction energies confirms that, for the most part, the inclusion of electron correlation or thermodynamic quantities makes little difference to the results. Where all relevant species could be fully optimized at the pBP/DN* level, isodesmic energies were almost identical to those obtained by the pBP/DN*//HF/6-31G* method.

Energies are given in atomic units (au) or kcal mol^{-1}. Bond lengths are given in Å and vibrational frequencies are reported in cm^{-1}. Dipole moments are given in Debye (D). Energies for all ions and molecules in this study are presented in Tables 1 and 2.

Results and discussion

Singlet–triplet splittings

Energies of singlet and triplet states of **13a**–**13c** and **14a**–**14d** as well as S_0–T_1 splittings at the HF/6-31G*, pBP/DN*//HF/6-31G*, and pBP/DN* levels are presented in Table 1.

S_0–T_1 splittings for unsubstituted-, **14a**, 4-methyl-, **14b,** and 4-chlorophenylnitreniumions, **14d**, have been determined previously at the BPW91/cc-pVDZ level and indicate that methyl and chloro (S_0–T_1 = –21.9 and –21.3 kcal mol^{-1}, respectively) lower the singlet state marginally relative to the triplet state when compared to phenylnitrenium ion (S_0–T_1 = –18.8 kcal mol^{-1}) (44). The pBP/DN* level performed

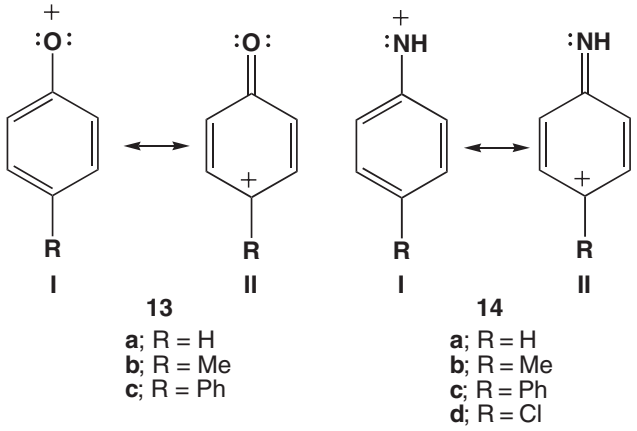
similarly for the unsubstituted and 4-methylphenylnitrenium ion (S_0–T_1 = –19.0 and –22.6 kcal mol^{-1}) and the splitting for the 4-chlorinated analogue was marginally higher (–24.5 kcal mol^{-1}). While there are no experimental values with which to compare these computed splittings, the pBP/DN* method works at least as well as Cramer's density functional approach using the correlation consistent polarized Valence double zeta basis set (44).



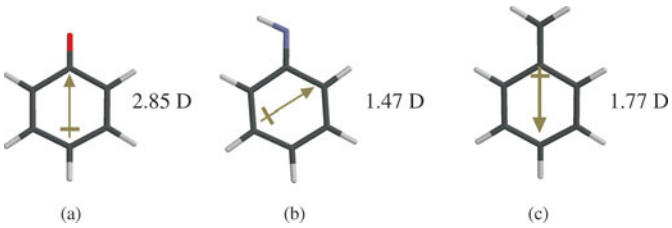


Table 1 gives the S_0–T_1 energy differences for phenyloxenium **13a** and its 4-methyl and 4-phenyl counterparts (**13b** and **13c**). HF/6-31G* predicts triplet states to be marginally lower than the singlet states. However, as expected, the inclusion of electron correlation at the pBP/DN* level radically alters the singlet state energy relative to the triplet state, at least in the cases studied. SCF convergence difficulties prevented calculation of the triplet state of **13c**, but the S_0–T_1 energies for **13a** and **13b** (–11.4 and –16.4 kcal mol^{-1}, respectively) indicate that, like phenylnitrenium ions, the donor methyl substituent stabilized the singlet state relative to hydrogen. While the S_0–T_1 differences are negative, the magnitude of the splitting is smaller than that found for the corresponding phenylnitrenium ions (–19.0 and –22.6 kcal mol^{-1}) although the impact of the donor methyl group appears greater in the oxenium ion case. The single point pBP/DN*//HF/6-31G* method, for which a value could also be obtained for **13c**, shows a similar trend for **13a** and **13b**, with comparable singlet–triplet splittings. However, the results indicate that a 4-phenyl group more strongly stabilizes the singlet state relative to the triplet state. This stabilization (–8.6 kcal mol^{-1} relative to **13a**) is significantly greater than that computed for the corresponding nitrenium ion (–3.2 kcal mol^{-1}).

In these reduced valence cations, it is expected that electron-donating groups will stabilize singlet states more than the triplets in line with conventional molecular orbital arguments; cationic resonance stabilization results in lowering in energies of valence electrons (in the HOMO), but the triplet states are radical-like, having one electron localized in a p_y orbital on the heteroatom and one more electron in the π system than the S_0 state. However, when compared to phenylnitrenium ions **14**, the greater stabilization by methyl and phenyl relative to hydrogen in the phenyloxenium ion case suggests that there is greater localization of positive charge on the 4 position. In valence bond terminology, there

is a greater preponderance of (II) in the resonance hybrid of **13** than is the case in **14**. The HF/6-31G* S_0 and T_1 ground-state geometries of **13c** are planar, signifying extensive π delocalization into the distal ring in both species. However, this would be expected to be more important in the singlet state than in the triplet state; while localization of charge on the 4 position in phenyloxenium ion is a consequence of the electronegativity of oxygen, in the triplet state there is no similar driving force for spin localization onto that position. The barriers to rotation about the connecting bond for the S_0 and T_1 states, computed at the pBP/DN*//HF/6-31G* level from the orthogonal conformations, are 18.6 and 2.4 kcal mol^{-1}, respectively. In addition, the interconnecting bond in the singlet state (1.421 Å) is considerably shorter than that in the triplet state (1.431 Å).

Properties of S_0 state phenyloxenium, phenylnitrenium, and phenylcarbenium ions

Evidence for a higher degree of localization of positive charge at the 4 position in **13** relative to **14** and **15** can be found in the properties of their respective S_0 states. Figure 1 illustrates the orientations and magnitudes of HF/6-31G* computed dipole moments in phenyloxenium **13a**, phenylnitrenium **14a**, and phenylcarbenium **15a** ions.

The electron deficiency in **15a** is clearly on the exocyclic carbon (Fig. 1*c*). In contrast, the magnitude and orientation of the dipole moment predicted for S_0 phenyloxenium ion **13a** clearly indicates a strong localization of positive charge at the 4 position in the ring. From the magnitude and orientation of the dipole moment in **14a**, appreciably less charge must reside on the ring. The contribution to the dipole in the direction of nitrogen and along the axis of the ring-to-nitrogen bond is estimated at 1.41 D, considerably less than for **13a**.[3] While computed charges should be treated with caution, in support of this, HF/6-31G* electrostatic charges at *O* in **13a** and *NH* in **14a** are –0.36 and –0.16, respectively, and for each species, total electrostatic charges at the ortho carbons are respectively +0.06 and –0.09 while at the para carbon they are calculated to be +0.4 and +0.24.

Greater localization of charge at the 4 position in **13** is evident from the optimized ground-state geometries. HF/6-31G* optimized geometries for **13a**, **14a**, and **15a** are presented together with those of the respective 4-hydroxylated products **16a**, **17a**, and **18a** in Fig. 2. A comparison of the bond lengths of **13a** (Fig. 2*a*) with those for **16a** (Fig. 2*d*) clearly indicates that the phenyloxenium ion has a stronger carbonyl bond than the hydration product as evidenced by the shorter C—O bond length. In addition, the degree of bond alternation around the ring in **13a** and **16a** is relatively similar. In contrast, the C—N bond in **14a** (Fig. 2*b*) is longer than that in the neutral imine (Fig. 2*e*). Although there is bond alternation around the ring, a comparison with that in **13a** (Fig. 2*a*) indicates a smaller degree of alternation in the nitrenium ion. In the carbenium ion case (Fig. 2*c*), the geometry accords with the exocyclic cationic form; the CH_2—C bond, in this case, is much longer than the cross-conjugated double bond in the hypothetical hydration product **18a** (Fig. 2*f*).

The short C=O bonds and high degree of alternation in the phenyl rings was reproduced in the 4-methyl (**13b**) and 4-biphenylyl (**13c**) cases and this was better reflected in both the C=O and the symmetric and antisymmetric $C_2{=}C_3$ ($C_5{=}C_6$) vibrational frequencies determined from full frequency analyses on the S_0 states of **13a**–**13c** and **14a**–**14c**. These, together with the vibrational frequencies for the hydrated adducts **16a**–**16c** and **17a**–**17c**, are presented in Table 3.

Introduction of a 4-methyl and 4-phenyl substituent stabilizes positive charge at the 4 position or, in valence bond terms, the resonance hybrid II of **13**. This is evidenced by greater differences between the C=O vibrational frequencies in **13b** and **13c** relative to the corresponding hydrated adducts **16b** and **16c**. While the $C_1{=}C_2/C_5{=}C_6$ symmetric and asymmetric stretch frequencies are lower than those in the neutral hydrated adducts, these too increase with electron donor substitution reflecting strengthening of the C=C bonds (Table 3). The effect of the 4 substituents upon the corresponding nitrenium ions is, however, much more marked. While the C=N stretch frequencies in **14a**–**14c** are significantly lower than those in the hydrated adducts **17a**–**17c**, the difference reduces by 20 and 47 cm^{-1}, respectively, upon introduction of a 4-methyl and 4-phenyl substituent. This indicates that while the oxenium ion **13** is essentially in resonance form II, the nitrenium ion **14** has an appreciable contribution from I; upon substitution by an electron donor methyl or phenyl group, the proportion of II is increased more markedly leading to larger changes in C=NH vibrational frequencies. In other words, unlike **13a**, **14a**, on account of the reduced electronegativity of nitrogen, can still sustain some positive charge on the nitrogen. This picture

[3] Dipole moment = 1.468 D, x = 1.16, y = 0.000, z = 0.890, CNH angle = 114°; the component from the N—H bond in the z direction, which is along the C—N bond, is –(1.16 tan 24°) = –0.516 D.

accords with reactivity patterns of arylnitrenium ions in that nucleophiles react on both the ring and at nitrogen (4–7, 12, 14, 48, 49).

Relative stabilities

Isodesmic rxn. [1] was used to estimate the hydration energies of phenyloxenium ions **13a**–**13c** relative to their corresponding nitrenium ions **14a**–**14c** and reflect relative stabilities of the correspondingly substituted ions.

From energies in Tables 1 and 2, the isodesmic energies from eq. [1] were calculated at the three levels indicated in

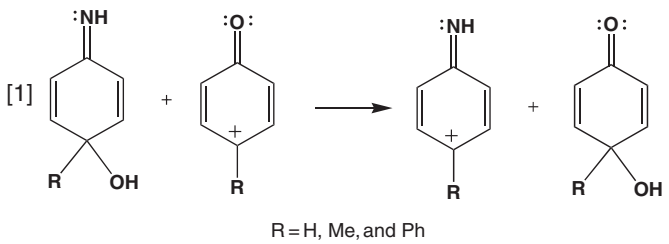

Table 4. The data show these energies to be largely independent of electron correlation as well as ZPEs and free energies in line with previous findings (50). The negative values indicate that, relative to their hydrated adducts **17** and **16**, phenylnitrenium ions are, in all three instances, more stable than the corresponding phenyloxenium ions, in line with their more delocalized positive charge. The difference between stabilities of **14c** and **13c** is in accord with the relative lifetimes of these ions in aqueous solution as determined from our competition reactions with azide (300 ns in the case of **14c** as opposed to 12 ns in the case of **13c** at 30 °C (37)). However, while a 4-methyl group exerts only a small influence upon the energies, the 4-phenyl group clearly provides greater relative stabilization to **13c** than to **14c** (the energy difference reduces in magnitude from 18 to 19 kcal mol^{-1} in the case of unsubstituted and methylated ions to 11 kcal mol^{-1} in the case of biphenylyl ions).

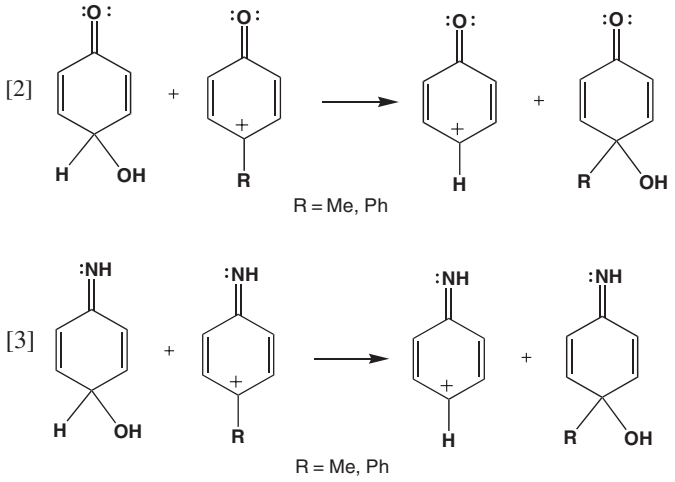

A similar conclusion can be reached from isodesmic reactions comparing the relative hydration energies of 4-methyl- **13b** and 4-biphenylyloxenium ions **13c** with the

unsubstituted ion **13a** (rxn. [2]) and rxn. [3] that gives corresponding estimates for the nitrenium ions **14b** and **14c** relative to **14a**.

Data for rxns. [2] and [3] in Table 4 clearly indicate that both methyl and phenyl stabilize both ions (positive values). However, whereas a 4-methyl group results in similar stabilization of the ions **13a** and **14a**, a 4-phenyl substituent stabilizes phenyloxenium ion by between 8 and 9 kcal mol^{-1} relative to the phenylnitrenium ion. This is a critical difference. This stabilization accounts for the fact that it is possible to generate and trap **13c** in aqueous media in a similar manner to the generation and trapping of **14b** and **14c** (4, 13, 16, 17, 37, 50). However, **13b** could not be observed under any of the conditions used for the trapping of **13c** (37, 38). We estimate, using the differences in hydration energies from isodesmic rxn. [2] (Table 4), and previously published correlations of nitrenium ion lifetimes and hydration energies of rxn. [3] that the lifetime of the 4-methylphenyloxenium would be of the order of 3–5 ps, approaching that of a transition state rather than an intermediate (38, 50).

The increased stabilization of phenyloxenium ion by a 4-phenyl group relative to phenylnitrenium ion also manifests itself in the ground-state geometries of the two ions (Fig. 3). Whereas **15c** and **14c** are nonplanar with inter-ring dihedrals of 22° and 28°, respectively, **13c** is computed to be planar at the HF/6-31G* level. The extent to which there is overlap between the two rings is also evident from the length of the connecting bonds as well as the barriers to rotation around the rings. The twist angles in biphenyls are determined by a balance between electronic and steric influences. In the case of **13c**, the resonance interaction is strong enough to overcome the strain imposed by the repulsion between *m* and *o′* hydrogens and the barrier to rotation about the C4—C4′ bond is clearly significantly higher than that for **14c** and **15c**.

The degree of delocalization in **13c**, **14c**, and **15c** clearly manifests itself in the nature of the LUMOs of all three. Relative contributions to the LUMO at the exocyclic atom and the 4 positions vary inversely (Fig. 4) and similar variations in LUMO contributions were found for the corresponding phenyl- and 4-methylphenylenium ions. Accordingly, in aqueous conditions, attack of water at the 4 position is the major process with biphenylyloxenium ion (37, 38), while biphenylylcarbenium ion reacts at the benzylic position. As alluded to previously, biphenylylnitrenium reacts with water at the 4 position, but is also known to react at nitrogen (4–7, 12, 14, 48, 49). In this series, there is also a progressively greater contribution to the LUMO from the distal ring from twisted **15c** to planar **13c** (Fig. 4). Solvolysis studies on biphenylyloxenium ion indicate that water ($k_s = 8.4 \times 10^7$ s^{-1}) and, to a degree, acetate ($k_{OAc} = 2.8 \times 10^8$ $(mol/L)^{-1}$ s^{-1}) are more selective nucleophiles than Br^- ($k_{Br^-} = 3.9 \times 10^9$ $(mol/L)^{-1}$ s^{-1}) and azide ($k_{Az} = 6.5 \times 10^9$ $(mol/L)^{-1}$ s^{-1}) (38). Our experimental studies have detected addition of water and acetate to the 4 position in 4-biphenylyloxenium ion (37). With the more reactive azide, the major products were **6** and **7**. While reversible attack of azide at the 4 position cannot be discounted, the formation of these products reflects the lower selectivity of azide when compared to water. In addition, the formation of the 4′-azidobiphenol (**7**) from azide–water competition reactions with **3** (Scheme 1) and the failure to detect the attack of azide at the 4′ position on the corresponding nitrenium ion, reflects the attendant planarity in this ion and the increased delocalization of the positive charge in **13c**. Bromide appeared to react on **13c** giving only 2-bromo-4-biphenol (37).

Conclusion

Phenyloxenium ions **13** are predicted to have a S_0 ground state that is lowered, relative to the T_1 state, by electron donor substituents. Analysis of computed ground-state geometries and IR vibrational frequencies shows that phenyloxenium ion is best described as a 4-oxo-2,5-cyclohexadienyl cation. Accordingly, it is stabilized effectively by a 4-phenyl substituent, which is coplanar to maximize charge delocalization. This results in products from attack of

Fig. 4. LUMO contributions to: (*a*) 4-biphenylyloxenium ion **13c**, (*b*) 4-biphenylylnitrenium ion **14c**, and (*c*) 4-biphenylylcarbenium ion **15c**.

nonselective nucleophiles like azide on both rings. The 4-methyl analogue **13b** is predicted to be considerably less stable in support of the experimental finding that it cannot be observed under conditions in which **13c** is readily detected. Relative to their hydrated products, 4-biphenylyloxenium ion is predicted to be less stable than 4-biphenylylnitrenium ion in support of their respective lifetimes in aqueous conditions. The difference in properties between nitrenium and oxenium ions can be ascribed to differences in the electronegativity of oxygen and nitrogen. Whereas nitrogen can sustain partial positive charge, the more electronegative oxygen atom in the phenyloxenium ion causes a high degree of charge localization on the ring. The attendant destabilization of oxenium ions relative to nitrenium ions is reflected in the aqueous solution lifetimes of **13c** and **14c** and in the difference in the ability to detect **14b** and **13b**.

The role of molecular geometry in the Wolff rearrangement of α-diazocarbonyl compounds — Conformational control or structural constraints?[1]

Vladimir V. Popik

Abstract: Relaxed scans of potential energy surfaces for the loss of nitrogen from four different diazocarbonyl compounds: 3-diazo-2-butanone (**1**), 2-diazocyclohexanone (**2**), methyl diazomalonate (**3**), and diazo Meldrum's acid (**4**), were conducted at the B3LYP/6-31+G(d,p) level. The geometries of species and transition states involved in the process were optimized at the B3LYP/6-311+G(3df,2p) level, while electronic energies were computed using the MP2(full)/aug-cc-pVTZ method. These calculations suggest that the rigidity of cyclic molecules, rather than the conformational structure of the starting diazocarbonyl compounds, defines the pathway of the dediazotization reaction. In acyclic diazocarbonyl compounds, loss of nitrogen results in the formation of a carbene, which is stabilized by the overlap of the system of carbonyl group and the unshared electron pair of a singlet carbene. On the contrary, in small- to medium-sized cyclic systems, carbonyl carbenes are unable to attain a stabilizing orthogonal conformation. Consequently, cyclic carbonyl carbenes are less stable, and the concerted Wolff rearrangement becomes the predominant process. Transition states for the concerted Wolff rearrangement and for the formation of carbonyl carbenes have a very similar geometry.

Key words: diazocarbonyl compounds, Wolff rearrangement, conformation, carbene, ketene.

Résumé : Opérant au niveau B3LYP/6-31+G(d,p) de la théorie, on a effectué un balayage des surfaces d'énergie potentielle pour la perte de l'azote à partir de quatre composés diazocarbonyles différents: 3-diazobutan-2-one (**1**), 2-diazocyclohexanone (**2**), diazomalonate de méthyle (**3**) et l'acide diazo de Meldrum (**4**). Les géométries des espèces et des états de transition impliqués dans le processus ont été optimisées au niveau B3LYP/6-311+G(3df,2p) alors que les énergies électroniques ont été calculées à l'aide de la méthode MP2(full)/aug-cc-pVTZ. Ces calculs suggèrent que la rigidité des molécules cycliques, plutôt que la structure conformationnelle des composés diazocarbonyles de départ, définit la voie réactionnelle de la réaction de dédiazotation. Dans les composés diazocarbonyles acycliques, la perte d'azote conduit à la formation d'un carbène qui est stabilisé par un recouvrement du système de groupe carbonyle et de la paire d'électrons non partagée du carbène singulet. Au contraire, dans les composés comportant des cycles petits ou moyens les carbonyl carbènes ne sont pas en mesure d'atteindre une conformation orthogonale stabilisante. En conséquence, avec les composés cycliques, les carbonyl carbènes sont moins stables et le réarrangement de Wolff concerté devient le processus prédominant. Les états de transition pour le réarrangement de Wolff concerté et la formation d'un carbonyl carbène ont des géométries très semblables.

Mots clés : composés diazocarbonyles, réarrangement de Wolff, conformation, carbène, cétène.

[Traduit par la Rédaction]

Introduction

Thermolysis or light-induced decomposition of α-diazocarbonyl compounds usually leads to products formed by the trapping of two different reactive intermediates, i.e., ketenes and α-carbonyl carbenes (1, 2). The generally accepted explanation of this dual reactivity is presented in Scheme 1. The loss of nitrogen from α-diazocarbonyl compounds results in the formation of α-carbonyl carbenes, which can exist in two different electronic states, i.e., singlet or triplet (3–5). Thermal decomposition or direct photolysis of α-diazocarbonyl compounds is usually dominated by the chemistry of singlet carbenes. Carbenes are very reactive species and readily undergo an O-H or C-H insertion, add to π bonds, or form ylides (6). Alternatively, an α-carbonyl carbene can rearrange to form a ketene. The latter can also be formed directly from the diazo compound, bypassing the α-carbonyl carbene step by the migration of the substituent X concerted with the loss of nitrogen (1, 7). Ketenes react with nucleophiles to produce corresponding enols, which then rapidly ketonize to yield the final product — carboxylic acid derivatives (8). The overall process is known as the Wolff rearrangement.

The ratio of ketene derived to carbenic products depends on the relative rates of bimolecular reactions of the α-carbonyl

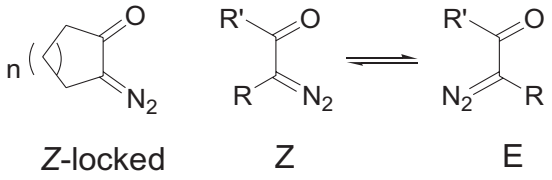
Scheme 2.



carbene and its rearrangement to ketene. The concentration and the reactivity of carbene trapping reagents also affect the outcome of the reaction.

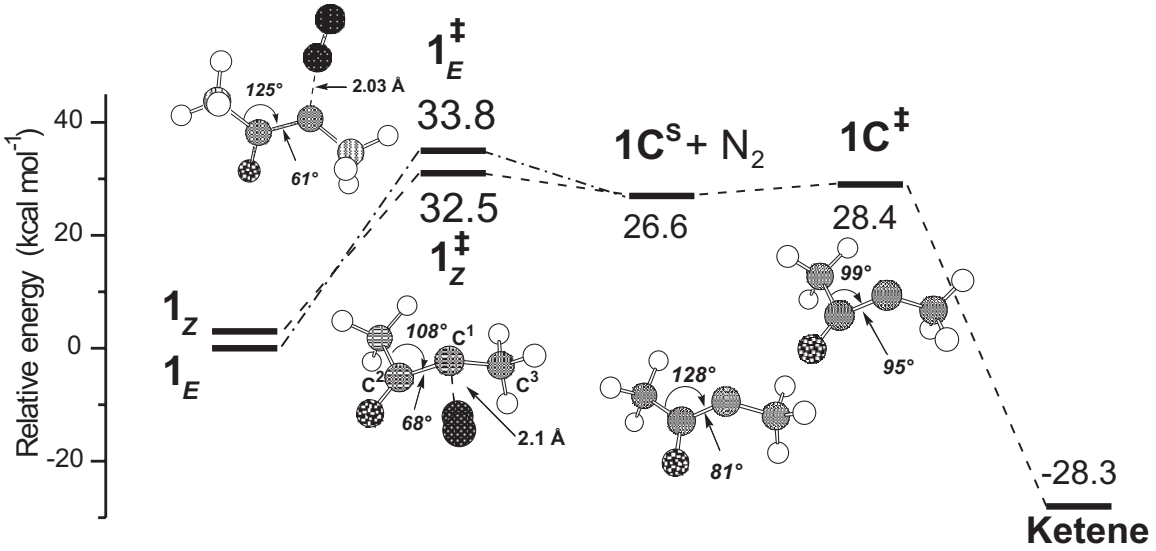
Another important feature of an α-carbonyl carbene intermediate, which allows for the detection of even very short-lived carbenes, is α-carbonyl carbene – α-carbonyl carbene isomerization, which is believed to proceed via an antiaromatic oxirene (Scheme 2) (9). Isotopic labeling of the diazo or carbonyl group carbon atom is commonly used to detect carbonyl carbene isomerization (10, 11).

The factors that direct the decomposition of α-diazocarbonyl compounds into a concerted Wolff rearrangement or carbene pathway are still not well-understood. It has been observed that cyclic diazo ketones usually produce high or quantitative yields of ketenes; while in the case of their acyclic analogs, the Wolff rearrangement is often accompanied or even completely suppressed by carbene reactions (12, 13). The low-temperature NMR experiments unequivocally proved that α-diazocarbonyl compounds exist as an equilibrium of two conformations with *s*-Z and *s*-E arrangements of diazo and carbonyl groups (Scheme 3) (14, 15). The *s*-Z isomer usually predominates in the equilibrium, unless steric repulsions of substituents R and R′ destabilize it in favor of the *s*-E form (3, 16).

Based on the differences in the reactivity of 3,3,6,6-tetramethyl-2-diazocyclohexanone, which is locked in the *s*-Z configuration, and 2,2,5,5-tetramethyl-4-diazo-3-hexanone,[2] which is forced to adopt the *s*-E conformation by bulky *tert*-butyl substituents, Kaplan and co-workers (13, 14*a*, 14*b*) postulated that *s*-Z conformers of α-diazocarbonyl compounds undergo a concerted Wolff rearrangement to ketenes, whereas the *s*-E form loses nitrogen to produce α-carbonyl carbene. The latter can undergo isomerization into ketenes or be trapped by external reagents. While this hypothesis has been adopted by other authors (6*a*, 17), some established *s*-E diazo ketones produce ketenes with ease (18). In addition,

Scheme 3.

the Wolff rearrangement of acyclic *Z*-diazo ketones is often accompanied by isotope scrambling, indicating participation of the α-carbonyl carbene (10).



To get a better understanding of the influence of structural factors on the reactivity of α-diazocarbonyl compounds, we undertook a detailed quantum mechanical study of four α-diazocarbonyl compounds: 3-diazo-2-butanone (**1**), 2-diazocyclohexanone (**2**), methyl diazomalonate (**3**), and diazo Meldrum's acid (**4**).

Diazo ketone **1** exists in solutions as a mixture of E and Z isomers (14*d*, 19) and produces a high yield of the Wolff rearrangement product upon irradiation (20). This reaction is accompanied by a complete scrambling of the ^{13}C label, indicating that it proceeds via the formation acetylmethyl carbene (10). Diazocyclohexanone **2** also undergoes the Wolff rearrangement upon irradiation or thermolysis (12*a*); however, isotope labeling experiments suggested a concerted mechanism (11). One of the most impressive examples of the structural control of the Wolff rearrangement is found in the family of diazomalonic acid esters. Cyclic isopropylidene diazomalonate (**4**) undergoes an efficient Wolff rearrangement both thermally (21) and photochemically (21, 22), while acyclic diazomalonates, such as **3**, produce only carbenic products in solution (23, 24). The reasons for such different reactivity are not clear, since **3** has the same Z,Z conformation of the 2-diazo-1,3-dicarbonyl fragment as the cyclic diazodiester **4** (23*c*).

[2] Geometrial optimization of this diazo compound that we conducted at the B3LYP/6-311+G(3df,2p) level of theory produced a planar *s*-E conformation.

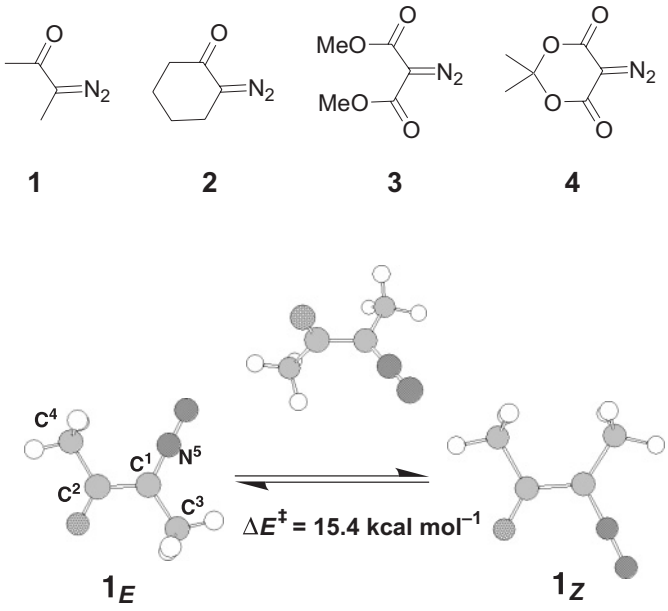
Structures represent B3LYP/6-311+G(3df,2p) optimized geometries of α-carbonyl carbene $\mathbf{1C^S}$ and transition states for the loss of nitrogen from *Z*-($\mathbf{1}_Z^{\ddagger}$) and *E*-($\mathbf{1}_E^{\ddagger}$) forms of the substrate and the Wolff rearrangement of the carbene ($\mathbf{1C}^{\ddagger}$). The bond distances are shown in Å, while bond angles and dihedral angles (highlighted in *italics*) are in degrees.

Results and discussion

Computational methods



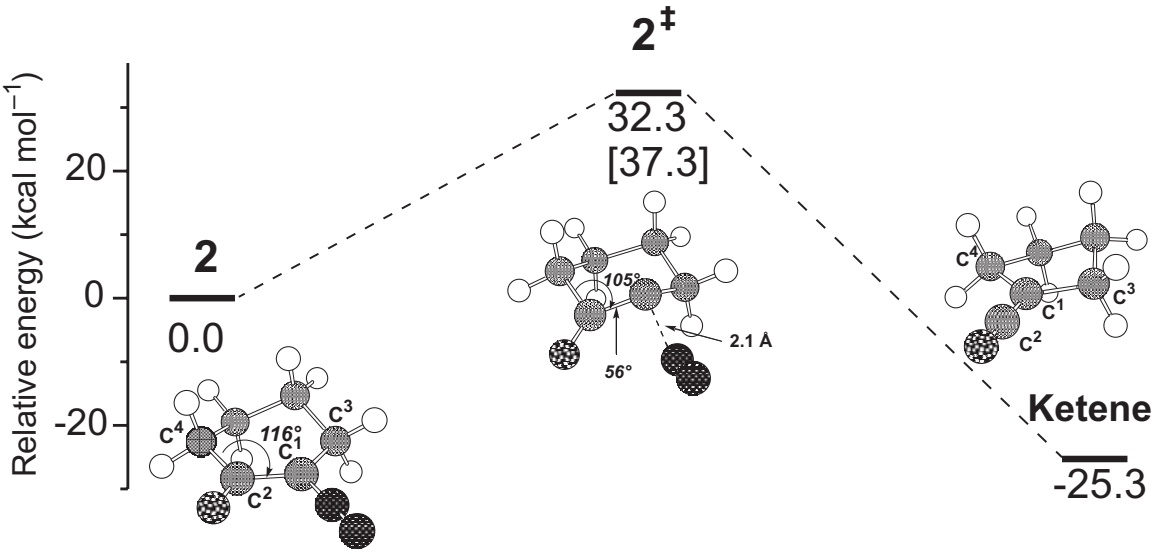
Geometries of the diazocarbonyl compounds **1**–**4** and the species involved in their decomposition were preoptimized at the B3LYP/6-31+G(d,p) level and then reoptimized using the extended triple-ζ 6-311+G(3df,2p) basis set. Some structures were also optimized at the MP2/6-31+G(d,p) level, while single-point energy calculations were conducted using the MP2(full)/aug-cc-pVTZ method.

3-Diazo-2-butanone (**1**) can exist in *E*-($\mathbf{1}_E$) and *Z*-($\mathbf{1}_Z$) conformations. According to the DFT calculation, both conformations are planar and the E conformation is 1.6 kcal mol^{-1} lower in energy (Scheme 4). In the transition state for the E to Z isomerization, the diazo group is orthogonal to the carbonyl group, and the process has an activation barrier of 15.4 kcal mol^{-1}. These numbers agree well with experimental values ($\Delta H°$= 1.45 kcal mol^{-1} and $\Delta H^{\ddagger}$ = 15.6 kcal mol^{-1} in $CDCl_3$) (1 cal = 4.184 J) (14*d*).

The loss of nitrogen from both conformers of diazobutanone **1** results in the formation of a singlet carbonyl carbene $\mathbf{1C^S}$ (Fig. 1). The electronic energies and representative structural parameters for the singlet carbenes $\mathbf{1C^S}$, transition states for deazotization of *E*-($\mathbf{1}_E^{\ddagger}$) and *Z*-($\mathbf{1}_Z^{\ddagger}$) conformers of diazobutanone, as well as for the Wolff rearrangement of the α-carbonyl carbene ($\mathbf{1C}^{\ddagger}$) are shown in Fig. 1.

The carbonyl group in singlet carbene $\mathbf{1C^S}$ is almost orthogonal to the plane of the carbene (C2-C1-C3, Fig. 1). Such geometry provides a better overlap of the orbital containing an unshared pair of electrons localized on the carbene carbon with the π system of the carbonyl groups. The triplet acetylmethyl carbene ($\mathbf{1C^T}$), on the other hand, was found to be planar. Similar differences in geometry were reported for several other α-carbonyl carbenes (21, 23*c*, 25). It is interesting to note that the B3LYP/6-311+G(3df,2p) calculations predict that triplet $\mathbf{1C^T}$ is slightly higher in energy

Scheme 4.



($\Delta E°$ = 0.8 kcal mol^{-1}) than its singlet counterpart, indicating that this α-carbonyl carbene has the singlet ground state. This conclusion is supported by the results of MP2 calculations. Optimization of $\mathbf{1C^T}$ and $\mathbf{1C^S}$ geometries at the UMP2/6-311+G(d,p) level produces exactly the same relative stability. Single-point UMP2(full)/aug-cc-pVTZ calculations predict an even larger singlet–triplet gap of –6.0 kcal mol^{-1}.

Another interesting feature of the thermal decomposition of diazo ketone **1** is the difference in the thermal stability of E and Z conformers. While the E conformation is more stable and is predominant in the equilibrium, the transition state for the decomposition of the Z conformer ($\mathbf{1}_Z^{\ddagger}$) is lower in energy by 1.3 kcal mol^{-1} (or 2.2 kcal mol^{-1} at the

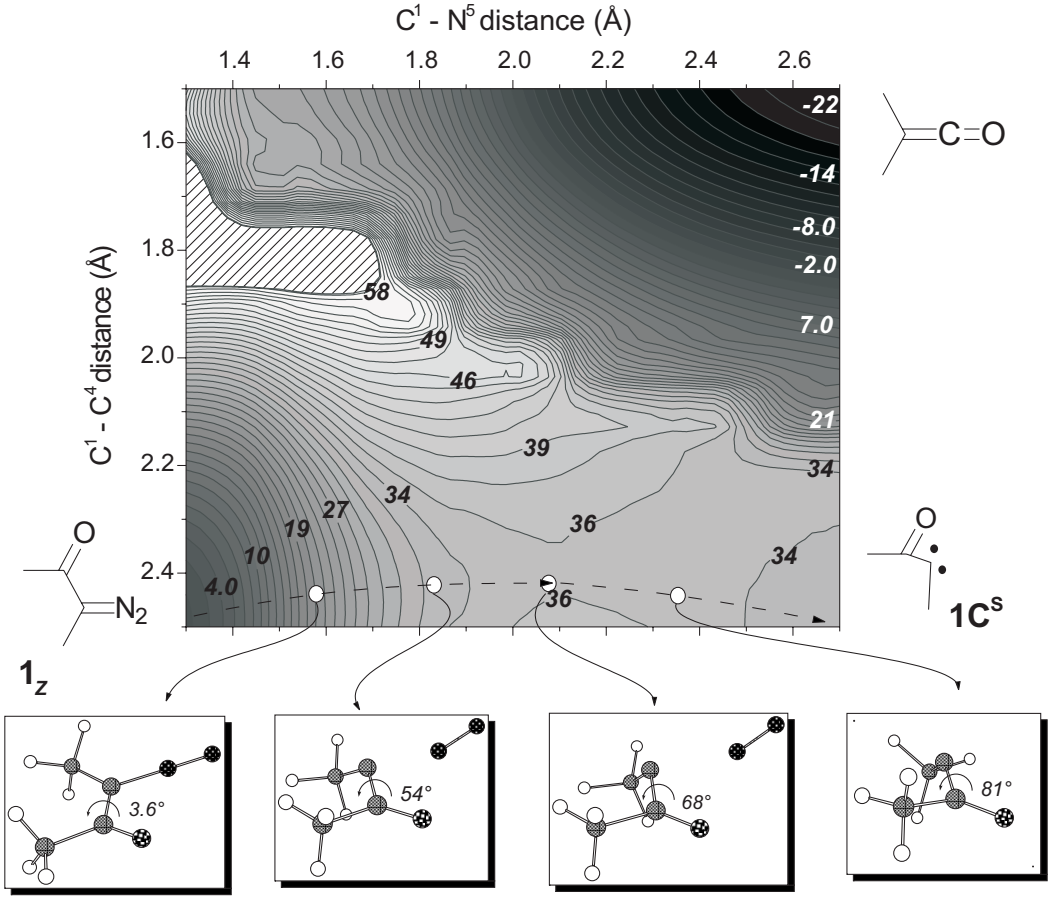
Fig. 2. Schematic potential energy profile for the decomposition of 2-diazohexanone (**2**). Energy are calculated at the B3LYP/6-311+G(3df,2p) and MP2(full)/aug-cc-pVTZ (in brackets) levels. Structures represent B3LYP/6-311+G(3df,2p) optimized geometries of **2**, transition states for the loss of nitrogen $\mathbf{2}^{\ddagger}$, and the cyclopentanylidene. The bond distances are shown in Å, while bond angles and dihedral angles (highlighted in *italics*) are in degrees.

MP2(full)/aug-cc-pVTZ level). A similar difference was observed for diazoacetone (1.5 kcal mol^{-1}).[3] These results suggest that the thermal decomposition of diazobutanone **1** proceeds mostly through the Z conformer, while photochemical reactions are dominated by the excitation of the E form of the substrate. The geometries of the transition states $\mathbf{1}_Z^{\ddagger}$ and $\mathbf{1}_E^{\ddagger}$ are also quite different. The carbonyl group valence angle in $\mathbf{1}_E^{\ddagger}$ is 125°, which is higher than in the starting material (116°) and is very close to the resulting carbene ($\mathbf{1C}^S$, 128°). The carbonyl angle in $\mathbf{1}_Z^{\ddagger}$, on the other hand, is even smaller than in the starting diazobutanone **1**. At first we interpreted this observation as an indication of a concerted mechanism for the *Z*-diazobutanone. However, IRC calculations, as well as optimization of the $\mathbf{1}_Z^{\ddagger}$ structure after ca. 10% displacement along the reaction path for the normal coordinate of the imaginary vibrational frequency, connect this transition state only to carbene $\mathbf{1C}^S$ and not to dimethylketene. This observation is in sharp contrast with a recent DFT study of diazoacetone decomposition.[3] The E conformer of the latter loses nitrogen to produce a carbene, while the Z conformer undergoes a concerted Wolff rearrangement. We thoroughly explored the corresponding area of PES, but were unable to locate the transition state for the concerted Wolff rearrangement of $\mathbf{1}_Z$. A similar fluctuation of the carbonyl valence angle was previously reported in the carbene-producing decomposition of the Z,Z conformer of methyl diazomalonate (25*b*).

2-Diazocyclohexanone (**2**) has a planar Z arrangement of the diazo and carbonyl groups locked by the cyclic structure (Fig. 2). DFT calculations predict that the thermal decomposition of **2** results in a concerted Wolff rearrangement, i.e., ketene is formed directly from the diazoketone precursors without a carbene intermediate. The corresponding cyclic carbonyl carbene (**2C**) is not even a real species. Every attempt at optimization of the geometry of **2C** using the DFT, HF, or MP2 method collapsed to a ketene structure. This observation allows us to conclude that the thermal Wolff rearrangement of **2** is a truly concerted process. However, it is interesting to note that the geometry of the diazocarbonyl fragment in the transition state $\mathbf{2}^{\ddagger}$ is surprisingly similar to that of $\mathbf{1}_Z^{\ddagger}$ (Fig. 2). The carbonyl group valence angle is 105°, while the dihedral angle between the carbonyl group and carbene planes is 56°. In other words, the geometry of the transition state for the concerted Wolff rearrangement of **2** is very close to that of a free α-carbonyl carbene. The electronic energies and representative structural parameters for **2** and the transition state for the concerted Wolff rearrangement $\mathbf{2}^{\ddagger}$ are shown in Fig. 2.

The potential energy diagrams for the decomposition of **3** and **4** were reported previously (25*b*). The loss of nitrogen from any of the three conformers of **3** results in the formation of biscarbomethoxycarbene. As in the case of **1** (vide supra), we were unable to locate a transition state for the concerted Wolff rearrangement of **3**. For the cyclic isopropylidene diazomalonate **4**, on the other hand, the concerted Wolff rearrangement is the preferred decomposition pathway. The results of quantum mechanical calculations agree well with experimental data on photolysis and thermolysis of **3** and **4** mentioned in the Introduction (22–25).



Potential energy surface (PES) scans

To analyze the effect of structural factors on the thermal decomposition of diazoketones, 3-D relaxed PES scans for the decomposition of diazo compounds **1**–**4** were conducted at the B3LYP/6-31+G(d,p) level of theory. The distances between nitrogen and carbon (C1) atoms of the diazo group, as well as between C1 and the atom migrating in the Wolff rearrangement (C4 or O4), were fixed in steps, while other de-

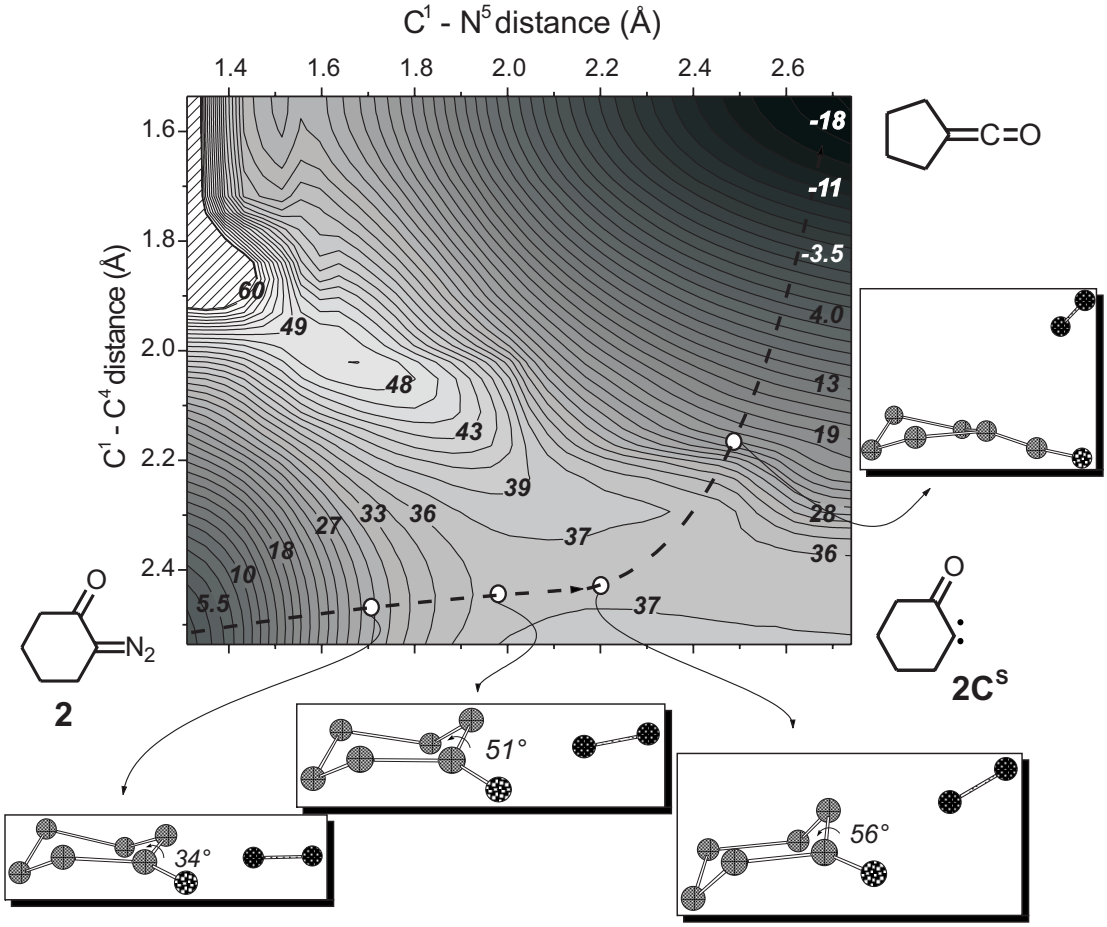
Fig. 3. Contour plot of the potential energy surface (PES) for the extrusion of nitrogen from *Z*-3-diazobutanone ($\mathbf{1}_Z$). Values shown on the isoergic lines represent the relative energy in kcal mol^{-1} (referenced to the starting diazo compound $\mathbf{1}_Z$). Structures shown under the PES plot represent optimized geometries of the system corresponding to the PES coordinates marked with empty circles.

grees of freedom were fully optimized. The bottom left corner of the contour plots correspond to the energy of the initial diazocarbonyl compound (**1**, **2**, **3**, or **4**). The extension of the C1—N bond without explicitly changing the C1—C4 (C1—O4 for **3** and **4**) distance leads to the formation of an α-carbonyl carbene (bottom right corner), while the elongation of the C1—N bond accompanied by the shortening of the C1—C4 distance leads to a ketene (upper right corner, Figs. 3–6).

The analysis of the PES plots for decomposition of the α-diazocarbonyl compounds **1**–**4**, shown in Figs. 3–6, allows us to conclude that the synchronous Wolff rearrangement is an unfavorable process for all of these substrates. Simultaneous cleavage of the C1—N bond and the migration of the substituent (C4 or O4) result in a steep rise in energy. The extrusion of nitrogen from diazo compounds **1**–**4** initially proceeds by the elongation of the C1—N bond only, while the C1—C4 (C1—O4) distance remains virtually unchanged. During this initial stage of decomposition, the carbon atom of the diazo group (C1) moves out of the plane of the carbonyl group (or groups). The changes in geometry of α-diazocarbonyl compounds **1**–**4** along the reaction path are illustrated by structures shown in Figs. 3–6.



The valley on the PES follows the elongation of the C1—N bond, eventually reaching the energy plateau at ca. 2.1–2.3 Å. In the plateau region of the PES, even significant changes in C1—N and C1—C4 (C1—O4) distances cause very little variation in energy. Transition states for both the concerted and stepwise Wolff rearrangement are located on this plateau and possess very similar geometries, which resemble that of an α-carbonyl carbene. Gradients felt by the system on the energy plateau define the outcome of the reaction, i.e., formation of the carbene or rearrangement to the ketene.

The PES plot for the decomposition of the Z conformer of 3-diazobutanone **1** shows that the energy plateau is reached comparatively early, at a C1—N distance of ca. 2.1 Å (Fig. 3). The dihedral angle between the carbonyl group and the C2-C1-C3 plane in this region is ca. 70°, which is very close to the geometry of the singlet acetylmethyl carbene ($\mathbf{1C}^{\mathbf{S}}$). There are downhill gradients leading from the plateau on the PES in the direction of the carbene $\mathbf{1C}^{\mathbf{S}}$ formation and the migration of C4. In other words, the landscape of the PES suggests the possibility of both a concerted Wolff rearrangement and an α-carbonyl carbene formation. However, the full saddle point optimization (opt = ts) of several geometries on this plateau converged to the same structure, i.e., the transition state for the carbene formation $\mathbf{1}_Z^{\ddagger}$ (vide supra).

The energy plateau on the PES for the dediazotization of **2** is also reached at a C1—N distance of ca. 2.1 Å (Fig. 4).

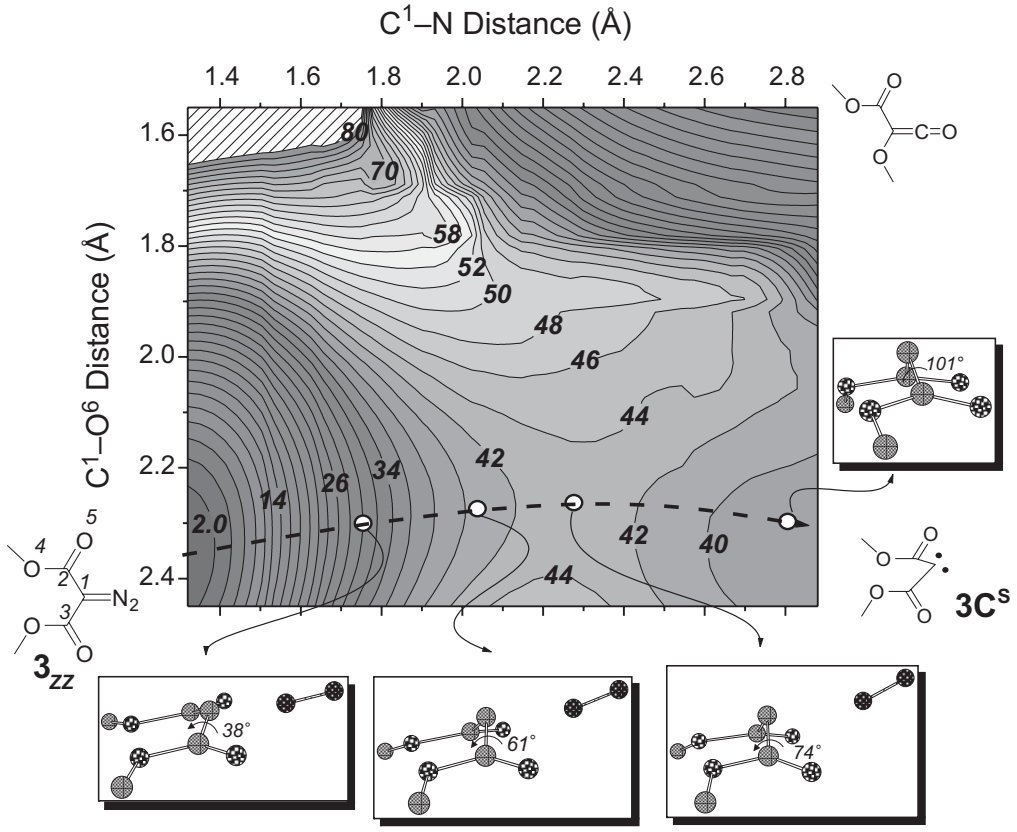
Fig. 4. Contour plot of the potential energy surface (PES) for the extrusion of nitrogen from 2-diazocyclohexanone (**2**). Values shown on the isoergic lines represent the relative energy in kcal mol^{-1} (referenced to **2**). Structures shown under the PES plot represent optimized geometries of the system corresponding to the PES coordinates marked with empty circles.

However, the deviation of C1 from planarity is substantially smaller, i.e., 51°–56°, apparently because of structural constraints. The only downhill gradient evident from the PES plot leads to the migration of the substituent C4 and the formation of the ketene. Therefore, the thermal Wolff rearrangement of **2** is predicted to be a concerted reaction. In fact, there is no energy minimum corresponding to the singlet carbonyl carbene **2C^S** (vide supra). In our opinion, this phenomenon stems from the inability of cyclic carbene **2C^S** to adopt a stable orthogonal conformation.



The landscape of PES surrounding methyl diazomalonate **3** (Fig. 5) is very similar to that of diazo ketone **1**. The extrusion of nitrogen from **3** initially proceeds by the elongation of the C1—N bond, while the C1—O4 distance remains virtually unchanged. This process is also accompanied by the shift of the carbon atom of the diazo group (C1) up from the plane of carbonyl groups reaching a dihedral angle of 74°. The energy plateau, however, is reached somewhat later, at a C1—N distance of ca. 2.25 Å, and lies higher in energy by ca. 8 kcal mol^{-1} more than in the case of **1**. This observation can be explained by the reduced ability of the ester carbonyl groups to participate in the resonance stabilization of the emerging carbene. There is a substantial downhill gradient leading the system from the high energy plateau towards the formation of biscarbomethoxycarbene **3C^S**, while the migration of the substituent (O4) is still an uphill process. The elongation of the C1—N bond beyond 2.3 Å in methyl diazomalonate **3** is, therefore, accompanied by an increase in the dihedral angle between the C3-C1-C2 plane and planes of carbonyl groups and results in an energy reduction, leading the system to the formation of a carbene (Fig. 5).

The energy plateau on the PES for the dediazotization of **4** is reached even later, at a C1—N distance of 2.45 Å and is ca. 16 kcal mol^{-1} higher than in the case of diazocyclohexanone **2** (Fig. 6). This increased energy barrier agrees well with the high thermal stability of this compound. The high activation energy of the thermal decomposition reaction is apparently due to both a reduced resonance stabilization of the emerging occupied orbital of carbene and structural rigidity, which does not allow **4** to achieve orthogonal conformation. In fact, the dihedral angle between the C2-C1-C3 plane and the carbonyl groups never extends above 60° at any point on this PES.

As a result, the elongation of the C1—N bond beyond 2.45 Å requires additional energy, while the migration of a substituent from that point on the PES is an exoergic process. In other words, **4** is predicted to undergo a concerted Wolff Rearrangement.

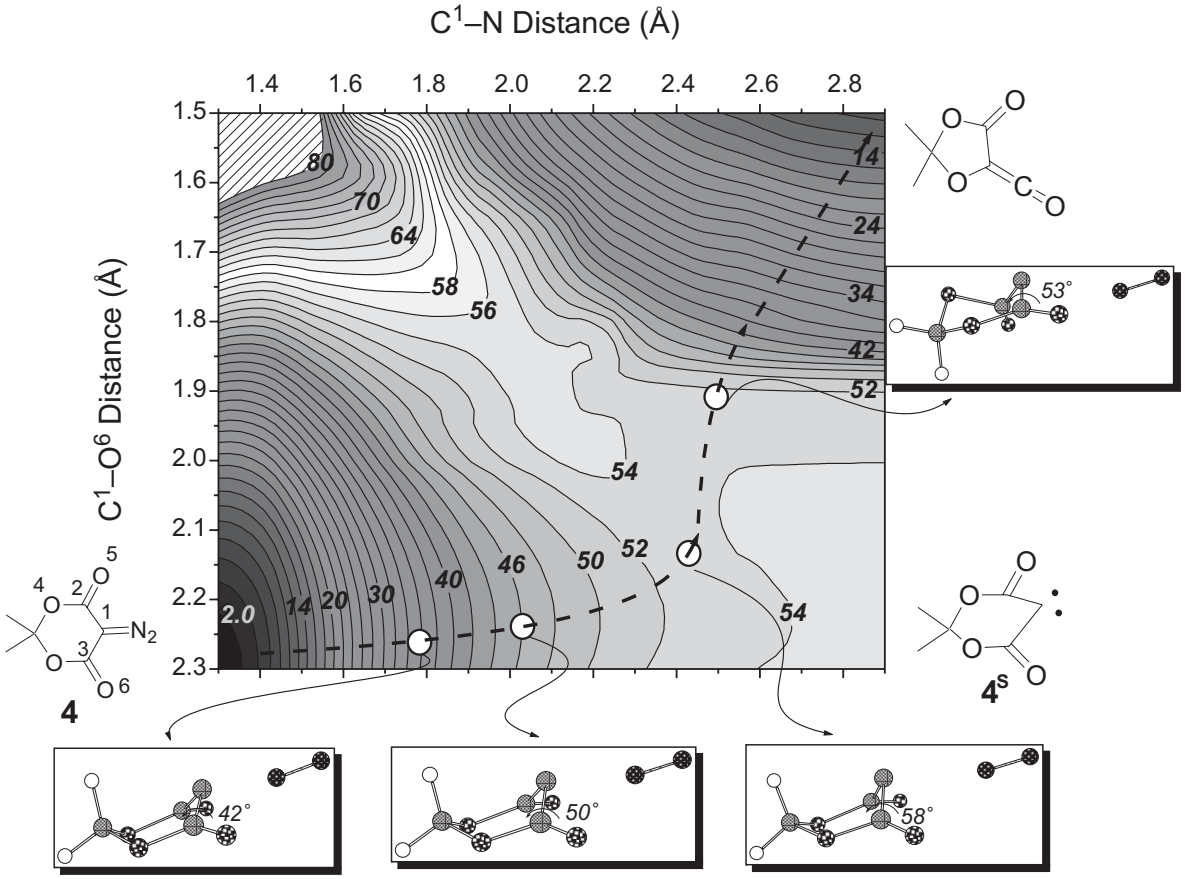
Fig. 5. Contour plot of the potential energy surface (PES) for the extrusion of nitrogen from the Z,Z conformer of methyl diazomalonate (**3**). Values shown on the isoergic lines represent the relative energy in kcal mol^{-1} (referenced to $\mathbf{3}_{ZZ}$). Structures shown under the PES plot represent optimized geometries of the system corresponding to the PES coordinates marked with empty circles.

In contrast with diazocyclohexanone **2**, the carbene **4C^S**, which can be produced from the cyclic diazomalonate **4**, is predicted to be a real intermediate by DFT calculations (21). There is an energy minimum on the PES corresponding to **4C^S**, and this structure has no imaginary frequencies. The energy well for this cyclic singlet dicarbonyl carbene is very shallow, and there's virtually no barrier ($\Delta E^{\ddagger} < 1$ kcal mol^{-1}) for the rearrangement to ketene (21). In addition, the energy of **4C^S** is higher than the energy of the transition state for the concerted Wolff rearrangement of **4**.

Conclusions

Analysis of the PES for the decomposition of four diazocarbonyl compounds — two cyclic structures with locked Z (**2**) and Z,Z (**4**), and Z (**1**) and Z,Z (**3**) conformers of their acyclic analogs — allows us to conclude that the outcome of the dediazotization reaction, i.e., the concerted Wolff rearrangement or formation of an α-carbonyl carbene, is defined by the structural constraints of the molecule. Both processes start by the extension of the C1—N bond accompanied by the out-of-plane shift of C1 until the system reaches the energy plateau at a C1—N distance in the 2.1–2.45 Å range. The direction of further transformation depends on the relative stability of the corresponding carbonyl carbene. Relatively deep energy wells correspond to carbenes produced from acyclic diazocarbonyl compounds (**1** and **3**), since they adopt an orthogonal conformation, which allows for a stabilizing conjugation of the π system of the carbonyl group with the lone pair of a singlet carbene. In cyclic diazocarbonyl compounds, such as **2** and **4**, carbenes are much higher in energy because they are unable to attain a stabilizing orthogonal conformation. Migration of the substituent, i.e., concerted Wolff rearrangement, becomes the only downhill process.



Experimental section

Theoretical procedures

Quantum mechanical calculations were carried out using the GAUSSIAN 98 suit of programs (26). Levels of theory examined ranged from the hybrid B3LYP (27) DFT calculations with the 6-31+G(d,p) (28) basis sets to the high-level composition procedure MP2(full)/aug-cc-pVTZ//B3LYP/6-311+G(3df,2p). For all the DFT calculations, zero-point vibrational energy (ZPVE) corrections, required to correct the raw relative energies to 0 K, were obtained from the B3LYP/6-31+G(d,p) method. Analytical second derivatives were computed to confirm each stationary point to be a minimum by yielding zero imaginary vibrational frequencies for the intermediates and one imaginary vibrational frequency for each transition state. The vibrational frequencies were scaled by 0.9772 (29). Initial geometry optimization, IRC calculations for transition states, and relaxed scans of poten-

tial energy surfaces were conducted at the B3LYP/6-31+G(d,p) level. In the PES scans, the C1—C4 (or O4) and C1—N coordinates were fixed in steps, while the other degrees of freedom were fully optimized. Each of the four potential energy surfaces consisted of about 160 points corresponding to different values of C1—C4 (or O4) and C1—N distances.

REVIEW / SYNTHÈSE

A comparison of the mechanisms of hydrolysis of benzimidates, esters, and amides in sulfuric acid media[1,2]

Robin A. Cox

Abstract: The mechanisms given in textbooks for both ester and amide hydrolysis in acid media are in need of revision. To illustrate this, benzimidates were chosen as model compounds for oxygen protonated benzamides. In aqueous sulfuric acid media they hydrolyze either by a mechanism involving attack of two water molecules at the carbonyl carbon to give a neutral tetrahedral intermediate directly, as in ester hydrolysis, or by an S_N2 attack of two water molecules at the alkyl group of the alkoxy oxygen to form the corresponding amide, or by both mechanisms, depending on the structure of the benzimidate. The major line of evidence leading to these conclusions is the behavior of the excess acidity plots resulting from the rate constants obtained for the hydrolyses as functions of acid concentration and temperature. The first of these mechanisms is in fact very similar to one found for the hydrolysis of benzamides, as inferred from: (1) similar excess acidity plot behaviour; and (2) the observed solvent isotope effects for amide hydrolysis, which are fully consistent with the involvement of two water molecules, but not with one or with three (or more). This mechanism starts out as essentially the same one as that found for ester hydrolysis under the same conditions. Differences arise because the neutral tetrahedral intermediate, formed directly as a result of the protonated substrate being attacked by two water molecules (not one), possesses an easily protonated nitrogen in the amide and benzimidate cases, explaining both the lack of ^{18}O exchange observed for amide hydrolysis and the irreversibility of the reaction. Protonated tetrahedral intermediates are too unstable to exist in the reaction media; in fact, protonation of an sp^3 hybridized oxygen to put a full positive charge on it is extremely difficult. (This means that individual protonated alcohol or ether species are unlikely to exist in these media either.) Thus, the reaction of the intermediate going to product or exchanged reactant is a general-acid-catalyzed process for esters. For amide hydrolysis, the situation is complicated by the fact that another, different, mechanism takes over in more strongly acidic media, according to the excess acidity plots. Some possibilities for this are given.

Key words: esters, amides, benzimidates, hydrolysis, excess acidity, mechanism, acid media.

Résumé : Les mécanismes donnés dans les manuels de chimie pour les hydrolyses tant des esters que des amides en milieu acide demandent à être révisés. Pour illustrer ce point, on a choisi les benzimidates comme composés modèles de benzamides protonés à l'oxygène. Dans des milieux contenant de l'acide sulfurique aqueux, suivant la nature du benzimidate, ils s'hydrolysent soit par un mécanisme impliquant une attaque de deux molécules d'eau au niveau du carbone portant le groupe carbonyle et ils conduisent directement à la formation d'un intermédiaire tétraédrique neutre, tel que dans le cas des hydrolyses d'esters, soit par une attaque S_N2 de deux molécules d'eau au niveau du groupe alkyle de l'oxygène alkoxy pour former l'amide correspondant ou par une combinaison des deux mécanismes. La principale ligne de signes conduisant à ces conclusions est le comportement des courbes d'excès d'acidité qui résultent des constantes de vitesse obtenues pour les hydrolyses en fonctions de la concentration de l'acide et de la température. Le premier de ces mécanismes est en fait très semblable à celui qu'on retrouve pour les benzamides, tel qu'on peut en déduire sur la base (1) de comportement semblable de la courbe d'excès d'acidité et (2) les effets isotopiques de solvant observés pour l'hydrolyse de l'amide qui est pleinement en accord avec une implication de deux molécules d'eau, mais pas avec une ou avec trois ou plus. Ce mécanisme débute essentiellement de la même manière que celui observé pour l'hydrolyse des esters dans les mêmes conditions. Les différences apparaissent parce que l'intermédiaire tétraédrique

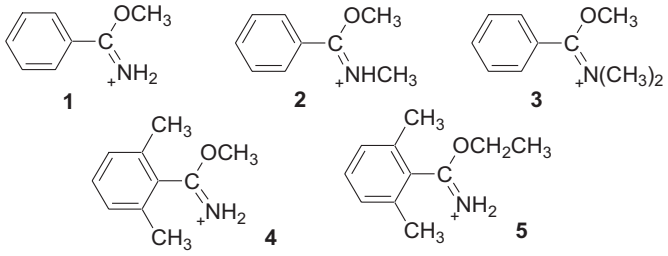
neutre, qui se forme directement par une attaque du substrat protoné par deux (pas une) molécules d'eau, comporte dans les cas de l'amide et du benzimidate, un azote qui peut facilement être protoné et ceci explique le fait que, lors de l'hydrolyse de l'amide, il n'y a pas d'échange de ^{18}O et que la réaction est irréversible. Les intermédiaires tétraédriques protonés sont trop instables pour exister dans le milieu réactionnel; en fait, la protonation d'un atome d'oxygène à hybridation sp^3 pour y placer une charge positive complète est extrêmement difficile. (Ceci signifie qu'il est peu probable que les espèces alcool ou éther protonées individuelles puissent exister dans ces milieux). Pour les esters, la réaction de l'intermédiaire conduisant au produit ou au réactif ayant subi un échange est donc un processus soumis à une catalyse acide générale. Pour l'hydrolyse des amides, la situation est compliquée par le fait que, en milieux fortement acides, selon les courbes d'excès d'acidité, un autre mécanisme, différent, prendrait le pas. On donne quelques possibilités pour ceci.

Mots clés : esters, amides, benzimidates, hydrolyse, acidité en excès, mécanisme, milieu acide.



[Traduit par la Rédaction]

Introduction

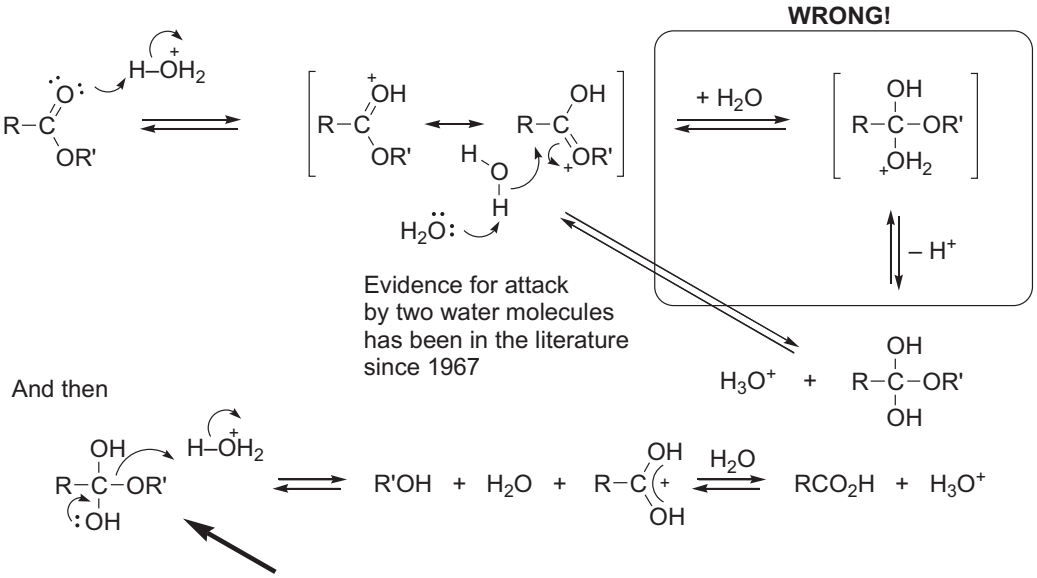
The excess acidity method for dealing with experimental data obtained as a function of acid concentration in acid media (1, 2) has shown itself to be a very useful way of obtaining information regarding the mechanisms of reactions that take place in these solutions, as well as providing standard-state pK_{BH+} and $\log k_0$ values, and $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values if data at different temperatures are available, which can be directly compared with one another and with values obtained for other reactions in aqueous and buffer media (2). Particularly for A2 reactions, the water activities in these media are often also needed (2), and it has recently been found that the values used historically for delineating reaction mechanisms in these media are the wrong ones, being mol-fraction-based values and thus having a different standard state from the molarities used for C_{H+} and the other concentrations (2). (This means that Bunnett *w* values (3) and Yates *r* values (4) listed in the literature are wrong, but these treatments are superceded by the excess acidity treatment anyway.) It has recently been found (2) that using the correct water activities makes no difference to the mechanism long since (5) deduced for ester hydrolysis in relatively dilute acids (up to a water:acid ratio of 1:1, which is 84.48 wt% for sulfuric acid) (5, 6). This is given in Scheme 1, and involves the participation of two water molecules with the protonated substrate in the rate-determining step to give a neutral tetrahedral intermediate directly (despite what is said in almost every introductory organic chemistry text (7), shown at the upper right in Scheme 1).

The Scheme 1 mechanism for esters is now widely accepted; in fact, a recent isotope effect study of the hydrolysis of methyl formate in dil. aq. HCl media has allowed delineation of the bond-making and bond-breaking processes in some detail (8). Recent theoretical calculations are also in agreement (9).

For amides, it had been thought that three (4, 10), or three and then one (11) water molecules were involved in the hydrolysis; but in contrast to the ester case, use of the correct water activity values does make a difference to the analysis (2), the correct number more likely being two (2). To clarify this situation, and because a previous analysis of lactam hydrolysis also used incorrect water activities and was inconclusive anyway (12), it was decided to reanalyze some rate constant results obtained for the hydrolysis of benzimidates in aqueous sulfuric acid media (13–15). Benzimidates are model compounds for oxygen protonated amides, the most likely protonated intermediates involved in amide hydrolysis (11). The compounds studied were **1**–**3**, in the case of **2** and **3** as their BF_4^- salts (13, 14), and **4** and **5** (15), for which rate constant data as functions of both acid concentration and temperature were available.

Results

Hydrolysis rate constants (k_ψ) as a function of acid concentration and temperature for **1**–**3** are taken from Smith and Yates (13, 14) and for **4** and **5** from McClelland (15). Values of the excess acidity *X* and correct water activities (a_{Nu}) were those used before (2). Recently, a new set of measurements of bisulfate ion concentration as a function of acid concentration and temperature in the sulfuric acid medium has become available (16); this was added to the computer program used to calculate concentrations and activities (2), but was not needed for this work.



$$[1] \qquad \log k_\psi = \log k_0 + (m^{\ddagger} - 1)m^*X + \log a_{Nu}$$

$$[2] \qquad \log k_0 = 10.31883 + \log T - (\Delta G^{\ddagger}/RT \ln 10) + (\Delta H^{\ddagger}/RT \ln 10)((T - \theta)/T)$$

The excess acidity rate equation that applies here, since the substrates already contain a full positive charge, is eq. [1] (2), with the nucleophile (Nu) being water; k_0 is the rate constant for the reaction in the standard state, infinite dilution in a hypothetical ideal 1 mol/L acid solution. The parameters m^* and $m^{\ddagger}$ are slope parameters applying to the transition state ($m^{\ddagger}$) (and the protonated substrate (m^*), irrelevant here). Since rate constants at several temperatures were available, $\log k_0$ was expanded according to the Clarke and Glew (17) formulation of eq. [2] (which I find preferable to the usual Eyring expansion (18), giving better numbers with the correct errors). The numerical term contains

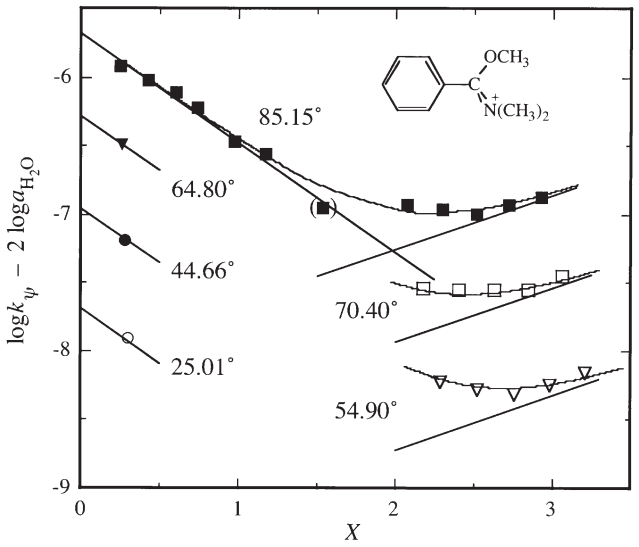
Scheme 1.



the Planck and Boltzmann constants (18), R is the gas constant (1.985 89 here), T the absolute temperature, and θ is the reference temperature of 298.15 K, 25 °C, at which the activation parameters are valid (17). The entropies of activation ($\Delta S^{\ddagger}$) are easily obtained from the free energies and enthalpies of activation, $\Delta G^{\ddagger}$ and $\Delta H^{\ddagger}$.

Using all of the experimental data simultaneously results in a triple linear regression with the variables being X, $\log a_{H_2O}$, and $((T - \theta)/T)$. When this is carried out for **1**, the slope against the water activity, the number of water molecules kinetically involved in the reaction (which I will continue to call r) calculates to 1.92 ± 0.16. For **4**, for which fewer, more error-prone, experimental data are available, r calculates to 2.55 ± 0.26. The slopes against X are quite different, being negative for **1** and positive for **4**, indicating different mechanisms. The situation is more complex for **2** and **3**, which react by both mechanisms, and the data require curve-fitting. There are too few data points available for **5** to give a reliable r value. Consequently, r was given the fixed value of 2.00 to simplify the computations, particularly for **2** and **3**.

The resulting excess acidity plot for **1** has already been published (Fig. 16 in ref. 2), and the plots for **3** and **4** are given here as Figs. 1 and 2. All these plots have 2 $\log a_{H_2O}$ subtracted from the y axis to be displayed as more easily understood lines. The parameters for all of the substrates reacting by the two mechanisms, $\log k_0$ values at 25 °C, excess acidity slopes, and the calculated activation parameters, are given in Table 1. The Table 1 information must be regarded as replacing similar information for some of these compounds previously given (11).

Fig. 1. Excess acidity plot against X according to eq. [1] for the hydrolysis of **3** at several temperatures, showing the two mechanisms.

Discussion

Ester hydrolysis

As shown in Scheme 1, ester hydrolysis in acidic media requires two water molecules. The reason for this is that protonated tetrahedral intermediates do not exist in these primarily aqueous media (19). They are too unstable to have finite lifetimes, and as Jencks points out, in order for a species to be a reaction intermediate, it must be capable of existing (have a finite lifetime, however short) in the reaction solution (19). In these Grötthus chain-transfer aqueous media, proton transfer takes place along hydrogen bonds, and the lifetime of any individual species with a full positive charge on an sp^3-hybridized oxygen is *really* short. As recent theoretical calculations (20) have shown, one cannot speak of individual H_3O^+ molecules as existing in these solutions at all, at least at room temperature, and the positive charge is effectively borne by the entire solvent, not by any

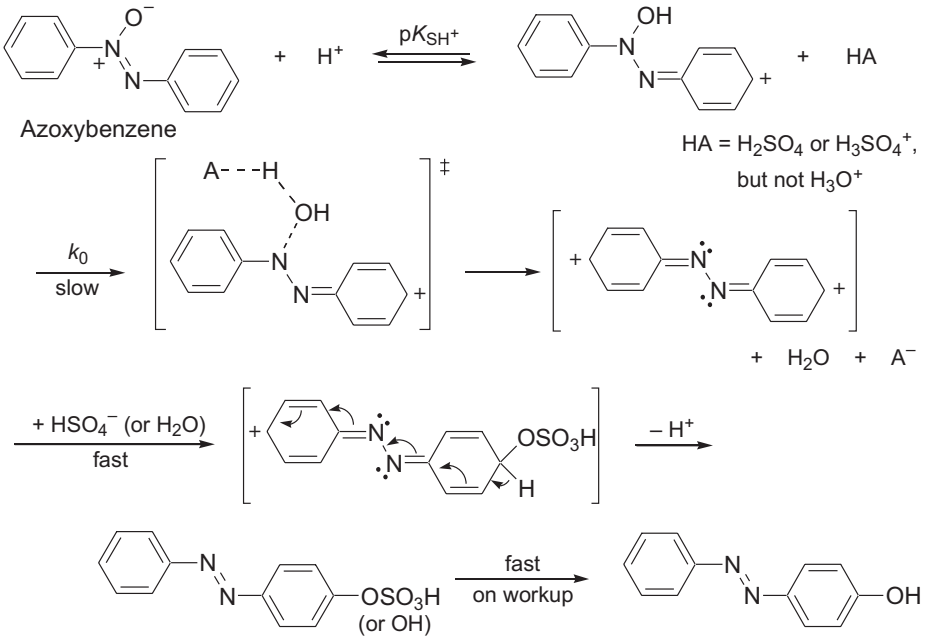
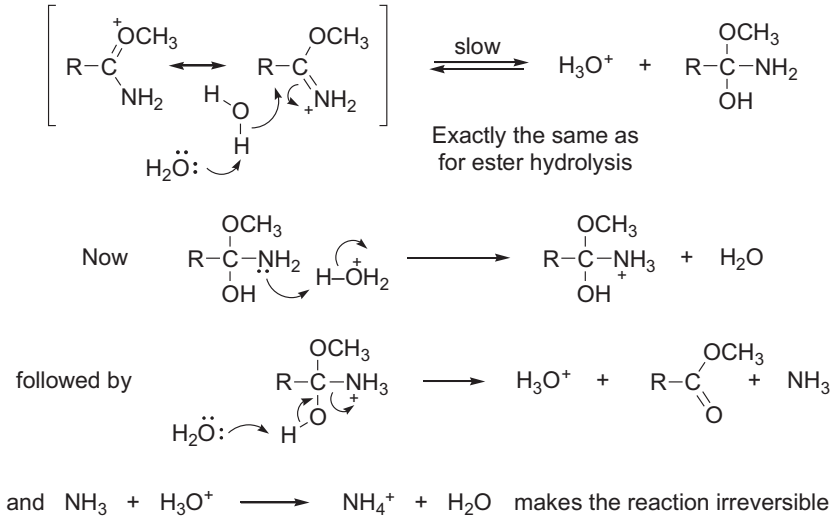
one specific oxygen atom (20). Referring to H_3O^+ is simply a convenience.

As a consequence, the reverse reaction back to starting material, often exchanged if the reaction is performed in ^{18}O-enriched media, must be general-acid-catalyzed as shown in Scheme 1. In practice, this would be very difficult to detect, and has not been looked for.



As another consequence, specific protonated alcohol molecules cannot exist in these media either. There are several reported measurements of pK_{BH}^+ values for alcohols in the literature, with reported values around –2 (21, 22). Not surprisingly, these are close to the value –1.743 taken for water, but this is a wholly artificial number, defined so as to be consistent with the definition used for weak acids in solution (23). As discussed, in aqueous acids the positive charge on what is referred to as H_3O^+ is in fact distributed into the solution as a whole (there is nothing equivalent to the "HA" of the definition as a definite species), and the same must be true of acidic alcohol solutions as well, with alcohol molecules taking the place of a quantity, up to maybe 10% for NMR studies, of the water molecules. The reported pK_{BH}^+ values are obtained from the variation of NMR chemical shifts or chemical shift differences of alcohols (proton or ^{13}C) in media of increasing acidity (21, 22), but, since the time base for NMR chemical shift measurements is in the millisecond range, the reported values cannot possibly refer to the increasing concentration of specific ROH_2^+ species but rather to the gradually increasing average positive charge on the alcohol oxygen with increasing acidity — a medium effect. This is different from the protonation of (say) esters or amides, also studied by ^{1}H NMR spectroscopy (24), where the positive charge can be delocalized internally by resonance, and one can speak of specific protonated species with finite lifetimes. It has always been a puzzle to me that I could not use the excess acidity treatment (2) to give accurate alcohol pK_{BH}^+ values, despite the existence of a great deal of very good, accurate chemical shifts as a function of acidity information, particularly for ethanol (21). I now know the reason — I should have been analyzing the spectra as a medium effect (25) and not as a protonation equilibrium. I will report further on this in the future.[3] Perhaps we will have to come up with different terminology, and not call the numbers measured for alcohols and related molecules in which the positive charge has perforce to be concentrated on a specific sp^3-hybridized oxygen with no delocalization possibilities, pK_{BH}^+ values at all.

Thus, it is highly likely that protonation of an sp^3-hybridized oxygen with no delocalization possibilities is in fact very difficult. There are hints of this in the literature. Azoxybenzene (see Scheme 2) has an entire formal negative charge on the oxygen, and the balancing positive charge on the azoxy nitrogen is delocalized into at least one and maybe both of the aromatic rings (26). One might think that protonation of this oxygen should be easy, but such is not the case, the molecule having a pK_{BH}^+ of –5.15 (half-protonated in 70% H_2SO_4) (26). The second protonation of this oxygen, required for the Wallach rearrangement of azoxybenzene (27, 28) (Scheme 2), is not an equilibrium process but rather requires general acid catalysis by H_2SO_4 or $H_3SO_4^+$, H_3O^+ not being a strong enough acid to catalyze the reaction at all (29). The formal O^- of nitro groups does not protonate before the superacid acidity region (30). The reported "pK_{BH}^+" values of ethers in the –1 to –2 range (31) could be taken to



[3] R.A. Cox. Work in progress.

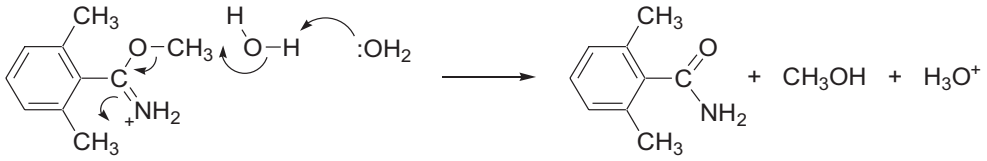
Scheme 2.

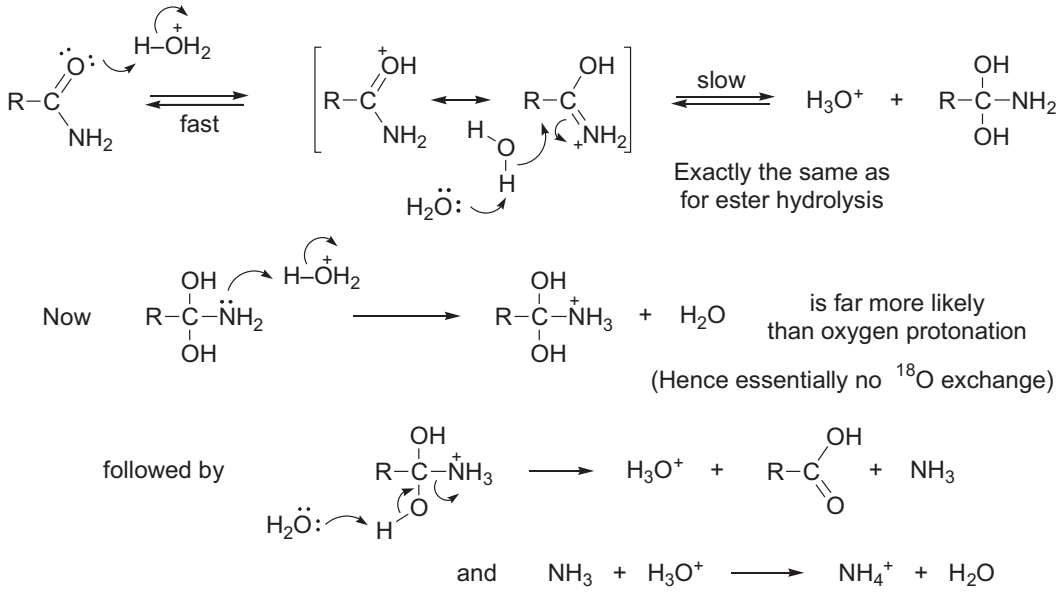
Scheme 3.

indicate that ethers should hydrolyze easily in dilute acid, but in fact, as is well-known, this process is very difficult, requiring boiling in strong acids having a strongly nucleophilic anion (HBr or HCl). Aromatic ethers, anisole, and related molecules with more alkoxy groups have reported pK_{BH}^+ values in the –3 to –11 range (32) and are as likely to protonate on one of the ring carbons as on one of the oxygens (33). Alcohols do undergo ^{18}O exchange in acid media, but this is not exactly a facile reaction either (34).



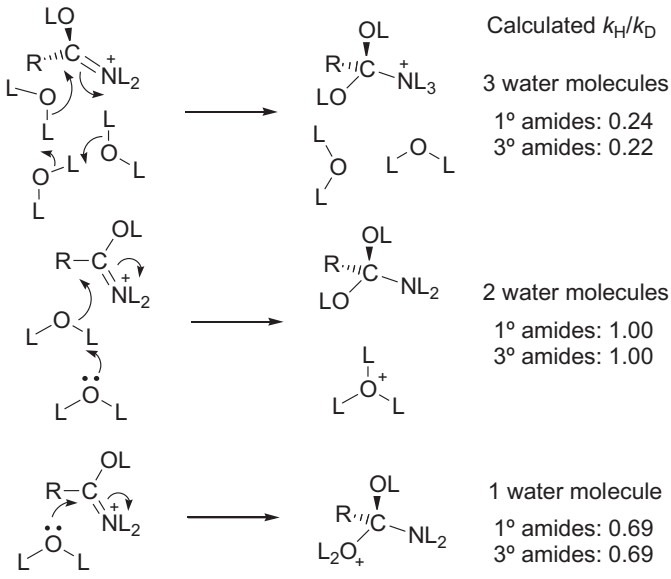
Benzimidate hydrolysis

Returning to the subject of this paper, the excess acidity plots, particularly Fig. 16 in ref. 2 and Fig. 2 here, are only linear on the assumption of two water molecules being involved in both of the benzimidate hydrolysis reaction mechanisms. The hydrolysis mechanism undergone by **1**, and by **2** and **3** at the lower acidities, is shown in Scheme 3. The *o*-methyl groups suppress this mechanism for **4** and **5** (15), and these are instead attacked at the O-methyl group by two water molecules as shown in Scheme 4. This mechanism also becomes important for **2** and **3** at the higher acidities. Product analysis supports both of these schemes (13–15); the amide products of Scheme 4 are less reactive than the imidates and their hydrolysis does not cause complications (13–15).



The rate-determining step in Scheme 3 is essentially the same as it is for the ester hydrolysis in Scheme 1, but the tetrahedral intermediate now possesses a basic nitrogen atom (pK_{BH}^+ probably not far from that of ammonia) and loss of ammonia and its protonation to NH_4^+ makes the reaction essentially irreversible. The Scheme 4 mechanism is a straightforward S_N2 process.

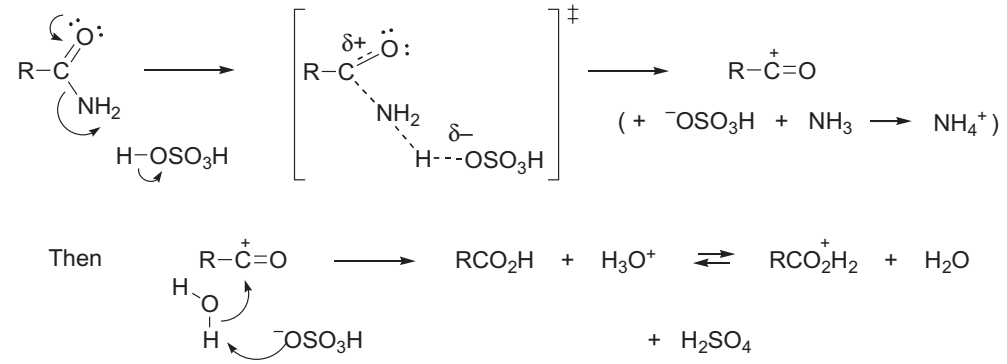
© 2005 NRC Canada



Scheme 4.

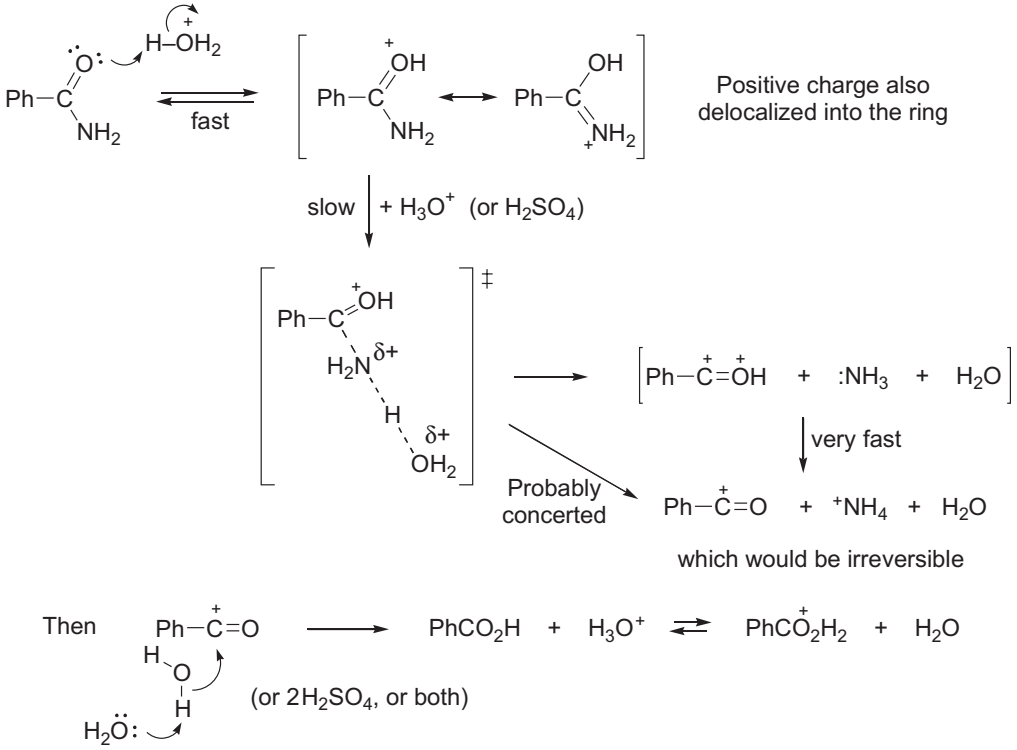
Scheme 5.

The information in Table 1 shows that, at least in the standard state, the Scheme 4 S_N2 reaction is a much more difficult process than is the Scheme 3 one, with rate constants essentially a thousand times smaller. Also the activation enthalpies are some 8 kcal mol^{-1} higher, but these are compensated to some extent by the less negative entropies of activation, as is often the case. This is probably simply because the attacking water molecules "see" more positive charge in the Scheme 3 case. However, the excess acidity slopes (probably related to the transition-state activity coefficient behaviour (35)) are quite different, negative for the Scheme 3 process but positive for the Scheme 4 one, which is why it takes over from the Scheme 3 mechanism in the more strongly acidic solutions for **2** and **3**.



Amide hydrolysis

By straightforward analogy, the hydrolysis mechanism for amides must therefore be that of Scheme 5, at least in the more dilute acid region. A great deal of high-quality experimental data is available for the hydrolysis of the benzamide equivalents of **1**–**3**; hydrolysis rate constants as functions of acid concentration and temperature (10, 14, 36), in aqueous sulfuric, perchloric, and hydrochloric acid media. Several years' work on this[3] unequivocally shows that, at least in the more dilute acidity region, two water molecules react with an oxygen protonated amide in the rate-determining step, according to the excess acidity plots for these compounds, exactly as found for the benzimidates in this study. This is in accord with an accumulating amount of other evidence. For instance, standard fractionation factors (37) can be used to calculate solvent isotope effects for amides reacting in regular and deuterated media with one, two, and three water molecules (shown in the following) (38).



The experimentally measured number (38) is 1.00, exactly in accord with the two-water-molecule mechanism, but certainly not for one involving one or three water molecules. Ironically, we have favoured both of the latter in the past (11). Originally, we liked the three-water-molecule mechanism because it enabled an *N*-protonated tetrahedral interme-

© 2005 NRC Canada

Scheme 6.

Scheme 7.

diate to be formed directly (see the previous section), but the solvent isotope effect work rules this out. Also Guthrie's multidimensional analysis is inconsistent with the involvement of three water molecules (39).[4] Scheme 5 is the correct mechanism.

Many years ago it was found that amide hydrolysis in acid involves very little ^{18}O exchange when the reaction is carried out in ^{18}O-enriched media (40), which is what would be expected according to Scheme 5 with its tetrahedral intermediate containing a highly basic nitrogen. Some exchange does take place, however; the early and the more recent work has been summarized in some detail (41), the Scheme 5 hydrolysis mechanism still being favoured (41).

However, this is not the whole story. My own work on the hydrolysis of the benzamide equivalents of **1**–**3**[3] is not yet ready for publication because another mechanism takes over from the Scheme 5 one in media in which there is still plenty of water present; the excess acidity plots begin to deviate upwards from the behavior predicted according to Scheme 5. At the time of writing, I do not know what this second mechanism is. Originally, we thought that bisulfate ion was taking over from water as a nucleophile in sulfuric acid (11), but this seems less likely now because the same behaviour is observed in perchloric acid media, where there is no alternate nucleophile present.[3]

One possibility is given as Scheme 6, where proton transfer is to nitrogen rather than to oxygen, possibly general-acid-catalyzed as shown (undissociated H_2SO_4 being the

[4] J.P. Guthrie. Personal communication (2002).

© 2005 NRC Canada

general acid in Scheme 6), forming an acylium ion that would rapidly collapse with water or bisulfate. General acid catalysis in strong acid media, first investigated by the Kresge group (42) and subsequently by us in connection with the Wallach rearrangement (29) (Scheme 2) actually appears to be much more common than is generally supposed. However, Scheme 6 starts from the unprotonated amide, which is decreasing in concentration with increasing acidity, and thus the reaction should rapidly slow down with increasing acidity, which it does not. Of course there could be a tautomerization from oxygen protonated amide to nitrogen protonated amide first, and this could then break up to acylium ion and ammonia in a simple A1 process, constituting another possible mechanism. The excess acidity behaviour does not really fit either of these very well, but an A1 process does seem possible.[3]

An intriguing possibility is shown in Scheme 7, which has the advantage of starting from the oxygen protonated amide, meaning that the rate would not decrease with increasing acidity as the Scheme 6 mechanism would predict. This is also visualized as being a general-acid-catalyzed process as shown. It is, of course, not likely that the protonated acylium species of Scheme 7 would actually form; the departing ammonia molecule would most likely take the OH^+ proton with it as NH_4^+ in a concerted process, but this is rather difficult to draw, so I have shown it as a separate process in Scheme 7. There is, in fact, precedent for a mechanism like this in the Wallach rearrangement of azoxybenzene (27, 29), given here for comparison as Scheme 2 (28), so it is not as unlikely as it appears at first glance. The Scheme 7 mechanism would also show no ^{18}O exchange (this experiment has only been carried out at relatively low acidities for amides) and would presumably only apply to amides in which the charge on the protonated species can be dispersed in some way, into the ring for the benzamides. Thus, ordinary alkyl amides may not show this behavior.

Acknowledgements

It is a pleasure to acknowledge many discussions of the material in this commentary with my friends and colleagues over the years, among them Stan Brown, Erwin Buncel, Peter Guthrie, John Marlier, Charles Perrin, Tom Tidwell, and particularly Jerry Kresge, who helped with the solvent isotope effect calculations. I think we are all pretty much in agreement now, at least on the basics.

Scientific genealogies of physical and mechanistic organic chemists[1]

John Andraos

Abstract: Scientific genealogy trees of scientists who contributed to the study of organic reaction mechanisms over the last century are presented. The trees show doctoral and post-doctoral connections among scientists as well as connections between scientific ideas. Contributions made by scientists working in laboratories at Canadian universities and at the National Research Council of Canada are noted throughout. These trees, covering more than two centuries, are of interest to senior scientists and young students of science alike in understanding the evolution of scientific ideas and in career development for aspiring scientists. Key patterns revealed by these trees pertaining to ideas and discoveries made, how they were made, connections between them, and who made them are also discussed.

Key words: reaction mechanisms, physical organic chemistry, scientific genealogies.

Résumé : On présente les arbres généalogiques des scientifiques qui ont contribué à l'étude des mécanismes des réactions organiques au cours du dernier siècle. Les arbres mettent aussi en évidence les relations doctorales et postdoctorales ainsi que les corrélations entre idées scientifiques. Dans toute cette présentation, on met en relief toutes les contributions des scientifiques qui ont travaillé dans les laboratoires des universités canadiennes et ceux du Conseil national de recherches du Canada. Ces arbres, qui couvrent plus de deux siècles, présentent de l'intérêt autant pour les scientifiques bien établis que pour les jeunes étudiants des sciences en leur permettant de comprendre l'évolution des idées scientifiques et le développement des carrières des scientifiques ambitieux. On discute aussi des patrons clés révélés par ces arbres en relation avec les idées et les découvertes qui ont été faites, qui les a faites, comment elles ont été faites et des relations entre elles.

Mots clés : mécanismes réactionnels, chimie organique physique, généalogies de scientifiques.

[Traduit par la Rédaction]

Introduction

In keeping with the theme of this special issue to emphasize the historical and current importance of mechanistic chemistry and the international impact that Canadian scientists have made to it, this paper presents scientific genealogy trees of prominent scientists who have made significant contributions to physical organic chemistry and reaction intermediate studies. Figure 1 shows a "super" tree with a timeline covering more than a century of scientific work that depicts key players as lynch pin nodes in the overall grand scheme of things. Detailed specific trees emanating from these people are available in the Supplementary material.[2] All of these trees were constructed using biographical information obtained from various sources: Poggendorff's Biographisches-literarisches Handwortenbuch zur Geschichte der exacten Naturwissenschaften (2nd ed., Wiley-VCH, Berlin), Biographical Memoirs of Fellows of the Royal Society (Vols. 1–50, The Royal Society, London), Obituary Notices of Fellows of the Royal Society (Vols. 1–9, The Royal Society, London), Biographical Memoirs of Fellows of the National Academy of Sciences of the United States of America (Vols. 1–84, National academy of Sciences, Washington, D.C.), Dictionary of Scientific Biography *Edited by* Charles C. Gillispie (Charles Scribner's Sons, New York), and various biographical references compiled in ref. 1. The following code applies to the trees: solid lines indicate doctoral advisor links, dashed lines indicate post-doctoral advisor links, boxes indicate people who brought knowledge from one country to another, and maple leaf icons indicate scientists who made contributions at Canadian universities and at the National Research Council of Canada. For each entry the name of the scientist is given along with the university where they did their doctoral work, the year of their Ph.D., and a chronological list of their notable contributions to the fields of physical organic chemistry and reaction intermediates. References to these contributions may be found in Tables S1, S2, S5, and S6 (Supplementary material) of

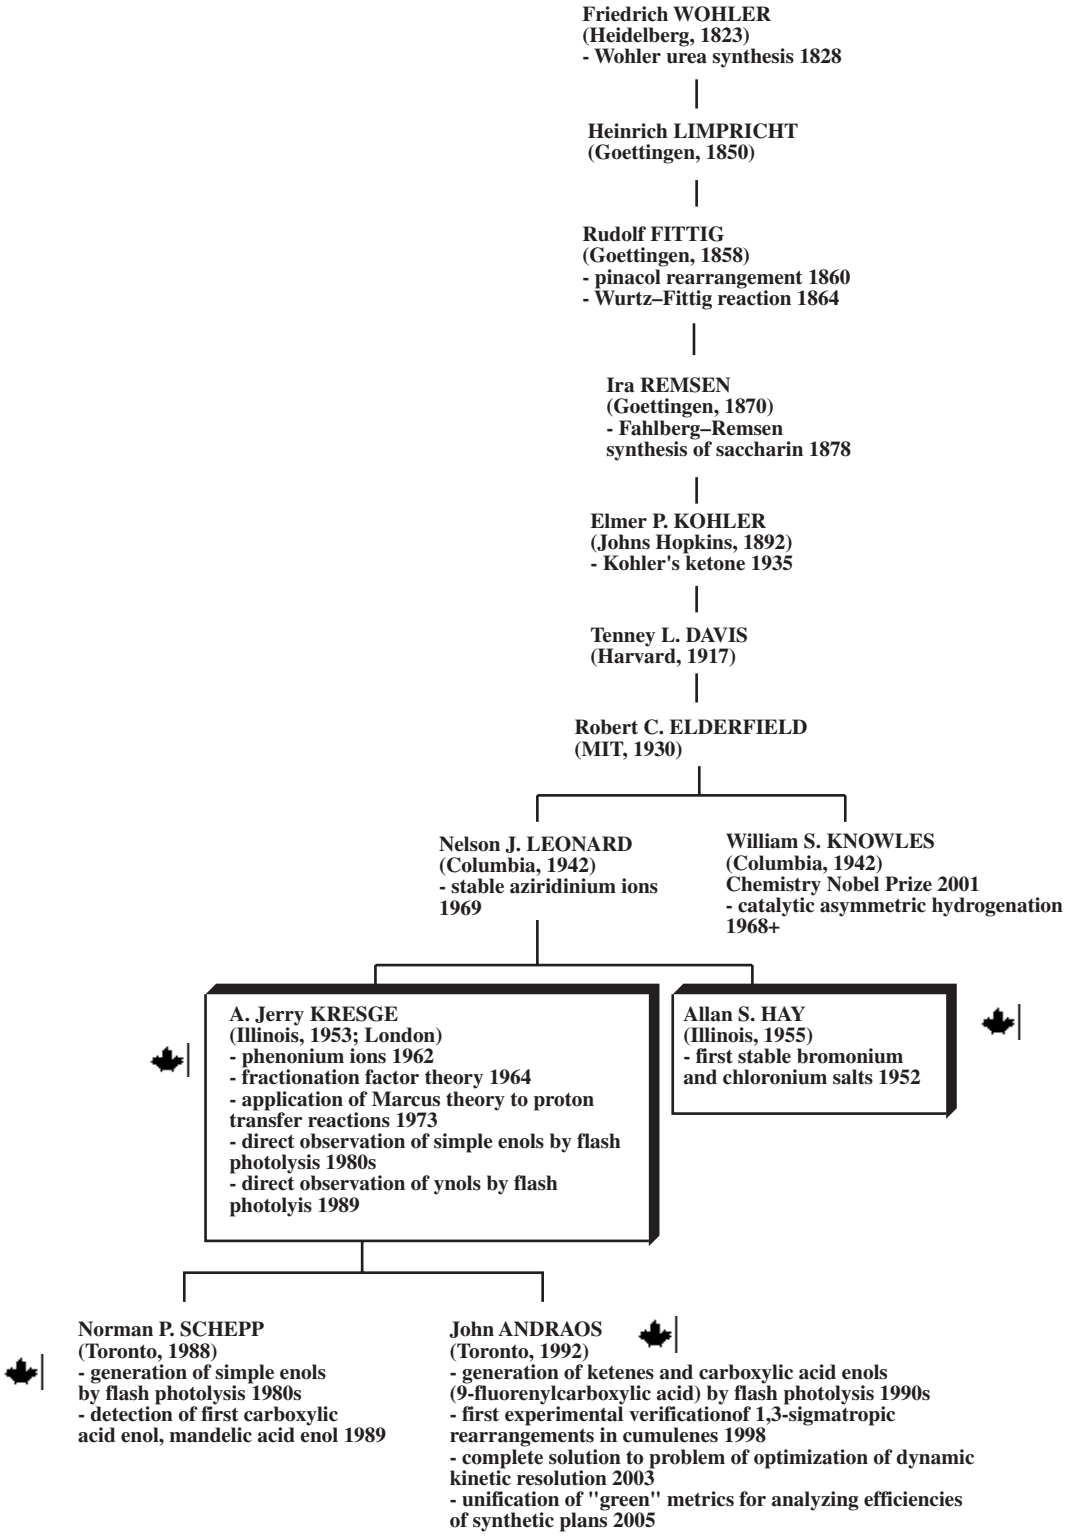
Fig. 1. Summary "super" scientific genealogy tree of key scientists whose scientific offspring contributed significantly to the development of mechanistic chemistry and to the discovery of reaction intermediates along with the timeline of the doctoral degree.



the following paper (2). These trees effectively trace how knowledge in physical organic chemistry emerged as a whole and how it came to Canada from the earliest times up to the year 2004. All professors of chemistry in Canada who made contributions to physical organic chemistry are included. In addition, particular attention was made to include in the compilation all Canadian contributors to this special issue. As an example, my personal scientific genealogy tree is shown in Fig. 2.

Though at first sight this compilation has obvious appeal to readers who may be interested only in the history of science, it is of far more fundamental and practical value with respect to conducting original research. From readings of biographical memoirs of famous scientists, one recognizes that nearly all of them can attribute their success in science in significant measure to their knowledge of how ideas progressed down the line from their forebears rather early in their careers in addition to the obvious traits of possessing intelligence, command of, and enthusiasm for their subject. Stamina, perseverance, and maintaining focus on key questions to be answered are particularly important virtues that academics require in the course of their work throughout their careers, especially when they are faced with convincing their peers of novel ideas that challenge established paradigms brought forward by scientists in positions of power and authority (3). One often can correctly guess that one must really have a good idea when one encounters stiff resistance to that idea. One is reminded of the following relevant statements made by a philosopher and physicist, respectively. "All truth passes through three stages before it is recognized. First, it is ridiculed. Second, it is violently opposed. Third, it is regarded as self-evident." (Arthur Schopenhauer, 1788–1860) (4). "A new scientific truth does not triumph by convincing its opponents and making them see the light, but rather because its opponents eventually die, and a new generation grows up that is familiar with it." (Max Planck, 1858–1947) (5).

Probably the most celebrated illustrations of these insights are the comments of Hermann Kolbe (1818–1884) on the imaginative ideas of Jacobus van't Hoff (1852–1911, first recipient of the Nobel Prize in Chemistry in 1901) concerning the connection between the observation of optical activity in compounds and the presence of asymmetric carbon atoms in their molecular structures as exemplified by the following quotations. "…the weeds of a seemingly learned and brilliant but actually trivial and empty Philosophy of Nature, which, after having been replaced some fifty years ago by the exact sciences, is now once more dug up by pseudo-scientists from the lumber room of human fallacies, and like a trollop, newly attired in elegant dress and make-up, is smuggled into respectable company, to which she does not belong." (6*a*). "Not long ago, I expressed the view that the lack of general education and of thorough training in chemistry was one of the causes of the deterioration of chemical research in Germany. Will anyone to whom my worries seem exaggerated please read, if he can, a recent memoir by a Herr van't Hoff on *La Chimie dans l'Espace*, a document crammed to the hilt with outpourings of childish fantasy…This Dr. J.H. van't Hoff, employed by the Veterinary Academy of Utrecht, has, so it seems, no taste for accurate

Fig. 2. Sample scientific genealogy tree showing doctoral advisor – student connections and flow of scientific ideas.

chemical research. He finds it more convenient to mount his Pegasus (evidently taken from the stables of the Veterinary Academy) and to announce how, on his bold flight to Mount Parnassus, he saw atoms arranged in space." (6*b*).

A modern example documented in recent celebrations of the most cited papers in the *Journal of the American Chemical Society* in the last 125 years is that of Lineweaver and Burk whose classic paper (7) is the most cited in that journal and yet at the time of review it was rejected several times by six reviewers, but the editor of the day took the risk and allowed publication (8). Now, of course, Lineweaver–Burk plots are routinely used in pharmacokinetic studies and are mentioned in virtually every undergraduate biochemistry textbook. Interestingly, the idea of plotting enzyme data in

© 2005 NRC Canada

this way came to them in their discussions when viewing data plots upsidedown as they were seated opposite each other at a desk! Another case is the postulation and discovery of the Koelsch radical in 1937 (9*a*), which was confirmed by ESR spectroscopy two decades later in 1957 (9*b*). This is actually an excellent example of how a new powerful technique helped to solve an old problem and thereby confirm prior indirect evidence of the existence of a chemical species.

Close examination of these genealogy trees reveals several important and revealing patterns that are relevant to the progression of the science itself and the career developments of the practitioners themselves. The following discussion is thus focused on two specific areas: the development of scientific discoveries in physical organic chemistry and reaction intermediates over time, and career development patterns among successful practitioners in the field. In the scientific development category we have: (1) leading chemists claiming discovery of the most number of reaction intermediates; (2) leading chemists claiming discovery of the most number of concepts in physical organic chemistry; (3) synthetic chemists who used principles and concepts in physical organic chemistry to advantage in organic synthesis; (4) physical and theoretical chemists who contributed to the development of physical organic chemistry concepts; and (5) highlights of achievements by Canadian chemists. In the career development category we have: (1) idea generation and connections, and distinguishing innovators from followers; and (2) leading academics in Canada who spawned the next generation of physical organic chemists in Canada. In the following compilation, leading scientists are listed in alphabetical order with their contributions. No ranking with respect to most important vs. least important discoveries is implied since all contributions are noteworthy and meritous. Other scientists not given here who made contributions are noted in the genealogy trees (see Supplementary material).[2]

Leading chemists claiming discovery of the most reaction intermediates include:

- Paul D. Bartlett (bridged halonium ions (1936–1937), aziridinium ions (1947), and episulfonium ions (1949))
- Keith U. Ingold (detection of phenyl radical (1953), benzyl radicals (1966), cumyloxy radicals (1969), peroxy radicals (1969), β-scission mechanism (1969), phosphinoyl radicals (1973), phosphinyl radicals (1973), and phosphinothionyl radicals (1973) by laser flash photolysis and electron spin resonance techniques)
- George A. Olah (bridged halonium ions (1951), arenium ions (1956), dications (1966), phenonium ions (1969), and benzidine rearrangement dication (1972), all by generation in magic acid and detected by NMR spectroscopy)
- Wilhelm Schlenk (stable carbanions (1910), ketyl radicals and radical anions (1911), metal radical anions (1914), the Schlenck–Brauns biradical or hydrocarbon (1915), and *p*-quinodimethanes (1919))
- Julius Stieglitz (nitrenes (1896), carbocations (1899), tetrahedral intermediates (1899), and nitrenium ions (1913), all conjectured from comparative analysis of product structures with substrate structures)
- Hermann Staudinger (ketenes (1905), *o*-quinonemethide (1911), and nitrenes (1917))
- Saul Winstein (bridged halonium ions (1939), acetoxonium ions (1942), nonclassical norbornyl cation (1949), methoxonium ions (1952), phenonium ions (1952), and stable *p*-quinonemethides (1960))

Leading physical organic chemists claiming introduction of the most number of named concepts in the field include:

- Louis P. Hammett (linear free energy relationships (1924), solvolysis reactions (1927), Hammett acidity function (1932), Hammett equation (1935), substitutent effects and constants (1935), general acidity functions (1937), Zucker–Hammett hypothesis (1939), and Acree–Curtin–Hammett principle (1954))
- Sir Christopher K. Ingold (concept of inductive effect (1923), concept of mesomeric or resonance effect (1924), concept of partial charges in chemical structures (1926), E1cb (1933), SN1 and SN2 (1934), E1 and E2 (1937–1948), and A1 and A2 (1941) mechanism categorizations, isotopic labelling experiment (1935), common ion effect (1940), normal salt effect (1940), principle of microscopic reversibility (1953–1969))
- William P. Jencks (tetrahedral intermediates and catalysis in esterification reactions (1964), More O'Ferrall – Jencks diagram (1970), Jencks azide clock (1977), and Keeffe–Jencks equations (1981)
- C. Garner Swain ("push–pull" mechanism (1948), Swain–Scott equation (1953), Swain–Schaad equation (1958), and Swain–Lupton equation (1968))
- Saul Winstein (anchimeric assistance or neighbouring group participation in solvolysis reactions (1939), normal salt effect (1940), Grunwald–Winstein equation (1948), intimate and solvent separated ion pairs (1952), special salt effects (1954), Winstein–Holness equation (1955), and concept of homoaromaticity and homoconjugation (1959))

Leading synthetic chemists who have used mechanistic ideas to advantage in organic synthesis strategies include:

- Adolf von Baeyer (concept of angle strain (1885) and carbonium ion theory (1901))
- Sir Derek H.R. Barton (the role of conformation in organic synthesis (1952))
- Emil Fischer (lock and key model of enzyme catalysis (1894), experimental verification of tetrahedral asymmetry at carbon (1914))
- Ernst O. Fischer (synthesis of transition-metal complexes of carbenes (1964), carbynes (1973), and ketenes (1983))
- Moses Gomberg and Werner Bachmann (synthesis of *o*- and *p*-quinonemethides (1913) and synthesis of stable metal ketyl radicals and ketyl radical anions (1927))
- Raymond U. Lemieux (Edward–Lemieux anomeric effect (1955–1969))
- Hans Meerwein (Wagner–Meerwein rearrangement reaction (1922), synthesis of Meerwein oxonium salts (1937), and discovery of insertion of carbenes into C—H bonds (1942))
- Sir Robert Robinson (curly arrow notation for reaction mechanisms depicting electron flow from electron donor sites to electron acceptor sites (1922–1932) and electronic theory of organic chemistry (1926))
- Georg Wittig (Diels–Alder trapping of generated benzyne intermediate (1942), synthesis of *o*-quinodimethanes (1948), launched ylide chemistry (1948), and developed

© 2005 NRC Canada

the Wittig reaction and Wittig reagents to effect ketone–olefin transformations (1954))
- Robert B. Woodward (elucidation of structure of metallocene "sandwich" complexes (1952), concept of Woodward–Hoffmann rules to explain stereochemical product outcomes in thermal and photochemical electrocyclic reactions (1965))

Leading physical and theoretical chemists who made important contributions to mechanistic chemistry include:
- Henry Eyring (development of the absolute rate and transition state theory and Eyring equation (1935), electrode kinetics (1939), heterogeneous catalysis (1940), and solvent effects in kinetics (1940))
- Gerhard Herzberg (detection and spectroscopic identification of methyl radicals and singlet and triplet methylene (1956–1959))
- Gilbert N. Lewis (development of concepts of covalent bonding (1916), octet rule (1916), electrophilicity and nucleophilicity (1921), Lewis acidity and basicity (1923), and inductive effect (1923), advanced the idea that radicals and other paramagnetic species could be studied by magnetic methods (1923), investigated the effect of resonance on electronic transitions (1939), and discovery of the triplet state of ketones (1944))
- Rudolph A. Marcus (development of the Rice–Ramsperger–Kassel–Marcus theory (1951) and development of concepts in electron transfer theory including the Marcus equation and prediction of the inverted region (1956))
- Ronald G.W. Norrish and Lord George Porter (discovery of the Norrish type I and type II reactions (1935), development of the flash photolysis technique (1949), detection of acetoxy radicals (1952), benzyl radicals (1957), and phenyl radicals (1968))
- Linus Pauling (concept of electronegativity and development of the Pauling scale (1932), investigation of aromatic sigma complexes (1935), concept of hybridization in bonding (1948), and development of the Corey–Pauling–Koltun (CPK) space-filling models (1959))
- Michael Polanyi (development of the Bell–Evans–Marcus–Hammond–Polanyi–Thornton–Leffler principle (1936))
- Edward Teller (Renner–Teller effect (1934), Teller–Redlich product rule (1935), Jahn–Teller effect (1936), and the concept of principle of least motion (1938))

Great Canadian contributors to mechanistic and reaction intermediates chemistry include:
- Ronald J. Gillespie (valence shell electron repulsion theory (1963) and use of magic or superacid media to detect carbocation intermediates (1968))
- Keith U. Ingold (detection of phenyl radical (1953), peroxy radicals (1969), β-scission mechanism (1969), phosphinoyl radicals (1973), phosphinyl radicals (1973), and phosphinothionyl radicals (1973) by laser flash photolysis and electron spin resonance techniques)
- A. Jerry Kresge (fractionation factor theory applied to solvent isotope effects (1964), application of Marcus electron transfer theory to proton transfer reactions (1973), and direct observations of enol (1980s), ynol (1989), ketene (1990s), and quinomethide intermediates by flash photolysis (2000s))
- Keith J. Laidler (application of theory of absolute reaction rates to problems in heterogenous catalysis (1940), electrode kinetics (1939), and solvent effects in kinetics (1940), investigation of kinetics of the urea–urease system (1949), thermal free-radical reactions (1951), investigation of pH effects on enzyme kinetics (1955), and investigation of temperature effects on enzyme kinetics (1979))
- Frederick P. Lossing (detection of phenyl radical (1953), *p*-quinodimethanes (1955), and acetoxyl radical (1955) by mass spectrometry, and investigation of free radicals in the gas phase by mass spectrometry (1957)
- Rudolph A. Marcus[3] (development of the Rice–Ramsperger–Kassel–Marcus theory (1951) and development of concepts in electron transfer theory including the Marcus equation and prediction of the inverted region (1956))
- E.W.R. Steacie (detection of benzyl radical (1954) and acetoxyl radical (1955))
- Thomas T. Tidwell (synthesis of persistent bis(trimethylsilyl)ketenes (1992), synthesis of persistent allenylketenes (1997), synthesis of persistent silylketenes (1999))
- J.C. Tito Scaiano (development of the probe technique for detecting spectroscopically "invisible" transients (1977), development of time-resolved microwave dielectric absorption spectroscopy (1982, with Professor Richard Fessenden), development of the two-laser two-colour laser flash photolysis experiment for detecting excited state species tandemly generated from short-lived ground state transients (1984), trapping of carbenes to yield ylides such as pyridine ylide and thiocarbonyl ylides (1986), detection of ketene zwitterions by flash photolysis (1992), and development of the laser drop experiment for studying multiphoton excitation of photoprecursors (1993)

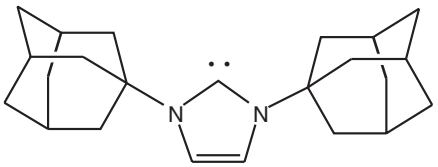
Successful academics invariably obtained their doctoral degrees and post-doctoral apprenticeships with scientists who were contemporary leaders in their fields. Horizontal comparisons across a contemporary generation in any tree reveal which ideas and discoveries were brought forward at nearly the same time. These also reveal people who may have been fellow colleagues, graduate students, or post-doctoral fellows at the bench in the same laboratory. A common trend is for people to do their post-doctoral training with the doctoral advisor of their own doctoral advisor, in effect their scientific "grandfather". This pattern is particularly effective in securing consistent and credible recommendation letters from people who know one another professionally as well as personally. The German term *doktorvater* (doctor father) best describes a successful intellectual relationship between student and advisor. The following quotation from the Acknowledgements page of the 1933 M.Sc. thesis of Carl A. Winkler describing his relationship with his advisor Otto Maass is particularly pertinent. "In the brief space of two years since this work was begun, under

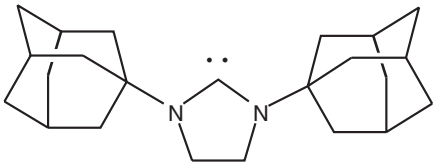
[3] Rudolph A. Marcus is included among the Canadians since he was born and raised in Montreal, Quebec and did his graduate work under Professor Carl Winkler at McGill University in 1946 and then became a post-doctoral fellow at NRC in Ottawa under E.W.R. Steacie. His theoretical training and later accomplishments in the study of electron transfer reactions came about from his association with Professor Oscar K. Rice at the University of North Carolina, who allowed him the freedom to pursue his ideas and publish on his own.

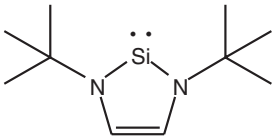
© 2005 NRC Canada

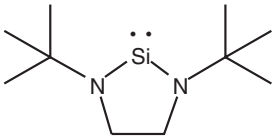
the direction of Dr. O. Maass, the writer has become aware of having worked not under, but with him. His generous assistance, invaluable and kindly criticisms, and unbound optimism, are emphasized by all those who have privileged to work with him. The interest which Dr. Maass evinces in the individual as a chemist is paralleled by his interest in the chemist as an individual. The author feels that to have worked with Dr. Maass is to have experienced the utmost in satisfactory relationships between student and director." (10).

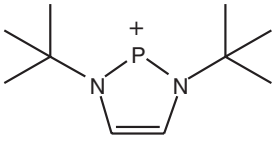
From the trees presented here one can readily deduce how personal relationships among scientists through advisor–student connections explain alliances with respect to collaborations or even rivalries and personal conflicts. In practical terms, it readily explains success in obtaining academic positions and academic job placement in particular institutions. Not surprisingly from the above quote, nearly 50 professors of chemistry across Canada, including Rudolf Marcus (1992 Nobel Chemistry Laureate), can trace their scientific genealogies directly to the Maass–Winkler combination, a statistical legacy that will likely remain unbroken. All of this information is hidden in the scientific literature and may not be so readily revealed, whether intentionally or unintentionally, particularly to new entering students in the field who may have the drive and intelligence to make the committment to research, but require career guidance to channel their efforts in the right direction. The demands of fulfilling degree requirements and maintaining focus on the research problems at hand pose additional challenges to maintain the "big picture" outlook. Networking at conferences and talking with people at colloquia and other gatherings is the best way to penetrate this important area of knowledge as it is essential for successful career development.

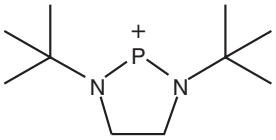


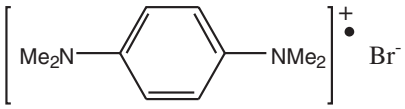


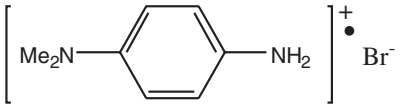


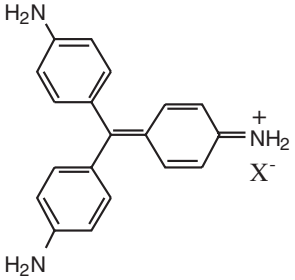


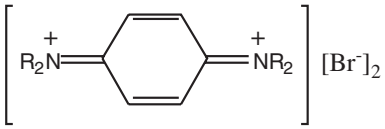


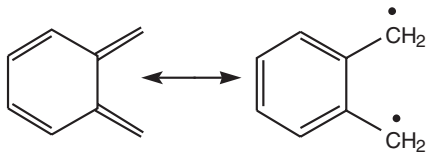












Another important spin-off of such genealogy trees is that predictability of what is important and worth looking into as a viable research question or area markedly improves when one knows the chronology of ideas and associates themselves with the key players in shaping those ideas or at least their direct scientific descendants. Naturally, as one would expect, the likelihood of making the "right connections" between various research areas increases as the size of the entire knowledge database grows. However, serendipity in the form of unexpected occurrences and chance "mistakes" always plays a strong hand and one must be prepared to recognize opportunities and act on them where possible. The most profound and dramatic connections often turn out to be those made between, at first sight, seemingly disparate fields. Nevertheless, despite the complexity of the maze, one is able to discern a certain logic in the ideas discovered over time, so that rather than them being presented or learned as a loose collection of dry facts, the trees serve to organize them into a meaningful whole. The big payoff is that student interest in the subject is enhanced and memory retention of information increases. A great motivation is the tantalizing prospect that if successful in significantly advancing the field, an aspiring student may one day join this growing "tree of knowledge". What is important is knowing the connections between ideas and the context and circumstances in which those discoveries were made, ascertaining the limitations and levels of approximation employed, performing full graphical critical point and dimensional analyses of key equations, and representing ideas using visualization techniques if possible. All of these can be best achieved by reading the published works of the originators of the discoveries themselves rather than relying solely on a textbook author's "hand-me-down" interpretation of them. Peter Dervan's following quote exemplifies the value of doing just that and how teaching can influence research. "During my first years at Cal Tech, I experienced how profoundly classroom teaching would influence my research. I taught Advanced Organic Chemistry, a reaction mechanisms course for graduate students. I never had the time to read in detail the original seminal papers of Winstein, Doering, Roberts, Olah and other pioneers of the field. Upon reading those key papers published mostly in the 1950s, I realized that these researchers set the stage for several decades of new inquiry in the field of reactive intermediates. My research should not be closing problems but rather opening new areas. I decided to choose a research problem that seemed hopeless in terms of current understanding, but would be suitable for thirty years of scientific inquiry." (11).

Those researchers who follow this track early in their career paths are able to ask more penetrating questions and to chart new directions with greater confidence and thereby do worthwhile research of high quality. Knowing what is important and what is not is one of the key skills in charting a research agenda. In short, being able to see the big picture is imperative for success. Hence, the impact on one's research plans is tremendous. In this vain, distinguishing innovators from followers becomes important. The reader may peruse these trees at leisure and consult them over several times and new ideas and revelations will surface. The reader is invited to explore these trees in a self-discovery approach and verify for themselves the previous points through their own personal experiences.

Table 1 lists some examples in the field of reaction intermediates of important idea and discovery connections between innovators and followers who themselves, in many cases, became innovators in their own right. Perusal of this list, particularly the structural similarities between juxtaposed reaction intermediates, illustrates and emphasizes points made in the preceding paragraph. Not surprisingly, therefore, students who have trained with any of the key scientific contributors or their immediate descendants are highly sought after as the next generation of academics. The thinking here is that their mentors' successes will likely rub off on them as they chart their own research agendas, particularly if their doktorvater relationship had been positive. In fact, the most effective way for a scientist's work to live beyond their time is for them to populate the next generation of academics with people that they have mentored, otherwise their names and work will inevitably be driven to extinction. This virtually guarantees that their ideas, contributions, and views will continue to influence scientific thought. Moreover, this strategy has a pay off for the advisor in the form of a "boomerang effect" with respect to fame, personal ego, the acquisition of prizes and research funds to continue their scientific work, and a growing publication list. However, this boomerang effect works in one direction; that is, if an advisor's students are sought after it implies that the above benefits follow, but the converse may not always be true

depending on how generous or selfish an advisor is in letting their students pursue their own ideas and allow them to shine. This leads to the key question a research student should ask of their prospective advisor before ranking them according to their area of research, prizes, their publication list, and other recognition measures: "What were the career fates of past students and research fellows who passed through that research group?". Sydney Brenner (2002 Physiology and Medicine Nobel Laureate) offers the following succinct insight in his autobiographical sketch on the point of reprioritization of selection criteria of advisors for students when choosing their potential research mentors (12): "I believe that a scientist should be judged by the quality of the people he has helped to produce and not by prizes or other honours bestowed on him."

These positive influences are tempered by the fact that the achievements of a research advisor are linked directly to the successes of their students. Simply put, an advisor is only as good as his or her students. Also, another tempering point is that there is an expectation and promise that these budding scientists make notable future discoveries and expand fundamental knowledge over their own careers. In this vein, faculty members in Canada who have been most successful in placing their students and post-doctoral fellows in academic positions in departments of chemistry in Canada in the fields of pure and applied physical organic chemistry and related areas are given in the following. University names in parentheses denote where these people have worked or are currently charting their careers.

Ronald J. Gillespie:
Felix Aubke (University of British Columbia)
Thomas Birchall (McMaster University)
Howard J. Clase (Memorial University)
Philip A.W. Dean (University of Western Ontario)
John S. Hartman (Brock University)
John B. Milne (University of Ottawa)
Jack Passmore (University of New Brunswick)
J. Wilson Quail (University of Saskatchewan)
Edward A. Robinson (University of Toronto)
Gary J. Schrobilgen (McMaster University)
John B. Senior (University of Saskatchewan)
Robert C. Thompson (University of British Columbia)
William A. Whitla (Mount Allison University)
J.C. Tito Scaiano:
Pamela A. Arnold (University of Ottawa)
Jeffrey T. Banks (Acadia University, University of New Brunswick)
Monica Barra (University of Waterloo)
Cornelia Bohne (University of Victoria)
Gonzalo Cosa (McGill University)
Frances L. Cozens (Dalhousie University)
Christopher Evans (Ryerson University)
William J. Leigh (McMaster University)
Matthew J. Lukeman (Acadia University)
William Skene (Université de Montréal)
Keith Yates:
Robin A. Cox (University of Toronto)
Alan C. Hopkinson (York University)
Robert A. McClelland (University of Toronto)
Robert S.B. McDonald (Mt. Saint Vincent University)
Paul G. Mezey (University of Saskatchewan, Memorial University)
James A. Pincock (Dalhousie University)
Oswald S. Tee (Concordia University)
Peter Wan (University of Victoria)
Keith U. Ingold:
Jeffrey T. Banks (Acadia University, University of New Brunswick)
Philip J. Dutton (University of Windsor)
Linda J. Johnston (NRC, Ottawa)
Janusz Lusztyk (NRC, Ottawa)
J.C. Tito Scaiano (NRC, University of Ottawa)
Danial D.M. Wayner (NRC, Ottawa)

Reaction intermediates in organic chemistry — The "big picture"[1]

John Andraos

Abstract: An overview of the discovery of reaction intermediates and associated concepts in physical organic chemistry is presented. Particular attention is paid to chronology of ideas, frequency of occurrence of reaction intermediates in the library of organic reactions used in organic synthesis, and the lexicon of scientific terms used in the language of physical organic chemistry. General logic decision trees are presented for the unique or near unique identification of reaction intermediates based on experimental techniques and common patterns of reactivity documented in the literature over the last century. Contributions made by scientists working in laboratories at Canadian universities and at the National Research Council of Canada are noted throughout.

Key words: physical organic chemistry, mechanistic chemistry, reaction intermediates.

Résumé : On présente une revue de la découverte d'intermédiaires réactionnels et de concepts apparentés en chimie organique physique. On porte une attention particulière à la chronologie des idées, la fréquence de la mention des intermédiaires réactionnels dans les relevés de réactions organiques utilisées en synthèse organique et le lexique des termes scientifiques utilisés dans le langage de la chimie organique physique. On présente des arbres décisionnels logiques et généraux pour l'identification unique ou pratiquement unique d'intermédiaires réactionnels basés sur des techniques expérimentales et sur des patrons communs de réactivité documentés dans la littérature pendant plus d'un siècle. On note partout les contributions faites par les scientifiques travaillant dans les laboratoires des universités canadiennes et dans ceux du Conseil national de recherches du Canada.

Mots clés : chimie organique physique, chimie mécanistique, intermédiaires réactionnels.

[Traduit par la Rédaction]

Introduction

The development of physical organic chemistry concepts is inextricably linked to the discovery and identification of reaction intermediates (1). Once chemists began amassing a library of chemical reactions that made it possible for one chemical structure to be transformed into another, thereby ushering in the vast and unlimited field of organic synthesis, it soon became apparent that patterns of reactivity among common structures emerged as a consequence of such transformations. The central questions of how and why particular products resulted in a given reaction from known substrate structures launched the field of mechanistic chemistry. These questions in turn evolved into others such as "how fast a particular reaction proceeds" and "how can one control the product outcome". The former launched an era of instrumentation development where various time-resolved techniques were invented to probe the temporal gap between substrate and product(s) of a given reaction. The latter question launched investigations into what parameters were important and to what degree in determining product outcomes. All of these questions were greatly influenced by ongoing parallel theoretical and experimental developments in the understanding, determination, and verification of chemical structure. Much of the success in structure elucidation and prediction and in time-resolved studies of reaction intermediates may be attributed to the birth of quantum mechanics and spectroscopy, which were the children of the happy marriage between physics and chemistry. Over time a certain "logic" to the understanding of organic reaction transformations emerged. Essentially the whole field of physical organic chemistry can be reduced to an algorithm that attempts to solve the inverse problem of determining the minimum possible set of elementary steps constituting a reaction mechanism that is consistent with experimental observations. It must also satisfy the fundamental condition that the sum of the elementary steps is the overall chemically balanced stoichiometric equation as prescribed by Lavoisier's conservation of mass law. This set of elementary steps may or may not involve transient structures or reaction intermediates between the known substrate structures and identified product structures. Transient structures may be observed directly or inferred indirectly. This inverse problem is akin to the one in algebra of factoring a complex polynomial into its constituent factors, or in number theory of factoring a natural number into its prime factors. However, an important difference between the two related inverse problems is that in mechanistic chemistry the set of "factors" may not be unique and that an iron-clad deductive proof of mechanism

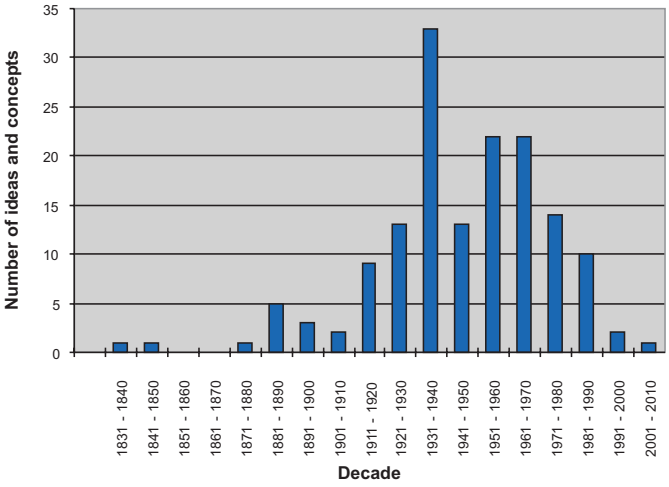
 doi: 10.1139/V05-175 © 2005 NRC Canada



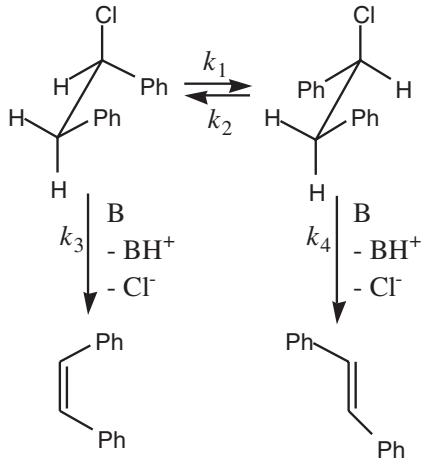
cannot be done. The best one can hope for is consistency among various observations and techniques used. This effectively means that every postulated mechanism, or "set of factors", is only confirmed by experimental evidence and techniques that are available at the time of discovery, and hence is always open to later revision pending reexamination by new techniques. Laidler in a commentary on the use and misuse of the concept of rate-controlling step states that "reaction mechanism can never be established with a high degree of confidence" (2). In mathematics the analogous proof once confirmed is always true for all time.

This paper outlines key developments in physical organic chemistry and shows how they have impacted studies of reaction intermediates. The approach is to present the "big picture", tracing both ideas and people in the field so that the reader can get a sense of scale of what has been accomplished as well as take stock of where we are at today in the field and identify new fruitful areas of future research. Particular attention is paid to chronology of ideas, frequency of occurrence of reaction intermediates in the library of organic reactions used in organic synthesis, and the lexicon of scientific terms used in the language of physical organic chemistry. General logic decision trees are presented for the unique or near unique identification of reaction intermediates based on experimental techniques and common patterns of reactivity documented in the literature over the last century. In keeping with the theme of this special issue, contributions made by scientists working in laboratories at Canadian universities and at the National Research Council of Canada are noted throughout.

Chronology of concepts in physical organic chemistry

Figure 1 shows a histogram of the timeline of discovery of key concepts in the field of physical organic chemistry and Table S1 (Supplementary material)[2] specifies them in a list along with the respective names of scientists who made these contributions. The celebrated ideas are named after particular scientists and the remainder are given special names. It is instructive to point out that when one begins learning about a field of science for the first time one can fast track their study by focusing on the "named things" in that field, since these represent the sign posts of what is important in the subject in question, especially ones that have stood the test of time, usage, and further experimentation by scientists at large. In a number of instances, ideas have been attributed to scientists with established reputations despite them not being the original discoverers. Recent works (3) have documented this phenomenon of incorrect attributions of discovery, priority, and credit of chemical names and eponyms in organic and physical chemistry. Examples relevant to the present compilation (4) include: (*i*) the Le Châtelier's principle of equilibria (1884) (5), which was discovered a few months earlier by Jacobus H. van't Hoff (1884) (6); (*ii*) the Arrhenius equation (1889) (7) also discovered earlier by van't Hoff (1884) (6); (*iii*) the steady-state

Fig. 1. Histogram showing timeline of discovery of key concepts in physical organic chemistry (growth of ideas and concepts).



approximation in chemical kinetics credited to Max Bodenstein in 1913, which was described earlier in that year by David Leonard Chapman and his student L.K. Underhill (8); (*iv*) the Michaelis–Menten mechanism of enzyme kinetics (9) (1913), which was first described earlier in 1892–1902 by Adrian J. Brown (10) and by Victor Henri (11) in 1901–1903 following work done in the laboratories of Wilhelm Ostwald in Leipzig and culminating in a doctoral thesis on the enzyme kinetics of diastase; (*v*) the Orton rearrangement (12) (1902) discovered earlier by Georg Bender (13) in 1866; and (*vi*) the Curtin–Hammett principle (14) (1954), which was originally formulated in 1907 by Solomon F. Acree (15). The last case has not been discussed before in the literature and deserves further comment here. No references to Acree's early work are mentioned in any of the well-known papers by Curtin, Hammett, and others including an extensive review of the topic by Seeman (16). Only two citations in the literature appear to mention Acree's contribution (17, 18). Hammett, in his book, refers to the principle as the "Curtin principle", but makes the following footnote: "Because Curtin is very generous in attributing credit, this is sometimes referred to as the Curtin–Hammett principle". Curtin, in turn, in his 1954 paper, published in an obscure journal and likely read by few chemists, refers to a private communication from Hammett in 1950 attributing that the idea originated from Hammett in his comment: "It was pointed out by Professor L.P. Hammett in 1950 that if the transition state theory is accepted and if rotation between the various possible conformations of the starting material is very rapid compared to the rate of the reaction, the relative amounts of products formed from the two critical conformations are completely independent of the relative populations of the conformations and depend only upon the difference in free energy of the transition states." The chemical reaction referred to in Curtin's work is the E2-base-catalyzed elimination of halide from 1,2-diphenyl-1-chloroethane to yield *cis*- and *trans*-stilbene (Scheme 1). Curiously, Curtin's paper

[2] Supplementary data for this article are available on the Web site or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. Scheme 1.

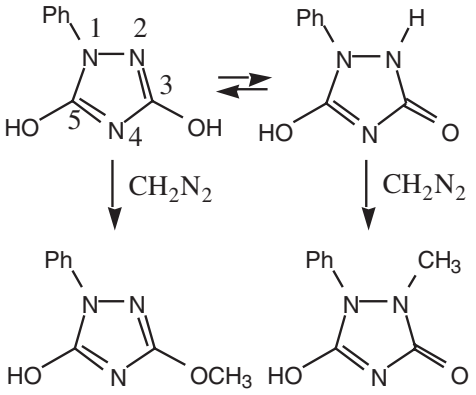
cis-stilbene *trans*-stilbene

does not present a precise mathematical relationship describing the phenomenon, but Hammett does in his book with the following equation given in eq. [1].

$$[1] \qquad \frac{\mathrm{d[trans-stilbene]}/\mathrm{d}t}{\mathrm{d[cis-stilbene]}/\mathrm{d}t} = \frac{q^{\#}_{\mathrm{trans}}}{q^{\#}_{\mathrm{cis}}}$$



where the qs refer to transition-state partition functions for the elimination steps, which in turn are related to the corresponding rate constants. However, Acree in 1907 studied the oxygen and nitrogen alkylations of tautomeric mixtures of 1-phenyl urazoles with diazomethane in ether solution (Scheme 2). He correctly concluded that "it is perfectly obvious that such reactions … do not give us decisive evidence in regard to the relative amounts of the enol and keto forms in any given amide group in which the change from one tautomeric form to the other is very rapid in comparison with the reactions between the two forms and the alkylating reagents." Furthermore, Acree derived an expression, identical in form to the Winstein–Holness equation, for the observed second-order rate constant for the appearance of total product as a function of the relative populations of the urazole enol and keto forms nearly a half-century before Winstein and Holness's celebrated paper of 1955 (19). The thread of this principle was taken up again nearly 50 years later in 2003 (18) when an experimentally accessible efficiency parameter, defined only in terms of the four relevant rate constants (see eq. [2]), was introduced as a means to gauge the true efficiency of resolution of a chemical system obeying kinetic schemes as shown in Schemes 1 and 2 and having starting materials that are stereochemically related. This parameter was able to account for all experimentally observed cases between and including the limits of complete dynamic kinetic resolution (Acree–Curtin–Hammett conditions) and complete kinetic resolution (anti-Acree–Curtin–Hammett conditions).

$$[2] \qquad \varepsilon_{\mathrm{DKR}} = \frac{rv+u}{rv+u+1}$$

where $r = k_3/k_4$, $u = k_1/k_3$, and $v = k_2/k_3$.

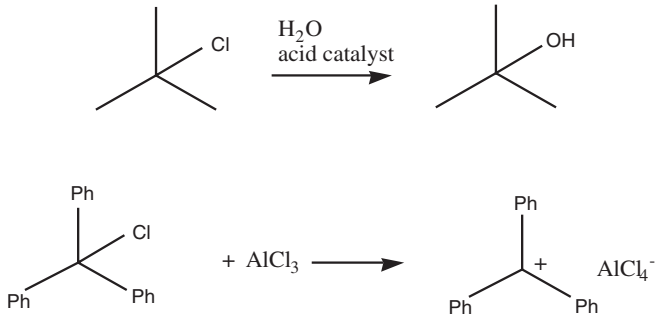
Scheme 3.

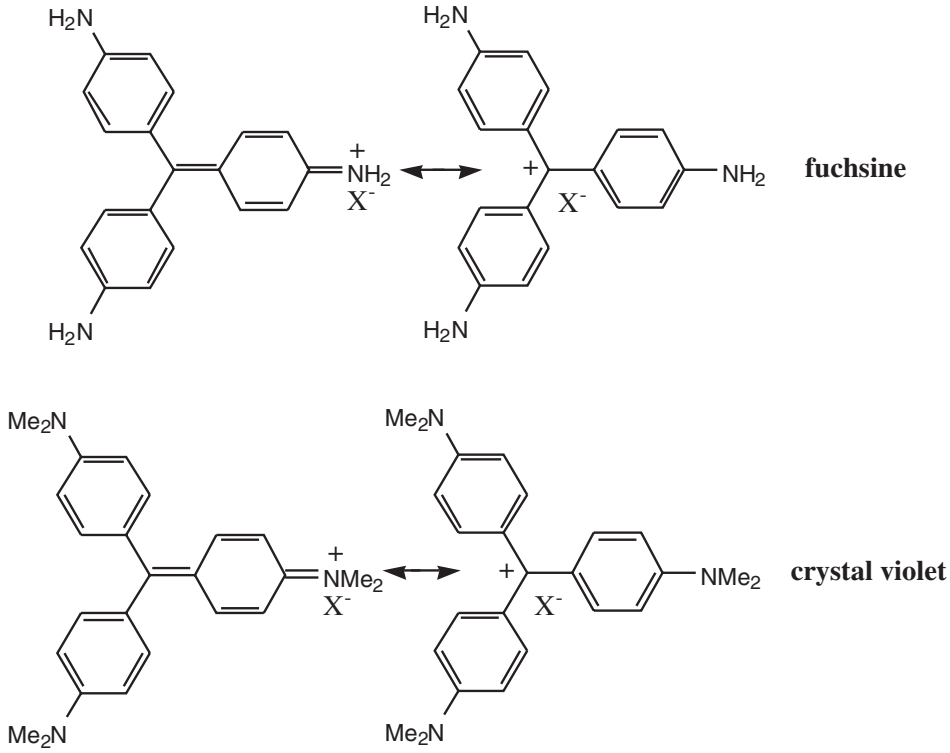


As written by Julius Stieglitz (1899):

Berzelius, Wilhelm Ostwald, and Jacobus H. van't Hoff. Ludwig Wilhelmy carried out the first reported kinetics experiment in 1850 when he examined the acid-catalyzed hydrolysis of cane sugar to invert sugar by polarimetry (22). The concept of the existence of reaction intermediates as chemical species of fleeting lifetimes originated in 1899 when Julius Stieglitz suggested the first mechanism of a chemical reaction when he examined the acid-catalyzed hydration of imidoethers via tetrahedral intermediates (Scheme 3) (23). James Norris in 1901 postulated the existence of carbocations, as it turns out the most extensively studied reaction intermediate class of all, when he examined the solvolysis of tertiary alkyl halides in acidic media (Scheme 4) (24). Almost simultaneously Adolf von Baeyer formulated the carbonium ion theory to account for the chemical behaviour and colour of triphenylmethane dyes such as fuchsine and crystal violet (Scheme 5) (25). A prominent American scientist, Gilbert N. Lewis, in the early part of the last century laid the foundation for a number of concepts that contributed greatly to the study of reaction mechanisms and reaction intermediates: octet rule in bonding (26), electrophilicity and nucleophilicity (27), inductive effect,[3] the prediction that radicals could be studied by magnetic methods,[4] Lewis acids and bases as electron acceptors and donors (27*b*), and the effect of resonance on electronic transitions (28).

Examination of the histogram in Fig. 1 shows the first "golden age" of physical organic chemistry in the 1930s and 1940s when simple reaction mechanisms were systematically categorized by type for the first time and new nomenclatures were introduced by Sir Christopher K. Ingold and his school such as Elcb (29), S_N1 and S_N2 (30), E1 and E2 (31), A1 and A2 (32), and B1 and B2 (32). Up to that time about 200 named organic reactions were already known since Wöhler's urea synthesis (33). The earliest attempts to understand reactivity in a systematic way were made by Sir Robert Robinson who formulated the familiar curly arrow notation to symbolize electron flow from electron donor groups to electron acceptor groups in an effort to determine patterns of reactivity in aromatic substitution reactions and to understand electronic effects of substituents on aromatic

Scheme 4.



rings (34), and by Arnold F. Holleman who introduced the concept of directing groups in such reactions (35). Both Robinson and Ingold formulated the electronic theory of organic chemistry (36) though a bitter controversy over priority developed between them (37). The next major advances to be put forward during this period were by Johannes Brönsted (38), who introduced a linear double logarithmic correlation between rate constants and acid strength for acid- and base-catalyzed proton transfer reactions, by Louis Hammett (39), who introduced the general concept of linear free energy relationships and the quantitative partitioning of substituent effects via substituent constants, and by Henry Eyring (40), who introduced transition-state theory that linked measurable kinetic and thermodynamic parameters to explain the dynamics of bond-making and bond-making processes in elementary steps of a reaction mechanism. In a short time after the discovery of deuterium by Harold Urey in 1932 (41) powerful techniques for probing the nature of such transition states, particularly those pertaining to the rate-determining step, emerged; namely the determination of isotope effects on rate constants and equilibrium constants (42), isotopic labelling experiments (43), and isotopic exchange experiments (44). All of these advances helped to rationalize chemical reactions and gave chemists the confidence to predict product outcomes for new reactions that had yet to be carried out.

In the second golden age of physical organic chemistry in the 1950s and 1960s, attention shifted to the United States

[3] See ref. 20*a*, p. 139.

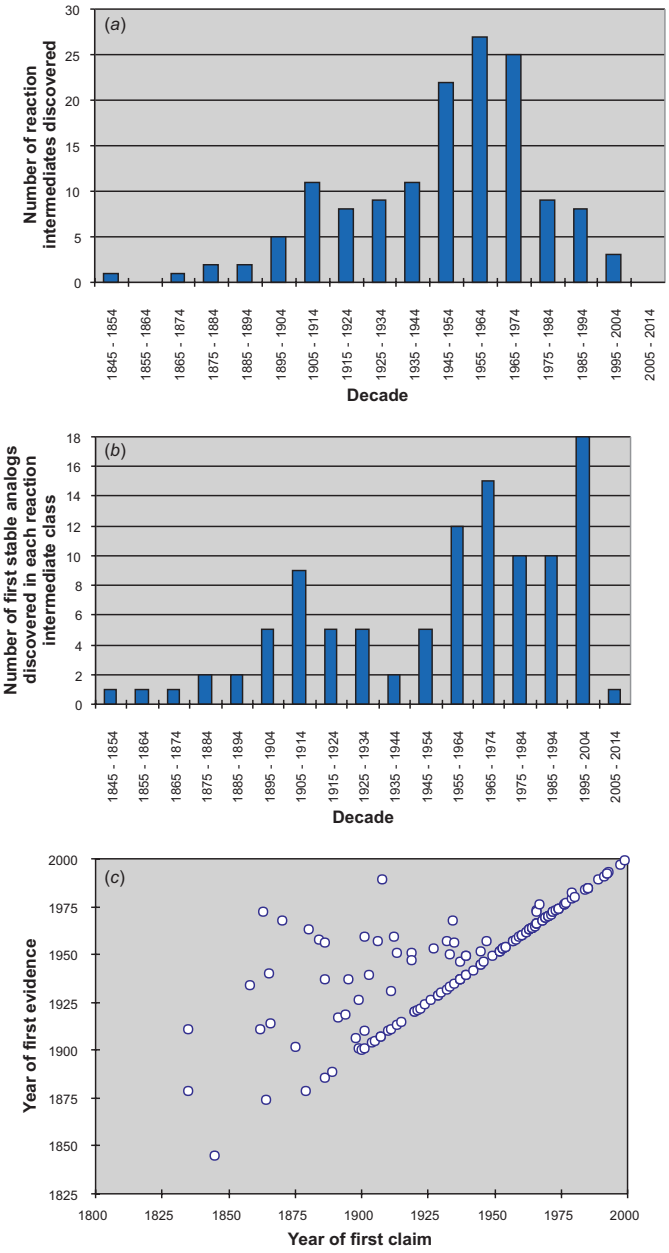
Scheme 5.

where the following people figured prominently in further developing ideas in the field: Paul D. Bartlett (Harvard), Ronald Breslow (Columbia), William von Eggers Doering (Columbia), George S. Hammond (Iowa State, Cal Tech), William P. Jencks (Brandeis), George A. Olah (USC), C. Garner Swain (MIT), Robert W. Taft, Jr. (Pennsylvania State, UC Irvine), Frank H. Westheimer (Harvard), and Saul Winstein (UCLA). Though Canadian university students of chemistry have heard of Winstein's name in connection with several concepts in physical organic chemistry as attested by the many things named after him, very few, if any, know that he was born and raised in Montreal, Quebec before embarking on a doctoral degree at Cal Tech under Howard J. Lucas and launching his legendary career at UCLA (45).

In this time period the invention of time-resolved techniques (46) for probing fast reactions resulted in an explosion of research on monitoring the temporal behaviours of a wide variety of transients in various media whose lifetimes are in the submillisecond to picosecond time domains. This second golden age was characterized by technological advances in instrumentation, which made it possible to probe the earliest stages of chemical processes in a reaction mechanism. The strength of these methods led mainly by flash photolysis provided direct observation of reaction intermediates by various kinetic and spectroscopic means. Both kinetic decay (or growth) curves and spectra of transients could thus be obtained. The invention of lasers by physicists and other electronic equipment by engineers and skilled technicians to rapidly convert optical signals into electrical signals and to capture, digitize, and store kinetic waveforms for subsequent analysis helped to propel this technique to the forefront of research. Modern day physical organic chemists ought to therefore give these scientists the credit and respect that they so rightly deserve. The main condition for making the chemistry work by this method was the fact that targeted transients had to be generated by some photochemical reaction. Other techniques based on rapid mixing of solutions such as stopped-flow (46) or on applying sudden perturbations of temperature on solutions, commonly called the T-jump technique (46), also contributed to the study of reaction intermediates, but to a lesser extent. Virtually every kind of spectroscopy has been modified to become time-resolved in one way or another. Another useful technique pioneered by George C. Pimentel (47) to probe reaction intermediates is that of generating them in noble gas matrices at low temperatures and inferring their structure by IR, microwave, or UV spectroscopy in conjunction with theoretical calculations of their geometries at various levels of theory. IR spectroscopy is particularly useful since observed spectra can be directly compared with vibrational frequencies calculated from analyses of corresponding geometry optimized structures.

In recent years emphasis has shifted to the syntheses of thermodynamically and (or) kinetically stable analogs of reaction intermediates, essentially putting them in a bottle. This has lead to a number of chemical curiosities (see Table S6 in the Supplementary materials).[2] Success can be achieved by judicious choice of substituents so as to impart stabilization by electronic and (or) steric effects or by generating them in exotic media that stabilize their structures such as "magic acid" (48), or by caging the intermediates in highly restricting media such as zeolite supercages (49). Another new frontier that is being examined is the probing of organometallic intermediate structures in important carbon–

© 2005 NRC Canada



carbon bond-forming reactions that utilize organometallic catalysts, particularly those containing palladium and other transition metals (50).

Table S2 (Supplementary material)[2] summarizes important coined terms used in physical organic chemistry and reaction intermediate studies. It is instructive to point out here that a very effective way for a scientist to carve out their scientific niche and get attention for their work is to coin a particular word or phrase that over time will end up being synonymous with the discovery that they have made or the concept that they initiated and their persona. Perusal of this list shows some well-known coined name – scientist associations as well as some surprises, which even the seasoned practitioner in the field may learn about for the first time. The true measure of worth and recognition of an idea or concept is when other scientists use that idea or concept in their own work and even go further by building on top of it.

Chronology of discovery of reaction intermediates

Figures 2*a* and 2*b* show timelines of discovery of reaction intermediates and of stable analogs. Original references, including reviews, and schemes depicting reactions for all of these intermediates are compiled in the extensive database of Tables S5 and S6 (Supplementary material).[2] The histogram in Fig. 2*a* shows that the greatest number of intermediates were discovered during the second golden age of physical organic chemistry (mid-1940s to mid-1970s) that coincided with the advent of time-resolved techniques. Table 1 gives a detailed list of this chronology from Fremy's nitroxide radical salt (1845) to Thomas Tidwell's bisketenes (2000). Figure 2*b* shows the timeline of discovery of stable analogs of reaction intermediates, where it is observed that most of the advances have been made in the last 40 years particularly between 1995 and 2004. Figure 2*c* shows the correlation between first claim and first evidence of intermediate identification by experimental means. Not surprisingly the correlation is worse from the mid-19th century to the mid-20th century and improves markedly from about 1950 to the present day. During the early years, many intermediates were conjectured with little experimental evidence. Several years had to pass before their identities were finally confirmed, again largely thanks to technological advances that had to be developed in order for this to happen. Notable intermediates with extended time gaps between claim and discovery include: (*i*) the dication intermediate in the benzidine rearrangement confirmed by George Olah in 1972, 109 years after A.W. Hofmann's discovery of the rearrangement reaction in 1863; (*ii*) oxirene in Wolff rearrangement confirmed by Imre G. Csizmadia and Otto P. Strausz in 1968, 98 years after Marcellin Berthelot's first claim in 1870, which was later proven false, for the oxidation of propyne in the presence of chromic acid; (*iii*) Wallach intermediate confirmed by George Olah in 1963 in magic acid, 83 years after Otto Wallach's discovery of the rearrangement of aromatic azo-*N*-oxides; (*iv*) ynols confirmed by Robin Hochstrasser, Jakob Wirz, and A. Jerry Kresge in 1989, 81 years after Hermann Staudinger's confirmation that the ketene structure is not that of a hydroxyacetylene and 69 years after Charles D. Hurd's conjecture of the keteno–ynol tautomerism; (*v*) ketyl radicals

Fig. 2. (*a*) Histogram showing the timeline of discovery of reaction intermediates. See Table S5[2] for specific structures and references. (*b*) Histogram showing the timeline of discovery of the first stable analogs of reaction intermediates in each class by direct synthesis. See Table S6 in the Supplementary material[2] for specific structures and references. (*c*) Graph showing the correlation between first claim and first evidence of intermediate identification by experimental means.

confirmed by Wilhelm Schlenk in 1911, 76 years after A. Laurent's observation of coloured solutions of aromatic ketones upon exposure to sodium metal in 1835; (*vi*) acetoxyl radicals confirmed in 1934, 76 years after B.C. Brodie's discovery of benzoyl peroxide in 1858; (*vii*) episulfonium ions confirmed by Reynold C. Fuson in 1940, 75 years after A. Cahours's synthesis of thiirane from dimethylsulfide and 1,2-dibromoethane in 1865; (*viii*) phenyl cation confirmed by Edward S. Lewis in 1954, 74 years after the discovery of

Year	Reaction intermediate discovered (scientists)[a]
1845	Fremy's nitroxide radical
1874	Sulfonium ions (A. von Oefele, C. Schoeller, A. Cahours)
1879	Radical cations (A. Laurent, C. Wurster, H. Wieland)
1879	Wurster salts
1886	Janovsky complex
1889	Meisenheimer–Jackson complexes
1900	Gomberg radical
1901	Carbocations (J. Stieglitz, J.F. Norris, A. Baeyer)
1901	Piloty's nitroxide radical
1902	Enols (E. Erlenmeyer, A. Lapworth)
1904	Thiele biradical
1905	Ketenes (H. Staudinger)
1906	Phosphonium ions (A. Michaelis, A.E. Arbuzov)
1907	Chichibabin biradical
1907	*o*-Quinodimethanes (R. Willstaetter)
1910	Carbanions (V. Grignard, W. Schlenk)
1910	Niementowski's nitroxide radical
1911	Ketyl radicals (A. Laurent, W. Schlenk)
1911	Carbenes (A. Geuther, H. Staudinger, J. Hine)
1911	*o*- and *p*-Quinonemethides (H. Staudinger)
1913	2,4- and 2,5-Cyclohexadienones (H. McCombie)
1914	Radical anions (M. Berthelot, W. Schlenk)
1915	Schlenk–Brauns biradical
1917	Nitrenes (F. Tiemann, H. Staudinger)
1919	Phosphonium ylides (A. Michaelis, H. Staudinger)
1920	Hydronium ions (L.S. Bagster, G. Cooling, M. Volmer)
1920	Hydrazyl radicals
1921	Pyridine ylides (W. Scheider)
1922	Sulfimine ylides (F. Mann, W.J. Pope)
1924	Flavylium salts (R. Robinson)
1926	Tetrahedral intermediates (J. Stieglitz, F. Swarts)
1926	Kenyon–Banfield radical
1929	Gas-phase alkyl radicals (F. Paneth)
1929	Ammonium ylides (C.K. Ingold)
1930	Sulfonium ylides (C.K. Ingold)
1931	Halonium ions (A. McKenzie, R. Kuhn, C.K. Ingold)
1932	Iminium ions (T.D. Stewart, W.E. Bradley)
1933	Solution-phase alkyl radicals (M.S. Kharasch)
1934	Acetoxy radicals (B.C. Brodie, D.H. Hey, W.A. Waters)
1935	Norrish type I and II biradcials
1937	Benzyl radicals (A. Michaelis, M.S. Kharasch)
1937	Aryl radicals (E. Bamberger, O. Kuehling, W.A. Waters)
1937	Acylium ions (L.P. Hammett, M. Bender)
1937	Acylammonium ions
1937	Meerwein salts
1939	Benzoyl radicals (J.F. Norris, H.H. Glazebrook, T.G. Pearson)
1939	Müller–Neuhoff biradical
1939	Mercurinium ions (H.J. Lucas)
1940	Episulfonium ions (A. Cahours, R.C. Fuson)
1942	Acetoxonium ions (S. Winstein)
1945	Phosphinyl radicals (M.S. Kharasch)
1945	Excited-state triplet ketones (G.N. Lewis, M. Kasha)
1946	Nitronium ions (C.K. Ingold, R.J. Gillespie)
1946	Aziridinium ions (J.S. Fruton, M. Bergmann)
1947	*p*-Quinodimethanes (W. Schlenk, M. Szwarc)
1949	Bridged carbocations (C.L. Wilson, S. Winstein)
1949	Nonclassical ions (C.L. Wilson, S. Winstein)
1949	Phenonium ions (D.J. Cram, S. Winstein)
1950	Germylenes (P. Royen, R. Schwarz, S.N. Glarum, C.A. Kraus)
1951	Nitrenium ions (J. Stieglitz, C.K. Ingold)
1951	Metallocenes (F. Hein, P.L. Pauson, G. Wilkinson, R.B. Woodward)
1952	Aromatic π complexes (M.J.S. Dewar, H.C. Brown)
1952	Metal carbenoids (P. Yates)
1952	Nitrosonium ions (C.K. Ingold)
1952	Methoxonium ions (S. Winstein)
1953	Benzynes (W.E. Bachmann, H.T. Clarke, J.D. Roberts)
1953	Aromatic σ complexes (M. Kilpatrick, G.A. Olah, H.C. Brown)
1953	Doering–Zeiss intermediate
1953	Peroxy radicals
1953	Phenoxyl radicals (E. Muller, C.D. Cook)
1954	Phosphonium betaines (G. Wittig)
1954	Tropylium ions (W.v.E. Doering)
1956	Nitrilium ions (E. Beckmann, F. Klages, W. Grill, I. Ugi)
1956	Wheland intermediate (H.C. Brown, G.A. Olah)
1957	Aminyl radicals (H. Wieland)
1957	Koelsch radical
1957	Silyl radicals (F.C. Whitmore, R.N. Haszeldine)
1957	Cyclopropenyl cations (R. Breslow)
1957	Flavinium salts (A. Robertson, W.B. Whalley)
1958	Phenyl cation (T. Sandmeyer, E.S. Lewis)
1958	1,3-Dioxolenium ions (H. Meerwein)
1959	Pyrylium salts (A. Werner, A.T. Balaban)
1959	Nitroxyl radicals (H. Wieland, K.H. Meyer, O.L. Lebedev)
1959	Phosphoranyl radicals (C. Walling)
1960	Thicarbonyl ylide (G. Wittig)
1960	Vinyl cations (C.A. Grob, P.E. Peterson)
1960	Wanzlich carbenes
1962	Nitrile ylide (R. Huisgen)
1962	Carbonyl oxide (Criegee zwitterion) (R. Criegee, P.D. Bartlett)
1963	Wallach intermediate (O. Wallach, **E. Buncel**, G.A. Olah)
1963	1,3-Dipole traps (R. Huisgen)
1963	Dinitrenes (A.M. Trozzolo, E. Wasserman)
1963	Verdazyl radicals (R. Kuhn)
1964	Violenes (S. Hünig)
1964	Thiophenoxyl radicals (U. Schmidt)
1964	Phenylselanyl radicals (U. Schmidt)
1964	Fischer carbene
1964	Vinylidene carbenes (H.D. Hartzler, W.J. le Noble)
1964	Iminoxyl radicals (J.R. Thomas)
1965	Phosphinoyl radicals
1966	Dications in magic acid (G.A. Olah)
1966	Acyl radicals (H.G. Kuivila, E.J. Walsh, Jr.)
1966	Stannyl radicals
1966	Silylenes (P.P. Gaspar)
1968	Oxirene (M. Berthelot, W. Madelung, **I.G. Csizmadia**, **O. Strausz**)
1968	Vinylidenes (G.H. Coleman, R.D. Maxwell, M.S. Newman, P.J. Stang)
1968	Allene oxides (J.K. Crandall)

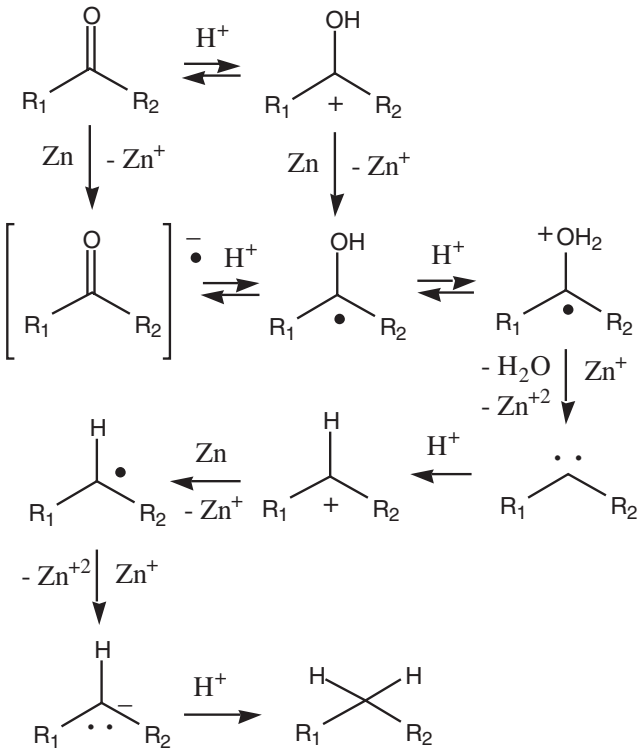
the Sandmeyer reaction in 1884; (*ix*) nitrilium ions confirmed by F. Klages, Ivar Ugi, and A. Hassner between 1956 and 1966, 70–80 years after the discovery of the Beckmann rearrangement of 1886; (*x*) pyrylium ions confirmed by A. Balaban's synthesis of pyrylium salts in 1959, 58 years after Alfred Werner's initial observations in 1901; (*xi*) benzyl radicals confirmed by Morris S. Kharasch in 1937, 51 years after August Michaelis's synthesis of tribenzylarsine from benzyl chloride and arsenic trichloride in 1886; and (*xii*) carbenes confirmed by Hermann Staudinger in 1911 in the thermal and photochemical Wolff rearrangement of diazoketones and by Jack Hine in 1950 in the haloform hydrolysis reaction under basic conditions 49 and 88 years, respectively, after A. Geuther's conjecture of their existence in the hydrolysis of chloroform in base in 1862.

Fig. 3. Pie chart showing the frequency of occurrence of reaction intermediate types in named organic reactions that constitute the library of reactions used in organic synthesis.



Reaction intermediates in organic synthesis

Figure 3 illustrates the frequencies of occurrence of each of the major classes of intermediates in the library of organic reactions used in synthesis and Table S3 (Supplementary material)[2] lists the specific reactions corresponding to each intermediate type. Organic reactions may be classified succinctly according to the following types: carbon–carbon and non-carbon–carbon bond-forming reactions (includes additions, cyclizations, and couplings), condensations, multicomponent reactions, oxidations and reductions with respect to the substrate of interest, rearrangements, substitutions, and fragmentations or eliminations. The first four reaction types figure prominently in skeletal building, or *aufbau* type, reactions, which are the most important class of organic reaction in synthesis. The documentation of carbon–carbon bond-forming reactions dates back to the early part of the 19th century with Faraday's electrochemical synthesis of hydrocarbons from carbon monoxide, carbonic acid, and hydrogen in 1834 (51), Robert Kane's aldol condensation in 1838 (52), and Strecker's synthesis of α-cyanoamines from aldehydes, hydrocyanic acid, and ammonia in 1850 (53). The top five most frequently appearing intermediates in organic reactions based on a library of 435 reactions (4, 54) are: tetrahedral intermediates (21%), enols and enolates (12%), carbanions (6%), metallocomplexes (6%), and carbenium ions (5%).

The ease or difficulty in elucidating reaction mechanisms depends on the reaction type. Tetrahedral intermediates, enols, enolates, and carbanions figure heavily in skeletal building reactions. It is fairly straightforward to write out reasonable reaction mechanisms for organic reactions involving these

species in carbon–carbon and non-carbon–carbon bond-forming reactions, condensations, and multicomponent reactions. Historically, substitution reactions and their associated mechanistic types (SN1, SN2, E1, E1cb, E2, and electrophilic and nucleophilic aromatic), as noted previously, are the best characterized. The elucidation of rearrangement reactions, on the other hand, is less straightforward and is strongly connected to the identification of specific reaction intermediates. Studies of carbenium ions and other cationic intermediates in acid-catalyzed reactions are particularly noteworthy in this regard such as the Wagner–Meerwein rearrangement. Generally, this class of reactions is the most challenging to elucidate and are often the subject of mechanistic puzzles. Labelling experiments are particularly helpful in decoding molecular reorganization processes. Oxidation and reduction reactions with respect to the substrate of interest are the least well-characterized mechanistically in terms of acquiring spectroscopic and kinetic data. This may be due to the fact that many of them occur in heterogeneous media, involve metals or organometallic species, or are surface reactions where traditional methods employed successfully in homogeneous phases may not be adequate to handle the complexities of kinetic treatments, in particular. It is probably in this class of reactions where mechanistic chemists may find it fruitful to explore uncharted territory, particularly with respect to inventing improved redox catalysts for industrial processes and understanding redox cascades in biological processes such as photosynthesis and nitrogen fixation that involve metal-containing enzymes. However, organometallic esters have been reasonably characterized for simple oxidation reactions such as the Criegee glycol cleavage (cyclic lead ester), Hooker oxidation (cyclic manganate ester), Jones oxidation (chromate ester), Lemieux–Johnson oxidation of olefins to 1,2-diols (cyclic osmate ester), Lemieux–Johnson oxidative cleavage of olefins to aldehydes (cyclic osmate ester), permanganate oxidation of olefins to 1,2-diols (cyclic manganate ester), Sarett procedure (chromate ester), Sharpless oxyamination (cyclic osmate ester and cyclic osmate amide), and Sharpless–Jacobsen dihydroxylation (cyclic osmate esters). Ozonides are also well-documented as intermediates in the Harries ozonolysis reaction. Browsing through Table S3[2] shows that reduction reactions may involve carbanion, carbene, radical, radical anions, or ylide intermediates. It is interesting to note that the Clemmensen reduction of ketone groups to methylene groups in acidic media potentially proceeds by the greatest number of intermediate types of any reaction. As shown in Scheme 6, the four-electron redox reaction can be postulated to proceed successively via radical anion, ketyl radical, carbene, carbenium ion, carbon centered radical, and finally carbanion intermediates. Table S4 (Supplementary material)[2] lists those named organic reactions that do not proceed via reaction intermediates and thus occur by concerted processes involving either asynchronous or synchronous bond-forming and bond-breaking processes in the transition states.

Identification of reaction intermediates — The underlying logic of it all

In determining the identity of a reaction intermediate in a thermal or photochemical transformation there are a number of steps that need to be followed. The first thing is to precisely determine the structures of the starting substrate structures as well as the final product structures, including their distribution. At this stage, comparison of product and reactant structures can lead to educated guesses as to the possible structures of transient species. This kind of analysis was the basis of understanding rearrangement reactions such as the Wagner–Meerwein rearrangement where carbocationic intermediates were postulated, or the Wolff and Curtius rearrangements where carbene and nitrene intermediates were conjectured. Julius Stieglitz, James F. Norris, and Frank C. Whitmore were the first to successfully use this technique in predicting likely transient species in such reactions (23, 24, 55). Astute chemists know that often it is the minor products of a reaction that give the most important clues as to the kind of mechanism that may be operative and the speciation of the suspect transient. Examples include liberated gases such as nitrogen (eliminated in Bamford–Stevens oxidation of hydrazones via carbenes, Curtius rearrangement via nitrenes, cyclopropanation with diazomethane via carbenes, diimide reduction via radicals, 1,3-dipolar additions of 1,2-diazoles to olefins, Gatterman reaction via arylium ions or aryl radicals, Gomberg–Bachmann and Meerwein arylation reactions via aryl cations, McFadyen–Stevens reaction via nitrenes, radical dehalogenation via radicals, Sandmeyer reaction via arylium ions or aryl radicals, Schiemann reaction via arylium ions or aryl radicals, Schmidt rearrangement via nitrenes, Staudinger reaction via nitrenes, Tiffeneau–Demjanov reaction via ring expansion, von Richter reaction via carbanions, Wharton reaction via tetrahedral intermediates, Wolff rearrangement reaction via carbenes, and Wolff–Kishner re-

© 2005 NRC Canada

duction via carbanions, iminium ions, and tetrahedral intermediates), hydrogen (eliminated in Chichibabin reaction via carbanions, Corey–Bakshi–Shibata reduction via ylides, Corey–Chaykovsky epoxidation reaction via carbanions, Gribble reduction of diarylketones via tetrahedral intermediates, Wadsworth–Horner–Emmons reaction via carbanions, and Williamson ether synthesis via alkoxides), carbon dioxide (decarboxylations in Borodin–Hunsdiecker reaction via acetoxy radicals, Corey–Winter reaction via carbenes and ylides, Dakin–West reaction via tetrahedral intermediates, diimide reduction via radicals, Eschweiler–Clarke reaction via iminium ions, Hofmann–Martius rearrangement via nitrenes, Hooker oxidation via enols, Kochi reaction via carbenium ions, Leuckart reaction via tetrahedral intermediates, Lossen rearrangement via nitrenes, malonates, and acetoacetates via tetrahedral intermediates, Perkin rearrangement via tetrahedral intermediates, and Schmidt rearrangement via nitrenes), ethylene (eliminated in ring-closing metathesis reactions via organometallic intermediates), hydrogen sulfide (eliminated in Willgerodt–Kindler reaction via tetrahedral intermediates and thiirenium ions), and sulfur dioxide (Ramberg–Bäckland rearrangement via carbanions). Products arising from recombination of fragments generated in a reaction are a signature of radicaloid processes such as 1,2-diphenylethane (dibenzyl), which arises by recombination of benzyl radicals.

There are a number of techniques that can be used to probe or interrogate a reaction between reactants and products. These fall into two main categories: indirect or direct methods. Under indirect methods we have: trapping or quenching kinetic and spectroscopic experiments, which introduce one or more chemical species that react noncompetitively or competitively with the generated intermediate, isolation of the trapped products from the quenching method, isotopic labelling studies, and pH – rate profile behaviour. Under direct methods we have: kinetic and spectroscopic time-resolved techniques that estimate the lifetimes and spectral properties of transient species, direct isolation or "freezing out" of intermediates in restricting media, and direct synthesis of thermodynamically and (or) kinetically stable analogs.

In the quenching technique one aims to use probe molecules that are unique or near-unique traps for the particular transient investigated, rather than promiscuous ones. One key assumption that needs to be experimentally verified is that the trapping agents should not undergo secondary reactions under the prescribed experimental conditions. Examples of specific traps are azide ion for carbenium ions; whereas, examples of promiscuous traps are oxygen that can quench excited state triplet species by triplet–triplet annhilation and carbon centred radicals to give peroxy radicals, and pyridine that can quench ketenes to ketene zwitterions and carbenes to pyridine–carbene ylides. However, specific quenching may not be so simple and often the strategy is to use a combination of trapping agents and then to look for consistency in their kinetic and spectroscopic behaviour. If an intermediate is suspected to be electrophilic then nucleophilic traps are selected, as in the case of cationic transients that are quenched by nucleophilic species with electron-donating groups, lone pairs of electrons, or negatively charged atoms. If an intermediate is suspected to be nucleophilic then electrophilic traps are chosen, as in the case of anionic transients that are quenched by electrophilic species with electron-withdrawing groups, electron-accepting centres, or positively charged atoms. Table 2 summarizes sets of quenchers that have been used to identify various reaction intermediate families. Sometimes trapping agents lead to secondary transients that themselves degrade. The probe technique to "see" spectroscopically invisible transients is particularly important here (56). For example, carbenes absorbing in the UV may be quenched by pyridine to yield coloured carbene ylides absorbing in the visible range, which in turn may be trapped with dimethoxycarbonylacetylene (Scheme 7). Transient ketenes may be first quenched by pyridine to produce ketene zwitterions. These adducts can conceivably undergo further trapping reactions with 1,4-dipolarophiles by analogy with pyridine carbene ylides that can be trapped with 1,3-dipolarophiles (Scheme 8) (57).

Isolation of the final products from quenching experiments can further corroborate structural assignments of the investigated transient species. Stereochemical aspects are often very helpful in this regard. Notable examples are the establishment of the connection between the Walden inversion rule and the S_N2 mechanism (58) and the trapping of singlet vs. triplet carbenes by olefins to give cyclopropane derivatives (59). The trapping of transients to yield stable isolable compounds such as transition-metal complexes has also been of great value. Ernst O. Fischer's pioneering work in trapping carbenes, carbynes, and ketenes using tungsten, molybdenum, and chromium carbonyls are good examples of this technique (60).

Deuterium and C13 labelling studies, including the measurement of kinetic primary and secondary isotope effects, can inform which bonds are being made and broken in particular steps in the proposed mechanism, particularly the rate-determining step. Scrambling of isotopic labels usually infers the presence of a symmetrical intermediate. For example, oxirenes have been inferred as possible intermediates in the Wolff rearrangement of diazoketones to carbenes and then ketenes (61), and thiirenium ions have been inferred in the cyclization–elimination reaction of thioalkoxy substituted vinyl sulfonates (62). If it is suspected that the transient structure has ionizable groups then the acquisition of pH – rate profiles are particularly useful, since their shapes reveal important kinetic and thermodynamic parameters. Enols are particularly noteworthy. Also, the form of buffer catalysis gives insights about whether general or specific acid- or base-catalysis mechanisms are operative. An important point to keep in mind is that such experiments need to be conducted in aqueous media so that meaningful kinetic and thermodynamic parameters can be determined, as well as their dependencies on acid or base concentration. Also, for meaningful comparisons to be made between related chemical structures of any reaction intermediate class, it is best to conduct experiments in a uniform medium under a standard set of conditions. For example, aqueous solution at an ionic strength of 0.1 mol/L NaCl or $NaClO_4$ at 25 °C and 1 atm (1 atm = 101.325 kPa).

The determination of rate laws for the dependence of observed rate constants on concentrations of various species gives important information about the molecularity and

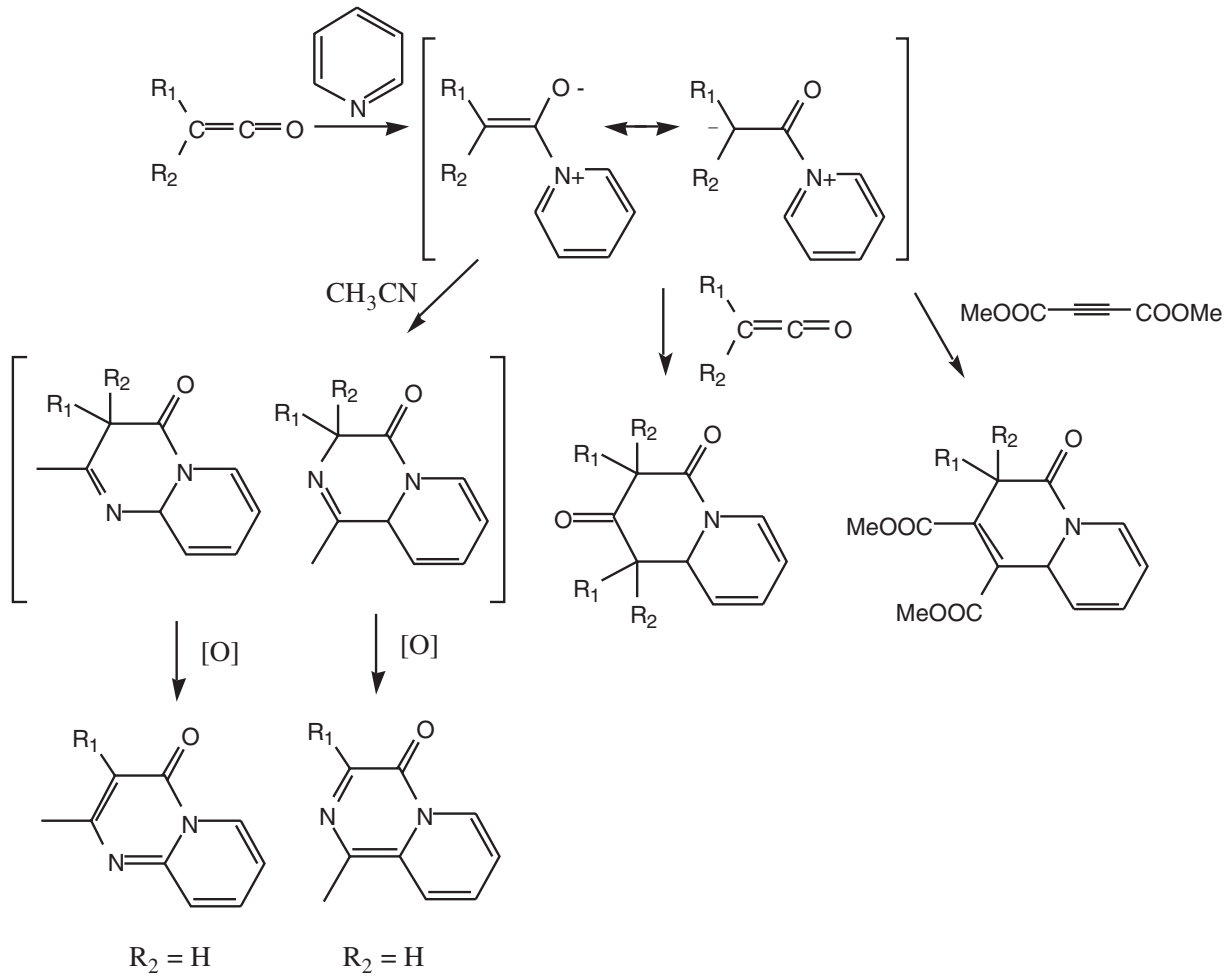
Table 2. List of quenchers used for each reaction intermediate group.



Reaction intermediate group	Quenchers used
Carbenes	Alcohols
	Diazocompounds
	Halogen donors (e.g., carbon tetrachloride, chloroform)
	Hydrogen donors (e.g., *n*-hexane, methanol, isopropanol, isooctane, trialkyltin hydride)
	Imines
	Ketones (e.g., Michler's ketone, acetone)
	Maleic acid, dimethyl ester
	Nitriles (e.g., acetonitrile)
	Olefins
	Oxygen
	Pyridine
	2,2,6,6-Tetramethylpiperidine-*N*-oxide (TEMPO)
	Thioketones (e.g., adamantanethione)
	Thiols
	Triethylamine
Carbocations	Alcohols (e.g., methanol, ethanol, hexafluoroisopropanol, trifluoroethanol)
	Azide ion
	1,3,5-Trimethoxybenzene
1,3-Dipoles	Hydrogen donors (e.g., *n*-hexane, methanol, isopropanol, isooctane, trialkyltin hydride)
	Olefins
Excited state triplets	Aromatics (e.g., azulene, xylenes, 1,4-dimethoxybenzene, 9,10-dibromoanthracene)
	Diethylsulfide
	Iodine
	Methyl viologen
	Olefins (e.g., acrylonitrile, styrene, methylmethacrylate, vinylacetate, 1,1-diphenylethene)
	Oxgyen
	Peroxy compounds (e.g., di-*tert*-butylperoxide, benzoyl peroxide)
	Phenols
	2,2,6,6-Tetramethylpiperidine-*N*-oxide (TEMPO)
	Triethylamine
	Nitrous oxide
	Di-*tert*-butylnitroxide
Ketenes	Alcohols
	Primary and secondary amines
	Pyridine
	2,2,6,6-Tetramethylpiperidine-*N*-oxide (TEMPO)
	Water
Nitrenes	Nitriles (e.g., acetonitrile)
Radicals	Alcohols
	Chloranil
	1,4-Cyclohexadiene
	2,3-Dichloro-5,6-dicyanobenzoquinone (DDQ)
	Halogen donors (e.g., carbon tetrachloride, chloroform)
	Hydrogen donors (e.g., *n*-hexane, methanol, isopropanol, isooctane, trialkyltin hydride)
	$Ni(acac)_2$, $Fe(acac)_3$
	Nitrones
	Nitroso compounds
	Olefins
	Oxygen
	2,2,6,6-Tetramethylpiperidine-*N*-oxide (TEMPO)
	Tetracyanoethylene (TCNE)
	Tetracyano-*p*-quinodimethane (TCNQ)
	Thiols

Scheme 8.

structure of the rate-limiting transition state. Limiting or asymptotic approximations with respect to relative rate constant magnitudes and (or) concentrations of catalyst, quencher, or reactant such as preequilibrium and steady-state approximations are especially useful in verifying rate law behaviours under simplified experimental conditions.

Direct methods are the most convincing in identifying transients, but comparisons of results with known reactions and with other indirect methods previously described are still necessary to obtain a complete story. Time-resolved techniques such as flash photolysis, pulse radiolysis, stopped-flow, and temperature jump allow both detailed kinetic and spectroscopic measurements to be made. In flash photolysis, pulse radiolysis, and temperature-jump techniques, chemical systems are suddenly perturbed by excitation pulses of light, electron beams, or heat, which results in the generation of the transient in solution. The stopped-flow technique involves rapid mixing of two solutions containing substrates. A thermal reaction proceeds giving rise to corresponding transient species once these solutions come into contact with one another. In all cases, once a transient is generated the optical density of the reaction solution is altered and the temporal dependence of this optical density change is monitored. The reaction solution is said to be "probed" by some spectroscopic means such as by UV–vis, IR, EPR, or NMR. Characteristic kinetic behaviours with respect to quenching experiments, such as magnitude of quenching rate constants, order of reaction, dependence of observed rate constants on catalyst concentration, and mathematical forms of the disappearance of substrate and appear-

© 2005 NRC Canada

ance of product as functions of time, and characteristic spectroscopic absorption markers, such as unique absorption bands, help to eliminate false candidates and narrow down the possibilities. The key condition to "catch" or view a transient is that the time resolution of the apparatus used must be smaller than the expected lifetime of the transient. Time resolutions range from several seconds in standard UV spectrophotometric devices to picoseconds in laser flash photolysis apparatuses. Obvious chemical constraints in using these techniques are the kinds of chemical reactions and precursors that are available to generate the appropriate intermediates. Photoreactions are necessary if flash photolysis is to be used and thermal reactions are necessary if T-jump or stopped flow is to be used. Often the choice of precursor is dictated by the suspected identity of the transient. Again, the library of known reactions is of great value in this selection.

Generation of intermediates in highly restricting media such as low-temperature noble gas matrices or organic glasses, or at room temperature in zeolites where the possibility of further reaction is severely impeded is also a powerful way of directly viewing transient species. Transients may be generated photochemically from appropriate precursors that are themselves trapped in a restricting matrix, or by flash vacuum pyrolysis of a substrate in the gas phase where the target intermediate is first generated and then subsequently trapped at 10 K in an argon matrix deposited on a KBr window using a cryostat apparatus. Once trapped, the spectrum of a transient may be obtained and its structure inferred from difference spectra in which the background spectrum of the matrix medium is subtracted out. Often such studies are done in conjunction with computational studies to determine their theoretically predicted IR, UV, or microwave spectra and to compare these with the experimental ones. Matching of spectra constitutes corroborative evidence for transient identification.

The most direct method is the synthesis of a thermodynamically stable analog, effectively bottling the intermediate as a *bona fide* isolable compound. This allows the complete characterization of the structure by conventional means such as boiling point, melting point, ^{1}H and ^{13}C NMR, IR, and UV spectroscopy, mass spectrometry, and X-ray crystallography. To make this strategy work, all available knowledge gained from previous methodologies is used. Thermodynamic stability is influenced by such factors as increased steric crowding, counterbalancing electronic effects by judicious choice of substituents, and topology. Highly stable analogs of reaction intermediates as summarized in Table S6 (Supplementary material)[2] have been found by using one or more of these strategies. Often such chemical curiosities have been discovered by accident rather than by design.

Like most of the thinking done in an empirical science, chemistry relies heavily on comparing new results with the growing empirically derived database or library of past results. The common paradigm is to select special reactions or conditions as "standards", which can be used as yardsticks or comparators for other reactions or conditions.[5] This, for example, is the basis of the linear free energy relationship analysis and compilation of various substituent constants advanced by Hammett, Taft, and others. Substituent effect experiments fine-tune our understanding of the nature of the rate-determining step, which involves a key intermediate. Such questions as charge distribution in the rate-determining transition state, its position along the reaction coordinate relative to reactants and immediate products, and degree of proton transfer, if applicable, may be answered. Also, changes in curvature of Brønsted and Hammett plots and pH – rate profiles may be interpreted as changes in rate-determining step occurring if downward bends (concave down curvature) are observed or as changes in reaction mechanism occurring if upward bends (concave up curvature) are observed.

Naturally, as the database of knowledge increases, comparisons between new and known reactions become more reliable and hence one's guesses as to the identity of reaction intermediates improve markedly. In terms of the decision trees shown in Figs. 4*a*–4*d*, one need not start at the top and work their way down, but begin somewhere in the middle and quickly gravitate to the likely transient structure in a few iterations of experimentation.

If one knew nothing about a suspected transient at all or had no precedent of analogous reactions to go by in the identification process, then the multiplicity assignment of the transient becomes the uppermost question in the decision tree. Overall, the key concept is to corroborate evidence from various methods so that a consistent picture is built for transient identification, keeping in mind the caveat given in the introduction that *definitive* proof is not possible, but *corroborative* proof is. It may be argued that corroborative proof may evolve into definitive proof the longer the evidence stands the test of time and further experimentation by ever more techniques. Corroboration of experimental results with theoretical computational studies of possible stable geometries and energetics of chemical species from reactants to products, including intervening intermediate structures with associated transition states in each step, is also a very useful strategy. The aim is to map out a complete energy reaction coordinate profile or surface showing the number of sequential elementary steps, the number of relevant transition states, the number of possible intermediates, the structures of all chemical species, and the energy differences between one structure and the next. Relationships such as the ones shown in eq. [3] become useful. The determination of reaction energy barriers and relative thermodynamic stabilities of reactants and products is important in identifying kinetic and thermodynamic control processes, particularly when they operate synergistically or antagonistically

[5] Unfortunately, nucleophilicity, which is a ubiquitous chemical phenomenon, continues to be poorly described in pure quantitative terms from a theoretical point of view. No one universal standard reaction or set of standard reactions have been found to describe nucleophilicity adequately for all chemical structures or reaction types. Practically all existing scales break down at some point. The best that has been accomplished is to use entirely empirical approaches such as the ones advanced by Mayr and co-workers (63) based on extensive families of correlations. On the other hand, proton and electron transfer reactions are both rigorously described in theoretical and quantitative terms. In such reactions protons or electrons are either consumed or produced regardless of the chemical structures of reactants and products involved. This commonality greatly simplifies comparisons between reactions.

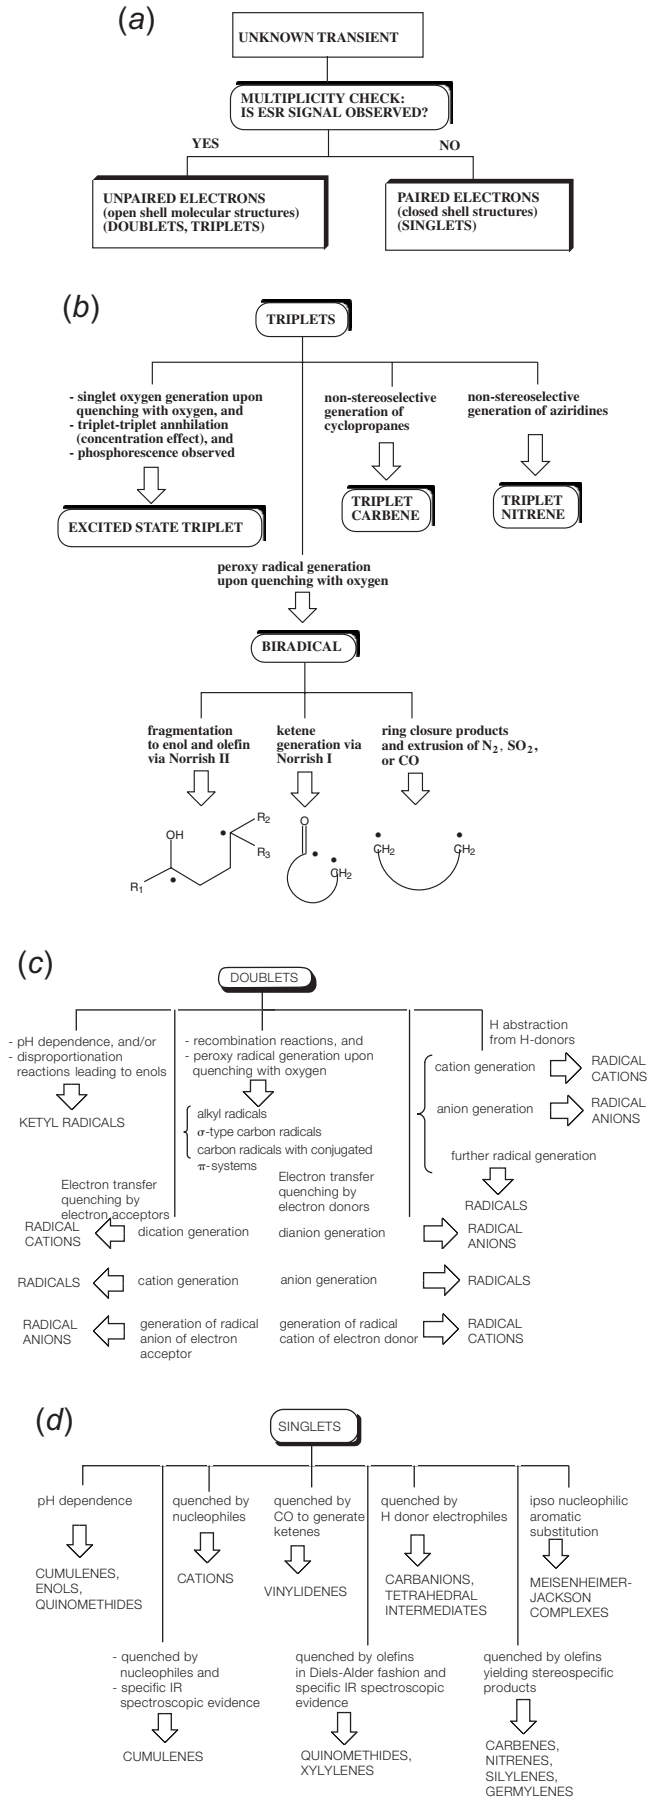

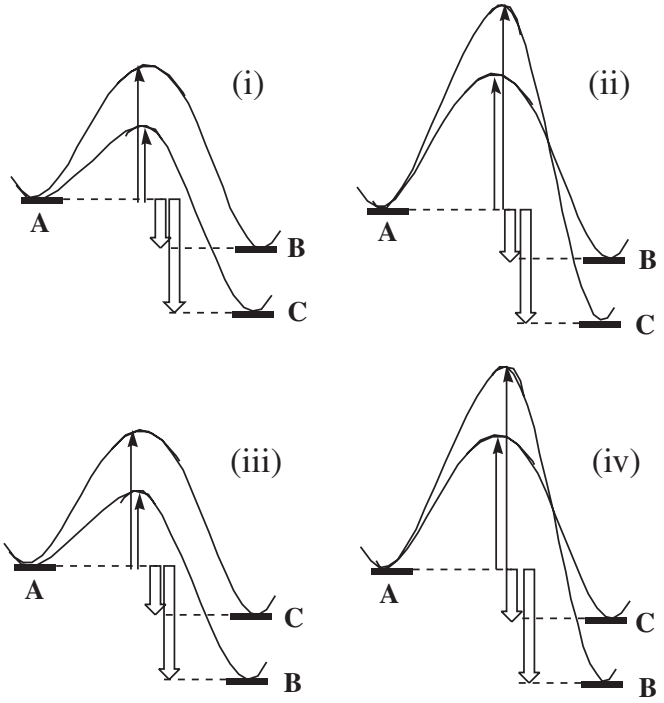

Fig. 4. (*a*) Decision tree showing the main separation of reaction intermediates according to multiplicity. (*b*) Decision tree for the identification reaction intermediates that have a triplet multiplicity. (*c*) Decision tree for the identification reaction intermediates that have a doublet multiplicity. (*d*) Decision tree for the identification reaction intermediates that have a singlet multiplicity.

Fig. 5. Kinetic and thermodynamic control processes for reaction scheme A → B + C. (*i*) Product C is both a thermodynamically and kinetically controlled product (synergistic); (*ii*) product C is a thermodynamically controlled product and product B is a kinetically controlled product (antagonistic); (*iii*) product B is both a thermodynamically and kinetically controlled product (synergistic); (*iv*) product B is a thermodynamically controlled product and product C is a kinetically controlled product (antagonistic).

(see Fig. 5). Complimentary agreement between experiment and theory is particularly satisfying in such analyses.

[3] Number of elementary steps in mechanism =

Number of transition states in mechanism

Number of reaction intermediates in mechanism =

Number of elementary steps in mechanism – 1

Within the realm of experimentation, probably the strongest evidence that can be obtained for the identity of a particular transient is if it can be generated from different precursors and by different techniques and if it can be shown that its spectroscopic and kinetic behaviours are the same irrespective of its origin or method of generation.

Acknowledgements

Parts of this work were presented at the 29th Ontario–Quebec Physical Organic Chemistry Mini-Symposium, 2–4 November 2001, York University, Toronto, Ontario.

The author thanks Wahab Farooq (University of Karachi, Pakistan) for contributions to the list of coined terms in physical organic chemistry. Though best efforts were made in this work to recognize as many key contributors to the study of reaction intermediates as far as possible, any remaining errors and (or) omissions in any of the compilations is unintentional.

Competitive endo- and exo-cyclic C–N fission in the hydrolysis of *N*-aroyl β-lactams[1]

Wing Y. Tsang, Naveed Ahmed, Karl Hemming, and Michael I. Page

Abstract: The balance between endo- and exo-cyclic C–N fission in the hydrolysis of *N*-aroyl β-lactams shows that the difference in reactivity between strained β-lactams and their acyclic analogues is minimal. Attack of hydroxide ion occurs preferentially at the exocyclic acyl centre rather than that of the β-lactam during the hydrolysis of *N*-*p*-nitrobenzoyl β-lactam. In general, both endo- and exo-cyclic C–N bond fission occurs in the alkaline hydrolysis of *N*-aroyl β-lactams, the ratio of which varies with the aryl substituent. Hence, the Brønsted β-values differ for the two processes: –0.55 for the ring-opening reaction and –1.54 for the exocyclic C–N bond fission reaction. For the pH-independent and acid-catalysed hydrolysis of *N*-benzoyl β-lactam, less than 3% of products are derived from exocyclic C–N bond fission.

Key words: β-lactams, hydrolysis, linear free energy relationships, strain.

Résumé : La balance entre la fission C–N endo- et exocyclique lors de l'hydrolyse de *N*-aroyl β-lactames montre que la différence de réactivité entre des lactames tendus et leurs analogues acyles est minimale. L'attaque par l'ion hydroxyde se fait préférentiellement au niveau du centre acyle exocyclique plutôt que sur celui du β-lactame lors de l'hydrolyse du *N*-*p*-nitrobenzoyl β-lactame. En général, il se produit des fissions des liaisons C–N tant endo- que exocycliques lors de l'hydrolyse alcaline des *N*-aroyl β-lactames et le rapport des deux varie en fonction de la nature du substituant. En conséquence, les valeurs β de Brønsted diffèrent pour les deux processus étant égales à –0,55 pour la réaction d'ouverture de cycle et de –1,54 pour la réaction de fission de la liaison C–N exocyclique. Les hydrolyses indépendantes du pH et catalysées par les acides du *N*-benzoyl β-lactame fournissent moins que 3 % de produits dérivés de la fission de la liaison C–N exocyclique.

Mots clés : β-lactames, hydrolyse, relations linéaires d'énergie libre, tension.

[Traduit par la Rédaction]

Introduction

β-Lactam antibiotics such as penicillins (**1**) and cephalosporins are often considered unusually reactive when compared with normal amides because most of their biologically important reactions involve the opening of the highly strained four-membered ring (1, 2). The effect of ring strain on the reactivity of β-lactams may be demonstrated by comparing the rates of the reactions of monocyclic β-lactams with their acyclic analogues. For example, and perhaps contrary to expectation, the rate of alkaline hydrolysis of β-lactams is, at most, 100-fold greater than that of an analogous acyclic amide. The second-order rate constant for the hydroxide ion catalysed hydrolysis of *N*-methyl β-lactam is only threefold greater than that for *N*,*N*-dimethyl acetamide (3).

Incorporating a benzamide as a potential leaving group into a simple azetidin-2-one gives the imide *N*-benzoyl β-lactam (**2**), which contains an endocyclic and an exocyclic acyl centre both of which are potential sites for nucleophilic attack. The hydrolysis of **2** could occur by two routes. For example, the hydroxide ion could attack the exocyclic carbonyl to generate benzoic acid and the intact β-lactam (Scheme 1, route a). The β-lactam could then undergo further reaction with the hydroxide ion to give a ring-opened β-amino acid. Alternatively, the hydroxide ion could attack the endocyclic β-lactam carbonyl to give a ring-opened product **3** (Scheme 1, route b). Many would expect this to be the dominant reaction pathway based on the belief that ring strain increases the reactivity of β-lactams. We were interested in exploring the balance between endo- and exo-cyclic C–N fission as a function of substituents in the aroyl group, and herein report further evidence that the difference in reactivity between strained β-lactams and their acyclic analogues is minimal.

Experimental section

Synthesis

N-Aroyl β-lactams were prepared according to the following general procedure: To a stirred solution of azetidin-2-one (0.5 g, 7.03 mmol) in dry dichloromethane (DCM, 20 mL) was added 4,4-dimethylaminopyridine (0.1 g, 0.82 mmol) at –78 °C, and a solution of aroyl chloride (1.57 g, 8.46 mmol) in dichloromethane (10 mL) dropwise over 5 min. Triethylamine (0.98 mL, 7.02 mmol) was added dropwise

Scheme 1.

over 10 min forming a white precipitate. The reaction mixture was stirred at –78 °C for 1 h and for a further 24 h at ambient temperature. DCM (10 mL) was added to the reaction mixture, and the solution was washed with water (15 mL) and saturated brine (2 × 15 mL). The organic layer was dried over anhydr. Na_2SO_4, and the solvent was removed under reduced pressure by rotary evaporation at 30 °C to yield a pale yellow oil, which was purified by column chromatography.

1-(4′-Methoxybenzoyl)-1-azetidin-2-one

Yield: 0.6 g (42%); mp 125–127 °C. IR υ_{max} (cm^{-1}, $CHCl_3$): 3020, 3009, 2975, 2912, 2842, 1784, 1668, 1606, 1325, 1259, 1195, 1108, 1028. ^1H NMR ($CDCl_3$) δ: 7.99 (2H, d, J = 8.88 Hz), 6.92 (2H, d, J = 8.97 Hz), 3.85 (3H, s, CH_3), 3.77 (2H, t, J = 5.44 Hz, CH_2N), 3.02 (2H, t, J = 5.45 Hz, CH_2CO). ^{13}C NMR ($CDCl_3$) δ: 165.23 (C=O), 163.92 (C=O), 132.57 (quaternary carbon), 131.92 (ArCH), 123.76 (quaternary carbon), 113.948 (ArCH), 55.21 (CH_3), 36.45 (CH_2N), 34.44 (CH_2CO). 1-(4′-Nitrobenzoyl)-1-azetidin-2-one

Yield: 1.23 g (80%); mp 130 to 131 °C. IR υ_{max} (cm^{-1}, $CHCl_3$): 3020, 1787, 1686, 1599, 1523, 1397, 1309, 1252, 1204, 992. ^1H NMR ($CDCl_3$) δ: 8.33 (2H, d, J = 8.75 Hz), 8.14 (2H, d, J = 8.74 Hz), 3.85 (2H, t, J = 5.58 Hz, CH_2N), 3.2 (2H, t, J = 5.57 Hz, CH_2CO). ^{13}C NMR ($CDCl_3$) δ: 164.16 (C=O), 163.79 (C=O), 150.29 (quaternary carbon), 137.32 (quaternary carbon), 130.76 (CH), 123.28 (CH), 37.0 (CH_2N), 35.5 (CH_2CO).

Kinetic procedures

Standard UV spectroscopy was carried out on a Cary 1E UV–vis spectrophotometer (Varian, Australia) equipped with a 12-compartment cell block. The instrument was used in a double beam mode, allowing six reaction cells to be followed in a single run. The cell block was thermostatted using a Peltier system.

The pH measurements were made with a ϕ40 pH meter (Beckman, Fullerton, California) using a semi-micro calomel electrode (Beckman). A calibration of the pH meter was carried out at 30 °C using pH 6.99 ± 0.01, 4.01 ± 0.02, or 9.95 ± 0.02 calibration buffers. For solution pH ≥ 3 and ≤ 11, the pH was controlled by the use of ≤0.2 mol/L buffer solutions of formate (pK_a 3.75), ethanoate (pK_a 4.72), MES (pK_a 6.1), MOPS (pK_a 7.2), TAPS (pK_a 8.4), CAPSO (pK_a 9.6), and CAPS (pK_a 10.4). Buffer solutions were prepared by partial neutralization of their sodium salts to the required pH. Hydroxide ion concentrations were calculated using pK_w (H_2O) = 13.83 at 30 °C (4).

In all experiments, temperatures were maintained at 30 °C and ionic strength at 1.0 mol/L with AnalaR grade KCl unless otherwise stated. AnalaR grade reagents and deionized water were used throughout. Organic solvents were glass-distilled prior to use and stored under nitrogen.

Reactions studied by UV spectrophotometry were commenced by injections (20 μL) of acetonitrile stock solutions 2×10^{-2} mol/L of the substrate into the cells containing preincubated buffer (2.0 mL). Final reaction cells contained ≤1% acetonitrile (*v*/*v*). The pH of the reaction cells was measured before and after each kinetic run at 30 °C; kinetic runs experiencing a change >0.05 units were rejected. Reactant disappearance or product appearance were followed at absorbance change maxima for individual compounds. The solubility of compounds was ensured by working within the linear range of absorbance in corresponding Beer–Lambert plots. Reaction concentrations were generally within the range of 2×10^{-5} to 2×10^{-4} mol/L. Pseudo-first-order rate constants from exponential plots of absorbance against time or gradients of initial slopes were obtained using the Cary Win UV kinetics application (Version 02.00(26)). The pH–rate profiles were modelled to theoretical equations using the Scientist program (V2.02, Micromath Software Ltd, Saint Louis, Missouri).

HPLC analysis

HPLC analysis was carried out on the Beckman System Gold HPLC with the 127 solvent module running a linear gradient program from solvent A (94% water, 5% acetonitrile, and 1% formic acid) to solvent B (20% water, 79% acetonitrile, and 1% formic acid) over a period of 30 min, using a RP-18 (5 μm) LiChrospher® 100 column, and monitored by the 168 diode array detector at 228 nm.

Results and discussion

The hydrolysis of *N*-benzoyl β-lactam

The rate of hydrolysis of **2** was studied by UV spectrophotometry in buffered solutions of various pH with 1% acetonitrile – water (*v*/*v*) and 1.0 mol/L ionic strength (KCl) at 30 °C. The hydrolysis of **2** shows simple first-order kinetics to give an observed rate constant (k_{obs}). The pseudo-first-order rate constant (k_{int}) for hydrolysis, obtained by extrapolating k_{obs} to zero-buffer concentration, shows acid-catalysed, pH-independent, and alkaline hydrolysis terms, the relative importance of which vary with pH (Fig. 1). The pseudo-first-order rate constant (k_{int}) has a first-order dependence on acid and hydroxide ion concentration, as indicated by the slope of unity on the acid and basic limb, respectively, of the plot of the logarithm of the rate constant (k_{int}) against pH. The pseudo-first-order rate constant can be fitted to eq. [1] using the Scientist program:

$$[1] \qquad \frac{\text{Rate}}{[\beta\text{-lactam}]} = k_{int} = k_o + k_H[H^+] + k_{OH}[OH^-]$$

The rate constants for acid-catalysed hydrolysis (k_H), pH-independent hydrolysis (k_o), and alkaline hydrolysis (k_{OH}) of **2** are $k_H = 3.19 \times 10^{-5}$ (mol/L)$^{-1}$ s^{-1}, $k_o = 8.92 \times 10^{-7}$ s^{-1}, and $k_{OH} = 11.2$ (mol/L)$^{-1}$ s^{-1}. The latter is in the range commonly observed for the alkaline hydrolysis of imides (5).

Alkaline hydrolysis of *N*-benzoyl β-lactam

The site of nucleophilic attack by the hydroxide ion on **2** is not obvious because the rates of alkaline hydrolysis of β-lactams with weakly basic leaving groups are similar to those for analogous acyclic amides (2, 6). The rate of alkaline hydrolysis was also studied by pH-stat to monitor the progress of the reaction by titrating against a NaOH solution. One equivalent of NaOH to the β-lactam concentration was consumed for the overall reaction, and the calculated second-order rate constant (k_{OH}) for the alkaline hydrolysis of **2** from a single pH-stat experiment, carried out at pH 10.50, was very similar to that determined by UV spectrophotometry. At the end of the reaction, the solution was analysed by HPLC with a UV detector. The presence of benzoic acid is clearly demonstrated as a new signal. No benzoic acid would be formed from the hydrolysis of the β-amido acid **3** under these conditions (Scheme 1, route b). Any hydrolysis to give benzoic acid via route b would also consume more than 1 equiv. of hydroxide ion to the β-lactam concentration in contrast to 1 equiv. as seen in the pH-stat experiment. The benzoic acid must then be formed from the alkaline hydrolysis of the exocyclic amide (Scheme 1, route a). Competing exo- and endo-cyclic C–N bond fission was also confirmed by studying the hydrolysis reaction in 1.0 mol/L NaOD–D_2O by ^{1}H NMR. The spectrum, taken immediately after mixing, shows no starting material but two pairs of distinctive triplets in the methylene region. One pair of the triplets belongs to the simple unsubstituted azetidin-2-one, identified by spiking the reaction mixture with the compound. For the other pair of triplets, two-dimensional ^{1}H, ^{13}C HMBC NMR shows a cross peak between the exocyclic carbonyl carbon and one of the triplets, which indicates that the exocyclic carbonyl was still attached to the ring skeleton, i.e., the β-amido acid hydrolysis product **3**.

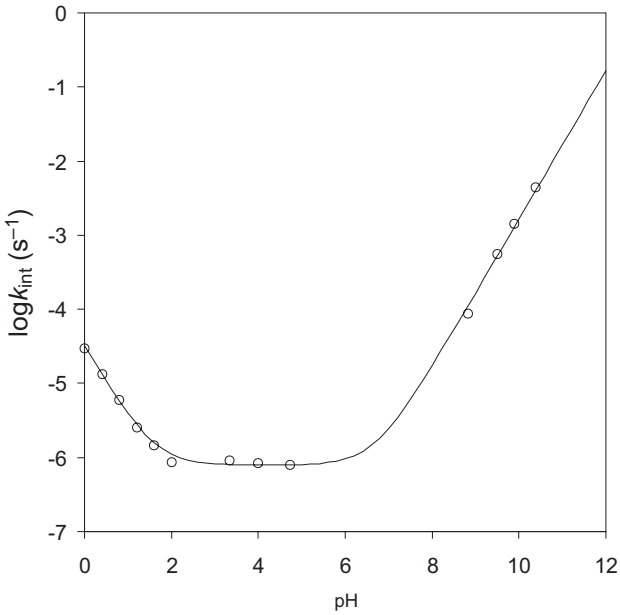

Fig. 1. The pH–rate profile for the hydrolysis of *N*-benzoyl β-lactam (**2**) in 1% acetonitrile – water (*v*/*v*) at 30 °C with 1.0 mol/L ionic strength.

The fractions of the unsubstituted azetidin-2-one and the β-amido acid **3** in H_2O, calculated using the ratio of their NMR signal integrals, are 0.19 and 0.81, respectively. The product ratio was the same when the reaction was carried out at pH 10.50, maintained by pH-stat. This indicates that the rates of hydrolysis of the β-lactam and the exocyclic amide have the same dependence on the hydroxide ion concentration. As the relative rates between two competing pathways in a parallel reaction are proportional to their product distribution (7), the second-order rate constant for the alkaline hydrolysis of the β-lactam of **2** (k_{OH}^{endo}) is 9.07 (mol/L)$^{-1}$ s^{-1} and that for the alkaline hydrolysis of the exocyclic amide (k_{OH}^{exo}) is 2.13 (mol/L)$^{-1}$ s^{-1} (Table 1).

The hydrolysis of *N*-benzoyl β-lactam shows no deuterium incorporation in the hydrolysis product β-amido acid, indicative of a direct addition–elimination mechanism of acyl transfer. The hydrolysis of *N*-acyl β-lactams thus occurs by competitive attack at the endo- and exo-cyclic carbonyl centres. The fact that exocyclic attack is competitive with endocyclic is yet another example of the surprisingly small difference in reactivity between β-lactams and acyclic amides (2, 6). If the rate-limiting step is attack of hydroxide ion on the β-lactam carbonyl carbon to form a tetrahedral intermediate, then the release of strain in the four-membered ring would not be realized in the transition state, although one may have anticipated a preferential conversion of a three-coordinate to a four-coordinate carbon in the four-

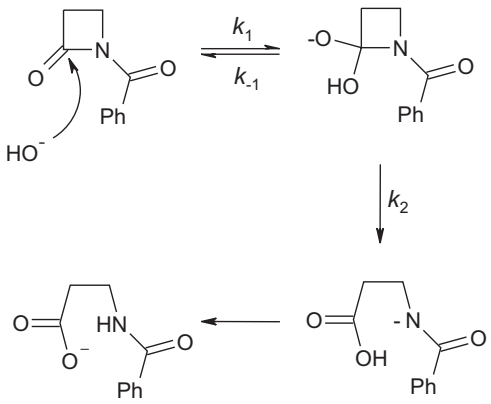
Table 1. The second-order rate constants for the hydrolysis at the endo- and exo-cyclic carbonyl centres of *N*-benzoyl β-lactam (**2**) in water and deuterium oxide with 1% acetonitrile (*v*/*v*) and 1.0 mol/L ionic strength (KCl) at 30 °C.

	Observed rate constants	Rate constants for endocyclic C–N fission	Rate constants for exocyclic C–N fission
k_{OH} ((mol/L)$^{-1}$ s^{-1})	11.2	9.07	2.13
k_{OD} ((mol/L)$^{-1}$ s^{-1})	15.1	12.2	2.87
SKIE[a]		0.74	0.74

[a]SKIE (solvent kinetic isotope effect).

membered ring. If the rate-limiting step is the breakdown of the tetrahedral intermediate or if the reaction is concerted, then this appears to be another example of the reluctance of four-membered rings to undergo facile opening (2, 8).



The apparent second-order rate constant (k_{OD}^{app}) for the alkaline hydrolysis of **2** in D_2O, using pK_w^{D2O} = 14.699 (4) and pD = pH meter reading + 0.40 (9), is 15.1 (mol/L)$^{-1}$ s^{-1}. The fraction of the unsubstituted azetidin-2-one and the β-amido acid **3** obtained from the ^{1}H NMR signal integrals of the products of the reaction in 1.0 mol/L NaOD–D_2O is identical to that obtained in 1.0 mol/L NaOH–H_2O. Therefore, the second-order rate constant for the alkaline hydrolysis of the exocyclic amide (k_{OD}^{exo}) is 2.87 (mol/L)$^{-1}$ s^{-1} and that for the alkaline hydrolysis of the β-lactam (k_{OD}^{endo}) is 12.2 (mol/L)$^{-1}$ s^{-1} (Table 1). As the ratio between the alkaline hydrolysis of the exocyclic amide and the β-lactam is the same in water and in deuterium oxide, the two reactions have, within experimental error, the same solvent kinetic isotope effect (k_{OH}/k_{OD}) of 0.74 (Table 1). The inverse solvent isotope effect is compatible with a rate-limiting formation of the tetrahedral intermediate or its breakdown by anion expulsion (Scheme 2).

The rate-limiting step for the alkaline hydrolysis of acyclic amides is normally the breakdown of the tetrahedral intermediate with partial protonation on the leaving group amine nitrogen (6, 10). However, with **2**, protonation on the amide nitrogen is thermodynamically unfavourable. The leaving group may be expelled in the rate-limiting step as an amide anion without N protonation **4** and is compatible with the observed inverse solvent kinetic isotope effect. C–N bond fission expelling an amide anion from the tetrahedral intermediate would be rate limiting if the expulsion of the amide anion is slower than the expulsion of an incoming hydroxide ion in the intermediate, i.e., $k_2 < k_{-1}$ (Scheme 2). The pK_a of amides like benzamide is about 15, so the pK_a of the conjugate acids of the groups expelled, water and amide, are very similar. The relative rate of C–O fission expelling alkoxide anions compared with C–N fission expelling amines of the same basicity is not easy to predict. Some reactions appear to favour amine expulsion (11), whereas others have faster rates for oxygen (2). A large negative charge development on the leaving group nitrogen is expected for expulsion of an amide anion. The hydrolysis was further studied by using linear free energy relationships to elucidate changes in effective charge in the transition state by monitoring the effect of changing the aryl substituents on reactivity.

Structure–activity relationships for the alkaline hydrolysis of *N*-aroyl β-lactams

The rates of alkaline hydrolysis of some aryl substituted

Scheme 2.

N-aroyl β-lactams were studied as a function of pH in 1% acetonitrile – water (*v*/*v*) with 1.0 mol/L ionic strength (KCl) at 30 °C by UV spectrophotometry. The pseudo-first-order rate constants (k_{int}) for the buffer-independent hydrolysis were obtained by extrapolating the observed rate constant to zero-buffer concentration. The apparent second-order rate constant (k_{OH}^{app}) for alkaline hydrolysis was obtained from the slope of the plot of the pseudo-first-order rate constant (k_{int}) against the hydroxide ion concentration. Using the fraction of products obtained, as previously described using ^{1}H NMR, the apparent second-order rate constants (k_{OH}^{app}) are then separated into the second-order rate constants for the alkaline hydrolysis of the exocyclic amide (k_{OH}^{exo}) and for the alkaline hydrolysis of the β-lactam (k_{OH}^{endo}) (Table 2). The product ratios between the unsubstituted azetidin-2-one and the β-amido acid hydrolysis product, and hence the relative rates of endo- and exo-cyclic C–N bond fission, depend on the nature of the para-substituents in the benzamide residue. Electron-withdrawing substituents favour attack at the exocyclic amide, presumably reflecting the relative importance of the electrophilicity of the carbonyl centre compared with the nucleofugality of the leaving group. The more electron-withdrawing is the substituent, the higher the ratio of exocyclic to endocyclic C–N bond fission and the greater the formation of the simple azetidin-2-one relative to the β-amido acid **3** as products. Exocyclic C–N bond fission is the dominant reaction in the alkaline hydrolysis of *N*-*p*-nitrobenzoyl β-lactam in preference to β-lactam hydrolysis (Table 2).

The observation that electron-withdrawing substituents enhance the rate of reaction is compatible with either rate-limiting formation of the tetrahedral intermediate or its breakdown with amide anion expulsion occurring in the

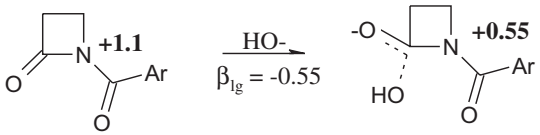
transition state. The difficulty with correlating the reaction rate to the ionization of the leaving group is the lack of available ionization constants of substituted benzamides. The ionization constants of substituted benzoic acids, as analogues of benzamides, were therefore used for the correlation.

The Brønsted-type plot of the rate constants for the alkaline hydrolysis of the β-lactam ring of *N*-aroyl β-lactams against the pK_a of the corresponding benzoic acids is shown in Fig. 2. This shows a good linear correlation, the slope of which gives the Brønsted β_{lg} value for the alkaline hydrolysis of *N*-aroyl β-lactams as –0.55. This indicates that in the transition state of the rate-limiting step of hydrolysis, the effective charge on the nitrogen atom in the amine leaving group becomes more negative relative to the reactant state by 0.55. The effective charge on the nitrogen of β-lactams is expected to be very similar to that of acyclic amides of +0.7 (13). There is no data on the effective charge on the nitrogen in imides. If there is no levelling of the resonance effect, then presumably the charge could be as high as 1.4. If amide resonance is reduced, then, effectively, imides could be treated as amides to which is attached an electron-withdrawing acyl group not involved in further resonance stabilization. This would make the effective charge on the imide nitrogen greater than 0.7 but less than 1.4. A crude estimation may be obtained from the difference in σ and σ$^-$ values for a *para*-acyl substituent, i.e., 0.50 and 0.84, respectively (13). The additional positive charge on the imide nitrogen due to a second electron-withdrawing but non-resonating acyl substitutent would be (0.5/0.84) × 0.7 = 0.42. This would make the effective charge on the imide nitrogen +1.1. This will be used in subsequent discussions, but a slightly smaller or larger value makes little difference to the conclusions.

Fig. 2. Brønsted plot for the second-order rate constant (k_{OH}), for the alkaline hydrolysis at the endocyclic (●) and exocyclic (○) carbonyl centre of *N*-aroyl β-lactams against the pK_a of the corresponding benzoic acid in 1% acetonitrile – water (*v*/*v*) at 30 °C. I = 1.0 mol/L (KCl).



The observed Brønsted value of –0.55 for the alkaline hydrolysis of the β-lactam ring of *N*-aroyl β-lactams is compatible with a late transition state for the formation of the tetrahedral intermediate **5**. The effective charge of +0.55 on N in the transition state structure indicates little or no C–N bond fission and that the nitrogen atom is still involved in normal amide resonance with the aroyl residue (Scheme 3). For comparison, the Brønsted β_{lg} value for the alkaline hydrolysis of N-substituted amides is –0.07 (6), which was interpreted in terms of general-acid-catalysed breakdown of the tetrahedral intermediate owing to partial proton transfer from water **6**. The rates of alkaline hydrolysis of *N*-aryl β-lactams generate a Brønsted β_{lg} of –0.44, which was taken as evidence of rate-limiting formation of the tetrahedral intermediate (2, 14).

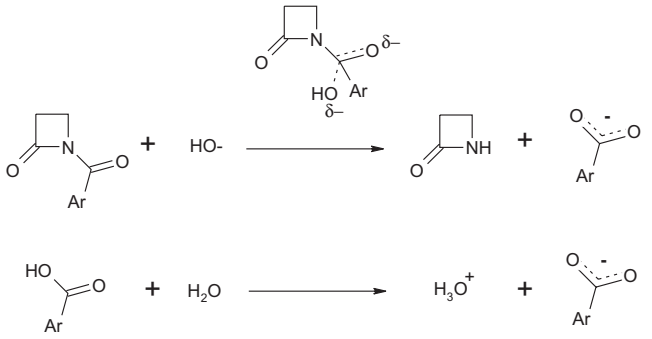
Scheme 3.



Extrapolating the data for the Brønsted plot for the alkaline hydrolysis of *N*-aryl β-lactams to the rate constant for the alkaline hydrolysis of *N*-benzoyl β-lactam gives an apparent pK_a of –7.5 for the leaving group amine. Formally this corresponds to the N protonation of benzamide, but as protonation of amides corresponds to O rather than N protonation, the predicted pK_a for N protonation of an amide is not unreasonable.

The Brønsted-type plot for the alkaline hydrolysis of the exocyclic amide of *N*-aroyl β-lactams against the pK_a of the corresponding benzoic acids is shown in Fig. 2. The plot is again reasonably linear, but the dependence of the rate on the pK_a is much greater with an apparent Brønsted β of –1.54. The correlation is intriguing, as the product of the exocyclic amide hydrolysis and that of ionization of the carboxylic acid are the same (Scheme 4). The Brønsted value of –1.54 indicates that the effective charge at the reaction centre in the transition state for the amide hydrolysis is more negative than that in the reactant imide compared with the charge in the carboxylate ion relative to that in the undissociated acid. This indicates that there is a relatively greater negative charge density in the transition state for the hydrolysis reaction than that in the carboxylate anion. This may indicate a rate-limiting formation of the tetrahedral intermediate with a late transition state or an early one in a rate-limiting breakdown because in the tetrahedral intermediate the negative charge is more localized. A similar linear free energy relationship was observed for the rates of alkaline hydrolysis of esters against the pK_a of the product carboxylic acid, which gave a Brønsted value of –1.3 (15). The localized negative charge on the oxygen anion in the tetrahedral intermediate is more dependent on the stabilizing effect of electron-withdrawing groups than the more stable delocalized negative charge in the carboxylate anion.

pH-Independent hydrolysis

The rate of hydrolysis of **2** is pH independent from pH 2–6 (Fig. 1). A product analysis using HPLC of the reaction at pH 3.99 (0.1 mol/L acetate buffer), ionic strength 1.0 mol/L (KCl), and at 60 °C was undertaken. The signal for **2** disappeared with time in an exponential manner, but that for benzoic acid, identified by spiking with the compound, was

Scheme 4.

formed in the hydrolysis in barely detectable amounts. Less than 3% of the hydrolysis pathway now occurs by exocyclic C–N fission. Furthermore, the acetate buffer probably affects the relative rates of hydrolysis of the β-lactam and the exocyclic amide. Buffer catalysis accounts for 17% of the observed rate of hydrolysis under the same experimental conditions as determined from kinetic measurements at different acetate concentrations. If, in an extreme case, the buffer-catalysed hydrolysis of **2** occurs exclusively at the exocyclic amide, a minimum of 17% of the product would be benzoic acid. However, as only a maximum of 3% is attributed to the hydrolysis of the exocyclic amide in the acetate buffer at pH 4, the pH-independent hydrolysis of **2** probably occurs exclusively with endocyclic C–N bond fission. This is in contrast to the 4:1 ratio of β-lactam and exocyclic amide hydrolysis seen for the alkaline hydrolysis of **2**. The exocyclic acyl centre must show a greater selectivity (β_{nuc}) towards nucleophilic attack by water and hydroxide ion, than that of the β-lactam.

The rate of hydrolysis of **2** was studied at different temperatures by UV spectrophotometry (Table 3). The entropy of activation ($\Delta S^{\ddagger}$) for the pH-independent hydrolysis is –228 J K^{-1} mol^{-1}, which is threefold more negative compared with –77.3 J K^{-1} mol^{-1} for the alkaline hydrolysis. The more negative entropy of activation for the pH-independent hydrolysis compared to that for the alkaline hydrolysis suggests a more ordered system for the pH-independent hydrolysis. The solvent kinetic isotope effect (k_{H_2O}/k_{D_2O}) for the pH-independent hydrolysis of **2** is 1.25, which indicates the transition state in the rate-limiting step involves a degree of proton transfer (Table 4). The entropy of activation ($\Delta S^{\ddagger}$) and the solvent kinetic isotope effect (k_{H_2O}/k_{D_2O}) is compatible with a hydrolysis mechanism involving nucleophilic attack by water that is general-base-catalysed by another water molecule such as that shown in **7**.

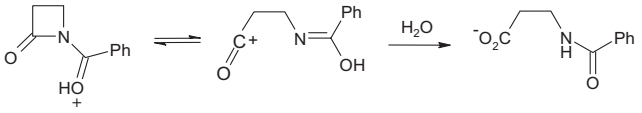
Table 4. The rate constants for the acid-catalysed hydrolysis (k_H), pH-independent hydrolysis (k_o), and alkaline hydrolysis (k_{OH}) of the β-lactam of *N*-aroyl β-lactams in 1% acetonitrile – water (*v*/*v*) with 1.0 mol/L ionic strength (KCl) at 30 °C.

	pK_a	k_o (s^{-1})	k_H ($(mol/L)^{-1}$ s^{-1})	k_{OH}^{endo} ($(mol/L)^{-1}$ s^{-1})
p-NO_2	3.44	3.51×10^{-6}	1.38×10^{-5}	26.5
p-Cl	3.99	1.23×10^{-6}	2.68×10^{-5}	13.8
p-H	4.20	8.92×10^{-7} (H_2O) 7.16×10^{-7} (D_2O)	3.19×10^{-5}	9.07
p-OMe	4.47	6.04×10^{-7}	7.75×10^{-5}	7.27
o-COOH	5.28			2.60

Note: The pK_a of the carboxylic acid corresponding to exocyclic aryl carboxamide is given as an indicator of the inductive effect of the substituent in the aromatic ring. pK_a values are taken from ref. 12.

The first-order rate constants (k_o) for the pH-independent hydrolysis of aryl substituted *N*-aroyl β-lactams were determined (Table 4) and generated a Brønsted β_{lg} value of –0.77. The Brønsted β_{lg} value for the pH-independent hydrolysis is slightly more negative than that for the alkaline hydrolysis (β_{lg} = –0.55) indicating a later transition state probably owing to water being a much weaker nucleophile than hydroxide ion.



Acid-catalysed hydrolysis

The acid-catalysed hydrolysis of **2** in 1.0 mol/L hydrochloric acid was also followed by HPLC at 30 °C. The signal for **2** disappeared with time in an exponential manner, but that for benzoic acid, identified by spiking with the compound, did not show any significant increase. It is estimated that benzoic acid formation accounted for less than 3% of the hydrolysis pathway.

The second-order rate constants (k_H) for the acid-catalysed hydrolysis of the β-lactam of *N*-aroyl β-lactams increase with electron-donating substituents in the aryl ring of the amide leaving group (Table 4). The rate constants are reasonably well-correlated with the pK_a of the corresponding benzoic acid to give a Brønsted β_{lg} value of 0.68. The change in effective charge of +0.68 indicates a transition state with significant protonation on the amide leaving group. There are three possible sites for protonation of **2**: the β-lactam nitrogen is the least basic compared with the β-lactam and the exocyclic carbonyl oxygens. Protonation on the exocyclic carbonyl oxygen is probably more favourable than protonation on the β-lactam carbonyl oxygen, as the carbonyl oxygen becomes less basic when it is attached to a four-membered ring system (16). Also, protonation on the exocyclic carbonyl oxygen may increase the nucleofugality of the leaving group in β-lactam ring opening.

The second-order rate constants for the acid-catalysed hydrolysis of **2** shows a greater dependence on temperature than that for alkaline hydrolysis (Table 3). The entropy of activation ($\Delta S^{\ddagger}$) for the acid-catalysed hydrolysis is –19.1 J K^{-1} mol^{-1}, which is threefold less negative compared with –77.3 J K^{-1} mol^{-1} for alkaline hydrolysis. The smaller entropy of activation for the acid-catalysed hydrolysis may be indicative of an A1 pathway and a unimolecular breakdown of the conjugate acid of the *N*-aroyl β-lactam. The acid-catalysed hydrolysis of the β-lactam in penicillins **1** and other β-lactams has been suggested to involve an A1 mechanism with protonation on the β-lactam nitrogen leading to intermediate formation of an acylium ion (6, 16). If the acid-catalysed hydrolysis of *N*-benzoyl β-lactam occurs by an A1 mechanism with O protonation on the exocyclic carbonyl, C–N bond fission would form a highly unstable acylium ion and an enol amide (Scheme 5).

Scheme 5.

In conclusion, it has been shown that the alkaline hydrolysis of *N*-aroyl β-lactams occurs at similar rates at the β-lactam and the exocyclic amide centres. Despite the strain energy of the four-membered ring, it is not released in the transition state to lower the activation energy and favour exclusive endocyclic C–N ring fission. The reluctance of four-membered rings to open rapidly has been noted previously (2). The competitive rates of hydrolysis at the endocyclic and exocyclic carbonyl centres provide an opportunity to investigate the relationship between the specificity and reactivity of the acyl centres towards enzymes.

A temperature-annealing effect on the host–guest complexation with γ-cyclodextrin[1]

P. John Wright and Cornelia Bohne

Abstract: Pyrene binds to γ-cyclodextrin and forms host–guest complexes with different stoichiometries. The fluorescence of pyrene was employed as a qualitative signature for these different complexes. Solutions prepared at room temperature were shown not to be in thermodynamic equilibrium, since a heating cycle of 20 min at 80 °C followed by cooling led to changes in the relative concentrations of the pyrene–γ-cyclodextrin complexes. This temperature-annealing effect has consequences when determining thermodynamic parameters such as equilibrium constants and host–guest stoichiometries.

Key words: cyclodextrin, pyrene, aggregates, fluorescence.

Résumé : Le pyrène se lie à la γ-cyclodextrine pour former des complexes hôte–invité de stoechiométries diverses. On a utilisé la fluorescence du pyrène comme signature qualitative de ces différents complexes. On a démontré que des solutions préparées à la température ambiante ne présentent pas d'équilibre thermodynamique puisqu'un cycle de chauffage de 20 min à 80 °C, suivi par un refroidissement, conduit à des changements dans les concentrations relatives des complexes pyrène–γ-cyclodextrine. Cet effet d'annellation lié à la température a des conséquences lorsqu'on veut déterminer des paramètres thermodynamiques, tels les constantes d'équilibre et les stoechiométries hôte–invité.

Mots clés : cyclodextrine, pyrène, agrégats, fluorescence.

Introduction

Cyclodextrins (CDs) are cyclic oligosaccharides that serve as hosts for guest complexation owing to their relatively hydrophobic cavity. CDs have been extensively employed to study host–guest complexation (1–5) and biomimetic systems (6–9). From a technological point of view, applications of CDs can be found in separation methods (10) and in food and drug formulations (11, 12). Most CDs complex guests with a 1:1 (guest:CD) stoichiometry (3), but CDs can also be involved in higher order complexes where more than one CD molecule is present in the complex.

In the thermodynamic characterization of CD host–guest complexes, it is normally assumed that aqueous CD solutions follow an ideal behavior, i.e., for a given weight of CD solubilized in water, the CD molecules are present as monomers. However, there is evidence that this assumption is not always applicable, especially at high CD concentrations. The osmotic pressures and activity coefficients for α- and γ-CD decrease with an increase in the CD concentration (≤120 mmol/L) (13), and the formation of CD dimers are suggested to be responsible for this effect. Light scattering experiments showed that solutions of CDs (≤50 mmol/L) contained aggregates (14, 15) larger than 100 nm, suggesting that the aggregate contains several CD molecules. The aggregation was more prominent for β-CD than for α- and γ-CD, and in the latter two cases it was suggested that the contribution of the aggregates to the total amount of the CD dissolved in aqueous solutions was small (15, 16). Aggregation can be minimized by increasing the temperature or the ionic strength of the solution (15). Indeed, the formation of aggregates, leading to hazy solutions and the formation of precipitates, is a problem in drug formulation (17).

The objective of this work was to determine if CD–guest solutions prepared at room temperature by dissolving the guest and CD in water constitutes a system in thermodynamic equilibrium. An annealing process was employed in which the solution was heated to a high temperature (80 °C) followed by cooling. The solubility of CDs is known to increase when the temperature is raised (4, 18), and the formation of aggregates is diminished at high temperatures (15). In addition, for a guest-appended CD, initial heating of the sample to 85 °C was shown to influence the types of complexes formed (19).

The addition of salts can affect the magnitude of the equilibrium constants between guests and CDs for 1:1, 1:2, and 2:2 (guest:CD) complexes (20–23). The effect depends on the nature and the concentration of the salts. It can be ascribed either to competitive complexation of anions to the CD cavity, since some anions were shown to bind weakly to CDs (24, 25), or to the water structure breaking–making effect of the salts, which is related to the Hoffmeister's series for protein solubility. The effect of salts on solute solubility is an empirical observation for which the mechanistic interpretation is not completely elucidated (26–30). Anions such as $^{-}$SCN and I^{-} are structure-breaking agents, and the

hydration energy of these ions is low, leaving more water molecules available to interact with other solutes. NaCl is neutral with respect to its solvation ability and does not significantly affect the solvation ability of water; whereas the sulfate anion is a structure-making agent. Since the addition of salts was shown to inhibit aggregation of CDs (15), we studied the effect of salt addition on the annealing effect for host–guest complexation.

We chose the pyrene–γ-CD system to investigate the effect of temperature annealing because three γ-CD complexes with different stoichiometries are formed (1:1, 1:2, and 2:2; Scheme 1) (31, 32). This system is expected to be more sensitive to the presence of CD aggregates than a system containing only a 1:1 host–guest complex. In addition, the investigation on the binding dynamics of pyrene to γ-CD showed that slow processes were present that occurred over tenths of seconds, which were likely to be related to the rearrangement of pyrene within CD complexes (31). A further rationale for using pyrene as the guest is that its photophysics are sensitive to the polarity of the environment and to the formation of pyrene dimers. The latter leads to the emission characteristically observed for excimers, which in an unconstrained solution are due to the interaction of a singlet excited state of pyrene with a ground-state molecule of pyrene. In the presence of γ-CD, the "excimer-like" broad emission centered around 473 nm is due to the inclusion of two pyrene molecules in the γ-CD complex (2:2) (31, 32). The intensities of the vibronic bands for the pyrene monomer emission respond differently to the solvent polarity. For this reason, the intensity ratio for the emission peak at 373 nm with respect to the intensity at 383 nm (I:III ratio) is high in water and low in nonpolar solvents (33, 34).

[1] Pyrene + γ-CD → Pyrene–γ-CD (1:1)

[2] Pyrene–γ-CD + γ-CD → Pyrene–$(\gamma\text{-CD})_2$ (1:2)

[3] 2Pyrene–γ-CD → $(\text{Pyrene})_2$–$(\gamma\text{-CD})_2$ (2:2)

Experimental

Materials

Pyrene (Aldrich, 99%) was recrystalized once from 95% ethanol, and its purity was checked in single photon counting experiments in which a mono-exponential decay was observed. γ-CD was either a gift from Cargill (lot No. F8025-12) or purchased from Cyclodextrin Technologies Development Inc. (lot 110080P008), and it was used without purification.

NaI (Aldrich, 99%), NaCl (Anachemia, 99%), Na_2SO_4 (BDH, 99%), NaSCN (Aldrich, 99%), and methanol (ACP, spectrograde) were used without purification. The water employed was deionized using a Sybron Barnstead system (≥17.8 MΩ).

Equipment

UV–vis absorption spectra were recorded on a Cary 1 spectrometer. Steady-state fluorescence spectra were measured with a PTI QM-2 fluorimeter and the temperature of the sample was kept constant using a Haake F3 bath. The excitation wavelength was 331 nm, and the emission spectra were measured between 350 and 600 nm. The bandwidths for the excitation and emission monochromator slits were 1.5 nm. The spectra were corrected for a baseline run containing all components with the exception of pyrene, which was subtracted from the fluorescence spectrum of pyrene. This procedure corrected for the Raman emission of the solvent and the small impurity emission present in the γ-CD sample. For quantitative measurements of the emission intensity, a standard deoxygenated and sealed sample containing pyrene in cyclohexane was employed for normalization purposes.

Time-resolved fluorescence measurements were performed with an Edinburgh OB 920 single photon counting system. The excitation source was a hydrogen-filled lamp. The instrument response function was collected with a Ludox (Aldrich) solution by scattering light at the excitation wavelength. A Lauda RM6 bath was used to keep the sample at a constant temperature. The excitation and emission wavelengths were set to 331 and 383 nm, respectively, and the bandpass for the excitation and emission monochromators was ca. 16 nm (2 mm slits). An iris was employed to ensure that the frequency for the stop pulses was less than 2.5% of the frequency for the excitation pulses. Data were analyzed using the Edinburgh software based on nonlinear least-squares fitting of the experimental data to a sum of exponentials. The instrument response function was very narrow for the time window measured (1 μs), and for this reason reconvolution of the decay with the instrument response function was not necessary. The fluorescence decays were fit to the sum of exponentials, and the goodness of the fit was judged by the χ^2 values (<1.2), the inspection of the randomness of the residuals, and the autocorrelation (35).

Methods

Sample preparation

Aqueous pyrene solutions (0.5 μmol/L) were prepared by injecting small amounts of a pyrene methanolic solution (0.5–1.5 mmol/L) into water in which the desired concentration of γ-CD had been dissolved. The samples were shaken for at least 12 h. Solutions containing NaCl, Na_2SO_4, or NaSCN were prepared as above by first preparing aqueous solutions of the salts. All measurements were performed in aerated solutions.

Temperature variation

Fluorescence spectra at the various temperatures were obtained by starting the collection of spectra at the lowest temperature (ca. 7 °C). Samples were kept at each temperature for at least 20 min. In some instances longer equilibration times were required to achieve constant emission intensities. After the spectra were collected at 59 °C, the sample was heated to 80 °C for 20 min and subsequent spectra were collected at decreasing temperatures. Experiments were also performed for which the annealing times were varied (20, 40, and 60 min). Spectra were recorded at 20 °C, and the samples were then heated to 80 °C and kept for the required time at the higher temperature before being cooled to 20 °C.

Determination of the I:III ratio and excimer emission intensity

The fluorescence intensities for the I and III bands of the monomer emission were measured at the emission maxima of 373 and 383 nm, respectively. The pyrene excimer emis-

© 2005 NRC Canada

sion intensity was measured at 473 nm, and was corrected for the residual monomer emission at 473 nm by

$$[4] \qquad E_{cor} = I_{473} - I_{383}\left(\frac{I_{473}(aq)}{I_{383}(aq)}\right)$$

where I_{473} is the uncorrected intensity measured, and the intensity at 383 nm (I_{383}) is multiplied by the ratio of intensities at 473 and 383 nm determined for the pyrene monomer emission in water (0.015).

Fluorescence quenching

Iodide was used as a quencher, and aqueous stock solutions (ca. 2.0 mol/L) were prepared daily and kept in the dark for the duration of the experiment. All experiments were acquired at 20.4 °C. Annealed samples were heated to 80 °C for 20 min and then recooled to 20.4 °C before the addition of quencher. The maximum quencher concentration employed was 50 mmol/L. The intensity in the absence of quencher (I_0) was corrected for the dilution of the fluorophore with the addition of quencher. The emission intensity for the monomer was recorded at 383 nm, which corresponds to the emission band that is insensitive to solvent polarity.

Results

Pyrene in the presence of γ-CD forms three types of complexes with 1:1, 1:2, and 2:2 (pyrene:γ-CD) stoichiometries (31, 32). The excimer-like emission of pyrene is a signature for the 2:2 complex. Therefore, the ratio of the excimer to the monomer emission intensities (E:M) is a measure of the fraction of pyrene in the 2:2 complex compared with the fraction of monomeric pyrene. The monomer emission of pyrene is a combination of the emission of free pyrene in solution and pyrene in the 1:1 and 1:2 complexes. The I:III ratio corresponds to the sum of the I:III ratios for each pyrene monomeric species taking into account the relative contribution of each species. For the experimental conditions employed in this work, the I:III ratio of pyrene was 1.75 ± 0.02 in water and was 0.58 ± 0.01 in cyclohexane. The I:III ratio for pyrene in the 1:2 complex was previously determined to be close to the ratio in cyclohexane (31). Pyrene in the 1:1 complex has an I:III ratio that is lower than in water, but not as low as in the 1:2 complex. It is important to note that the previous interpretation of the formation of the 1:2 complex (31, 32) was based on the implicit assumption that γ-CD is monomeric in aqueous solution. These experiments would be equally consistent with the incorporation of one pyrene molecule in an aggregate containing two or more γ-CDs. For this reason, we will identify the pyrene–γ-CD complex where the guest is in a very nonpolar environment as a 1:*n* complex.

The temperature annealing experiments in which the pyrene emission in the presence of γ-CD was measured at several temperatures, took approximately 12 h to complete. We also observed that nonannealed samples of pyrene–γ-CD that were kept for a period of months in the dark formed hazy solutions. For this reason, it was important to establish that the changes in the emission spectra observed in the annealing experiment were not due to slow changes to the solution that would occur regardless of a temperature change. A control experiment was run in which a sample was divided in half. One half was kept at room temperature and the other half was used for the temperature-annealing experiment. The fluorescence spectra for both samples were measured after 12 and 24 h of sample preparation and completion of the experiment. The pyrene emission intensities, I:III ratios, and E:M ratios did not change over this period of time in either case. This result showed that no loss of pyrene owing to its adsorption onto the glass surface of the vials occurred and that the sample composition did not change over a 24 h period.

NaCl, Na_2SO_4, and NaSCN were used as electrolytes to study the effect of salt addition on pyrene complexation to γ-CD. None of these salts (0.2 mol/L) had an effect on the I:III ratio for pyrene (0.5 μmol/L) in an aqueous solution (1.75 ± 0.02). The I:III ratio in water is known to decrease with increasing temperature, whereas the value for this ratio is constant in cyclohexane (36). A temperature-annealing experiment for pyrene in water showed that upon cooling, the same I:III ratios were obtained at each temperature as those measured prior to heating the sample. The fluorescence decays for pyrene in water in the absence and presence of NaCl or Na_2SO_4 were mono-exponential, and the singlet excited state lifetime was 135 ± 2 ns. This value was the same as previously reported for pyrene in aerated aqueous solutions (36, 37). In the presence of thiocyanide, a shorter lifetime of 85 ns was measured indicating that $^{-}$SCN quenches the singlet excited state of pyrene with a moderate efficiency (2.2×10^7 $(mol/L)^{-1}$ s^{-1}).

The temperature-annealing experiments were performed by measuring the steady-state pyrene emission spectra starting at a low temperature (ca. 7 °C) and progressively increasing the temperature to ca. 60 °C. At this point the sample cell was removed from the fluorimeter and was heated in an external bath at 80 °C for 20 min. After the heating period, the emission spectra were measured at decreasing temperatures. The amount of 2:2 complex in the presence of 20 mmol/L γ-CD compared with pyrene in the monomeric form was higher at the lower temperatures (Figs. 1 and 2). In addition, the I:III ratio was lower when the temperature was low (Fig. 2). Annealing of the solution at 80 °C led to a decrease in the excimer intensity and an increase in the I:III ratio for the spectra measured at 59.3 °C (compare points **b** and **c** in Fig. 2). These results indicate that annealing at high temperatures decreases the amount of 2:2 complex and that the monomeric pyrene species were on average located in a more polar environment. Further cooling of the solution after the annealing procedure led to an increase in the excimer intensity at the expense of the monomer intensity, but only a moderate decrease was observed for the I:III ratio (Fig. 2). The same behavior was observed for solutions in the presence of NaCl or Na_2SO_4. In contrast, the behavior in the presence of NaSCN was different (Fig. 3). The annealing process led to a marked increase of the E:M ratio (inset Fig. 3).

In the presence of 50 mmol/L γ-CD at temperatures equal to or below 20 °C, the fraction of monomeric pyrene in solution is negligible based on calculations using the equilibrium constants previously determined at 20 °C (31). At this high γ-CD concentration, the I:III ratio at temperatures equal to

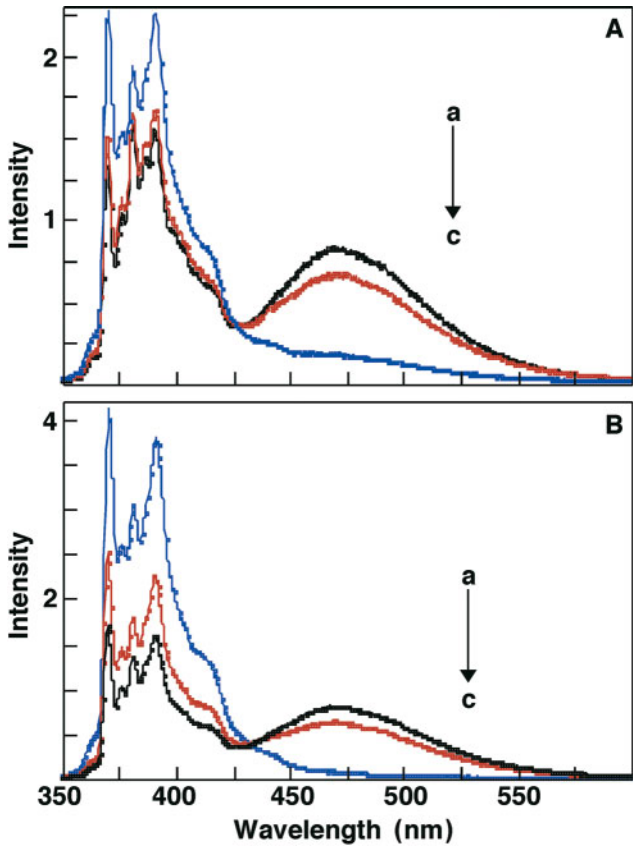
Fig. 1. Pyrene fluorescence spectra in the presence of 20 mmol/L γ-CD and 0.2 mol/L NaCl at 7.0 °C (black, **a**), 20.4 °C (red, **b**), and 59.3 °C (blue, **c**). (A) The first spectrum was taken at 7 °C and the temperature was raised to 59.3 °C. (B) The sample was annealed for 20 min at 80 °C and the first spectrum after the annealing process was taken at 59.3 °C, and the sample was then cooled.



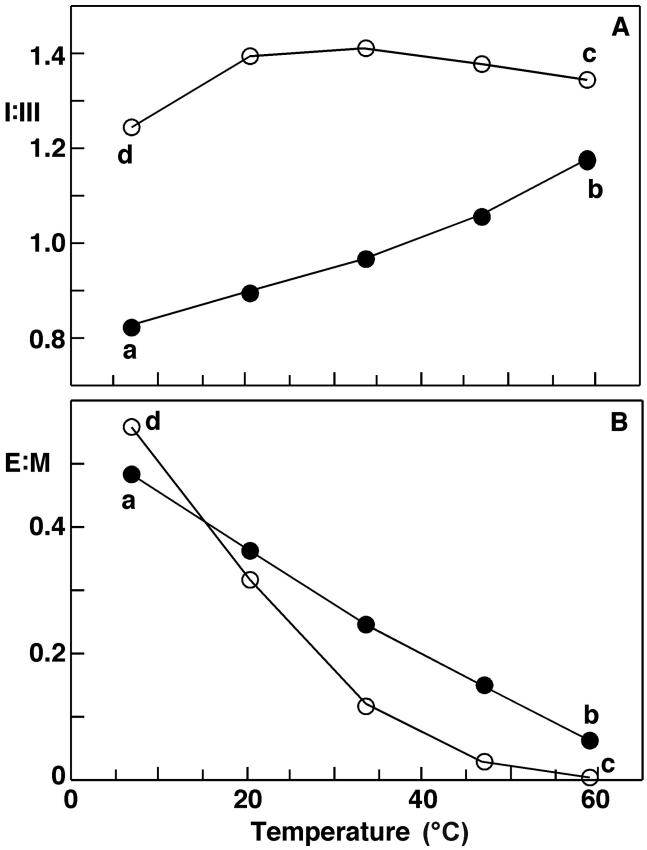


Fig. 2. Change of the I:III (A) and the E:M ratios (B) of the pyrene fluorescence in the presence of 20 mmol/L γ-CD and 0.2 mol/L NaCl as the temperature was raised (solid symbols, from **a** to **b**). The sample was annealed for 20 min at 80 °C (from **b** to **c**) followed by cooling of the sample (open symbols from **c** to **d**). The solid lines were added to connect the data points for the heating and cooling cycles and do not have any physical meaning.

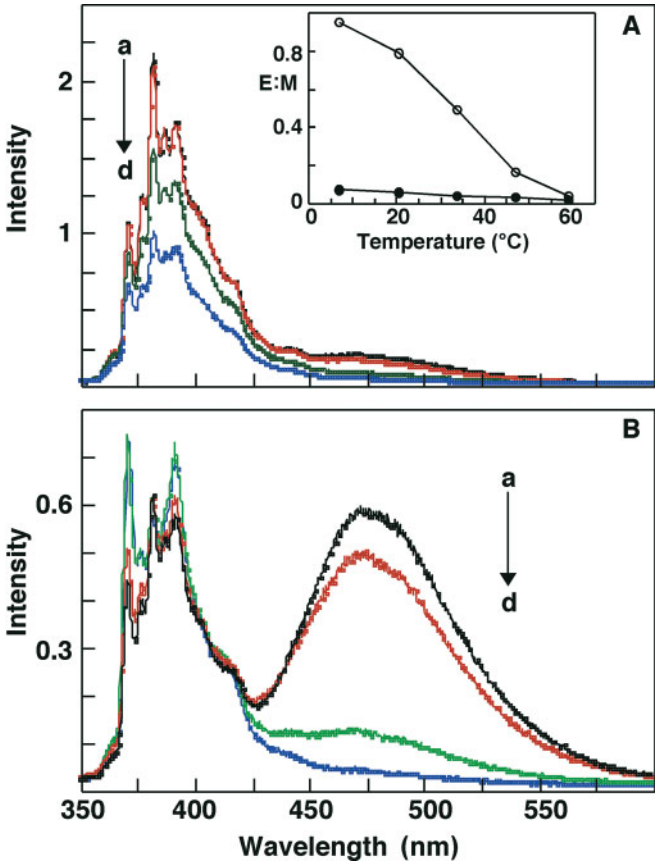
or below 20 °C was a measure of the fraction of pyrene in a 1:1 and 1:*n* complex. For all salts employed, the I:III ratio at 20 °C was higher after the annealing process (Fig. 4).

A control experiment was performed in which samples were heated from 20 to 80 °C and kept at the higher temperature for 20, 40, or 60 min. The purpose of this experiment was to determine if heating of the samples containing the pyrene–γ-CD complexes for longer periods of time would enhance the changes observed for the shorter heating period. This experiment was performed for pyrene in 20 mmol/L γ-CD in the absence of salt and in the presence of NaCl or NaSCN. Some loss of pyrene was observed after the longer heating periods, probably owing to evaporation. For this reason, the only possible comparison was for the I:III ratios. The I:III ratios measured at 20 °C increased from 0.70 to 1.37 ± 0.03 for the three heating periods in the case of the pyrene–γ-CD system in the absence of added salt. The increase observed in the presence of NaSCN was from 0.60 to 1.11 ± 0.06; whereas in the presence of NaCl the change was from 0.73 to 1.4 ± 0.1. These results show that heating for 20 min was sufficient to achieve the annealing process.



The lifetimes of the pyrene monomer emission in the presence of 20 mmol/L γ-CD were determined using the single photon counting technique. The emission decays were measured at 20 °C before and after annealing the samples at 80 °C for 20 min. The decays were fitted to the sum of two exponentials, where the shorter lifetime around 120–140 ns corresponds to the pyrene in the 1:1 complex, and the component with a long lifetime (330–350 ns) corresponds to the pyrene in the 1:*n* complex. The objective of the lifetime studies was to determine if a change occurred for the pre-exponential factors, which are related to the concentration of the 1:1 and 1:*n* species. In the presence and absence of all salts, the pre-exponential factor corresponding to the short lifetime increased after the annealing process at the expense of the pre-exponential factor for the longer lifetime.

Iodide anions are efficient quenchers of the emission of pyrene, where the quenching rate constant (k_q) is 1.1×10^9 $(mol/L)^{-1}$ s^{-1} (38). For steady-state emission spectra, quenching is observed as a decrease of the intensity (I) compared with the intensity (I_0) in the absence of quencher (Q), where the Stern–Volmer constant (K_{SV}) is equal to the product of the quenching rate constant and the lifetime in the absence of quencher. In the case of pyrene in water, the value for K_{SV} is 162 $(mol/L)^{-1}$.

$$[5] \qquad I_0/I = 1 + K_{SV}[Q]$$

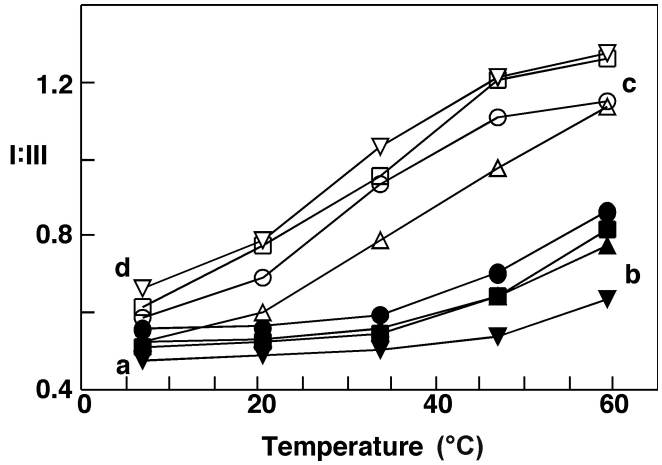
Fig. 3. Pyrene fluorescence spectra in the presence of 50 mmol/L γ-CD and 0.2 mol/L NaSCN at 7.0 °C (black, **a**), 20.4 °C (red, **b**), 46.9 °C (green, **c**), and 59.3 °C (blue, **d**). (A) The first spectrum was taken at 7 °C and the temperature was raised to 59.3 °C. (B) The sample was annealed for 20 min at 80 °C and the first spectrum after the annealing process was taken at 59.3 °C and the sample was then cooled. The inset shows the E:M ratio for the heating (solid symbols) and cooling process (open symbols).

Complexation of pyrene to γ-CD led to a marked decrease in the quenching efficiency by iodide anions (31). Quenching experiments by iodide for the monomer emission were performed to determine if the annealing process significantly altered the protection efficiency provided by γ-CD. The I:III ratios of pyrene are known to decrease with the addition of iodide anions because the pyrene species with high I:III ratios (i.e., free pyrene and 1:1 complex) are quenched more efficiently than the pyrene in the 1:*n* complex (31). The decrease of the I:III ratio was observed for the sample before and after the annealing process at 80 °C (Fig. 5). In the absence of salt, the quenching efficiency for samples containing 20 mmol/L γ-CD was similar before and after the annealing process (K_{SV} = 12 ± 1 (mol/L)$^{-1}$). When NaCl or Na_2SO_4 was added to these samples, the quenching efficiency after the annealing process was higher than before the temperature was raised (Fig. 6). However, when the γ-CD concentration was 50 mmol/L, the quenching efficiency after the annealing process was always smaller in the absence of salt and in the presence of NaCl or Na_2SO_4 (Fig. 6). Quenching experiments in the presence of NaSCN were

Fig. 4. Change of the I:III ratio of the pyrene fluorescence in the presence of 50 mmol/L γ-CD as the temperature was raised (solid symbols, from **a** to **b**). The sample was annealed for 20 min at 80 °C (from **b** to **c**) followed by cooling of the sample (open symbols from **c** to **d**). ○, absence of salt; □, presence of 0.2 mol/L NaCl; △, presence of 0.2 mol/L Na_2SO_4, and ▽, presence of 0.2 mol/L NaSCN. The solid lines were added to connect the data points for the heating and cooling cycles and do not have any physical meaning.



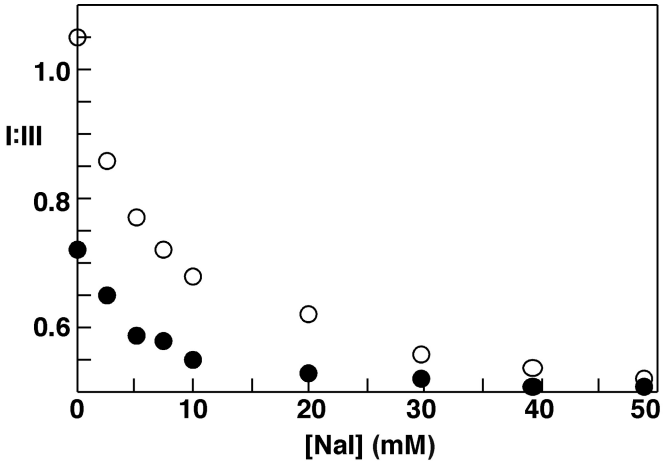


Fig. 5. Dependence of the I:III ratio for pyrene in the presence of 20 mmol/L γ-CD with the iodide anion concentration at 20.4 °C. The closed symbols are for a sample prepared at room temperature and the open symbols are for the same sample after temperature annealing at 80 °C for 20 min.

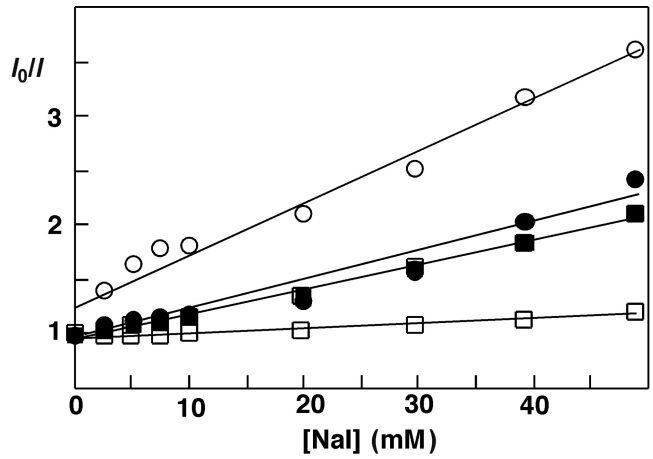

complex because both iodide and thiocyanide anions are quenchers of the pyrene emission, and a detailed analysis was not pursued.

Discussion

The very slow change of the pyrene–γ-CD solution over periods of months is evident from the formation of hazy solutions. This phenomenon seems to be common and is known to be a problem in drug formulation (17). The presence of aggregates when CDs are dissolved in water has been previously reported (14–16), and it could lead to

Fig. 6. Quenching plot at 20.4 °C for the pyrene monomer fluorescence measured at 383 nm in the presence of 0.2 mol/L Na_2SO_4 for γ-CD concentrations of 20 mmol/L (○) and 50 mmol/L (□). The solid symbols correspond to samples prepared at room temperature and the open symbols are for samples after temperature annealing at 80 °C for 20 min. The solid lines correspond to the fit of the experimental data to eq. [5].

changes in the host–guest composition for CD solutions. The objective of this work was to determine whether the presence of aggregates for aqueous γ-CD solutions was an important factor when determining the types of host–guest complexes formed. The temperature-annealing experiments performed determined that dissolving CD in water and letting the samples equilibrate for 12 h does not yield solutions at a thermodynamic equilibrium.

A consequence of CD aggregation would be the decrease of the effective monomer concentration, and in the case of the formation of only 1:1 complexes, the aggregate presence would yield apparent equilibrium constants that are too high. The investigation of the aggregation effect for systems where only 1:1 complexes are formed would require the determination of equilibrium constants for different annealing procedures. The pyrene–γ-CD system can be more conveniently used as a diagnostic system for the temperature-annealing effect because more than one CD complex is present and the change in the fraction of each CD species can be identified from changes in the I:III and E:M ratios. Changes in the I:III ratio can be qualitatively related to the changes in the ratio of the 1:1 complex to the sum of the 1:1 and 1:*n* complexes; whereas changes in the E:M ratio indicate how prevalent the formation of the 2:2 complex is compared with the CD complexes containing one pyrene. The objective of this work was to qualitatively determine the extent to which the formation of aggregates affects the distribution of host–guest complexes involving γ-CDs. The intent was not to determine the thermodynamics (equilibrium constants and host–guest stoichiometries) for each experimental condition (different temperatures and presence of different salts) investigated.

The increase in temperature led to a decrease in the E:M ratio and an increase in the I:III ratio, suggesting a decrease in the concentrations of the 1:*n* and 2:2 complexes. This trend was observed for γ-CD concentrations of 20 and 50 mmol/L. A temperature dependence on the equilibrium constants is an expected result. The result that is not consistent with a solution in thermodynamic equilibrium is the fact that upon cooling the samples, the distribution of the CD complexes was not the same as observed before the heating cycle. The different values for the I:III and E:M ratios during the cooling procedure are indicative of changes in the sample composition.

The solubility of CDs increases as the temperature is raised (18), and an increase in temperature was shown to decrease the amount of CD aggregates in solution (15). For this reason, we infer that the annealing process breaks up CD aggregates containing two or more CD molecules. No further changes to the pyrene spectroscopy were observed when the annealing time at 80 °C was increased from 20 to 60 min, suggesting that the annealing process was complete within 20 min.

The I:III ratio increases and the E:M decreases for a solution of pyrene–γ-CD (20 mmol/L) at 59.3 °C after the annealing process. The breakup of the CD aggregates leads to an increase in the monomeric pyrene in the form of free pyrene or pyrene in the 1:1 complex, which is responsible for the increase in the I:III ratio. Two different processes could explain the decrease in the 2:2 concentration after the annealing procedure: (*i*) the concentration of the 1:1 complex decreases, and since the 2:2 complex is formed from two 1:1 complexes, the concentration of the 2:2 complex also decreases; or (*ii*) some of the pyrene dimers are formed within aggregates, which upon dissociation liberate pyrene, leading to a decrease in the excimer intensity. When the solutions are cooled, the E:M ratios for temperatures of 20 and 7 °C are either similar or somewhat higher than those observed for the samples that were not annealed. If dimers were formed in CD aggregates containing more than two γ-CDs, these aggregates should also have been present at the low temperatures before the annealing procedure and the E:M ratio should have decreased during the cooling cycle. Therefore, the significant decrease of the E:M ratio at 59.3 °C is due to a decrease in the concentration of the 1:1 complex. The increase of the pre-exponential factors in the fluorescence decay kinetics for the species with the shorter lifetime supports the assignment that the fraction of 1:*n* complexes decreases after the annealing process at 80 °C.

At 50 mmol/L γ-CD, the concentration of the 2:2 complex is ca. 5 to 10 times lower than at a CD concentration of 20 mmol/L. In addition, at the higher γ-CD concentration the concentration of free pyrene at 20 °C is negligible. This situation is not altered after the annealing period at 80 °C for temperatures below 25 °C. At higher temperatures the I:III ratio is close to one, suggesting that some free pyrene could be present in solution. At 59.3 °C, the annealing process clearly led to a change in the composition of the monomeric pyrene species, suggesting that there was a substantial breakup of the γ-CD aggregates.

The quenching experiments by iodide in the presence of 50 mmol/L γ-CD at 20 °C showed that after the annealing process at 80 °C the quenching efficiency decreased. Under these conditions the I:III ratio is lower than 0.7. These results indicate that even after the annealing process pyrene was located in 1:*n* complexes and that the singlet excited state of pyrene was more protected than before the annealing process. Relocation of the pyrene closer to the oxygens that

© 2005 NRC Canada

line the interior of the CD cavities could explain the increase in the I:III ratio despite the higher protection of the excited pyrene from quenching by iodide anions in the aqueous phase.

The annealing process of the pyrene–γ-CD system was studied in the presence of various salts. The three factors that motivated these studies were the fact that the addition of salts was previously shown to change the equilibrium constants between guests and CDs (20–22); the fact that it was suggested that an increase in the ionic strength could break up the CD aggregates (15); and the fact that we used an ionic quencher to investigate the protection provided by the CD for the interaction of the included guest with the quencher. The salts employed were chosen to represent an anion that is strongly hydrated and is therefore called a structure-making salt (Na_2SO_4), a salt with low hydration energy (NaSCN, structure breaking), and a salt which is relatively neutral with respect to its solvation ability (NaCl). The addition of NaCl was used to test how the ionic strength affects the system without affecting the hydration ability of the solvent. Iodide was used as the quencher and according to the classification above, it is a structure-breaking salt.

The changes in the I:III and E:M ratios in the heating and cooling cycles were similar for pyrene–γ-CD solutions in the absence of salt and in the presence of NaCl and Na_2SO_4 at both γ-CD concentrations studied (20 and 50 mmol/L). Therefore, the increase in ionic strength or the addition of structure-making salts at moderate concentrations (0.2 mol/L) did not significantly alter the redistribution of species during the temperature-annealing process. A more subtle effect was observed when analyzing the quenching results, where in the absence of salts the quenching efficiency did not change for a concentration of 20 mmol/L γ-CD, but it increased in the presence of NaCl and Na_2SO_4. The reasons for this difference are not immediately obvious and are not observed at the higher γ-CD concentration (50 mmol/L), where the quenching efficiency decreased in the absence of salt and in the presence of NaCl and Na_2SO_4. The fact that the same trends were observed in the presence of NaCl and Na_2SO_4 is a good indication that the addition of up to 50 mmol/L iodide does not alter the distribution of the pyrene–γ-CD complexes. The iodide anion is a structure-breaking salt, and if its addition was substantially changing the distribution of the pyrene–γ-CD complexes, one would expect this effect to be attenuated in the presence of a structure-making salt such as Na_2SO_4.

The addition of NaSCN led to a much larger change in the E:M ratio during the annealing process when compared with the changes observed in the absence of salt and in the presence of NaCl and Na_2SO_4. One important difference is that the thiocyanide anion was shown to bind to α- and β-CD, whereas the chloride and sulfate anions seem to bind only weakly to CDs (23–25). It is possible that the changes observed in the presence of NaSCN were due to competitive binding in addition to a change in the hydration ability of water. A further increase in complexity is the fact that the thiocyanide anion was shown to quench the singlet excited state of pyrene. This effect would lead to a larger decrease of the emission intensity when pyrene relocates from the 1:*n* complexes to the 1:1 complex and to water. The only conclusion we can reach for the addition of NaSCN in this qualitative study is that its effect is very different from that for NaCl and Na_2SO_4. Any mechanistic determination to see if this observation is due to the presence of a water-structure-breaking salt or due to competitive binding would require detailed studies where equilibrium constants are determined, which are beyond the scope of this study.

Conclusions

The temperature-annealing experiments showed that samples of γ-CD prepared at room temperature and left to equilibrate for 12 h do not achieve a thermodynamic equilibrium. The formation of aggregates affects the concentration of guest–CD complexes present in solution. A consequence of this observation is that equilibrium constants determined under conditions where CD aggregates are present in solution are incorrect. This problem may be more pronounced in the case of β-CD, where the formation of aggregates was reported to be more prevalent than for α- and γ-CD (15). An additional uncertainty is that the degree of hydration may have an effect on the formation of aggregates, since it was shown that the dissolution rate of hydrated and anhydrous β-CD are very different (18). The presence of aggregates and the different methods of sample preparation are probably the reason why for some systems the equilibrium constants and guest–CD stoichiometries reported show significant discrepancies. Indeed, this may be the reason for the large differences observed for the pyrene–γ-CD system used in this study (31, 32, 39, 40). To ensure that a thermodynamic equilibrium is achieved, we advise that solutions containing CDs should be heated at high temperature for a period of time before the guest–CD solutions are prepared.

Dissociation of the phenanthroimidazole dimer — A highly delocalized radical — Gomberg revisited[1]

Eric Kiepek, Yuhui Zhou, Shmaryahu Hoz, Ester Rozental, Peter M. Kazmaier, and Erwin Buncel

Abstract: Results of a calculational study at the B3LYP/6-3/G* level concerning the dimerization of the phenanthroimidazole radical are reported herein. The optimized minimum energies of six dimer structures corresponding to C—C, C—N, and N—N bonding have been obtained. The lowest energy dimer is found to be that resulting from N—N bonding (**12**). However, this does not correspond to an X-ray structure study of the experimentally isolated dimer (**13**), which reveals C—N bonding, as is also deduced from an NMR investigation. The variance between the experimental structure and the calculational lowest energy one is examined on the basis of steric interactions: virtually retained planarity, and hence, full conjugation in the two phenanthroimidazole halves in **12**, vs. twisting and lack of coplanarity in the other dimer structures. Importantly, spin density calculations reveal a negligible spin density on the nitrogens, rendering dimer **12** formation through N—N bonding highly improbable. A bond dissociation energy of 16.5 kcal/mol (1 cal = 4.184 J) is calculated for the experimental dimer **13**, which is by far the lowest C—N bond energy recorded so far in the literature. As well, this value is of the same order of magnitude as the calculated C—C BDE in hexaphenylethane, which had been postulated by Gomberg in 1900 as the molecule formed on dimerization of the triphenymethyl radical, but so far not observed experimentally.

Key words: delocalized radical dimerization, phenanthroimidazole dimer, Gomberg's dimer, X-ray structure, C—N bond dissociation energy.

Résumé : On a effectué des calculs au niveau B3LYP/6-3/G* sur la dimérisation du radical phénanthroimidazole. On a obtenu les énergies minimales optimisées de six structures dimères correspondant aux liaisons C—C, C—N et N—N. On a trouvé que le dimère de plus faible énergie résulte de la liaison N—N (**12**). Toutefois, ce résultat de calcul ne correspond pas à l'étude de structure par diffraction des rayons X qui a été faite sur le dimère **13** isolé expérimentalement et dans laquelle on observe une liaison C—N, tel qu'on peut aussi le déduire d'une étude par spectroscopie RMN. Pour essayer d'expliquer les causes de la variance entre l'énergie minimale déduite sur la base de calculs théoriques et la structure observée expérimentalement, on a fait appel aux interactions stériques ainsi qu'au caractère planaire maintenu et, en conséquence, à la conjugaison complète des deux moitiés de phénanthroimidazole dans **12** par opposition à la déformation et au manque de caractère coplanaire dans les autres structures dimères. Il est aussi important de noter que les calculs de densité de spin révèlent la présence d'une densité de spin négligeable sur les azotes qui rend la formation du dimère **12** par une liaison N—N très improbable. On a évalué à 16,5 kcal/mol (1 cal = 4,184 J) l'énergie de dissociation de liaison pour le dimère expérimental **13** et cette valeur est de loin l'énergie de liaison C—N enregistrée à ce jour dans la littérature. De plus, cette valeur est du même ordre de grandeur que celle calculée pour la liaison BDE C—C de l'hexaphénylméthane qui, selon Gomberg en 1900, serait la molécule qui se formerait lors de la dimérisation du radical triphénylméthyle mais qui n'a jamais été observée expérimentalement.

Mots clés : dimérisation d'un radical délocalisé, dimère phénanthroimidazole, dimère de Gomberg, structure déterminée par rayons X, énergie de dissociation d'une liaison C—N.

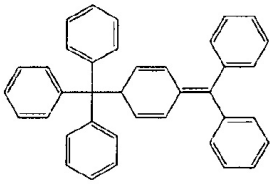
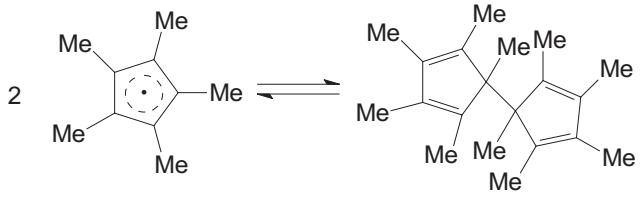
Introduction



The dimerization of delocalized radicals has been of interest since 1900 when Gomberg concluded that dimerization of the triphenylmethyl radical **1** produced, in a straightforward manner, the anticipated hexaphenylethane **2** (1). However, it was much later, in 1968, that the correct structure of the dimer was shown to be the unsymmetrical molcule **3** (2). This brought forth new interest, including attempts to synthesize the authentic molecule **2** (3), so far without success.

1

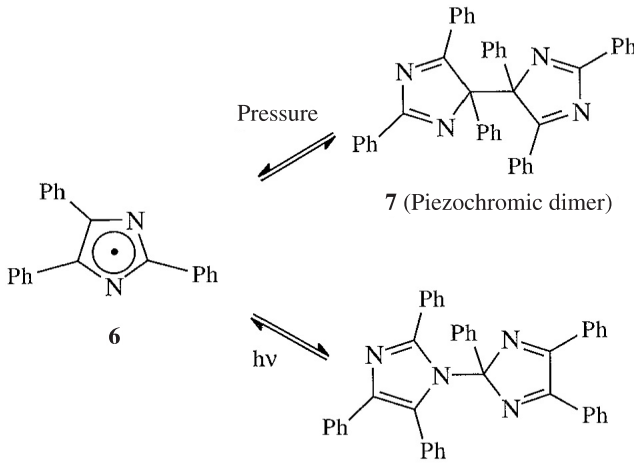
2



3

Discussions concerning the possible synthesis of **2** are of course tied to its bond dissociation energy (BDE) and various calculational methods have been directed toward this end. Very recently, applying a three-level hybrid quantum mechanical (ONIOM) method, Vreven and Morokuma (4) derived a BDE of 16.6 kcal/mol (1 cal = 4.184 J) for **2**, and hence concluded that its synthesis could in fact be feasible.

Davies and Lusztyk (5) experimentally investigated a somewhat related dimerization (Scheme 1), namely that of the delocalized pentamethylcyclopentadienyl radical **4**, which produced the dimer **5** in a diffusion-controlled process ($2k_t = 2 \times 10^9$ (mol/L)$^{-1}$ s^{-1} at 25 °C in hexane). The dimer, in turn, on heating to 70–120 °C dissociates to the radical, identified by its ESR spectrum. In a subsequent study, Ingold and co-workers (6) studied the equilibrium as a function of temperature (92–120 °C) and thereby obtained ΔH = 18.8 kcal/mol as the enthalpy of dissociation, i.e., comparable to the calculated BDE of hexaphenylethane referred to previously (4). Factors contributing to the ease of dissociation of dimer **5** are the strain energy, calculated by MM2 as 33.4 kcal/mol (6), and the inherent resonance stabilization of the Me_5C_5 radical **4** (5).



Our interest in these and related systems arose from the reports that the radical **6**, formed on oxidation of triphenylimidazole (7), gives rise to piezochromic dimer **7** under pressure and photochromic dimer **8** on irradiation (Scheme 2). As part of a wider study on thermochromic and photochromic molecules (8), it was our aim to devise pressure- and sheer-sensitive dye molcules that could be used as sensors in polymer processing (9). We thus extended

Scheme 1.

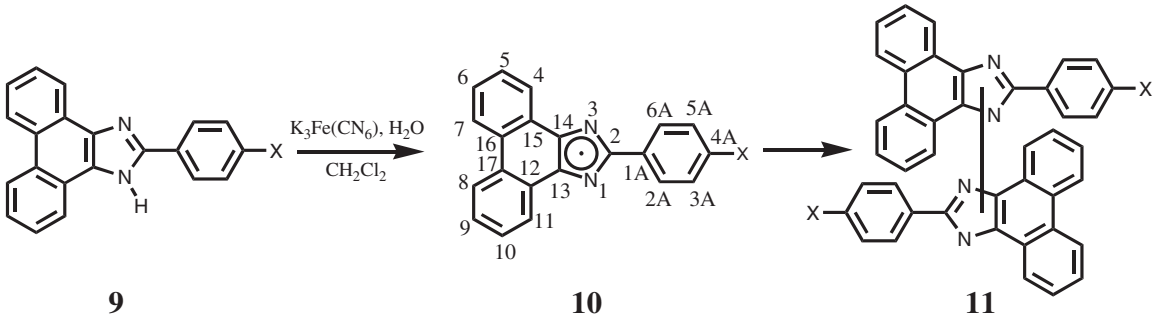
4 **5**

Scheme 2.

7 (Piezochromic dimer)

8 (Photochromic dimer)

the conjugation system shown in Scheme 1 to the radical derived from 2-(*p*-bromophenyl)phenanthroimidazole **9** (X = Br) and its dimerization, shown in Scheme 3 (10).



As in the case of the triphenylmethyl radical, where dimerization can occur in more than one sense, there are actually six modes available for recombination of radical **10**: via N—N bonding (**12**), C—N bonding (**13**, **14**), and C—C bonding (**15**–**17**) (Fig. 1). We have presented NMR evidence (10) that the dimer produced has the structure **13** (X = Br), i.e., C—N bonding.

In the current work we have undertaken a computational study of the unsubstituted molecule **11** (X = H) aimed to determine the relative energies of the six possible dimers as well as their bond dissociation energies. Unexpectedly, we have found that the computationally lowest energy dimer is not **13** with C—N bonding, but **12** with N—N bonding. To resolve this contradiction, an X-ray structure analysis was undertaken (**11**, X = Br) and has confirmed the earlier NMR structure of **13** (X = Br) for the isolated dimer. We conclude that the fact that **12**, the computationally most stable isomer, is not the one experimentally obtained, stems from a kinetic barrier owing to low spin densities on the nitrogen atoms.

Another finding of interest is of a very low C—N BDE in **13** (X = H, 16.5 kcal/mol), apparently the lowest C—N BDE recorded so far.

Results

Calculational studies — Dimer energies, bond dissociation energies, radical spin densities, and CH_3· addition energies

1. Dimer energies

*(a) Geometry optimized minimum energies (*E*)*

Optimized minimum energies of the six dimer structures using the B3LYP/6-31G*//B3LYP/6-31G* methodology are given in Table 1 while the corresponding optimized geometries are shown in Fig. 2.

(b) Zero point corrected energy (E_o'*)*

A frequency calculation was performed to obtain the zero point vibrational energy (E_{ZPE}). This value was added to E to give the zero point corrected energy (E_o').

[1] $$E_o' = E + E_{ZPE}$$

The resulting E_o' values are included in Table 1.

(c) Counterpoise and zero point corrected energies (E_o*)*

The counterpoise energy correction (E_{corr}) (11) was performed next for all six dimers and the values are given in Table 1. The counterpoise and zero point corrected energies (E_o) are then given by:

[2] $$E_o = E + E_{ZPE} + E_{corr}$$

(d) Relative dimer energies

According to Table 1, the lowest E_o value corresponds to dimer **12** and this was arbitrarily selected as the reference level with E_o = O. The relative energies (ΔE_o) of the other dimers are then given in Table 2. They range from ΔE_o = 12.2 kcal/mol for dimer **13** to ΔE_o = 25.4 kcal/mol for **17**.

2. Bond dissociation energies

To calculate BDEs, calculations for the radical were first performed using the methodology in sections 1(*a*) and 1(*b*). Data are included in Table 1. The radical structure is shown in Scheme 3.

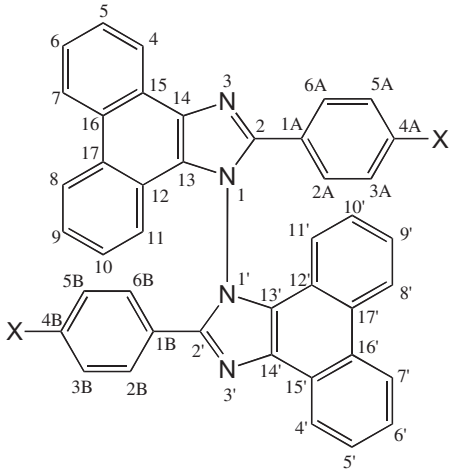
Bond dissociation energies are calculated via the equation:

[3] $$BDE = 2E_o^{Rad} - E_o$$

where the E_o values (eq. [2]) are taken from Table 1, while E_o^{Rad} is the geometry optimized minimum energy of the free radical species and is also found in Table 1.

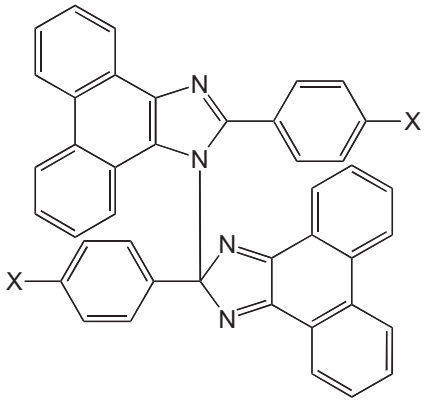
3. Radical spin densities

Spin densities of the optimized minimum energy structure **10** (X = H) were obtained using the B3LYP/6-31G* methodology. Spin density values at the various atomic centres of the radical are tabulated in Table 3.



4. CH_3· addition to radical

The change in energy on going from an sp^2 hybridized state of the radical to the sp^3 state on methylation was evaluated for the C2, C13, and N1 atomic centres. Geometry optimization was performed as in sections 1(*a*) and 1(*b*). Table 4 presents the relevant energy terms.



According to Table 4, the lowest E_o value is found for the N1-Me structure and this is taken as the zero level for comparison with the other two structures. One hence obtains for the C2-Me and C13-Me structures ΔE_o^{Me} values of 12.3 and 18.5 kcal/mol, respectively.

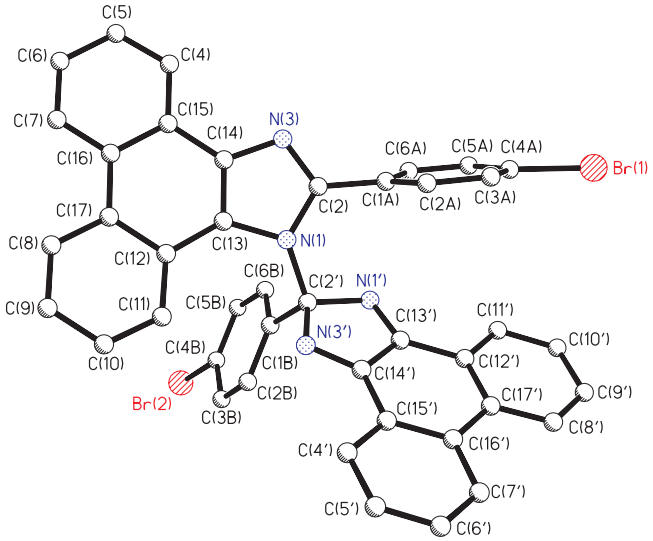
Discussion

As noted in the Introduction, the dimerization of delocalized radicals has been of interest since Gomberg's studies with the triphenylmethyl radical in 1900 (1). That and the follow-up studies demonstrated that delocalized radicals can recombine in more than one sense giving rise to two or more structurally different dimer isomers. Dimerization of the phenanthroimidazole radical system can in principle give rise to six likely dimers that would be produced via N—N, C—N, and C—C bonding. We have previously reported a NMR study of the isolated dimer, which indicated a structure involving C—N bonding (10).



In light of the continuing theoretical and experimental studies pertaining to the dimerization of delocalized radicals (4–6) and the unusual nature of the phenanthroimidazole system, it was desirable to follow up the NMR study with calculation of the relative energies of the six dimers and the corresponding N—N, C—N, and C—C bond dissociation energies in juxtaposition. In the following, we discuss the divergence revealed between the results of the calculational studies on relative dimer energies vis-à-vis the actual structure obtained earlier by NMR and currently confirmed by X-ray work.

Next, we discuss the origin of the variance between the X-ray data and the computed structure. Finally, we return to the conundrum posed by Gomberg's original conclusions.

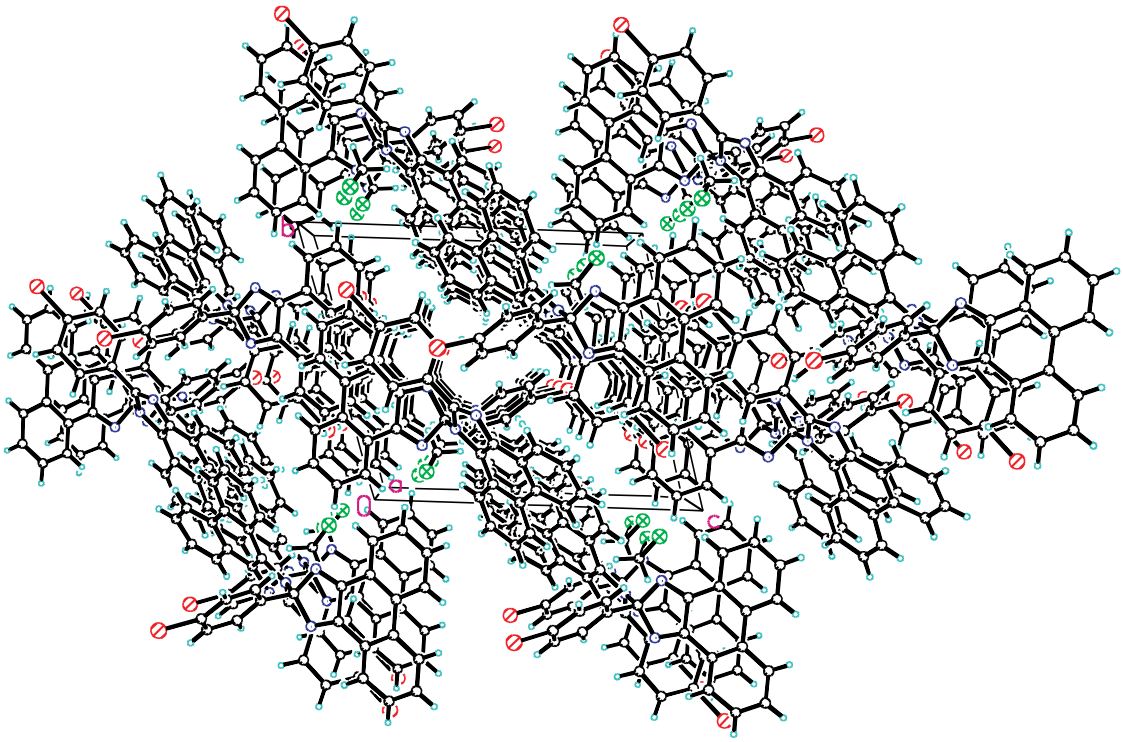

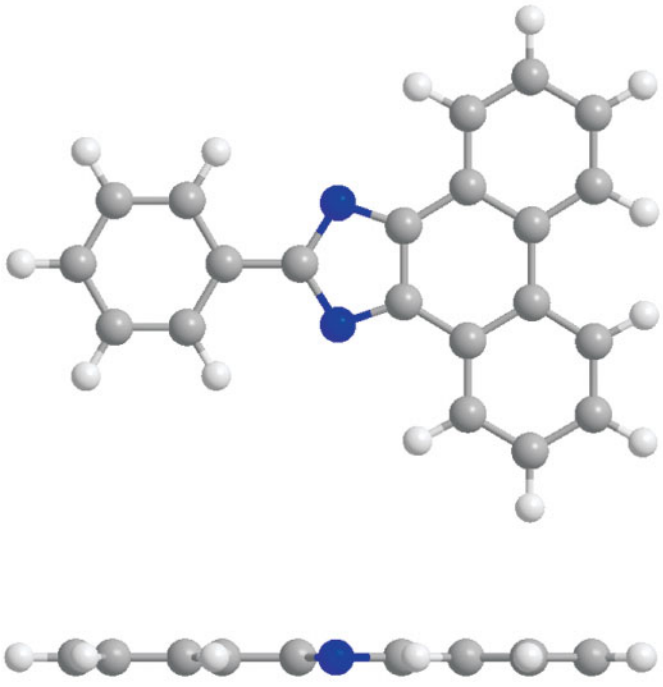

Fig. 5. Three-dimensional structure of radical **10**. Note the planarity of the molecule.

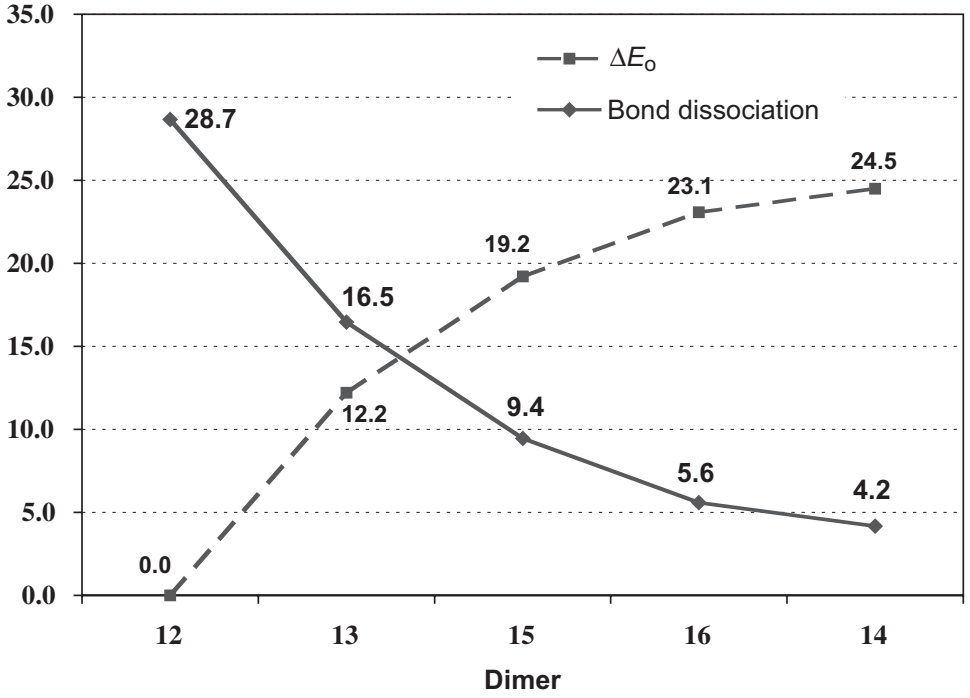
Theoretical study of dimerization of free radical 10

Optimization of the free radical species using B3LYP/6-31G* calculations of the optimized geometry yields a planar structure (**10**, Fig. 5) with C_{2v} symmetry. This allows maximum conjugation among the π systems comprising the imidazole, the phenanthro, and phenyl rings.

As mentioned previously, combination of the two radicals (**10**) can occur in six different ways: N—N bonding results in only one unique product because of symmetry (**12**); N—C bonding can occur in two ways, N1 to C2 (**13**) and N1 to C13 (**14**) of the second radical; C—C bonding occurs as C2 to C2 (**15**), C2 to C13 (**16**), or C13 to C13 (**17**) of the second radical (Fig. 1). The relative stabilization and bond dissociation energies of the various dimers are presented in Table 4 and in Fig. 6 in graphical form.



Interestingly, the computationally most stable structure is **12** (N—N bonding), whereas **13** (C—N bonding) is the isomer obtained experimentally. Before dealing with this conundrum, we will first discuss the order of stability of the various isomers.

Stability order of the dimers

Since the energetics of bond formation between two radicals is the outcome of the structural changes made in each of these radicals, we have separately studied the effect of bonding at the three different sites: N1, C2, and C13 on the monomeric unit. This was achieved by the addition of a methyl radical to the monomer radical at these positions. The results are given in Table 4. As can be seen from this table, the most stable bond is formed with the nitrogen, probably because this does not impact on the aromaticity of any of the rings, and planarity is maintained. On the other hand, methylation at C2 disrupts the aromaticity of the imidazole ring while methylation at C13 disrupts the aromaticity of both the imidazole and the phenanthro systems. This is reflected in the stability order. Thus, except for a slight change of pattern, the stability order of the dimers reflect the num-

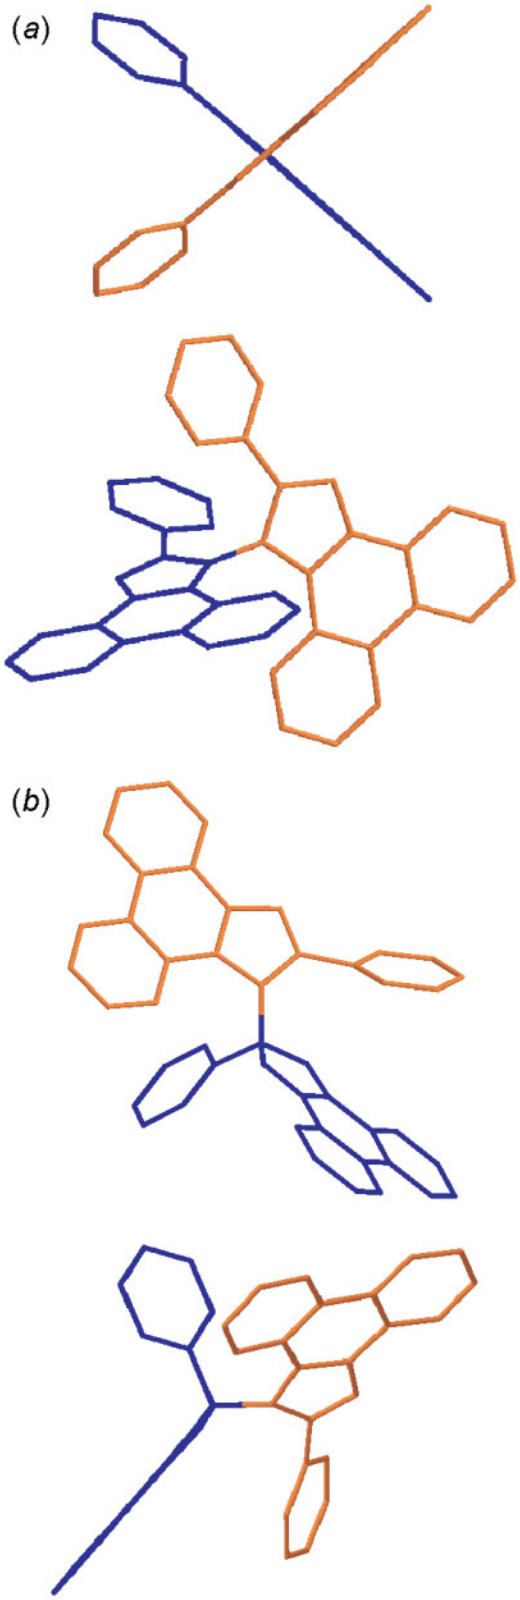
© 2005 NRC Canada

Fig. 6. The relative stabilities (dashed line) and bond dissociation energies (solid line) of the six dimers.

ber of rings in which aromaticity is disrupted. The computationally most stable dimer (**12**) is the one in which aromaticity is retained for all rings. The least stable isomer is **17** in which four ring systems have lost aromaticity. In between, the only deviation from this order is in the two isomers **14** and **16** where the difference between them amounts to only 1.4 kcal/mol. The loss of planarity of the phenanthro systems of dimers **14**, **16**, and **17** can be seen readily in the three-dimensional structures shown in Fig. 2.

It is significant that the experimentally obtained isomer (**13**), having disrupted aromaticity in one ring, comes second to the most stable computed isomer (**12**). To resolve this contradiction between computational and experimental structural assignments, we opted for the unambiguous X-ray structure determination. In fact, X-ray analysis has shown that, indeed, the structure of the experimentally isolated dimer corresponds to **13**.

Shown in Fig. 7 are two perspective structures of each of these two isomers. The important structural characteristics of **12** and **13** previously discussed are readily seen in these perspectives. The perspectives of the other dimers are given in the Supplementary material.[3]



The origin of the conundrum implicit in the results presented hitherto remains to be considered. In fact, it is appropriate to address two questions: (*a*) it is common knowledge that N—N bonds are rather weak. Then what is the reason that in the present system the N—N bonding is the strongest one (28.7 kcal/mol) as opposed to C—N bonding (16.5 kcal/mol) of the isolated dimer (Table 2)? (*b*) On the assumption that the computations indeed reflect the actual stabilities, then why is the computationally most stable isomer not the one isolated?

In fact, the first question casts doubt on the validity of these calculations. We believe that in general, the reason for the low binding energy between nitrogen atoms results from the interelectronic pair–pair repulsion. Where this interaction does not exist, for example, in the triple bond of the N_2 molecule, the bond energy of this molecule (225 kcal/mol) is larger by 25 kcal/mol than that of the triple bond in acetylene (200 kcal/mol). In the present system, the two planar units in **12** are orthogonal to each other (see Figs. 2 and 7*a*) in this way avoiding a destabilizing interaction between the two p–π systems on the nitrogens. In addition, this isomer is the only system among the six where aromaticity is retained in all rings and planarity is not hampered. Therefore, general considerations indeed point to this isomer as being the most stable one.

We now turn to the second question — why isomer **12** is not obtained. We assume that this is a result of a kinetic selectivity; namely, this (N—N) isomer is slow to be formed. A possible origin for sluggishness in radical combination reactions could be because of low spin densities on the relevant atoms. To explore this possibility, we have calculated the spin density distribution in the radical monomer. The results are given in Table 3. The data in this table show that the spin density on the nitrogen is indeed very small (~5%). While this does not rule out the possibility of the N—N bond formation or reflect on its strength, it reflects on the probability of its formation upon encountering two radicals in the appropriate orientation (~0.25%). The fact that the spin density on C2 is 32% significantly increases the probability for the formation of **13**. Using this logic, it might be assumed that dimer **15** (C2—C2) would be the dominant dimer formed; however, the bond dissociation energy of **15** is calculated at 9 kcal/mol, making the formation of the stable dimer highly unlikely. Thus, working under thermodynamic control conditions, **12** would probably have been the experimentally obtained isomer. However, under the experi-

© 2005 NRC Canada

Fig. 7. (*a*) Perspective presentation of dimer **12**. (*b*) Perspective presentation of dimer **13**.

mental conditions used, the equilibrium is shifted to one side by the precipitation of **13**, giving rise in this way to the formation of the thermodynamically less stable isomer.

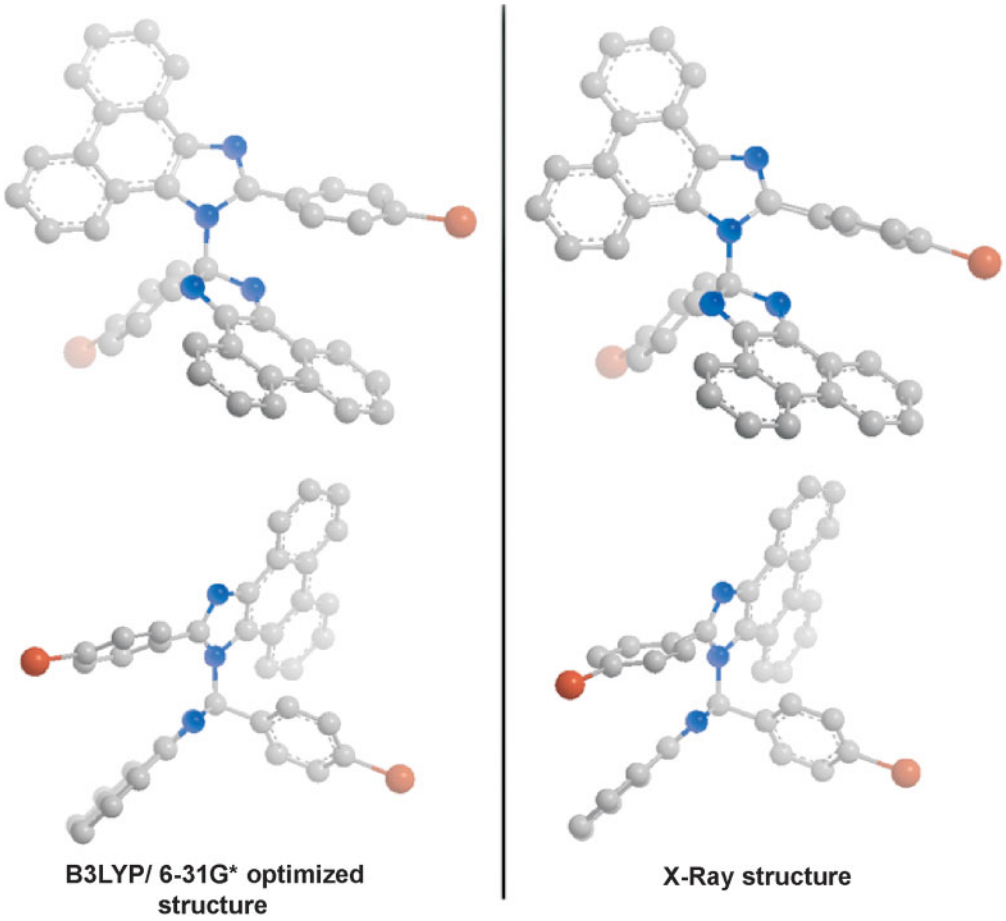
Comparison of the X-ray data with the calculated structure

The overall structure of dimer **13** as determined by X-ray analysis and the computed optimized geometry using B3LYP is shown in Fig. 8. Clearly, there is a close correspondence.

For all atoms, the bond lengths and angles of dimer **13** calculated by the B3LYP/6-31G* geometry optimization were within 1% of the bond lengths and angles measured by X-ray. The maximum difference in bond lengths between the theoretical geometry and the measured geometry was 3.3% (C1B—C2B). However, the dihedral angle is not the same for all atoms in the computed and X-ray geometries. These differences arise from different degrees of rotation along both the N1—C2 bond axis and the C2—C1A bond axis in the two different geometries. The differing amounts of rotation along these axes result in: (1) the two halves of the dimers being slightly more rotated in the measured X-ray geometry than in the calculated geometry; and (2) the phenyl group being more rotated (i.e., less in plane with the imidazole group) in the X-ray model than in the computed model. It is important to note that the X-ray data was collected from a crystal structure in which many dimers were stacked in a crystalline form (see Fig. 4), while the computed model was based on a single molecule, isolated in space. Despite these differences, there is quite good agreement between the two structures. Bond lengths, bond angles, and dihedral angles for the X-ray geometry and the calculated geometry are reported as Supplementary material (Tables S6–S8).[3]

Gomberg's premature assignment, Morukama's predictions, and dimer bond energies

Gomberg's mistaken assignment of structure on recombination of two triphenylmethyl radicals and the subsequent correction some 60 years later (vide supra) have become classics of modern chemistry. Though hexaphenylethane, Gomberg's predicted dimer, has not yet been synthesized, Morukama's recent calculations, which have assigned a BDE of 16.6 kcal/mol to the central C—C bond, have led these authors to suggest that synthesis of hexaphenylethane should, in fact, be possible.



Our study poses an interesting juxtaposition to the previous section. On one hand, the calculations have shown that the actual dimer isomer (**13**) produced from the dimerization of radical **10** is not the most thermodynamically stable one. On the other hand, however, the BDE of the C—N in dimer formation is calculated as 16.5 kcal/mol, i.e., only a shade below Morukama's calculated BDE. Note also that a normal C—N bond is quoted as having a BDE of ca. 70 kcal/mol, easily making our C—N bond as having the lowest recorded BDE. (According to a recent compilation, the lowest C—N BDE reported so far is 26.3 kcal/mol) (12).

Conclusions

An X-ray structure study on the molecule formed by dimerization of the phenanthroimidazole radical **10** has been shown to be **13** resulting from C—N bond formation between two radicals. This agrees with conclusions based on a NMR study. However, as a contradistinction, the results of a computational study using the B3LYP/6-31G* methodology

© 2005 NRC Canada

Fig. 8. A comparison of the B3LYP/6-31G* optimized geometry of dimer **13** with X = Br with the experimentally measured geometry of the same molecule. Note that the phenyl group (in the upper half of the dimer) is slightly less in plane with the imidazole group in the X-ray structure than in the B3LYP/6-31G* structure. (See Supplementary Tables S6–S8 for detailed comparison of the X-ray and computed geometries: bond angles, bond lengths, and dihedral angles).[3]

has revealed that the lowest energy dimer results not from C—N (or C—C) bond formation, but rather from N—N bond formation. We concluded that although **12** is the computationally most stable isomer, the low spin density on the nitrogen kinetically discourages N—N bond formation. An interesting juxtaposition in the present results vis-à-vis Gomberg's dimer and Morukama's calculations is revealed by the present work.

Experimental section

X-ray structure determination

A crystal of the compound (yellowish, plate-shaped, size 0.4 mm × 0.2 mm × 0.1 mm) was mounted and sealed on a glass fiber with epoxy glue. Data collection was performed on a Bruker SMART CCD 1000 X-ray diffractometer with graphite monochromated Mo K_α radiation (λ = 0.710 73 Å), operating at 50 kV and 35 mA at 27 °C over 2θ ranges of 3.62°~56.76°. No significant decay was observed during the data collection.

Data were processed on a Pentium PC using the Bruker AXS Windows NT SHELXTL software package (version 5.10) (13). Neutral atom scattering factors were taken from Cromer and Waber (14). The raw intensity data were converted (including corrections for scan speed, background, and Lorentz and polarization effects) to structure amplitudes and their esds using the program SAINT, which corrects for *L*p and decay. Absorption corrections were applied using the SADABS program. The crystal is a triclinic space group *P*-1, based on the systematic absences, *E* statistics, and successful refinement of the structure. The structure was solved by direct methods. Full-matrix least-square refinements minimizing the function $\Sigma w(F_o^2 - F_c^2)^2$ were applied to the compound. All non-hydrogen atoms were refined anisotropically. The positions for all hydrogen atoms were calculated, and their contributions were included in the structure factor calculations with isotropic thermal parameters 1.2 times that of the attached carbon atoms (1.5 times for methyl hydrogens).

Convergence to final R_1 = 0.0554 and wR_2 = 0.1469 by using 8249 independent reflections and 460 parameters was achieved (eq. [4]), with the largest residual peak and hole to be 0.848 and –0.275 e/Å^3, respectively. Crystallographic data, experimental details, and refinement summary are given in Table 5. The molecular structure and cell packing are shown in Figs. 3 and 4.

Photochemistry of 9-methylbicyclo[3.3.1]nonyl aryl ketones — A novel 1,5-disproportionation of 1,4-hydroxy biradicals and asymmetric induction using the solid-state ionic chiral auxiliary method[1]

Shuang Chen, Brian O. Patrick, and John R. Scheffer

Abstract: A novel 1,5-disproportionation reaction has been discovered for 1,4-hydroxy biradicals derived from the photolysis of 9-methylbicyclo[3.3.1]nonyl phenyl ketones (**1**), which undergo mainly Yang cyclization both in solution and the solid state. By applying the solid-state ionic chiral auxiliary method of asymmetric synthesis to the Yang cyclization, enantiomeric excesses as high as 95% were achieved at high reaction conversions. The origin of the reaction selectivity is discussed with the help of X-ray crystallography. In addition, the solid-state photoreaction of ketone **1b** was found to occur in a single crystal-to-single crystal fashion.

Key words: photochemistry, 1,4-hydroxy biradical, disproportionation, asymmetric induction, ionic chiral auxiliary, single crystal-to-single crystal reaction.

Résumé : On a découvert une nouvelle réaction de dismutation pour les 1,4-dihydroxy biradicaux obtenus par photolyse des 9-méthylbicyclo[3.3.1]nonyl (phényl) cétones (**1**) qui subissent principalement une cyclisation de Yang tant en solution qu'à l'état solide. En appliquant à la cyclisation de Yang la méthode de l'auxiliaire chiral ionique en phase solide, il a été possible d'obtenir des excès énantiomériques pouvant atteindre 95 % avec des taux de conversion élevés. On discute de l'origine de la sélectivité de la réaction à l'aide de la cristallographie des rayons X. De plus, on a trouvé que, à l'état solide, la réaction de la cétone **1b** s'effectue d'une façon allant d'un cristal unique à un cristal unique.

Mots clés : photochimie, 1,4-dihydroxy biradical, dismutation, induction asymétrique, auxiliaire chiral ionique, réaction d'un cristal unique à un cristal unique.

[Traduit par la Rédaction]

Introduction

Triplet 1,4-hydroxy biradicals formed in the γ-hydrogen abstraction step of the photochemical Norrish–Yang type II reaction have three possible fates: reverse hydrogen transfer to regenerate the starting ketone in its ground state, cleavage of the central carbon–carbon bond to form an alkene and an enol, and Yang cyclization to form a cyclobutanol derivative (Scheme 1) (1). In this paper, we report a fourth reaction pathway, a novel 1,5-disproportionation, observed for the 1,4-hydroxy biradicals derived from hydrogen abstraction of 9-methylbicyclo[3.3.1]nonyl phenyl ketones (**1**). The study of the photochemistry of 9-methylbicyclo[3.3.1]nonyl phenyl ketones (**1**) complements our earlier studies on the solid-state Norrish–Yang type II photochemistry of adamantyl phenyl ketones and norbornyl phenyl ketones (**2** and **3**) (Scheme 1) (2, 3). In these two previous systems, hydrogen abstraction occurred from either a rigid six-membered ring or a rigid five-membered ring, while in the bicyclo[3.3.1]nonyl phenyl ketone system hydrogen abstraction occurs from a relatively flexible six-membered ring, allowing for the effects of small changes in ring geometry on the hydrogen abstraction process and the reaction outcome to be examined. Moreover, 9-methylbicyclo[3.3.1]nonyl phenyl ketones (**1**) are achiral molecules that give mainly chiral Yang photocyclization products upon photolysis. As hydrogen abstraction of either of the two enantiotopic γ-hydrogen atoms could occur, this allows the enantioselectivity of the reaction to be studied using the solid-state ionic chiral auxiliary method (4).

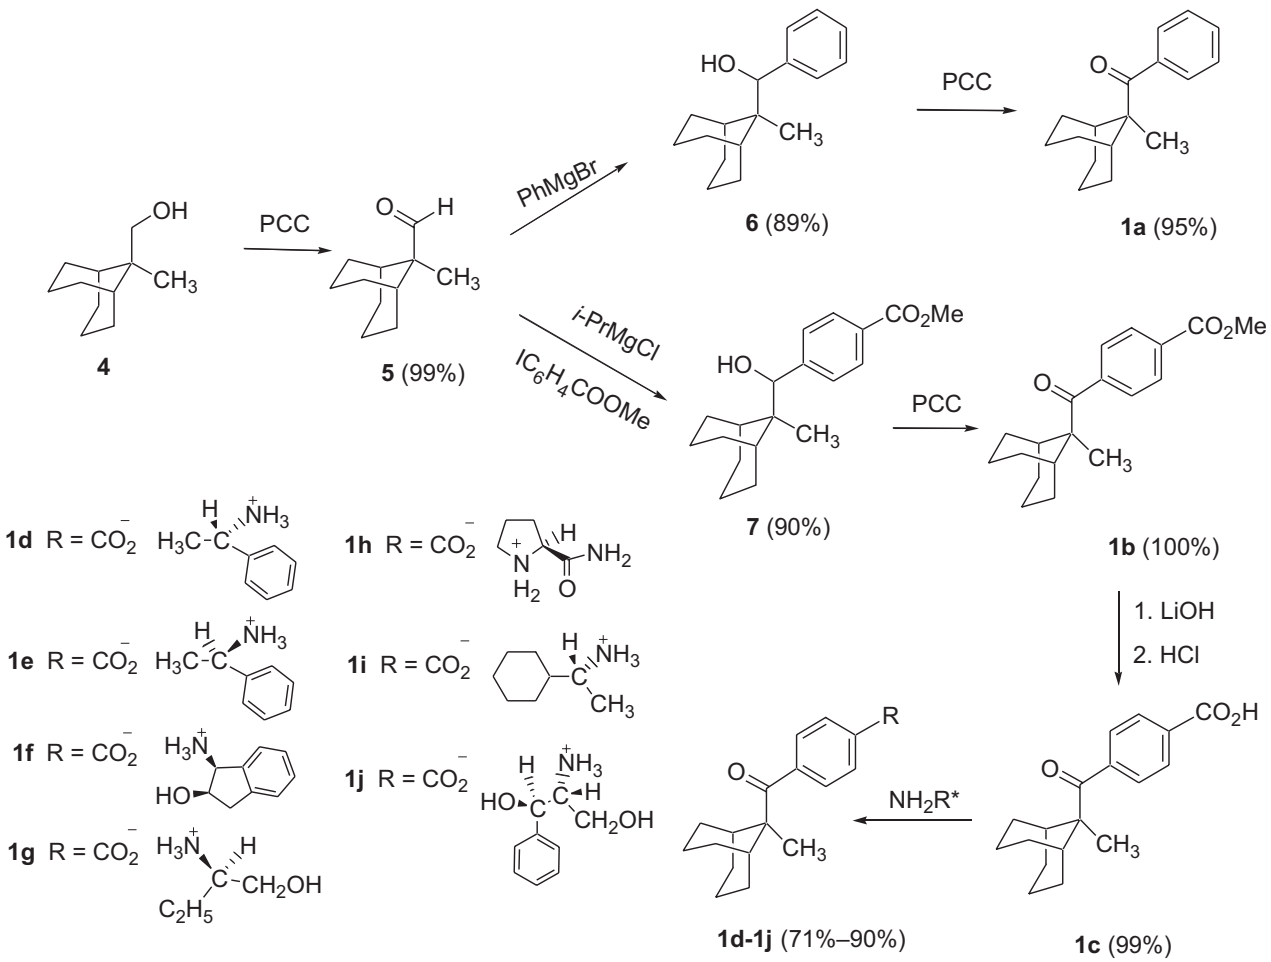
Results and discussion



9-Methylbicyclo[3.3.1]nonyl phenyl ketones (**1a** and **1b**) were prepared by standard synthetic methods (Scheme 2) from the known compound 9-methylbicyclo[3.3.1]nonyl methanol (**4**) (5). Hydrolysis of ester **1b** afforded the corresponding keto acid **1c**, which was then reacted with various optically pure amines to form chiral salts **1d**–**1j** through acid–base chemistry. All these compounds were fully characterized by ^{1}H and ^{13}C NMR, FT-IR, HR-MS, UV, and elemental analysis (see details in the Experimental section).

Fig. 1. ORTEP representation of (*a*) ketone **1a** and (*b*) ketone **1b**.

Single crystal X-ray crystallographic determinations were also performed for compounds **1a** and **1b** (Fig. 1).

The photochemistry of aryl ketones **1a** and **1b** was explored in both solution and the crystalline state. The reaction products were readily obtained by preparative scale solution photolysis and the solid-state reactions were performed on an analytical scale to determine the mode of reactivity in that medium. The details of the experiments as well as the apparatus used are given in the Experimental section. Table 1 and Scheme 3 summarize the photochemical results in both media. As shown in Scheme 3 and Table 1, like the analogous compounds **2** and **3** (2, 3), solution photolysis of ketones **1a** and **1b** primarily yielded Yang photocyclization products **9a** and **9b**.

Interestingly, photolysis of ketones **1a** and **1b** also afforded small amounts (<5%) of the unusual 1,5-disproportionation products **10a** and **10b** (Scheme 3). These minor products are presumably formed by a novel disproportionation of the intermediate 1,4-hydroxy biradical **8** in which a hydrogen atom on C5 is transferred to the radical center on C1. As far as we are aware, this type of disproportionation reaction is unknown for 1,4-hydroxy biradicals, although the corresponding process has been observed for a 1,5-hydroxy biradical (6). The stereochemistry of the major photoproducts (**9a** and **9b**) was later determined to be that in which the aryl group is in the endo position, although generation of *exo*-aryl products is theoretically possible. It is interesting to note that in the photochemistry of 9-methyl substituted ketones **1a** and **1b**, no Norrish type I or type II photocleavage products could be identified, although traces (<1%) of several unknown photoproducts could be detected by GC. The

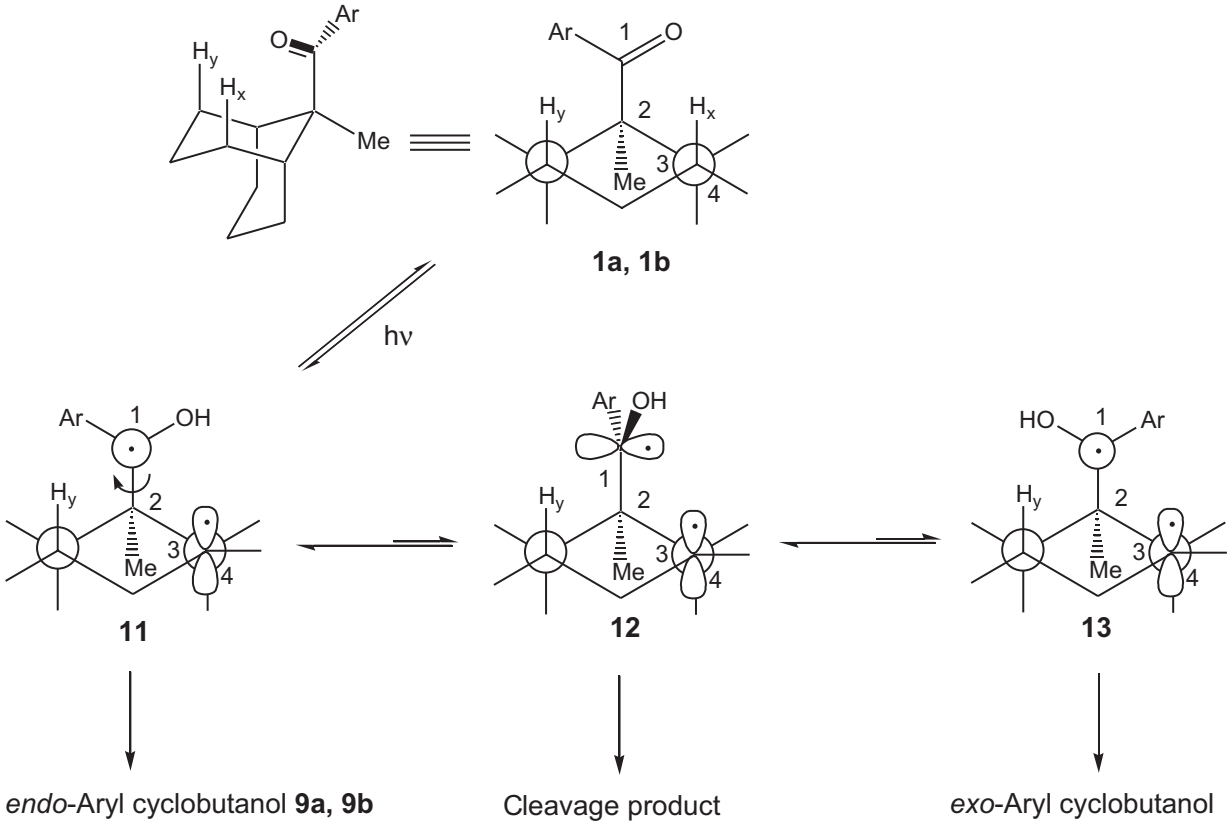
results of solid-state photolysis of ketones **1a** and **1b** were strikingly similar to their solution counterparts, with **1a** and **1b** affording photoproducts **9a** and **9b** (90%–92%) and **10a** and **10b** (5%). All the photoproducts were fully characterized by 1D ^1H and ^{13}C (BB and APT) NMR, 2D ^1H–^1H COSY, ^1H–^{13}C HMQC, HMBC and NOESY, FT-IR, HR-MS, as well as by elemental analysis. The structures of photoproducts **10a**, **9b**, and **10b** were also confirmed by X-ray crystallography (Fig. 2). The details of the separation conditions along with the analytical data for each of the products are given in the Experimental section.

As described above, 9-methylated bicyclo[3.3.1]nonyl phenyl ketones **1a** and **1b** underwent Yang photocyclization and yielded *endo*-aryl cyclobutanols **9a** and **9b** as major photoproducts, both in solution and the solid state. In this case, it is relevant to ask why neither *exo*-aryl cyclobutanols nor photocleavage products were obtained. To answer this question, consider the idealized reaction pathway shown in Scheme 4. X-ray crystallography shows that in the crystalline state ketones **1a** and **1b** adopt chair–chair conformations in which the benzoyl group is in the axial position and the mean plane of the carbonyl group is roughly orthogonal to the plane bisecting the bicyclo[3.3.1]nonane ring between γ-hydrogen atoms H_x and H_y. In this case, H_x is in closer proximity to the carbonyl oxygen than H_y (for H_x: d = 2.50 Å in ketone **1a**, and 2.52 Å in ketone **1b**; for H_y: d = 3.49 Å in ketone **1a**, and 3.69 Å in ketone **1b**). The other γ-hydrogen abstraction parameters (ω, Δ, and θ) in Table 2 also suggest that H_x is in a more favorable position for hydrogen abstraction than H_y (7).



Upon photoexcitation and hydrogen abstraction, 1,4-hydroxy biradical intermediate **11** will be generated. Since hydrogen abstraction in the solid state is considered to occur with minimum movement of the heavy atoms, geometric data derived from the ground-state ketone can be used to analyze the behavior of the corresponding 1,4-hydroxy biradical intermediate (8). For this purpose, we define two torsional angles with reference to Fig. 3*a*, which is a depiction of the 1,4-hydroxy biradicals derived from ketones **1a** and **1b**. Angle φ_1 is defined as the dihedral angle between the C2—C3 bond and the p orbital on C1, and the angle φ_4 is likewise defined as the analogous angle between the C2—C3 bond and the p orbital on C4. The p orbitals at C1 and

C4 are assumed to be orthogonal to the O-C1-C2 and C3-C4-C5 planes, respectively. It is generally believed that cleavage of 1,4-hydroxy biradicals is favored by good overlap between the p orbitals on C1 and C4 with the C2—C3 bond (9). The overlap between these orbitals is proportional to $\cos\varphi_1$ and $\cos\varphi_4$ (10), and the best geometry for cleavage can be expected when φ_1 and $\varphi_4 = 0°$ and $\cos\varphi_1 = \cos\varphi_4 = 1$. The values of $\cos\varphi_1$ and $\cos\varphi_4$ for the two ketones investigated in the present study are given in Table 3. Also shown in Table 3 are the values of the angle β, defined as the dihedral angle between the p orbital on C1 and the C2–C4 vector (Fig. 3*b*). The most favorable geometry for cyclization exists when $\beta = 0°$, i.e., when the p orbital on C1 is pointing directly at the p orbital on C4. Table 3 also gives the values of the distance (*D*), defined as the distance between C1 and C4. For Yang photocyclization to be successful, the radical-containing carbon atoms C1 and C4 must be close to one another, i.e., $D < 3.4$ Å, which is the sum of the van der Waals radii for two carbon atoms (11).

Table 3. Geometric data for ketones **1a** and **1b**.

Ketone	φ_1 (°)	$\cos\varphi_1$	φ_4 (°)	$\cos\varphi_4$	β (°)	*D* (Å)
1a	65	0.42	35	0.82	35	3.01
1b	59	0.52	36	0.81	28	2.90

With $\cos\varphi_4 \approx 80\%$ and $\cos\varphi_1 \approx 50\%$ (only 50% of maximum overlap between the p orbital on C1 and the C2—C3 bond), the geometry of biradical intermediate **11** is poor for cleavage, as cleavage requires good overlap of both p orbitals with the cleaving C2—C3 bond. But this biradical has a good geometry for cyclization, with $\beta \approx 30°$ (indicating there is reasonably good overlap of the two p orbitals at C1 and C4) and $D = 2.90$ Å in ketone **1b**, and 3.01 Å in ketone **1a**. As a result, cyclization of biradical **11** with retention of configuration at C1 and C4 leads to the predominant *endo*-aryl photoproducts **9a** and **9b**. On the other hand, for cleavage to occur, an approximate 90° rotation of the aryl and hydroxyl groups about the C1—C2 bond of biradical **11** is required to align the p orbital on C1 with the C2—C3 σ bond (see Scheme 4, structure **12**). An additional 90° rotation of the aryl and hydroxyl groups about the C1—C2 bond leads to biradical **13**, closure of which would give *exo*-aryl cyclobutanol products. Both processes require rotations about the C1—C2 bond and are unfavorable because of Ar/α-CH_3 eclipsing, a phenomenon known as the "α-alkyl group effect" (12). Therefore, *endo*-aryl cyclobutanols **9a**

Scheme 5.

and **9b** are the major products formed in the photoreaction of ketones **1a** and **1b**.

Formation of minor photoproducts **10a** and **10b** observed in the photolysis of ketones **1a** and **1b** can be seen to be the result of a 1,5-disproportionation of biradical intermediate **14**, which in turn is formed by a ring flip of initially formed biradical **8** (Scheme 5).[3] X-ray crystallographic analysis showed that the distance between C1 and the equatorial hydrogen atom on C5 in ketones **1a** and **1b** is 4.08 and 4.02 Å, respectively. It is unlikely that 1,5-disproportionation could take place directly from the chair–chair biradical **8** without a significant geometry change of the bicyclic ring. On the other hand, a ring flip of biradical **8** at the C5 end leads to the boat–chair biradical **14** in which the flagpole hydrogen atom on C5 is brought close to the radical center on C1 (13), and a 1,5-disproportionation process should easily occur. Because this ring-flipping process is energetically unfavorable, in an established equilibrium, the population of biradical **14** is less than that of biradical **8**. Moreover, because 1,5-disproportionation requires breaking a C—H bond, it is likely to be a slower process than Yang cyclization. Therefore, only small amounts of disproportionation products **10a** and **10b** were observed in the photolysis of ketones **1a** and **1b**.

In comparison with our previous studies on the photochemistry of adamantyl phenyl and norbornyl phenyl ketones (**2** and **3**) in which Yang cyclization was found to be the sole reaction pathway (no 1,5-disproportionation product was obtained owing to the rigidity of adamantyl and norbornyl ring skeletons) (2, 3), the present study not only corroborates this main reaction pattern for bicyclic and tricyclic phenyl ketones, but also shows that small changes in the flexibility of the bicyclic ring system can lead to a new reaction pattern, in this case a novel 1,5-disproportionation reaction.

To apply the solid-state ionic chiral auxiliary method to asymmetric induction in the photochemistry of 9-methylbicyclo[3.3.1]nonyl phenyl ketones, a number of crystalline salts (**1d–1j**, Scheme 2) were prepared by reaction of keto acid **1c** with commercially available optically pure amines. The amines were selected according to two criteria: (*i*) the pK_a of the reacting acid should be lower than that of the protonated amine by about 3 pK_a units (14, 15) because this ensures complete proton transfer from the acid to the amine instead of formation of a neutral hydrogen bonded complex; (*ii*) the amine selected should not possess chromophores that interfere with the aryl ketone absorption at 320–330 nm. The formation of an ammonium carboxylate linkage between the acid and amine was confirmed by the melting point and FT-IR spectrum of each salt. The melting points of all the salts are different from both those of keto acid **1c** and the corresponding amines. In the IR spectrum of keto acid **1c**, the C=O stretches of the ketone and carboxylic acid exist as broadened bands at 1695 and 1680 cm^{-1}, respectively. In the spectra of the salts, these absorptions are replaced by a single sharper band at ~1675 cm^{-1} corresponding to the C=O stretch of the ketone. At the same time, two new intense bands (1300–1600 cm^{-1}) owing to the symmetric and asymmetric stretches of the carboxylate anion are observed (16). The 1:1 acid–base stoichiometry of all the salts was confirmed by ^{1}H NMR spectroscopy, ESI (or LSI-MS) mass spectrometry, and elemental analysis.

[3] An alternative mechanism for the formation of minor photoproducts **10a** and **10b** involving initial δ-hydrogen atom abstraction followed by disproportionation is deemed unlikely on two counts: the general and well-established kinetic preference for γ over δ-hydrogen abstraction (1*a*), and in the specific case of ketones **1a** and **1b**, impossibly long C=O···H_δ distances (4.40 and 4.38 Å, respectively).

To determine whether the ionic chiral auxiliary has any effect on the product distribution or the steric course of the photoreaction in solution, a number of the optically active salts were photolyzed in a mixture of acetonitrile and water. Following irradiation, the reaction mixture was treated with excess ethereal diazomethane solution to form the corresponding methyl esters **9b** and **10b**. All the solution-state reactions essentially afforded the same product ratio of cyclobutanol **9b** and alkene **10b** as that observed in the solution photolysis of keto ester **1b**. Photoproduct **9b** was subsequently determined to be racemic. The enantiomeric excess of photoproduct **10b** was not measured owing to its small quantity in the reaction mixture. These results show that, in solution, the anisotropy of the chiral ammonium ion has no influence on the reaction selectivity.

Each of the salts listed in Scheme 2 was irradiated in the crystalline state. No color change or melting of the crystals was observed during the reaction, and following irradiation, the crystals were dissolved in ethyl acetate or methanol and treated with excess ethereal diazomethane to form the corresponding methyl esters **9b** and **10b**. Following diazomethane treatment, the organic layer containing the esterified photoproducts and starting material was washed with water and filtered through a short-path silica gel column to remove the chiral auxiliary. The mixture was then analyzed by GC for yield and conversion. Owing to the overlap of the product and starting ketone peaks in the chiral HPLC analysis, achiral preparative HPLC was used to isolate photoproduct **9b** (Waters Radialpak™ μPorasil™ silica column, 10% EtOAc in hexanes, 5 mL/min). Following purification, the enantiomeric excess of photoproduct **9b** was measured using chiral HPLC (Chiralcel® OC column, 2% isopropanol in hexanes, 0.5 mL/min). The results of the solid-state photolysis of chiral salts **1d**–**1j** are summarized in Table 4. Irradiation of the salts in the crystalline state leads to asymmetric induction with product ees ranging from 3% to 95%. The highest ee was observed for salt **1i** formed between acid **1c** and (*R*)-(–)-1-cyclohexylethylamine, where an enantiomeric excess of 95% was achieved at 38% reaction conversion.

Photolysis of the (*S*)-(–)-1-phenylethylamine and (*R*)-(+)-1-phenylethylamine salts (**1d** and **1e**) afforded nearly equal optical yields of the enantiomers of cyclobutanol **9b** (after diazomethane workup). This allows direct access to both enantiomers by simple exchange of the ionic chiral auxiliary. Table 4 also shows that the product ee declines with increasing reaction conversion. This is not unexpected, since the salts react to give products that presumably do not "fit" into the original crystal lattice, and defect sites are generated. As the reaction proceeds, the rigidity and regularity of the crystal lattice is gradually lost. As a result, the topochemical control is reduced and enantioselectivity declines. Low-temperature photolysis can be used to partially compensate this effect. As shown in Table 4, for reactions conducted at reduced temperature (–20 °C), enantioselectivities are better than those obtained at room temperature. Specifically, at –20 °C, quantitative conversion to cyclobutanol **9b** from salt **1d** occurred in 81% ee in comparison to 70% ee at room temperature. Further reducing the reaction temperature to –70 °C provided limited improvement in enantioselectivity, while much longer irradiation times were required.

To date, salts **1d**–**1j** have resisted attempts to determine their X-ray crystal structures; thus, we were not able to correlate the observed enantioselectivity with the solid-state structure. Nevertheless, the high ees observed in the solid state can be explained by a conformational effect, a situation that has been seen in other solid-state enantioselective Norrish–Yang type II reactions (17). In the solid state, the role of the ionic chiral auxiliary is to preorganize the photoreactant in a homochiral conformation in which the carbonyl group of the substrate is positioned to abstract only one of the two diastereotopic γ hydrogens in the initial step of the photoreaction. With topochemical control persisting in the solid state, formation of a single enantiomer of the product is achieved following removal of the chiral auxiliary, thereby transforming conformational chirality into configurational chirality.

Among the salts studied, salt **1j** showed a particularly low enantioselectivity (3% ee). The low enantioselectivity observed is likely due to the phenomenon of *conformational enantiomerism* (18) in which equal amounts of both enantiomeric conformers of the photolabile carboxylate exist within the crystal lattice. Each conformer abstracts one of the two diastereotopic γ hydrogens and forms opposite enantiomers of the same photoproduct after workup. In addition,

Fig. 4. ORTEP representation of: (*a*) ketone **1b** showing γ hydrogens H_x and H_y; (*b*) mixed crystal composed of 75% of ketone **1b** (gray) and 25% of photoproduct **9b** (black); (*c*) crystal packing diagram of the mixed crystal.

crystal disorder could also be a cause for the low enantioselectivity observed in the photolysis of salt **1j**. In a disordered crystal, two or more conformations of the reactive ion are distributed randomly throughout the crystal (static disorder) or are thermally interconverting (dynamic disorder). Since attempts to grow crystals of salt **1j** suitable for X-ray analysis were not successful, the exact reason for the low enantioselectivity of salt **1j** remains to be determined.

During our photochemical studies, we noticed that crystals of ketone **1b** did not change in appearance upon irradiation. This suggested the occurrence of a single-crystal-to-single-crystal reaction (19), which allowed the structures of both reactant and product to be obtained at various stages of reaction. Figure 4*a* shows the crystal structure of ketone **1b** prior to photolysis, and Fig. 4*b* depicts the superposition of ketone **1b** and its photoproduct in the mixed crystal following 25% conversion to the corresponding cyclobutanol **9b**. The extent of conversion was determined through refinement of the atom site occupancy factors in the X-ray crystallographic study. Figure 4*a* predicts preferential abstraction of H_x over H_y, and in agreement with this, the molecular structure of the photoproduct shows that the carbon atom to which H_x was attached is in fact part of the newly formed four-membered ring. The crystal structures also reveal that closure of the biradical does occur with "retention of configuration" at the carbonyl carbon. The reactant and product have similar geometries in which the aryl group portion of the molecule remains essentially unchanged during photolysis, while an upward movement of the γ carbon occurs to allow for cyclobutane ring formation. The corresponding alteration of the bicyclic ring skeleton is significant but a close atom-for-atom correspondence between the photoreactant and photoproduct is maintained. Also observed was a change in the orientation of the carbon–oxygen bond during the change in hybridization at the carbonyl carbon from sp^2 to sp^3. Accompanying this was a change in the length of the C—O bond from 1.22 to 1.33 Å. While these motions are significantly greater than those accompanying other unimolecular single crystal-to-single crystal photoreactions,[4] the overall packing arrangement of the crystal (Fig. 4*c*) remains unchanged, and as a result, the process still occurs in a topochemical fashion.

Summary

The photochemistry of several 9-methylbicyclo[3.3.1]-nonyl phenyl ketones was studied in solution and the solid state. In both media, Yang photocyclization was found to be the major process for α-methylated bicyclo[3.3.1]nonyl phenyl ketones (**1a** and **1b**), with *endo*-aryl cyclobutanols (**9a** and **9b**) being the major products. An unusual 1,4-hydroxy biradical disproportionation reaction was also observed during the photolysis of ketones **1a** and **1b**, although it was a minor process (<5%). By utilizing the *ionic chiral auxiliary* method, high enantioselectivities (up to 95%) were achieved for a number of the optically active salts on photolysis in the solid state. In addition, structure–reactivity correlation studies were performed based on the crystal structure data of ketones **1a** and **1b** to rationalize their photochemical behavior. The solid-state photoreaction of ketone **1b** was found to occur in a topochemically controlled, single crystal-to-single crystal fashion.

[4] For examples of unimolecular single-crystal-to-single-crystal photochemical reactions, see refs. 2 and 3.

Experimental section

Commercial spectral grade solvents were used for photochemical experiments unless otherwise stated. For synthetic use tetrahydrofuran and diethyl ether were dried over the sodium ketyl of benzophenone, dichloromethane was dried over calcium hydride, and acetonitrile was distilled from P_2O_5. All reactions were performed under a nitrogen atmosphere unless otherwise noted. Melting points were determined on a Fisher-Johns hot-stage apparatus and were uncorrected. Analytical TLC was performed on 0.20 mm silica gel 60-F plates and visualized under UV light and (or) by staining with I_2 or phosphomolybdic acid. Preparative chromatography was performed using either the flash column method with silica gel (particle size 230–400 mesh) or radial elution chromatography on a Harrison Research Chromatron (model 7924T) with self-coated silica gel plates (1 or 2 mm thickness with EM Science silica gel 60 PF254 containing gypsum 7749-3). IR spectra were recorded on a PerkinElmer 1710 Fourier transform spectrometer. UV spectra were recorded on a PerkinElmer Lambda-4B UV–vis spectrometer at 25 °C. High-resolution mass spectra were obtained from a Kratos MS 50 instrument using electron impact (EI) ionization at 70 eV, a Kratos MS 80 spectrometer using desorption chemical ionization (CI) with the ionizing gas noted, a Kratos Concept IIHQ hybrid spectrometer using liquid secondary ionization (LSI-MS), or a Micromass LCT spectrometer using electrospray ionization (ESI). Elemental analyses were performed by the University of British Columbia (UBC) microanalytical service on a Carlo Erba CHN Model 1106 analyzer. ^{1}H NMR spectra were obtained at either 300 or 400 MHz on Bruker AV-300 or Bruker AV-400 instruments. ^{13}C NMR spectra were recorded at either 75 or 100 MHz. Some spectra are supported by data from the attached proton test (APT). Where these are given, (-ve) denotes a negative APT peak corresponding to a methine (CH) or methyl (CH_3) carbon centre, while no assignment signifies a quaternary or methylene (CH_2) carbon center.

9-Methylbicyclo[3.3.1]nonyl carboxaldehyde (5) and 9-methylbicyclo[3.3.1]nonyl phenyl methanol (6)

A mixture of PCC (1.40 g, 6.48 mmol) and Celite® 545 (2.79 g) was ground with a mortar and pestle until homogeneous. This solid was added to a solution of alcohol **4** (5) (545 mg, 3.24 mmol) in anhydrous dichloromethane (40 mL) and the mixture stirred for 2 h at room temperature. The reaction mixture was filtered through a column of Florisil® and the remaining solids triturated well with anhydr. Et_2O. Removal of solvent in vacuo gave aldehyde **5** (538 mg, 100%) as colorless oil, which was found to be unstable and was used without further purification. To a cold (0 °C) solution of phenyl magnesium bromide in THF (25 mL) was added aldehyde **5** (538 mg, 3.24 mmol in 5 mL of THF). The reaction was stirred in the cold (0 °C) for 2 h and quenched with 5% aq. NH_4Cl solution (15 mL). THF was removed and the resultant aqueous phase was extracted with Et_2O (3 × 20 mL). The combined ethereal extracts were washed with H_2O (20 mL) and brine (20 mL), followed by drying ($MgSO_4$) and removal of the solvent in vacuo. Silica gel chromatography (5% EtOAc in petroleum ether) afforded alcohol **6** (706 mg, 89%) as a white solid, mp 118–118.5 °C (EtOAc – petroleum ether). IR (KBr, cm^{-1}): 3395, 2943, 2912, 2868, 1491, 1461, 1020, 892, 761, 732, 703, 567. ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 0.85 (s, 3H), 1.27 (br, 1H), 1.39 (m, 1H), 1.50–1.62 (m, 4H), 1.66 (s, 1H), 1.68–1.99 (m, 5H), 2.00–2.20 (m, 2H), 2.37 (m, 1H), 5.40 (s, 1H), 7.23 (m, 1H), 7.29 (m, 2H), 7.37 (m, 2H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ: 16.54 (-ve), 20.58, 20.87, 27.20, 27.60, 27.74, 27.85, 32.24 (-ve), 32.92 (-ve), 39.65, 74.13 (-ve), 126.93 (-ve), 127.47 (-ve), 127.55 (-ve), 142.45. HR-MS (CI) calcd. for $C_{17}H_{24}O$: 244.1827; found: 244.1834. Anal. calcd. for $C_{17}H_{24}O$: C 83.55, H 9.90; found: C 83.95, H 10.02.

9-Benzoyl-9-methylbicyclo[3.3.1]nonanes (1a)

A mixture of PCC (1.15 g, 5.33 mmol) and Celite® 545 (2.30 g) was ground with a mortar and pestle until homogeneous. This solid was added to a solution of alcohol **6** (651 mg, 2.66 mmol) in anhydrous dichloromethane (30 mL) and the reaction mixture was stirred for 10 h at room temperature. The reaction mixture was filtered through a column of Florisil® and the remaining solids well triturated with anhydr. Et_2O. Removal of solvent in vacuo and silica gel chromatography (3% Et_2O in petroleum ether) gave ketone **1a** (612 mg, 95%) as a white solid, mp 67 to 68 °C (EtOAc – petroleum ether). UV–vis (2.39×10^{-4} mol/L, MeOH, nm ((mol/L)$^{-1}$ cm^{-1})): 285 (1178), 330 (720). IR (KBr, cm^{-1}): 2960, 2913, 2865, 1672, 1444, 1266, 1232, 1216, 1124, 963, 932, 721, 696, 663. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.30–1.93 (m, 13H), 2.02–2.17 (m, 2H), 2.34 (br, 2H), 7.33–7.46 (m, 3H), 7.70–7.75 (m, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 20.20, 20.98, 23.63 (-ve), 26.82, 29.02, 33.90 (-ve), 50.79, 127.84 (-ve), 127.97 (-ve), 130.83 (-ve), 139.34, 209.84. HR-MS (EI) calcd. for $C_{17}H_{22}O$: 242.1671; found: 242.1670. Anal. calcd. for $C_{17}H_{22}O$: C 84.25, H 9.15; found: C 84.45, H 9.13. This structure was confirmed by X-ray crystallographic analysis.

(9-Methyl)bicyclo[3.3.1]non-9-yl (*p*-carbomethoxy)phenyl methanol (7)

A mixture of PCC (3.71 g, 17.2 mmol) and Celite® 545 (5.00 g) was ground with a mortar and pestle until homogeneous. This solid was added to a solution of alcohol **4** (5) (1.81 g, 10.8 mmol) in anhydrous dichloromethane (120 mL) and the mixture was stirred for 2 h at room temperature. The reaction mixture was filtered through a column of Florisil® and the remaining solids well triturated with anhydr. Et_2O. Removal of solvent in vacuo gave aldehyde **5** (1.79 g, 99%) as colorless oil, which was used without further purification. To a cold (–40 °C) solution of methyl 4-iodobenzoate (2.85 g, 10.9 mmol) in THF (60 mL) was added isopropylmagnesium chloride (5.7 mL of a 2.0 mol/L solution in THF, 11.4 mmol) over 10 min. The reaction was stirred in the cold (–40 °C) for 1 h. A solution of aldehyde **5** (1.73 g, 10.4 mmol) previously obtained in THF (20 mL) was added. The reaction was stirred at –40 °C for 3 h and quenched with 5% aq. NH_4Cl (100 mL). THF was removed in vacuo and the resultant aqueous phase was extracted with Et_2O (3 × 70 mL). The combined ethereal extracts were washed with brine (2 × 100 mL), followed by drying ($MgSO_4$) and removal of the solvent in vacuo. Silica gel chromatography (14% EtOAc in petroleum ether) afforded alcohol **7** (2.82 g, 90%) as a white powder, mp 135–137 °C (EtOAc – petro-

leum ether). IR (KBr, cm^{-1}): 3516 (br), 2950, 2913, 2868, 1724, 1610, 1490, 1460, 1436, 1283, 1192, 1111, 1034, 1018, 909, 869, 812, 770, 736, 715, 573. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.79 (s, 3H), 1.90–2.40 (m, 15H), 3.88 (s, 3H), 5.43 (s, 1H), 7.42 (d, *J* = 8.4 Hz, 2H), 7.93 (d, *J* = 8.4 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 16.56 (-ve), 20.48, 20.78, 27.15, 27.62 (br), 27.76, 32.19 (-ve), 32.90 (-ve), 39.91, 52.00 (-ve), 73.82 (-ve), 127.49 (-ve), 128.68 (-ve), 147.91 (br), 167.07. HR-MS (CI) calcd. for $C_{19}H_{30}NO_3$: 320.2226 $(M + NH_4)^+$; found: 320.2222. Anal. calcd. for $C_{19}H_{26}O_3$: C 75.46, H 8.67; found: C 75.48, H 8.73.

9-(*p*-Carbomethoxybenzoyl)-9-methylbicyclo[3.3.1]nonane (1b)

A mixture of PCC (3.09 g, 14.3 mmol) and Celite® 545 (5.0 g) was ground with a mortar and pestle until homogeneous. This solid was added to a solution of alcohol **7** (2.71 g, 8.96 mmol) in anhydrous dichloromethane (100 mL) and the resulting mixture was stirred for 12 h at room temperature. The reaction mixture was filtered through a column of Florisil® and the remaining solids triturated well with anhydr. Et_2O. Removal of solvent in vacuo gave ketone **1b** (2.69 g, 100%) as a white solid, mp 137 to 138 °C (EtOAc–hexanes). ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.48 (s, 3H), 1.32–1.94 (m, 10H), 2.08 (m, 2H), 2.29 (br, 2H), 3.92 (s, 3H), 7.74 (d, *J* = 8.5 Hz, 2H), 8.03 (d, *J* = 8.5 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 20.10, 20.89, 23.64 (-ve), 26.71, 29.03, 33.74 (-ve), 51.04, 52.32 (-ve), 127.69 (-ve), 129.27 (-ve), 131.89, 143.20, 166.36, 209.71. IR (KBr, cm^{-1}): 2950, 2906, 2857, 1722, 1666, 1497, 1435, 1401, 1279, 1235, 1190, 1108, 1017, 960, 934, 862, 738, 703. UV–vis (1.46×10^{-4} mol/L, MeOH, nm ($(mol/L)^{-1}$ cm^{-1})): 285 (1459), 330 (194). HR-MS (EI) calcd. for $C_{19}H_{24}O_3$: 300.1725; found: 300.1729. Anal. calcd. for $C_{19}H_{24}O_3$: C 75.97, H 8.05; found: C 75.80, H 8.00. This structure was confirmed by X-ray crystallographic analysis.

9-(*p*-Carboxybenzoyl)-9-methylbicyclo[3.3.1]nonane (1c)

To a solution of ester **1b** (2.45 g, 8.16 mmol) in THF (50 mL) was added a solution of lithium hydroxide monohydrate (3.42 g, 81.6 mmol, in 25 mL of water). The reaction was stirred at room temperature for 20 h. The reaction solution was diluted with Et_2O (200 mL) and extracted with water (3 × 100 mL). The combined aqueous extracts were acidified with concd. HCl and extracted with Et_2O (3 × 100 mL). The combined organic extracts were washed with water (100 mL) and brine (100 mL), then dried over $MgSO_4$. Removal of solvent in vacuo yielded acid **1c** (2.31 g, 99%) as a white powder, mp 224–226 °C (EtOH–H_2O). IR (KBr, cm^{-1}): 3080–2720 (br), 2950, 2906, 2863, 1695, 1680, 1568, 1505, 1431, 1401, 1316, 1295, 1214, 1126, 968, 933, 860, 807, 761, 731, 698, 543. ^1H NMR (DMSO, 300 MHz) δ: 1.20–2.16 (m, 15H), 2.22 (br, 2H), 7.82 (d, *J* = 8.2 Hz, 2H), 7.98 (d, *J* = 8.2 Hz, 2H). (No COOH signal was observed owing to proton exchange with a trace amount of water in the solvent). ^{13}C NMR (DMSO, 75 MHz) δ: 19.66, 20.41, 23.05 (-ve), 26.16, 28.47, 33.10 (-ve), 50.22, 127.71 (-ve), 129.12 (-ve), 132.78, 142.24, 166.66, 209.02. UV–vis (1.68×10^{-4} mol/L, MeOH, nm ($(mol/L)^{-1}$ cm^{-1})): 285 (2994), 335 (333). HR-MS (EI) calcd. for $C_{18}H_{22}O_3$: 286.1569; found: 286.1567. Anal. calcd. for $C_{18}H_{22}O_3$: C 75.50, H 7.74; found: C 75.23, H 7.67.

(*S*)-(–)-1-Phenylethylamine salt (1d)

Keto acid **1c** (86 mg, 0.30 mmol) and (*S*)-(–)-1-phenylethylamine (40 μL, 38 mg, 0.31 mmol) were dissolved in a hot mixture of acetonitrile and methanol. Upon cooling to room temperature, filtration gave salt **1d** as colorless needles (98 mg, 80%), mp 211–213 °C (MeOH–CH_3CN). IR (KBr, cm^{-1}): 3447, 2915, 2862, 2767, 1667, 1615, 1518, 1455, 1395, 1232, 1219, 1124, 1092, 965, 932, 844, 825, 764, 745, 695, 539. ^1H NMR (CD_3OD, 300 MHz) δ: 1.30–2.25 (m, 18H), 2.33 (br, 2H), 4.42 (q, *J* = 6.8 Hz, 1H), 7.41 (m, 5H), 7.73 (d, *J* = 8.4 Hz, 2H), 7.95 (d, *J* = 8.4 Hz, 2H). ^{13}C NMR (CD_3OD, 75 MHz) δ: 20.96 (-ve), 21.26, 22.01, 24.16 (-ve), 27.80, 30.11, 35.25 (-ve), 52.05, 52.26 (-ve), 127.60 (-ve), 128.44 (-ve), 129.89 (-ve), 130.05 (-ve), 130.26 (-ve), 140.11, 141.37, 141.99, 173.98, 212.09. HR-MS (LSI-MS) calcd. for $C_{26}H_{34}NO_3$: 408.2539 $(M + H^+)$; found: 408.2538. Anal. calcd. for $C_{26}H_{33}NO_3$: C 76.62, H 8.16, N 3.44; found: C 76.34, H 8.15, N 3.43.

(*R*)-(+)-1-Phenylethylamine salt (1e)

Keto acid **1c** (57 mg, 0.20 mmol) and (*R*)-(+)-1-phenylethylamine (27 μL, 25 mg, 0.21 mmol) were dissolved in a hot mixture of acetonitrile and methanol. Upon cooling to room temperature, filtration gave salt **1e** as colorless needles (64 mg, 79%), mp 211–213 °C (MeOH–CH_3CN). IR (KBr, cm^{-1}): 3446, 2915, 2864, 2766, 1668, 1615, 1519, 1456, 1396, 1232, 1219, 1124, 1092, 966, 933, 844, 825, 764, 744, 695, 539. ^1H NMR (CD_3OD, 300 MHz) δ: 1.30–2.25 (m, 18H), 2.33 (br, 2H), 4.42 (q, *J* = 6.8 Hz, 1H), 7.41 (m, 5H), 7.73 (d, *J* = 8.4 Hz, 2H), 7.95 (d, *J* = 8.4 Hz, 2H). ^{13}C NMR (CD_3OD, 75 MHz) δ: 20.96 (-ve), 21.26, 22.01, 24.16 (-ve), 27.80, 30.11, 35.25 (-ve), 52.05, 52.26 (-ve), 127.60 (-ve), 128.44 (-ve), 129.89 (-ve), 130.05 (-ve), 130.26 (-ve), 140.20, 141.37, 141.99, 173.98, 212.09. HR-MS (ESI) calcd. for $C_{26}H_{34}NO_3$: 408.2539 $(M + H^+)$; found: 408.2544. Anal. calcd. for $C_{26}H_{33}NO_3$: C 76.62, H 8.16, N 3.44; found: C 76.35, H 8.46, N 3.47.

(1*S*,2*R*)-(–)-*cis*-1-Amino-2-indanol salt (1f)

Salt **1f** was prepared by dissolving 57 mg (0.20 mmol) of keto acid **1c** and 31 mg (0.21 mmol) of (1*S*,2*R*)-(–)-*cis*-1-amino-2-indanol in a hot mixture of acetonitrile and methanol. Upon cooling to room temperature, filtration gave salt **1f** as an off-white powder (71 mg, 81%), mp 190 °C (dec) (MeOH–CH_3CN). IR (KBr, cm^{-1}): 3235, 2913, 2862, 2625, 1670, 1619, 1580, 1535, 1452, 1397, 1267, 1216, 1093, 966, 932, 844, 823, 803, 741, 567. ^1H NMR (CD_3OD, 300 MHz) δ: 1.28–2.00 (m, 13H), 2.18 (m, 2H), 2.33 (br, 2H), 3.01 (dd, *J* = 5.9, 16.3 Hz, 1H), 3.22 (dd, *J* = 6.4, 16.3 Hz, 1H), 4.54 (d, *J* = 5.9 Hz, 1H), 4.70 (dd, *J* = 5.9, 11.3 Hz, 1H), 7.31 (m, 3H), 7.46 (d, *J* = 7.3 Hz, 2H), 7.73 (d, *J* = 8.4 Hz, 2H), 7.96 (d, *J* = 8.4 Hz, 2H). ^{13}C NMR (CD_3OD, 75 MHz) δ: 21.24, 22.00, 24.15 (-ve), 27.80, 30.10, 35.24 (-ve), 40.09, 52.05, 58.71 (-ve), 72.08 (-ve), 126.14 (-ve), 126.64 (-ve), 128.40 (-ve), 129.44 (-ve), 129.89 (-ve), 130.77 (-ve), 138.47, 141.28, 141.99, 142.77, 174.11, 212.11. HR-MS (ESI) calcd. for $C_{27}H_{34}NO_4$: 436.2488 $(M + H^+)$; found: 436.2486. Anal.

(1*R*,2*R*)-(–)-2-Amino-1-phenyl-1,3-propanediol salt (1j)

Salt **1j** was prepared by dissolving keto acid **1c** (57 mg, 0.20 mmol) and (1*R*,2*R*)-(–)-2-amino-1-phenyl-1,3-propanediol (35 mg, 0.21 mmol) in a hot mixture of acetonitrile and methanol. Upon cooling to room temperature, filtration gave salt **1j** as a white powder (76 mg, 84%), mp 142 to 143 °C (MeOH–CH_3CN). IR (KBr, cm^{-1}): 3367, 2914, 2864, 1668, 1582, 1542, 1493, 1453, 1386, 1229, 1124, 1039, 968, 960, 932, 868, 840, 803, 746, 700, 572, 540. ^{1}H NMR (CD_3OD, 300 MHz) δ: 1.25–1.73 (m, 8H), 1.51 (s, 3H), 1.89 (m, 2H), 2.17 (m, 2H), 2.33 (br, 2H), 3.26 (m, 1H), 3.47 (m, 2H), 4.73 (d, *J* = 8.6 Hz, 1H), 7.37 (m, 5H), 7.72 (d, *J* = 8.6 Hz, 2H), 7.96 (d, *J* = 8.6 Hz, 2H). ^{13}C NMR (CD_3OD, 75 MHz) δ: 21.23, 21.98, 24.15 (-ve), 27.81, 30.10, 35.26 (-ve), 52.06, 60.23, 60.29 (-ve), 72.54 (-ve), 127.86 (-ve), 128.42 (-ve), 129.51 (-ve), 129.74 (-ve), 129.89 (-ve), 141.38, 141.97, 142.23, 174.13, 212.15. HR-MS (ESI) calcd. for $C_{27}H_{36}NO_5$: 454.2593 (M + H^+); found: 454.2599. Anal. calcd. for $C_{27}H_{35}NO_5$: C 71.50, H 7.78, N 3.09; found: C 71.34, H 8.05, N 3.41.

Photochemistry

Both solution- and solid-state photolyses were carried out by using a 450 W Hanovia medium-pressure mercury lamp in a water-cooled immersion well. Light from the lamp was filtered through a Pyrex (λ ≥ 290 nm) immersion well. For preparative scale solution-state photolyses, samples were dissolved in HPLC grade or spectral grade solvents and were purged with nitrogen for at least 15 min prior to irradiation. The reactions were performed either in sealed reaction vessels or under a positive pressure of nitrogen. Yields and conversions were calculated based on the mass of the isolated products. For analytical solid-state photolyses, the procedure consisted of crushing ca. 5 mg of the salt to be photolyzed between two Pyrex microscope slides, taping the plates together, sealing the resulting sandwiches in polyethylene bags under a positive nitrogen atmosphere, and irradiating the ensembles with the output from a water-cooled 450 W medium-pressure mercury lamp. Photolyses were generally carried out at room temperature. For some runs that required low temperature during photolysis, a Cryocool CC-100 II immersion cooling system (Neslab Instrument Inc.) was used with ethanol as the coolant. The salts were irradiated for varying lengths of time to determine the dependence of the ee values on the extent of conversion. To achieve high conversions it was usually necessary to rotate the sample 180° midway through the irradiation, exposing the rear side of the slide to the light and allowing as much of the sample as possible to react. For neutral molecules, the sample was directly analyzed by GC. The reaction mixtures containing chiral organic salts were first derivatized to their corresponding methyl esters by treatment with excess ethereal diazomethane solution and then washed with water and subjected to short-path silica gel chromatography to remove the chiral auxiliary. The mixtures were then analyzed by GC for conversion as well as product composition. Yields and conversions of the solid-state reactions were determined based on the average integration of at least two GC analyses. The overall precision of the reported GC results is estimated to be ±1%.

Preparative photolysis of ketone 1a

A solution of ketone **1a** (485 mg, 2.00 mmol) in acetonitrile (40 mL) was purged with nitrogen for 30 min and irradiated for 7 h. Removal of the solvent in vacuo followed by silica gel chromatography (6% EtOAc in petroleum ether) afforded starting material **1a** (17 mg, 4%), cyclobutanol **9a** (442 mg, 91%), and alkene **10a** (19 mg, 4%).

Data for cyclobutanol 9a

This structure was confirmed by X-ray crystallographic analysis.

X-ray crystal structure analyses

Crystal data for compounds **1a**, **1b**, **9b**, **10a**, and **10b** were collected using a Rigaku/AFC7 four-circle diffractometer equipped with an ADSC Quantum CCD detector. The X-ray source was graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å). Structures were solved by means of direct methods (SHELXS-97 (20) for **1a**, SIR92 (21) for **1b**, **9b**, **10a**, and **10b**), and all refinements were carried out by full-matrix least-squres procedures (SHELXL-97) (22) using anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were introduced in calculated positions and only one overall isotropic displacement parameter was refined. The CCDC reference numbers are CCDC 255968–255972 for compounds **1a**, **1b**, **9b**, **10a**, and **10b**, respectively, and 260038 for the mixed crystal resulting from partial solid-state photolysis of ketone **1b**.[5]

Crystal structure determination of ketone 1a

Single crystals of **1a** were recrystallized from EtOAc – petroleum ether, mounted in inert oil, and transferred to the cold nitrogen stream of the diffractometer. Crystal data: $C_{17}H_{22}O$, MW = 242.35, triclinic, a = 6.938 Å, b = 10.104 Å, c = 10.197 Å, α = 101.473°, β = 98.041°, γ = 104.520°, V = 664.48 Å^3, T = 173 K, space group P, Z = 2, μ(Mo Kα) = 0.073 mm^{-1}, reflections measured = 4092, unique = 2552, $R1$ = 0.0402, $wR2$ = 0.1053, GoF = 1.046.

Crystal structure determination of ketone 1b and its single crystal-to-single crystal reaction

Single crystals of **1b** were recrystallized from EtOAc–hexanes, mounted in inert oil and transferred to the cold nitrogen stream of the diffractometer. Crystal data: $C_{19}H_{24}O_3$, MW = 300.38, monoclinic, a = 6.5508(3) Å, b = 11.0233(6) Å, c = 21.4693(13) Å, β = 92.627(2)°, V =

Regioselective S—O vs. C—O bond cleavage in sulfenate ester radical anions[1]

Donald L.B. Stringle and Mark S. Workentin

Abstract: The electron transfer (ET) reduction of benzyl benzenesulfenate ester (**1**) and *tert*-butyl benzenesulfenate ester (**2**) was investigated using electrochemical techniques. Analysis of the cyclic voltammetry of each compound suggests that the ET reduction proceeds via a stepwise dissociative mechanism. The voltammograms of **1** are similar to those of diaryl disulfides and it was found through controlled potential electrolysis (CPE) product studies that ET reduction leads to S—O bond cleavage. The voltammograms of **2** are dramatically different with a sharper dissociative wave occurring at a more negative peak potential. CPE experiments indicate products that result from ET leading to C—O bond cleavage in this case. DFT calculations of the singly occupied molecular orbitals (SOMOs) of **1** and **2** were performed and offer a rationale for the different reactivity of the two radical anions.

Key words: sulfenate esters, dissociative electron transfer, electrochemistry, radical anions.

Résumé : On a étudié la réaction de réduction par transfert d'électron (TE) du benzènesulfénate de benzyle (**1**) et du benzènesulfénate de *tert*-butyle (**2**) en faisant appel à des techniques électrochimiques. L'analyse de la voltampérométrie cyclique de chaque composé suggère que la réduction par TE se produit par un mécanisme par dissociations successives. Le voltampérogramme du composé **1** est semblable à celui des disulfures de diaryles et, sur la base d'études des produits par électrolyse à potentiel contrôlé (EPC), on a trouvé que la réduction par TE conduit à une coupure de la liaison S—O. Le voltampérogramme du composé **2** est dramatiquement différent et il présente une vague dissociative qui se présente à un pic de potentiel beaucoup plus négatif. Les études d'EPC indiquent que, dans ce cas, les produits qui résultent d'un TE proviennent d'une coupure d'une liaison C—O. Des calculs effectués sur la base de la théorie de la densité fonctionnelle des orbitales moléculaires à occupation singulet (SOMO) des composés **1** et **2** et ils permettent de présenter une rationalisation pour les réactivités différentes des deux radicaux anions.

Mots clés : esters de l'acide sulfénique, transfert d'électron avec dissociation, électrochimie, radicaux anions.

[Traduit par la Rédaction]

Introduction

A major focus of our group has been the study of dissociative electron transfer (ET) reactions through electrochemical methods. The work provides an opportunity to investigate many aspects of ET reactions, but also allows for investigation into the reactivity of the intermediate species formed upon ET. Studies of 9,10-diphenylanthracene endoperoxide found that upon ET reduction, O—O bond cleavage occurred generating an alkoxyl radical (1, 2). It was observed that an O-neophyl type rearrangement at the alkoxyl radical could occur in competition with its ET reduction. Similarly, the dissociative ET reduction of 3,3,6,6-tetraaryl-1,2-dioxanes involved formation of a distonic radical anion (where the radical and anionic centres are spatially and electronically distinct), which could be reduced or could fragment (3). The fragmentation pathway led to a homogeneous ET-fragmentation radical anion chain reaction that was responsible for a potential dependence on the product ratios of controlled potential electrolysis (CPE) experiments. Both cases demonstrate the unique reactivity that can be observed upon generation of radical anion species by electrochemical means, and how the reactivity can be controlled by adjusting the potential at which they are formed. In this sense, the electrochemical generation of radical anions makes for ideal circumstances to investigate their reactivity.

The study of sulfenate esters developed as an extension to our work on the ET reduction of peroxides (4–7) and endoperoxides (1–3, 8–10) and the work of others concerning the ET reduction of diaryl disulfides (11–14). The ET reduction of the O—O bonds in peroxides and endoperoxides and the S—S bonds in diaryl disulfides are characterized by unusually large values for the intrinsic barrier for the ET ($\Delta G_0^{\ddagger}$). For the ET reduction of peroxides and endoperoxides the ET is shown to cleave the O—O bond via a concerted dissociative mechanism where electron uptake and bond cleavage are simultaneous. In this case, the large intrinsic barrier is a result of a contribution from the bond dissociation energy of the fragmenting bond. In contrast, the reduction of diaryl disulfides was shown to follow a stepwise dissociative mechanism, with the formation of a radical anion intermediate that leads to fragmentation of the S—S bond in a second

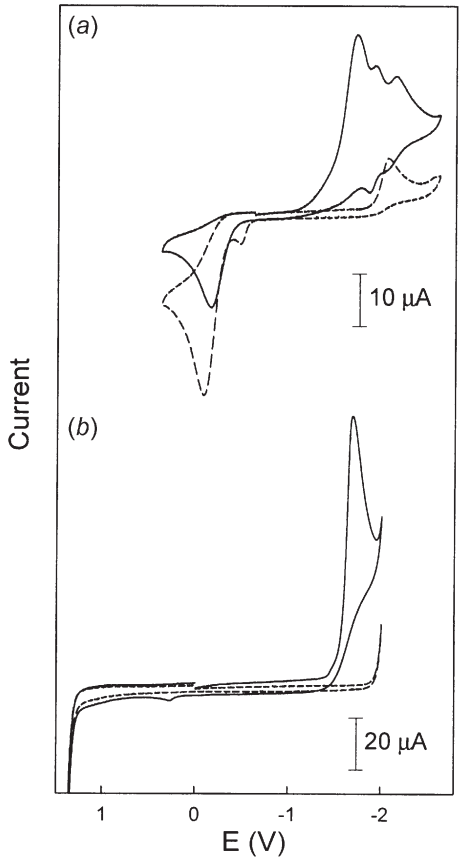
step. For the disulfides, the large intrinsic barrier was shown to be the result of contributions due to a significant S—S bond stretching upon ET forming a loosely bound radical anion intermediate. To further examine the factors that govern the stepwise vs. concerted mechanism in these types of bonded systems, we initiated this study of the ET to sulfenate esters, which contain a single S—O bond.

Although isoelectronic with peroxides (O—O) and disulfides (S—S), the S—O bonded sulfenate esters might reasonably be expected to show some differences in reactivity because the relative size and electronegativity of the two atoms in the bond are different. Because the chemistry of a compound initiated by ET and photochemical excitation often follow similar pathways, then it is constructive to note that in the many investigations of the photochemistry of sulfenate esters it is uniformly demonstrated that S—O bond cleavage occurs upon excitation (15, 16), similar to both peroxides and disulfides that undergo photolytic O—O and S—S cleavage, respectively. This offers reason to suspect that upon ET reduction these compounds would then undergo S—O cleavage as well. However, a computational study by Gregory and Jenks (17) suggests that compared to R-O-O-R′ peroxides, sulfenic esters (R-S-O-R′) can have much weaker R′—O bonds than the stronger central S—O or the corresponding R—S bonds. This suggests that sulfenic esters may indeed exhibit different reactivity compared to peroxides and disulfides. In this study the ET reduction of benzyl benzenesulfenate ester (**1**) and *tert*-butyl benzenesulfenate ester (**2**), shown in Scheme 1, was examined. These substrates vary only in the ester functionality, which is ideal for probing the impact of this group on the reactivity. Both substrates are derivatives of benzenesulfenic acid, which provides a convenient handle for comparison to diaryl disulfides. The work reported here details the analysis of the cyclic voltammetry (CV) and the CPE for each compound to determine the mechanism of the initial ET and investigate the reactivity of any radical anion species formed through ET reduction.



Results and discussion

ET reduction of benzyl benzenesulfenate ester (1)

The cyclic voltammetry of **1** was performed in dimethylformamide (DMF) with 0.1 mol/L tetrabutylammonium perchlorate (TBAP) as supporting electrolyte. The pertinent CV data for both **1** and **2** are listed in Table 1. A representative CV of **1** in the absence of acid is shown in Fig. 1*a*. When scanning cathodically, a broad wave with low peak current is observed at –1.68 V vs. SCE at 0.1 V/s, which is assigned as the dissociative wave of **1**. This wave is irreversible at all scan rates investigated (0.1–50.0 V/s). The peak current corrected for scan rate and concentration is 107 μA for a 2 mmol/L solution. The peak current provides an indication of the number of electrons involved in the reduction step. The E_p shifts negatively with increasing scan rate by 83 mV/decade. The peak breadth also increases, from values of 117 to 124 mV at 0.1 and 1.0 V/s, respectively, which leads to the corresponding decrease in the transfer coefficient (α), with values of 0.41 and 0.38 at the same scan

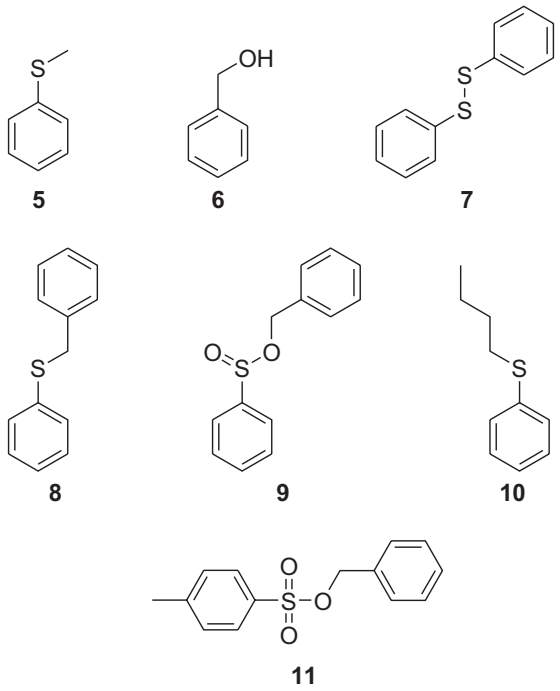
Fig. 1. Representative CVs of **1** in 0.1 mol/L TBAP–DMF at 0.1 V/s: (*a*) **1** (2.3 mmol/L) before (solid line) and after (dashed line) introduction of 6.1 C of charge into the cell; (*b*) **1** (2.2 mmol/L) in the presence of acetanilide (40 mmol/L) and MeOTs (40 mmol/L) before (solid line) and after (dashed line) introduction of 10.3 C of charge into the cell.

rates. A shoulder is present on the tail of this wave and following this is another small wave that appears to be quasi-reversible. Both of the latter two features are present due to the reduction of products formed from parent–child reactions, where **1** (the parent) reacts with a basic or nucleophilic anionic species (the child) generated from the ET reduction of **1**. Reversing to scan anodically, a large oxidation near 0 V vs. SCE is observed and is attributed primarily to the oxidation of phenylthiolate (**3**) to the phenylthiyl radical (18). Because of the similarity in oxidation potentials, this wave may also include the oxidation of phenylmethoxide anion (**4**), and at slower scan rates this wave does appear to be composed of two overlapping oxidation peaks. The presence of **3** is confirmed by reversing the scan direction to scan cathodically following this large oxidation peak. A reduction wave attributable to diphenyl disulfide is observed, though this wave is exceedingly broad because of fouling of the working electrode by the putative phenylthiyl radicals. The analysis of the CVs indicates that the ET reduction occurs by the mechanism shown in Scheme 2. The initial ET occurs to form a radical anion intermediate, which then cleaves at the S—O bond in a separate step. The cleavage of the radical anion generates phenylthiolate (**3**) and the phenylmethoxyl radical. The alternate mode of cleavage (phenylthiyl radical and phenylmethoxide anion) is less favoured as the phenylthiyl radical is estimated to have a more negative reduction potential than the phenylmethoxyl radical (18). Regardless of the mode of cleavage, the reduction potential of the radical formed is far positive of the reduction potential of **1** and undergoes a rapid ET to give the phenylmethoxide anion (**4**).

Scheme 2. Proposed mechanism for the ET reduction of **1**.



The reduction waves following the dissociative wave of **1** are due to products from the reactions involving the anionic species **3** or **4** reacting with **1** or the medium. The addition of an acid, such as acetanilide or 2,2,2-trifluoroethanol (TFE), will result in the protonation of **4**, eliminating any reactions of this anion with **1**. The pK_as of benzenethiol, acetanilide, and TFE as determined in DMSO are 10.3, 21.45, and 23.45, respectively (19). Given the relative pK_a values for these compounds, it is apparent why acetanilide and TFE have a limited capacity to protonate **3**. Therefore, the addition of these acids does not hinder the ability of **3** to react with **1**, even when present in large excess. In this case, to trap any **3** produced in the reduction of **1** a nucleophile trap such as methyl *p*-toluenesulfonate (MeOTs) or methyl iodide (MeI) is added.

The addition of both an acid and nucleophile trap is necessary to observe the full peak current. For example, the addition of 2 equiv. of TFE results in an increase in the peak current from 107 to 148 μA. The addition of 1 equiv. of MeOTs caused a further increase from 148 to 164 μA. It was also observed that addition of MeOTs alone was not capable of stopping the parent–child reactions, as an increase in the peak current of the dissociative wave is observed with the addition of acetanilide to a cell containing **1** and a large excess of MeOTs. It would seem that both the anions generated from reduction of **1** are participating in some form of parent–child reaction, therefore it is necessary to add both an acid and a nucleophile trapping agent to observe the maximum peak current.

The voltammetry responds differently to the addition of each reagent. Upon initial addition of acid the peak sharpens, especially apparent at higher scan rates, with α values ranging from 0.44 at 0.1 V/s to 0.53 at 1.0 V/s and then down to 0.37 at 10.0 V/s. The E_p continues to shift negatively as in the absence of acid by 74 mV/decade. The dissociative wave sharpens even further with the addition of MeOTs, most noticeably at the foot of the wave. This is carried over to the values of α, ranging from 0.50 to 0.52 to 0.37 at 0.1, 1.0, and 10.0 V/s, respectively. The addition of both reagents to the cell eliminates the shoulder on the tail

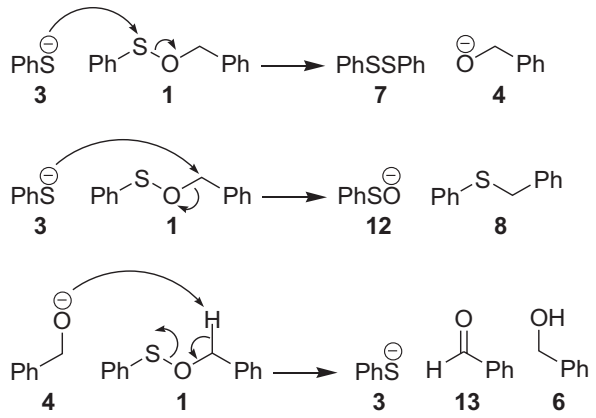
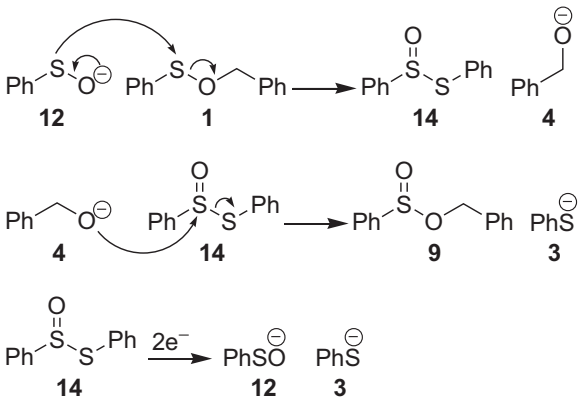
Scheme 3. Products obtained from the CPE of **1**.



of the dissociative wave and no reduction waves are observed following it prior to the reduction of MeOTs occurring around –2.1 V vs. SCE. This is evidence that it has stopped any parent–child reactions and any products from the reduction that have been trapped are not electroactive in the potential window investigated. The large oxidation near 0 V vs. SCE also disappears, though it remains present in the voltammetry of **1** until MeOTs is added, again confirming its assignment as the oxidation of **3**.

Analysis of the data obtained from voltammograms performed in the presence of both acid and a nucleophile trapping agent allows an important conclusion concerning the mechanism of reduction to be drawn. The values for the peak width, peak current, and the shift in the peak potential are all similar to an electrochemically reversible process (i.e., the reduction of nitrobenzene) suggesting that the bond cleavage, and not the ET, is the rate-determining step. This implies that the ET reduction is occurring by a stepwise dissociative mechanism.

CPE experiments carried out in the absence of both acid and MeOTs required only 1.1 electron equiv., this value being the average obtained over several experiments. CVs taken before and after complete electrolysis are shown in Fig. 1*a*. Following complete reduction, the dissociative wave has completely disappeared while a small irreversible wave at more negative potentials is present. Scanning anodically, it was found that the peak attributed to the oxidation of **3** significantly increased. The cell solution was acidified and MeOTs was added following the electrolysis to aid in product isolation. The majority of the DMF and TFE were removed in vacuo with mild heating (60 °C). The residue was then subjected to column chromatography. Analysis of the fractions obtained by GC and GC–MS indicated the products summarized in Scheme 3. The major products of the reduction, methyl phenyl sulfide (**5**), benzyl alcohol (**6**), and diphenyl disulfide (**7**), could be identified using GC by comparison with authentic samples. Benzyl phenyl sulfide (**8**), a minor product, could also be identified by GC comparison. The identities of these products were further confirmed by mass spectrometry. The identities of the other minor products of reduction, benzylbenzenesulfinate (**9**), *n*-butyl phenyl sulfide (**10**), and benzyl *p*-toluenesulfonate (**11**), are based on their mass spectra. There were some minor products present that could not be conclusively identified by their mass spectra. Compounds **6**–**9** are products derived from parent–child processes. The remaining products are attributed to secondary reactions involving products of the reduction (**3** and **4**) with the solvent, electrolyte, or MeOTs. Because of the significance of these secondary reactions, a similar electrolysis was carried out, only switching to acetonitrile (MeCN) as the solvent, which was then worked up as previously described. GC–MS analysis revealed that switching the electrolysis solvent did not simplify the product mixture, and that products produced from reaction with MeCN were also present.

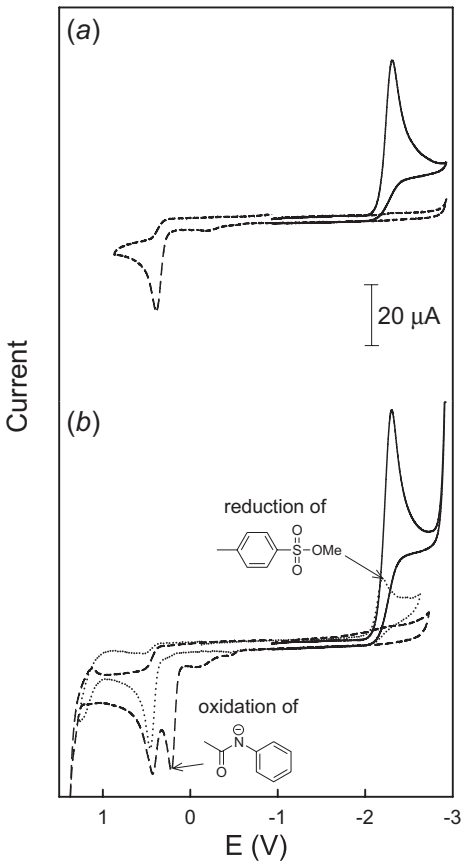


Scheme 4. Parent–child reactions involved in the ET reduction of **1**.

Based on the products observed in the DMF electrolysis, the reactions shown in Scheme 4 have been postulated for the parent–child processes. The first reaction is a nucleophilic attack at the sulfur atom of **1** by **3** to give diphenyl disulfide (**7**) and **4**. The reaction is believed to be occurring, but is in essence inconsequential as **4** is produced by direct ET to **1**. Also, at the potential at which the electrolysis is performed, any **7** formed by this reaction will be reduced to give 2 equiv. of **3**. This reaction will not affect either the products observed or the charge required for complete electrolysis. The second reaction involves attack at the benzyl carbon of **1** by **3** to give the benzenesulfenate anion and benzyl phenyl sulfide (**8**). This reaction accounts for the observance of **8** as a product from electrolysis and accounts for the lower charge consumption, as the reduction potential of **8** is negative of the electrode potential during electrolysis. The final parent–child reaction is the deprotonation of the benzyl carbon of **1** to give benzyl alcohol (**6**), benzaldehyde (**13**), and **3**. Benzaldehyde was observed as a minor product in the CPE experiments carried out in MeCN. The reduction potential of **13** is very close to that of **1** with $E^{\circ}_{\mathbf{13}} = -1.85$ V vs. SCE, and it is suggested that the shoulder on the dissociative wave is due to the reduction of **13** (Fig 1*a*). For

© 2005 NRC Canada

Scheme 5. Reactions accounting for the formation of **9**.

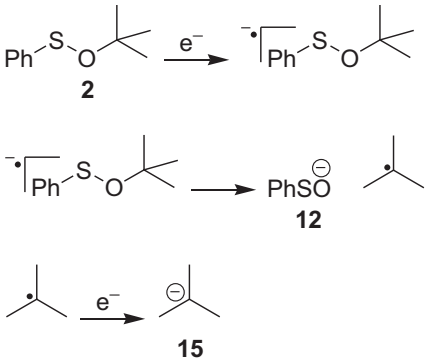


these reasons it is suspected that **13** will be reduced to its radical anion during the electrolysis of **1**. Reduction of **13** in aprotic solvent leads to the formation of 1,2-diphenylethane-1,2-diol (20–25); however, this compound was not observed as a product of our experiments. As the presence of acid is required to observe the full peak current of the dissociative wave of **1**, there must be a parent–child reaction involving **4** and **1**. Also, reaction between **4** and **1** to give **13** will result in a net decrease in the charge required for complete electrolysis, even if **13** is reduced to its radical anion. The products that were not conclusively identified were consistent with products from reactions between **3** and **13** and could account for the lack of products serving as evidence of the presence of **13**. On these grounds, we propose the reaction shown in Scheme 4 as the most likely reaction between **1** and **4**.

The formation of benzyl benzenesulfinate (**9**) cannot be directly accounted for through a parent–child reaction. However, in the reaction leading to **8** the benzenesulfenate anion (**12**) is generated. A possible reaction of this anion with **1** is illustrated in Scheme 5. Attack at the sulfur atom of **1** by **12** generates phenyl benzenethiosulfinate (**14**), while releasing **4**. A subsequent reaction between **4** and **14** could lead to the formation of **9**. Compound **14** could also be generated from attack of **12** on **7** with the release of **3**. The other primary process available to **14** would be ET reduction, which would lead to the generation of **12** and **3**.

When the reduction is performed in the presence of both MeOTs and acetanilide, a smooth conversion to phenyl methyl sulfide and benzyl alcohol by two-electron reduction is observed. It can be seen in Fig. 1*b* that no electroactive reagents remain following complete reduction of **1**. Both HPLC and GC results confirm quantitative formation of phenyl methyl sulfide (**5**). GC was used to determine the concentration of benzyl alcohol produced under these conditions, though it was difficult to achieve consistent results, even for the standards used for calibration. GC calibration indicates that 76% of the maximum amount of benzyl alcohol is recovered when the reduction is carried out with acid and MeOTs. These results were consistent with quantitative formation of benzyl alcohol given the error associated with these measurements. Considering that **5** is formed quantitatively and the two-electron stoichiometry for the complete reduction, it is assumed that a less than quantitative return of benzyl alcohol is primarily due to loss during the work-up.

Fig. 2. Representative CVs of **2** in 0.1 mol/L TBAP–DMF at 0.1 V/s: (*a*) **2** (2.4 mmol/L) before (solid line) and after (dashed line) introduction of 6.0 C of charge into the cell; (*b*) **2** (2.3 mmol/L) in the presence of acetanilide (40 mmol/L) before (solid line) and after (dashed line) introduction of 11.2 C of charge into the cell and following the subsequent addition of 2.7 mmol/L MeOTs (dotted line).



Analysis of the CV and CPE experimental data leads to the conclusion that the ET reduction of **1** occurs via a stepwise dissociative mechanism and the intermediate radical anion cleaves at the S—O bond.

ET reduction of *tert*-butyl benzenesulfenate ester (2)

The CV experiments of **2** were performed in 0.1 mol/L TBAP in DMF and the relevant voltammetric data are listed in Table 1 for comparison to the CV data obtained for compound **1**. A representative CV of **2** in 0.1 mol/L TBAP–DMF solution is shown in Fig. 2. A narrow, irreversible wave is observed at –2.28 V vs. SCE at 0.1 V/s. A negative shifting of the E_p with increasing scan rate is observed at a rate of 103 mV/decade. The peak width increases with increasing scan rate leading to decreasing values of the transfer coefficient. The α values at 0.1, 1.0, and 10.0 V/s are 0.58, 0.50, and 0.37, respectively. These data are in accord with the heterogeneous ET occurring by a stepwise dissociative mechanism, although the shifting of the E_p is higher than generally observed for systems proceeding by a stepwise mechanism. The dissociative wave is the only peak present on the cathodic scan, and reversing to the anodic scan reveals only small oxidation waves, starting at –0.4 V

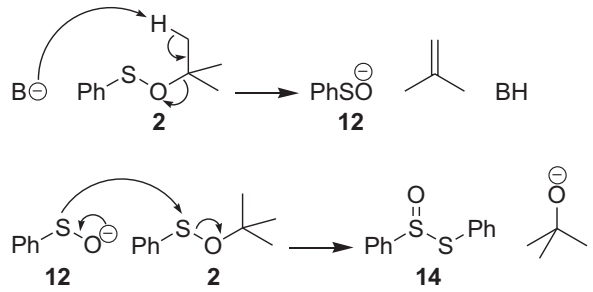
Scheme 6. Mechanism for the ET reduction of **2**.

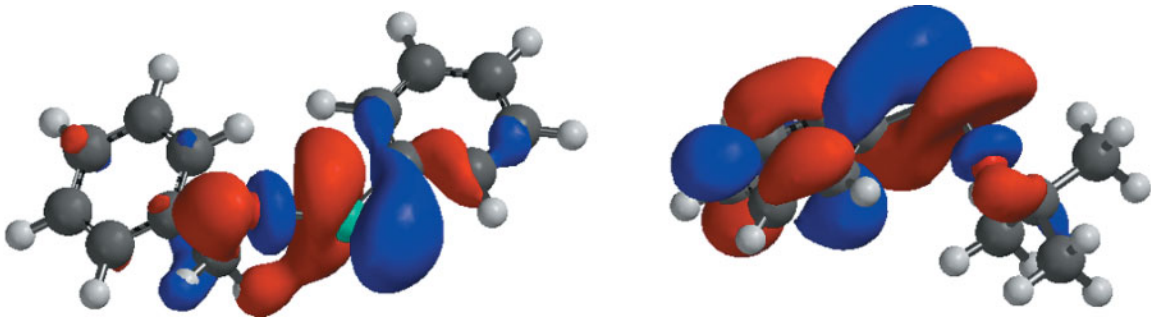


vs. SCE through to the largest oxidation wave occurring at 0.45 V vs. SCE at 0.2 V/s. The origin of these oxidations will be discussed in the context of the electrolysis experiments. It is sufficient at this point to note that unlike the voltammograms for **1**, only a small oxidation is present near 0 V vs. SCE. This is an indication that **3** is being produced only in a limited quantity, and the addition of nucleophile traps is deemed unnecessary when studying the electrochemistry of **2**. In comparison, for the reduction of **1** a large oxidation wave due to **3** is observed indicating a significant amount of **3** is produced, leading to the conclusion that the radical anion dissociates by S—O cleavage. Limited production of **3** is an indication that S—O bond cleavage is not occurring appreciably and that instead the radical anion of **2** dissociates by breaking the C—O bond as illustrated in Scheme 6. In this scheme, compound **2** is initially reduced by an ET to its radical anion, which then fragments in a separate step. The C—O bond is cleaved in the fragmentation step resulting in the formation of benzenesulfenate anion (**12**) and the *tert*-butyl radical. The standard reduction potential of this radical is estimated to be –1.54 V vs. SCE (18), which is positive of the E_p of **2**, therefore a heterogeneous ET can reduce this radical to give the *tert*-butyl anion (**15**).

The addition of a weak, nonnucleophilic acid, such as acetanilide or TFE, causes a significant increase in the peak current. The peak current values, corrected for both concentration and scan rate are 147 μA without acid and 170 μA with acid for a 2 mmol/L solution. Again, some parent–child interaction is responsible for a lower observed peak current in the absence of a reagent to trap the reactive species. The peak not only increased in current, but became narrower, which was especially apparent at higher scan rates. This is demonstrated in the value of the transfer coefficient, ranging from 0.55 to 0.50 and 0.43 at scan rates of 0.1, 1.0, and 10.0 V/s, respectively. Also, the observed shift in the E_p with increasing scan rate decreased from 103 to 72 mV/decade, a value that is more consistent with ET by a stepwise dissociative mechanism. The addition of acid did not dramatically affect the oxidation waves observed in the absence of acid, as it appears that the products responsible for these oxidation peaks are produced in the same quantity in the presence and absence of acid.

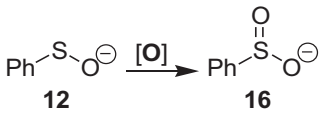
To confirm that C—O bond cleavage was occurring in the ET reduction of **2**, CPE experiments were necessary. Performing CPE in the absence of acid required only 1.1 electron equiv. for the complete reduction of **2**. This

Scheme 7. Parent–child reactions involved in the ET reduction of **2**.



demonstrates that the parent–child process is highly effective when reduction is carried out on the electrolysis scale. Figure 2*a* shows CVs of **2** taken before and after the electrolysis. It can be seen that following electrolysis there are no products that are electroactive at negative potentials. However, anodic scans reveal that a large oxidation peak is present at 0.45 V vs. SCE at 0.2 V/s. Small peaks occurring at slightly more negative potentials are also present. Electrolysis performed with a large excess of acetanilide present require 1.96 F/mol (i.e., 2 electron equiv.) for complete reduction indicating that only acid is necessary to effectively suppress any parent-child reactions. Figure 2*b* shows the before and after CVs from the CPE of **2** with acid and it is seen that again no reducible products are observed and the large oxidation at 0.45 V vs. SCE seen in the voltammetry following CPE without acid is present. There is a large peak just negative of this oxidation, which is due to the oxidation of the acetanilide anion. Figure 2*b* shows that the addition of MeOTs following electrolysis will remove the oxidation peak of the acetanilide anion along with the smaller oxidation waves also present. The large wave at 0.45 V remains unaffected by the addition of MeOTs. Washing of the cell contents with an organic solvent and water proved inadequate in identifying the products of reduction as essentially no products could be detected in the organic residue by GC or ^{1}H NMR spectroscopy. In place of typical product analysis, it was decided to further analyze the large oxidation wave present in the CVs of the products of electrolysis.

Given that little to no **3** was observed in the CVs of **2**, C—O bond cleavage is believed to be occurring as shown in Scheme 6. Based on the anions formed from this reduction, the reactions illustrated in Scheme 7 are the proposed parent–child reactions believed to be occurring. The first reaction involves removal of a proton from the terminal methyl groups of **2**. The base involved in this reaction could be the *tert*-butyl anion or more likely the basic species generated from proton abstraction by the *tert*-butyl anion. Deprotonation of **2** generates isobutylene and benzenesulfenate anion (**12**). Therefore, the same product is observed in the voltammetry whether formed from direct reduction or from deprotonation of **2**. This accounts for the observance of the same oxidation wave following the electrolysis of **2** with or without acid.



The second possible parent–child reaction involves nucleophilic attack of **2** by **12**. This process is identical to that proposed in the formation of **9** from the ET reduction of **1**, as previously shown. Again, phenyl thiobenzenesulfinate (**14**) is produced only now with the *tert*-butoxide anion as

Fig. 3. Depiction of the SOMOs of the radical anions of **1** (left) and **2** (right) as determined by DFT calculations.

Scheme 8.

the leaving group. The presence of *tert*-butoxide is believed to account for the small oxidation wave at –0.4 V vs. SCE in the CVs of **2**. Any **14** produced will likely be reduced to return to **12** and **3** (Scheme 5) and this reaction accounts for the oxidation wave at 0 V vs. SCE attributed to the oxidation of **3**.

However, the primary product from CPE of **2** in the presence and absence of acid is responsible for the oxidation peak at 0.45 V vs. SCE. We attribute this peak to the oxidation of benzenesulfinate (**16**), which is formed from the oxidation of **12** (Scheme 8). Evidence in favour of this assignment comes from the addition of sodium benzenesulfinate to the cell solution following CPE of **2**. The peak at 0.45 V increased in peak current and no new peaks were observed, while the E_p remained relatively constant indicating that the peak was likely due to the oxidation of benzenesulfinate. Independent CV experiments were performed that confirmed that the E_p of the sodium benzenesulfinate coincided with that of the oxidation wave observed in the electroysis of **2**. By varying the concentration of the sodium benzensulfinate the current response was calibrated and the concentration of **16** formed in the electrolysis was determined. As much as 75% of **2** was converted to **16** in the electrolysis performed without acid, and **16** was present in 96% of the starting concentration of **2** for CPE experiments performed with acid. How the conversion of **12** to **16** occurs is not completely understood. Previous studies of the electrolysis of phenyl benzenethiosulfinate also reported a similar oxidation wave that was attributed to **16** (26). In this study it was hypothesized that a disproportionation reaction between two molecules of **12** was occurring to give **3** and **16**. While it is possible that this process occurs, the relative peak currents of the oxidation peaks due to **3** and **16** indicate that it is not the primary process leading to the generation of **16**. It is difficult to assign a particular pathway for the oxidation of benzenesulfenate. Oxidation by perchlorate is unfavourable and oxidation by the solvent requires a significant amount of residual water to be present. It should be recognized that the E_p of an irreversible wave is not the most reliable means of identifying an unknown present in solution and that the wave could be due to the oxidation of benzenesulfenate and that the oxidation peaks of benzenesulfenate and benzenesulfinate simply coincide. Since benzenesulfenate is a highly unstable species, it was not possible to obtain an authentic sample to check this assertion.

Table 2. Bond lengths (Å) calculated for the equilibrium conformers of **1** and **2** and their respective radical anions.

Bond	**1** (Å)	$\mathbf{1}^{\cdot-}$ (Å)	**2** (Å)	$\mathbf{2}^{\cdot-}$ (Å)
C—S	1.764	1.734	1.765	1.787
S—O	1.702	1.776	1.702	1.668
O—C	1.423	1.384	1.441	1.439

DFT calculations of the SOMOs

It is interesting to compare the differences in the ET reactions of **1** and **2** that result as a difference in the O group. The most intriguing result of changing the ester moiety is the resulting change in the mode of fragmentation of the radical anions. The factors that result in the difference in cleavage reactions are not obvious. The same anionic fragment, either phenyl thiolate (**11**) or benzenesulfinate (**22**), would result from S—O and C—O cleavage of each compound, so it is not related to a thermodynamic advantage imparted by the stability of the anionic product. In both cases the carbon radical formed from C—O cleavage would be relatively stable; estimates of the reduction potentials of the benzyl radical and the *tert*-butyl radical have them near –1.34 and –1.54 V vs. SCE (18), respectively.

The difference seems to be related to differences in the electronic configuration of the radical anion intermediate for each of **1** and **2**. The SOMO for each of these compounds was determined by performing PM3 calculations to determine the equilibrium conformer of the radical anion and then density functional theory calculations at the BLYP-3//6-31** level were performed to arrive at the SOMO for each compound. The results of these computations are depicted in Fig. 3. The SOMO of the radical anion of **1** was largely associated with the S—O bond while the SOMO of the radical anion of **2** was largely delocalized over the phenyl ring and S atom. The respective bond lengths of the starting compound and its radical anion determined by PM3 calculations are given in Table 2. The ET to **1** causes significant lengthening of the S—O bond, while the S—O bond of **2** shortens upon ET. For **1** the majority of the additional charge is associated with the S—O bond and S—O cleavage is the result. For **2** the charge is delocalized onto the phenyl ring with only a limited effect on the S—O and C—O bonds, and

© 2005 NRC Canada

cleavage follows the most thermodynamically favourable pathway. Gregory and Jenks (17) have performed calculations for the homolytic cleavage of disulfides, peroxides, and sulfenate esters. While it was found that S—S and O—O cleavage were the most energetically viable pathways for disulfides and peroxides, the results indicated that fissure at the C—O bond is the most thermodynamically favourable mode of cleavage for a sulfenate ester. Our experimental results indicate that such an advantage is present in the radical anion of **2** as well.

Regioselective bond cleavages were observed by Houmam et al. (27) in their study of the ET reduction of benzyl thiocyanates, where differences in the mode of cleavage were observed for benzylthiocyanate and 4-nitrobenzylthiocyanate. The differences in this case were related to the radical anion intermediate, with benzylthiocyanate forming a σ* type radical anion akin to compound **1** and nitrobenzylthiocyanate forming a π* radical anion intermediate as was observed for **2**. In this case, the difference in the electron distribution of the radical anions of **1** and **2** must be related to the nature of the ester functionality as opposed to the aromatic moiety. The electron-donating capacity of the *tert*-butyl group increases the electron density on the O atom shifting the SOMO onto the aromatic ring. The benzyl group has the opposite effect, decreasing the electron density at the O atom and drawing the SOMO onto the S—O bond.

Conclusions

The ET reduction of benzyl benzenesulfenate ester (**1**) and *tert*-butyl benzenesulfenate ester (**2**) has been investigated. In each case, ET reduction generates a radical anion intermediate that subsequently undergoes bond cleavage. The bond that cleaves upon reduction, however, differs for the two compounds. ET reduction of **1** leads to S—O bond cleavage to give phenylthiolate and phenylmethoxide in an overall two-electron process. Complicating secondary reactions are effectively suppressed by addition of appropriate trapping reagents. The ET reduction of **2** leads to C—O cleavage of the radical anion. In the presence of acid the reduction proceeds to quantitatively generate benzenesulfenate. The difference in the mode of cleavage for these two radical anions is most likely related to the electron distribution in the radical anion. The additional charge on the radical anion of **1** is largely associated with the S—O bond, leading to significant S—O bond stretching upon ET and ultimately, bond fragmentation. The additional electron on the radical anion of **2** is largely associated with the phenyl ring and S atom so the dissociation of the radical anion follows the most thermodynamically favourable pathway, which in this case is C—O cleavage.

Experimental

General

The NMR spectra were obtained using a Varian Mercury 400 MHz spectrometer using the solvent peak ($CDCl_3$, 7.28 ppm) as the reference. ^1H and ^{13}C NMR spectra were recorded at 400.1 and 100.6 MHz, respectively. Mass spectra were performed using a MAT 8200 Finigan high-resolution mass spectrometer. GC was performed using an Agilent technologies GC 6890N gas chromatograph. HPLC was carried out using a Waters 600 controller and Waters Delta 600 pump, a Waters 2487 dual λ absorbance detector all interfaced to a PC using Millenium software, and a Hamilton PRP-1 column.

Calculations were performed on a PC using the SPARTAN program, which performed the PM3 and DFT calculations. The method for the calculations of the SOMOs of the sulfenate ester radical anions involved a geometry optimization of the structure using semiempirical PM3 calculations followed by a single-point energy DFT calculation using the B3LYP//6-31G** basis set.

Electrochemical apparatus and procedures

Cyclic voltammetry was performed using either a PAR 283 or PAR 263 model EG & G potentiostat interfaced to a personal computer using the M270 DOS-based software. A standard three electrode arrangement, with working, counter, and reference electrodes, was employed. The cell was maintained at a constant temperature of 25 °C with continuous purging using high purity Ar gas throughout the experiment. The working electrode was a 3 mm diameter glassy carbon rod (Tokai) sealed in a glass tube with epoxy resin. The working electrode was cleaned prior to use by polishing with 0.25 μm diamond paste, rinsing with 2-propanol, and placed in a sonicator in 2-propanol for 10 min. Electrochemical activation of the electrode was performed by cycling several times between 0 and –2.7 V at 0.2 V/s in the background solution. The counter electrode was a platinum plate, which was symmetrically placed under the working electrode. The reference electrode consisted of a silver wire immersed in a 0.1 mol/L solution of the electrolyte in the appropriate solvent contained in a narrow glass tube with a fine sintered glass tip. The reference potential was calibrated following each experiment using the ferrocene/ferrocenium couple whose standard potential under our conditions was 0.464 V vs. SCE. All reported potentials are referenced to SCE.

The CPE experiments were carried out using the same cell set up protocol and a similar cell arrangement. In controlled potential electrolysis, there is the inclusion of a second working electrode, which is a 2.5 cm (dia.) × 0.8 cm (width) glassy carbon disk, custom fit into a Teflon jacket that attaches to a Radiometer ED-101 rotating disk assembly. A radiometer CTV101 speed control unit was used to regulate the velocity of the rotating disk electrode (RDE), which was maintained at 4500 rpm for these experiments.

Materials

Dry solvents were obtained from an Innovative Technology SPS-400-5 solvent purification system and were stored a maximum of 5 days under an N_2 atmosphere. Tetrabutylammonium perchlorate (Aldrich, Fluka) was purified by multiple recrystallizations from 95% EtOH and the crystals subsequently vacuum-dried at 60 °C overnight. The recrystallized and dried electrolyte was then stored in a dehumidifying cabinet. Benzyl alcohol, benzaldehyde, diphenyl disulfide, thioanisole, benzenethiol, sulfuryl chloride, and *m*-chloroperbenzoic acid were purchased from Aldrich and purified by standard procedures when necessary.

© 2005 NRC Canada

Benzyl benzenesulfenate ester (1)

Compound **1** was prepared by the reaction of lithium phenylmethoxide and benzenesulfenyl chloride as previously reported (28). The crude product was a deep yellow oil, which was purified by vacuum distillation at 100 °C and >0.5 mmHg (1 mmHg = 133.322 4 Pa) using a Kugelrohr apparatus to give a pale yellow oil. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.43 (m, 2H), 7.26–7.32 (m, 4H), 7.17–7.22 (m, 2H), 7.09–7.15 (m, 2H), 4.70 (s, 2H). ^{13}C NMR ($CDCl_3$) δ: 140.13, 136.92, 128.96, 128.39, 127.32, 127.02, 126.69, 124.32, 79.50.

tert-*Butyl benzenesulfenate ester (2)*

Compound **2** was prepared by reaction of *tert*-butyl alcohol and benzenesulfenyl chloride in the presence of pyridine as previously reported (29). Purification was performed by column chromatography using hexanes – ethyl acetate (4:1) as the eluent to give a clear, colourless oil. ^{1}H NMR ($CDCl_3$) δ: 7.66–7.70 (m, 2H), 7.49–7.53 (m, 3H), 1.56 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 146.46, 131.54, 128.90, 124.86, 82.87, 29.87.

Benzyl phenyl sulfide (8)

Compound **8** was prepared by the addition of a solution of benzylbromide (5.9 mmol) in ~25 mL CH_2Cl_2 to a flask containing benzenethiol (5.8 mmol) and pyridine (6.2 mmol) dissolved in 25 mL of CH_2Cl_2. The reaction mixture was washed with aq. K_2CO_3 solution, which was then washed with CH_2Cl_2. The organic extracts were combined and washed three times with H_2O and dried over anhydr. Na_2SO_4. The crude product was purified by column chromatography with hexanes – ethyl acetate (10:1) as the eluent. ^{1}H NMR ($CDCl_3$) δ: 7.21–7.37 (m, 10H), 4.17 (s, 2H). ^{13}C NMR ($CDCl_3$) δ: 137.33, 136.28, 129.64, 128.73, 128.39, 127.08, 127.02, 126.21, 38.88.

Phenyl benzenethiosulfinate (14)

Compound **14** was prepared by the oxidation of diphenyl disulfide with *m*-chloroperbenzoic acid according to accepted literature methods (30–32). Column chromatography was employed for the purification using hexanes – ethyl acetate (10:1) as the eluent. ^{1}H NMR ($CDCl_3$) δ: 7.64–7.68 (m, 2H), 7.47–7.56 (m, 5H), 7.41–7.46 (m, 1H), 7.34–7.40 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 143.96, 135.33, 131.50, 130.26, 129.24, 128.89, 127.52, 124.29.

Identification of products from the CPE experiments of 1

Product mixtures and authentic samples were subjected to analysis by GC using a 15 m HP-5 column. The method used to obtain the gas chromatograms is as follows: the initial temperature is 80 °C and upon initiation the temperature is increased to 280 °C at a rate of 15°/min and held at 280 °C for 5 min. Following partial separation of the products into two major fractions by column chromatography, the fractions of the product mixture were analyzed by GC–MS. The method for the GC of these analyses is as follows: the temperature is initially set at 60 °C and held for 3 min. The temperature is then ramped to 300 °C by 15°/min.

Methyl phenyl sulfide (5)

The presence of **5** in the product mixtures could be inferred from the observation of a peak in the GC chromatogram of the product mixture with the same retention time as an authentic sample of **5** purchased from Aldrich. GC–MS of this peak had the following major peaks: 124 (100%) M^+, 109 (47%) $M^+ - CH_3$, 91 (57%) $M^+ - SH$, 78 (65%) $M^+ - SCH_2$.

Benzyl alcohol (6)

The presence of **6** in the product mixtures was determined from the observation of a peak in the GC chromatograms of the products with the same retention time as an authentic sample of **6** purchased from Aldrich. The corresponding peak in the GC–MS had the following mass spectrum characteristics: 108 (100%) M^+, 91 (25%) $M^+ - OH$, 79 (75%) $M^+ - CHO$.

Diphenyl disulfide (7)

The presence of **7** in the product mixtures was determined from the observation of a peak in the GC chromatograms of the products with the same retention time as an authentic sample of **7** purchased from Aldrich. The corresponding peak in the GC–MS had the following mass spectrum characteristics: 218 (100%) M^+, 185 (28%) $M^+ - HS$, 154 (30%) $M^+ - H_2S_2$, 140 (10%) $M^+ - C_6H_6$, 109 (99%) $M^+ - SC_6H_6$, 65 (42%), 109 – CS.

Benzyl phenyl sulfide (8)

The presence of **8** in the product mixtures was determined from the observation of a peak in the GC chromatograms of the products with the same retention time as an authentic sample of **8** prepared as previously described. The corresponding peak in the GC–MS had the following mass spectrum characteristics: 200 (83%) M^+, 109 (19%) $M^+ - C_7H_7$, 91 (100%) $M^+ - C_6H_5S$, 65 (45%), 109 – CS.

Benzyl benzenesulfinate (9)

The presence of **9** in the product mixtures was determined from the analysis of the GC–MS of the product mixture. The peak assigned to this product had the following mass spectrum characteristics: 232 (1%) M^+, 167 (6%) $M^+ - C_5H_5$, 153 (2%) 167 – CH_2, 125 (6%) $M^+ - C_7H_7O$, 91 (100%) $M^+ - C_6H_5O_2S$, 77 (23%) 91 – CH_2, 65 (9%) $M^+ - C_8H_8O_2S$.

n-*Butyl phenyl sulfide (10)*

The presence of **10** in the product mixtures was determined from the analysis of the GC–MS of the product mixture. The peak assigned to this product had the following mass spectrum characteristics: 166 (77%) M^+, 152 (4%) $M^+ - CH_2$, 123 (100%) $M^+ - C_3H_7$, 109 (49%) $M^+ - C_4H_9$, 91 (5%) $M^+ - C_3H_7S$, 77 (11%) $M^+ - SC_4H_9$, 65 (12%), 109 – CS.

Benzyl* p-*toluenesulfonate (11)

The presence of **11** in the product mixtures was determined from the analysis of the GC–MS of the product mixture. The peak assigned to this product had the following mass spectrum characteristics: 262 (12%) M^+, 244 (3%) $M^+ - H_2O$, 186 (3%) $M^+ - C_6H_5$, 107 (100%) $M^+ - C_7H_7O_2S$, 91 (12%) $M^+ - C_7H_7O_3S$, 79 (52%), 107 – CO.

© 2005 NRC Canada

Benzaldehyde (13)

The presence of **13** in the product mixtures from CPE experiments performed in MeCN was determined from the observation of a peak in the GC chromatograms of the products with the same retention time as an authentic sample of **13** purchased from Aldrich. The corresponding peak in the GC–MS had the following mass spectrum characteristics: 108 (100%) M^+, 91 (26%) $M^+ - OH$, 79 (73%) $M^+ - CHO$.

The mechanisms of hydrolysis of alkyl *N*-alkylthioncarbamate esters at 100 °C[1]

Eduardo Humeres, Maria de Nazaré M. Sanchez, Conceição M.L. Lobato, Nito A. Debacher, and Eduardo P. de Souza

Abstract: The hydrolysis of ethyl *N*-ethylthioncarbamate (ETE) at 100 °C was studied in the range of 7 mol/L HCl to 4 mol/L NaOH. The pH–rate profile showed that the hydrolysis occurred through specific acid catalysis at pH < 2, spontaneous hydrolysis at pH 2–6.5, and specific basic catalysis at pH > 6.5. The Hammett acidity plot and the excess acidity plot against X were linear. The Bunnett–Olsen plot gave a negative slope indicating that the conjugate acid was less hydrated than the neutral substrate. It was concluded that the acid hydrolysis occurred by an A1 mechanism. The neutral species hydrolyzed with general base catalysis shown by the Brønsted plot with $\beta = 0.48 \pm 0.04$. Water acted as a general base catalyst with (pseudo-)first-order rate constant, $k_N = 3.06 \times 10^{-7}$ s^{-1}. At pH > 6.5 the rate constants increased, reaching a plateau at high basicity. The basic hydrolysis rate constant of ethyl *N*,*N*-diethylthioncarbamate, which must react by a $B_{Ac}2$ mechanism, increased linearly at 1–3 mol/L NaOH with a second-order rate constant, $k_2 = 2.3 \times 10^{-4}$ (mol/L)$^{-1}$ s^{-1}, which was 10 times slower than that expected for ETE. Experiments of ETE in 0.6 mol/L NaOH with an excess of ethylamine led to the formation of diethyl thiourea, presenting strong evidence that the basic hydrolysis occurred by the E1cb mechanism. In the rate-determining step, the E1cb mechanism involved the elimination of ethoxide ion from the thioncarbamate anion, producing an isothiocyanate intermediate that decomposed rapidly to form ethylamine, ethanol, and COS.

Key words: alkylthioncarbamate esters, ethyl *N*-ethylthioncarbamate, ethyl *N*,*N*-diethylthioncarbamate, hydrolysis, mechanism.

Résumé : Opérant à 100 °C, dans des milieux allant du HCl à 7 mol/L au NaOH à 4 mol/L, on a étudié la réaction d'hydrolyse du *N*-éthylthionecarbamate d'éthyle (ETE). Le profile de la vitesse en fonction du pH montre que l'hydrolyse se produit par le biais d'une catalyse acide spécifique à des pH inférieurs à 2, par une hydrolyse spontanée à des pH allant de 2 à 6,5 et par une hydrolyse par catalyse basique à des pH supérieurs à 6,5. La courbe d'acidité de Hammett et la courbe d'excès d'acidité en fonction de X sont linéaires. La courbe de Bunnett–Olsen donne une pente négative qui indique que l'acide conjugué est moins hydraté que le substrat neutre. On en conclut que l'hydrolyse acide se produit par un mécanisme A1. L'espère neutre s'hydrolyse par une catalyse générale basique mise en évidence par la courbe de Brønsted avec une valeur de $\beta = 0{,}48 \pm 0{,}04$. L'eau agit comme catalyseur basique général avec une constante de vitesse de (pseudo-)premier ordre, $k_N = 3{,}06 \times 10^{-7}$ s^{-1}. À des pH supérieurs à 6,5, les constantes de vitesse augmentent pour atteindre un plateau aux pH élevés. Pour l'hydrolyse basique du *N*,*N*-diéthylthionecarbamate d'éthyle, qui doit obligatoirement réagir par un mécanisme $B_{Ac}2$, la constante de vitesse augmente d'une façon linéaire dans le NaOH à des concentrations allant de 1 à 3 mol/L et la constante de vitesse du deuxième ordre, $k_2 = 2{,}3 \times 10^{-4}$ (mol/L)$^{-1}$ s^{-1}, est 10 fois plus lente que celle attendue pour l'ETE. Des expériences avec l'ETE dans du NaOH à 0,6 mol/L, en présence d'un excès d'éthylamine, conduit à la formation de diéthylthiourée, ce qui suggère fortement que l'hydrolyse basique se produit par un mécanisme E1cb. Dans l'étape cinétiquement déterminante, le mécanisme E1cb implique l'élimination de l'ion éthylate à partir de l'anion thionecarbamate avec formation d'un intermédiaire isothiocyanate qui se décompose rapidement pour former de l'éthylamine, de l'éthanol et du COS.

Mots clés : alkylthionecarbamates d'esters, *N*-éthylthionecarbamate d'éthyle, *N*,*N*-diéthylthionecarbamate d'éthyle, hydrolyse, mécanisme.

Introduction

The reaction of carbon dioxide and carbon disulfide with alkoxides, halides, and amines produces derivatives that are important pesticides (eq. [1]) (1). Carbamic acid acid esters (**1**, X = O) are widely used as insecticides because of their ability to inhibit the enzyme acetylcholinesterase. Thioncarbamic esters (**1**, X = S) are used as fungicides and bactericides (2), nematocides (3), collectors in flotation (4), and in a variety of industrial applications (5). The formation of the highly stable thioncarbamate group has been used to immobilize enzymes in a cellulose matrix (eq. [1], R = cellulose, R″ = enzyme) (6).

The biological activity depends on the C=X group (X = O, S) because of the different properties of the oxo and sulfo groups. The carbonyl can stabilize α-carbocations better than sulfur, but this capacity is inverted for carbanions. The thiocarbonyl is a powerful electron-withdrawing group because sulfur can easily accept electrons.

There is a duality of mechanisms for the basic hydrolysis of carbamates and thioncarbamate esters depending on the availability of a proton on the nitrogen atom of the ester. Mechanism $B_{Ac}2$ applies if there is no proton on the nitrogen (*N*,*N*-disubstituted nitrogen), but if the nitrogen contains a proton, mechanism E1cb might apply, although not necessarily. All aryl esters follow this pattern. Alkyl carbamates apparently follow the $B_{Ac}2$ mechanism. However, no information exists about the mechanisms involved in the hydrolysis of alkyl thioncarbamate esters.

In this work, we studied the hydrolysis (at 100 °C) of ethyl *N*-ethylthioncarbamate in the range of 7 mol/L of HCl to 4 mol/L of NaOH, to obtain an insight into the mechanisms involved.

Experimental

Materials

Reagents were all of analytical grade and were used without further purification. Distilled water was deionized and deoxygenated by boiling and cooling under nitrogen. Ethylamine was distilled (bp 18 °C), condensed in a trap cooled with liquid nitrogen, and bubbled into water to obtain a 2 mol/L solution. UV spectra and kinetics were obtained using a Cary 219 spectrophotometer. All compounds were identified by ^{1}H NMR and IR spectra.

Ethyl *O*-ethylxanthate (EXE)

Potassium *O*-ethylxanthate (EXK) was obtained using the classical procedure (7), adding 60 mL of carbon disulfide to a cooled solution of 56 g (1 mol) potassium hydroxide in 200 mL of ethanol. The product was recrystallyzed twice in ethanol; λ_{max} (ethanol) 301 nm. Ethyl *O*-ethylxanthate was obtained after refluxing a solution of EXK (32 g, 0.2 mol) and ethyl bromide (21.8 g, 0.2 mol) for 4 h in 50 mL of ethanol. The product was washed with water, dried over anhydrous sodium sulfate, and distilled under vacuum: bp 35 °C at 1 mmHg (lit. value (8) bp 78 °C at 18 mmHg) (1 mmHg = 133.322 4 Pa); λ_{max} (water) 283 nm.

Ethyl *N*-ethylthioncarbamate (ETE)

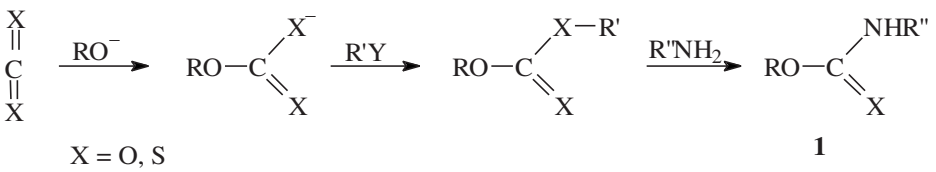
Ethyl *O*-ethylxanthate (13.3 g, 0.1 mol) was dissolved in 10 mL of ethanol, and an aqueous solution of ethylamine (0.11 mol) at pH 11 was added with cooling, allowing the solution to react for 24 h at 10 °C under constant stirring. The ethanol was eliminated under vacuum in a rotatory evaporator and the product was washed with water, dried over anhydrous sodium sulfate, and distilled under vacuum: bp 74 °C at 1 mmHg (lit. value (9) bp 78 °C at 3 mmHg); λ_{max} (water) 242 nm.

Ethyl *N*,*N*-diethylthioncarbamate (DETE)

A solution of 10 g (75 mmol) of EXE and 6 g (82 mmol) of diethylamine in 200 mL of ethanol was allowed to react at room temperature. The reaction was followed via UV spectrophotometry by the disappearance of the band at 283 nm because of EXE and the appearance of the band at 245 nm because of DETE. The product was distilled under vacuum: bp 85 °C at 1 mmHg; λ_{max} (water) 245 nm.

1,3-Diethyl thiourea (DETU) (10)

Ethyl isothiocyanate (4.5 g of a 90% aqueous solution) was slowly added to 8.7 g of a 70% aqueous solution of ethylamine. The reaction was exothermic and the mixture was cooled in an ice bath. The water was evaporated at 60 °C, and the crystals were recrystallized twice in dried ethanol; mp 77.1 °C (lit. value (11, 12) mp 72–78 °C); λ_{max} (methanol) 210 and 234 nm.



Reverse base dissociation constant of ethyl *N*-ethylthioncarbamate ($-pK_b$)

The dissociation constant was obtained at 25 °C from a series of measurements of the absorbance at 242 nm of a ca. 10^{-5} mol/L solution of the substrate, in the range of H_- = 10–15. The initial solution was 0.01 mol/L NaOH and known volumes of a 8 mol/L NaOH solution were added, correcting the absorbance for the dilution and the absorbance of the base. The UV spectra in the range of pH 7 to 2.7 mol/L NaOH, μ = 5 (NaCl) showed a single isosbestic point at 228 nm. Inversion of the basicity after the titration showed that the dissociation at 25 °C was reversible, with no noticeable reaction. The value of $-pK_b = 13.6 = pK_2$ (see the following) was calculated from the inflection point of the plot of the corrected absorbance vs. H_- for NaOH (Fig. 1) (13).

Correction of pH and pK_a with temperature

The pH of the solutions was measured at 25 °C and corrected to 100 °C as described elsewhere (14). The same

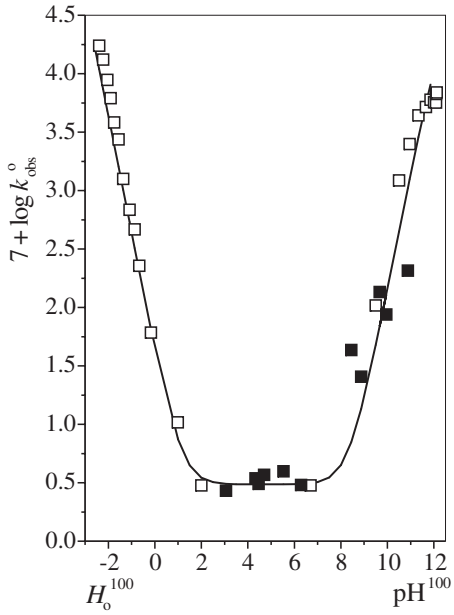
Fig. 1. Titration curve of ETE at 25 °C.

method was followed to calculate the pK_as of the buffers at 100 °C.

Kinetics

Kinetics were studied at 100 °C in distilled deoxygenated water in the range of H_o = –2.4 to 4 mol/L NaOH. The kinetic solution (50 mL) had a final concentration of ca. 10^{-4} mol/L; samples of 3 mL were placed in sealed glass ampoules and immersed in a thermostat at 100 °C. The samples were collected at different times and quenched in a Dewar bath with salted ice. The kinetics were followed spectrophotometrically at 25 °C by the disappearance of ETE at 242 nm or at 230 nm for the basic hydrolysis. The disappearance of DETE was followed at 245 nm. All runs were followed for at least three half-lives and the ln ΔA vs. time plots produced straight lines that were considered when $r \geq 0.99$. The pH of unbuffered runs was controlled at the end of the experiment and showed no change.



For the kinetics under strong basic conditions, the rate constants were also calculated by the Guggenheim method (15) because of a precipitate of sulfur that interfered with the absorbance readings. The rate constants for the slowest kinetics were obtained from initial rates.

Product analysis

The products of the hydrolysis of ETE were characterized in a preparative run at 2.5 mol/L NaOH and 100 °C, allowing a 50 min reaction. A sample was extracted with chloroform, and ethylamine was identified as a product by GLC. Another sample was extracted with cyclohexane, and ethanol was also identified as a product by GLC.

To trap the isothiocyanate intermediate, a preparative run of the hydrolysis of ETE in the presence of ethylamine was carried out. An aqueous solution of 4.5 mmol/L ETE, 0.6 mol/L NaOH, and 3 mol/L ethylamine was refluxed for 30 min, and after cooling, it was neutralized with HCl. The products were extracted with chloroform, concentrated in a rotatory evaporator, dried over anhydrous sodium sulphate, and then analyzed by TLC (silica gel, MeOH). A single spot was found with R_f 0.75, the same as an authentic sample of 1,3-diethyl thiourea. This result was confirmed by UV spectra.

Fig. 2. pH–rate profile of the hydrolysis of ETE at 100 °C. Unbuffered (□) and values extrapolated to zero buffer concentration (■).

Activation parameters

Activation parameters were calculated from the rate constants in the temperature range of 90–110 °C by least-squares fitting to the Eyring equation.

Results and discussion

pH–rate profile of ETE

The pH–rate profile was obtained at 100 °C in the range of H_o = –2.4 to pH 12 (Fig. 2). The values of k^o_{obs} were obtained in the absence of buffer or extrapolated to zero buffer concentration, and the pH was corrected for the temperature as has been previously described (14).

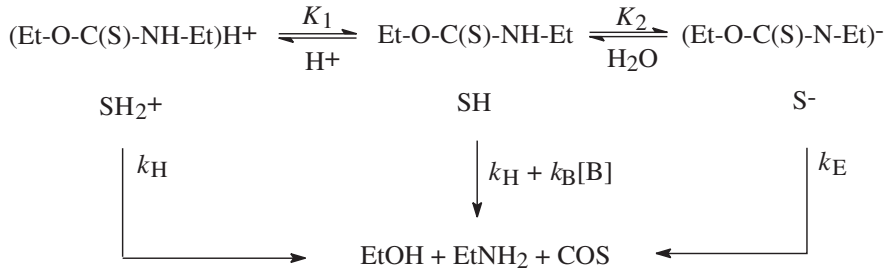
In the acid range of pH < 2, HCl was used and the H_o values obtained at 25 °C from the excess acidity X, and the HCl acid molarity (C_{H^+}) was corrected at 100 °C for the change of the excess acidity X with temperature (eqs. [2] and [3]) (16).

[2] $$-H_o = X + \log C_{H^+}$$

[3] $$X_T = X_{25^\circ}\left(\frac{298.15}{T}\right)$$

At pH > 10, H_- was calculated from

[4] $$H_- = pK_w^{100} + \log[OH^-]$$



where pK_w^{100} = 12.26 (14*b*, 17).

In the 0.05–1.0 mol/L NaOH range at 25 °C, these values are less than 0.1% different from those obtained from the acidity function using thioacetamide as an indicator (13).

The profile was divided into three regions. At pH < 2, $\log k^o_{obs}$ increases with acid concentration by a specific acid catalysis mechanism. In the range of pH 2–6.5, the rate constants were independent of the pH. A specific basic hydroly-

© 2005 NRC Canada

Scheme 1. Kinetic scheme of the hydrolysis of ETE.

sis occurred at pH > 6.5, and the rate constants reached a plateau in the region of pH > 12. The pH–rate profile can be described according to Scheme 1 by eq. [5].

$$[5] \qquad k^{o}_{obs} = k_H \frac{a_{H^+}}{K_1 K'} + \frac{k_N}{K'} + \frac{k_E K_2 [OH^-]}{K_w K'}$$

where

$$K' = \frac{a_{H^+}}{K_1} + 1 + \frac{K_2}{a_{H^+}} \text{ and } a_{H^+} = h_o \text{ when pH} < 2.$$

In Scheme 1, K_1 and K_2 are the acid and reverse base dissociation constants of species SH_2^+ and SH, respectively, k_H is the specific acid hydrolysis rate constant, and k_N and k_E are the rate constants of spontaneous and basic hydrolysis, respectively. Equation [5] assumes that the basic hydrolysis occurs by the E1cb mechanism as will be discussed in the following.

Acid hydrolysis

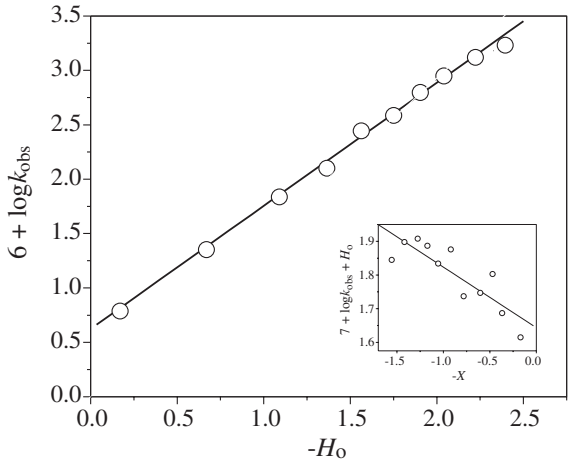
At HCl concentrations higher than 1 mol/L, the terms due to spontaneous and basic hydrolysis in eq. [5] are very small compared to those of acid hydrolysis because

$$k_H \frac{a_{H^+}}{K_1 K'} >> \frac{k_N}{K'} + \frac{k_E K_2 [OH^-]}{K_w K'}$$

and eq. [5] becomes

$$[6] \qquad k^{o}_{obs} = \frac{k_H h_o}{h_o + K_1}$$

and, when the ester is predominantly protonated, $k^{o}_{obs} = k_H$ at that acidity range.



Several plots showed that the acid hydrolysis occurred by the A1 mechanism. The Hammett plot of $\log k_{obs}$ vs. $-H_o$ (Fig. 3) was linear with a slope of 1.14 (r = 0.999), close to the unity value expected by the Zucker–Hammett hypothesis for this mechanism (18).

The pH–rate profile suggests that in the of 1–7 mol/L HCl concentration range, the substrate is unprotonated, and the relevant rate equation is eq. [7] (19)

$$[7] \qquad \log k^{o}_{obs} - \log C_{H^+} = \log \frac{k_o}{k_1} + m^{\ddagger} m^* X$$

where k_o is the medium-independent specific acid catalysis rate constant. The excess acidity assumption is that the term containing the activity coefficient of the transition state $f_{\ddagger}$ is linearly related to the activity coefficient ratio containing the conjugate acid SH_2^+ (20), and that this is linear in X (eq. [8]).

Fig. 3. Hammett plot for the acid hydrolysis of ETE at 100 °C. Insert: Bunnett–Olsen plot.

$$[8] \qquad \log \frac{f_{SH} f_{H^+}}{f_{\ddagger}} = m^{\ddagger} \log \frac{f_{SH} f_{H^+}}{f_{SH_2^+}} = m^{\ddagger} m^* X$$

The excess acidity slope value (m^*) is associated with solvation differences between SH and SH_2^+ (21). For A1 reactions, $m^{\ddagger} > 1$ and the excess acidity plots are linear for A1 mechanisms, while these plots are curved for A2 mechanisms.

The linearity of the excess acidity plot against X of the hydrolysis of ETE in HCl is shown in Fig. 4, where $m^{\ddagger} m^*$ = 1.18, $\log (k_o/K_1)$ = –5.36, and r = 0.996.

We do not know the value of m^* for ETE, but the Bunnett–Olsen plot gave $\phi_{\ddagger}$ = –0.18 (r = 0.854) from eq. [9] for unprotonated substrates (Fig. 3, insert) (22).

$$[9] \qquad \log k^{o}_{obs} + H_o = \left(\log \frac{k_o}{K_1} \right) + \phi_{\ddagger} (H_o + \log C_{H^+})$$

Although the correlation coefficient is lower, the negative slope indicates that SH_2^+, whose structure should be closer to the transition state, is less hydrated than SH as expected for the A1 mechanism. We note that for HCl, $H_o + \log C_{H^+} = -X$, and eq. [9] is equivalent to eq. [7], where $m^{\ddagger} m^* = 1 - \phi_{\ddagger}$, and the value of $\log (k_o/K_1) = -5.36$ is the same as that found in the excess acidity plot.

In Table 1, it can be observed that the activation parameters for the acid hydrolysis at 2.5 mol/L HCl, $\Delta G^{\ddagger} = \Delta H^{\ddagger}$, because $\Delta S^{\ddagger}$ (–1.6 ± 2.2 cal mol^{-1} K^{-1}, 1 cal = 4.184 J) is

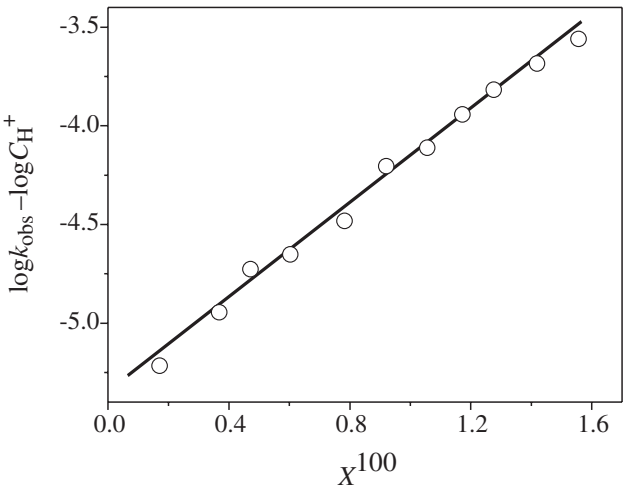
Basic (DETE)	NaOH (2.0 mol/L)	27.7±1.8	21.3±.0.9	–17.2±2.5

Note: Standard state: 1 mol/L, 100 °C.

Fig. 4. Excess acidity plot against X of the hydrolysis of ETE in HCl at 100 °C.



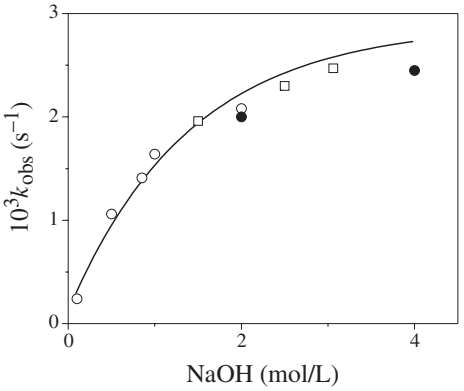


Fig. 5. Basic hydrolysis of ETE at 100 °C. Average from values calculated from the Guggenheim method and assuming absorbance = 0 at t_∞ (○); calculated from the Guggenheim method (□); average calculated from the Guggenheim method at 4 μ (NaCl) (●).

close to zero considering the standard deviation. This value is characteristic of an A1 mechanism (23).

The conjugate acid SH_2^+ should be preferentially N-protonated to produce ethylamine by breaking the N—C bond, and an ethyl thionformyl cation (S=C$^+$-OEt), which hydrolyzes rapidly to produce COS and ethanol.

Basic hydrolysis

At pH > 6.5, the pH–rate profile of ETE presented an increase of the rate constants that reached a plateau at high basicity (Fig. 5).

At high basicity, $K' = 1 + \dfrac{K_2}{a_{H^+}}$

because $1 + \dfrac{K_2}{a_{H^+}} >> \dfrac{a_{H^+}}{K_1}$.

Also $k^{o}_{obs} >> k_N$ and $\dfrac{k_E K_2[OH^-]}{K_w K'} >> k_H \dfrac{a_{H^+}}{K_1 K'} + \dfrac{k_N}{K'}$.

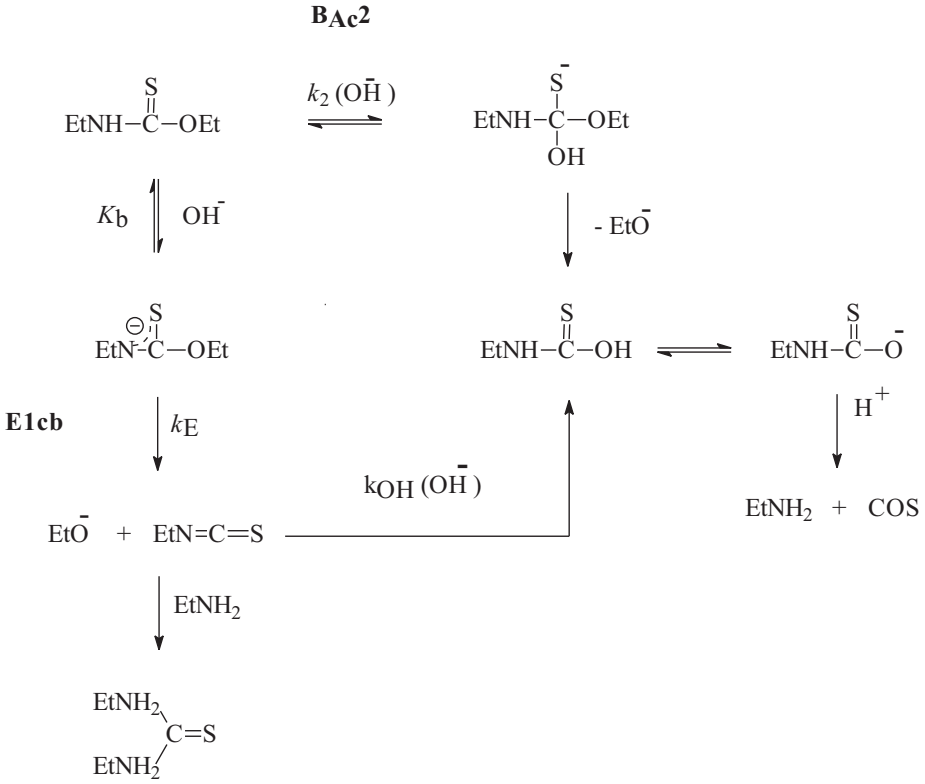
Therefore,

$$[10] \qquad k^{o}_{obs} = \frac{k_E K_2[OH^-]}{K_w + K_2[OH^-]} = \frac{k_E K_2}{a_{H^+} + K_2}$$

The reciprocal plot of $1/k^{o}_{obs}$ vs. $1/[OH^-]$ was linear (r = 0.999) and allowed the calculation of $k_E = 3.79 \times 10^{-3}$ s^{-1} and $pK_2 = -pK_b = 12.43$. At 25 °C the experimental value of pK_2 was 13.6. The difference of 1.2 pK units with temperature is about the same as that found for the *N*-aryl thioncarbamate series (24).

Equation [5] assumed that the specific basic catalysis occurs through the E1cb mechanism, but it is also possible that it occurs by a $B_{Ac}2$ mechanism as shown in Scheme 2. Both have been observed for carbamate esters (25, 26).

The E1cb mechanism eliminates ethoxide ion from the thioncarbamate anion in the rate-determining step, producing an isothiocyanate intermediate that decomposes rapidly to form ethylamine and COS as products. The $B_{Ac}2$ mechanism produces a tetrahedral intermediate in the slow step, which forms the products through several consecutive fast reactions. Neither of these mechanisms can be kinetically distinguished, as shown by eqs. [11] and [12].



$$[11] \qquad k_{obs} = \frac{k_E K_2}{a_{H^+} + K_2} \text{ (E1cb)}$$

$$[12] \qquad k_{obs} = \frac{k_2 K_w}{a_{H^+} + K_2} \text{ ($B_{Ac}2$)}$$

For ETE, the reciprocal plot from the $B_{Ac}2$ kinetic equation gave $k_2 = 2.58 \times 10^{-3}$ (mol/L)$^{-1}$ s^{-1} and the same pK_2 = 12.43 found from the E1cb equation. To hydrolyze by E1cb mechanism, the substrate must form the conjugate base by ionization of the N—H bond. Therefore, the basic hydrolysis of DETE must occur by the $B_{Ac}2$ mechanism. The hydrolysis rate constant of DETE increased linearly at 1–3 mol/L of NaOH with a second-order rate constant, $k_2 = 2.3 \times 10^{-4}$ (mol/L)$^{-1}$ s^{-1}, i.e., 10 times slower than the value expected for ETE. It has been noted in earlier works that *N*-alkyl carbamate esters hydrolyze more rapidly than *N*,*N*-dialkyl esters (27, 28).

© 2005 NRC Canada

Scheme 2. Mechanisms involved in the basic hydrolysis of ETE at 100 °C.

The alternative of either mechanism depends on the difference of free energy of activation to overpass the kinetic barrier. Comparison of $\Delta G^{\ddagger}$ of DETE and ETE results in a difference of ca. 1 kcal mol^{-1} more favorable to the E1cb path (Table 1). For ETE, the total barrier is divided into two terms: the basic N-H ionization to form the thioncarbamate anion (pK_2 = 13.6, Scheme 1, $\Delta G^{\ddagger}$ = 21.2 kcal mol^{-1}), and the expulsion of the ethoxide anion producing ethyl isothiocyanate ($\Delta G^{\ddagger}$ = 26.2 kcal mol^{-1}). In comparison to the carbamate analogues, the path through the E1cb mechanism of ETE is greatly favored because of the decrease in pK_2 owing to the strong electron-withdrawing effect of the thiocarbonyl group. It corresponds to a pK_a = 24.7 at 100 °C, or 16 pK units higher than ethylamine. This is a reasonable value because, for alkyldithiocarbamates, a decrease in the basicity of the N by 14 pK units with respect to the parent amine was calculated (29).

For the carbamate ester series, it was observed that reactions occurring through the E1cb mechanism were much faster than those ocurring through the $B_{Ac}2$ mechanism (25–27, 30) because of a sharp decrease in $\Delta H^{\ddagger}$ (25–27). The activation parameters of ETE and DETE are also consistent with this observation as shown in Table 1.

One important feature of the E1cb mechanism is the formation of the ethyl isothiocyanate intermediate. Experiments with ETE in 0.6 mol/L of NaOH in the presence of an excess of ethylamine showed the formation of diethyl thiourea (Scheme 2). Diethyl thiourea could only be formed from the isothiocyanate because ethylaminolysis of ethyl *O*-ethylxanthate produced only ethyl *N*-ethylthioncarbamate, and the reaction did not go further (31). Therefore, this result provides strong evidence that the basic hydrolysis occurs by the E1cb mechanism, the same as was found for aryl *N*-arylcarbamates (26), aryl *N*-arylthioncarbamates (32), and ethyl *N*-arylthioncarbamates (24).

The curve of the pH–rate profile in Fig. 2 was drawn using eq. [5], written as eq. [13]

$$[13] \quad k^{o}_{obs} = \frac{k_H}{K_1} a_{H^+} + k_N + \frac{k_E K_2}{a_{H^+} + K_2}$$

where $\log \frac{k_H}{K_1} = -5.36$.

General catalysis

The E1cb mechanism in Scheme 2 involves a fast preequilibrium deprotonation by hydroxide ion followed by a slow elimination of the ethoxide ion. However, for weak bases the deprotonation step is the rate-determining step, followed by a fast elimination reaction. This mechanism leads to general base catalysis.

General base catalysis was observed for ETE in the pH 3–11 range (Table 2) for conjugate bases of oxy acids and ammonium ion. The rate constants increased linearly with increasing concentration of the general base. No catalysis was detected for acetate within the experimental error. For succinate, tetraborate, and carbonate, monoanion and dianion species are present at the experimental pH, and both can act as catalysts. The molar fractions of the monoanions and dianions were considered to calculate the second-order general base catalysis rate constant (k_B).

The Brønsted plot of logk_B vs. pK_a, statistically corrected (Fig. 6), gave a straight line for the conjugate bases of oxy acids (without hydroxide ion) with β = 0.48 ± 0.04 (r = 0.989). Ethylamine was about two orders of magnitude more

[k] From eq. [12] assuming a $B_{Ac}2$ mechanism.

Fig. 6. Brønsted plot of the general catalysis of the hydrolysis of methyl *N*-methylthioncarbamate at 100 °C. Without considering ethylamine and hydroxide ion, $\beta = 0.48 \pm 0.04$ ($r = 0.989$).

effective as a catalyst than the corresponding oxy acid, which is to be expected, since it is a better nucleophile toward the thiocarbonyl group. The second-order rate constant k_B for OH^- was calculated assuming the $B_{Ac}2$ mechanism (eq. [12]), and its low value is attributed to the high hydration of the ion (13). Nevertheless, the fast and reversible deprotonation of ETE at 25 °C (see Experimental) showed that the specific basic catalysis must form the ester anion in a fast step at 100 °C, which slowly decomposed to produce ethyl isothiocyanate by the E1cb mechanism.

For the series of carbamate and thioncarbamate esters, only a small general base catalysis was observed for *p*-nitrophenyl *N*-methylcarbamate (30), and no general catalysis was observed for alkyl *N*-arylthioncarbamates (24) or aryl *N*-arylthioncarbamates (32). The slow proton transfer step from ETE is a consequence of the high pK_a (24.7) of the N-H dissociation. For *N*-arylthioncarbamates, the dissociation is ca. 3 pK units more favorable.

Water catalysis

The Brønsted plot showed that water acts as a general base in the pH-independent region of the pH–rate profile, and therefore in that region, k_{obs} can be expressed by eq. [14], where k_N is the water-catalyzed (pseudo-)first-order rate constant, and k_B is the catalytic coefficient of the general bases.

$$[14] \quad k_{obs} = k_N + k_B[B]$$

The value of $k_N = 3.06 \times 10^{-7}$ s^{-1} was obtained from the average of k_{obs} extrapolated to zero buffer concentration in the pH 2–6.5 range. The total molecularity of the reaction is at least two, but the exact value cannot be determined from the kinetic data, since the water concentration remained constant. In the absence of other general bases, the water-catalyzed, pH-independent hydrolysis is the only reaction.

The activation parameters for the water catalysis are shown in Table 1. It is known that water can catalyze a reaction as a nucleophile, a general acid, or a general base. The hydrolysis of activated amides and carboxylic esters are water-catalyzed between pH 2.0 and 5.5 via a dipolar activated complex in which two water molecules, one acting as a nucleophile and one acting as a general base, are involved (33). In carboxylic ester hydrolysis, values of the entropy of activation of –30 to –40 cal mol^{-1} K^{-1} are common (34),

© 2005 NRC Canada

while for primary and secondary halides and sulfonates they are ca. –10 cal mol^{-1} K^{-1} (35). For reactions where the nucleophilic attack of water on a thiocarbonyl is catalyzed by a second molecule of water, the entropy of activation is in the –40 to –25 cal mol^{-1} K^{-1} range (36). The value of the entropy of activation (–27.3 cal mol^{-1} K^{-1}) for the water catalysis of ETE is consistent with the postulated mechanism, considering the lack of examples where water catalyzes a reaction exclusively as a general base. The large value of β = 0.48 obtained from the Brønsted plot suggests that the transition state is highly polar resulting in electrostriction of the bulk solvent, inducing a number of water molecules to be tightly constrained, which results in a large negative entropy of activation.

Conclusions

The acid hydrolysis of ETE at 100 °C occurs through an A1 mechanism, most likely with N-protonation and formation of ethylamine by N—C bond breakage, and an ethyl thionformyl cation ($S=C^{+}$-OEt) that hydrolyzes rapidly to produce COS and ethanol.

At pH 2–6.5, where the main species is the neutral substrate, the hydrolysis is pH-independent and is catalyzed by water as a general base. General bases catalyze the slow proton transfer from the neutral species to form an isothiocyanate intermediate.

The ETE anion hydrolyzes with specific basic catalysis by E1cb mechanism, forming ethyl isothiocyanate in the rate-determining step, which decomposes rapidly to products.

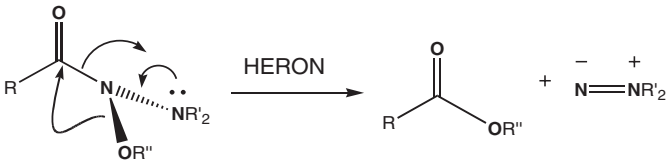
The HERON reaction — Origin, theoretical background, and prevalence[1]

Stephen A. Glover, Arvi Rauk, Jeanne M. Buccigross, John J. Campbell, Gerard P. Hammond, Guoning Mo, Luke E. Andrews, and Ashley-Mae E. Gillson

Abstract: The origin of the HERON reaction is reviewed from a historical perspective and shown to have its foundation in the unusual properties of bisheteroatom-substituted amides, so-called anomeric amides. The reaction involves migration of anomerically destabilized oxo-substituents on an amide nitrogen to the amide carbon and dissociation of the amide bond. Computational work providing a theoretical basis for the reaction is presented, together with physical organic measurements that support results therefrom. The rearrangement has been observed in a number of chemical transformations of *N*-alkoxy-*N*-aminoamides, reactions of 1-acyloxy-1-alkoxydiazenes, *N*-alkoxy-*N*-aminocarbamates, *N*-alkoxyhydroxamic acids, as well as in the gas-phase reactions of *N*-acyloxy-*N*-alkoxyamides.

Key words: HERON reaction, anomeric amides, rearrangements, hindered esters, concerted reactions.



Résumé : On a fait une revue historique de l'origine de la réaction HERON et on montre que sa base réside dans les propriétés inhabituelles des amides portant des substituants bishétéroatomiques, les amides dits anomères. La réaction implique la migration de substituants oxo anomériquement déstabilisée de l'azote d'un amide vers le carbone de l'amide accompagnée d'une dissociation de la liaison amide. On présente un ensemble de calculs théoriques qui sert de base pour expliquer la réaction ainsi que des mesures de chimie organique physique qui supportent les résultats de ces calculs. Le réarrangement a été observé dans un certain nombre de transformations chimiques de *N*-alkoxy-*N*-aminoamides, dans les réactions de 1-acyloxy-1-alkyoxydiazènes, de *N*-alkoxy-*N*-aminocarbamates et d'acides *N*-alkoxyhydroxamiques ainsi que dans les réactions en phase gazeuse de *N*-acyloxy-*N*-alkoxyamides.

Mots clés : réaction HERON, amides anomères, réarrangements, esters stériquement empêchés, réactions concertées.

Introduction

The HERON reaction (Scheme 1) was conceived during our investigations into the reactions of a highly unusual class of mutagenic amides, the *N*-acyloxy-*N*-alkoxyamides (1, 2). It was annointed at the Second Heron Island Conference on Reactive Intermediates and Unusual Molecules, which was held on Heron Island in 1994, and, more recently, confirmed as a named reaction in the 13th edition of *The Merck Index* (3). *N*-Acyloxy-*N*-alkoxyamides are members of the class of anomeric amides that bear two heteroatoms bonded to the amide nitrogen (4). These highly unusual amides are direct-acting mutagens in that they mutate *Salmonella typhimurium* in the Ames test without the need for metabolic activation. Since the initial discovery (5, 6), we have synthesized well over 70 examples and nearly all those that we have tested are mutagenic (7). The direct mutagenicity of this class of amides has led to a quantitative structure–activity relationship (QSAR) from which we can predict the mutagenic activity of virtual congeners, but, equally as interesting, we can identify and quantify unusual molecular interactions of structural elements with DNA (8).

Scheme 1.

Structure of anomeric amides

N-Acyloxy-*N*-alkoxyamides, as with all anomeric amides, possess pyramidalized nitrogen atoms (4). Early computational work at the AM1 level confirmed a tendency to highly developed sp^3 hybridization at nitrogen (2, 4), and, subsequently, so too have more rigorous ab initio calculations at both the HF/6-31G* and the B3LYP/6-31G* density functional theory (DFT) levels of theory (9–11). This conformational

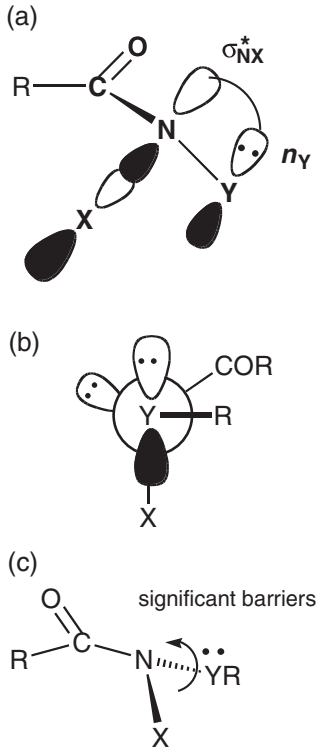
Fig. 1. (*a*) Facile amide isomerism in anomeric amides. (*b*) Stabilization that raises isomerization barriers in planar amides.



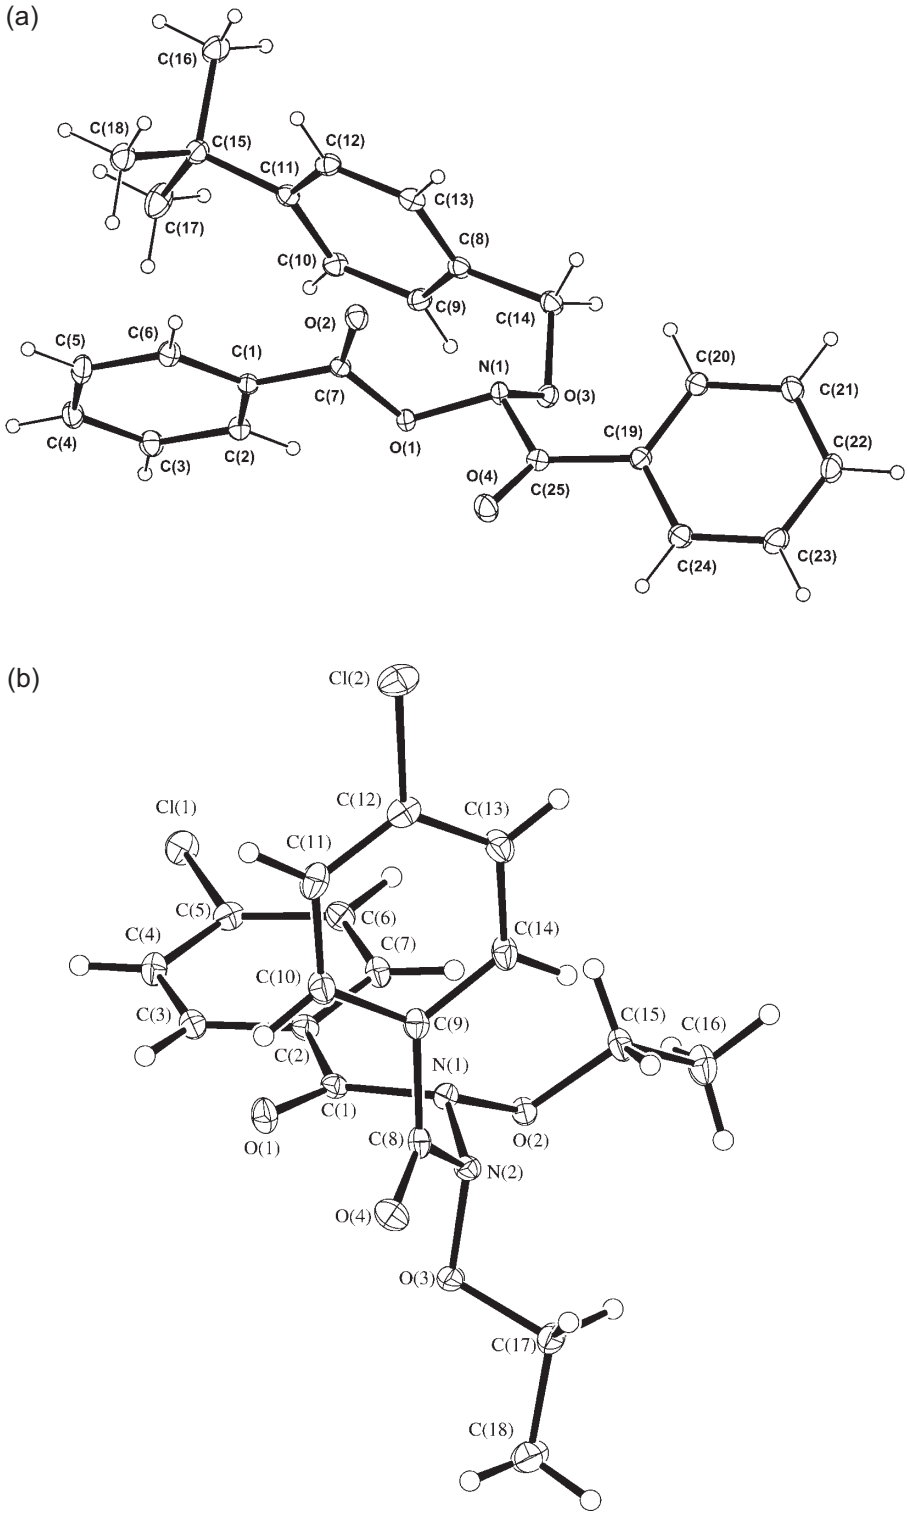
change is readily interpreted in terms of electronegativity of the nitrogen substituents.

It is well-known that atoms geminally substituted with heteroatoms tend towards pyramidality. In qualitative terms, relative to sp^2 hybridization, sp^3 hybridization at the central atom and the consequent increase in p character in the σ bonds enables electron density to be closer to the more electronegative ligands. Thus, anomeric amides possess a nitrogen that substantially deviates from planarity and the increased "s" content of the lone pair drastically reduces lone pair delocalization onto the carbonyl. The intrinsic barrier to rotation about the N—C(O) bonds (Fig. 1*a*), a barrier that is significant in normal amides (12) and hydroxamic esters, (9, 13) and which often leads to dynamic effects in their ^1H NMR spectra at room temperature, is largely lost. Wiberg (14) recently argued that the barrier in "normal" amides is a combination of a π type HOMO–LUMO overlap between the lone pair on nitrogen and the $\pi^*_{C=O}$ molecular orbital combined with a synergistic σ type back donation to the electronegative sp^2 nitrogen (Fig. 1*b*). In anomeric amides both effects disappear on account of the sp^3 hybridization at nitrogen and barriers to isomerization have been found to be drastically reduced or are too low to be measured by dynamic NMR methods (4, 10). Ab initio calculations confirm these properties (4, 9, 10, 15).

N-Acyloxy-*N*-alkoxyamides amides should have longer than normal N—C(O) bonds and shorter carbonyl bonds resulting in higher than expected IR carbonyl stretch frequencies. This has been experimentally determined in that all *N*-acyloxy-*N*-alkoxyamides exhibit amide carbonyl stretch frequencies between 1710 and 1760 cm^{-1} (4). In addition, these amides sustain anomeric effects through the amide nitrogen by which the lone pair on one heteroatom (Y) interacts with the σ* orbital between nitrogen and the other heteroatom X (Fig. 2*a*), thus shortening the Y—N bond and weakening the N—X bond. The ground-state conformations in anomeric amides should facilitate this overlap and, depending upon its strength, barriers to rotation about the N—Y bond can be expected to be greater than predicted by steric effects alone (Figs. 2*b* and 2*c*).

The structural features outlined above have been verified by X-ray crystallography. We recently published the structures of the "most pyramidal" amides, both *N*-acyloxy-*N*-alkoxyamides, which verify the conformational effects previously described (Fig. 3*a*) (16). Not only do they exhibit highly pyramidal nitrogens (avg. angle ~ 108°) and very long N—C bonds, their alkoxy O—N bonds are shortened while the N—O acyl bond is long. Similarly, the related *N*,*N*′-dialkoxy-*N*,*N*′-diacylhydrazine possesses pyramidal nitrogens, long N—C bonds and a short N—N bond (Fig. 3*b*). Both structures exhibit a conformational preference that clearly optimizes either the n_O— σ^*_{NO} or the n_N—σ^*_{NO} overlap (15, 16).

Fig. 2. (*a*) Anomeric overlap, (*b*) conformational preference, and (*c*) rotationally restricted bond in anomeric amides.



Reactivity of anomeric amides

The XNY system should be polarized as shown in Fig. 4. Where Y is a strong electron pair donor (e.g., nitrogen), and X a strongly electron affinic atom such as halogen or in the case of *N*-acyloxy-*N*-alkoxyamides, the acyloxy oxygen, elimination might be expected yielding in the process a stabilized nitrenium ion (Fig. 4*a*). Work in these laboratories and elsewhere has established that nitrenium ions are strongly stabilized by neighbouring heteroatoms (17–28). Such a process would be promoted by polar solvents as well as acid or Lewis acid complexation with X. Thus, unimolecular decomposition would be expected in strongly anomeric systems.

In S_N2 reactions, substituents at the central atom that can stabilize cationic character will also stabilize the S_N2 transition state leading to longer bonds to both the nucleophile and the leaving group (29–31). Thus, in systems with moderate anomeric overlap, this together with negative hyperconjugation and anchimeric assisted weakening of the N—X bond should promote S_N2 reactions at nitrogen leading to loss of X^- (Fig. 4*b*).

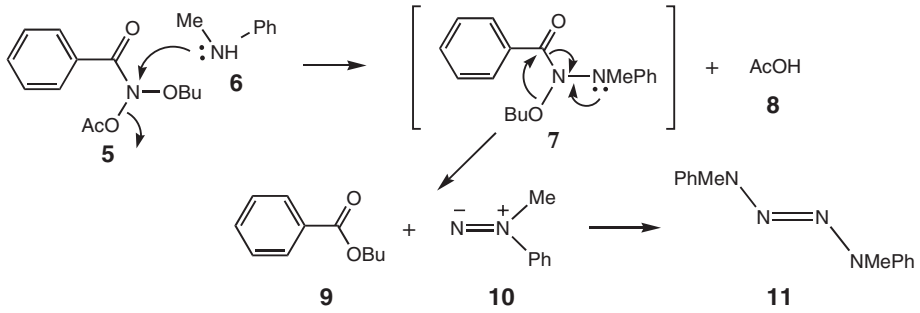
Discussion

The HERON reaction

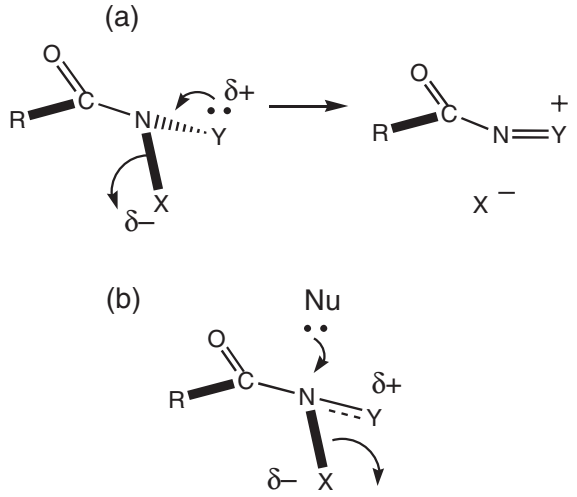


As a part of an investigation into the mechanism of their mutagenic action we subjected *N*-acetoxy-*N*-alkoxybenzamides **1** to a range of solvolytic studies and reactions with potential biological nucleophiles (1, 4, 6, 11, 21, 32–34). They hydrolyse very slowly at neutral pH, but, as predicted, upon protonation on the acetoxy group **2** with acid catalysis in aqueous acetonitrile, they undergo rapid decomposition by the unusual $A_{Al}1$ mechanism leading to *N*-acyl-*N*-alkoxynitrenium ions **3**, which react rapidly with water leading to

© 2005 NRC Canada

Scheme 2.

Scheme 3.



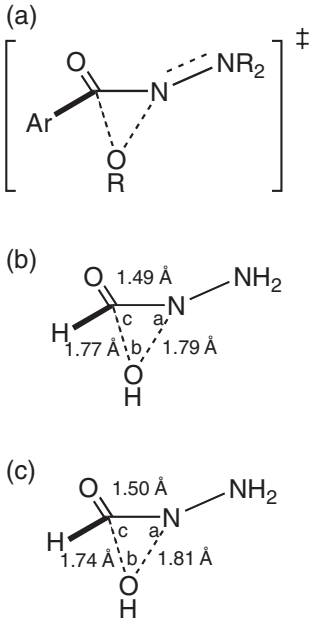
N-alkoxyhydroxamic acids **4** and a variety of secondary products (Scheme 2).

However, a fundamental difference between these and all other conventional amides is that they are susceptible to S_N2 reactions at the amide nitrogen. Treatment of *N*-acyloxy-*N*-alkoxybenzamides with aromatic amines in methanol results in S_N2 displacement of the acyloxy group to give, as intermediates, *N*-alkoxy-*N*-arylaminobenzamides (1, 11, 35). These too are strongly anomeric on account of a high energy lone pair on nitrogen and the electronegative oxygen of the alkoxyl group. With *N*-methyl aniline (**6**) in methanol or aqueous acetonitrile, *N*-acetoxy-*N*-butoxybenzamide (**5**) afforded an excellent yield of butyl benzoate (**9**) and acetic acid (**8**). Close examination of these highly coloured reaction mixtures indicated the presence of crystals of *N*,*N*′-dimethyl-*N*,*N*′-diphenyl tetrazene (**11**) (Scheme 3). A crossover experiment using a mixture of *N*-acetoxy-*N*-butoxy-*p*-toluamide and *N*-acetoxy-*N*-ethoxybenzamide afforded clean yields of butyl *p*-toluate and ethyl benzoate, thus pointing to an intramolecular rearrangement.

In Scheme 3, the S_N2 reaction leads to the intermediate *N*-butoxy-*N*-(*N*′-methylanilino)benzamide (**7**). Anomeric weakening of the N—O bond in **7** results not in heterolysis to alkoxide ion, which would be energetically unfavourable, but rather migration of the butoxyl group from the amide nitrogen to the carbonyl carbon and heterolysis of the N—C bond. This reaction results in the formation of 1-methyl-1-phenyldiazene (**10**), which under the reaction conditions dimerizes to the tetrazene **11**. These rearrangement processes are characterized by a transition state in which the alkoxyl group migrates from the amide nitrogen to the carbonyl carbon (Fig. 5*a*) and therefore involves heteroatom rearrangements on nitrogen, the HERON reaction[3] (2).

Thus, the HERON reaction, as well as the unique properties of *N*-acyloxy-*N*-alkoxyamides, can be ascribed to the configuration at nitrogen, namely bisheteroatom substitution.

Fig. 4. (*a*) Anomerically induced elimination. (*b*) S_N2 reaction at nitrogen.



Computational verification of the HERON reaction

This reaction, though published in the early 1990s, was named in the literature in a 1995 paper in which we presented a semiempirical molecular orbital treatment of the HERON reactions of a range of anomeric amides (2). AM1 predicted, adequately, the ground-state properties of various anomeric amides, as well as the relative propensity for HERON migration of a variety of geminal heteroatom substituents on nitrogen. In general, the activation energy was lowered with an amino substituent and more electronegative migrating atoms or electron-deficient groups. In the case of

[3] Presented to the 2nd Heron Island Conference on Reactive Intermediates and Unusual Molecules. The authors are grateful to Professor Richard Wong who suggested that the reaction deserved to be named.

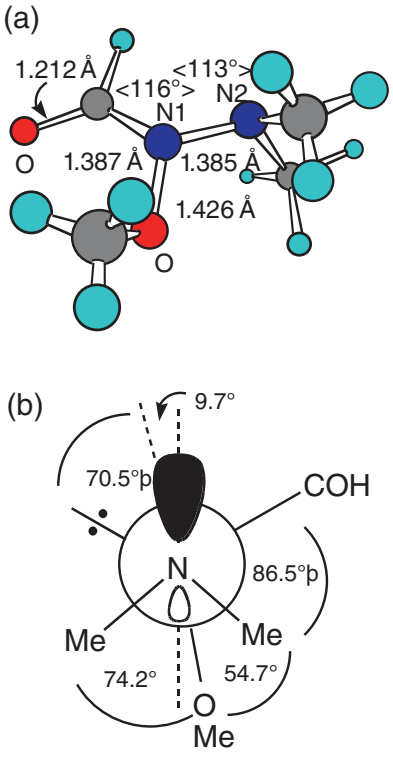
Fig. 5. (*a*) Transition state for a HERON reaction of an *N*-alkoxy-*N*-aminoamide. Computed transition states for the migration of hydroxyl in *N*-amino-*N*-hydroxyformamide at: (*b*) AM1 (a = 65°, b = 45°, and c = 65°) and (*c*) HF/6-31G* (a = 63°, b = 48°, and c = 69°) levels.



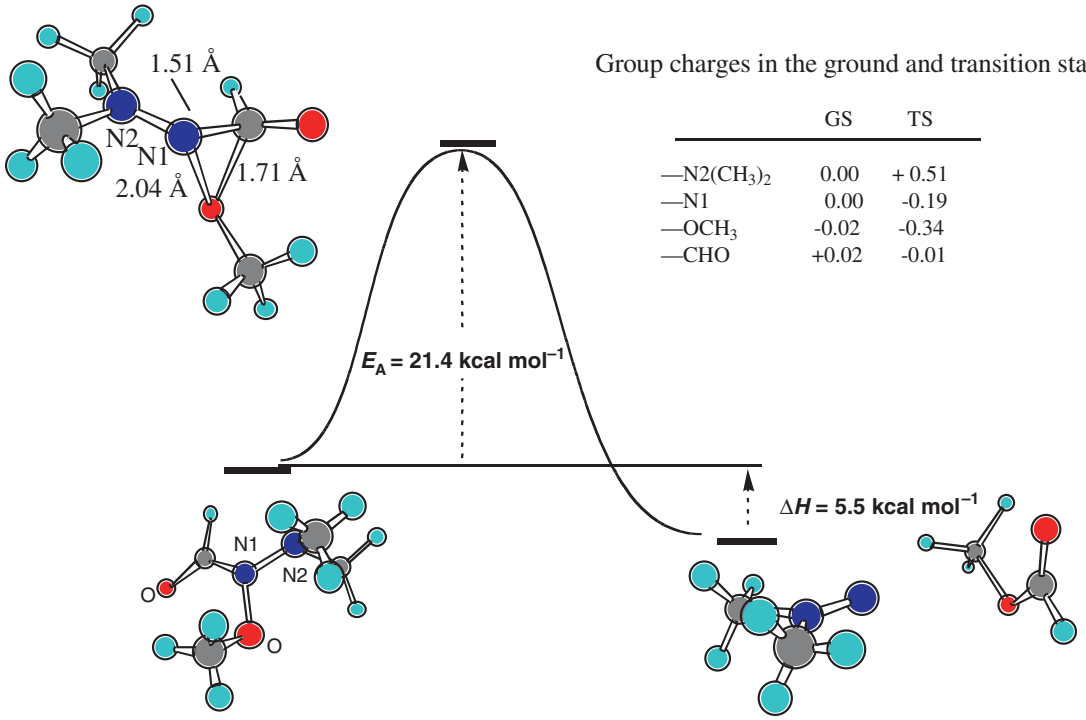
N-alkoxy-*N*-aminoamides, we attributed this to better anomeric weakening of the N—OR bond through a favourable interaction between a high energy nitrogen lone pair and a low energy N—OR σ* orbital. A transition state was predicted that indicated partial bonding between the migrating oxygen and both the amide nitrogen and carbon atoms in a plane perpendicular to that of N-C=O (Fig. 5*b*). The amide bond was largely unaltered. A similar result was obtained from HF/6-31G* calculations (Fig. 5*c*).

In a comprehensive study using DFT, we showed that anomeric substitution can be expected to lead to the conformational changes outlined in Fig. 2 in a wide range of amides (9). At this more reliable computational level, bis-heteroatom substitution leads to pyramidal amide nitrogens, lengthened N—CO bonds, shortened Y—N bonds, conformations about which optimize n_Y— σ^*_{NX} overlap. A subsequent, detailed B3LYP/6-31G* investigation of the congener, *N*-methoxy-*N*-dimethylaminoformamide, a model for the intermediate **7** in the HERON reaction indicated all these features (Fig. 6*a*) (10) and predicted: a strongly pyramidal nitrogen (avg. angles at nitrogen of 116°); a long N—C bond of 1.39 Å (computed to be 1.36 Å in formamide); a short N—N bond of 1.38 Å (1.45 Å in hydrazines); an extraordinarily low barrier of 13 kcal mol^{-1} (1 cal = 4.184 J) to E–Z isomerization about the N—C bond (typically 19–24 kcal mol^{-1} in conventional amides); a remarkably high barrier of 14 kcal mol^{-1} to rotation about the formally single N—N bond; an orientation of the amino substituent that optimized the anomeric overlap with the vicinal N—O bond (Fig. 6*b*).

A DFT evaluation of the HERON reaction of *N*-methoxy-*N*-dimethylaminoformamide to give methyl formate and 1,1-dimethyldiazene confirmed the earlier predictions at the AM1 and HF/6-31G* level (Fig. 7). The activation energy in

Fig. 6. (*a*) Lowest energy conformation of *N*-methoxy-*N*-dimethylaminoformamide (< x > = avg. angle). (*b*) Newman projection along the N—N bond.

the gas phase is modest at 21.4 kcal mol^{-1}, and the rearrangement is predicted to be exothermic by some 5.5 kcal mol^{-1} (36). The transition-state geometry shows that the N—C bond is intact, and the carbonyl bond is virtually unaltered. An intrinsic reaction coordinate study indicated that the N—C bond cleaves in concert with O—C bond formation after the transition state. In essence, this reaction represents an intramolecular S_N2 reaction on the amide carbonyl. Further analysis of the computed transition state indicates the charge redistribution (Fig. 7). Predictably, N2 becomes more positive at the transition state, while N1 and the migrating group develop negative charge. Electron-releasing groups on the donor nitrogen and electron-withdrawing groups on the migrating oxygen should lower the energy of the transition state, which should also proceed better in polar solvents that can stabilize this charge separation. Interestingly, there is no appreciable change in charge at the carbonyl and neither electron-donor groups nor electron-withdrawing groups at this position should exert a major influence upon the energetics of the reaction.



Experimental evidence in support of these computational results has accrued from a number of reactivity studies.

The HERON reaction of *N*-amino-*N*-alkoxyamides

We have routinely used the S_N2 reaction of *N*-acyloxy-*N*-alkoxyamides and *N*-methylaniline as a measure of their susceptibility to nucleophilic attack at nitrogen, and hence, to possible reactions with nucleophilic centres in DNA. The reactions can be followed in d_4-methanol and can be monitored through the disappearance of the mutagen or aniline and the formation of ester and tetrazene. HERON

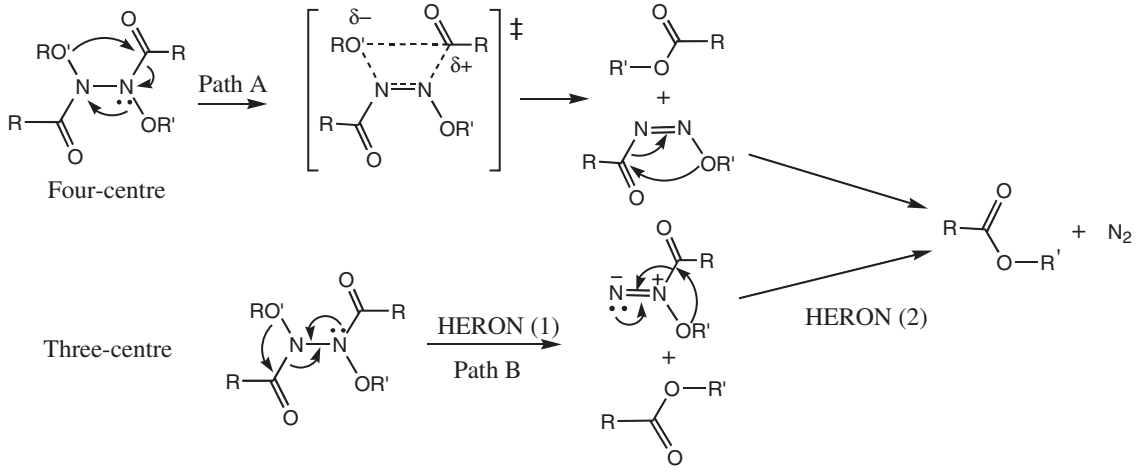
Fig. 7. Energetics and transition-state properties for the HERON reaction of *N*-methoxy-*N*-dimethylaminoformamide to 1,1-dimethyldiazene and methyl formate.

rearrangement of the intermediate *N*-alkoxy-*N*-(*N*-methylanilino)benzamides proceeds with a low activation energy in methanol as it has never been detected under these reaction conditions, even at temperatures well below ambient (34). This is not surprising as the B3LYP/6-31G* activation energy for the model reaction in the gas phase is an upper limit and it would probably be significantly lower in solution.

A related class of analogues, the *N*,*N*′-diacyl-*N*,*N*′-dialkoxyhydrazines **12**, are readily generated by oxidative dimerization of hydroxamic esters (37–40) and by dimerization of alkoxyamidyl radicals formed upon oxidation of hydroxamic esters or photolysis of *N*-alkoxy-*N*-haloamides (41, 42). In a recent study we have demonstrated that these hydrazines exhibit all the hallmarks of anomeric amides (15). Their carbonyl stretch frequencies in solution are in the range of 1700–1744 cm^{-1}, while those of their precursor hydroxamic esters are in the range 1680–1690 cm^{-1} (4, 15). This accords with pyramidal nitrogen atoms, and in the case of *N*,*N*′-diacetyl-*N*,*N*′-di(*p*-chlorobenzyloxy)hydrazine, dynamic NMR methods afforded a low amide isomerization barrier of just 12.9 kcal mol^{-1}. For a range of such *N*,*N*′-diacyl-*N*,*N*′-dialkoxyhydrazines, we also obtained barriers for isomerization about the N—N bond that were in the range of 15–17 kcal mol^{-1}, which is indicative of a strong NNO anomeric interaction (15). Furthermore, from IR studies, these hydrazines appear to be unsymmetrical in both the solution and the solid phase, displaying two carbonyls;[4] one-half of the hydrazine can be regarded as a donor substituent on the other anomerically substituted nitrogen.

This spectroscopic evidence is supported by the X-ray structure of *N*,*N*′-di(*p*-chlorobenzoyl)-*N*,*N*′-diethoxyhydrazine (Fig. 3*b*). This *N*,*N*′-diacyl-*N*,*N*′-dialkoxyhydrazine is asymmetrical in nature and both nitrogens are strongly pyramidal with avg. angles at N(1) and N(2) of 113.6° and 114.4°, respectively. Furthermore, there is evidence for an anomeric interaction in the direction of N(2). The N(2)—O(3) bond nearly bisects the C(1)-N(1)-O(2) angle with torsion angles of 69.4° and –66.7° to N(1)—C(1) and N(1)—O(2) bonds, respectively, while the N(2)—O(3) bond is nearly 0.01 Å longer then the N(1)—O(2) bond. Both could be accounted for by overlap between the N(1) lone pair and the N(2)—O(3) antibonding orbital.

Upon mild heating, *N*,*N*′-diacyl-*N*,*N*′-dialkoxyhydrazines were known to decompose intramolecularly to 2 equiv. of ester and nitrogen by a reaction mechanism originally purported to involve two, four-centre rearrangements (Scheme 4, path A). Rate-enhancing donor acyl substituents were believed to stabilize intrinsic acylium character in the first, rate-determining step (39, 43).



The discovery of the HERON reaction process instigated a reevaluation of the mechanistic details of this reaction by our group (44) and, coincidentally, by Barton and co-workers (40). Both studies involved the synthesis and thermal decomposition of an asymmetrical hydrazine. In our study, *N*-benzoyl-*N*-benzyloxy-*N*′-butoxy-*N*′-(*p*-chlorobenzoyl)hydrazine (**12a**) decomposed at room temperature in $CDCl_3$ affording largely benzyl benzoate (**13a**) and butyl *p*-chlorobenzoate (**13b**) from two, three-centre processes (Scheme 4, path B). Similarly, Barton and co-workers exclusively rearranged **12b** to a 1:1 mixture of **13c** and **13d** (40).

AM1 calculations carried out by both ourselves (44) and Barton's group (40), and subsequent high level calculations

[4] These are due to symmetrical and asymmetrical coupled stretch modes rather than individual frequencies for each carbonyl (15).

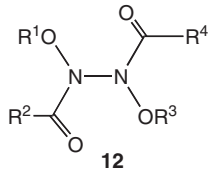
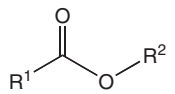
Scheme 4.



carried out by Thomson and Hall (45) on **12d**–**12f**, supported this mechanism in which the second step, also a HERON-type reaction, has a very low activation barrier. For hydrazine model **12d**, they calculated an activation barrier of 25 kcal mol^{-1} at the CCSD(T)//B3P86 level for HERON (1) in Scheme 4, a step that was exothermic by 13 kcal mol^{-1}. At the B3P86//B3P86 level, activation barriers for **12d**, **12e**, and **12f** were 24, 23, and 35 kcal mol^{-1}, respectively. The second HERON reaction (HERON (2), Scheme 4) of the diazene intermediate is computed to have a low activation barrier of just 2 kcal mol^{-1} and the extrusion of nitrogen is exothermic by 104 kcal mol^{-1}! Similar results were obtained for HERON (2) for the methylated models **12e** and **12f**. They also reported that a concerted pathway to two molecules of ester and nitrogen was not viable.

The transition state for HERON (1), computed for the rearrangement of methoxyl in **12f**, resembled that previously computed for the HERON reaction of *N*-methoxy-*N*-dimethylaminoformamide to give methyl formate and 1,1-dimethyldiazene (36). The transition state for the second step was very early in accordance with the exothermic nature of this step. B3LYP/6-31G*calculations from our group for a similar rearrangement of 1-formyl-1-methoxydiazene confirmed this and will be dealt with later in this review (46).



The initial, rate-determining step in the HERON reaction of hydrazines **14a**–**14e** and **15a**–**15e** proceeds with modest activation barriers of between 22 and 30 kcal mol^{-1} and negative entropies of activation (36). Thus, the experimental values are in excellent agreement with our activation energy for the HERON reaction of *N*,*N*-dimethylamino-*N*-methoxyformamide (21 kcal mol^{-1}, Fig. 7) and those computed by Thomson and Hall (45) for models **12d**–**12f**.

The unimolecular rate constants at 298 K for decomposition of a series of *N*,*N*′-di(*p*-substituted benzoyl)-*N*,*N*′-diethoxyhydrazines (**14a**–**14e**) in mesitylene correlated with Hammett σ^+ constants with $\rho = -0.35$, reflecting the stabilization of the transition state by electron-releasing acyl substituents adjacent to the donor nitrogen (Fig. 8*a*). The rates constants at 298 K for a series of *N*,*N*′-diacetyl-*N*,*N*′-di(*p*-substituted benzyloxy)hydrazines (**15a**–**15e**) correlated with Hammett σ constants, but with positive slope ($\rho = 1.02$), thus reflecting the stabilization of the transition state by electron-withdrawing alkoxyl substituents (Fig. 8*b*). Both results con-

firmed the charge distribution at the transition state for the HERON rearrangement (Fig. 7) (36). Furthermore, members of the benzoyl series react about two orders of magnitude faster at 298 K than the benzyloxy series (typically 3×10^{-6} vs. 5×10^{-8} L mol^{-1} s^{-1}). This can be understood since, in the benzoyl series, a donor group facilitates development of positive charge at the donor nitrogen but has little effect upon the acyl carbon in the migration, since this accrues little charge in the transition state (Figs. 7 and 8*a*). However, while an electron-withdrawing group on the alkoxyl group will stabilize negative charge in the migrating group, it will destabilize the developing positive charge on the adjacent donor nitrogen (Figs. 7 and 8*b*).

Thus, the thermal rearrangement of *N*,*N*′-diacyl-*N*,*N*′-dialkoxyhydrazines to esters and nitrogen is a HERON reac-

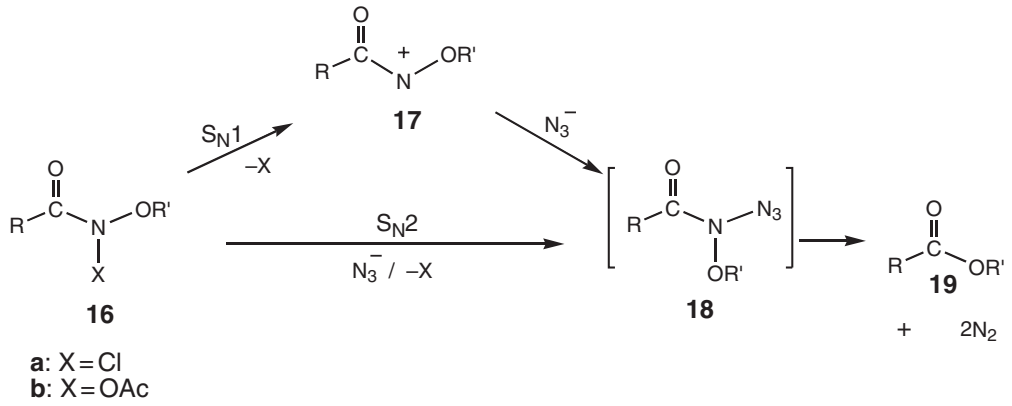
Scheme 5.



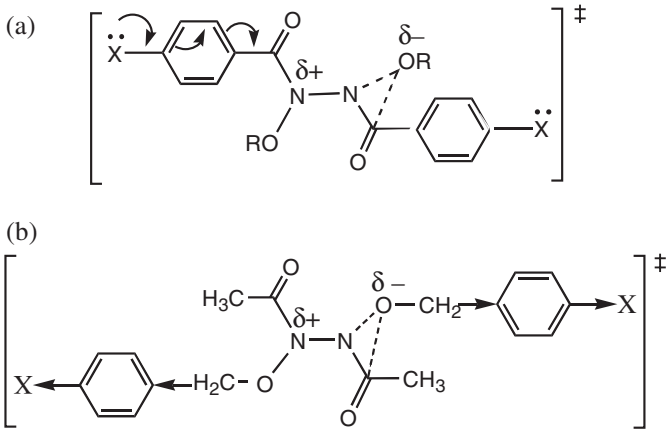


Fig. 8. Influence on the HERON transition states of: (*a*) electron-rich benzoyl groups in **14**; and (*b*) electron-deficient benzyloxy groups in **15**.

tion and their reduced rates of reactivity (probably on account of weaker donor capacity of one nitrogen because of acyl substitution) enabled us to confirm the theoretical transition-state properties.

This concerted reaction was flagged by Barton and coworkers (40) as an excellent synthesis of sterically hindered esters. For example, decomposition of **12c** afforded *tert*-butyl 1-adamantanecarboxylate (**13e**) in 87% yield.

The HERON reaction of 1-acyl-1-alkoxydiazenes

N-Alkoxy-*N*-chloroamides (**16a**) and *N*-acetoxy-*N*-alkoxyamides (**16b**) react with sodium azide at room temperature giving the ester **19**, derived from the alkoxyl and acyl groups of the hydroxamic ester, as well as nitrogen. In the case of both *N*-alkoxy-*N*-chloroamides and *N*-acyloxy-*N*-alkoxyamides, crossover experiments indicated that the reaction exclusively yields the carboxylic ester derived from the corresponding alkoxyl and acyl group (35). Both an S_N1 process involving the nitrenium ion **17** and direct S_N2 mechanism are possible under these conditions (Scheme 5). The reactions are extremely fast in aqueous organic solvents but can be monitored dilatometrically at 295 K and have been found to proceed by the bimolecular process yielding 2 equiv. of nitrogen, with rate constants of around 2 L mol^{-1} s^{-1}. Bimolecular reactions of *N*-acyloxy-*N*-alkoxyamides with *N*-methylanilines (34) and glutathione or L-cysteine methyl ester[5] are slower by two to three orders of magnitude. *N*-Alkoxy-*N*-azidoamides **18** are believed to form as reactive intermediates (35, 46).

Calculations on the lowest energy structure for *N*-azido-*N*-methoxyformamide (**20**) at HF/6-31G* (35) and B3LYP/6-31G* (46) indicate that the azido adduct lies at a potential energy minimum and is typically anomeric with avg. angles at nitrogen of 112° and 113° (Fig. 9*a*), and a conformation that supports one anomeric overlap, that being between the oxygen lone pair and the N1—N2 bond (Figs. 9*b* and 9*c*).

Production of methylformate and two molecules of nitrogen can occur by three routes. The first possibility involves a HERON reaction yielding ester **21** and tetrazene **22**, which is the source of 2 equiv. of nitrogen (Scheme 6, path A). Alternatively, an initial loss of nitrogen could give 1,1-diazene (Scheme 6, path B), which undergoes a HERON reaction producing ester and a second equivalent of nitrogen (Scheme 6, path C). The latter process is identical to the HERON (2) step in the decomposition of *N*,*N*′-diacyl-*N*,*N*′-dialkoxyamides (Scheme 4). A concerted rearrangement with loss of nitrogen (Scheme 6, path D) is also possible. Once again, we have used computational methods to determine the most likely reaction mechanism. All three reactions are highly exothermic (137 kcal mol^{-1}), but neither path A nor path D was found to be a viable competitor to the stepwise dissociation into 1,1-diazene (**23**) and nitrogen (Scheme 6, paths B and C). The azidonitrene in path A decomposes with zero activation energy to two molecules of nitrogen and no transition state for the concerted pathway could be found without prior loss of nitrogen as occurs in path B. Loss of nitrogen from *N*-azido-*N*-methoxyformamide in path B is exothermic by between 42 and 44 kcal mol^{-1} depending upon the ground-state geometry and has very low activation barriers of between 5 and 8 kcal mol^{-1}. The transition states all show stretching of the N4—N5 bonds of about 0.24 Å and sp^2 hybridization at the amide nitrogen. In addition, the N3—N4 bonds shorten by about 0.11–0.13 Å. The connected ground-state, transition-state, and 1,1-diazene ge-

[5] At 308 K, gluthione reacted in d_6-DMSO–D_2O with bimolecular rate constants of around 2.6 × 10^{-2} L mol^{-1} s^{-1}; at 303 K in d_4-methanol, L-cysteine methyl ester reacted with a rate constant of 1.6 × 10^{-2} L mol^{-1} s^{-1}.

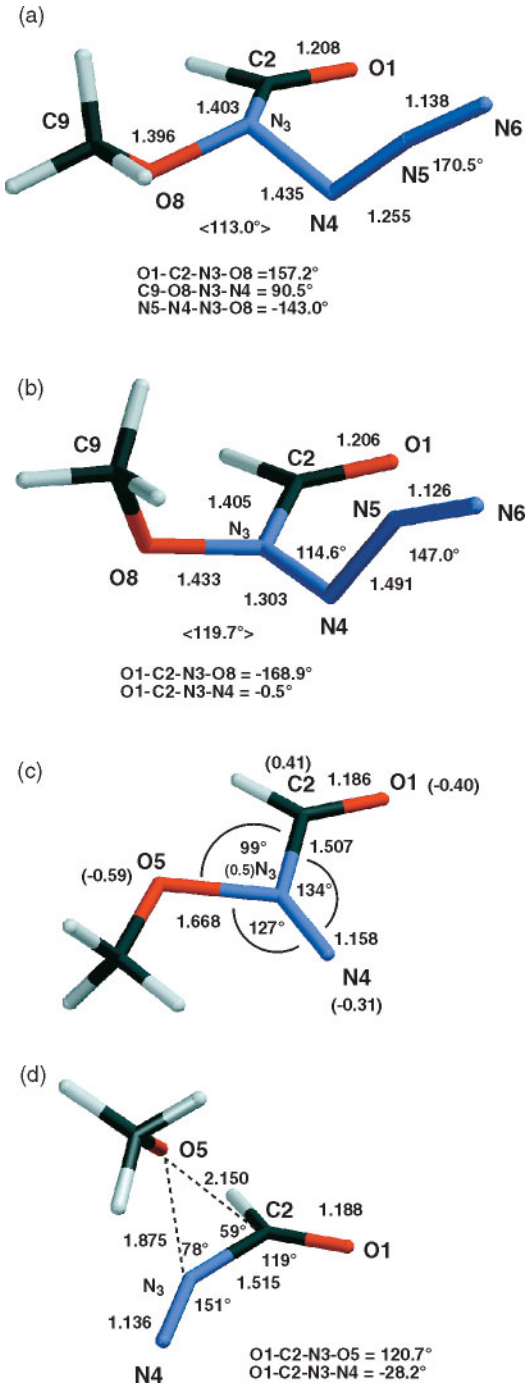
ometries from the lowest energy conformer of *N*-azido-*N*-methoxyformamide are given in Fig. 10.

Rearrangement of 1-formyl-1-methoxydiazene to nitrogen and methylformate (Scheme 6, path C) is a HERON reaction and is an identical process to the second step for the thermal decomposition of *N*,*N*′-diacyl-*N*,*N*′-dialkoxyhydrazines. At the B3LYP/6-31G* level, the transition state (Fig. 10*d*) is early with an activation barrier of only 2.8 kcal mol^{-1}, and the second step is overall exothermic by approximately 95 kcal mol^{-1}. Our result is completely in line with that of Hall and Thomson's (45), previously described for the simpler system (E_A = 2 kcal mol^{-1}, ΔE = 104 kcal mol^{-1}).



We have utilized the favourable energetics and concerted rearrangement of *N*-alkoxy-*N*-azidoamides to esters and nitrogen in the facile synthesis of highly hindered esters from *N*-chlorohydramic esters (Table 1). Yields rival those of Barton's group (40) from HERON decomposition of the hydrazines. Precursors for both syntheses are the hydroxamic esters, but the hydrazine method involves prior oxidative dimerization, whereas the intermediates in our synthesis are the *N*-chlorohydroxamic esters that are very readily generated from hydroxamic esters in quantitative yield using *tert*-butyl hypochlorite.

The HERON reaction in alcoholysis of dialkyl azodicarboxylates

Azodicarboxylates **24** are a class of nitrogen electrophiles that have been used widely in the Mitsunobu reaction, an effective synthetic protocol for activating alcohols to esterification (largely with inversion of configuration) (47–49). Reactions in alcohols have produced both symmetrical and unsymmetrical dialkylcarbonates as side products or as the major product (50, 51). Direct alcoholysis of azodicarboxylate esters has been described by several groups (38, 52–54). Azodicarboxylates **24** were reported to be stable in ethanol, but vigorously decomposed upon addition of bases such as alkoxides and sodium acetate (52). The hydrazines **25** were believed to be unstable intermediates, although reports are contradictory. Galynker and Still (55) reported that

they were major, stable side products from Mitsonobu tosylation reactions. However, based on our observations azodicarboxylates **24** are most likely to undergo a HERON rearrangement upon nucleophilic addition.

In support of this, we found that diethyl azodicarboxylate (**24a**) and diisopropyl azodicarboxylate (**24b**) were completely stable in methanol, but upon addition of sodium methoxide, sodium acetate, or sodium hydroxide, they decomposed with a spontaneous evolution of an equivalent of nitrogen, liberation of heat, and a change of colour from the characteristic yellow of the azodicarboxylates to pink. The products of decomposition in a methanolic solution of sodium methoxide or sodium acetate were identified spectroscopically and by GLC as ethyl methyl carbonate (**26a**) and ethyl formate (**27a**), and in the case of the reaction of **24b**, ^{1}H NMR analysis of the reaction mixture indicated the presence of methyl isopropyl carbonate (**26b**) and isopropyl formate (**27b**) in an approximate ratio of 1:1.

In support of this, we found that diethyl azodicarboxylate (**24a**) and diisopropyl azodicarboxylate (**24b**) were completely stable in methanol, but upon addition of sodium methoxide, sodium acetate, or sodium hydroxide, they decomposed with a spontaneous evolution of an equivalent of nitrogen, liberation of heat, and a change of colour from the characteristic yellow of the azodicarboxylates to pink. The products of decomposition in a methanolic solution of sodium methoxide or sodium acetate were identified spectroscopically and by GLC as ethyl methyl carbonate (**26a**) and ethyl formate (**27a**), and in the case of the reaction of **24b**, ^{1}H NMR analysis of the reaction mixture indicated the presence of methyl isopropyl carbonate (**26b**) and isopropyl formate (**27b**) in an approximate ratio of 1:1.

Formation of mixed carbonates might be rationalized by carbonyl addition followed by acyl cleavage. However, there is ample evidence from Mitsonobu chemistry that azodicarboxylates undergo nucleophilic attack at nitrogen. The HF/6-31G* computed lowest energy conformer of dimethyl azodicarboxylate has the ester groups orthogonal to the nitrogen double bond and the LUMO of **24c** is essentially a pure $\pi^*_{N=N}$ orbital (Fig. 11*a*). The second lowest unoccupied orbital possesses $\pi^*_{C=O}$ character, but is nearly 2.5 eV higher in energy. Nucleophiles, including methoxide, would be pre-

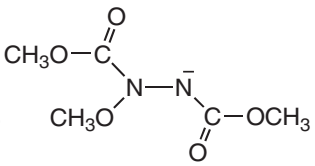
Fig. 11. (*a*) HF/6-31G* LUMO orbital of dimethyl azodicarboxylate (**24c**). (*b*) HF/6-31G* geometry of *N,N′*-dicarbomethoxy-*N*-methoxyhydrazine.



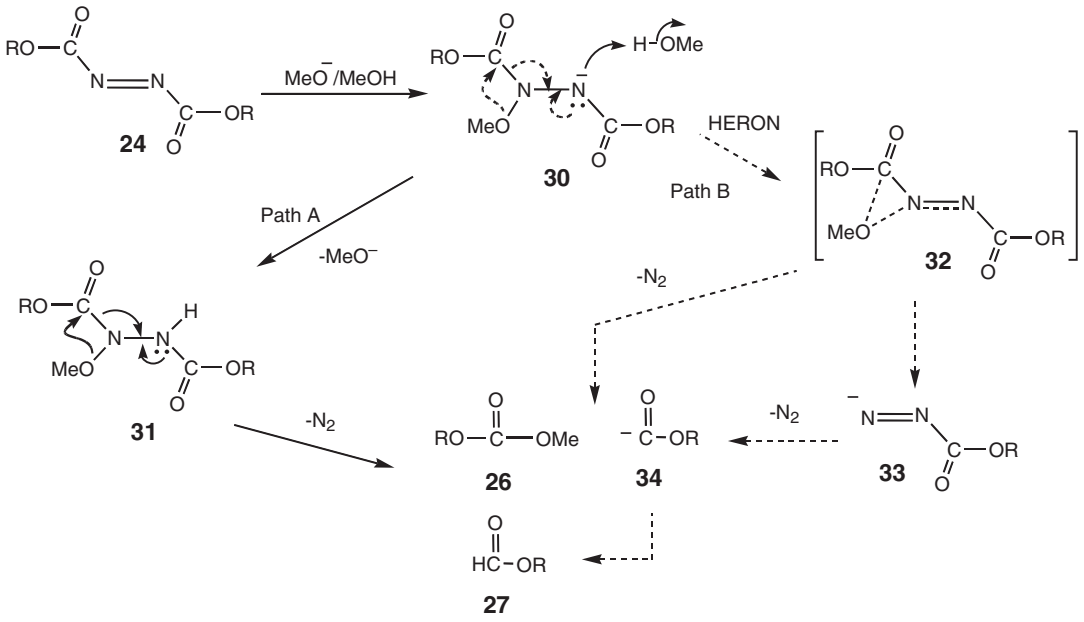
dicted to attack azodicarboxylates exclusively at the nitrogen atoms. In addition, while the anionic carbonyl adduct **28** is slightly more stable than the azo adduct **29** in the gas phase, it is slightly less stable if aqueous solvation is incorporated (Table 2).

Scheme 7 depicts possible mechanisms for the conversion of dialkyl azodicarboxylates into mixed carbonates. Attack at the azo group would result in the intermediate **30** in which the neighbouring nitrogen has anionic character. The anion could be protonated giving **31** (Scheme 7, path A) or, alternatively, could undergo a HERON reaction (Scheme 7, path B) with the formation of the mixed dialkyl carbonate **26** and

28

29

alkyl formate anion **34**, which ultimately leads to alkyl formate **27**.



However, path A followed by HERON reaction of **31** is less likely. Firstly, methoxide must be a stronger base than **30**, and secondly, **31** is likely to be much more stable than the *N,N′*-diacyl-*N,N′*-dialkoxyhydrazines; according to HF/6-31G* calculations (Fig. 11*b*), the amide lone pair is strongly conjugated with the carbonyl, since the nitrogen is largely sp^2 at the protonated nitrogen (avg. angle at nitrogen 119.6°). Compared to the *N,N′*-diacyl-*N,N′*-dialkoxyhydrazines, which are computed to have N—N bond lengths of around 1.355 Å (15), this "half-anomeric" hydrazine has a much longer N—N bond (1.381 Å), reflecting poor anomeric overlap. In keeping with this, we could not locate a transition state for a HERON reaction of this structure.

In **30**, the anionic lone pair is very high in energy resulting in a strong anomeric overlap and driving force for the rearrangement. The process has an analogy in the previously reported, facile HERON reaction of the conjugate anion of *N*-alkoxyhydroxamic esters described in the following example (33).

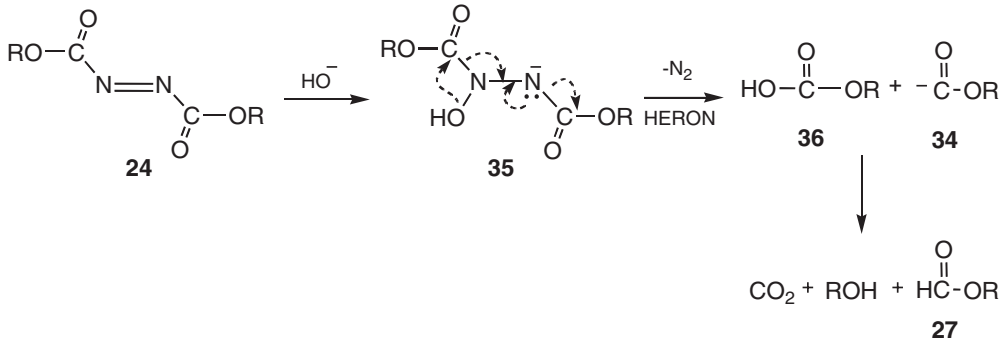


Table 2 gives calculated energies for the reactant, transition state, and products from the HERON reaction of *N,N′*-dicarbomethoxy-*N*-methoxy anion (**29**). In the gas phase, the rearrangement has an extremely low E_A of 6.5 kcal mol^{-1} (14.8 kcal mol^{-1} with solvation), and in this case, leads initially to the carbonyl adduct **28**, which is similar in energy and is a stationary point. It is proposed that **28** directly decomposes to nitrogen and an acyl anion, which scavenges a proton from methanol. The methoxycarbonyldiazene anion (**33**) (R = Me) that would be formed by cleavage of the amide bond is computed to be a metastable point on the energy surface and spontaneously rearranges to an acyl anion and nitrogen. Overall, the reaction is exothermic by 14.4 kcal mol^{-1} (17.4 kcal mol^{-1} with solvation).

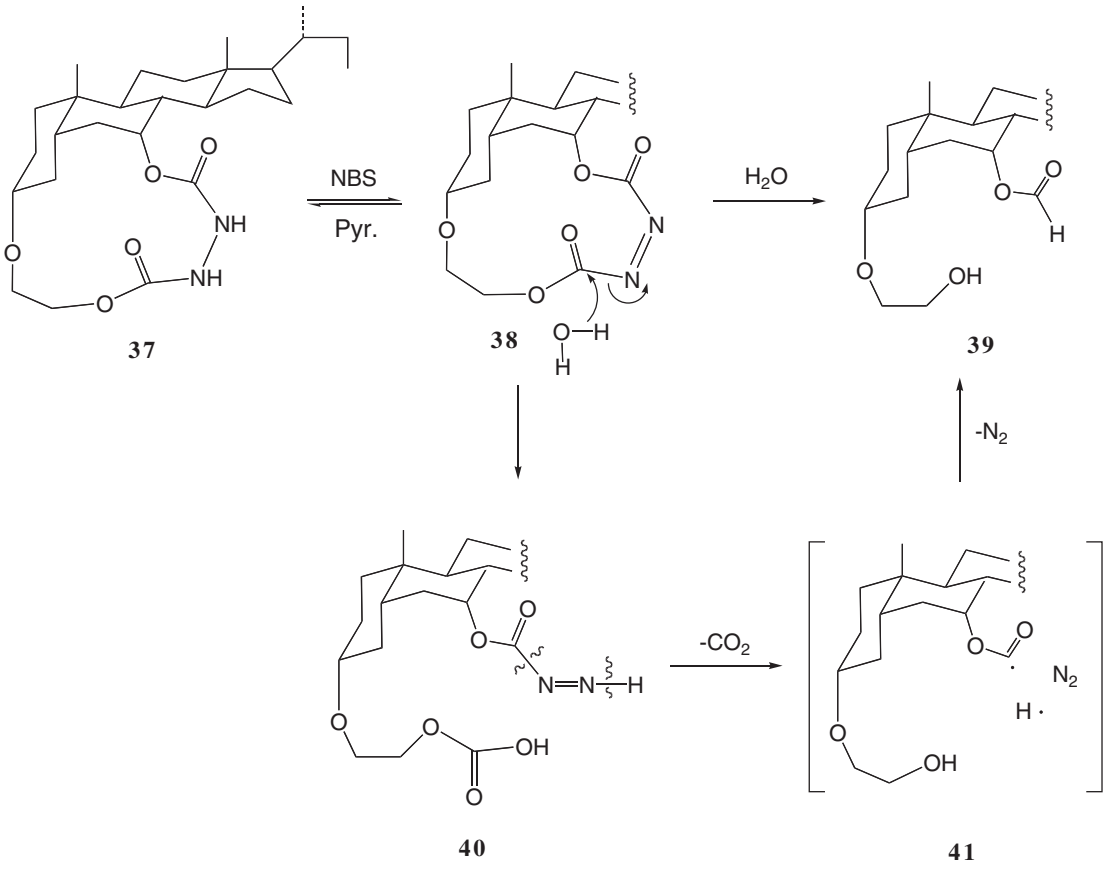
Scheme 7.

Scheme 8.

In a methanolic solution of potassium hydroxide, **24a** and **24b** exothermically decomposed with immediate evolution of nitrogen and formation of ethyl and isopropyl formate. In the case of **24b**, isopropanol was isolated as a product. Reaction according to Scheme 7 would result in formation of the alkyl hydrogen carbonate **36**, which under the basic reaction conditions, would probably decompose to alcohol and carbon dioxide (Scheme 8).

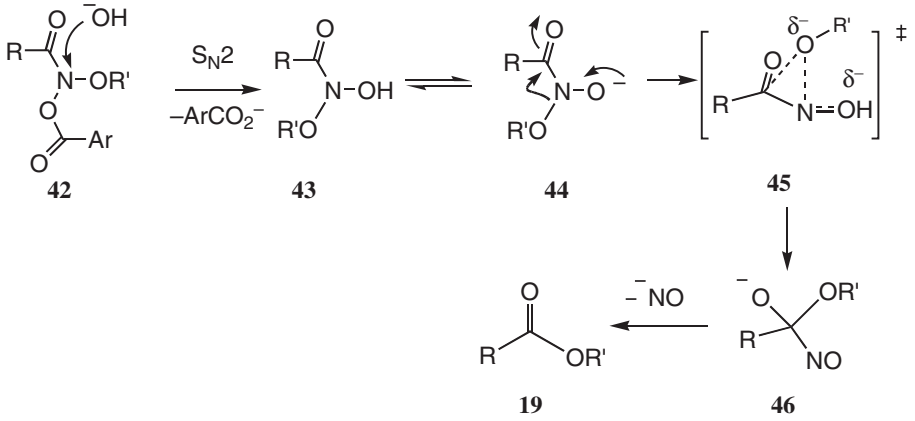
The formation of alkyl formate by this reaction represents a more acceptable route than that proposed by Vederas and co-workers (57) for the formation of steroidal formate ester (**39**) from *N*-bromosuccinimide oxidation of chiral diazane (**37**) (Scheme 9). The intermediate azodicarboxylate **38** was thought to react with water giving **40** by attack at carbonyl. Decarboxylation and radical decomposition of **40** via **41** completed the process. Homolytic decomposition of **40** to give **41** is considered by the author to be a highly unlikely process as is the reaction of water at the carbonyl of **38**.

The HERON reaction of *N*-alkoxyhydroxamic acids



Treatment of *N*-acyloxy-*N*-alkoxybenzamides (**42a**) with dilute aqueous sodium hydroxide, at room temperature, resulted in the rapid formation of alkyl benzoates **19** (33). A crossover experiment using *N*-acetoxy-*N*-butoxy-*p*-chlorobenzamide and *N*-acetoxy-*N*-benzyloxybenzamide resulted in the exclusive formation of butyl *p*-chlorobenzoate (46%) and benzyl benzoate (43.3%) esters along with the hydrolysis products, *p*-chlorobenzoic and benzoic acid. This result indicates that ester formation involves an intramolecular process.

Using a series of *N*-(*p*-substituted benzoyloxy) mutagens, it was shown to occur by S_N2 reaction of hydroxide at nitrogen, which gives hydroxamic acid (**43**) as an intermediate (Scheme 10) (33). The presence of excess base would ensure conversion of the hydroxamic acid intermediate into the conjugate anion **44** resulting in a HERON reaction and formation of ester **19** and presumably NO^-. The formation of noncrossover esters in the acid-catalysed solvolyses of *N*-acetoxy-*N*-alkoxyamides **1** at low acid concentrations, according to Scheme 2, has also been observed. Such reactions produce the *N*-alkoxy-*N*-benzoylnitrenium ion **3** from **2** and, by solvolysis, *N*-alkoxyhydroxamic acid (**4**) directly (32).



While the lone pair on the hydroxy oxygen of hydroxamic acid (**43**) would be tightly bound, resulting in a weak n_{OH}—σ^*_{N-OR} interaction, the anion **44** would possess a high energy pair of electrons, thus enhancing the anomeric effect

b: R = R' = Me

in a similar fashion to the amide anion **30** previously described and which drives that HERON reaction. Calculations on the rearrangement of *N*-methoxy-*N*-methanohydroxamate anion (**44b**) (Fig. 12*a*) to methyl formate (**19b**) indicated an early transition state (**45b**) (Fig. 12*b*) that leads to the tetrahedral alkoxide intermediate (**46b**) (Fig. 12*c*), which presumably decomposes by elimination of NO^-. B3LYP/6-31G*//HF/6-31G* results (Table 3) gave an activation energy for the HERON step of only 5.3 kcal mol^{-1} (10.0 kcal mol^{-1} including solvation effects). Formation of the tetrahedral intermediate was exothermic by 10.7 kcal mol^{-1} and the overall reaction was endothermic by 21 kcal mol^{-1} with solvation, which suggests reversibility of the HERON step in this case.

Recently, Shtamburg et al. (58) studied the methanolysis of a variety of *N*-acetoxy-*N*-alkoxy derivatives of carbamate **47a**, urea **47b**, and benzamide **50** and found that, with the exception of the benzamide, acyloxy substitution at nitrogen

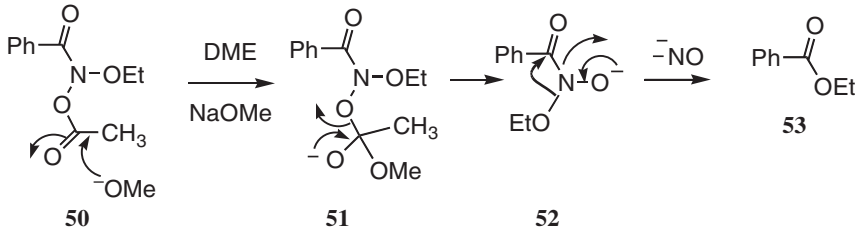
and loss of acetic acid was a useful means of obtaining the corresponding symmetrical and asymmetrical *N*,*N*-dialkoxy derivatives **48** (Scheme 11).

The reaction with *N*-acetoxy-*N*-ethoxybenzamide (**50**) did not result in substitution at nitrogen and a reaction in an aprotic medium with sodium methoxide afforded methyl and ethyl benzoates. They attributed the formation of methyl benzoate to methoxide reaction at the amide carbonyl and the formation of ethyl benzoate (**53**) to a HERON reaction. Presumably, in this medium, attack at the carbonyl of the acetoxyl group would directly lead, by fragmentation of **51**, to the conjugate anion of the *N*-ethoxybenzohydroxamic acid (**52**), followed by the HERON migration of the ethoxy substituent from nitrogen to the benzamide carbonyl (Scheme 12).



The HERON reaction of *N*-acyloxy-*N*-alkoxyamides in the gas phase

HERON rearrangement of *N*-acyloxy-*N*-alkoxyamides has not been observed. In polar solvents (aqueous acetonitrile) anomeric weakening of the AcO—N bond favours heterolysis over migration of the acyloxy substituent. Migration would yield anhydrides, which have never been observed as side products from the $A_{Al}1$ or S_N2 reactions of *N*-acyloxy-*N*-alkoxyamides of our group (1, 6, 21, 32–34) or Shtamburg's recent studies (58).

ESI-tandem mass spectrometric studies on a number of *N*-acyloxy-*N*-alkoxyamides indicated that under these conditions, free from solvent, the sodiated parent ion can be detected, which fragmented under collision-induced dissociative conditions into three sodiated product ions (Table 4). These products exhibited masses corresponding to the sodiated *N*-alkoxyamidyl radical (**54**), which in most cases was the

major pathway (Scheme 13, path A), but the second most intense product ion was the sodiated anhydride **56** formed through HERON rearrangement of the acyl group (Scheme 13, path B). The alternative ester **62** that would be formed through a HERON migration of the alkoxy group (Scheme 13, path C) was a weak product ion in all cases where it was present and absent in the fragmentations of all aliphatic amides (**60h–60l**). The fragments from the reaction processes are presumed to be acyloxyl radical (**55**), alkoxynitrene (**57**), and acyloxynitrene (**59**).

According to B3LYP/6-31G*//HF/6-31G* calculations on **60m** and its HERON rearrangement products in the gas phase, migration of the acyloxyl group is favoured over the alkoxyl group by about 4 kcal mol^{-1} (Table 5). The transition states (Figs. 13*b*–13*d*) are relatively similar with the migrating oxygen perpendicular to the ONC(O) plane, though the HERON transition state for acyl appears looser (Fig. 13*b*), which would be expected because of the polarities involved.

Two conformations of the transition state for methoxyl migration (Figs. 13*c* and 13*d*) were found with very similar energies.

The magnitude of the activation energies indicates that such migrations are unlikely to compete with heterolysis of the N—OAc bond, particularly in polar solvents. While the influence of the spectator sodium ion on these reactions is unknown, clearly, the ESI-MS–MS data reflects the expected migration tendencies of acyl vs. alkoxyl moieties in these substrates. The alkoxyl oxygen, though much more electronegative than nitrogen, is a better donor atom than the acyloxy oxygen, which is bonded to an electron-withdrawing carbonyl carbon, and hence, the acyl group migration would be preferred.

Conclusions

The HERON reaction is one of the newest named reactions (3). In this review we have outlined the discovery of this reaction, theoretical support for the process, as well as instances where there are good grounds to expect its participation. Certainly, it is involved in the reactions of NNO anomeric amides that have tetrahedral amide nitrogens, which is a consequence of the favourable anomeric interaction in those configurations. These reactions, which involve migration of groups from an amide nitrogen to an amide carbonyl carbon, contrast with the known migrations in the reverse direction that are exemplified by the well-documented Hoffman (59), Lossen (60), and Curtius (61) reactions. The reaction is also found in the conversion of 1-acyl-1-alkoxydiazenes, a second step in the thermal decompositions

of *N*,*N*′-diacyl-*N*,*N*′-dialkoxyhydrazines and *N*-alkoxy-*N*-azidoamides that are formed by S_N2 reactions of azide with *N*-chloro- and *N*-acyloxy-*N*-alkoxyamides. The mechanism is also implicated in the reactions of some ONO anomeric amides as exemplified by the rearrangements of alkoxyl groups in basic or weakly acidic solutions of *N*-alkoxyhydroxamic acids, and, most recently, in the gas-phase rearrangements of *N*-acyloxy-*N*-alkoxyamides. In the future, other anomeric amides such as *N*-alkoxy-*N*-haloamides or *N*-amino-*N*-haloamides may well be found to undergo HERON processes.

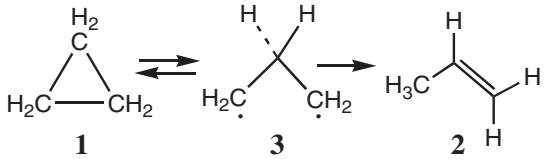
Deuterium kinetic isotope effects on the thermal isomerizations of deuteriocyclopropane to deuterium-labeled propenes[1]

John E. Baldwin and Stephanie R. Singer

Abstract: The gas-phase thermal isomerizations of deuteriocyclopropane to the four possible monodeuterium-labeled propenes have been followed at 435 °C. The observed distribution of products provides estimates of two deuterium kinetic isotope effects, the secondary k_H^s/k_D^s for the carbon–carbon bond cleavage leading to trimethylene diradical reactive intermediates and the primary k_H^p/k_D^p ratio for a [1,2] shift of a hydrogen or deuterium leading from the diradical to a labeled propene. The values determined are k_H^s/k_D^s = 1.09 ± 0.03 and k_H^p/k_D^p = 1.55 ± 0.06. The experimental k_H^s/k_D^s value found agrees well with some, but not all, earlier calculated values and conjectures.

Key words: cyclopropane, thermal rearrangement, kinetic isotope effects.

Résumé : Opérant à 435 °C, on a étudié les réactions d'isomérisation thermiques en phase gazeuse du deutérocyclopropane qui conduisent aux quatre propènes monodeutérés possibles. La distribution observée des produits permet d'évaluer deux des effets isotopiques cinétiques, l'effet isotopique secondaire k_H^s/k_D^s pour la rupture de la liaison carbone–carbone conduisant à la formation d'intermédiaires réactifs diradicalaires triméthylènes et le rapport primaire k_H^p/k_D^p pour le déplacement [1,2] d'un atome d'hydrogène ou de deutérium qui conduit du diradical à un propène marqué. Les valeurs déterminées sont k_H^s/k_D^s = 1,09 ± 0,03 et k_H^p/k_D^p = 1,55 ± 0,06. La valeur expérimentale trouvée pour k_H^s/k_D^s est en bon accord avec les quelques-unes des hypothèses et des valeurs calculées antérieurement, mais pas nécessairement toutes.



Mots clés : cyclopropane, réarrangement thermique, effets isotopiques cinétiques.

[Traduit par la Rédaction]

Introduction

The thermal chemistry of cyclopropane is marvelously complex relative to the small size and high symmetry of the hydrocarbon. This minimal cycloalkane (**1**) undergoes a thermal structural isomerization to propene (**2**) (1, 2). Deuterium-labeled analogs exhibit thermal stereomutations (3), which have been demonstrated to occur through both one-center and two-center epimerizations (4). The structural isomerization and the two types of stereomutations are generally held to involve transient formation of a trimethylene diradical reactive intermediate (**3**), which may revert to cyclopropane or shift a hydrogen from C2 to C1 to afford propene (5–8). The transition-state structure for the rate-determining step in this formulation leading from **3** to **2** has been characterized in several high-level theoretical calculations (9–12).

Interpretations of experimental data providing information about rate constants for the one-center and two-center thermal epimerizations observed for the 1,2-d_2-labeled cyclopropanes depend on secondary deuterium kinetic isotope effects. The importance of k_H^s/k_D^s is easy to grasp: the C1—C2 and C1—C3 bonds of 1,2-d_2-labeled cyclopropanes might well break at different rates. A net one-center epimerization at C1 could occur through cleavage of the C1—C2 bond (rate constant k_1) or when C1—C3 breaks (rate constant k_1'). Simultaneous two-center epimerizations at C1 and C2 (rate constant k_{12}) or at C1 and C3 (rate constant k_{13}) could occur at different rates. The latter two-center event would contribute to an observable one-center epimerization at C1. All of which gets complicated. With rate constant ratios defined as $f_1 = k_1'/k_1$ and $f_{12} = k_{13}/k_{12}$, the two experimental observables, k_i (for the geometrical isomerization equilibrating *cis*- and *trans*-1,2-d_2-cyclopropane) and k_α (for racemization of nonracemic *trans*-1,2-d_2-cyclopropane), are related to the mechanistic rate constant ratio k_{12}/k_1 as in eqs. [1] and [2] (13).

1 **3** **2**

$$[1] \quad \frac{k_i}{k_\alpha} = \frac{2 + \dfrac{(2f_{12}k_{12})}{(k_1 + f_1k_1)}}{1 + \dfrac{(k_{12} + f_{12}k_{12})}{(k_1 + f_1k_1)}}$$

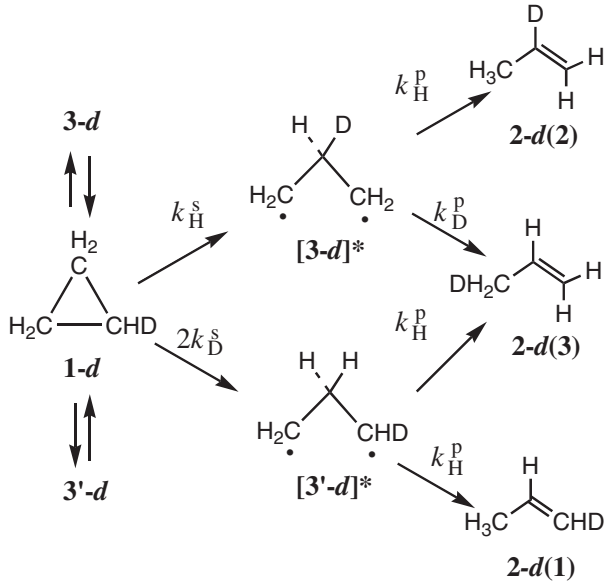
$$[2]\qquad \frac{k_{12}}{k_1} = \frac{2 - \dfrac{k_i}{k_\alpha}}{\dfrac{k_i}{k_\alpha}\dfrac{(1+f_{12})}{(1+f_1)} - \dfrac{2f_{12}}{(1+f_1)}}$$

One way to simplify eq. [2] is to suppose, quite reasonably, that $f_1 \approx f_{12}$, and let $f = f_1 = f_{12}$ (13). One is left with an equation linking two observables with three unknowns (eq. [3]).

$$[3]\qquad \frac{k_{12}}{k_1} = \frac{2 - \dfrac{k_i}{k_\alpha}}{\dfrac{k_i}{k_\alpha} - \dfrac{2f}{(1+f)}}$$



If one could estimate a reliable value of f, then k_{12}/k_1 could be derived from a reliable experimental k_i/k_α ratio. For example, if k_i/k_α were 1.07 as was reported for stereomutations of a nonracemic *trans*-1,2-d_2-cyclopropane at 422.5 °C and f were assumed to be 1.1 (4), then according to eq. [3], k_{12}/k_1 would be 42, a large number leading to the conclusion that the "double methylene rotation mechanism operates to the virtual exclusion of any other pathway" (4). Or one could view the experimental data as leading to the conclusion that double methylene rotation is favored over single methylene rotation by a factor of ≈50 (14).

Later experimental work with a nonracemic 1-^{13}C-1,2,3-d_3-cyclopropane concluded that k_{12}/k_1 is 1 ± 0.2 (15), a finding that has prompted considerable theoretical attention but no consensus on the mechanistic details of the stereomutations or on the dynamics of trimethylene diradicals.

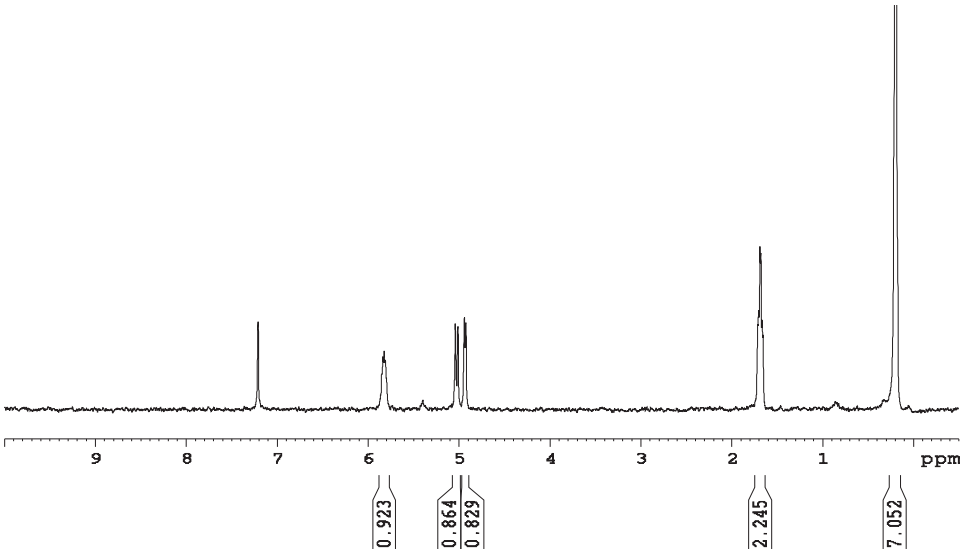
Three groups have provided theory-based estimates of f or k_H/k_D (k_{12}) based on harmonic vibrational frequencies and various kinetic models: 1.13 and 1.12 (at 422.5 °C) (16, 17), and 1.09 (at 400 °C) (18). Other calculations have given rise to theory-based estimates of k_{12}/k_1, an undertaking sensitive to the kinetic model adopted, especially whether or not trimethylene is an intermediate to which transition-state theory may be applied, the potential energy surface used, and whether semiclassical or quantum dynamics calculations are employed. These published theory-based k_{12}/k_1 ratios are 0.94 (17), 1.18 (18), 1.35 (13), 2.2 (19), 2.3 (13), 3.5 (13), and 4.73 (18). The lower ratios are favored when transition-state theory models are applied to the transient trimethylene diradical (20); the higher ratios are calculated using dynamic models in which redistributions of vibrational energy compete poorly with momentum-preserving transits of the diradical over the potential energy surface.

The values of calculated k_H/k_D (k_{12}) ratios depend on the accuracy of theory-derived transition structures and vibrational frequencies, the broad potential energy surface on which the trimethylene diradical lives its brief existence, and whether explicit consideration of torsional potentials may be appropriate; the calculated values may not be correct. Other reasonable values might be more accurate (13). If the ratio f is uncertain within the range 0.8–1.1, and if k_i/k_α were 1.07, then corresponding values of k_{12}/k_1 would be in the range from 5 to 42 (13). Or if f were 0.8 and k_i/k_α were indeed 1.07 then k_{12}/k_1 would be 5, a value close to one theory-based estimate (18). The k_{12}/k_1 ratio is obviously a sensitive function of the value of f. But the k_{12}/k_1 ratio is also a sensitive function of the experimental value of k_i/k_α (eq. [3]).

Fig. 1. Isomerization paths from **1-*d*** to four monodeuteriopropenes.

There have been no *experimentally* estimated values of the secondary deuterium kinetic isotope effect associated with homolytic thermal cleavage of a cyclopropane C—C bond, and no attempts yet published to face the more exacting challenge of measuring the k_H^s/k_D^s ratios for k_1 and k_{12} for the stereomutations of appropriate isotopically labeled cyclopropanes. The present work describes experiments leading to two deuterium kinetic isotope effects of import to thermal cyclopropane-to-propene isomerizations, the secondary k_H^s/k_D^s ratio for C—C bond cleavage and the primary k_H^p/k_D^p effect on [1,2] shifts leading from a deuterium-labeled trimethylene diradical to labeled propenes.

Results and discussion



Deuteriocyclopropane (**1-*d***) was identified as a labeled cyclopropane suitable for gaining an experimental value for the secondary k_H^s/k_D^s effect on the C—C cleavage of cyclopropane. It is easily made and presents no complications related to stereomutations: all one-center and two-center epimerizations for this molecule are unobservable. The isomerizations of **1-*d*** could lead to four monodeuterium-labeled propenes, as diagrammed in Fig. 1. The E- and Z-isomers of **2-*d*(1)** are not shown explicitly.

The model depicted in Fig. 1 recognizes that the lifetime of trimethylene diradicals, about 120 fs (20), is too short for significant intramolecular redistributions of vibrational energy under the gas-phase reaction conditions. Trimethylene diradicals **3-*d*** and **3′-*d***, which lack sufficient vibrational energy to give propenes, revert to **1-*d***. Related trimethylene diradicals with additional isotopic labeling could give rise to stereoisomeric cyclopropanes but not related propenes.

The fractions of trimethylene diradicals having sufficient thermal energy to proceed to propene products would be proportional to $k_H^s/(k_H^s + 2k_D^s)$ for [**3-*d***]* and $2k_D^s/(k_H^s + 2k_D^s)$ for [**3′-*d***]*. The second isotopomer [**3′-*d***]* would be favored, for two CHD—CH_2 bonds of **1-*d*** could be broken.

© 2005 NRC Canada

Fig. 2. ^{2}H NMR spectrum at 92.1 MHz of propene-*d* isomers from the thermal rearrangement of **1-*d*** for 12.5 h at 435 °C.

Diradical [**3-*d***]* could react with rate constant k_H^p to yield **2-*d*(2)**, and with rate constant k_D^p to afford **2-*d*(3)**. The second energized trimethylene diradical ([**3′-*d***]*) could react further through $k^p{}_H$ to give **2-*d*(3)** and through k_H^p in the other direction to provide a mixture of both isomers of **2-*d*(1)**.

All four rate constants for hydrogen shifts in Fig. 1 (k_H^s, k_H^p leading to **2-*d*(2)**, k_H^p leading to **2-*d*(3)**, and k_H^p leading to **2-*d*(1)**) might be conditioned by secondary k_H/k_D effects. The possible β-secondary k_H/k_D contribution to the k_H^s/k_D^s ratio will be considered further when comparisons with theory-predicted k_H^s/k_D^s values are made. Possible secondary effects for the [1,2] shifts associated with rate constants k_H^p for reactions of [**3-*d***]* or [**3′-*d***]* were neglected. The k_H^p/k_D^p ratio was assumed to be largely determined by the primary [1,2] shifts of H vs. D.

Given the model of Fig. 1, the relative concentrations of deuterium-labeled propenes in product mixtures would be as expressed in the proportional relationships shown in eqs. [4]–[6].

[4] $$\textbf{2-}\boldsymbol{d}\textbf{(1)} \propto 2k_H^p k_D^s/(k_H^s + 2k_D^s)$$

[5] $$\textbf{2-}\boldsymbol{d}\textbf{(2)} \propto k_H^p k_H^s/(k_H^s + 2k_D^s)$$

[6] $$\textbf{2-}\boldsymbol{d}\textbf{(3)} \propto (k_H^s k_D^p + 2k_D^s k_H^p)/(k_H^s + 2k_D^s)$$

These proportionalities may be expressed more conveniently by dividing the right-hand sides of each of these three expressions by $k_D^s k_D^p/(k_H^s + 2k_D^s)$ (eqs. [7]–[9]).

[7] $$\textbf{2-}\boldsymbol{d}\textbf{(1)} \propto 2k_H^p/k_D^p$$

[8] $$\textbf{2-}\boldsymbol{d}\textbf{(2)} \propto (k_H^s/k_D^s) \times (k_H^p/k_D^p)$$

[9] $$\textbf{2-}\boldsymbol{d}\textbf{(3)} \propto k_H^s/k_D^s + 2k_H^p/k_D^p$$

The product mixtures from a series of five gas-phase thermal rearrangements of **1-*d*** at 435 °C with cyclopentane as the bath gas were analyzed by ^{2}H NMR in nine independent integrations. A representative spectrum of a product mixture is shown in Fig. 2. The ^{2}H NMR resonance signals are as expected (21), with the distinct vicinal $^3J_{H\text{-}D}$ coupling constants for the E- and Z-isomers of **2-*d*(1)** in clear evidence. Unreacted **1-*d*** is evident as a doublet centered at 0.22 ppm, with $^2J_{H\text{-}D}$ = 0.95 Hz.

The intensities of the various ^{2}H NMR absorptions were determined without broadband proton decoupling so as to obviate possible NOE effects. For all but one integration, the pulse delay was 50 s; for the last 20 h run, the delay was 10 s. No significant differences in relative intensities at different reaction times were noted (Table 1), and no appreciable complications from secondary reactions were evident. Two minor absorptions (at 5.4 and 0.9 ppm) were contributed by unidentified side products (Fig. 2).

The relative ^{2}H NMR integral intensities of Z- and E-isomers of **2-*d*(1)** were 17.2 ± 0.46% and 17.3 ± 0.39%, respectively, equal within experimental uncertainties. The relative intensities for **2-*d*** isomers and for unreacted **1-*d*** as a function of reaction time showed a simple exponential decay of starting material corresponding to a rate constant for isomerzations of 1.13×10^{-5} s^{-1}. The high-pressure rate constant for rearrangement of unlabeled cyclopropane at 435 °C may be calculated from the activation parameters reported by Chambers and Kistiakowsky (22), $\log_{10} A$ = 15.17, E_a 65.0 kcal/mol (1 cal = 4.184 J): it is 1.29×10^{-5} s^{-1}, just slightly larger than the rate constant derived here. The difference may be ascribed to a combination of two factors: the pressure in the kinetic bulb during thermal reactions with cyclopentane present as a bath gas (113 to 114 torr, 1 torr = 133.322 4 Pa), is less than would be required to give kinetic behavior at the high-pressure limit, and deuterium kinetic isotope effects could lower the rate of isomerization moderately.

The experimental data summarized in Table 1 and the relationships shown in eqs. [7]–[9] lead easily to values for the two deuterium isotope effects involved, k_H^s/k_D^s for cleaving a cyclopropane C—C bond and k_H^p/k_D^p for shifting a hydrogen or deuterium from C2 to C1 in the trimethylene diradical **3-*d***. The three expressions (eqs. [7]–[9]) are just proportionalities; they can be used to formulate two independent equations with two unknowns. From eqs. [7] and [8], eq. [10] follows, and $k_H^s/k_D^s = 2 \times 18.8/34.6 = 1.09$.

Table 1. Relative intensities of ^{2}H NMR absorptions for propene-*d* products from thermal isomerizations of deuteriocyclopropane at 435 °C.

Time (h)	**2-*d*(2)** (%) (5.87 ppm)	**2-*d*(1)** (Z and E) (%) (5.07 and 4.98 ppm)	**2-*d*(3)** (%) (1.64 ppm)
7.5	18.6	34.7	46.7
10	18.9	35.4	45.7
10	18.8	35.2	46.0
12.5	19.7	34.5	45.8
12.5	19.0	34.8	46.2
5	18.0	33.3	48.7
20	18.9	33.9	47.2
20	18.4	34.4	47.2
20	18.5	35.3	46.2
Average	18.8	34.6	46.6
Standard deviation	0.4	0.6	0.8
Relative error	1.9	1.7	1.7

[10] $$[\mathbf{2\text{-}d(1)}]/[\mathbf{2\text{-}d(2)}] = 2/(k_H^s/k_D^s)$$

An equation may be constructed from eqs. [8] and [9] with but a single unknown, the primary kinetic isotope effect rate-constant ratio, k_H^p/k_D^p (eq. [11]).

[11] $$[\mathbf{2\text{-}d(3)}]/[\mathbf{2\text{-}d(2)}] = (k_H^s/k_D^s + 2k_H^p/k_D^p)/[(k_H^s/k_D^s) \times (k_H^p/k_D^p)]$$

Rearranging eq. [11] to express k_H^p/k_D^p as a function of knowns gives eq. [12], which leads at once to the solution $k_H^p/k_D^p = 1.55$.

[12] $$k_H^p/k_D^p = (k_H^s/k_D^s)/\{(k_H^s/k_D^s) \times [\mathbf{2\text{-}d(3)}]/[\mathbf{2\text{-}d(2)}] - 2\}$$

When the experimental uncertainties in the integrated NMR absorption intensities are taken into account, the two isotope effects and error estimates are $k_H^s/k_D^s = 1.09 \pm 0.03$ and $k_H^p/k_D^p = 1.55 \pm 0.06$.

How significantly would these estimates be altered if a minor contribution to the overall isomerization from a different path, one involving a direct rate-determining isomerization of **1-*d*** to a monodeuterium-labeled singlet 1-propylidene reactive intermediate, followed by a very rapid [1,2]-hydrogen or [1,2]-deuterium shift (12)? Were this hypothetical path a contributor, there would be some bias favoring the formation of **2-*d*(2)** at the expense of the other three propene-*d* isotopomers. Primary kinetic isotope effects could be involved at two stages, during formation of a propylene-*d* intermediate or during a [1,2] shift. But a contribution of as much as 10% by such a path would not lead to significant changes in the estimated values for k_H^s/k_D^s (1.09 ± 0.03) and k_H^p/k_D^p (1.55 ± 0.06). Were the primary k_H/k_D effects on the cyclopropane to 1-propylene to propene route equal to 1.6, and the secondary effect 1.09 once again, the changes in the calculated distributions of **2-*d*** isomers would lead to calculated k_H^s/k_D^s and k_H^p/k_D^p values of 1.11 and 1.63, estimates very close to the values based on taking the trimethylene diradical intermediate mechanistic model to be the only path. A minor contribution from the 1-propylidene route would not influence the two kinetic isotope effect estimations significantly (23).

The kinetic model adopted and the experimental observations of the present work define k_H^s/k_D^s as the ratio of rate constants leading from **1-*d*** to [**3-*d***]* and from **1-*d*** to [**3′-*d***]*. The value obtained for k_H^s/k_D^s (1.09 ± 0.03) is a composite of α and β effects. The α effect influences the cleavage leading to **3′-*d*** and the β effect influences the cleavage leading to **3-*d***, each relative to the rate constant for cleaving one C—C bond in unlabeled cyclopropane. Thus, k_H^s/k_D^s is a ratio of one rate constant modified by a β secondary effect divided by one conditioned by an α effect.

Direct comparisons with the theory-derived values for k_{13} vs. k_{12} rate constants in 1,2-d_2-cyclopropanes previously cited, 1.13 and 1.12 (at 422.5 °C) (16, 17) and 1.09 (at 400 °C) (18), are appropriate, for k_{13} in conditioned by the product of one α and one β effect, while k_{12} is conditioned by the product of two α effects. The k_{13}/k_{12} ratio, the *f* factor, is equivalent to the present k_H^s/k_D^s ratio. Thus, the experimental value 1.09 ± 0.03 is completely consistent with the value assumed in 1975 (4) and with the several subsequent theory-derived values (16–18).

The hypothetical $k_H^s/k_D^s = 0.8$ value may successfully serve as a device for reinterpreting one reported k_i/k_α value for 1,2-d_2-cyclopropanes (1.07) as consistent with $k_{12}/k_1 \approx 5$, a ratio found in one theory-based model for the stereomutations (18). With $k_H^s/k_D^s = 0.8$, the earlier conclusion (4) that $k_{12}/k_1 \approx 42$ could be abandoned, while the experimentally reported (4) rate constant ratio ($k_i/k_\alpha = 1.07$) could remain unquestioned. The present experimental value ($k_H^s/k_D^s = 1.09 \pm 0.03$) makes the hypothetical $k_H^s/k_D^s = 0.8$ value seem unlikely. The discrepancies in the literature as to the k_{12}/k_1 ratio for cyclopropane stereomutations may hinge more plausibly on problems associated with experimental determinations of k_i and k_α values than in different judgments on the k_H^s/k_D^s ratio (15*e*).

Experimental section

Deuteriocyclopropane

To an oven-dried, heavy-walled tube fitted with a stopcock and provided with an argon atmosphere and a tiny stir-

© 2005 NRC Canada

ring bar was added, in turn, AIBN (0.10 g, 0.61 mmol), Bu_3SnD (2.0 g, 1.8 mL, 6.8 mmol), and cyclopropyl bromide (0.39 g, 3.2 mmol). The stopcock was closed and the reaction tube was heated at 85 °C for 5 h. The reaction mixture was then cooled to room temperature; the stopcock was opened to allow the volatile materials in the product mixture to be collected in an evacuated glass coil cooled in liquid nitrogen. The deuterium-labeled cyclopropane product was purified and isolated by preparative gas chromatography (15*c*) using a modified Varian Aerograph A90-P3 instrument and a 0.63 cm × 3.7 m 20% SE-30 60/80 mesh Chromosorb W HMDS column.

Thermal isomerizations

The glass collection vessel containing the preparative GC purified **1-*d*** was connected to a glass adapter containing 3 Å molecular sieves; the adapter led to a vacuum line. The sample was cooled with liquid nitrogen and the helium present was removed from the collection vessel and the vacuum line. The cooling bath was removed to allow the gas to volatilize and fill the vacuum line. The pressure of gas in the line was noted, and the **1-*d*** sample was condensed in a small cold finger in the vacuum line close to the kinetic bulb with liquid nitrogen and a small Dewar. The pressure remaining in the line was noted, and a stopcock was closed to isolate the condensed **1-*d***. The difference in the two pressures recorded and the volume of the line defined the amount of **1-*d*** that had been condensed. The **1-*d*** remaining in the line was removed. Cyclopentane (anhydrous, Aldrich, Milwaukee, Wisconsin) in a glass coil was degassed 3 times using a freeze–thaw routine, allowed to warm, and admitted to the vacuum line. The pressure in the line was noted, the cyclopentane was condensed into the small cold finger containing the **1-*d*** sample, the stopcock was closed to isolate the condensed hydrocarbons, and the pressure in the line from the remaining cyclopentane was noted. The two pressure readings provided a measure of the amount of cyclopentane that had been condensed. The cyclopentane remaining in the line was pumped off.

The condensed mixture of **1-*d*** and cyclopentane was allowed to expand into an evacuated 280 mL kinetic bulb over a 2 min period by appropriate manipulations of stopcocks and warming the cold finger with hot water. The kinetic bulb was closed, the small amount of reactant and cyclopentane remaining between the cold finger and the cut-off stopcock atop the kinetic bulb was determined manometrically and then evacuated from the vacuum line.

When the designated time for a thermal isomerization had elapsed, the reaction mixture was quickly transferred from the kinetic bulb and collected in an evacuated u-tube immersed in liquid nitrogen. Subsequently the product mixture was transferred from the u-tube to a degassed NMR tube containing $CHCl_3$ and immersed in liquid nitrogen; the tube was sealed and the product mixture was analyzed by ^2H NMR spectroscopy at 92.1 MHz.

Thermal runs over 7.5, 10, 12.5, and 20 h used from 8.7 to 9.2 mg of **1-*d*** and 42 to 43 mg of cyclopentane; pressures in the kinetic bulb were 113 to 114 torr. The single run over 15 h employed 8.3 mg of **1-*d*** and no cyclopentane; the pressure was only 24 torr. The isomerization for this run was notably slower, but the distribution of **2-*d*** products was consistent with the distributions observed in other product mixtures (Table 1). The conversion vs. time data used to calculate the rate constant 1.29×10^{-5} s^{-1} for the **1-*d*** to **2-*d*** isomerizations did not include the run in which cyclopentane was not present.

The kinetics of the spontaneous, proton- and Al^{III}-catalysed hydrolysis of 1,5-anhydrocellobiitol — Models for cellulose depolymerization in paper aging and alkaline pulping, and a benchmark for cellulase efficiency[1]

John William Baty and Michael L. Sinnott

Abstract: The kinetics of the spontaneous, proton- and Al^{III}-catalysed hydrolyses of the C1—O4′ bond in 1,5-anhydrocellobiitol have been measured at elevated temperatures (125.0–220.0 °C). Data for the first two processes extrapolate to the expression $k = (8.6 \pm 2.1 \times 10^{-16}) + (1.4 \pm 0.2 \times 10^{-9\text{-pH}})$ s^{-1} at 25 °C. These room-temperature figures were used to model cellulose depolymerization by the af Ekenstam equation. The spontaneous process is too slow to contribute to loss of paper strength on aging, and even the acid-catalysed process is significant only below ~pH 4.0. However, the spontaneous hydrolysis readily accounts for the reduction of cellulose degree of polymerization (DP) during alkaline (e.g., kraft) pulping of cellulose fibres. Efficient electrophilic catalysis by Al^{III} was observed at 150.0 °C in 0.1 mol/L succinate buffers of room temperature pH 3.05 and 3.35 ($k_2 = 8.1 \pm 0.4 \times 10^{-3}$ and $4.2 \pm 0.2 \times 10^{-3}$ $(mol/L)^{-1}$ s^{-1}, respectively). The apparent activation energy of the Al^{III}-catalysed process was 31 ± 4 kJ mol^{-1}, lower than that of the proton-catalysed path, suggesting the electrophilic catalysis increases in importance as the temperature approaches ambient. Consequently, it appears that the culprit in the impermanence of "rosin-alum"-sized paper is Al^{III}, directly acting as a Lewis acid, not the Al^{III} hydration sphere as a Brønsted acid. Conservation measures should either address this or be generic (e.g., low-temperature storage).

Key words: cellulose, hydrolysis, kraft pulping, paper conservation, rosin-alum sizing.

Résumé : Opérant à des températures élevées (125,0 à 220,0 °C), on a mesuré les vitesses des réactions d'hydrolyse, spontanée et catalysées par le proton ou l'aluminium(III), de la liaison C1—O4′ du 1,5-anhydrocellobiitol. Les données pour les deux premiers processus conduisent à l'expression $k = (8{,}6 \pm 2{,}1 \times 10^{-16}) + (1{,}4 \pm 0{,}2 \times 10^{-9\text{-pH}})$ s^{-1} extrapolée à 25 °C. On a utilisé ces valeurs à la température ambiante comme modèle pour la dépolymérisation de la cellulose par l'équation de af Ekenstam. Le processus spontané est trop lent pour contribuer à une perte de la force du papier avec l'âge; le processus catalysé par un acide n'est significatif qu'à des pH inférieurs à environ 4,0. Toutefois, l'hydrolyse spontanée permet d'expliquer facilement la réduction du degré de polymérisation (DP) de la cellulose durant le traitement alcalin (kraft) des fibres de cellulose. On a observé une catalyse électrophile efficace par l'aluminium(III) à 150,0 °C, dans des tampons de succinate, à la température ambiante et à des pH de 3,05 et 3,35 ($k_2 = 8{,}1 \pm 0{,}4 \times 10^{-3}$ et $4{,}2 \pm 0{,}2 \times 10^{-3}$ $(mol/L)^{-1}$ s^{-1} respectivement). L'énergie d'activation apparente pour le processus catalysé par l'aluminium(III) est de 31 ± 4 kJ mol^{-1}, inférieure à celle du processus catalysé par le proton, ce qui suggère que la catalyse électrophile augmente en importance lorsque la température tend vers la température ambiante. En conséquence, il semble que le coupable de la non permanence du papier collage à la rosine et à l'alun serait l'aluminium(III) qui agirait directement comme acide de Lewis et non pas la sphère d'hydratation de l'aluminium(III) qui agirait comme un acide de Brønsted. Les mesures de conservation devraient tenir compte de ces conclusions ou être génériques, tel qu'un entreposage à basse température.

Mots clés : cellulose, hydrolyse, pulpage alcalin, conservation du papier, traitement à la rosine et à l'alun.

Introduction

The loss of mechanical strength of cellulose fibres with age is an important limiting factor in the preservation of paper documents and, to a lesser extent, textiles. The degradation of paper in particular threatens much of our written cultural heritage (1). Loss of paper strength is associated with a decrease in the degree of polymerization (DP) of the cellulose in the paper fibres (2*a*). Some depolymerization arises from initial oxidation of the hydroxyls in cellulose to carbonyl groups, which can then promote E1cb-like elimination of O4 and its substituent, leading to cellulose chain cleavage. The oxidation can arise from excess use of oxidative bleaching agents or photooxidation (3).

However, much paper degradation (particularly that occurring under conditions of archival storage) does not occur by these routes, and appears to be a hydrolysis. Hydrolytic degradation is confirmed by the detection of glucose, cellobiose, and cellotriose in naturally aged papers (4). Paper is 4%–9% water by weight (5), and the aqueous hydrolysis of the β(1→4) link in the noncrystalline regions of the cellulose fibre is the depolymerization route.

We here report studies of the kinetics of hydrolysis of 1,5-anhydrocellobiitol by spontaneous and electrophile-catalysed routes. We also report data on the hydrolysis of this compound by the well-known acid-catalysed mechanism, but at high-temperature and (room-temperature) pH 3.1–4.0, to permit comparison with the first two routes without large extrapolation of acid strength. This compound, rather than cellobiose itself, was used as the model for the β(1→4) link in cellulose to avoid the carbonyl group rearrangement and elimination reactions, which had vitiated a previous attempt to measure the rate of spontaneous hydrolysis of a β(1→4) glucan link (6).

The spontaneous hydrolysis of 2,4-dinitrophenyl glycosides has been known for some time (7) and effects of glycone structure have been studied in detail (8). Since the glucopyranosyl cation is "too unstable to exist" in contact with an anionic leaving group (9), such hydrolyses are S_N2 (A_ND_N) reactions with "exploded" transition states with little bonding to either nucleophilic water or the leaving group (10). Multiple kinetic isotope effects with fluoride as a leaving group support such a picture (11). The $\log k_{hyd}$ vs. pH plot for 2,4-dinitrophenyl β-galactopyranoside was horizontal between pH 2 and 8, that for *p*-nitrophenyl β-glucopyranoside between pH 3 and 6 (12). However, the expectation that the horizontal region for such plots would get smaller as the leaving group became worse was confounded by the recent discovery of a spontaneous hydrolysis pathway for methyl glycosides. Wolfenden et al. (13) measured the rates of methyl β- and α-D-glucopyranoside and -ribofuranoside hydrolysis at 180–260 °C and observed rates independent of the buffer room-temperature pH between 7 and 11. Their data for methyl β-D-glucopyranoside extrapolate to a rate of $4.7 \pm 2.1 \times 10^{-15}$ s^{-1} at 25 °C, a figure they noted may be of significance to paper degradation. We considered that departure of the 4-anion of glucose might be faster than that of methoxide for steric and electronic reasons. The anticipated β_{lg} value of the spontaneous hydrolysis of glycosides is expected to be between that for the spontaneous hydrolyses of aryloxytetrahydropyrans (–1.18) and methoxymethyl carboxylates (–0.82) (14). The former generates a solvent-equilibrated tetrahydropyranyl cation; the latter is an unambiguous S_N2 (A_ND_N) reaction. The pK_a of methanol is 15.54 (15); whereas that for the 2-OH of glucose is 14.0 (16), and the 4-OH is likely to be similar. Further, it seems as if the β(1→4) linkage between two hexopyranose units is somewhat crowded: equilibrium constants for the hydrolysis of lactose and allolactose (the β(1→6) isomer) at 37 °C are 152 ± 19 mol/L and ~44 mol/L, respectively (17). It seemed likely that the spontaneous hydrolysis of 1,5-anhydrocellobiitol would be faster than that of methyl β-D-glucopyranoside by over one order of magnitude because of electronic effects, and a factor of ~2 through steric acceleration. Were this to be the case at room temperature, spontaneous hydrolysis would be a major contributor to paper degradation.

Paper from around the middle of the 19th century until about the mid-1970s loses mechanical strength comparatively quickly, so that 19th and early 20th century documents can be in worse condition than books and papers from the 17th and 18th centuries. The culprit is "rosin-alum" sizing (sizing with diterpene acids and aluminium sulfate — not $KAl(SO_4)_2{\cdot}12H_2O$), invented in 1800 and widespread by the 1840s (18). Paper conservators have hitherto assumed that rosin-alum-sized paper principally degrades via the proton-catalysed mechanism, with the aluminium hydration sphere acting as a source of protons (19). Policies of mass deacidification of documents have followed from this assumption (20) despite occasional paper technology studies suggesting the picture was more complicated. For example, differing activation energies from differential thermal analyses led Parks to conclude, "Sulfuric acid has a destabilizing effect qualitatively different from that of [aluminium sulfate]…" (21). Barański et al. (22) measured the macroscopic kinetics of the degradation of $Al_2(SO_4)_3$-impregnated papers and concluded that mixed-control-type kinetic equations, taking into account other processes, were required. In 1993, it was remarked "Considering that rosin sizing is still widely used after 140 years, and that in commercial operations aluminium compounds are invariably involved, it is a matter for some astonishment that we still do not know for certain the exact mechanism by which aluminium compounds affect permanence…" (23).

We hypothesized that Al^{III} species in rosin-alum-sized paper might be directly acting as electrophiles rather than as a source of protons. The hypothesis had a chemical precedent in the electrophilic catalysis of the hydrolysis of 8-quinolinyl β-D-glucopyranosides by first-row transition metal ions (24, 25) and a possible biochemical one in the Mg^{II}-dependence of the hydrolysis of *O*-glycosides by the *lacZ* β-galactosidase of *Escherichia coli* (26). A preliminary report of catalysis of 1,5-anhydrocellobiitol hydrolysis by Al^{III} has been published (27); we now report full details and apply the measured rate data to the depolymerization of cellulose, modelled with the af Ekenstam equation.

The proton-catalysed hydrolysis of cellulose has received much attention over the years. Macroscopic kinetic studies have been prompted by technology, such as the industrial manufacture of microcrystalline cellulose (28), the development of biomass fuels and feeds (29, 30*a*), the acid pulping of biomass for paper (30*b*), and the permanence and conservation of cellulosic textiles and paper (31, 32). The acid-

© 2005 NRC Canada

catalysed hydrolysis of glycosides in general has been extensively studied. Pyranosides hydrolyse by initial protonation of the exocyclic oxygen atom followed by C1-O1 fission. In the case of alkyl glycosides, the protonation step is a pre-equilibrium one (i.e., specific acid catalysis) (33, 34). Any nucleophilic involvement is questionable. The leaving group is electrically neutral (and, with a late transition state, results in $\beta_{lg} \sim 0$). Recent work on 2-deoxy-β-glucopyranosyl pyridinium salts, with likewise an electrically neutral leaving group, suggests that the rate-determining step is formation of a solvent-separated ion-pair-molecule complex (i.e., $X^-//Glu^+Py$) (35). An analogous process would explain the dependence of acid-catalysed hydrolysis reactions on the nature, but not the nucleophilicity, of anions present (33, 36). Limited data for the hydrolysis of 1,5-anhydrocellobiitol in mildly acid media were therefore obtained, largely to establish the "turnround" point on the pH–rate profile, and to compare to the electrophile-catalysed process.

Materials and methods

1,5-Anhydrocellobiitol ((4-*O*-β-D-glucopyranosyl)-1,5-anhydro-D-glucitol) was prepared according to Zhang (37), who adapted Fletcher's route to 1,5-anhydroglucitol (38). Reduction of ethyl (heptacetyl-β-cellobiosyl) xanthate with Raney nickel afforded hepa-*O*-acetyl-1,5-anhydrocellobiitol, mp 194 to 195 °C (lit. value (39) mp 194 to 195 °C). Zemplén deacetylation afforded a material mp of 170 °C (decomp.), lit. value (39) mp 172 °C (decomp.), $[\alpha]_D^{20}$ 29° (lit. value 29.3). Spin-decoupled ^{13}C NMR 10 lines, d 103 (C1), double intensity 76.5 (C6 and C6′), and 79.5 (C5 and C5′).

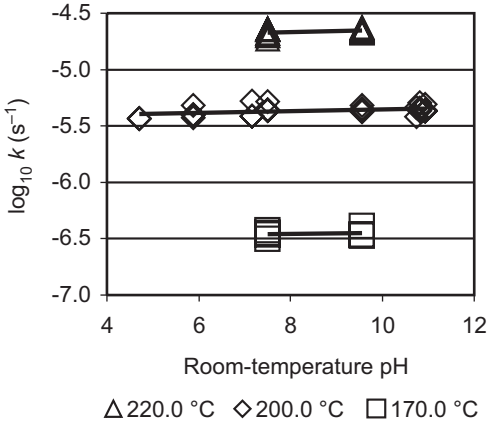
Reaction solutions containing 1,5-anhydrocellobiitol substrate in buffer (including, where applicable, catalysts or catalytic controls) were sealed inside small ampoules made from melting point capillaries (Fisher Scientific Co.) and submerged into a thermostatted oil bath (Labovisco-PMT Tamson TC 9E). Oil temperatures were verified using a mercury-in-glass thermometer calibrated by the UK National Physical Laboratory, Teddington. After various time intervals the ampoules were removed, opened, and the proportions of 1,5-anhydrocellobiitol and 1,5-anhydroglucitol analyzed by high-performance liquid chromatography – refractive index detection (pH 3.0–4.0, all components by Gilson Medical Instruments, Inc., supplied by Anachem Ltd., Luton, Beds, UK, except the column by YMC (YMC-Polyamine II)) or high-performance anion exchange chromatography – pulsed amperometric detection (pH 4.7–11.0, all components by Dionex (UK) Ltd., Camberley, Surrey, UK, including the CarboPac PA-10 column). Because of the high surface area of the capillaries and the exposure time of hours to days, warm-up and cool-down times were negligible.

The concentration of substrate in the sample solutions was selected for optimal detection. For refractive index detection (HPLC) this was 10 mmol/L and for pulsed amperometric detection (HPAE) it was 3.07×10^{-4} mol/L. One hydrolysis product of 1,5-anhydrocellobiitol, glucose, is expected to degrade rapidly at high temperatures to carboxylic acids and other compounds (13, 40). To accommodate these, a ratio of 10:1 molar ionic strength buffer to molar substrate was selected for all reactions conducted. The pH of all samples was measured at room temperature and rechecked with narrow-range pH paper after exposure. Oxygen – acid buffer systems, with small heats of ionization, were used to minimize dpH/d*T*. Further criteria for buffer suitability were solubility in the chromatographic mobile phase and noninterference with detection. For HPLC–RI, succinic acid – succinate buffers (pH 3.0–4.0) were selected. For HPAE–PAD, acetic acid – acetate (pH 4.7), monobasic phosphate – dibasic phosphate (pH 5.9–7.5), and dibasic phosphate – tribasic phosphate (pH 9.6–10.7) were used.

We considered general acid catalysis of substrate hydrolysis by buffers highly unlikely in these studies. General acid catalysis of glycosides is favoured where acidic leaving groups make the conjugate acid of the substrate too unstable to exist (34). The mode of acid catalysis of the hydrolysis of *p*-nitrophenyl glucopyranoside changes from general at 45 °C to specific at 75 °C (41).

The Al^{III} ion has a complicated aqueous coordination chemistry, with certain insoluble species predominating under certain conditions (42). Therefore, in the electrophilic catalysis study, samples were monitored for any loss of homogeneity. Samples exhibiting a loss of homogeneity were discarded because of the risk of crystal entrainment. The Al^{III} ion was added as $Al_2(SO_4)_3 \cdot nH_2O$, the salt employed in the rosin-alum-sizing method. In the study comparing the rates of proton vs. electrophilic catalysis, concentrations of $Al_2(SO_4)_3$ ranging from 0 to 20 mmol/L were employed.

Results and discussion



The spontaneous hydrolysis of 1,5-anhydrocellobiitol

Figure 1 shows $\log_{10}k_{obs}$ for hydrolysis of 1,5-anhydrocellobiitol as a function of room-temperature pH at three temperatures; individual constants are listed in the Supplementary material.[4] The gradients of these plots are 0.017 ± 0.005 at 220.0 °C, 0.007 ± 0.004 at 200.0 °C, and 0.005 ± 0.012 at 170.0 °C, effectively zero. The alkaline degradation mechanisms of 1,5-anhydrocellobiitol observed by Brandon occurred in NaOH solution (0.5–2.5 mol/L, H_- 14–15) (43*a*) and are therefore unlikely to be important in our pH range. As expected, a pH-independent reaction similar to methyl β-D-glucopyranoside has been observed. At 220.0 °C, where the two sets of data can be compared without extrapolation, the rate for 1.5-anhydrocellobiitol is about an order of magnitude faster than for methyl β-D-glucopyranoside ($\log_{10}k_{obs}$ = –4.66 ± 0.03 and ~–5.8, respectively), confirming our analysis of electronic and steric effects. The E_a from data at 220.0, 200.0, and 170.0 °C is 149 ± 2 kJ mol^{-1} at (room-temperature) pH 7.5, and 151 ± 2 kJ mol^{-1} at (room-temperature) pH 9.6. An average figure for the entropy change of activation at ambient temperature ($\Delta S^{\ddagger}_{25\,°C}$) is calculated to be –38 ± 3 J mol^{-1} K^{-1}.

Fig. 1. k_{obs} vs. room-temperature pH. The pH dependence of the spontaneous hydrolysis of 1,5-anhydrocellobiitol measured at three temperatures.

Our E_a figure is significantly higher than the value from Wolfenden et al. (13) for the spontaneous hydrolysis of methyl β-D-glucopyranoside (124 ± 6 kJ mol^{-1}), but is in line with their unpublished results on the spontaneous hydrolysis of trehalose (155 kJ mol^{-1}, personal communication from R. Wolfenden). The value for the spontaneous hydrolysis of methyl β-D-glucopyranoside is similar to that of several 2,4-dinitrophenyl β-D-glycopyranosides (108–126 kJ mol^{-1}), which, however, react some 10^{10}-fold faster (8). Our value for $\Delta S^{\ddagger}_{25\,°C}$ is lower than has been observed in other spontaneous hydrolysis systems, but not as low as observed by Wolfenden et al. (13) for methyl β-D-glucopyranoside (–99.6 ± 3.1 J mol^{-1} K^{-1}). The difference in our E_a for 1,5-anhydrocellobiitol from the value obtained by Wolfenden et al. (13) for methyl β-D-glucopyranoside is such that while the spontaneous hydrolysis of 1,5-anhydrocellobiitol is faster at the temperatures tested, it extrapolated to lower rates at ambient temperatures (8.6 ± 2.1 × 10^{-16} s^{-1} at 25.0 °C as against 4.7 ± 2.1 × 10^{-15} s^{-1}). It may be that departure of methoxide requires immobilization of a water molecule as proton donor, but that departure of the glucose 1-anion or 4-anion does not.

True endoglucanases have k_{cat} values around 30 s^{-1} when acting on long cellooligosaccharides (44). They therefore achieve a rate enhancement of ~3 × 10^{16} over the uncatalysed mechanism measured with our model.

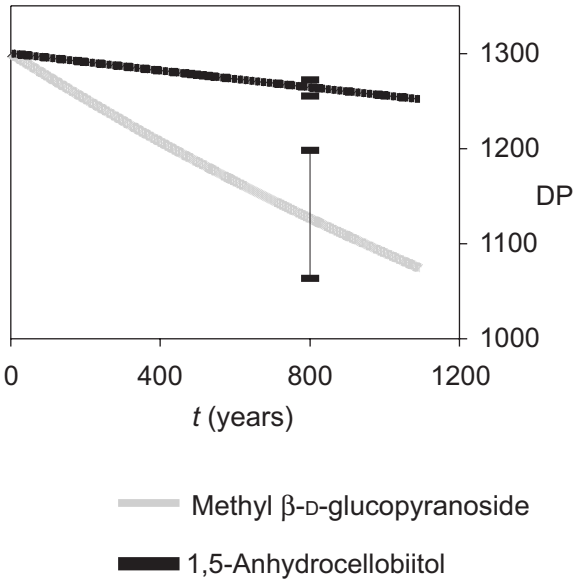
Depolymerization of cellulose modelled using the af Ekenstam equation

af Ekenstam derived eq. [1] relating the degree of polymerization to the first-order rate constant for the cleavage of a specific linkage. Random chain fission and rates of cleavage independent of position in the chain were assumed (45).

$$[1] \qquad \ln(1 - DP_t^{-1}) - \ln(1 - DP_0^{-1}) = -kt$$

where DP_0 and DP_t are the degrees of polymerization initially and at time t, respectively, and k is the first-order microscopic rate constant for cleavage of an individual linkage, assumed to be invariant across the chain. Whilst this equation is normally used to calculate k from DP data, we reversed the process, inputting k from our model studies. This assumes that the cellulose is in dilute aqueous solution, like the model. The periodic crystalline regions of native cellulose, which are sites of very limited aqueous chemistry, are therefore neglected. Therefore, our results will overestimate the true rate of cellulose depolymerization by a particular mechanism.

Fig. 2. DP vs. t at 25 °C. Calculated from af Ekenstam eq. [1], substituting a DP_0 of 1300 and the extrapolated values for $k_{25\,°C}$ from methyl β-D-glucopyranoside (13) and 1,5-anhydrocellobiitol.



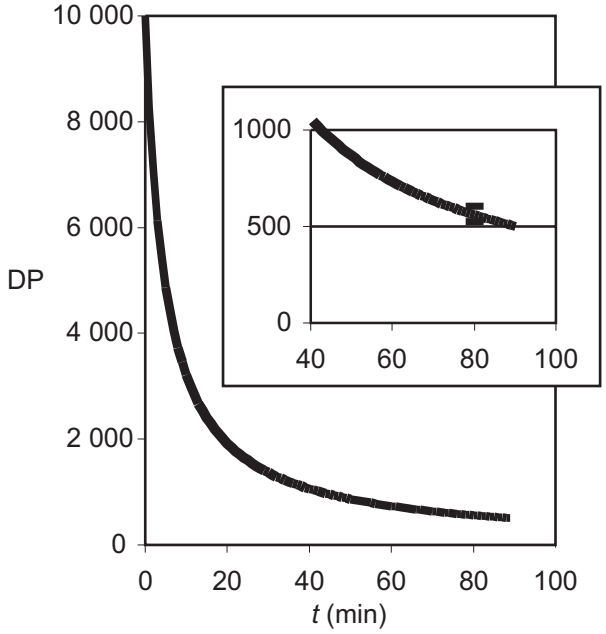


Figure 2 models cellulose depolymerization due to the spontaneous hydrolysis mechanism over time at 25 °C. The DP_0 used (1300) is that commonly taken for the cellulose in softwood kraft pulp (2*b*, 46); the specific rate constants used are that previously given for 1,5-anhydrocellobiitol and that reported by Wolfenden et al. (13) for methyl β-D-glucopyranoside. These models strongly suggest that spontaneous hydrolysis is not likely to be a problem encountered in neutral and alkaline papers in archives. The retained DP of ~1250 after 1000 years is far more than the ~400 at which brittleness becomes a problem in paper (2*a*).

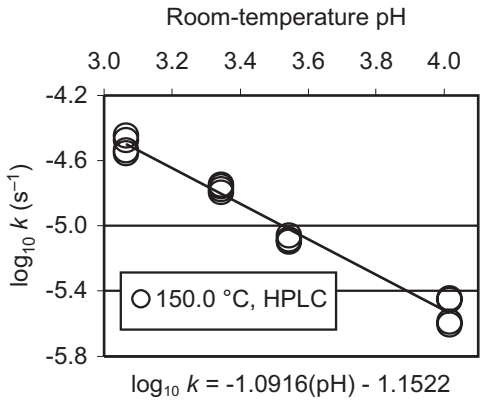
A major element of the kraft process of paper pulping is the "cook phase" in which wood chips are exposed to conditions of pH 12–14 and 170–173 °C for roughly 90 min after warm-up (47). In this process, a DP loss from the biosynthetic ~10 000 (30*c*) to ~1300 occurs (2*b*). This loss in DP has been attributed to alkaline degradation mechanisms including β-alkoxy elimination (also known as the "peeling reaction" because it proceeds endwise) and unimolecular nucleophilic substitution that results from hydroxyl ionization. Previous molecular model studies of this process have not identified a spontaneous hydrolysis mechanism (43*b*, 48–50).

Figure 3 plots DP vs. t, showing the depolymerization of cellulose because of spontaneous hydrolysis modelled with 1,5-anhydrocellobiitol using the af Ekenstam eq. [1] and a DP_0 value of 10 000. The specific rate constant used in this model (3.5 ± 0.3 × 10^{-7} s^{-1}) is the average value of two data series obtained with good precision at 170.0 °C. (See Fig. 1 and Supplementary material).[4] As previously argued, the hydrolysis of 1,5-anhydrocellobiitol observed at these pH values will be exclusively due to the spontaneous hydrolysis

© 2005 NRC Canada

Fig. 3. DP vs. t at 170.0 °C. Depolymerization of cellulose during kraft cooking owing exclusively to spontaneous hydrolysis, modelled with 1,5-anhydrocellobiitol using af Ekenstam eq. [1] and a DP_0 of 10 000. The k_{obs} value used is an average of two data series (pH 7.5 and 9.6) obtained at 170.0 °C. Inset: Detail of depolymerization (40–90 min).

mechanism. As shown in the inset of Fig. 3, this model predicts that spontaneous hydrolysis alone reduces the DP of the cellulose to 502 ± 37 after 90 min under kraft cooking conditions, which is appreciably shorter than the actual DP after kraft cooking. An overestimate of DP loss, however, is expected here for two reasons. First, as previously noted, this model assumes that all of each cellulose chain is soluble. Second, in native wood chips, cellulose is part of a composite in which the matrix is (hydrophobic) lignin. On the introduction of the wood chips into the digester, only the surface of the chips is in contact with the kraft cooking liquor. Nonetheless, the reduction in DP is so large as to point unambiguously to the spontaneous hydrolysis mechanism as a primary mechanism of cellulose depolymerization in the kraft process.



Given the relation between DP and paper strength, spontaneous hydrolysis is the primary mechanism in limiting the strength of papers made from kraft pulp.

The proton-catalysed hydrolysis of 1,5-anhydrocellobiitol

The slope of the plot (Fig. 4) of $\log_{10}k_{obs}$ (150.0 °C) vs. room temperature pH between pH 3.1 and 4.0 has a value of 1.09 ± 0.04, showing the expected 1:1 dependence of the specific rate constant to proton concentration. The pH changes were brought about by changing the buffer ratio in the same buffer system (succinic acid – succinate), which means that changes of pH within the series are temperature-independent, even if the change in absolute pH with temperature is large.

The E_a obtained from k_{obs} (room-temperature pH 3.5) between 140.0 and 175.0 °C, is 140 ± 1 kJ mol^{-1} (27). Extrapolation to 25.0 °C gives a value of 4.5 ± 0.7 × 10^{-13} s^{-1}, 525 times faster than the spontaneous hydrolysis. Equating $-\log_{10}[H^+]$ with measured pH at 25.0 °C gives a second-order rate constant for the proton-catalysed reaction of 1.4 ± 0.2 × 10^{-9} (mol/L)$^{-1}$ s^{-1}. For the hydrolysis at 25.0 °C, we can thus write eq. [2], valid from very acidic conditions to ~pH 12.3.

Fig. 4. $\log_{10}k_{obs}$ vs. pH. The pH dependence of the specific acid catalysis of 1,5-anhydrocellobiitol (150.0 °C).

$$[2] \quad k_{hyd,\ 25\ °C} = (8.6 \pm 2.1 \times 10^{-16}) + (1.4 \pm 0.2 \times 10^{-9\text{-pH}})\ s^{-1}$$

Therefore, the acid-catalysed hydrolysis becomes comparable with the spontaneous one only at pH 6.0.

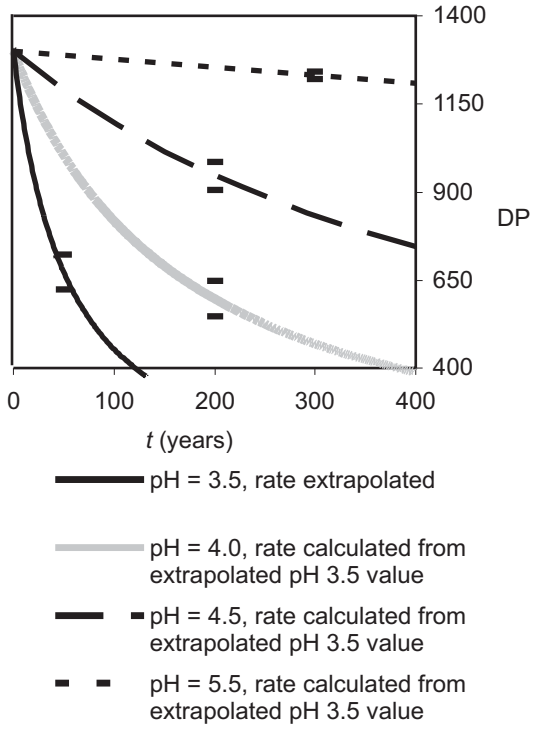
The activation energy calculated for hydrolysis in succinic acid buffers of room-temperature pH 3.5 will include the heat of ionization of succinic acid. The value (140 ± 1 kJ mol^{-1}) is close to activation energies measured with stoichiometric concentrations of mineral acids (e.g., 141.3 kJ mol^{-1} for methyl β-D-glucopyranoside, 138.8 kJ mol^{-1} for 2-propyl β-D-glucopyranoside, or 134.2 kJ mol^{-1} for the sterically acclerated 1-adamantyl β-D-glucopyranoside (51)), which do not include such a contribution. Therefore, the heat of ionization of succinic acid appears to be low, as is expected for an oxygen acid.

Modelling depolymerization using the af Ekenstam equation

Figure 5 models the depolymerization of cellulose in paper fibres ($DP_0 \cong 1300$) using af Ekenstam eq. [1] inputting the extrapolated value of $k_{25.0\ °C}$ (4.5 ± 0.7 × 10^{-13} s^{-1}) for 1,5-anhydrocellobiitol at pH 3.5. The other pH values were calculated from the pH 3.5 extrapolated value, assuming rates that were first-order in protons. The af Ekenstam equation will overestimate the rate of hydrolysis, since it assumes an aqueous environment throughout all cellulose chains. It is clear that even paper of pH 3.5 — at the lower end of the range of even "acid" papers — will have a usable lifetime of several decades before it reaches the failure criterion of DP = 400, the point at which paper becomes unusably brittle (2*a*). Although of greater significance than spontaneous hydrolysis, it seems unlikely that proton catalysis plays a major role in paper aging.

© 2005 NRC Canada

Fig. 5. Four hundred years of aging: DP vs. *t* at 25 °C. The depolymerization of cellulose in papermaking fibres modelled using af Ekenstam eq. [1], substituting 1300 for DP_0, and specific rate constants obtained from the model compound, 1,5-anhydrocellobiitol. The rate at pH 3.5 (succinic acid – succinate buffer, no Al^{III}) was extrapolated. All other pH values were calculated from the extrapolated rate based on first-order kinetics in H^+.



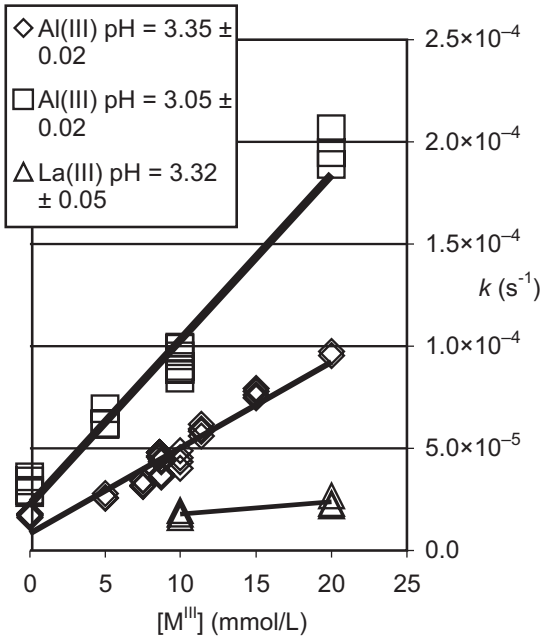


Fig. 6. *k* vs. [M^{III}]. First-order rate constants for hydrolysis of 1,5-anhydrocellobiitol (150.0 °C) as a function of added trivalent metal sulfates (27).

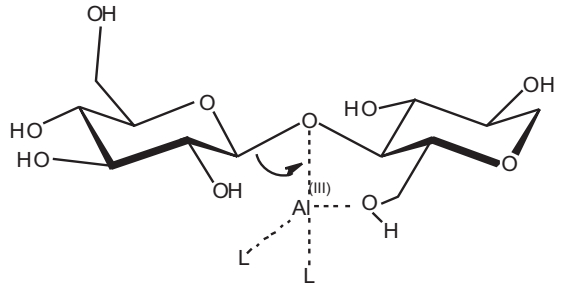
The Al^{III}-catalysed hydrolysis of 1,5-anhydrocellobiitol

Figure 6 shows the effect of added $Al_2(SO_4)_3$ and $La_2(SO_4)_3$ on k_{obs} for hydrolysis (150.0 °C) of 1,5-anhydrocellobiitol (10 mmol/L) in 100 mmol/L succinate buffers with the room-temperature pH values shown. The much greater effect of Al^{III} than La^{III} establishes that the increase in rate is not due to a change in ionic strength. (Although maximum added salt concentration was only 20% that of the buffer, if the concept of ionic strength, defined as $1/2\ \Sigma c_i z_i^2$, is applicable to these concentrated solutions, it is not constant, since we used salts of a divalent anion and trivalent cation (27)).

Competitive chelation of Al^{III} by succinate, substrate hydroxyls, and substrate glycosidic oxygen is expected, with Al^{III} in solution likely to be completely coordinated by the succinate and sulfate (42). Because of this anation, the rate of hydrolysis is expected to be lower than that which would be observed with $AlCl_3$, which possesses a noncoordinating cation (42, 52). Despite anation, unambiguous effects over the control are still observed. A clear pH dependence in the rate of the electrophilic hydrolysis is noted in this pH range. The apparent second-order rate constant at pH 3.05 is 8.1 ± 0.4 × 10^{-3} $(mol/L)^{-1}$ s^{-1}; at pH 3.35 it is 4.2 ± 0.2 × 10^{-3} $(mol/L)^{-1}$ s^{-1}, showing approximate proportionality of the second-order rate constant to the proton concentration.[5]

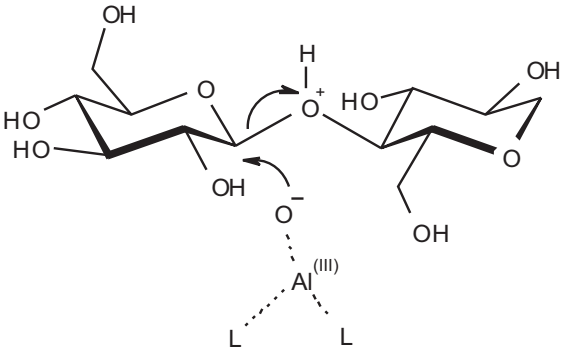
Presumably, this is due to protonated aluminium species being more electrophilic than unprotonated ones. Aluminium(III) exists in a variety of coordination compounds under papermaking conditions and it is not certain whether this particular pH dependence will extend to other pH ranges. It does suggest, however, that the relative importance of electrophilic catalysis to proton catalysis under ambient conditions will be pH-independent (27).

At 20 mmol/L of Al^{III}, k_{obs} was measured at 150.0 and 125.0 °C in buffers of room-temperature pH 3.33, and gave an E_a value of 109 ± 3 kJ mol^{-1} (27). This is appreciably lower than the value for proton-catalysed hydrolysis, suggesting that the electrophilic pathway will increase in importance as the temperature is lowered. Although the proton-catalysed pathway contributes ~10% to k_{obs} at 20 mmol/L of Al^{III} at 150.0 °C, the lower energy of activation means that this contribution, small anyway, decreases with temperature.



Conceivably, a kinetically equivalent pathway of hydrolysis could proceed, not from the coordination of Al^{III} with cellulose as in Scheme 1, but from the kinetically equivalent nucleophilic attack by an Al^{III}-coordinated oxygen atom on the conjugate acid of the substrate as in Scheme 2. However, as discussed in the Introduction, the sensitivity of such processes to nucleophilicity varies from weak to imperceptible. For example, in 2,4-dinitrophenolate production from 2,4-dinitrophenyl β-D-glucopyranoside, Bennet and Sinnott (53) showed sodium azide (1.0 mol/L) increased the rate by only 40%.

Electrophilic catalysis by Al^{III} was demonstrated with mmol/L concentrations of catalyst and substrate in homogeneous solution. In rosin-alum-sized paper there is more than enough aluminium to catalyse such a process: Priest et al.



[5] In the preliminary communication, an error of 10^2 in these derived constants, immediately apparent from the displayed graphs, was unfortunately made.

© 2005 NRC Canada

Scheme 1. 1,5-Anhydrocellobiitol, showing a possible coordination pattern for Al^{III} (27). Coordination by O6′ is speculative, but has a possible precedent in the intramolecular conversion of lactose into allolactose by the *lacZ* β-galactosidase of *E. coli* where Mg^{II} may be the electrophile (26).

Scheme 2. A kinetically equivalent pathway to the electrophile-catalysed hydrolysis: hydrolysis proceeding from nucleophilic substitution of an Al^{III}-coordinated oxygen atom. This mechanism is deemed unlikely to cause the observed acceleration because of the minimal effect of even very strong nucleophiles in these systems (52).

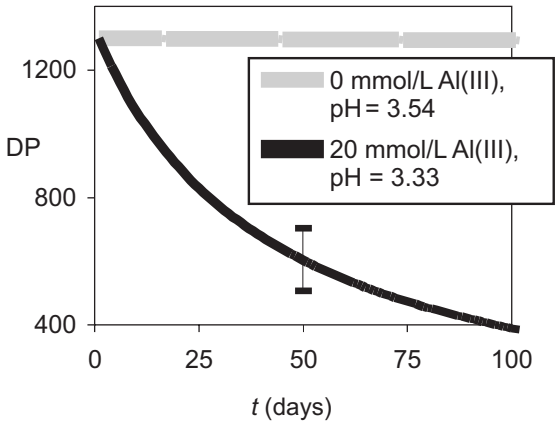
(54) found a range of 1.3%–6.7% $Al_2(SO_4)_3$ (average 3.8%) per weight of oven-dried 20th century papers (AAS of acid extracts). Thus, in principle, concentrations of Al^{III} in the molar range are possible in the 5%–7% aqueous phase in such papers, although in practice much of the aluminium will be precipitated or adsorbed.

Mechanism of electrophilic catalysis of 1,5-anhydrocellobiitol hydrolysis by Al^{III}

Given the rate of water exchange in the inner sphere of Al^{III} (55), ligand exchange about Al^{III} is unlikely to be rate-determining. The identities of these ligands in the model system will include aquo, sulfate, and succinate, whilst in the paper sheet they will be many and various. Particularly given that in crystalline cellulose I the conformation about C5-C6 is the usually disfavoured *tg* conformation (56), the possibility exists that Al^{III} is chelated as shown in Scheme 1 in the productive complex. A possible biochemical precedent for 6-OH coordination may be found in the intramolecular conversion of lactose into allolactose by *E. coli* β-galactosidase, which contains an active-site Mg^{II} (26). Aluminium(III), which has a similar Pauling ionic radius (50 pm) to Mg^{II} (65 pm), is expected to coordinate in a similar manner.

Figure 7 models the depolymerization of cellulose using the af Ekenstam eq. [1] inputting 1300 for DP_0 and k_{obs} values from 20 mmol/L $Al_2(SO_4)_3$ catalysed 1,5-anhydrocellobiitol samples (room temperature pH 3.33) extrapolated to 25 °C. This model suggests that paper of this composition would be extremely impermanent, reaching the failure criterion of DP ≅ 400 after 96 days. Such impermanence will be exaggerated, particularly as raising the pH will decrease the electrophilicity of the aluminium in the paper sheet. However, Murray (57), implicating rosin-alum sizing soon after its introduction, commented, "One letter which I had forwarded by post fell to pieces by the way…". Even papers of such pronounced impermanence can be preserved for centuries using the preservation technique of cold storage. The same k_{obs} values used in Fig. 7 (20 mmol/L $Al_2(SO_4)_3$, pH 3.33), but extrapolated to –20 °C, are plotted using af Ekenstam eq. [1] in Fig. 8.

Fig. 7. DP vs. *t* at 25 °C. The depolymerization of cellulose in papermaking fibres modelled using af Ekenstam eq. [1], substituting a DP_0 of 1300 and $k_{25\ °C}$ for 1,5-anhydrocellobiitol hydrolyses as labelled.



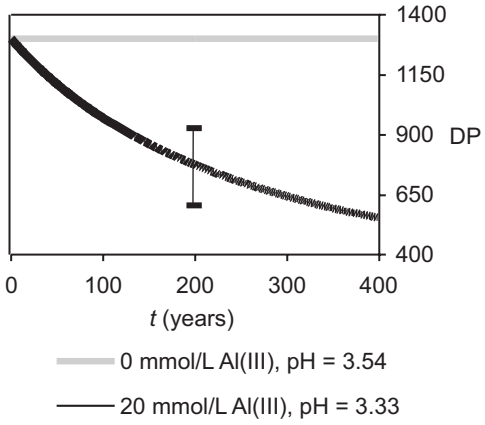


Fig. 8. Four hundred years of aging at –20 °C: DP vs. *t* at 25 °C. The depolymerization of cellulose in papermaking fibres under cold storage conditions. Modelled using the af Ekenstam eq. [1], substituting 1300 for DP_0, and specific rate constants obtained from the model compound, 1,5-anhydrocellobiitol.

Conclusions

The spontaneous hydrolysis of the β(1→4) link in cellulose, modelled in 1,5-anhydrocellobiitol, is too slow to contribute to reduction in degree of polymerization of cellulose

(and hence loss of paper strength) during aging of paper under archival storage conditions, but does completely account for the reduction in cellulose DP during kraft pulping. The proton-catalysed pathway is adequate to account for reduction in cellulose DP during aging only of the most acidic papers. Efficient electrophilic catalysis by Al^{III} has been demonstrated, and is likely to be the origin of the impermanence of all rosin-alum-sized papers.

Whilst more work is needed to determine the details of the Al^{III}-catalysed hydrolysis, it is clear that programs of document deacidification (such as that currently under way in the US Library of Congress (20)) will have, at best, a direct effect only on the most acidic of papers, and only the indirect one of reducing the electrophilicity of metal ions on other acid papers. Deacidification procedures that add metals (especially deacidification by dimethyl cadmium) are likely to be counterproductive.

It would appear that generic document storage techniques should be more widely adopted. The preservation technique of cold storage, widely used to preserve photographic materials, slows the rate of all detrimental reactions and does not entail the chemical alteration of the object. If a chemical alteration is absolutely necessary, it should at least target the real culprit of impermanence, e.g., complex the Al^{III} ion in rosin-alum-sized papers with fluoride.

Benzenesulfonyl chloride with primary and secondary amines in aqueous media — Unexpected high conversions to sulfonamides at high pH[1]

James F. King, Manjinder S. Gill, and Petru Ciubotaru

Abstract: We have determined pH–yield profiles under pseudo-first-order conditions of the reactions of benzenesulfonyl chloride with a set of primary and secondary water-soluble alkylamines, and have found with certain amines, such as dibutylamine, a profile taking the form of a sigmoid pH–yield curve with relatively high yields of the sulfonamide persisting with increasing basicity up to and including 1.0 mol/L sodium hydroxide. This behaviour is quantitatively accounted for by invoking, in addition to the usual second-order reaction of the sulfonyl chloride with the amine, two third-order terms (*i*) one first-order in sulfonyl chloride, amine and hydroxide anion, and (*ii*) another first-order in sulfonyl chloride and second-order in the amine. The importance of the third-order terms correlates approximately with the total number of alkyl carbon atoms in the amine, and this in turn is regarded as related to the hydrophobic character of the amine. Experiments to test this picture included: (*i*) observation of a bell-shaped curve with bis(2-methoxyethyl)amine, (*ii*) in the reaction of dibutylamine in THF–H_2O (1:1), and also (*iii*) in the reaction of dibutylamine in 1.0 mol/L tetrabutylammonium bromide, and (*iv*) increase in the contributions of the third-order terms in 1.0 mol/L aqueous sodium chloride. Preparative reactions with dibutylamine, 1-octylamine, and hexamethylenimine in 1.0 mol/L aqueous sodium hydroxide with a 5% excess of benzenesulfonyl chloride gave, respectively, 94%, 98%, and 97% yields of the corresponding sulfonamides.

Key words: sulfonyl chlorides, primary and secondary amines, pH–yield profiles, organic synthesis in water, hydrophobic effects.

Résumé : On a déterminé les profils pH–rendement dans des conditions de pseudo-premier ordre des réactions du chlorure de benzènesulfonyle avec un ensemble d'alkylamines primaires et secondaires solubles dans l'eau et on a trouvé avec certaines amines, telle la dibutylamine, que le profil de la courbe pH–rendement prend une forme sigmoïde, avec des rendements relativement élevés de sulfonamide qui persistent avec une augmentation de la basicité jusqu'à l'hydroxyde de sodium 1,0 mol/L. Ce comportement peut être expliqué quantitativement en invoquant, en plus de la réaction habituelle du deuxième ordre du chlorure de sulfonyle avec l'amine, deux termes de troisième ordre (*i*) une du premier ordre en chlorure de sulfonyle, en amine et en ion hydroxyde et (*ii*) un autre du premier ordre en chlorure de sulfonyle et du deuxième ordre en amine. L'importance des termes du troisième ordre donne une corrélation approximative avec le nombre total d'atomes de carbone de la chaîne alkyle de l'amine et ceci peut alors être considéré comme relié au caractère hydrophobe de l'amine. Les expériences réalisées pour évaluer cette hypothèse incluent (*i*) l'observation d'une courbe en forme de cloche avec la bis(2-méthoxyéthyl)amine et (*ii*) dans la réaction avec la dibutylamine dans un mélange THF–H_2O (1 : 1) et aussi (*iii*) dans la réaction de la butylamine dans le bromure de tétrabutylammonium à 1,0 mol/L et (*iv*) une augmentation dans les contributions des termes du troisième ordre dans le chlorure de sodium aqueux à 1,0 mol/L. Les réactions préparatives avec de la dibutylamine, de la 1-octylamine et de l'hexaméthylèneimine dans de l'hydroxyde de sodium aqueux à 1,0 mol/L, en présence d'un excès de 5 % de chlorure de benzènesulfonyle ont donné respectivement des rendements de 94 %, 98 % et 97 % des sulfonamides correspondants.

Mots clés : chlorures de sulfonyle, amines primaires et secondaires, profils pH–rendement, synthèse organique en milieu aqueux, effets hydrophobes.

Introduction

In recent times we have seen an increase of interest in the use of water as a solvent for organic synthesis. Selectivity and simplicity, and perhaps most significantly, cheapness, low toxicity, and general environmental acceptability, are among the benefits ascribed to reactions in water (1). Our role in this revival has included pointing to eqs. [1] and [2] for, respectively, (*i*) finding pH_{max}, the optimal pH for carrying out reactions in water between a nucleophile (Nu) and a hydrolysable electrophile (E), and (*ii*) pointing to the merits of pH–yield profiles for seeing the variation in yield with change in pH in such reactions when carried out under pseudo-first-order conditions (2).

$$[1] \qquad pH_{max} = 1/2\ [\log(k_w/k_{OH}) + pK_w + pK_a]$$

$$[2] \qquad f_p = \frac{k_N[Nu]}{k_w + k_{OH}[OH^-] + k_N[Nu]} = \frac{k_N Nu_T K_a/([H^+] + K_a)}{k_w + k_{OH}K_w/[H^+] + k_N Nu_T K_a/([H^+] + K_a)}$$

We were gratified to find in the reactions tested experimentally, namely, benzenesulfonyl chloride with amines or phenoxide anions, benzoyl chloride or acetic anhydride with amines, and allyl bromide with β-dicarbonyl enolates, that eq. [1] was invariably obeyed and eq. [2] commonly followed. (Rate constants are defined in Scheme 1; [Nu] = concentration of free amine, $Nu_T = [Nu] + [NuH^+]$, i.e., the total concentration of the amine species).

Two forms of deviation from eq. [2] have been encountered, and to see how these may arise, it is appropriate to recall that conformance to eqs. [1] and [2] requires that the rate law for the nucleophile–electrophile reaction in water be given by eq. [3].

$$[3] \qquad k_{obs} = k_w + k_{OH}[OH^-] + k_N[Nu]$$

One form of deviation from eq. [2] was noted in the reactions of benzenesulfonyl chloride with phenoxide anions (3) and also with acetic anhydride and primary or secondary amines (2*b*), and was ascribed to the consumption of a portion (usually <10%) of the electrophile (E) by hydrolysis assisted by the nucleophile (Nu) acting as a general base. Addition of a term, $k_{GB}[Nu]$, to eq. [3], and modifying eq. [2] by including the $k_{GB}[Nu]$ term in the denominator as in eq. [4], led to quantitative agreement of theory and experiment.

$$[4] \qquad f_p = \frac{k_N Nu_T K_a/([H^+] + K_a)}{k_w + k_{OH}K_w/[H^+] + (k_N + k_{GB})Nu_T K_a/([H^+] + K_a)}$$

The second deviation from eq. [2] was initially noted in the reaction of benzenesulfonyl chloride with benzylamine (Fig. 2 of ref. 2*a*); eq. [3] accurately predicts the yields for pH values 6–11, but not for pH 12, where the experimental yield is 65% and the predicted yield only 45%. We decided to look more closely into this system and found, as is described in this paper, an apparently hitherto unobserved third-order reaction in which we have evidence of the intervention of hydrophobic effects. As a corollary to this conclusion, we wish to draw attention to the usefulness of pH–yield experiments in the general problem of elucidating the factors influencing the interaction of water with organic materials. The present paper is largely taken from two theses (4); preliminary descriptions of our initial observations have been given in conference presentations (5).

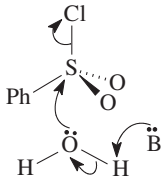
Scheme 1.

First order reaction

$$PhSO_2Cl + 2\ H_2O \xrightarrow{k_w} PhSO_2OH + Cl^- + H_3O^+$$

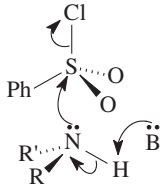
Second order reactions

$$PhSO_2Cl + H_2O + OH^- \xrightarrow{k_{OH}} PhSO_2OH + Cl^- + H_2O$$



$$PhSO_2Cl + RR'NH + H_2O \xrightarrow{k_N} PhSO_2NRR' + Cl^- + H_3O^+$$

$$PhSO_2Cl + H_2O + RR'NH \xrightarrow{k_{GB}} PhSO_2OH + Cl^- + RR'NH_2^+$$



Third order reactions

$$PhSO_2Cl + 2\ RR'NH \xrightarrow{k_{NN}} PhSO_2NRR' + Cl^- + RR'NH_2^+$$

$$PhSO_2Cl + RR'NH + OH^- \xrightarrow{k_{NOH}} PhSO_2NRR' + Cl^- + H_2O$$

B = H_2O, RR'NH, OH^-

Results and discussion

Methods and materials

The products of the reactions showed acceptable IR and ^1H and ^{13}C NMR spectra, and, where the sulfonamide was previously known, the properties were in accord with earlier reports. Those sulfonamides not previously reported have been characterized by spectra and high-resolution mass spectrum (HR-MS) molecular weight determination as described in the Experimental; further spectroscopic information on the known compounds is given elsewhere (4).

Our procedures for rate measurement by pH-stat (6) and determination of product yields by simple weighing of products (2) have already been described. In our initial experiments, we encountered a difficulty in reproducing results at high pH, and at least some of the problem is believed to arise because of the high rates of the reactions being observed and their sensitivity to mixing procedures. By using very rapid stirring and making sure that the mixing protocols varied as little as possible from one run to another, a fair measure of reproducibility was generally observed; further details are provided in the Experimental section. For reac-

Fig. 1. pH–yield profiles for the reaction of benzenesulfonyl chloride (initial concentration 7.8×10^{-4} mol/L) with primary amines (0.01 mol/L) in water at 25.0 °C. Allylamine (●); benzylamine (□); and butylamine (▲). Points are experimental and lines are drawn using eq. [5] and the appropriate parameters from Table 1.

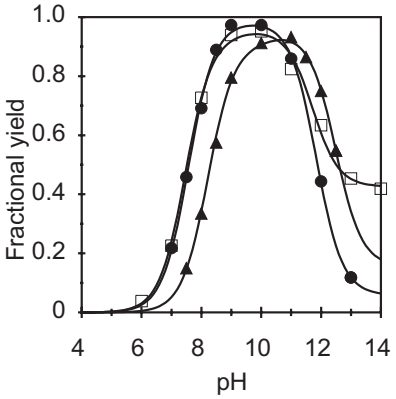

Fig. 2. pH–yield profiles for the reaction of benzenesulfonyl chloride (initial concentration 7.8×10^{-4} mol/L) with primary amines (0.01 mol/L) in water at 25.0 °C: 2-Methoxyethylamine (□); 1-octylamine (●); and *tert*-butylamine (▲). Points are experimental and lines are drawn using eq. [5] and the appropriate parameters from Table 1.

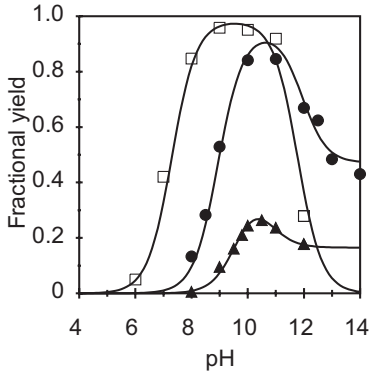

Fig. 3. pH–yield profiles for the reaction of benzenesulfonyl chloride (initial concentration 7.8×10^{-4} mol/L) with secondary amines (0.01 mol/L) in water at 25.0 °C: Dimethylamine (●); dibutylamine (▼); dipropylamine (■); and diethylamine (▲). Points are experimental and lines are drawn using eq. [5] and the appropriate parameters from Table 1.

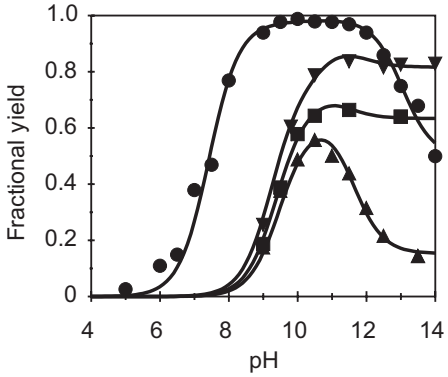

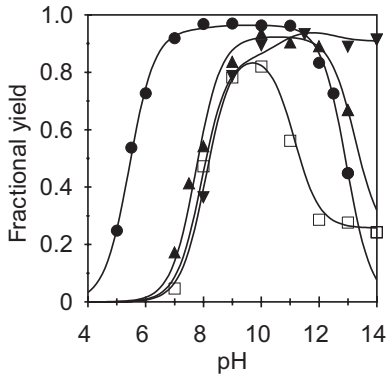

Fig. 4. pH–yield profiles for the reaction of benzenesulfonyl chloride (initial concentration 7.8×10^{-4} mol/L) with secondary amines (0.01 mol/L) in water at 25.0 °C: Morpholine (●); piperidine (▲); diallylamine (□); and hexamethylenimine (▼). Points are experimental and lines are drawn using eq. [5] and the appropriate parameters from Table 1.

tions on a scale too small for the weights to be informative, yields were determined by quantitative UV analysis or by gas chromatography as indicated in the Experimental section.

pH–yield profiles

Initial pH–yield profiles with primary and secondary amines (Figs. 1–4) revealed a consistent pattern. The amines with the smallest or most hydrophilic alkyl groups, e.g., allylamine and butylamine (Fig. 1), 2-methoxyethylamine (Fig. 2), and morpholine and piperidine (Fig. 4) and, to a lesser extent, dimethylamine (Fig. 3) and piperidine (Fig. 4), showed roughly bell-shaped curves as observed earlier. Others, however, notably dibutylamine (Fig. 3) and hexamethylenimine (Fig. 4), showed sigmoid pH–yield curves strongly reminiscent of simple titration curves. Other amines, e.g., diethylamine, dipropylamine, benzylamine, octylamine, and *tert*-butylamine, showed intermediate behaviour, with a clearly visible maximum yield near the expected pH_{max}, but with the yield in the pH 13 to 14 region not near zero but rather roughly half of that at pH_{max}.

This observation that the amines with the largest number of carbons showed the greatest tendency for a high yield of sulfonamide at high pH suggested that the hydrophobic alkyl groups could be leading to some form of association of organic molecules, especially at high pH where two factors, (*i*) maximum concentrations of the (unprotonated) amines and (*ii*) highest ionic strength due to the high concentration of NaOH, combine to provide an environment most likely to yield molecular association. One way of treating such hydrophobic factors would be to postulate two third-order terms involving, respectively, (*i*) sulfonyl chloride and two molecules of the amine (the k_{NN} term) and (*ii*) sulfonyl chloride, amine, and sodium hydroxide (the k_{NOH} term). These are included in the full reaction scheme shown in Scheme 1. The rate constants derived from this treatment of the pH–rate and pH–yield results are given in Table 1.

One should note in Scheme 1 that the simple second-order reaction of the sulfonyl chloride with amine to yield the sulfonamide (the k_N reaction), as well as the simple hydrolysis term (k_W term), are written with a molecule of water not

Table 1. Rate constants for the reaction of benzenesulfonyl chloride with primary and secondary amines in water at 25.0 °C.

Amine	pK_a[a]	k_{Nu}[b] ((mol/L)$^{-1}$ s^{-1})	k_N[c] ((mol/L)$^{-1}$ s^{-1})	k_{GB}[c] ((mol/L)$^{-1}$ s^{-1})	k_{NN}[c] ((mol/L)$^{-2}$ s^{-1})	k_{NOH}[c] ((mol/L)$^{-2}$ s^{-1})
Allylamine	9.49		25	<0.1	4.7×10^2	2.5×10^2
Benzylamine	9.34	22.7	21.5	1.2	1.4×10^3	3.0×10^3
2-Methoxyethylamine	9.2	23.8	23.8	<0.1	<1	<1
Butylamine	10.59	70.2	65.3	4.9	7.5×10^3	7.5×10^2
Octylamine	10.65	73	73	<0.1	1.1×10^5	1.7×10^4
tert-Butylamine	10.55		1	0.09	(3)	8.0×10^2
Dimethylamine	10.64	499	489	10	4.6×10^4	3.8×10^3
Diethylamine	10.98	6.1	6.1	<0.1	6.0×10^2	7.3×10^2
Dipropylamine	11	8.9	8.9	<0.1	5×10^2	7.0×10^3
Dibutylamine	11.25	25.7	25.7	<0.1	4×10^3	1.8×10^4
Diallylamine	9.29		5.4	0.4	<1	1.3×10^3
Piperidine	11.22	899	8.4×10^2	60	(2×10^2)	1.1×10^3
Morpholine	8.36	126	1.2×10^2	6	2.6×10^2	<1
Hexamethylenimine	11.11	440	3.8×10^2	60	9.0×10^4	4.0×10^4
Bis(2-methoxyethyl)amine	8.89	1.94	1.94	<0.01	(1×10^2)	3.4×10^2

[a] pK_a values are from the collection of Jencks and Regenstein (7), except for the value for hexamethylenimine, which is from ref. 8, and that for bis(2-methoxyethyl)amine, which was determined by the method of Albert and Serjeant (9).

[b] The k_{Nu} values were obtained from pH-stat rate measurements of the reaction of benzenesulfonyl chloride (initial concentration 0.001 mol/L) with 0.01 mol/L solutions of the amine in water at 25.0 °C, as previously described (6). This procedure yields k_{Nu} as defined by the following modified form of eq. [3]: $k_{obs} = k_w + k_{OH}[OH^-] + k_{Nu}[Nu]$, where $k_{Nu} = k_N + k_{GB}$; Rogne's values (10) for k_w and k_{OH} (3.06×10^{-3} s^{-1} and 40.4 (mol/L)$^{-1}$ s^{-1}, respectively) were used.

[c] The values of k_N, k_{GB}, k_{NN}, and k_{NOH} were obtained by an iterative manual least-squares procedure involving (*i*) assuming initially that $k_N \approx k_{Nu}$ (i.e., $k_{GB} \approx 0$) and finding (by the least-squares method) values for k_{NN} and k_{NOH} using eq. [5], (*ii*) evaluation of k_{GB} from the three to five f_p points at lowest pH (believed to be only minimally influenced by k_{NN} and k_{NOH}) and finding the best least-squares fit within the constraint $k_N + k_{GB} = k_{Nu}$, and, where appropriate, (*iii*) another round of least-squares calculations using both k_N and k_{GB} values carried out to obtain k_{NN} and k_{NOH} yielding minimal least-squares sums. In the three cases for which k_{Nu} values were not measured, a preliminary value of k_N was obtained by the best least-squares fit of the three to five f_p points at lowest pH, followed then by the procedure previously given for the other amines starting with k_{Nu}. The value preceded by the less than sign (<) has been found to give a poorer least-squares fit than zero, i.e., the parameter is experimentally indistinguishable from zero. Parentheses enclosing a few values indicate low reliability as indicated by a low sensitivity of the least-squares sum to change in that parameter.

required by minimal stoichiometry. This "extra" molecule of water is included to reflect the high likelihood of general base catalysis by water in these reactions in accord with Jenck's "libido rule" (11), which asserts that general base catalysis is observed when the hydrogen being removed in the reaction changes its acidity during the course of the reaction from initially too weak to react with the general base, to finally strong enough to readily protonate the general base. In the present reaction of benzenesulfonyl chloride with an amine, the hydrogen on the amine starts with a pK_a around 35 and ends up in the absence of general base intervention in an *N*-protonated sulfonamide with a pK_a around –5 or lower (12); note that water, the amine, and hydroxide anion (pK_as of conjugate acids are –1.7, ~10, and 15.7, respectively) are all capable of acting as general bases for sulfonamide formation. General base catalysis by a second molecule of water in the simple hydrolysis of sulfonyl chlorides has been discussed elsewhere (13). The merit of looking at the simple sulfonamide formation in this way becomes apparent on inspection of structures **1** and **2** whereby one may see that the third-order terms (k_{NOH} and k_{NN}) are simply the aminolysis analogues of the hydrolyses involving general base catalysis by hydroxide and the amine, respectively.

With the addition of the third-order reactions, we obtain eq. [5], the equation describing the pH–yield profile.

$$[5] \qquad f_p = \frac{k_N[Nu] + k_{NN}[Nu]^2 + k_{NOH}[Nu][OH^-]}{k_w + k_{OH}[OH^-] + k_N[Nu] + k_{GB}[Nu] + k_{NN}[Nu]^2 + k_{NOH}[Nu][OH^-]}$$

Equation [5] may be expanded to be a function of $[H^+]$ (or pH) by substituting $[Nu] = Nu_T K_a/[H^+]$ and $[OH^-] = K_W/[H^+]$.

As is shown in Figs. 5 and 6, by including the k_{NN} and k_{NOH} terms the pH–yield profiles for three different initial concentrations of dibutylamine are satisfactorily reproduced by the same values of two parameters (k_{NN} and k_{NOH}), along with, of course, the previously measured rate constants k_w, k_{OH}, and k_{Nu}. With the other amines the same parameters (including also a k_{GB} term with some amines) in varying degrees of relative importance suffice to provide a satisfactory fit to the observed pH–yield profiles.

By this treatment the only two reactions of any consequence in this pH 13 to 14 region are the hydroxide promoted reactions, the k_{OH} reaction leading to the hydrolysis

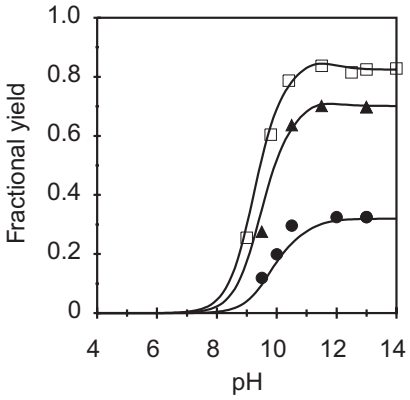
Fig. 5. pH–yield profiles for the reaction of benzenesulfonyl chloride with three concentrations of dibutylamine: 0.01 mol/L (□), 0.005 mol/L (▲), and 0.001 mol/L (●). Points are experimental and lines are drawn using eq. [5] and the appropriate parameters from Table 1.



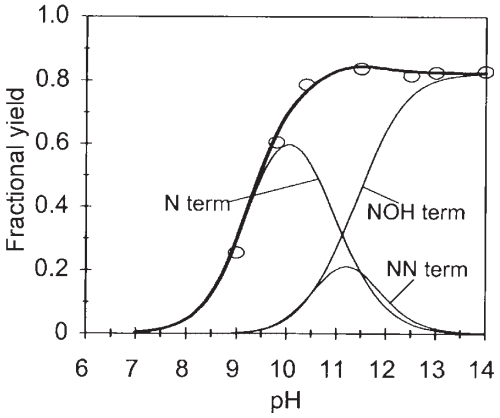


Fig. 6. pH–yield profiles for the reaction of benzenesulfonyl chloride with dibutylamine (0.01 mol/L) showing the estimated contributions of the individual sulfonamide forming reactions. The individual reactions are each shown by a light line with the appropriate subscript for that reaction from Scheme 1; the bold line gives f_p, the sum of the three component contributions.

product and the k_{NOH} process giving the sulfonamide, and hence the product ratio (amide:acid) for the reaction in the pH 13 to 14 region is given simply by the ratio of the rates of these two processes, i.e., $k_{NOH}[Nu][OH^-]/k_{OH}[OH^-]$. At high pH, $Nu_T \approx [Nu]$ and with cancelling of the $[OH^-]$s, the product ratio $\approx k_{NOH}Nu_T/k_{OH}$. Similar reasoning from eq. [5] gives $f_{p14} \approx k_{NOH}Nu_T/(k_{NOH}Nu_T + k_{OH})$, which in turn leads to a serviceable approximation for obtaining a rough value for k_{NOH}, i.e., $k_{NOH} \approx k_{OH}/[(1/f_{p14} - 1)Nu_T]$, where f_{p14} is the (actual or extrapolated) fractional yield at pH 14.

The case for the k_{NN} term is perhaps less obvious than that for k_{NOH} but it appears appropriate to include it at this stage because (*i*) it yields a substantially better fit to most observed pH–yield curves, and (*ii*) it appears to be such an eminently likely process that its possible role would have to be specifically examined anyway. As expected, the contribution of the k_{NN} term diminishes to negligible at very low amine concentrations.

It should be mentioned that the k_{GB} term is of limited importance for most reactions in "straight" water. It was evidently negligible (<1) for six of the amines and was found to be less than 10% of k_N in all cases except hexamethylenimine; as will be discussed later, one of the effects of using 1 mol/L NaCl as solvent is a detectable increase in the k_{GB} term for certain amines.

An essential feature to notice in the rate constants in Table 1 is the variation as the alkyl group increases in number of carbon atoms. We illustrate by noting the pattern in k_N for the sequence dimethylamine, diethylamine, dipropylamine, and dibutylamine (490, 6.1, 8.9, and 25.7 $(mol/L)^{-1}$ s^{-1}, respectively). The drop in rate on changing from methyl to ethyl is common among nucleophilic reactions of alkylamines and is ascribed to increased nonbonding interactions in the transition state with the extra carbon in the alkyl group (14). With most nucleophilic reactions, however, the following pattern is found: ethyl ≥ propyl ≥ butyl, etc. With k_N, however, there appears to be a small increase with size: ethyl ≈ propyl < butyl. This, we suggest, points to a hydrophobic effect (1*a*, 15) even with the second-order terms. The effect on the third-order rate constants is more dramatic, with the k_{NOH} values for diethylamine, dipropylamine, and dibutylamine being 7.3×10^2, 7×10^3, and 1.8×10^4 $(mol/L)^{-2}$ s^{-1}, respectively. In our view, it is fully consistent with the influence of hydrophobic effects, to regard both the second-order (k_N) and third-order (k_{NOH}) reactions as proceeding by way of an initial amine – sulfonyl chloride complex and that the complex reacts in a second step with either water or hydroxide anion, respectively. The formation of this complex is increased as the number of carbons in the alkyl group(s) (and hence the hydrophobic character) of the amine increases. With the second-order process, the second step of the reaction is believed to involve reaction of this complex with water acting as a general base as shown in structure **2** (B = H_2O). This reaction is comparatively slow, and the transition states accordingly reflect well-developed steric effects of the alkyl groups; increase of the "size" of the alkyl group will therefore have two distinct effects: (*i*) acceleration of the reaction by the hydrophobic effect; and (*ii*) slowing of the reaction by the steric effect, with the net result in this instance being a modest increase (approximately fourfold) on going from ethyl to butyl. With the third-order (k_{NOH}) process, the second step, namely reaction of the complex with hydroxide anion (**2**, B = OH^-), is a fast reaction with an early transition state in which the steric effects of the alkyl groups plays a smaller role than the hydrophobic effect; the result is a 25-fold change on going from diethylamine to dibutylamine.

Tests of the proposed mechanisms

The agreement of the observed and calculated pH–yield curves and the consistency of the rate constants with a picture invoking a hydrophobic effect, though gratifying, is not in itself sufficient to establish the mechanism outlined in Scheme 1. Views on the complex field of hydrophobic effects (1*a*, 15) appear to concur in that the effect is (*i*) increased by addition of certain solutes, especially salts such as sodium chloride and sodium hydroxide, labeled as "salting out"or "hydrophobic", and (*ii*) diminished by other solutes such as organic solvents (ethanol, DMSO, THF) or certain other salts labeled as "salting in" or "antihydropho-

[a]Apparent pK_a values determined in the specified media by the procedure of Albert and Serjeant (9). pH values were meter readings in the medium in question, after standardization with aqueous buffers.
[b]Rate constants were obtained as described in footnotes *b* and *c* of Table 1.

Fig. 7. pH–yield profiles for the reaction of benzenesulfonyl chloride (initial concentration 7.8×10^{-4} mol/L) with amines (0.01 mol/L) in THF–H_2O (1:1) at 25.0 °C: aniline (Δ), benzylamine (○), and dibutylamine (□). Points are experimental and lines are drawn using eq. [5] and the appropriate parameters from Table 2, plus $k_w = 1.5. \times 10^{-4}$ s^{-1} and $k_{OH} = 1.8$ (mol/L)$^{-1}$ s^{-1} determined from the pH–rate profile for this medium (4*a*).

bic", such as guanidinium bromide or tetrabutylammonium bromide. Accordingly, we have determined the effect of adding examples of hydrophobic and antihydrophobic solutes to the reaction mixtures and seeing the effect on the pH–yield profiles.

Reactions in THF–H_2O (1:1)

Our first venture was to carry out the reaction in aq. THF (1:1). The results for aniline, benzylamine, and dibutylamine are shown in Fig. 7. The curve for aniline is qualitatively similar to that in water alone but with a lowered value for k_N (in water, $k_N = 4.6$, $k_{GB} \approx 0$ (mol/L)$^{-1}$ s^{-1} (2*a*); in THF–H_2O (1:1), $k_N = 0.32$, $k_{GB} \approx 0.006$ (mol/L)$^{-1}$ s^{-1}; see Table 2). The effect on the other two amines was much more striking — and gratifying. With benzylamine there was no sign of any hydrophobic effect and with dibutylamine only a small sign of a possible third-order term was in evidence. Clearly, in THF–H_2O (1:1) the putative hydrophobic effect is very much reduced.

It is of interest that with THF–H_2O (1:4), the pH–yield profile for benzylamine is qualitatively very similar to that in water alone; a third-order term (k_{NOH}), somewhat reduced relative to k_N, is required to fit the curve adequately (4*a*).

It should be noted that the aq. THF experiments were also of interest for the practical purpose of determining the effects of cosolvent on the validity of our pH_{max} equation (eq. [1]) for use with amines with sufficiently low water solubility to make the experiment impracticable without addition of cosolvent. The chief effect of adding the organic solvent appears to be the well-known lowering of the apparent pK_a of the amine; the pK_a' values are shown in Table 2. pH_{max} values calculated from eq. [1] using pK_a' values determined in the solvent in question are in good accord with the experimental ones. pH_{max}, as given in eq. [1], may be regarded as the average of pK_a and pH_i, with $pH_i = k_W/k_{OH} + K_w$, where pH_i is the inflection point in a pH–rate profile (i.e., the pH at which $k_W = k_{OH}[OH^-]$). Values of pH_i for a sizable array of electrophilic reagents were tabulated in our earlier study (2*a*), and it was of interest to see the effect of solvent change on pH_i. We found, in fact, that the pH_i values are very similar: 9.88 in water (2*a*), 9.95 in THF–H_2O (1:4), and 9.92 in THF–H_2O (1:1). This suggests that the effect of the solvent change is similar for both the water and hydroxide promoted reactions.

Bis(2-methoxyethyl)amine

If indeed the effect noted at high pH with dibutylamine is, in fact, due to hydrophobic association of benzenesulfonyl chloride and dibutylamine, it is to be expected that a secondary amine of similar size and shape, but with relatively hydrophilic groups on the nitrogen atom, would show less of this effect. To test this idea we have studied the reaction of bis(2-methoxyethyl)amine ($(CH_3OCH_2CH_2)_2NH$), which is an approximate isostere of dibutylamine in which one methylene group in each chain is replaced by the relatively polar ether oxygen. The pH–yield profile for bis(2-methoxyethyl)amine is shown in Fig. 8. As may be readily seen from inspection of the curve or by inspection of the k_{NN} and k_{NOH} values (Table 1), the results are consistent with a much reduced hydrophobic effect relative to dibutylamine.

Reactions in aq. NaCl solutions

pH yield profiles for dimethylamine, dipropylamine, and dibutylamine in 1 mol/L aqueous sodium chloride solution are shown in Fig. 9, and those for diethylamine in both 1

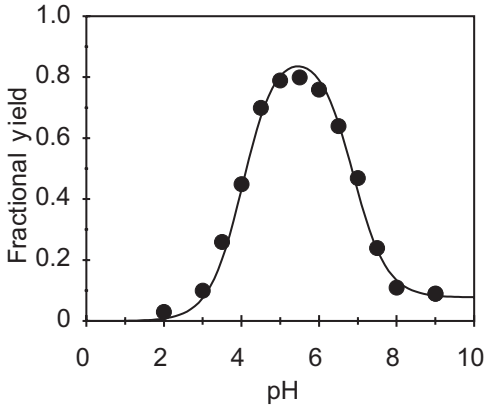
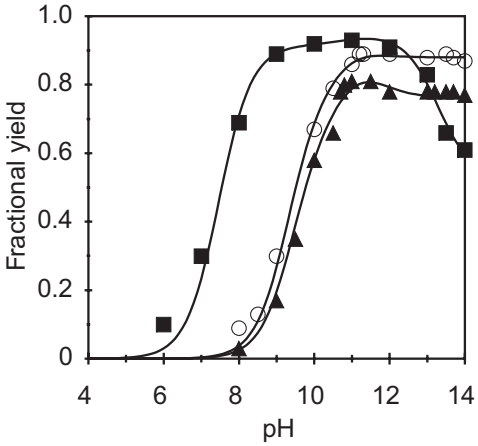
Fig. 8. pH–yield profile for the reaction of benzenesulfonyl chloride (initial concentration 7.8×10^{-4} mol/L) with bis(2-methoxyethyl)amine (0.01 mol/L). Points are experimental and the line is drawn using eq. [5] and the appropriate parameters from Table 1.





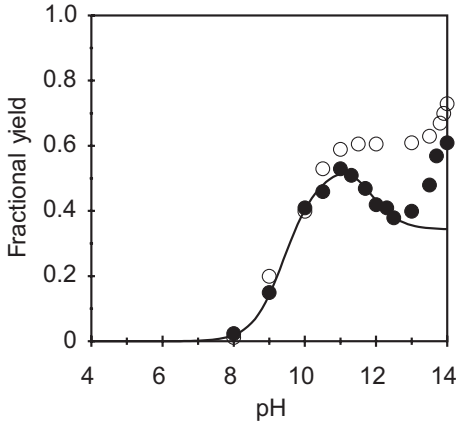


Fig. 9. pH–yield profiles for the reaction of benzenesulfonyl chloride (initial concentration 7.8×10^{-4} mol/L) with amines (0.01 mol/L) in aq. NaCl (1.0 mol/L) at 25.0 °C: dimethylamine (■); dibutylamine (○); and dipropylamine (▲). Points are experimental and lines are drawn using eq. [5] and the appropriate parameters from Table 2, plus $k_w = 2.74. \times 10^{-3}$ s^{-1} and $k_{OH} = 34.1$ (mol/L)$^{-1}$ s^{-1} determined from the pH–rate profile for this medium (4*b*).

and 2 mol/L NaCl solutions in Fig. 10; the derived rate constants for the reactions in 1 mol/L NaCl are listed in Table 2.

In considering these results we must remember that much of the effect of the sodium chloride is due to a change in ionic strength, i.e., it leads to a more polar medium that is more favorable than plain water to the development of charge separation in the transition state. Most of the changes that are observed in the reactions of dimethylamine are consistent with such an ionic strength effect. We note, for example, a modest increase in k_N and, interestingly, a more substantial effect (sevenfold increase) in k_{GB}. This latter result is consistent with greater charge separation in the transition state in the k_{GB} term than in the k_N process. A sizable increase in k_{GB} (relative to k_N) is also noted with diethylamine along with a smaller increase with dipropylamine, again presumably for the same reason.

Fig. 10. pH–yield profiles for the reaction of benzenesulfonyl chloride (initial concentration 7.8×10^{-4} mol/L) with diethylamine (0.01 mol/L) in aq. NaCl at 25.0 °C: 1.0 mol/L (●) and 2.0 mol/L (○). Points are experimental and the line is drawn using eq. [5] as described for Fig. 9.

The hydrophobic effect is expected to be stronger in sodium chloride solution than in water, and consistent with this is the observation in the rise in the "plateau level", i.e., the value of f_p in the pH range 11–14 with both dipropylamine and dibutylamine, reflecting a small increase in k_{NOH} relative to k_N on going from water to 1 mol/L NaCl solution.

The case of diethylamine is particularly interesting, showing not only an increase in the plateau level (around pH 12 to 13), but also a further increase in f_p presumably associated with an increase of k_{NOH} with change in ionic strength as the pH changes from 13 to 14. If this picture is correct, it is interesting — and surprising — that no analogous change in the pH region 13 to 14 is apparent with dipropylamine or dibutylamine. One possibility is that with these amines any changes in k_{NOH} are cancelled by other effects such as association of the amine with concomitant reduction in the concentration of the free amine and hence of the rate of the reaction. It is of interest in this connection to look at the solubilities (at 25 °C) of these amines in water and 1 mol/L NaCl solution: dibutylamine, 0.0348 and 0.0226 mol/L, respectively; dipropylamine, 0.4434 and 0.2483 mol/L, respectively; diethylamine, soluble in all proportions in both media. The hydrophobic effect (salting out) clearly shows with both dibutylamine and dipropylamine. Note that no line is drawn through the points for 2 mol/L NaCl, as we were unable to measure k_w and k_{OH} in this medium; the standard kinetic plots did not yield straight lines pointing, not surprisingly, to nonideal solution behaviour.

It is evident that the full picture is probably very complex and that an extensive study would be required for a more complete understanding of the reactions in NaCl. It is our view, however, that our observations, when taken with other results presented in this study, are in full accord with the presence of a hydrophobic effect on the k_{NOH} terms of the reactions of diethylamine, dipropylamine, and dibutylamine in NaCl solutions.

Reactions in aqueous tetrabutylammonium bromide solution

Solutions of tetrabutylammonium bromide are known to lead to salting in of organic solutes. Accordingly, in the light

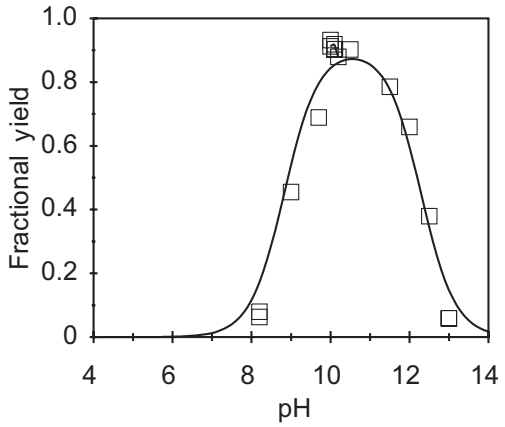
Table 3. Observed % yields in the reactions of benzenesulfonyl chloride with primary and secondary amines under preparative conditions.

Amine	% Yield below pH_{max} (pH)	% Yield at pH_{max}[a] (pH)	% Yield in 1.0 mol/L NaOH
Butylamine	86.5 (8.2)	99.0 (10.2)	44.9, 44.0
2-Methoxyethylamine	58.1 (7.0)	99.2 (9.5)	56
1-Octylamine	96.1 (8.5)	96.5 (10.3)	98.3
Dimethylamine			91
Diethylamine	51.7 (9.0)	94.8 (10.4)	87
Dibutylamine	77.7 (9.0)	88.4, 86.5 (10.6)	94
Dipentylamine[b]	94.3 (9.0)	96.6 (10.5)	97.8
Morpholine	44.8 (5.5)	99.0 (9.15)	73.2
Piperidine	75.5 (8.0)	94.9 (10.55)	89
Hexamethylenimine	85.1 (8.0)	99.6 (10.6)	97
Diisobutylamine[c]			69.9
Diallylamine			76.9
Bis(2-methoxyethyl)amine		91.0 (9.39)	59.0, 61.0



Note: Benzenesulfonyl chloride (0.67 mL, 5.25 mmol) added to a solution (50 mL) of the amine (0.1 mol/L) either (*i*) adjusted to the specified pH or (*ii*) in 1.0 mol/L aq. NaOH at 25 °C.

[a] pH_{max} calculated from eq. [1] using the pK_a values given in footnotes *b* and *c* and in Table 1.

[b] pK_a = 11.18 (17).

[c] pK_a = 10.50 (7).

Fig. 11. pH–yield profile for the reaction of benzenesulfonyl chloride (initial concentration 0.001 mol/L) with dibutylamine (0.01 mol/L) in aqueous tetrabutylammonium bromide (1.0 mol/L) at 25.0 °C. Points are experimental. The line is drawn using eq. [2] with $k_w = 3.06 \times 10^{-3}$ s^{-1}, $k_{OH} = 40.4$ (mol/L)$^{-1}$ s^{-1}, and $k_N = 71$ (mol/L)$^{-1}$ s^{-1} (see text).

of what has already been presented in this paper, it is to be expected that the postulated hydrophobic effect would be reduced by carrying out the reaction in aqueous tetrabutylammonium bromide solution. In accord with this picture we noted that the solubility of dibutylamine increased from 0.0348 mol/L in water to 0.0834 mol/L in 1.0 mol/L aqueous tetrabutylammonium bromide solution.

The pH–yield profile for the reaction of benzenesulfonyl chloride (0.001 mol/L) with dibutylamine (0.01 mol/L) in 1 mol/L $Bu_4N^+Br^-$ at 25 °C is shown in Fig. 11. It is immediately evident that the points form the normal bell shape associated with a system conforming to eq. [2] without any need to invoke third-order terms. The line shown, which is obtained from eq. [2] using the k_w, k_{OH}, and pK_a parameters for water plus $k_N = 71$ (mol/L)$^{-1}$ s^{-1} (a value obtained by a manual least-squares fit to the experimental points), is presented to illustrate that the data for the reaction in tetrabutylammonium bromide can indeed be readily accommodated on the basis of eq. [2] without invoking k_{NOH} or k_{NN}. In other words, the phenomena leading to the sigmoid pH–yield curve with benzenesulfonyl chloride and dibutylamine in water would appear to have disappeared in the tetrabutylammonium bromide solution, as predicted by the hydrophobic effect picture.

Yields at high pH under preparative conditions

The pseudo-first-order conditions used in determining most of the pH–yield profiles in this study involved low concentrations of the sulfonyl chloride with a 10-fold or greater excess of the (total) amine. It is of interest to see to what extent the unusual features of reactions at high pH shown in our pH–yield experiments show up under reaction conditions more typical of organic synthesis.

Reactions were carried out by adding a 5% excess of benzenesulfonyl chloride to a 0.1 mol/L solution of the amine; these concentrations are distinctly higher than those used in constructing the pH–yield profiles. As may be seen from the results in Table 3, the yields at pH_{max} are high (usually close to or above 95%); yields below pH_{max} are invariably lower though the difference is small in some cases. The yields in 1.0 mol/L NaOH ("pH 14") generally follow expectation based on pH–yield profiles. Some of the yields in 1.0 mol/L NaOH are high, e.g., octylamine (98.3%), dipentylamine (97.8%), and hexamethylenimine (97.0%). For these substrates, the high pH procedure is a simple and surprisingly efficient procedure for preparing the benzenesulfonamides; note that the reaction leading to these yields is primarily (99% or more) due to the k_{NOH} term.

These results prompted us to see if any other electrophiles reacted with dibutylamine with any sign of the involvement of third-order terms. Accordingly, we compared preparative runs at pH 11.40 (pH_{max}) and in 1.0 mol/L NaOH between benzoyl chloride and dibutylamine and obtained yields of

© 2005 NRC Canada

97.5% and 84.2% (4*a*), respectively; neither this nor a limited number of points in a (partial) pH–yield profile pointed to any sign of a third-order term. In addition, we had previously examined the pH–yield behaviour of acetic anhydride with primary and secondary amines (2*b*), but had not specifically looked at the reaction with dibutylamine. A pH–yield profile of this reaction over the pH range 8.0–13.0 was found (4*b*) to be well-described by eq. [4] with $k_N = 2.5 \times 10^3$ $(mol/L)^{-1}$ s^{-1} and $k_{GB} = 90$ $(mol/L)^{-1}$ s^{-1} taken with the parameters previously used (2*b*). We conclude that neither benzoyl chloride nor acetic anhydride shows a detectable third-order term in its reaction with dibutylamine under our conditions. It is probably not surprising that acetic anhydride should show no detectable third-order term, since the anhydride must be comparatively hydrophilic. The observation of a third-order term with benzenesulfonyl chloride and the failure to see any sign of a third-order term with its carbonyl analogue, benzoyl chloride, raises the interesting question: Why the difference? We have no firm evidence on the point, but we note that the arrangement shown by **2** could be close to an energy minimum for the electrophile–nucleophile complex prior to any reaction. Movement of the electrons as shown should take place readily and directly lead to the sulfonamide in the favourable conformation in which the free electron pair on the nitrogen is gauche to both oxygens (16). With benzoyl chloride, on the other hand, no such favourable arrangement of the amine – acid chloride complex comes readily to mind.

Concluding comment

In this study we present evidence that the general reaction of benzenesulfonyl chloride with primary and secondary amines in water requires at least one, and probably two, third-order terms (the k_{NOH} and k_{NN} terms, respectively). The principal observation that led to this proposal was obtained from pH–yield profiles, which showed, in all but the simplest or most hydrophilic amines, higher yields of the sulfonamide than predicted by the simplest mechanism. The third-order terms show up especially with simple alkylamines containing six or more alkyl carbon atoms, in accord with the intervention of hydrophobic phenomena. Experiments designed to disclose hydrophobic influences are in accord with this view.

In principle, the existence of the third-order terms should be detectable by conventional pH–rate studies, but as may be seen from the rate constants in Table 1, the half-lives of the reactions in the pH range in which the third-order terms are important, are inconveniently short for at least the simpler rate measurement techniques. The method of pH–yield profiles is a very easy procedure, which readily leads to information on an array of pH-dependent processes. Use of this procedure appears to be limited by variable yields under ostensibly identical conditions; this circumstance appears to arise as a result of either (*i*) extremely fast reactions that lead to difficulties with mixing effects or (*ii*) problems arising from low solubilities. Within the range in which reproducible results are readily obtained, pH–yield profiles can be a convenient source of valuable information, and further exploitation of the method is foreseen.

Experimental

Kinetic determinations were carried out with a pH-stat apparatus consisting of a Radiometer pH meter (PHM 25) equipped with GK2401B combination glass electrode (pH range 0–14, temperature range 0–100 °C), and an Aminco automatic burette with a 3 mL syringe reservoir. The reaction vessel used was a Radiometer V520 vessel equipped with a Radiometer V525 thermostatting jacket. The temperature was maintained with the aid of a Haake FJ constant temperature circulating apparatus. Stirring was accomplished with the use of a magnetic stirrer and the time was measured with a Precision Scientific Co. electric timer. The pH apparatus used for the pH–yield profiles consisted of either a Sargent-Welch 6000 meter with a Fisher all range (pH 1–14) combination electrode or a Radiometer pH meter (PHM 25) as previously described. Evaporation of solvents was carried out with a Büchi Rotovap apparatus connected to a water aspirator, and last traces of solvent were removed under vacuum until constant weight of the product was attained. Melting points were obtained using either a Kofler hot stage or a Gallenkamp apparatus and are uncorrected. ^1H and ^{13}C NMR spectra were obtained using Varian Gemini 300 and Varian Gemini 200 spectrometers. IR spectra were obtained with either a PerkinElmer 2000 FT-IR spectrometer or a Nicolet 205 FT-IR spectrometer. Reagent grade NaCl was used in the experiments carried out in aqueous salt solutions; in a few experiments with secondary amines, recrystallized NaCl was used, but no significant difference from reagent grade NaCl was detected. Benzenesulfonyl chloride and all the amines were fractionally distilled prior to use. Dichloromethane was dried over calcium hydride and distilled prior to use. The hydrochloride salts of amines were prepared by addition of hydrogen chloride to solutions of the amines in ether. The hydrochloride precipitates were collected by filtration, recrystallized, and dried to constant weight; melting points agreed with literature values. Authentic specimens of the sulfonamides for comparison were typically prepared from reaction of benzenesulfonyl chloride with excess amine or with an equivalent amount of amine in the presence of excess triethylamine, in dichloromethane at 0 °C to rt for 1–3 h. The reaction mixture was treated with water; the aqueous layer was made acidic and was extracted with dichloromethane (3 × 50 mL). The organic layer was dried over anhydr. $MgSO_4$ and the solvent evaporated to the give the corresponding sulfonamides in good yields (60%–90%). Melting points (where previously reported) were in accord with literature values; all sulfonamides showed IR, ^1H and ^{13}C NMR spectra, and exact mass values in accord with the assigned structures. Further details on known sulfonamides may be found elsewhere (4); properties of previously unknown sulfonamides are given in the following.

N-(2-Methoxyethyl)benzenesulfonamide

Clear liquid. IR (neat, cm^{-1}) ν_{max}: 3283 (br, s), 2930 (s), 2892 (s), 1448 (s), 1329 (s), 1162 (s), 1126 (s), 1090 (s), 1026 (w), 955 (w). ^1H NMR δ: 3.12 (q, 2H), 3.23 (s, 3H), 3.38 (t, 2H), 5.44 (t, 1H, NH), 7.48–7.61 (m, 3H), 7.85–7.90 (m, 2H). ^{13}C NMR δ: 42.7, 58.5, 70.4, 126.8, 129.0, 132.5, 139.8. Reaction of benzenesulfonyl chloride with amines

Construction of pH–yield profiles

Benzenesulfonyl chloride (50 μL, 0.392 mmol) was quickly injected from a 50 μL syringe into a vigorously stirred solution of the amine (0.01 mol/L or 0.02 mol/L) in water (500 mL) in a 800 mL beaker, previously adjusted to the desired pH with dilute HCl or NaOH. The pH was maintained by dropwise addition of NaOH (0.5 mol/L or 0.1 mol/L) until it remained stable. The reaction mixture was acidified to pH 2 with 1 mol/L H_2SO_4 and extracted with dichloromethane; the organic layer was dried over anhydr. $MgSO_4$, filtered, and the solvent was evaporated as previously described. The product was identified by comparison of its ^1H NMR with that of an authentic sample. The yields were calculated from the constant weight of the product, based on the theoretical yield, and shown as experimental points in the figures. For the reactions at pH 14 and 13, 1 mol/L NaOH and 0.1 mol/L NaOH (500 mL), respectively, were used. In the reaction with dimethylamine the beaker was covered with Parafilm owing to the volatility of the amine. Reactions in NaCl solutions were carried out similarly, except for the use of 0.5, 1.0, or 2.0 mol/L NaCl solutions in place of water.

Reactions at lower concentrations required a modified procedure. The reaction was conducted with amine concentrations of 0.002 or 0.001 mol/L and was carried out as previosuly described except that the extracted solution of dichloromethane was dried over anhydr. $MgSO_4$ and filtered into a volumetric flask (100 or 250 mL) and the volume was made up to mark with dichloromethane. The UV spectrum of the solution was obtained and absorption at a particular wavelength was recorded, for example, for *N*,*N*-dibutylbenzenesulfonamide at λ = 275 nm. The yields were calculated from a calibration curve, which was obtained from solutions of the corresponding sulfonamide (product) of known concentrations in dichloromethane vs. the UV absorptions at that particular wavelength.

For reactions in THF–H_2O, the previous procedure was followed except that instead of water (500 mL), THF + H_2O (100 + 400 mL) was used for THF–H_2O (20:80) and THF + H_2O (250 + 250 mL) was used for THF–H_2O (50:50). After the reaction was completed at a particular pH, the pH of the reaction mixture was adjusted to 7 and most of the THF was removed on the rotatory evaporator. The reaction mixture was acidified to pH 2, followed by the workup as described before. The yields are shown in Fig. 7 and the derived rate constants listed in Table 2.

Reactions in tetrabutylammonium bromide (for reasons of economy) were carried out on a relatively small scale: benzenesulfonyl chloride (4.43 mg, 0.0251 mmol) in THF (32 μL) was injected into 25 mL of an aqueous solution of 1.0 mol/L in $Bu_4N^+Br^-$ and 0.01 mol/L in dibutylamine adjusted to the desired pH as previously described. Workup involved acidification to pH 1 with HBr, extraction with ether (3 × 10 mL), drying of the extract with $MgSO_4$, and evaporation of the solvent to 25 mL. A known quantity of nitrobenzene was added as internal standard and the amount of sulfonamide determined by GC. Two larger scale runs using 0.032 mL of benzenesulfonyl chloride in 250 mL of a solution 1 mol/L in tetrabutylammonium bromide and 0.01 mol/L in dibutylamine carried out as previously described with simple weighing of the product, gave yields of 17% and 69% at pH 14.0 and 10.0, respectively, in agreement with the smaller scale results.

Reactions under preparative conditions

Benzenesulfonyl chloride (0.67 mL, 5.25 mmol) was injected into a solution of the amine (0.1 mol/L) in 50 mL of water contained in a 100 mL beaker and previously adjusted to the desired pH, and the mixture stirred until reaction was complete (typically 1 to 2 h). The mixture was then acidified to pH 2 with 1 mol/L H_2SO_4 and worked up by extraction with dichloromethane as described for the pH–yield profiles in water; yields are listed in Table 3.

Acknowledgements

We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support of this study. We thank Professor Mark Workentin for the use of his GC apparatus and John Villella, Kevin Kulbaba, and Rana Ibrahim for valuable preliminary experiments.

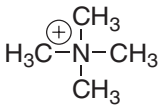
Formation and stability of organic zwitterions — The carbon acid pK_as of the trimethylsulfonium and tetramethylphosphonium cations in water[1]

Ana Rios, AnnMarie C. O'Donoghue, Tina L. Amyes, and John P. Richard

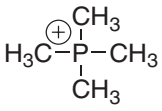
Abstract: We report second-order rate constants of k_{DO} = 7.5 × 10^{-4} and 9.9 × 10^{-5} $(mol/L)^{-1}$ s^{-1} for exchange for deuterium of the first methyl proton of the trimethylsulfonium and tetramethylphosphonium cations, respectively, in D_2O at 25 °C and I = 1.0 (KCl). The data were analyzed to give the following carbon acidities for these cationic carbon acids in water: $(CH_3)_3S^+$, pK_a = 28.5; $(CH_3)_4P^+$, pK_a = 29.4. These acidities are close to those of the neutral carbon acids acetonitrile and dimethylacetamide. This provides evidence that a portion of the stabilization of the cyanomethyl carbanion is due to resonance delocalization of negative charge from carbon to cyano nitrogen.

Key words: carbon acids, carbanions, ylides, proton transfer.



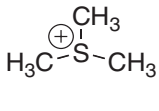
Résumé : Opérant dans le D_2O, à 25 °C et une valeur de I = 1,0 (KCl), on a déterminé que les constantes de vitesse du deuxième ordre pour l'échange du deutérium du premier proton méthyle des cations triméthylsulfonium et tétraméthylphosphonium sont respectivement de k_{DO} = 7,5 × 10^{-4} et 9,9 × 10^{-5} $(mol/L)^{-1}$ s^{-1}. Les données ont été analysées pour en tirer les acidités carboniques suivantes pour ces acides carboniques cationiques dans l'eau: $(CH_3)_3S^+$, pK_a = 28,5 et $(CH_3)_4P^+$, pK_a = 29,4. Ces acidités se rapprochent de celles d'autres acides carboniques, tel l'acétonitrile et le diméthylacétamide. Ces résultats montrent qu'une portion de la stabilization du carbanion cyanométhyle est due à une délocalization de résonance de la charge négative du carbone vers l'azote du groupe cyano.

Mots clés : acides carboniques, carbanions, ylures, transfert de proton.



[Traduit par la Rédaction]

Introduction



We are interested in characterizing the effects of strongly electron-withdrawing substituents on carbon acidity and have reported the kinetic and thermodynamic acidities of a variety of weak carbon acids in water (1–12). The very low carbon acidity of methane (13) is increased by substituents that provide polar and (or) resonance stabilization of negative charge at the methyl carbanion; and the most powerful purely polar stabilization of a methyl carbanion is provided by a cationic group at a neighboring atom. In 1955 Doering and Hoffmann (14) reported rate constants for deprotonation of the tetramethylammonium, tetramethylphosphonium, and trimethylsulfonium cations by hydroxide ion at several temperatures. Their data showed that the tetramethylammonium cation is a significantly weaker carbon acid than the tetramethylphosphonium and trimethylsulfonium cations. Thus, the ylides of phosphonium and sulfonium cations are stabilized relative to the corresponding ylides of ammonium cations by the greater polarizability of phosphorus and sulfur than of nitrogen, and possibly by hyperconjugation (15, 16) and back-bonding from carbon to the *d*-orbitals of phosphorus and sulfur (17).

Me_4N^+

Me_4P^+

Me_3S^+

In recent years there have been several studies that document the relatively strong carbon acidity of alkyl sulfonium (18–26) and alkyl phosphonium (27, 28) cations. However, the carbon acid pK_as for the parent tetramethylphosphonium and trimethylsulfonium cations in aqueous solution have not been reported. To this end, we have determined the rate constants for deprotonation of the tetramethylphosphonium cation (**Me_4P^+**) and trimethylsulfonium cation (**Me_3S^+**) in D_2O at 25 °C, using modern NMR methods to monitor transfer of deuterium from the solvent to carbon acid. Our results agree well with the results of Doering and Hoffmann (14); they extended earlier work by showing that there is no catalysis of deprotonation of these cationic carbon acids by buffer bases. An analysis of these data by the methods that we have developed to determine equilibrium carbon acidities in water (1–

12) provides the carbon acid pK_as for deprotonation of $\mathbf{Me_4P^+}$ and $\mathbf{Me_3S^+}$ in water.

Experimental

Materials

All organic and inorganic chemicals were reagent grade or better and were used without further purification. Trimethylsulfonium methyl sulfate, tetramethylphosphonium chloride, tetramethylammonium chloride, quinuclidine hydrochloride, 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP), 2,2,2-trifluoroethanol (TFE), and KOD (40% wt, +98% D) were from Aldrich. Deuterium oxide (99.9% D) and deuterium chloride (35% *w*/*w*, 99.5% D) were from Cambridge Isotope Laboratories.

Preparation of solutions

The acidic proton of quinuclidine hydrochloride was exchanged for deuterium before use as described previously (1). TFE and HFIP were dissolved directly in D_2O (99.9% D), but at no time did this introduce >0.5 atom% of protium into the solvent. Quinuclidine, trifluoroethanol, and HFIP buffers were prepared by dissolving their acidic forms and KCl in D_2O followed by the addition of KOD to give the desired acid:base ratio or pD at I = 1.0 (KCl).

Solution pD was determined at 25 °C using an Orion Model 720A pH meter equipped with a Radiometer GK2321C or pHC4006-9 combination electrode. Values of pD were obtained by adding 0.40 to the observed reading of the pH meter (29). The concentration of deuterioxide ion at any pD was calculated from eq. [1], where $K_w = 10^{-14.87}$ (mol/L)^2 is the ion product of D_2O at 25 °C (30) and γ_{OL} = 0.79 or 0.75 is the apparent activity coefficient of lyoxide ion under our experimental conditions determined by the GK2321C or the pHC4006-9 electrode, respectively (2).

$$[1] \qquad [DO^-] = \frac{10^{pD-pK_w}}{\gamma_{OL}}$$

^{1}H NMR spectroscopy

^{1}H NMR spectra at 500 MHz were recorded in D_2O at 25 °C on a Varian Unity Inova 500 spectrometer. The relaxation times for the methyl protons of $\mathbf{Me_3S^+}$ and $\mathbf{Me_4P^+}$, determined for 10 mmol/L solutions of substrate at I = 1.0 (KCl), were found to be in the range of T_1 = 6 to 7 s. The relaxation delay between pulses was at least 10-fold greater than the longest T_1 of the protons of interest. Chemical shifts were reported relative to HOD at 4.67 ppm. Baselines were subjected to a first-order drift correction before the determination of the integrated peak areas.

Kinetic measurements

All reactions were carried out in D_2O at 25 °C and a constant ionic strength of 1.0 maintained with potassium chloride. The deuterium exchange reactions of $\mathbf{Me_3S^+}$ and $\mathbf{Me_4P^+}$ in buffered solutions were initiated by mixing solutions of the substrate and the buffer at the same pD and ionic strength (I = 1.0, KCl) to give a final substrate concentration of 10 mmol/L. The reactions of $\mathbf{Me_4P^+}$ and $\mathbf{Me_4N^+}$ in alkaline solutions of D_2O were initiated by mixing solutions of the substrate and KOD at the same ionic strength (I = 1.0, KCl) to give a final substrate concentration of 10 mmol/L. At timed intervals an aliquot (600 μL) was removed from the reaction mixture and the pD was adjusted to 7 to 8 by the addition of concentrated DCl and 50 μL of 0.4 mol/L phosphate buffer in D_2O. The aliquots were either analyzed immediately by ^{1}H NMR spectroscopy or were frozen for analysis at a later time.

The exchange for deuterium of the first proton of the methyl groups of $\mathbf{Me_3S^+}$ was followed by monitoring the disappearance of the singlet at 2.911 ppm owing to the CH_3 groups and the appearance of the triplet at 2.899 ppm (J_{HD} = 2 Hz) owing to the CH_2D groups, by ^{1}H NMR. The exchange for deuterium of the first proton of the methyl groups of $\mathbf{Me_4P^+}$ was followed by monitoring the disappearance of the doublet at 1.867 ppm (J_{HP} = 16 Hz) owing to the CH_3 groups and the appearance of the doublet of triplets at 1.852 ppm (J_{HP} = 16 Hz, J_{HD} = 2.5 Hz) owing to the CH_2D groups. The reactions were followed during the exchange for deuterium of up to 25% and 5% of the first proton of the methyl groups of $\mathbf{Me_3S^+}$ and $\mathbf{Me_4P^+}$, respectively.

$$[2] \qquad R = \frac{A_{CH_3}}{A_{CH_3} + \frac{A_{CH_2D}}{2}}$$

$$[3] \qquad \ln R = -k_{obsd}t$$

Values of R, which is a measure of the progress of the deuterium exchange reaction (4, 31), were calculated according to eq. [2], where A_{CH_3} and A_{CH_2D} are the integrated areas of the signals owing to the CH_3 and CH_2D groups, respectively. During the early stages of the reaction of $\mathbf{Me_3S^+}$, it was possible to obtain baseline separation of only the most upfield peak of the triplet owing to the CH_2D groups. In these cases, the total integrated area of the triplet due to the CH_2D groups (A_{CH_2D}) was obtained by multiplying the integrated area of the resolved peak by three, and the area of the singlet owing to the CH_3 groups (A_{CH_3}) was obtained as the difference between the total peak area for both the singlet and the triplet and A_{CH_2D} (2). For the reaction of $\mathbf{Me_4P^+}$, only the most upfield peak of the doublet of triplets due to the CH_2D groups was cleanly resolved. The area of the doublet of triplets due to the CH_2D groups (A_{CH_2D}) was obtained by multiplying the integrated area of the resolved peak by six, and the area of the doublet due to the CH_3 groups (A_{CH_3}) was obtained as the difference between the total peak area for all the signals and A_{CH_2D}.

Semilogarithmic plots of reaction progress (R) against time were linear with negative slopes equal to k_{obsd} (s^{-1}, eq. [3]), which is the rate constant for exchange of a *single* proton of the substrate.

A triplet at 3.164 ppm (J = 0.5 Hz) was observed for the four equivalent methyl groups of the tetramethylammonium cation. No signal for a CH_2D group was observed after the incubation of the substrate in the presence of 1.0 mol/L KOD at 25 °C for 16 days. Several spurious signals appeared during this prolonged reaction time, but no attempt was made to assign these signals.

Results

The exchange for deuterium of the first proton of the methyl groups of **Me_3S^+** and **Me_4P^+** in D_2O at 25 °C and I = 1.0 (KCl) was followed by ^1H NMR spectroscopy at 500 MHz (Scheme 1). Deuterium exchange at **Me_3S^+** results in disappearance of the singlet at 2.911 ppm owing to the CH_3 groups and appearance of an upfield-shifted triplet at 2.899 ppm owing to the CH_2D groups. Similarly, exchange at **Me_4P^+** results in disappearance of the doublet at 1.867 ppm and the appearance of a doublet of triplets at 1.852 ppm owing to the CH_2D groups. The deuterium isotope effect on the ^1H NMR chemical shift and the H–D coupling constant are similar to those observed in our previous work (1, 2, 4–6, 9, 10, 32, 33).

First-order rate constants (k_{obsd} (s^{-1})) for exchange for deuterium of a *single* proton of the cationic carbon acids were determined as the slopes of semilogarithmic plots of reaction progress R (eq. [2]) against time according to eq. [3] (not shown). The reaction of **Me_3S^+** to give the monodeuteriated product occurs nine times as fast as the exchange of a *single* proton of the reactant, so that $k_{ex} = 9k_{obsd}$ where k_{ex} (s^{-1}) is the first-order rate constant for exchange of the first proton of the reactant to give the monodeuteriated product (Scheme 1A) (4, 31). Similarly, the reaction of **Me_4P^+** to give the monodeuteriated product occurs 12 times as fast as the exchange of a *single* proton of the reactant, so that $k_{ex} = 12k_{obsd}$ (Scheme 1B) (4, 31).

Table 1 gives the values of k_{ex} (s^{-1}) for the deuterium exchange reactions of **Me_3S^+** and **Me_4P^+** in the presence of various concentrations of deuterioxide ion or added buffers in D_2O at 25 °C and I = 1.0 (KCl). There is no significant change in the value of k_{ex} for the deuterium exchange reaction of **Me_4P^+** as the concentration of trifluoroethanol buffer is increased from 0.092 to 0.37 mol/L at pD 12.3. Similarly, the value of k_{ex} for the deuterium exchange reaction of **Me_3S^+** is independent of the concentration of added hexafluoroisopropanol, quinuclidine, or trifluoroethanol buffers (Table 1). The absence of buffer catalysis of deuterium exchange shows that, in basic solution, these cationic carbon acids are deprotonated exclusively by the solvent.

Scheme 1.

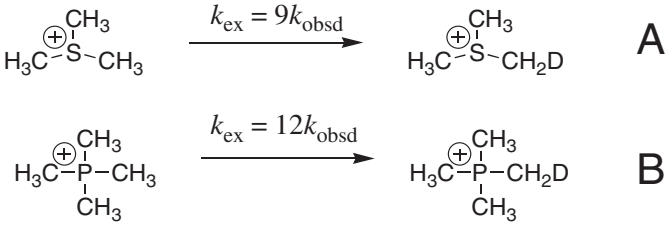

Figure 1 shows the dependence of k_{ex} (s^{-1}) on the concentration of deuterioxide ion in D_2O for the deuterium exchange reaction of **Me_4P^+**. The slope of this correlation gives $k_{DO} = 9.9 \times 10^{-5}$ $(mol/L)^{-1}$ s^{-1} (eq. [4]) where k_{DO} is the second-order rate constant for deuterium exchange catalyzed by the deuterioxide ion.

$$[4] \qquad k_{ex} = k_{DO}[DO^-]$$

Fig. 1. Dependence of k_{ex} (s^{-1}) for exchange for deuterium of the first proton of $\mathbf{Me_4P^+}$ on the concentration of deuterioxide ion in D_2O at 25 °C and I = 1.0 (KCl). The slope gives the second-order rate constant (k_{DO}) for DO^--catalyzed deuterium exchange.

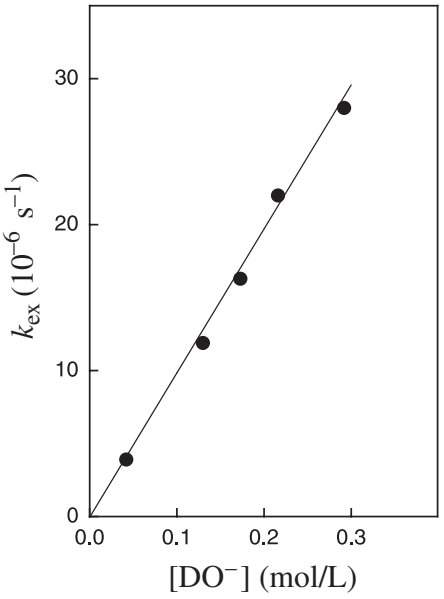

Figure 2 shows the pD–rate profiles for the deuterium exchange reactions of $\mathbf{Me_4P^+}$ (●) and $\mathbf{Me_3S^+}$ (◆). In cases where values of k_{ex} were determined over a range of buffer concentrations (Table 1), the values of pD and k_{ex} for the reaction at the lowest buffer concentration were used for Fig. 2. The solid line through the data for $\mathbf{Me_4P^+}$ was calculated from the value of $k_{DO} = 9.9 \times 10^{-5}$ $(mol/L)^{-1}$ s^{-1} using eq. [5]. A value of $k_{DO} = 7.5 \times 10^{-4}$ $(mol/L)^{-1}$ s^{-1} for $\mathbf{Me_3S^+}$ was determined from the fit of the data to eq. [5] (10). Figure 2 also shows data for the deuterium exchange reactions of acetonitrile (■) (4) and dimethylacetamide (▲) (10) taken from our earlier work.

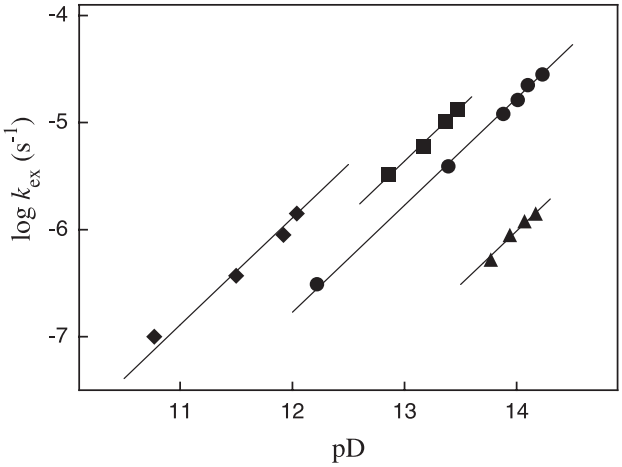

$$[5] \qquad \log k_{ex} = \log\left(\frac{k_{DO}K_w}{\gamma_{OL}}\right) + \text{pD}$$

There was no detectable formation of a CH_2D group after the reaction of $\mathbf{Me_4N^+}$ in 1.0 mol/L KOD in D_2O at 25 °C for 16 days. During this time, the appearance of several unidentified NMR signals showed that there were other reaction(s) of $\mathbf{Me_4N^+}$, but these were not characterized. A peak for a CH_2D group that is 1% of the area of the peak due to the CH_3 groups could have been easily detected in these experiments. This was used to calculate an upper limit of $k_{DO} < 4 \times 10^{-8}$ $(mol/L)^{-1}$ s^{-1} for the deuterium exchange reaction of $\mathbf{Me_4N^+}$ catalyzed by deuterioxide ion.

Discussion

The present work was initiated for the following reasons: (1) We wanted to determine second-order rate constants for the deuterioxide ion catalyzed deuterium exchange reactions of $\mathbf{Me_4P^+}$ and $\mathbf{Me_3S^+}$ using modern analytical methods and under the same conditions used in our other studies of the acidity of weak carbon acids. (2) We wanted to determine if these deuterium exchange reactions are catalyzed by buffer bases. (3) We wanted to obtain pK_as for these cationic carbon acids in water and to draw comparisons with the other data that we have reported over the last decade or so.

Fig. 2. pD–rate profiles of k_{ex} for deuterioxide ion catalyzed exchange for deuterium of the first proton of $\mathbf{Me_3S^+}$ (◆, this work), $\mathbf{Me_4P^+}$ (●, this work), CH_3CN (■, data from ref. 4), and $CH_3C(O)NMe_2$ (▲, data from ref. 10) in D_2O at 25 °C and I = 1.0 (KCl).

In 1955 Doering and Hoffmann (14) monitored the deuterium exchange reactions of several cationic carbon acids in D_2O by combustion of the recovered carbon acid to a mixture of D_2O and H_2O, whose deuterium enrichment was then determined by the "method of the falling drop". Table 2 shows that the second-order rate constants (k_{DO}) for deuterioxide-ion-catalyzed exchange of the first proton of $\mathbf{Me_4P^+}$ and $\mathbf{Me_3S^+}$ determined here agree to within 33% with the earlier values of Doering and Hoffmann (14). The slightly higher values reported in the earlier work were obtained at a temperature of 26.8 °C compared with 25 °C used in this work.

Rate-determining step for hydron exchange

The rate constant (k_{DO}) for exchange of the first proton of these cationic carbon acids in D_2O may be limited either by the chemical step of proton transfer from the substrate to deuterioxide ion (k_p, Scheme 2), or if this step is reversible ($k_{-p} >> k_{reorg}$), by the rate constant for reorganization of solvent to place a molecule of D_2O in a position to deliver a labeled hydron to the ylide, $k_{reorg} \approx 10^{11}$ s^{-1} (Scheme 2) (4, 11, 34). It has been shown in earlier work that reorganization of solvent is largely rate-determining for the lyoxide ion catalyzed deprotonation of cyanoalkanes (4). The following comparisons between proton transfer at cyanoalkanes and at $\mathbf{Me_4P^+}$ and $\mathbf{Me_3S^+}$ provide strong evidence that these reactions proceed with the common rate-determining step of solvent reorganization.

(1) There is a simple correlation between the decreasing importance of buffer catalysis of carbon deprotonation on moving from dihydroxyacetone phosphate (35) to acetamide (10) (Scheme 3) and the increasing reactivity and decreasing lifetime of the carbanion product of carbon deprotonation (10). No buffer catalysis is observed for the limiting case where the reorganization of solvent

to place a molecule of D_2O in a position to deliver a labeled hydron to the carbanion is rate-determining, because it is not possible for the buffer catalyst to increase the rate of solvent reorganization. Therefore, the observation that there is no buffer catalysis of carbon deprotonation either of cyanoalkanes (4) or of **Me_4P^+** and **Me_3S^+** (this work) is consistent with a common rate-determining step of solvent reorganization (k_{reorg}, Scheme 2) for these three proton transfer reactions.

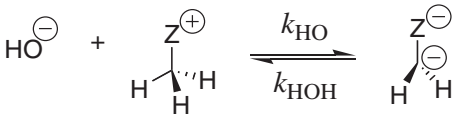
(2) There are similar intrinsic rate constants at $\Delta pK_a = 0$ of $k_o \approx 10^4$ (mol/L)$^{-1}$ s^{-1} for deprotonation of the dimethyl-9-fluorenylsulfonium ion (**1**) by primary amines in water–DMSO (95:5) (20) and $k_o \approx 10^{3.6}$ (mol/L)$^{-1}$ s^{-1} for deprotonation of 9-cyanofluorene (**2**) in water–DMSO (90:10) (18). This shows that the α-SMe_2^+ and α-CN substituents have similar effects on the Marcus intrinsic barrier for proton transfer at carbon. The rate constants $k_{DO} = 2.7 \times 10^{-4}$ (mol/L)$^{-1}$ s^{-1} for deprotonation of acetonitrile (4) and $k_{DO} = 7.5 \times 10^{-4}$ (mol/L)$^{-1}$ s^{-1} for deprotonation of **Me_3S^+** (this work) are also similar. The reactions, which proceed with similar rate constants and Marcus intrinsic barriers, also have a similar thermodynamic drive force (12, 36, 37). Therefore, if $k_{-p} > k_{reorg} \approx 10^{11}$ s^{-1} for deprotonation of CH_3CN, as proposed in earlier work (4, 34), then the same relationship must hold for deprotonation of **Me_3S^+**. We are not aware of any data that would allow us to estimate the effect of an α-PMe_3^+ substituent on the intrinsic barrier to deprotonation of carbon.

Carbon acid pK_as

Table 2 gives the carbon acid pK_as for deprotonation of **Me_4P^+** and **Me_3S^+** in water obtained in this work. These pK_as were calculated using eq. [6] derived from Scheme 4 where k_{HO} is the second-order rate constant for deprotonation of the carbon acid by hydroxide ion in H_2O (Table 2), $k_{HOH} = k_{reorg} = 10^{11}$ s^{-1} is the first-order rate constant for protonation of the carbanion zwitterion by solvent water (4, 10, 11, 34), and $K_w = 10^{-14}$ (mol/L)^2 is the ion product of water.



$$[6] \qquad pK_a = pK_w + \log\left(\frac{k_{HOH}}{k_{HO}}\right)$$

The values of k_{HO} (Table 2) were calculated from the corresponding rate constants for deprotonation of the carbon acids by deuterioxide ion (Table 1) using the relationship $k_{HO} = k_{DO}/2.4$ where 2.4 is the maximum secondary solvent deuterium isotope effect on the reactivity of lyoxide ion (38). This is appropriate because almost the entire difference in the basicity of deuterioxide and hydroxide ions will be expressed in the transition state for carbanion formation when solvent reorganization is rate-determining for exchange (4). The principle of microscopic reversibility requires that the reverse protonation of these carbanion zwitterions by solvent water is also limited mainly by solvent reorganization, with a rate constant on the order of that for the dielectric relaxation of water, $k_{HOH} = k_{reorg} = 10^{11}$ s^{-1} (39–41).

The greater carbon acidity of **Me_3S^+** and **Me_4P^+** than of **Me_4N^+** (Table 1) is well-known (14). It represents the greater stabilization of sulfur and phosphorus than of nitrogen ylides from polarization of charge by the larger third-row atoms and, possibly, by hyperconjugation (15, 16) and back-bonding from carbon to the d orbitals of sulfur and phosphorus (17).

We are not able to account for the difference between the reported pK_as of 28.5 (Table 2) and 18.2 (42) for deprotonation of **Me_3S^+** in water and DMSO, respectively. The change from DMSO to water causes a large decrease in pK_a when the conjugate base of the acid is a strong hydrogen bond acceptor (42), and this solvent effect on pK_a becomes less with decreasing stabilization of the conjugate base by hydrogen bonding to water. However, a substantially lower pK_a for **Me_3S^+** in the organic solvent DMSO than in water would require an unprecedented preferential solvation of the products of proton transfer by DMSO. The pK_a of 18.2 for deprotonation of **Me_3S^+** in DMSO is also inconsistent with the pK_a of 17.8 for deprotonation of the benzylic carbon of **$Me_2(PhCH_2)S^+$** in DMSO (24) because the α-phenyl substituent should result in a substantial increase in carbon acidity. We note that the pK_a of 18.2 for **Me_3S^+** in DMSO was reported in a Table in a review article (42), but to the best of our knowledge, it has not been further documented.

Scheme 4.

Substituent effects on carbon acidity

Computational studies provide evidence for formal resonance delocalization of negative charge onto nitrogen at the cyanomethyl carbanion (43). However, it is not clear whether this delocalization of charge results in a large stabilization of this carbanion. For example, delocalization of negative charge at the acetate anion provides a simple explanation for the relatively high acidity of acetic acid. However, it has been proposed that this high acidity is largely due to inductive stabilization of negative charge by the electron-withdrawing carbonyl group (44). The following observations provide evidence that there is significant stabilization of the cyanomethyl carbanion by both polar and resonance interactions between the negative charge and the α-CN group.

(1) The polar effect of a cationic α-substituent on carbanion stability must be larger than the polar effect of the neutral α-cyano group, where the interaction is between the formal negative charge of the carbanion and the *partial* positive charge of the cyano dipole. Therefore, the essentially identical values of pK_a = 28.9 for acetonitrile (4) and pK_a = 29.0 for a *single methyl* group of **Me_3S^+** (Table 2) show that there is sufficient resonance stabilization of the cyanomethyl carbanion to balance the greater stabilization of the sulfur ylide from polarization and back-bonding effects.

(2) The Hammett substituent constants σ = 0.82 for *p*-NMe_3^+ and σ = 0.66 for *p*-CN (45) show that a *p*-NMe_3^+ substituent provides a larger stabilization of negative charge than does a *p*-CN substituent when the interaction occurs across a benzene ring. By comparison, the observation that pK_a = 28.9 for acetonitrile is much lower than pK_a > 33.4 for a *single methyl* group of **Me_4N^+** (Table 2) shows that an α-CN substituent provides a substantially larger stabilization of negative charge at a neighboring carbon than does an α-NMe_3^+ group. This shows that there is sufficient resonance stabilization of the cyanomethyl carbanion to balance the greater polar stabilization of the nitrogen ylide.

© 2005 NRC Canada

It is interesting that no large intrinsic barrier to proton transfer arises from the requirement for the movement of negative charge from nitrogen to carbon on moving to the transition state for protonation of α-cyano carbanions (4, 12, 46, 47). As discussed earlier (4), the proton transfer to α-cyano carbanions resembles proton transfer to acetate anion (48) in that the requirement for localization of negative charge at the reacting basic atom (carbon or oxygen) proceeding to the transition state does not result in a large intrinsic barrier for proton transfer.

The α-fluorenyl group at the dimethyl-9-fluorenylsulfonium ion (**1**, pK_a = 13.7 in water–DMSO (95:5) (20)) causes a 16-unit decrease in the statistically corrected pK_a of 29.5 for a *single proton* of $\mathbf{Me_3S^+}$, while the α-fluorenyl group at 9-cyanofluorene (**2**, pK_a = 10.7 in water–DMSO (90:10) (18)) causes a larger 19-unit decrease in the statistically corrected pK_a of 29.4 for a *single proton* of acetonitrile. This shows that the addition of an α-fluorenyl group results in a larger attenuation of the α-SMe_2^+ than of the α-CN substituent effect on carbon acidity. We suggest that this reflects the particularly sharp falloff ($1/r^4$) in the stabilization of negative charge by polarization onto a atom with increasing radius of separation of the interacting centers (45).

Synthesis of novel sulfonyl-stabilized phosphorus ylides, and the kinetics and mechanism of their conventional and flash vacuum pyrolysis reactions[1]

Rasha F. Al-Bashir, Nouria A. Al-Awadi, and Osman M.E. El-Dusouqui

Abstract: Nine substituted sulfonyl-stabilized phosphorus ylides were prepared by treating their intermediate ylide analogues with phenylmethanesulfonyl fluoride. The stoichiometric ratio of the reactants for each preparation needed to be adjusted according to the basicity of each ylide intermediate. The nine ylide compounds were then subjected to conventional (sealed-tube) gas-phase pyrolysis at 470–545 K. The pyrolytic reactions were homogeneous and obeyed a first-order rate equation. The values of the Arrhenius log A (s^{-1}) and E_a (kJ mol^{-1}) obtained for these reactions averaged 11.12 ± 2.00 and 131.8 ± 24.4, respectively. Analysis of the pyrolysates from conventional pyrolysis and from flash vacuum pyrolysis at 600 K showed the products to be complex mixtures of triphenylphosphine, triphenylphosphine oxide, triphenylphosphine sulfide, and symmetric and unsymmetric alkenes. Conventional pyrolysis also gave novel mixed sulfones and, for the *p*-methoxyaryl substituent, *p*-anisaldehyde. The products of the reactions under study are explained on the basis of a mechanism involving a sulfonyl carbene intermediate, and the reaction mechanism is used to rationalize the kinetic results and molecular reactivities.

Key words: ylides, synthesis, pyrolysis, kinetics, mechanism.

Résumé : La réaction d'analogues d'ylures intermédiaires avec le fluorure de phénylméthanesulfonyle a permis de préparer neuf ylures de phosphores substitués, stabilisés par un groupe sulfonyle. Le rapport stoechiométrique des réactifs nécessaires pour chacune des préparations a été ajusté en fonction de la basicité de chaque ylure intermédiaire. On a ensuite soumis chacun des neuf ylures à une pyrolyse à phase gazeuse, en tube scellé, à des températures allant de 470 à 545 K. Les réactions pyrolytiques sont homogènes et obéissent à une équation de vitesse du premier ordre. Les valeurs moyennes pour les paramètres d'Arrhenius, log A (s^{-1}) et E_a (kJ mol^{-1}), obtenues pour ces réactions sont respectivement de 11,12 ± 2,00 et de 131,8 ± 24,4. L'analyse des produits de pyrolyse conventionnelle et de pyrolyse éclair sous vide à 600 K montrent que les produits correspondent à des mélanges complexes comprenant de la triphénylphosphine, de l'oxyde de triphénylphosphine, de sulfure de triphénylphosphine ainsi que des alcènes symétriques et non symétriques. La pyrolyse conventionnelle conduit aussi à de nouvelles sulfones mixtes et, dans le cas du substituant *p*-méthoxyaryle, à du *p*-anisaldéhyde. Les produits des réactions obtenus dans cette étude sont expliqués sur la base d'un mécanisme impliquant un intermédiaire sulfonylcarbène et on utilise le mécanisme réactionnel pour rationaliser les résultats cinétiques et les réactivités molaires.

Mots clés : ylures, synthèse, pyrolyse, cinétique, mécanisme.

Introduction

Reports on the synthesis of sulfonyl-stabilized phosphorus ylides suggest two formal steps in the preparation: first, a base, butyl lithium (BuLi), reacts with the appropriate quaternary phosphonium halide salt (QS) in a nitrogen atmosphere to give an intermediate ylide, which then proceeds to react with the designated sulfonyl fluoride (RSO_2F) to form the target ylide (1–4). In the present study, this procedure was found, however, not to be uniform and straightforward, as the stoichiometric ratio of the reactants (QS:BuLi:RSO_2F) needed to be adjusted according to the basic strength of the ylide intermediate formed in the first step. Besides, it has been noted that α-sulfonyl ylides cannot be prepared by treatment of the intermediate ylides with sulfonyl chloride derivatives, since this procedure results in the formation of α-chloro ylides instead of the target sulfonyl-stabilized phosphorus ylides (4). Hence, sulfonyl fluorides were used instead.

Aitken et al. (1) have shown that flash vacuum pyrolysis at 600 K of sulfonyl-stabilized phosphorus ylides gave Ph_3P, Ph_3PO, Ph_3PS, and alkenes (either symmetric or unsymmetric). These products are consistent with the formation of

Scheme 1. Reaction pathway for ylides **3**–**9**.

a sulfonyl carbene intermediate. The phosphorus oxides and sulfides can be accounted for by the separate extrusion of Ph_3P and SO_2, which then partly combine to give Ph_3PO and Ph_3PS, and the validity of this was confirmed by control experiments (1). The sulfonyl-stabilized ylides were obtained as stable, high-melting solids with characteristic spectral data including diagnostic ^{31}P NMR signals at δ 16.9–21.7 ppm. Here, we report the results of a study on the kinetics and reaction product of thermolysis of nine substituted sulfonyl-stabilized phosphorus ylides using conventional (sealed-tube (ST); static) pyrolysis (CP), and compare the products of reaction with those from flash vacuum pyrolysis (FVP). The kinetic investigation also provides a novel insight into molecular reactivities and the effects of substituents on the pyrolysis of stabilized phosphorus ylides.

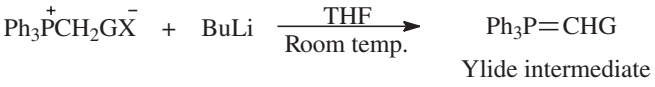
The nine ylide compounds under study are derivatives of [(benzylsulfonyl)methylene](triphenyl)phosphorane (Ph_3P=C(G)SO_2CH_2Ph) in which the substituent (G) is: *p*-CNC_6H_4 (**1**), *p*-$NO_2C_6H_4$ (**2**), *m*-$NO_2C_6H_4$ (**3**), *p*-ClC_6H_4 (**4**), *m*-ClC_6H_4 (**5**), C_6H_5 (**6**), *p*-$CH_3C_6H_4$ (**7**), *p*-$CH_3OC_6H_4$ (**8**), and CH_3 (**9**), respectively.

Results and discussion

Synthesis

Synthesis of ylides **3**–**9** according to literature procedures (1) required the ratio of the reactants, quaternary phosphonium halide salt ($Ph_3P^+CH_2GX^-$) : BuLi : phenylmethanesulfonyl fluoride ($PhCH_2SO_2F$), to be 2:2:1; as these reactions involve transylidation to regenerate one molecule of quaternary phosphonium fluoride salt (Scheme 1). In these cases, the basicity of the ylide intermediate formed in step 1 is high enough for it to act also as the base needed to abstract the proton from the quaternary phosphonium salt formed in step 2*a* to give the target ylide in transylidation step 2*b*. The electron-withdrawing substituents (CN and *p*-NO_2) of the phenyl group in ylides **1** and **2**, respectively, will decrease the protophilic character of the multiple bond of these ylides relative to that of ylides **3**–**9**, and so the amount of BuLi base had to be doubled to avoid formation of excess ylide intermediate and to provide the base required in step 2*b* (Scheme 2). Accordingly, the reactant ratio of quaternary phosphonium halide salt : BuLi : phenylmethanesulfonyl fluoride was adjusted to 1:2:1.

Attempts to synthesize ylide **1** (G = *p*-CNC_6H_4) using the ratio of 2:2:1 failed to give any ylide product. Besides, it is of interest to note that the reactant ratio of 1:2:1, which gave ylide **2** (G = *p*-$NO_2C_6H_4$) in 72% yield, failed to give ylide **3** (G = *m*-$NO_2C_6H_4$), which, however, was obtained in 65% yield when the reactant ratio of 2:2:1 was used instead; this same ratio was also used for ylides **3**–**9**. The present findings indicate that the basicity of the ylide intermediate obtained in the initial step of the reaction determines whether the intermediate ylide is basic enough to act as the proton scavenger in the transylidation reaction, or that the stronger BuLi base is needed to complete the reaction. The stoichiomeric ratio of the reactants as well as the % yield of the target ylides correlate well with the expected relative basicities of the intermediate ylides as judged by the electron-donating and electron-withdrawing effect of the group in substituent G.



Pyrolysates and reaction mechanism

Reaction products for complete pyrolysis were obtained for all nine substrates (*i*) in a FVP (flow) reactor at 600 K, and (*ii*) in a sealed-tube pyrolyser (static method) at temperatures exceeding those used in the kinetic investigations. The static-method reactions (CP reaction) were allowed ample residence time to ensure maximum pyrolysis. The constituents of the pyrolysates obtained by this method were isolated

using preparative liquid chromatography (PLC) and analyzed using GC–MS, FT-IR, and ^{1}H NMR techniques. The pyrolysates from FVP were collected in a cold trap. FVP and CP gave identical products of Ph_3P, Ph_3PO, Ph_3PS, and alkenes (symmetric and unsymmetric) (Scheme 3). However, static pyrolysis of the ylides followed by PLC gave better separation and isolation profiles of alkenes, and allowed the identification of more reaction products, including *p*-anisaldehyde and mixed sulfones, which were not detected in the pyrolysates from FVP. It is noteworthy that the static (sealed-tube) method provides longer residence time for novel pyrolytic reaction pathways. Identification and characterization of the constituents of the pyrolysates are detailed in the Experimental section.

[(Benzylsulfonyl)(4-cyanophenyl)methylene](triphenyl)-phosphorane (ylide 1)

The analysis of the pyrolysates — separated as oils — showed 4-cynostilbene, which was separated in pure form on PLC. *trans*-Stilbene and novel *trans*-4,4′-dicyanostilbene were also isolated in a very pure state as well from a separate fraction. In a third fraction, (4-cyanobenzyl)benzyl sulfone identified for the first time in the present study, was isolated as a novel sulfone only by CP.

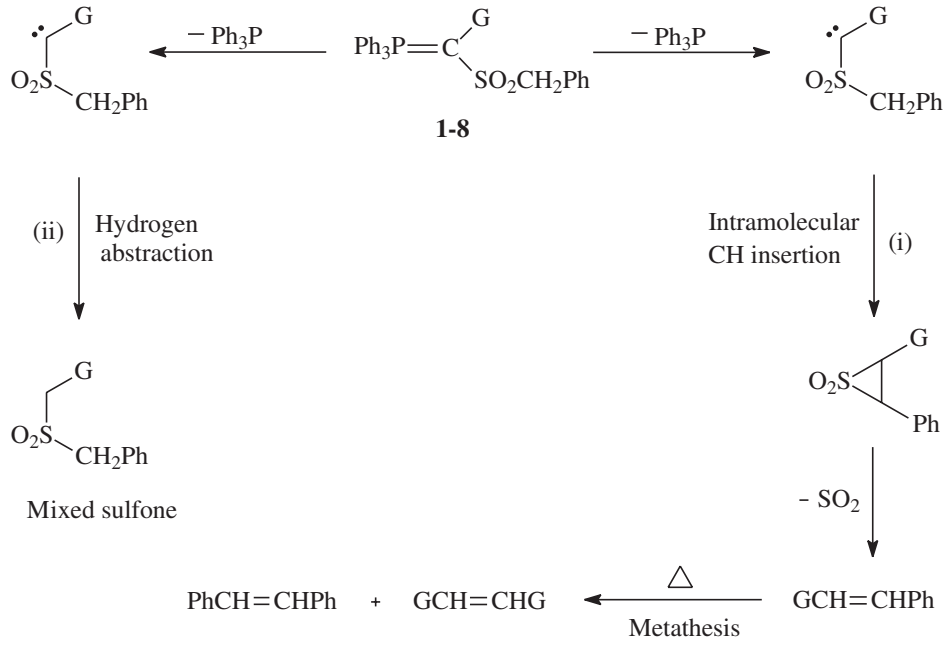
[(Benzylsulfonyl)(4-nitrophenyl)methylene](triphenyl)-phosphorane (ylide 2)

Analysis by ^{1}H NMR, IR, and MS showed a mixture of alkenes, namely, *trans*-4-nitrostilbene and *trans*-stilbene, both clearly identified. A major fraction, novel (4-nitrobenzyl)benzylsulfone, isolated by CP only, was properly characterized and identified.

[(Benzylsulfonyl)(3-nitrophenyl)methylene](triphenyl)-phosphorane (ylide 3)

The analysis of the products of reaction of this ylide showed a mixture of two alkenes: *trans*-3-nitrostilbene (major fraction) and *trans*-stilbene; the latter identified only through the static method. Besides, (3-nitrobenzyl)benzyl sulfone was isolated and clearly identified as a novel compound using the static pyrolysis technique.

[(Benzylsulfonyl)(4-chlorophenyl)methylene](triphenyl)-phosphorane (ylide 4)



The spectral analysis (^{1}H NMR, IR, and MS) of the products proved the presence of 4,4′-dichlorostilbene, which was separated in a pure form by PLC. Both *trans*-4-chlorostilbene and *trans*-stilbene were present as well in small amounts. The ^{1}H NMR for *trans*-4-chlorostilbene in $CDCl_3$ showed signals (5) at δ 6.83 (1H, d, J = 16.4 Hz), 6.91 (1H, d, J = 16.4 Hz), 7.07–7.42 (9H, m). MS *m/z*: 216 (34% abundance) molecular ion, 215 (17%), 214 (100%) base peak, 179 (45%), 178 (59%). Novel (4-chlorobenzyl)benzyl sulfone obtained by the static technique was separated as a pure fraction on PLC.

[(Benzylsulfonyl)(3-chlorophenyl)methylene](triphenyl)phosphorane (ylide 5)

Reaction product separation on PLC showed 3-chlorostilbene, 3,3′-dichlorostilbene, and *trans*-stilbene. ^{1}H

Scheme 4. Generation and further reaction of the sulfonyl carbene intermediate of ylides **1**–**8**.

NMR for *trans*-3,3′-dichlorostilbene in $CDCl_3$ showed diagnostic signals (6) at δ 7.03 (2H, s), 7.32–7.42 (8H, m), and for *trans*-3-chlorostilbene (7) at δ 6.85 (1H, d, *J* = 16.5 Hz), 6.92 (1H, d, *J* = 16.5 Hz), 7.11–7.42 (9H, m). (3-Chlorobenzyl)benzyl sulfone was also isolated for the first time in this study using CP.

It is to be noted that FVP does not give the sulfone products.

Ylides 6, 7, and 9

The FVP at 600 K of these ylides has been studied before (1). In each case a mixture of Ph_3P, Ph_3PO, and Ph_3PS was produced together with various alkenes, exactly as observed in the present study for ylides **1**–**5**. Static pyrolysis of these ylides gave products identical to those obtained through FVP.

[(Benzylsulfonyl)(4-methoxyphenyl)methylene](triphenyl)-phosphorane (ylide 8)

The spectral analysis of the products by both FVP and the static method showed *trans*-methoxystilbene; δ_H ($CDCl_3$) (6): 4.01 (3H, s), 6.88 (2H, d, *J* = 8.5 Hz), 6.98 (1H, d, *J* = 16.3 Hz), 7.08 (1H, d, *J* = 16.3 Hz), 7.10–7.55 (m, 7H). MS *m*/*z*: 210 ($M^{+\cdot}$, 22% abundance) molecular ion, 209 (100%) base peak, and fragment ions at 194 (12%), 195 (6%), 165 (33%), 166 (10%), 152 (6%), 135 (16%), 121 (33%).

In a separate fraction, *trans*-4,4′-dimethoxystilbene was identified; δ_H ($CDCl_3$) (8): 3.86 (6H, s), 6.91 (4H, d, *J* = 6.85 Hz), 6.95 (2H, s), 7.45 (4H, d, *J* = 6.85 Hz). MS *m*/*z*: 240 ($M^{+\cdot}$, 100%), molecular ion and base peak, fragment ions (9) at 226 (18%), 225 (49%), 165 (45%), 153 (28%), 152 (32%), 120 (12%). Besides, *trans*-stilbene was also isolated in a third fraction, but the sulfone fraction could not be identified even on using CP. Instead, 4-methoxybenzyaldehyde (*p*-anisaldehyde) was isolated in a very pure state.

According to these results, the composition of the products of the gas-phase pyrolysis of the substituted sulfonyl-stabilized ylides (**1**–**9**) was as shown in Scheme 3. Based on the overall pyrolysate composition, a feasible reaction mechanism is proposed to account for the product of the gas-phase pyrolytic reaction of the sulfonyl-stabilized phosphorus ylides (**1**–**9**) under study. The mechanism involves the formation and further reaction of a sulfonyl carbene intermediate (1).

In the case of ylides **1**–**8** (Scheme 4): (*i*) The carbene intermediate obtained reacts by an intramolecular CH insertion process to give thiirane dioxide, followed by loss of SO_2, alkene metathesis, and the partial reaction of Ph_3P with SO_2 to give Ph_3PO and Ph_3PS; (*ii*) the carbene intermediate abstracts hydrogen in a novel reaction, observed only in pyrolysis by the static method of ylides **1**–**5** (all with an electron-withdrawing group in substituent G), to give mixed sulfones (Scheme 4). It is to be noted that for ylide **6** (G = Ph) and ylides **7** and **8** (electron-donating groups in G) no such sulfone products were detected in the pyrolysates. The formation of 4-methoxybenzaldehyde (*p*-anisaldehyde) by ylide **8** involves a novel route in which the carbene centre seems to abstract O and H possibly through a free radical pathway to give the aldehyde. An earlier study on the pyrolysis of arylsulphonyl-stabilized phosphorus ylides reports aldehyde formation for substrates in which the aryl substituent is an *o*-methoxyphenyl group (1).

When G = CH_3 (ylide **9**), literature reports (1, 3) suggest two pathways (Scheme 5) for the reaction of the sulfonyl carbene intermediates.

Kinetic analysis

The kinetic data of the pyrolytic gas-phase elimination reactions of the nine ylides (**1**–**9**) under study are given in Table 1. Each rate constant at any given temperature represents an average from a set of three values obtained in three separate kinetic runs conducted at the same temperature. The agreement among the values of the rate constant in each set is within ±2%. Each kinetic run was monitored until 90%–95% of the reaction was completed, and the range of 44 ±

6 K over which the reactions were followed is in accord with the temperature range deemed necessary for reliable kinetic analysis of thermal gas-phase elimination reactions (10, 11). Arrhenius parameters were obtained using the results from Table 1. The Arrhenius plots were linear over the studied temperature and reaction range, with correlation coefficients of the order of 0.990 ± 0.009. A representative plot is given in Fig. 1 for [(benzylsulphonyl)(4-cyanophenyl)methylene](triphenyl)phosphorane (ylide **1**), with a correlation coefficient of 0.999. Arrhenius log A (s^{-1}), $\Delta S^{\ddagger}$ (J K^{-1} mol^{-1}), the energy of activation (E_a, kJ mol^{-1}), and the first-order rate constants (k, s^{-1}) of the pyrolysis reactions at 500 K are recorded in Table 1. The values for $\Delta S^{\ddagger}$ (J K^{-1} mol^{-1}) are negative or small (positive) suggesting higher structural organization and the formation of an ordered transition state.

Fig. 1. Arrhenius plot for the pyrolysis of ylide **1**.

Molecular reactivities and substituent effects

The first-order rate constants at 500 K of the gas-phase pyrolytic reactions of ylides **1**–**9** and the rate constant ratio (relative rate, k_{rel}) of the ylides are summarized in Table 2.

The main features of the kinetic results are as follows:

1. The rate of pyrolysis of ylide **9**, where G = CH_3, is ca. 3 times faster than the rate of pyrolysis of ylide **6**, where G = C_6H_5; this represents the highiest increment in reactivity in the series of ylides under consideration and is attributed to the fact that the reactive carbene intermediate of ylide **9** can react either by 1,3-H insertion or 1,2-H insertion followed by the elimination of SO_2. The pyrolysates 1-phenylpropene and dibenzyl prove the possibility of both modes of insertion, where G is the aromatic phenyl group, the carbene intermediate can react only by 1,3-insertion.
2. Introducing *p*-methyl and *p*-methoxy groups into the aromatic ring ylides **7** and **8** respectively, has increased the rate of pyrolysis by almost 2.3 times for both ylides; this could be explained in terms of the electron-donating nature of these substituents and their influence on the carbene intermediate suggested (Schemes 4 and 5).
3. When electron-withdrawing substituents (*p*-Cl, *m*-Cl, and *p*-CN) were introduced into ylides **4**, **5**, and **7**, respectively, the reactivity was reduced; this indicates that these substituents destabilize the carbene intermediate.
4. Introducing the nitro group at the *para* and *meta* positions of ylides **3** and **4**, respectively, resulted in no change on the reactivity compared to ylide **6** (G = C_6H_5); this unique behaviour of the nitro group in the gas-phase thermal elimination reactions of organic compounds has been reported in other studies (12).

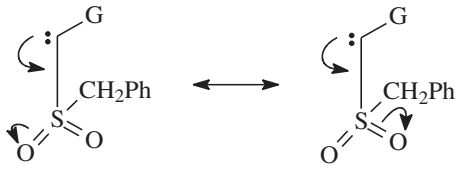
8	*p*-$CH_3OC_6H_4$	12.48	2.35
9	CH_3	16.17	3.04

5. It is important to note that these sulfonyl carbene intermediates are already stabilized by conjugative interaction with the sulfonyl group (Scheme 6), and this might be the reason behind the relatively small substituent effects obtained.

These features of the kinetic results support the reaction pathways suggested and that the formation of the carbene intermediate is the rate-controlling step.

Experimental

Materials, techniques, and instrumentation



The required quaternary phosphonium salts were prepared by the reaction of the appropriate alkyl halide with triphenylphosphine in boiling toluene. The phenylmethanesulfonyl fluoride, BuLi, and dry THF are commercially available from Aldrich. Further drying of THF was made by distillation from potassium benzophenone ketyl under N_2. The ylides and the constituents of their pyrolysates were characterized using GC–MS, FT-IR, ^{1}H NMR, ^{13}C NMR, and ^{31}P NMR spectroscopy. Instrumentation included a Finnigan Mat INCOSXL for GC–MS studies, a PerkinElmer 2000 spectrometer for FT-IR, and a Bruker DPX 400 spectrometer for the NMR analysis. Kinetic runs and pyrolysates preparation for reaction product analysis using a sealed-tube pyrolyser (conventional static pyrolysis) were conducted in a Chemical Data System (CDS) custom-made pyrolyzer comprising an insulated aluminum block fitted with a platinum-resistance thermometer and thermocouple connected to a Comark microprocessor thermometer. The temperature of the aluminum block was controlled by a digital Eurotherm 093 precision temperature regulator. Aluminum was chosen for its low temperature gradient and resistance to elevated temperatures. HPLC analysis of kinetic runs was carried out on a Waters prope (pump model 515 and UV detector model 2487).

FVP was conducted in a fused-quartz tube, which was housed in a sublimation oven. The latter was connected to a hot zone pyrolyzer under low pressure ending with a U-shaped trap cooled in liquid nitrogen.

Synthesis and characterization of ylides (1–9)

The details of the synthesis of the novel sulfonyl-stabilized ylides **1** and **3**–**5** are given in the following, while ylides **2** and **6**–**9** were prepared following literature procedures (1, 3). The general procedure A for the synthesis of ylides **1** and **2**, and procedure B for the preparation of ylides **3**–**9** are described hereafter.

Scheme 6. Carbene intermediate stabilization by conjugative interaction with sulfonyl groups.

Synthesis

Procedure A

In the synthesis of ylides **1** and **2**, a solution of 1.6 mol/L BuLi in hexane (7.5 mmol) was slowly added from a syringe to a stirred suspension of the corresponding quaternary phosphonium salt (7.5 mmol) in dry THF (50 mL) at room temperature under nitrogen. The mixture was stirred for about 1 h, and then an equivalent amount of phenylmethanesulfonyl fluoride (7.5 mmol) in dry THF (ca. 5 mL) was added all at once. The reaction mixture was stirred further for 5 h, followed by the addition of another portion of BuLi in hexane (7.5 mmol). The crude material was dissolved in dichloromethane (100 mL), washed with water (3 × 75 mL), dried, and concentrated under vacuum. The residual oil was triturated with a suitable solvent to obtain the pure ylide.

Procedure B

For the preparation of ylides **3**–**9**, a suspension of the appropriate quaternary phosphonium salt (15 mmol) in dry THF (100 mL) was stirred at room temperature under nitrogen while a solution of 1.6 mol/L BuLi in hexane (15.6 mmol) was slowly added from a syringe. The mixture was stirred further for about 1 h, and then a solution of phenylmethanesulfonyl fluoride (7.5 mmol) in dry THF (10 mL) was added dropwise to the ylide solution. The mixture was kept stirring overnight, and the reaction mixture was then filtered and the filtrate was evaporated. The residue was dissolved in dichloromethane (150 mL) and washed with water (3 × 75 mL), dried and the solvent evaporated (1, 3).

A problem encountered in the preparation of stabilized ylides in general, and in the synthesis of the present ylides, they were often difficult to crystallize in pure form from the oils obtained following the evaporation step. Since the products hydrolyzed when chromatography was attempted, and decomposed on sublimation, the safer option was their trituration with suitable solvents to obtain the pure ylides (13).

Characterization

Ylides **2** and **6**–**9** were gratefully received from Dr. Alan Aitken, University of St. Andrews, St. Andrews, Fife UK. The ylides were purified, recrystallized from dichloromethane–ether (ylide **2**), ethylacetate (ylides **6**–**9**), and characterized before use.

[(Benzylsulfonyl)(4-cyanophenyl)methylene](triphenyl)-phosphorane (1)

The quaternary phosphonium salt, 4-cyanobenzyltriphenylphosphonium bromide (**$Ph_3P^+CH_2$*p*-$NCC_6H_4Br^-$**), was prepared by refluxing 10.49 g of triphenylphosphine (0.04 mol) and 7.84 g (0.04 mol) of α-bromo-*p*-tolunitrile in 60 mL toluene for 18 h to get 11 g (ca. 60%) of the salt; mp 326–329 °C (14). ^{1}H NMR ($CDCl_3$) (15) δ_H: 5.92 (2H, d, J = 15.6 Hz), 7.32 (2H, d, J = 8 Hz), 7.43 (2H, dd, J = 2.3, 8.2 Hz), 7.57–7.61 (6H, m), 7.73–7.83 (9H, m). ^{13}C NMR (DMSO) ($J_{P\text{-}C}$) δ_C: 29.17 (d, J = 46.6 Hz, P-CH_2), 112.22 (d, J = 3.8 Hz), 118.50 (d, J = 85.3 Hz, C-1 of P-Ph), 119.37 (d, J = 2 Hz), 131.26 (d, J = 12.5 Hz, C-3 of P-Ph), 132.80 (d, J = 5.4 Hz), 133.64 (d, J = 3 Hz, C-4 of P-Ph), 135.09 (d, J = 10 Hz, C-2 of P-Ph), 135.15 (d, J = 8.2 Hz), 136.32 (d, J = 2.7 Hz). ^{31}P NMR ($CDCl_3$) δ_P: 25.12. Anal. calcd. for $C_{26}H_{21}BrNP$ (%): C 68.12, H 4.58, N 3.06; found: C 68.10, H 4.63, N 3.17.

The target ylide **1** was prepared by treating the obtained salt with BuLi followed by phenylmethanesulfonyl fluoride in a 1:2:1 ratio, as shown in procedure B. The yellow material that remained after evaporation of the solvent was triturated with diethyl ether to afford a solid material, which was recrystallized from acetonitrile to give 1.80 g of yellow crystals (ca. 45%); mp 276–278 °C. IR υ_{max} (cm^{-1}): 2216, 1594, 1285, 1263, 1177, 1141, 1101, 994, 695, 544, 514. ^{1}H NMR ($CDCl_3$) δ_H: 3.88 (2H, s), 6.95 (2H, d, J = 8 Hz), 7.09 (2H, d, J = 8 Hz), 7.16 (2H, d, J = 8 Hz), 7.25–7.28 (2H, m), 7.30–7.34 (1H, m), 7.40–7.45 (6H, m), 7.54–7.61 (9H, m). ^{13}C NMR ($CDCl_3$) ($J_{P\text{-}C}$) δ_C: 51.3 (d, J = 126 Hz, P=C), 62.9 (CH_2), 106.5 (C≡N), 120.13, 126.55 (d, J = 92 Hz, C-1 of P-Ph), 128.37, 128.77, 129.10 (d, J = 12 Hz, C-3 of P-Ph), 131.17 (2C), 131.46 (d, J = 9 Hz), 132.37 (d, J = 5.4 Hz), 132.67 (d, J = 3 Hz, C-4 of P-Ph), 132,46 (d, J = 9.7 Hz), 134.48 (d, J = 10 Hz, C-2 of P-Ph), 142.65 (d, J = 9.5 Hz). ^{31}P NMR ($CDCl_3$) δ_P: 19.36. MS *m*/*z*: 531 ($M^{+\cdot}$, 2), 440 (25), 392 (14), 376 (16), 277 (18), 262 (68), 183 (55), 105 (100). Anal. calcd. for $C_{33}H_{26}NO_2PS$ (%): C 74.58, H 4.90, N 2.64, S 6.03; found: C 74.71, H 5.12, N 3.01, S 5.68.

[(Benzylsulfonyl)(4-nitrophenyl)methylene](triphenyl)-phosphorane (2)

Obtained by treating the obtained salt with BuLi followed by phenylmethanesulfonyl fluoride in a 1:2:1 ratio. Yield: 72%, mp 275 to 276 °C (3). IR υ_{max} (cm^{-1}): 1582, 1490, 1334, 1284, 1264, 1142, 1107, 992, 936, 695 (3). ^{1}H NMR ($CDCl_3$) δ_H (3): 3.86 (2H, s), 6.84 (2H, d, J = 8.9 Hz), 7.11 (2H, d, J = 7.1 Hz), 7.29–7.34 (3H, m), 7.43–7.48 (6H, m), 7.56–7.66 (9H, m), 7.71 (2H, d, J = 8.8 Hz). ^{13}C NMR ($CDCl_3$) ($J_{P\text{-}C}$) δ_C: 54.03 (d, J = 124 Hz, P=C), 63.10, 123.10, 126.00 (d, J = 92 Hz, C-1 of P-Ph), 128.55, 128.87, 129.29 (d, J = 12 Hz, C-3 of P-Ph), 130.53 (d, J = 6 Hz), 131.00, 131.52, 132.93 (d, J = 3 Hz, C-4 of P-Ph), 134.63 (d, J = 10 Hz, C-2 of P-Ph), 143.11, 145.81 (d, J = 10 Hz). ^{31}P NMR ($CDCl_3$) δ_P: 19.21. Kinetic measurements and product analysis

Stock solution (7 mL) was prepared by dissolving 6–10 mg of the ylide in acetonitrile as the solvent to give a concentration of 1000–2000 ppm. Internal standard was then added, the amount of which was adjusted to give the desired peak area ratio of ylide to standard (2.5:1). The solvent and the internal standard were selected because both are stable under the conditions of pyrolysis and they do not react with either ylide or product. The internal standards used in this study were chlorobenzene, 1,3-dichlorobenzene, and 1,2,4-trichlorobenzene. Each mixture was filtered before use to ensure a homogenous solution.

The weight ratio of the ylide with respect to the internal standard was calculated from the ratio of the ylide peak area to the peak area of the internal standard. The kinetic rate was obtained by tracing the rate of disappearance of the ylide with respect to the internal standard as follows:

An aliquot part (0.2 mL) of each solution containing the ylide and the internal standard was pipetted into the reaction tube, and the tube was placed in the pyrolyzer for 6 min under nonthermal conditions. A sample was analyzed using the HPLC probe with the UV detector at a wavelength of 256 or 210 nm, and the standardization value (A_o) was then calculated. Several HPLC measurements were obtained with an accuracy of ≥2%. The temperature of the pyrolysis block was then raised until approximately 10% pyrolysis was deemed to occur over 900 s. This process was repeated after each 10–15 °C rise in the temperature of the pyrolyzer until >90% pyrolysis was achieved. The relative ratios of the integration values of the sample and the internal standard (*A*) at the pyrolysis temperature were then calculated. At least three kinetic runs were carried out at each reaction temperature following each 10–15 °C rise in the pyrolyzer temperature to ensure reproducible values of *A*. Treatment of the

Comparison of the nucleophilicities of alcohols and alkoxides[1]

Thanh Binh Phan and Herbert Mayr

Abstract: The kinetics of the reactions of benzhydrylium ions with some alcohols and alkoxides dissolved in the corresponding alcohols were photometrically investigated. Using the correlation equation log k (20 °C) = $s(E + N)$, the N and s parameters of methoxide, ethoxide, *n*-propoxide, and isopropoxide in alcohol–acetonitrile (91:9, *v*/*v*) were determined. The cosolvent acetonitrile has only a little influence on the rate constants of the reactions of alcohols and alkoxides. The order of N values ($OH^- << MeO^- < EtO^- < n\text{-}PrO^- < i\text{-}PrO^-$) shows that alkoxides differ only moderately in reactivity but are considerably more nucleophilic than hydroxide. As a consequence, the nucleophilic reactivity of a 0.5 mmol/L aqueous hydroxide solution increases by a factor of 13 when 10% (*v*/*v*) methanol is added. In 1–10 mmol/L alkoxide solutions in alcohols, weak electrophiles react considerably faster with alkoxides than with the corresponding alcohols. With increasing electrophilicity, the preference for alkoxides decreases, and electrophiles of $-3 < E < 3$ react with alkoxides (1–10 mmol/L) and alcohols with comparable rates. Stronger electrophiles will react with alcohols exclusively when alkoxides are present in concentrations ≤10 mmol/L.

Key words: kinetics, alcohol, alkoxide, linear free energy relationship, nucleophilicity.

Résumé : Faisant appel à la photométrie, on a étudié la cinétique des réactions d'ions benzhydrylium avec quelques alcools et alcoolates dissous dans les alcools correspondants. Utilisant l'équation de corrélation log k (20 °C) = $s(E + N)$ on a déterminé les paramètres N et s du méthylate, de l'éthylate, du propylate et de l'isopropylate dans un mélange 91 : 9 (*v*/*v*) d'alcool et d'acétonitrile. L'acétonitrile utilisé comme cosolvant n'a que peu d'effet sur les constantes de vitesse des réactions des alcools et des alcoolates. L'ordre des valeurs de N ($OH^- << MeO^- < EtO^- < n\text{-}PrO^- < i\text{-}PrO^-$) montre que les réactivités des alcoolates ne diffèrent que légèrement, mais qu'ils sont beaucoup plus nucléophiles que l'hydroxyde. En conséquence, la réactivité nucléophile d'une solution d'hydroxyde aqueux à une concentration de 0,5 mmol/L augmente par un facteur de 13 quand on lui ajoute 10 % (*v*/*v*) de méthanol. Dans des solutions d'alcoolates à des concentrations allant de 1 à 10 mmol/L, les électrophiles faibles réagissent beaucoup plus rapidement avec les alcoolates qu'avec les alcools correspondants. Avec une augmentation du caractère électrophile, la préférence des alcoolates diminue et les électrophiles de $-3 < E < 3$ réagissent avec les alcools et les alcoolates (à des concentrations allant de 1 à 10 mmol/L) avec des vitesses comparables. Les électrophiles plus forts ne réagissent qu'avec les alcools lorsque les alcoolates sont présents à des concentrations inférieures à 10 mmol/L.

Mots clés : cinétique, alcool, alcoolate, relation linéaire d'énergie libre, caractère nucléophile.

[Traduit par la Rédaction]

Introduction

Knowledge of relative nucleophilicities of alcohols and alkoxides is essential for the understanding of the course of numerous nucleophilic additions and substitutions involving these reagents. However, alcohols and alkoxides widely differ in nucleophilicity, and the choice of reaction partners that are suitable for kinetic investigations with both types of reagents has not been trivial (1).

Recently, we have demonstrated that benzhydrylium ions of variable reactivity can be used as reference electrophiles for comparing *n*-, π-, and σ-nucleophiles of widely differing reactivity (2). Equation [1], where E is an electrophilicity parameter and N and s are nucleophile specific parameters, allows one to predict rate constants for the reactions of nucleophiles with benzhydrylium ions with a standard deviation of less than a factor of 2; rate constants for the reactions with other types of carbocations and with Michael acceptors can be calculated with an accuracy better than a factor of 10–100 (2, 3). This precision is remarkable in view of the large structural variety and the more than 30 orders of magnitude presently covered by this correlation.

$$\log k\ (20\ ^\circ\mathrm{C}) = s(N + E) \qquad [1]$$

Recently, we have reported nucleophilicity parameters for typical solvents, which we have termed N_1 to indicate that

their use in eq. [1] gives rise to first-order rate constants (4). Alkoxides, one of the most important classes of nucleophiles, have so far not yet been characterized in this way. Since knowledge of their *N* and *s* parameters is crucial for a systematic analysis of nucleophilic aromatic substitutions as well as of S_N2 reactions, we set out to determine their nucleophilicity parameters as defined by eq. [1].

Results and discussion

Nucleophilic reactivities of alcohols

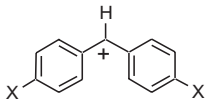
The rates of the reactions of methanol and ethanol with a series of benzhydrylium ions (Table 1) have been previously reported (4). We have now employed the same method for determining the rates of the reactions of *n*-propanol and isopropanol with benzhydrylium ions (eq. [2]).

[2] $$Ar_2CH^+BF_4^- + ROH \rightarrow Ar_2CHOR + HBF_4$$

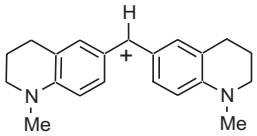
Due to the presence of amino substituents in the aryl groups, the addition of extra bases for neutralizing the liberated HBF_4 was not necessary. Most of the reactions were studied with 9% acetonitrile (*v*/*v*) as the cosolvent by mixing 10 volume parts of alcohol with one volume part of a solution of $Ar_2CH^+BF_4^-$ in acetonitrile in a stopped-flow instrument. However, the reactions of $(lil)_2CH^+$ and $(jul)_2CH^+$ with alcohols are sufficiently slow that they can also be studied in pure alcohols. Since the first-order decay rates of $(lil)_2CH^+$ and $(jul)_2CH^+$ in *n*-propanol–acetonitrile (91:9, *v*/*v*) are only 46% and 10% slower than in pure *n*-propanol, respectively (see the footnotes of Table 2), the influence of the cosolvent acetonitrile is only of minor importance for the following structure reactivity discussions.

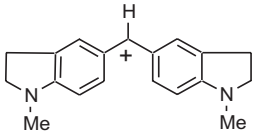
Plots of $\log k_1$ (Table 2) vs. the electrophilicity parameter (*E*) of the benzhydrylium ions (Table 1) gave straight lines (Fig. 1) from which, according to eq. [1], the nucleophilicity parameter (N_1) and slope parameter (*s*) were derived (Table 3). Division of the first-order rate constants in Table 2 by the molar concentrations of the alcohols gave second-order rate constants. Their plots vs. *E* gave correlation lines, which are parallel to those in Fig. 1, and gave rise to the nucleophilicity parameters (*N*), which are also listed in Table 3.

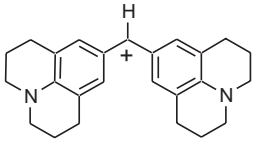
Nucleophilic reactivities of alkoxides



Because of the fast reactions of most benzhydrylium ions with alcohols, it was again necessary to study the reactivities of alkoxides in the corresponding alcohols in the presence of 9% (*v*/*v*) acetonitrile. Such solutions were obtained by mixing 10 parts of a solution of sodium alkoxide in the corresponding alcohol with 1 part of a solution of a benzhydrylium tetrafluoroborate in acetonitrile in a stopped-flow instrument. The reactions of $(lil)_2CH^+$ with alcohols were slow enough, however, that for this carbenium ion the influence of the cosolvent acetonitrile could be studied.







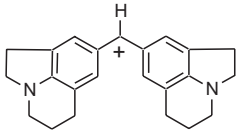


Figure 2 shows that the pseudo-first-order rate constant (k_{obs}) for the decay of $(lil)_2CH^+$ increases linearly with $[MeO^-]$ in both pure methanol and in methanol–acetonitrile (91:9, *v*/*v*). The nucleophilic reactivity of methoxide is approximately 42% larger in pure methanol than in methanol–acetonitrile (91:9, *v*/*v*) (Fig. 2). Analogously, the nucleophilic reactivities of OH^- in H_2O and of other alkoxides in the corresponding alcohols slightly decrease when 9% acetonitrile is added as a cosolvent (Table 4).

The intercepts of almost zero shown in Fig. 2 reflect the observation that the rates of the reactions of the alcohols with the carbocations (4) are negligible compared with the

i-PrO^-	17.71	0.58	17.03	0.63

[a]From reactions with benzhydrylium ions (Table 5).
[b]From reactions with benzhydrylium ions and quinone methides (Tables 5 and 6).
[c]From ref. 6.

Plots of the rate constants listed in Table 5 vs. the electrophilicity parameter *E* (Fig. 3) show an increase of the nucleophilicities of RO^- in ROH–CH_3CN mixtures in the order $OH^- << MeO^- < EtO^- < n\text{-}PrO^- < i\text{-}PrO^-$.

Intercepts and slopes of the correlations in Fig. 3 give the *N* and *s* parameters listed in the left part of Table 7. Since the cosolvent acetonitrile has only a little influence on the rate constants of the reactions of alkoxides with benzhydrylium ions (Table 4), one can combine the rate constants for the reactions of RO^- with benzhydrylium ions in alcohol–acetonitrile (91:9, *v*/*v*) (Table 5) and the corresponding rate constants for the reactions of RO^- with quinone methides in pure alcohols (Table 6) to give the reactivity parameters *N* and *s* listed on the right of Table 7.

Table 8 compares the relative reactivities of HO^- and RO^- in H_2O and ROH, respectively, toward $(ind)_2CH^+$, 1,3,5-trinitrobenzene (7), *n*-butyl bromide (8), and benzyl chloride (9).

[a]% (*v*/*v*).
[b]In H_2O, from ref. 20.

It is obvious that the relative reactivities of hydroxide and alkoxides (dissolved in their conjugate acids H_2O or ROH) toward carbocations, 1,3,5-trinitrobenzene, and alkyl halides depend on the electrophiles. While methoxide in methanol is 5 times less reactive than ethoxide in ethanol toward carbocations and 1,3,5-trinitrobenzene, their reactivities in S_N2 reactions are almost identical (Table 8). How can one explain these differences?

Previously, good correlations between Ritchie's nucleophilicity parameter (N_+) (derived from reactions with carbocations (1*a*, 10)) and Swain–Scott's parameter (*n*) (derived from reactions with methyl halides (11)), as well as between our nucleophilicity parameter (N_1) (derived from reactions with benzhydrylium ions (4)) and Kevill's solvent nucleophilicity (N_T) (derived from reactions with methylsulfonium ions (12)), have been reported (4, 13, 14).

Since the electrophilicities of the benzhydrylium ions have been demonstrated to be almost independent of the solvent (15), one can assume that the relative reactivities toward $(ind)_2CH^+$ (first line of Table 8) predominantly reflect the relative nucleophilicities of hydroxide and alkoxides in the corresponding solvents, i.e., *i*-PrO^- in *i*-PrOH is 5 times more nucleophilic than EtO^- in EtOH, which is 5 times more nucleophilic than MeO^- in MeOH. In S_N2 reactions, the differences in nucleophilicity will generally be attenuated, and we have reported that approximately half of the differences in nucleophilicities toward carbocations are found in S_N2 reactions with methyl sulfonium ions (4). The S_N2 reactions with alkyl halides will furthermore be affected by the variable electrophilic component of the solvent as expressed by Winstein–Grunwald's solvent ionizing power (*Y*) (16), which decreases in the order H_2O >> MeOH > EtOH > *i*-PrOH (17). A combination of the two effects, as expressed by the extended Winstein–Grunwald equation (12*b*, 18) accounts for the different reactivity order toward *n*-BuBr and $PhCH_2Cl$. Thus, MeO^- in MeOH and EtO^- in EtOH show similar reactivities toward these alkyl halides because the higher nucleophilicity of EtO^- as compared to that of MeO^- (Table 7) is compensated by the higher ionizing power of MeOH as compared to that of ethanol. The reactivity order *i*-PrO^- in *i*-PrOH < EtO^- in EtOH in reactions with *n*-BuBr and $PhCH_2Cl$ can be analogously be attributed to the variable electrophilic contribution of the solvents.

The striking differences in nucleophilicity between basic aqueous and basic alcoholic solutions shown in Fig. 3 suggest that the nucleophilicities of basic aqueous solutions may considerably be enhanced by adding small amounts of alcohols. Table 9 and Fig. 4 indicate that this is indeed the case. However, because of the higher pK_a values of propanol and ethanol, 10% (*v*/*v*) of these alcohols cause an increase of only a factor of 4 to 5. In contrast, 10% (*v*/*v*) methanol increases the nucleophilicity of a 0.5 mmol/L OH^- solution by a factor of 13 (19). This tremendous effect, resulting from the low pK_a value of methanol and the high nucleophilicity of methoxide, may be utilized in synthetic procedures.

Comparison of alcohols and alkoxides

Let us finally turn to the comparison of the nucleophilicities of alcohols and alkoxides, which can be derived from Tables 2 and 5. It was found that the second-order rate constants for alkoxides are generally 5–7 orders of magnitude greater than the first-order rate constants for alcohols. As a consequence, in 10 or 1 mmol/L solutions of alkoxides in alcohols, weak electrophiles will react almost exclusively with alkoxides and not with the solvents (Fig. 5). This ratio decreases with increasing reactivities of the carbocations be-

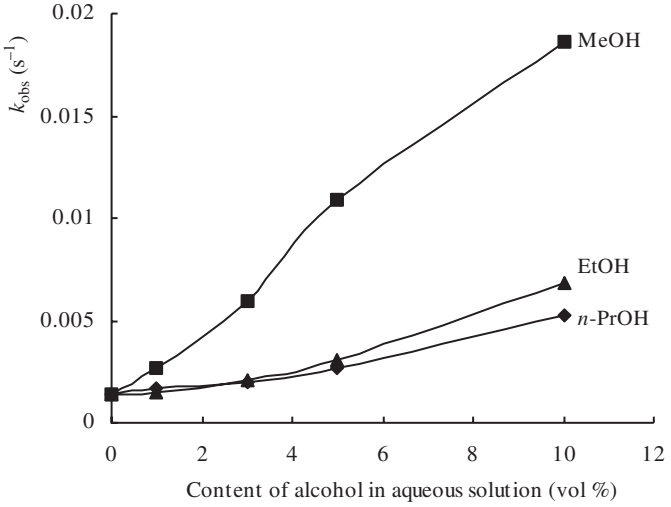
Fig. 4. Effect of alcohol additives on the pseudo-first-order rate constants (k_{obs}, s^{-1}, at 20 °C) of the decay of $(jul)_2CH^+BF_4^-$ (0.014 mmol/L) in basic water–acetonitrile (91:9, *v*/*v*) solutions ($[OH^-] + [RO^-] = 0.5$ mmol/L).



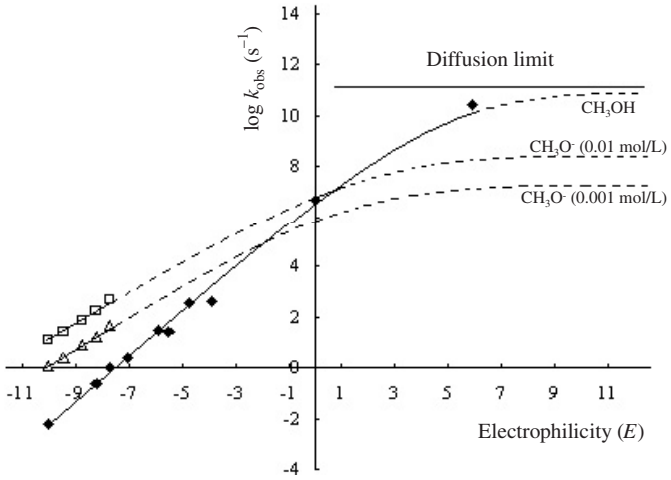


Fig. 5. Pseudo-first-order rate constants (k_{obs}, s^{-1}, at 20 °C) for the reactions of carbocations with methoxide and methanol in 1 and 10 mmol/L solutions of methoxide in methanol–acetonitrile (91:9, *v*/*v*). The rate constant for the reaction of Ph_2CH^+ (E = 5.90) with methanol was taken from ref. 22.

cause of the greater slopes of the alcohol correlations, and in the range $-3 < E < 3$, crossing of the correlation lines takes place. Highly reactive carbocations will almost exclusively react with the solvent that is present in higher concentration and not with the more nucleophilic alkoxides (21).

Though the kinetic investigations in this study were performed with benzhydrylium ions and quinone methides as reference electrophiles, the conclusions are of more general validity. Since eq. [1] has been demonstrated to generally hold for reactions of nucleophiles with various types of π electrophiles (5, 23*a*), e.g., other types of carbocations (3), Michael acceptors (23*b*), and electron-deficient arenes (24, 25), one can use the reactivity parameters determined in this work to predict whether alcohols or alkoxides are the effective nucleophiles in reactions of these electrophiles with alcoholic alkoxide solutions.

Experimental

Materials

Solvents

Reagent grade methanol (99.8%) was purchased from Acros (Nidderau), and absolute ethanol and *n*-propanol were distilled from magnesium and iodine. Anhydrous isopropanol (99.5%) was purchased from Aldrich (Munich). Anhydrous acetonitrile (99.5%) was purchased from Merck (Darmstadt).

Alkoxides

Sodium methoxide and sodium ethoxide were purchased from Acros (Nidderau). Stock solutions of other sodium alkoxides (*n*-propoxide and isopropoxide) were prepared by adding freshly cut sodium metal prewashed in the corresponding solvents to pure solvents maintained in an atmosphere of dry nitrogen. Solutions thus prepared were stored under dry nitrogen and analyzed immediately before use by titration with 0.1 mol/L HCl to the phenolphthalein-endpoint. Stock solutions of the sodium alkoxides were usually 0.1–0.15 mol/L. Solutions of lower concentrations were prepared by dilution.

Kinetic measurements

Because the reactions of the colored reference electrophiles with nucleophiles gave rise to colorless products, the decay of the absorptions of the electrophiles was followed by UV–vis spectroscopy (4, 6, 15*a*, 26).

The temperature of the solutions during all kinetic studies was kept constant (20 ± 0.1 °C) by using a circulating bath thermostat.

The rates of slow reactions ($\tau_{1/2} > 10$ s at 20 °C) were determined by using a J&M Tidas diode array spectrophotometer, which was controlled by Labcontrol Spectacle software and connected to a Hellma 661.502-QX quartz Suprasil immersion probe (5 mm light path) via fiber optic cables and standard SMA connectors. Hi-Tech SF-61DX2 stopped-flow spectrophotometer systems (controlled by Hi-Tech KinetAsyst2 software) were used for the investigation of rapid reactions (10 ms < $\tau_{1/2}$ < 10 s at 20 °C).

The stopped-flow experiments were performed by mixing 10 volume parts of the alcohols or solutions of the alkoxides in the corresponding alcohols with 1 volume part of the solutions of the reference electrophiles in acetonitrile to yield 91:9 (*v*/*v*) mixtures of alcohols and acetonitrile. The first-order or pseudo-first-order rate constants (k_{obs}, s^{-1}) were obtained by least-squares fitting of the absorbance A of the electrophiles to the single-exponential ($A_t = A_0 \exp(-k_{obs}t) + C$).

The first-order rate constants (k_1, s^{-1}) of the reactions of alcohols with the reference electrophiles were calculated as mean values of the k_{obs} obtained from several runs.

Alkoxide concentrations were at least 10 times as high as those of the electrophiles, resulting in pseudo-first-order kinetics with an exponential decay of the electrophile concentrations. As the k_{obs} increase linearly with the concentrations of the alkoxides, the slopes of the correlations correspond to

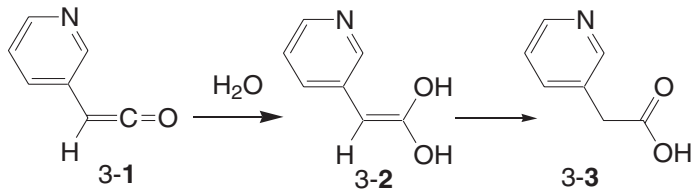
Acid enol and dihydropyridine intermediates in pyridylketene hydration — A computational study[1]

Andrei V. Fedorov, Katayoun Najafian, Thomas T. Tidwell, and Sinisa Vukovic

Abstract: 3-Pyridylketene (3-**1**) is found experimentally to undergo hydration forming an intermediate acid enol 3-**2**; whereas 2- and 4-pyridylketenes (2-**1** and 4-**1**), instead, form (carboxymethylene)dihydropyridine intermediates 2-**4** and 4-**4**, which live much longer than 3-**2**. Density functional calculations have been carried out to elucidate the hydration reactivity of these ketenes, and reveal that the dihydropyridine intermediates 2-**4** and 4-**4** are more stable than the unobserved acid enols 2-**2** and 4-**2** by 6.23 and 12.2 kcal/mol, respectively. For 3-**1** a pathway was calculated utilizing two H_2O molecules leading to the acid enol intermediate 3-**2**, which then forms 3-pyridylacetic acid (3-**3**). Hydration of 4-pyridylketene involves net 1,6-addition of water, and a pathway involving a bridge of six H_2O molecules connecting the pyridyl nitrogen and the carbonyl carbon was determined.

Key words: mechanisms of pyridylketene hydration, computations, enols, dihydropyridines.



Résumé : On a démontré expérimentalement que le 3-pyridylcétène (3-**1**) subit une hydratation qui conduit à la formation d'un intermédiaire acide énolique 3-**2** alors que les 2- et 4-pyridylcétènes (2-**1** et 4-**1**) conduisent plutôt à la formation d'intermédiaires (carboxyméthylène)dihydropyridines 2-**4** et 4-**4** dont les temps de vie sont beaucoup plus longs que celui du composé 3-**2**. On a effectué des calculs de densité fonctionnelle pour élucider la réactivité de ces cétènes vis-à-vis de l'hydratation et ils ont démontré que les intermédiaires dihydropyridines 2-**4** et 4-**4** sont beaucoup plus stables que les acides énoliques 2-**2** et 4-**2** qui n'ont jamais été isolés et que les différences d'énergie sont respectivement de 6,23 et 12,2 kcal/mol. Pour le composé 3-**1**, on a calculé une voie réactionnelle qui fait appel à deux molécules d'eau et qui conduit à l'intermédiaire acide énolique 3-**2** et finalement à l'acide 3-pyridylacétique (3-**3**). L'hydratation du 4-pyridylcétène implique une addition 1,6 d'eau et on a déterminé une voie réactionnelle impliquant un pont de six molécules d'eau reliant l'azote de la pyridine et le carbone du groupe carbonyle.

Mots clés : mécanisme de l'hydratation de pyridylcétènes, calculs, énols, dihydropyridine.

[Traduit par la Rédaction]

Introduction

In recent experimental studies in our laboratory (1) the 2-, 3-, and 4-pyridylketenes (2-**1**, 3-**1**, and 4-**1**) were generated as transient intermediates by laser flash photolysis of the corresponding diazo ketones in CH_3CN solution, with confirmation of the structures by the observation of the characteristic ketenyl absorptions at 2127, 2125, and 2128 cm^{-1}, respectively, using time-resolved infrared spectroscopy (TRIR) (1*d*). Studies of the hydration reactivity of these species using UV spectroscopy (1*a*) have shown that 3-**1** undergoes hydration to 3-pyridylacetic acid (3-**3**) via a transient acid enol intermediate 3-**2** comparable to that formed from phenylketene (1*b*). Two processes were observed in the reaction of 3-**1** and were assigned to the formation and decay of acid enol intermediate 3-**2** (eq. [1]) (1*a*). However, hydration of 2-**1** and 4-**1** did not form observable enols **2**, but instead, gave transient intermediates identified as (carboxymethylene)dihydropyridines (2-**4** and 4-**4**), resulting from the conjugate addition of H_2O (eqs. [2] and [3]) (1*a*). In the case of 2-**1**, the longer-lived transient decayed with biexponential kinetics, and it was proposed that both *Z*-2-**4a**

[5] 

and *E*-2-**4** were formed, possibly from the two conformers of 2-**1** (1*a*).

Previous examinations of the mechanisms of ketene hydration (2) include the classic experimental studies of arylketenes (2*a*) and of ketene itself (2*b*), and theoretical studies for ketene (3). The rate constants for the reaction of arylketenes **5** with H_2O were correlated with Hammett σ constants for the substituents with a slope of 1.2 (2*b*), indicative of rate-limiting nucleophilic attack of water on the carbonyl carbon in the ketene plane (2), with stabilization of partial negative charge in the transition state by the aryl group (eq. [4]) (3*a*).

Computational studies of the hydration of ketene favor structures in which multiple water molecules are involved, and for two H_2O molecules a cyclic transition state **6** is preferred, with a much lower barrier than for the addition of a single water molecule (3). This leads to the enol **7** of acetic acid (eq. [5]), and for some ketenes the acid enol intermediates have been detected by UV spectroscopy, including the recent studies of phenylketene (**5**, R = H) itself (1*b*). The acid enol $Ar_2C{=}C(OH)_2$ from ditipylketene ($Ar_2C{=}C{=}O$, Ar = 2,4,6-*i*-$Pr_3C_6H_2$) has been directly observed as a long-lived species in solution by NMR (4).

The N-H···O hydrogen bonding in *Z*-2-**4** (eq. [2]) is of additional interest for its resemblance to that observed in similar systems involving N-H···O hydrogen bonding proposed to be stabilized by resonance-assisted hydrogen bonds (RAHB) (5). The related example of intramolecular hydrogen bonding in the enol of acetylacetone has also been recently reinvestigated (5*d*).

The goal of the present study was a computational examination of the hydration of the pyridylketenes (2-**1**, 3-**1**, and 4-**1**), with an effort to answer such questions as the contrast between the behavior of 4-**1** in hydration and amination, forming a dihydropyridine and an enol, respectively, and to test the validity of the interpretations of the experimental results. It was also intended to see if any evidence for stabilization due to RAHB or pseudopericyclic transition states (6) could be found.

Results

Structures and energies of 2-**1**, 3-**1**, and 4-**1** and their hydration products were calculated at the B3LYP/6-311+G**//B3LYP/6-311+G** level using GAUSSIAN 98 (7), as reported in Table 1. The energies were corrected using calculated zero point vibrational energies (ZPVE). Relative energies (kcal/mol) for the different conformations were *syn*-2-**1** (0.0), *anti*-2-**1** (1.3), *syn*-3-**1** (4.2), *anti*-3-**1** (3.9), and 4-**1** (2.9); and the barriers to rotation about the aryl–ketenyl bond relative to the minimum energy conformation for each isomer were 7.2, 3.7, and 4.8 kcal/mol, respectively (Table 1).

The hydration products for the addition of one and two H_2O molecules examined include complexes **14**, transition structures **15**, acid enols **2**, (carboxymethylene)dihydropyridine

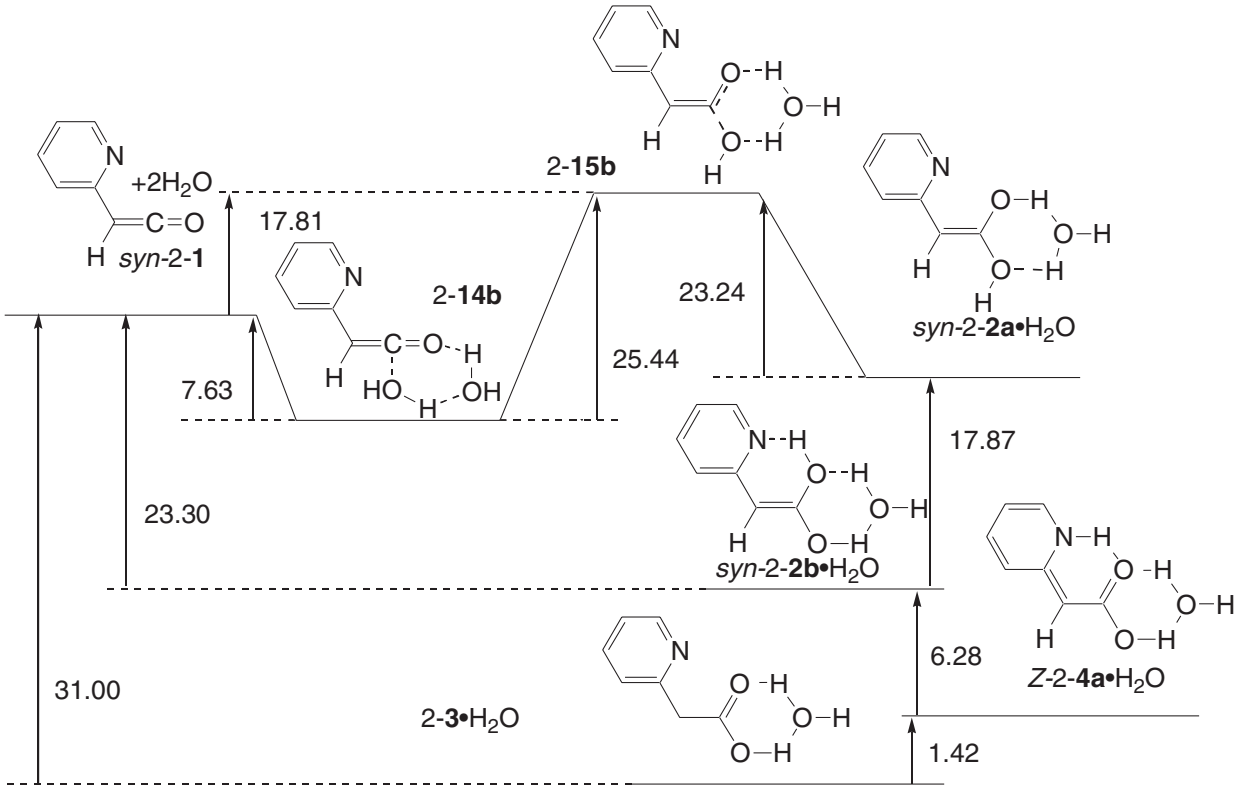
Table 1 (*concluded*).

[a]ZPVE = zero point vibrational energy.

intermediates 2-**4** and 4-**4**, and product arylacetic acids **3**. Energies are given in Table 1, and the reaction profile for hydration of *syn*-2-pyridylketene (*syn*-2-**1**) with two H_2O molecules is shown in Fig. 1. This shows the formation of initial complex 2-**14b**, transition structure 2-**15b**, and acid enol *syn*-2-**2a**·H_2O, which is 5.4 kcal/mol more stable than the reactants. The isomeric acid enol *syn*-2-**2b**·H_2O is a further 17.9 kcal/mol more stable, and this provides a measure of the strength of the intramolecular hydrogen bond. The dihydropyridine tautomer *Z*-2-**4a**·H_2O is more stable by an additional 6.3 kcal/mol, with a hydrogen bond length NH···O of 1.812 Å, while the acid *syn*-2-**3c**·H_2O is another 1.4 kcal/mol more stable. Profiles for the other reactions are given in Figs. S1–S3 (Supporting information).[4] For comparison a number of structures were also calculated at the B3LYP/6-31++G**//B3LYP/6-31++G** level, and the energy differences between pairs of intermediates were very similar in all cases at the two levels of theory (Table S2, Supporting information).[4]



The initially formed acid enols 2-**1**, 3-**1**, and 2-**2a** are calculated to be 5.4, 10.3, and 10.8 kcal/mol, respectively, more stable than the separated reactants. 2-Carboxymethylene-1,4-dihydropyridine (2-**4**) is 12.2 kcal/mol more stable than the acid enol 4-**2** (Scheme 1).

The conversion from 4-pyridylketene to 4-carboxymethylene-1,4-dihydropyridine (4-**4**) in water is expected to involve the participation of a bridge of water molecules to enable proton addition to nitrogen and OH addition to the ketenyl carbon by a relay mechanism in which successive proton transfers occur. To simulate this process, the struc-

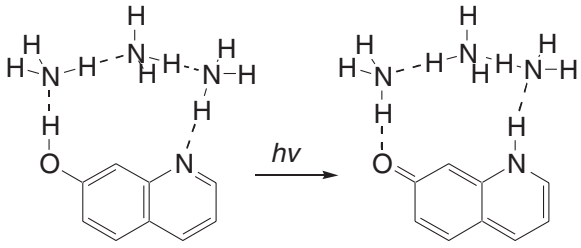
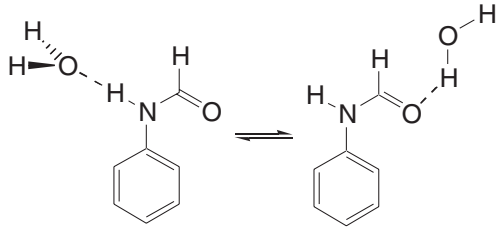
Fig. 1. B3LYP/6-311+G**//B3LYP/6-311+G** calculated energy changes (kcal/mol) for hydration of 2-pyridylketene (2-**1**).



Scheme 1. Relative energies (kcal/mol) of hydrates of 4-pyridylketene (4-**1**).



tures of reaction with a chain of six H_2O molecules between the nitrogen and the ketenyl group were calculated. These include an initial ketene complex 4-**1**·6H_2O, the complexed acid enol 4-**2**·5H_2O, and 4-**4**·5H_2O (Fig. 2). The complexed ketene 4-**1**·6H_2O has the water bridge largely in the plane of the pyridylketene and was calculated to be 37.3 kcal/mol more stable than the separated reactants at the B3LYP/6-311+G**//B3LYP/6-311+G** level (Table 1). This stabilization arises from the seven hydrogen bonds present in the complex. The water bridges in 4-**4**·5H_2O and in the acid enol 4-**2**·5H_2O are above the pyridyl plane, and the dihydropyridine 4-**4**·5H_2O is computed to be more stable than the enediol 4-**2**·5H_2O by 7.4 kcal/mol at the B3LYP/6-31G*//B3LYP/6-31G* level (Table S3, Supporting information).[4] This compares to the difference among the intermediates without the 5H_2O of 12.2 kcal/mol (Scheme 1).

Other similar structures with the same or different numbers of water molecules are expected to contribute to the species present in solution, and no single structure, but rather many, would be involved in the transformation in solution. An analogous relay mechanism for hydrogen transfer between oxygen and quinolyl nitrogen utilizing a bridge of three NH_3 molecules has recently been demonstrated by an experimental and computational study (eq. [6]) (8*a*). In another example of this type of process, the barrier to migration of a single water molecule hydrogen bonded to the nitrogen moving to the carbonyl oxygen of *N*-phenyl formamide was measured experimentally and calculated at the B3LYP/6-31+G* level, with a calculated barrier of 3.2 kcal/mol compared with the averaged experimental barrier of 2.6 kcal/mol (eq. [7]) (8*b*). Other reactions involving chains of water molecules to effect proton transfer have also been reported (8*c*–8*e*).

Fig. 2. Calculated structures of 4-pyridylketene complex (4-**1**·6H_2O), dihydropyridine 4-**4**·5H_2O, and acid enol 4-**2**·5H_2O (B3LYP/6-31G*//B3LYP/6-31G*) from hydration of ketene 4-**1** with a bridge of six H_2O molecules.

Scheme 2. Relative energies (kcal/mol) of hydrates of 2-pyridylketene (2-**1**).

Calculated relative energies (Table 1) of various monohydrates of 2-pyridylketene are summarized in Scheme 2, and the 2-carboxymethylene-1,2-dihydropyridine intermediate *Z*-2-**4a** with an intramolecular hydrogen bond from the carbonyl oxygen to the pyridyl nitrogen was calculated to be 5.5 kcal/mol more stable than *Z*-2-**4b** with a hydrogen bond to the hydroxyl oxygen, and 5.3 kcal/mol more stable than the hydrogen bonded acid enol *syn*-2-**2b**. The energy difference between the acid enols *syn*-2-**2a** and *syn*-2-**2b** of 17.1 kcal/mol provides a measure of the strength of

© 2005 NRC Canada

the hydrogen bond in the acid enols. The hydrogen bonded dihydropyridine *Z*-2-**4a** is 8.3 kcal/mol more stable than *E*-2-**4a**.

Discussion

The transition structures **15** for the addition of two H_2O molecules to the ketenyl group with the formation of acid enols are 17.8, 13.2, and 12.6 kcal/mol, respectively, higher in energy than the separated reactants for 2-**1**, 3-**1**, and 4-**1**. These follow the order of the experimental rate constant ratios of the ketenes 4-**1**:3-**1**:2-**1** of 4.5:2.3:1.0 for hydration and 17:4.0:1.0 for amination. Therefore, 4-pyridylketene has the lowest calculated barrier and is the most reactive, while 2-pyridylketene has the highest calculated barrier and the lowest observed reactivity. The computed stability of the isomers at the B3LYP/6-311+G** level is 2-**1** > 4-**1** > 3-**1**, so the orders of reactivity do not strictly follow the ground state stabilities. The rate constant ratio ($k_{(\text{ketene to intermediate})}/k_{(\text{intermediate to product})}$) for amination of 4-**1** is 6.2, but for hydration of 4-**1** this ratio is 2.4×10^3. The difference between the two lies in the fact that hydration of 4-**1** results in the formation of a long-lived intermediate shown to be 4-**4** (eq. [3]); whereas no such intermediate is detected in amination.

The fundamental difference in the reaction pathways is that in hydration 1,6-addition to 4-pyridylketene can occur by a relay mechanism through a network of water molecules to effect nucleophilic addition to the carbonyl carbon together with electrophilic protonation at nitrogen (Fig. 2; see also Scheme S5, Supporting information).[4] This can be readily achieved in solvent H_2O, as illustrated for six H_2O molecules in Fig. 2, but is not feasible for amination, in which the concentration of *n*-butylamine in CH_3CN used was between 10^{-4} and 10^{-3} mol/L (1*d*). This is well-illustrated by the reaction of eq. [6], in which stepwise transfer of the proton through the ammonia "wire" was demonstrated experimentally and computationally (8*a*). 4-Carboxymethylene-1,4-dihydropyridine (4-**4**) is relatively long-lived, as conversion of this species to the product acid also requires the participation of a number of water molecules. It may be seen that one of the water molecules in 4-**4**·5H_2O (Fig. 2) has a water molecule well-positioned for proton donation to C2 of the incipient pyridylacetic acid.

The dihydropyridine intermediates 2-**4** can be assigned as the *E*-2-**4** and *Z*-2-**4** structures, respectively, and their formation in a 28:72 ratio corresponds to the equilibrium ratio of the anti and syn conformations of 2-pyridylketene (2-**1**) predicted by computations and observed experimentally by trapping in an argon matrix at 10 K (9). However, the conformations of 2-**1** may have different reactivities. Dihydropyridine *Z*-2-**4** is stabilized by an intramolecular hydrogen bond and is longer lived than the E stereoisomer. Both of the dihydropyridyl structures (*Z*-2-**4** and *E*-2-**4**) are longer lived than the enol 3-**2** (eq. [6]), and this may reflect the greater stability of *Z*-2-**4** and *E*-2-**4** and the greater degree of bond reorganization needed for conversion to the acid.

Conclusion

In summary, the computations predict that the transient carboxymethylene–dihydropyridines formed in hydration of 2-**1** and 4-**1** are more stable than the acid enols, which is in agreement with experiment. The computed reaction pathway for hydration of 3-**1** leads to an acid enol transient, and no dihydropyridine is possible. Structures of isomeric dihydropyridine transients from hydration of 2-**1** have also been calculated, and these correspond to the two experimentally observed transients in this reaction. A structure with a bridge of six H_2O molecules between the carbonyl carbon of 2-**1** and the pyridyl nitrogen has been calculated, as well as the structure of the dihydropyridine that would result from proton addition to nitrogen and OH addition to ketenyl carbonyl by a relay mechanism involving six H_2O molecules connecting the ring nitrogen and the keteneyl group. No evidence for the conceptually attractive pseudopericyclic mechanism is found for hydration of 2-**1**, and the computational studies provide no evidence for or against the stabilization of the dihydropyrine intermediate *Z*-2-**4a** by resonance-assisted hydrogen bonding.

The addition of alkynes to a tetrasilyldisilene — Evidence for a biradical intermediate[1]

Stephen E. Gottschling, Michael C. Jennings, and Kim M. Baines

Abstract: The addition of two newly developed mechanistic probes, (*trans*,*trans*-2-methoxy-3-phenylcyclopropyl)ethyne (**1**) and (*trans*,*trans*-2-methoxy-1-methyl-3-phenylcyclopropyl)ethyne (**2**), to tetrakis(*tert*-butyldimethylsilyl)disilene (**3**) has been investigated. The addition of **1** to **3** gave 1-[2-(*cis*-2-methoxy-3-phenylcyclopropylidene)vinyl]-1,1,2,2-tetrakis-(*tert*-butyldimethylsilyl)disilane (**5**) as the major product; whereas addition of alkyne **2** to the disilene gave three stereoisomers of 1,1,2,2-tetrakis(*tert*-butyldimethylsilyl)-6-methoxy-5-methyl-7-phenyl-1,2-disilacyclohepta-3,4-diene (**7**–**9**) and 1,1,2,2-tetrakis(*tert*-butyldimethylsilyl)-3-(*trans*,*trans*-2-methoxy-1-methyl-3-phenylcyclopropyl)-1,2-disilacyclobut-3-ene (**10**) as the major products. The formation of cycloheptaallenes **7**–**9** provides convincing evidence that the addition of alkynes to tetrasilyldisilenes involves the formation of a biradical intermediate.

Key words: disilene, alkyne, cycloaddition, reaction mechanism, mechanistic probe.

Résumé : On a étudié l'addition de deux sondes mécanistiques développées récemment, le (*trans*,*trans*-2-méthoxy-3-phénylcyclopropyl)éthyne (**1**) et le (*trans*,*trans*-2-méthoxy-1-méthyl-3-phénylcyclopropyl)éthyne (**2**) sur le tétrakis(*tert*-butyldiméthylsilyl)disilène (**3**). L'addition du composé **1** sur **3** conduit à la formation du 1-[2-(*cis*-méthoxy-3-phényl-cyclopropylidène)vinyl]-1,1,2,2-tétrakis(*tert*-butyldiméthylsilyl)disilane (**5**) comme produit principal alors que l'addition de l'alcyne **2** au disilène conduit à trois stéréoisomères du 1,1,2,2-tétrakis(*tert*-butyldiméthylsilyl)-6-méthoxy-5-méthyl-7-phényl-1,2-disilacyclohepta-3,4-diène (**7**–**9**) et au 1,1,2,2-tétrakis(*tert*-butyldiméthylsilyl)-3-(*trans*,*trans*-2-méthoxy-1-méthyl-3-phénylcyclopropyl)-1,2-disilacyclobut-3-ène (**10**) comme produits principaux. La formation des cycloheptaallènes **7**–**9** apporte une preuve évidente que l'addition d'alcynes à des tétrasilyldisilènes implique la formation d'une intermédiaire biradicalaire.

Mots clés : disilène, alcyne, cycloaddition, mécanisme réactionnel, sonde mécanistique.

[Traduit par la Rédaction]

Introduction

The discovery of stable disilenes over 20 years ago was significant not only because it permitted a detailed characterization of these novel compounds, but also because it provided a facile route to derivatives that could easily be elaborated to more complex structures not readily available by any other means (1). Since their discovery, many researchers have explored the synthetic utility of disilenes; however, without a more complete understanding of the mechanisms of their reactions (2), the applications of this chemistry will be limited. With this goal in mind, we have investigated the mechanisms of the addition of both aldehydes (3, 4) and alkynes (5) to tetramesityldisilene.

In our study of the mechanism of the addition of alkynes to tetramesityldisilene, we have utilized the rapid ring-opening rearrangement of α-cyclopropylvinyl radicals or cations as mechanistic probes (5). The judicious placement of appropriate substituents on cyclopropyl alkynes **1** and **2** enables the discrimination between the formation of an α-cyclopropylvinyl radical, cation, or anion based on the regioselective rearrangements of these intermediates, or lack thereof. We have demonstrated that the vinyl radical will open rapidly ($k_R \sim 10^{10}$ s^{-1}) and regioselectively toward the phenyl substituent, whereas a vinyl cation adjacent to the three-membered ring opens rapidly ($k_R \sim 10^{10}$–10^{12} s^{-1}) toward the methoxy substituent (Scheme 1). The vinyl anion (as modeled by the lithium derivative) is stable towards ring opening (6). Furthermore, the large rate constants for the structural rearrangements of the radical and cation ensures that the ring opening will effectively compete with other possible reactions.

The addition of cyclopropyl alkyne **2** to the prototypical tetraaryldisilene (tetramesityldisilene (5)) resulted in the formation of four products: three stereoisomers of 1,1,2,2-tetramesityl-6-methoxy-5-methyl-7-phenyl-1,2-disilacyclohepta-3,4-diene and 1,1,2,2-tetramesityl-3-(2-methoxy-1-methyl-3-phenylcyclopropyl)disilacyclobut-3-ene (Scheme 2). The structure of the seven-membered ring, particularly the placement of the phenyl substituent, provides convincing

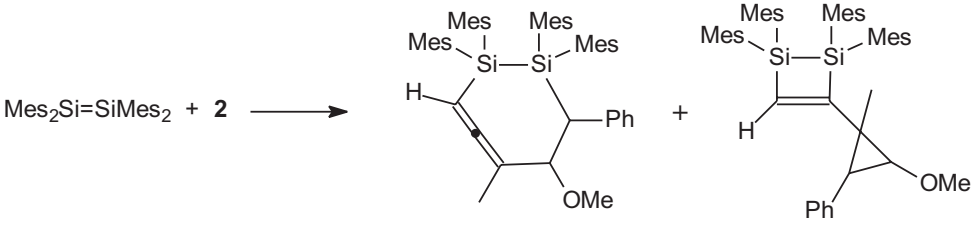
Scheme 1.

evidence that the addition of the alkyne to the disilene involved the formation of a 1,4-biradical intermediate, which opened regioselectively towards the phenyl substituent before ring closure. Closure of the biradical to give the disilacyclobutene appears to compete with ring opening.

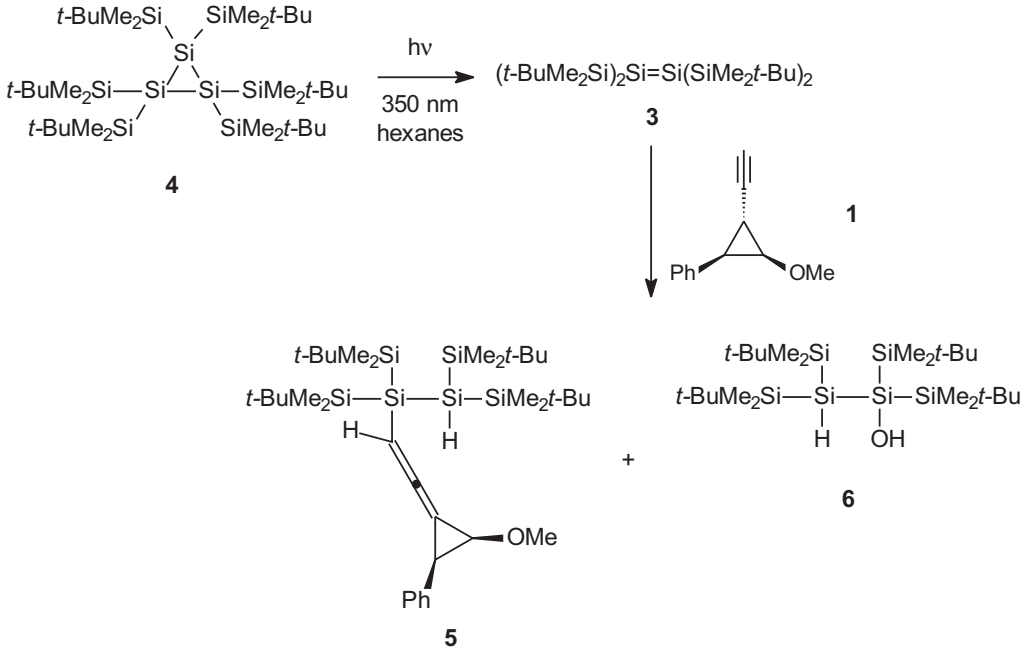
We now wish to extend our study and examine the mechanism of the addition of the alkyne probes to other prototypical disilenes. A comparison of the reactivity of tetraaryl- and tetrasilyl-substituted disilenes reveals some notable differences, particularly in reactions with alkenes (1*f*, 7) and alkynes (7*a*, 8). In general, the tetrasilyldisilenes are more prone to ene reactions than are their aryl counterparts. Furthermore, silyl substitution on the double bond also dramatically influences the E/Z isomerization barrier in disilenes: the barrier is much greater in tetraaryldisilenes than in the silyl derivatives (~25 vs. 15 kcal/mol, respectively) (1 cal = 4.184 J) (1*f*, 1*i*). Given these differences, we have now investigated the addition of the alkyne mechanistic probes **1** and **2** to tetrakis(*tert*-butyldimethylsilyl)disilene (**3**), and have compared the results with our previous work on tetramesityldisilene (5).

Results



An excess of alkyne **1** was added to a deep orange solution of disilene **3** obtained by photolysis of hexakis(*tert*-butyldimethylsilyl)cyclotrisilane (**4**) (9) in hexanes. The solution was allowed to stir for 16 h. Chromatographic purification of the crude oil obtained after removal of the solvent from the reaction mixture yielded one major product identified as 1-[2-(*cis*-2-methoxy-3-phenyl-cyclopropylidene)vinyl]-1,1,2,2-tetrakis(*tert*-butyldimethylsilyl)disilane (**5**) (see Scheme 3). The structure of **5** was assigned based on the NMR and IR spectroscopic data of the compound. An absorption at 1972 cm^{-1} in the IR spectrum of **5** as well as a signal at 197.73 ppm in the ^{13}C NMR spectrum of **5** are consistent with the presence of an allene moiety. The IR spectrum of **5** also contained an absorption at 2064 cm^{-1}, characteristic of an Si—H bond. The ^{1}H, ^{13}C, and ^{29}Si NMR spectra of **5** revealed a complete lack of symmetry in the molecule. Finally, the chemical shifts, splitting pattern, and coupling constants of a three-spin system, 5.80 ppm (dd, J = 3.3, 5.7 Hz), 3.84 ppm (dd, J = 3.3, 5.7 Hz), and 2.81 ppm (t, J = 5.7 Hz), were consistent with an allenylidene cyclopropane moiety with two vicinal substituents (phenyl and methoxy) on the three-membered ring. The cis stereochemistry of the vicinal cyclopropyl hydrogens was assigned based on the observed coupling constant between these two nuclei (J = 5.7 Hz). Coupling constants for cis vicinal hydrogens on a 1-methoxy-2-phenyl-substituted cyclopropane typically range between 6 and 8 Hz (6, 10); the coupling constants for the trans isomers are 2–4 Hz in magnitude (11). 1,4-Di-*tert*-butyl-2-hydroxy-1,1,4,4-tetramethyl-2,3-bis(*tert*-butyldimethylsilyl)tetrasilane (**6**) (7*a*) was also isolated from the reaction mixture in low yield. Presumably, disilane **6** is formed by reaction of **3** with adventitious water.

An excess of alkyne **2** was added to a deep orange solution of disilene **3**, once again, obtained by photolysis of hexakis(*tert*-butyldimethylsilyl)cyclotrisilane (**4**) (9) in hexanes. The solution was allowed to stir for 20–40 h. Analysis of the crude product by ^{1}H NMR spectroscopy revealed a mixture of **7**, **8**, **9**, **10**, and **6** (~27:14:16:32:11, respectively) in addition to unreacted **2** and **4** (Scheme 4). Compounds **7** (9%–24% isolated yield), **8** (0%–9% isolated yield), **10** (26%–29% isolated yield), **6** (6%–13% isolated yield), **4** (11%–15% recovery), and **2** (1%–6% recovery) were isolated by chromatographic separation of the crude residue. Compound **9** was not isolated after chromatography and was therefore identified and characterized by analysis of the crude product mixture. Compound **11** (7%–15%), although not observed in the ^{1}H NMR spectrum of the crude product, was also isolated from the chromatographic plate.



The structures of **7**–**9** were determined by ^{1}H, ^{1}H–^{1}H gCOSY, ^{1}H–^{13}C gHMQC and gHMBC, ^{1}H–^{29}Si gHMBC NMR and IR spectroscopy. The rationale behind the structural assignment is discussed for **7**. Similar logic was used to establish the structures of **8** and **9**. An absorption at 1926 cm^{-1} in the IR spectrum of **7**, as well as a signal at 211.8 ppm in the ^{13}C spectrum, indicated the presence of an allene group in the molecule. The correlations observed in the ^{1}H–^{1}H gCOSY spectrum of **7** and the multiplicities of the signals observed in the ^{1}H NMR spectrum of **7** are consistent with a $CH{=}C{=}C(CH_3)CHCH$ spin system (fragment 1, Scheme 5): 1.81 ppm (d, 3H, J = 3.7 Hz), 3.95 ppm (d, 1H, J = 9.8 Hz), 4.83 (dd, 1H, J = 2.0, 9.8 Hz), 5.64 ppm (dq, 1H, J = 2.0, 3.7 Hz). A correlation was observed in the ^{1}H–^{1}H gCOSY spectrum of **7** between the signal at 4.83 ppm and the one at 5.64 ppm, assigned to the allenic proton. No such correlation is observed for the signal at 3.95 ppm in the ^{1}H NMR spectrum of **7**. Additionally, a correlation was observed in the ^{1}H–^{13}C gHMBC NMR spectrum of **7** between the signal at 4.83 ppm in the ^{1}H dimension and the signal at 211.8 ppm in the ^{13}C dimension

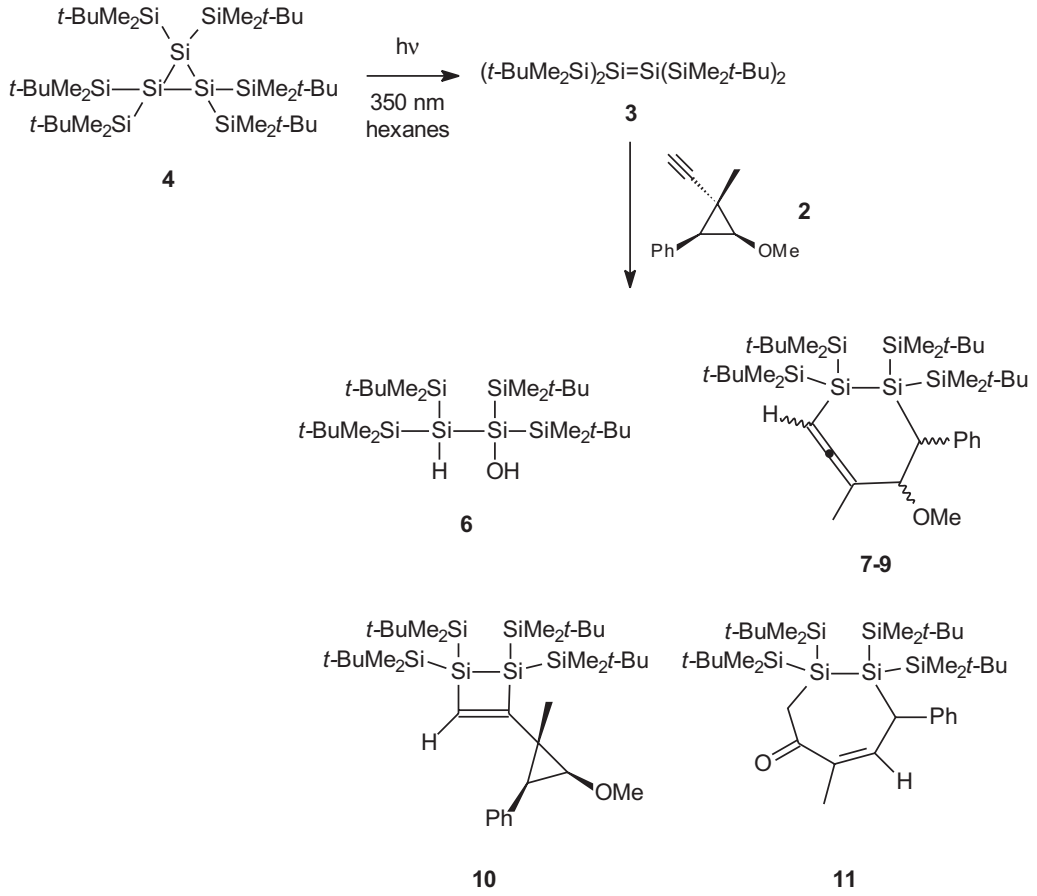
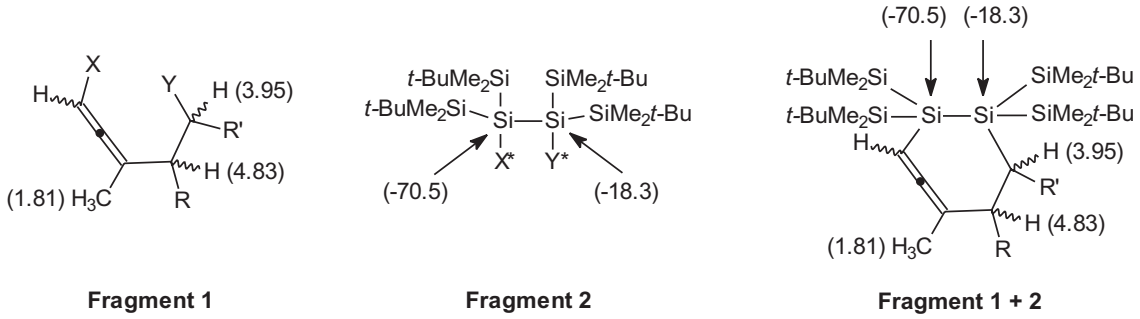
Scheme 2.

Scheme 3.



assigned to the sp-hydridized central allenic carbon. No such correlation was observed for the signal at 3.95 ppm in the ^{1}H dimension. All of these data lead to the assignment of the ^{1}H signals as shown fragment 1 (Scheme 5).



Examination of the ^{1}H NMR spectrum of **7** in the range of 0–1.5 ppm reveals six different signals integrating for 3H each (SiMe), one signal integrating for 6H ($SiMe_2$), and four signals each integrating for 9H (*t*-Bu). In addition, the presence of six different signals in the ^{29}Si dimension of the ^{1}H–^{29}Si gHMBC spectrum of **7**: four signals at 0.5, –1.1, –1.3, and –2.3 ppm, assigned to the four *t*-$BuMe_2Si$ groups based on the chemical shift and the observed correlations, and two signals at –70.5 and –18.3 ppm assigned to the ring silicons. The upfield signals also correlated to four SiMe groups providing evidence that the *t*-$BuMe_2Si$ groups remained attached to silicon. These data are consistent with a tetrakis(*tert*-butyldimethylsilyl)disilane fragment in which no symmetry exists (fragment 2, Scheme 5). Correlations were observed in the ^{1}H–^{29}Si gHMBC spectrum of **7** between the doublet at 1.81 ppm in the ^{1}H dimension, assigned to the vinylic methyl group, and the signal at –70.5 ppm in the ^{29}Si dimension, and thus, the signal at –70.5 ppm was assigned to the ^{29}Si atom attached to the sp^2-hybridized carbon. Additionally, a correlation was observed between the doublet at 3.95 ppm in the ^{1}H dimension and the signals at –18.3 and –70.5 ppm in the ^{29}Si dimension. These correlations suggest that fragments 1 and 2 are linked as shown in Scheme 5 to make a 1,2-disilacyclohepta-3,4-diene ring. The gHMBC and gHMQC spectra were critical in the assignment of the regiochemistry of the phenyl and methoxy groups on the seven-membered ring. A correlation was observed between the doublet of doublets at 4.83 ppm in the ^{1}H dimension of the ^{1}H–^{13}C gHMQC spectrum of compound **7** and the signal at 82.0 ppm in the ^{13}C dimension. A correlation was also observed between the doublet at 3.95 ppm in the ^{1}H dimension and the signal at 46.4 ppm in the ^{13}C dimension. The ^{13}C chemical shifts are consistent with the H assigned to the signal at 4.83 ppm being located on the carbon adjacent to the methoxy group, and the H giving rise to the signal at 3.95 ppm being located on the carbon attached to the phenyl group. Further evidence for the assignment of this regiochemistry was observed in the ^{1}H–^{13}C gHMBC NMR spectrum of **7**. A correlation was observed between the doublet of doublets at 4.83 ppm in the ^{1}H dimension and the signal at 56.80 ppm in the ^{13}C dimension assigned to the methoxy group. A correlation was also observed between the doublet at 3.95 ppm in the ^{1}H dimension and signals at 143.8 and 131.3 ppm in the ^{13}C dimension assigned to the ipso and ortho carbon atoms of the phenyl group, respectively. Finally, in the ^{1}H–^{29}Si gHMBC NMR spectrum of **7**, correlations were observed between the doublet at 3.95 ppm in the ^{1}H dimension and signals at –18.3 and –70.5 ppm (vide

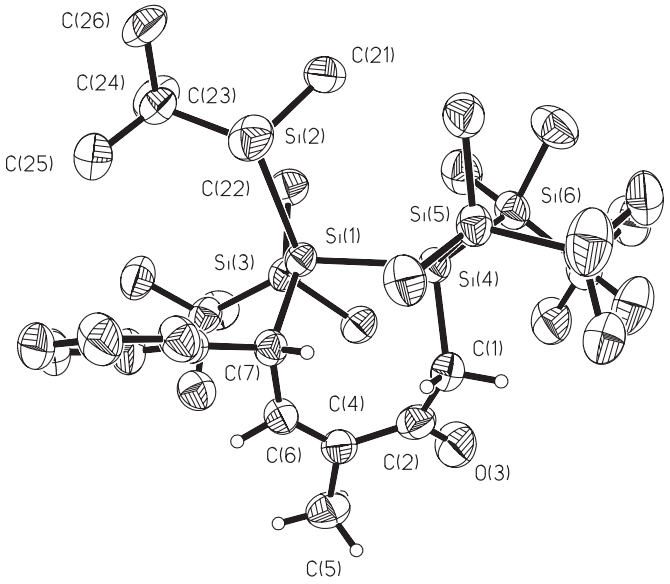
Scheme 4.

Scheme 5.



$^{1}H/^{29}Si$ chemical shifts are given in brackets

supra), and at –1.1 and –1.3 ppm in the ^{29}Si dimension, which have been assigned to the endocyclic ring silicon atoms and the silicon atoms in the *tert*-butyldimethylsilyl groups attached to the silicon at –18.3 ppm, respectively. The doublet of doublets at 4.83 ppm in the ^{1}H dimension correlated to only one ^{29}Si signal at –18.3 ppm. These data are completely consistent with the proposed regiochemistry in **7**. Similar correlations were observed in the NMR spectra of disilacyclohepta-1,2-dienes **8** and **9**. The regiochemistry of all three isomers was determined to be the same.

A molecular ion was not observed in the EI-MS of **7** or **8**. A signal was, however, observed at *m*/*z* 688, which is consistent with the molecular weight of the disilacycloheptenone **11**, which was isolated after chromatographic separation of the crude product mixture. It is believed that compounds **7** and **8** are converted to **11** during the course of mass spectrometric analysis. Compound **11** was identified and characterized by ^{1}H, ^{1}H–^{1}H gCOSY, ^{1}H–^{13}C gHMQC and gHMBC, ^{1}H–^{29}Si gHMBC NMR and IR spectroscopy, as well as mass spectrometry. The identity of **11** was unambiguously confirmed by X-ray analysis (Fig. 1). The most notable feature of the structure is the Si(1)—Si(4) bond length of 2.4572(13) Å, which is considerably longer that the average bond length of 2.35 Å. This is likely due to the steric crowd-

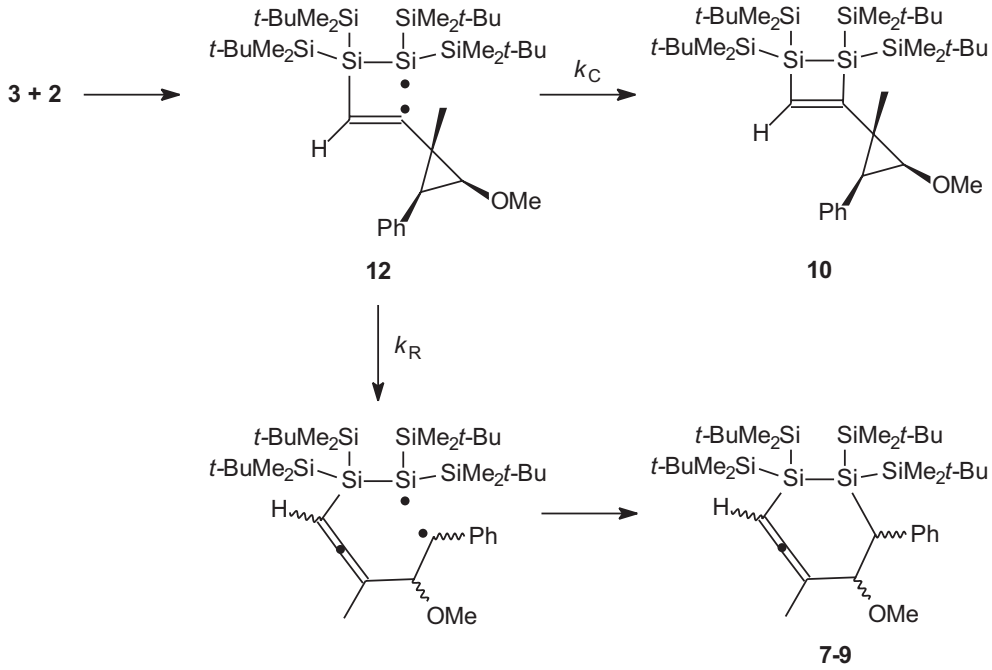
Fig. 1. Molecular structure of 1,1,2,2-tetrakis(*tert*-butydimethylsilyl)-5-methyl-3-phenyl-1,2-disilacyclohept-4-en-6-one (**11**). Thermal ellipsoids are drawn at the 50% probability level.

ing of the bulky *tert*-butyldimethylsilyl substituents. Consistent with this, distortions about the silicon atoms were also observed: C(7)-Si(1)-Si(4) (96.99(11)°), C(23)-Si(2)-Si(1) (121.97(12)°), C(33)-Si(3)-Si(1) (122.43(12)°), C(1)-Si(4)-Si(5) (96.89(11)°), C(53)-Si(5)-Si(4) (118.71(12)°), and C(63)-Si(6)-Si(4) (117.30(14)°). All other bond lengths and angles were within normal values.

The highest mass ion cluster in the mass spectrum of **10** was observed at *m/z* 702, consistent with the formation of a 1:1 adduct between disilene **3** and alkyne **2**. Six different ^{29}Si were apparent in the ^{1}H–^{29}Si gHMBC spectrum of **10**: 4.8, 1.3, –0.7, –1.3, –45.7, and –66.0 ppm. The four downfield signals can be assigned to the four *t*-BuMe_2Si groups based on the observed correlations in the ^{1}H–^{29}Si gHMBC NMR spectrum: each signal correlated to both SiMe and *t*-Bu signals in the ^{1}H dimension. Furthermore, correlations were observed between the SiMe groups in the ^{1}H dimension and the signals at –66 and –45.7 ppm in the ^{29}Si dimension, leading to the conclusion that the *t*-BuMe_2Si groups are attached to silicon. Signals at 174.65 and 140.07 ppm were observed in the ^{13}C NMR spectrum of **10** and were assigned to the sp^2-hybridized carbons in a dimetallacyclobutene ring based on observed correlations in the ^{1}H–^{13}C gHMQC and gHMBC NMR spectra of **10,** and by comparison to the chemical shifts of ring carbons in related dimetallacyclobutenes (12). Furthermore, the vinylic hydrogen exhibited a measurable coupling constant to both ring silicons providing additional evidence for the disilacyclobutene structure. All remaining NMR spectroscopic data were consistent with a structure in which the cyclopropane ring was intact. The cis stereochemistry of the phenyl and methoxy substituents on the cyclopropyl ring was assigned based on the coupling constant of the ring hydrogens (J = 6.7 Hz) (6, 10, 11). The stereochemical relation of the methyl substituent to the phenyl and methoxy groups was not determined but has been tentatively assigned as cis to both substituents on the assumption that its stereochemical configuration remained unchanged during the course of the reaction.

Discussion



Addition of alkyne **1** to tetrasilyldisilene **3** resulted in the formation of allene **5** as the major product (Scheme 3). Allene **5** appears to be the result of a formal ene reaction between the alkyne and the disilene. Interestingly, Kira and coworkers (7*a*) observed the formation of a 2-allenyltetrasilane upon the addition of 1-hexyne to disilene **3**. Analysis of the structure of allene **5** provides little insight into the mechanism by which the ene reaction has occurred. While no ring opening of the cyclopropane was observed, it is not possible to confidently state that a vinyl radical or cation was *not* formed adjacent to the cyclopropyl ring during the course of the reaction because the relative rates of cyclopropyl ring opening and disproportionation of a biradical (or zwitterion) through a six-membered ring transition state are unknown. Alternatively, it is possible that the reaction proceeds through a concerted pathway or a pathway involving formation of zwitterionic intermediate in which a vinyl anion is adjacent to the cyclopropyl ring. Opening of the cyclopropyl ring is not expected to occur under these conditions.

In an attempt to avoid formation of an allene, alkyne **2** was added to disilene **3**. Alkyne **2** lacks a hydrogen in the appropriate position for an ene reaction. Addition of alkyne **2** to **3** resulted in the formation of compounds **6–10** (Scheme 4). Once again, 2-hydroxytetrasilane (**6**) is most likely formed by the addition of adventitious water to the disilene.

The formation of disilacycloheptadienes **7–9** provides clear evidence that cyclopropyl ring opening has occurred upon addition of alkyne **2** to disilene **3,** consistent with the formation of a reactive intermediate during the course of the reaction. The relative position of the phenyl substituent within disilacycloheptadienes **7–9** has been determined to be adjacent to the ring silicon in all isomers by NMR spectroscopy. This regiochemistry is consistent with cyclopropylvinyl rearrangement occurring towards the phenyl group and provides unambiguous evidence that the addition of alkynes to the tetrasilyldisilene occurs through a stepwise reaction mechanism via the formation of a *biradical* intermediate as shown in Scheme 6. Thus, addition of alkyne **2** to disilene **3** leads to the 1,4-biradical intermediate **12**. Biradical **12** can then either cyclize to form disilacyclobutene **10** or regioselectively rearrange towards the phenyl substituent to form a new 1,7-biradical, which can then close to yield the observed products (**7–9**). The formation of disilacyclobutene **10** indicates that ring closure (k_C) of biradical **12** effectively competes with rearrangement. Analysis of the product ratios (disilacycloheptadienes–disilacyclobutenes) determined by ^{1}H NMR spectroscopy by competition kinetics allows the rate constant for ring closure (k_C) to be estimated. Using the value of 1.6×10^{10} s^{-1} as an approximation for the rate constant for rearrangement (k_R) of biradical **12** (6*b*), k_C was estimated to be 9×10^{9} s^{-1}. This is remarkably similar to the estimate obtained for the rate constant for ring closure of the analogous 1,4-biradical in the addition of alkyne **2** to tetramesityldisilene (4×10^{9} s^{-1}). The formation of **7–9** is

© 2005 NRC Canada

Scheme 6.

not consistent with a mechanism in which a zwitterionic intermediate is formed. If a cation were generated adjacent to the cyclopropyl ring, the evidence indicates that the rearrangement would occur towards the methoxy substituent; if an anion was generated adjacent to the cyclopropyl ring, the evidence indicates that no rearrangement would occur (6*a*).

Compound **11** was not observed in the crude reaction mixture; however, it was isolated after chromatographic separation of the products. The disilacycloheptadienone is likely formed from all three disilacyclohepta-3,4-diene isomers (**7**–**9**) by hydration of the allene moiety followed by loss of methanol to produce the observed enone. The presence of the allene functionality within the seven-membered ring of compounds **7**–**9** imparts a significant amount of ring strain (13). It is, therefore, not surprising that the hydration of the allene would readily occur to relieve some of this strain. The stability of the tetrasilyl-substituted disilacyclohepta-1,2-diene ring system towards hydration can be compared with the analogous mesityl-substituted ring systems, formed by the addition of alkyne **2** to tetramesityldisilene (5). In this case, hydration of the allene moiety did not occur upon chromatography. Evidently, the mesityl group is more effective at shielding the strained allene moiety. Assuming **11** is formed from all three disilacycloheptadiene isomers, the position of the phenyl substituent adjacent to the ring silicon in **11** provides additional evidence for the regiochemical assignments of the phenyl and methoxy substituents in **7**–**9**.

The organic modification of silicon surfaces is currently of much interest (14). In particular, the reactivity of silicon dimers on the reconstructed Si(100) 2 × 1 surface towards alkynes has been extensively studied (15). We believe that tetrasilyldisilenes may act as excellent models for the strained dimers on the reconstructed Si(100) 2 × 1 surface. Indeed, the addition of alkynes to the dimers on the surface has been theoretically examined (16). The cycloaddition of acetylene or butadiyne to the surface was found to follow a pathway involving a biradical intermediate. Our experimental results corroborate these findings.

In summary, the results presented herein, taken with our previous work (5), indicate that the addition of alkynes to both tetraaryl- and tetrasilyl-substituted disilenes involves the formation of a biradical intermediate. Furthermore, our work suggests that the reactivity of molecular disilenes and the silicon dimers of the reconstructed Si(100) 2 × 1 surface are comparable.

Experimental

General details

All experiments were carried out in flame-dried glassware under an inert atmosphere of argon. Hexanes were dried either using a solvent purification system (Innovative Technology Inc., Newburyport, Massachusetts) in which the solvent was passed through an alumina-packed column or by distillation from LAH. Chromatography was carried out on conventional preparative plates or by column chromatography using silica gel. Photolyses were carried out at 350 nm using a Rayonet photochemical reactor. NMR spectra were recorded on a Varian Mercury 400, a Varian Inova 400, or a Varian Inova 600 NMR spectrometer. The standards were as follows: residual C_6D_5H (7.15 ppm) for ^1H; C_6D_6 central transition (128.00 ppm) for ^{13}C; and Me_4Si as an external standard (0.00 ppm) for ^{29}Si. The ^{13}C chemical shifts of compounds **7**–**9** and **11** were extracted from the ^1H–^{13}C gHSQC and gHMBC spectra. IR spectra were obtained as thin films on a PerkinElmer System 2000 FT IR spectrometer. Electron impact (70 eV) mass spectra were obtained using a Finnegan MAT model 8200 mass spectrometer (reported in mass-to-charge units (*m*/*z*) with ion identity and intensities relative to the base peak in parentheses). (*trans*,*trans*-2-Methoxy-3-phenylcyclopropyl)ethyne (**1**) (6*a*), (*trans*,*trans*-2-methoxy-1-methyl-3-phenylcyclopropyl)ethyne (**2**) (6*a*),

© 2005 NRC Canada

and hexakis(*tert*-butyldimethylsilyl)cyclotrisilane (**4**) (9) were prepared according to the previously reported procedures.

Addition of 1 to 3

4 (43.0 mg, 0.06 mmol) was dissolved in degassed hexanes (5 mL) and photolyzed for 24 h at 10 °C to give a deep red-orange solution. A solution of **1** (17.1 mg, 0.1 mmol) dissolved in degassed hexanes (3 mL) was added to the red-orange solution. The mixture was allowed to stir for 16 h. During this time, the deep red-orange colour faded to pale orange. The solvent was removed by rotary evaporation to give a light orange residue. After separation of the residue by preparative TLC (hexanes–CH_2Cl_2, 90:10), **5** (36.3 mg, 81% yield based on 21% recovery of **4**), **6** (7*a*) (2.4 mg, 7%), **4** (9.2 mg, 21% recovery), and **1** (6.0 mg, 35% recovery) were obtained.

*1-[2-(***cis***-2-Methoxy-3-phenylcyclopropylidene)vinyl]-1,1,2,2-tetrakis(***tert***-butyldimethylsilyl)disilane (5)*

EI-MS m/*z* (%): 688 (M^+, 3), 673 (M^+ – Me, 3), 631 (M^+ – *t*-Bu, 7), 573 (M^+ – *t*-BuMe_2Si, 20), 429 (M^+ – (*t*-BuMe_2Si)$_2$SiH, 29), 73 ($SiMe_3$, 100). HR-MS calcd. for $C_{36}H_{72}OSi_6$: 688.4199 (M^+); found: 688.4206.

Addition of 2 to 3

4 (44 mg, 0.06 mmol) was dissolved in degassed hexanes (4 mL). The solution was photolyzed at 350 nm for 30 h at room temperature to give a deep red-orange solution. A solution of **2** (22.0 mg, 0.12 mmol) dissolved in degassed hexanes (2 mL) was added to the red-orange solution. The mixture was allowed to stir for 40 h. During this time, the deep red-orange colour of the solution faded to pale orange. The solvent was then removed by rotary evaporation to give a light yellow residue (67.3 mg). Analysis of the crude product by ^{1}H NMR spectroscopy revealed a mixture of **7**, **8**, **9**, **10**, and **6** (~27:14:16:32:11, respectively). The components of the residue were separated by preparative TLC (hexanes–CH_2Cl_2, 50:50) to yield **10** (11.5 mg, 22%), **7** (12.3 mg, 24%), and **11** (7.3 mg, 15%). A band was also obtained containing a mixture of **4**, **8**, **10**, **6**, and **2** (28:26:18:20:8, 20 mg). Separation of this band (hexanes–CH_2Cl_2, 90:10) yielded **4** (5.7 mg, 13% recovery), **10** (3.1 mg, 6% for a 28% total yield), **2** (0.3 mg, 1% recovery), and a mixture (3.3 mg, 81:19) of **6** (7%) (7*a*) and **4** (1% for a 14% total recovery). It was difficult to obtain **7** and **11** cleanly; they were contaminated with minor amounts of unidentified compounds. When the crude reaction mixture was chromatographically separated using a different eluent (hexanes–CH_2Cl_2, 75:25), **8** (9%) was obtained as a mixture with **6** (**8**:**6** = 40:60) and was characterized as such. Compound **9** was identified in the crude reaction mixture but could not be isolated.

Table 1. Crystal data for **11**.

Empirical formula	$C_{36}H_{72}OSi_6$
Formula mass	689.48
Colour and habit	Colourless plate
Crystal dimensions (mm)	0.35 × 0.25 × 0.10
Crystal system	Triclinic
Space group	*P*-1
Z	2
a (Å)	9.430 7(6)
b (Å)	11.793 0(5)
c (Å)	19.865 6(8)
α (°)	97.676(3)
β (°)	95.360(3)
γ (°)	102.652(3)
Collection ranges	$-11 \le h \le 9$, $-13 \le k \le 14$, $-23 \le l \le 23$
Temperature (K)	296(2)
Volume (Å^3)	2 119.15(18)
D_{calcd} (mg/m^3)	1.081
Radiation	Mo K_α (λ = 0.710 73 Å)
Absorption coeff. (mm^{-1})	0.222
Absorption correction	Multiscan
F(000)	760
θ Range for data collection (°)	2.72–25.00
Reflections collected	23 050
Independent reflections	7 206 (R_{int} = 0.093)
Completeness to θ = 25.00° (%)	96.8
Data, restraints, parameters	7 206, 0, 376
Max and min transmission	0.978 1 and 0.926 4
Goodness-of-fit on F^2	1.036
Final *R* indices [$I > 2\sigma(I)$]	R_1 = 0.065 4, wR_2 = 0.171 6
R indices (all data)	R_1 = 0.093 0, wR_2 = 0.195 1
Refinement method	Full-matrix least-squares on F^2
Largest diff. peak and hole (e Å^{-3})	0.606 and –0.399

Crystals of **11** were grown from a concentrated methylene chloride solution by slow diffusion of acetonitrile. A colourless plate was mounted on a glass fibre. Data were collected at room temperature (23 °C) on a Nonius Kappa CCD diffractometer with COLLECT (Nonius B.V., Delft, The Netherlands, 1998). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using DENZO (Nonius B.V., Delft, The Netherlands, 1998). The data were scaled using SCALEPACK (Nonius B.V., Delft, The Netherlands, 1998). The crystal data and refinement parameters for **11** are listed in Table 1. The SHELXTL-NT V6.1 (Bruker AXS,

© 2005 NRC Canada

Madison, Wisconsin) suite of programs was used to solve the structure by direct methods. Subsequent difference Fourier syntheses allowed the remaining atoms to be located. The molecule was very well behaved. All of the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atom positions were geometrically calculated and were included as riding on their respective carbon atoms. The largest residue electron density peak (0.606 e $Å^{-3}$) was associated with one of the Si—Si bonds. CCDC 270736 (**11**) contains the supplementary crystallographic data for this paper.[3]

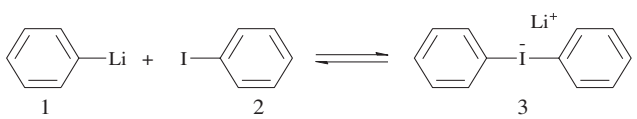
Mechanism of the lithium–iodine exchange in an iodothiophene[1]

Hans J. Reich and Wesley L. Whipple

Abstract: Solutions of 2-lithio-5-methylthiophene (**4**) were characterized using DNMR techniques and shown to be a mixture of monomer and dimer in THF–Et_2O (3:2). The hypervalent iodine ate complex **5** ($Ar_2I^-Li^+$), a presumed intermediate in the Li–I exchange with 2-iodo-5-methylthiophene, was observed by ^{13}C and ^7Li NMR spectroscopy at low temperatures (–130 °C). At higher temperatures, the ate complex coalesced with 2-lithio-5-methylthiophene. A kinetic scheme was developed, which accounts for the exchange of the monomer **4M**, dimer **4D**, and 2-iodo-5-methylthiophene (**6**) with the ate complex **5**. The rates of the various exchanges were obtained through a DNMR analysis of the variable temperature ^{13}C and ^7Li NMR spectra, and the thermodynamic and activation parameters were calculated. The monomer **4M** and the ate complex **5** have similar reactivity as aryl donors in the Li–I exchange reaction, but **4M** is at least 1000 times as reactive as the dimer **4D** towards the iodide.

Key words: halogen–metal exchange, lithium iodinate, iodine ate complex, lithium reagent, aggregate reactivity.

Résumé : On a caractérisé des solutions de 2-lithio-5-méthylthiophène (**4**) en faisant appel à des techniques de RMN dynamique (RMND) et on a pu démontrer que, dans le THF–Et_2O (3 : 2), elles comprennent un monomère et un dimère. Faisant appel à la RMN du ^{13}C et du ^7Li à basse température (–130 °C), on a pu observer le complexe **5** de l'iodate hypervalent ($Ar_2I^-Li^+$), un intermédiaire supposé dans l'échange Li–I avec le 2-iodo-5-méthylthiophène. À des températures supérieures, il y a coalescence du complexe are avec le 2-lithio-5-méthylthiophène. On a développé un schéma cinétique qui permet de tenir compte de l'échange du monomère **4M**, du dimère **4D** et du 2-iodo-5-méthylthiophène (**6**) avec le complexe ate **5**. On a obtenu les vitesses des divers échanges par une analyse RMN des spectres RMN du ^{13}C et du ^7Li à des températures variables et on en a calculé les paramètres thermodynamiques et d'activation. Vis-à-vis des donneurs aryles, dans une réaction d'échange Li–I, les réactivités du monomère **4M** et du complexe ate **5** sont semblables; toutefois, vis-à-vis de l'iode, le monomère **4M** est au moins mille fois plus réactif que le dimère **4D**.



Mots clés : échange halogène–métal, iodate de lithium, complexe ate de l'iode, réactif de lithium, réactivité d'un agrégat.

[Traduit par la Rédaction]

Introduction

The lithium–metalloid exchange, independently discovered by Gilman et al. (1) and Wittig et al. (2) is an effective route for the formation of many organolithium reagents inaccessible by other methods. Understanding the mechanism of this process provides greater insight and predictability into the factors that influence reactivity. The reaction has commanded substantial research interest over the past 60 years (3*a*), where four-centered (4), SET (3*a*–3*c*, 5), S_N2 (6), and ate complex mechanisms (7*a*, 8) have been suggested. Investigation of the lithium–metalloid exchange identified ate complexes as permissible intermediates, including those of I (7*b*, 7*c*, 9), Te (7*c*–7*e*, 10*a*, 10*b*), Se (7*d*, 7*f*, 10*b*), Sn (7*g*, 11, 12), Si (13), and Hg (7*b*, 7*c*). Iodine ate complexes have also been detected as intermediates in the Li–Mg exchange (14). Both experimental (7*e*, 15) and computational (3*d*, 8) studies have addressed the ease of formation of various ate complexes. The relative rates of the lithium–metalloid exchanges follow the trend: I > Te >> Sn >> Br > Se >> S.

In previous reports of the lithium–iodine exchange of phenyllithium (**1**) with iodobenzene (**2**) we have kinetically and spectroscopically identified the stable hypervalent ate complex **3** as present in solution (7*b*, 7*c*, 7*e*). Direct involvement of **3** in the exchange process could not be proven, since analysis of the kinetic processes was complicated by the unfavorable equilibrium between phenyllithium monomer and dimer, and the degenerate exchange between **2** and **3**.

1 2 3

We report here our results on the solution structure of 5-methyl-2-thienyllithium (**4**) and its behavior in the lithium–iodine exchange using low-temperature, multinuclear NMR techniques. The use of **4**, with its favorable NMR properties, ease of handling, and considerably higher monomer to dimer ratio compared to PhLi, has allowed measurement of the rates and equilibria of exchange between monomer **4M** and

Results and discussion

The NMR study we set out to perform used four kinds of samples, all in THF–ether (3:2) solution (this mixed solvent system is close in donor strength to that of pure THF and allows the measurement of NMR spectra down to –135 °C). In each case variable temperature ^{6}Li, ^{7}Li, and ^{13}C NMR spectra were measured. They are:

1. Solutions of the lithium reagent **4** to define the aggregates (**4M** and **4D**) present (Figs. 1A and 2). The concentration and temperature dependence of the equilibrium constant (K_1) and the temperature dependence of the exchange rates k_1 and k_{-1} were determined from these samples (Figs. 3 and 4).

Fig. 1. ^{13}C NMR spectra in THF–ether (3:2). (A) 0.10 mol/L of **4** at –133 °C (the inset showing the C-2 signals is from a 0.2 mol/L ^{6}Li-labeled sample, where the dimer C-2 signal was processed by multiplying the FID with a Gaussian function before Fourier transformation (LB = –6.1, GB = 0.1). The coupling constants are believed accurate to ±0.2 Hz (D = **4D**, M = **4M**). (B) A 1:1 ratio of **4** and **6** with 9 equiv. of HMPA (T = 2-methylthiophene, protonation product). (C) The iodide **6**.

2. Solutions with a 1:1 ratio of lithium reagent **4** and iodide **6** with excess HMPA present (Fig. 1B). In such solutions K_2 becomes very large, leaving **5** as the only detectable species (7*a*, 7*b*) and allowing its NMR identification and characterization.
3. Solutions with an excess of lithium reagent over iodide (Fig. 5). Line-shape fitting of the ^{7}Li NMR spectra of these samples allow estimation of k_2 at each temperature, using as input the values of K_1, K_2, k_1, and k_3 obtained from samples 1 and 4.
4. Solutions with an excess of iodide **6** over lithium reagent **4** (Fig. 6). In these solutions **4M**, **5**, **6**, and, at temperatures above –85 °C, **4D**, are in rapid exchange and it is possible to measure the temperature dependence of the ate complex association constant K_2 from analysis of the averaged peak positions in the ^{13}C NMR spectra, using K_1 obtained from samples 1 and the chemical shifts of the individual species. Line-shape analysis of these samples also allowed measurement of k_3 and an estimate of k_4.

The solution structure of 2-lithio-5-methylthiophene

Previous studies of 2-thienyllithium reagents have included X-ray structures of the ether solvated tetramer of **4** (7*h*), several substituted lithiothiophenes,[3] and 2-lithiobenzothiophene (16*a*), as well as a report of the solution ^{13}C NMR spectrum of 2-lithiothiophene itself (17). We have recently

[3] Several single crystal X-ray structures have been reported in the Cambridge Structural Database as private communications (1999). 3-Dimethylaminomethyl-2-lithiothiophene dimer (LEDSES): A.L. Spek, M.T. Lakin, and R. den Besten. 3-Methoxy-2-lithiothiophene (HIGPOC): A.L. Spek and N. Veldman. 3-Bromo-2-lithiothiophene TMEDA dimer (HIGXUQ): A.L. Spek. 2-Lithiothiophene dimer (JUJXER): A.L. Fig. 2. Selected ^{13}C and ^{7}Li NMR spectra of a variable temperature study of 0.101 mol/L 5-methyl-2-thienyllithium (**4**) in THF–ether (3:2). These spectra were simulated to obtain k_1, k_{-1}, and K_1 (eq. [1]). Monomer (M), dimer (D).

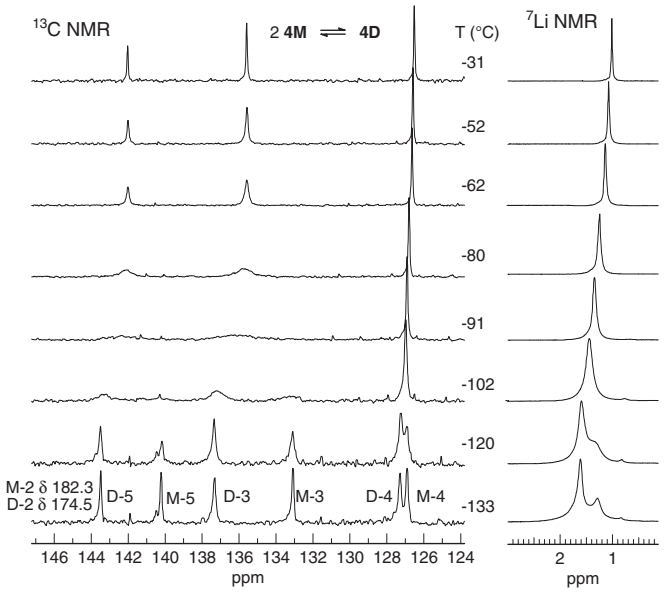

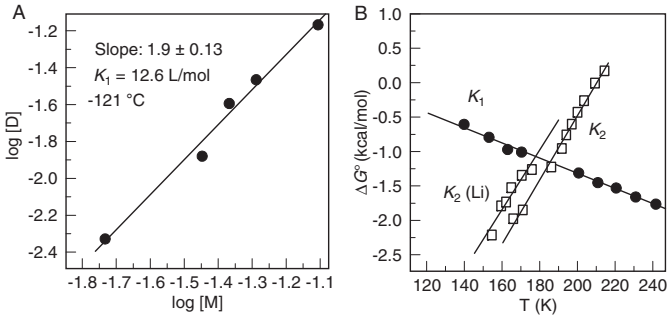

Fig. 3. (A) Concentration dependence of the **4M** and **4D** ratio in THF–ether (3:2) at –121 °C. (B) Temperature dependence of free energy ($\Delta G = RT \ln(K_{eq})$) for the monomer dimer equilibrium (K_1, eq. [1]) and the ate complex equilibrium (K_2, eq. [2]).

reported detailed NMR studies of a series of lithiothiophenes, including some with ortho chelating groups (7*i*).

Clean solutions of **4** were readily available since the precursor 2-methylthiophene is easily metalated with *n*-BuLi (17, 18), and the pure reagent can be crystallized from THF or ether (7*h*). Figure 1A reports the ^{13}C NMR spectrum of 95.5% ^{6}Li-labeled **4** (19) in THF–ether (3:2) at –121 °C. There are two sets of carbon signals, corresponding to two distinct lithium species (19*a*). Each showed fully resolved ^{13}C–^{6}Li scalar coupling of the ipso carbon signals at 182.3 ppm (1:1:1 triplet, ^{1}J = 15.3 Hz) and 174.5 ppm (1:2:3:2:1 pentet, ^{1}J = 7.8 Hz), respectively (19*b*). The assignment of the two species as monomer **4M** and dimer **4D** derives from the lithium–carbon coupling, as well as from a variable concentration study, which showed that the two species differ in aggregation state by a factor of two (slope of the log[M] vs. log[D] plot was 1.9 ± 0.13, K_1 = 12.6 (mol/L)$^{-1}$ at –128 °C, Fig. 3*a*) (7*j*, 7*k*, 16*b*). In addition,

Fig. 4. Temperature dependence of the free energy of activation (calculated from a form of the Eyring equation, $\Delta G^{\ddagger} = RT[23.76 + \ln(T/k_r)] = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$) for the monomer–dimer exchange (k_1 (●) from line-shape analysis of the spectra in Fig. 2, eq. [1]), ate complex formation (k_2 (▲) from Fig. 6, eq. [2]), and ate complex – iodide exchange (k_3 (□) from Fig. 7, eq. [3]).

Fig. 6. Variable temperature NMR spectra of solutions of **4** and **6** in THF–ether (3:2) with excess iodide. The two panels are from experiments with slightly different concentrations. (A) ^{13}C NMR spectra. The dotted spectra are simulations of the C-3 resonance, as described in the text. (B) ^{7}Li NMR spectra. The insets are vertical expansions showing the build-up and eventual coalescence of **4D** with the average of the other signals as temperature increased.

Li–C coupling, C-5 as a quaternary carbon by an INEPT experiment, on the literature assignments for 2-lithiothiophene (17), and on the correlation between equivalent carbons of **4M**, **4D**, **5**, and **6** provided by the coalescence experiments (Figs. 2, 5, and 6). Thus, the carbons of **6** could be readily assigned from shift parameters (20), and this allowed carbon signal assignments of all of the other compounds.

A variable temperature experiment of **4** is shown in Fig. 2. Each pair of ^{13}C and ^{7}Li NMR signals for **4M** and **4D** coalesced between –120 and –91 °C. Complete line-shape simulations of these spectra were used to determine the rates of interconversion for monomer and dimer. The relationship between the pseudo-first-order NMR rate constants (k_{MD} and k_{DM}) obtained from the simulation and the mechanistic rate constants k_1 and k_{-1} of eq. [1] is straightforward: k_{-1} is also a first-order rate constant (it is best to think of a first-order rate as the fraction of substrate converted per unit time), so $k_{-1} = k_{DM}$. The monomer to dimer conversion k_1 is a second-order rate constant (fractional conversion per unit time per molar concentration of reactant), and thus $k_{MD} = k_1[\mathbf{4M}]$. The activation parameters in eq. [1] were calculated from the temperature dependence of k_1 and k_{-1} (see Fig. 4). The simulation also gave the concentration of monomer and dimer as a function of temperature (for the four low temperature points from the areas of the two C-3 peaks, for the five high temperature points from the peak position of the averaged C-3 signals), and hence the thermodynamic parameters for the dimer–monomer equilibrium (Fig. 3B).

Lithium–iodine exchange of 2-lithio 5-methyl-thiophene

Solutions containing both **4** and **5** show complex DNMR behavior because of the presence of four species (**4M**, **4D**, **5**, and **6**) whose relative concentrations are strongly temperature dependent and which are all undergoing mutual exchange involving at least three different rate constants (k_1, k_2, and k_3). Figure 1 shows spectra of **4** and **6** and a 1:1 mixture of the two, the latter with 9 equiv. of hexamethylphosphoric triamide (HMPA) present, which has the effect of greatly increasing K_2 (7*a*, 7*b*). The presence of a new species in Fig 1B, the ate complex **5**, can be readily seen, since the ^{13}C signals for C-3, C-4, and C-5 are upfield of all three constituents, and so cannot simply be a dynamic average of them.

Examination of samples in THF–ether (3:2) with varying ratios of iodide and lithium reagent revealed that there were two limiting behaviors. With excess lithium reagent the signals of three of the components present (**4D**, **4M**, and **5**) could be decoalesced. There is not a detectable amount of **6** at the lower temperature limit of the solvent system (Fig. 5). On the other hand, when iodide was in excess there was (with a minor exception) a single, strongly temperature dependent set of ^{13}C and ^{7}Li signals throughout the accessible temperature range (Fig. 6).

The spectra of Fig. 5 can be interpreted as follows. At the lowest temperatures the signals of the ate complex **5** are decoalesced from those of the monomer **4M** and dimer **4D**. The formation constant (K_2) of **5** is high, and since there is excess lithium reagent, there is no detectable iodide **6**. Between –130 and –115 °C the signals of **5** and **4M** coalesce (eq. [2]). The signals of **4D** are not appreciably affected by this process. Between –110 and –90 °C the **4D** signals coalesce with the averaged signals of **5** and **4M**. Starting at ca. –110 °C, the shift of the equilibrium of eq. [2] (K_2) away from ate complex toward the iodide and lithium reagent becomes apparent as indicated by the downfield shift of the three visible signals (the C-3, C-4, and C-5 signals of **5** are all upfield of those of **4M**, **4D**, and **6**).

Figure 6 cannot be interpreted with only the eq. [1] and [2] processes, since the lowest temperature spectrum should show excess iodide **6** and the ate complex **5** in slow exchange, just as was seen for excess **4** in Fig. 5 (the process k_2 is slow on the NMR timescale at this temperature). We propose that here, as seen for the PhLi–PhI system (7*b*, 7*c*), there is another exchange process that averages the signals of **5** and **6**. The ate complex is behaving as a carbanion donor, and transferring an aryl group to the iodide to form a new ate complex (k_3, eq. [3]). When there is a stoichiometric excess of lithium reagent, there is no corresponding process that can average the lithium reagent and ate complex signals, and so the signals can be decoalesced (Fig. 5).

We will perform a quantitative analysis of the thermodynamics and kinetics of the Li–I exchange as revealed by the spectra of Figs. 5 and 6. First, we will determine the ate complex association constant K_2 from an analysis of chemical shifts and peak positions in the ^{13}C NMR spectra of Fig. 6 using the information on k_1 and K_1 gleaned from Fig. 2 and similar experiments. This allows us to extract the

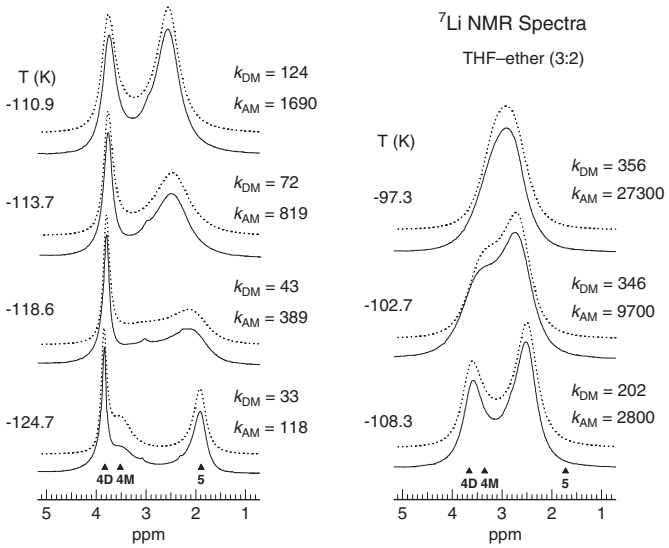
$$k_{MA} = k_2[\mathbf{6}] \qquad k_{DM} = k_{-1} + \frac{k_4[\mathbf{6}]}{2} \qquad k_{MD} = k_1[\mathbf{4M}] + k_{-4}[\mathbf{5}]$$

Li–I exchange rate constant k_2 from the spectra of Fig. 5, and sets the stage for determining k_3 as well as estimating the maximum rate of exchange of the dimer **4D** with the iodide **6** (k_4).

Determination of the ate complex association constant (K_2)

We have used the chemical shift of the C-3 signal in the ^{13}C NMR spectra of an experiment like the one in Fig. 6A to determine the composition of the sample. At each temperature above coalescence (–87 to –59 °C) an iterative computer program was used to calculate the concentration of all species for a series of trial ate complex concentrations until the calculated averaged ^{13}C NMR chemical shift matched the experimental one. These calculations used the previously determined values of K_1 (eq. [1]), the concentrations of the component species, and the chemical shifts of each compound as input. The shifts of **4M**, **4D**, and **5** were found to be temperature independent and those of **6** were extrapolated from spectra of pure **6** taken at a series of temperatures.

Two additional data points were derived from the ^{7}Li NMR spectra. At –117, –107, –102, and –98 °C it was possible to detect the signal of **4D** (see insets, Fig. 6B). The area of this signal was determined at the two temperatures at which it is best defined (–102 and –107 °C), and these values were then used to calculate the concentrations of the other species using the known value of K_1.



From the concentrations, K_2 can be calculated at each temperature and the thermodynamic parameters for the ate complex equilibrium determined (see eq. [2], Fig. 3B). The large negative entropy of formation of the ate complexes (–48.6 eu) is similar to that found for the formation of lithium diphenyliodinate **3** (–44 eu) (7*c*) and other systems (7*d*, 7*f*, 13). This loss of entropy derives from loss of translational and rotational motion for the component iodide and lithium reagent, as well as the extra THF molecules frozen by the very electrophilic free lithium cation of the ate complex (7*b*, 7*c*), compared to the strongly C-bound cation of the aryllithium reagent (7*l*).

Determination of the rate of Li–I exchange (k_2)

We next simulated the NMR spectra of Fig. 5 to determine values for k_2 and k_{-2}. The ^{13}C signals were rather noisy, and simulations were not very well defined. However, the ^{7}Li NMR signals had superb signal-to-noise and had the decisive advantage that the degenerate exchange of iodide and ate complex (eq. [3]) does not affect the ^{7}Li line shape, since this process leaves the lithium signal unchanged.

A significant problem for simulations of the ^{7}Li spectra is the quite variable quadrupolar T_1 relaxation rates (21), which could not be independently measured because of interference from dynamic effects. Since the lines were fifty to several hundred Hz wide in the crucial part of the simulation, we anticipated that errors in line width would not greatly affect the accuracy of the rate constants determined. We assigned inherent line widths of 4 Hz for **5**, 8 Hz for **4D**, and 10 Hz for **4M** based on the low temperature spectra and the behavior of other related aryllithium species. An iterative process was used to establish optimum populations and rates (see the Experimental section) using the exchange matrix shown in Fig. 7. The exchange matrix includes contributions from the reaction of dimer with iodide (k_4 process, eq. [4]). The values of k_{-1} in solutions containing **6** were actually smaller than those determined for solutions of just the lithium reagent. Since no detectable contribution from k_4 is present, it was set to zero, leaving only k_{DM} (k_{-1}) and k_{AM} (k_{-2}) to be adjusted (7*m*).

Fig. 8. Line-shape simulation of the variable temperature ^{7}Li NMR spectra of Fig. 5B (**4** (0.117 mol/L) and **6** (0.046 mol/L) in THF–ether (3:2)). Lower lines are experimental data, upper dotted lines are simulations using the rate constants shown and the exchange matrix of Fig. 7.

The simulations are presented in Fig. 8. An excellent match between experimental and calculated spectra was achieved, with k_{-1} within a factor of two of those values determined from solutions of **4** (Fig. 2) and K_2 values within a factor of four of those determined from analysis of the previous ^{13}C NMR shifts of Fig. 6 (see Fig. 4). There are a number of potential reasons for these discrepancies: the chemical shifts may have a slight temperature dependence, the assumption of T_1 values for the three lithium species may have been too crude, and there may have been small variations in solvent composition between experiments. Both K_1 and K_2 are very solvent sensitive. For example, K_1 decreased by a factor of 5.7 between 60% and 80% THF in ether at –117 °C. The values for k_2 and k_{-2} as a function of temperature are shown in an Eyring plot in Fig. 4, leading to the activation parameters reported in eq. [2].

Rate of exchange of ate complex with iodide (k_3)

We are now in a position to attempt a simulation of the ^{13}C NMR line shifts of Fig. 6, which involves, in addition to

Fig. 9. (A) Spectrum of a solution of **4** and **6** at –131 °C. (B) Optimal simulation. (C) Simulation with no contribution from the process of eq. [3] (k_3) (7*m*). See Fig. 10 for the definitions of k_{AI} and k_{AM}.

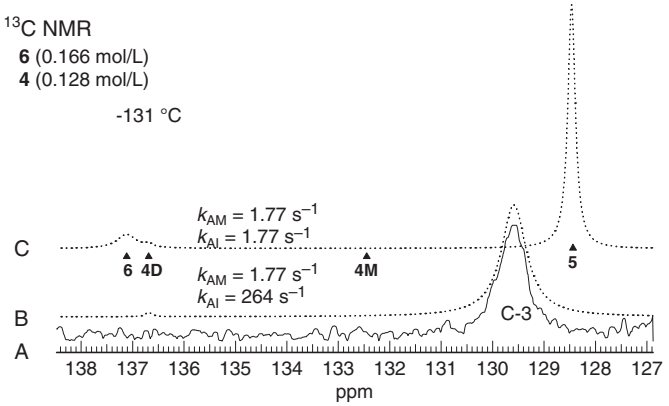

Fig. 10. Exchange matrix for the interactions between **4M**, **4D**, **5**, and **6**. See eqs. [1]–[4] for definitions of the rate constants.

$$\begin{array}{c} \\ \mathrm{A} \\ \mathrm{D} \\ \mathrm{M} \\ \mathrm{I} \end{array} \begin{bmatrix} \mathrm{A}\ (\mathbf{5}) & \mathrm{D}\ (\mathbf{4D}) & \mathrm{M}\ (\mathbf{4M}) & \mathrm{I}\ (\mathbf{6}) \\ i2\pi(\nu_A) - 1/T - \Sigma k_{AX} & k_{AD} & k_{AM} & k_{AI} \\ k_{DA} & i2\pi(\nu_D) - 1/T - \Sigma k_{DX} & k_{DM} & k_{DI} \\ k_{MA} & k_{MD} & i2\pi(\nu_M) - 1/T - \Sigma k_{MX} & k_{MI} \\ k_{IA} & k_{ID} & k_{IM} & i2\pi(\nu_I) - 1/T - \Sigma k_{IX} \end{bmatrix} = E$$

$$k_{AD} = \frac{k_{-4}[\mathbf{4M}]}{2} \qquad k_{DA} = \frac{k_4[\mathbf{6}]}{2}$$

$$k_{AM} = k_{-2} \qquad k_{MA} = k_2[\mathbf{6}]$$

$$k_{AI} = k_{-2} + \frac{k_3[\mathbf{6}]}{2} + \frac{k_{-4}[\mathbf{4M}]}{2}$$

$$k_{IA} = k_2[\mathbf{4M}] + k_3[\mathbf{5}]$$

$$k_{DM} = k_{-1} \qquad k_{MD} = k_1[\mathbf{4M}] + k_{-4}[\mathbf{5}]$$

$$k_{DI} = 0 \qquad k_{ID} = 0$$

$$k_{MI} = 0 \qquad k_{IM} = \frac{k_{-4}[\mathbf{4M}]}{2}$$

the eq. [1] and [2] processes, the bimolecular exchange between ate complex and iodide (k_3, eq. [3]). We used the values of k_1, k_2, K_1, and K_2 calculated from the thermodynamic and activation parameters in eqs. [1] and [2] to determine the NMR rates and populations of **4M**, **4D**, **5**, and **6** at each temperature. Neither the populations nor the k_1 and k_2 rate constants were allowed to vary in the simulation. Any excess broadening of the iodide **6** and ate complex **5** signals over that predicted by k_2 can then be assigned to k_3, the iodide – ate complex exchange of eq. [3]. This is illustrated in Fig. 9, which shows simulations of the –131 °C spectrum. At this temperature the iodide signal would be decoalesced if $k_{AI} = k_{AM}$ (Fig. 9C), i.e., if k_2 was the only mechanism for exchange. This can be compared with the simulation in Fig. 9B, which has the rate k_{AI} optimally adjusted to fit the actual spectrum.

The exchange matrix and the relationship between first-order NMR rate constants (k_{AD}, k_{AM}, k_{AI}, etc.) and their mechanistic equivalents (k_1, k_2, k_3, k_4, etc.) is shown in Fig. 10. This simulation is complicated by the fact that temperatures low enough for decoalescence cannot be achieved. In addition, values for k_3 and k_{-3} are calculated from k_2 and k_{-2} ($k_3 = (k_{IA} - k_2[\mathbf{4M}])/[\mathbf{5}]$, $k_{-3} = (2k_{AI} - k_{-2})/[\mathbf{6}]$), and so the limited accuracy of k_2 because of the small temperature range and scatter of the $\Delta G^{\ddagger}$ vs. T plot (Fig. 4) directly affects the accuracy of the k_3 values.

The simulation worked reasonably well (insets in Fig. 6A), although there were small errors in the chemical shift of the averaged signal, which is not surprising considering the accumulation of calculated values that comprise the input. The most likely source is small errors in the value of K_2 used to calculate the concentrations. Only at the four lowest temperatures in Fig. 6 were the spectra significantly affected by the value of k_3, so we report data only at these temperatures. Although there is significant broadening at intermediate temperatures (–87 and –81 °C), this is largely due to the monomer–dimer exchange (k_1) and is not very sensitive to k_3. Activation parameters are shown in eq. [3]. We did not perform experiments to verify that the k_3 process was first order in **6** by repeating this experiment with variable iodide concentrations. However, such an experiment was previously performed for a PhLi–PhI solution in THF–HMPA (7*b*), where first-order behavior in iodide was demonstrated by a DNMR study.

The data obtained show the astonishing result that the monomeric lithium reagent and the ate complex have comparable reactivity as donors in the Li–I exchange. In another test of ate complex reactivity, the reaction of PhLi–PhI with hexamethyldisiloxane in THF–HMPA, PhLi is at least a factor of 10^5 more reactive than $Ph_2I^-Li^+$ (7*a*). This estimate is based on the reduction in k_{obs} for the silylation reaction when excess PhI was added to a solution of PhLi in THF–HMPA. Of course, in this case the PhLi has been greatly activated by complexation to HMPA (by a factor of 10^3 or more) (7*j*), so a direct comparison is not very meaningful. We considered that the k_2 process might be approaching diffusion control, and thus suffer from rate compression, but diffusion-controlled processes at –102 °C in THF–ether should have rates of ca 1×10^9 s^{-1} $(mol/L)^{-1}$, about 10^3 times faster than the measured bimolecular rate (k_2). A more likely explanation is that the rate-limiting (or partial-limiting) step for the Li–I exchange (eq. [2]) is C—Li bond dissociation (CIP to SIP) or solvent association with or dissociation from the lithium cation. Barriers to dissociation of THF from lithium species can be substantially higher than the activation energies of the Li–I exchange measured here (7*n*, 22, 23). This is in principle testable (the Li–I exchange should have fractional or zero order in iodide) by repeating the experiment of Fig. 5 at various concentrations, to establish whether consistent rates would be obtained. Unfortunately, the concentration of iodide is not easily manipulated in solutions with excess lithium reagent, the only conditions where k_{-2} can be measured.

It is the interference by the process of eq. [3] that prevents us from demonstrating by DNMR techniques whether the ate complex is an obligatory intermediate in the Li–I exchange. This would require showing that the exchange rates of iodide and lithium reagent were the same and that the ate complex lifetime was correctly predicted from the lifetimes of the reaction partners. To achieve this, signals for all three components (**4M**, **5**, and **6**) must be visible in a sample so that lifetimes of all three can be simultaneously measured. As can be seen from Figs. 5 and 6, at no point can ^{13}C signals of all three species be seen. This is in part because at the low temperatures where rates are slow enough to observe individual signals, K_2 is so large that the concentrations of **4M** or **6** (whichever is stoichiometrically limiting) is too small to detect, and in part because k_3 is too large.

© 2005 NRC Canada

Rate of Li–I exchange for the dimer (k_4)

The observation that the ^{7}Li NMR signal of the dimer **4D** could be decoalesced from the averaged signal comprising the lithiums of **4M** and **5** in Fig. 6B shows that the dimer is not undergoing Li–I exchange (eq. [4]) under conditions where exchange of monomer is rapid. The ^{7}Li NMR signal of **4D** at –102 °C is 60 Hz wide. At the same temperature the ^{13}C NMR signal of **4D** in a sample containing only **4** is 80 Hz (Fig. 2), so there is no detectable broadening assignable to the Li–I exchange of dimer, the k_4 process. If we estimate that no more than 10 Hz of the 60 Hz line width of the lithium signal could be due to the k_4 process, then the NMR rate constant $k_{DA} \leq 31$ s^{-1} ($\pi\Delta\nu$), and the physical rate constant $k_4 = k_{DA}/[\mathbf{6}] \leq 670$ s^{-1} (mol/L)$^{-1}$. Since the rate of exchange of the iodide with monomer (k_2) is 6.7×10^6 s^{-1} (mol/L)$^{-1}$ at –102 °C (see eq. [2]), reaction of dimer with the iodide is at least a factor of 1000 slower than reaction of the monomer. Although many reactivity effects of organolithium reagents have been ascribed to aggregation phenomena, determination of quantitative and qualitative differences between reactivity of different aggregates of an organolithium species under the same conditions has rarely been reported (24, 25). This result shows that the common assumption that higher aggregates are less reactive than lower ones holds well in this monomer–dimer case, and that the differences can be quite large.

Summary

A DNMR investigation of 2-lithio-5-methylthiophene (**4**) showed this lithium reagent to be a mixture of monomer and 4-center dimer in THF–ether (3:2). Solutions of **4** and the corresponding iodide **6** undergo Li–I exchange on the NMR timescale. The ate complex **5**, a probable intermediate in the exchange, is formed with a high association constant at low temperature (–130 °C), but is largely dissociated at temperatures above –70 °C. A variable-temperature DNMR kinetic analysis showed that three exchange processes occurred on the NMR timescale, the monomer dimer exchange (eq. [1]), the Li–I exchange of the monomeric lithium reagent (eq. [2]), and direct exchange between the ate complex and the iodide (eq. [3]). The ate complex **5** is comparable in reactivity to the monomeric lithium reagent **4M** in the Li–I exchange process. The data obtained also allowed an estimate of the upper limit of a fourth process, the Li–I exchange of the dimer (eq. [4]). The bimolecular rate constants at –102 °C are shown in the following:

Rate constant	k ((mol/L)$^{-1}$ s^{-1})	k_{rel}
k_1 (eq. [1])	6.8×10^3	1/100
k_2 (eq. [2])	6.7×10^5	1.0
k_3 (eq. [3])	1.3×10^6	1.9
k_4 (eq. [4])	$<6.6\times10^2$	<1/1000

The lithium iodine exchange reaction has been mechanistically controversial since its discovery in 1938. The present DNMR investigation, together with other related papers (7*a*–7*c*), places aryl iodine ate complexes (**5**) firmly into the mechanistic picture in two roles: as a permissible intermediate in the exchange itself (our results do not make it an obligatory intermediate), and as a reactive partner in its own right in donating a thienyl anion to iodothiophene (eq. [3]). The latter observation suggests that ate complexes may be reactive partners in reactions when lithium reagents are prepared by Li–I exchange. The fact that solutions of iodide and lithium reagent are stable in samples where upwards of 10^9 Li–I exchanges have occurred during an experiment provides a strong argument that single electron transfer reactions involving aryl radical intermediates play no role in the reaction, since cage effects of this magnitude would seem impossible.

Experimental section

General

All glassware was dried in an oven at 110 °C for at least 2 h and flushed with N_2 for at least 5 min. All reactions were performed under an atmosphere of dry nitrogen.

Instrumentation

GC analyses were performed using a 12 m × 0.32 mm SE-30 capillary column, with He pressure of 6.0 psi (1 psi = 6.894 757 kPa), column flow rate (split ratio 300:1) of 3 mL/min, and column temperature of 90 °C. Retention times and response factors with respect to *n*-undecane are as follows: 2-iodo-5-methylthiophene (2.77 min, 2.39), 2-(methylthio)-5-methylthiophene (2.87 min, 1.99), *n*-undecane (2.67 min, 1.00). For a 1:1 molar solution of compound: $C_{11}H_{24}$, the response factor = (peak area $C_{11}H_{24}$)/(peak area compound).

^{13}C, ^{7}Li, and ^{6}Li NMR spectra were obtained on a Bruker AM-360 spectrometer operating at 90.56, 139.96, and 53.00 MHz, respectively. The NMR spectra were acquired unlocked and in non-deuterated solvents unless otherwise stated. For ^{13}C NMR, a 30° pulse of 5 μs repeated every 2.9 s was used. An exponential line broadening of 2–5 Hz was used, and a 64 K transform was carried out over a spectral width of 20 800 Hz. ^{13}C NMR chemical shifts are reported in ppm relative to TMS (δ 0.0), using THF as an internal reference. ^{7}Li NMR spectra were recorded over a spectral width of 1400 Hz (8K data points) using a 10 μs pulse and ^{6}Li NMR spectra over a spectral width of 2907 Hz (8K data points) with a pulse width of 10 μs and a recycle delay of 4 s. Both ^{7}Li and ^{6}Li NMR chemical shifts were referenced to external 0.30 mol/L LiCl in MeOH (δ 0.0 ≈ –100 °C) (19*c*). *n*-Bu-^{6}Li (95.5% enriched) was prepared by literature procedures (7*l*).

Probe temperatures were measured (decoupler turned off) by replacing the sample with an open tube containing the same solvent and the sensor of a RTD (platinum resistance) thermometer, which was designed to measure temperatures from –150 °C to 50 °C, and was calibrated using ice water (0.01 °C) and CO_2 (–78.5 °C). The accuracy of the resistance thermometer was checked with the melting points of toluene (–95.00 °C) and methylcyclohexane (–126.6 °C) and were found to be within 0.4 °C of the reported value. Samples were allowed to equilibrate for at least 8 min in the probe prior to tuning the spectrometer and acquiring the spectrum. Probe temperatures were confirmed following the acquisition of each spectrum.

DNMR simulations were performed with the Binsch DNMR program (26) and with WINDNMR (7*m*).

Solvents

THF and Et_2O were freshly distilled from sodium benzophenone ketyl prior to use. The THF still was recharged every 3 weeks to insure that no benzene (formed by cleavage of benzophenone) accumulated in the THF. Solutions of organolithium reagents were titrated by use of 1-propanol with 1,10-phenanthroline as the indicator (27). 2-Methylthiophene was commercially available.

Preparation of stock solutions of 2-lithio-5-methylthiophene (4)

To a solution of 2-methylthiophene (2.4 mL, 25 mmol) in 5 mL of THF at –78 °C was added 13.3 mL of a 1.88 mol/L solution of *n*-BuLi or *n*-Bu^{6}Li (25 mmol). The reaction mixture was warmed to 0 °C for 10 min, then cooled to –78 °C. Crystals formed in the centrifuge tube within 10 min. The supernatant was removed from the crystals, which were washed two times with 6 mL of THF, each time removing the excess solvent by cannula. The crystals were dissolved in ca. 15 mL of THF to give a solution of **4** in THF, which was determined to be 0.95 mol/L. The solution of **4** was stable for several months at –20 °C.

2-Iodo-5-methylthiophene (6)

To a solution of 2-methylthiophene (96.8 μL/mmol, 1.94 mL, 20 mmol) in 20 mL of THF at –78 °C was added a solution of *n*-BuLi (1.88 mol/L, 10.6 mL, 20 mmol). The solution of **4** was warmed to 0 °C and added dropwise to a suspension of 1,2-diiodoethane in THF at –78 °C. The mixture was stirred at –78 °C for 1 h, warmed to 0 °C for 2 h, and partitioned between 200 mL of Et_2O–pentane (1:1) and 150 mL of $NaHCO_3$. The organic layer (purple) was washed with 50 mL of 0.5 mol/L $Na_2S_2O_3$, 200 mL of water, 150 mL of brine, and passed through a cone of Na_2SO_4. Evaporation of the solvent gave a light brown liquid (4.34 g, 97%), which was purified by Kugelrohr distillation (bp 40–60 °C (1 mm Hg)) giving a colorless liquid. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 2.46 (d, J = 0.94 Hz, 3H), 6.45 (dq, J = 3.7, 0.9 Hz, 1H), 7.01 (d, J = 3.67 Hz, 1H). ^{13}C NMR (THF–Et_2O (60:40), –116 °C, 90.556 MHz) δ: 15.4, 73.2, 128.34, 137.4, 146.3 (28).

The preparation of NMR samples of 2-lithio-5-methylthiophene (4)

To a septum-capped 10 mm NMR tube under N_2 was added 0.05 mL of a 1.42 mol/L solution of 2-lithio-5-methylthiophene (**4**) and 1 mL of THF. The NMR tube containing the dilute solution of **4** was rolled so that all of the surface of the NMR tube and septum came in contact with the organolithium solution (to dry the NMR tube). The solution of **4** was removed from the NMR tube with a syringe. A solution of **4** in THF (1.42 mol/L, 0.20 mL, 0.288 mmol) was added to the NMR containing a static N_2 needle. THF (1.8 mL) and Et_2O (1.2 mL) was added to the tube and the solution was mixed with a vortex mixer. The contents of the tube were cooled to –78 °C and the septum was sealed with parafilm.

The determination of concentration for NMR samples

To the NMR solution was added Me_2S_2 and 25 μL (0.118 mmol) of *n*-undecane. The mixture was added to 10 mL of pentane and 1 to 2 drops of 30% NaOH and the mixture dried with Na_2SO_4. The organic solution was analyzed by GC to determine the relative concentrations of the components vs. *n*-undecane.

Concentration dependence of 4

Seven samples of **4** in THF–ether (3:2) were prepared by appropriate dilution of a 0.78 mol/L sample of **4** in THF. Spectra (^{13}C, ^{7}Li) of each sample were taken at –121 °C. After the experiment, the concentration of **4** in each sample was determined by quenching with Me_2S_2 and GC analysis. The spectra from the five samples with the highest concentrations were integrated (C-3) by line-shape simulation. The data are shown in Table 1 and Fig. 3A.

Temperature dependence of 4

A 0.101 mol/L sample of **4** in THF–ether (3:2) was prepared and a series of ^{13}C and ^{7}Li NMR spectra were taken at accurately determined temperatures. Sample spectra are shown in Fig. 2. The spectra of the C-3 carbons were simulated. Line widths in the absence of exchange were determined from the solvent peaks. Below coalescence the line positions and populations of **4M** and **4D** were allowed to vary in the simulation. For determination of the thermodynamic parameters above coalescence, the populations were calculated from the chemical shift of the averaged peaks. Several experiments were performed to determine ΔH_1 and ΔS_1 at various concentrations: the ΔH_1 values varied from 0.8 to 1.4 kcal/mol and the ΔS_1 values from 10.5 to 14.5 eu, giving some measure of the reproducibility of these experiments. One significant variable may be accurately reproducing solvent composition for the NMR samples, since the K_1 values are very sensitive to the ratio of THF to ether.

For determination of the kinetic parameters, the populations during and above coalescence were calculated from the ΔH_1 and ΔS_1 values given in eq. [1]. Data used and derived from the simulations are shown in Table 2. Activation parameters were determined from the values of k_1 and k_{-1} and are shown in eq. [1].

The preparation of NMR samples of 4 containing 2-iodo-5-methylthiophene (6)

The sample preparation is the same as described in the previous section, except after the NMR tube was dried, Et_2O was added (22 °C) followed by **6**. The sample was mixed with a vortex mixer, cooled to –78 °C, then a solution of **4** in THF was added. The sides of the NMR tube were washed with the THF, which was added last.

[a]Concentrations calculated from the fraction of dimer in the ^{7}Li NMR spectra.

Determination of the ate complex association constant (K_2)

A sample 0.156 mol/L in **6** and 0.123 mol/L in **4** was prepared using the previous procedure. ^{13}C and ^{7}Li NMR spectra were taken at 13 temperatures between –117 and –59 °C (Fig. 6). The ^{13}C NMR chemical shift of the averaged C-3 carbon in the spectra from –87 to –59 °C was used to determine the concentrations of **4M**, **4D**, **5**, and **6**. Input parameters were the values of the chemical shifts of the individual compounds (δ 132.6 for **4M**, δ 136.8 for **4D**, δ 128.7 for **5**, the shifts of **6** were temperature dependent and calculated using the formula δ = 0.002 815(T °C) + 137.500), the observed chemical shift in the averaged spectrum, the stoichiometric concentrations of **4** and **6**, and the value of K_1 calculated from ΔH_1 and ΔS_1. The input data were then used to iteratively calculate values for all concentrations using test values of K_2 until the average δ for all species matched observed δ for C-3. Data are presented in Table 3.

Two additional K_2 values were determined at –107 and –102 °C, where it is possible to detect the signal of **4D** (see Fig. 6B and insets). From the relative area of the dimer peak the concentrations of the other species could be determined by a similar iterative process. The area of this signal was determined at the two temperatures at which it is best defined (–102 and –107 °C), where **4D** corresponds to 1.4% and 0.6% of total peak area. These values were then used to calculate the concentrations of the other species using the known value of K_1.

Determination of ate complex association and dissociation rate constants (k_2 and k_{-2})

A sample 0.117 mol/L in **4** and 0.046 mol/L in **6** in THF–ether (3:2) was prepared by the general procedure, and ^{7}Li and ^{13}C NMR spectra were measured at a series of accurately measured temperatures (Fig. 5). The ^{7}Li signals were simulated as follows. The population of the exchanging species (**4M**, **4D**, **5**, and **6**) were calculated from the known concentrations and the values of K_1 and K_2 at each temperature, and values for k_1 and k_{-1} were calculated from the activation parameters of eq. [1]. These were used to start the simulation. The line width in the absence of exchange for the simulations was problematic, since it is likely to be both

compound specific (different rates of quadrupolar relaxation for different lithium environments) and temperature sensitive. In the absence of actual information, the line widths were set at 4, 8, and 10 Hz for **5**, **4D**, and **4M**, respectively, based on values for several related species. The simulations were performed with the program WINDNMR (7*m*) using the exchange matrix of Fig. 7. The relative values of **4M** and **4D** fit well, but small changes in the relative populations of **5** were required for a good fit for all nuclei. Chemical shifts were assumed to be temperature independent (no actual measurements could be performed because dynamic broadening occurred at too low a temperature) and were set by fitting the spectrum at 142 K. After an optimal fit was achieved, we redetermined K_2 at each temperature, shown as K_2(Li) in Fig. 3B ($\Delta H_2 = -8.8 \pm 1$ kcal/mol, $\Delta S_2 = -43.3 \pm 1$ eu). New concentrations of all species were calculated with these parameters, and a final fitting was performed with the calculated concentrations frozen, modifying only k_{AI} and k_{AM}. Only the spectra from –124 to –97 °C provided good definition for the individual rates, and data for these temperatures are shown in Table 4 and Fig. 4.

Determination of rate constants for ate complex exchange with iodide (k_3, k_{-3})

The ^{13}C NMR spectra in Fig. 6A were simulated to extract values for the rate of **5/6** exchange. A sample was prepared 0.166 mol/L in **6** and 0.128 mol/L in **4** in THF–ether (3:2). In the simulations the population of all of the species was calculated from the values of K_1 and K_2 determined from ΔH_1 and ΔS_1, and values of k_1, k_{-1}, k_2, and k_{-2} were calculated from the values for the activation parameters in eqs. [1] and [2]. The exchange matrix is shown in Fig. 10, the numeric data in Table 5, and the simulated spectra in Fig. 6A.

Influence of the number of water molecules on the mechanism of *N*-sulfinylaniline hydrolysis[1]

Elena V. Ivanova and Heidi M. Muchall

Abstract: The mechanism of the uncatalyzed hydrolysis of *N*-sulfinylaniline (Ph-N=S=O) has been studied with B3LYP/6-31+G(2d,2p) in the gas phase, with explicit treatment of water molecules. Hydrolysis involves water attack on sulfur, with a close to perpendicular alignment of a water molecule and the NSO plane in both prereaction complexes and transition states for the rate-determining step. Consequently, the distance of the weak S···O interaction, together with the efficiency of protonation of either nitrogen (attack across the N=S bond) or oxygen (attack across the S=O bond) atoms of the NSO group, determines the height of the activation barrier for hydrolysis. While the reaction with one water molecule is characterized by an unreasonably high enthalpy of activation, a cooperative effect from the weak interactions appears with the inclusion of a second water molecule, where both participate in the reaction, and the activation enthalpy drops significantly. The preference for attack across the S=O bond that is found in the reaction with one water molecule switches to a dominance of attack across the N=S bond in the reaction with three water molecules.

Key words: N-sulfinylaniline, hydrolysis, mechanism, density functional theory (DFT).

Résumé : Faisant appel à des calculs théoriques au niveau B3LYP/6-31+G(2d,2p), on a étudié le mécanisme de l'hydrolyse non catalysée du *N*-sulfinylaniline (Ph-N=S=O) en phase gazeuse, en faisant un traitement explicite des molécules d'eau. Dans l'étape cinétiquement déterminante, l'hydrolyse implique une attaque de l'eau sur le soufre, avec un alignement pratiquement perpendiculaire d'une molécule d'eau et du plan NSO tant dans les complexes préréactionnels que dans les états de transition. En conséquence, la distance de la faible interaction S···O ainsi que l'efficacité de la protonation de l'atome d'azote (attaque à travers la liaison N=S) ou de l'atome d'oxygène (attaque à travers la liaison S=O) du groupe NSO détermine la hauteur de la barrière d'activation de l'hydrolyse. Alors que la réaction avec une molécule d'eau est caractérisée par une enthalpie d'activation anormalement élevée, il semble se développer un effet de synergie avec les interactions faibles lors de l'inclusion d'une deuxième molécule d'eau alors que les deux participent à la réaction et que l'enthalpie d'activation diminue d'une façon significative. La préférence pour l'attaque à travers la liaison S=O qui caractérise la réaction avec une molécule d'eau se déplace vers une dominance pour une attaque à travers la liaison N=S dans la réaction avec trois molécules d'eau.

Mots clés : N-sulfinylaniline, hydrolyse, mécanisme, théorie de la densité fonctionnelle.

[Traduit par la Rédaction]

Introduction

Our interest in the electronic and molecular structures of NSO species (1, 2) is closely related to their reactivity. *N*-Sulfinylamines (R-N=S=O) were first prepared by Michaelis in 1890 (3) and their reaction with water was one of the first properties to be observed experimentally. While aromatic *N*-sulfinylamines are insoluble in water and hydrolized very slowly in it as well as in dilute acids, warm alkaline solutions or concentrated acids lead to their rapid hydrolysis (4). Aromatic *N*-sulfinylamines in particular are widely employed in synthetic organic chemistry, as they readily undergo a variety of cycloaddition reactions to yield N,S-heterocycles (Diels–Alder reactions as both dienes and dienophiles (5–7), 1,2-cycloadditions, and 1,3-dipolar additions (8, 9)). Common to all these reactions is the attack on the sulfur of the NSO group, and hydrolysis can be considered as the prototype reaction. Therefore, an understanding of the initial steps of the hydrolysis reaction mechanism of *N*-sulfinylaniline is fundamental to its exploitation in similar reactions involving *N*-sulfinylamines.

Scheme 1.

$$RNSO + H_2O \longrightarrow RNHS(O)OH \longrightarrow RNH_2 + SO_2$$

The mechanism for hydrolysis of *N*-sulfinylamines is believed to proceed through nucleophilic addition of a water molecule to the NSO group with the formation of sulfinamic acid, followed by the acid's fast decomposition to sulfur dioxide and a primary amine (Scheme 1) (10). Aromatic *N*-sulfinylamines are known to be somewhat resistant towards water, whereas aliphatic *N*-sulfinylamines hydrolyze more readily (4). For *N*-sulfinylaniline (Ph-N=S=O), kinetics studies using UV spectroscopy showed neutral hydrolysis to be a

slow process (11, 12), with an induction period of approximately 4 h (12). The reaction is complicated by autocatalysis from aniline, formed as a product of the reaction, which explains the relatively low activation energy of 9.88 kcal mol^{-1} (1 cal = 4.184 J) in a water–1,4-dioxane (1:1) solution (11). In the presence of pyridine as a base or with a combination of pyridine and a carboxylic acid, the rate of reaction increases significantly (12). General base catalysis was proposed for the hydrolysis in the presence of pyridine, where the formation of a pyridine–water complex increases the nucleophilic properties of water and facilitates its interaction with the electrophilic sulfur atom. This is proposed to be the rate-determining step of hydrolysis. It is a third-order reaction, first-order in each *N*-sulfinylaniline, water, and pyridine, with an overall rate constant of 2.96×10^3 L^2 mol^{-2} s^{-1} and a low enthalpy of activation of 5.7 kcal mol^{-1} for the 20–40 °C temperature range.

For the combined catalysis by pyridine and a carboxylic acid, initial protonation of either nitrogen or oxygen atoms of the NSO group was predicted (12). This would lead to an increase in the net positive charge on the sulfur atom and promote the addition of a water molecule to the NSO group. This acid catalysis is not part of the discussion in the present paper.

While literature data on the hydrolysis of *N*-sulfinyl compounds are limited (11, 12), the hydrolysis of their cumulated analogs (isocyanates, R-N=C=O) was intensively studied, both experimentally (13–15) and computationally (16). Based on their structural similarities, one might expect similar reactivities for these two classes of compounds. And while the NCO group is more or less linear, whereas the NSO group is bent with a sulfur bond angle of 120.6° as determined from X-ray diffraction analysis (17), the similar solvent kinetic isotope effects $k(H_2O)/k(D_2O)$ of 1.65 for PhNCO (14) and 1.73 for PhNSO (12) seem to support the idea of similar reactivities and possibly similar mechanisms in the hydrolysis of these compounds.

A second-order dependence on water was found in the neutral hydrolysis of alkyl- and aryl-substituted isocyanates (13, 14, 16), where one molecule acts as a general acid and the other as a general base. This is closely related to the base-catalyzed hydrolysis of *N*-sulfinylaniline, if one water molecule is considered to take the role of the catalyst (pyridine). For the hydrolysis of 4-chlorophenyl isocyanate, however, a third-order dependence with respect to water concentration was reported (15). We therefore decided to explore the neutral hydrolysis of *N*-sulfinylaniline computationally to determine its mechanism and the number of water molecules involved.

Computational details

All geometry optimizations were performed with the Becke3 (18) – Lee, Young, and Parr (B3LYP) hybrid density functional (19) with the 6-31+G(2d,2p) basis set, using the GAUSSIAN 98 suite of programs (20). This computational level best reproduces the observed geometry (X-ray analysis) of *N*-sulfinylaniline (17), and the basis set superposition error (BSSE) (21) consists of less than 0.7 kcal mol^{-1} for the ternary complexes (counterpoise = 3, full geometry optimization).[3] All structures were optimized without constraints. The complexes and their transition states were studied in the gas phase, as it was found in similar studies of the hydrolysis of isocyanates (16) and amides (22) that the inclusion of the solvent as a dielectric continuum only leads to a small decrease in the activation barrier. Vibrational frequencies and zero-point vibrational energies (ZPVE) were obtained at the preceding level of theory. The identity of each transition state was additionally verified using the intrinsic reaction coordinate (IRC) method (23, 24). The total (E_{tot}) and ZPVE-corrected energies (E_{tot} + ZPVE), as well as the enthalpies of the complexes and their transition states, are summarized in Table 1. Throughout the paper, we will report only the enthalpy term at standard state, unless stated otherwise. We chose enthalpies over Gibbs free energies because an enthalpy is available (12) for comparison. Furthermore, the entropy contribution ($-T\Delta S$) to the Gibbs free energy barrier, on average 5.8 kcal mol^{-1}, is practically independent of the number of water molecules: it varies from 5.1 to 6.5 kcal mol^{-1} without apparent pattern for 1–5 H_2O. Net atomic charges were obtained within the quantum theory of atoms in molecules (QTAIM) (25) with the AIMPAC module PROAIM (26). The natural bond orbital (NBO) program (NBO 3.1) (27) was used to study the charge transfer in the complexes (28).

Results and discussion

Approach to the problem

While the NSO group is commonly considered a heterocumulene and, from ^{17}O NMR (29) and computational (2) studies, the S=O bond is best described as a four-electron bond not unlike the carbonyl C=O bond, the electronic structure of *N*-sulfinyl species can be represented as a set of resonance structures, shown in Scheme 2. Obviously, a change of substituent on nitrogen can change the reactivity of the NSO group; nevertheless, sulfur is the most positive centre and either nitrogen or oxygen is considered as the negative end of the bond dipole. We chose to study the computationally expensive *N*-sulfinylaniline (**1**) (instead of the more common approach to substitute the phenyl group for a smaller methyl group or the H atom (16)) because it is the only compound for which quantitative experimental data are available, and for comparison with the reactivities of aliphatic *N*-sulfinyl species in a subsequent paper.[4]

The calculated net atomic charges of **1** confirm the idea of sulfur being the most electrophilic atom of the NSO group (Fig. 1). Consequently, in a nucleophilic attack, the oxygen atom of the water molecule with a negative charge of

[3] We used the counterpoise correction method to verify the applicability of our chosen level of theory, and the BSSEs obtained with full geometry optimization for three structures are shown in Table 1. Our results of the study of other methods (HF and MP2) with various basis sets will be summarized elsewhere.

[4] A change in mechanism seems to be a common trait in the hydrolysis of NSO species with electron-donating substituents. For HNSO, the transition states for reaction with one water molecule are isoenthalpic, and the different mechanisms for CCl_3NSO hydrolysis do not seem to exhibit a dependence of preference on the number of water molecules. –1.151 au is expected to attack the sulfur atom. A proton can then be transferred to either the oxygen (attack across the S=O bond, path a) or the nitrogen (attack across the N=S bond, path b) atom of the NSO group (Scheme 3), similar to hydrogen isocyanate hydrolysis (16).

Reaction across the S=O bond includes two steps, the protonation of oxygen with formation of *N*-phenylsulfurimidic acid and a subsequent 1,3-hydrogen shift to form the intermediate *N*-phenylsulfinamic acid, which decomposes with formation of the final products, aniline and sulfur dioxide. Reaction across the N=S bond, on the other hand, is a one-step process that directly yields *N*-phenylsulfinamic acid.

Structures from the interaction across the S=O bond are denoted with the letter "**a**", those from the interaction across

Scheme 3.

the N=S bond with the letter "**b**". Structures with interactions across both S=O and N=S bonds are given the letter "**c**". The subscript "w" is used for the designation of atoms that belong to water molecules. In the description of complexes with multiple water molecules, "H_{w1}" determines a hydrogen atom of the water molecule that interacts with the oxygen atom of the S=O bond, and "H_{w2}", a hydrogen atom of the water molecule that interacts with the nitrogen atom of the N=S bond.

In the following, we examine how the preference for reaction across the N=S or S=O bond depends on the number of water molecules participating in the reaction. The complete reaction coordinate for the hydrolysis of **1** is presented for the participation of two water molecules.

Reaction of *N*-sulfinylaniline with one water molecule

Interaction with one water molecule is the simplest model in the study of the hydrolysis of *N*-sulfinylaniline (**1**). Even though the formation of a prereaction complex usually precedes the reaction, we were only able to locate complex **2a** with water situated on top of the S=O bond (Fig. 2). Our search for **2b** with water on top of the N=S bond produced numerous hydrogen-bonded complexes, but there does not

2a **2a-TS** **2b-TS**

seem to be a stationary point on the potential energy surface for **2b**.[5]

The intermolecular distance between the sulfur atom and the oxygen atom of water (O_w) in **2a** is 319.0 pm (Table 2), with the water molecule forming a close to perpendicular alignment with the plane of **1** (the $NSOO_w$ dihedral angle is 101.9°). Even though this distance is less than 325.0 pm, which is the accepted value for the sum of the van der Waals radii of oxygen and sulfur atoms (30), according to an analysis of the electron density within QTAIM, there is no interaction between these atoms.[5] The complex **2a** is stabilized by a hydrogen bond with an $O\cdots H_w$ distance of 240.4 pm and an OH_wO_w angle of 130.8°. This nonideal hydrogen bond geometry is in good agreement with the small stabilization energy of 0.6 kcal mol^{-1} upon complex formation (Table 3). The perpendicular attack on sulfur is in stark contrast to the in-plane attack of water on the carbon atom in HNCO (16).

The activation enthalpy for the reaction of **1** with one water molecule is very high with 31.8 and 35.7 kcal mol^{-1} for transition states **2a-TS** and **2b-TS**, respectively (Fig. 2 and Table 3). The barriers are calculated from the enthalpies of the reagents for lack of complex **2b** as a reference. The reaction across the S=O bond (path a) is favoured by 3.9 kcal mol^{-1}.

Reaction of *N*-sulfinylaniline with two water molecules

Introduction of a second water molecule allows the formation of a water dimer, which increases the nucleophilic properties of water towards the electrophilic sulfur. The negative charge on the oxygen atom of the original water molecule is increased by 0.045 au from –1.151 au in the monomer to –1.196 au in the dimer (Fig. 1). Unlike in the interaction with one water molecule, both prereaction complexes **3a** and **3b** were located (Fig. 3). This is also different from HNCO hydrolysis in that prereaction complexes of HNCO with water chains (dimers and trimers) were not found (16). Selected geometrical parameters of **3a** and **3b** are shown in Table 2. Stabilization in both complexes is achieved through an $S\cdots O_w$ interaction along with hydrogen bond formation. The $S\cdots O_w$ interaction is mostly due to the electrostatic attraction between sulfur and water oxygen atoms, combined with some charge transfer from the lone pair of O_w into the antibonding orbital of the N=S bond ($\pi^*_{N=S}$), found for **3a** from an NBO analysis.[5] As expected, complexation across the S=O bond primarily affects the S—O bond length, and complexation across the N=S bond mainly influences the N—S bond length. The lengthening of both bonds in their respective complexes to a similar degree coincides with the contraction of the second cumulated double bond (the changes in bond lengths from **1** are given in Table 2 for ease of comparison). But while **3a** exhibits the close to perpendicular arrangement between the plane of **1** and the water molecule complexed to sulfur that we also observed for **2a**, there is a much larger deviation from 90° found in **3b**. In addition, the $S\cdots O_w$ intermolecular distance in **3b** is significantly larger than that in **3a**, suggesting a nonideal arrangement of its constituent fragments. These findings are nicely in accord with those for complexation with one water molecule and offer an explanation as to why **2b** could not be located. The requirements of a perpendicular attack of O_w on sulfur and an in-plane $N\cdots H_wO$ hydrogen bond (the $OSNH_{w2}$ dihedral in **3b** is close to 180°, Table 2) prevent the formation of **2b** and render **3b** somewhat strained. This interpreta-

[5] A detailed analysis of hydrogen bonding and other weak interactions in the complexes and their transition states will be presented elsewhere. Manuscript in preparation.

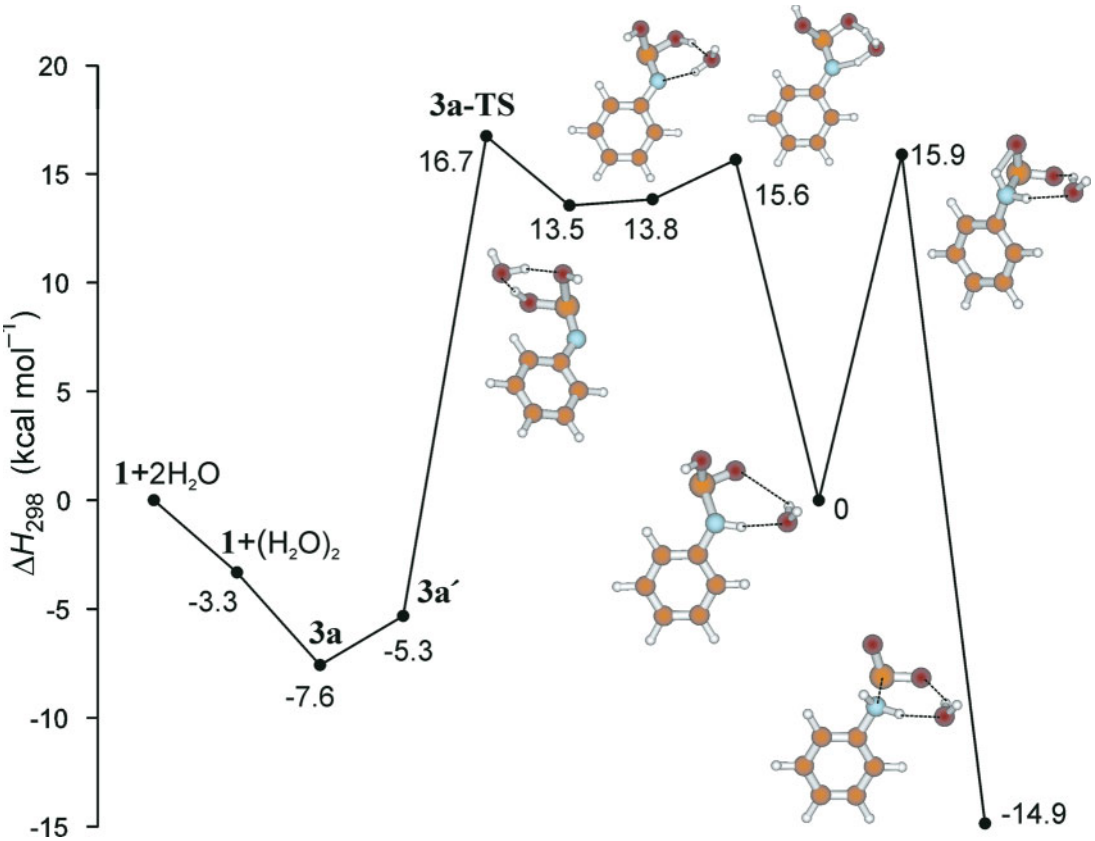
Fig. 3. Optimized complexes **3a** and **3b** for the interaction of **1** with the water dimer, and transition states **3a-TS** and **3b-TS**. Weak interactions in the transition states are given with solid lines.

tion is supported by the relative energies of **3a** and **3b**, with **3b** less stable by 1.6 kcal mol^{-1}. The formation of six-membered cycles reduces the strain that exists in the four-membered cycles of transition states **2a-TS** and **2b-TS** in the reaction of **1** with one water molecule. The full reaction coordinates for the reaction of *N*-sulfinylaniline (**1**) with two water molecules are given in Fig. 4 for water addition across the S=O bond (path a) and in Fig. 5 for addition across the N=S bond (path b).



The formation of **3a** is favourable by 7.6 kcal mol^{-1} with a stabilization of 4.3 kcal mol^{-1} in addition to the 3.3 kcal mol^{-1} of energy gain due to water dimer formation. The experimental enthalpy of association in the water dimer was found to be –3.59 ± 0.5 kcal mol^{-1} at 373 K (31). As was proposed (12), hydration of sulfur with protonation of oxygen of **1** is indeed the rate-determining step of the reaction. The activation enthalpy is 24.3 kcal mol^{-1}, a value that includes 2.3 kcal mol^{-1} because of the loss of planarity in **1** (**1** in **3a** is planar whereas in both the complex **3a′** and the transition state **3a-TS**, CCNS and CNSO torsional angles are 6.1° and 23.6°, respectively). The torsions allow a decrease of the S···O$_w$ interatomic distance from 314.6 pm in **3a** to 299.4 pm in **3a′**, and this shortening of about 15 pm increases the strength of the interaction and facilitates the hydration of sulfur. Further along the reaction path, the water molecule in the primary reaction product (the complex of *N*-phenylsulfurimidic acid and water) changes its orientation, which allows it to abstract a proton from one hydroxyl group of *N*-phenylsulfurimidic acid and simultaneously protonate the acid's nitrogen atom. This "water-assisted" 1,3-hydrogen shift[6] requires only 1.8 kcal mol^{-1} and yields the complex of *N*-phenylsulfinamic acid and water in which the orientation of the water molecule cannot facilitate the protonation of nitrogen. Thus, the unassisted decomposition of *N*-phenylsulfinamic acid into the complex of aniline, sulfur dioxide, and water requires the large activation enthalpy of 15.9 kcal mol^{-1}. We find exactly the same value, 15.9 kcal mol^{-1}, for the enthalpy of activation for the decomposition of *N*-phenylsulfinamic acid in the absence of any water.[6]

The formation of **3b** is less favourable than that of **3a**, as previously discussed, and only shows a stabilization of 2.7 kcal mol^{-1} in addition to the stabilization from water dimer formation (Fig. 5). The reaction of the water dimer with **1** again is the rate-determining step and an activation enthalpy of 24.8 kcal mol^{-1} is required, which is only 0.5 kcal mol^{-1} higher than (and therefore comparable with) that for the reaction across the S=O bond. As in Fig. 4, this activation barrier includes 1.8 kcal mol^{-1} because of the torsion of the NSO group out of the plane of the aromatic ring (the CCNS and CNSO torsional angles of 46.0° and 7.9°, respectively, are similar in the complex **3b′** and in the transition state **3b-TS**). As in **3a′**, the S···O$_w$ interaction is strengthened through a decrease in the intermolecular distance by 37 pm, from 377.9 pm in **3b** to 340.9 pm in **3b′**. Unlike **3a-TS** in Fig. 4, **3b-TS** in Fig. 5 directly yields the

[6]We, of course, only present a subset of possibilities of hydrogen bond formation on the potential energy surface for reaction of *N*-sulfinylaniline (**1**) with two water molecules. We believe that the chosen structures explain the formation of the final products and in some cases show the importance of the explicit treatment of water along the reaction pathway. Thus, we exclude, for example, the nonassisted 1,3-hydrogen shift in *N*-phenylsulfurimidic acid.

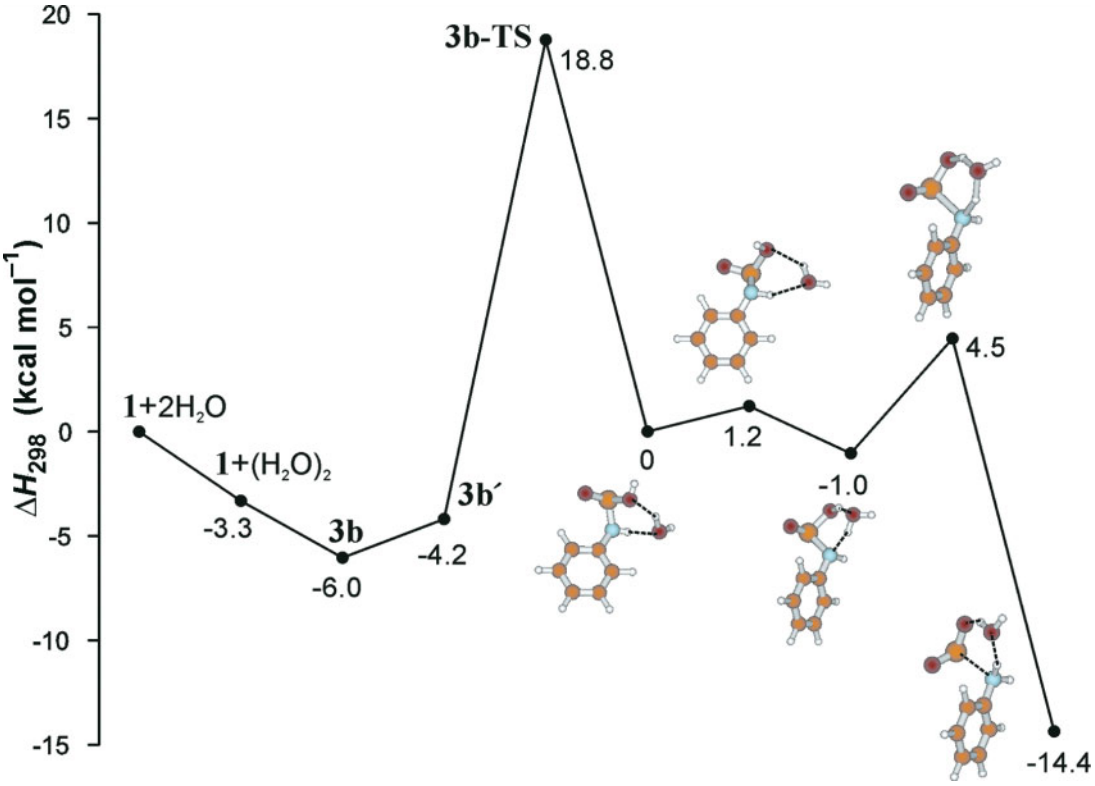
Fig. 4. Enthalpy profile for the reaction of **1** with two water molecules (path a), attack across the S=O bond.

complex of *N*-phenylsulfinamic acid and water. Hydrogen bonding to the hydroxyl group of *N*-phenylsulfinamic acid allows for a reorientation of the water molecule that moves it into the ideal position for protonation of the nitrogen atom and facilitates the decomposition of the acid. In this water-assisted decomposition the activation barrier is decreased with respect to the nonassisted barrier in Fig. 4 by more than 10 kcal mol^{-1} to a mere 5.5 kcal mol^{-1}. This finding, as well as the assistance of water in the 1,3-hydrogen shift, which was discussed in the previous mechanism (path a, Fig. 4), demonstrates the importance of the explicit treatment of water molecules in these hydrolysis reactions, a conclusion that was drawn earlier in amide (32, 33) and isocyanate hydrolysis (16).



The increase in the number of water molecules from one to two allows a decrease in the activation barriers for the hydrolysis reaction of approximately 8–11 kcal mol^{-1} (from 32.4 in **2a-TS** to 24.3 kcal mol^{-1} in **3a-TS**, and from 35.7[7] in **2b-TS** to 24.8 kcal mol^{-1} in **3b-TS**). This is at least partially due to the relief of strain on going from four-membered cycles in **2a-TS** and **2b-TS** to the six-membered cycles in **3a-TS** and **3b-TS**, as was mentioned earlier. The N=S bond demonstrates a higher sensitivity to this effect because the hydroxyl group of the second water molecule now approaches **1** in the NSO plane (with a OSNH$_{w2}$ torsional angle of 177.2°, Table 2), where the nitrogen lone pair lies, confirming the idea of donor–acceptor directionality in hydrogen bond formation.

Our finding about the almost equal probability of both mechanisms owing to activation barriers of 24.3 kcal mol^{-1} for path a and 24.8 kcal mol^{-1} for path b seems quite different from the results for HNCO hydrolysis (16). Calculations in the gas phase and in a solvent field based on the polarizable continuum model (PCM) with MP2/6-31G(d,p), along with other methods, have shown that even though two water molecules are important for HNCO hydrolysis, in all cases studied (the presence of one, two, and three water molecules was considered), reaction across the N=C bond is favoured. With two water molecules, for example, the activation energy decreases from 28 kcal mol^{-1} for reaction across the C=O bond to 11 kcal mol^{-1} for reaction across the N=C bond (values reported in the paper are E_{tot} + ZPVE, given in kJ mol^{-1}, and based on the corrected energies of the reactants). In the presence of a solvent field this difference becomes much smaller though, 15 kcal mol^{-1} for reaction across C=O to 18 kcal mol^{-1} for reaction across N=C (single point energy calculations on the gas-phase optimized geometries). To be able to compare results more directly, we also report ZPVE corrected energies in Table 1. From these, we obtain an activation energy of 19.2 kcal mol^{-1} for reaction across S=O and 21.1 kcal mol^{-1} for that across N=S, both based on the corrected energies for **1** and two water mole-

[7] As previously discussed, this value is not based on the enthalpy of the prereaction complex, but rather on the enthalpies of the reactants, **1** and water.

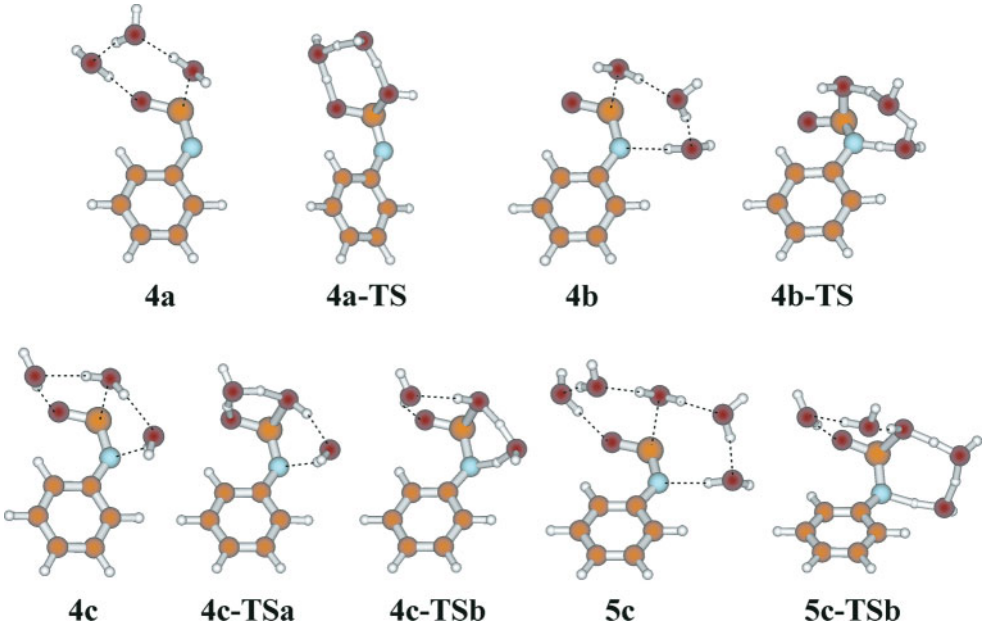
Fig. 5. Enthalpy profile for the reaction of **1** with two water molecules (path b), attack across the N=S bond.

cules. Obviously, the direct comparison is limited by the different substituents (phenyl in **1** and hydrogen in HNCO), and further analysis of the difference between RNSO and RNCO hydrolysis will only be reported in our forthcoming paper on substituent effects in the reactivity of NSO species.[4]

Reaction of *N*-sulfinylaniline with three and five water molecules

Compared to the reaction of *N*-sulfinylaniline with one and two water molecules, water trimer complexation to **1** in **4a** and **4b** (Fig. 6) further increases the flexibility of the systems owing to formation of eight-membered cycles. As can be seen from Table 2, the lengths and, consequently, the strengths of the S=O and N=S bonds do not differ much in complexes of **1** with two (**3a**, **3b**) and three (**4a**, **4b**) water molecules. But inclusion of the third water molecule significantly strengthens the weak S···O$_w$ interaction. The effect is especially pronounced for complexation of the water trimer across the N=S bond. The S···O$_w$ intermolecular distance decreases by 81.7 pm, from 377.9 pm in **3b** to 296.2 pm in **4b** (Table 2). For complexation towards the S=O bond this effect is less pronounced, but still important, as the S···O$_w$ distance decreases by 16.7 pm going from **3a** to **4a**. Along with this, a contraction of the N···H$_{w2}$ hydrogen bond by 4.7 pm is found going from **3b** to **4b**. In contrast, comparing **3a** and **4a**, the O···H$_{w1}$ hydrogen bond distance increases by 3.4 pm.



The strengthening of the S···O$_w$ intermolecular interaction in complexes **4a** and **4b** further decreases the activation barrier for hydrolysis by approximately 2–5 kcal mol^{-1} for the two pathways (from 24.3 in **3a-TS** to 22.4 kcal mol^{-1} in **4a-TS** for the reaction across the S=O bond, and from 24.8 in **3b-TS** to 19.9 kcal mol^{-1} in **4b-TS** for the reaction across the N=S bond, Table 3). The one-step mechanism, reaction across the N=S bond, is now favoured by 2.5 kcal mol^{-1}, as two requirements, "perpendicular" attack on sulfur (NSOO$_w$ torsional angle 107.0°) and in-plane protonation of nitrogen (OSNH$_{w2}$ torsional angle 170.2°), are fulfilled without apparent strain.

The two different attacks on the NSO group are combined in **4c**, where hydrogen bonding to both nitrogen and oxygen atoms of the NSO group assists in the strengthening of the S···O$_w$ interaction, which is 12.2 and 13.9 pm shorter than in **4a** and **4b**, respectively (Table 2). But both hydrogen-bonding interactions are weaker in **4c** than in either **4a** or **4b**. The increase in the O···H$_{w1}$ distance in **4c** from **4a** by 1.7 pm is considered to be insignificant, and this is reflected in the enthalpy barrier of 22.5 kcal mol^{-1} for reaction via **4c-TSa**, which is similar to the activation enthalpy of 22.4 kcal mol^{-1} for **4a-TS**. In contrast, the increase in the N···H$_{w2}$ intermolecular distance in **4c** from **4b** by 41.7 pm, together with a less favourable OSNH$_{w2}$ dihedral angle of 122.0° in **4c**, contributes to **4c-TSb** being less stable than **4b-TS** and increases the activation barrier by 4.1 kcal mol^{-1}.

As can be seen from Figs. 3 and 6, the structures for **4c-TSa** and **4c-TSb** are very similar to those obtained for reaction of **1** with two water molecules (**3a-TS** and **3b-TS**). The third water molecule in complex **4c**, and consequently in **4c-TS4a** and **4c-TSb**, might be seen as a bystander that does not directly react with **1**, yet it participates through hydrogen bond formation, which weakens both S=O and N=S bonds (Table 2). The elongation of these bonds from those in **1** is less efficient than in **3a** and **3b** and consists of 0.6 pm for the S=O and 0.1 pm for the N=S bond in **4c**, but the weak-

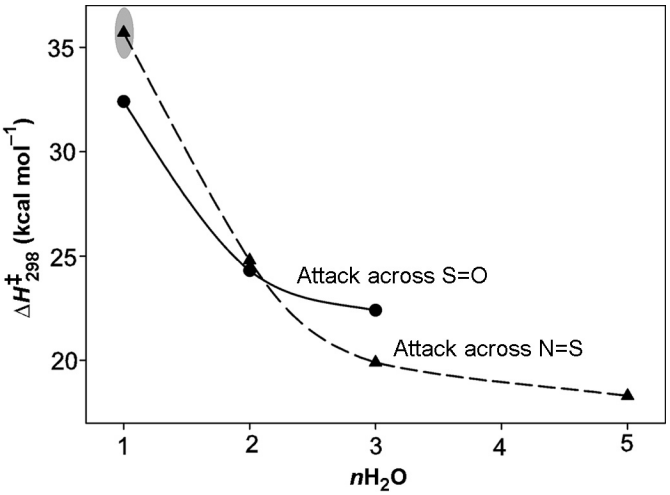
Fig. 6. Optimized structures **4a**–**4c** and **5c** for the interaction of **1** with three and five water molecules, and transition states **4a-TS**, **4b-TS, 4c-TSa, 4c-TSb**, and **5c-TSb** for hydrolysis.



ening of the bonds of the NSO group is accompanied by a significant shortening of the S···O_w intermolecular distance in **4c** by 30.6 and 93.9 pm from **3a** and **3b**, respectively, which facilitates hydrolysis. This is reflected in a decrease in the activation barrier (by 2.2 kcal mol^{-1} in **4c-TSa** compared to **3a-TS**, and by 0.8 kcal mol^{-1} in **4c-TSb** compared to **3b-TS**).

Complex **5c** (Fig. 6) represents the combination of **4a**, **4b**, and **4c** in that both points of attack to the NSO group are connected as in **4c**, but the strain in **4c** is removed by the inclusion of water molecules, similar to **4a** and **4b**. The S···O_w intermolecular distance of 271.8 pm in **5c** is found to be the shortest among all complexes studied. The O···H_{w1} distance in **5c** is shorter than in both **4a** and **4c**, whereas the N···H_{w2} interaction is much shorter (by 39.5 pm) in **5c** than in **4c**, but longer by 2.2 pm compared to **4b**. The increase in the number of water molecules up to five further decreases the activation enthalpy for the hydrolysis reaction (only the reaction across the N=S bond was studied), but the barrier through **5c-TSb** is only 1.6 kcal mol^{-1} smaller than that in the corresponding reaction with three water molecules (**4c-TSb**).

Our results from the study of the influence of the number of water molecules in the hydrolysis of *N*-sulfinylaniline (**1**) are summarized in Fig. 7, which shows the decrease in the activation enthalpy with an increase in the number of water molecules for both pathways (reaction across the S=O and the N=S bond). For the reaction across N=S with one water molecule, the grey zone in Fig. 7, see the previous discussion.[7] The reaction barriers with one water molecule are prohibitively large, and therefore two water molecules are important for hydrolysis, as is suggested by the solvent isotope effect (12). Similar conclusions were drawn in the computational study of HNCO hydrolysis (16). However, there is a crossover in mechanism at this point, and participation of a third water molecule only benefits the reaction across the N=S bond, in contrast to HNCO hydrolysis (16). Such a third-order dependence on water concentration has been proposed for the hydrolysis of the related 4-chlorophenyl isocyanate (15). Figure 7 also suggests that the values for the enthalpy barriers are more or less converged for both pathways (with three water molecules for attack across S=O and five water molecules for that across N=S), and that larger numbers of water molecules need not be considered. The "converged" values for the activation enthalpy of about 23 kcal mol^{-1} for path a and 18 kcal mol^{-1} for path b are obviously still much higher than the experimentally determined values of 9.88 (11) and 5.7 kcal mol^{-1} (12). But as both experimental barriers were determined for a catalyzed hydrolysis (autocatalysis from aniline in the former case, pyridine catalysis in the latter), this is not surprising.

Conclusions

We have presented a computational study on complexes of *N*-sulfinylaniline (Ph-N=S=O, **1**) with one to three and five water molecules and on the mechanism of neutral hydrolysis of **1**. While the complex of **1** with one water molecule does not possess an interaction between the sulfur atom and the water oxygen atom, water chains of two, three, and five molecules lead to increasingly strong S···O interactions. In these complexes, water attacks on sulfur close to perpendicular to the NSO plane.

Two mechanisms have been investigated for reaction of **1** with one to three water molecules, hydration of the sulfur atom with protonation of either oxygen or nitrogen atoms of the NSO group. The full reaction coordinate was probed for hydrolysis with two water molecules, and S···O interaction with proton transfer from water is found to be the rate-determining step in both mechanisms. Unrealistically high activation barriers are found for reaction with one water molecule, and two water molecules are important for hydrolysis. This is in good agreement with the first-order dependence in both water and base that was observed for the base-catalyzed reaction, if one water molecule is considered to take the role of the base. Reaction across the S=O bond is preferred with one water molecule, whereas an increase in the number of water molecules leads to a change in mechanism. For two water molecules, both mechanisms are equally probable; for three water molecules, reaction across the N=S bond is favoured. As expected, the calculated enthalpies of activation for the neutral hydrolysis reaction are several kcal mol^{-1} larger than the experimentally determined barriers for the base-catalyzed reaction.

The results presented here have revealed differences between PhNSO and HNCO, the smallest member of the related isocyanates, in both complexation with water and mechanism for hydrolysis with an increasing number of water molecules. We are currently investigating this further with a study of substituent effects in *N*-sulfinylamine hydrolysis.

S_N2 and S_N2' reaction dynamics of cyclopropenyl chloride with halide ion — A direct ab initio molecular dynamics (MD) study[1]

Hiroto Tachikawa

Abstract: Direct ab initio molecular dynamics (MD) calculations have been carried out for the reaction of cyclopropenyl chloride with halide ion (F^-) ($F^- + (CH)_3Cl \rightarrow F(CH)_3 + Cl^-$) in gas phase. Both S_N2 and S_N2' channels were found as product channels. These channels are strongly dependent on the collision angle of F^- to the target $(CH)_3Cl$ molecule. The collision at one of the carbon atoms of the C=C double bond leads to the S_N2' reaction channel; whereas the collision at the methylene carbon atom leads to the S_N2 reaction channel. The reactions proceed via a direct mechanism without long-lived complexes. The reaction mechanism is discussed on the basis of the theoretical results.

Key words: S_N2 reaction, direct ab initio molecular dynamics, halogen exchange, reaction mechanism.

Résumé : On a effectué des calculs de dynamique moléculaire ab initio directs pour la réaction en phase gazeuse du chlorure de cyclopropényle avec l'ion fluorure (F^-) ($F^- + (CH)_3Cl \rightarrow F(CH)_3 + Cl^-$). On a trouvé que les voies S_N2 et S_N2' peuvent toutes les deux conduire au produit. Ces voies dépendent fortement de l'angle de collision du F^- sur la molécule cible $(CH)_3Cl$. Une collision sur un des atomes de carbone de la double liaison C=C conduit à une voie S_N2' alors qu'une collision sur l'atome de carbone méthylène conduit à une voie S_N2. La réaction se produit par le biais d'un mécanisme direct sans complexes de longue vie. On discute du mécanisme réactionnel sur la base des résultats théoriques.

Mots clés : réaction S_N2, calculs de dynamique moléculaire ab initio directs, échange d'halogène, mécanisme réactionnel.

[Traduit par la Rédaction]

Introduction

Bimolecular nucleophilic substitution (S_N2) reactions have been the focus of extensive theoretical and experimental works in recent years because of their central importance and basic reaction in organic and bioorganic chemistries (1, 2). In particular, the reaction of halide ion (X^-) plays an important role in several organic reactions.

For the reaction dynamics of the halogen exchange S_N2 reaction of a type, $X^- + RY \rightarrow RX + Y^-$ (X, Y = F, Cl, or Br), where R is an alkyl group. Hase and his co-workers (3, 4) have done extensive investigations by means of the classical trajectory method with ab initio fitted analytical potential energy functions. Several characteristic features for the halogen exchange S_N2 reactions have been elucidated from their results. However, the reactions previously investigated are only in the case of methyl halide (R = CH_3). There is no dynamics study on a more complicated system. This is due to the fact that dimension, which should be included in the calculation, will greatly increase as the number of atoms in the reaction system is increased. Therefore, the procedure of the fitting becomes more difficult and more complicated in a larger system.

In the present study, we have investigated a S_N2 reaction of cyclopropenyl chloride with halide ion (F^-), i.e., R = $(CH)_3$,

$$[1] \qquad F^- + (CH)_3Cl \rightarrow F(CH)_3 + Cl^-$$

by means of the direct ab initio molecular dynamics (MD) method. In this method, we do not need a fitting procedure of PES to an analytical function. Therefore, it is suitable to investigate a complex S_N2 reaction using the direct ab initio trajectory method. In previous papers, we have carried out direct ab initio MD calculations for the S_N2 reactions, $F^-(H_2O)_n + CH_3Cl$ (n = 0–1) (5–9) and $OH^- + CH_3Cl \rightarrow CH_3OH + Cl^-$ (10). Mechanism, collision energy dependence, and branching ratios of the product channels were predicted from the calculations. Also, it was suggested that the direct ab initio MD method is a powerful tool for investigating the reaction dynamics for the reactions with large degrees of freedom.

Figure 1 shows an illustration of the reaction scheme of cyclopropenyl chloride with halide ion (F^-). Cyclopropenyl chloride ($(CH)_3Cl$) is constructed of a three-membered ring with one double bond and a chlorine atom is substituted in the methylene (CH_2) group. Therefore, the reactive collisions of X^- ion take place in a σ attack S_N2 site, a π attack S_N2' (anti) site, and a π attack S_N2' (syn) site. For the reaction of F^-, three reaction channels will be expected: S_N2, S_N2' (anti), and S_N2' (syn).

Fig. 1. Schematic illustration of the reaction of cyclopropenylchloride with F^- (F^- + $(CH)_3Cl$). Three reaction channels are possible for reactive collision.

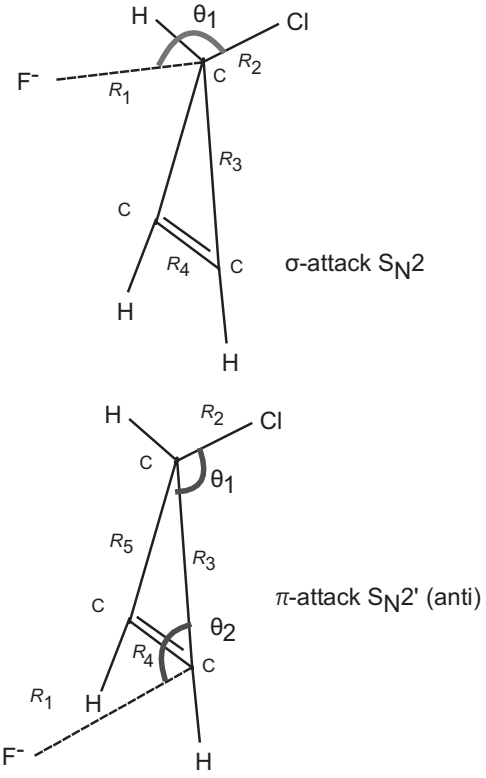
From a theoretical point of view, Kim et al. (11) investigated the potential energy diagram for the symmetric S_N2 reaction

[2] $X^- + (CH)_3X \rightarrow X(CH)_3 + X^-$ (X = F, Cl, or Br)

by means of ab initio calculation. Their calculations indicated that there are double minima corresponding to pre- and late-complexes, while the transition state is lower in energy than the initial separation. The barrier height increases in the order S_N2' (anti) < S_N2' (syn) < S_N2 for X = F. For the symmetric S_N2 rxn. [2], static ab initio calculations have been thus carried out (11), and the energetics are well-elucidated. On the other hand, there is no dynamics study for rxn. [1] because the reaction has many degrees of freedom ($3N - 6 = 18$, where N is the number of atoms in the reaction system). Furthermore, the energetics for the asymmetric reaction, $X^- + (CH)_3Y \rightarrow X(CH)_3 + Y^-$ (X or Y = F, Cl, or Br), are not clearly understood.

In the present paper, a direct ab initio MD calculation (12–15) is carried out for rxn. [1] to elucidate the reaction mechanism and to obtain the dynamics feature. The reaction mechanism will be discussed on the basis of theoretical results. Note that this work is the first study to investigate the dynamics of rxn. [1].

Methods of calculation



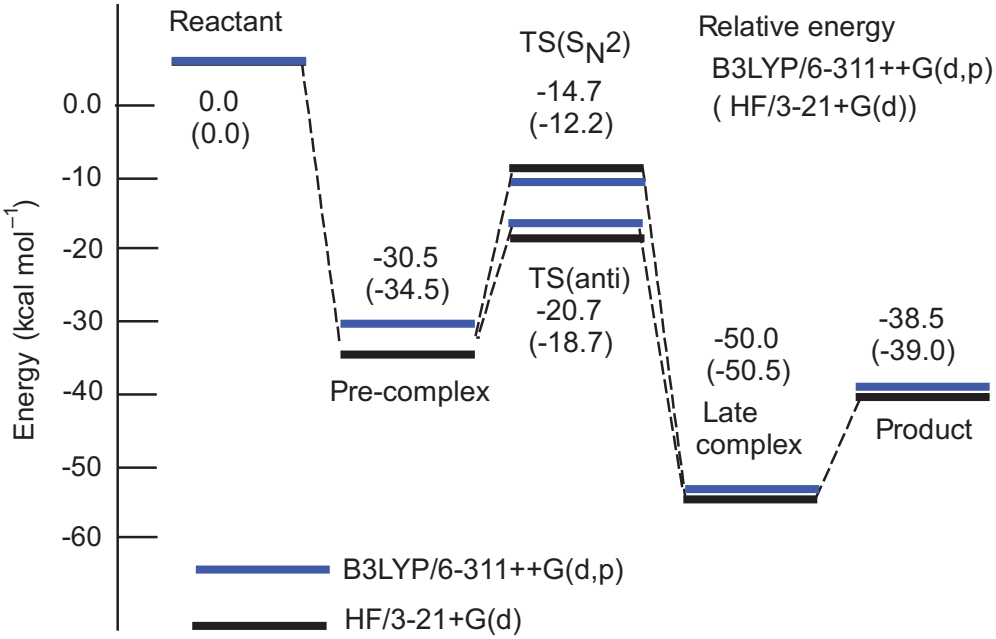
The Hartree–Fock (HF)/3-21+G(d) optimized geometry of $(CH)_3Cl$ was chosen as an initial structure. At the start of the trajectory calculation, atomic velocities of $(CH)_3Cl$ were adjusted to give a mean temperature of 10 K. Temperature of the reaction system is defined by

$$[3] \qquad T = \frac{1}{3kN}\left\langle \sum_i m_i v_i^2 \right\rangle$$

where N is number of atoms, v_i and m_i are the velocity and mass of the ith atom, and k is Boltzmann's constant.

Figure 2 shows the structure and geometrical parameters of the reaction system. We examined S_N2 and S_N2' (anti) collisions in the present work. At initial separations, i.e., F^- + $(CH)_3Cl$, the angles of F-$(CH)_3$-Cl (θ_1) were randomly generated from 0.0° to 180°. The distances between F^- and

Fig. 2. Geometrical parameters for the reaction system F^- + $(CH)_3Cl$.



$(CH)_3Cl$ (R_1) were also generated within 8.0–10.0 Å. A total of 40 geometrical configurations were randomly generated, and 40 trajectories were analyzed for constant collision energy (E_{coll} = 5.0 kcal/mol, 1 cal = 4.184 J). The equations of motion for n atoms in the reaction system are given by

$$[4] \qquad \frac{dQ_j}{dt} = \frac{\partial H}{\partial P_j}$$
$$\frac{dP_j}{dt} = \frac{\partial H}{\partial Q_j} = \frac{\partial U}{\partial Q_j}$$

where j = 1–3N, H is the classical Hamiltonian, U is the potential energy of the reaction system, Q_j is the Cartesian co-

Fig. 3. Potential energy profile of the reaction $F^- + (CH)_3Cl \rightarrow (CH)_3F + Cl^-$, calculated at the B3LYP/6-311++G(d,p) and HF/3-21+G(d) levels. The values are relative energies (in kcal/mol) calculated at the B3LYP/6-311++G(d,p) level. The HF/3-21+G(d) values are given in parenthesis.

ordinate of the jth mode, and P_j is conjugated momentum. These equations were numerically solved by the standard fourth-order Runge–Kutta and sixth-order Adams–Moulton combined algorithm. No symmetry restriction was applied to the calculation of the gradients. The time step size was chosen as 0.2 fs, and a total of 5000 steps were integrated for each dynamics calculation. The drift of the total energy is confirmed to be less than 0.001% at all steps in the trajectory. The rotational quantum number of F^- at initial separation was assumed to be zero ($J = 0$). All static ab initio calculations were carried out using the GAUSSIAN03 program package (16).

Results and discussion

Potential energy diagram for the reaction

The potential energy diagram for rxn. [1] is illustrated in Fig. 3. The calculations are carried out at the B3LYP/6-311++G(d,p) level. The values obtained at the HF/3-21+G(d) level are also given for comparison. Zero level corresponds to the energy of the reactant at the initial separation between F^- and $(CH)_3Cl$. The precomplex, expressed by $F^-\cdots(CH)_3Cl$, was first formed in the entrance region. The binding energy of F^- to $(CH)_3Cl$ is calculated to be 30.5 kcal/mol at the B3LYP/6-311++G(d,p) level. From this point, the reaction is branched to two channels. These are the S_N2 and S_N2' (anti) channels. Both transition states (TS) for the two channels are lower in energy than that of the reactant. The energy levels of the TSs for S_N2 and S_N2' (anti) channels are calculated to be –14.7 and –20.7 kcal/mol relative to the reactant, respectively. These energy levels for S_N2 and S_N2' (anti) channels correspond to barrier heights of 15.8 and 9.8 kcal/mol relative to the precomplex, respectively.

After leaving the TS, the energy is suddenly decreased, and the reaction point reaches the late complex in the exit region. The late complex is expressed by $F(CH)_3\cdots Cl^-$, where one of the hydrogen atoms of $F(CH)_3$ orients the Cl^- ion. Finally, the reaction point reaches the product ($(CH)_3F + Cl^-$).

It should be noted that the energy diagram calculated at the HF/3-21+G(d) level resembles that of the B3LYP/6-311++G(d,p) level. The heat of reaction was calculated to be $-\Delta H = 39.0$ kcal/mol, which is in reasonable agreement with that of the higher level calculation (38.5 kcal mo1^{-1}). The energy levels for the TSs for S_N2 and S_N2' (anti) channels are –12.2 and –18.7 kcal/mol at the HF/3-21+G(d) level. The corresponding energies obtained were –14.7 and –20.7 kcal/mol at the B3LYP/6-311++G(d,p) level. Thus, the HF/3-21+G(d) calculation would give a reasonable multidimensional potential energy surface (PES) for the S_N2 reaction, $F^- + (CH)_3Cl \rightarrow F(CH)_3 + Cl^-$. At the very least, this level of theory is applicable to a qualitative argument for rxn. [1].

The relative energies for stationary points along the reaction $F^- + (CH)_3Cl$ are given in Table 1. Zero-point vibrational energies (ZPEs) are also considered in the relative energies (given in parenthesis). The relative energies for pre- and late-complexes and product state are similar to each other. It was found that the B3LYP calculation seems to slightly underestimate the barrier heights for rxn. [1] by comparison with the MP2 calculation.

The optimized structures at the stationary points of the $F^- + (CH)_3Cl$ reaction system are illustrated in Fig. 4. In the transition state for the S_N2 reaction channel denoted to TS(S_N2), the F^- ion is located at $R_1 = 2.360$ Å, while the C—Cl bond length is elongated to be $R_2 = 2.384$ Å. The angle for F-C-Cl was calculated to be 170°, implying that the structure at the transition state is close to collinear. The C—F and C—Cl bond lengths the transition state for the S_N2

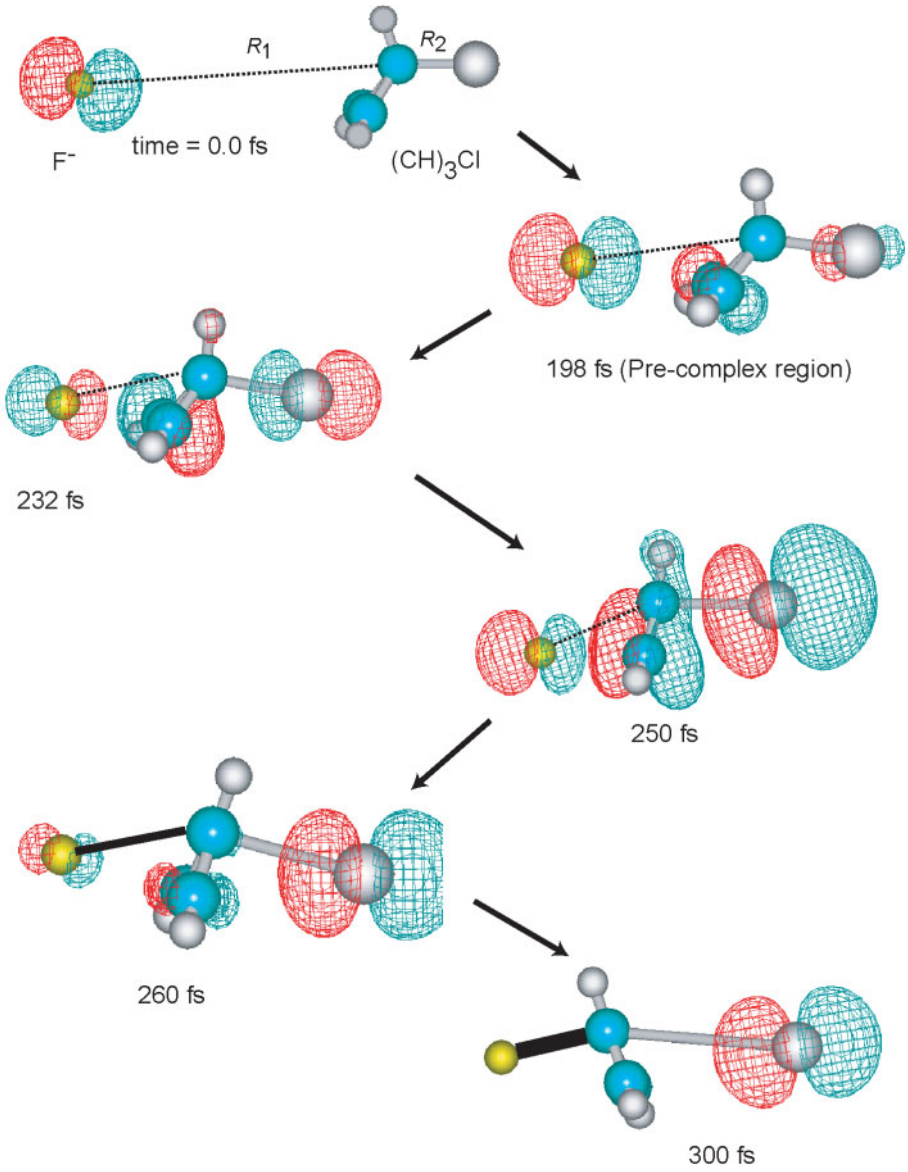
(anti) channel were calculated to be 2.318 and 3.079 Å, respectively. At the pre- and late-complexes, the halide ions bind to a hydrogen atom of $(CH)_3X$ (X = F or Cl). Details of the static properties of the reaction system, such as the geometrical structures, vibrational frequencies, and intrinsic reaction coordinate (IRC), will be discussed in a forthcoming paper.[2]

S_N2 reaction dynamics — S_N2 channel

First, a sample trajectory for the S_N2 reaction channel is discussed in this section. Snapshots of the geometrical configuration for the S_N2 reaction are given in Fig. 5. At time zero, the F^- ion is located at 8.00 Å from the center-of-mass of $(CH)_3Cl$ (R_1 = 7.342 Å). The center-of-mass collision energy is 5.0 kcal/mol. The structural parameters of $(CH)_3Cl$ were calculated as follows: the C—Cl, C1—C2, and C2=C3 bond lengths are R_2 = 1.813 Å, R_3 = 1.4876 Å, and R_4 = 1.292 Å, respectively. The highest occupied molecular orbital (HOMO) is localized in the F^- ion.

At the start of the reaction, the F^- ion gradually approaches $(CH)_3Cl$, and arrives at the precomplex region at 198 fs. The distance of F^- from the C1 atom is R_1 = 3.672 Å. The C—Cl bond is elongated from R_2 = 1.813–1.902 Å. The HOMO of the reaction system is illustrated in Fig. 5: a 2p orbital of F^- interacts slightly with the lowest unoccupied MO (LUMO) of $(CH)_3Cl$.



The trajectory passes the transition-state region at 230 fs. F^- collides the C=C double bond of $(CH)_3Cl$ at 232 fs, and the F^- distance is R_1 = 2.933 Å. The C—Cl bond length is further elongated, and the value is calculated at R_2 = 2.115 Å. The HOMO is delocalized over the complex.

At 250 fs, F^- is closer to the C1 atom. Distribution of HOMO on the Cl atom becomes larger. The geometrical parameters are R_1 = 2.761 Å and R_2 = 2.463 Å, while the C1—C2 and C2—C3 bond lengths are 1.363 and 1.331 Å, respectively, indicating that the double bond of the C2=C3 bond becomes a single bond as at 250 fs. Walden inversion of the carbon atom (C1) occurs at 260 fs and then it reaches the late complex at 300 fs. At the final stage, the products ($(CH)_3F$ and Cl^-) are formed, and Cl^- leaves rapidly from $(CH)_3F$. It was clearly found that the 2p orbital of F^- strongly interacts with C—Cl σ* orbital.

[2] H. Tachikawa. To be published.

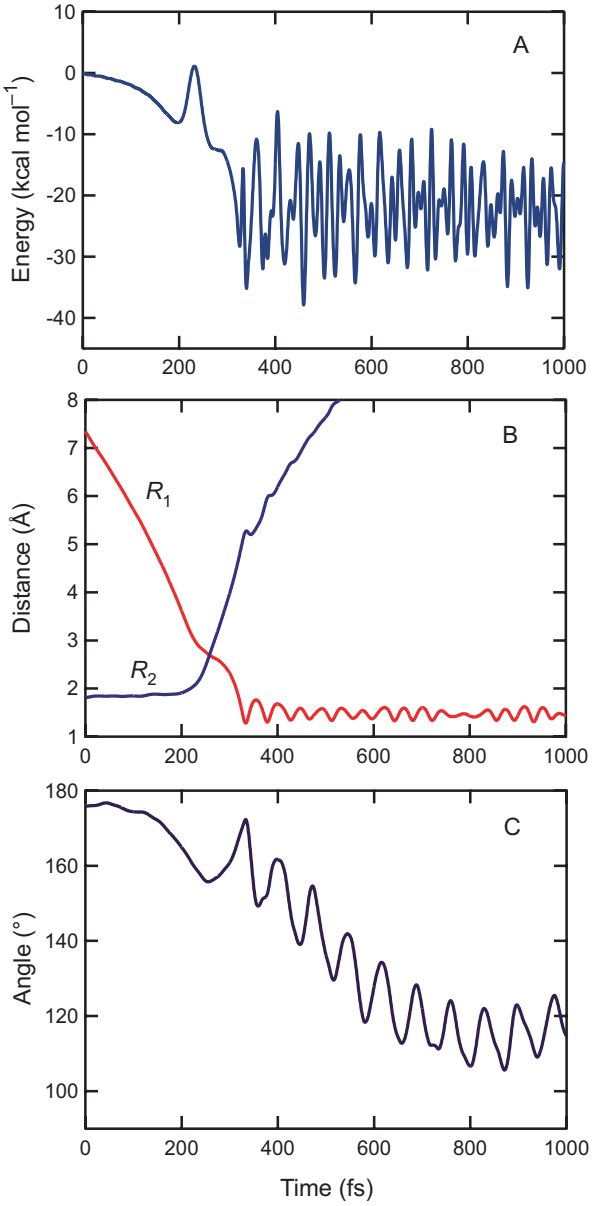
Fig. 5. Snapshots of the conformations for the sample trajectory of the S_N2 reaction channel. The initial parameters are the distances, R_1 = 7.3424 Å, R_2 = 1.8133 Å, R_3 = 1.4876, and R_4 = 1.2915 Å. The center-of-mass collision energy (E_{coll}) is 5.0 kcal/mol. The 3-21+G(d) basis set was used for the reaction system. The time propagations for HOMO are illustrated by the iso surface.

To elucidate the reaction dynamics of F^- with $(CH)_3Cl$ in more detail, time propagation of the potential energy (PE), intra- and inter-molecular distances and angles are plotted in Fig. 6. This trajectory corresponds to that given in Fig. 5. The PE of the reaction system plotted as a function of reaction time is given in Fig. 6A. Parts B and C of Fig. 6 give the intermolecular distances (R_1 and R_2) and angles (θ_1), respectively.



At time zero, F^- is located at R_1 = 7.342 Å from $(CH)_3Cl$. After starting of the reaction, PE gradually decreases as reaction time is increased, and it reaches –10.0 kcal/mol at 198 fs. This point corresponds to the precomplex region expressed by $F^-\cdots(CH)_3Cl$. The peak of PE is found at 232 fs. This peak is formed by the collision of F^- at the C=C double bond of $(CH)_3Cl$. However, the S_N2' reaction does not occur in the case of this trajectory because F^- collides at the center of the C=C bond, not at the carbon atom (C). Walden inversion and bond-forming and bond-breaking processes take place at 250–300 fs (transition-state region). The time propagation of R_1, R_2, and θ_1 around 200–300 fs shows explicit evidence of the S_N2 reaction. After the Walden inversion, the trajectory passes the late complex region (340 fs) and PE vibrates strikingly. This is due to the fact that the excess energy formed by the reaction is efficiently transferred into the C—F stretching mode of $(CH)_3F$. The translational energy of Cl^- is calculated to be 2.4 kcal/mol, which is 5.4% of the total available energy of the reaction. Almost all the energy of the reaction is transferred into the internal modes of $(CH)_3F$ in the case of this trajectory.

S_N2 reaction dynamics — S_N2' (anti) channel

A sample trajectory for the S_N2 (anti) reaction channel is

Fig. 6. Results of the sample trajectory for the S_N2 reaction channel. (A) Potential energy of the system, (B) inter- and intra-atomic distances (R_1 and R_2), and (C) angles vs. reaction time. The initial condition for the trajectory calculation is the same as that in Fig. 5.

discussed in this section. Snapshots of the geometrical configuration for the S_N2 (anti) reaction are given in Fig. 7. The F^- ion is located at R_1 = 6.228 Å at time zero. The center-of-mass collision energy is 5.0 kcal/mol. The HOMO is composed of a 2p orbital of the F^- ion.

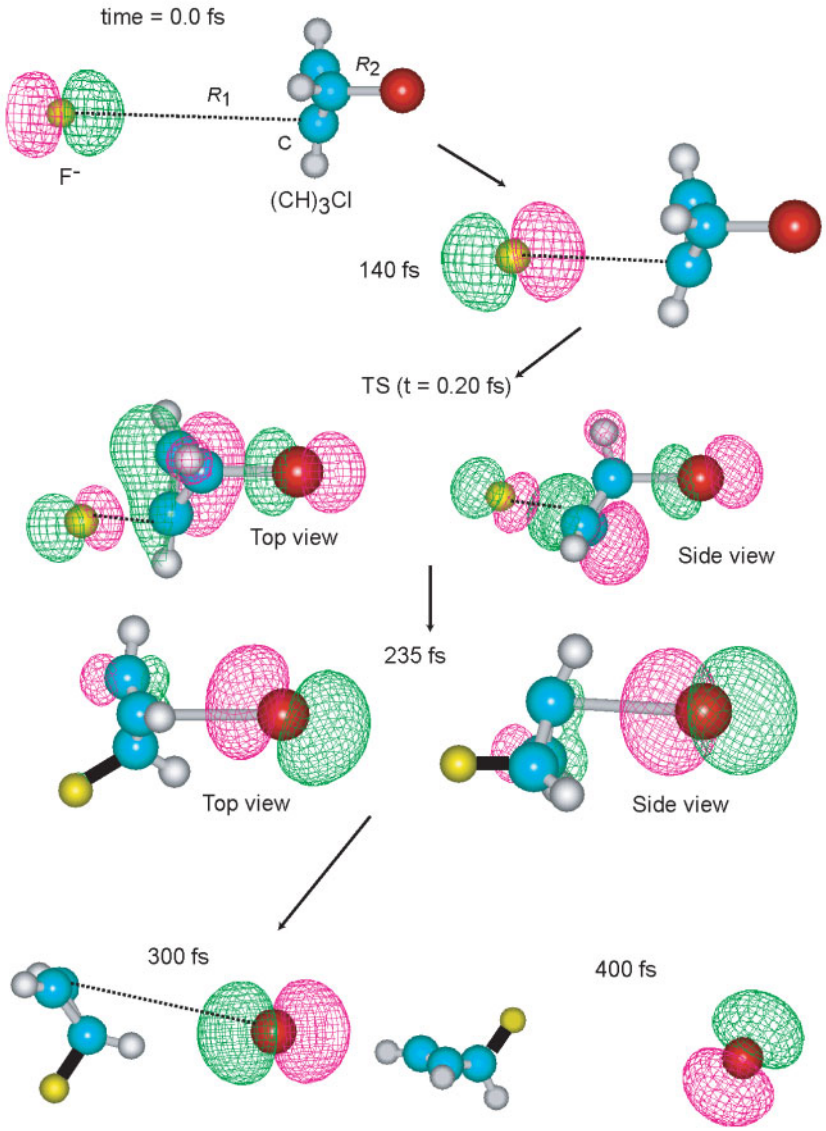
At 140 fs, the distance of F^- from the C2 atom is R_1 = 3.626 Å and the C—Cl bond length is 1.895 Å. After that, the trajectory arrives at the precomplex region at 175 fs (R_1 = 2.659 Å and R_2 = 1.9273 Å). At 200 fs, the trajectory reaches the transition-state region. The HOMO of the system is composed of the C—F σ* orbital (LUMO) of $(CH)_3Cl$ and the HOMO of F^-. The F^- distance is R_1 = 1.522 Å at 235 fs, where the trajectory passes the late complex region. The C—Cl bond is largely elongated (R_2 = 2.934 Å).

From the present results, it is explicitly found that the bond forming of C—F and the bond breaking of C—Cl take place as a result of the approaching of F^- to $(CH)_3Cl$. The 2p orbital of F^- gradually interacts with the orbital of $(CH)_3Cl$. As a result of the collision of the F^- ion at the C2 atom of $(CH)_3Cl$, the Cl^- ion is dissociated from the $(CH)_3Cl$: namely, the S_N2' (anti) reaction takes place.

Time propagations of the potential energy, intra- and inter-molecular distances and angles are plotted in Fig. 8. At time zero, F^- is 8.0 Å from $(CH)_3Cl$. After the reaction has started, PE gradually decreases as reaction time is increased, and it reaches –10.0 kcal/mol at 190 fs. During this process, the R_1 distance linearly deceases as a function of reaction time, and the energy of the system decreases. This means that the approach of F^- to $(CH)_3Cl$ causes an energy lowering because of the attractive ion–dipole interaction. At 190 fs, PE reaches a minimum corresponding to the precomplex expressed by $F^-\cdots(CH)_3Cl$. The lifetime of the complex is very short (τ < 30 fs), and the trajectory rapidly reaches the TS. After TS, PE suddenly decreases to –38.0 kcal/mol at 220 fs. This point is located in the late-complex region. PE rapidly vibrates with an amplitude of ca.10 kcal/mol after the reaction. The relative translational energy between Cl^- and $(CH)_3F$ was calculated to be 8.4 kcal/mol, which is ca. 20% of the total available energy of the reaction.

The time propagations of the C—C bond lengths (R_3, R_4, and R_5) are plotted in Fig. 8C. Before reaction, the bond lengths are R_3 = R_5 = 1.487 Å and R_4 = 1.292 Å, indicating that R_4 is the C=C double bond at time zero. The C2—C3 bond is drastically changed from 1.292 to 1.50 Å around 200 fs. Also, at the same time, R_5 (= C1—C3) is suddenly changed from 1.478 to 1.300 Å. This indicates that the exchanges of single and double bonds are occurred in the transition-state region.

Discussion



Summary

In the present study, direct ab initio MD calculations were carried out for rxn. [1] using the 3-21+G(d) basis set. Two reaction channels were examined: namely, S_N2 and S_N2' (anti) channels. The dynamics calculations showed that both reaction channels mainly occur by direct mechanism: namely, the trajectory quickly passes through the TS and the complex regions (pre- and late-complex regions). This is due to the fact that the reaction energy is significantly large (about 38 kcal/mol) and also, the basins of the complex regions are shallow for the product channel. Therefore, almost all trajectories proceed via direct mechanism.

The reaction channel is strongly dependent on the collision site of F^- around the $(CH)_3Cl$ molecule. Almost all trajectories lead to the S_N2' reaction channel, while specific collision gives the S_N2 reaction channel. This result originates from the lower activation barrier of the S_N2' (anti) channel. The branching ratios of reaction channels are roughly estimated from the results of the trajectory calculation: they are 0.2 for S_N2 and 0.8 for S_N2' (anti). However, the ratios were obtained from only 40 trajectories. To eluci-

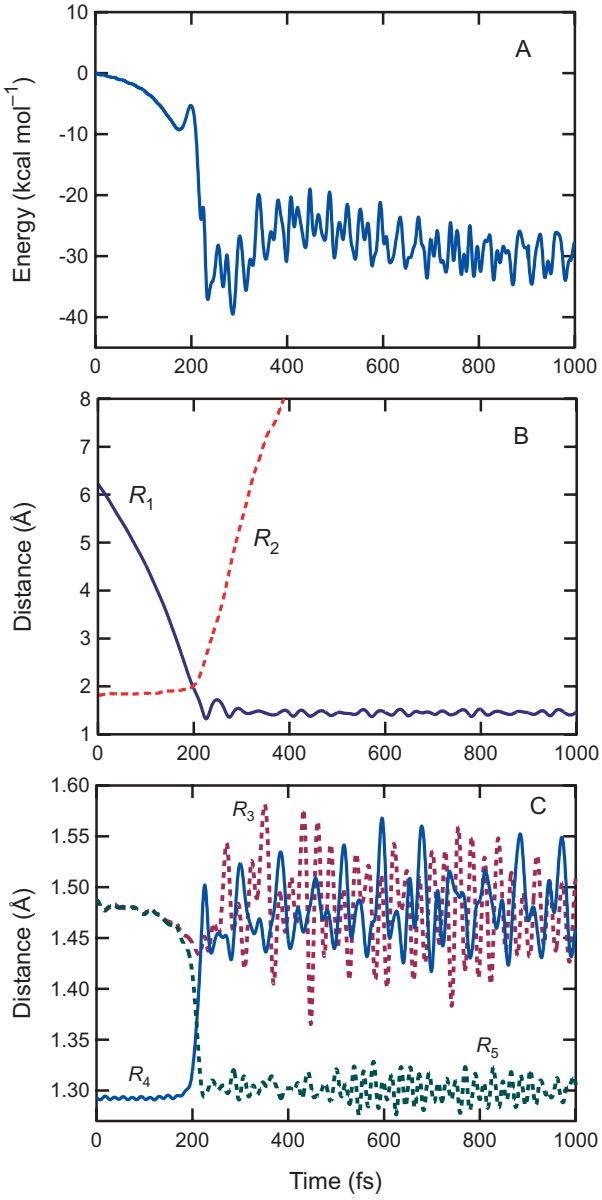
Fig. 7. Snapshots of the conformations for the sample trajectory of the S_N2' (anti) reaction channel. The initial parameters are the distances, R_1 = 6.228 Å, R_2 = 1.815 Å, R_3 = 1.482, and R_4 = 1.291 Å. The center-of-mass collision energy (E_{coll}) is 5.0 kcal/mol. The 3-21+G(d) basis set was used for the reaction system. The time propagations for HOMO are illustrated by the iso surface.

date more accurate values, a larger number of trajectories will be required.[2]

In the present study, S_N2 and S_N2' (anti) channels were examined in low-collision energy (E_{coll} = 5 kcal/mol); whereas the S_N2' (syn) channel was not considered. This is due to the fact that the S_N2' (syn) channel has a high activation barrier and needs higher collision energy. In the forthcoming work, we will calculate the S_N2' (syn) channel.[2]

Comparison with previous studies



Recently, a PE diagram for the similar S_N2 reaction (rxn. [2]) was calculated by Kim et al. (11). Their calculations indicated that the energy level of the transition state for rxn. [2] is lower than that of the initial separation, which is in good agreement with the present calculation. The reaction they used is the symmetric system (X = Y), which is slightly different from the present system. However, the structures at the stationary points are very similar to those of the present calculations.

Concluding remarks

We have introduced several approximations to calculate the PES and to treat the reaction dynamics. First, we assumed a HF/3-21+G(d) multidimensional PES in the trajectory calculations throughout. As shown in the Results and discussion, the energy profile calculated at the HF/3-21+G(d) level is in good agreement with that of the B3LYP/6-311++G(d,p) level, and it reasonably reproduces the PES. Therefore, it is enough to discuss at least qualitatively the reaction dynamics for the F^- + $(CH)_3Cl$ reaction system. However, more accurate wave functions and accurate methods may provide a deeper insight into the dynamics.

Fig. 8. Results of the sample trajectory for the S_N2' (anti) channel. (A) Potential energy of the system, (B) inter- and intra-atomic distances (R_1 and R_2), and (C) C—C bond lengths (R_3, R_4, and R_5) vs. reaction time. The initial condition of the trajectory calculation is the same as that in Fig. 7.

Second, we calculated only 40 trajectories for constant collision energy (E_{coll} = 5.0 kcal/mol). The number of trajectories in the present work may be enough to discuss the at least qualitative feature of the dynamics. However, larger number of trajectories in wide range of collision energies would give a more detailed reaction mechanism. Despite several assumptions introduced here, the results enable us to obtain valuable information on the mechanism of the S_N2 and S_N2' (anti) reactions. The trajectory calculations for the random collisions are now in progress.[2]

Linear free energy relationship and kinetic isotope effects as measures for the transition-state variation — A case of the neophyl system[1]

Salai Cheettu Ammal and Hiroshi Yamataka

Abstract: Ab initio calculations at the MP2/6-31G* level and density functional theory (B3LYP/6-311+G**) calculations have been performed on acid-catalyzed ionizations of substituted neophyl alcohols to investigate whether a variation of the transition-state (TS) structure is reflected in the kinetic isotope effects (KIE) and linear free energy relationship. The effect of substituents on KIEs, TS structures, and activation and reaction energies was calculated. This study revealed that a curved Brønsted-type plot could arise for a single-step process from the variation of TS structure with the substituent, whereas the Hammett plots with a dual-parameter treatment can not detect such TS variation. The variation of KIEs at various positions of neophyl alcohol reflects the variation of TS structures in a manner consistent with the More O'Ferrall – Jencks type reaction diagram analyses.

Key words: transition-state variation, substituent effect, kinetic isotope effect, linear free energy relationship.

Résumé : On a effectué des calculs ab initio au niveau MP2/6-31G* et des calculs de théorie de la densité fonctionnelle (B3LYP/6-311+G**) sur les ionisations catalysées par les acides d'alcools néophyliques afin de déterminer si une variation dans la structure de l'état de transition (ET) se reflète dans les effets isotopiques cinétiques (EIC) et les relations linéaires d'énergie libre. On a calculé l'effet des substituants sur les EIC, les structures des ET et les énergies d'activation et de réaction. Sur la base de la variation de la structure de l'ET avec un substituant, cette étude révèle qu'une relation de type Brønsted incurvée peut apparaître pour un processus impliquant une seule étape; toutefois, les courbes de Hammett avec un traitement à double paramètre ne permettent pas de détecter de telles variations dans l'ET. La variation des EIC selon diverses positions de l'alcool néophylique sont un reflet des structures de l'ET d'une manière qui est en accord avec les analyses de diagrammes réactionnel de type More O'Ferral – Jencks.

Mots clés : variation de l'état de transition, effet de substituant, effet isotopique cinétique, relation linéaire d'énergie libre.

[Traduit par la Rédaction]

Introduction

Anchimeric assistance involving aryl groups in the solvolyses of β-arylalkyl systems has been the subject of numerous investigations (1). The solvolysis reaction of neophyl (2-phenyl-2-methylpropyl) derivatives is known to be the best example for this study because of its mechanistic simplicity. It is generally accepted that the solvolysis of neophyl derivatives proceeds through a discrete aryl-assisted (k_Δ) transition state (TS), which cascades downward to the tertiary carbenium ion (Scheme 1) (2, 3). The rate of this solvolysis reflects only the aryl-assisted ionization step, and is not complicated either by an internal return or by nucleophilic solvent assistance (3). A series of experimental studies on these reactions demonstrated that substituents in the phenyl ring have marked effects on the solvolysis rate (4, 5).

Linear free energy relationships (LFER), such as the Hammett and Brønsted equations, have been extensively used to analyze the reaction mechanism and to determine the structure of the TSs (6). According to the traditional interpretation, linear Hammett and Brønsted plots are expected for a series of reactions proceeding through similar TS structures. A curvature in the Brønsted-type plots has generally been attributed to a change in the rate-determining step (RDS) of a multistep reaction (7–12), and a curved Hammett plot has been taken as evidence either for a change in mechanism or a change in the RDS (13–16). Indeed, except for the S_N1/S_N2 and the E2 borderline cases of benzylic systems, where substituents on the central carbon readily change the structure of the three-centered or four-centered TS (15, 16), an unequivocal example of nonlinear Hammett plots due to a variation of the TS structure is rare. However, our recent computational studies on the ionization of substituted phenylethyl alcohols suggested that the variation of the TS

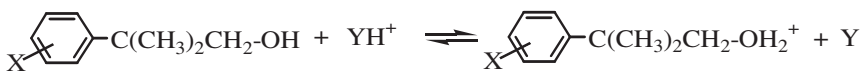
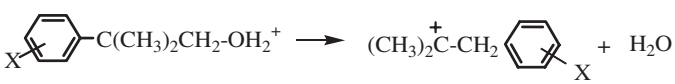
structure for a series of reactions could result in a nonlinear Brønsted-type plot, whereas the Hammett plot with a dual-parameter treatment could not detect such TS variation (17).



The concept of a variable TS has been of great use in explaining the mechanistic properties of organic reactions, and several methods have been proposed for detecting variations in TS structure. Kinetic isotope effects (KIEs) using a successive labeling technique are known to be the most effective tool for obtaining information on the variation of TS structures for a series of reactions (18–20). For the acetolysis of neophyl arenesufonates, KIEs were measured at four different positions in the molecule (α-^{14}C, α-D_2, β-^{14}C, and Ph1-^{14}C) as listed in Table 1 (19, 21). Model calculations of the KIEs by the BEBOVIB method allowed the authors to estimate the TS location and its variation with substituents on the reaction coordinate (19).



In the present study, the acid-catalyzed ionization of substituted neophyl alcohols (eq. [1*a*]) was examined computationally. This study was comprised of four phases. In the first phase, we studied to what extent the reactivity and the TS structure varies with substituents. Secondly, we examined how LFER can be used to study the effect of substituents on the reactivity and on the variation of the TS structure. In the third phase, KIEs at different positions were calculated to assess if they reflect the TS variations. Finally, the More O'Ferrall – Jencks type reaction map (22) was used to locate the position of the calculated TS and compare the results with the previous estimation based on the BEBOVIB calculations. The calculated results were compared with the experimental results whenever possible and also with the closely related 2-phenylethyl system at each stage.

Computational methods

All stable structures, including the substituted neophyl alcohols, protonated neophyl alcohols, TSs, and tertiary cations were fully optimized at the HF/6-31G*, B3LYP/6-31G*, B3LYP/6-311+G**, and MP2/6-31G* levels of theory with the GAUSSIAN 98 package of programs (23). Each stationary point was adequately characterized by normal coordinate analysis and thermochemical data was obtained

from the harmonic frequencies. Natural bond orbital (NBO) analysis was also carried out using the NBO program, Version 3.1 (24) available in the GAUSSIAN 98 suite. Bond orders were calculated according to the conventional Pauling bond order – bond length expression (eq. [2]),

$$[2] \qquad R = R^0 - 0.3 \ln n$$

where *R* and R^0 refer to bond lengths with bond order *n* and 1.0, respectively (25).

Results and discussion

Effect of various methods and basis sets

Figure 1 shows the structures of the TS and the product cation for the parent compound. Unlike the phenylethyl alcohols, whose reactions gave symmetrical phenonium ions irrespective of the substituent (17), the reactions of neophyl alcohols gave rearranged tertiary carbocations. It is interesting to see that the product cation exhibits a strong interaction between the aromatic ring and the carbocation center. Our calculations show that the structures of these cations depend very much on the substituents as well as the computational method. Table 2 lists the selected structural parameters for the TS and the cations together with the activation and reaction energies calculated at different levels of theory for the parent as well as the *p*-OMe and *p*-NO_2 substituted substrates. The HF calculations indicate a large variation in the interaction of the aromatic ring with the tertiary carbocation center of the product cation when the substituent is changed from an electron-donating *p*-OMe ($R_{C\beta\text{-}Ph1}$ = 1.641 Å) to an electron-withdrawing *p*-NO_2 group ($R_{C\beta\text{-}Ph1}$ = 2.334 Å). On the other hand, the MP2 calculations show the least variation in C_β—Ph1 bond length (1.712 Å for *p*-OMe and 1.865 Å for *p*-NO_2). The structures calculated with different basis sets at the B3LYP level are quite similar. The structures of the TS (Table 2) also depend on the method of calculation. The activation and reaction energies calculated at B3LYP/6-311+G** are lower; whereas MP2 calculations predict higher energies. Substituent effects on the enthalpies and free energies are found to be very similar at all the levels of calculations employed. We use the enthalpy values and the results obtained from MP2/6-31G* calculations to discuss the effect of substitutions throughout. B3LYP/6-311+G** results are used whenever a direct comparison is made with the corresponding phenylethyl alcohols, since only the B3LYP results are available for this system (17).

Structure of the TS and product cation

Table 3 presents selected geometrical parameters of the substituted product cations and the TSs, together with a selected natural population. The structural parameters ($R_{C\beta\text{-}Ph1}$ and θ′) and the charge on the aromatic ring (q_{Ar}) for the substituted product cations shown in Table 3 clearly indicates that a strong interaction exists between the aromatic ring and the tertiary carbocation center. The interaction becomes weaker when the substituent on the phenyl ring is changed from an electron-donating to an electron-withdrawing group as seen in the C_β—Ph1 bond distance and the bond angle (θ′). Substituents did not change the structure of neophyl alcohol and protonated neophyl alcohol much; whereas substantial changes are observed in the structures of the TSs. The variation in the C—O bond length and the C_α-C_β-C_{Ph1} bond angle (θ) of the TS with different substituents clearly

[c]Change of the group positive charge between the reactant and the TS relative to that between the reactant and the phenonium ion.

indicated that the TS structure for a more electron-donating substituent is more reactantlike ($R_{C\text{-}O}$ = 1.88 Å and θ = 88° for *p*-OMe and $R_{C\text{-}O}$ = 2.01 Å and θ = 84° for *p*-NO_2). The group charge on the aromatic moiety (q_{Ar}) indicates a strong interaction between the aromatic ring and the cationic center in both the TSs and the product cations for all the substitutents. The charge becomes more positive in the reactant alcohol and in the product cation with a more electron-donating substituent, which is consistent with the nature of the substituent. In contrast, the group charge (q_{Ar}) is nearly constant for the TS. Here, an electron-donating substituent not only makes the aromatic moiety more positive but also shifts the TS more reactantlike, and the two effects are balanced in the charge distribution. The position of the TS along the reaction coordinate can be seen in the ratio of the change of the group charge on the aromatic ring on going from the reactant to the TS over the corresponding change between the reactant and the product cation ($\Delta q^{\ddagger}/\Delta q$); the ratio increases smoothly when the substituent becomes more electron-withdrawing. A clear picture of the TS variations can be seen in Fig. 2, where the C—O and C_α—C_{Ph1} bond orders were plotted against the reaction enthalpy. These results clearly indicate that the position of the TS indeed varies with the substituent and the variation is consistent with the Hammond postulate (26).

Fig. 2. Variation of the TS bond orders vs. the reaction enthalpy. Open circles refer to $n_{C\text{-}O}$ and closed triangles denote $n_{C\alpha\text{-}Ph1}$. Values are at the MP2/6-31G* level of theory.

Reaction energetics

Table 4 lists the activation and reaction enthalpies calculated for 14 different substituents at HF/6-31G*, B3LYP/6-31G*, MP2/6-31G*, and B3LYP/6-311+G** levels of theory. We used protonated water trimer as the proton source (YH^+ in eq. [1*a*]) for the initial protonation of alcohol, but the choice of the proton source does not affect the substituent effect. The effect of substitution is well-pronounced both in the activation and reaction enthalpies; a higher activation enthalpy leading to a more endothermic product for a more electron-withdrawing substituent is predicted at all levels. Correlation among the results at different methods gave excellent linear plots with slopes of nearly unity for both $\Delta H^{\ddagger}$ and ΔH. It is interesting to note that the plots of the relative equilibrium constants of substituted neophyl alcohols calculated at the B3LYP/6-311+G** level against those of substituted phenylethyl alcohols (17) (Fig. 3) gave a reasonably good straight line (R^2 = 0.989) with a slope of 0.66, even though the product in the equilibrium is the tertiary cation for the neophyl system; whereas it is the phenonium ion for the phenylethyl system. Owing to the stable nature of the tertiary carbocations, only a little or no interaction is generally assumed to exist between the phenyl group and the carbocation center in the cationic intermediates of neophyl alcohols and thus substituent effects on the cations are expected to be very small. However, our calculations clearly

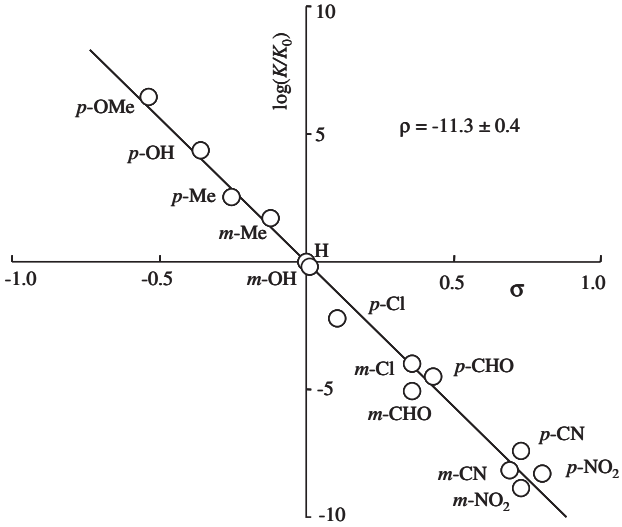
Fig. 3. log–log plot for the ionization constants of substituted neophyl alcohols against substituted phenylethyl alcohols.



indicate that the substituent effect on the cations is quite significant because of the strong interaction between the tertiary carbocation center and the phenyl group, consistent with the structures of the cations as listed in Table 3.

Linear free energy relationship

The TSs of the present reactions are stabilized by the through-conjugation between the electron-donating substituents at the para position and the cationic reaction center. Substituent effects in such systems can be described by the well-known linear aromatic structure–reactivity relationship (LArSR, eq. [3]), often called the Yukawa–Tsuno equation, which is a multiparameter extension of the Hammett equation to quantify the role of enhanced resonance effects (27). In eq. [3], the term $\sigma^+ - \sigma^0$ measures the ability for π delocalization of π electron-donating substituents, and r^+ is a resonance-demand parameter characteristic of a given reaction.

Fig. 4. LArSR plot for the hydroxide transfer equilibrium of substituted neophyl alcohols and the corresponding product cations at 25 °C.

[3] $$\log(k/k_0) = \rho[\sigma^0 + r^+ (\sigma^+ - \sigma^0)]$$

The LArSR plots for the calculated acid-catalyzed ionization equilibrium of substituted neophyl alcohols are displayed in Fig. 4. We used the substituent constants (σ^0 and σ^+) derived from a series of gas-phase reactions (28). The figure shows that the LArSR treatment nicely correlates the substituent effect for the equilibrium process with a large ρ value of –11.3 at the MP2/6-31G* level (–9.9 at B3LYP/6-311+G**) and a r^+ value of 0.62. The exalted r^+ value and the large ρ value observed in the reactions of the substituted neophyl system were rationalized in terms of a direct π interaction between the aryl π system and the carbocation center at the transition state (5*b*). The ρ value obtained in the present case (9.9) is smaller than the ρ value obtained from our earlier calculations (17) on the phenylethyl alcohols (14.9 at B3LYP/6-311+G**), reflecting less positive charge developed on the aromatic ring of the neophyl product cations. On the other hand, the apparent r^+ value (0.62) is quite similar to that for the phenylethyl alcohol (r^+ = 0.65). This indicates that the relative importance of resonance to inductive stabilization by the substituents in the product tertiary cations is similar to that in the phenonium ions.

Figure 5 shows the LArSR plots for the ionization rate constants of substituted neophyl alcohols. The Hammett correlation gave a reasonably good straight line with r^+ = 0.27 and ρ = –8.9. We have previously reported the same r^+ value for the substituted phenylethyl alcohols (17). The similarity in these two reactions is most clearly illustrated in Fig. 6, which displays the log–log plots of the relative rate constants of substituted neophyl alcohols against those of substituted phenylethyl alcohols calculated at the B3LYP/6-311+G** level. The plots show an excellent linearity (R^2 = 0.999) with a slope of 0.89. The slope of less than unity was found, which indicates that the TS for the neophyl system is

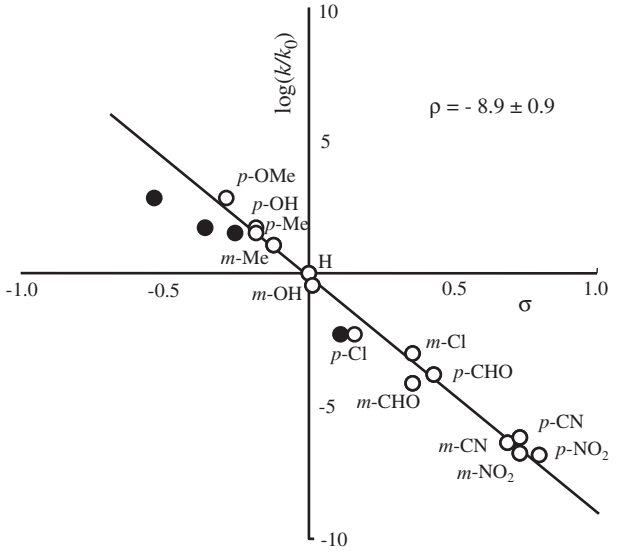
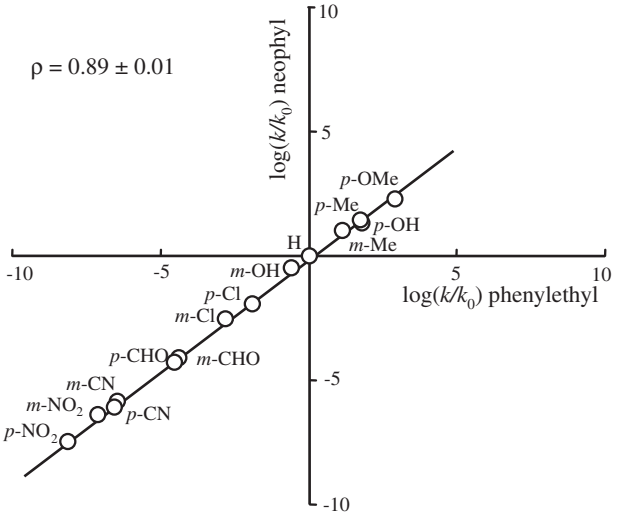
Fig. 5. Substituent effects for the acid-catalyzed ionization of neophyl alcohol at 25 °C. Open circles represent $r^+ = 0.27$ and filled circles represent $r^+ = 0.62$.





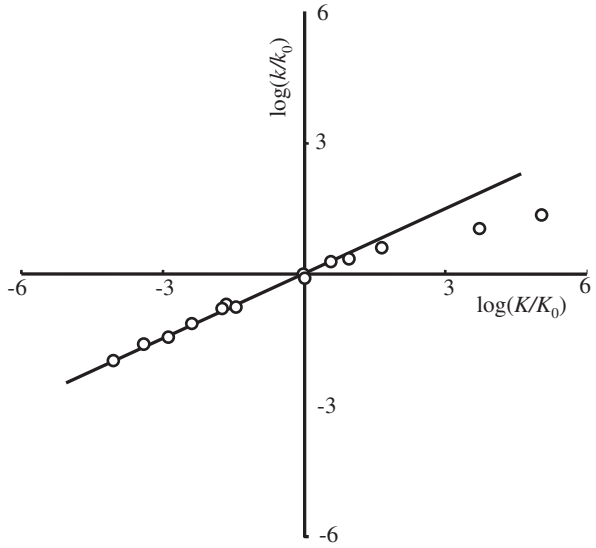


Fig. 6. log–log plot for the rate constants of substituted neophyl alcohols against substituted phenylethyl alcohols.

more reactantlike than the corresponding TS for the phenylethyl system for each substituent.

The Brønsted-type rate-equilibrium relation is applied to the elementary process of ionization of protonated neophyl alcohols to the product cations (eq. [1*c*]), and the substituent effects on the rate were plotted against those of the equilibrium in Fig. 7. A curved plot of the same type as that found for the phenylethyl alcohols (17) was obtained with a larger tangent slope for a reactant with a more electron-withdrawing substituent. The analysis of this curved Brønsted-type plot resulted in the formation of two distinct lines, each belonging to the least reactive compounds (*p*-NO_2, *m*-NO_2, *p*-CN, *m*-CN, *p*-CHO, *m*-Cl, and *m*-CHO) with a slope of 0.51 and the most reactive compounds (*p*-OMe, *p*-OH, *p*-Me, and *m*-Me) with a slope of 0.24. The biphase correlation arises from the variation of the TS structures with the substituents.

Fig. 7. Brønsted-type relation for the ionization of protonated neophyl alcohol to the product cation at 25 °C.

The following questions arise for the LFER treatments. First, why did the LArSR treatment on the rate process give linear plots, while the Brønsted-type plots gave a curved correlation? The linearity in the LArSR analysis was probably attained because the dual-parameter treatment masked a possible curvature of the plot. If the set of σ values obtained for the equilibrium (i.e., $r^+ = 0.62$) was used, a curved Hammett plot would be obtained, similar to that of the Brønsted-type plot in Fig. 7. Secondly, the LArSR treatment of the experimental kinetic data on the acetolysis of neophyl brosylates was reported to give a r^+ value of 0.58 (5*b*), a value closer to that calculated for the equilibrium (0.62). Then, why is the r^+ value for the gas-phase reaction (0.27) much smaller than that in solution? The reason is probably related to the large TS variations in the gas-phase reaction. Thus, the smaller r^+ value was obtained because the TS becomes more reactantlike, so the substituent effect becomes smaller for a strongly electron-donating substituent (*p*-OMe, *p*-OH). Such TS variation should in principle give curved Hammett plots, but as previously mentioned, the dual-parameter treatment in LArSR gave a straight line with a smaller r^+ value. Thus, caution should be paid when studying the reaction mechanism and its variation from LArSR analyses.

The different behavior in the LArSR analysis for the gas-phase and solution reactions probably arises from the larger TS variation with the substituent in the gas phase than in solution because of a large variation of the activation energy in the gas phase. The TS variation with the substituent in the solution phase could be minimized because of the multiple interaction mechanisms available in solution.

The fact that the Brønsted-type plot gave a curved correlation raises another point of interest. In the literature, curved or biphasic plots have often been taken as evidence for a shift of the rate-determining step in a multistep process. In other words, a single concerted mechanism has often been expected to give a straight-line correlation. However, the present study clearly indicated that such an argument may not be true in some cases and that a curved Brønsted plot can arise from variable TS.

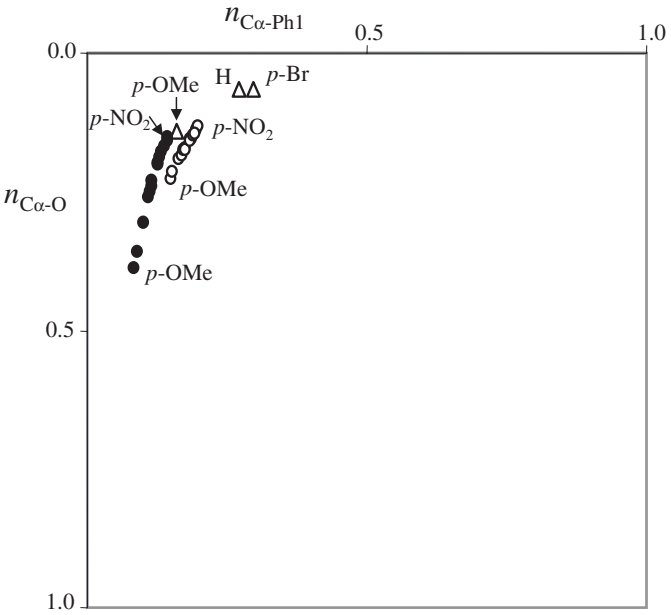
Note: Numbers in italics are the EIEs for the protonation of alcohol (eq. [1*b*]).

Kinetic isotope effects and TS variation

Kinetic isotope effects have been used to provide experimental estimates of TS geometry and its variation. Table 5 presents the KIEs for the ionization reaction of substituted neophyl alcohols calculated from the isotopic shifts of vibrational frequencies at MP2/6-31G* after scaling with a factor of 0.94 (29) by using the Bigeleisen equation (30). Numbers shown in *italics* are the equilibrium IEs (EIEs) for protonation of the alcohols. The IEs were calculated at six different positions for the para-substituted compounds at 25 °C.

The protonation of the reactant alcohol induced a change in the reactant structure. For the parent compound, the protonation made the C_α—O bond longer (from 1.429 to 1.576 Å), the C_β—C_{Ph1} bond longer (from 1.526 to 1.533 Å), and the C_α-C_β-C_{Ph1} bond angle smaller (from 107.0° to 101.0°). The calculated EIE values are consistent with the structural variation; the carbon-14 EIE at the α position is larger than unity with larger values for the electron-donating substituents. The EIEs for the carbon isotopes at the β and γ positions were not significant. On the contrary, the α-D_2 EIEs became inverse because the protonation on the oxygen affects the strength and mode of frequencies related to α-D; the magnitude of a secondary deuterium IE is known to depend on the number of coordinates in which the deuterium atom is involved, and thus inverse deuterium IE on protonation arises (17, 31).



The KIEs were calculated with reference to the individual alcohols. They cannot be directly compared with the experimental data in solution, but the calculated trends may mirror the behavior in solution. The α-^{14}C, β-^{14}C, Ph1-^{14}C, and α-D_2 KIEs for neophyl brosylate were measured in AcOH at 75 °C as 1.093, 1.014, 1.023, and 1.214, respectively. In the acetolysis, *p*-methoxyneophyl tosylate gave a carbon-14 KIE at the α position of 1.117 at 50 °C, and the *p*-methoxyneophyl brosylate gave a Ph1 carbon-14 KIE of 1.006 at 40 °C (Table 1).

The calculated KIEs reasonably agree with the experimental values at all positions except for the α-D_2 KIEs. The variation of KIEs with the substituents at all positions should reflect the variation of the TS structures. The calculated α-^{14}C KIEs (1.120–1.124) are in the range of those reported for S_N2-type reactions (32), consistent with an S_N2-like, three-centered TS at the α-carbon. Since the magnitude of the KIE in this type of TS depends on the balance of the two reacting bonds ($C_\alpha\cdots C_{Ph1}$ and $C_\alpha\cdots OH_2$), large α-^{14}C KIEs suggest well-balanced TSs. A small variation of the α-^{14}C KIEs with the substituent is consistent with recent calculations, which showed that the magnitude of the α-C KIE changes little in such three-centered S_N2 TSs (33). The magnitude of the α-D_2 KIE is larger for an electron-withdrawing substituent, indicating that the total bonding at C_α is smaller at the TS (looser TS) because the change in the $C_\alpha\cdots O$ bond with the substituent is greater than the change in the $C_\alpha\cdots C_{Ph1}$ bond. When the phenyl group migrates from C_β to C_α, significant bonding change occurs at the β-carbon in the transition state, which should be reflected in the β-^{14}C KIE. The larger β-^{14}C KIE observed for the *p*-NO_2 substituent (1.012) indicates a later TS for the electron-withdrawing substituent. Although the isotope substitution at the γ-carbons gave almost null KIEs, distinct inverse deuterium KIEs were obtained at the γ position, which is consistent with the inductively electron-donating nature of deuterium. A more inverse γ-D_6 KIE for a more electron-withdrawing substituent is consistent with a more productlike TS for such a derivative. Finally, the Ph1-carbon-14 KIEs listed in Table 5 clearly indicate the change in the TS position along the reaction coordinate: a smaller Ph1-^{14}C KIE (1.022) for X = *p*-OMe and a larger value (1.029) for X = *p*-NO_2, reflecting a reactantlike TS for the electron-donating substituent.

The TS variation with the substituents can be displayed by the two-dimensional More O'Ferrall – Jencks diagram depicting the calculated C_α—O bond order against the C_α—C_{Ph1} bond order, as shown in Fig. 8. The lower left – upper right diagonal reflects the early late character of the transition structures, whereas the perpendicular diagonal represents variation from a loose (upper left corner) to a tight TS geometry (lower right corner). The diagram shows that in all cases the C_α—O bond cleavage goes ahead of the C_α—C_{Ph1} formation resulting in a carbocationic character developed at the α-carbon in the TS, and the sum of the two bond orders varies from 0.38 (*p*-OMe) to 0.33 (*p*-NO_2). The TS variation with substituent on the More O'Ferrall – Jencks diagram is fully consistent with the variation of the calculated KIEs.

Fig. 8. More O'Ferrall – Jencks diagram. Open triangles refer to the experimental values; open circles and filled circles correspond to the calculated values at MP2/6-31G* and B3LYP/6-311+G** levels, respectively.

The positions of the TSs for acetolyses of neophyl esters with three different substituents (*p*-OMe, H, and *p*-Br), which have previously been located based on the experimental KIEs and BEBOVIB calculations (19), are shown with triangles in Fig. 8. Comparison of the TS locations thus previously estimated and those calculated in the present study revealed that the results are in reasonable agreement with each other even though one is the TS position for the gas-phase reaction, and the other was estimated for reactions in solution. In particular, both methods predict loose TS structures regardless of substituent, and a more reactantlike TS for a more electron-donating substituent. This agreement suggests that the previously used method of combined experimental KIE measurements and BEBOVIB calculations is a useful method to estimate the TS location on the reaction coordinate.

Concluding remarks

The computational study on the ionization reaction of substituted neophyl alcohols revealed that substituents on the phenyl ring have marked effects on the reactivity and that the structure of the TS varies with substituent. The variations of activation and reaction enthalpies and of the TS structures with the substituent are consistent with the Leffler–Hammond postulate. The calculations gave a curved Brønsted-type plot, which arises from the variation of TS structure with the substituent. On the other hand, the Hammett correlation with a dual-parameter treatment (LArSR) gave reasonably good straight lines for both the rate and equilibrium of the gas-phase ionization process with different r^+ values (0.27 for the rate and 0.62 for the equilibrium process). The TS variation could not be detected by the Hammett plots because the dual-parameter treatment masked otherwise curved Hammett plots. The calculated KIE values are similar to the available experimental results and correlate very well with the TS structure variation with substituents. The position of the TSs on the More O'Ferrall – Jencks diagram obtained from the calculations supported the previous analysis based on the experimental KIEs and the BEBOVIB calculations.

Acknowledgements

The calculations were carried out in part at the Research Center for Computational Science, Okazaki National Research Institute. The study was supported by the Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology, Japan and by the Rikkyo University Frontier project "Life's Adaptation Strategies to Environmental Changes".

A computational study of the 1,3-dipolar cycloaddition reaction mechanism for nitrilimines[1]

Robert C. Mawhinney, Heidi M. Muchall, and Gilles H. Peslherbe

Abstract: The [3+2] and [1+2] cycloaddition pathways between ethene and a series of 13 nitrilimines (R^1CNNR^2) have been examined by density functional theory [PBE0/6-311++G(2df,pd)] calculations. All reactions have low barriers ranging from 14.14 ($R^1 = CH_3$, $R^2 = H$) to 1.01 ($R^1 = R^2 = F$) kcal mol^{-1}, and large reaction exothermicities consistent with the transient nature of nitrilimines. The [3+2] and [1+2] transition-state structures are very similar, mainly differing in the relative orientation of their fragments and the newly forming C—C bond distance, and exhibit only minor deviations from the structures of the reactants. Both reaction pathways are concerted and asynchronous, but the [1+2] reaction has a greater degree of asynchronicity. Examination of the frontier molecular orbitals reveals that both the [3+2] and [1+2] barrier heights are related to two sets of orbital interactions, with the interaction between the lowest unoccupied molecular orbital π_5^{NN} of nitrilimine and the highest occupied molecular orbital of ethene in common. The second interaction in both cases is carbene-like. A relationship between the weights of the 1,3-dipolar resonance contribution in the various nitrilimines and the corresponding [3+2] barrier heights was not found, but a good correlation could be found between the [1+2] barrier heights and both the 1,3-dipolar and carbene contributions. Inspection of the potential energy surface in the vicinity of the two transition states for the reaction between unsubstituted nitrilimine and ethene suggests that the observed [3+2] product is a result of an initial carbene-like approach of the two fragments followed by a ridge bifurcation that leads to the [3+2] product minimum.

Key words: nitrilimines, 1,3-dipole, carbene, [3+2] cycloaddition, [1+2] cycloaddition, density functional theory (DFT).

Résumé : Les réactions de cycloaddition [3+2] et [1+2] entre l'éthène et une série de treize nitrilimines (R^1CNNR^2) ont été étudiées par calculs de théorie de la fonctionelle de densité [PBE0/6-311++G(2df,pd)]. Les réactions sont caratérisées par des barrières variant de 14,14 ($R^1 = CH_3$, $R^2 = H$) à 1,01 ($R^1 = R^2 = F$) kcal mol^{-1} et une forte exothermicité qui reflète la nature transitoire des nitrilimines. La structure des états de transition, très proche de celle des réactifs, est très semblable pour les réactions de cycloaddition [3+2] et [1+2] et ne diffère que par l'orientation relative des fragments et par la longueur de la liaison C—C qui se forme au cours de la réaction. Les deux chemins de réactions sont concertés et aynchrones, avec une asynchronicité plus prononcée pour la réaction [1+2]. Les orbitales moléculaires frontières démontrent que les barrières de réaction [3+2] et [1+2] sont reliées à deux groupes d'interactions orbitalaires qui ont en commun l'interaction entre la plus basse orbitale moléculaire inoccupée π_5^{NN} de la nitrilimine et la plus haute orbitale moléculaire occupée de l'éthène. La seconde interaction est de type carbène pour les deux réactions. Une corrélation entre la contribution de la forme de résonance 1,3-dipolaire des nitrilimines et les barrières de réaction [3+2] correspondantes n'a pu être trouvée. Par contre, une forte corrélation est observée entre les barrières de réaction [1+2] et les contributions 1,3-dipolaires et carbèniques. L'examen de la surface d'énergie potentielle à proximité des deux états de transition de la réaction entre la nitrilimine non-substituée et l'éthène suggère que le produit [3+2] résulte d'une approche initiale des deux fragments de type carbénique, suivie d'une bifurcation à la crête de la surface qui conduit au minimum d'énergie potentielle du produit [3+2].

Mots clés : nitrilimines, 1,3-dipolaire, carbène, cycloaddition [3+2], cycloaddition [1+2], théorie de la fonctionelle de densité.

Introduction

The addition of a 1,3-dipole, a system of three atoms over which four π electrons are distributed, to a dipolarophile, typically an alkene or alkyne, is the most commonly used synthetic method for forming five-membered heterocyclic molecules. The mechanism for these [3+2] reactions has been the subject of numerous articles and remains an open problem in physical organic chemistry (1–7). Originally, Huisgen (8–10) proposed a concerted, single-step mechanism with the two new bonds partially formed at the transition state, akin to that for the Diels–Alder cycloaddition. Shortly thereafter, an alternative two-step mechanism involving a biradical intermediate was presented by Firestone

Scheme 1.

(11–14). Since then, much work (1–7) has focused on distinguishing between the two mechanisms and, as Firestone originally alluded to (11), a duality of mechanism appears to exist. The majority of the initial explorations of Huisgen et al. (15–20) centered around the nitrilimine 1,3-dipole (R^1CNNR^2) for which the cycloaddition reactions are commonly believed to proceed via the concerted mechanism (7, 21, 22). Interestingly, no theoretical studies of an alternative pathway have been reported, even though this 1,3-dipole is at the heart of the original mechanism debate (9, 11, 23).

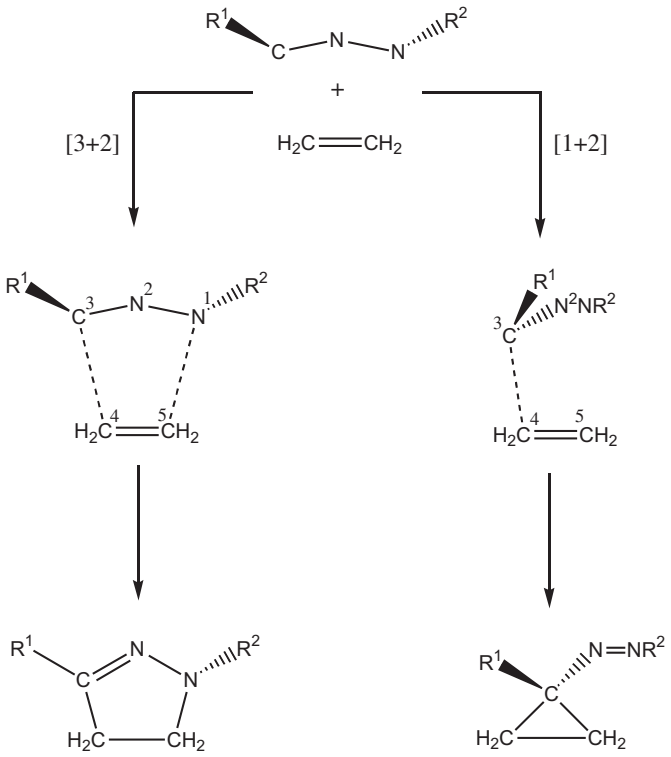
The nitrilimine 1,3-dipole is normally formed in situ as a transient, highly reactive species, which tends to dimerize, forming either dihydrotetrazines or bis(azo)ethenes, but in the presence of either electron-rich or electron-poor dipolarophiles, it readily undergoes [3+2] cycloadditions (24, 25). Stabilized nitrilimines also have been synthesized and they generally exhibit similar reactivity to their transient counterparts. Slight modifications of the substituents on the stabilized nitrilimine, though, have revealed that the philicity can be modified, with some nitrilimines acting strictly as nucleophiles and others as electrophiles (25, 26). A second important factor for the nitrilimine cycloaddition reactions is their regioselectivity, since the addition to unsymmetric dipolarophiles can result in two possible regioisomeric products. Nevertheless, nitrilimines appear to be highly selective with the newly formed bond to the carbon terminus typically with the less-substituted atom of the dipolarophile (24). Still, a recent study has revealed that changing the C-substituent of nitrilimine, from Br to H, results in an unexpected complete reversal in regioselectivity (27).

Employing resonance theory, Huisgen (28) explained the observed [3+2] reactivity in nitrilimines and related systems, and generalized the 1,3-dipole concept. For nitrilimines, several resonance structures have been invoked to explain their reactivity and electronic structure (Scheme 1) (28–31). In his original formulation, Huisgen (28) suggested that the electron sextet structures, the dipolar (**RS-D**) and carbenic (**RS-C**) forms, make only small contributions to the electronic structure of any 1,3-dipole owing to the lack of octet stabilization, but it was still this minor contribution that directed the course of reaction. In a recent study (32),[4] we evaluated the weights of various resonance contributions for a series of nitrilimines, using density functional methods combined with natural resonance theory (33–35), and found that the **RS-D** and **RS-C** structures were considerably more important than previously believed, and were even the dominant contributors in all systems studied. More interestingly, for some cases such as diaminonitrilimine ($R^1 = R^2 = NH_2$), **RS-C** was by far the primary resonance form.

The most fundamental of cycloadditions, a [1+2] reaction, occurs between carbenes and alkenes forming cyclopropanes (36, 37). Many carbenes are ambiphilic, reacting with both electron-rich and electron-poor alkenes, but varying the substituents can induce either electrophilic or nucleophilic behaviour exclusively (38). The mechanism for this fundamental reaction has been extensively studied (39–43), and theoretical studies suggest that the reaction between singlet carbenes and alkenes is a highly asynchronous yet concerted process, which was recently confirmed by kinetic isotope effect experiments (41). Given the significant carbene character contribution to the electronic structure in nitrilimines for certain substituents, it may be possible to observe [1+2] type reactivity.

In this paper we explore the [3+2] and [1+2] cycloaddition reaction pathways (Scheme 2) between ethene and nitrilimine, examining the effects of C-substitution, N-substitution, and symmetric C,N-disubstitution with CH_3, NH_2, OH, and F, and show that the [1+2] reaction path is an integral part of the early stages of the [3+2] mechanism. To the best of our knowledge, this is the first study of the [1+2] reaction in nitrilimines and the first attempt to examine systematically the effects of nitrilimine substituents on the [3+2] reaction.

Computational methods



All calculations were carried out using the GAUSSIAN 98 suite of programs (44). The minima for all reactants and products, as well as transition-state (TS) stationary points, were obtained using the Perdew–Burke–Ernzerhof (PBE0) hybrid density functional (45–47) and a relatively large 6-311++G(2df,pd) basis set (48, 49). The nature of all stationary points was confirmed by vibrational analysis and the relative energies reported throughout include unscaled zero-point energy corrections. A stability analysis was performed on all stationary points to confirm that a lower energy broken-symmetry solution did not exist. Additionally, for reactions of the unsubstituted nitrilimine, biradical structures were explicitly searched for,[5] but in all calculations only closed shell structures could be obtained. Intrinsic reaction coordinate (IRC) calculations (50, 51), using mass-weighted

Cartesian coordinates, were performed to confirm the relationship between TS structures and reactants and products.

Molecular geometries and energetics of cycloaddition reactions

Reactions of unsubstituted nitrilimine

Results for the [3+2] and [1+2] cycloaddition reactions between ethene and unsubstituted nitrilimine are collected in Table 1 and in the Supplemental material.[6] The results for the [3+2] reaction are in good agreement with a recent study at the B3LYP/6-31G(d) level of theory (7). The distances predicted by PBE0/6-311++G(2df,pd) are consistently smaller than the B3LYP values, by ca. 1% on average, but exhibit the same changes along the reaction coordinate. As expected, both methods predict a highly exothermic reaction and only a small barrier. With PBE0/6-311++G(2df,pd) the product is 5.1 kcal mol^{-1} more stable and the barrier is 0.38 kcal mol^{-1} lower than with B3LYP/6-31G(d).[7] In the earlier study, single point calculations at the CCSD(T)/6-311G(d,p) level, using B3LYP/6-31G(d) geometries, were also reported (7). Using the same approach with the PBE0/6-311++G(2df,pd) geometries, we find an even better agreement, with the above differences reduced to 0.3 and 0.06 kcal mol^{-1}, respectively. While there are no previous studies of the [1+2] cycloaddition reaction for comparison, the TS geometry involving the nitrilimine resembles those for the addition of dichlorocarbene and difluorocarbene to ethene (42) in that all cycloadditions are highly asynchronous.

The [3+2] reaction is kinetically favoured, with a reaction barrier that is ca. 4 kcal mol^{-1} smaller than that for the [1+2] reaction. The [1+2] and [3+2] TSs are remarkably similar with respect to geometrical changes from the reactants. The main differences are the C3—C4 distance (1.992 vs. 2.290 Å) and the C5-C4-C3-N2 dihedral angle (88.5° vs. –0.3°). The high asynchronicity of bond formation in the [1+2] TS is obvious, as both newly formed bonds have the same length in the product. Based on geometrical arguments, i.e., the ratio between the bond length in the product and the interatomic distance in the TS, bond formation is 76% complete for the C3—C4 and 60% complete for the C3—C5 bond at the TS. In the [3+2] TS structure, the C3—C4 distance is shorter than the N1—C5 distance, while the reverse is found in the product, demonstrating that the reaction is also significantly asynchronous, with the C3—C4 bond 66% formed and the N1—C5 bond 60% formed. While the N1—C5 bond in the [3+2] TS and the C3—C5 bond in the [1+2] TS are formed to the same extent, C3—C4 bond formation has proceeded further in the [1+2] TS, consistent with the Hammond postulate (52), where a later transition state is associated with a higher barrier and a less exothermic reaction (the relative energies for the two products (Δ^2-pyrazoline and azocyclopropane) are –60.5 and –35.5 kcal mol^{-1}, respectively).

Reactions of substituted nitrilimines

Naturally, all [3+2] products studied are more stable than their [1+2] counterparts and substitution increases the exothermicity of both reactions.[6] However, as observed for unsubstituted nitrilimine, both reaction paths have rather small barriers and fall under kinetic control (Table 1). To explore the effects of substitution, selected geometric parameters for the TS structures and relative barrier heights (E_a) for the two cycloaddition pathways are given in Table 1 for substituted nitrilimines. Three of the TSs for the [1+2] reaction path could not be located (see the following). Substitution does not dramatically affect the geometry of the CNN backbone from that observed in the parent nitrilimine (32)[4], consistent with an early TS. The C5-C4-C3-N2 dihedral angle in the [3+2] TSs is relatively unaffected, with only C-substitution by NH_2 causing any significant deviation from 0°, while in the [1+2] TSs it ranges from 95.6° ($R^1 = CH_3$, R^2 = H or CH_3) to 56.2° ($R^1 = R^2 = F$). The largest effect of substitution is on the newly forming C3—C4 bond, increasing the internuclear separation by as much as 0.245 Å in the [3+2] TSs and 0.252 Å in the [1+2] TSs. The increase in separation between the two fragments generally results in a smaller E_a. In the majority of cases, the [3+2] reaction remains kinetically favoured but, as also observed for the products,[6] substitution at N has a larger effect on the [1+2] reaction, lowering the E_a by as much as 8 kcal mol^{-1}. This results in two cases (R^1 = H, R^2 = OH and R^1 = H, R^2 = F) in which the [1+2] reaction is favoured and two cases (R^1 = H, $R^2 = NH_2$ and $R^1 = R^2 = F$), where the two barriers are within 1 kcal mol^{-1}.

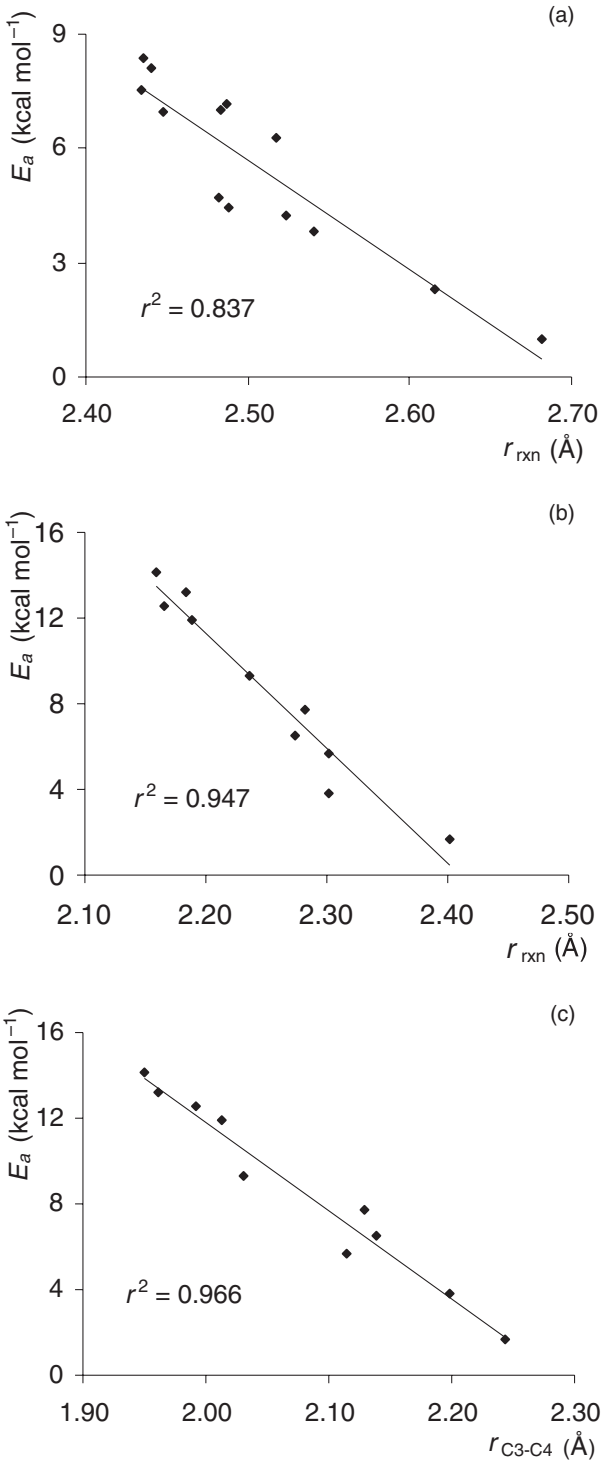
In all cases, the C3—C4 bond is formed to a larger extent than either the N1—C5 bond in the [3+2] TS or the C3—C5 bond in the [1+2] TS, demonstrating that both reactions remain asynchronous for substituted nitrilimines. The degree of asynchronicity, as measured by the difference in the extent of formation of the two new bonds, varies from 8% (R^1 = H, R^2 = F) to 2% (R^1 = F, R^2 = H) in the [3+2] TS and from 18% (R^1 = CH_3, R^2 = H or CH_3) to 10% (R^1 = H, R^2 = F) in the [1+2] TS. As expected, all [1+2] reactions are more asynchronous than their [3+2] analogs (41) and, like the reactions of the unsubstituted nitrilimine, the N1—C5 bond of the [3+2] TS and the C3—C5 bond of the [1+2] TS have virtually the same degree of formation, differing by no more than 2% with respect to one another. However, the extent of C3—C4 bond formation in the two TS structures is affected differently by substitution. In the majority of cases, the difference in % C3—C4 bond formation between the two TS structures is ca. 11%, but in four systems (R^1 = H, R^2 = NH_2; R^1 = H, R^2 = OH; R^1 = H, R^2 = F; and R^1 = R^2 = F) the difference is no more than 6%.



According to the Hammond postulate, the reaction rate should be related to the position of the transition state along the reaction coordinate (52). The reaction coordinate for carbene cycloadditions, as defined by Keating et al. (41), is the distance between the carbene carbon and the midpoint of the alkene double bond. Similarly, the reaction coordinate for the [3+2] cycloaddition reaction can be defined as the distance between the C3-N2-N1 incentre (the geometric midpoint of the C3-N2-N1 fragment) and the midpoint of the alkene bond. We will use these two approximate reaction coordinates, denoted r_{rxn} (Scheme 3), for the [3+2] and [1+2] reactions. The relationship between E_a and r_{rxn} for the various [3+2] and [1+2] reactions are shown in Fig. 1. For the [3+2] reaction, the linear correlation coefficient (r^2 = 0.837) suggests that r_{rxn} captures only part of the full reac-

Fig. 1. The relationship between: (*a*) the [3+2] E_a and the corresponding r_{rxn} coordinate at the transition state; (*b*) the [1+2] E_a and the corresponding r_{rxn} coordinate at the transition state; and (*c*) the [1+2] E_a and the $r_{C3\text{-}C4}$ coordinate at the transition state. See Scheme 3 for the definitions of r_{rxn}.

tion coordinate, yet r_{rxn} is considerably more representative of the reaction than either $r_{N1\text{-}C5}$ or $r_{C3\text{-}C4}$, which correlate poorly with E_a (r^2 = 0.56 and 0.60, respectively). For the [1+2] reaction, the correlation coefficient (r^2 = 0.947) indicates that r_{rxn} captures the majority of the features of the full reaction coordinate. However, the correlation between E_a and $r_{C3\text{-}C4}$ is even better (r^2 = 0.966, Fig. 1*c*), suggesting that the [1+2] reaction is fully controlled by the approach of the nitrilimine carbon to only one ethene carbon atom.

Scheme 4.

Properties governing nitrilimine reactivity

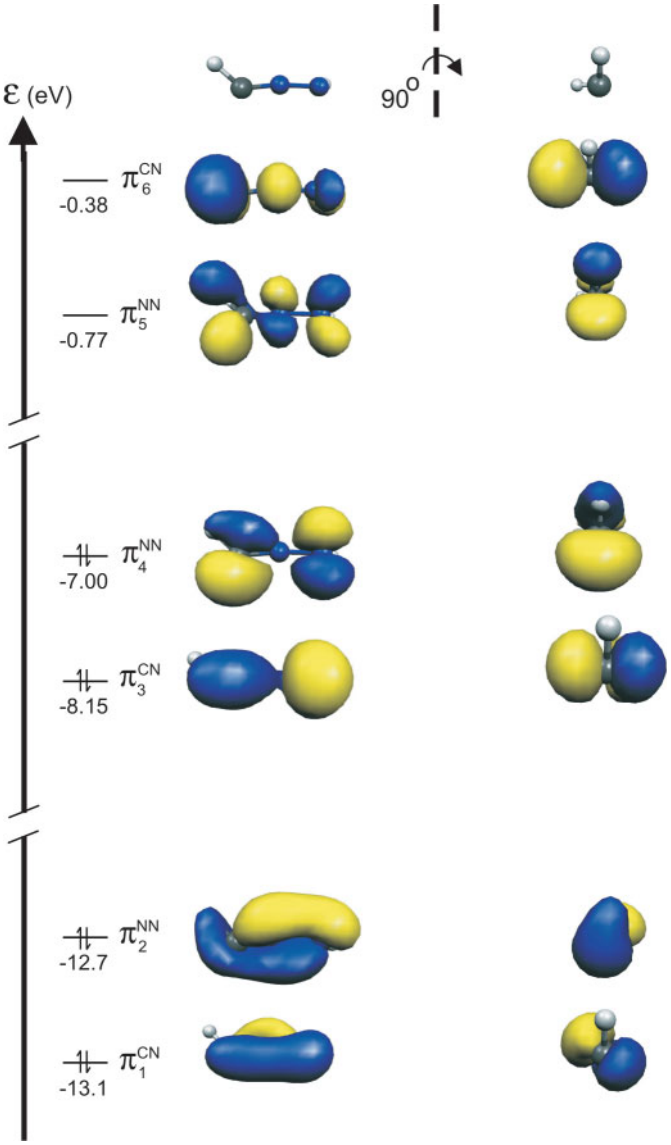
According to the Hammond postulate (52), the low barrier heights and large reaction exothermicities indicate that both reactions are characterized by early transition states. This suggests that variations in reactivity largely depend on the properties of the reactants. Accordingly, in this section we examine the relationship between the properties of nitrilimines and their reactivity.

Frontier molecular orbitals

Frontier molecular orbital theory (FMO) has been extensively used to explain reactivity and regioselectivity in both [3+2] 1,3-dipolar (53, 54) and [1+2] carbene (55) cycloaddition reactions. Simplified representations of the important molecular orbital interactions between the HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital) of ethene and either a dipole (a-b-c) or a carbene (R^1-C-R^2) are given in Scheme 4. As noted in previous studies, the major effect of substitution is a change in orbital energy, while the orbital shapes retain the same qualitative features (54, 56). To identify the proper orbitals of nitrilimine involved in the two reactions, the four highest occupied and two lowest unoccupied Kohn–Sham orbitals of unsubstituted nitrilimine are shown in Fig. 2. All have pseudo-π symmetry (there is no strict σ–π separation in the C_1 symmetrical molecules) and can be characterized as either π^{CN} or π^{NN}. According to Scheme 4, the nitrilimine

© 2005 NRC Canada

orbitals involved in the [3+2] interactions are π_4^{NN} and π_5^{NN}, and those for the [1+2] interactions are π_4^{NN} and π_6^{CN}. Unlike carbenes, which are restricted to one occupied sp^2 orbital and one unoccupied p orbital on carbon, nitrilimines have two additional molecular orbitals (π_3^{CN} and π_5^{NN}) with the correct orientation for the [1+2] cycloaddition reaction. Therefore, π_5^{NN} may interact as LUMO and π_3^{CN} as HOMO with the corresponding ethene orbitals in a [1+2] fashion. These additional interactions, along with the typical [1+2] and [3+2] interactions for the addition of nitrilimine to ethene, are displayed in Scheme 5.



Both nitrilimines and carbenes are generally described as ambiphilic, reacting with both electron-rich and electron-poor alkenes, but varying substituents can induce either exclusive electrophilic or nucleophilic behaviour (24, 25, 37, 38). In FMO terms, electrophilic behaviour is attributed to systems where the $HOMO_{dipolarophile} - LUMO_{dipole}$ energy difference is smaller, nucleophilic behaviour to systems where the $HOMO_{dipole} - LUMO_{dipolarophile}$ energy difference is smaller, and ambiphilic behaviour corresponds to situations in which both energy differences are similar (53, 54). The energy differences associated with the four main orbital interactions (**A**–**D**, Scheme 5) between ethene and the various nitrilimines are given in Table 2. In the majority of cases, the smallest energy difference is $\Delta E_{\mathbf{B}}$, but in four systems (R^1 = OH, R^2 = H; R^1 = F, R^2 = H; R^1 = R^2 = OH; and R^1 = R^2 = F) $\Delta E_{\mathbf{C}}$ is lower, and only in one (R^1 = H, R^2 = F), $\Delta E_{\mathbf{D}}$ is the smallest. Despite the swap in the character of the lowest energy orbital interaction, the next lowest orbital energy difference is generally within ca. 1 eV and corresponds to an interaction of opposite character, consistent with the known ambiphilic reactivity of most nitrilimines (24). Exceptions where the two lowest energy interactions exhibit the same character appear for *N*-fluoro substituted nitrilimines (R^1 = H or F, R^2 = F).

The relative energy of a transition state for a reaction with a small barrier and large reaction exothermicity can be predicted from the relative energy of a weakly interacting complex. The original derivation of the equation for this interaction energy was given by Salem and contained three terms, representing closed shell interactions, coulombic interactions, and orbital overlap (57–59). In many implementations, though, the first two terms are commonly neglected and the relative energy of the complex is predicted from the orbital overlap alone (53, 54). The orbital interaction terms for a general [3+2] and [1+2] reaction with ethene (Scheme 4) are given in eqs. [1] and [2], respectively,

$$[1]\qquad \Delta E = \frac{[C_{HOMO(C4)}C_{LUMO(a)} + C_{HOMO(C5)}C_{LUMO(c)}]^2\ \beta^2}{\varepsilon_{HOMO(Ethene)} - \varepsilon_{LUMO(Dipole)}} + \frac{[C_{HOMO(a)}C_{LUMO(C4)} + C_{HOMO(c)}C_{LUMO(C5)}]^2\ \beta^2}{\varepsilon_{HOMO(Dipole)} - \varepsilon_{LUMO(Ethene)}}$$

$$[2]\qquad \Delta E = \frac{[C_{HOMO(C4)}C_{LUMO(C)} + C_{HOMO(C5)}C_{LUMO(C)}]^2\ \beta^2}{\varepsilon_{HOMO(Ethene)} - \varepsilon_{LUMO(Carbene)}} + \frac{[C_{HOMO(C)}C_{LUMO(C4)} + C_{HOMO(C)}C_{LUMO(C5)}]^2\ \beta^2}{\varepsilon_{HOMO(Carbene)} - \varepsilon_{LUMO(Ethene)}}$$

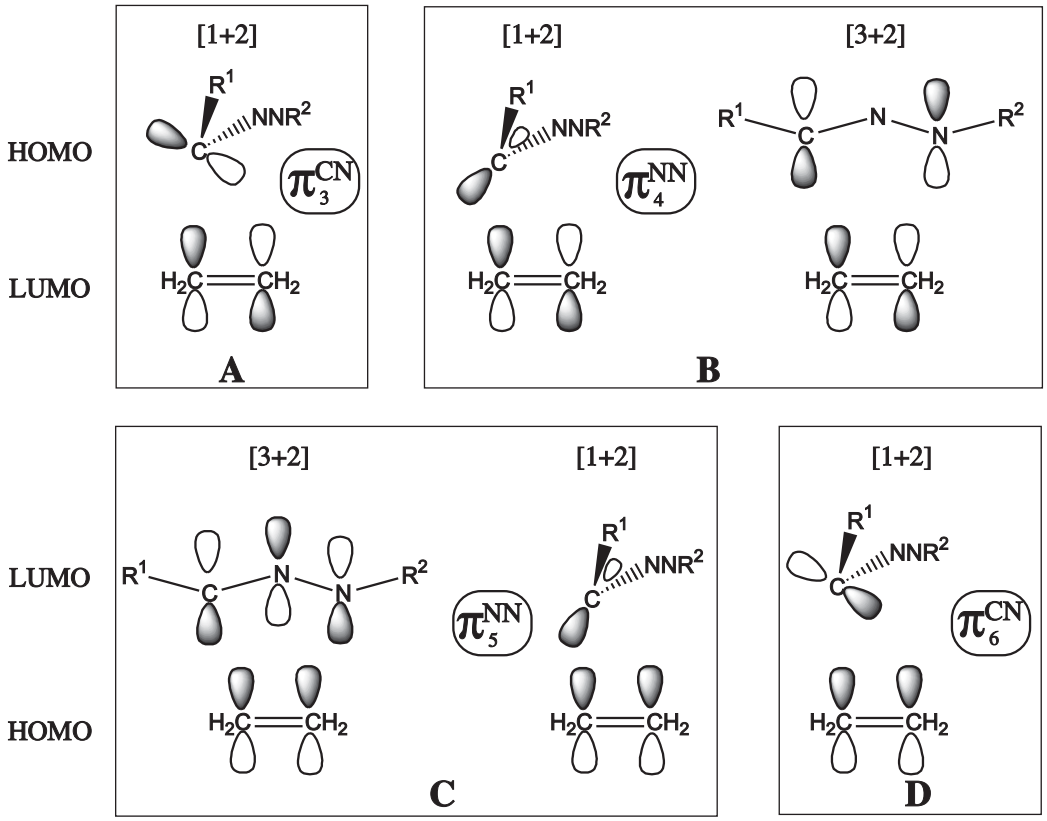


Fig. 2. Two representations of the six π-type molecular orbitals (0.05 au isosurface) of unsubstituted nitrilimine along with orbital energies.

where the denominator is the energy difference between the FMOs involved in the interaction and the numerator contains products of the atomic orbital coefficients at the centres where the two bonds are formed, and the resonance integral (β) is a measure of the interaction strength. These equations can readily be expanded to include additional orbital interactions. Since the ethene orbitals are the same throughout and the shapes of the nitrilimine orbitals are qualitatively similar (32), one may assume that the atomic orbital coefficients are relatively constant, and their products may be approximated by a general factor (*K*). Additionally, the distance between the interacting centres is moderately invariant (Table 1), and so β may also be considered constant. A similar approach has been used to explain the effects of substitution on the reactivity of phenylazide (54). Applying these approximations results in simplified eqs. [3] and [4] for the [3+2] and [1+2] interaction energies, respectively.

Scheme 5.

$$[3] \qquad \Delta E^{[3+2]} = K\beta^2\left[\frac{1}{\varepsilon_{\mathrm{HOMO(Ethene)}} - \varepsilon_{\mathrm{LUMO(Dipole)}}} + \frac{1}{\varepsilon_{\mathrm{HOMO(Dipole)}} - \varepsilon_{\mathrm{LUMO(Ethene)}}}\right]$$

$$[4] \qquad \Delta E^{[1+2]} = K\beta^2\left[\frac{1}{\varepsilon_{\mathrm{HOMO(Ethene)}} - \varepsilon_{\mathrm{LUMO(Carbene)}}} + \frac{1}{\varepsilon_{\mathrm{HOMO(Carbene)}} - \varepsilon_{\mathrm{LUMO(Ethene)}}}\right]$$

Following a systematic examination of the relationship between the barrier heights for both reaction types and all possible combinations of orbital interactions (Scheme 5), we present the best correlations in Figs. 3*a* and 3*b*. Naturally, for the [3+2] reaction, the barrier heights correlate with $1/\Delta E_{\mathbf{B}} + 1/\Delta E_{\mathbf{C}}$ ($r^2 = 0.728$). While a somewhat better correlation ($r^2 = 0.790$) is achieved for $1/\Delta E_{\mathbf{C}}$ alone, suggesting that π_5^{NN} plays a key role in [3+2] reactivity, the best correlation ($r^2 = 0.797$) involves $1/\Delta E_{\mathbf{C}}$ in conjunction with $1/\Delta E_{\mathbf{A}}$, formally a [1+2] orbital interaction (Fig. 3*a*, eq. [5]). The best correlation ($r^2 = 0.794$) for the [1+2] reaction barrier is for $1/\Delta E_{\mathbf{C}} + 1/\Delta E_{\mathbf{D}}$, both of which involve an unoccupied orbital of nitrilimine interacting with the HOMO of ethene (Fig. 3*b*, eq. [6]). As the relationships in eqs. [5] and [6] are linear, the differences in barrier heights (ΔE_a) between the [1+2] E_a and the [3+2] E_a can be approximated by eq. [7] for which results are plotted in Fig. 3*c*. Since the assumption of a constant numerator can not be expected to hold in the combined relationship, the correlation is slightly worse ($r^2 = 0.740$) than those for the individual relationships. None of the other potential combinations of individual relationships results in a reasonable correlation.

$$[5] \qquad E_a^{[3+2]} = m\left[\frac{1}{\varepsilon_{\mathrm{HOMO(Ethene)}} - \varepsilon_{\mathrm{LUMO}(\pi_5^{\mathrm{NN}})}} + \frac{1}{\varepsilon_{\mathrm{HOMO}(\pi_3^{\mathrm{CN}})} - \varepsilon_{\mathrm{LUMO(Ethene)}}}\right] + b$$

$$[6] \qquad E_a^{[1+2]} = m\left[\frac{1}{\varepsilon_{\mathrm{HOMO(Ethene)}} - \varepsilon_{\mathrm{LUMO}(\pi_5^{\mathrm{NN}})}} + \frac{1}{\varepsilon_{\mathrm{HOMO(Ethene)}} - \varepsilon_{\mathrm{LUMO}(\pi_6^{\mathrm{CN}})}}\right] + b$$

$$[7] \qquad \Delta E_a \approx \left[\frac{1}{\varepsilon_{\mathrm{HOMO(Ethene)}} - \varepsilon_{\mathrm{LUMO}(\pi_6^{\mathrm{NN}})}} + \frac{1}{\varepsilon_{\mathrm{HOMO}(\pi_3^{\mathrm{CN}})} - \varepsilon_{\mathrm{LUMO(Ethene)}}}\right] + b$$

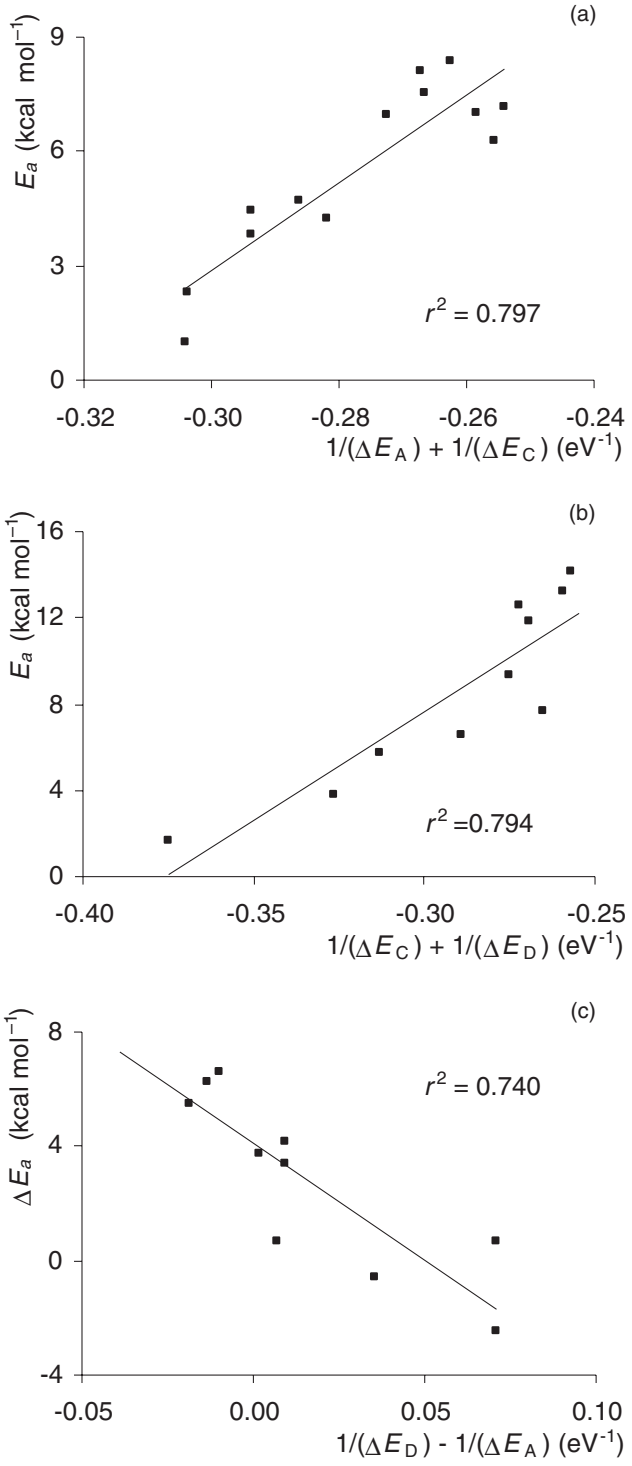
Resonance contributions



Huisgen (28) recognized early that any molecule that can be ascribed a 1,3-dipolar resonance structure could undergo a [3+2] reaction. Recently, we assessed the weights of the individual resonance contributions of nitrilimine and found that the 1,3-dipolar **RS-D** and the carbenic **RS-C** structures (Scheme 1) are the dominant contributors, consistent with the reactivity previously noted (32)[4].

Relationships between the 1,3-dipolar resonance contribution and the [3+2] E_a, and between the carbene resonance contributions and the [1+2] E_a, are given in Fig. 4 for the various nitrilimines. As expected, the carbene character of the different nitrilimines is well-correlated ($r^2 = 0.987$)[8] with the [1+2] barrier heights (Fig. 4*a*). On the other hand, there is no relationship ($r^2 = 0.319$) between the various [3+2] barrier heights and the 1,3-dipolar contribution (Fig. 4*b*), and even the slope of the trend line is opposite to that expected, suggesting that the 1,3-dipolar resonance structure is not a factor in the observed nitrilimine [3+2] reactivity. Interestingly, contributions from the 1,3-dipolar resonance form (**RS-D**) show a good correlation ($r^2 = 0.935$)[8] with the nitrilimine [1+2] barrier height (Fig. 4*c*), with the slope of the trend line opposite to that for the **RS-C** relationship, implying that an increase in 1,3-dipolar character disfavours the [1+2] pathway.

The nitrilimine cycloaddition mechanism

Considerable uncertainty still surrounds the 1,3-dipolar cycloaddition mechanism (1–4, 6). Two mechanisms have been proposed: (*i*) a concerted, single-step process with the two new bonds partially formed at the transition state (8–10, 60); and (*ii*) a two-step process with initial biradical formation followed by bond rotation and ring closure (11–13). The

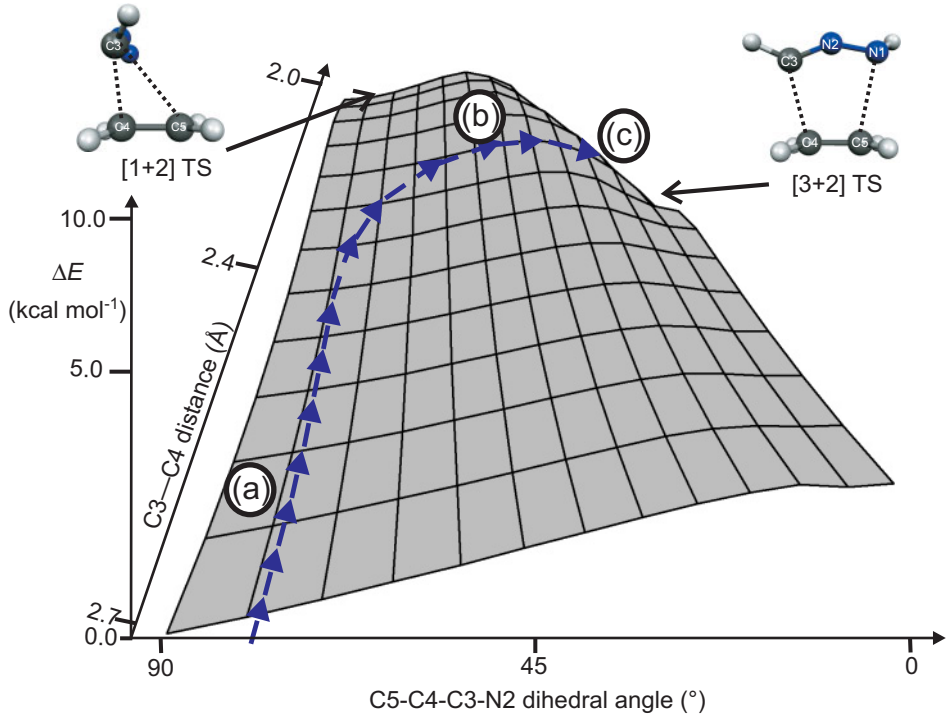
Fig. 4. The relationship between reactivity and % resonance contribution from natural resonance theory for: (*a*) the [1+2] E_a and the carbenic resonance (**RS-C**) contribution;[8] (*b*) the [3+2] E_a and the dipolar resonance (**RS-D**) contribution; and (*c*) the [1+2] E_a and the dipolar resonance (**RS-D**) contribution.[8] Resonance structures **RS-C** and **RS-D** are depicted in Scheme 1.

majority of 1,3-dipolar cycloaddition reactions are believed to proceed via a concerted mechanism (23), although there are now several reports of reactions with a biradical mechanism (1, 61–65).

For the nitrilimine [3+2] reaction, neither mechanism can be readily adopted. As previously mentioned, all calculated TS structures were stable with respect to a broken-symmetry solution to the wave function and no biradical TS could be located. Therefore, a biradical mechanism must be ruled out. From electronic structure considerations, we noted that [3+2] reactivity was not related to the changes in contributions from the 1,3-dipolar resonance structure, **RS-D** (Scheme 1), but was partially controlled by FMO interaction **A** (Scheme 5), formally a carbene-type orbital interaction, and an increase in the **RS-D** contribution resulted in higher [1+2] reaction barriers. Additionally, the fundamental differences between the two TS structures are the C3—C4 interatomic distance, which is slightly shorter in the [1+2] TS, and the C5-C4-C3-N2 dihedral angle. The difference in the dihedral angle between the two TS structures is linearly dependent ($r^2 = 0.842$) on the weight of the **RS-C** contribution, with the difference diminishing as the %**RS-C** increases. Considering that both reaction pathways evolve from the same starting point and the only difference is the orientation of approach (i.e., the C5-C4-C3-N2 dihedral angle), it is not surprising that the [3+2] reaction may involve some characteristics of a [1+2] reaction, especially in the early stages of the reaction. In the following, we suggest that the two reaction paths are not independent, but that the overall mechanism is a combination of the two pathways.



A relaxed potential energy scan was performed for the unsubstituted nitrilimine attacking ethene, varying the C5-C4-C3-N2 dihedral angle from 90° to 0° and the C3—C4 distance from 2.7 to 2.0 Å (Fig. 5). At large internuclear distances (2.7 Å), the [1+2] approach is favoured by 0.65 kcal mol^{-1} and there is a barrier to rotation of 0.85 kcal mol^{-1} at a dihedral angle of about 15°. As the C3—C4 distance decreases, the barrier to rotation steadily increases, while the location of the barrier shifts to larger dihedral angles. At a C3—C4 distance of 2.0 Å, corresponding to the distance at the [1+2] TS, the barrier to rotation is 1.29 kcal mol^{-1} at a dihedral angle of 50°. The [1+2] pathway is favoured up to about 2.3 Å. Beyond 2.3 Å, the [3+2] pathway steadily becomes more favourable as product formation begins, while the [1+2] approach results in an increase in energy until the TS at about 2.0 Å. Although the calculated energy differences are relatively small and generally within what may be considered the error limits of the model chemistry, it has been shown that the PBE0 functional is capable of reproducing experimental conformational equilibria that are a result of even smaller energy differences (66).

Obviously, many factors have been ignored, such as zero-point energy corrections and entropic factors, but both pathways should have comparable contributions since they are part of the same bimolecular process. Also, in the initial stages of reaction, the majority of approach trajectories (~90%)[9] result in the [1+2] pathway, highlighting the high statistical probability for this pathway. Therefore, as a general mechanism for nitrilimine cycloadditions, a statistically

[9] Only an initial dihedral angle range of ±20° leads to the [3+2] TS and all other dihedrals lead to the [1+2] TS.

Fig. 5. Relaxed potential energy surface in the vicinity of the two transition states for the reaction between unsubstituted nitrilimine and ethene. (*a*) Initial carbene-type approach, (*b*) ridge-bifurcation, and (*c*) formation of the [3+2] product.

and possibly thermodynamically favoured initial carbene-type attack occurs, up until a specific C3—C4 internuclear distance where the [3+2] reaction pathway becomes favoured, and a ridge-type bifurcation takes place with rotation about the C3—C4 bond axis (Fig. 5). The final product is typically still the thermodynamically, and for the most part kinetically, favoured Δ^2-pyrazoline, but the regio- and stereo-selectivity observed in the final product is a result of: (*i*) the initial carbene-type approach; and (*ii*) the position of the bifurcation region, which is a function of the difference in barrier heights for the two pathways (ΔE_a) and the magnitude of the rotation barrier. Recall that a [1+2] TS structure was not obtained for three systems ($R^1 = NH_2$, $R^2 = H$; $R^1 = R^2 = NH_2$; and $R^1 = R^2 = OH$). Inspection of the potential energy surface in the region of the [3+2] and [1+2] TSs for these systems reveals that there is no barrier to rotation, hence no ridge-inflection point, and therefore a [1+2] TS cannot be located. For diaminonitrilimine ($R^1 = R^2 = NH_2$), this is fully consistent with its description as a (possibly) stable carbene (32),[4,10] whose large nucleophilic character prevents its [1+2] addition to electron-rich alkenes.

Conclusion

Electronic structure calculations reveal that both the [3+2] and [1+2] cycloaddition pathways between ethene and a series of nitrilimines have low barriers and large reaction exothermicities, consistent with the transient nature of nitrilimines. In the majority of cases, the [3+2] reaction is preferred, but the [1+2] pathway can be favoured by varying the N-substituents. Both reactions proceed with concerted, asynchronous mechanisms, with the [1+2] pathway exhibiting a greater degree of asynchronicity. The geometries of the [1+2] and [3+2] TSs are similar and the fundamental difference lies in the orientation of the approaching reactants, i.e., the C5-C4-C3-N2 dihedral angle. The [3+2] reaction barrier is controlled by two orbital interactions, one of which is carbene-like in nature, and the [1+2] barrier is related to the interaction between the HOMO of ethene and the two unoccupied π orbitals of nitrilimine. The potential energy surface in the vicinity of the [3+2] and [1+2] TSs reveals that the initial phase of the reaction corresponds to a carbene-like attack of the nitrilimine, which after crossing a ridge-inflection region of the surface, eventually results in the formation of the [3+2] product. Further work is currently being carried out to examine the effects of ethene substitution and to design experiments that can confirm our proposed mechanism.

Pople, Schneider, and Bernstein — A truly seminal treatise of NMR[1]

John D. Roberts

Abstract: The appearance of the authoritative and comprehensive book, *High-Resolution Nuclear Resonance Spectroscopy*, by John A. Pople, William G. Schneider, and Harold J. Bernstein in 1959 came at just the right time for chemists and other scientists to develop a clear vision of the wide breadth of applications of this critical emerging field and, in addition, to have the opportunity to learn the underlying basic theory in substantial detail.

Key words: Pople, Schneider, Bernstein, NMR theory, NMR applications.

Résumé : Le traité compréhensif de John A. Pople, William G. Schneider et Harold J. Bernstein, *High-Resolution Nuclear Resonance Spectroscopy* a fait autorité et son apparition en 1959 est arrivée juste au bon moment pour permettre aux chimistes et aux scientifiques de se faire une idée claire de l'étendue des applications de ce nouveau domaine critique alors en émergence et, de plus, d'avoir une opportunité d'apprendre en détail la théorie de base sous-jacente.

Mots clés : Pople, Schneider, Bernstein, théorie de la RMN, applications de la RMN.

[Traduit par la Rédaction]

Introduction

The progress of chemistry often occurs in spurts, especially as new ideas emerge or new understandings are achieved. Many such spurts are facilitated by especially significant books. Some of these books are of such nature to stay in print for many years; others are more ephemeral because they appear soon after a new field opens and although they may be especially timely when they first appear, before long they may be left behind as their impact leads to new applications and new insights. The first category includes such books as Lewis and Randall's *Thermodynamics* (1), Pauling and Wilson's *Quantum Mechanics* (2), Pauling's *Nautre of the Chemical Bond* (3), Sidgwick's *Organic Chemistry of Nitrogen* (4), and Hammett's *Physical Organic Chemistry* (5).

In 1952, while at MIT, I first was exposed to the possibilities of NMR in chemistry in a personal lecture by Richard A. Ogg of Stanford, but my level of comprehension of the physics involved was insufficient to take any action other than to note that Ogg's boundless enthusiasm surely meant that, for someone, NMR would be a winning research area. Two years later, William D. Phillips showed me actual spectra of organic compounds and what could be gleaned from them, especially such information as the rates of rotation about the C—N bond of *N*,*N*-dimethylformamide. That exposure led to an intense campaign to get a NMR spectrometer at Caltech to be under the general supervision of the organic group. Linus Pauling was unenthusiastic, because he thought such a spectrometer would be best supervised by more knowledgeable persons with experience in magnetic resonance and expertise in electronics. He relented when it was pointed out that NMR should be well-suited to investigate the borderline between resonance and tautomerism. Our installation was one of the very first Varian NMRs to be installed in an academic institution.

My initial plan was to determine the structure of diketene, a festering problem for many years, but Herbert S. Gutowsky (probably the first chemist to do extensive research on NMR with self-built instrumentation) got there first (6). A secondary goal was to determine the structure of Feist's acid, which was successful in confirming the material to be 3-methylene-1,2-cyclopropanedicarboxylic acid (7). But actually, my first paper using NMR was concerned with whether the very broad line observed for the N-H proton of pyrrole was the result of proton exchange or (as it turned out) ^{14}N quadrupolar interactions (8). I ran these and several hundred other NMR spectra over the next year with little clue as to the basics of how an NMR spectrometer actually worked. But as I caught on to more of it, my enthusiasm grew, and in the summer of 1958, an invitation to speak at a Reaction Mechanisms Conference at Bryn Mawr provided an opportunity to give a lecture on the subject to physical organic chemists. The response was so favorable, a missionary zeal quickly developed to write a book based on the lecture material.

It did not take long to realize that when one writes a book about an especially fast moving field, such as NMR, it is somewhat like writing in water. I experienced that feeling in 1959 with my book *Nuclear Magnetic Resonance* (9), even though my purpose of the book was simple: an alert to organic chemists of the possibilities of NMR in their area

Fig. 1. (*a*) John A. Pople (10/31/1925 – 3/15/2004) was born in Somerset, UK, showed strong mathematical skills at a very early age, received a Ph.D. in mathematics at Cambridge in 1948, started in NMR in 1955, worked two summers at NRC in Ottawa with Schneider and Bernstein. His later interests were in quantum theory of molecular properties, he was knighted in 2003 and awarded the Nobel Prize in Chemistry in 1998. (Photo taken in the 1950s.) (*b*) William G. Schneider (6/1/1915 –) was born in Saskatchewan, took B.Sc. and M.S. at the University of Saskatchewan, received a Ph.D. in physical chemistry at McGill in 1941, worked as a postdoctoral fellow at Harvard (1941–1943), vice president and president (1965–1980) of the Pure Chemistry Division at NRC (1943–1980), and he was awarded the Order of Canada in 1977. (Photo taken in the 1950s from the NRC Archives.) (*c*) Harold J. Bernstein (8/26/1914 – 12/14/84) was born in Toronto and had his advanced education at the University of Toronto culminating with a Ph.D. in physical chemistry in 1938, postdoctoral scholar in Copenhagen (1938–1940), worked with NRC in chemistry from 1946 to his retirement in 1981. Following the publication of PSB, he gradually moved to research in Raman spectroscopy. (Photo taken in 1967 from the NRC Archives.)

and a hope of imparting simple general ideas of how it worked — at least at the level I knew it then. This book did, however, achieve two distinctions: (*a*) being the first advanced chemistry monograph with four-color illustrations, and (*b*) being the first book to publish the now ubiquitous problems in which students are given a NMR spectrum and an empirical formula and asked to deduce the molecular structure.

But the fact is that I was thoroughly upstaged shortly after publication, when still in 1959, a very different NMR book appeared on the scene, entitled *High-resolution Nuclear Magnetic Resonance* by John A. Pople, William G. Schneider, and Harold J. Bernstein (10). This book was itself to a degree ephemeral because of rapid experimental development of the field, but it still achieved a longer-term impact than otherwise might have been expected through its authoritative discussions of the basic theory of NMR, chemical shifts, spin–spin splitting, relaxation, and rate effects. One would presume that much of the theoretical part was written by John A. Pople, well-known for his work on applications of quantum mechanics to chemistry, who was then at the National Physical Laboratory at Teddington, UK. The extensive information on chemical applications was surely largely the work of William G. Schneider and Harold J. Bernstein at the National Research Council Canada (NRC) in Ottawa. The cooperative effort of the three authors says much for the acumen of NRC in getting into new areas of great promise.

The book by Pople, Schneider, and Bernstein (PSB, Fig. 1) was monumental. It was comprehensive and covered a wide range of applications using a wide range of NMR-active nuclei. At the same time, it supplied very authoritative, but not always user-friendly, theory for organic chemists. Many of those applications involved studies made by the authors at NRC. These included excellent and substantial work on the analysis of the shifts and couplings in a variety of organic heterocyclic compounds, such as pyridine, lutidine, quinoline, and isoquinoline, as well as substituted cyclohexanes. Hydrogen bonding was studied in considerable detail by changes in the chemical shifts of the acidic protons of carboxylic acids, as a function of concentration mostly in non-polar aprotic solvents. Related research was reported on the substantial changes in the proton shift of chloroform dissolved in aromatic solvents. Other important work involved changes in the relative keto–enol concentrations as a function of solvent.

Having already had some experience in organic chemical applications, I was especially interested in PSB's account of the theory of spin–spin splitting and how to extract spin–spin couplings from non-first-order spectra. When I wrote my NMR book, I was at the level of the dogma on shifts and spin–spin couplings that is taught in most elementary organic courses today. One of the principal tenets of the dogma relating to shifts was that electronegative substituents caused downfield proton shifts. Other tenets for spin–spin splitting included the notion that protons with the same chemical shift do not split one another (but not why), the $n+1$ rule for predicting proton–proton splittings, and also that proton–proton couplings are normally not significant when the protons are separated by more than three bonds. However, I did mention in my book the seemingly anoma-

© 2005 NRC Canada

lous AA′XX′ spectrum of 1,1-difluoroethene described by McConnell (11) and made it embarrassingly clear that I did not understand how it came about, although I was sufficiently interested to produce a higher resolution spectrum than the published one.

It should not be surprising that I was clearly an avid customer for PSB's methods for calculating spectral line positions. Although previously an advocate for organic chemists learning to apply Hückel MO theory to organic compounds (12), I needed a powerful catalyst for seeing the connection between the behavior of electrons in orbitals and of magnetic nuclei interacting with one another in a magnetic field. Fortunately, for my then colleague, Harden McConnell, this area of theory was like mother's milk and in a "*mano a mano*" struggle on July 4, 1956, he hoisted me over the energy barrier to use it. The ultimate result was a 105 page book (13) explaining in a way that I could understand a rather small number of pages of PSB. By the time I completed my manuscript, my copy of PSB was literally coming apart at the seams with the top of the pages deeply blackened, particularly in those areas covering the theory of NMR. Unfortunately, my manuscript was written and submitted just before it became commonplace to calculate and plot spectra as was done early on by Wiberg and Nist (14).

Others, such as Ray Lemieux (15) and Ted Schaefer (16) who achieved recognition of their own NMR research progress by way of the citation index approbations expressed strong appreciation for the contributions and inspiration provided to them by Schneider and Bernstein during the periods in which each worked at NRC.

The word *seminal* is used so much today in describing more or less new things in science that its real meaning is almost lost, but PSB's book sets a standard for the word by its timeliness, breadth, and depth of coverage at a crucial stage of NMR development. Furthermore, the book sparked the enthusiasm of chemists generally and it led them to demand more and better NMR spectrometers. The resulting market for machines turned out to be quite large and led to the early fierce and continuing competition among the instrument makers: Varian, Bruker, JEOL, and Nicolet (later GE) to provide customers with both routine and cutting-edge instrumentation representing the epitome of high technology.

Almost 60 years since the demonstration of NMR in the condensed phase (17, 18), the field is still growing almost explosively with applications in MRI (19), quantum computing (20), protein structure determinations (21), and optical detection of changes in force associated with excitation of nuclei in a magnetic field (22). The future of NMR is very bright indeed.

Intramolecular general acid catalysis of sulfate transfer — Nucleophilic attack by oxyanions on the SO_3^- group[1]

Anthony J. Kirby, José Carlos Gesser, Florian Hollfelder, Jacks P. Priebe, and Faruk Nome

Abstract: The mechanism of hydrolysis of 8-*N*,*N*-dimethylaminonaphthyl sulfate closely resembles that of the corresponding phosphate monoester. Nucleophilic attack by water on the sulfate group of the zwitterion is catalyzed by the neighbouring dimethylammonium group, acting as a particularly efficient general acid through the intramolecular hydrogen bond. This hydrogen bond is present in both reactant and product, but is strongest in the transition state. Transfer of the sulfuryl group to oxygen nucleophiles, including water and carboxylate anions, shows steric and electrostatic effects, and a sensitivity to basicity which is low, but significantly higher than expected for uncatalyzed transfer of the SO_3^- group.

Key words: sulfate, sulfatase, intramolecular, general acid catalysis, promiscuity.

Résumé : Le mécanisme d'hydrolyse du sulfate de 8-*N*,*N*-diméthylaminonaphtyle ressemble fortement à celui du monophosphate correspondant. L'attaque nucléophile de l'eau sur le groupe sulfate du zwitterion est catalysée par le groupe diméthylammonium voisin qui agit comme un acide général particulièrement efficace par le biais de la liaison hydrogène intramoléculaire. Cette liaison hydrogène est présente tant dans le réactif que dans le produit, mais elle est encore plus forte dans l'état de transition. Le transfert du groupe sulfuryle vers les oxygènes nucléophiles, y compris l'eau et les anions carboxylates, est soumis à des effets stériques et électrostatiques et à une faible sensibilité à la basicité qui est toutefois supérieure à celle attendue pour un transfert non catalysé du groupe SO_3^-.

Mots clés : sulfate, sulfatase, intramoléculaire, catalyse acide générale, promiscuité.

[Traduit par la Rédaction]

Introduction

Interest in the biological chemistry of sulfate esters has grown rapidly in recent years, as it has become apparent that they are involved in a whole range of biological processes besides detoxification. These include molecular recognition and cell signaling, hormone regulation, and viral entry into cells (1, 2). The two types of enzyme involved in the metabolism of biological sulfates, the sulfatases and sulfotransferases, both catalyse the transfer of the SO_3 group between nucleophilic, typically oxygen, centres, but have evolved different mechanistic strategies. The sulfotransferases (1) generally use an "activated sulfate", PAPS, with a good, phosphate ester leaving group, to transfer SO_3 to a target nucleophile (Scheme 1), just as kinases use ATP to transfer the PO_3^- group to generate phosphate monoesters.

The sulfatases, by contrast, have evolved to transfer SO_3 from sulfate esters to a common, weak nucleophile, water, and like phosphatases, must activate both nucleophile and leaving group. Most attention, not surprisingly, has focused on their mechanistically ingenious use of a unique enzyme nucleophile, an OH group of a hydrated α-formylglycine residue (3, 4) (generated by post-translational oxidation of Ser or Cys). The sulfated enzyme intermediate is thus not an inconveniently stable alkyl sulfate (a potential alkylating agent) but a species **1** (Scheme 2), which rapidily eliminates sulfate to regenerate active enzyme.

The (presumably concerted) first step of this mechanism involves two key proton transfers. The nucleophilic OH group (more acidic by some 2 p*K* units than a serine OH) needs to be deprotonated, either in a preequilibrium or by a general base as part of the reaction. And the leaving group

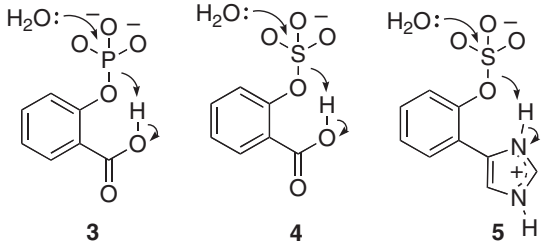
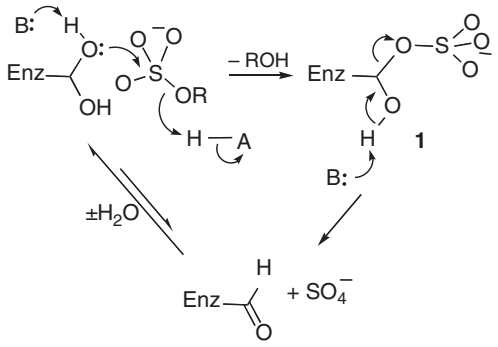
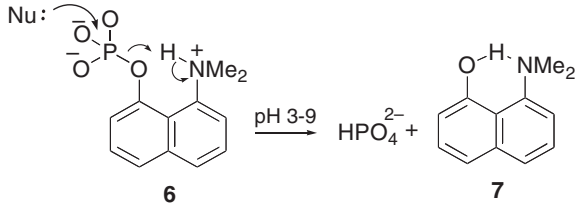


Scheme 1.

requires protonation by a general acid: sulfatases typically use the NH^+ groups of histidines and lysines (2). In this work we examine both reactions, using the model sulfate ester **2**, which has a built-in general acid that we expect from previous work to be catalytically efficient.



The similarities between the reactions of sulfate and phosphate monoesters $RO\text{-}SO_3^-$ and $RO\text{-}PO_3^{2-}$ are well-documented (and close enough that some phosphatases and sulfatases show significant crossover activity, as discussed in the following). Rates of hydrolysis depend strongly on the basicity of the leaving group, with slopes of linear plots of $\log k_{hyd}$ vs. pK_a of the conjugate acid ROH of the order of 1.2–1.3 in both cases. Cleavage of the bonds to the leaving group RO^- might therefore be expected to also be susceptible to relatively efficient general acid catalysis. Efficient catalysis by the COOH group was observed many years ago for salicyl phosphate **3** (5, 6) and sulfate **4** (7, 8). But catalysis of the hydrolysis of the sulfate group of **5** by the neighbouring imidazolium group (9), the best model for this part of the sulfatase mechanism, is typically inefficient (10), with the rate acceleration ascribed to intramolecular general acid catalysis only 49-fold (9).



We have recently shown (11) that the phosphate monoester analogue **6** (closely analogous to the zwitterion **2z**) is hydrolyzed with highly efficient general acid catalysis by NH^+, supporting a rate acceleration of 2.4×10^5 at 60 °C. The key to efficient catalysis is the strong intramolecular hydrogen bond to the neighbouring dimethylammonium group (Scheme 3, Nu = H_2O). The attack of nucleophiles other than water is also catalyzed, and oxyanions are no less reactive than neutral amine nucleophiles of similar basicity. This

Scheme 2.

Scheme 3.

is remarkable since oxyanions do not normally react at a significant rate with the PO_3^{2-} group of reactive phosphate monoesters. Apparently, electrostatic repulsion among the reacting anions disappears when hydrolysis is catalyzed by a properly positioned *cationic* general acid (11). Since no data are available to characterize nucleophilic attack by oxyanions on sulfate monoesters, we have examined the spontaneous hydrolysis of **2z** and its catalysis by oxyanion nucleophiles, which are also potential general bases.

Methods and results

Materials

^1H NMR spectra were obtained on Bruker AW-200 and Varian Mercury Plus 400 MHz instruments using sodium 3-(trimethylsilyl)propionate as internal standard. IR spectra were obtained using KBr discs on PerkinElmer FT 16 PC and ABB BOMEM model FTLA 2000 instruments.

Melting points were measured on a hot stage Fisher-Johns MQAPF 301 instrument from Microquímica, and are uncorrected. pH values were measured at the end of each kinetic run using a Hanna pH200 digital pH meter, calibrated using standard buffer solutions (Carlo Erba, Milan, Italy) at pH 4.00, 7.00, and 10.00.

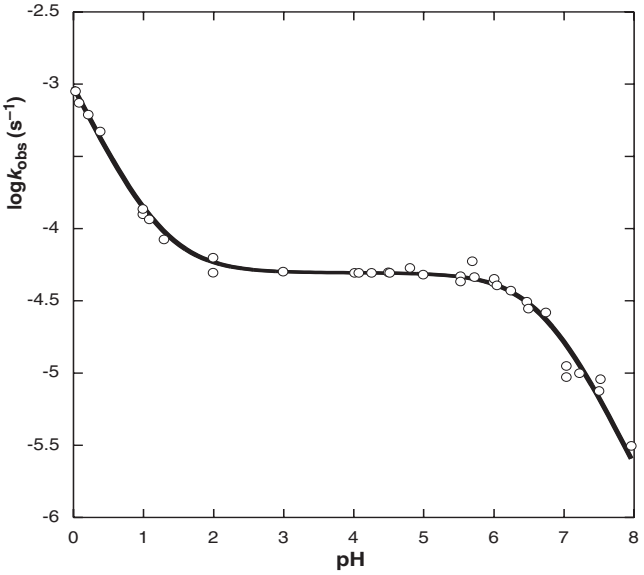
All solvents used in synthetic procedures were purified according to the best literature precedents (12, 13). Buffers and salts were used as supplied by Nuclear (São Paulo, Brazil), Vetec (Rio de Janeiro, Brazil), Carlo Erba (Milan, Italy), Merck (Darmstadt, Germany), and Aldrich (Milwaukee, Wisconsin), without further purification. 4-Nitrophenol (99%), DCl (37% in D_2O), and D_2O (99.9%) were supplied by Aldrich and Cambridge Isotope Laboratories (Andover, Massachusetts). 4-Nitrophenylsulfate and 8-*N*,*N*-dimethylaminonaphthyl sulfate (from the corresponding naphthol (14)) were synthesized as the potassium salts according to a literature method, modified in the latter case as follows.

© 2005 NRC Canada

Potassium 8-*N*,*N*-dimethylaminonaphthyl-1-sulfate (2)

A solution of 8-*N*,*N*-dimethylamino-1-naphthol (14) in pyridine was added in a single portion (15) to a cooled solution of the pyridine·SO_3 complex. After reaction and evaporation of the solvent, the syrupy residue was redissolved in water and the pH adjusted to 8.0–8.5 with KOH. The solid residue obtained by evaporation was triturated with dry acetonitrile and centrifuged (16). The supernatant was evaporated and the solid obtained dissolved in hot ethanol, cooled, and filtered under vacuum. Repetition of this procedure improved the purity of the product, but was always accompanied by a certain amount of hydrolysis to small amounts of the naphthol and inorganic sulfate. The compound used in the kinetic experiments was at least 96% pure. UV–vis λ_{max} (H_2O): 300 nm. ^{1}H NMR (400 MHz, D_2O) δ: 7.75 (d, 1H, J = 5.5 Hz), 7.54 (d, 1H, J = 5.5 Hz), 7.52 (d, 1H, J = 5.5 Hz), 7.44 (t, 1H, J = 5.5 Hz), 7.41 (t, 1H, J = 5.5 Hz), 7.15 (d, 1H, J = 5.5 Hz), 2.74 (s, 6H, NMe_2).

Kinetic measurements



UV–vis spectra and kinetic runs were followed in the thermostatted cell compartment of a Varian Cary 50 spectrophotometer, and analysed on the dedicated microcomputer using the Cary WINUV 3.00 data acquisition and kinetics software program.

Kinetic measurements were carried out in aqueous solution, at 60 °C and ionic strength 1.0 mol/L (KCl), by following the appearance of 8-*N*,*N*-dimethylamino-1-naphthol, at three separate wavelengths (304, 316, and 320 nm). For the spectroscopic pK_a determination, baseline corrections (referred to 500 nm) allowed accurate assignment of isosbestic points. pH in the kinetic runs was maintained using HCl (at pH < 3.0) and the following buffers, generally at 0.01 mol/L: acetic acid – potassium acetate (pH 4–5.25), potassium phosphate (pH 5.5–7.5), and boric acid – borate (pH 7.75–9). For kinetic runs in D_2O at 60 °C, the pD was obtained by adding 0.25 to the meter reading (17). Reactions were initiated by adding 50 μL aliquots of a 1.25×10^{-3} mol/L stock solution of potassium 8-*N*,*N*-dimethylaminonaphthylsulfate to preheated buffer solution in 10 mm (3 mL) quartz cells, to give a final concentration of 2.5×10^{-5} mol/L. Reactions were followed by taking an average of 280 absorbance readings over at least three half-lives. Calculated rate constants showed standard errors of <1% over the three wavelengths for which data were collected. Observed rate constants for hydrolysis in HCl and DCl, and at pH 4.50 as a function of temperature (Tables S1–S3), are available as Supplemental material.[4]

Spectroscopic determination of the pK_a of 8-dimethylamino-1-napthyl sulfate (2)

Spectra were recorded at 25 °C, at 14 pH values between 4.0 and 10.0. Isosbestic points were observed at 270 and 300 nm, with λ_{max} at 290 nm at pH 4 and 330 nm at pH 10.0. The value obtained (6.98 ± 0.03) is similar to the kinetic pK_a of 6.70 ± 0.05 at 60 °C derived from the pH–rate profile for hydrolysis (Fig. 1). It is more than 2 units higher than expected for the system lacking the sulfate group, as discussed in the following.

Fig. 1. pH dependence of the rate of hydrolysis of 8-*N*,*N*-dimethylaminonaphthyl-1-sulfate (**2**) at 60 °C and ionic strength 1.0 mol/L. The points are experimental, and the curve calculated, using eq. [2] and the constants summarized in Table 2.

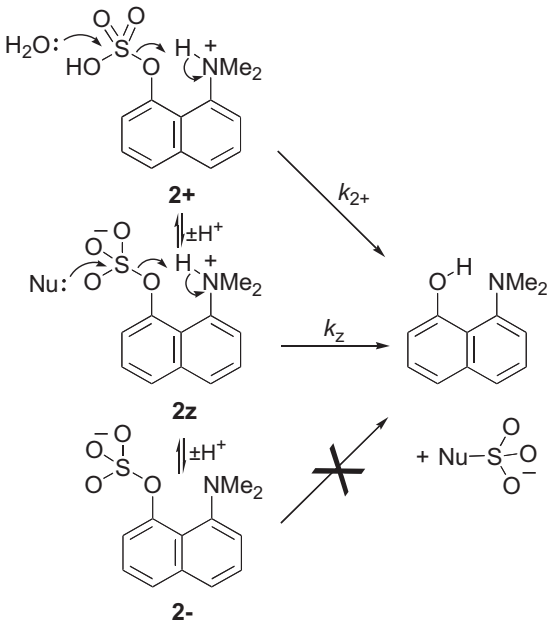
Hydrolysis of 8-*N*,*N*-dimethylaminonaphthyl-1-sulfate (2)

The pH–rate profile for the hydrolysis of **2** from pH 0 to 8.0 (Fig. 1) shows three distinct regions. (*i*) At pH < 2, the rate increases linearly with a_H, with a slope of –1, as expected for an acid-catalyzed reaction. (*ii*) A pH-independent reaction between pH 3.0–6.0 corresponds to the spontaneous hydrolysis of the ionic species **2z** present in this region, while the fall off in region (*iii*) at pH > 6.5 is consistent with the ionization of this species to form an unreactive conjugate base. The apparent pK_a at 60 °C is 6.70 ± 0.05.

Much precedent, from mechanistic work on the hydrolysis of simple aryl sulfates and on the phosphate monoester **6** under similar conditions, suggests the mechanisms outlined in Scheme 4, which translate into the kinetic expression of eq. [1]:

$$[1] \qquad k_{obs} = k_{2+}\chi_{2+} + k_{2z}\chi_{2z}$$

(The uncatalyzed reaction of the anion is not significant under the conditions used, as shown by the absence of reaction at high pH). Equation [1] can be simplified to eq. [2] because the pK_a of **2+** is expected to be of the order of –(4–6),[5] far from the pH region.



$$[2] \qquad k_{obs} = (k_H a_H + k_{2z}) \frac{a_H}{(a_H + K_{2z})}$$

[4] Supplementary data for this article are available on the Web site or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 4052. For more information on obtaining material refer to http://cisti-icist.nrc-cnrc.gc.ca/irm/unpub_e.shtml.

[5] Estimate based on a figure of ca. –3.5 for $MeOSO_3OH$ (J.P. Guthrie. Can. J. Chem. **56**, 2342 (1978)). The value will be lower for an aromatic sulfate, and reduced further by hydrogen bonding to the neighbouring NH^+. The value will be lower for an aromatic sulfate, and reduced further by hydrogen bonding to the neighbouring NH^+.

Scheme 4.

A least-squares fit to eq. [2] of the data shown in Table 1 gives the values of the rate and dissociation constants shown in Table 2: these define the calculated curve of Fig. 1.

Activation parameters

Activation parameters, based on the Eyring equation (18), were obtained for the spontaneous hydrolysis of the zwitterion **2z** from rate measurements at pH 4.55, done in triplicate at seven different temperatures in the range 60–90 °C. The correlation coefficient for the Arrhenius plot was 0.991. The results appear in Table 2, the data in Table S3.[4]

Solvent isotope effect

Rates of hydrolysis of **2** were compared in H_2O and D_2O in two regions of pH. In acid, between 0.52 and 1.06 mol/L, and at pH 4.55, in the pH-independent region where the reaction is the spontaneous hydrolysis of the zwitterion. Plotting k_{obs} vs. [LCl] in the acid region (for data see Tables S1 and S2)[4] gives good straight lines, with correlation coefficients of $r = 0.994$. The slopes give second-order rate constants for HCl–H_2O and DCl–D_2O of $1.67 \pm 0.10 \times 10^{-3}$ and $2.06 \pm 0.08 \times 10^{-3}$ $(mol/L)^{-1}$ s^{-1}, respectively, and thus an inverse isotope effect for the reaction in acid ($k_H/k_D = 0.81 \pm 0.08$). Rate constants at pH 4.55 were measured in triplicate: the values obtained ($k_{H_2O} = (4.95 \pm 0.20) \times 10^{-5}$ s^{-1} and $k_{D_2O} = (2.57 \pm 0.35) \times 10^{-5}$ s^{-1}, Table 2) give a kinetic isotope effect in this region ($k_{H_2O}/k_{D_2O} = 1.93 \pm 0.39$).

On the basis of the good linear free energy relationship ($r = 0.996$, slope = 1.346) among the rate constants for the hydrolysis of four simple aryl sulfates (extrapolated to 60 °C using Fendler's data (16)) and the pK_a of the leaving group, the rate of spontaneous hydrolysis of **2z** corresponds to that expected for a simple aryl sulfate with a leaving group (congugate acid) of $pK_a = 5.11$. The rate acceleration attributable to intramolecular general acid catalysis by the dimethylammonium group (based on a pK_a of 9.40 for 1-

naphthol (14)) is thus ca. 6×10^5 at 60 °C, and $>10^6$ at 25 °C.

Reactions with nucleophiles

The hydrolysis of **2z** is catalyzed by oxyanions in the plateau region. The data are shown in Table 3: rate enhancements of up to 78% are observed in the presence of 1 mol/L of nucleophile. These rate enhancements are clearly not specific ion effects because they depend on the basicity of the oxyanion, and to some extent on steric effects, as expected for nucleophilic reactions. The points for water and for acetate and substituted acetates (see the Discussion section) give an excellent Brønsted correlation, with $\beta_{nuc} = 0.26 \pm 0.01$.

Discussion

Hydrolysis of 2z

The estimated rate acceleration for the hydrolysis of the zwitterion **2z** is 6×10^5 at 60 °C, and the rate that is expected for a simple aryl sulfate ester with a leaving group (conjugate acid) of pK_a = 5.1 (16). The rate acceleration for the hydrolysis of the phosphate ester **6**, estimated in the same way, is 2.4×10^5 at 60 °C, and the rate that expected for a simple aryl phosphate ester with a leaving group (conjugate acid) of pK_a = 5.2. The close similarity of these figures suggests that the reactions of the two systems are also closely similar. In both cases, the efficiency of catalysis is reduced by the net stabilizing effect of the intramolecular hydrogen bond in the reactant (as revealed by the increase of >2 units in the pK_a of the dimethylammonium group of **2z**, and the similar but larger effect for **6**).[6] However, intramolecular general acid catalysis is still notably efficient, with **2z** hydrolyzed faster than the reaction of **5** by some three orders of magnitude, in water at 25 °C.

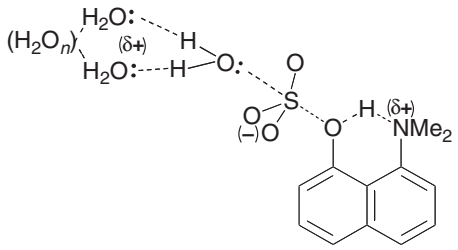
Other similarities are the absolute rates (**2z** is hydrolyzed just over 3 times more slowly at 60°) and the solvent deuterium isotope effects (k_{H_2O}/k_{D_2O}), which are identical ($k_H/k_D = 0.8 \pm 0.1$) for the acid-catalyzed reactions and low and normal for the plateau reactions ($k_H/k_D = 1.93 \pm 0.39$ for **2z**, 1.46 ± 0.04 for **6**). The activation parameters show the small differences typical for esters of these types, with entropies of activation small and negative for **2z** and small and positive for **6**. Thus, the enthalpy of activation for the hydrolysis of **2z** is similar to the value (24.7 kcal dm^3 mol^{-1}, 1 cal = 4.184 J) measured by Fendler and Fendler (16) for the hydrolysis of *o*-nitrophenyl sulfate. The low negative entropy of activation is similar within the experimental uncertainty to values (–17.4 and –18.5 eu) reported for 2,4- and 2,5-dinitrophenylsulfates (16, 19), and is consistent with a minimal net involvement of water (and perhaps a more significant release of (the more strongly) solvating water molecules from the phosphate dianion).

Mechanism

These close similarities in the hydrolysis reactions of **2z** and **6** clearly suggest that the mechanisms are also similar, and Scheme 4 is based on our conclusions for the phosphate ester. In neither system is there any significant reaction for the fully deprotonated form (**2**$^-$ in Scheme 4).

Hydrolysis in acid

C—O cleavage is not a serious possibility for an unactivated aromatic system, and for hydrolysis in acid there appears to be no convincing alternative to intramolecular general-acid-catalyzed attack of water on the neutral SO_3H group (Scheme 4, k_{2+}). The small inverse deuterium kinetic isotope effect is consistent with a reaction involving a preequilibrium proton transfer (20). A specific rate constant for the hydrolysis of **2+** can be estimated by assuming a pK_a for the sulfate S—OH group. Taking this pK_a to be –(5 ± 1), as previously discussed, gives an estimate for $\log(k_{2+}) = 1.93 \pm 1$ s^{-1}, corresponding to a rate acceleration of $1.8 \times 10^7 \pm 1$, of the same order of magnitude as that ($>10^8$-fold) estimated for catalysis by the same group of the hydrolysis of the cationic phosphoric acid ($PO(OH)_2$) form of **6**. The intramolecular hydrogen bond from NH^+ to the leaving group oxygen, which stabilizes the reactant **2z**, is expected, and appears to be, weak or nonexistent in the cation **2+** because the dimethylammonium group of the diethyl triester of **6** has a pK_a = 4.63, in the region expected for a naphthylammonium cation (21).



Spontaneous hydrolysis of the zwitterion 2z

The simple mechanism for the hydrolysis of **2z** (k_z with Nu = H_2O) suggested in Scheme 4 is also based on that described for the comparable, closely similar reaction of the phosphate ester **6** (11). It is expected to involve weak (but essential) bonding to the incoming nucleophile (see the following), thus accounting for the small negative entropy of activation. The involvement of the NH^+ group as a general acid will have no significant effect on the entropy term, since the proton transfer takes place within a strong hydrogen bond, which remains in place throughout the reaction. S—O cleavage can be presumed to be well-advanced, as appears invariably to be the case for the spontaneous cleavage of aryl sulfate monoesters. The solvent deuterium kinetic isotope effect ($k_{H_2O}/k_{D_2O} = 1.93 \pm 0.39$) is significant but small, as generally observed for reactions of derivatives of 8-dimethylamino-1-naphthol showing efficient intramolecular general acid catalysis (6, 11, 14, 21). (The closest comparison is with the hydrolysis of the methyl phosphodiester de-

[6]We expect this hydrogen bonding to result also in the lengthening of the S—OAr bond of **2z** that generally accompanies increased rates of cleavage (T.A.S. Brandao, J.P. Priebe, A.S. Damasceno, A.J. Bortoluzzia, A.J. Kirby, and F. Nome. J. Mol. Struct. **734**, 205 (2005); A.J. Kirby. Adv. Phys. Org. Chem. **29**, 87 (1994)), but have not been able to grow suitable crystals to confirm this prediction.

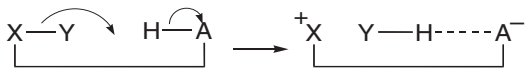
Scheme 5.



rived from **6** for which we find k_{H_2O}/k_{D_2O} = 1.72 ± 0.14.[7] This reaction involves a mechanism similar to k_z in Scheme 4, and the pK_a of the catalytic dimethylammonium group is also close to 7). The contribution to the solvent deuterium kinetic isotope effect from the in-flight proton of the general acid is small for reactions involving efficient intramolecular general acid catalysis because the transition state is typically early. (Perhaps also because the hydron transfer takes place within a hydrogen bond that is *strengthened* in the transition state, thus producing an inverse contribution to the overall observed isotope effect).[8]

The involvement (weak) of water as a nucleophile is not expected to contribute substantially to the observed solvent deuterium isotope effect, since k_{H_2O}/k_{D_2O} for the spontaneous hydrolysis of 4-nitrophenyl sulfate is only 1.26 (19). Thus, the kinetic parameters observed for the reaction of **2z** are consistent with the transition state shown in Scheme 5. The key to efficient catalysis is the strong intramolecular hydrogen bond, already present in the reactant state, stronger in the product naphthol **7**, and strongest in the transition state.

The key hydrogen bond

Phenomenologically, the key to efficient intramolecular general acid catalysis of X–Y cleavage (in the sense X^+Y^-) is the unique proton of a group HA, properly positioned and sufficiently acidic to form a strong hydrogen bond to the developing negative charge on Y^-.

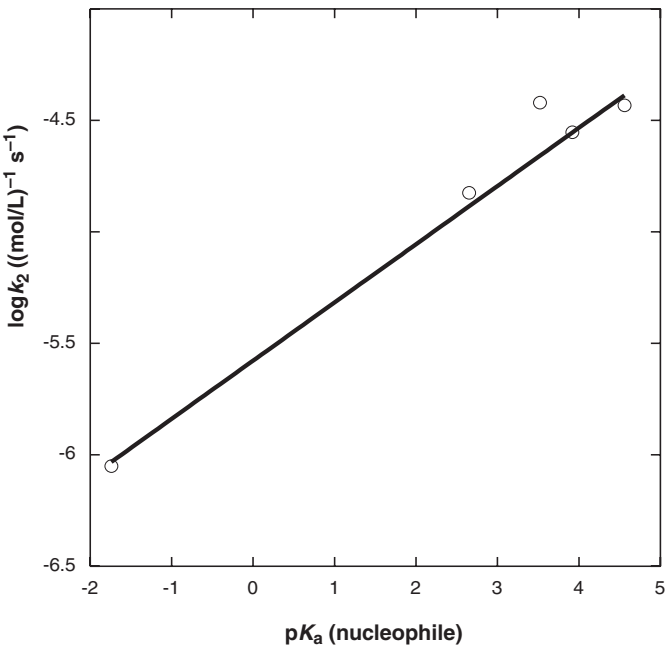
The simplest experimental indication of a strong intramolecular hydrogen bond in a given system is a substantial increase in the pK_a of the relevant group HY in the product, associated with a proton exchange rate markedly slower than diffusion-controlled. (The pK_a of the dimethylammonium group of **2z** (6.98 at 25 °C) is raised substantially compared to the value of 4.83 at 28 °C observed (22) for *N*,*N*-dimethylammonium-1-naphthalene. We attribute this effect primarily to a relatively strong N—H···O—SO_3^- hydrogen bond: any electrostatic stabilization must be minor because a greater enhancement (pK_a of Me_2NH^+ raised to 7.75) is observed in the corresponding N—H···OMe system (23)).

The requirement that the proton of the general acid be unique defines the acid HA as necessarily monobasic: a COOH group complies, NH_n^+ does not if $n > 1$. Thus, only *N*,*N*-dialkylammonium groups show efficient general acid catalysis and much enhanced pK_as in peri-naphthylammonium systems. The low efficiency of the imidazolium group of **5**, for example, is presumably a consequence of the availability of the second exchangeable proton of the general acid. We note that special arrangements in many enzyme active sites ensure that the distal NH(+) of catalytic histidine imidazoles is not in rapid exchange with the medium.

Reactions with nucleophiles

The attack of nucleophilic amines on the SO_3^- group has been studied by several authors. Attack on sulfur competes with attack on phosphorus for phenyl phosphosulfate (24) and PAPS (25), and with attack on carbon for 4-nitrophenyl sulfate (26). The data for attack on sulfur consistently show a low sensitivity to the basicity of the nucleophile, with β_{nuc} = 0.20 for the reactions with 4-nitrophenyl sulfate. There is no good evidence for attack by oxyanions, though 0.8 mol/L KF occasions a 65% rate increase (and 0.8 mol/L KI an 80% rate decrease) in the rate of hydrolysis at 35 °C. Similarly the rate of hydrolysis of 2,4-dinitrophenyl sulfate increases linearly with fluoride concentration, by up to 17% for 1 mol/L NaF at 45 °C (16).

The hydrolysis of **2z** is catalyzed by oxyanions in the plateau region, with rate enhancements of up to 78% in the presence of 1 mol/L of nucleophile (Table 3). The second-order rate constants depend on the basicity of the oxyanion, and the four points for water, acetate, and substituted acetates (see the next section) give a good Brønsted correlation, with β_{nuc} = 0.26 ± 0.01. This is larger than the value of β_{nuc} = 0.20 observed for the reactions of amines with (the less reactive) 4-nitrophenyl sulfate, and consistent with relatively weak bonding to the nucleophile in the transition state, which is nevertheless somewhat tighter for the intramolecular general-acid-catalyzed reaction. A comparable effect in the same direction (0.20 compared with 0.13 or less for the intermolecular reactions) is observed for the reactions with nucleophiles of the corresponding phosphate ester **6** (11).



There is good, though largely indirect, evidence that the reactions of **2z** with nucleophiles involve nucleophilic, rather than general base catalysis of hydrolysis. (And good reason to expect S—O rather than C—O cleavage. Aromatic nucleophilic substitution involving the displacement of sulfate dianion by weak carboxylate nucleophiles is not expected from the unactivated aromatic ring system of **2**. And it would be much more strongly sensitive to the basicity of the nucleophile (β_{nuc} is typically 0.7–0.8 (27, 28)) than observed for the reactions of **2z**).

1. General base catalysis has never been reported for the reactions of nucleophiles with simple SO_3^- systems. Reactions of amines with 4-nitrophenyl sulfate (19) show steric effects and entropies of activation typical of nucleophilic, bimolecular processes, typically low sensitivity to the basicity of the nucleophile, and no solvent deuterium isotope effects. All the evidence is consistent with nucleophilic catalysis, albeit with a weak involvement of the committed nucleophile in the transition state typical of SO_3 group transfers.

Fig. 2. Brønsted plot for the reactions of oxygen nucleophiles with **2z**. Data from Table 3. The least-squares line drawn is based on the four points for water and for acetate and substituted acetate anions (see the text).

2. The SO_3^- group of this system behaves *in detail* as expected for nucleophilic attack on a monoester $ROSO_3^-$ with a good leaving group.
3. Formate reacts faster than acetate with **2z**, showing a positive deviation from the Brønsted plot of Fig. 2; though from the observed Brønsted β of 0.26 formate should, other things being equal, and certainly for general base catalysis, react almost twice fast as acetate. This is not a unique observation: second-order rate constants for nucleophilic attack on PO_3^{2-} groups by acetate are generally smaller than for formate (11, 29), despite the higher basicity of acetate; so it is not unexpected that the same should apply to attack on the SO_3^- group. This behaviour can be understood in terms of a combination of steric and electrostatic effects, as follows: (*a*) There is no significant difference in basicity, and thus in intrinsic nucleophilic reactivity between the E and Z lone pairs of the carboxylate group (Scheme 6) (30). (*b*) If attack on PO_3^{2-} or SO_3^- involves a Z lone pair (**A** in Scheme 6) any steric effect of the acyl substituent R′ will be negligible, but the second O^- will inevitably come into close proximity to the negatively charged oxygens of the substrate phosphate or sulfate group. (*c*) The consequent repulsive electrostatic effect is avoided if reaction involves the E lone pair (**B** in Scheme 6), but then the steric requirements of the acyl substituent come into play. (*d*) Steric effects decrease in the order R′ > O^- > H. The balance of effects is evidently such that only formate reacts predominantly in mode **B**, and for this reason we have used only the points for water and for acetate and substituted acetate anions to calculate the Brønsted β for the reaction of **2z** (Fig. 2). For nucleophilic attack on neutral, e.g., C=O or alkyl carbon centres, no such electrostatic effect is involved, and acetate generally reacts faster as a nucleophile. These effects do not apply to general base catalysis for which acetate is reliably more reactive.

Scheme 6.

Thus, the evidence is strong that the reactions of **2z** with oxygen nucleophiles involve nucleophilic rather than general base catalysis. It is not, however, sufficient to rule out completely the possibility of a minor contribution from the latter mechanism.

Implications

This work is relevant to sulfate transfer in the context of enzyme evolution. In some cases, phosphatases and sulfatases belong to the same structural superfamily (31, 32) and some have been shown to be catalytically promiscuous. For example, *Escherichia coli* alkaline phosphatase also catalyses sulfate transfer at a measurable rate (33). Though some 10^{10} times slower (in terms of k_{cat}/K_M) than the native reaction, this corresponds to a rate enhancement of 10^9 compared to background for the promiscuous activity. Similarly, we find that arylsulfatase A has promiscuous phosphatase activity, with a rate acceleration $>10^{12}$ over background.[9] Duplication of a gene encoding a bifunctional catalyst could provide a modest advantage of the new activity, to be increased by further selection for higher promiscuous activity of the second gene copy. If catalytic promiscuity is a key to evolution (34–38), then catalytic "crossover" features, such as the effect of a properly positioned general acid on a family of reactions, are logical stepping stones in the process of molecular evolution of catalysis.

Dynamics of the transient species generated upon photolysis of diarylmethanes within zeolites — Deprotonation and oxidation reactions[1]

Suzanne Shea, Norman P. Schepp, Amy E. Keirstead, and Frances L. Cozens

Abstract: The oxidation of diarylmethanes is a multistep process involving initial formation of a radical cation, deprotonation of the radical cation to the radical, and oxidation of the radical to the carbocation. The dynamics and efficiency of the last two steps in this process, namely deprotonation and oxidation, in acidic zeolites and non-acid zeolites are examined in the present work as a function of the acidity of the diarylmethane radical cations and the oxidation potential of the diarylmethyl radicals. Our results indicate that rate constants for deprotonation strongly depend on the acidity of the radical cations, but not on the composition of the zeolites. In addition, oxidation of the radicals to the diarylmethyl cations is strongly dependent on both the oxidation potential of the radicals and the oxidizing ability of the zeolite. This dependence allows oxidation potentials of the zeolites to be estimated.

Key words: radical cations, carbocations, zeolites, laser flash photolysis.

Résumé : L'oxydation de diarylméthanes est un processus en plusieurs étapes qui implique la formation initiale d'un cation radical, une déprotonation du cation radical et une oxydation du radical en carbocation. On a étudié la dynamique et l'efficacité des deux dernières étapes de ce processus, soit la déprotonation et l'oxydation, dans des zéolites acides et des zéolites non acides, en fonction de l'acidité des cations radicaux diarylméthanes et du potentiel d'oxydation des radicaux diarylméthyles. Les résultats obtenus indiquent que les constantes de vitesse pour la déprotonation dépendent fortement de l'acidité des cations radicaux, mais pas sur la composition des zéolites. De plus, l'oxydation des radicaux en cations diarylméthyles est fortement dépendante à la fois sur le potentiel d'oxydation des radicaux et sur l'habilité des zéolites à oxyder. Cette dépendance permet d'évaluer les potentiels d'oxydation des zéolites.

Mots clés : cations radicaux, carbocations, zéolites, photolyse éclair au laser.

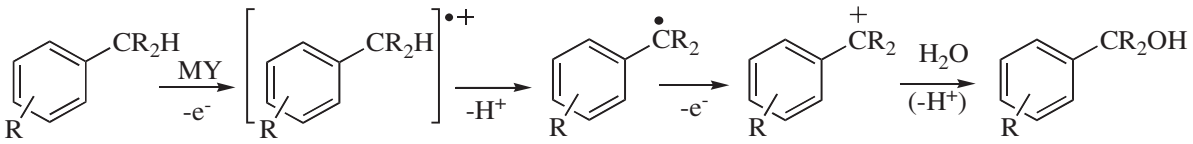
Introduction

Zeolites are crystalline aluminosilicate materials comprised of SiO_4 and AlO_4^- tetrahedra that are arranged in a three-dimensional array to form an open framework structure that consists of pores and channels whose size and shape vary widely (1–6). The presence of tetravalent aluminum gives rise to a net negative charge in the backbone, which must be balanced with a charge-balancing cation, typically alkali metals or protons. While the void cavities and channels of the zeolite are capable of accommodating molecular guests, zeolites are not simply inert vessels, but have been shown to participate as electron donors and acceptors in both thermal (7, 8) and photoinduced (9–14) electron transfer reactions. The high density of negative charge on the zeolite framework is thought to provide an environment well-suited for the generation of positively charged species and in fact, carbocations can be thermally generated within proton-exchanged zeolites (15). The redox properties of the zeolite are highly dependent on the nature of the charge-balancing cations (16), and it has been shown that proton-exchanged zeolites are much more powerful oxidizing agents than alkali cation-exchanged zeolites (17). These acidic solids have been the subject of extensive research because of their catalytic ability and wide use as industrial catalysts, particularly for the refinement of petroleum products (4, 18, 19).



Zeolites have been shown to be good hosts for the study of cationic intermediates because of the stabilization provided by the internal electrostatic fields within the voids of the microporous solids and also by the confined environment, which provides protection of the cationic center from

nucleophilic species (11, 20, 21). When a positively charged species is encapsulated within these solids, the whole lattice of the zeolite can act as a counteranion, insulating and protecting the carbocation from attack by external nucleophiles. This stabilization has been found to be dramatic in many cases in which the tight fit between the organic guest and the zeolite occurs (22). These characteristics, combined with the wide range of crystalline structures available and the ability to tailor the zeolite to the reaction of interest, have made zeolites the host of choice for many studies of organic cations (9, 17, 23). Organic radical cations formed within the zeolite framework have also been the subject of much interest. Photoionization reactions leading to radical cation formation have been shown to be easily carried out within zeolite frameworks, making zeolites convenient host materials to study the photoinduced formation of radical cations (10, 21).

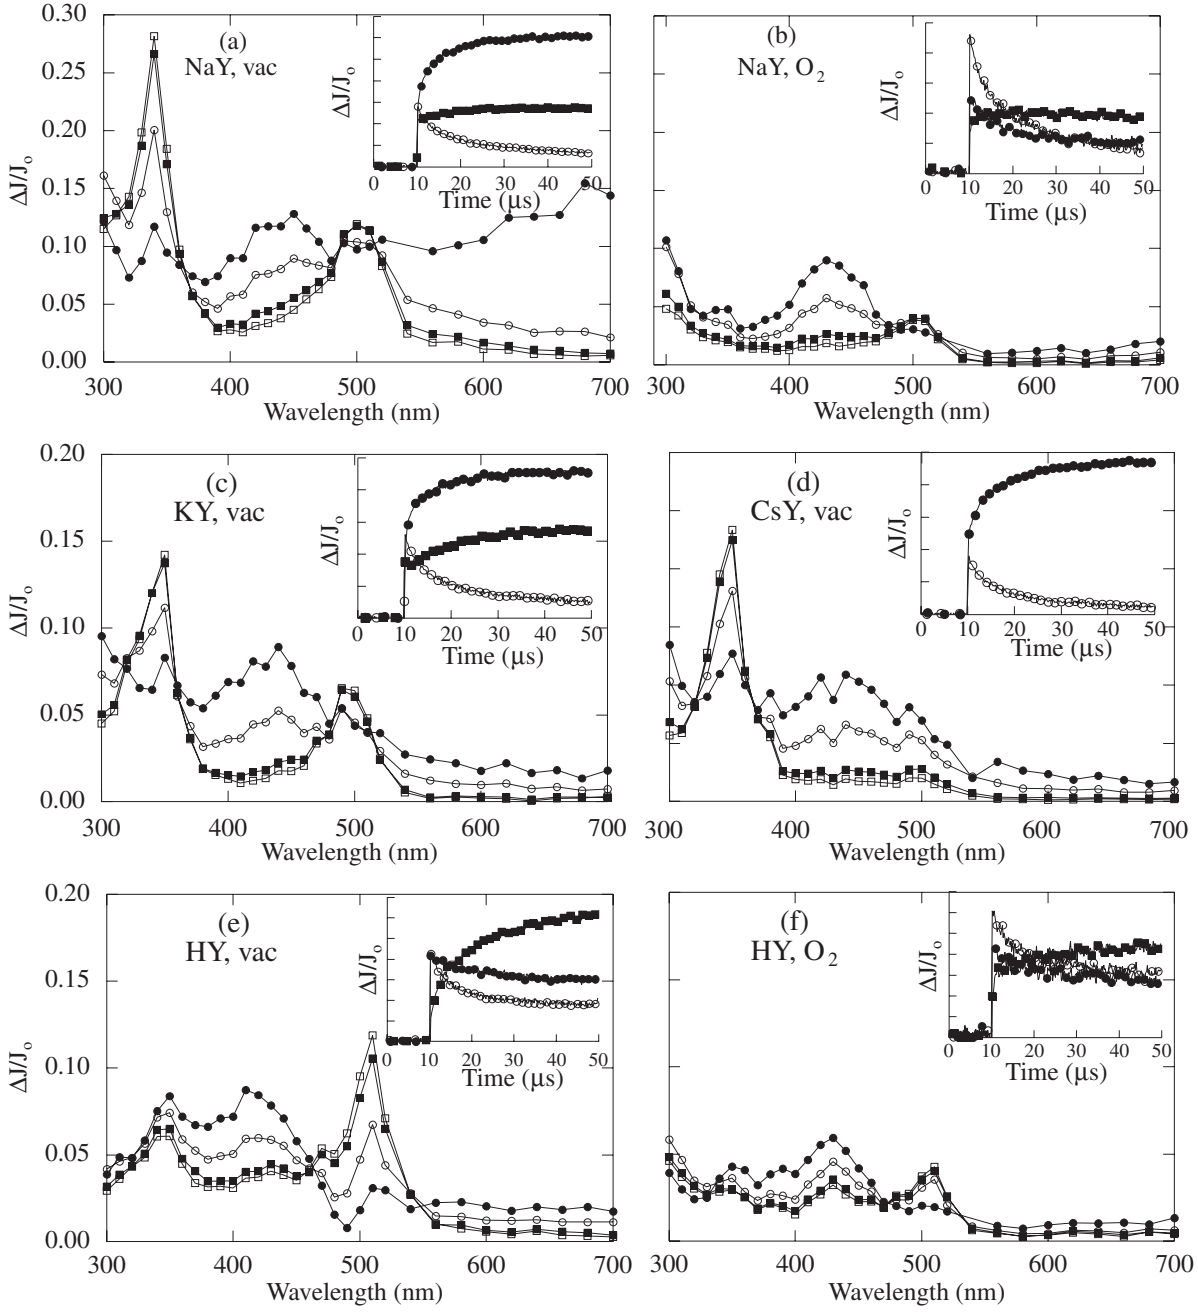
It has long been known that arylmethanes can be oxidized when incorporated into acidic zeolites (17, 24, 25). The mechanism for this reaction is thought to involve initial one-electron oxidation to the arylmethane radical cation that then deprotonates to yield the corresponding arylmethyl radical. A second one-electron oxidation can occur to convert the radical to the carbocation, which is then trapped by water to give the arylmethyl alcohol (eq. [1]).

While several studies have appeared concerning the identification of radical cations and carbocations upon incorporation of arylmethane derivatives in acidic zeolites (26–28), little is known about the absolute kinetics of the individual reactions involved in the overall oxidation process. In addition, quantitative information regarding the effect of the acidity of the arylmethane radical cations and the oxidation potential of the arylmethyl radicals on the dynamics of these processes is not currently available. In the present work, we examine the intrazeolite behaviour of a series of diarylmethanes incorporated into both proton-exchanged (HY) and alkali cation-exchanged (NaY, KY, CsY) zeolites. Our results show that the dynamics of the deprotonation of the diarylmethane radical cations to diarylmethyl radicals strongly depends on radical cation acidity, and that oxidation of the diarylmethyl radicals to the corresponding diarylmethyl cations depends both on the oxidation potential of the radical and the oxidizing ability of the zeolite.

Results

Dianisylmethane (An_2CH_2) in NaY, KY, CsY, and HY

Laser flash photolysis (266 nm) of dianisylmethane in NaY under vacuum conditions resulted in the transient diffuse reflectance spectra shown in Fig. 1*a*. These spectra show the presence of absorption at 450 nm formed promptly within the laser pulse. With a time resolution of ca. 100 ns for the diffuse reflectance laser system, prompt formation of the band at 450 nm indicates that it was generated with a rate constant $>10^7$ s^{-1}. The band at 450 nm was not stable and decayed close to baseline (inset, Fig. 1*a*) over the 40 μs timescale of the experiment. Nonlinear least-squares analysis using a first-order rate expression[4] gave a rate constant ($k = 1.2 \times 10^5$ s^{-1}) for the decay of the 450 nm band. After saturation of the zeolite with molecular oxygen, the band at 450 nm was still observed (Fig. 1*b*) and its decay remained unchanged. In solution, the dianisylmethane radical cation ($An_2CH_2^{\cdot+}$) is known to have an absorption maximum at 450 nm and to be unaffected by oxygen (29, 30). Thus, the transient at 450 nm is assigned to $An_2CH_2^{\cdot+}$ (eq. [2], $R_1 = R_2 = OCH_3$).



The radical cation is presumably formed by rapid photoionization of the incorporated dianisylmethane. Consistent with this mechanism is the observation of short-lived Na_3^{2+} clusters at wavelengths greater than 510 nm (Fig. 1*a*) produced when electrons are trapped by the counterbalancing sodium cations (10, 13, 31–33).

As $An_2CH_2^{\cdot+}$ decayed, a new transient species with a sharp absorption band at 340 nm grew in with a rate constant of 1.4×10^5 s^{-1}. Under vacuum conditions the transient responsible for this absorption did not decay over the timescale of the experiment, while the transient had a very short lifetime in the presence of oxygen (Fig. 1*b*). This transient is attributed to the dianisylmethyl radical ($An_2CH\cdot$), which in solution is known to have an absorption maximum at 340 nm (34) and to react rapidly with oxygen. Radical formation likely occurs by deprotonation (vide infra) of the initially

Fig. 1. Transient diffuse reflectance spectra recorded 400 ns (●), 4.00 μs (○), 18.8 μs (■), and 32.0 μs (□) after 266 nm laser flash photolysis of An_2CH_2 in: (*a*) NaY under vacuum conditions; (*b*) NaY under oxygen conditions; (*c*) KY under vacuum conditions; (*d*) CsY under vacuum conditions; (*e*) HY under vacuum conditions; and (*f*) HY under oxygen conditions. Insets show kinetic traces collected at 340 nm (●), 440 nm (○), and 500 nm (■).

formed radical cation (eq. [2]), which is typically the dominant reaction of the $An_2CH_2^{\cdot+}$ in solution (29, 30). This mechanism for radical formation is supported by the similarity between the rate constants for the decay of $An_2CH_2^{\cdot+}$ at 450 nm (1.2×10^5 s^{-1}) and the growth of the radical at 340 nm (1.4×10^5 s^{-1}).

Close examination of the spectral data in Fig. 1*a* also shows some prompt absorption at 340 nm due to $An_2CH\cdot$ prior to the time-resolved growth. Thus, while most of the radicals were formed in a time-resolved manner after the laser pulse, a small fraction were generated more rapidly within the laser pulse with a rate constant $>10^7$ s^{-1}.

A fourth transient species with strong absorption at 500 nm is also present in the spectra in Fig. 1*a*. This transient was long-lived and did not decay under both vacuum and oxygen-saturated conditions over the longest timescale available on our laser system (10 ms). The location of the absorption band and the lack of sensitivity toward oxygen are consistent with the identification of the 500 nm transient as the dianisylmethyl cation (An_2CH^+) (34).

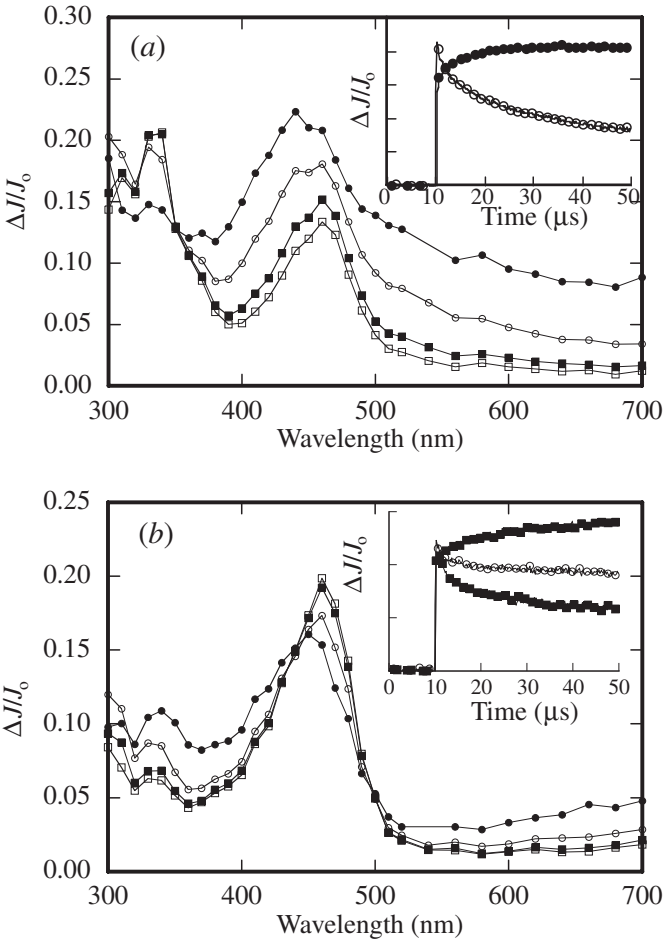
Like $An_2CH\cdot$, whose formation had a small prompt component and a larger time-resolved component, the formation of An_2CH^+ under vacuum conditions took place over two different time regimes. In this case, An_2CH^+ was mostly formed promptly within the laser pulse with a rate constant $>10^7$ s^{-1}, with the time-resolved component being comparatively small. The rate constant for the growth was measured to be 1.5×10^5 s^{-1}, which is similar to the rate constant for the decay of $An_2CH_2^{\cdot+}$. Under oxygen, both the prompt and time-resolved components of carbocation formation were still readily observable, but with substantially reduced intensity.

The results obtained upon laser flash photolysis of dianisylmethane in KY under vacuum conditions (Fig. 1*c*) were similar to those obtained for zeolite NaY. $An_2CH_2^{\cdot+}$ with absorption at 450 nm was formed promptly within the laser pulse and then decayed with a rate constant of 1.3×10^5 s^{-1}. Concomitant with this decay was a growth ($k = 1.4 \times 10^5$ s^{-1}) at 350 nm attributed to the formation of $An_2CH\cdot$. The long-lived An_2CH^+ was also observed at 500 nm and exhibited both prompt formation and a small amount of time-resolved growth ($k = 0.9 \times 10^5$ s^{-1}), similar to that seen in zeolite NaY.

In CsY, both $An_2CH_2^{\cdot+}$ and $An_2CH\cdot$ were again observed (Fig. 1*d*). The decay of the radical cation and the growth of the radical took place with similar rate constants of 1.4×10^5 s^{-1}. However, in this case, no distinct absorption at 500 nm was evident, indicating that An_2CH^+ was not generated in this zeolite.



In the acidic zeolite HY, laser irradiation of dianisylmethane under hydrated vacuum conditions led to the formation of $An_2CH_2^{\cdot+}$ (Fig. 1*e*), which decayed with a rate constant of 1.2×10^5 s^{-1} that is similar to the rate constants previously measured in the alkali metal-exchanged Y zeolites. The decay of $An_2CH_2^{\cdot+}$ did not lead to a significant buildup of the radical $An_2CH\cdot$ at 350 nm. Instead, absorption at 510 nm owing to An_2CH^+ grew in with a rate constant of 0.9×10^5 s^{-1}. Some $An_2CH\cdot$ was formed promptly within the laser pulse. The radical was unusually reactive in HY and decayed with a rate constant of 1.1×10^5 s^{-1}, similar to the decay of $An_2CH_2^{\cdot+}$ and the growth of An_2CH^+.

The addition of oxygen to the dianisylmethane–HY composite did not significantly alter the transient diffuse reflectance spectra (Fig. 1*f*), which again showed $An_2CH_2^{\cdot+}$ decaying to give An_2CH^+ at 510 nm. The rate constants for decay of the radical cation and growth of the carbocation were not influenced by the presence of oxygen; however, the amount of An_2CH^+ formed was reduced to approximately half that observed under vacuum conditions.

Anisylphenylmethane ($AnPhCH_2$) in NaY, KY, CsY, and HY

The transient diffuse reflectance spectra obtained upon 266 nm laser irradiation of $AnPhCH_2$ in NaY under vacuum conditions showed the prompt formation of a transient with strong absorption at 440 nm (Fig. 2*a*) assigned to the anisylphenylmethane radical cation ($AnPhCH_2^{\cdot+}$) (29). The radical cation was not stable, but its decay was difficult to quantify because of the presence of residual absorption at 460 nm (vide infra) that also decayed slowly over the timescale of the experiment, as well as the presence of absorption due to Na^+-electron complexes. Analysis of the decay at 440 nm

Fig. 2. Transient diffuse reflectance spectra recorded 400 ns (●), 4.00 μs (○), 18.8 μs (■), and 32.0 μs (□) after 266 nm laser flash photolysis of $AnPhCH_2$ in: (*a*) NaY under vacuum conditions; and (*b*) HY under vacuum conditions. Insets show kinetic traces collected at 340 nm (●), 430 nm (○), and 460 nm (■).

was therefore carried out using a double first-order expression that led to a rate constant of 1.4×10^5 s^{-1} for the decay of $AnPhCH_2^{\cdot+}$. The spectra also feature an absorption band at 340 nm due to the anisylphenylmethyl radical ($AnPhCH\cdot$) (29, 34). The radical grew in with a rate constant of 1.8×10^5 s^{-1}. This is similar to the rate constant for the decay of $AnPhCH_2^{\cdot+}$, indicating that the radical was formed by deprotonation of $AnPhCH_2^{\cdot+}$ (eq. [2], $R_1 = H$, $R_2 = OCH_3$). Significant absorption was present at 340 nm immediately after the laser pulse. Thus, some prompt radical formation did occur prior to the time-resolved component.

After complete decay of $AnPhCH_2^{\cdot+}$, considerable absorption remained with a maximum at 460 nm. This matches well with the absorption spectrum of the anisylphenylmethyl cation ($AnPhCH^+$) (29). Due to the overlap in absorption of $AnPhCH_2^{\cdot+}$ and $AnPhCH^+$, it is difficult to determine if $AnPhCH^+$ was generated promptly within the laser pulse, or if its formation followed the decay of $AnPhCH_2^{\cdot+}$. Significant prompt formation likely did occur, as suggested by the shoulder at 460 nm in the diffuse reflectance spectrum recorded immediately after the laser pulse (Fig. 2*a*). The addition of oxygen to the sample did not significantly affect the

© 2005 NRC Canada

decay of the band at 440 nm, but the relative amount of residual absorption at 460 nm was reduced (see Supplemental material).[5] Absorption due to AnPhCH· at 340 nm was quenched upon addition of oxygen to the sample, which is consistent with the known reactivity of carbon-centered radicals.

Results similar to those described were obtained upon laser photolysis of $AnPhCH_2$ in both KY and CsY under vacuum conditions. The transient diffuse reflectance spectra again featured absorption of $AnPhCH_2^{\cdot+}$ that decayed on the timescale of the experiment and a band at 340 nm owing to AnPhCH· that exhibited a time-resolved growth. The rate constants for the decay of $AnPhCH_2^{\cdot+}$ and the growth of AnPhCH· in both KY and CsY were very similar (Table 1). The only major difference in the results obtained in these two zeolites was that substantial absorption at 460 nm due to the $AnPhCH^+$ was observed after the decay of $AnPhCH_2^{\cdot+}$ in KY, while $AnPhCH_2^{\cdot+}$ decayed to the baseline in CsY. Thus, $AnPhCH^+$ was generated in KY, but not in CsY.

In the acidic zeolite HY under hydrated vacuum conditions, the spectrum immediately after the laser pulse consisted of a strong band at 450 nm and a weaker band 340 nm (Fig. 2*b*). The band at 340 nm was quenched by oxygen and can be attributed to AnPhCH·. However, unlike the situation in the non-acidic zeolites where both prompt and time-resolved components were observed for the formation of AnPhCH·, only the prompt component was observed in HY. In addition, AnPhCH· was not stable in HY and decayed with a rate constant of 1.2×10^5 s^{-1}.

The absorption band at 450 nm did not decay, but instead increased in intensity as a function of time with a rate constant of 0.9×10^5 s^{-1} and shifted to 460 nm. These results indicate that both $AnPhCH_2^{\cdot+}$ and $AnPhCH^+$ were formed promptly within the laser pulse to give a composite band with a maximum at 450 nm. The small decrease in absorption at 420 nm on the side of the initially formed 450 nm composite band was presumably due to the decay of $AnPhCH_2^{\cdot+}$. The time-resolved increase leading to the final spectrum with a maximum at 460 nm is consistent with an additional time-resolved component for the formation of $AnPhCH^+$.

Upon the addition of oxygen to the sample, the absorption spectrum immediately after the laser pulse showed a strong band at 450 nm due to $AnPhCH^+$. A distinct shoulder at 410–430 nm was also evident, presumably because of $AnPhCH_2^{\cdot+}$. Under these conditions, there was no time-resolved growth of the carbocation at 450 nm; only a small decay due to the disappearance of $AnPhCH_2^{\cdot+}$ was observed.

Ditolylmethane (Tol_2CH_2) in NaY, KY, CsY, and HY

The transient diffuse reflectance spectra obtained upon laser irradiation of ditolylmethane in NaY under vacuum conditions (Fig. 3*a*) clearly show a sharp absorption band at 340 nm formed promptly within the laser pulse. This transient species, which reacted rapidly with oxygen, can be identified as the ditolylmethyl radical (Tol_2CH·) (34).

The ditolylmethane radical cation ($Tol_2CH_2^{\cdot+}$) has not been observed in solution, but its absorption spectrum should be similar to the 1,4-dimethylbenzene radical cation, which has a weak absorption band at 450 nm together with a stronger band at 305 nm in acetonitrile (35). A broad absorption centered at 460 nm is evident in Fig. 3*a*. However, this band is not likely due to the formation of $Tol_2CH_2^{\cdot+}$. In particular, the decay at 460 nm did not lead to the formation of the radical at 340 nm as would be expected if the band at 460 nm was due to $Tol_2CH_2^{\cdot+}$. In addition, the absorption band at 460 nm changed under oxygen conditions to give a transient with a narrow absorption band at 470 nm. The location and shape of this band is not consistent with the known spectrum of the $Tol_2CH_2^{\cdot+}$, but does agree well with the presence of the ditolylmethyl cation (Tol_2CH^+) (34). Thus, the broad absorption at 460 nm under vacuum conditions is most likely due to prompt formation of Tol_2CH^+, together with an oxygen sensitive transient such as sodium clusters (21) or the triplet excited state of ditolylmethane, which has broad absorption from 330 to 530 nm (36, 37). The inability to detect $Tol_2CH_2^{\cdot+}$ suggests that it is very unstable in NaY and undergoes deprotonation within the duration of the laser pulse to rapidly generate Tol_2CH·.

The absence of absorption due to $Tol_2CH_2^{\cdot+}$ was also evident in the spectra generated upon irradiation of ditolylmethane in KY. Only prompt formation of a sharp band at 340 nm owing to Tol_2CH· was observed, together with broad absorption due to trapped electrons or triplet ditolylmethane. In this zeolite, no substantial absorption due to Tol_2CH^+ at 470 nm was apparent. Thus, Tol_2CH^+ was not generated in KY. Results obtained in CsY were very similar to those in KY: only the prompt formation of Tol_2CH· was observed, with no evidence for the presence of $Tol_2CH_2^{\cdot+}$ or the formation of Tol_2CH^+.

Both Tol_2CH· and Tol_2CH^+ were readily observed upon laser irradiation of Tol_2CH_2 in HY (Fig. 3*b*). The absorption at 470 nm due to Tol_2CH^+ under vacuum conditions consisted of a large prompt component as well as a small time-resolved component. The rate constant for this delayed component was determined to be 0.9×10^5 s^{-1}. Tol_2CH· absorption at 340 nm was completely formed promptly within the laser pulse, with no time-resolved growth component. The radical was long-lived, but did show some decay over the timescale of the experiment. This decay could not be reliably analyzed because of the large residual absorption remaining 40 μs after the laser pulse. The time-resolved component of Tol_2CH^+ formation, together with absorption due to Tol_2CH·, was quenched under oxygen-saturated conditions, but prompt carbocation formation was still observed.

Diphenylmethane (Ph_2CH_2) in NaY, KY, CsY, and HY

The time-resolved diffuse reflectance spectra obtained upon laser flash photolysis (266 nm) of diphenylmethane in each of the four zeolites (NaY, KY, CsY, and HY) under vacuum conditions showed a strong absorption band centered at 330 nm (Figs. 4*a* (NaY) and 4*b* (HY)) because of the forma-

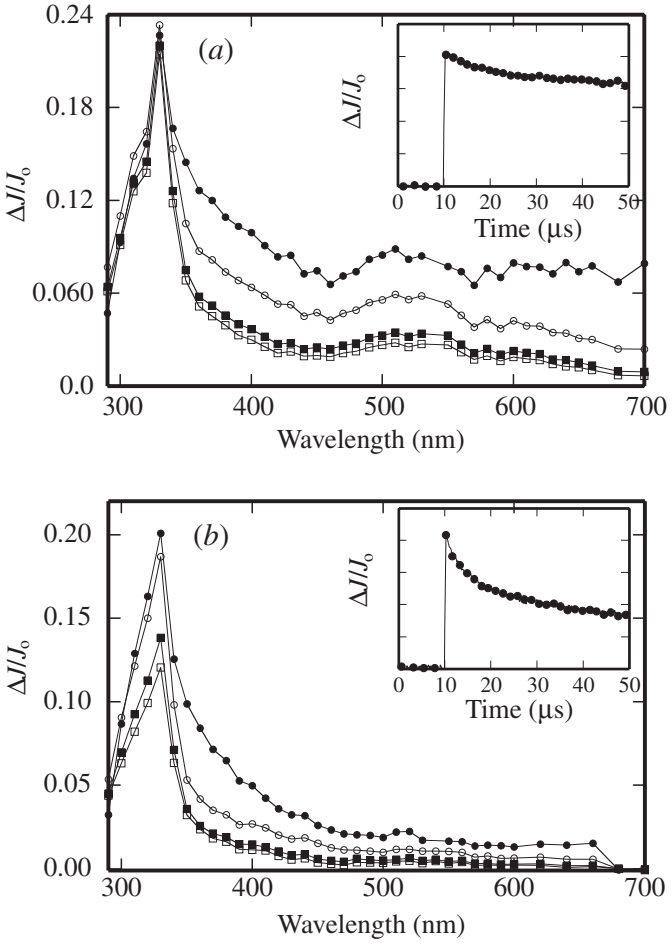
Note: Not observed (not obs.) and no growth (no gr.)
[a]Errors in the fitted data are typically small (±1%). However, due to the challenges associated with preparing zeolite samples in a reproducible manner, actual errors are closer to ±10%.
[b]All measurements were made at room temperature (22 ± 1 °C).
[c]Transient not observed.
[d]Transient formed promptly with no subsequent time-resolved growth.
[e]Time-resolved data obscured because of overlapping C^{+}/RC^{+} absorption bands.

Fig. 3. Transient diffuse reflectance spectra recorded 400 ns (●), 4.00 μs (○), 18.8 μs (■), and 32.0 μs (□) after 266 nm laser flash photolysis of Tol_2CH_2 in: (*a*) NaY under vacuum conditions; and (*b*) HY under vacuum conditions. Insets show kinetic traces collected at 340 nm (●) and 470 nm (■).

tion of the diphenylmethyl radical (Ph_2CH·) (34, 38). No absorption due to $Ph_2CH_2^{\cdot+}$ or Ph_2CH^{+} was evident in any of the four zeolites examined.

The transient diffuse reflectance spectra obtained in NaY and KY did include broad absorption stretching from ca. 400 to 700 nm that can be attributed to trapped electrons. In addition, an unexpected transient with absorption at 530 nm was observed in both KY and CsY. The transient species responsible for this absorption was quenched by oxygen. The absorption at 530 nm is not consistent with the presence of the diphenylmethane radical cation (λ_{max} for toluene radical cation ≈ 430 nm) (35) or the diphenylmethyl cation (λ_{max} = 435 nm) (34), but may be due to the diphenylmethane radical anion (λ_{max} = 530 nm) (39) generated by trapping of a photoionized electron by diphenylmethane, or by direct electron transfer from the framework to excited diphenylmethane.



Discussion

Generation and deprotonation of diarylmethane radical cations

It is well-established that radical cations of organic mate-

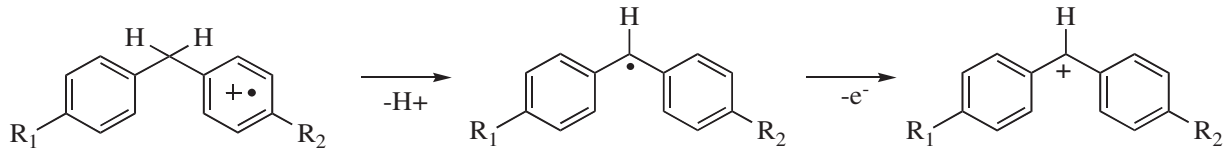
Fig. 4. Transient diffuse reflectance spectra recorded 400 ns (●), 4.00 μs (○), 18.8 μs (■), and 32.0 μs (□) after 266 nm laser flash photolysis of Ph_2CH_2 in: (*a*) NaY under vacuum conditions; and (*b*) HY under vacuum conditions. Insets show kinetic traces collected at 340 nm (●).

rials incorporated within zeolites can be generated by direct irradiation of the precursor with the zeolite framework acting as the electron acceptor (10, 21). The results obtained in the present work provide either direct or indirect evidence that each of the four diarylmethanes do undergo photoionization within the cation-exchanged Y-zeolites. For An_2CH_2 and $AnPhCH_2$, direct evidence supporting photoionization comes from the observation of the absorption bands associated with their radical cations. For Tol_2CH_2 and Ph_2CH_2, the radical cations were not observed. However, prompt formation of the corresponding diarylmethyl radicals was observed, and the presence of these species can most reasonably be explained by initial formation of short-lived radical cations generated by photoionization of the neutral precursors, followed by rapid deprotonation ($>10^7$ s^{-1}) within the time duration of the laser pulse.

Diarylmethyl radicals were also observed upon direct 266 nm irradiation of An_2CH_2 and $AnPhCH_2$, but with these two substrates, most of the observed radicals were formed in a time-resolved manner with rate constants that ranged from 1.3×10^5 to 1.8×10^5 s^{-1} in NaY, KY, and CsY. These rate constants quite closely matched the rate constants for the decay of the radical cations, which provides good evidence that radical generation occurred by deprotonation of the radical cations. Some prompt formation of $An_2CH\cdot$ and $AnPhCH\cdot$ was observed upon irradiation of An_2CH_2 and $AnPhCH_2$ in the alkali-metal-exchanged zeolites. This suggests that radical cations generated by photoionization exist in at least two sites within the zeolites that exhibit considerably different deprotonation abilities (40, 41). One of these sites induces rapid deprotonation that leads to prompt radical growth, while the other induces a slower deprotonation.

It has previously been demonstrated that rate constants for deprotonation of arylmethyl radical cations in solution inversely correlate with thermodynamic stability of the radical cations (29). Thus, stabilized arylmethyl radical cations, such as those bearing electron-donating methoxy groups on the aromatic ring, undergo deprotonation reactions more slowly than nonstabilized radical cations. The relatively slow deprotonation recorded in the present work for $An_2CH_2^{\cdot+}$ and $AnPhCH_2^{\cdot+}$ radical cations compared to the fast deprotonation for $Tol_2CH_2^{\cdot+}$ and $Ph_2CH_2^{\cdot+}$ therefore agree well with expectations based on the relative stability of these radical cations.



The absolute rate constants for the deprotonation reaction can in some cases be compared with those measured in solution. In particular, the rate constant for the conversion of $An_2CH_2^{\cdot+}$ to the dianisylmethyl radical in acetonitrile is approximately 2.5×10^5 s^{-1} (29), a value that is slightly greater than the rate constant of 1.1×10^5 s^{-1} in NaY. While competing processes may contribute to the decay of the radical cation, the differences in the rate constants from solution to NaY suggest that deprotonation in NaY is somewhat slower than in acetonitrile. It has also been demonstrated that the lifetime of $An_2CH_2^{\cdot+}$ in acetonitrile is very similar to the lifetime of $AnPhCH_2^{\cdot+}$ (29). The small difference measured in the present work between the decays of these two radical cations in zeolites is thus consistent with results obtained in solution.

While rate constants for the deprotonation of Tol_2CH_2 and Ph_2CH_2 radical cations have not been measured, previous results (42) have shown that the 1,4-dimethylbenzene radical cation is almost four orders of magnitude more reactive than the 4-methylanisole radical cation. Thus, replacing a methoxy group with a methyl group greatly decreases the lifetime of the radical cation. This is consistent with our inability to observe neither the ditolylmethane nor the diphenylmethane radical cations in the present work.

For $An_2CH_2^{\cdot+}$ and $AnPhCH_2^{\cdot+}$, which could be observed in all of the zeolites, the nature of the counterbalancing cation had little influence on the rate constant for the conversion of the radical cation to the radical. Thus, the increased Brønsted basicity associated with zeolites (11) as the counterion is changed from Na^+ to Cs^+ is not manifested in the radical cation decay kinetics, despite the evidence that deprotonation of the radical cations is a significant process.

In the strongly acidic HY zeolite, the diarylmethyl radicals that would be formed by deprotonation of diarylmethane radical cations should rapidly reprotonate, thus effectively shifting the radical cation – radical acid–base equilibrium to the radical cation side. Under these circumstances, the radical cations would be expected to have considerably longer lifetimes in HY compared with the nonacidic zeolites. Instead, $An_2CH_2^{\cdot+}$ decayed in HY with a rate

© 2005 NRC Canada

[3] 

constant that was very similar to its decay in the non-acidic alkali-metal-exchanged zeolites. Furthermore, no increase in the lifetimes of $Tol_2CH_2^{\cdot+}$ and $Ph_2CH_2^{\cdot+}$ was evident in HY, as these radical cations were still too short lived to be observed. The continued rapid decay of these radical cations, particularly in the case of $An_2CH_2^{\cdot+}$, is likely due to rapid oxidation of the diarylmethyl radicals in HY, which does not allow reprotonation of the radical to take place. This is discussed in further detail in the following.

Diarylmethyl cation formation

To discuss the mechanism for carbocation formation, it is useful to first summarize some relevant results and establish some revealing trends. First, in evacuated zeolites, formation of the diarylmethyl cations took place over one or two distinct time regimes, depending on the identity of the counterion and the structure of the substrate. A substantial fraction of An_2CH^+ in NaY and KY was formed promptly within the laser pulse with a rate constant $>10^7$ s^{-1}, and a smaller fraction was generated more slowly with rate constants similar to those for the decay of the radical cation and the growth of the radical. In HY, only time-resolved formation of An_2CH^+ was observed, while this carbocation was not detected in CsY. For $AnPhCH^+$, overlapping absorption of the radical cation and the carbocation made it difficult to evaluate the fraction of carbocation derived from prompt and time-resolved processes, but time-resolved formation was distinctly observed in HY. Only prompt formation of Tol_2CH^+ was observed in NaY, but a small amount of time-resolved formation was present in HY. No carbocation was observed upon irradiation of Ph_2CH_2 in any of the zeolites. Since the diphenylmethyl cation generated by other means is quite long-lived in HY (41), its absence upon irradiation of Ph_2CH_2 in HY in the present experiments suggests that it is not formed.

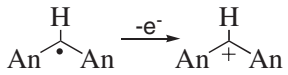
The results outlined above reveal several important trends about the conditions needed for delayed formation of the carbocations. First, in the non-acidic zeolites, only the most stable carbocation (An_2CH^+) showed time-resolved formation. In addition, this delayed formation of An_2CH^+ was observed in NaY and KY, but not in CsY. In the acidic HY, three carbocations (An_2CH^+, $AnPhCH^+$, and Tol_2CH^+) showed delayed formation, but the efficiency decreased upon going from the more stable An_2CH^+ to the less stable Tol_2CH^+. Thus, *these trends show that the presence of delayed carbocation formation depends both on the stability of the carbocation and the nature of the counterion.*

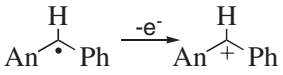
Trends concerning prompt carbocation formation can also be extracted from the results described above. Prompt carbocation formation was observed in NaY for An_2CH^+ and Tol_2CH^+ (and likely $AnPhCH^+$), but not for the less stable Ph_2CH^+. However, in KY only An_2CH^+ and $AnPhCH^+$ showed evidence for prompt carbocation formation. Thus, *prompt carbocation formation also depends both on the stability of the carbocation and the nature of the counterion.*

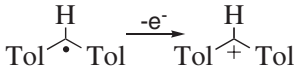
Second, under oxygenated conditions, the time-resolved growth of An_2CH^+ was almost completely quenched in NaY, and was considerably reduced in HY. Similarly, the delayed growth of $AnPhCH^+$ and Tol_2CH^+ observed in evacuated HY was no longer present under oxygen-saturated conditions. In addition, while prompt formation of An_2CH^+, $AnPhCH^+$, and Tol_2CH^+ in NaY continued to be observed in the presence of oxygen, there was a general reduction in intensity compared with non-oxygenated conditions. Thus, since carbocations themselves are not directly influenced by the presence of oxygen, *the quenching effect of oxygen strongly suggests that the precursor to the carbocation is a species such as a radical or triplet that is reactive toward oxygen.*

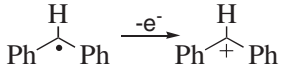
One mechanism for carbocation formation that agrees well with many of the trends and observations previously outlined involves zeolite-induced oxidation of the radical generated upon deprotonation of the diarylmethane radical cations (eq. [3]).

This mechanism is nicely consistent with the effect of changing counterion and substrate structure on the yield of the carbocations. In particular, the oxidizing ability of Y zeolites follows the order HY > NaY > KY > CsY (16), and this order matches the yield of time-resolved carbocation formation as a function of counterion. Furthermore, An_2CH^+ was generated under milder conditions than Tol_2CH^+, while Ph_2CH^+ was not detected even in the highly oxidizing HY zeolite. Since the oxidation potentials of the radicals increase in the order $An_2CH\cdot$ < $AnPhCH\cdot$ < $Tol_2CH\cdot$ < $Ph_2CH\cdot$ (Table 2), the mechanism in eq. [3] agrees well with the effect of substrate structure on carbocation formation.









In addition, the efficiency of carbocation formation was substantially diminished upon addition of oxygen to the zeolite samples. Since neither the radical cations nor the carbocations are sensitive to oxygen, while the diarylmethyl radicals are quenched by oxygen, the observed decrease in the formation of the carbocation under oxygen conditions is consistent with the radicals being their immediate precursor.

If carbocation formation did take place via oxidation of the radical, a correlation would normally be expected between the decay of the radical and the growth of the carbocation. The current results show that such correlations are sometimes present: the radicals ($An_2CH\cdot$, $AnPhCH\cdot$, and $Tol_2CH\cdot$) in HY did decay as their corresponding carbocations grew in. However, a more typical correlation observed in the present work is that between the decays of the radical cations and the growths of the carbocations, particularly for the formation of An_2CH^+ in NaY, KY, and HY. As well, the radicals ($An_2CH\cdot$, $AnPhCH\cdot$, and $Tol_2CH\cdot$) observed in NaY under vacuum conditions were long-lived, and were not converted to their corresponding carbocations over the timescale of the experiments.

These results can be rationalized on the assumption that, in the inhomogeneous environment of the zeolites (40), the radicals may initially have been generated in or near sites that have substantially different oxidizing abilities. Thus, in

Table 2. Summary of time-resolved diarylmethyl cation (C^+) formation in Y zeolites by oxidation of diarylmethyl radicals, and oxidation potentials (vs. SCE in acetonitrile) for the diarylmethyl radicals.

Radical	E_{ox} ($R\cdot/R^+$ vs. SCE)	HY ($E_{red} \approx$ 0.23–0.35 V)[a]	NaY ($E_{red} \approx$ 0.04–0.16 V)[a]	KY ($E_{red} \approx$ 0.04–0.16 V)[a]	CsY ($E_{red} <$ 0.04 V)[a]
	≈0.04[b]	Time resolved	Time resolved	Time resolved	No C^+
	0.16[c]	Time resolved	Only prompt	Only prompt	No C^+
	0.23[d]	Time resolved	Only prompt	No C^+	No C^+
	0.35[d]	No C^+	No C^+	No C^+	No C^+

Note: Also included are estimates of reduction potentials of zeolites (vs. SCE, see text).

[a]Estimated as described in the text (vs. SCE).

[b]Oxidation potential not available. However, the oxidation potential for $An_2C^+CH_3$ has been measured as E_{ox} = –0.06 V vs. SCE in acetonitrile (43); replacing the methyl group in $An_2C^+CH_3$ with hydrogen to give An_2CH^+ should increase the oxidation potential by ca. 0.10 (44), leaving an oxidation potential for An_2CH^+ of ca. 0.04.

[c]Reference 45.

[d]Reference 46.

some cases, the radicals generated by deprotonation were created in a nonoxidizing environment and were not rapidly converted to the carbocations. These radicals may slowly migrate to an oxidizing site and eventually be oxidized to the carbocation, but this process would not be observed over the 40 μs timescale of our experiments, and the radicals would appear as long-lived. In other cases, the radicals were generated in an environment where they were oxidized as rapidly as they were formed. Under these conditions, deprotonation of the radical cations would be the rate-determining step, and the growth of the carbocations would match the decay of the radical cations.

The rapid oxidation of the radicals appeared to reach an extreme in the highly oxidizing HY zeolite. In zeolite, very little $An_2CH\cdot$ or $AnPhCH\cdot$ radicals were observed. Presumably, almost all these radicals were generated near highly oxidizing sites so that the majority of deprotonation events were coupled with an oxidizing event. Such rapid oxidation of radicals may also explain the higher than expected reactivity of the radical cations in HY. Instead of a radical cation – radical equilibrium being established in favour of the radical cation in the highly acidic medium, the radicals formed by deprotonation are immediately trapped by oxidation to the carbocation. Essentially, the radicals are diverted away from a reprotonation pathway by the presence of the oxidation pathway, and no equilibrium state is established.

As previously mentioned, prompt radical formation occurs to some extent by rapid deprotonation of a small fraction of the radical cations. If this situation was coupled with rapid oxidation of the radical, one would expect to observe prompt carbocation formation. This combination of rapid deprotonation and rapid oxidation provides a reasonable explanation for prompt carbocation formation upon irradiation of An_2CH_2 and $AnPhCH_2$ in NaY and KY and Tol_2CH_2 in NaY, KY, and HY. It is also possible that prompt carbocation formation is aided by a two-photon process whereby one photon generates the diarylmethane radical cation that rapidly deprotonates to give the radical, and a second photon within the same laser pulse is absorbed by the radical to give the excited radical (34). Since excited radicals are known to be more easily oxidized than ground-state radicals (47), this two-photon sequence would be expected to promote prompt carbocation formation.

Table 2 presents a qualitative summary to illustrate whether or not prompt and (or) time-resolved formation of the diarylmethyl cations was observed in the zeolites studied, and also includes oxidation potentials for the diarylmethyl radicals. Using the assumption that the rapid radical oxidations are exergonic, we can use the information in Table 2 to estimate "upper" and "lower" limits for the oxidizing ability of the cation- and proton-exchanged Y zeolites (22). Due to the possibility that prompt carbocation may be caused by two-photon ionization of the radicals, only the time-resolved formation of the diarylmethyl cations is used to signal that a particular zeolite is a sufficiently strong oxidant to induce oxidation of the radicals to carbocations. Time-resolved formation of the dianisylmethyl cation was observed in HY, NaY, and KY, but not in CsY. Given that the oxidation potential for $An_2CH\cdot \approx 0.04$ V,[6] we can estimate the reduction potentials for sites within HY, NaY, and KY that oxidize the radical to be >0.04 V, and <0.04 V for CsY. No obvious time-resolved growth of $AnPhCH^+$ was present in NaY or KY, thus limiting the oxidizing ability of these zeolites to <0.16 V. Time-resolved growth of Tol_2CH^+ was observed only in HY, which further indicates that the reduction potential for HY is >0.23 V. Finally, $Ph_2CH\cdot$ was not

[6]All oxidation potentials are vs. SCE in acetonitrile.

© 2005 NRC Canada

oxidized to Ph_2CH^+ in any of the zeolites, even HY. Thus, the reduction potential for HY should be <0.35 V.

Conclusions

The results clearly show that conversion of photogenerated diarylmethane radical cations to diarylmethyl radicals by deprotonation is an efficient process, with the dynamics of deprotonation depending on the acidity of the radical cations, but not the basicity of the zeolites. Subsequent conversion of the radicals to the diarylmethyl cations can also be rapid, but only when the oxidizing ability of the zeolite exceeds the oxidation potential of the radical. HY is the strongest oxidizing zeolite of the four Y zeolites used, with a reduction potential between 0.23 and 0.35 V. CsY is the poorest oxidant, with a reduction potential at least 0.20 V lower than HY.

Experimental

Materials

Faujasite zeolite NaY was commercially available from Aldrich (LZY52 molecular sieves, Si/Al = 2.4) and used as received. HY was prepared from NH_4^+Y (Aldrich) by calcining the zeolite at 500 °C to promote loss of NH_3. The cation-exchanged zeolites were prepared by washing the zeolites with their corresponding chloride salts. The % exchange was typically 97% for KY and 47% for CsY (16). The solvents used for the preparation of zeolite samples were spectroscopic grade (99.98%, Omnisolv, EMD Chemicals) and used as received.

Diphenylmethane was commercially available from Aldrich and was purified by distillation and column chromatography (silica, 70–270 mesh) prior to use. Dianisylmethane (bis(4-methoxyphenyl)methane), anisylphenylmethane (4-methoxyphenylphenylmethane), and ditolylmethane (bis(4-methylphenyl)methane) were prepared from their corresponding ketones (Aldrich) using the Huang–Minlon procedure (48). The products were purified on silica by column chromatography using hexane as the eluant. Melting point determinations and (or) gas chromatography (GC) were used to establish purity. All melting points and ^1H and ^{13}C NMR (Bruker 250 MHz using $CDCl_3$ as the solvent) matched literature values (49, 50).

Zeolite sample preparation

The zeolites were activated at 475 °C for at least 12 h before use; typically ~300 mg of zeolite was activated overnight and allowed to cool to room temperature in a dry environment. A solution of the diarylmethane (about 5 mg) dissolved in 15 mL of hexanes was rapidly added to 5 mL of hexanes containing the activated zeolite. The sample was magnetically stirred for 1 h after which time the sample was centrifuged and the solvent was decanted. Fresh solvent was added to wash the zeolite surface. The sample was stirred for another 30 min, centrifuged, and the solvent was decanted. The diarylmethane–zeolite complex was transferred to a dessicator and dried under vacuum of 10^{-2} torr (1 torr = 133.322 4 Pa) for at least 4 h. The samples were then transferred to 3 mm × 7 mm quartz sample cells, evacuated (10^{-3} torr) for several hours, and sealed prior to laser irradiation.

The amount of organic material incorporated into the zeolite was calculated from the difference between the initial amount of the diarylmethane and the amount that was recovered in the combined solutions measured by UV absorption. With hexane as the carrier solvent, it was found that >90% of the diarylmethanes were incorporated into the zeolite. In each case, the loading level for the diarylmethanes was $\langle S \rangle = 0.10 \pm 0.01$ (i.e., one molecule in every 10 supercages).

No color change was observed upon incorporation of the diarylmethanes into the alkali cation-exchanged zeolites, indicating that the substrates were not thermally converted to coloured carbocations within these zeolites. The thermal stability of An_2CH_2 and $AnPhCH_2$ within the alkali-exchanged zeolite NaY was studied in more detail by examining the material obtained after continuous extraction of An_2CH_2–NaY and $AnPhCH_2$–NaY composites prepared as previously described for the laser experiments. The extraction procedure involved placing the organic/zeolite composite in a filter thimble and subjecting the sample to continuous extraction using a Soxlet apparatus and refluxing CH_2Cl_2 for 7 days. GC analysis (Varian Saturn 11, 35 m capillary column crosslinked 5% phenylmethylsilicone) of the extracted material indicated that 80% of unreacted diarylmethanes was recovered (relative to the amount originally incorporated). No other materials were observed in the extracted material by GC, leading to the conclusion that the diarylmethanes were stable within the zeolites.

In HY, no colour change was observed upon incorporation of Tol_2CH_2 and Ph_2CH_2, again suggesting that these materials were thermally stable within the acidic zeolite. On the other hand, the zeolite samples displayed a pale pink colour upon incorporation of An_2CH_2 and $AnPhCH_2$. Steady-state diffuse reflectance of these samples showed absorption at 510 nm for the An_2CH_2–HY composite, and at 460 nm for the $AnPhCH_2$–HY composite, indicating that the coloration was due to thermal conversion of the substrates to their corresponding carbocations. The colour was completely removed upon exposure of the samples to atmospheric moisture because of quenching of the carbocations with water. After continuous extraction of these hydrated samples, An_2CH_2 or $AnPhCH_2$ were still the only compounds detected by GC. No evidence of the diarylmethanols or diarylketones, which would be formed by oxidation of the diarylmethanols, was found in the GC traces. Thus, while some decomposition took place in HY, the lack of substantial colour together with exclusive extraction of the unreacted diarylmethanes suggests that decomposition was minor. To ensure that no carbocations were present in the laser experiments, samples of An_2CH_2 and $AnPhCH_2$ in HY were initially prepared in the same way as previously described for the other samples, but then hydrated by exposure to the atmosphere to remove the coloration and reevacuated prior to laser irradiation. There was no further evidence for the presence of carbocations following this supplementary treatment.

Laser flash photolysis

The nanosecond laser flash photolysis system with diffuse

reflectance detection at Dalhousie University is of standard design and has been previously described (51). The samples, typically ~300 mg of zeolite, were contained in 3 mm × 7 mm laser cells made out of Suprasil quartz tubing and degassed at reduced pressure (10^{-3} torr) prior to photolysis. For the oxygen-quenching experiments, oxygen was passed through the sample for at least 30 min prior to photolysis. The excitation source was the fourth harmonic from a Continuum Nd:YAG NY-61 laser (266 nm, ≤8 ns/pulse, ≤15 mJ/pulse). Transient signals from a monochromator/photomultiplier system were initially captured by a Tektronix 620A digital oscilloscope and transferred to a Power Macintosh computer. The experiments are computer controlled using the Power Macintosh and software written using the Labview™ programming language.

Data analysis

The data analysis was based on the fraction of reflected light absorbed by the transient (reflectance change, $R = \Delta J/J_o$), where J_o is the reflectance intensity before excitation and ΔJ is the change in the reflectance after excitation. Zeolites are known to contain several different microenvironments, and as a result, time-resolved decays or growths of transients in zeolites frequently fit better to a multiple first-order rate equation ($R_t = R_\infty + \Delta R_1 e^{-k1t} + \Delta R_2 e^{k2t} + \ldots$) than to a single first-order rate equation ($R_t = R_\infty + \Delta R_1 e^{-k1t}$). In the present work, the growths and decays of transients sometimes fit very well to a simple first-order expression; other times, the data fit better to a double first-order expression, but were still well-described by a single first-order rate equation. Thus, for consistency across all time-resolved processes, all rate constant calculations, unless otherwise specified, were carried out by nonlinear squares fitting of the data to a single first-order rate equation.

Valence bond calculations on the transition state for the E2 reaction of fluoride ion with ethyl fluoride — Implications for the More O'Ferrall – Jencks diagram[1]

Wei Wu, Sason Shaik, and William H. Saunders, Jr.

Abstract: A valence bond self-consistent field (VBSCF) calculation has been carried out on the bimolecular elimination (E2) reaction of fluoride ion with ethyl fluoride. The transition state was first optimized at HF/6-31+G and the resulting orbitals were used in the VBSCF calculation. A transition-state hybrid consisting of four structures ($F^-H\text{-}CH_2\text{-}CH_2\text{-}F$, $F\text{-}HCH_2{=}CH_2F^-$, $F\text{-}H^-CH_2\text{-}CH_2\text{-}F$, and $F^-H\text{-}CH_2\text{-}CH_2{}^+F^-$) failed to give a reasonable energy. Incorporation of four charge-separated structures ($F^-H^+{-}CH_2\text{-}CH_2\text{-}F$, $F^-H^+{-}CH_2\text{-}CH_2{}^+F^-$, $F^-H^+CH_2{=}CH_2F^-$, and $F\text{-}H^-CH_2\text{-}CH_2{}^+F^-$) for a total of eight resulted in an energy slightly below Hartree–Fock. A full-space VBSCF calculation utilizing 50 structures showed that the eight structures give a sufficiently accurate wave function. The transition state is dominated by charge-separated structures, leading to a greater degree of charge separation than in either the reactant or product complex. Therefore, the transition state does not evolve synchronously from the reactants, and explicit allowance should be made for this fact when applying descriptions of the reaction path, such as that in the More O'Ferrall – Jencks diagram.

Key words: elimination reaction, E2, transition state, VBSCF calculation, XMVB programs.

Résumé : On a effectué des calculs de liaison de valence en champ autocohérent (VBSCF) sur la réaction d'élimination bimoléculaire (E2) de l'ion fluorure à partir du fluoroéthane. Dans une première étape, on a optimisé l'état de transition au niveau HF/6-31+G et on a utilisé les orbitales qui en ont résulté dans les calculs VBSCF. Un état de transition hybride formé des quatre structures ($F^-H\text{-}CH_2\text{-}CH_2\text{-}F$, $F\text{-}HCH_2{=}CH_2F^-$, $F\text{-}H^-CH_2\text{-}CH_2\text{-}F$ et $F^-H\text{-}CH_2\text{-}CH_2{}^+F^-$) ne permet pas d'obtenir une énergie raisonnable. L'incorporation des quatre structures à charges séparées ($F^-H^+{-}CH_2\text{-}CH_2\text{-}F$, $F^-H^+{-}CH_2\text{-}CH_2{}^+F^-$, $F^-H^+CH_2{=}CH_2F^-$ et $F\text{-}H^-CH_2\text{-}CH_2{}^+F^-$) pour un total de huit structures conduit à une énergie légèrement inférieure à celle prévue par des calculs de Hartree–Fock. Un calcul VBSCF à plein espace, faisant appel à 50 structures a permis de montrer que les huit structures conduisent à une fonction d'onde suffisamment exacte. L'état de transition est dominé par les structures à charges séparées et ceci conduit à un degré plus élevé de séparation de charge qui est plus élevé que dans le réactif ou dans le complexe du produit. De cette façon, l'état de transition n'évolue pas d'une façon synchrone avec les réactifs et on doit en conséquence faire des prévisions explicites pour ce fait lorsqu'on applique les descriptions de la voie réactionnelle, par exemple dans le diagramme de More O'Ferrall – Jencks.

Mots clés : réaction d'élimination, E2, état de transition, calcul de liaison de valence en champ autocohérent, programmes XMVB.

Introduction

The bimolecular elimination (E2) reaction

[1] $$B^- + H\text{-}CR_2\text{-}CR_2\text{-}X \rightarrow B\text{-}H + CR_2{=}CR_2 + X^-$$

has long been of interest to mechanistic chemists both for its own sake and as a model for other complex processes in which more than two bonds are undergoing changes in the course of the reaction. It was originally shown by Hanhart and Ingold (1) to be second order, first order in base and first order in substrate. Later works have pointed out that the bonding changes need not be synchronous, although they occur in a single elementary step. Proton transfer at the transition state may be more advanced than the C—X bond breakage, or vice versa (2–5). The possible variations in transition-state structure can be represented by means of a

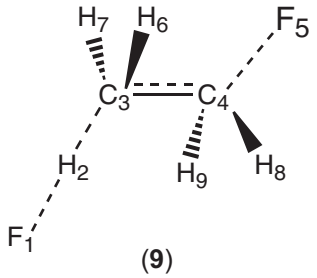
Fig. 1. More O'Ferrall – Jencks diagram.



More O'Ferrall – Jencks diagram (6–8). In the diagram (Fig. 1) a completely synchronous process is represented by a diagonal line from reactants **1** to products **2**. A two-step (E1cB) process is represented by a straight line from reactants **1** to carbanionic intermediate **3** followed by a straight line from the intermediate to product **2**. An E1cB-like process is then represented by a line that curves toward **3** but does not go through it and proceeds on to **2** in a single step. Another two-step (E1) process goes from reactant to carbocation **4** and from there on to **2**. An E1-like concerted process is represented by a line that curves toward **4** but proceeds directly in a single step to **2**. Substituent effects and isotope effects have been extensively used in efforts to determine the locations on the diagram of the transition states for E2 reactions with various reactants under various reaction conditions (9).

An alternative description of the possibilities for E2 transition states was suggested by Pross and Shaik (10). They proposed a valence bond (VB) formalism in which the structures contributing to a transition-state hybrid are taken to be **5**–**8** ($F^{-}H\text{-}CH_2\text{-}CH_2\text{-}F$ (**5**), $F\text{-}HCH_2{=}CH_2F^{-}$ (**6**), $F\text{-}H^{-}CH_2\text{-}CH_2\text{-}F$ (**7**), and $F^{-}H\text{-}CH_2\text{-}CH_2{}^{+}F^{-}$ (**8**)). While these may appear to be the same as **1**–**4**, respectively, there is a crucial difference. **1** and **2** represent stable species, while **3** represents a stable species in an E1cB reaction and **4** represents a stable species in an E1 reaction. In contrast, **5**–**8** are hypothetical species with the transition-state geometry but the electron distributions of **1**–**4**, respectively. They represent, however, reasonable guesses for important contributors to the transition-state hybrid. Other structures are possible but were not considered in the initial qualitative model (10). With this idea in mind, we set out to perform quantitative valence bond self-consistent field (VBSCF) calculations on the E2 reaction of fluoride ion with ethyl fluoride.

Computational procedures

The first step was geometric optimization of the transition-state structure at the HF/6-31+G level utilizing the GAUSSIAN 98 (11) programs. A vibrational analysis showed that the structure was a stationary point with one imaginary frequency corresponding to the reaction coordinate. The choice of a relatively low level was dictated by the fact that the computation time in VB calculations rises very rapidly with an increase in the number of basis functions. Even with the further constraints described in the following, some VB calculations required 3 days or more on a dual-processor SGI Octane workstation. The number of active orbitals was further restricted by freezing all inner-shell electrons and those outer-shell electrons that occupy orbitals orthogonal to the active orbitals in the *xz* plane.

(**9**)

In structure **9**, the atoms directly involved in the reaction are F1, H2, C3, C4, and F5. These atoms are all in the *xz* plane. The nonreacting hydrogens can also be constrained to this plane by taking linear combinations: H6 + H7 and H8 + H9. Thus, all p_y orbitals are orthogonal to the reacting orbitals and can be frozen. The active electrons are then taken to be the eight electrons in the bonds undergoing change in the course of the reaction plus an unshared pair on each of the atoms F1 and F5 for a total of 12. The integrals from the Gaussian calculation are transformed to a VB set by utilizing the Xiamen programs (XMVB) (12, 13). The six active orbitals are chosen as those highest filled orbitals that contain no p_y contributions. The XMVB can then be used to optimize simultaneously each of the contributors to the hybrid and the hybrid itself. Each contributor can also be optimized separately if desired.

Results and discussion

Our first effort was to optimize a hybrid consisting of the structures **5**–**8**. The results are shown in Table 1. The individual contributors are all very high energy relative to the Hartree–Fock value, and the hybrid of all four is still more than 100 kcal/mol (1 cal = 4.184 J) above the Hartree–Fock value. In principle, a VBSCF calculation ought to give a lower energy than a comparable Hartree–Fock calculation because the VBSCF method takes implicit account of electron correlation. In the present case a very low energy cannot be expected because all but 12 of the electrons are frozen in their respective orbitals, which consequently are unable to adapt to changes in the active electrons. Even so, an energy more than 100 kcal/mol higher than the Hartree–Fock value is unacceptable.

There are evidently contributing structures beyond **5**–**8** that need to be considered. In our previous work on proton transfer processes (14, 19), we found that a triple ion structure of the type $X^{-}H^{+}X^{-}$ was necessary to describe the transition state. Ionic structures are known, in fact, to be very important for bonds involving halogens, and especially so

[a]Energies are relative to the Hartree–Fock energy from the Gaussian calculation at HF/6-31+G.

for fluorine-containing bonds, where the mixing of the ionic structures leads to considerable stabilization via covalent–ionic resonance energies (15–18). Thus, **10** (F^-H^+-CH_2-CH_2-F) is an obvious choice, and we also added a structure with alternating charges (F^-H^+-CH_2-$CH_2^+F^-$ (**11**)). Indeed, these structures proved to be of considerably lower energy than **5**–**8**, and generate a hybrid with energy more than 100 kcal/mol below the hybrid of **5**–**8** (Table 2), even better than the energies we achieved in similarly complex processes — identity-reaction proton transfers from acids that yield resonance-stabilized anions (14).

To determine whether other significant structures were needed, we carried out a calculation on a complete set of 50 VB structures. There are five orbitals on five centers with six electrons, leading to 50 structures that are constructed as follows: (*i*) monoanionic structures, which involve a monoanion on a given site and two covalent bonds on the other sites — these covalent bonds have two possible ways of coupling the four electrons (Rumer structures) with five possible anionic sites, which lead to 10 structures; (*ii*) dianionic centers must have one cationic center and one covalent bond, leading to $[(5 \times 4)/2] \times 3 = 30$ structures; (*iii*) trianionic structures have two cationic centers, leading to a total of $(5 \times 4 \times 3)/6 = 10$ structures. This model gives an energy 9.5 kcal/mol lower than the Hartree–Fock value. Most of the structures possess high-energy features such as long bonds, adjacent charges of the same sign, or reversed charges (H^- and F^+), and thus make only very minor contributions to the hybrid; but eight of the fifty structures (**5**–**8** and **10**–**11**) along with two new ones ($F^-H^+CH_2$=CH_2F^- (**12**) and F-H^-CH_2-$CH_2^+F^-$ (**13**)) were of significant importance. Their weights total 0.986 out of 1.000 for the full 50 structures.

Table 3. Weights of contributors to the eight-structure hybrid of the F···H···CH_2==CH_2···F transition state.

Contributor	Weight
5	0.010
6	0.166
7	0.053
8	0.017
10	0.046
11	0.276
12	0.317
13	0.115

The eight-structure hybrid has a slightly lower energy than the Hartree–Fock values (Table 2). The weights of the individual contributors to this hybrid are recorded in Table 3. They compare well with the relative weights of the full calculation. Therefore, a sufficiently accurate wave function is deemed to be the one with eight structures. Note that the original structures **5**–**8** have a total weight of barely 25%, while the charge-separated structures **10**–**13** make up 75%. The transition structure is clearly not formed in a synchronous fashion of covalent bond switching but possesses a high degree of charge separation. Of course, since the charge-separated structures maintain large covalent–ionic resonance energies with the covalent structures (15–18), the charge separation does not mean that the transition state is ionic.

One may question whether this picture represents a real physical situation or is an artifact of the VB method. Table 4 compares charges calculated from the VB data[3] with Mulliken and NPA (natural population analysis) (20) charges calculated at MP2/6-31+G*//MP2/6-31+G*. While the charge alternation is somewhat stronger in the VB charges, the same pattern is clearly evident in the charges calculated at the correlation-corrected SCFMO level, with the NPA charges being closer to the VB charges. Structures optimized at the MP2/6-31+G* level have been found to give physically reasonable results for a variety of E2 reactions (21–23). Thus, there is no reason to doubt the reliability of the VB charges and the contributions of the charge-separated resonance structures that give rise to the charge distribution. The agreement is better than expected considering that all electrons are active in the SCFMO calculation but only 12 (one-third of the total) are active in the VB calculation.

Another question is why the VB calculation requires at least eight structures to describe the transition state when the More O'Ferrall – Jencks diagram requires only four. There are two reasons for this difference. The first is that even a normal covalent bond may require charge-separated contributors for an adequate description (15–18). Covalent contri-

α-CH_2[a]	0.444	0.267	0.350
F	–0.927	–0.780	–0.849

Note: VB = valance bond; NPA = natural population analysis.
[a]α refers to the carbon bearing the fluorine, and β refers to the carbon bearing the hydrogen in transit.

butors in a VB calculation have electron pairs shared equally between any two adjacent atoms. Thus, a polar bond, such as H-F or C-F, must include ionic contributors of the type H^+F^- or C^+F^- for a proper VB description. Even a homonuclear C=C bond, such as that in ethylene, requires two equivalent charge-separated contributors $H_2C^+C^-H_2$ in a VB calculation to correctly reproduce the properties of the molecule (24). This requirement can be thought of as allowing for the polarizability of the π bond. It is consequently not surprising that the E2 transition state requires charge-separated structures. The question is whether it requires them more than does the reactant or the product.

This question was examined by means of models of the reactant and product complexes. These models were set up under constraints intended to ensure that they were geometrically similar to the transition state. The F···H···C system was constrained to be linear, and planarity of the reacting bonds was enforced. For the reactant complex, the F···H bond length was fixed at 2.0 Å and the remaining parameters optimized except for the linearity of F···H···C. This gave a stationary point with no imaginary frequencies though probably not a global minimum. The C···F bond length in the product complex was fixed at 2.3 Å and the remaining parameters were optimized, again with the exceptions cited for the reactant complex. In this case, the species possessed one imaginary frequency, but no model with a reasonable C···F distance was a stationary point. The imaginary frequency corresponds to a vibration in which an essentially planar ethylene moiety twists about an axis through the C=C perpendicular to the plane of the carbons and hydrogens. FH and F^- remain almost stationary in this vibration. Thus, the model appears to be an ethylene interacting electrostatically with the leaving group and the conjugate acid.

The reactant and product complexes are compared with the transition state in Tables 5 and 6. Both show that the weights and group charges do not change monotonically from reactant to transition state to product. Charge-separated contributors (**8**, **10**–**13**) account for 68% of the reactant, 77% of the transition state, and 73% of the product. The prominence of **11** in the transition state is mainly responsible. The charges (Table 6) show even more clearly the degree of charge separation in the transition state. The proton in transit and the α-CH_2 are more positive and the β-CH_2 is more negative than in either the reactant or the product. The base has transferred 76% of its charge to the substrate, while the leaving group has acquired 88% of its final charge in the transition state. By these measures, the transition state is much closer to product than to reactant, and the positive charge on H-CH_2CH_2 is about 0.2 units greater than in the reactant, mainly due to the increased charge on the proton in transit. The large positive charge on the proton in transit and the large negative charge on the β-CH_2 are reminiscent of the behavior observed in proton transfers from acids that yield resonance-stabilized anions (14, 21, 25–28), which are the examples of the principle of nonperfect synchronization (29–31).

Table 5. Comparison of contributor weights for reactant complex, transition state, and product complex in the E2 reaction of F^- and C_2H_5F.

Table 6. Comparison of valance bond group charges for reactant complex, transition state, and product complex in the E2 reaction of F^- and C_2H_5F.

Group	Reactant complex	Transition state	Product complex
F	–1.000	–0.703	–0.611
H	0.451	0.639	0.607
β-CH_2	–0.436	–0.454	–0.306
α-CH_2	0.411	0.444	0.310
F	–0.383	–0.927	–1.000

The relevance of these observations to the More O'Ferrall – Jencks diagram is that the diagram takes no explicit account of such charge-localized transition states. While there is nothing about the diagram that excludes this possibility, it has in the past encouraged a tacit assumption that in atom or group transfers bond breaking and bond making occur synchronously. For example, calculations of isotope effects in elimination reactions often employ models in which total bonding to a given atom or group remains constant along the reaction coordinate (32, 33). The present results make it clear that one must be alert for evidence of nonperfect synchronization when considering transition states of elimination reactions or of proton transfers in general. Work is currently under way to determine the effect of the base and leaving group on the extent of charge localization in the transition state.

Elimination reactions — Calculation of rate constants from equilibrium constants and distortion energies by means of no barrier theory[1]

J. Peter Guthrie, Leonardo Leandro, and Vladimir Pitchko

Abstract: No barrier theory has been applied to the E2 reactions of five alkyl bromides with ethanolic ethoxide. The model used for these reactions is that the reaction proceeds from the encounter complex of base and alkyl halide to the product encounter complex of halide ion and alkene (and alcohol), and requires five simple processes, which combine to give the concerted elimination: transfer of a proton from carbon to base; a change in geometry at the carbon which loses a proton from sp^3 to sp^2; breaking the C-leaving group bond; a change in geometry at the carbon which loses the leaving group from sp^3 to sp^2; and a change in the length of the carbon–carbon bond. The free energy of activation can be calculated with an rms error of 2.58 kcal mol^{-1} (1 cal = 4.184 J).

Key words: Elimination, no barrier theory, rate constant, equilibrium constant.

Résumé : On a appliqué la théorie sans barrière à l'étude des réactions E2 de cinq bromures d'alkyles avec de l'éthanolate éthanolique. Le modèle utilisé pour ces réactions est celui d'une réaction qui se produit à partir d'un complexe de rencontre de la base et de l'halogénure d'alkyle et qui conduit au complexe de rencontre du produit avec l'ion halogénure, l'alcène (et l'alcool) et qui nécessite cinq processus simples qui se combinent pour conduit à une élimination concertée: le transfert d'un proton du carbone à la base; une modification de la géométrie au niveau du carbone qui perd un hydrogène et qui passe de sp^3 à sp^2; un changement de géométrie au niveau du carbone qui perd le groupe partant et qui passe de sp^3 à sp^2; la rupture de la liaison du carbone-groupe partant et un changement dans la longueur de la liaison carbone–carbone. On a calculé l'énergie libre d'activation avec une erreur de 2,58 kcal/mol (1 cal = 4,184 J).

Mots clés : élimination, théorie sans barrière, constante de vitesse, constante d'équilibre.

[Traduit par la Rédaction]

Introduction

The E2 elimination reaction is one of the type examples of a concerted process, with strict stereoelectronic requirements for a coplanar arrangement of both carbons, proton and leaving group, and a strong preference for anti vs. syn geometry. Some years ago we showed that this reaction could be described in terms of the multidimensional Marcus theory, using equilibrium constants and intrinsic barriers for the two limiting stepwise processes (solvolysis to give a carbocation–leaving group ion pair, and proton transfer to give a carbanion) (1). This treatment had the disadvantage of requiring two intrinsic barriers, which had to be evaluated from kinetics for simpler reactions. In addition, it was not clear how justified the essential assumption, of a transferable intrinsic barrier for C–Br cleavage with the same value for tertiary, secondary, and even primary alkyl halides, really was.

Recently we developed the no barrier theory (NBT), which permits the calculation of rate constants from equilibrium constants and certain distortion energies with no input of kinetic information. In the present manuscript we wish to report the application of this approach to the E2 elimination of simple alkyl halides in ethanol.

Theory and calculations

No barrier theory depends on the following postulates:

(1) Reactants[3] are in equilibrium with the starting material or product at each point along each reaction coordinate.
(2) For any process where only one elementary reaction coordinate changes, the energy will be a quadratic function of the corresponding reaction coordinate.
(3) Heterolytic bond cleavage constitutes an elementary reaction coordinate.

(4) Proton transfer between two atoms constitutes an elementary reaction coordinate.
(5) For an anion to react at carbon, it must first undergo partial desolvation so that its reactive lone pair can be in van der Waals contact with the carbon.

For convenience in carrying out the calculations, all coordinates are defined to run from 0 at the starting material to 1 at the product.

To apply the theory to a reaction such as the E2 requires calculation of the energies of each of the corner intermediates where one, two, or more of the simple processes have gone to completion. These energies depend on equilibrium constants for any bond making, bond breaking, or proton transfer steps, any distortion energies (calculated relative to the equilibrium species with the same bonding arrangement), any hydrogen bond interactions or electrostatic interactions when species (molecules or ions) are brought together in the encounter complex, the entropic cost of the encounter complex formation, and any obligatory desolvation. Once all of these corner energies are in hand, the reaction energy hypersurface can be calculated and the transition state free energy can be determined.

Once the energies of the corners of the reaction hypercube are defined, the postulates allow the free energy hypersurface to be defined, at least approximately. The various sequences of calculations, which lead to the energy of a point on the hypersurface, lead to similar but not identical values, so we take the average as the best estimate.

From the postulates, the free energy surface for the reaction hypercube (a square for two dimensions, a cube for three, and an appropriate hypercube for higher dimensions) can be deduced. To calculate the energy at a point (v,w,x,y,z), an iterative process is used, where one dimension, e.g., v, is set, and the energies for the corresponding section through the reaction hypercube, which will be a hypercube with one less dimension, are calculated; for example, in this case: (v,0,0,0,0), (v,1,0,0,0), (v,0,1,0,0), … (v,1,1,1,1). The process is now repeated for this $n - 1$ dimensional hypercube, fixing another of the coordinates at the value for the desired point and calculating the corners of the corresponding ($n - 2$) dimensional hypercube. This iterative process is continued until one reaches a two-dimensional hypercube (a square) for which there are only two ways to calculate the energy of the point. Both are used and the average is taken. There are clearly many such alternative paths for a five-dimensional hypercube. At each stage the energy is calculated in each possible way and the average is taken.

To define the hypersurface, the energy of each corner must be calculated. The major contributions to the energy at most corners will be the distortion energy calculated by the ab initio or DFT method, relative to the equilibrium species with the same bonding arrangement. However, we also try to include all known interactions affecting the energy of the corner: ΔpK_a for proton transfers, hydrogen bonding interactions if present, electrostatic interactions if present, and desolvation if present. Desolvation must be taken into account whenever a potential bonding contact requires the loss of a strong interaction with solvent replaced by only a weak interaction with the reactant until a covalent bonding begins.

The limiting stepwise alternatives to the concerted E2 reaction are the S_N1 reaction leading to the carbocation and the E1cb reaction leading to the carbanion. On each energy hypersurface, eight of the corners are more or less distorted forms of the carbocation and eight are more or less distorted forms of the carbanion. Thus, the nature of the E2 reaction requires four equilibrium species to be considered for each reaction. These are as follows: the alkyl halide, the alkene, the carbocation from C-halide bond cleavage, and the carbanion (from loss of a proton on a carbon β to the halide). The carbanion is not a real intermediate because it would lose halide extremely rapidly if it were ever to form. The carbanion would also react, with essentially no barrier, to reabstract the proton from ethanol. The carbocation would react with the bromide ion with, in most cases, essentially no barrier to form the alkyl bromide; only in the cases of *tert*-butyl and 1-phenylethyl cations is there a small barrier to reaction with bromide. However, the carbanion is a conceptual intermediate in a stepwise E1cb version of the E2 and would be a real intermediate given adequate anion stabilizing substituents; the carbocation is a conceptual intermediate in a stepwise E1 version of the E2 and would be a real intermediate given adequate cation stabilizing substituents. The corner species corresponding to the ions will not generally have exactly the equilibrium geometry of the ion, but will have a mix of geometrical features from starting material and product. Nonetheless, one corner will be close to being the carbocation of the hypothetical stepwise reaction, and another one will be close to being the corresponding carbanion.

Equilibrium constants for elimination reactions

To begin the process of calculating the energy of all the corners of the reaction diagram, we require the overall equilibrium constants for the elimination reactions. For ethyl, isopropyl, and *tert*-butyl bromides these equilibrium constants have been reported (1). For 1-bromo-1-phenylethane and 1-bromo-2-phenylethane the free energies of the alkyl halides have not been reported, so values were obtained by computation using the G3MP2B3 method (2). The free energy of formation of styrene has been reported (3), although not the free energy of transfer to ethanol, which was calculated by the IPCM method.

The free energies of solvation were calculated using the IPCM method in Gaussian. This method gives ΔG_{solv} on the 1 mol/L (g) to 1 mol/L (aq) standard states. This can be converted to the free energy of transfer (ΔG_t), 1 atm (g) to 1 mol/L (aq) (1 atm = 101.325 kPa), by adding 1.90 kcal/mol (1 cal = 4.184 J). This method was used for all species except for H^+, Br^-, and H_2O. For H^+ we used either the Zhan and Dixon value for ΔG_t to water (–262.4 kcal/mol) (4), for the computational free energies with a free energy for gaseous H^+ (–6.28 kcal/mol) (5) based on the Sackur–Tetrode equation (6), or the conventional value for $\Delta G_f(aq)[H^+]$ (0.0) along with Marcus' (7) value for the free energy of transfer for H^+ from water to ethanol. For Br^- we used the NIST value for the conventional solvation energy in water (8) and the free energy of transfer from water to ethanol given by Marcus (7). We calculated ΔG_t (gas at 1 atm, ethanolic solution at 1 mol/L) for water from data given by Pemberton and Mash (9). From the total vapor pressure of a dilute solution of water in ethanol and the mol fraction of water in the vapor phase, we can calculate the

partial pressure of H_2O above the solution. From the mol fraction of water in the liquid phase, we can calculate the molar concentration of water. With the concentration of water in the liquid phase and the partial pressure of water above the solution in hand, we calculated the free energy of transfer at 303.15 and 323.15 K, the two temperatures studied by Pemberton and Mash, and then extrapolated to 298.15 K. The data and further details about the calculations are given in Appendix A and Table A1. All of the free energies of formation are found in Table 1.

In this way one calculates, from the free energies of formation in Table 1,

$$PhCH(Br)CH_3 + EtO^- \rightleftharpoons PhCH=CH_2 + Br^- + EtOH \qquad \Delta G° = -22.07$$

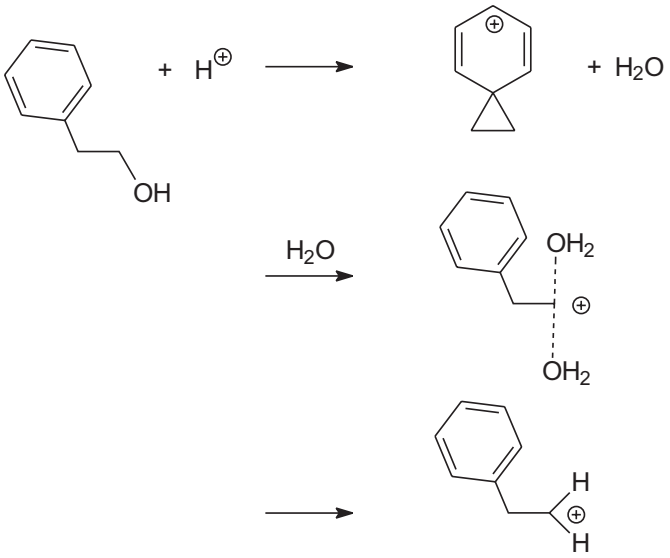
$$PhCH_2CH_2Br + EtO^- \rightleftharpoons PhCH=CH_2 + Br^- + EtOH \qquad \Delta G° = -22.56$$

Cation energies

The free energies of the ethyl, isopropyl and *tert*-butyl cations relative to the bromides were calculated after Abraham (10) as previously reported (1); energies for the phenylethyl cations were derived from DFT calculations as described below.

Free energies of the phenylethyl cations were calculated starting with the pK_R process for the corresponding alcohols. We have shown that for substituted benzyl alcohols, the relative values of pK_R can be calculated based on the gas-phase free energies using B3LYP/GTLarge//B3LYP/6-31G** and the free energies of solvation using IPCM/B3LYP/6-31G**. In other work we have shown that the pK_R values for a range of alcohols, alkyl, as well as benzyl, can be calculated using G3MP2B3 gas-phase free energies and IPCM/B3LYP/6-31G* free energies of solvation, with an rms error of 2.9 in pK_R, which can be reduced to 1.2 by scaling the solvation energies.[4] For 2-phenylethanol we calculated the gas-phase thermochemical quantities using G3MP2B3 and IPCM/B3LYP/6-31G* free energies of solvation. We have no basis for scaling the solvation energies in ethanol, and by analogy with cations in water, we must expect them to be in error by

[4]J.P. Guthrie. Manuscript in preparation.



© 2005 NRC Canada

several kcal/mol. However, since the 2-phenylethyl cation is a high energy species, which will be quite far from the transition state, we expect that the transition state free energy will be insensitive to errors in the cation free energy.

We first calculated gas-phase thermodynamic quantities for each species. For 2-phenylethanol and 2-phenylethyl bromide the entropy value reported by Gaussian was corrected for the existence of multiple conformers (11). This correction was based on a conformational search using the GMXX routine in PCModel (12). The entropy of mixing given by PCModel includes contributions from indistinguishable rotamers, and thus, needs to be corrected to include only distinguishable conformations, including enantiomeric conformers. Then using the free energies of transfer of each species, we calculated the free energy of reaction in ethanol, and from the free energies of all species except the cation, this value can now be determined. This slightly roundabout procedure avoids most of the problems of multiple standard states for ionic species in solution. It is still necessary to be alert to the two conventions for free energies of formation in gas (ab initio where the assumed initial state is the nuclei and electrons infinitely separated in vacuum, and the thermochemical convention where the initial state has the elements in their standard state).

For 1-phenylethanol, $pK_R = -15.4$ has been reported by Amyes et al. (13). We have calculated the free energies of transfer for all species from gas to both water and ethanol and have taken the difference as the free energy of transfer from water to ethanol. There will be some cumulation of error, but one may hope there is also some cancellation of error from matching contributions on the left and right sides of the equilibrium equation. From the pK_R in water we calculated the corresponding free energy change in ethanol. From the free energies of all species except the cation we can now calculate the free energy of formation of the cation.

Free energies of formation for all species are contained in Table 1.

For 2-phenylethyl cation the situation was more complicated. The preferred form of the cation, both in the gas phase and in solution, is the phenonium ion. If the conformation is locked so that the phenyl cannot bridge, then the primary cation will not be a true intermediate because specific solvation by two equivalent solvent molecules would give the S_N2 transition state. (This was examined using water as solvent because water is smaller and more symmetrical than ethanol, which facilitates the calculations.) The ion needed as a starting point for calculating the cation corner of the reaction diagram would be the bare ion without specific solvation. We calculated the solvation energy of this hypothetical species by the continuum solvent approximation using the IPCM method:

[1] $\text{Ph-CH}_2\text{-CH}_2^+ + \text{H}_2\text{O} \rightleftharpoons \text{Ph-CH}_2\text{-CH}_2\text{-OH} + \text{H}^+$

$\Delta G^\circ = 55.20$ (EtOH)

From the calculated equilibrium free energy for rxn. [1] and the free energies of formation for the other species, already evaluated, we can calculate the free energy of formation for $\text{Ph-CH}_2\text{-CH}_2^+$ in ethanol as $\Delta G_f^\circ = 113.60$. Now with the free energies of formation in hand for all species in eq. [2] we can evaluate the standard free energy change in ethanol as $\Delta G^\circ = 63.95$.

[2] $\text{PhCH}_2\text{CH}_2\text{Br} \rightleftharpoons \text{Ph-CH}_2\text{-CH}_2^+ + \text{Br}^-$

We used the value estimated (1) by the procedure suggested by Abraham (10) to estimate the free energy of ion pair formation from ethyl cation and Br^-, i.e., $\Delta G_{ip} = -3.1$; this leads to a free energy change in ethanol for eq. [3] of 60.85.

[3] $\text{PhCH}_2\text{CH}_2\text{Br} \rightleftharpoons (\text{Ph-CH}_2\text{-CH}_2^+, \text{Br}^-)$

By analogous calculations, we deduce the free energy changes for rxns. [4]–[6]:

[4] $\text{PhCH(CH}_3)^+ + \text{H}_2\text{O} \rightleftharpoons \text{PhCH(CH}_3\text{)-OH} + \text{H}^+$

$\Delta G^\circ = 20.56$ (EtOH)

[5] $\text{PhCH(CH}_3\text{)-Br} \rightleftharpoons \text{PhCH(CH}_3\text{)}^+ + \text{Br}^-$

$\Delta G^\circ = 26.92$ (EtOH)

[6] $\text{PhCH(CH}_3\text{)-Br} \rightleftharpoons (\text{PhCH(CH}_3\text{)}^+, \text{Br}^-)$

$\Delta G^\circ = 23.82$ (EtOH)

Similarly we used the value estimated (1) by the procedure suggested by Abraham (10) for ion pair formation from isopropyl cation and Br^-, i.e., $\Delta G_{ip} = -3.1$; this leads to a free energy change for eq. [6] of 23.82.

Calculation of pK_a values for cations

For each cation we can define a pK_a for the loss of a proton to give the corresponding alkene. Since we now have the free energies of formation for each species in ethanol, it is straightforward to calculate the pK_a values. The values calculated are found in Table 2.

Calculation of pK_a values for alkyl bromides

For the anion equilibria we need the pK_a values for CH ionization. The starting point is toluene for which there is a reasonably good estimation of pK_a in water. Streitwieser and

$PhCH(CH_3)Br$	53.0
$PhCH_2CH_2Br$	38.2

Ni (14) measured the rate of exchange and extrapolated to 25 °C, obtaining a rate constant for hydroxide of 7.4×10^{-17} $(mol/L)^{-1}$ s^{-1}. They used a rate constant for the reaction of water based on measurements of the bimolecular reaction in THF. This seems likely to be too low because water in THF will be far less acidic than water in water as a result of the absence of hydrogen bonding solvation for hydroxide. Instead, we used the rate constant for reorganization of water, following Richard (15), namely $k = 10^{11}$ s^{-1}. This leads to a $K_a = K_w$ $(k_{OH}/k_w) = 10^{-14}$ $[(7.4\times10^{-17})/10^{11}] = 7.4 \times 10^{-42}$, or p$K_a$ = 41.13. This is close to the value estimated by Bordwell for DMSO solution, namely 43 (16).

Cram (17) cites three studies of the relative rates of hydrogen isotope exchange in ethylbenzene relative to toluene; the relative rates are 0.14 (NH_3/NH_2K, 10°), 0.12 ($cC_6H_{11}NH_2/cC_6H_{11}NHK$, 50°), and 0.22 ($CH_3SOCH_3$/*t*-BuOK, 30°). Over a range of solvents the relative rate is 0.16 ± 0.5. It seems reasonable that the rate constant for the reverse reaction will be the same limiting value in both cases, so this will also be the ratio of acidity constants. This leads to a pK_a for the α-hydrogen of ethylbenzene of 41.13 – log(0.16) = 41.9 in water.

The effect of the β-bromine is estimated from the linear free energy relationships (LFER) for ionization of alcohols, taking $RCH_2OH \rightarrow RCH_2O^-$ as a model for $RCH_2CH_2R' \rightarrow RCH_2CH\text{-}R'$. The best model for the effect of solvent on the ρ* value for this reaction is a recent study of substituted acetic acids (18) in which it was found that the pK_a shift from acetic acid to chloroacetic acid was essentially the same in the two solvents. Based on this model we used the ρ* value for ionization of alcohols in water (ρ* = –1.32) (19) for the ionization of $PhCH_2CH_2X$. This leads to a predicted shift in pK_a of 1.32 × 2.84 = 3.75, and a pK_a for $PhCH_2CH_2Br$ of 38.2. The shift in pK_a from water to ethanol is taken as 5.7, as before (1). This leads to a pK_a for $PhCH_2CH_2Br$ of 43.9 in ethanol.

This value does not appear to be logically consistent with the pK_a for alkyl bromides of 47 used previously (1). It can be expected that the effect of a conjugated phenyl will be more than 3 pK_a units. The previously used value was based on Streitwieser's experimental values of cesium ion pair pK_a values in cyclohexylamine (20), which were reported to be equivalent to the pK_a values in methanol. This meant that they were very close to the desired pK_a values in ethanol. Given the more recent pK_a value for ethyl benzene deduced above, 43 in water, thus 48 in ethanol, a value of 51 for ethane in ethanol no longer looks reasonable. Instead, we started with Jorgensen's computational value for ethane (21) from which we deduced (1) a value of 54 for ethyl bromide (and isopropyl and *tert*-butyl bromides).

For the pK_a of $PhCH(CH_3)Br$ we started with the pK_a for ethyl bromide of 54 as estimated above. The effect of the β-phenyl is estimated using ρ* = –1.32 as 0.99, which leads to a pK_a for $PhCH(CH_3)Br$ in ethanol of 53. The pK_a values for all the alkyl bromides discussed are found in Table 2.

Electrostatic interactions

The "carbocation" corners are actually ion triples. The electrostatic interaction in such an ion triple is calculated from the relative positions of the charges, assuming a uniform dielectric constant, which is the same as the effective dielectric constant for a simple ion pair. The interaction is then scaled to ion-pair formation in ethanol, using the data for simple spherical ions. For KCl, the ion-pair association constant in ethanol (22) leads to $\Delta G_{ip} = -2.7$. This is the free energy for the formation of an ion pair from spherically symmetrical singly charged anion and cation. We partition this free energy into the statistical and electrostatic contributions using the equation (23) derived by Fuoss (24) and Eigen (25), picking an interaction distance to give $\Delta G_{overall} = \Delta G_{encounter} + \Delta G_{electrostatic} = -2.7$ kcal/mol in ethanol. The corresponding contributions can be calculated from the terms in this equation as $\Delta G_{encounter} = 1.44$ and $\Delta G_{electrostatic} = -4.14$. Simple electrostatic calculations are used to calculate the electrostatic interaction energy for the geometry in a cluster.

Desolvation energies

The free energy of transfer from water to ethanol for bromide ion is +18.2 kJ (4.35 kcal) (26), and from water to acetone (similar dielectric constant, no hydrogen bonding) it is +42 kJ (10.04 kcal) (26). From these we calculated that the free energy of transfer from ethanol to acetone is +5.69 kcal/mol. Taking the solvation number of bromide in ethanol as three (27), the loss of solvating ethanol would then be worth 1.90 kcal/mol.

The cost of losing a hydrogen bond from ethanol to ethanol can be estimated from the difference in the free energies of transfer for ethanol and dimethyl ether from ethanol to chloroform (slightly polar, non-hydrogen bond accepting solvent). These calculations are explained in Appendix B and Table B1. The difference in the free energy of transfer from ethanol to chloroform for ethanol and dimethyl ether is 1.74 kcal/mol, which is taken as the cost of losing one hydrogen bond from OH to solvent.

The total desolvation energy for EtOH:ethene:Br^- would then be 3.64 kcal/mol.

Hydrogen bonds

For all hydrogen bonds we used the Stahl–Jencks equation (28) to estimate the free energy of hydrogen bond formation. Corners with a carbanion hydrogen bonded to solvent will clearly have a strong hydrogen bond, but this is implicit in the pK_a values, which are estimated for the reactions in solu-

© 2005 NRC Canada

tion, thus including hydrogen bonding solvation. To use the Stahl–Jencks equation (28)

$$[7] \qquad \log K_{HB} = \tau\,(pK_a^{prosolv} - pK_a^{BH})\,(pK_a^{HA} - pK_a^{solv}) - \log[solv]$$

in ethanol we need to determine the τ parameter in ethanol. This would require either a study of hydrogen bonding equilibria, which has not been done, or an indirect calculation. The simplest approach is that of Funderberk and Jencks (29), who reported an electrostatic calculation. This approach derives τ from two quantities: the effect of a plus charge on pK_a for X-CH_2-Z vs. X-CH_2-ZH^+ and the attenuation factor for transmission of the substituent effects. We have found no data that allow the determination of the attenuation factor in ethanol; there are some data (see Appendix C and Table C1) for methanol (30) that suggest that the attenuation factor is similar to that in water. There is considerable scatter in the attenuation factors which can be calculated, but no basis for saying that the fall-off factor is different in methanol vs. water. If this is true, then it is reasonable to expect a very similar fall-off factor in ethanol.

What is the effect of a plus charge on pK_a in ethanol? The situation is more complicated than it might seem; see Appendix D and Table D1. The effect of a charge (in glycine) on the pK_a of a carboxylic acid is roughly the same in water or aqueous ethanol, at least up to 60% or 70% ethanol. One can also look at the effects of substituents in different solvents; see Table 3. The traditional expectation is that the substituent effects are larger in ethanol than in water. This is based on the studies of benzoic acids (31). However, some studies of the substituted acetic acids tell a different story; see XCH_2COOH data from Headley et al. (18). The sensitivity to the substituent effects is unaffected by solvent! A possible explanation is preferential solvent orientation, with the hydroxyl groups being close to the very polarized atoms of the substituted acetic acid, while the ethyl group of ethanol is close to the benzene ring in the benzoic acids. This would mean similar attenuation of field effects for all alcohol solvents in the acetic acid case, but much less attenuation in the benzoic acids, where the low dielectric constant volume between substituent and acid is greater in organic solvents.

The Funderburk–Jencks equation (29) is

$$[8] \qquad \tau = \frac{(\text{attenuation factor})^4}{pK_a^{ZH+CH_2XH} - pK_a^{ZCH_2XH}}$$

For the moment the available data suggest that using the Stahl–Jencks (28) parameters for water may the best approximation.

Experimental rate constants

The rate constants for the reactions of 1-phenylethylbromide and 2-phenylethylbromide were reported by McLennan (32). The rate constants determined at 50 °C in ethanol for the reaction of free ethoxide with the alkyl bromide were 1-Phenylethylbromide: $k = 7.95 \times 10^{-4}$ $(mol/L)^{-1}$ s^{-1} ($\Delta G^{\ddagger}$ = 23.58) and 2-Phenylethylbromide: $k = 45 \times 10^{-4}$ $(mol/L)^{-1}$ s^{-1} ($\Delta G^{\ddagger}$ = 22.46).

The free energies of activation calculated from these rate constants are likely to be very close to the desired free energies of activation at 25 °C. For a number of simple alkyl halides Ingold (33) gives Arrhenius *A* values in ethanol or aqueous ethanol, and these are consistently about 10^{11}. Such a value leads to $\Delta S^{\ddagger} = -10.36$. For a 25° change in reaction temperature $\Delta S^{\ddagger} = -10.36$ leads to a change of 0.26 in $\Delta G^{\ddagger}$, which is almost negligible for our purposes. Corrected values are: $\Delta G^{\ddagger}$ = 23.32 kcal/mol for 1-phenylethyl bromide and $\Delta G^{\ddagger}$ = 22.20 kcal/mol for 2-phenylethyl bromide in ethanol at 25 °C. The rate constants for ethyl, isopropyl, and *tert*-butyl bromides taken from the literature were as reported previously (1).

Table 3. Effect of substituents on pK_a values for carboxylic acids in various solvents.

Model used for the E2 reaction

The model, which is used in applying NBT to the E2 eliminations, is that the reaction proceeds from the encounter complex of base and alkyl halide to the product encounter complex of halide ion, alkene (and alcohol), and that the five simple processes that combine to give the concerted elimination are: transfer of a proton from carbon to base; change in geometry at the carbon, which loses a proton from sp^3 to sp^2; breaking the C-leaving group bond; change in geometry at the carbon, which loses the leaving group from sp^3 to sp^2; change in the length of the carbon–carbon bond.

Computer programs for calculations

To ease the burden of the number of calculations, which must be carried out to evaluate the relative energies of all corners (32 per reaction for a five-dimensional model), we have written computer programs, which: (*a*) examine the structures of the initial and final complexes and pick out the reaction dimensions; (*b*) construct structure files for each corner, and for the form of the starting material, product, cation or anion contained in that complex ready for the MO calculation of the energy; (*c*) extract results (distortion energies) from the set of output files; (*d*) calculate the corner energies involving all the effects included in the model; (*e*) search for the transition state.

Initial structures were generated and optimized using PCModel (12). All molecular orbital calculations were carried out using GAUSSIAN 98 (34) or GAUSSIAN 03 (35). Heats of formation or entropies were calculated using the G3MP2B3 (2) method in Gaussian; distortion energies were calculated at the B3LYP/6-31+G** level using DFT and the B3LYP (36, 37) method. Solvation energies were calculated at the IPCM/B3LYP/6-31G(d)//B3LYP/6-31G(d) level using the IPCM continuum solvation method (38).

Note: The reaction is the ethoxide induced elimination of alkyl bromide in ethanol at 25 °C; distortion energies are in kcal/mol; if the reactive conformation of the starting alkyl bromide or product alkene is not the same as the lowest energy conformation, then these corners will have distortion energies. The dimensions are not defined in the same way for all compounds; the programs, which assign dimensions, do so in a logical but not necessarily a convenient (for humans) fashion. For ethyl, isopropyl, and 2-phenylethyl bromides, the dimensions are: *v*, C-Br bond breaking; *w*, proton transfer; *x*, C(H) geometry; *y*, C(Br) geometry; *z*, bond length. For *tert*-butyl and 1-phenylethyl bromides, the dimensions are: *v*, C-Br bond breaking; *w*, proton transfer; *x*, C(Br) geometry; *y*, C(H) geometry; *z*, bond length.

Results

To apply the model to a specific E2 reaction, we calculated the free energies of the various corner species: starting material, products, cation, and anion as previously described, and then the specific corner species by including all the interactions previously described. The distortion energies relative to the starting material, product, cation, and anion were calculated at the B3LYP/6-31+G** level, with geometries of the parent species altered according to the reaction dimensions, which had changed. For each distorted structure a partial optimization was carried out with the variables defining the reaction locked at the values specified for that structure. The distortion energies calculated are found in Table 4. These values, combined with the proton transfer equilibria, hydrogen bond equilibria, ion-pair equilibria, desolvation, etc., lead to the corner energies in Table 5. Finally searching the energy hypersurface defined by the corner energies and the postulates of NBT lead to the transition state energies and coordinates found in Table 6.

To examine the nature of the transition state, we projected the five-dimensional reaction diagram onto a two-dimensional diagram with the carbocation (really ion triple) and carbanion corners as the two intermediates to be considered. This requires a two-stage projection. Because of the nature of the reaction dimensions, the carbocation corner corresponds to (1,0,0,1,0) and the carbanion to (0,1,0,0,0); the initial state (0,0,0,0,0) is taken to be alkyl halide and ethoxide, and the product, (1,1,1,1,1) to be alkene, ethanol, and bromide. The carbanion is assumed to be approximately tetrahedral, while the carbocation is planar. The *x* and *z* dimensions are 0 for both intermediates and the product, so we first projected these dimensions onto a three-dimensional cube (*v*,*w*,*y*) and then projected *v* and *y* onto a new dimension corresponding to the progress towards the carbocation, while *w* represents progress towards the carbanion.

Note: The reaction is the ethoxide-induced elimination of alkyl bromide in ethanol at 25 °C; distortion energies are in kcal/mol; explanations as for Table 4.

Table 6. Observed and calculated free energies of activation for the E2 reactions of alkyl bromides with ethanolic ethoxide ion at 25 °C and transition state positions.

Compound	ΔG^*_{obs}	ΔG^*_{calc}	Dif.	*v*	*w*	*x*	*y*	*z*	*c*+	*c*–
CH_3CH_2Br	26.46	25.69	–0.76	0.406	0.609	0.469	0.141	0.344	0.274	0.609
$(CH_3)_2CHBr$	25.13	23.12	–2.01	0.422	0.609	0.297	0.250	0.359	0.336	0.609
$(CH_3)_3Br$	23.63	21.67	–1.96	0.391	0.531	0.313	0.281	0.281	0.352	0.531
$PhCH(Br)CH_3$	23.58	23.54	–0.04	0.438	0.375	0.344	0.563	0.188	0.376	0.344
$PhCH_2CH_2Br$	22.46	24.66	2.20	0.25	0.563	0.375	0.375	0.375	0.313	0.563

Note: *v*, *w*, *x*, *y*, *z* are the "simple process coordinates"; *c*+ is the projection of the transition-state position on the initial state to "carbocation" dimension; *c*– is the the projection of the transition-state position on the initial state to "carbanion" dimension; see the text for a discussion of these dimensions and projections.

The resulting positions of the transition states, projected onto a two-dimensional reaction diagram, are shown in Fig. 1. The results are mostly as expected: the transition state for 2-phenylethyl bromide has the least carbocation character and the most carbanion character; the transition state for *tert*-butyl and 1-phenylethyl bromide have the most carbocation character and the least carbanion character.

Discussion

The goal of this approach for calculating the rate constants is to use the equilibrium information and the usual models of physical organic chemistry to predict the rate constants without using any empirical kinetic information. A problem, which arises from time to time, is that we need

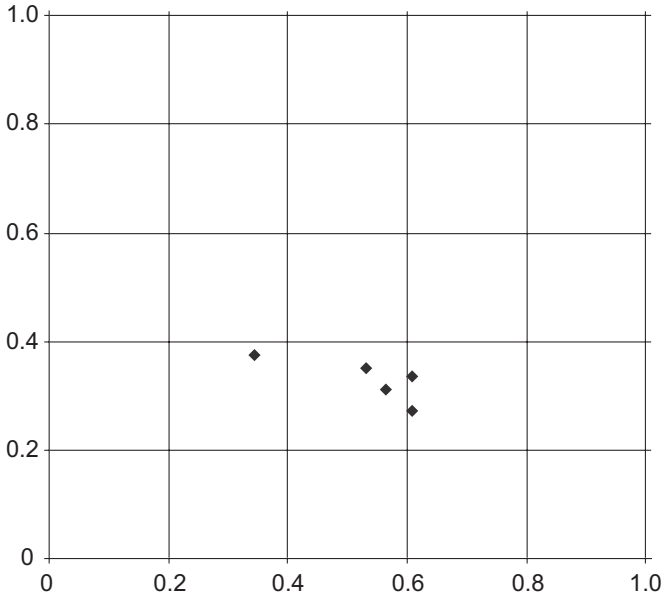
Fig. 1. Projected transition-state positions for the E2 reactions discussed here. (1,0) is the ion triple (ethoxide, carbocation, and bromide); (0,1) is the carbanion; (1,1) is the product complex. Projected coordinates calculated as described in the text and taken from Table 6.



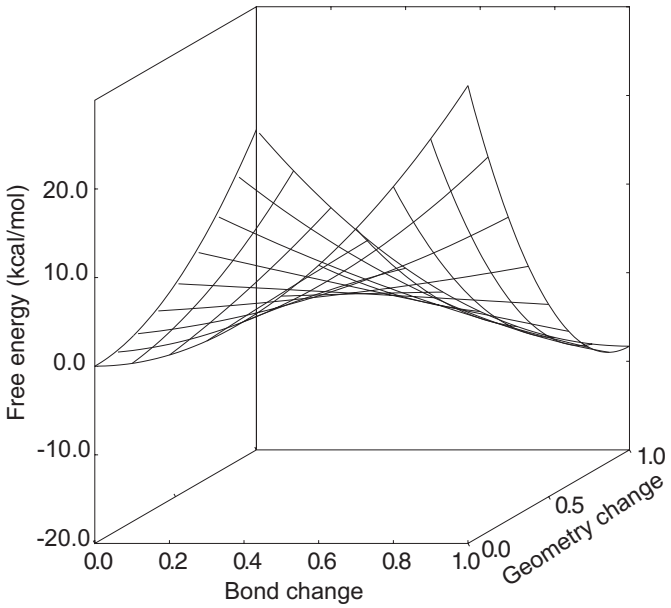


Fig. 2. A two-dimensional reaction diagram with the free energy orthogonal to the two reaction dimensions.

quantitative estimates for quantities normally talked about qualitatively. Such a problem arises when desolvation must be considered: it is generally accepted that ethoxide is strongly solvated and if one of the solvent molecules is lost and replaced by a weakly interacting molecule, then there will be a thermodynamic cost. What is not generally accepted is any general way to estimate this desolvation cost. Two kinds of desolvation arise in this work. There is a cost for having bromide and the OH of ethanol in contact with the product alkene; here we estimated the cost based on the free energies of transfer from a solvent capable of hydrogen bonding to one which is not. The energies involved are relatively small, so we should have satisfactory accuracy. Although bromide is not really a hydrogen bond acceptor, it will be better solvated by the more polar OH group of ethanol than the π cloud of an alkene. There is also a desolvation to consider when ethoxide is in contact with a C-H of an alkyl halide or a carbocation. We have based the estimates used in this work on the change in basicity of ethanol from water to DMSO, assuming this reflects the loss of three hydrogen bonds. If one were to use the very high pK_a of the CH of an alkyl bromide in the Stahl–Jencks equation, then a desolvation larger than 6.1 kcal/mol estimated previously would be obtained. This seems unrealistic because the ethoxide could at very low cost move slightly farther from the CH and lessen the interaction. Since this is a very low cost motion, it need not constitute an additional dimension. What is more problematic is the situation of ethoxide in "hydrogen bonding" contact with the β-CH of a carbocation. This hydrogen is, at equilibrium, a very strong acid, and thus, expected to form a strong hydrogen bond. However, when looking at the interaction of water with the β-CH of isopropyl cation (with the H oriented for hyperconjugation) the interaction is quite weak (G3MP2B3 calculations). The H_2O isopropyl cation complex has a noticeably elongated C—H bond 1.19 vs. 1.11 Å for the uncomplexed β-CH on the other methyl with the hyperconjugation orientation. Thus, even for a weak interaction there is noticeable elongation. This is in accord with the usual assumptions that hydrogen bonding involves partial proton transfer (normally to a slight extent only). For the situation of interest for this work, ethoxide in contact with a β-CH of a carbocation, this becomes a serious problem because a significant bond lengthening would be expected (if in fact the proton did not simply transfer) yet by the definition of a corner species the C—H bond length is locked at the initial value. This means that the hydrogen bond energy calculated by the Stahl–Jencks equation will be in error to some large but unknown extent. This poses a problem: on one hand if we regard the situation as ethoxide having lost a hydrogen bond to ethanol and forced to be in contact with a CH, then a desolvation of 6.1 kcal/mol is predicted; on the other hand we regard the situation as an ethoxide in contact with a quite acidic CH capable of forming a hydrogen bond then a complexation negative by several kcal/mol is predicted. There are reasons to believe both extremes are wrong, but at the moment apparently there is no way to make a better calculation. For the moment the best course of action seems to set the desolvation–hydrogen bonding to zero, at least between the two extremes. The saving thing is that the carbocation is in most cases a relatively high energy intermediate in ethanol and thus, the transition-state energy is relatively insensitive to errors in the energy of carbocation corners.

Despite these uncertainties in some of the quantities needed to calculate the rate constants by NBT, the overall predictions are quite good. The rms error in the free energy of activation for five E2 reactions is 1.63 kcal/mol; the reactions have $\Delta G^{\ddagger}$ values ranging from 22.20 to 26.46 kcal/mol, corresponding to the rate constants ranging from 3.3×10^{-4} to 2.5×10^{-7} $(mol/L)^{-1}$ s^{-1}.

It is surprising that the transition state positions are so similar for all the reactions considered in this work. There is

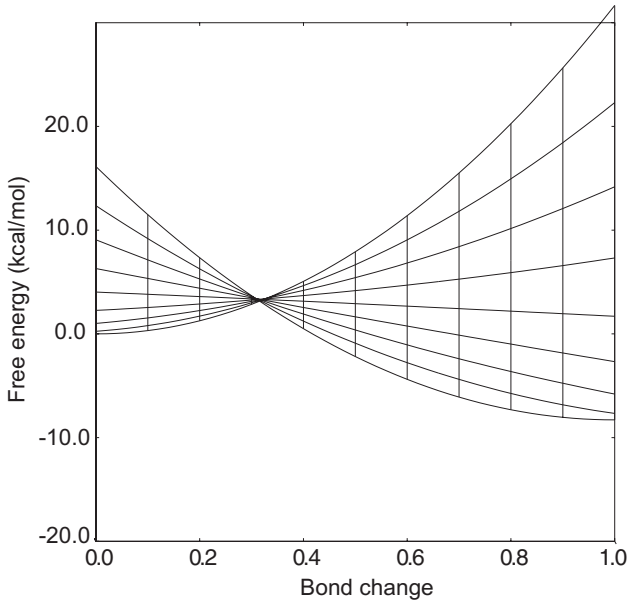
Fig. 3. Projection of the diagram in Fig. 2 onto the bond change — free energy plane to illustrate the crossover implied by our model.



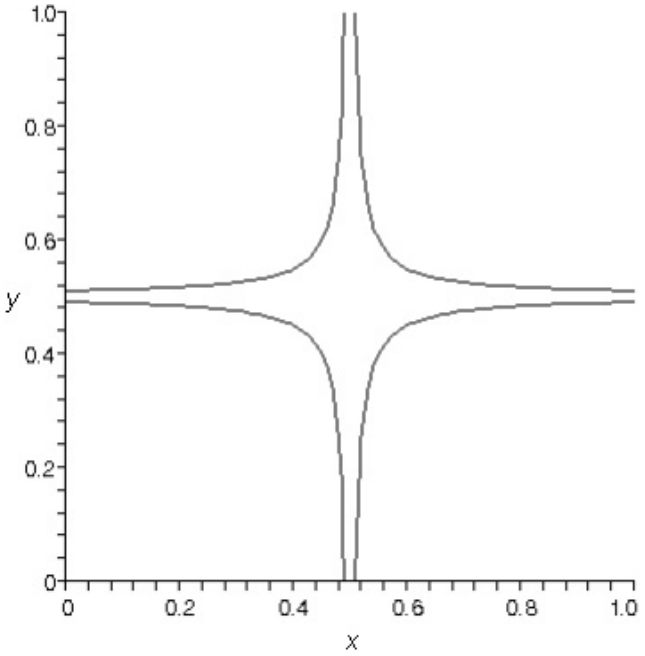


Fig. 4. Region of the reaction diagram with energy similar to that of the transition state (schematic with the transition state arbitrarily set at (0.5, 0.5)).

variation, which is in the expected directions, but the total variation is small. It should be kept in mind that the NBT model is designed to specify the transition-state energies and may not be well-suited to the specified transition-state positions. In particular, we expect that there will be a significant region of hyperspace with very similar energy centered in the transition state. This is most easily seen in a 2-dimensional case. Figure 2 shows a "two-dimensional" reaction diagram, with energy as a third dimension. The assumption of NBT is that for a proper choice of coordinates, when only one coordinate changes, the energy is a quadratic function of that coordinate, rising from a minimum at the lower energy end to the higher energy end. Thus, when the initial and final edge quadratics have the same energy, the energy along the orthogonal coordinate will be approximately constant. This can be seen by a projection as in Fig. 3 where we projected along the geometric distortion coordinate to make clear the crossover between the initial and final parabolas. Alternatively, by looking at a 2D diagram with only reaction coordinates as axes, it is expected that for the coordinates of the transition state there is an approximately cross-shaped region of the reaction coordinate space where energy will be essentially the same. This is illustrated in Fig. 4. A similar analysis for a 3D system shows that for each face there is one point where energy along the coordinate orthogonal to the face is essentially independent of that coordinate and there is a starlike region of hyperspace with essentially the same energy. Analogous situations obtain for the higher dimensional reaction coordinate diagrams, but such a diagram for a 5D reaction, such as the E2, is very difficult to present in an intelligible fashion.

A corollary of this analysis is that in addition to the traditionally assumed reaction path with all reaction dimensions changing at once as the path passes from the starting material through the center of the reaction diagram and through the transition state to the product, there are many alternative paths, which access the region of the transition-state energy by a lower dimensional path, then proceed through to the transition state and finish by another lower dimensional path.

The algorithm currently used to find the transition state finds the lowest energy point from which it is possible to proceed to either starting material or product without going higher in energy. There are typically hundreds or thousands of candidates, many of very similar energies, which are examined in turn; there is no guarantee that the traditionally pictured transition will be the one reported, and not one of very similar energies far along one of the arms of the star. Thus, the energy may be quite good, but the position may not be well-specified.

Appendix B

Experimental values for the partitioning of ethanol from gas to ethanol and from gas to chloroform (log L = 2.80 (B1)) were available, but values had to be estimated for dimethyl ether. The partitioning constant (log L) from gas to ethanol for diethyl ether could be calculated using Abraham's solvatochromic equation with coefficients from ref. B2 and the values for the solvatochromic parameters for diethyl ether from ref. B3. Since log L can be estimated by group additivity, a contribution for [CH_2] could be calculated from data for a series of normal hydrocarbons (B2). Subtracting this contribution (0.44) twice from the value for diethyl ether gave log L for dimethyl ether as 1.63. Similarly, a contribution for [CH_2] to log L from gas to chloroform could be calculated from data for hexane, octane, and cyclohexane as 0.54. Subtracting this contribution twice from the experimental value of log L for diethyl ether (3.05 (B1)) gave the desired value for dimethyl ether. It is now straightforward to calculate the partition constant from ethanol to chloroform for ethanol (log P = –0.93) and dimethyl ether (log P = 0.34), and thus, the free energies of transfer (ethanol, ΔG_t = 1.27; dimethyl ether, ΔG_t = –0.47) and finally the difference in the free energies of transfer, which is the cost of losing one hydrogen bond form OH to solvent. This was found to be 1.74 kcal/mol.

Table B1. Free energies of transfer from ethanol to chloroform.

Compound	$\log L^{EtOH}$	$\log L^{CHCl_3}$	$\log P^{EtOH>CHCl_3}$	$\Delta G_t^{EtOH>CHCl_3}$
EtOH	3.73[a]	2.8[b]	–0.93	1.27
Me_2O	1.63[c]	1.98[c]	0.34	–0.47

Note: At 25 °C; log L is concn. (mol/L) solute in solvent–concn. (mol/L) solute in gas phase; $\log P^{EtOH>CHCl_3}$ is concn. (mol/L) in $CHCl_3$–concn. (mol/L) in EtOH; $\Delta G_t^{EtOH>CHCl_3}$ is $-2.303RT$ log P; units for ΔG_t are kcal/mol. The cost of losing one hydrogen bond = 1.27 – (–0.47) = 1.74 kcal/mol.

[a]Experimental value, based on the vapor pressure of ethanol.

[b]Experimental value, ref. B1.

Appendix C

Available pK_a values permitting calculation of fall-off factors are given in Table B1. We first calculated the difference in pK_a upon introducing a substituent (δpK_a). Then we calculated the fall-off factor as the ratio of δpK_a with two intervening CH_2s to δpK_a with only one intervening CH_2. An alternative calculation is to take the square root of the ratio of δpK_a with three intervening CH_2s to δpK_a with only one intervening CH_2. Simple average values are: methanol, 0.47 ± 0.26; water, 0.33 ± 0.14. Although the average for methanol is larger, the range of values overlaps and the standard deviations are large. One cannot conclude that these values differ.

Table C1. Fall-off factors in water and methanol.

	Methanol				Water			
Acid	pK_a	δpK_a[a]	F[b]	F′[c]	pK_a	δpK_a[a]	F[b]	F′[c]
CH_3COOH	9.63	0.0			4.76			
$BrCH_2COOH$	8.06	1.57			2.86	1.90		
$ClCH_2COOH$	7.88	1.75			2.86	1.90		
$BrCH_2CH_2COOH$	9.00	0.63	0.40		4.02	0.74	0.38	
$ClCH_2CH_2COOH$	9.18	0.45	0.26		4.08	0.74	0.38	
$BrCH_2CH_2CH_2COOH$					4.58	0.18	0.24	0.30
$ClCH_2CH_2CH_2COOH$	9.29	0.34	0.76	0.44	4.52	0.24	0.32	0.36

Note: pK_a values from ref. C1.

[a]pK_a–pK_a for acetic acid.

[b]Fall-off factor: δpK_a for n CH_2s/(δpK_a for (n – 1) CH_2s).

[c]Fall-off factor: $\sqrt{}$(δpK_a for $(CH_2)_3$/δpK_a for CH_2).

Appendix D

Data on the effect of a charge are hard to find, but one imperfect example is the pK_a for glycine dissociation in water and aqueous ethanol. The effect of changing solvent on the pK_a of glycine is smaller than that on the pK_a of benzoic acid, suggesting that there is no increase in the effect of a plus charge on changing solvent. The effect of changing solvent on the pK_a of glycine or acetic acid are very similar (the slopes of plots of pK_a vs. % ethanol are 0.022 for acetic acid, 0.016 for glycine, and 0.028 for benzoic acid); thus, the effect of a charged substituent is about the same.

Table D1. Effect of solvent on pK_a values for benzoic acid, acetic acid, and glycine.

Solvent: % ethanol	pK_a benzoic acid	pK_a glycine	pK_a acetic acid
0	4.18,[a] 4.21[b]	2.38,[a] 2.34[c]	4.76[d]

On the displacement reactions of organic substances in water[1]

J.M.W. Scott

Abstract: The hydrolyses of a series of organic halides, nitrates, sulphonates, and perchlorates are examined from the standpoint of thermodynamics, kinetics, temperature dependence, isotope effects, the Kurz equation, and the Guthrie linear free energy relationship. The thermodynamics of several definite bimolecular displacements are also examined. Some mechanistic revisions are suggested to reach an improved accommodation with the experimental observations.

Key words: kinetics, thermodynamics, hydrolytic displacements, mechanism, ionic displacements, nucleofugality, linear free energy relationships.

Résumé : On a étudié la thermodynamique, la cinétique, l'influence de la température, les effets isotopiques, l'équation de Kurz et la relation linéaire d'énergie libre de Guthrie de l'hydrolyse d'une série d'halogénures, de nitrates, de sulfonates et de perchlorates organiques. On a aussi examiné des caractéristiques thermodynamiques de plusieurs déplacements bimoléculaires bien définis. On suggère quelques révisions mécanistiques pour mieux réfléter les observations expérimentales.

Mots clés : cinétique, thermodynamique, déplacements hydrolytiques, mécanisme, déplacements ioniques, nucléofugacité, relation linéaire d'énergie libre.

[Traduit par la Rédaction]

Prologue

"Because people are unwilling to challenge the expertise of their colleagues, or experts in other areas, the Old Guard can continue for many years to obstruct innovations they dislike. All experts may be equal, but some are more equal than others!" (M.J.S. Dewar in *A semiempirical life* (p. 180, 1992)).

"……. of all forms of mental activity, the most difficult to induce even in the minds of the young, who may be presumed not to have lost their flexibility, is the art of handling the same bundle of data as before, but placing them in a new system of relations with one another by giving them a different framework, all of which virtually means putting on a different thinking cap ……" (Herbert Butterfield in *The origins of modern science 1300–1800* (p. 1, 1957)).

"…. one cannot be a self respecting scientist without being a rebel" (Roger Penrose in *Nature's imagination* (Chap. 2, p. 12, 1995)).

Introduction and synopsis

The present review incorporates 17 sections with the purpose of scrutinizing the original Hughes–Ingold S_N1–S_N2 mechanistic description for displacements at a saturated carbon atom *in water*

Received 14 April 2005. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 8 December 2005.

[2]M.J. Blandamer, R.E. Robertson, and J.M.W. Scott. Unpublished material.

$$[1] \quad RX + 2H_2O \rightleftharpoons ROH + H_3O^+ + X^-$$

and includes displacements with charged nucleophiles in the same solvent. For a substantial range of structural alterations in (*a*) the organic group (R), (*b*) leaving group (X) of RX, and (*c*) the attacking nucleophile, the observed reactivity sequences intimate that the simple S_N1–S_N2 descriptions are inadequate and require revision.

The study of displacement reactions has generated a variety of concepts that are central to modern organic chemistry and studies in this area have continued to attract interest during the second half of the last century (1–24).[2] Mixed aqueous solvents have been the favoured media for kinetic studies of displacement reactions. In some cases the nonaqueous co-solvent may compete with the water as a nucleophile. The latter possibility complicates the kinetics particularly if the product-forming step is partly or wholly rate-determining. For the sake of simplicity, the present review largely confines attention to situations where the displacements occur in pure water and is only comprehensive from this particular viewpoint. The focus on aqueous systems is not meant to imply that the mechanisms of displacements in water are simple.

Section 1 examines the thermodynamics of the two reactions

$$[2] \quad CH_3X + 2H_2O \rightleftharpoons CH_3OH + H_3O^+ + X^-$$

$$[3] \quad CH_3X + OH^- \rightleftharpoons CH_3OH + X^-$$

with X = F, Cl, Br, and I in solvent water. The calculated equilibrium constants with the measured and calculated kinetic data for the eight reactions summarized by eqs. [2] and [3] suggest that the processes described by eq. [2] necessarily involve the intermediate production of the methyloxon-

 doi: 10.1139/V05-166 © 2005 NRC Canada

ium ion ($CH_3OH_2^+$) and that proton loss from this species is the *last step* in the hydrolysis. Indeed, eq. [2] as it stands omits the crucial fact that the product methanol will react with the hydronium ion to give the methyloxonium ion

$$[4] \quad CH_3OH + H_3O^+ \rightleftharpoons CH_3OH_2^+ + H_2O \ (K_e = 9.1 \times 10^{-3})$$

and consequently eq. [2] is a superficial account of an aqueous solution originally containing a methyl halide.

Section 2 examines the thermodynamics of the classical S_N2 displacements in water summarized by

$$[5] \quad Y^- + CH_3X \rightleftharpoons CH_3Y + X^-$$

where X = F, Cl, Br, and I: Y^- = F^-, Cl^-, Br^- and I^-, measured by Moelwyn-Hughes and several co-workers. A probing thermodynamic analysis of the rate measurements suggest that there is considerable evidence that the mechanism for these reactions is more complex than hitherto realized.

The mechanistic hypothesis that broaches the intermediacy of $CH_3OH_2^+$ for the reaction described by eq. [2] is elaborated in section 3 by analysing rxns. [2] and [3] for a wide range of leaving groups via the Kurz equation. These considerations vindicate the conclusions established in section 1 and concomitantly provide an improved understanding of the relative rates of solvolysis for a wide range of substrates in ordinary water and deuterium oxide often designated as the kinetic solvent isotope effect (KSIE) that is examined further in section 4. The small KSIE evinces no primary character and this observation is consistent with the nucleophilic water molecule, either light or heavy, shedding either its proton or deuteron to the solvent in a final fast step. Thus, the KSIE is consistent with the intermediacy of $CH_3OH_2^+$.

Solvolytic reactions in water give rise to activation energies that normally *decrease* with temperature. This observation may be discussed in thermodynamic terms involving genuine negative heat capacities of activation. However, there is alternative explanation in terms of kinetic complexity originally proposed by Albery and Robinson (21). The two contending interpretations are examined in sections 5 and 6 where it is concluded that the kinetic explanation has a slight edge. This judgment suggests that a more elaborate analysis of the raw experimental concentration–time data might be revealing. The revised analysis is reported in section 7 using numerical methods that were precluded when the raw data were initially measured. The amended analysis in sections 6 and 7 marginally favours reaction complexity as a source of the non-Arrhenius temperature dependence.

Section 8 presents some general observations concerning solvolytic reactivity as a function of the structure of the leaving group. This discussion is continued in section 9 with an examination of the Swain–Lohmann equation together with a modified version of this particular linear free energy relationship (LFER). The latter relationships show some unexpected and revealing similarities between the reactivity sequences of primary centres and those related to caged secondary substrates.

Section 10 examines and extends the Guthrie LFER that correlates rates of solvolysis of a series of methyl substrates (CH_3X with X variable) with the pK_a of HX. This correlation was confined originally to molecules yielding oxygenated anions on heterolysis. However, this LFER fails when the methyl halides are included.

Section 11 examines the Guthrie LFER for a wide range of halogen displacements at both carbon and inorganic (metallic) centres. The failure of the Guthrie LFER to embrace both oxygenated ions and halide ions as leaving groups in a single LFER possibly reflects internal return phenomena in the case of the halogen leaving groups. The kinetic data offers a measure of confirmation of the pK_a values calculated for the halogen acids by Myers.

Section 12 proffers an overview of the earlier discussions with respect to the reactivity of primary, secondary, and tertiary substrates in water. The various LFER correlations developed earlier provide reliable estimates of the solvolytic reactivity of several tertiary sulphonates in water.

Section 13 shifts the discussion to correlations between solvolytic reactivity and the gas-phase enthalpy of ionization of RX in cases where the immediate steric situation in the vicinity of the reacting carbon atom remains sensibly constant as the structure of the organic part of RX is altered e.g., structures such as RCH_2X. The various correlations detailed in the earlier sections give rise to an interesting array of conflicting reaction coordinate parameters. The discussion in section 13 shows that the degree of heterolysis of the RX bond in solution appears to *increase* as the enthalpy of ionization RX *decreases*. Previous quantum mechanical studies of varying degrees of sophistication to calculate the energy of heterolytic fission of RX in the gas phase are briefly considered.

Section 14 introduces a new LFER that relates to two series of molecules RX(1) and RX(2) with fixed leaving groups X(1) and X(2) and variable R groups. When X(1) = mesylate and X(2) = bromide, the new LFER underpins comment on the previous investigations by Hoffmann relating to the reactivity of these and other similar leaving groups.

Section 15 examines the possible origins of the curved Hammett plots that frequently characterize both solvolytic and definite S_N2 displacements, possibly proceeding by complex mechanisms.

Section 16 relates the Kurz analysis to secondary α-deuterium isotope effects involving such pairs as CH_3–CD_3, CH_3CH_2–CH_3CD_2, and $(CH_3)_2CH$–$(CH_3)_2CD$ with several leaving groups. Finally, section 17 offers some brief comments on the limitations of mechanistic organic chemistry.

1. The thermodynamics and kinetics of the reaction of the methyl halides with water and the lyate ion

The reactions of the methyl halides with water (w) and lyate (l) ion form the initial focus of the present contribution.

$$[6] \quad CH_3X + 2H_2O \underset{k_{bw}}{\overset{k_{fw}}{\rightleftharpoons}} CH_3OH + H_3O^+ + X^-$$

$\Delta H^{\ominus}$	–9.653	–4.703	–4.673	–1.653
$\Delta S^{\ominus}$	–21.676	–6.186	–1.346	1.749
$\Delta G^{\ominus}$	–3.190	–2.859	–4.271	–2.188
$K_{ew}\times10^{-2}$	2.18	1.25	13.5	0.40
$k_{fw}(21, 39)^a$	7.89×10^{-10}	2.39×10^{-8}	4.07×10^{-7}	7.35×10^{-8}
k_{bw}	3.62×10^{-12}	1.91×10^{-10}	3.01×10^{-10}	1.84×10^{-9}
$k_{fl}(9, 37, 42)^a$	5.85×10^{-7}	6.57×10^{-6}	1.46×10^{-4}	6.340×10^{-5}
k_{bl}	2.68×10^{-23}	5.3×10^{-22}	1.08×10^{-21}	1.58×10^{-19}

Note: MeX: X = F, Cl, Br and I: T = 298.15 K. $\Delta H_f^o(H_2O,liq)$ = –68.32 (29); $S(H_2O,liq)$ = 16.72 (29); $\Delta H_f^o(CH_3OH,sln)$ = –58.77 (30); $\Delta H_f^o(OH^-,sln)$ = –54.98 (29)); $S(CH_3OH,sln)$ = 30.29 (30); $S(OH^-,sln)$ = –2.61 (29). Enthalpies and the Gibbs function are reported in kcal and entropies in cal mol^{-1} K^{-1}. The units for the forward rate constants for k_{fw} are s^{-1} and for k_{fl}, L mol^{-1} s^{-1}. The units for the k_{bl} are the same as those for the forward reaction. The units for the back reaction in water are less obvious. The back reaction can be assumed to be a third-order reaction (Rate = $k_{bw}[MeOH][H_3O^+][X^-]$) with dimensions for k_{bw} of L^2 mol^{-2} s^{-1}. However, we argue in the text that the retro-hydrolysis takes place minimally by two second-order steps (see section 1). No attempt was made to assess the significance of the water concentration in calculating the reverse rate constants for the reactions in water.

[a]Some of the data in this table have been reprocessed with superior least-squares algorithms and this may account for any small differences from previously reported data.

$$[7]\qquad CH_3X + OH^- \underset{k_{bl}}{\overset{k_{fl}}{\rightleftharpoons}} CH_3OH + X^-$$

The pioneer studies of these displacements with R = CH_3, X = F, Cl, Br, and I (eq. [6]) were carried out by Moelwyn-Hughes (9 and refs. therein) alone and later with other authors. The Henry's Law constants (K_{hl}) that quantify the equilibria for the methyl halides

$$[8]\qquad CH_3X(aq) \overset{K_{hl}}{\rightleftharpoons} CH_3X(g)$$

have been measured by Glew and Moelwyn-Hughes (25) and these data are also important in the present context.

The kinetic studies launched by Moelwyn-Hughes have been repeated and extended by Robertson and numerous coworkers (6, 15)[2] using improved technology at the National Research Council in Ottawa and later at the University of Calgary. A remarkable body of data exist because of these efforts.[2] Other contributions by Albery and Robinson (21), Guthrie (23), Kurz (24), and Blandamer and Scott (22) are also important to the present considerations.

The thermochemistry of several methyl esters hydrolysing in pure water has been examined thoroughly by Guthrie (23): for earlier contributions see (26–28). The reactions of the methyl halides (CH_3X, X = F, Cl, Br, and I) with water and hydroxide ion were omitted from Guthrie's study, although the required thermochemical and kinetic data related to eqs. [6] and [7] were available at the time. A complete thermochemical account of the rxns. [6] and [7] can be calculated from the data assembled in Tables 1 and 2. The computed equilibrium constants (K_{ew}) for the reactions summarized by eq. [6] and the analogous quantities for eq. [7] (K_{el}) are also presented in Tables 1 and 2. Granted that the reactions of the methyl halides with water and the lyate ion are simple S_N2 displacements, i.e., a single transition state separates the reactants and products, then the values of k_{bw} and k_{bl} for the reverse reactions can be estimated from the measured forward rate constants (k_{fw} and k_{fl}) and the appropriate computed equilibrium constants (K_{ew} and K_{el}).

Several significant points emerge from these calculations. First, the second-order rate constants (k_{bl}) are relatively small and the related equilibrium constants (K_{el}) are correspondingly large. In contrast, the k_{bw} rate constants are comparable to the k_{fw} values and, necessarily, the equilibrium constants K_{ew} are relatively close to unity. Alternatively, the processes in which individual halide anions attack methyl alcohol are relatively slow reactions and, by inference, *cannot form any significant part of the* k_{bw} *process*. This means that the postulate previously advanced, namely that the *hydrolysis reaction* is a simple S_N2 process, is possibly in error. There is one further point to be made: eq. [6] is *an approximate description* of the reaction of the methyl halides with water because in the presence of hydronium ion from the hydrolysis some of the methanol will be converted into the methyloxonium ion (see eq. [11]). This important fact adds substance to the following discussion.

Second, the back reaction rate constants for the water and lyate, namely, k_{bw} and k_{bl} reactions *have different dimensions* if eq. [6] is considered sufficient to describe the water reaction completely. Thus, the back reaction for the former process is third order, whereas the back reaction with lyate ion is second order. Hence, k_{bw} and k_{bl} cannot be compared numerically. Generally speaking, the chemical literature concerned with kinetics regards third-order reactions with a good deal of scepticism because fruitful ternary collisions are improbable events. Granted that the grounds for this scepticism are valid, then the back reaction for water must be regarded as occurring minimally by two steps. There are

at least a pair of second-order reversible two-step mechanisms that can be envisaged for the water back reaction. The first two-step mechanism involves the halide ion X^- attacking methanol liberating lyate ion

[9] $$CH_3OH + X^- \rightleftharpoons CH_3X + OH^- \text{ (slow)}$$

followed by the reaction of the generated lyate ion with hydronium ion.

[10] $$H_3O^+ + OH^- \rightleftharpoons 2H_2O \text{ (fast)}$$

The second two-step mechanism consists of a relatively rapid attack of hydronium ion on methanol

[11] $$CH_3OH + H_3O^+ \rightleftharpoons CH_3OH_2^+ + H_2O \text{ (fast)}$$

followed by

[12] $$CH_3OH_2^+ + X^- \rightleftharpoons CH_3X + H_2O$$ (fast relative to eq. [9])

A comparison of eqs. [9] and [10] vs. eqs. [11] and [12] reasonably favours the latter sequence because eq. [9] describes a very slow reaction: see k_{bl} in Table 1. On the other hand, eqs. [11] and [12] describe a proton transfer and an ion combination reaction, respectively: both these processes should be fast relative to a combination of eqs. [9] and [10].

These considerations reasonably lead to the conclusion that the *first* step of the retro-hydrolysis must involve the protonation of the alcohol to form the methyloxonium ion. If *protonation* is the first reaction of the reverse hydrolysis, the law of microscopic reversibility (4, 9, 18) in the form (18): "*The mechanism of a reversible reaction in the rearward direction is identical to the mechanism in the forward direction run backward*", predicates that *proton loss must be the last step* in the hydrolysis. This represents the first significant departure from the conventional description of these reactions, although Guthrie (23) suggests that the hydrolysis is a two-step reaction that proceeds via the methyloxonium ion ($CH_3OH_2^+$). On the other hand, Guthrie offers no reason for invoking the methyloxonium ion as an intermediate, and further, does not mention that his proposal requires that proton loss must be the *last step* in the hydrolysis.

Perhaps the tone of some of the previous remarks is too categorical in the sense that there are few places in the chemical literature where the detailed mechanism of a displacement at a primary centre by water, usually described as a typical example of an S_N2 process, is carefully delineated. There is a general tendency to consider that the exothermic character associated with the partial formation of a solvated proton in an S_N2 transition state provides an important driving force for fission of the carbon – leaving group bond (34). The thermodynamic argument previously presented does not substantiate this idea and it is at variance with the facts related to the synthesis of alkyl halides from the related alcohols under acid conditions. Of course, in favourable conditions the latter reaction may involve free carbocations generated via alkyloxonium ions. This is an uncongenial proposition in the case of methyl alcohol.

Here, the simple S_N2 description for the reaction of water with the methyl halides conceived in terms of the following three *concerted* events (*i*) carbon–oxygen bond formation between the attacking water molecule and the reacting carbon atom, (*ii*) proton transfer, and (*iii*) loss of the neutral or ionic leaving group, is *explicitly discarded.*

The retro-hydrolysis reaction is considered to occur in the following manner. The protonation of the alcohol is the first step

[13] $$CH_3OH + H_3O^+ \rightleftharpoons CH_3OH_2^+ + H_2O$$

There are two possible routes to the termination of the methyl halide synthesis from the methyloxonium ion and the halide ion: (*i*) the formation of the carbon–halogen bond and the loss of a water from the oxonium ion are postulated to be concerted processes or (*ii*) an intermediate exists between the methyloxonium ion and the fully formed methyl halide. The precursor of the latter might be either an ion pair or a Doering and Zeiss (35) intermediate. In the following scheme, the intermediate is specified as an ion pair, either intimate or solvent separated, merely for convenience: for

© 2005 NRC Canada

the present, the existence of an intermediate is a necessary feature required for future considerations. Thus, the remaining steps for the reverse hydrolysis are specified

[14] $X^- + CH_3OH_2^+ \rightleftharpoons X^-\cdots CH_3OH_2^+$

and

[15] $X^-\cdots CH_3OH_2^+ \rightleftharpoons CH_3X + H_2O$

Microscopic reversibility (see the previous section) demands that the mechanism for the hydrolysis is the reverse of rxns. [13]–[15], namely

[16] $$H_2O + CH_3X \underset{k_2}{\overset{k_1}{\rightleftharpoons}} H_2O\cdots CH_3^+\cdots X^- \underset{k_4}{\overset{k_3}{\rightleftharpoons}} CH_3OH_2^+ + X^- + H_2O \underset{k_6}{\overset{k_5}{\rightleftharpoons}} CH_3OH + H_3O^+ + X^-$$

There are two possible paths for the destruction of $H_2O\cdots CH_3^+\cdots X^-$. The first involves the complete ionization of the CH_3—X bond from the intermediate $H_2O\cdots CH_3^+\cdots X^-$ *without* the formation of a definite solvent-separated intermediate. The other arm of the bifurcation involves such an intermediate, specifically, $H_2O\cdots CH_3^+|H_2O|X^+$. This particular structure does not imply the eventual equivalence of the two water molecules, i.e., the inversion of the reacting carbon atom may still predominate if the inserted water molecule departs with the anion. Otherwise, it will be distributed between the leaving group and the carbon atom on the collapse of the intermediate. Thus, a mechanism that recognises the importance of solvent separation for the methyl compounds is possibly favoured, a point of view to be justified shortly.

The sequence of chemical events described by eq. [16] and the subsequent discussion will have a profound influence on the temperature dependence of the rate constants that characterize the aqueous displacement reactions leading to energies of activation that might show *either positive or negative temperature coefficients* that will be "mixed" with *bona fide* heat capacity changes: see sections 5 and 6, and refs. 6, 15, 21, and 22. The remainder of this contribution attempts to put the implications of eq. [16] on a firmer footing.

The k_5 and k_6 steps are, relatively speaking, well-established because the related equilibrium constant has been measured by Kurz and Saitz[3] ($pK_a = -2.04$). The other steps described by the rate constants k_1, k_2, k_3, and k_4 in eq. [16] are likely to be viewed less favourably and some further considerations originally presented by Kurz are important to our extended argument. The Kurz analysis is presented in section 3.

2. A thermodynamic analysis of some classical S_N2 displacements

The theoretical concept known as the S_N2 mechanism was originally established by the Ingold school (1, 8) and extended by others (2, 9, 11–13).This mechanism represents the conventional description of many displacement reactions in both organic and inorganic chemistry. More recently the S_N2 concept has been extended to gas-phase substitutions with notable success (17).

For carbon chemistry the isotopic exchange

[17] $CH_3I + I^{-*} \rightleftharpoons CH_3I^* + I^-$

exemplifies a prototypical example of such reactions in solution. The conventional wisdom postulates that this reaction is characterized by a symmetrical transition state (T.S.) with two identical partial bonds uniting the iodine atoms to the central carbon atom that is coplanar with the three symmetrically disposed hydrogens attached to it.

In contrast to the isotopic exchange reaction, displacements featuring a nucleophile and leaving group that differ, e.g., cyanide for the former reagent and iodide for the latter.

[18] $CH_3I + CN^- \rightleftharpoons CH_3CN + I^-$

These particular reagents attenuate the symmetries manifested for the displacement described by eq. [17]. The bonding of the departing and incoming reagents in this reaction is necessarily different, and concomitantly, the coplanarity of the hydrogen atoms with the reacting carbon atom is no longer assured. In the Marcus (36) theory of these reactions (13, 37, 38), the symmetry of the transition state is related to the thermochemical characteristics of the displacement, i.e., whether the reaction is either "uphill" (endoergonic), or "downhill" (exoergonic), or "on the level" (thermoneutral). The thermodynamic properties easily translate into structural information only for the symmetrical displacements that give rise to what are known as intrinsic barriers. For systems described by eq. [18], the collinearity of the reacting atoms in attacking and departing reagents with the reacting carbon atom is maintained, but the precise position of the hydrogen atoms attached to the carbon atom is uncertain.

Experimentally, when the concentrations of A and B are comparable, S_N2 displacements provide classic examples of second-order kinetics

[19] $$A + B \rightleftharpoons [T.S.] \underset{k_b}{\overset{k_f}{\rightleftharpoons}} C + D$$

The second-order rate constants k_f and k_b characterize the forward and back reactions with a *single* transition state separating the reactants and products. The Erying theory of reaction rates (39) requires the transition state to be in equilibrium with both the reactants, A and B, and the products, C and D.

When A = CH_3X (X = F, Cl, Br, and I) and B equals either OH^- or CN^-, these reactions are essentially irreversible, i.e., k_b is very small (see Table 1 and refs. 40 and 41). On the other hand, when B = F^-, Cl^-, Br^-, and I^-, the displacements summarized by eq. [19] are reversible in the sense that the rate constants can be measured for either the forward or reverse processes.

When [A] » [B] or vice versa, the reactions generalized by eq. [19] demonstrate pseudo-first-order kinetics with respect

[3] J. Kurz and R.M. Saitz. Private communication to R.E. Robertson. ca. 1979.

© 2005 NRC Canada

to the reagent present at the lower concentration. When the excess reagent is the solvent, a long-standing problem arises. In such cases, the solvent supplies both the reacting medium as well as the nucleophile, and the molecularity of the transition state for the displacement is ambiguous with respect to the solvent because alternative mechanisms are theoretically possible in which bond breaking and making are distinct kinetic processes: this is the so-called S_N1 mechanism. The focus in the present section is predominately concerned with those displacements that are traditionally regarded as displaying bimolecular transition states. Nonconcerted descriptions for traditional S_N2 displacements have been occasionally proposed. Such departures from the conventional wisdom (42, 43) have been subjected to critical scrutiny and, by and large, have been repudiated vigorously (33, 44, 45).

Albery and Robinson (21) described the hydrolysis reaction of *tert*-butyl chloride in water by the mechanism

$$[20] \quad A + B \underset{k_2}{\overset{k_1}{\rightleftharpoons}} I \xrightarrow{k_3} \text{Products}$$

and demonstrated that such a kinetic scheme would result in an observed activation energy that decreases with temperature. In more formal terms, a reaction proceeding by the mechanism presented in eq. [20] displays an apparent negative heat capacity of activation (6, 15). This particular description for the hydrolysis of *tert*-butyl chloride in which A represents the solvent water and B the substrate with [A] » [B] is certainly acceptable. However, the equation for the temperature dependence of the pseudo-first-order constants that describe the hydrolysis of *tert*-butyl chloride derived from the steady-state treatment of the kinetic scheme represented by eq. [20] also gives excellent fits for *several primary substrates* hydrolysing in water. This awkward and anomalous fact will be considered further in section 6.

The algebra related to the change of composition of systems reacting according to eq. [19] is standard fare in texts concerned with the basics of physical chemistry and monographs devoted to chemical kinetics. The mechanism represented by eq. [20] with one of either A or B in excess can be considered in terms of the steady-state theorem or without such approximations (21, 22).

The situation when the concentrations of species A and B are comparable and they react via a definite intermediate gives rise to *nonlinear differential equations* that require numerical integration (46). Some of the concentration–time data provided by such integrations that incorporate particular values of the rate constants k_1, k_2, and k_3 may provide acceptable numerical fits to the simple integrated second-order expressions (46). This sinister fact means that such fits may be actively misleading. More specifically, acceptable data fits to integrated second-order expressions do not necessarily confirm that a reaction is a simple S_N2 process.

Similarly, it has been shown (20) that the relationship that exists between the rate constants for racemization (k_r) and isotopic exchange (k_e), namely $k_r = 2k_e$ is a necessary but not a sufficient condition for the racemization and exchange processes to be characterized by the S_N2 displacement. The mechanism

$$[21] \quad (+)RX + X^- \underset{k_2}{\overset{k_\alpha}{\rightleftharpoons}} (T.S.) \underset{k_\alpha}{\overset{k_2}{\rightleftharpoons}} I \rightleftharpoons (T.S.) \rightleftharpoons (-)RX + X^-$$

$$[22] \quad RX + X^{-*} \underset{k_2}{\overset{k_\beta}{\rightleftharpoons}} (T.S.) \underset{k_\gamma}{\overset{k_2}{\rightleftharpoons}} I \rightleftharpoons (T.S.) \rightleftharpoons RX^* + X^-$$

where k_α, k_β, and k_γ are pseudo-first-order constants related to the second-order rate constant k_1 via the equations $k_\alpha = k_1[X^-]$, $k_\beta = k_1[RX]$, and $k_\gamma = k_1[X^-]$. The processes described by eqs. [21] and [22] involving the intermediate I also furnish the relationship $k_r = 2k_e$. Thus, this classical test does not guarantee that the simple S_N2 mechanism is operative. Readers are referred to the original paper (20) for further details.

The most important examples of simple S_N2 displacements are provided by the halide exchange reactions of the methyl halides

$$[23] \quad Y^- + CH_3X \overset{K_e}{\rightleftharpoons} CH_3Y + X^-$$

where $Y = F^-$, Cl^-, Br^-, and I^- and X = F, Cl, Br, and I (9, 40, 41). Granted that the 16 displacements all take place by the classical S_N2 mechanism, then the number of transition states implied by eq. [23] is *less* than the number of reactions. Thus, there are *four unique transition states* for the symmetrical exchanges ($Y^- = X^-$) that define four intrinsic barriers (13, 17, 38). On the other hand, there are only *six additional transition states* for the remaining 12 unsymmetrical displacements because the transition state for the process

$$[24] \quad X^- + CH_3Y \rightleftharpoons CH_3X + Y^-$$

is identical to that for the displacement described by eq. [23]. The thermodynamic quantities that characterize the 10 unique transition states, namely, $G^\ddagger$, $H^\ddagger$, $S^\ddagger$, and $C_p^\ddagger$ form the elements of a series of 4 × 4 Hermitian matrices $\lambda(i,j)(X^\ddagger)$ where $X = G, H, S$, and C_p. The entropy matrix is

$$[25] \quad \lambda(i,j)(S^\ddagger) = \begin{bmatrix} S^\ddagger(1,1) & S^\ddagger(1,2) & S^\ddagger(1,3) & S^\ddagger(1,4) \\ S^\ddagger(2,1) & S^\ddagger(2,2) & S^\ddagger(3,2) & S^\ddagger(2,4) \\ S^\ddagger(3,1) & S^\ddagger(3,2) & S^\ddagger(3,3) & S^\ddagger(3,4) \\ S^\ddagger(4,1) & S^\ddagger(4,2) & S^\ddagger(4,3) & S^\ddagger(4,4) \end{bmatrix}$$

with the conditions

$$[26] \quad S^\ddagger(i,i) \neq S^\ddagger(j,j) \text{ with } j = i = 1\text{–}4$$

and

$$[27] \quad S^\ddagger(i,j) = S^\ddagger(j,i) \text{ with } i \neq j = 1\text{–}4$$

Granted that the temperature dependence of the rates of the halide exchanges summarized by eq. [23] have been measured and other appropriate initial state thermodynamic data are available, then the formal requirements imposed on the matrix depicted in eq. [25] by the S_N2 mechanism specified by eqs. [26] and [27] can be tested.

Note: $\Delta G^{\ddagger}$ and $\Delta H^{\ddagger}$ are in kcal mol^{-1} and $\Delta S^{\ddagger}$ in cal mol^{-1} K^{-1}. C.C. is the correlation coefficient.

For any particular substitution, the following equations define any corresponding element $S^{\ddagger}(i, j)$ of the matrix in eq. [25] related to the displacements represented by eq. [23].

$$[28]\quad \Delta S^{\ddagger}(CH_3X,Y^-sln) = S^{\ddagger}(CH_3X,Y^-sln) - S(CH_3X,sln) - S(Y^-sln)$$

$$[29]\quad \therefore S^{\ddagger}(CH_3,Y^-sln) = \Delta S^{\ddagger}(CH_3X,Y^-sln) + S(CH_3X,sln) + S(Y^-sln)$$

$$[30]\quad K_{hl} = p(CH_3X)/C(CH_3X,sln)$$

$$[31]\quad \Delta S_{hl} = S_g(CH_3X) - S(CH_3X,sln)$$

$$[32]\quad S(CH_3X,sln) = S_g(CH_3X) - \Delta S_{hl}$$

where $S(Y^-sln)$ is the aqueous entropy of the anion Y^-, $\Delta S^{\ddagger}(CH_3X,Y^-sln)$ is the entropy of activation for the anion Y^- attacking CH_3X, $S^{\ddagger}(CH_3X,Y^-sln)$ is the entropy of the related transition state, $S(CH_3X,sln)$ is the entropy of CH_3X in solution, and ΔS_{hl} is the entropy of escape for CH_3X from solution (sln) to the gas phase (g) determined from the temperature dependence of the Henry's Law constant K_{hl} defined in eq. [30]. The third law gas-phase entropies $S_g(CH_3X)$ at 298.15 K are well-established tabulated quantities (29, 30, 47–49) and need no further explanation here. The enthalpy equations related to the entropy expressions (eqs. [28]–[32]) can also be calculated from the data in refs. 29, 30, and 47–49.

The thermodynamic data also provide the means of calculating the equilibrium constants for the processes described by eqs. [23] and [24]. Granted that the off-diagonal processes are genuine S_N2 processes, the kinetic equilibrium constants $K_e = k_f/k_b$ can be compared with the values of the equilibrium constants calculated from purely thermochemical data.

Calculations related to experimental quantities

Gibbs energies, entropies, and enthalpies of activation

The temperature dependence of the rate constants for 11 of the 12 nonsymmetric exchanges have been measured in water by Moelwyn-Hughes and co-workers (9, 40, 41). Swart and LeRoux (50) have measured the temperature dependence of the reaction described by eq. [17] in water. These rate constants have been reanalysed via the Eyring (39) equation

$$[33]\quad k_r = \kappa kTK^{\ddagger}/\hbar \text{ or } K^{\ddagger} = k_r\hbar/kT \ (\kappa = 1)$$

in conjunction with the Eyring version of the van't Hoff equation

$$[34]\quad \ln K^{\ddagger} = -\Delta H^{\ddagger}/RT + \Delta S^{\ddagger}/R$$

on the assumption that the transmission coefficient (κ) in eq. [33] is unity and that over the temperature ranges studied, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are true constants. The data were fitted to eq. [34] with $\ln K^{\ddagger}$ as defined by eq. [33] as the ordinate and $1/T$ as the abscissa by a linear least-squares procedure providing $\Delta S^{\ddagger}/R$ from the intercept and $-\Delta H^{\ddagger}/R$ from the slope. The Gibbs energies of activation ($\Delta G^{\ddagger}$ at 298.15 K) were calculated from the extrapolated or interpolated value of $\ln K^{\ddagger}$ at 298.15 K from eq. [34] using

$$[35]\quad \Delta G^{\ddagger} = -RT \ln K^{\ddagger}$$

The errors for all the thermodynamic quantities, namely, $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$, were calculated from the expressions specified in Margeneau and Murphy (51). These exercises were repeated by fitting the rate data to

$$[36]\quad k_r = (kT/\hbar)\exp(-\Delta H^{\ddagger}/RT + \Delta S^{\ddagger}/R)$$

by a weighted, nonlinear routine (52). There were no marked differences between the values of $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ and the probable errors in these quantities calculated by the two methods, and the correlation coefficients calculated for the linear regressions were all satisfactory. The thermodynamic kinetic data are reported in Table 3.

Initial state quantities

The determination of the initial state thermodynamic quantities from the Henry's Law studies proved more problematical than the quantities that characterize activation. The former were calculated from the temperature dependence of Henry's Law equilibrium constants K_{hl} (X = F, Cl, Br, and I)

$$[37]\quad CH_3X(sln) \overset{K_{hl}}{\rightleftharpoons} CH_3X(g)$$

measured by Glew and Moelwyn-Hughes (25). To avoid "cratic" terms for these measurements, a hypothetical ideal

standard state is required involving concentrations on the molar scale in both the gaseous and solution phases. However, because we are dealing with reversible chemical processes of simple stoichiometry, the standard state corrections to calculate $S(CH_3X,sln)$ are identical for both the forward (eq. [23]) and reverse (eq. [24]) chemical processes, and in the comparison of $S^{\ddagger}(i,j)$ and $S^{\ddagger}(j,i)$ they have no ultimate significance other than to meet the necessary requirements for the comparison with earlier reported quantities employed in the analysis presented and discussed in the following (see Table 2).

Moelwyn-Hughes and Glew fitted the four K_{hl}/T data sets for the methyl halides to the Valentiner equation

$$[38] \quad \ln K_{hl} = A/T + B \ln T + C$$

although the methodology used for this exercise was not revealed. The choice of an equation to describe the temperature dependence of either equilibrium constants or rate constants is arbitrary and this is very evident with the Henry's Law data (for a detailed discussion of such matters see the refs. in sections 5 and 6). Thus, although the fits to eq. [38] of the K_{hl} data for methyl fluoride are excellent for both linear and nonlinear regressions, they are relatively poor for the other methyl halides.

The calculation of $S^{\ddagger}$ and $H^{\ddagger}$ at 298.15 K requires ΔS_{hl} and ΔH_{hl} at this temperature and it was decided to adopt the following approach. The values from the Valentiner regressions were averaged with values calculated from three and five temperatures straddling 298.15 K using the two-parameter van't Hoff equation

$$[39] \quad \ln K_{hl} = -\Delta H_{hl}/RT + \Delta S_{hl}/R$$

The total K_{hl}/T data sets for the individual methyl halides were also fitted to various equations of the form of which eq. [38] is a particular example

$$[40] \quad \ln K_{hl} = A + Bf_1(T) + Cf_2(T)$$

The appropriate manipulations and differentiations with respect to T of eq. [40] give

$$[41] \quad \Delta H_{hl} = RT^2[Bf_1'(T) + Cf_2'(T)]$$

$$[42] \quad \Delta S_{hl} = R\{A + B[f_1(T) + Tf_1'(T)] + [Cf_2(T) + Tf_2'(T)]\}$$

The fits as judged by the Gauss criterion (55) proved to be relatively insensitive to the nature of $f_1(T)$ and $f_2(T)$. Values from the various possibilities represented by eqs. [40]–[42] for the four methyl halides adequately compared with those calculated with the other methods previously outlined via eqs. [39] and [40]. The Henry's Law data for methyl fluoride are apparently superior probably because of its higher volatility and low reactivity with water. The remaining methyl halides are more reactive with water (see Table 1) and become less volatile with increasing molecular weight, adding to the difficulty of precise measurements. The deviations for the averaged enthalpy and entropy functions characteristic of the Henry's Law measurements reported in Table 2 are based on all these calculations without reporting the numerical details of the various regressions used to obtain these quantities. There has been no attempt to hide the inadequacies in these data.

Discussion

For five reversible displacements the entropies of the transition states obtained from the appropriate calculations reveal that $S^{\ddagger}(i,j) \neq S^{\ddagger}(j,i)$ (see Table 4B). For $H^{\ddagger}(i,j)$ and $H^{\ddagger}(j,i)$ the picture alters; the data yield three cases where $H^{\ddagger}(i,j)$ and $H^{\ddagger}(j,i)$ fail to overlap and two cases where $H^{\ddagger}(i,j) \approx H^{\ddagger}(j,i)$ (see Table 4A). Thus, the combined score related to the $H^{\ddagger}$ and $S^{\ddagger}$ parameters is 80% suggesting that these reactions do not take place by the classical S_N2 mechanism. A comparison of the $\Delta H^{\ominus}$, $\Delta S^{\ominus}$, and $\Delta G^{\ominus}$ functions calculated from the kinetic data with that calculated from purely thermodynamic data show that the Gibbs energies are in reasonable agreement. In some cases compensations occur between $\Delta H^{\ominus}$ and $\Delta S^{\ominus}$ when the latter quantities differ from those calculated from kinetics, i.e., the kinetic and thermodynamic values of ΔG^{-} may agree although the quantities $\Delta H^{\ominus}$ and $\Delta S^{\ominus}$ fail to do so (see Table 5).

Although the experimental efforts by Moelwyn-Hughes and his co-workers related to the displacements and equilibria described, respectively, by eqs. [23] and [37] remain admirable, another sustained attack on the challenges these measurements represent might put the tentative conclusions drawn in the present section on a securer footing.

3. Kurz — The acidity of the protons in the attacking water molecule

Several years ago Kurz (24) pointed out that, if the reactions between a simple substrate RX with water and lyate ion are uncomplicated S_N2 displacements, then the ratio of the rate constants k_l/k_w provides a measure of the acidity of the hydrogens that form part of the attacking nucleophilic water molecule. The reactions summarized by eqs. [6] and [7] with halide and other anions as leaving groups are used to illustrate this idea. Kurz's treatment is not without conceptual difficulties, but, for the present, the basic premises of his work are accepted without qualification.

The Eyring theory (39) relates the rate constant k_w associated with eq. [6]

$$[43] \quad k_w = \kappa(w)(kT/\hbar)K_w^{\ddagger}$$

and the rate constant k_l associated with eq. [7]

$$[44] \quad k_l = \kappa(l)(kT/\hbar)K_l^{\ddagger}$$

where the symbols in eqs. [43] and [44] refer to the transmission coefficients $\kappa(w)$ and $\kappa(l)$, and k, T, and $\hbar$ have their conventional meanings. Expressing the quotients that define the equilibrium constants $K_w^{\ddagger}$ and $K_l^{\ddagger}$ in terms of concentrations rather than the more appropriate activities gives

$$[45] \quad k_w = \kappa(w)(kT/\hbar)\{[H_2O\text{-}CH_3\text{-}X]/[CH_3X][H_2O]\}$$

and

$$[46] \quad k_l = \kappa(l)(kT/\hbar)\{[HO\text{-}CH_3\text{-}X]/[CH_3X][OH^-]\}$$

Only the composition of the two transition states are represented in eqs. [45] and [46]; no attempt is made to specify the disposition of the charges in these symbolic expressions. The acidity constant of the transition state ($K_a^{\ddagger}$) produced

when a water molecule attacks the CH_3X species is defined in the normal way

$$[47] \quad K_a^{\ddagger} = [HO\text{-}CH_3\text{-}X][H^+]/[H_2O\text{-}CH_3\text{-}X]$$

and, granted the condition that the transmission coefficients are equal, i.e., $\kappa(l) = \kappa(w)$, then some trivial manipulations that combine eqs. [45]–[47] at T = 298.15 K give

$$[48] \quad pK_a^{\ddagger} = 15.74 - \log(k_l/k_w)$$

Generally $k_l > k_w$, hence the magnitude of $pK_a^{\ddagger}$ calculated from eq. [48] is less than 15.74, which requires the hydrogens of the coordinated water molecule in the transition state to be *more acidic* than those in bulk water. This trend is in the direction anticipated for the protons of a water molecule bonded to a developing cationic centre. Data related to a series of methyl and ethyl substrates are presented in Table 6 and the calculated $pK_a^{\ddagger}$ values range from 13.72 for ethyl tosylate to 11.06 for methyl iodide. In comparison (63) with typical organic acids such as phenols ($pK_a \approx 8.0 \pm 2.0$) and carboxylic acids ($pK_a \approx 3.0 \pm 2.0$), the water hydrogens in the various transition states are weakly acidic. Indeed, if Kurz's model is valid, the acidity of the water hydrogens in the transition state is close to that of bulk water, and concomitantly, bonding between the nucleophilic water molecule and the reacting substrate is presumably weak in comparison with a fully formed methyloxonium ion. These qualitative considerations can be put on a more quantitative footing.

© 2005 NRC Canada

The range of acidity for the hydrogens of the nucleophile is from $pK_a = 15.76$ for a free water molecule to $pK_a = -2.04$ for the methyloxonium ion,[3] giving a total range of 17.80 pK_a units. The average $pK_a^{\ddagger}$ for the hydrolyses listed in Table 6 is 12.01, hence the average fractional movement of the reacting systems along the reaction coordinate is calculated to be: (15.76 – 12.01)/17.8 = 0.21. The latter value represents a reactantlike transition state *with respect to the attacking water molecule.* The magnitude of the reaction coordinate parameter estimated in this way differs from the values adopted by Albery and Kreevoy (13) in their Marcusian analysis of methyl transfers. These workers calculated reaction coordinate parameters that were larger than 0.21. The latter value is also uncomfortably small when compared to the Brönsted exponent of unity associated with the Guthrie LFER that indicates a productlike transition state with respect to the leaving group. Guthrie's work (23) will be examined in greater detail later. Obviously, there is no a priori rule or requirement for the extent of O—H bond breaking associated with the attacking water molecule to match the extent of C—X bond fission in the activated complex. *In any case, if intermediates are involved in a reaction, i.e., the reaction occurs in steps, such matters become extremely complex and the notion of a singular and simple reaction coordinate is less compelling*.

The classical studies of Hughes and Ingold (1–3, 8, 10) consider that values of k_l/k_w greater than unity are indicative of the S_N2 mechanism for the *hydrolysis reaction,* although the exact physical basis of this mechanistic test is not obvious. Indeed, the considerations presented by Kurz (24) might be regarded fairly as the first attempt to give a definite physical meaning to the ratio k_l/k_w. For many substrates, k_l cannot be measured because the magnitude of the rate constant characteristic of the hydrolysis reaction is large enough to swamp the reaction with lyate ion. However, if eq. [48] is to remain physically valid, the ratio k_l/k_w must remain finite within the framework of the current interpretation and must be numerically greater than unity. Nevertheless, Streitwieser (2) has tabulated such ratios as zero. Values of k_l/k_w less than unity would imply that a water molecule interacting with an incipient positive charge is less acidic than bulk water and, as such, is a physically uncongenial proposition.

The data in Table 6 related to the previous analysis display some odd features. Thus, although the reactivities of methyl perchlorate and methyl fluoride are separated by ca. six orders of magnitude for both water and the lyate ion, for each substrate, the acidities of the water hydrogens in their respective transition states are virtually identical. There is a modest trend for the acidity of the water protons to become higher as the *nucleophilicity* of the leaving group increases. This observation implies more "push" is required from the nucleophilic water molecule when the leaving group is a good nucleophile; this is an eminently reasonable proposition. The attack of water on ethyl tosylate produces the weakest acid. This observation is in accord with the conventional wisdom, namely, that α methylation *decreases* the importance of nucleophilic assistance in solvolytic displacements. Equation [48] is revealing with respect to some other features of the hydrolysis reaction.

The rate of proton transfer from acids to water is well-known to be a function of the strength of the acid from which the proton departs, and concomitantly, obeys an adequate Brönsted relationship, although the Brönsted exponent becomes smaller for very strong acids. However, the rates of proton loss ($k_p^{\ddagger}$) can be estimated safely to at least an order of magnitude from such a Brönsted correlation for weaker acids ($pK_a > 3.00$)

$$[49] \quad \log k_p^{\ddagger} = 10.95 \pm 0.12 - (1.01 \pm 0.02)pK_a \ (8,0.998)$$

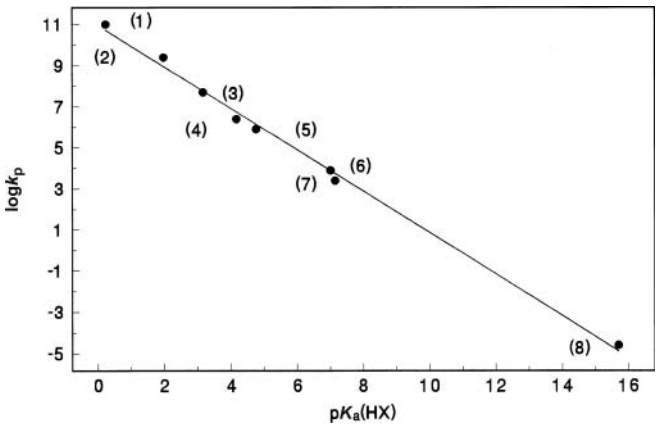
Equation [49] was generated from data collected by Caldin (64) reported in Table 7. The numbers in parenthesis at the terminus of eq. [49] refer to the number of data point pairs and the related correlation coefficient, respectively. This mode of representation for these statistical quantities will be adopted in the rest of the review.

The correlation represented by eq. [49] is illustrated in Fig. 1 and it differs from the LFER reported by Grunwald (65), namely,

$$[50] \quad \log k_p^{\ddagger} = 11.74 - 0.54pK_a$$

that is restricted to stronger acids with pK_a values less than 3.00. Equations [48] and [49] may be combined to give

$$[51] \quad \log k_p^{\ddagger} = 1.01 \log(k_l/k_w) - 4.93$$



The $k_p^{\ddagger}$ rate constants calculated from eq. [49] are reported in the final column of Table 6 and give rise to half-

lives for proton transfer ($t_{1/2} = \ln 2/k_p^{\ddagger}$) that are several orders of magnitude longer than the lifetime of the transition state (ca. 1×10^{-13} s). Hence, the Kurz equation confirms the notion that *proton loss occurs later along the reaction coordinate* and does not necessarily coincide with the maxima in that coordinate, vindicating conclusions drawn on the basis of alternative evidence presented in section 1.

It should be noted Kurz (24) recognises that the lifetime of the transition state is insufficient to allow the hydrogens that form part of the attacking water molecule to be in true thermal acid–base equilibrium with the bulk solvent. Notwithstanding the latter limitation, the Kurz equation is in accord with the notion that the transfer of the proton in a hydrolysis reaction takes place from *a stronger acidic species generated later along the reaction coordinate*. This latter requirement is in accord with eq. [12] and evinces further credibility when the KSIE is examined. The KSIE is measured by the ratio $k(H_2O)/k(D_2O)$ (6, 66).

4. The rates of solvolysis in light and heavy water — The kinetic solvent isotope effect (KSIE)

Writing in 1964, Robertson (6) observed that the impetus for KSIE measurements was underpinned by the notion "... that there should be an indication of a primary isotope effect arising from nucleophilic interaction in the case of displacement by the S_N2 mechanism, but this would be absent for those molecules reacting by the S_N1 mechanism. Hence it was anticipated that the $k(H_2O)/k(D_2O)$ ratios would provide a new test for distinguishing between these two important mechanisms. No indication of such a difference was found for the hydrolysis of sulphonates and halides."

Typical measurements that confirm Robertson's final remark in the preceding quote are provided by the α methylated alkyl chlorides RCl (R = methyl, ethyl, 2-propyl, and *tert*-butyl). These reactants give ratios $k(H_2O)/k(D_2O)$ = 1.28, 1.26, 1.33, and 1.38 (66), respectively. The apparent insensitivity of the KSIE to the mechanistic categories postulated by the Ingold school (1, 8) prompted explanations of the observed ratios in terms of solvation differences for both the ground and transition states in the two isotopic solvents (see refs. 4, 6, and particularly 15).

The solvation hypothesis was developed in considerable detail by Swain and Thorton (4, 67). An alternative treatment was presented by Schowen (68) using isotopic fractionation factor theory. Schowen's calculations retained the conventional features of the original S_N2 and S_N1 mechanisms and provided theoretical ratios for the KSIE ranging from unity to 3.1 for the former route and from unity to 1.35 for the latter. These theoretical estimates suggest the magnitude of the experimental ratios imply the transition states for the S_N2 substrates are reactantlike and those for the S_N1 substrates productlike.

Two important points emerge from Schowen's analysis. First, the range of theoretical estimates confirms Robertson's expectations recorded in the previous quotation. Secondly, the experimental KSIE values for primary centres indicate that the nucleophilic water is reactantlike, or alternatively the KSIE does not reveal much incipient proton/deuteron formation. This agrees with conclusions reported in sections 1 and 3; however, this result for primary carbon centres is totally at variance with the Guthrie LFER (23) considered later.

The larger KSIE anticipated for S_N2 displacements reflects the notion that fission of one of the oxygen–hydrogen bonds of the attacking nucleophilic water molecule might be advanced in a simple S_N2 transition state. The previous discussion suggests that the heterolytic fission of the oxygen–hydrogen bond of the nucleophilic water molecule is the *last process* in the hydrolysis reaction. Because the pK_a values of the α methylated oxonium ions ROH_2^+ (R = methyl, ethyl, 2-propyl, and *tert*-butyl) are –2.04, –1.95, –1.86, and –3.7, respectively (69),[3] the rates of proton transfer from these acids estimated from eq. [50] will approach the theoretical limit. Such rapid kinetic events are unlikely to contribute to the observed rate constant that is *controlled by other much slower processes.*

Similar considerations must hold for other substrates that may react via more complicated schemes such as the Winstein mechanism (70)

$$\text{[52]}\quad RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R^+X^-(\text{int}) \underset{k_4}{\overset{k_3}{\rightleftharpoons}} R^+||X^-(\text{ss}) \underset{k_6}{\overset{k_5}{\rightleftharpoons}} R^+ + X^-$$

$$\downarrow k_{1n} \qquad \downarrow k_{2n} \qquad \downarrow k_{3n} \qquad \downarrow k_{4n}$$

$$P \qquad P \qquad P \qquad P$$

The participants involved are intimate (int) and solvent separated (ss) ion pairs along with free carbocations. The rate constants k_r(r = 1–6) relate in pairs to the heterolytic equilibria implied by eq. [52] and the rate constants k_{nr}(r = 1–4) describe the irreversible nucleophilic components of the overall displacement leading to product P. Equation [52] does not alter the considerations previously presented, but merely describes alternative routes to alkyloxonium ions or carbocations more elaborate than those represented by eq. [12].

Robertson and co-workers (66) also measured changes in the enthalpy of activation $\delta_I\Delta H^{\ddagger}$ and the entropy of activation $\delta_I\Delta S^{\ddagger}$ that characterize ordinary water and deuterium oxide for several solvolytic substrates and these thermodynamic quantities demonstrate a respectable linear relationship (see Table 8 and Fig. 2). This observation is of no great significance by itself, however, when similar quantities that characterize the transfer of simple salts from water to heavy water ($\delta_I\Delta H$(sln) and $\delta_I\Delta S$(sln) (71)) are included in the plot, the values for transfer and activation reside in the *same region* of the coordinate system. The thermodynamic quantities derived from kinetic studies are intrinsically more complex because two transfers are involved, namely, the initial and transition states (15). In contrast, the paired ion transfers depend only on a single difference between G, H, and S for the ions in the two isotopic solvents. The initial state transfers for the methyl halides measured by Swain and Thornton (67) provide thermodynamic quantities that are in the same general region as those obtained from ion and kinetic transfers. The combination of the initial state and kinetic data so as to characterize the transition-state transfers would merely move the points along rather than away from the H,S vector.

For $B_{Ac}2$ solvolytic reactions that are partly characterized by rate-determining proton transfers (72), the related quantities $\delta_I\Delta H^{\ddagger}$ and $\delta_I\Delta S^{\ddagger}$ *are remote from regions of the plot that correspond to the displacements with which this review*

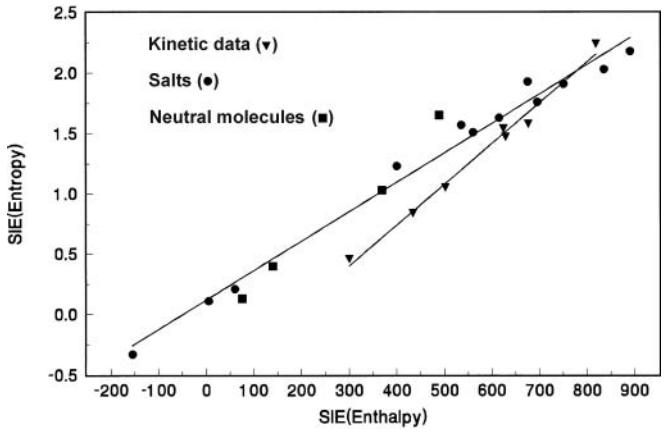
MeI	369.0	1.03
$B_{Ac}2$ mechanisms (KSIE) — Hydrolysis of carboxylic anhydrides (21)[a]		
Acetic	118.0	2.52
Propionic	–200.0	1.22
Succinic	338.0	3.15
Phthalic	460.0	3.23



Note: Solvent isotope effect (SIE); kinetic solvent isotope effect (KSIE). The saline transfers refer to 25 °C and the methyl halides to 29.4 °C. The temperature for the kinetic transfers is less well-defined but will correspond to 0 °C < T < 25 °C. The units are cal/mol for the enthalpy function and cal mol^{-1} K^{-1} for the entropy. In Fig. 2, both the KSIE and SIE data are correlated on a single graph.

[a]These values for $\delta_I\Delta H$ and $\delta_I\Delta S$ are poorly correlated with the other data in the table (see related text).

is primarily concerned. The coincidence of the ion transfer and activation quantities is not definitive mechanistic information, but nevertheless, offers further confirmation that the proton transfer in the S_N hydrolyses occurs *after* the rate-determining step.

Neither the KSIE nor the Kurz analysis illuminates the extent and importance of the variation of nucleophilic assistance in the α-methylated substrates as previously defined in the way Robertson originally anticipated (6, 66). On the basis of more revealing investigations, current opinion (73) apparently casts doubt on the notion that *tert*-butyl substrates react via the classical S_N1 route involving the free *tert*-butyl carbocation. If this be the case, the possible significance of the *tert*-butyloxonium ion formation rather than the *tert*-butyl cation becomes an important question. Cases involving

Fig. 2. Correlation between enthalpy and entropy of transfer ($\delta_I\Delta H$ and $\delta_I\Delta S$) for ionic compounds (●), neutral molecules (■), and activation parameters (▼).

free carbocations do not necessarily require the intermediate formation of the related oxonium ion because the electrophilic attack of the carbocation on water and proton loss might be concerted processes. Further comment on these classical conundrums will be presented later. Clearly, the mechanism represented by eq. [12] is not at variance with the main features of the KSIE. Further evidence for the complexity exemplified by eq. [12] is revealed by the non-Arrhenius temperature dependence of the rates of hydrolysis of numerous simple halides and sulphonates. This well-established feature of hydrolyses in water (6, 15) and mixed aqueous solvents (7) will be examined in section 5.

5. The non-Arrhenius behaviour of solvolytic displacements — Heat capacities of activation

Moelwyn-Hughes (74) appears to have been the first author to focus sustained attention on the fact that solvolytic displacements in water do not obey the Arrhenius equation in the simple form

$$[53] \quad k = \exp(A(1) + A(2)/T)$$

The quantities k and T have their usual significance; $A(1)$ and $A(2)$ are empirical constants. The alternative and more usual version of this equation gives physical meaning to the constants $A(1)$ and $A(2)$

$$[54] \quad \ln k = -E_a/RT + \ln A$$

where E_a is the activation energy, the quantity A is usually interpreted as the product of a collision number Z and a probability factor P, i.e., $A = PZ$, and R is the gas constant.

Considerable experimental care is required to establish departures from eq. [53] or [54] and the related problems have been discussed by Robertson in an earlier review (6). An example of the level of precision and reproducibility obtained by the Robertson group is exemplified by some of the rate constants that characterize the hydrolysis of allyl bromide made by the author between 1957 and 1959 (75). The raw resistance – time data have been reexamined using various least-squares algorithms and the results from these computations are reported in Table 9. The measurements approach a

© 2005 NRC Canada

level of precision and reproducibility (0.03%) for solution kinetic data that was achieved by Shiner's group (70) by a more elaborate methodology.

The inadequacies of eq. [54] raise a whole range of theoretical and practical issues that have been thoroughly detailed elsewhere (6, 15, 77, 78). One solution to the mathematical representation of the non-Arrhenius dependence augments eq. [53] with the term $A(3)\ln T$ to give

$$[55] \quad \ln k = A(1) + A(2)/T + A(3)\ln T$$

Equation [55] is usually known as the Valentiner equation (77). A simple interpretation of the failure of eq. [54] emerges from eq. [55] and leads to the conclusion that a finite heat capacity of activation ($\Delta C_p^{\ddagger}$) exists between the reactants and the transition state. Alternatively, E_a is a function of temperature, and in terms of eq. [55], $\Delta C_p^{\ddagger}$ is finite but independent of temperature. For a broad range of substrates eq. [55] gives an adequate account of the *k*–*T* data sets, and empirically, $\Delta C_p^{\ddagger}$ was found to be negative (6, 7). This important fact was considered to signify a quasi-ionic transition state (6). The odd exception to the rule that $\Delta C_p^{\ddagger}$ is negative is exemplified by the rate constants that characterize the hydrolysis of 4-methoxybenzyl trifluoroacetate. This latter observation has its own particular explanation involving a mixed $S_N/B_{Ac}2$ mechanism (79).

Moelwyn-Hughes (80) has drawn an elaborate analogy between the solvolytic displacements considered as ionogenic reactions and the ionization of carboxylic acids

$$[56] \quad RCOOH + H_2O \rightleftharpoons RCOO^- + H_3O^+$$

The average heat capacity change that characterizes these important organic reactions is ca. –40 cal mol^{-1} K^{-1} (1 cal = 4.184 J). In a similar vein, Robertson (81) estimated the heat capacity change for the hypothetical model process from available thermochemical data

$$[57] \quad Ar(aq) \rightleftharpoons Cl^-(aq)$$

and found $\Delta C_p \approx -70$ cal mol^{-1} K^{-1}. These important models are considered to mimic an ionic solvolytic reaction and should not be overlooked. On the other hand, such analogies raise a variety of issues as to how quantities as complex as heat capacities behave along the reaction coordinate for reactions only vaguely related to the carboxylic acid equilibria. Furthermore, the model for the ionization of carboxylic acids represented by eq. [56] is neither unique nor necessarily correct (82–86). Until these matters are resolved, the felicity of the models proposed by Robertson and Moelwyn-Hughes for the non-Arrhenius behaviour of displacement reactions must remain in doubt. Indeed, some values of $\Delta C_p^{\ddagger}$ calculated from the appropriate *k*–*T* data sets are either uncomfortably large (87, 88) or essentially zero, e.g., the data reported in this communication for neopentyl methane sulphonate (see Appendix A). These observations suggest that the interpretations of finite negative $\Delta C_p^{\ddagger}$ values presented by Robertson and Moelwyn-Hughes based primarily on the importance of solvation may require revision, a possibility recognised and exploited by Albery and Robinson (21).

$SD\times10^{6}$	2.78	2.48	2.08	2.68	2.36
$k\times10^{4d}$	1.8857	1.8901	1.8904	1.8876	1.8885
$SD\times10^{8}$	8.07	13.80	7.67	9.57	22.70

Note: k = rate constant in s^{-1}; SD = standard deviation. For details concerning the Robertson–Guggenheim method, see section 7. Attempts have been made to test the conclusions that might be drawn from this experimental data by producing synthetic resistance data at 298.155 K (≈25 °C) and 318.17 K (≈45 °C) with the pseudo-first-order constants (k) of 1.7×10^{-5} and 1.8885×10^{-4}, respectively. The concentration of the acid (HBr) at any time (C_t) is given by $C_t = C_o[1 - \exp(-kt)]$ for a true first-order process. The related expressions for the resistance as a function of time were: $1/R_t = 428.05C_t/(1000\kappa) - 157.87C_t^{3/2}/(1000\kappa)$ for 25 °C and $1/R_t = 552.00C_t/(1000\kappa) - 222.43C_t^{3/2}/(1000\kappa)$ for 45 °C. The numerical coefficients in these expressions for $1/R_t$ were calculated from information and data in Harned and Owen (76). The cell constant (κ) was given a value of unity. For $C_o = 1 \times 10^{-3}$, the analogues for footnotes *c* and *d* at 25 °C from the synthetic data differed from each other on average by 0.93% in contrast to the experimental data by 2.35%. For 45 °C, the corresponding data are 1.14% and 5.16%. Thus, the retardation of the rates along the $1/R_t$ vs. t curve is 2–5 times that anticipated on the basis of the approximation $C_t \approx 1/R_t$. This observation is regarded as indicative rather definitive. The Guggenheim algorithm applied to to the synthetic gave a value of k that differed from the input value by 0.35%–0.60%, which matches the reproducibility of the rate constants.

[d] Linear least-squares based on the infinity value from the calculation in footnote *c*.

6. The Albery–Robinson treatment of the non-Arrhenius temperature dependence of solvolytic displacements in water

In 1968 Albery and Robinson (21) reported an important study of the temperature dependence of the solvolysis of *tert*-butyl chloride in water. In their analysis of the non-Arrhenius temperature dependence, the solvation model was virtually discarded as the major source of these phenomena. To interpret the temperature dependence of the measured pseudo-first-order rate constants as a function of temperature for the hydrolysis of *tert*-butyl chloride, Albery and Robinson postulated that this reaction involved an unspecified intermediate "I"

[58] $t\text{-BuCl} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{I} \xrightarrow{k_3} \text{Products}$

The application of the steady-state theorem to eq. [58], after some standard manipulations, gives for the observed rate constant k_o

$$[59] \quad k_o = k_1k_3/(k_2 + k_3)$$

The quantities k_1, k_2, and k_3 are, respectively, the three rate constants that characterize either first-or *pseudo*-first-order component reactions. If the temperature dependencies of the component rate constants k_n (n = 1–3) in eq. [59] are given by expressions identical to eq. [53] then

$$[60] \quad k_n = \exp(A_n(1) + A_n(2)/T)$$

Combining the three equations summarized by eq. [60] with eq. [59] provides an expression for the temperature dependence of k_o

$$[61] \quad k_o = \exp(A + B/T)/[1 + \exp(C + D/T)]$$

The constants A, B, C, and D of eq. [61] are functions of the six constants summarized by eq. [60] specified by the relationships: $A = A_1(1)$, $B = A_1(2)$, $C = A_2(1) - A_3(1)$, and $D = A_2(2) - A_3(2)$.

Both eqs. [55] and [56] give an adequate representation of all the data that relate to the temperature dependence of the hydrolysis of *tert*-butyl chloride measured in three separate locations (21, 89, 90). Indeed, there is little to choose between the details recorded in Table 10 for *tert*-butyl chloride and several other substrates chosen at random, where the two equations are statistically compared using the Gauss criterion (G.C.) (53, also see Appendix B). Further details of the results for the *tert*-butyl chloride hydrolysis are reported in Appendices B and C. Notwithstanding the excellent fits of these data to eq. [62], there are several important problems associated with this particular expression.

First, eq. [61] gives a satisfactory account of the temperature dependence of a whole range of substrates for which the kinetic scheme described by eqs. [58] and [59] would be considered as uncongenial (91), i.e., the mechanism represented by eq. [58] might be acceptable for tertiary substrates but not for reacting primary centres. Some of the data related to this comment are assembled in Table 10 where the Albery–Robinson equation appears to have a slight edge over eq. [60]. Secondly, eq. [61] demonstrates some odd properties when attempts are made to give physical meaning to the four constants that it contains. This important limitation was neglected by Albery and Robinson (21) in their original presentation and this problem is considered in greater detail in the following.

Dividing eq. [61] by the exponential term present in the denominator gives

$$[62] \quad k_o = \exp[(A - C) + (B - D)/T]/[1 + \exp -(C + D/T)]$$

Equation [62] is of the *same form* as eq. [61]. It follows that there are *two different numerical solutions* for the constants A, B, C, and D that provide identical fits for a particular k–T data set. These are: (*i*) A, B, C, and D and (*ii*) $A - C$, $B - D$, $-C$, and $-D$, respectively. There are no obvious reasons for preferring either solution corresponding to eqs. [61] and [62], respectively.

This anomaly is, at least, partly ameliorated by the observation that the expression for apparent heat capacity of activation

$$[63] \quad \Delta C_p^{\ddagger} = -(k_2k_3)^2[E(2) - E(3)]^2/RT^2(k_2 + k_3)^2$$

obtained by the appropriate differentiations of eq. [59] is always negative because the component expressions in eq. [63] are all necessarily positive. The apparent heat capacity is also independent of whether eq. [61] or [62] is employed to express the temperature dependence. The symbols in eq. [63] have their usual meanings and the activation energies $E(1)$, $E(2)$, and $E(3)$ are those associated with the k_1, k_2, and k_3 steps and are assumed to be true constants. However, although the structure of eq. [63] necessitates that $\Delta C_p^{\ddagger}$ is always negative, in contrast to the solvation model represented by eq. [55], this quantity is no longer independent of temperature because: (*i*) k_2 and k_3 are temperature dependent and (*ii*) eq. [63] contains a term in T^2 in the denominator.

The Albery–Robinson treatment of the non-Arrhenius temperature dependence of hydrolytic reactions has features in accordance with eq. [12] if certain conditions are met. These are: (*i*) the k_5 and k_6 rate constants are large and (*ii*) external return represented by the k_4 step is unimportant under the normal conditions of solvolysis, i.e., the substrate concentration is small. The constant k_4 describes a second-order process and because the methyloxonium ion is a very strong acid in water, then the maximum value of the term $[CH_3OH_2^+][X^-] \approx 1 \times 10^{-11}$ under the normal conditions of hydrolysis with the initial concentration of the substrate set at ca. 1×10^{-3} mol/L. Hence, the magnitude of k_4 must approach that for a diffusion-controlled reaction for external return to be significant. External return is signified by pseudo-first-order solvolytic rate constants that decrease systematically with time (1, 2, 8). Generally speaking, this feature was not detected in the systems investigated by Robertson and co-workers although the method of determin-

ing the rate constants from the raw experimental data was not conducive to the detection of departures from simple first-order behaviour (6).[2] On the other hand, Hammett (92) has reported that the solvolysis of ethyl 4-methyl benzenesulphonate may not be a simple first-order process, and likewise, Moelwyn-Hughes and Glew (9, 32) use a relatively complex kinetic scheme to quantify composition changes as a function of time for the hydrolysis of methyl fluoride. These latter observations may have significance in the present context and are addressed further later.

The Albery–Robinson treatment of the non-Arrhenius temperature dependence of solvolytic rate constants represents an important innovation because attention is drawn to the possibility that observed rate constants may be complex and that this complexity may have profound implications as to the meaning of such quantities as $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ obtained from the temperature dependence of observed rate constants. Indeed, the latter suggestion may have a wider currency, explaining why activation energies in solution have rarely provided either unambiguous mechanistic information or fail to reflect structural changes in a systematic way, leading one distinguished author to describe temperature dependence studies as "a fetish" (93). However, the Albery–Robinson treatment, notwithstanding its novelty, interest, and utility, overlooks several approximations and it is important to examine the oversights associated with this model.

The Albery–Robinson kinetic scheme described by eq. [58] is more accurately represented (22, 94) by the following differential equation presented in matrix form (see Appendix D)

$$[64]\quad \begin{bmatrix} (D+k_1) & -k_2 & \\ -k_1 & (D+k_2+k_3) & \\ & k_3 & D \end{bmatrix} \begin{bmatrix} A \\ B \\ C \end{bmatrix} = 0$$

where the operator $D \equiv \mathrm{d}/\mathrm{d}t$ and B represents I in eq. [58]. The matrix represented by eq. [64] gives rise to the auxiliary cubic

$$[65]\quad \lambda[\lambda^2 + \lambda(k_1 + k_2 + k_3) + k_1k_3] = 0$$

When solved, eq. [65] gives rise to three roots: λ_1, λ_2, and λ_3, one of which is zero, here arbitrarily λ_3. The other two roots are defined by the quadratic part of eq. [65], and with their signs changed, define the two dynamic constants that describe the time evolution of the chemical system described by eq. [58].

The composition of the system with respect to the three components, namely, *A*, *B*, and *C* at any time "*t*", is given by the general expression

$$[66]\quad X_n = \alpha_{n1}\exp(-\lambda_1 t) + \alpha_{n2}\exp(-\lambda_2 t) + \alpha_{n3}$$

with n = 1–3. When $n = 1$, $X_n = A$, for $n = 2$, $X_n = B$ and for $n = 3$, $X_n = C$. The amplitude factors in eq. [66] α_{nr}, (n = 1–3 and r = 1–3) are functions of the initial concentration of *A*, namely A_o together with k_1, k_2, k_3, and the two dynamic constants, λ_1 and λ_2. If $\lambda_2 < \lambda_1$, then λ_2 will, generally speaking, dominate the time evolution of the system described by eq. [66]; concomitantly, λ_2 will correspond approximately to the measured rate constant.

If the temperature dependence of λ_2 approximates to the that of k_o, this possibility can be examined formally in three ways. The first approximation identifies λ_2 with k_o in the steady-state expression given in eq. [59]. A second approximation can be developed from the simple theory of quadratic equations. Some elementary considerations give

$$[67]\quad \lambda_1 + \lambda_2 = k_1 + k_2 + k_3$$

$$[68]\quad \lambda_1\lambda_2 = k_1k_3$$

Dividing eq. [67] by eq. [68] gives

$$[69]\quad 1/\lambda_1 + 1/\lambda_2 = (k_1 + k_2 + k_3)/k_1k_3$$

which, because $\lambda_1 > \lambda_2$, gives

$$[70]\quad \lambda_2 \approx k_1k_3/(k_1 + k_2 + k_3)$$

Equation [70] is clearly similar to the steady-state expression (eq. [59]), augmented by an extra term k_1 in the denominator. This equation will not be considered further here.

Finally, the ramifications of eqs. [67] and [68] can be investigated further with fewer approximations by defining apparent activation energies ($\Delta E(n)^{\ddagger}$) and heat capacities ($\Delta C_p(n)^{\ddagger}$) (n = 1 and *2*) via the Arrhenius version of the van't Hoff equation (22).

$$[71]\quad \partial\ln(\lambda_n)/\partial T = \Delta E(n)^{\ddagger}/RT^2$$

from which

$$[72]\quad \Delta C_p(n)^{\ddagger} = \partial\Delta E(n)^{\ddagger}/\partial T$$

Granted that the activation energies $E(1)$–$E(3)$ associated with steps k_1–k_3 are true constants, the appropriate differentiations of eqs. [67] and [68] with respect to temperature combined with eqs. [71] and [72] give

$$[73]\quad \lambda_1\Delta E(1)^{\ddagger} + \lambda_2\Delta E(2)^{\ddagger} = k_1E(1) + k_2E(2) + k_3E(3)$$

$$[74]\quad \Delta E(1)^{\ddagger} + \Delta E(2)^{\ddagger} = E(1) + E(3)$$

Further differentiation of eqs. [73] and [74] with respect to temperature gives

© 2005 NRC Canada

$$\lambda_1\Delta C_p(1)^{\ddagger} + \lambda_2\Delta C_p(2)^{\ddagger} + [\lambda_1\Delta E(1)^{\ddagger 2} + \lambda_2\Delta E(2)^{\ddagger 2}]/RT^2 = [k_1E(1)^2 + k_2E(2)^2 + k_3E(3)^2]/RT^2$$

or

[75] $$\lambda_1\Delta C_p(1)^{\ddagger} + \lambda_2\Delta C_p(2)^{\ddagger} = [k_1E(1)^2 + k_2E(2)^2 + k_3E(3)^2 - \lambda_1\Delta E(1)^{\ddagger 2} - \lambda_2\Delta E(2)^{\ddagger 2}]/RT^2$$

and

[76] $$\Delta C_p(1)^{\ddagger} + \Delta C_p(2)^{\ddagger} = 0$$

The simultaneous linear eqs. [73] and [74] can be solved to give $\Delta E(1)^{\ddagger}$ and $\Delta E(2)^{\ddagger}$ as functions of temperature and similarly, eqs. [75] and [76] can be solved to establish the behaviour of $\Delta C_p(1)^{\ddagger}$ and $\Delta C_p(2)^{\ddagger}$ with respect to temperature.

The preceding formalities emphasize the approximate nature of the original Albery–Robinson expressions represented by eqs. [59] and [61] and imply that little physical meaning can be attributed to the quantities *A*, *B*, *C*, and *D* obtained from *k*/*T* data fits to eq. [61]. Notwithstanding these limitations, the satisfactory *k*/*T* data fits to eq. [61] give a measure of credibility to the notion that an intermediate of the sort postulated in eq. [12] exists when simple solvolytic displacements take place in water unless opinion regards the solvation models originally presented by Robertson and Moelwyn-Hughes (90) to be more reasonable and attractive. Although the choice between these alternatives is not clear-cut, in our opinion, other evidence presented in the following ultimately favours the implications of the Albery–Robinson model, which, although weak in its details, remains as a potent mechanistic clue.

The formalities previously presented, particularly eq. [66] that contains two exponential terms rather than a single term, prompts a reexamination of the raw resistance – time data from which the solvolytic rate constants were established with the hope that such probings might reveal features previously overlooked. This exercise is briefly described in section 7.

7. A reexamination of the Robertson–Guggenheim method

The basic physical and chemical situation examined by the Robertson group (6, 15)[2] consists of a dilute aqueous solution of the substrate RX ($C_o \approx 1 \times 10^{-3} - 5 \times 10^{-4}$ mol/L) that reacts according to eq. [6], steadily increasing the concentration of ions in the solution. The reacting solution is at a fixed temperature controlled to better than ±0.005 K. The ions produced by the chemical reaction are monitored by measuring the electrical resistance (*R*) of the solution. For a fixed temperature, a given conductance cell, and a fixed electrolyte, the relationship between *R* and the concentration *C* of the ionic product is adequately quantified by a version of the Onsager equation (76)

[77] $$1/R = \alpha C + \beta C^{3/2}$$

where the two constants α and β depend on the conditions previously specified, namely the electrolyte, the solvent, the cell dimensions, and the temperature. In the following analysis, it is assumed that the ions from the autoprotolysis of the solvent water make no significant contribution to *R* and the electrolyte is strong.

If the reactant RX is converted to the products by a simple first-order process, then the concentration of the acid $C_t(HX)$ ($HX \equiv H_3O^+ + X^-$) is given by

[78] $$C_t(HX) = C_o(HX) + C_o(RX)[1 - \exp(-kt)]$$

where $C_o(HX)$ is the concentration of the acid product when the resistance measurements commence and $C_o(RX)$ is the concentration of the substrate at that time. Because of various manipulative problems, concentration determinations cannot commence immediately after the reactant and water are mixed. Hence, the concentration of the product acid is always finite when the resistance measurements commence.

If the linear term in *C* dominates eq. [77], a reasonable assumption because: (*i*) $|\beta| < |\alpha|$ and (*ii*) $C^{3/2} < C$ when $C <$ unity. With these approximations, eq. [78] can be recast in the approximate form

[79] $$1/R = B(1) - B(2)\exp(-kt)$$

where $B(1)$ and $B(2)$ are constants related to the constants in eq. [78] and α in eq. [77]. Resistance–time data can be fitted to eq. [79] using a suitable nonlinear least-squares algorithm generating the first-order rate constant (*k*) and the disposable constants $B(1)$ and $B(2)$. However, such a method of deriving *k* from the *R*–*t* data sets was not a practical proposition in the early days of Robertson's investigations. In consequence, the Guggenheim (95) algorithm was adopted in conjunction with large scale plots (ca. 48″(X) vs. 36″(Y)) to calculate *k* from the resistance–time data.

The Guggenheim method of evaluating *k* involves two sets of resistances: the first set is measured over the first half-life ($t_{1/2}$) of the reaction yielding $R_{t(1)}$, $R_{t(2)}$, $R_{t(3)}$... $R_{t(n)}$. The second set separated from the first set by an interval τ such that $\tau > 2t_{1/2}$ and is measured at the same time intervals as the first set over a period that corresponds roughly to the third half-life of the reaction. This yields the resistances $R_{t(1)+\tau}$, $R_{t(2)+\tau}$, $R_{t(3)+\tau}$... $R_{t(n)+\tau}$. For the resistances measured in the first half-life, eq. [79] gives

[80] $$1/R_t = B(1) - B(2)\exp(-kt)$$

and for those measured in the third half-life

[81] $$1/R_{t+\tau} = B(1) - B(2)\exp[-k(t + \tau)]$$

Subtracting eq. [80] from eq. [81] yields

[82] $$1/R_{t+\tau} - 1/R_t = B(2)\exp(-kt)[1 - \exp(-k\tau)]$$

Equation [82] can be regressed in either linear or nonlinear forms to establish *k* from the R_t,$R_{t+\tau}/t$ data sets. However, the use of this equation does not allow the observed resistances to be compared to a calculated set from the rate constant and times. The latter limitation can be circumvented in the following manner. Eliminating the term $B(2)\exp(-kt)$ between eqs. [80] and [81] generates a version of the Kedzy–Swinbourne equation (96–99)

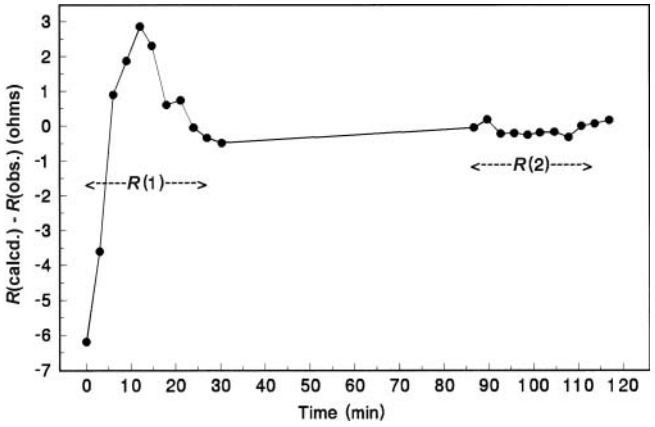
[83] $$1/R_t - B(1) = [1/R_{t+\tau} - B(1)]/\exp(-k\tau)$$

that can be rearranged to give

[84] $$1/R_{t+\tau} = \exp(-k\tau)(1/R_t) + B(1)[1 - \exp(-k\tau)]$$

© 2005 NRC Canada

Thus, a regression of $1/R_{t+\tau}$ as Y vs. $1/R_t$ as X gives $\exp(-k\tau)$ as the slope and $B(1)[1 - \exp(-k\tau)]$ as the intercept. Because k is available from the Guggenheim least-squares analysis, τ can be calculated from the slope ($\exp(-k\tau)$). A linear least-squares is now possible for the complete data set $R_t, R_{t+\tau}/t, t + \tau$ because the times $t(1) + \tau$, $t(2) + \tau$... $t(n) + \tau$ can be absolutely characterized. A least-squares correlation of $1/R$ as Y with $\exp(-kt)$ as X according to eq. [79] yields $B(1)$ and $B(2)$ from which the resistances can be regenerated and compared with the observed values.



The preceding analysis has been applied to the raw resistance–time data for allyl bromide measured by the author between 1957–1959 and reported later with Robertson (75). This data set was selected because the hydrolysis of allyl bromide generated the most reproducible rate constants when *numerically* processed using eq. [82]. The reproducibility of not less than four rate constants measured at each of 13 temperatures averaged at 0.26 ± 0.09%. The measurements at 44.987 and 25.005 °C were selected for further analysis and the data from these calculations are reported in Table 9. The reported pseudo-first-order rate constants for each run were calculated in four ways: (*i*) a linear least-squares using eq. [82] using both sets of resistances in a numerical version of the Guggenheim algorithm; (*ii*) a nonlinear least-squares using the R_t values; (*iii*) a nonlinear least-squares using the $R_{t+\tau}$ values; and (*iv*) a linear least-squares technique using eq. [82] after the quantity $B(1)$ had been established on the basis of the regression in item (*iii*).

Both sets of data (T = 44.987 and 25.005 °C) show a reduction in the observed rate constants between the first half-life (R_t values) and the third half-life ($R_{t+\tau}$ values) of 4% that is approximately eight times the experimental error. Furthermore, the resistances regenerated from eq. [79] show systematic rather than random deviations (see Fig 3). These computed departures from strict first-order behaviour are in the anticipated direction when a more elaborate treatment of the Albery–Robinson mechanism is presented (see the previous paragraph), i.e., the double exponential expression (eq. [66]) that *might approximately describe* the production of acid with time would yield results in which the first-order rate constant becomes smaller with time. However, the present evidence is better regarded as indicative rather than compelling because other factors such as: (*i*) the linearization of eq. [77]; (*ii*) the possible nonlinearity of the conductance bridge; and finally, (*iii*) inadequate thermostatting might give rise to the effects these calculations establish.

Using the enthalpy of activation for the hydrolysis of allyl bromide (21.5 kcal mol^{-1} at 45 °C) in conjunction with the differential form of the Van't Hoff equation suggests that a temperature change of 0.37 K would be required at 45 °C to give a 4% retardation of the rate constant. This temperature drift is *well outside* that tolerated during the time–resistance measurements required for the rate constant determinations so item (*iii*) in the preceding paragraph can be safely discarded.

Sections 1–7 provide information that suggests that displacements at primary, secondary, and tertiary carbon atoms in water cannot be reconciled with the notion of simple S_N1 and S_N2 displacements. In the remaining sections, further influences of structure on reactivity are examined, particularly related to the nature of the leaving group or nucleofuge, a topic that hitherto has received less systematic attention.

Fig. 3. Deviations between calculated and observed resistances for run A82T related to the hydrolysis of allyl bromide.

8. Nucleofugality and mechanism

The purpose of the present section is to examine the solvolytic reactivity of a molecule (RX) in water as a function of anionic and neutral leaving groups. Generally speaking, the reactivity of RX has been primarily discussed in terms of the structure of the alkyl group (1–12). However, here, attention is focused on a wide variety of leaving groups associated with several organic structures, namely, the methyl, ethyl, allyl, 2-propyl, cyclohexyl, *tert*-butyl, 1-adamantyl, 2-adamantyl, benzyl, and 3- and 4-substituted benzyl structures. Such a range of solvolytic substrates is sufficient to embrace displacement reactions spanning the extremes of the classical S_N1–S_N2 mechanistic spectrum including the more elaborate descriptions represented by eqs. [16] and [52].

Leaving-group reactivity is intrinsically complex. Thus, it should be recognised at the outset that the order of reactivity manifested by RX as a function of X may not be independent of R. For instance, when X = Br or I the order of reactivity at 298.15 K is sometimes Br > I for R = methyl (60), ethyl,[2] allyl (75), and 2-propyl (6),[2] but for other structural environments, namely, R = *tert*-butyl (9) and 1-adamantyl (100, 101), the sequence I > Br is observed, an order that is considered here as "normal". This change in the order of reactivity of bromide and iodide leaving groups suggests the factors affecting nucleofugality are subtle, although the differences between bromide and iodide as nucleofuges are always small.

The *neutral* hydrolyses of carboxylate esters of strong carboxylic acids, e.g., trifluoroacetic acid, are also complex. Thus, most primary and secondary trifuoroacetate esters appear to react by an acyl-oxygen $B_{Ac}2$ path, whereas the tertiary esters heterolyse via an alkyl-oxygen S_N route. A reactive primary ester such as 4-methoxybenzyl trifluoroacetate demonstrates "mixed kinetics", reacting by both the $B_{Ac}2$ and S_N mechanisms (79, 102–105). On the other hand, *tert*-butyl trifluoroacetate appears to react predominately by the same mechanism as *tert*-butyl chloride, namely, via the alkyl-oxygen path (102–105). Thus, the entropies of activation at 25 °C for *tert*-butyl chloride and *tert*-butyl trifluoroacetate are both positive and similar in magnitude, 10.1 and 13.0 cal mol^{-1} K^{-1}, respectively. The secondary isotope ef-

© 2005 NRC Canada

fects (k(H)/k(D)) for the *tert*-butyl-d_9 compounds with chloride ion and trifluoroacetate ion as leaving groups are 2.2 and 2.6, respectively, and the KSIE ratios for these substrates are 1.22 and 1.38, respectively. The energy of activation for *tert*-butyl acetate is high (106) and this observation is consistent with an S_N route for this substrate.

The change in mechanism from $B_{Ac}2$ to S_N in the solvolytic behaviour with increasing homology for the simple α-methylated alkyl trifluoroacetates is presumably related to two energetic influences; the first, steric and the second, electronic. For a series of 4-substituted benzyl trifluoroacetates, the steric features are essentially constant for either mechanism. Hence, the changing electronic influences on each path as the ring substituent alters will dominate the observed reactivity sequence. The gas-phase enthalpy of ionization of a series of 4-substituted benzyl trifluoroacetates

[85] $ArCH_2OOCCF_3 \rightarrow ArCH_2^+ + CF_3COO^-$

should parallel those of the corresponding benzyl chlorides (105) (see section 13). On this basis, the reactivity sequence for the S_N mechanism should increase $CH_3O > CH_3 > H > Cl > NO_2$, and intuitively, that for the $B_{Ac}2$ mechanism should be in the opposite sense. A blend of these separate reactivity sequences is observed in practice, the mechanistic change occurring between the methoxy and methyl substrates. Thus, in two acetone water mixtures the four substrates with the substituents NO_2, Cl, H, and CH_3 in the 4-position react by the $B_{Ac}2$ mechanism and provide excellent Hammett plots with *positive* slopes. These correlations are presented in Fig. 4 and the data are recorded in Table 11. The numerical details related to the Fig. 4 are given in the following equations for: (*i*) acetone–water (~29%, *v*/*v*)

[86] $$\log k_o = 0.878 \pm 0.007\sigma - 3.284 \pm 0.003 \ (4,0.9993)$$

$$k(CH_3O, B_{Ac}2) = 3.75 \times 10^{-4}\ s^{-1} : k(CH_3O, S_N) = 2.68 \times 10^{-4}\ s^{-1}$$

and (*ii*) acetone–water (~5%, *v*/*v*)

[87] $$\log k_o = 0.643 \pm 0.01\sigma - 2.621 \pm 0.005 \ (4,0.9993)$$

$$k(CH_3O, B_{Ac}2) = 1.89 \times 10^{-3}\ s^{-1} : k(CH_3O, S_N) = 1.33 \times 10^{-3}\ s^{-1}$$

The $k(S_N)$ rate constants for 4-methoxybenzyl trifluoroacetate were obtained by calculating the $k(B_{Ac}2)$ rate constants by extrapolating the Hammett plots (eqs. [86] and [87]) with $\sigma(CH_3O) = -0.16$ and subtracting this value from k_o according to the equation

[88] $k_o = k(B_{Ac}2) + k(S_N)$

The change in reactivity of the 4-methoxybenzyl trifluoroacetate between the two acetone–water mixtures for the $k(S_N)$ process corresponds to a Grunwald–Winstein m value of 0.81. The latter value is consistent with an S_N process offering confirmation of the conclusions drawn from the behaviour of the α methylated substrates. The change in reactivity between the two acetone–water mixtures demonstrated for the $k(B_{Ac}2)$ rate constants is very close to that calculated for the S_N rate constants, and evidently, the Grunwald–Winstein m parameter is insensitive to the mechanistic shift $B_{Ac}2$ to S_N for 4-methoxybenzyl trifluoroacetate. The KSIE also confirms the conclusions drawn on the basis of the substituent effects on the benzyl trifluoroacetate solvolysis.

Swain and Lohmann (4, 107) presented the first formal attempt to quantify leaving-group ability, but their work has attracted little attention and is notably absent in two fairly recent accounts of linear free energy relationships (108). Hoffmann (109) has used tosylate–bromide ratios as a mechanistic criterion, and there is a study by Bentley and Dewar (110) that also indirectly relates to the work of Hoffmann (109) and Swain and Scott (111). These contributions will be subsequently considered. In his discussion of the Swain–Lohmann LFER, Thornton (4) suggests that for anionic leaving groups X^- nucleofugality correlates with the pK_a of the acid HX. This hypothesis will be examined via the Guthrie LFER in section 10.

9. The Swain–Lohmann equation and derivative linear free energy relationships

The formalities of the Swain–Lohmann equation are similar to those adopted by Swain and Scott (111) in their development of an empirical scale of nucleophilicity represented

© 2005 NRC Canada

by the Swain–Scott LFER. To establish a scale of nucleofugality for the displacement

[89] $N + RX \rightleftharpoons RN + X$

it is necessary to define standard reagents and conditions. These are: (*i*) the leaving group X; (*ii*) the nucleophile N; (*iii*) the substrate RX; (*iv*) the solvent; and (*v*) the temperature. For the Swain–Lohmann equation, these are: Br^-, CH_3O^-, CH_3Br, CH_3OH, and 298.15 K, respectively. For a series of leaving groups X, the quantity *L* appropriate to each individual leaving group X is defined by the equation

[90] $$L = \log k(CH_3X) - \log k_o(CH_3Br) = \log[k(CH_3X)/k_o(CH_3Br)]$$

The broader influence of structure on leaving-group reactivity can now be examined via structural changes of N and R together with the same changes in the leaving group X that established the *L* scale via eq. [90]. Further options include the examination of the influence of solvent and temperature on the defined quantities.

Thus, for a selected N, R, solvent, and temperature, a series of second-order rate constants are generated when X is varied, which are then correlated with *L*. The resulting LFER is anticipated to be of the form

[91] $$\log[k(RX/N)/k(RBr/N)] = \gamma L$$

where γ is a constant characteristic of N, R, the temperature, and the solvent.

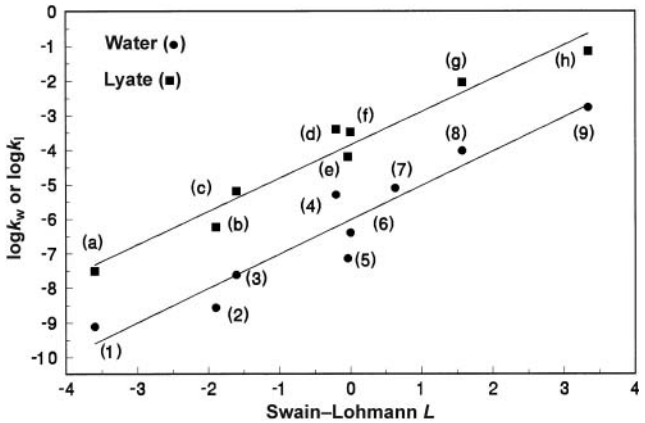
The *L* data are meagre and those given in Table 12 are selected from Thornton (4); apparently, the papers promised in Thornton's book (4) have failed to materialize, a point also raised by Bentley and Dewar (110). Other data for testing eq. [91] are provided by the rate constants that describe eqs. [6] and [7] for a series of methyl compounds reported in Table 6. A plot relating to the reactions with water and hydroxide ion as nucleophiles is shown in Fig. 5. A least-squares treatment of the two correlations for the water reactions gives

[92] $$\log k_w(CH_3X) = (0.993 \pm 0.078)L - 6.019 \pm 0.15 \quad (9,0.955)$$

and

[93] $$\log k_l(CH_3X) = (0.963 \pm 0.057)L - 3.900 \pm 0.13 \quad (8,0.977)$$

with aqueous hydroxide as the nucleophile. The correlation coefficients suggest that the relationships represented by eqs. [92] and [93] are only fair.



The Swain–Lohmann LFER is broad in scope because, as previously mentioned, the applications of the *L* values are, in principle, required to accommodate a variety of structural and environmental changes. Because our interest is confined to water, the Swain–Lohmann correlations are replaced here by what are designated to be the equivalent Hammett–Pfluger (115) forms. This tactic discards the notion of a standard data set, but retains a fixed solvent and temperature, namely, water and 298.15 K. The equivalent Hammett–Pfluger form is

[94] $$\log k(RX) = \gamma \log k(R'X) + C$$

and all the rate constants for RX and R′X are confined to hydrolysis in pure water. The constants in eq. [94], namely, γ and *C*, are empirically defined by the two R groups, the leaving groups, the solvent, and the temperature. Here, the organic groups R′ and R are selected pairs from a range of structures previously mentioned. The least-squares lines for

© 2005 NRC Canada

a selection of such pairings are presented in the following in terms of eqs. [95]–[99]. The correlations are conservatively judged to be satisfactory and are an improvement to the correlations described by eqs. [92] and [93].

[95] $\log k(\mathrm{EtX}) = (0.997 \pm 0.025)\ \log k(\mathrm{CH_3X}) + 0.038 \pm 0.13\ (9,0.995)$

[96] $\log k(\mathrm{allylX}) = (1.140 \pm 0.08)\ \log k(\mathrm{CH_3X}) + 2.85 \pm 0.58\ (4,0.983)$

[97] $\log k(\mathrm{2\text{-}AdX}) = (1.416 \pm 0.06)\log k(\mathrm{CH_3X}) + 3.852 \pm 0.29\ (7,0.991)$

[98] $\log k(\mathrm{c\text{-}HexX}) = (1.001 \pm 0.057)\ \log k(\mathrm{2\text{-}PrX}) + 0.071 \pm 0.30\ (4,0.993)$

[99] $\log k(\mathrm{1\text{-}AdX}) = (0.959 \pm 0.040)\ \log k(t\text{-BuX}) - 1.862 \pm 0.13\ (6,0.993)$

Three of the correlations represented by eqs. [95], [97], and [99] are illustrated in Figs. 6, 7, and 8, respectively, and the related data are presented in Tables 13–16. The sources for the solvolytic data are reported in each table. For cases that required the extrapolation of rate data from measurements in mixed solvent systems at temperatures either lower or higher than the standard temperature, a brief outline of the least-squares and other numerical techniques employed to obtain a rate constant in water at 298.15 K is reported at the foot of Table 16. These details relate to the Grunwald–Winstein (118, 137–141, 143), Eyring, and Arrhenius equations, all in their respective linear forms. Some further comment on eqs. [95]–[99] is important to our general thesis.

The correlation represented by eq. [97] is notable in that the ordinate covers nearly 10 orders of magnitude. Equation [99] with R′ = *t*-Bu and R = 1-adamantyl embraces both anionic (Cl^-, Br^-, I^-, NO_3^-, CF_3COO^-) and neutral ($(CH_3)_2S$) leaving groups, the latter generated from the hydrolyses of the related sulphonium ions. As far as we are aware, eq. [99] provides the first real opportunity to predict the rates of hydrolysis for some tertiary sulphonates with fair precision, and this enhances a further discussion of Hofmann's ideas (109) presented later. Simple open-chain tertiary sulphonates are apparently very labile (109), and in consequence, these substances cannot be examined directly. Facile elimination appears to take precedence over substitution for these structures.

Some speculative comment of the mechanistic significance of eqs. [95]–[97] is in order. Presumably heterolytic fission of the 1- and 2-adamantyl substrates proceeds via front-side attack involving the solvent separation of intimate ion pairs. This conclusion has been confirmed by the elegant work of the Milton–Harris group (144, 145), who demonstrated that a series of 2-adamantyl-4-substituted-benzenesulphonates solvolysing in EtOH–H_2O mixtures yielded products that depend on the leaving group. Thus, the product ratios *R*, defined by *R* = ([2-AdOH][EtOH])/([2-AdOEt][H_2O]), alter with the pK_a of the acid related to the leaving group, becoming more selective as the pK_a decreases (see Fig. 9 and Table 17). Because rearside nucleophilic assistance is precluded for 2-adamantyl substrates, the *R* values indicate that

solvent-separated ion pairs such as 2-Ad$^+$|H_2O|X$^-$ and 2-Ad$^+$|EtOH|X$^-$ are important intermediates in the displacements of 2-adamantyl substrates.

Clearly, the LFER represented by eq. [97] covering nearly 10 orders of magnitude reasonably suggests that the heterolysis of the methyl substrates consists of chemical events analogous to those that characterize the heterolytic fission of 2-adamantyl substrates, i.e., the reaction of the methyl compounds probably involves *both backside and frontside* assistance in sequence. The notion that the several processes that must contribute to this description occur in a concerted manner involving termolecular and possibly higher order processes is uncongenial particularly for primary substrates.

The earlier sections of this paper concerned with the Kurz equation and the KSIE suggest that the hydrolyses at primary carbon centres are characterized by *weak* but definite nucleophilic assistance and solvent separation prior to heterolysis. Other centres, either secondary or tertiary, involve even less or no nucleophilic assistance with a further driving force represented by solvent separation of a partly heterolysed bond. It is conceivable that increased stability of the carbocation arising from internal electron delocalization, e.g., 4-methoxybenzyl chloride and related secondary and tertiary structures, might produce situations where the need for solvent insertion becomes less, and that cases where the heterolysis occurs without the intervention of front-side solvent separation may be a definite mechanistic category for the displacement process. This proposal offers a possible explanation of the curved Hammett plot using the σ or σ^+ substituent scales with the substituted benzyl chloride hydrolyses — the negative slope *decreases* as the substituent

2-Ad mesylate (*ii*)[b]	8	1.098±0.020	–3.933±0.037	0.998	–7.770±0.037
4-MeO-benzyl chloride (*i*)[c]	5	0.848±0.016	0.426±0.047	0.998	–2.537±0.029
4-MeO-benzyl chloride (*ii*)[c]	5	0.952±0.013	0.406±0.045	0.999	–2.921±0.025

Note: For details of the Grunwald–Winstein LFER, see refs. 118, 137–141. The "*Y*" values for mixtures of either MeOH–H_2O or EtOH–H_2O were interpolated using spline functions, which are particularly suited to this purpose (see ref. 139 for a suitable algorithm). The errors for m, logk_o, and log$k$(H_2O) (k(H_2O) is the rate extrapolated to pure water) were calculated by formulae given in ref. 51. The correlation coefficients (C.C.) were calculated from a formula given in ref. 140. The correlations as a whole are best described as adequate. The source of the N rate constants for each substrate is indicated in Tables 12–15. Rates were corrected to 298.15 K by either the Arrhenius or Eyring equations.

[a]2-Ad-4-TMABS is 2-adamantyl 4-trimethyammoniumbenzene sulphonate.

[b]The rate of hydrolysis has been measured by Robertson[2] (log k (298.15 K) = –3.9329; k = 1.489 × 10^{-4} s^{-1}. Correlations for 2-Ad mesylates (*i*) and (*ii*) give rate constants of 1.167 × 10^{-4} and 1.027 × 10^{-4} s^{-1}, respectively. The Grunwald Winstein LFER correlation for 2-adamantyl mesylate (*ii*) excludes the water point, but, in contrast the LFER for 2-adamantyl mesylate (*i*) includes the water point. Correlations (*i*) and (*ii*) give some idea of the errors incorporated into the data when the Grunwald–Winstein LFER is used to estimate the pure water rates. For 2-adamantyl mesylates this amounts to 2% to 3% in log k. With other more reactive substrates, the errors may be larger. More precise measurements in solvent mixtures richer in water in combination with measurements at temperatures lower than 298.15 K for more reliable extrapolations to pure water are desirable.

[c]Data are from ref. 142.

Fig. 9. Correlation of product selectivity with acid strength measured via σ^+.

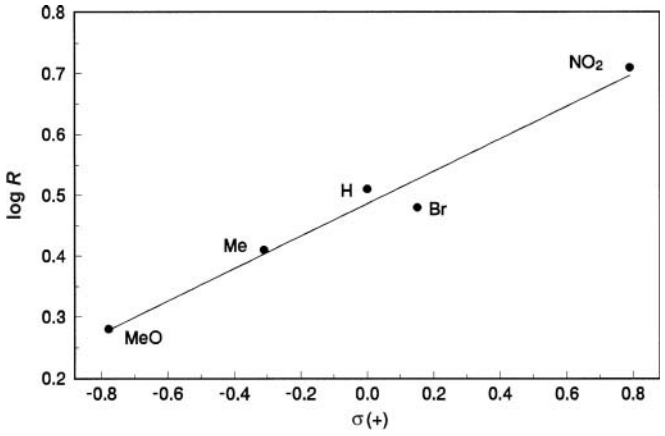

Table 17. Selectivity quantities related to the products obtained from the solvolysis of a series of 2-adamantyl 4-substituted benzenesulphonates.

X*	R[a]	log R	–log k[b]
MeO	1.94	0.28	5.226
Me	2.56	0.41	5.098
H	3.25	0.51	4.934
Br	3.05	0.48	4.711
NO_2	5.20	0.71	4.205

Note: X* is the 4-substituent.

[a]R = ([2-AdOH][EtOH])/([2-AdOEt][H_2O]) determined for the solvolysis of substrates in ethanol–water mixtures.

[b]k is the the first-order rate constant in water (T = 298.15 K) for the related methyl 4-substituted benzenesulphonates.[2] Note that the methyl esters become more reactive as the acid related to the leaving group becomes stronger and 2-adamanty esters react more selectively with the solvent.

constant becomes more *positive*. These matters will subsequently be elaborated.

The simple interpretation of the Kurz equation and eq. [97] adopted here has been independently considered and scrutinized by Albery and Kreevoy (13, 38) in an extension of the Marcus theory (36) of electron and proton transfers to methyl transfers.

[100] $Y + CH_3X \rightleftharpoons CH_3Y + X$

The analysis offered by these workers argues that the Kurz equation, as presented in section 3, cannot be used to accurately estimate the position of the transition state along the reaction coordinate for either the water or hydroxide reaction. The basis of this edictal conclusion is obscure but appears to have its origins in the notion that there are two conceivable values for the intrinsic barrier for the symmetrical exchange.

[101] $OH^- + CH_3OH \rightleftharpoons CH_3OH + OH^-$

One barrier supposedly involves the solvated lyate ion, the other, the desolvated version of the same molecular species. The special status reserved for the lyate ion is obscure, unless one of the paths embraces some sort of Grotthuss (146) chain phenomena that is absent in an alternative desolvation process.

© 2005 NRC Canada

Other simple anions involved in the Albery and Kreevoy (13) analysis might display similar phenomena, particularly fluoride, because HF is a weak acid and the fluoride leaving group is known to be susceptible to acid catalysis. In any case, the veracity of the conclusions derived from the Marcus theory applied to methyl transfers is contingent on the notion that a *single* barrier separates reactants and products. *The single barrier description is regarded here to be an hypothesis rather than a fact.* Indeed, the repudiation of the single barrier description for all S_N displacements in water is central to this paper, the present contentions originating from considerations detailed in sections 1–8.

Because data suitable for testing the Swain–Lohmann LFER are relatively scarce and the correlations represented by eqs. [92] and [93] are indifferent, an examination of the possibilities represented by Thornton's suggested correlation between nucleofugality and acid strength is more profitable. This proposal also draws further attention to the important contributions by Guthrie (23), Lewis et al. (37), and by Albery and Kreevoy (13). The interesting Brönsted LFER reported by Guthrie (23) will be considered next. Guthrie's failure to connect his work with the Swain–Lohmann LFER is both notable and puzzling because his work partly elucidates the fundamental factors that underpin the Swain–Lohmann LFER.

10. The Guthrie Brönsted LFER

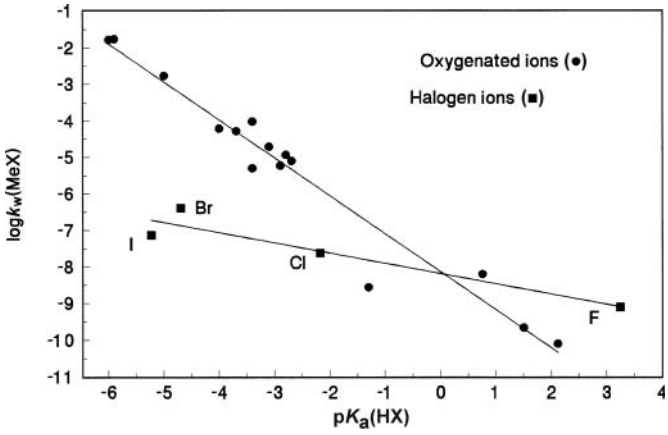
In an important investigation, Guthrie (23) examined the thermodynamics and kinetics that characterize the hydrolysis of several methyl esters derived from a series of oxyacids. The study is significant on two counts. First, Guthrie critically scrutinized the existing pK_a data for a series of strong oxyacids (82). Second, Guthrie showed that the pseudo-first-order rate constants (k_w) that characterize the hydrolyses of the *methyl esters related to the oxyacids* measured at 298.15 K show an excellent Brönsted LFER (147, 148) (see Table 12 and Fig. 10).

$$[102]\quad \log k_w(CH_3X) = -7.922 \pm 0.092 - (1.008 \pm 0.025)pK_a(HX)\ (14,0.992)$$

The 14 leaving groups are those in Table 12 excluding the NO_3^- and halogen anions.

It is tempting to identify the close proximity of the Guthrie LFER exponent to unity with a productlike transition state for the oxygenated leaving groups. However, a careful analysis of the individual Gibbs energy terms that contribute to the ionization of the acid ($\Delta G^{\ominus}(i)$) together with the energy of activation ($\Delta G^{\ddagger}(RX)$) suggests the magnitude of the slope of the Guthrie LFER cannot be given a straightforward interpretation.

Thus, for the ionization of the acid



$$[103]\quad HX + H_2O \rightleftarrows H_3O^+ + X^-$$

the change in Gibbs energy ($\Delta G^{\ominus}(i)$) are given by:

$$[104]\quad \Delta G^{\ominus}(i) = G(H_3O^+) + G(X^-) - G(HX) - G(H_2O)$$

If δ_x is an operator denoting changes in the leaving group then

Fig. 10. Guthrie LFER for hydrolysis. The leaving groups are: oxygenated ions (●), halide ions (■).

$$[105]\quad \delta_x\Delta G^{\ominus}(i) = \delta_x G(X^-) - \delta_x G(HX)$$

because the terms $\delta_x G(H_3O^+) = \delta_x G(H_2O) = 0$. For the reaction

$$[106]\quad RX + 2H_2O \rightleftharpoons ROH + H_3O^+ + X^-$$

the variation of the free energy of activation with the leaving group X is given by

$$[107]\quad \delta_x\Delta G^{\ddagger}(RX) = \delta_x G^{\ddagger}(RX) - \delta_x G_i(RX)$$

granted that $\delta_x G(H_2O) = 0$. Hence, the Brönsted slope is a function of four quantities: $\delta_x G(X^-)$, $\delta_x G(HX)$, $\delta_x G^{\ddagger}(RX)$, and $\delta_x G_i(RX)$. This analysis demonstrates that the solvolytic Guthrie exponent is a complex quantity and its intricacy is increased when other acids that do not give oxygenated anions, e.g., the halogen acids, are included in the correlation.

This analysis may also explain why Guthrie was reluctant to draw any significant mechanistic conclusions from the magnitude of the exponent. Nevertheless, the latter quantity is suggestive that transition states that characterize the hydrolyses are productlike with respect to the leaving group for esters yielding oxygenated anions. However, a productlike leaving group conflicts with Schowen's (68) estimate based on the KSIE and with our extended discussion of the Kurz equation (see sections 3 and 4). Such paradoxes are possibly explained by the postulate, namely, that discordant reaction coordinate parameters signify that the reaction takes place by a mechanism involving more than one step.

Guthrie's failure to offer mechanistic comment on eq. [102] may also be a consequence of the harsh criticism levelled at such correlations by Abraham and McClellan (33, 44, 45), although a similar correlation of the Grunwald–Winstein Y quantities (118, 137–141) with the Gibbs energy of ionic solvation of potassium chloride in methanol–water mixtures presented by Hudson and Saville (149) curiously escapes their reproach.

Clearly, Guthrie's LFER (23) validates Thorton's hypothesis (4) for a *restricted* series of acids for which the conjugate bases are oxygenated anions, namely, that the nucleofugality of any leaving group X tracks the strength of the acid HX. Although both kinetic data for the hydrolysis of the methyl halides are available, (see Tables 3 and 12) and carefully cal-

culated pK_a(HX) values exist for the halogen acids HX, (X = F, Cl, Br and I) (112–114), Guthrie (23) excluded these acids from his correlation. This important omission is remedied in section 11.

11. The strength of the hydrohalic acids and the Guthrie LFER

The pK_a values for the halogen acids have been estimated via a thermodynamic cycle by Myers (114). Because the pK_a of hydrofluoric acid is known, Myers' calculation for the other three acids is partly calibrated. The cycle Myers used gave a value for hydrofluoric acid in acceptable accord with the experimental and readers are referred to his paper for details. The inclusion of the $k_w(CH_3X)$ rate constants and the related pK_a(HX) values for X = F, Cl, Br, and I, adds four points to the Guthrie LFER, but the new data are *poorly* represented by eq. [102]. The deviations from eq. [102] are large and *fall on a line of lower slope* (see Fig. 10). The order of reactivity of methyl bromide and iodide is incorrectly predicted on the basis of the pK_a values of HBr and HI, but, because the pK_a values of HBr and HI are close ($\Delta pK_a \approx 1$ unit), their predictive utility might be lost in the intricacy of the total displacement process. At the present juncture there is a more compelling question, namely, is the departure of the methyl halide leaving groups from the Guthrie LFER a consequence of either erroneous kinetic or equilibrium data?

To answer this question other kinetic data describing halogen displacements in water at 298.15 K for other reacting centres were sought and evaluated. Rate constants for the following reactions

[108] $t\text{-BuX} + 2H_2O \rightarrow t\text{-BuOH} + H_3O^+ + X^-$

[109] $\log k = (-0.773 \pm 0.038)pK_a - 3.66 \pm 0.15$ (4,0.995)

[110] $1\text{Ad-X} + 2H_2O \rightarrow 1\text{-AdOH} + H_3O^+ + X^-$

[111] $\log k = (-0.757 \pm 0.035)pK_a - 5.59 \pm 0.14$ (4,0.995)

[112] $[Co(NH_3)_5X]^{2+} + 2H_2O \rightarrow [Co(NH_3)_5OH]^{2+} + H_3O^+ + X^-$

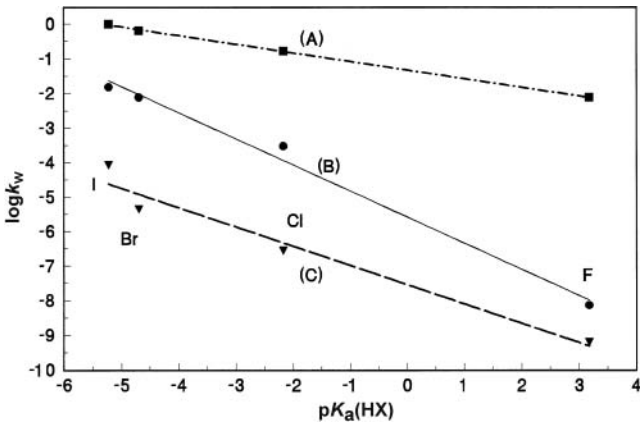
[113] $\log k = (-0.327 \pm 0.013)pK_a - 1.275 \pm 0.052$ (4,0.9997)

[114] $[Co(NH_3)_5X]^{2+} + OH^- \rightarrow [Co(NH_3)_5OH]^{2+} + X^-$

[115] $\log k = (-0.327 \pm 0.013)pK_a - 1.275 \pm 0.052$ (4,0.997)

[116] $\log k = (-0.366 \pm 0.021)pK_a - 0.696 \pm 0.086$ (4,0.993)

[117] $[Cr(H_2O)_5X]^{2+} + 2H_2O \rightarrow [Cr(H_2O)_6]^{2+} + H_3O^+ + X^-$



[118] $\log k = (-0.558 \pm 0.054)pK_a - 7.55 \pm 0.21$ (4,0.982)

with X = F, Cl, Br, and I are presented with their sources in Table 18. For the reaction described by eq. [114], two sets of data are reported in eqs. [115] and [116]. They are discordant, but no effort has been made to pursue the sources of this anomaly.

The hydrolyses and base attack rates have been correlated with the Myers' pK_a values in two ways: the pK_a quantities function as both the *dependent* and *independent* variable in the regressions. The least-squares lines quoted in the preceding are with the pK_a in the latter category and some representative samples of these correlations are presented in Fig. 11. From the six correlations in which the pK_a values are in the former category, six values of each of the four pK_a(HX) values can be calculated from the regressions. The mean values for each acid on this basis are reported in Table 18. These quantities are in satisfactory agreement with Myers' values and imply an average error equivalent to ≈300 cal in the four cycles. The six Guthrie correlations validate Myers' estimates of the pK_a values for the hydrogen halides. Further kinetic data for other leaving groups for which the pK_a values of the related acids can be measured are available for some of the reactions described by eqs. [108] and [110].

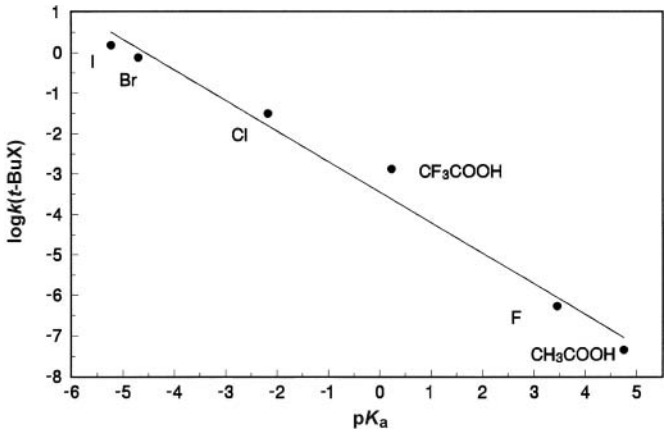
Fig. 11. Guthrie LFER for displacements of: (A) *tert*-butyl substrates; (B) chromium halides; and (C) cobalt halides. In graph (A) the log *k* axis is increased by five units for clarity of presentation. For details, see reactions [112], [114], and [117].



Thus, for the *tert*-butyl substrates the leaving groups embrace all the halide, acetate, and trifluoroacetate anions giving a Guthrie LFER,

[119] $\log k(t\text{-BuX}) = (-0.755 \pm 0.035)\mathrm{p}K_a - 3.44 \pm 0.14$ (6,0.991)

covering nearly 10 orders of magnitude on the abscissa. This correlation includes six acids (see Fig. 12) raising the number of acids for which the pK_a values that can be determined by conventional means to *three*. Thus, eq. [119] provides further confirmation of Myers' calculation and other insights into the details of the displacement reactions. For instance, the slope of the line represented by eq. [119] is enhanced relative to that for the methyl halides, suggesting that the tertiary centres produce a more ionic transition state in accord with the conventional wisdom. Paradoxically, the slope is still *less* than that for the hydrolysis of methyl esters giving rise to oxygenated anions. This observation suggests without compelling proof that the slopes of the Guthrie correlations are partly related to return phenomena, a hypothesis difficult to establish with certainty.

Fig. 12. Guthrie LFER for displacements of *tert*-butyl substrates.

The rate constants for *tert*-butyl fluoride and acetate involve large extrapolations to calculate the rate constants at 298.15 K. On the other hand, the extrapolations for the chloride, bromide, iodide, and trifluoroacetate are much smaller. The rate constants related to these four substrates give an excellent Guthrie LFER.

[120] $\log k = (-0.5606 \pm 0.0025)\mathrm{p}K_a - 2.745 \pm 0.009$ (4,0.99996)

This particular LFER offers convincing confirmation of Myers' estimates of the pK_a values for the halogen acids.

12. Primary, secondary, and tertiary substrates

General comment

The five Guthrie LFERs that accommodate the organic and inorganic halogen displacements described by eqs. [108] to [119] in section 11 confirm Myers' pK_a calculations for the hydrohalic acids. Consequently, the failure of the methyl halides to fit eq. [89] (see Figs. 10–12 and Table 18) does *not* appear to reside in erroneous estimates of the pK_a values for the hydrohalic acids. Instead, the deviations from the original Guthrie LFER (eq. [89]) offer a significant mechanistic clue that can be discussed in terms of two *modified* versions of the Winstein mechanism.

[121] $$\mathrm{W + RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \underset{\text{(int)}}{W\text{-}R^+X^-} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \underset{\text{(ss)}}{W\text{-}R^+|W|X^-} \underset{k_6}{\overset{k_5}{\rightleftharpoons}} W\text{-}R^+ + X^- + H_2O \xrightarrow{\text{fast}} ROH + H_3O^+ + X^-}$$

$$k_8\uparrow\downarrow k_7$$

$$WR^+ + X^- + H_2O \xrightarrow{\text{fast}} ROH + H_3O^+ + X^-$$

and

[122] $$\mathrm{RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \underset{\text{(int)}}{R^+X^-} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \underset{\text{(ss)}}{R^+|W|X^-} \underset{k_6}{\overset{k_5}{\rightleftharpoons}} R^+W + X^- + H_2O \xrightarrow{\text{fast}} ROH + H_3O^+ + X^-}$$

$$k_8\uparrow\downarrow k_7$$

$$R^+ + X^- + W \xrightarrow{\text{fast}} R^+W + H_2O + X^- \xrightarrow{\text{fast}} ROH + H_3O^+ + X^-$$

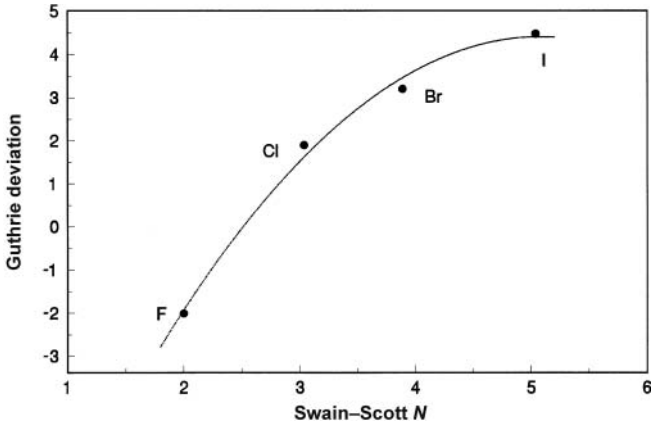
© 2005 NRC Canada

Equations [121] and [122] describe the mechanistic possibilities between the noncaged and caged substrates, respectively.

The rate constants k_7 and k_8 relate to the heterolyses of either nucleophilically assisted intimate ion pairs (eq. [121]) or intimate ion pairs (eq. [122]). The destruction of the two types of intimate and solvent-separated ion pairs might occur via the intermediate production of an oxonium ion followed by proton transfer to the solvent. Alternatively, the formation of the hydronium ion and the alcohol might proceed via a single concerted step, which has not been detailed in eqs. [121] and [122]. The two schemes described by these equations are sufficiently flexible to accommodate the departures from the Guthrie LFER evinced by the methyl halides. It should be clearly understood that the evidence for such complexity is indirect. There is no hope at present of establishing numerical values for the component rate constants in the schemes represented by eqs. [121] and [122].

There may be noncaged substrates for which backside attack is stereochemically possible but energetically superfluous, i.e., such substrates are candidates for the ionic displacement without backside nucleophilic assistance (eq. [122]). This mechanism is obviously similar to the classical S_N1 mechanism of heterolysis, taking place via an intimate ion pair noting that the leaving group may depart either with or without frontside solvent assistance.

If R(1) and R(2) refer to organic groups that heterolyse according to eqs. [121] and [122], respectively, then the basic hypothesis postulated here is that the structures W-$R(1)^+|W|X^-$ and $R(2)^+|W|X^-$ containing identical leaving groups show analogous properties and that the LFER represented by eq. [97] and illustrated in Fig. 7 substantiates such an analogy.



In water, leaving groups fall into four distinct categories: (*i*) poor nucleophiles and good leaving groups, e.g., sulphonates, perchlorates; (*ii*) poor nucleophiles and poor leaving groups, e.g., fluorides, acetates; (*iii*) good nucleophiles and good leaving groups, e.g., bromides, iodides; (*iv*) good nucleophiles and poor leaving groups, e.g., cyanides, thiosulphates.

Substrates for which rearside nucleophilic assistance is stereochemically possible and energetically significant are accommodated by the scheme represented by eq. [121]. Leaving groups (X) that are poor nucleophiles react by the k_1, k_2, and k_7 steps, i.e., return from the intimate ion pair is significant for all leaving groups. In cases where the nucleofuge combines good leaving group propensities with marked nucleophilic properties such as Br^- and I^-, all eight rate constants (k_1–k_8) may contribute to the observed rate, although there is little compelling evidence that external return at any stage is significant in water. In principle, external return requires second-order reactions that are obviously inhibited by low substrate concentrations.

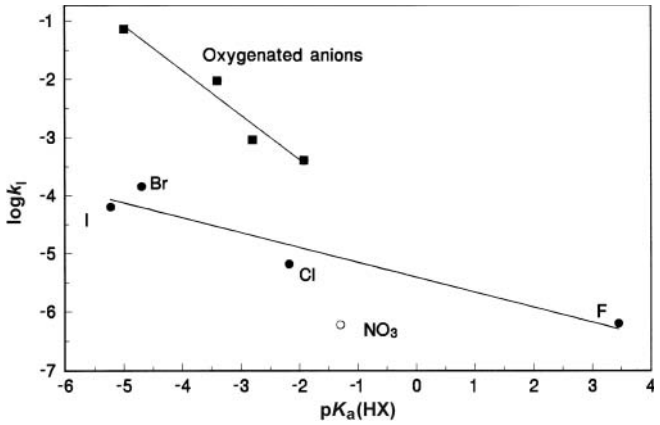
Primary substrates

The large deviations from the original Guthrie LFER exhibited by the methyl halides noted in section 11 are attributed reasonably to the fact that the halogen anions, particularly iodide and bromide, are good nucleophiles and leaving groups. The deviations $\Delta\log k_r(CH_3X)$ from eq. [102] for X = F, Cl, Br, and I can be estimated from the expression

Fig. 13. Deviations of the methyl halides from the Guthrie LFER vs. Swain–Scott *N* values.

$$[123]\quad \Delta\log k_r(CH_3X) = \log k_o(CH_3X) + 7.92 + 1.008pK_a(HX)$$

where $\log k_o(CH_3X)$ is the observed rate constant for CH_3X and the other terms on the RHS of eq. [123] are derived from eq. [102]. The $\Delta\log k_r(CH_3X)$ quantities estimated from eq. [123] for the halogen leaving groups give a smooth correlation with the structurally related *N* values established from the Swain–Scott equation (111) (see Fig. 13).



Finally, if the model represented by eq. [121] is correct, the observed rate constant for any system reacting according to this equation will be a complex function of the several component rate constants that describe this mechanism. Granted that an extended Albery–Robinson model for $\Delta C_p^{\ddagger}$ furnishes the major source of this quantity, then the sequence of rate constants k_n (n = 1–7) for the primary and other substrates will give rise to an apparent $\Delta C_p^{\ddagger}$ for these substances (15, 21, 22, 77, 94).

The data in Table 9 are sufficient to extend the Guthrie LFER to eq. [7]. Thus, the replacement of nucleophilic water by the hydroxide ion in the Guthrie LFER (see Fig. 14) also demonstrates the bifurcation evident for the water reactions, although the departure from the line defined by the oxygenated anions is now roughly half the extent observed with water. This is to be anticipated because, granted the hydroxide ion is a stronger nucleophile than water, then the deviations from the line for the oxygenated ions should be *less* because the *differences between the nucleophilic power of the attacking nucleophile and leaving group are presumably more balanced when hydroxide is the nucleophile*. This explanation is congruent with that offered to explain why the $pK_a^{\ddagger}$ calculated from the Kurz equation reached a minimum for methyl iodide, a substrate for which the leaving group combines substantial nucleophilic and leaving-group abilities.

These considerations can be examined in another way. The rate constants for both the attack of water and lyate ion are available for five methyl esters that yield oxygenated anions (see Table 6). The rate constants characteristic of these substrates when reacting with water and lyate ion display a respectable LFER.

© 2005 NRC Canada

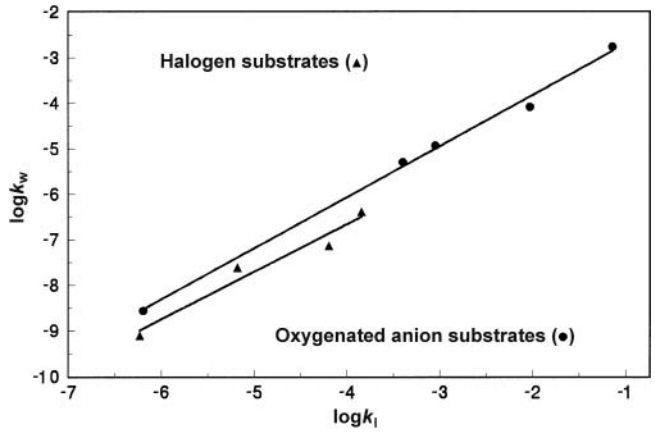
Fig. 14. Guthrie LFER for lyate ion displacements.

[124] $\log k_w = (1.123 \pm 0.029) \log k_l - 1.576 \pm 0.099$ (5,0.998)

The four methyl halides provide an analogous but separate relationship.

[125] $\log k_w = (1.044 \pm 0.11) \log k_l - 2.485 \pm 0.52$ (4,0.978)

The overlapping slopes of [124] and [125] suggest the selectivities of water and hydroxide are close. However, a more telling observation is provided when eqs. [124] and [125] are considered together (see Fig. 15). All the methyl halides are *less* reactive with water than is predicted on the basis of their reactivity with lyate ion, i.e., the related methyl halide LFER plots *below* the LFER defined by the oxygenated anionic leaving groups. Presumably, this reflects the poor nucleophilicity of the oxygenated anions in comparison with the halide anions and suggests indirectly return phenomena are more prevalent when water reacts with the methyl halides, contrasting with esters related to the oxygenated anions. These observations are consistent with the larger (more positive) $\Delta C_p^{\ddagger}$ values observed for the sulphonates compared with halides as leaving groups. The separation of the lines in Fig. 15 is also reminiscent of the more marked separation shown in the Guthrie LFER in Fig. 10.



Hartshorn (10), following Winstein and co-workers, has pointed out that the rates of solvolyses of series of primary mesylates related to the methyl, ethyl, propyl, 2-methylpropyl, and neopentyl alcohols provide important mechanistic information. In both ethanol and water the reactivity (log *k*) of this series of substrates *decreases* with increasing homology and can be correlated with the Taft steric substituent constant E_s (108).

[126] $\log(k(\text{EtOH})) = 3.54 \pm 0.09 - (1.97 \pm 0.10)E_s$ (4,0.995)

[127] $\log(k(H_2O)) = -2.56 \pm 0.03 - (0.483 \pm 0.025)E_s$ (5,0.990)

[128] $\log(k(\text{TFA})) = (1.99 \pm 0.36)E_s + 0.836 \pm 0.32$ (5,0.907)

Fig. 15. A LFER for methyl substrates: upper and lower lines, respectively, relate to oxygenated and halide nucleofuges.

The Taft constants (E_s) were taken from a compilation by Shorter (108) and the data related to eqs. [126]–[128] are presented in Table 19. The coefficient of E_s increases by a factor of 4 in solvent ethanol compared to water. However, when the displacements are conducted in trifluoroacetic acid the coefficient of E_s *changes sign* and the reactivity *increases* with increasing homology, presumably, as a consequence of anchimeric assistance particularly in the case of the last two alkyl mesylates in the sequence. The *smaller influence* of the organic groups in water compared to ethanol suggests that the phenomena that underpin the behaviour observed in trifluoroacetic may contribute to the reactivity sequence observed in water. Thus, it is possible that the 2-methylpropyl and neopentyl mesylates react by two routes in water by a mixed mechanism, namely, by achimerically assisted and an unassisted displacement. This proposal offers a plausible explanation of the negligible $\Delta C_p^{\ddagger}$ for the neopentyl mesylate reported here. The details related to this observation are reported in Appendix B. Scott and co-workers (79) have discussed the details of an $S_N/B_{Ac}2$ mixed mechanism (see section 8). Unfortunately, the products from the hydrolysis of the 2-methylpropyl and neopentyl mesylates were not examined when the rate constants were established in water, and consequently, further confirmation of the mixed mechanism suggestion for the negligible $\Delta C_p^{\ddagger}$ for the hydrolysis of neopentyl mesylate awaits further verification.

Secondary substrates

The 2-adamantyl systems are important mechanistically for reasons reviewed by Bentley (144, 156). The rate ratios for the 2-adamantyl, cyclopentyl, cyclohexyl, and 2-propyl toslylates in solvents trifluoroacetic acid, ethanol, formic acid, and acetic acid are reported in Table 20A. The rate constants in water for various nucleofuges are also reported in Table 20B. In Table 20C the corresponding ratios for the same organic groups are reported for the nitrates, mesylates, and bromides in water. Granted that the nucleophilic properties of TFA are meagre, then the sequence of rate for these tosylates in this solvent are considered to reflect a limiting mechanism. The behaviour of the nucleophilic components of the ratios that are reported in parentheses for water and the other solvents and calculated according to Bentley's recipe (144) show that the values for water are similar to those

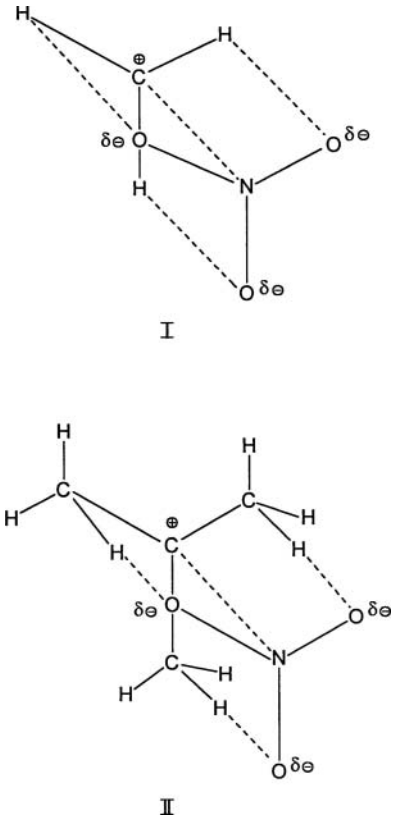
Note: The importance of nucleophilicity measured by the quantity R_x(solvent)/R_d in part A and by R_{xw}/R_d recorded in part C, where x = a–h is demonstrated. The importance of nucleophilicity measured by the quantity R_{xy}/R_d is recorded in parentheses. For details, see ref. 144, and for data in water, see footnote 2 in the text.

[a]R_a = k(R-tosylate)/k(2-Ad-tosylate) in EtOH. R_a(EtOH) = R_a/R_d.
[b]R_b = k(R-tosylate)/k(2-Ad-tosylate) in CH_3COOH. $R_b(CH_3COOH) = R_b/R_d$.
[c]R_c = k(R-tosylate)/k(2-Ad-tosylate) in HCOOH. R_c(HCOOH) = R_c/R_d.
[d]R_d = k(R-tosylate)/k(2-Ad-tosylate) in trifluoroacetic acid.
[e]Units are in electron volts. For details, see ref. 144 and for data in water, see footnote 2 in the text.
[f]Mean value estimated from eqs. [97] and [180]: the agreement is fair.
[g]R_e = $k(RNO_3)/k(2\text{-}AdNO_3)$ in H_2O. $R_{ew} = R_e/R_d$.
[h]R_f = k(RBr)/k(2-AdBr) in H_2O. $R_{fw} = R_f/R_d$.
[i]R_g = k(R-mesylate)/k(2-Ad-mesylate) in H_2O. $R_{gw} = R_g/R_d$.
[j]R_h = k(R-tosylate)/k(2-Ad-tosylate) in H_2O. $R_{hw} = R_h/R_d$.



listed for acetic and formic acid. The other leaving groups, namely, nitrate, bromide, and mesylate have not been measured in trifluoroacetic acid, but the ratios for these leaving groups in water are comparable to the tosylates in water. The magnitudes of the nucleophilic components for the tosylates in water track the ionization potentials of the related organic radicals in the anticipated sense, i.e increased nucleophilic interaction accompanies an increase in the ionization potential of the radical. However, the rate constants themselves display the order cyclopentyl > 2-propyl > cyclohexyl, whereas the order of I_p(R·) is cyclohexyl < cyclopentyl < 2-propyl. The possible influence of return phenomena in the observed rate constant may be the source of this discrepancy. A wider range of data for different leaving groups in trifluoroacetic acid might be more revealing.

Tertiary substrates

The excellent LFER between *tert*-butyl and 1-adamantyl substrates in solvent water represented by eq. [99] involving the anionic leaving groups Cl, Br, I, TFA, NO_3 and the departure of the neutral molecule $(CH_3)_2S$ provides estimates of the rates of hydrolysis for other tertiary esters. Thus, the rates of *tert*-butyl tosylate, mesylate, picrate, and 4-nitrobenzoate can be established via eq. [99] from the corresponding known rates of related 1-adamantyl substrates. Similarly, the rates of hydrolysis of 1-adamantyl fluoride and acetate can

© 2005 NRC Canada

Fig. 16. Conformational possibilities for methyl nitrate and *tert*-butyl nitrate.

be calculated from the rates of the related *tert*-butyl compounds (see Table 14).

The Guthrie LFER for the *tert*-butyl substrates shows the same bifurcated behaviour as the methyl compounds between the halogen and the sulphonate esters. Tertiary butyl nitrate appears to be more reactive than might have been predicted on the basis of the relatively low reactivity of primary and secondary nitrates. The deviations of the nitrate esters from the Guthrie LFER may be a consequence of the stereochemistry and the symmetry of the incipient methyl, 2-propyl, and *tert*-butyl carbocations relative to the symmetry of the forming nitrate anion (see Fig. 16). The interactions of hydrogen atoms carrying increments of positive charge attached to the α-carbon for primary compounds interacting with suitably eclipsed negatively charged oxygen atoms of the nitrate anion would stabilize such structures. On the other hand, similar interactions for the *tert*-butyl cation might be repulsive rather than attractive. Such a lowering of the activation energy by intramolecular repulsions are likely to be less significant for the sulphonates because the S—O bond distances are larger than in similar structures containing nitrogen rather than sulphur.

The LFER represented by eq. [99] shows that the difference $\Delta G^{\ddagger}$(1-adamantyl) – $\Delta G^{\ddagger}$(*tert*-butyl) is, to a good first approximation, independent of the leaving group and has a constant value at ca. 2.600 kcal. This is in the opposite sense to the free energy change in the gas phase reported for

[129] $t\text{-Bu}^{+} + \text{1-AdBr} \rightleftharpoons t\text{-BuBr} + \text{1-Ad}^{+}$

quoted by Bentley and Carter (127) who give $\Delta G^{-} \approx -10$ kcal. Clearly, the relative stability of the 1-adamantyl and *tert*-butyl cations indicated by this equilibrium is not reflected in the kinetic behaviour of the related substrates reacting in water. The origin of the small constant difference between the 1-adamantyl and *tert*-butyl substrates is not easily interpreted on the basis of the thermodynamics associated with eq. [129], but may be associated again with return phenomena. For open chain as opposed to caged secondary and tertiary carbon centres, nucleophilic assistance in water may be a marginal matter. Less drastic steric strain energy influences may also contribute to the activation process for the open chain and caged substrates. The relative importance of such phenomena is not easily deduced from kinetic measurements alone in the case of the 1-adamantyl and *tert*-butyl derivatives.

13. Quantum mechanical and thermochemical calculations and their relation to solvolytic reactivity

Some general considerations

This section derives from studies by Evans (28), Franklin (157), Robertson (34), Dewar (138, 160–167), Streitwieser (2, 168–170), Martin (173, 177) and various members of is group (172, 174–176, 178, 179), Muller (180), Gold (181), Mason (182), and their respective co-workers.

Attention is directed primarily to measures of the extent of transition-state heterolysis for displacement processes for a series of primary reacting centres. The application of the Marcusian treatment to methyl transfers by Albery and Kreevoy (13) can be considered to scrutinize the same problem for several methyl substrates. This latter approach to organic reactivity probes transition-state structure via connections between Gibbs energies derived from rate and equilibrium constants. The same topic has been examined indirectly on a relative basis by Dewar and co-workers (110, 160) and Streitweiser (2, 168) for various arylmethyl substrates featuring a variety of leaving groups and solvent systems. Their approach correlates Gibbs energies of activation with what are essentially the energetics of gas phase heterolysis. The Guthrie LFER discussed in section 10 also illuminates this problem, although Guthrie himself eschewed comment (23).

In the middle of the last century Winstein and Marshall (183) drew attention to the relevance of the *internal properties* of molecules participating in solvolytic displacement reactions, particularly with respect to the reactivity of the α-methylated series that in the present context consists of substrates CH_3X, CH_3CH_2X, $(CH_3)_2CHX$, and $(CH_3)_3CX$ with X = either chloride or tosylate, reacting according to eq. [6]. These workers pointed out that the effect of each additional methyl group should increase the rate constant a 1000-fold for a limiting process. In water for X = Cl, the ratios are $1 : 3.2 : 8.9 : 1.24 \times 10^6$, with the ratio quoted for ethyl chloride less secure than those for the other substrates. From other data reported here with X = tosylate the ratios are $1 : 0.85 : 51.4 : 1.3 \times 10^8$. According to Ingold (1, 8) such sequences of reactivity with increasing α substitution signalize a shift towards the classical ionization mechanism

© 2005 NRC Canada

for the secondary and tertiary substrates. This simple conclusion must be regarded as tentative because of the observations reported here, particularly those in section 9. Nevertheless, the large increase in the rate constant between sPrX and *t*-BuX (X = chloride or tosylate) more than matches the change in reactivity suggested by Winstein and Marshall (183) for a limiting process.

In a contemporary study, Franklin (157) estimated the solvolytic rate constants of the *tert*-butyl halides (*t*-BuX, X = Cl, Br, and I) by simplifying techniques developed by the Evans–Polanyi group (28). The Gibbs energy of activation in solution ($\Delta G^{\ddagger}$) for an assumed S_N1 displacement was identified with the Gibbs energy of ionization (ΔG_s^i) of the alkyl halide in solution (sln).

$$[130]\quad RX(sln) \rightleftharpoons R^+(sln) + X^-(sln)$$

The quantity ΔG_s^i was calculated using a thermodynamic cycle (2, 34, 109, 157) yielding the expression

$$[131]\quad \Delta G^{\ddagger} \approx \Delta G_s^i = \Delta G(e) + \Delta G_g^i + \Delta G(s)$$

The terms $\Delta G(e)$, ΔG_g^i, and $\Delta G(s)$ refer to the Gibbs energies that characterize the processes: the transfer of the reactant from the solvent to the gas phase, the heterolysis of the reactant in the gas phase, and the Gibbs energy of solvation of the resulting anion and cation, respectively. Franklin (157) demonstrated that eq. [131] gave values of $\Delta G^{\ddagger}$ close to those calculated from the observed solvolytic rate constants (k_r) via the Eyring equation.

$$[132]\quad k_r = (kT/\hbar)\exp(-\Delta G^{\ddagger}/RT)$$

The various terms in eq. [132] having their usual meaning (see eqs. [43] and [44]).

The Franklin cycle provides a strategic route for the application of quantum mechanics (QM) to nucleophilic displacements at a saturated carbon atom adopting either the Dewar (PMO) or Huckel (HMO) molecular orbital (MO) methods including more advanced QM techniques (93, 110, 160, 161, 162–167, 169). The Franklin cycle also clarifies some shortcomings of the HMO and PMO (162) methods when employed in this and other contexts. These defects are augmented by approximations concerning the solvation of the ground and activated states and the details are developed in the following.

Expressing ΔG_g^i in eq. [131] in terms of the enthalpy and entropy functions gives

$$[133]\quad \Delta G_g^i = \Delta H_g^i - T\Delta S_g^i$$

Combining eqs. [133] and [131] yields

$$[134]\quad \Delta G^{\ddagger} = \Delta G(e) + \Delta H_g^i - T\Delta S_g^i + \Delta G(s)$$

Dewar and Sampson (160) and others (110, 179, 182), focused their attention on a series of arylmethyl substrates ($ArCH_2$-X, X = Cl, Br, I, and tosylate). If the operator δ_{Ar} denotes structural changes in the arylmethyl group, e.g., Ar = phenyl, 1-naphthyl, 2-naphthyl,…, etc., then operating on eq. [134] with δ_{Ar} gives

$$[135]\quad \delta_{Ar}\Delta G^{\ddagger} = \delta_{Ar}\Delta G(e) + \delta_{Ar}\Delta H_g^i - \delta_{Ar}T\Delta S_g^i + \delta_{Ar}\Delta G(s)$$

Dewar and Sampson make the following assumptions

$$[136]\quad \delta_{Ar}\Delta G^{\ddagger} \approx \delta_{Ar}\Delta H_g^i \approx \delta_{Ar}\Delta E_g^i \approx \delta_{Ar}\Delta E_{\pi}$$

where ΔE_{π} is the π electron energy difference between the arylmethyl carbocation and the related arylmethyl chloride. These approximations require that the two solvation terms and the entropy term in eq. [135] are zero, i.e., $\delta_{Ar}\Delta G(e) = 0$, $\delta_{Ar}T\Delta S_g^i = 0$, and $\delta_{Ar}\Delta G(s) = 0$.

The constancy of the solvation terms for such a series of arylmethyl carbocations has been queried by Mason (182), in terms of squared dependence on charge (q^2) and an inverse dependence on radius ($1/r$) demanded by the Born equation (184) for ionic solvation. This equation requires that the solvation of a *delocalized* single charge is *less* than that for a *localized* single charge, granted that the radii associated with the localized charge and each fragment of delocalized charge are identical.

To establish Mason's proposal, the arylmethyl carbocation is considered to consist of a framework of trigonal carbon atoms of equal radius with a single charge (q) fragmented into n fractional charges q_1, q_2, $q_3 ... q_n$ that are located at what are known as starred positions of the carbocation framework. Then, if these conditions are met, for any q_n, because $q_n < 1$, then $q_n^2 < q_n$. Hence, the sum of the squares of the fractional charges is less than the square of a single charge and by inference, the energy of solvation of the localized charge will be greater than for a fragmented single charge. The above reasoning justifies Mason's thesis. However, his analysis is not unique and other interpretations have been presented by Streitwieser and Nair (169) that, in essence, leave the approximations related to eq. [135] more or less intact.

The assumptions made between eqs. [135] and [136] frequently underpin reactivity studies interpreted by either QM or the classical electronic theory of organic chemistry. The justification of these manoeuvres has been formalized by Bell (186) in detail and less convincingly by Dewar (160, 161).

Such approximations include the possibility that the enthalpy and entropy terms that characterize the solvation of both ions and neutral molecules obey a version of the Barclay–Butler rule (34, 185). These correlations attenuate the variations of the Gibbs energies of solvation with structure either for ions or neutral substrates. Such cancellations occur via linear enthalpy–entropy correlations for both the ions and neutral molecules leaving the related Gibbs energy terms virtually constant as required by eq. [135]. Discussions of the influence solvation phenomena on more complex kinetic models (15, 22) and those represented by eqs. [121] and [122] have been, as far as we are aware, neglected.

Thermochemically, the problem of calculating the quantity ΔH_g^i as a function of the structure of the arylmethyl chloride involves three terms

$$[137]\quad \Delta H_g^i = D(ArCH_2\text{-}Cl) + I_p(ArCH_2^{\cdot}) + E_f(Cl^{\cdot})$$

© 2005 NRC Canada

that are: the bond dissociation energy (D(ArCH$_2$-Cl)) of the arylmethyl chloride, the ionization potential (I_p(ArCH$_2^{\cdot}$) of the arylmethyl radical, and the electron affinity (E_f(Cl$^{\cdot}$)) of the chlorine atom. Operating on eq. [137] with δ_{Ar},

$$[138]\quad \delta_{Ar}\Delta H_g^i = \delta_{Ar}D(\mathrm{ArCH_2\text{-}Cl}) + \delta_{Ar}I_p(\mathrm{ArCH_2^{\cdot}}) + \delta_{Ar}E_f(\mathrm{Cl^{\cdot}})$$

Clearly, $\delta_{Ar}E_f(\mathrm{Cl^{\cdot}}) = 0$, and hence, eq. [136] becomes

$$[139]\quad \delta_{Ar}\Delta G^{\ddagger} = \delta_{Ar}D(\mathrm{ArCH_2\text{-}Cl}) + \delta_{Ar}I_p(\mathrm{ArCH_2^{\cdot}})$$

that on integration gives

$$[140]\quad \Delta G^{\ddagger} = D(\mathrm{ArCH_2\text{-}Cl}) + I_p(\mathrm{ArCH_2^{\cdot}}) + C$$

Equation [140] demonstrates that *two variable thermochemical terms* contribute to ΔE_π in eq. [136]. Hence, these drastic simplifications to eq. [135] are equivalent to

$$[141]\quad \Delta G^{\ddagger} \approx \Delta E_\pi + C$$

where changes in ΔE_π with structure are rigorously defined by the RHS of eq. [139].

In terms of either PMO or HMO quantities eq. [141] can be recast

$$[142]\quad \Delta G^{\ddagger} = Q_f\beta + C$$

where Q_f is a structurally dependent numerical factor calculated from either the HMO or the PMO theories and β is a resonance integral: a "constant" disposable quantity in either the PMO or HMO contexts (180, 182, 192). The ΔE_π term can be calculated from more elaborate quantum mechanical algorithms without in any way compromising the thermodynamic analysis and the approximations previously presented.

Intuitively, eq. [142] might also be modified

$$[143]\quad \Delta G^{\ddagger} = \gamma\Delta H_g^i + C$$

with γ assumed to be in the range $0 < \gamma < 1$ with γ and C constants for a given series of displacements with a fixed leaving group, in a specified solvent at a fixed temperature. It is tacitly assumed that the organic group varies structurally in a systematic manner. In either of their respective contexts, the quantities γ and β are considered to provide measures of the ionic character of the displacement. Alternatively, γ and β may be considered as reaction coordinate parameters. The significance of the energetics of gas-phase heterolyses to the related displacements in solution has been briefly discussed elsewhere (2, 28, 79).

Dewar and Sampson's original PMO calculation of ΔE_π *lumps the two variable terms* on the RHS of eq. [140]. In their treatment, the Q_f parameter in eq. [142] is equal to $2a_{or}$, a quantity that relates to the linear coefficients of the nonbonding molecular orbitals (NBMO) for each arylmethyl carbocation or radical at their respective *extracyclic carbon atoms*. However, in thermodynamic terms the Dewar and Sampson calculation is in effect confined to the *first term* of eq. [140] because the unpaired electron in *all alternant arylmethyl radicals* occupies the NBMO of energy equal to α, the carbon Coulomb integral, a quantity common to both the HMO and PMO formalisms. Indeed, both theories assume the energy of the NBMO to be identical *for the carbons in all odd alternant radicals and carbocations.* This represents a major weakness of this approach because, experimentally, $\delta_{Ar}I_p(\mathrm{ArCH_2\cdot})$ is the dominant term in eq. [138], i.e., $\delta_{Ar}I_p(\mathrm{ArCH_2\cdot}) > \delta_{Ar}D(\mathrm{ArCH_2\text{-}Cl})$ (83, 193, 194) (see Table 21 and Figs. 17 and 18).

The ΔE_π values estimated by Dewar and Harget reported by Dewar and Bentley (110) presumably calculated by a self-consistent field (SCF) method, still account only for ca. 70% of the *measured* values of $\delta_{Ar}\Delta H_g^i$ for the benzyl, 1-naphthylmethyl, and 2-naphthylmethyl carbocations and further appraisal of such matters is presented at the end of this section.

In view of the last observation, a question of methodology now arises. The use of QM at any level of sophistication (17, 93, 110, 169, 187) to provide a quantitative understanding of chemical reactivity in the present and other contexts, e.g., aromatic substitution (163–167), invokes predominately *gas-phase* models at absolute zero to calculate the energy changes between either reactants and products or reactants and transition states with the further crucial assumption that the reactants and products are separated by a *single* barrier. These energy changes are then compared with reactivities observed *in solution* measured in terms of a Gibbs energy calculated from either rate or equilibrium constants established at a finite temperature. The first question that might be raised queries the calibre of the QM estimates *as gas-phase calculations*. Specifically, how well does the QM reproduce the *measured* gas-phase thermochemical quantities? If such computations are inadequate on their own terms, then, by the same token, their reliability with respect to understanding chemical reactivity *in solution at a finite temperature* is at least partly compromised. Some further comment related to this topic is presented at the end of this section.

Calculation of thermochemical quantities

The calculation of ΔH_g^i for a series of alkyl chlorides using eq. [137] requires values of D(R-Cl), I_p(R$^{\cdot}$), and E_f(Cl$^{\cdot}$). Such quantities for a particular series of alkyl halides are frequently unavailable. In cases where the corresponding values for D(R-Br) and D(R-I) are known, these can be used to estimate values for the chloride using the following analysis (see Table 22. A preliminary discussion of these matters was given by Scott and Winter and co-worker (79) that relates to more sustained approaches to such matters by Benson and co-worker (206, 207).

If X1 and X2 are two different leaving groups relating to the heterolytic process described by eq. [130] then

$$[144]\quad \Delta H_g^i(\mathrm{RX1}) = \Delta H_f^o(\mathrm{R^+}) + \Delta H_f^o(\mathrm{X1^-}) - \Delta H_f^o(\mathrm{RX1})$$

$$[145]\quad \Delta H_g^i(\mathrm{RX2}) = \Delta H_f^o(\mathrm{R^+}) + \Delta H_f^o(\mathrm{X2^-}) - \Delta H_f^o(\mathrm{RX2})$$

where the symbols in eqs. [144] and [145] have their conventional meanings.

Subtracting eq. [145] from eq. [144]

$$[146]\quad \Delta H_g^i(\mathrm{RX1}) - \Delta H_g^i(\mathrm{RX2}) = \Delta H_f^o(\mathrm{RX2}) - \Delta H_f^o(\mathrm{RX1}) + \Delta H_f^o(\mathrm{X1^-}) - \Delta H_f^o(\mathrm{X2^-})$$

that after a trivial manipulation provides

$$[147]\quad \Delta H_g^i(RX1) = \Delta H_g^i(RX2) + [\Delta H_f^o(RX2) - \Delta H_f^o(RX1)] + [\Delta H_f^o(X1^-) - \Delta H_f^o(X2^-)]$$

If the relationship

$$[148]\quad \delta_R \Delta H_g^i(RX1) = \delta_R \Delta H_g^i(RX2)$$

is to be an acceptable approximation, then, according to eq. [147], two conditions are required

$$[149]\quad \delta_R[\Delta H_f^o(RX2) - \Delta H_f^o(RX1)] = 0$$

and

$$[150]\quad \delta_R[\Delta H_f^o(X1^-) - \Delta H_f^o(X2^-)] = 0$$

Equation [150] is obviously true and integrating [149] gives

[151] $\Delta H_f^o(RX2) - \Delta H_f^o(RX1) = \text{constant}$

In the case of homolytic fission, the analogous equation to [144] is

[152] $D(RX1) - D(RX2) = [\Delta H_f^o(RX2) - \Delta H_f^o(RX1)] + \Delta H_f^o(X1^{\cdot}) - \Delta H_f^o(X2^{\cdot})$

that requires the similar conditions to those appropriate to eq. [146].

With X1 = Cl and X2 = Br, ΔH_f^o(RCl) and ΔH_f^o(RBr) are linearly related for various alkyl groups and the data that underpin these relationships for a series of alkyl chlorides, bromides, and iodides are reported in Table 22. For X1 = Cl and X2 = Br the empirical relationship is

[153] $\Delta H_f^o(RCl) = (0.9880 \pm 0.015)\Delta H_f^o(RBr) - 11.62 \pm 0.30$ (6,0.9990)

and similarly, when X1 = Cl and X2 = I

[154] $\Delta H_f^o(RCl) = (1.067 \pm 0.014)\Delta H_f^o(RI) - 24.33 \pm 0.18$ (6,0.9993)

Rearranging eq. [153] gives

[155] $(0.9880 \pm 0.015)\Delta H_f^o(RBr) - \Delta H_f^o(RCl) = 11.62 \pm 0.30$

and the similar manipulation of eq. [154] gives

[156] $(1.067 \pm 0.014)\Delta H_f^o(RI) - \Delta H_f^o(RCl) = 24.33 \pm 0.18$

The relationships [155] and [156] represent *the empirical versions* of eq. [151] and because the coefficients of ΔH_f^o(RI) and ΔH_f^o(RBr) are sufficiently close to unity in eqs. [155] and [156], these relationships can be combined

Table 22. Thermochemical data related to a series of alkyl halides.

Alkyl group	ΔH_f^o(RCl)	ΔH_f^o(RBr)	ΔH_f^o(RI)
Methyl	–20.63	–9.00	3.34
Allyl	–0.15	–11.80	22.9
Ethyl	–26.70	–15.30	–2.00
s-Propyl	–35.00	–23.20	–10.00
tert-Butyl	–43.80	–32.00	–17.60
n-Propyl	–31.00	–21.00	–7.30
Benzyl	8.14[a] (7.6)[b]	20.00	30.40

Note: Most of the data in Table 22 is from ref. 47.

[a]Extrapolated value. Skinner (189) gives 3.0 ± 1 based on a value of –7.8 kcal mol^{-1} for the heat of formation of the liquid benzyl chloride, which is discrepant with the value of –16.8 kcal mol^{-1} reported by Stull et al. (47). The vapour pressure data reported by Partington (190) correspond to a latent heat of evaporation for benzyl chloride of 11.2 kcal mol^{-1}, which is consistent with the values reported by Skinner (189) for the gaseous and liquid phases. Skinner (189) reports that the heat of formation of the benzyl radical is 38–46.5 kcal mol^{-1}, which is narrowed slightly by Walsh et al. (191) to 44.1 ± 3.1 kcal mol^{-1}. These data yield a value of 68 ± 4 kcal mol^{-1} for D(PhCH$_2$-Cl). The value reported by Shaik et al. (75 kcal mol^{-1}) (17) is well above the upper limit of this value. Shaik et al. give no references for the origins of the elevated value reported. The value calculated from ΔH_f^o(PhCH$_2$Cl) in Table 22 and ΔH_f^o(PhCH$_2^{\cdot}$) corresponds to that reported by Swarc and Taylor (192) is higher than the value obtained by Lossing et al. (193) using electron impact studies, which gave 60.4 kcal mol^{-1}. Two values for D(PhCH$_2$-Br) of 50.5 and 44.7 kcal mol^{-1} reported in refs. 194 and 193, respectively, give values for the chloride of 64.32 and 56.62 kcal mol^{-1} using eq. [157]. A further value for D(PhCH$_2$-Br) reported by Gellner and Skinner (195) based on the heat of hydrolysis of benzyl bromide treated in the same way gave 62.42 kcal mol^{-1}. Five measured values for D(PhCH$_2$-I) in combination with eq. [158] give 65.63 (196), 61.63 (193), 64.03 (197), and 69.83 (198) kcal mol^{-1} and 63.13 kcal mol^{-1} (195) for D(PhCH$_2$-Cl). The mean of these 10 values is 63.77 ± 3.41 kcal mol^{-1}. Values for the electron affinity of the chlorine atom (Cl$^{\cdot}$) vary widely: 93 (199), 83 (200), 83.26 (201), 87.3 (195), and 83.2 (114). The value reported in ref. 201 is adopted here. Values for the ionization potentials of the various radicals are predominately from Lossing and co-workers, reported and summarized in several articles (200, 202–205).

[b]Value in parenthesis calculated using the MNDO algorithm (188).

Note: Units for I_p(R$^{\cdot}$) are electron volts. Units for D(RCl) and ΔH^{i}_{g}(R-X) are kcal mol^{-1}. There are a variety of ways the existing thermochemical data can be used to estimate these quantities. These data were established via eqs. [160]–[162] using all the collected data. A data set restricted to *measured* values for the halogens (Cl, Br, and I) provides the following correlations for six alkyl groups, namely, methyl, allyl, benzyl, 1-naphthymethyl, 2-naphthylmethyl, and 4-phenylbenzyl, the bromides and iodides corrected to a value for the chloride by eq. [157] or [158]. The ionization potentials were calculated from the appropriate equation, either eq. [159] or [161]. $\Delta G^{\ddagger}$(obs.) is the observed Gibbs energy of activation and $\Delta G^{\ddagger}$(calcd.) is the calculated Gibbs energy of activation from eq. [168]. For sources of kinetic data for the unsubstituted and substituted benzyl chlorides see Table 26.

[a]Slopes in parenthesis calculated according to eq. [170].

[b]Values used to establish eqs. [160]–[162].

[c]Values were estimated from eq. [159].

[d]Calculated from log$k$(H_2O) = (0.8607 ± 0.0182) log$k$(HCOOH) + 0.924 ± 0.109 (see Table 24).

with the appropriate enthalpy difference between the halogen atoms to give the *approximate* relationships

[157] D(RCl) – D(RBr) ≈ 13.92 kcal

[158] D(RCl) – D(RI) ≈ 26.63 kcal

Equations [157] and [158] can be applied to experimental values for D($PhCH_2Br$) and D($PhCH_2I$) to estimate D($PhCH_2Cl$) and this is a tactic applicable to other alkyl groups. The values of D($PhCH_2Cl$) collected and calculated via eqs. [157] and [158] are reported in the extensive footnote to Table 22.

Changes in D($PhCH_2Cl$) as a consequence of substituents in the 3- and 4-positions in the benzene ring were calculated from data reported in texts authored by either Cotrell (208) or Trotman-Dickenson (209). These corrections are small and are within the errors reported for the heat of formation for the benzyl radical (see footnote *a* to Table 22). Swarc's group also provided further data for bond dissociation energies used here (210–212).

The ionization potentials for various radicals are those reported by Lossing's group (200, 202–205). In cases where data are absent for 3- and 4-substituted benzyl radicals, a correlation between existing values and the Hammett–Brown σ^+ substituent constants (215, 216) gives the relationship

[159] $I_p(R^{\cdot}) = (1.060 \pm 0.037)\sigma^+ + 7.782 \pm 0.017$ (10,0.987)

provided estimates for the unknown ionization potentials (see also Table 23).

The simple Dewar and Sampson (160) analysis for the calculation of ΔE_π gives an acceptable account of the *bond dissociation term* D(R-Cl) for six structures (see Table 23).

[160] $D(RCl) = (35.55 \pm 1.36)2a_{or} + 9.85 \pm 2.24$ (6,0.962)

and I_p(R$^{\cdot}$) for the related radicals is given by an equation indirectly related to the HMO/PMO methodology

[161] $I_p(R^{\cdot}) = (3.432 \pm 0.066)S(q^2) + 6.418 \pm 0.035$ (6,0.998)

4-*tert*-Butylbenzyl	5.241[d]	4.000[d]	3.675

Note: k_a is the first-order rate in HCOOH and k_w is the first-order rate in H_2O. The units for k_a and k_w are s^{-1}. k_w(calcd.) is the calculated hydrolysis rate constant and $\log k_w$(calcd.) is calculated from eq. [*ii*]. Equation [*i*]: $\log k_w$(calcd.) = (0.8607 ± 0.0182) $\log k_a$ + 0.9236 ± 0.109 (6,0.998) was obtained from a linear least-squares regression using six of the results from this table. The complete data set gives eq. [*ii*]: $\log k_w$ = (0.8122 ± 0.0229) $\log k_a$ + 0.582 ± 0.140 (12,0.991); see also Fig. 19.

where the term $S(q^2)$ represents the sum of the squares of the charge distribution of either the arylmethyl carbocation or the related free radical. The charge distribution can be easily calculated using Dewar's PMO method (158, 159, 162). Equations [160] and [161] are illustrated in Figs. 17 and 18.

Changing the energy units of eq. [161] from ev to kcal followed by the addition of eq. [144] to the resulting expression and setting the electron affinity of the chloride atom at –83.26 kcal, gives an empirical relationship between ΔH_g^i and the PMO quantities $S(q^2)$ and a_{or}

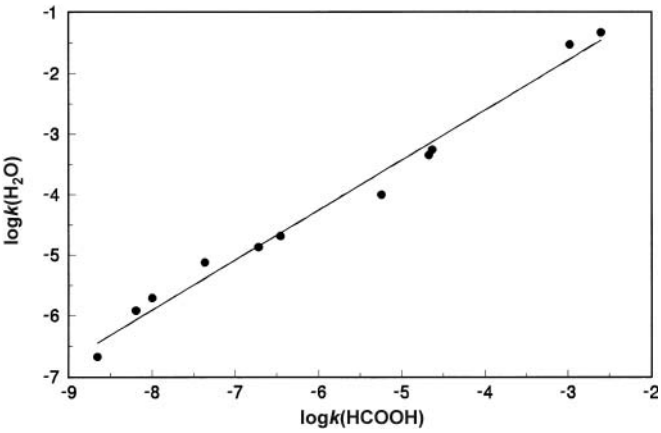
$$[162] \quad \Delta H_g^i = 79.14S(q^2) + 71.11a_{or} + 74.58$$

For six chlorides (RCl) that cover a range of ca. 70 kcal in ΔH_g^i, the relationship between ΔH_g^i(calcd.) and ΔH_g^i(obs.) calculated via eq. [162] is

$$[163] \quad \Delta H_g^i(\text{calcd.}) = (1.007 \pm 0.019)\Delta H_g^i(\text{obs.}) - 1.11 \pm 3.22 \ (6,0.998)$$

with R = methyl, allyl, benzyl, 4-phenylbenzyl, 1-naphthylmethyl, and 2-naphthylmethyl.

The combined correlation between Dewar's PMO quantities ($S(q^2)$, $2a_{or}$) and ΔH_g^i represented by eq. [162] was used either by extrapolation or interpolation to estimate $\Delta H_g^i(ArCH_2\text{-}Cl)$ in cases where no measurements exist. These estimates are considered to be the best currently available and are recorded in Tables 21 and 23.



Slopes from the correlations between $\Delta G^‡$ and ΔH_g^i

The $\Delta H_g^i(ArCH_2\text{-}Cl)$ values provide an improved perspective from which the meaning of the slopes of the PMO or HMO correlations with $\Delta G^‡$ for a variety of arylmethyl substrate displacements (2, 110, 160, 162, 168, 179) can be evaluated. Similar comments apply to what Bentley and Dewar (110) designate as "Streitwieser Plots". The way the ΔH_g^i values are used here is relatively free of ambiguity compared with correlations with the purely theoretical quantities that are discussed further at the end of this section. Equation [143] may be tested against a wealth of solvolytic data for arylmethyl tosylates and halides collected in Table 21. The data in Table 21 include $\Delta G^‡$ from kinetic measurements for the classical S_N2 process in acetone

$$[164] \quad I^- + ArCH_2Cl \rightarrow ArCH_2I + Cl^-$$

usually known as the Finklestein reaction. Intuitively, the shift in mechanism from an ionic solvolytic displacement process to a definite second-order bimolecular displacement should lead to a reduction of the coefficient of ΔH_g^i, namely, γ in eq. [143], i.e., $\delta_{Ar}\Delta G^‡$ (S_N1) > $\delta_{Ar}\Delta G^‡$ (definite S_N2). This proposal anticipates that *less charge* is transferred from

Note: The first 17 rows of this table relate to correlations between $\Delta G^{\ddagger}$(I)–$\Delta G^{\ddagger}$(XVII) and $\Delta H_g^i(ArCH_2X)$ from the data in Table 21. The subsequent rows in this table are in *groups of three* and provide a few examples of Streitwieser plots (see ref. 110). The first row in the group is a Streitwieser plot (SPA) between $\Delta G^{\ddagger}$(I) and $\Delta G^{\ddagger}$ for the solvent system specified in the next row. The second and third rows correlate $\Delta G^{\ddagger}$(I) and $\Delta G^{\ddagger}$ with ΔH_g^i again because the number of data point pairs is necessarily reduced, e.g., there are only *four* matching entries for $\Delta G^{\ddagger}$(I) and $\Delta G^{\ddagger}$(II) in Table 21.

[a] N is the number of the regression points and C.C. is the correlation coefficient.

[b] S data are from ref. 2.

[c] DB data are from Tables I and II of ref. 110.

[d] Streitwieser plot (SPA).

[e] Streitwieser plot vs. ΔH_g^i (SPB).

[f] Streitwieser plot of $\Delta G^{\ddagger}$(I) vs. ΔH_g^i (SPC) for rates in 80% EtOH–H_2O; the slopes differ because the number of data points from column $\Delta G^{\ddagger}$(I) differ in each regression. The mean slope is 0.060 ± 0.004. This particular calculation is repeated for each of the other solvents. The slopes differ because the number of substrates is not uniform in the other solvent systems. The mean of the six values is 0.060 ± 0.004. For all the data, the slope is 0.0803 ± 0.0085; cf. the first entry in this table. The slopes of the matching SPB plots involving the matching data from the related $\Delta G^{\ddagger}$(I–XVII) columns involving less than the complete data set are often in very poor agreement with the slopes from the complete data set. The Streitwieser plots present the elimination of ΔH_g^i between two simultaneous equations related to eq. [141] for two different solvent systems.

[i]Calculated from data in footnote 2 in the text.

the conjugated aromatic system in definite bimolecular processes. Generally speaking, the least-squares correlations presented in Table 25 confirm this anticipated behaviour, noting that the correlation coefficients are not impressive. Nevertheless, the correlations generalized by eq. [143] definitely establish that the gas-phase heat of ionization is a significant quantity in determining the rate of heterolysis in both solvolytic and definite bimolecular displacements for the arylmethyl substrates listed in Tables 21 and 23.

The slopes (γ) related to eq. [143] are reported in Table 25. The maximum value of γ was observed in moist formic acid (γ = 0.25), confirming the conventional wisdom that this solvent facilitates heterolysis. However, the level of heterolysis assessed at 25% is remote from complete heterolytic fragmentation. The solvolysis of three arylmethyl iodides in 8O% EtOH–H_2O gives the minimum value of γ (0.040) that is *less* than that for the definitive bimolecular process, namely, the Finklestein reaction (γ = 0.053). However, the careful studies undertaken by Stein (217) and Boronius and Pataki (218) show that without a detailed examination of the concentration dependence of rate constants for displacement in acetone with respect to the attacking iodide ion, it is not possible to extract a meaningful value of the second-order rate constant for this reaction from a single determination of the second-order rate constant. Hence, the comparison of a series of Finklestein displacements with the solvolytic processes is less certain than the comparison of the solvolytic processes with each other.

The maximum of γ is observed in formic acid and becomes less in solvents of reduced ionizing power as measured by Grunwald–Winstein Y values. For various leaving groups under comparable conditions of solvent and temperature, the order of γ is tosylate (γ = 0.11) > chloride (γ = 0.062) > bromide (γ = 0.044) > iodide (γ = 0.040). These magnitudes are all much less than unity, suggesting all the displacements are remote from the complete heterolysis of the carbon – leaving group bond.

The slopes for the halide leaving groups increase regularly as the pK_a of the halogen acid increases. On this basis, the tosylate should be located between the chloride and bromide (see Table 13). However, return phenomena, presumably least for the tosylate, may influence the slopes of the $\Delta G^{\ddagger}$ vs. ΔH_g^i correlations. Bentley and Dewar (110) ignore this possibility, partly because their discussion is focused on the classical S_N1 and S_N2 (1, 8) descriptions of the displacements rather than the more elaborate schemes suggested here, e.g., eqs. [121] and [122].

Although toluenesulphonic acid is a weaker acid than hydrogen bromide, nevertheless, the organic tosylates (see section 9 and Table 12) react faster than bromides in both solvolytic and definite bimolecular displacements. The higher reactivity of the tosylates in comparison with the bromides is tentatively explained here on the basis of less return for the former than the latter leaving group (Table 26). This rationalization draws substance from the observation that $\Delta C_p^{\ddagger}$ is less negative for the sulphonates in water. This represents indirect evidence based on the Albery–Robinson revised interpretation of $\Delta C_p^{\ddagger}$ values discussed in section 6. The extended use of ΔH_g^i for arylmethyl chlorides to the other leaving groups, namely, bromides, iodides, and the sulphonates, is formally justified (see eqs. [132] and [133]. Thermochemical data for the alkyl sulphonates that would

verify the assumed additivity phenomena are, unfortunately, not available.

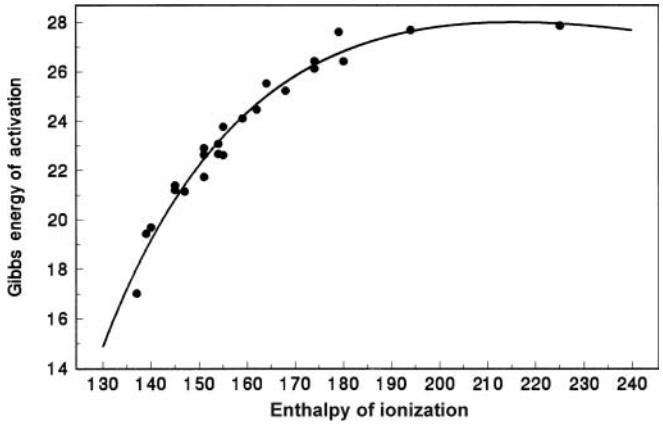
The halide anomaly

Although ΔH_g^i(RX) correctly predicts the order of reactivity for a series of primary alkyl chlorides, the extension of this relationship to any particular series of alkyl halides, e.g., the series RX, (X = F, Cl, Br, and I), implies the order of reactivity should be: I > Br > Cl > F. However, the observed order often follows the sequence Br > I > Cl > > F, an experimental fact frequently ignored in monographs (5, 17), reviews (14), and texts (1, 8). This "abnormal order" for the bromide and iodide is characteristic of the hydrolysis of primary and secondary bromides and iodides in water[2] and the arylmethyl bromides and iodides in 80% aqueous ethanol reported by Bentley and Dewar (110). The same order also characterizes the reaction of hydroxide ion and several other charged nucleophiles with the methyl halides (42). It has been argued that this order of reactivity signifies mechanistic complexity (42) but this proposal was vigorously rejected (33, 44, 45). In contrast, the tertiary halides represented by the *tert*-butyl and 1-adamantyl halides appear to follow the order expected based on ΔH_g^i(RX), namely, I > Br > Cl > F. Here, this latter sequence is designated as normal and is also the order anticipated on the basis of the pK_a(HX) values for the halogen acids discussed earlier. Subsequently, we define the normal order as one strictly following the atomic numbers of the halogen atoms either in an increasing or decreasing mode as is appropriate. Several inorganic displacements previously detailed in section 11 also display the normal order (see Table 18).

Generally speaking, most displacements involving bromide and iodide as leaving groups characterized by second-order kinetics display rate constants for which the k(I)/k(Br) ratios are *less than unity*. The odd exception to this rule represented by the rate constants that quantify the reaction of fluoride ion with methyl iodide and bromide is notable (42). The second-order rates for the nucleophiles (N_r), represented by water, hydroxide, cyanide, iodide, chloride, and thiosulphate, provide a satisfactory Swain–Scott (42, 111) LFER for methyl bromide and methyl iodide.

$$[165]\quad \log k(CH_3I,N_r) = (1.18 \pm 0.05)\ \log k(CH_3Br,N_r) + 0.303 \pm 0.21\ (6,0.993)$$

The data for this correlation are presented in Table 27. Subtracting $\log k(CH_3Br,N_r)$ from both sides of eq. [165] gives



$$[166]\quad \log[k(CH_3I,N_r)/k(CH_3Br,N_r)] = (0.18 \pm 0.05)\ \log[k(CH_3Br,N_r)] + 0.303 \pm 0.21$$

Because the Swain–Scott nucleophilic constant N (or N_r) is defined in terms of $\log[k(CH_3Br,N_r)/k(CH_3Br,H_2O)]$, it follows from eq. [166] that the iodide–bromide ratios diminish with an increase in nucleophilic power as measured by N for methyl substrates. This particular observation suggests that *electron access* to the reacting carbon either from *external* or *internal* sources dominates the ratio. Furthermore, the electrostatic repulsion between the incoming nucleophile and the leaving group across the reacting carbon is likely to attenuate return phenomena. Hyperconjugative intramolecular electron release is important for the *tert*-butyl and 1-adamantyl iodides and bromides but presumably less so for the adamantyl substrates because the rigid structure of these compounds inhibits the change in geometry of the reacting carbon that facilitates hyperconjugation. The iodide–bromide ratio is larger for the former organic group. A small amount of rearside nucleophilic assistance that is necessarily absent in the case of the adamantyl compounds cannot be totally discounted in the case of the *tert*-butyl substrates.

The behaviour of bromide–iodide ratios for the arylmethyl systems is more difficult to understand. The *slopes* of the $\Delta G^{\ddagger}$ vs. ΔH_g^i for the arylmethyl halides ($ArCH_2X$, X = Cl, Br, and I, Cl > Br > I) show a *normal* halogen order, but this does not correlate with the reactivity sequence for a fixed arylmethyl system, which is Br > I > Cl. The slopes of the Swain–Scott LFER that are related to a definite bimolecular process are in a normal sequence: Cl < Br < I (42), but se-

Fig. 20. Correlation between the rates of hydrolysis for a series of primary chlorides (RCl) and the enthalpy of ionization of RCl.

lectivity and reactivity fail to correlate here too, reactivity being in the order Br > I > Cl. This contrasts with more recent product studies elsewhere for displacement reactions in which there is a good match between selectivity and reactivity (220, 221). However, the interpretations related to the latter study (221) do not appear to conflict with the main thesis of this contribution.

Nonlinear relationships between $\Delta G^{\ddagger}$ and ΔH_g^i

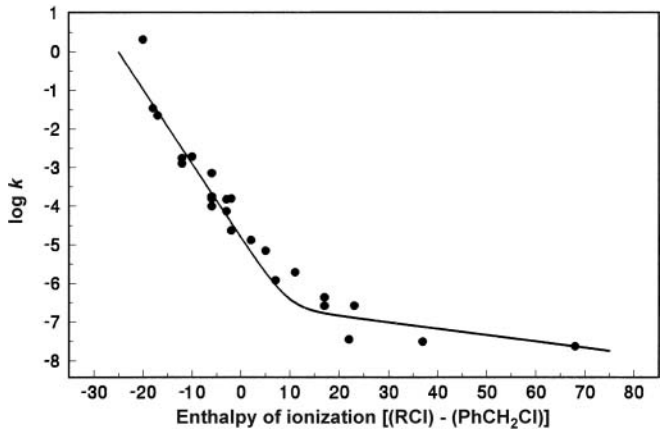
Nonlinear expressions that relate $\Delta G^{\ddagger}$ to ΔH_g^i can be developed to describe the hydrolytic reactivity for a more extended series of primary organic substrates ranging from methyl chloride to 4-methoxybenzyl chloride (see Table 23). This reaction series embraces a range of just under 100 kcal in ΔH_g^i on the abscissa (see Fig. 20).

The $\Delta G^{\ddagger}$ values for these substrates produce a fairly smooth curve that can be fitted to *empirical* equations either of the form $\Delta G^{\ddagger} = f(\Delta H_g^i)$ or $\ln(k) = f(\Delta H_g^i)$. A suitable empirical function that adequately relates $\Delta G^{\ddagger}$ to ΔH_g^i is

$$[167] \quad \Delta G^{\ddagger} = A(1) + A(2)/(\Delta H_g^i + 1) + A(3)/(\Delta H_g^i + 1)^2$$

A linear least-squares fit of the available data for the chlorides reported in Table 23 and and illustrated in Fig. 19 gives

$$[168] \quad \Delta G^{\ddagger} = 1.3377 \times 10^4/(\Delta H_g^i + 1) - 1.4461 \times 10^6/(\Delta H_g^i + 1)^2 - 2.94625$$



The observed and calculated values from eq. [168] give an adequate linear correlation

$$[169] \quad \Delta G^{\ddagger}(\text{calcd.}) = (0.970 \pm 0.024)\Delta G^{\ddagger}(\text{obs.}) + 0.698 \pm 0.577 \ (24, 0.985)$$

The slope at any point on the curve represented by eq. [167] can be obtained from the differential coefficient $\partial\Delta G^{\ddagger}/\partial\Delta H_g^i = \gamma$ and this quantity can be assigned the same meaning it has in eq. [143].

$$[170] \quad \partial\Delta G^{\ddagger}/\partial\Delta H_g^i = \gamma = -[A(2)/(\Delta H_g^i + 1)^2 + 2A(3)/(\Delta H_g^i + 1)^3]$$

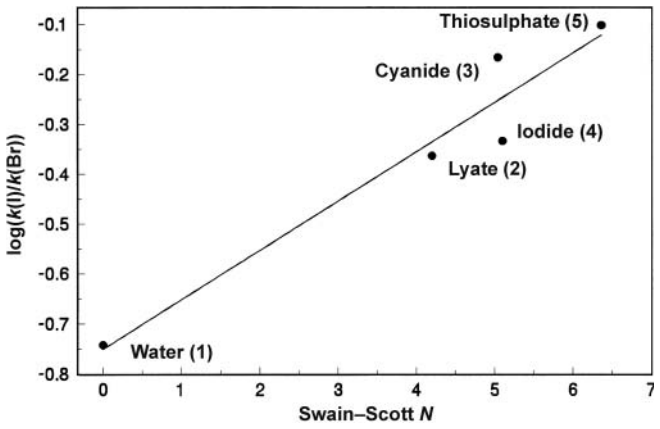
Fig. 21. Alternative correlation of the rates of hydrolysis for a series of primary chlorides (RCl) and the relative enthalpies of ionization of RCl (RCl – $PhCH_2Cl$).

When the differential coefficient in eq. [170] is unity, $\Delta H_g^i \approx 111$ kcal. The slope for the most reactive substrate, namely, 4-methoxybenzyl chloride, is ≈0.40 ($\Delta H_g^i = 138$ kcal). On the basis of eqs. [168] and [170] none of the primary reactants between methyl chloride and 4-methoxybenzyl chloride approach a limiting (S_N1) mechanism when probed by this simple-minded criterion. On the other hand, eqs. [168] and [170] demonstrate that the reacting carbon becomes increasingly more electron deficient at some point on the reaction coordinate as ΔH_g^i is reduced — an eminently reasonable proposition.

The previous analysis (eqs. [144]–[158]) shows that the ΔH_g^i values for the chlorides can be used to correlate with $\Delta G^{\ddagger}$ for other leaving groups. For a series of organic methanesulphonates, the slope of the $\Delta G^{\ddagger}$ vs. ΔH_g^i plot for any particular alkyl methanesulphonate suggests the transition state is more ionic than for the corresponding chloride. This provides further evidence that the reacting carbon atom for sulphonate esters is more electron deficient than in the case of the related chlorides, a conclusion matching the findings of Bentley and Dewar (110) and Guthrie (23) established in other ways previously discussed. There is also an indirect link with Hoffmann's (109) use of the bromide–tosylate ratios as a basis for mechanistic diagnosis that will be examined in the next section.

A previously mentioned second tactic develops a definite correlation between ΔH_g^i and the rate of hydrolysis for a series of primary chlorides described by the bifurcated mechanism that forms part of the series of chemical events represented by eq. [121]. The equation

$$[171] \quad k_o \approx K_e(k_3 + k_7)$$



represents a simplified version of this scheme. The assumption that the two terms $K_e k_3$ and $K_e k_7$ related to ΔH_g^i exponentially gives

$$[172] \quad k_o = A(1)\exp(-A(2)\Delta H_g^i) + A(3)\exp(-A(4)\Delta H_g^i))$$

The fit of the experimental of the rate data to eq. [172] for a series of primary chlorides reacting in water listed in Table 23 to this expression via a grid search routine for $A(n)$ (n = 1–4) gave

Fig. 22. Variation of k(iodide)/k(bromide) ratios for a series of displacements in water. (1) Water, (2) lyate ion, (3) cyanide ion, (4) iodide ion, (5) thiosulphate ion.

$$[173]\quad \ln k_o = \ln[11.62\ \exp(-0.463\Delta H_g^i) + 13.10\ \exp(-0.0774\Delta H_g^i)]$$

and is illustrated in Fig. 21. A linear least-squares correlation between the observed rates and calculated from eq. [173] to base 10 gives

$$[174]\quad \log k_o(\text{calcd.}) = (1.010 \pm 0.031)\ \log k_o(\text{obs.}) - 0.186 \pm 0.155\ (24,0.977)$$

that is slightly inferior to eq. [168]. The fit to eq. [173] suggests that two distinct processes combine to give the observed rate constant as ΔH_g^i changes resulting in a mixed kinetics situation similar to that described for the substituted benzyl trifluoroacetates (see section 8, particularly, eq. [88]). A similar treatment underpins the discussion of curved Hammett plots in section 15 (Fig. 22).

It should be pointed out that the classical bifurcation for displacement reactions was between the S_N1 and S_N2 mechanisms. This split is accommodated here by the appropriate parts of eqs. [122] and [121]. Such a shift would involve processes *with and without backside assistance*. Equation [170] refers to a mechanism *with or without frontside assistance*. It is possible that actual substitutions as structure changes alter the ease of heterolysis and involve a meld of both these paths when rearside attack is unhindered. Such a mechanism is too complex to warrant further discussion.

Alternative quantum mechanical calculations

The present section briefly examines the use of more elaborate quantum mechanical energy calculations that relate to solvolytic displacements instead of energies estimated via either the HMO and PMO methods. We note that the primitive HMO and PMO methodologies depend on the application of the *aufbau* principle involving bonding, nonbonding, and antibonding orbitals. This principle apparently discards the fundamental tenet that all electrons within a given atom or molecule are identical. We would like to tackle the problems addressed here in a more rigorous manner that Ogilvie (222) demands, but the details of these techniques are not revealed. Our attitude to these matters has been briefly reported elsewhere (223).

[e]Reference 168.

Fry and co-workers (188) have calculated the heats of formation of a series of substituted benzyl chlorides and the related substituted benzyl carbocations using the MINDO algorithm. These quantities can be combined with the heat of formation of the chloride ion at 58.3 kcal mol^{-1} to give ΔH_g^i(MINDO) for the processes

$$[175]\quad \text{X-C}_6\text{H}_4\text{CH}_2\text{Cl} \rightarrow \text{X-C}_6\text{H}_4\text{CH}_2^+ + \text{Cl}^-$$

with X = 4-H, 4-CH_3O, 4-CH_3, 3-CH_3, 4-Cl, 3-Cl, and 4-CF_3, which when compared with thermochemical values ΔH_g^i(T) gives

$$[176]\quad \Delta H_g^i(\text{MINDO}) = (0.629 \pm 0.058)\Delta H_g^i(\text{T}) + 55.7 \pm 9.9\ (7,0.957)$$

Both Bentley and Dewar (110) and Streitwieser et al. (170) report energies of stabilization relative to the benzyl cation for series of arylmethyl cations. Streitwieser's data (170) correlate with the thermochemical data

$$[177]\quad \Delta\Delta E_\pi = (1.13 \pm 0.13)\Delta H_g^i(\text{T}) - 186.0 \pm 19.5\ (9,0.913)$$

and similar data reported by Bentley and Dewar (110) give

$$[178]\quad \Delta\Delta E_\pi = (0.665 \pm 0.104)\Delta H_g^i(\text{T}) - 109.6 \pm 15.5\ (6,0.89)$$

Streitwieser (168) has also reported a correction to the simple HMO levels presented as ΔE_ω, which give a satisfactory correlation with ΔH_g^i(T).

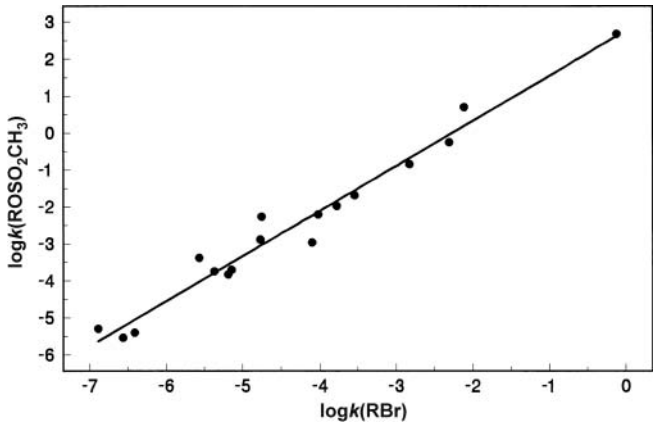
Note: Italicized values interpolated and extrapolated from other Hoffmann linear free energy relationships. See section 14 of the text. log$k$($ROSO_2CH_3$) = (1.220 ± 0.038) log(RBr) + 2.77 ± 0.18 (17,0.985).

[179] $\Delta H_g^i(T) = (-64.16 \pm 1.48)\Delta E_\omega - 260.0 \pm 2.58$ (13,0.994)



This is not surprising because the dependent and independent variables in eq. [176] have similar origins. It should be pointed out here that the calibration from measured thermochemical data that allow the calculation of $\Delta H_g^i(T)$ for the arylmethyl systems of interest covers 70% of the total range of this quantity. Attention is also drawn to the observation that the slopes of eqs. [177] and [178] both demonstrate considerable departures from unity. Clearly, in all cases, the more advanced methods correctly predict trends but require scaling to reproduce the experimentally based thermochemical values. The data for these correlations are reported in Table 28.

14. The Hoffmann criterion — A new linearfree energy relationship

Hoffmann's (109) use of the rate constant ratios k(R-tosylate)/k(R-Br) as mechanistic criteria can also be scrutinized in terms of a LFER similar to those examined in section 9. Instead of fixing two R groups and varying the leaving groups, as discussed in section 9, the two leaving groups are fixed and the organic groups are varied over primary, secondary, and tertiary organic structures. The Streitwieser Plots examined in section 13 involving tosylates and chlorides represent similar correlations, although in this particular LFER the substrates are confined to primary carbon centres.

The rate data for the bromide and tosylate leaving groups reacting in water are relatively meagre in comparison with the k(R-mesylate)/k(R-Br) ratios. Hence, the LFER is developed here in terms of the mesylate and bromide rate constants and the data are recorded in Table 29. The minor kinetic differences between tosylate and mesylate as leaving groups are considered inconsequential for these displacements in the present context. The data recorded in Table 29 give rise to

Fig. 23. Hoffmann LFER between the rates of hydrolysis for a series of organic methanesulphonates and chlorides.

[180] log$k$(R-mesylate) = (1.220 ± 0.038) log$k$(R-Br) + 2.77 ± 0.18 (17,0.985)

Equation [180] is illustrated in Fig. 23 and embraces over six orders of magnitude on each axis. Available data for other leaving groups when paired with bromide give

[181] log$k$(R-NO_3) = (1.085 ± 0.028) log$k$(R-Br) – 1.332 ± 0.12 (12,0.993)

and

[182] log$k$(R-Cl) = (0.847 ± 0.040) log$k$(R-Br) – 1.689 ± 0.19 (7,0.988)

© 2005 NRC Canada

The Hoffmann criterion proposes that the ratio k(R-mesylate)/k(R-Br) is "large" for limiting (S_N1) displacements and smaller for those with S_N2 character. However, because structural changes are treated as "continuous" in physical approaches to the reactivity of organic substances, the Hoffmann ratios that are related to the LFER represented by eq. [180] are constitutionally unsuited for making *sharp mechanistic distinctions* (72, 181).

The subtraction of log$k$(RBr) from both sides of eq. [180] gives

$$[183] \quad \log[k(\text{R-mesylate})/k(\text{R-Br})] = 0.220\ \log k(\text{R-Br}) + 2.77$$

Thus, the focal quantity related to Hoffmann's discussion here, namely, the ratio k(R-mesylate)/k(R-Br), rather than k(R-tosylate)/k(R-Br), is trivially an increasing function of the reactivity of the bromide if the coefficient of log$k$(R-Br) is greater than zero and vice versa if the coefficient is less than zero. Equation [183] is clearly in the former category.

On the basis of thermodynamic considerations, the mesylate–bromide ratio should reach a limiting value that is a function of the Gibbs energy differences related to: (*i*) the gas-phase heterolysis of the paired alkyl mesylates and bromides; (*ii*) the solvation difference between the mesylate and bromide anions; and (*iii*) initial state differences. To a first approximation, items (*i*)–(*iii*) are all expected to be constant for the classical S_N1 mechanism (see section 13, particularly eq. [131] and ref. 34). For cases where the mechanism is not limiting and kinetic complexity is prevalent, e.g., the Winstein scheme and analogous alternatives (see eqs. [52], [121], and [122]), the simple thermodynamic differences previously listed *would only contribute to part of the observed ratio.* Indeed, Hoffmann's mechanistic analysis is limited to that appropriate to a simple classical S_N1 reaction as originally envisaged by the Ingold (1, 8) school. Any return processes, either internal or external, invalidate the meaning of the rate ratio in Hoffmann's terms. Return processes are likely to favour the bromide in comparison with the mesylate anion because these ions are good and poor nucleophiles, respectively. Hence, the increasing ratio for the faster reacting substrates probably reflects reduced return phenomena combined with an increased tendency towards a more limiting (S_N1) process for both the mesylates and the bromides as the relative reactivity of the latter substrate increases.

The problem of mesylate–bromide ratios has also been considered indirectly by Bentley and Dewar (110) within the framework of the simple Ingold S_N1–S_N2 dichotomy and this is considered in section 13. These workers anticipate the order for increasing carbocation character for a series of arylmethyl halides to be I > Br > Cl. However, this is in the opposite order they observed based on an analysis linked to the simple Ingold mechanistic dichotomy that is based on the γ quantities mentioned in section 13. For the arylmethyl halides, the latter quantities are in the order γ(Cl) > γ(Br) > γ(I) indicating that the extent of heterolysis increases in the order I < Br < Cl rather than the opposite sequence suggested by Bentley and Dewar (110). Again, no kinetic complexity was attributed to the observed rate constants and the possible significance of return phenomena either internal or external to their work was overlooked for all the leaving groups they considered.

15. Curved Hammett plots

Curved plots frequently characterize attempts to apply the Hammett LFER to the rate constants that characterize solvolytic and definite bimolecular nucleophilic displacements of substituted benzyl substrates (see, particularly, refs. 2, 216, and 217). The solvolysis of the 3- and 4-substituted dimethylphenylcarbinyl chlorides (215) and the α-phenylethyl chlorides (70) represent a notable exception to this observation. The former displacements underpin and define the σ^+ scale that is apparently uncluttered with either differential solvation phenomena or significant mechanistic changes — a proposition evident from the observation that the σ^+ quantities give a satisfactory Hammett plot with the ionization potentials of the substituted benzyl radicals measured in the *gas phase* (200, 202–205) (see eq. [159]). Thus, displacements at these activated secondary and tertiary carbon centres are presumably dominated by internal energy changes on activation rather than solvation, although the conditions $\delta_{Ar}[\Delta G^{\ddagger}(ArCH_3)_2CCl)] \approx 0.3\delta_{Ar}[I_p(ArCH^{\cdot})]$ and $\delta_{Ar}[\Delta G^{\ddagger}(Ar(CH_3)_2CCl)] \approx \delta_{Ar}[\Delta G^{\ddagger}(Ar(CH_3)HCCl)]$ respectively hint that something less than a limiting mechanism is operative for both series of substrates (see section 13). This contrasts with the solvolytic rate constants that characterize displacements involving primary benzyl systems, which inevitably give curved Hammett plots with correlations employing either the σ^+ or σ substituent constants.

Curved Hammett plots for benzyl displacements are often explained (2, 224) in terms of the differential influence of the substituents on concerted bond-making and bond-breaking processes in the transition state. Such bonding changes result in concave up plots with the minimal reactivity usually coinciding with the unsubstituted substrate. Negative substituents located at the 3- and 4-ring positions are postulated to facilitate bond breaking relative to hydrogen, whereas positive substituents in the same locations expedite bond formation relative to the standard atom. Thus, the observed rate constants reflect a meld of two distinct influences by the 3- and 4-substituents on the bonding in a bimolecular transition state.

Nevertheless, there are alternative possibilities that can be offered to explain the curvature of Hammett correlations. It is possible that the observed rate constants for these displacements are a function of two or more rate constants (e.g., eq. [58]) and that these quantities correlate *individually and accurately* with the appropriate Hammett substituent constants. This proposal can be examined further for the mechanism described by eq. [58] using either the steady-state expression eq. [59] or eqs. [67] and [68]. Here the second, more rigorous, of these alternatives is preferred and the equations basic to this mechanism are repeated here for convenience: $\lambda_1 + \lambda_2 = k_1 + k_2 + k_3$ and $\lambda_1\lambda_2 = k_1k_3$.

The differentiations necessary to develop the formalities of the Hammett analysis are simplified by conducting the mathematical manipulations in terms of natural rather than decadic logarithms with the central premise that the individual processes in eq. [58] obey a linear Hammett LFER. This means that each k_n (n = 1–3) using either the σ or σ^+ scales

© 2005 NRC Canada

gives rise to ρ_n values (n = 1–3) defined by the equations summarized by

$$[184] \quad \frac{\partial \ln k_n}{\partial \sigma} = \rho_n = \text{constant } (n = 1\text{–}3)$$

Two slopes ($\boldsymbol{P}_r$, r = 1 or 2) of the Hammett correlation related to eq. [58] are defined in terms of the dynamic constants λ_1 and λ_2

$$[185] \quad \frac{\partial \ln \lambda_r}{\partial \sigma} = \boldsymbol{P}_r \quad (r = 1 \text{ or } 2)$$

At this point in the mathematical analysis it is not immediately obvious which of either $\boldsymbol{P}_1$ or $\boldsymbol{P}_2$ is related to the experimental observations, so the formalities are conducted assuming that $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ have parity until all of the pertinent expressions have been derived. The appropriate differentiations with respect to σ of eqs. [67] and [68] lead to relationships between $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ to rate constants that characterize the mechanism described by eq. [58].

Differentiating eqs. [67] and [68] with respect to σ provides the linear system

$$[186] \quad \lambda_1 \boldsymbol{P}_1 + \lambda_2 \boldsymbol{P}_2 = k_1\rho_1 + k_2\rho_2 + k_3\rho_3$$

$$[187] \quad \boldsymbol{P}_1 + \boldsymbol{P}_2 = \rho_1 + \rho_3$$

Simultaneously solving [186] and [187] for $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ on the assumption that $\lambda_2 < \lambda_1$ (see the previous paragraph) gives

$$[188] \quad \boldsymbol{P}_1 = [k_1\rho_1 + k_2\rho_2 + k_3\rho_3 - \lambda_1(\rho_1 + \rho_3)]/(\lambda_1 - \lambda_2)$$

$$[189] \quad \boldsymbol{P}_2 = [k_1\rho_1 + k_2\rho_2 + k_3\rho_3 - \lambda_2(\rho_1 + \rho_3)]/(\lambda_2 - \lambda_1)$$

Because $k_n = f(\sigma)$ and $\lambda_r = f(k_n)$, the slope of the Hammett plot given by either eqs. [188] or [189] is not constant but depends on σ. In short, the related Hammett plot must be curved.

Differentiating [186] and [187] with respect to σ to obtain the second differential gives

$$[190] \quad \lambda_1(\boldsymbol{P}_1)^2 + \lambda_2(\boldsymbol{P}_2)^2 + \frac{\lambda_1 \partial \boldsymbol{P}_1}{\partial \sigma} + \frac{\lambda_2 \partial \boldsymbol{P}_2}{\partial \sigma} = k_1(\rho_1)^2 + k_2(\rho_2)^2 + k_3(\rho_3)^2$$

$$[191] \quad \frac{\partial \boldsymbol{P}_1}{\partial \sigma} + \frac{\partial \boldsymbol{P}_2}{\partial \sigma} = 0$$

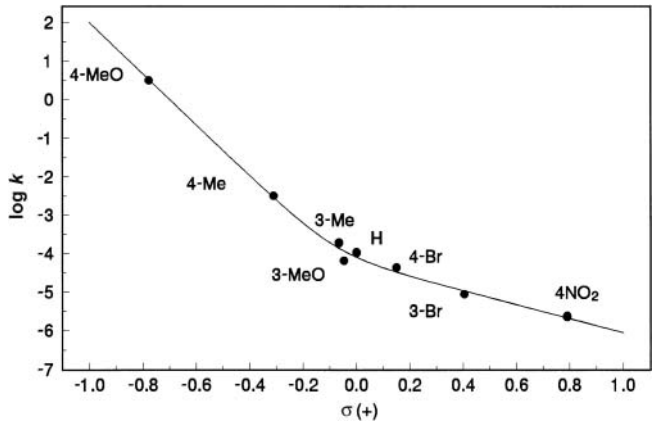
For either a maximum or minimum in the log$k$(obs.) or here in the $\ln\lambda_1$ or $\ln\lambda_2$ vs. σ coordinate system, $\boldsymbol{P}_1 = 0$ and $\boldsymbol{P}_2 = 0$, and hence, the first two expressions on the LHS of eq. [190] are zero. Additionally, the three terms on the RHS of eq. [190] are necessarily positive because $k_n > 0$ and $\rho_n^2 > 0$ (n = 1–3). The time evolution of the chemical system described by eq. [58] is given by eq. [66]. This expression involves two exponential terms containing λ_1 and λ_2. Generally speaking, the smaller dynamic constant, arbitrarily λ_2 (see eq. [70]), will dominate the changes of concentration with time. Hence, $\boldsymbol{P}_2$ and the differential of $\boldsymbol{P}_2$ with respect to σ provide the information to fix the behaviour of the Hammett plots related to the mechanism described by eq. [58]. Simultaneously solving eqs. [190] and [191] gives

$$[192] \quad \frac{\partial \boldsymbol{P}_1}{\partial \sigma} = [k_1(\rho_1)^2 + k_2(\rho_2)^2 + k_3(\rho_3)^2]/(\lambda_1 - \lambda_2) \; (>0 \rightarrow \text{minimum})$$

$$[193] \quad \frac{\partial \boldsymbol{P}_2}{\partial \sigma} = [k_1(\rho_1)^2 + k_2(\rho_2)^2 + k_3(\rho_3)^2]/(\lambda_2 - \lambda_1) \; (<0 \rightarrow \text{maximum})$$

The differential coefficient in eq. [193] is *negative* corresponding to a maxima in the logλ_2 vs. σ coordinate system. Such unusual behaviour has been observed recently by Kevil et al. (225) for the methanolysis of a series of benzyl tosylates and is suggestive of the mechanism represented by eq. [58] for these displacements. However, this analysis will not explain the more usual observation for substitutions at a saturated carbon atom in which either the Hammett correlations show a definite minima or steadily increasing slope (more positive) with increasing σ. This behaviour is exemplified by the hydrolysis of a series of substituted benzyl chlorides and tosylates (see Table 26). The data for the two former reaction series are presented in Table 26 and the related Hammett plots are illustrated in Figs. 24 and 25.

Fig. 24. Curved Hammett LFER for the hydrolysis of a series of benzyl tosylates in acetone–water mixtures.



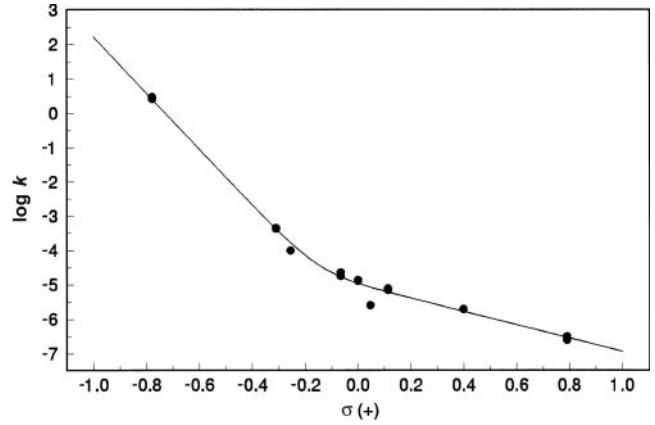


Fig. 25. Curved Hammett LFER for the hydrolysis of a series of benzyl chlorides.

© 2005 NRC Canada

Clearly, the mechanism represented by eq. [58] fails to quantify the curved Hammett profiles.

A Hammett plot with either a definite minimum or a continuously increasing slope as σ increases requires a revised model. The observed profile can be understood in terms of a bifurcated mechanism such as

$$[194]\qquad \begin{array}{l} \qquad\qquad\qquad\qquad\qquad\qquad \overset{\text{fast}}{\text{W-R}^+ + \text{X}^- \rightarrow}\ \text{Route } R(1) \\ \text{RX} + \text{W} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{W-R}^+\text{X}^- \begin{array}{l} \nearrow k_3 \\ \searrow k_4 \end{array} \\ \qquad\qquad\qquad\qquad\qquad\qquad \overset{\text{fast}}{\text{W-R}^+|\text{W}|\text{X}^- \rightarrow}\ \text{Route } R(2) \end{array}$$

In this scheme, the nucleophilically assisted ion pair can react directly to give an oxonium ion route ($R(1)$) or via a solvent separated ion pair ($R(2)$). It is important to note here that the mechanism represented by eq. [194] will add a positive component to the apparent heat capacity of activation for which there is a well-established similar example (79) that involves a bifurcation between S_N and $B_{Ac}2$ mechanisms. Other bifurcations are possible within the framework of the Winstein scheme, but we favour the sequences in eq. [194] for the benzyl chlorides and tosylates in Table 26.

The matrix formulation (see Appendix D) of the rate equations associated with the mechanism described by eq. [194] is

$$[195]\qquad \begin{bmatrix} (D + k_1) & -k_2 & & \\ -k_1 & (D + k_2 + k_3 + k_4) & & \\ & -k_3 & D & \\ & -k_4 & & D \end{bmatrix} \begin{bmatrix} A \\ B \\ P(1) \\ P(2) \end{bmatrix} = 0$$

where the operator $D \equiv \mathrm{d}/\mathrm{d}t$. Equation [195] gives rise to the auxiliary quartic equation

$$[196]\qquad \lambda^2[\lambda^2 + \lambda(k_1 + k_2 + k_3 + k_4) + k_1k_3 + k_1k_4] = 0$$

and the related dynamic constants λ_1 and λ_2, aside from the two trivial roots of zero, relate to the component rate constants of the bifurcated mechanism in eq. [194] by

$$[197]\qquad \lambda_1 + \lambda_2 = k_1 + k_2 + k_3 + k_4$$

$$[198]\qquad \lambda_1\lambda_2 = k_1k_3 + k_1k_4$$

In this case, the repetition of the analysis elaborated in eqs. [67], [68], and [184]–[191] is superfluous. The differentiation of eq. [198] twice with respect to σ suffices to establish the required conditions for $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$, namely,

$$[199]\qquad \frac{\partial \boldsymbol{P}_1}{\partial \sigma} + \frac{\partial \boldsymbol{P}_2}{\partial \sigma} = k_3k_4(\rho_4 - \rho_3)^2/(k_3 + k_4)^2$$

Equation [199] confirms that the second differentials related to $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$, in contrast to those in eq. [191] can, in principle, be positive, whereas in the case of eq. [191], the requirement that the first differential corresponding to the smaller dynamic constant is impossible. Hence, the curved Hammett plots provide indirect evidence that the hydrolysis reactions are complex. It should be emphasized that the preceding treatment of curved Hammett profiles remains true for the mechanisms considered under all situations, whereas previous analysis appears to be confined to steady-state treatments (216).

Two groups of rate data are consistent with eq. [194], namely, the solvolysis of a series of benzyl tosylates measured by Kochi and Hammond (226) in acetone–water mixtures and the hydrolysis of a series of benzyl chlorides measured by several groups reported in Table 26. In both cases, the rate data can be fitted to a simplified equation of the form

$$[200]\qquad \log k_o = \log[10^{(a(1)+b(1)x)} + 10^{(a(2)+b(2)x)}]$$

that relates to eq. [167] in an earlier section and eq. [194]. The quantity k_o is the observed rate constant, x is the Hammett σ^+ substituent constant, and the quantities $a(1)$, $b(1)$, $a(2)$, and $b(2)$ are empirical constants. In the case of the rate data reported in Table 26 for a series of substituted benzyl chlorides and tosylates, the empirical constants were established by a grid search routine.

For the benzyl tosylate rate data, the numerical constants are: $a(1) = -4.641$, $b(1) = -6.639$, $a(2) = -4.237$, and $b(2) = -1.813$. The correlation between the observed and calculated (k_c) rate constants from eq. [200] using the values for $a(1)$, $b(1)$, $a(2)$, and $b(2)$ gives

$$[201]\qquad \log k_c = (0.9934 \pm 0.0168)\ \log k_o(-0.037 \pm 0.071)\ (18,0.9950)$$

Similarly, for the benzyl chloride rate data, the constants are $a(1) = -5.950$, $b(1) = -8.170$, $a(2) = -4.999$, and $b(2) = -1.930$. The equation corresponding to [201] is

$$[202]\qquad \log k_c = (0.9856 \pm 0.0153)\ \log k_o(-0.024 \pm 0.072)\ (16,0.9963)$$

The curves calculated from the derived empirical constants along with the experimental points are illustrated in Figs. 24 and 25. Both sets of data give adequate fits to eq. [200] supporting the bifurcated mechanism described by eq. [194].

The two differing coefficients of σ^+, namely $b(1)$ and $b(2)$, for the individual curve fits for both the benzyl chlorides and tosylates are suggestive of mechanistic shifts, the more negative values suggesting pathways involving a more electron-deficient carbon atom. The smaller (more negative) coefficients of σ^+ are comparable to the slope of the Hammett correlation for the solvolysis of the dimethylcarbinyl chlorides (215)

$$[203]\qquad \log k_o = (-4.48 \pm 0.02)\sigma^+ - 3.90 \pm 0.01\ (9,0.998)$$

and that of the α-phenylethyl chlorides (70),

$$[204]\qquad \log k_o = (-6.41 \pm 0.02)\sigma^+ - 2.28 \pm 0.11\ (8,0.992)$$

but these comparisons are not clear-cut because of drastic solvent changes that are involved in the comparison.

The steady-state treatment related to eq. [194] for k_o for the removal of the substrate RX gives

$$[205]\qquad k_o = k_1(k_3 + k_4)/(k_2 + k_3 + k_4)$$

The smaller of the two dynamic constants correlates with k_o. Synthetic data generated by solving eq. [188] to give the products $\boldsymbol{P}(1)$ and $\boldsymbol{P}(2)$ as a function time can be processed

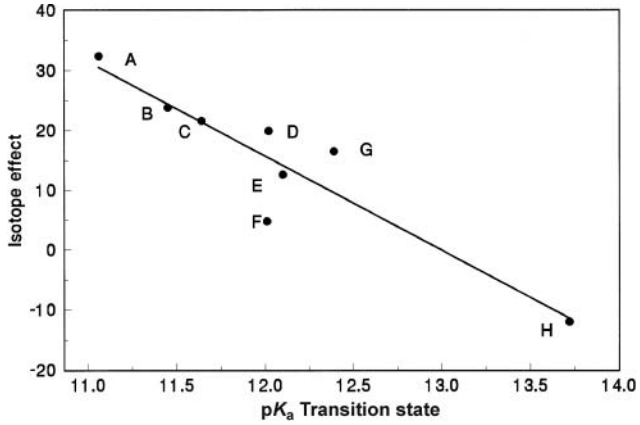
Table 30. α-Deuterium secondary isotope effects and related transition-state acidities for primary substrates.

Hydrogen substrate	$pK_a^{\ddagger a}$	$\delta_I\Delta G^{\ddagger}$(obs.)[b]	$\delta_I\Delta G^{\ddagger}$(calcd.)[c]	Δ^d
Methyl chloride	12.02	19.900	15.403	–4.50
Methyl bromide	11.45	23.800	24.390	+0.59
Methyl iodide	11.06	32.400	30.539	–1.86
Methyl mesylate	12.10	12.600	14.142	+1.54
Methyl sulphate	12.01	4.800	15.561	+10.76
Methyl perchlorate	12.39	16.500	9.570	–6.93
Methyl nitrate	11.64	21.600	21.394	–0.21
Ethyl tosylate	13.72	–12.000	–11.399	+0.60

[a] $pK_a^{\ddagger}$ is the transition-state acidity constant (see section 3).
[b] $\delta_I\Delta G^{\ddagger}$(obs.) is the observed isotope effect (eq. [207]); Units in calories. Data is from ref. 55.
[c] $\delta_I\Delta G^{\ddagger}$(calcd.) is the calculated isotope effect according to the least-squares correlation (eq. [206]).
[d] $\Delta = \delta_I\Delta G^{\ddagger}$(calcd.) – $\delta_I\Delta G^{\ddagger}$(obs.).

to yield a pseudo-first-order rate constant (k_o) that, generally speaking, closely matches the smaller of the dynamic constants λ_2 rather than k_o given by eq. [205], i.e., the more elaborate analyses via eqs. [67] and [68] for eq. [58] and eqs. [197] and [198] for eq. [194] are more reliable.



16. Secondary hydrogen–deuterium isotope effects

Secondary isotope effects have contributed to an understanding of solvolytic displacements (2, 4, 55, 70, 227–230). Here we offer brief comment on α-deuterium effects for primary and secondary displacements in the light of the Kurz (24) analysis that clarifies the meaning of the k_l/k_w ratios discussed in section 3. Kurz considers that this ratio gives a measure of the acidity of the protons that are components of the attacking water molecule (see eq. [48]).

It is reasonable to assume that increasing interaction of the attacking water molecule with the incipient positive carbon centre will be paralleled by increasing acidity of the water protons. The α-deuterium effects are usually interpreted in terms of the "tightness" of a S_N2 transition state that is anticipated to be a function of the nucleophilicity of both the nucleofuge and the nucleophilicity of the attacking nucleophile. According to the conventional wisdom, the tightness, when translated into vibrational terms, influences the out-of-plane vibrations of the α-hydrogens that are postulated to dominate the magnitude of the ratio, $k(H)/k(D)$. Thus, "tighter" transition states are to be anticipated with leaving groups that combine enhanced leaving group and nucleophilic properties. In this role, the bromide and iodide ions are surely preeminent: both are good nucleophiles and good leaving groups. Hence, the transition-state water molecules are expected to display enhanced acidity for these leaving groups and this speculation is born out in practice. Indeed, there is a definite trend between the isotope effect and $pK_a^{\ddagger}$ for the eight structures in Table 30, the isotope effect passing from inverse ($k(H)/k(D) < 1$) to normal ($k(H)/k(D) > 1$) as the nucleophilicity of the nucleofuge decreases.

$$[206]\quad \delta_I\Delta G^{\ddagger} = (-15.77 \pm 1.8)pK_a^{\ddagger} + 204.9 \pm 21.8\ (8,0.92)$$

Fig. 26. Correlation isotope effects with $pK_a^{\ddagger}$ (also see section 3). (A) CH_3I, (B) CH_3Br, (C) CH_3NO_3, (D) CH_3Cl, (E) $CH_3SO_3CH_3$, (F) $(CH_3)_2SO_4$, (G) CH_3ClO_4, (H) 4-CH_3-$C_6H_4SO_3CH_2CH_3$.

Departures from eq. [206] that are evident in Fig. 26 are probably a consequence of the difficulty of normalizing the isotope effects to a common temperature. This is accomplished here and elsewhere (230) by the expression

$$[207]\quad \delta_I\Delta G^{\ddagger} = -(RT/n)\{\ln[k(H)/k(D)]\}$$

an equation that is, at best, a compromise. The symbols R, T, k, H, and D in eq. [207] have their usual connotation and "n" specifies the number of deuterium atoms attached to the reacting α-carbon, three, two, and one for the methyl, ethyl, and 2-propyl derivatives, respectively. It should be noted that Halevi (230) reports data with the negative sign in eq. [207] dropped.

When the $pK_a^{\ddagger}$ reaches 15.74, according to eq. [206], $k(H)/k(D) = 1.07 \pm 0.01$ for a single deuterium. This ratio corresponds to the acidity of the nucleophilic water molecule being identical to that of bulk water at 298.15 K, suggesting that nucleophilic assistance at this value of $pK_a^{\ddagger}$ has become negligible. A further increase in the α-deuterium isotope effect beyond 1.07 ± 0.01 for other alkyl groups more reactive than methyl possibly corresponds to further loosening of the RX bond that, in the case of *p*-methylbenzyl chloride and nitrate, lead to normal ratios $k(H)/k(D) = 1.06$ and 1.08 per deuterium, respectively (229), in good agreement with the calculated limiting value from

© 2005 NRC Canada

eq. [206]. These are suggestive of the mechanism given in eq. [122], but the evidence for this proposal is not definitive.

The extension of the Kurz analysis to displacements at a secondary carbon centre is not possible at the present time because the rate constants for lyate ion attack on secondary substrates have not been measured in water. The k(H)/k(D) ratios for the α-deuterated 2-propyl group linked to halide and sulphonic acid leaving groups are normal (70) and in the terminal parts of the limiting region and beyond, i.e., 1.05–1.13. Halevi (230) regards these ratios to be characteristic of a predominately "dissociative" displacement. However, there are problems with this conclusion. The rates of the 2-propyl sulphonates and the nitrate and the related 2-adamantyl derivatives are almost equal in water, the former esters being only marginally more reactive (see Tables 13, 14, and 21B. The small enhancement manifested by the 2-propyl esters can be attributed to a meagre measure of nucleophilic assistance necessarily absent in the case of the adamantyl compounds. However, the extent of such assistance, measured by Bentley's ratio $R(H_2O)/R$(TFA) (144) suggests a level of interaction in the case of the open chain secondary compounds well beyond the actual difference in reactivity between the open chain and hindered substrates and is at variance with the large normal isotope effects previously mentioned. There is a hint here that suggests that the 2-propyl substrates heterolyse via the intervention of an intimate ion pair that is predominately removed by the *frontside* rather than *backside* attack of a water molecule and that this sequence of chemical events represents a significant and possible mechanistic category.

17. Conclusions

The aim of the present contribution has been to highlight facts and issues that are at variance with the notion that simple displacements in water, particularly those associated with primary carbon atoms, are adequately described by the S_N2 mechanism. The theoretical discussions of related matters by Dewar and Carrion (231) and Wolfe and co-workers (17) do not seem to clarify these issues. Indeed, it would appear that the intricacies in solution are not necessarily reflected in gasphase phenomena, although simple gas-phase phenomena definitely offer a measure of illumination of reactivity in the condensed phase. An appropriate general philosophy towards mechanistic studies has been presented aptly by Hirsch (232): "It is a basic tenet that a mechanism can never be proven. In order for a mechanism to be accepted the experimental observations must rule out all other conceivable mechanisms. If we accept the premise that the current approach to the analysis of reaction mechanism is itself a cohesive and viable model, we recognise therefore the limitation of this approach is the ability of human beings to conceive possible mechanisms."

Note: Gauss criterion = $2.168\ 27\times10^{-3}$.

Table B2. Thermodynamic parameters characterizing the hydrolysis of *tert*-butyl chloride.

T (K)	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$	k
273.15	25.059	+18.96	7.040×10^{-4}
298.15	22.187	+8.90	2.975×10^{-2}
323.15	19.314	–0.36	4.868×10^{-1}
348.15	16.441	–8.92	3.888
373.15	13.568	–16.89	1.788×10^{1}

Note: Heat capacity = –114.91 cal mol^{-1} K^{-1}. The Gauss criterion (G.C.) is given by G.C. = $[\Sigma d^2/(N-P)]^{1/2}$ where Σd^2 = sum of the squares of deviations for N data point pairs and P is the number of parameters being determined. For example, $P = 3$ for the Valentiner equation (eq. [B1]) and $P = 4$ in the case of the Albery–Robinson equation (eq. [B2]: $k_o = \exp[(A-C)+(B-D)/T]/[1+\exp-(C+D/T)]$). This expression is also given in ref. B1, but is not designated as the Gauss criterion there, although Wentworth's paper is based on Deming's book (B2), which in turn is totally derivative of Gauss' work.

Note: Gauss criterion = $2.074\,83\times10^{-4}$, sum of deviations = $1.891\,37\times10^{-3}$. [C2] $k_o = \exp[(A - C) + (B - D)/T]/[1 + \exp -(C + D/T)]$. Coefficients of eq. [C2]: $A - C = -8.118\,089\times10^{3} \pm 5.929\times10^{2}$, $B - D = 2.486\,841\times10^{1} \pm 1.738$, $-C = 4.944\,060\times10^{3} \pm 3.509\times10^{2}$, $-D = -1.580\,097\times10^{1}\times10^{-1} \pm 8.297\times10^{-1}$.

Appendix D.

Readers unfamiliar with the matrix approach to the system of linear differential equations that describe the system

[D1] $$A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B \xrightarrow{k_3} C$$

can find a rudimentary treatment of the time evolution of this system in Hammett's book (D1). There is a minor error in the stoichiometric mass balance expression (eq. [76], p. 74) that should read

[D2] $$A + B + C = A_o$$

© 2005 NRC Canada

where A, B, and C are the concentrations of the chemical species A, B, and C at any time "t"; A_o is the concentration of A at zero time. The relationship

[D3] $dA/dt + dB/dt + dC/dt = 0$

is obtained by differentiating eq. [D2] with respect to time. Equation [D3], when combined with other relationships reported by Hammett, provides the differential equation for the species B

[D4] $d^2B/dt^2 + (k_1 + k_2 + k_3)dB/dt + k_1k_3B = 0$

Hammett solves this equation, but the particulars of the solution are more transparent via the matrix method reported in section 6 of this paper (eq. [D5]).

[D5] $$\begin{bmatrix} (D + k_1) & -k_2 & \\ -k_1 & (D + k_2 + k_3) & \\ & k_3 & D \end{bmatrix} \begin{bmatrix} A \\ B \\ C \end{bmatrix} = 0$$

Evaluating the determinant defined by the matrix in eq. [D5] gives for operator part of this equation

[D6] $D(D^2 + (k_1 + k_2 + k_3)D + k_1k_3)$

Clearly, the *quadratic component* of this equation when operating on either A, B, or C yields three differntial equations, one of which is identical to eq. [D4] involving species B.

The complete version of [D6] operating on B is

[D7] $(D^3 + (k_1 + k_2 + k_3)D^2 + k_1k_3D)B = 0$

The corresponding differential equations for A and C are identical in form to eq. [D7].

To solve eq. [D7], let

[D8] $B = \exp(\lambda t)$

Since $DB = dB/dt = \lambda B$, $D^2B = d^2B/dt^2 = \lambda^2B$, and $D^3 = d^3B/dt^3 = \lambda^3B$, substituting the first, second and third differentials in eq. [D7] gives $[\lambda^3 + (k_1 + k_2 + k_3)\lambda^2 + k_1k_3\lambda] \exp(\lambda t) = 0$.

Dividing by $\exp(\lambda t)$ (noting $\exp(\lambda t) \neq 0$) gives the cubic *auxiliary equation*

[D9] $\lambda^3 + (k_1 + k_2 + k_3)\lambda^2 + k_1k_3\lambda = 0$

If the roots of the cubic are respectively λ_1, λ_2, and λ_3 with the latter root set arbitrarily to zero (λ is a factor of eq. [D9]), then the other two negative roots of the residual quadratic *with their signs changed* define the dynamic constants that describe the time evolution of the chemical system represented by eq. [D1]. The dynamic contants are functions of k_1, k_2, and k_3. If $k_1 + k_2 + k_3 = P$ and $k_1k_3 = Q$, then $\lambda_1 = [P + (P^2 - 4Q)^{1/2}]/2$ and $\lambda_2 = [P - (P^2 - 4Q)^{1/2}]/2$.

The solution for A, B, and C as functions of time are linear combinations of exponential functions of the three roots

[D10] $X_n = \alpha_n \exp(-\lambda_1 t) + \alpha_{rn} \exp(-\lambda_2 t) + \alpha_{rn}$

where the final term on the RHS of eq. [D10] relates to the root $\lambda = 0$. The quantities X_n (n = 1–3) refer to the concentrations of A, B, and C any time t, respectively. The constants or amplitudes α_{nr} (n = 1–3, r = 1–3) may be evaluated from the various boundary conditions that characterize the chemical system represented by eq. [D1]. This matter is not pursued further here. There are other more sophisticated versions of this part of the exercise using linear and matrix algebra, which are presented in Ritchie's monograph (D2). Further relevant information can be found in books by Hollingsworth (D3), Leon (D4), and Caunt (D5); refs. D6 and D7 also contain useful material.

A multinuclear solid-state magnetic resonance study of silver nitrate triphenylphosphine

Se-Woung Oh, Guy M. Bernard, Roderick E. Wasylishen, Robert McDonald, and Michael J. Ferguson

Abstract: Variable-temperature solid-state ^{31}P, ^{15}N, and ^{2}H NMR spectroscopy, X-ray diffraction, and differential scanning calorimetry studies of the 1:1 adduct of silver nitrate and triphenylphosphine ($AgNO_3 \cdot PPh_3$) reveal a solid–solid phase transition at 300 K. The principal components of the phosphorus and nitrogen chemical shift tensors for both phases are determined from NMR spectra of MAS and stationary samples. In addition, the indirect spin-spin coupling between phosphorus and the naturally occurring isotopes of silver (^{107}Ag and ^{109}Ag) are resolved. Experimental ^{2}H NMR line shapes for silver nitrate perdeuterated triphenylphosphine are those characteristic of rigid phenyl groups at temperatures above and below the phase-transition temperature. Powder and single-crystal X-ray diffraction data for $AgNO_3 \cdot PPh_3$ obtained at 193, 295, and 313 K are reported; data obtained at 193 and 295 K are almost identical, but are significantly different from those obtained at 313 K and from an earlier single-crystal X-ray diffraction investigation performed at 298 K. All X-ray studies found that $AgNO_3 \cdot PPh_3$ crystallizes in the monoclinic form, space group $P2_1/c$.

Key words: 1:1 silver nitrate triphenylphosphine adduct, solid-state NMR, X-ray diffraction, phase transition.

Résumé : Des études à températures variables de spectroscopie RMN du ^{31}P, du ^{15}N et du ^{2}H à l'état solide, de diffraction des rayons X et de calorimétrie à balayage différentiel sur une adduit 1 : 1 de nitrate d'argent et de triphénylphosphine, $AgNO_3 \cdot PPh_3$, mettent en évidence l'existence d'une transition de phase solide-solide à 300 K. En se basant sur les spectres RMN d'échantillons stationnaires et à l'angle magique de spin, on a déterminé les principaux composants des tenseurs de déplacement chimique du phosphore et de l'azote pour les deux phases. De plus, on a résolu le couplage spin-spin indirect entre le phosphore et les isotopes naturels de l'argent, ^{107}Ag et ^{109}Ag. Aux températures supérieures et inférieures à la température de transition, les formes expérimentales des raies RMN du ^{2}H de l'adduit nitrate d'argent/triphénylphosphine perdeutérée sont caractéristiques de groupes phényles rigides. On rapporte aussi des données de diffraction des rayons X obtenues sur des poudres et sur des cristaux uniques de $AgNO_3 \cdot PPh_3$, à 193, 295 et 313 K; les données obtenues à 193 et 295 K sont presque identiques, mais elles diffèrent beaucoup de celles obtenues à 313 K ainsi que de celles obtenues antérieurement dans une étude de diffraction des rayons X effectuée à 298 K. Toutes les études de diffraction des rayons X indiquent que le $AgNO_3 \cdot PPh_3$, cristallise dans la forme monoclinique, groupe d'espace $P2_1/c$.

Mots clés : adduit 1 : 1 de nitrate d'argent et de triphénylphosphine, RMN à l'état solide, diffraction des rayons X, transition de phase.

[Traduit par la Rédaction]

Introduction

The versatility of silver in coordination chemistry has prompted numerous structural studies (1, 2). For example, silver nitrate can form a variety of adducts with phosphorus-containing ligands (2, 3); the phosphine-to-silver ratio may vary from one to four depending on the nature of the ligand and on the stoichiometric ratios used in the syntheses (4). In the case of triphenylphosphine, structures for the 1:1, 2:1, 3:1, and 4:1 adducts are available from earlier single-crystal X-ray diffraction (XRD) studies (3, 4).

In an early solid-state ^{31}P magic-angle spinning (MAS) NMR study, Barron et al. (4) investigated all four adducts of $AgNO_3 \cdot (PPh_3)_n$, $n = 1$–4. For the 1:1 adduct, they observed a broad doublet, centred at $\delta_{iso} = 11.7$ ppm, with a splitting of approximately 780 Hz that arises from indirect spin-spin

coupling (J) of ^{31}P to both ^{107}Ag and ^{109}Ag, which are spin-1/2 nuclei with similar magnetogyric ratios and natural abundances.

Several years ago, we examined ^{31}P NMR spectra of the 1:1 adduct of solid $AgNO_3 \cdot PPh_3$ and observed well-resolved doublets resulting from indirect spin-spin coupling to ^{107}Ag (^1J = 707 Hz) and to ^{109}Ag (^1J = 813 Hz);[3] as expected, the ratio of the spin-spin coupling corresponds to the ratio $\gamma(^{107}Ag)/\gamma(^{109}Ag)$. However, we were puzzled by the presence of additional peaks in our spectra, occurring at different chemical shifts. These peaks exhibited the same splitting pattern as those attributed to the 1:1 adduct. Also, the relative intensities of the two sets of ^{31}P NMR peaks seemed irreproducible. Initially, we ascribed the additional peaks to the presence of a polymorph (5–8) of the 1:1 adduct. However, all attempts to consistently isolate a "pure" polymorph by preparing the sample in various solvent systems under a variety of conditions (e.g., darkness) failed. Our earlier work was performed using rotors restricted to a maximum MAS frequency (ν_{rot}) of 4 kHz. Recently, we reinvestigated $AgNO_3 \cdot PPh_3$ with the goals of understanding our earlier irreproducible results and of obtaining unambiguous ^{31}P NMR spectra from which the chemical shift (CS) tensors could be determined. For the latter study, our NMR measurements were made using rotors that allowed spinning frequencies in excess of 4 kHz. This work indicates that the intensity of the additional peaks depends on the degree of heating arising from sample spinning. Here we present a comprehensive solid-state NMR study of the 1:1 adduct of $AgNO_3 \cdot PPh_3$, corroborated with the results of differential scanning calorimetry (DSC), as well as single-crystal and powder X-ray diffraction experiments.

Experimental

Sample preparation

The 1:1 adduct of $AgNO_3 \cdot PPh_3$ was prepared as reported in the literature (3). Because the adduct may be light sensitive, all synthetic work was undertaken in a dark room. Triphenylphosphine (1.2 g, 4.5 mmol), recrystallized from methanol, was dissolved in 50 mL of methanol, which had been heated to 313 K, and mixed with a solution containing 1.0 g (5.9 mmol) of silver nitrate in 5 mL of acetonitrile and 20 mL of methanol. The mixture was stirred for 2 min and allowed to stand overnight at room temperature. The precipitate that formed was washed five times with 1 mL of methanol after decantation, dried at room temperature, and placed in an evacuated desiccator for 1 h. The colourless solid was recrystallized using either methanol, acetonitrile, or methylene chloride at room temperature. Perdeuterated $AgNO_3 \cdot PPh_3$ was prepared from $AgNO_3$ and tri(phenyl-d_5)phosphine (Sigma-Aldrich Canada Ltd., Oakville, Ontario, 99% ^2H) as previously described. Nitrogen-15 enriched $AgNO_3$ was obtained by reacting 0.6 g Ag powder (Alfa Aesar, Ward Hill, Massachusetts) in ^{15}N-labelled nitric acid (1 mL; Sigma-Aldrich Canada Ltd., Oakville, Ontario, 98% ^{15}N, 40 wt% solution in water). After the reaction was complete, 1 mL of distilled water was added to the solution, which was then filtered and dried in an oven at 393 K to yield $Ag^{15}NO_3$ (0.75 g). $Ag^{15}NO_3 \cdot PPh_3$ was prepared from $Ag^{15}NO_3$ and triphenyphosphine as previously described for the natural abundance sample.

Solid-state NMR spectroscopy

Phosphorus-31 NMR spectra of stationary and MAS samples of $AgNO_3 \cdot PPh_3$ were acquired on Chemagnetics CMX Infinity 200 (B_0 = 4.70 T) as well as Bruker Avance 300 (B_0 = 7.05 T) and 500 (B_0 = 11.75 T) NMR spectrometers with cross-polarization (CP) from ^1H under the Hartmann–Hahn match condition (9). Samples were packed in 7.5 or 4 mm o.d. rotors for spectra acquired on the Chemagnetics and Bruker spectrometers, respectively. Proton 90° pulse widths of 4.5 or 3.5 μs, a contact time of 2 ms, and a pulse delay of 60 s were used to acquire most ^{31}P NMR spectra. Some ^{31}P NMR spectra were acquired with single-pulse excitation and ^1H decoupling on the Bruker Avance 300 NMR spectrometer using a 90° pulse width of 4 μs and a pulse delay of 1 h. Phosphorus-31 NMR chemical shifts were referenced with respect to 85% aqueous phosphoric acid (H_3PO_4) by setting the isotropic peak of external solid ammonium dihydrogen phosphate ($NH_4H_2PO_4$) to 0.81 ppm (10).

Nitrogen-15 NMR spectra of stationary and MAS samples of $AgNO_3 \cdot PPh_3$ were acquired with CP at 20.3 MHz on the CMX Infinity 200 NMR spectrometer using the same acquisition parameters as for the ^{31}P NMR experiments apart from a 6.0 ms contact time. Nitrogen-15 NMR chemical shifts were referenced with respect to external neat ammonia ($^{15}NH_3$(l)) at 293 K by setting the isotropic peak of solid ammonium nitrate ($^{15}NH_4NO_3$) to 23.80 ppm at room temperature (10). Another common nitrogen NMR reference (CH_3NO_2(l)) appears at 381.9 ppm relative to the nitrogen signal of NH_3(l).[4]

Principal components of the phosphorus and nitrogen CS tensors are assigned using the convention $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, representing the directions of least, intermediate, and greatest shielding, respectively. For convenience, CS tensors are discussed in terms of their isotropic chemical shifts ($\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$), their span ($\Omega = \delta_{11} - \delta_{33}$), and their skew ($\kappa = 3(\delta_{22} - \delta_{iso})/\Omega$) (11). Spectra of stationary samples were simulated using WSOLIDS, a program written in this laboratory (12).

Deuterium NMR spectra of stationary perdeuterated $AgNO_3 \cdot PPh_3$ were acquired on the CMX Infinity 200 NMR spectrometer with a 5 mm double resonance solenoid probe using the quadrupolar-echo pulse sequence ($90^\circ_x - \tau - 90^\circ_y - \tau$ – acq) (13–16) with a ^2H 90° pulse of 3 μs, τ = 20 μs, and a pulse delay of 60 s. Samples were packed into a 5 mm o.d. glass container. Perdeuterated poly(methyl methacrylate) was used to optimize experimental conditions. Prior to Fourier transformation (FT), the initial points of the free-induction decay (FID) were deleted to ensure that the first point was at the top of the echo (10).

Variable-temperature (VT) solid-state ^{31}P, ^{15}N, ^2H, and ^{207}Pb NMR experiments were performed on the Chemagnetics CMX Infinity 200 NMR spectrometer. The temperature was varied from 247 to 319 K and calibrated using the

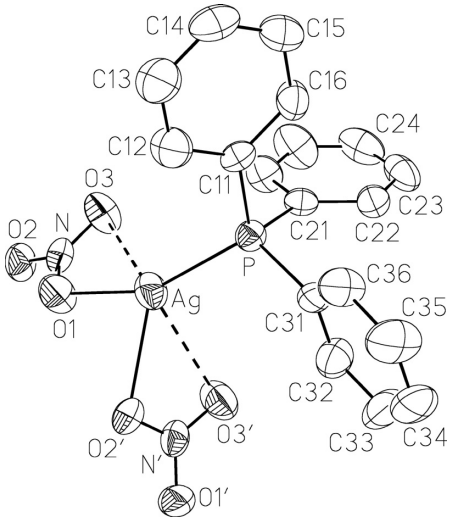
[a]Determined by X-ray diffraction on a single crystal. Refinement of F_o^2 for all reflections (all of these having $F_o^2 \geq -3\sigma(F_o^2)$). Weighted R factors (wR_2) and all goodnesses-of-fit (S) are based on F_o^2; conventional R factors (R_1) are based on F_o, with F_o set to zero for negative F_o^2. The observed criterion of $F_o^2 > 3\sigma(F_o^2)$ is used only for calculating R_1, and is not relevant to the choice of reflections for refinement. R factors based on F_o^2 are statistically about twice as large as those based on F_o, and R factors based on all data will be even larger.
[b]Determined by powder X-ray diffraction.
[c]$R_1 = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$.

isotropic ^{207}Pb NMR peak of lead(II) nitrate (17–19). For this calibration, a mixture containing 15% lead nitrate and 85% $AgNO_3{\cdot}PPh_3$ was packed into a 7.5 mm o.d. rotor. Lead-207 NMR chemical shifts were referenced by setting the isotropic peak of solid lead(II) nitrate, acquired at 294 K with ν_{rot} = 1.0 kHz, to –3505.5 ppm (17).

Proton spin-lattice relaxation times (T_1) were indirectly estimated through the observation of the ^{31}P NMR peak intensities in a CP experiment (20, 21), using the progressive saturation FT technique (22). Peak intensities were obtained with various inter-pulse delays, to a maximum of 5400 s. To establish a steady state before measuring the signal intensity, two FIDs preceded the one that was measured.

Differential scanning calorimetry



DSC was performed with a Pyris DSC1 from PerkinElmer Instruments, Inc. Approximately 6.5 mg of sample was used for the measurements with a scanning rate of 5 K/min; data were collected between 293 and 323 K.

X-ray diffraction

A single crystal of $AgNO_3{\cdot}PPh_3$ recrystallized from methanol, dimensions 0.20 mm × 0.17 mm × 0.08 mm, was selected for the single-crystal XRD experiments. Diffraction data were obtained with a Bruker PLATFORM/SMART 1000 CCD diffractometer (Mo Kα, λ = 0.710 73 Å graphite monochromator), operating at 193 or 295 K. For data acquired at 193 K, 10 098 reflections were collected in the range 5.24° < 2θ < 53.24° of which 3613 were independent. For the data acquired at 295 K, 8097 reflections were collected in the range 5.24° < 2θ < 52.86° of which 3553 were independent. The structure was solved by direct methods using DIRDIF-99 (23) and refined with SHELXL-93 (24).

Powder X-ray diffraction data were collected at 295 and 313 K on an Inel powder diffractometer equipped with a CPS 120 position-sensitive detector and Cu Kα$_1$ radiation (Si standard). Programs used for data collection and analysis were those supplied by Inel. Cell parameters were refined by least-squares methods on 24–40 reflections in the X-ray powder pattern with the program UnitCell (25). Calculated intensities were obtained using the program PowderCell (26).

Fig. 1. Perspective view of the 1:1 adduct of silver nitrate triphenylphosphine showing the atom labelling scheme and including interactions with the nearest-neighbour symmetry-related nitrate ion; the structure was obtained at 295 K. Non-hydrogen atoms are represented by Gaussian ellipsoids at the 50% probability level. The hydrogen atoms are not shown.

Results and discussion

Solid-state NMR spectra of MAS samples

Phosphorus

To facilitate the discussion of the NMR spectra the structure of $AgNO_3{\cdot}PPh_3$, as determined by single-crystal X-ray crystallography at 295 K (vide infra), is shown in Fig. 1 (see also Tables 1 and 2). On the basis of the crystal structure, one site is expected for the ^{31}P NMR spectra of MAS samples; however, spectra acquired at room temperature generally consisted of eight peaks attributed to two peaks (see Fig. 2 for a typical spectrum), four peaks centred at 13.2 ppm and four centred at 12.0 ppm. These are hereinafter referred to as sites I and II, respectively. Four peaks are expected for a single phosphorus NMR site of $AgNO_3{\cdot}PPh_3$,

a pair of doublets arising from indirect spin-spin coupling to ^{107}Ag and ^{109}Ag with 51.8% and 48.2% natural abundance, respectively (27, 28). Another interesting observation was that the intensities of the peaks centred at 13.2 ppm, relative to those centred at 12.0 ppm, increase with MAS frequency. This was observed for all samples of $AgNO_3{\cdot}PPh_3$, regardless of the solvent used to prepare the sample.

Sample heating resulting from MAS is well-known (17, 18, 29, 30); the effect, arising from friction between the rotor and the bearing gas, has been described by Doty and Ellis (31). Hence, the possibility that the spinning-frequency dependence of the ^{31}P NMR spectra arises from a solid–solid phase transition induced by sample heating was considered; this has been previously observed for other samples (32, 33).

To investigate the temperature dependence of the ^{31}P NMR signals for $AgNO_3{\cdot}PPh_3$, spectra were acquired from 247 to 319 K (Fig. 3*a*). At 319 K, only the peaks centred at 13.2 ppm were observed, while only those centred at 12.0 ppm were observed at 247 K. These observations suggest that sites I and II correspond to different phases of solid $AgNO_3{\cdot}PPh_3$, and that the solid–solid phase transition occurs between 286 and 306 K. The isotropic phosphorus chemical

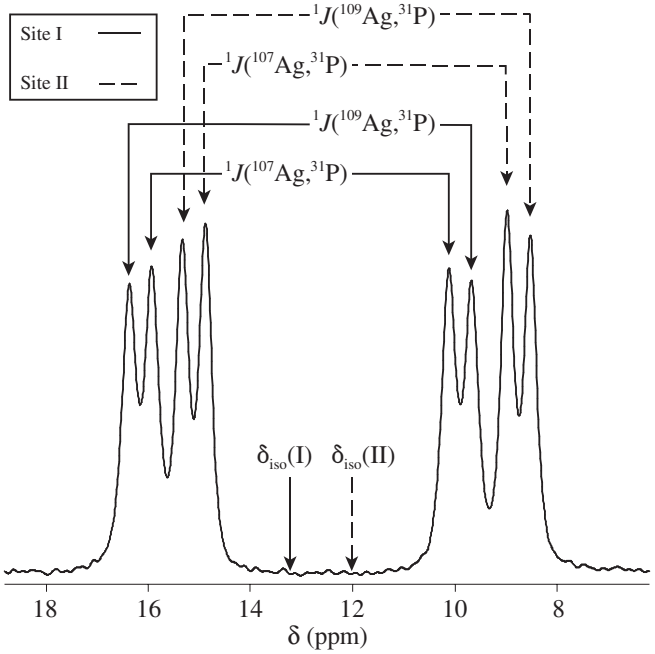

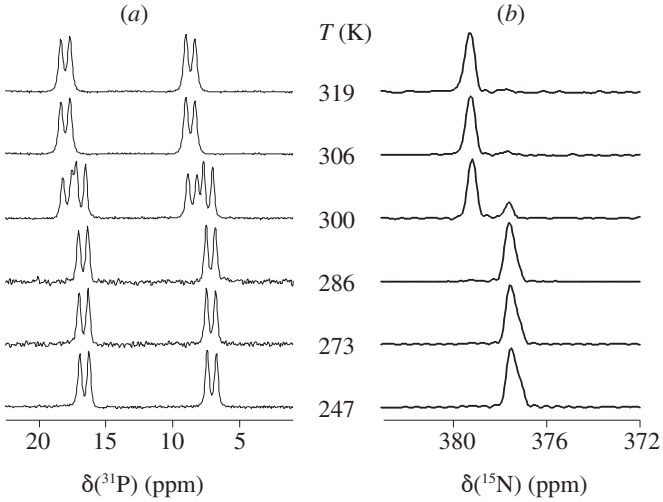

Fig. 3. (*a*) Phosphorus-31 and (*b*) nitrogen-15 NMR spectra of MAS samples of $AgNO_3{\cdot}PPh_3$ acquired with CP at various temperatures; B_0 = 4.70 T and ν_{rot} = 3.0 kHz. Because splittings due to ^2J(Ag,N) are not resolved, a single peak is observed for each site in the ^{15}N spectra.

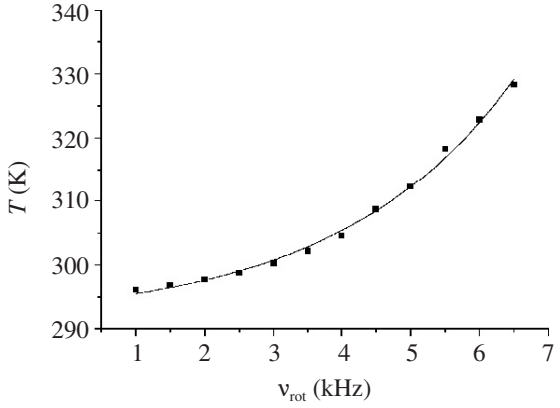

shifts for both phases vary slightly with temperature, but the values of $^1J(^{109}Ag,^{31}P)$ and $^1J(^{107}Ag,^{31}P)$ for the two phases are independent of temperature over the range examined. In the discussion that follows, the high- and low-temperature phases, corresponding to sites I and II, respectively, will be referred to as phases I and II.

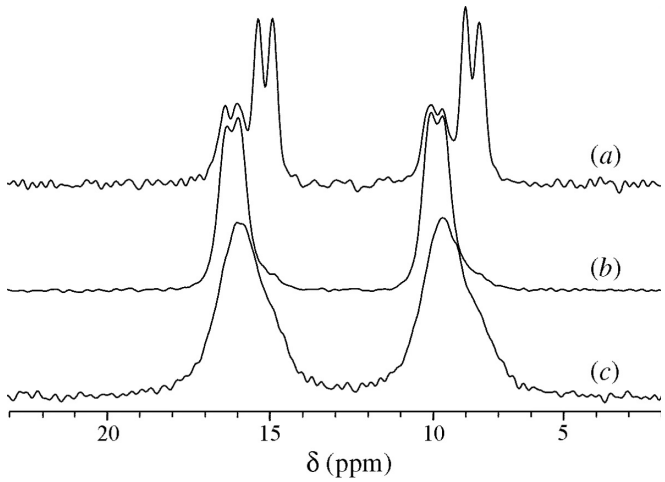
Fig. 4. Internal temperature of a sample packed in a 7.5 mm Chemagnetics probe as a function of ν_{rot}, based on ^{207}Pb NMR chemical shifts for $Pb(NO_3)_2$. The solid line is a fit of the experimental points according to T (K) = 3.0 exp(ν_{rot}/2500) + 291.2, with R^2 = 0.9960.

$Ag^{15}NO_3{\cdot}PPh_3$ were acquired at various temperatures (see Fig. 3*b*). These experiments confirm that the peaks at 377 and 379 ppm correspond to the high- and low-temperature phases, respectively, and that a phase transition occurs in the 286–306 K range. The temperature and the spinning-frequency dependence of the ^{15}N NMR spectra are similar to those observed for ^{31}P NMR, apart from the ratio of phase I to phase II for spectra acquired at 300 K. This is attributed to the fact that these spectra were acquired near the phase-transition temperature. VT ^{15}N NMR has been used previously to investigate the thermal behaviour of other nitrates. For example, ^{15}N NMR chemical shift data were determined for the five solid phases of ammonium nitrate using VT ^{15}N NMR spectroscopy of MAS and stationary samples (33–35).



Temperature calibration

To determine the internal temperature of the samples during MAS, ^{207}Pb NMR spectra of a mixture of lead(II) nitrate and $AgNO_3{\cdot}PPh_3$ were acquired as a function of MAS frequency; the internal temperature was calculated from the ^{207}Pb chemical shifts (Fig. 4). These experiments confirm that the temperature of the sample, when in the rotor, changes approximately exponentially as the MAS frequency increases. A sample in a 7.5 mm Chemagnetics rotor spinning at 3 kHz in a laboratory at 295 K was heated to approximately 300 K.

Deuterium isotope effect

Phosphorus-31 NMR spectra of a perdeuterated sample of $AgNO_3{\cdot}PPh_3$ were also acquired. These spectra exhibit the same splitting patterns and similar spinning-frequency dependence as those for the natural abundance sample, but the isotropic ^{31}P NMR chemical shifts of all peaks were shifted by approximately 0.8 ppm to lower frequency upon substitution of hydrogen for deuterium in $AgNO_3{\cdot}PPh_3$. Substitution of a heavier isotope of a given atom has long been known to induce chemical shifts, usually to lower frequency, in the resonance frequencies of neighbouring nuclei (36, 37). The magnitude of these isotope shifts depends on the ratio of the masses of the substituted nuclei, the chemical shift range of the observed nucleus, and the number of intervening bonds between the site of isotopic substitution and the observed nucleus; for multiple isotopic substitution, the effect is usually additive (38–40). Isotope shifts are usually obtained from samples dissolved in isotropic solutions, but there have been a few reports of solid-state NMR measurements (41–45). Perdeuterated $AgNO_3{\cdot}PPh_3$ has six ^2H nuclei 3-bonds distant, six ^2H nuclei 4-bonds distant, and three ^2H nuclei 5-bonds distant from the phosphorus atom. Each deuterium may contribute to the overall isotope shift in the ^{31}P NMR resonance of perdeuterated $AgNO_3{\cdot}PPh_3$; however, determining their individual contributions is not possible unless the phenyl rings are selectively ^2H enriched.

Fig. 5. Effect of sample grinding on the solid-state ^{31}P NMR spectra of $AgNO_3{\cdot}PPh_3$. Trace (*a*) is that obtained from a sample that was packed into a rotor without grinding; trace (*b*) is that from a sample that was not subjected to intense grinding; and trace (*c*) is that obtained from a sample following intense grinding for 90 s. All spectra were acquired at room temperature with CP at ν_{rot} = 3.0 kHz and B_0 = 4.70 T.

Effect of sample grinding

For solid-state NMR experiments, grinding samples prior to packing in an NMR rotor is common practice. We found that the peaks in the ^{31}P NMR spectra of $AgNO_3{\cdot}PPh_3$ were broadened when the solid sample was ground using a mortar and a pestle (Fig. 5). When the sample was ground mildly, peaks corresponding to phase I were obtained at room temperature, but lowering the temperature resulted in a single site, corresponding to phase II. This behaviour is identical to that observed when spinning the sample at high frequencies, suggesting that the transition is induced by sample heating during grinding. Solid-solid phase transitions induced by grinding have been previously reported (46, 47). In their solid-state NMR investigation of poly(L-alanine) at various temperatures, Wildman et al. (46) attributed a phase transition induced by grinding to mechanical shear forces rather than to sample heating. However, contrary to the results of these studies, more intense grinding of $AgNO_3{\cdot}PPh_3$ gave rise to a broad peak spread between those assigned for phases I and II, with maximum intensity at the resonance frequency of the high-temperature phase (Fig. 5*c*). These broad peaks, suggesting the presence of an amorphous

© 2005 NRC Canada

phase, persist when the sample is cooled. A DSC scan of such a sample indicates that there is no phase transition at the expected temperature (~300 K). A stable amorphous phase induced by grinding for CS-891, a testosterone inhibitor, has been reported (48).

Further investigations of the solid–solid phase transition in $AgNO_3 \cdot PPh_3$

DSC

To investigate the phase transition indicated by the ^{31}P and ^{15}N NMR experiments, DSC measurements were performed. A broad endothermic peak was observed from the DSC scans of natural abundance or perdeuterated $AgNO_3 \cdot PPh_3$, confirming a solid–solid phase transition. This transition was observed at approximately 301 K (onset temperature at 300 K) for $AgNO_3 \cdot PPh_3$ at natural abundance. This is consistent with the observation of two NMR sites in the ^{31}P and ^{15}N NMR spectra of MAS samples acquired at room temperature and with the fact that such a sample spinning at 3.0 kHz is heated to 300 K. DSC measurements on a perdeuterated sample of $AgNO_3 \cdot PPh_3$ also indicate a phase transition, but at a higher temperature, 310 K (onset temperature at 309 K). The higher transition temperature for the perdeuterated sample is attributed to the deuterium isotope effect, and has been observed for many other compounds (49). For example, the hexagonal-to-cubic phase transition for norbornane-d_4 is elevated by 25 K compared to the temperature for this transition in the natural abundance sample (50).

X-ray diffraction

XRD data for $AgNO_3 \cdot PPh_3$ collected on single crystals at 193 and 295 K are given in Tables 1 and 2. These data were collected on the same crystal, but when the temperature was increased to 298 K, the single crystal crumbled. All attempts to grow a single crystal in our laboratory at or above 298 K failed. Hence, the cell parameters were investigated via powder XRD; cell parameters determined by this method at 295 and 313 K are also listed in Table 1. The latter temperature was selected since NMR and DSC experiments indicate that $AgNO_3 \cdot PPh_3$ is definitely in the high-temperature phase at this temperature. Also listed in Tables 1 and 2 are the single-crystal structure data reported by Stein and Knobler (3), collected at 298 K.

Cell parameters determined via powder XRD at 295 K are, within error, in agreement with those determined from a single crystal at the same temperature. Likewise, powder XRD data collected at 313 K are similar to those obtained by Stein and Knobler from their analysis of a single crystal at 298 K (3); small differences between the latter two structures are consistent with changes in cell parameters induced by temperature (51). Both powder and single-crystal XRD data indicate that $AgNO_3 \cdot PPh_3$ exists in the same space group for the two phases, with similar cell parameters apart from a much greater value for the angle β in the high-temperature phase. Both methods also indicate that the high-temperature phase has a lower density, as expected. The structure obtained at 298 K by Stein and Knobler (3) is consistent with the NMR and DSC data obtained for the high-temperature phase previously discussed — the phase-transition temperature obtained via DSC is thought to be slightly elevated, a consequence of super heating (52). However, we can not discount the possibility that these authors obtained the structure for a polymorph of $AgNO_3 \cdot PPh_3$ that we were unable to isolate.

Our X-ray diffraction data for the low-temperature phase indicate that two nitrate anions are in proximity to each silver atom (see Fig. 1). The minor differences in the crystal structures of $AgNO_3 \cdot PPh_3$ obtained at 193 and 295 K (Tables 1 and 2) are consistent with temperature effects on crystal structures (51); there are significant differences, however, between the structure determined at 295 K and that determined at 298 K by Stein and Knobler (3). For example, the Ag—O1 and Ag—O3 bonds are 0.1 Å shorter and 0.4 Å longer, respectively, for the structure obtained in our laboratory. The P-Ag-O and O-Ag-O bond angles are also significantly different in the structures obtained here and in ref. 3. The X-ray diffraction data consistently shows that, regardless of phase, $AgNO_3 \cdot PPh_3$ exists in the space group $P2_1/c$ with four molecules per unit cell. Note that the four molecules in the unit cell are related by symmetry, explaining why single ^{31}P and ^{15}N NMR sites are observed for a single phase of $AgNO_3 \cdot PPh_3$.

Proton spin-lattice relaxation times

While optimizing experimental conditions for the ^{31}P and ^{15}N CP experiments, we noticed that the ^1H T_1s are much longer when $AgNO_3 \cdot PPh_3$ is in phase II rather than in phase I. Values for T_1 were estimated using the progressive saturation technique (22) from $T_1 = -t/\ln(0.5)$ where t was the time preceding the ^1H 90° pulse that gave rise to the peak that had 50% of the maximum intensity; the latter was obtained with $t >> T_1$ (53). This experiment shows that $T_1(I) \approx 65$ s and $T_1(II) \approx 300$ s. The significance of these differences is discussed in the following section.

Deuterium NMR

The phase transition previously discussed, as well as the difference between the ^1H T_1s for $AgNO_3 \cdot PPh_3$ in phases I and II, may be associated with the onset of motion of the phenyl rings of $AgNO_3 \cdot PPh_3$ at elevated temperatures (54). Since solid-state ^2H NMR spectroscopy is a sensitive probe of internal motion (10, 54), the technique has been applied to investigate the phenyl-ring dynamics of compounds such as phenylpropylammonium chloride (55), phenylalanine (56, 57), or the insulin fragment Gly-Phe-Phe (58). Rotation of phenyl rings about its C_{ipso}—P bond can occur either by small-step diffusion or by π flips (54). Both types of rotation are predicted to result in significant changes in the ^2H NMR line shape compared to that expected in the absence of motion. As well, the ^2H NMR line shapes arising from rapid π flips are significantly different from those arising from small-step diffusion (54). To investigate the dynamics of the phenyl rings of $AgNO_3 \cdot PPh_3$, ^2H NMR spectra of a perdeuterated sample were acquired at temperatures ranging from 293 to 364 K. At temperatures below 350 K, the ^2H NMR spectra are typical of those previously observed for rigid phenyl groups (54, 56, 57). Simulation of the line shape indicates that the quadrupolar coupling (C_Q) is 176 ± 5 kHz and that the asymmetry in the electric field gradient (η_Q) is 0.03. A spectrum obtained at 364 K contains small

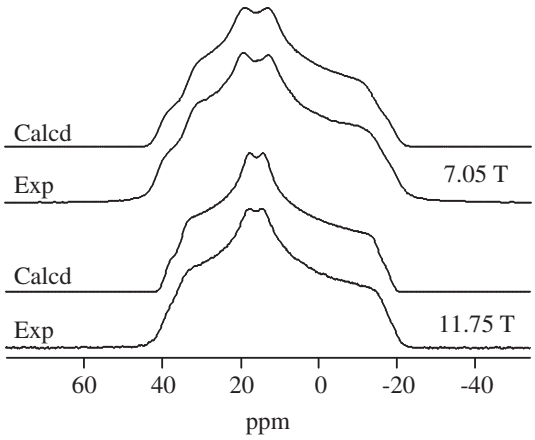
[a] $\Delta^{31}P(^{2/1}H) = \delta_{iso}[AgNO_3{\cdot}^{31}P(C_6D_5)_3] - \delta_{iso}[AgNO_3{\cdot}^{31}P(C_6H_5)_3]$.

inner singularities with a splitting of 32 kHz, consistent with the onset of π flips about the P—C_{ipso} bond (54).

DSC measurements indicate that a phase transition occurs at approximately 310 K for perdeuterated $AgNO_3{\cdot}PPh_3$, and the ^{1}H T_1s are very different for phases I and II. The much shorter ^{1}H T_1 value for phase I is probably a consequence of motion of the phenyl groups, yet there is no indication of significant motion of the phenyl rings from the ^{2}H NMR line shapes obtained near the phase-transition temperature. Small-angle torsional oscillations about the P—C_{ipso} bond may result in shorter ^{1}H T_1 values, but this motion would be difficult to detect by ^{2}H NMR (54). As well, it is possible that the phenyl rings do undergo π flips about the P—C_{ipso} bond, but on a timescale that is significantly greater than C_Q^{-1}, approximately 5×10^{-6} s (54).



Characterization of phosphorus and nitrogen chemical shift (CS) tensors

Phosphorus CS tensors

Phosphorus-31 NMR spectra of a stationary sample of the low- and high-temperature phases of $AgNO_3{\cdot}PPh_3$ were acquired at room temperature at B_0 = 4.7, 7.05, and 11.75 T. Spectra obtained for the low-temperature phase are shown in Fig. 6; those for the high-temperature phase are similar. In the absence of external heat sources, such as that arising from MAS, transitions from phases I to II occur very slowly at 295 K. Hence, spectra for both phases were acquired at this temperature after the sample had been either heated or cooled overnight to obtain the desired phase; to verify that only one phase was contributing to the given spectrum, spectra of MAS samples (ν_{rot} = 1.5 kHz) were acquired immediately before and after acquisition of the spectra of stationary samples.

The line shapes of the ^{31}P NMR spectra (Fig. 6) arise from the anisotropy in the magnetic shielding, as well at the direct and indirect $^{107/109}$Ag–P spin-spin interactions, R_{DD} and J_{iso}, respectively (10, 59). Seven independent parameters must be determined to describe these spectra (10, 60–62): the three principal components of the CS tensor, two

Fig. 6. Experimental and calculated ^{31}P NMR spectra of a stationary sample of phase II of $AgNO_3{\cdot}PPh_3$, acquired at 295 K. Fifty-eight and sixty-eight transients, respectively, were added for spectra acquired at 7.05 and 11.75 T.

polar angles describing the orientation of the dipolar vector in the principal axis system of the CS tensor, as well as the $^{107/109}$Ag,^{31}P direct and indirect spin-spin coupling constants. Values for δ_{iso} and J_{iso} were determined from spectra of MAS samples and R_{DD} was estimated (59) from the Ag—P bond length determined at 295 and 298 K (3) (Table 2). The remaining four parameters were determined by simulation of the NMR spectra of stationary samples; spectra were obtained at more than one applied magnetic field to ensure that spectral features were properly assigned (10). The phosphorus CS tensor data for each phase, derived from the simulations, are given in Table 3. The orientation dependence of the dipolar interaction (59) yields θ_{ii} (i = 1, 2, or 3), the angle formed by the CS tensor component δ_{ii} with the Ag—P bond (62–65). However, calculated line shapes are invariant to rotation of the CS tensor about the dipolar vector, since in such cases the angles formed by the tensor components with the dipolar vector are unchanged. Hence, experimentally one determines the orientation of the tensor components relative

© 2005 NRC Canada

to the dipolar vector, but not the orientation of the CS tensor in the molecular framework. The θ_{ii}, listed in Table 3, indicate that the principal components of the phosphorus CS tensors for $AgNO_3{\cdot}PPh_3$ in phases I or II approximately straddle the Ag—P bond.

Comparison of the phosphorus CS tensor principal components for $AgNO_3{\cdot}PPh_3$ with those for triphenylphosphine (PPh_3) suggests that coordination of the PPh_3 ligand with silver nitrate has a moderate effect on the phosphorus CS tensor. That for triphenylphosphine is axially symmetric with $\delta_{11} = \delta_{22} = 9$ ppm and $\delta_{33} = -42$ ppm; the latter component is along the C_3 symmetry axis (66). The nonaxial symmetry of the phosphorus CS tensor for $AgNO_3{\cdot}PPh_3$ is a consequence of the nonsymmetrical environment about the phosphorus nucleus of $AgNO_3{\cdot}PPh_3$. A direct comparison of the CS tensor components would require knowledge of the CS tensor orientation for $AgNO_3{\cdot}PPh_3$, but the shielding clearly has not undergone a large change upon coordination of PPh_3 with Ag. For example, the spans and isotropic values for the phosphorus CS tensors for PPh_3 and $AgNO_3{\cdot}PPh_3$ are similar. This is in contrast to numerous ^{31}P NMR studies of phosphorus–metal complexes (67) that indicate that the phosphorus nucleus is sensitive to metal coordination (27, 68, 69). For example, the three phosphorus CS tensors for the PPh_3 groups of $Rh(PPh_3)_3Cl$ are distinct, with spans ranging from 150 to 271 ppm (70), compared to a span of 51 ppm for triphenyl phosphine (66).

Nitrogen CS tensors

The nitrogen CS tensor data for the two phases of $AgNO_3{\cdot}PPh_3$ obtained from analyses of ^{15}N NMR spectra for stationary samples (not shown) are summarized in Table 4. The principal components of the nitrogen CS tensors for the two phases are similar, although the span is greater and the skew is less for phase II than for phase I. Because of the small values of $R(^{107/109}Ag,^{15}N)$, we are unable to determine orientations for the principal components of the nitrogen CS tensors relative to the dipolar vector, but previous NMR studies and first-principles calculations indicate that nitrogen CS tensors for nitrates are axially symmetric with the direction of greatest shielding perpendicular to the plane of the anion (33, 71, 72). The nitrogen CS tensor principal components for $AgNO_3{\cdot}PPh_3$ are similar to those for the nitrogen nucleus of silver nitrate (71) and for other nitrates (33, 67, 72). This insensitivity of the nitrogen shielding tensor to coordination with silver is not surprising, since the nitrogen atom is not directly involved in coordination with Ag. The nonaxial symmetry observed here is a consequence of the nonsymmetric environment about the nitrogen atom of $AgNO_3{\cdot}PPh_3$.

Conclusions

In this study we have found that two ^{31}P NMR sites with variable relative intensities in high-resolution ^{31}P NMR spectra of solid silver nitrate triphenylphoshine at ambient temperature are a consequence of a solid–solid phase transition at 299 ± 2 K. This phase transition has been confirmed by multinuclear magnetic resonance measurements, DSC, and X-ray diffraction. There are only minor differences in the crystal structures determined by X-ray diffraction experiments conducted at 193 and 295 K, both of which correspond to phase II. Powder XRD data for phase I, obtained at 313 K, are consistent with the structure reported by Stein and Knobler (3); this structure is significantly different from that obtained at 295 K. In the course of our study we characterized nitrogen and phosphorus chemical shift tensors for $AgNO_3{\cdot}PPh_3$ in both solid phases. In the ^{31}P and ^{15}N NMR spectra, the NMR signals arising from the low-temperature phase are more shielded than those for the high-temperature phase. The proton T_1s are longer when $AgNO_3{\cdot}PPh_3$ is in phase II rather than phase I. Although the shorter T_1 for the former must be a consequence of motion of the phenyl rings at the higher temperature, this motion is not directly evident from the ^2H NMR line shapes. Replacement of the phenyl group hydrogen atoms by deuterium results in a 0.8 ppm shift to low frequency in the ^{31}P NMR peaks. Finally, we noticed that grinding samples of $AgNO_3{\cdot}PPh_3$ may cause line broadening in solid-state NMR spectra, apparently because of the formation of an amorphous phase, which persists over a long period of time and over a range of temperatures.[5]

This work has shown that many factors, such as temperature and sample preparation, must be considered when studying transition-metal complexes. The ability to obtain pure phases of $AgNO_3{\cdot}PPh_3$ through the selection of the appropriate temperature has been demonstrated.

Table 4. Nitrogen chemical shift tensor parameters for phases I and II of silver nitrate triphenylphosphine.

Parameter	Phase I	Phase II
δ_{11} (ppm)	449±0.5	457±0.5
δ_{22} (ppm)	438±0.6	434±0.6
δ_{33} (ppm)	249±0.5	242±0.5
δ_{iso} (ppm)	379±0.2	377±0.2
Ω (ppm)	200±1	215±1
κ	0.89±0.02	0.79±0.02

Note: Spectra for both phases were obtained at room temperature, see text.

Addendum

Since submitting this manuscript, Xu and Harris (73) reported the observation of a solid–solid phase transition in sodium acetate induced by magic angle spinning.

The detrimental effect of orotic acid substitution in the peptide nucleic acid strand on the stability of PNA_2:NA triple helices

Robert H.E. Hudson and Filip Wojciechowski

Abstract: We have investigated the incorporation of C6 derivatives of uracil into polypyrimidine peptide nucleic acid oligomers. Starting with uracil-6-carboxylic acid (orotic acid), a peptide nucleic acid monomer compatible with Fmoc-based synthesis was prepared. This monomer then served as a convertible nucleobase whereupon treatment of the resin-bound methyl orotate containing hexamers with hydroxide or amines cleanly converted the ester to an orotic acid or orotamide-containing peptide nucleic acid. Peptide nucleic acid hexamers containing the C6-modified nucleobase hybridized to both poly(riboadenylic acid) and poly(deoxyriboadenylic acid) via triplex formation. Complexes formed with poly(riboadenylic acid) were more stable than those formed with poly(dexoyriboadenylic acid), as measured by temperature-dependent UV spectroscopy. However, both of these complexes were destabilized relative to the complexes formed by an unmodified peptide nucleic acid oligomers. Internal or doubly substituted hexamers are destabilized more strongly than a terminally substituted one, and the type of substitution (carboxamide, ester, carboxylic acid) affects the overall triplex stability. These results clearly show that incorporation of a C6-substituted uracil into polypyrimidine PNA is detrimental to triplex formation. We have also extended this chemistry to incorporate uracil-5-methylcarboxylate into a peptide nucleic acid hexamer. After on-resin conversion of the C5 ester to the 3-(*N*,*N*-dimethylamino)propylamide, significant stabilization of the triplex formed with poly(riboadenylic acid) was observed, which illustrates the compatibility of C5 substitution with peptide nucleic acid directed triple helix formation.

Key words: peptide nucleic acid, triple helix, orotic acid, orotamide, PNA.

Résumé : On a étudié l'incorporation de dérivés en C6 de l'uracile dans la polypyrimidine, des oligomères du peptide de l'acide nucléique. Utilisant l'acide uracile-6-carboxylique (acide orotique) comme produit de départ, on a préparé un monomère compatible avec une synthèse à base de dérivés Fmoc. Ce monomère a ensuite été utilisé comme nucléobase convertible qui, par traitement des hexamères contenant de l'orotate de méthyle lié à une résine de l'hydroxyde ou par des amines, conduit à la formation propre d'un peptide de l'acide nucléique qui contient de l'acide orotique ou un orotamide. Les peptides d'hexamères contenant de la nucléobase modifiée par un dérivé en C6 donnent, par le biais de la formation d'un triplex, une hybridisation tant avec l'acide poly(riboadénylique) qu'avec l'acide poly(désoxyriboadénylique). Sur la base des résultats de spectroscopie UV mesurés en fonction de la température, on a observé que les complexes formés à partir de l'acide poly(riboadénylique) sont plus stables que ceux formés à partir de l'acide poly(désoxyriboadénylique). Toutefois, ces deux complexes sont déstabilisés par rapport aux complexes formés à partir d'oligomères non modifiés du peptide de l'acide nucléique. Les hexamères internes ou doublement substitués sont encore plus déstabilisés que les hexamères substitués en position terminale; de plus, le type de substitution (carboxamide, ester ou acide carboxylique) affecte aussi la stabilité globale du triplex. Ces résultats montrent clairement que l'incorporation d'uraciles substitués en C6 dans une polypyrimidine de l'acide polynucléique est nuisible à la formation de triplex. On a aussi étendu cette chimie à l'introduction d'un uracile 5-carboxylate de méthyle dans un peptide hexamère de l'acide nucléique. Après une conversion sur la résine de l'ester en position C5 en un 3-(*N*,*N*-diméthylamino)propylamide, on a observé une stabilisation importante du triplex formé avec de l'acide poly(riboadénylique); ce qui illustre la compatibilité d'une substitution en C5 avec un peptide de l'acide nucléique en vue de former une hélice triple.

Mots clés : peptide de l'acide nucléique, triple hélice, acide orotique, orotamide, acide polynucléique.

Introduction

Modified nucleobases have been intensively studied in the field of nucleic acids (NAs) for a plethora of reasons (reviewed in 1, 2). Inclusion of modified nucleobases in RNA and DNA provides a route to modulation of the hybridization properties (stability, selectivity), artificial expansion of the genetic code, incorporation of reporter groups, inclusion of reactive sites for conjugation or further chemistry, and the ability to undertake fundamental studies on the forces stabilizing nucleic acid complexes, to name but a few current areas of interest. The study of modified or unnatural nucleobases combined with oligonucleotide analogues containing backbone structural alterations is a less well-developed area (3). However, the intersection of these two types of modifications is fertile ground, in general, for the synthesis and investigation of oligomers with tunable properties.

In some of our previous work, we have exploited established chemistry to incorporate modified nucleobases into peptide nucleic acid (PNA) (4). Peptide nucleic acid is an oligonucleotide mimic based on a polyamide backbone, which is structurally compatible with the formation of helical complexes with natural DNA or RNA (Fig. 1) (5). Due to its modular nature, it is relatively straightforward to incorporate modifications into the *N*-(2-aminoethyl)glycine backbone, the methylene carbonyl linker, or the nucleobase, either separately or in concert. Thus, the first generation of peptide nucleic acid is a convenient scaffold for surveying the effects of changes in these portions of the molecule. Modification of the nucleobases has the advantage of being able to introduce a diversity of functional groups (e.g., charged, hydrophilic, lipophilic) or sites for conjugation or further chemistry that do not interfere with the base-pairing face. Additionally, nucleobase modifications can be done without introducing chirality. Avoiding changing any of the $-CH_2-$ groups in the backbone and linker region is key to a modification that circumvents the additional synthetic complexity, challenges to maintaining the integrity of the chiral center during synthesis/deprotection, and possible consequences to hybridization (6).

The introduction of modified nucleobases into oligonucleotides usually involves time-consuming and laborious synthesis of a variety of individual nucleobase-modified monomers each requiring a multistep synthesis. A clever solution to this drawback is to perform a post-synthetic step on an oligomer containing a convertible nucleobase (7). Herein, we describe the efficient synthesis of a methyl orotate (MO) PNA monomer, its smooth incorporation into an oligomer and straightforward on-resin derivatization to various oligomers. To our knowledge orotic acid or orotamides have not been incorporated into oligonucleotides, therefore their effects on PNA cannot be predicted by analogy. To gain some insight on the possible consequences of exchanging a thymine nucleobase for an orotic acid derivative, a qualitative molecular modeling exercise was undertaken. Working from existing structural information, the modeling suggested each of PNA:DNA duplexes (8), PNA:RNA duplexes (9), and

Fig. 1. Structures of DNA and PNA.

PNA_2:DNA triple helical complexes (10) could possibly accommodate C6 substitution, although each structure showed some deformation from the starting conformation.[2] Given the plasticity of PNA conformations, we decided to experimentally investigate all three types of complexes, and the results for triple helices are reported herein. As a point of comparison, we have also prepared an oligomer possessing a carboxamide substitution at C5 of uracil. In DNA chemistry, substituents at the C5 position of uracil are known to occupy the major grove and are generally tolerated (2).

Experimental

General

All chemicals were obtained from commercial sources and were of ACS reagent grade or higher and were used without further purification, unless noted. Solvents for solution-phase chemistry were obtained from Caledon Laboratories Ltd. (Georgetown, Ontario) and were dried by passing through columns packed with activated alumina (Innovative Technology, Inc., Newburyport, Massachusetts). Reagents for peptide synthesis were obtained from NovaBiochem (San Diego, California) and synthesis grade solvent from Caledon Laboratories. ^{1}H NMR spectra were recorded at 400.085 MHz and chemical shifts were referenced to the residual proton of the deuterated solvent, and ^{13}C NMR spectra were recorded at 100.609 MHz were referenced to the ^{13}C NMR signal of the solvent used. The reported melting points are uncorrected.

Methyl orotate (2)

Orotic acid monohydrate (24.0 g, 138 mmol) was suspended in methanol (3.0 L) and HCl gas (60 g) was bubbled into the suspension. Reflux was maintained for 24 h after which time the suspension had cleared. The volume was reduced by two-thirds, and cooled for 5 h below 0 °C. The white crystals were collected by filtration and washed with cold methanol to yield 21.3 g (91%). TLC (EtOAc–MeOH, 80:20): R_f 0.58; mp 249–251 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.40 (s, 1H), 11.16 (s, 1H), 6.03 (s, 1H), 3.83 (s, 3H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 163.5, 160.5, 150.5, 141.1, 103.5, 53.4.

[2] HyperChem 5.1 was used to modify a central thymine or uracil nucleobase in a trimer that was excised from existing structures. The nucleobase was modified to possess a 6-carboxamide group and was geometrically optimized using the MM+ force field, while the remainder of the structure was held fixed.

***tert*-Butyl (methyl orotate-1-yl)acetate (3)**

Methyl orotate (18.9 g, 111.0 mmol) was suspended in dry DMF (600 mL) and K_2CO_3 (15.34 g, 111.0 mmol) was added and the mixture was stirred under N_2 at room temperature for 30 min. *tert*-Butyl bromoacetate (18.0 mL, 122.0 mmol) was added dropwise over 1 h and the suspension was vigorously stirred for 48 h under an atmosphere of nitrogen. The mixture was filtered and solvent removed in vacuo, the residue was extracted with ethyl acetate (4 × 250 mL) and water (100 mL). The combined organic phase was washed with brine, dried (Na_2SO_4), filtered, and concentrated in vacuo. The material contained a small amount of dialkylated product, which could be removed by recrystallization from absolute ethanol to yield 19.3 g (61%) of a white solid. TLC (EtOAc–MeOH, 90:10): R_f 0.76; mp 186–188 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.85 (s, 1H), 6.13 (s, 1H), 4.60 (s, 2H), 3.80 (s, 3H), 1.40 (s, 9H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 167.1, 162.2, 161.5, 151.0, 143.8, 105.6, 81.8, 53.7, 46.2, 27.6. HR-MS (EI) calcd. for $C_{12}H_{16}N_2O_6$: 284.1009; found: 284.1009.

(Methyl orotate-1-yl)acetic acid (4)

Compound **3** (7.0 g, 24.6 mmol) was suspended in 80 mL of CH_2Cl_2 and cooled to 0 °C, the mixture was stirred under nitrogen, and Et_3SiH (3.9 mL, 24.4 mmol) was added. TFA (80 mL) was added dropwise over 30 min, with stirring under nitrogen. The solution was stirred for 1 h while in an ice bath and then allowed to warm to room temperature for 3 h. The mixture was evaporated to dryness in vacuo and the remaining volatiles were removed by successive co-evaporations with CH_2Cl_2 (3×) and diethyl ether (1×). The white solid was triturated with a mixture of 30 mL of CH_2Cl_2 and 60 mL of diethyl ether and cooled below 0 °C for 12 h; filtration gave 5.04 g (89%) of a white solid. TLC (EtOAc–MeOH–AcOH, 80:15:5): R_f 0.35; mp 206 to 207 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.84 (s, 1H), 6.13 (s, 1H), 4.62 (s, 2H), 3.80 (s, 3H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 169.6, 162.3, 161.6, 151.5, 144.0, 105.5, 53.70, 45.8. HR-MS (EI) calcd. for $C_{12}H_8N_2O_6$: 228.0382; found: 228.0377.

***tert*-Butyl *N*-[2-Fmoc-aminoethyl]-*N*-[(methyl orotate-1-yl)acetyl]glycinate (5)**

Compound **4** (4.0 g, 17.5 mmol) and HOBt hydrate (2.68 g, 17.53 mmol) were dissolved in 20 mL DMF and stirred for 10 min while kept under a nitrogen atmosphere. DCC (3.61 g, 17.5 mmol) was added and the mixture was stirred on ice for 30 min. The free Fmoc-backbone *tert*-butyl ester (**2**) (6.95 g, 17.53 mmol) was dissolved in 5 mL CH_2Cl_2 and added to the mixture. The reaction mixture was stirred for 24 h at room temperature, extracted with EtOAc (4 × 150 mL) and phosphate buffer (pH ~ 4.5, 2 × 50 mL), and the combined organic phase was washed with sodium bicarbonate (2 × 50 mL) and brine (50 mL), dried (Na_2SO_4), filtered, and concentrated in vacuo. The solid was recrystallized from a mixture of 10 mL of MeOH and 25 mL of isopropanol, and isolated by filtration to give 7.44 g (70%) of a white solid. TLC (EtOAc–MeOH, 90:10): R_f 0.74; mp (dec.) 171–173 °C. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 11.79 (br s, 1H), 7.88 (d, 2H, J = 7.4 Hz), 7.66 (d, 2H, J = 6.9 Hz), 7.40 (t, 2H, J = 7.3 Hz), 7.31 (t, 2H, J = 7.5 Hz), 6.09 (br s, 1H), 5.05 (s, ma., 1.2H) and 4.86 (s, mi., 0.8H), 4.36–4.18 (m) and 3.90 (s, ma.) (5H), 3.75 (s, 3H), 3.39–3.07 (m, 4H). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 167.9, 167.4, 162.2, 161.6, 156.3, 151.1, 144.7, 143.9, 140.8, 127.6, 127.1, 125.1, 120.1, 80.9, 65.5, 53.5, 48.9, 46.8, 44.6, 41.8, 27.7. HR-MS (ESI-TOF) calcd. for sodium adduct $C_{31}H_{34}N_4O_9Na$: 629.2225; found: 629.2217.

***N*-[2-Fmoc-aminoethyl]-*N*-[(methyl orotate-1-yl)acetyl]glycine (6)**

Compound **5** (5.20 g, 8.57 mmol) was suspended in 30 mL of CH_2Cl_2 and cooled to 0 °C and the mixture was stirred under nitrogen, and Et_3SiH (1.37 mL, 8.57 mmol) was added. TFA (30 mL) was added dropwise over 30 min while stirring on ice under an atmosphere of nitrogen. The solution was stirred for an additional hour while in the ice bath and then allowed to warm to room temperature while stirring was continued for an additional 4 h, after which TLC analysis showed complete consumption of the starting material. The mixture was evaporated to dryness in vacuo and the remaining volatiles were removed by repeated co-evaporation with CH_2Cl_2 and diethyl ether. The white solid was triturated with a mixture of 30 mL of CH_2Cl_2 and 60 mL of diethyl ether and cooled below 0 °C for 12 h. The product was isolated by filtration to give 3.87 g (82%) of a white solid. TLC (EtOAc–MeOH–AcOH, 80:15:5): R_f 0.30; mp (dec.) 157 to 158 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.81 (br s, 1H), 7.89 (d, 2H, J = 7.4 Hz), 7.66 (d, 2H, J = 6.8 Hz), 7.40 (t, 2H, J = 7.4 Hz), 7.32 (t, 2H, J = 7.4 Hz), 6.07 (br s, 1H), 5.05 (s, ma., 1.2H) and 4.86 (s, mi., 0.8H), 4.34–4.20 (m) and 3.93 (s, ma.) (5H), 3.74 (s, 3H), 3.37–3.08 (m, 4H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 170.4, 167.4, 162.3, 161.7, 156.5, 151.2, 144.8, 144.0, 140.8, 127.7, 127.1, 125.2, 120.2, 105.2, 65.6, 53.6, 48.0, 47.1, 46.8, 45.0, 44.6. HR-MS (ESI-TOF) calcd. for sodium adduct $C_{27}H_{26}N_4O_9Na$: 573.1599; found: 573.1595.

5-Hydroxymethyluracil (7)

Triethylamine (42.0 mL, 0.30 mol) was added to a suspension of uracil (22.4 g, 0.20 mol) and paraformaldehyde (18.0 g, 0.60 mol) in 600 mL of water. The solution turned clear when heated to 65 °C and was allowed to stir for 12 h at 65 °C. The water was removed under vacuum until approximately 50 mL of volume remained. To the residue was added 60 mL of 95% ethanol and the solution was allowed to stand for 30 min at room temperature and further cooled at 4 °C. The white precipitate was collected by filtration and was washed with 95% ethanol. The procedure of concentrating the filtrate and precipitation with 95% ethanol was repeated three times and the combined mass was 25.3 g (89%) of a white solid. TLC ($CHCl_3$–MeOH, 80:20): R_f 0.15; mp (dec.) 360 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.06 (s, 1H), 10.71 (s, 1H), 7.23 (s, 1H), 4.84 (s, 1H), 4.08 (s, 2H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 163.0, 151.5, 138.5, 112.8, 56.0.

5-Formyluracil (8)

Hydroxymethyluracil (21.50 g, 151.30 mmol) was dissolved in 800 mL of water by heating to approximately 90 °C. The solution was then cooled to 45 °C, $K_2S_2O_8$ (75.0 g, 277.4 mmol) and $AgNO_3$ (0.80 g, 4.71 mmol) were

© 2005 NRC Canada

added, and the product began to slowly precipitate. The reaction was stirred for a further 20 min at 40 °C and then cooled to room temperature over 15 min while stirring was continued. The suspension was then placed at 4 °C, the off-white crystals were collected by filtration, and rinsed with 50 mL of cold water to yield 17.65 g (83%) of the title compound; mp 302–304 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.89 (s, 1H), 11.49 (s, 1H), 9.72 (s, 1H), 8.12 (s, 1H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 186.8, 162.6, 150.6, 149.4, 110.2.

Uracil-5-carboxylic acid (9)

5-Formyluracil (4.30 g, 30.70 mmol) was dissolved in 350 mL of water by heating to reflux. To this solution was added $K_2S_2O_8$ (8.30 g, 30.70 mmol) and $AgNO_3$ (50 mg, 0.29 mmol), and the reaction was stirred while cooling to 65 °C over 30 min. A precipitate formed upon concentrating the volume to 50 mL. This mixture was cooled to 4 °C to promote the precipitation, and the product was subsequently collected by filtration. The title compound was purified by suspending it in 125 mL of water, adding 4 mol/L NaOH until a clear solution was obtained, and reprecipitating the compound by dropwise addition of concd. HCl until pH 2.0. Cooling the mixture to 4 °C followed by filtration yielded 3.34 g (70%) of a white solid; mp (dec.) 286–288 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 12.73 (s, 1H), 11.99 (s, 2H), 8.25 (s, 1H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 165.2, 163.5, 150.4, 150.2, 101.2.

Uracil-5-methylcarboxylate (10)

Uracil-5-carboxylic acid (2.50 g, 16.00 mmol) was suspended in methanol (150 mL) and HCl gas was bubbled into the suspension. The HCl was generated by the dropwise combination of 40 mL of concd. H_2SO_4 and 40 mL of concd. HCl. Once the mixture was saturated with HCl, it was refluxed for 12 h and then the solvent was removed in vacuo. The product was then recystallized from methanol to yield 2.34 g (86%) of a white solid. TLC (EtOAc–MeOH, 90:10): R_f 0.52; mp (dec.) 267 to 268 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.61 (s, 1H), 11.31 (s, 1H), 8.12 (s, 1H), 3.67 (s, 3H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 163.2, 160.1, 150.6, 149.7, 102.9, 51.4. HR-MS (EI) calcd. for $C_6H_6N_2O_4$: 170.0328; found: 170.0324.

***tert*-Butyl (uracil-5-methylcarboxylate-1-yl)acetate (11)**

Uracil-5-methylcarboxylate (2.06 g, 12.11 mmol) was dissolved in dry DMF (40 mL), and K_2CO_3 (1.67 g, 12.11 mmol) was added. *tert*-Butyl bromoacetate (1.79 mL, 12.11 mmol) was added dropwise to the stirred mixture and stirring was continued for 24 h while the reaction mixture was kept under an atmosphere of nitrogen. The reaction mixture was filtered to remove the undissolved potassium carbonate and then the solvent was removed in vacuo. The residue was extracted with ethyl acetate (3 × 75 mL) and water (25 mL). The combined organic layers were then washed with brine, dried (Na_2SO_4), filtered, and concentrated in vacuo. The crude product was recrystallized from methanol to yield 2.14 g (62%) of a white solid. TLC (EtOAc–MeOH, 90:10): R_f 0.71; mp 179 to 180 °C. ^{1}H NMR (400 MHz, $CHCl_3$, ppm) δ: 8.69 (s, 1H), 8.19 (s, 1H), 4.43 (s, 2H), 3.86 (s, 3H), 1.47 (s, 9H). ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.79 (s, 1H), 8.59 (s, 1H), 4.53 (s, 2H), 3.71 (s, 3H), 1.40 (s, 9H). ^{13}C NMR (100 MHz, $CHCl_3$, ppm) δ: 165.6, 163.2, 158.8, 152.3, 149.6, 105.3, 84.1, 52.5, 49.9, 28.0. HR-MS (EI) calcd. for $C_{12}H_{16}N_2O_6$: 284.1009; found: 284.1009.

(Uracil-5-methylcarboxylate-1-yl)acetic acid (12)

Compound **11** (1.61 g, 5.66 mmol) and Et_3SiH (0.75 mL, 4.70 mmol) were suspended in 20 mL DCM, cooled to 0 °C, and 15 mL of TFA was added dropwise. The reaction was stirred for 1 h on ice and an additional 2.5 h at room temperature. The mixture was evaporated to dryness in vacuo and the remaining volatiles were removed by co-evaporation with CH_2Cl_2 and diethyl ether. The compound was triturated with a mixture of approximately 5 mL of CH_2Cl_2 and 80 mL of diethyl ether and cooled to 0 °C overnight. Filtration and drying under vacuum gave 1.22 g (94%) of a white solid. TLC (EtOAc–MeOH–AcOH, 80:15:5): R_f 0.16; mp 227–229 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 11.68 (s, 1H), 8.59 (s, 1H), 4.55 (s, 2H), 3.70 (s, 3H). ^{13}C NMR (100 MHz, $CHCl_3$, ppm) δ: 169.2, 163.0, 159.5, 153.4, 150.2, 103.4, 51.6, 49.2. HR-MS (EI) calcd. for $C_{12}H_8N_2O_6$: 228.0382; found: 228.0375.

***tert*-Butyl *N*-[2-Fmoc-aminoethyl]-*N*-[(uracil-5-methylcarboxylate-1-yl)acetyl]glycinate (13)**

Compound **12** (0.210 g, 0.92 mmol), HOBt hydrate (0.141 g, 0.92 mmol), and DCC (0.190 g, 0.92 mmol) were dissolved in 3 mL of DMF and stirred under nitrogen for 15 min. The free amine form of the Fmoc-backbone *tert*-butyl ester (0.365 g, 0.92 mmol) was dissolved in a minimal amount of DMF and added to the mixture along with Hünings base (0.169 mL, 0.97 mmol). The reaction was stirred for 24 h at room temperature and extracted with EtOAc, sodium bicarbonate, phosphate buffer (pH ~ 4.5), and brine. The combined organic phases were dried (Na_2SO_4), filtered, and concentrated in vacuo. The solid was purified by flash chromatography (DCM–MeOH gradient) to yield 0.298 g (55%) of a white solid. TLC (EtOAc–MeOH, 90:10): R_f 0.67; mp (dec.) 135–137 °C. ^{1}H NMR (400 MHz, DMSO, ppm) δ: 8.43 (s, ma., 0.6H), 8.34 (s, mi., 0.4H), 7.89 (d, 2H, J = 7.4 Hz), 7.68 (m, 2H), 7.40 (t, 2H, J = 7.4 Hz), 7.32 (t, 2H, J = 7.4 Hz), 7.24 (m, 1H), 4.85 (s, ma., 1.2H) and 4.86 (s, mi., 0.8H), 4.34–4.16 (m) and 3.98 (s, ma.) (5H), 3.68 (s, 3H), 3.28–3.02 (m, 4H). ^{13}C NMR (100 MHz, DMSO, ppm) δ: 167.9, 166.8, 163.0, 159.5, 156.1, 153.7, 150.1, 143.9, 140.8, 127.6, 127.1, 125.1, 120.1, 103.2, 81.0, 65.5, 51.5, 50.0, 48.8, 48.3, 46.7, 27.7. HR-MS (ESI-TOF) calcd. for sodium adduct $C_{31}H_{34}N_4O_9Na$: 629.2225; found: 629.2254.

***N*-[2-Fmoc-aminoethyl]-*N*-[(uracil-5-methylcarboxylate-1-yl)acetyl]glycine (14)**

Compound **13** (0.250 g, 0.41 mmol) and Et_3SiH (59.0 uL, 0.37 mmol) were suspended in 2 mL DCM, cooled to 0 °C, 3 mL of TFA was added dropwise, and the reaction was stirred for 1 h in an ice bath and 2.0 h at room temperature. The mixture was evaporated to dryness in vacuo and the remaining volatiles were removed by co-evaporation sequentially with CH_2Cl_2 and diethyl ether. The solid was slurried in CH_2Cl_2–diethyl ether, cooled to 0 °C for 12 h, and subse-

Synthesis of PNA oligomers

PNA hexamers were synthesized on a 5 or 10 μmol scale using the standard FastMoc module on an Applied Biosystems 433A synthesizer employing NovaSyn TGR (Rink amide) resin.

Cleavage from resin

To 6 mg (~1 μmol) of the appropriate resin-bound oligomer (**8**–**10**), in a peptide vessel, was added a 1 mL solution containing ice-cold TFA–Et_3SiH (0.975:0.025), the vessel was purged with nitrogen and the mixture was shaken for 2 h. The solution was emptied into a 5 mL flask and the resin was rinsed with 0.5 mL of TFA. The combined TFA was evaporated with a stream of nitrogen and 3 mL of cold ether was added. Upon 1 h of cooling, the ether was decanted and a white precipitate was collected. The solid was dissolved in 0.1% TFA–H_2O, filtered, and purified under RP-HPLC.

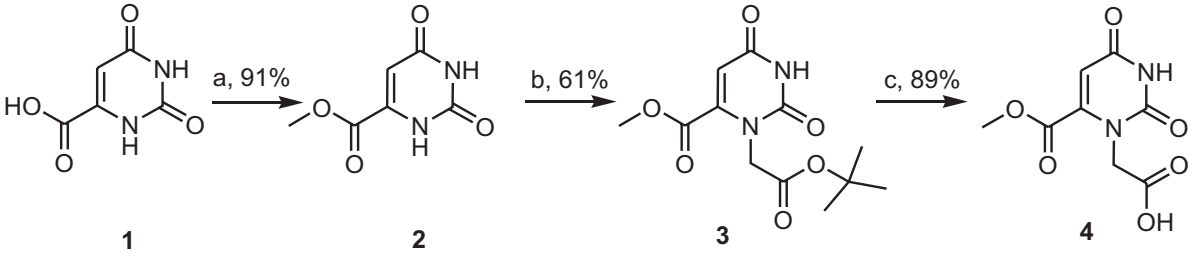
Hydrolysis of methyl orotate oligomers

To 6 mg (~1 μmol) of the appropriate resin-bound oligomer (**8**–**10**), in a microfuge tube (Eppendorf), was added 50 μL of THF and 100 μL of 1 mol/L NaOH. The tubes were allowed to stand for 30 min and heated to 50 °C for a further 30 min. The resin was transferred to a peptide vessel, rinsed with H_2O, THF, and DCM. The resin was dried in vacuo and cleavage and release of the orotic-acid-containing oligomers was performed as previously described.

On resin aminolysis of oligomers containing C5 or C6 esters

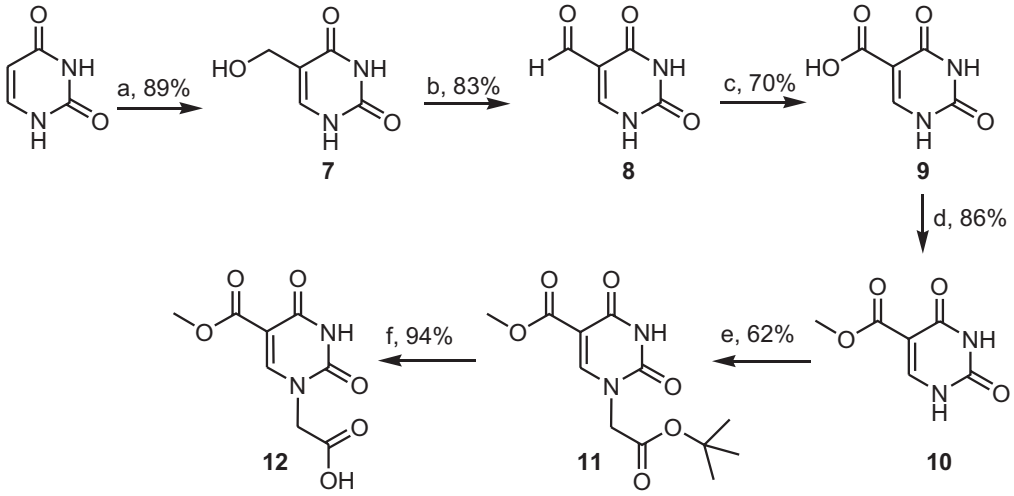
To 6 mg (~1 μmol) of the appropriate resin bound oligomer (**1**–**3**, **19**), in a glass vial, was added 1 mL of the appropriate amine, the vial was purged with nitrogen, capped and allowed to stir for 6 h at 55 °C. The resin was transferred to a peptide vessel and rinsed with DCM. Cleavage and release of the orotamide-containing oligomers was performed as previously described.

Purification of PNAs



Crude PNA, isolated as previously described, was redissolved in 0.1% TFA in water (approximately 4 mg/mL) and purified by reversed phase HPLC using a 250 mm × 4.6 mm, C18-bonded phase, 100 pore, 5 μm particle size column. A binary gradient elution was used 0–5 min, 100% A; 5–20 min, 100% to 80% A; 20–40 min, 80% to 70% A, wherein solvent A is 0.1% TFA in water and solvent B is 0.1% TFA in MeCN.

Characterization of base-modified PNAs



Mass spectral analysis of oligomers was done at the Dr. Don Rix Protein Identification and UWO Biological Mass Spectrometry Laboratory. Electrospray ionization time-of-flight mass spectrometry (ESI-TOF MS) was done with mass calibration provided by Glu-fibrinopeptide 1 (m/z (+2) = 785.842, monoisotopic mass), myoglobin (M^+ = 16951.499, average mass), or histatin 5 (M^+ = 3034.515, monoisotopic mass). Matrix-asisisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) was performed using α-cyano-4-hydroxycinnamic acid as the matrix, and calibration for monoisotopic masses was provided by angio-

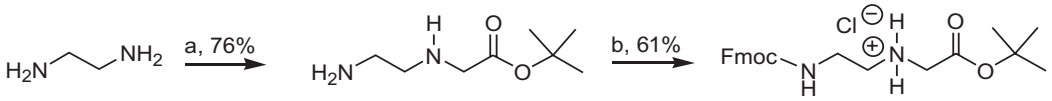
Binding analysis

Poly(riboadenylic acid) (poly(rA)) and poly(deoxyriboadenylic acid) (poly(dA)) were purchased from Sigma (Milwaukee, Wisconsin). Thermal denaturation of PNA:NA complexes (~2 μmol/L in nucleobases) were measured at 260 nm with a temperature ramp of 0.5 °C/min. A minimum of two independent samples were run in triplicate and the T_m was estimated by the first derivative method. Identical ionic conditions (150 mmol/L NaCl, 10 mmol/L Na_2HPO_4, 1 mmol/L EDTA at pH 7.0) were used for both the thermal denaturation studies and the determination of binding stoichiometry by the method of continuous variations. The error associated with the reported T_m values is ±0.5 °C.

Binding stoichiometry was determined by linear least-squares fitting of the curves. For the example, the two lines: $y = 0.2935x + 0.4744$ and $y = 0.3028x + 0.064$ fit the experimental data and gives the binding stoichiometry (calcd. 0.66; found: $0.69\chi_{PNA}$).

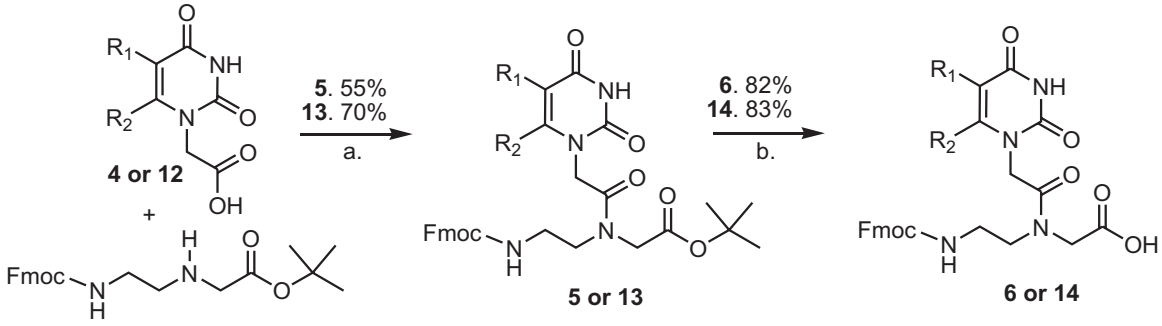
Results and discussion

Synthesis of PNA monomers



Our initial approach to incorporate C6 derivatives of uracil into PNA involved the synthesis of individual orotamide monomers for discrete incorporation into oligomers. This approach proved to be inefficient and, ultimately, synthetically intractable (4). We therefore decided to pursue the post-synthetic modification strategy based on a methyl orotate containing oligomer, thus exploring its feasibility as a convertible nucleobase. Synthesis of the methyl orotate monomer was achieved in five steps with an overall yield of 28%, compounds **2**–**6** were easy to handle and purified by recrystallization or trituration.

The nucleobase submonomer was approached by the standard Fisher esterification of orotic acid **1**, which gave methyl orotate **2** in high yield. The methyl ester was chosen as a simple, orthogonal protecting group to the Fmoc-protected amine and the acid labile *tert*-butyl group for carboxyl protection. The alkylation of **2** with *tert*-butyl bromoacetate and potassium carbonate gave **3** and acidolysis of the *tert*-butyl ester gave (methyl orotate-1-yl)acetic acid (**4**, Scheme 1). The alkylation at N1 of methyl orotate was confirmed by 2D NMR (gHMBC) spectroscopy. Compound **3** showed coupling from the methylene protons of CH_2-COO-*t*-Bu (singlet at δ 4.60) to both C6 (δ 143.8) and C2 (δ 151.0), while no coupling to C4 (δ 162.2) was observed.



The synthesis of uracil-5-methylcarboxylate, as shown in Scheme 2, began with 5-hydroxymethyluracil, which is easily synthesized in high yield by the well-known reaction of uracil with formaldehyde (11). The oxidation of 5-hydroxymethyluracil to the carboxylic acid may be achieved in one step, but we found that 5-formyluracil cleanly precip-

itated during the course of the reaction using potassium persulfate and catalytic silver nitrate by a modified procedure of Ziegler and Brossmer (12). The 5-formyluracil may subsequently be dissolved in boiling water and subjected to another round of oxidation with potassium persulfate and catalytic silver nitrate to give the carboxylic acid. Next Fisher esterfication, alkylation, and acidolysis as previously described gave (uracil-5-methylcarboxylate-1-yl)acetic acid, compound **12**. Although the C5-methyl carboxylate nucleoside has been prepared by carbonylation of 5-iodo-2-deoxyuridine (15), the stepwise process previously described is preferable to us because it is technically very simple, may be done on a large (multigram) scale in good chemical yields, and furnishes intermediates that are useful for other studies (4). Once the C5-ester had been installed, compound **10** was alkylated at N1 to give **11** and the regiochemistry for this reaction was confirmed by 2D NMR (gHMBC) spectroscopy. Compound **11** showed coupling from the methylene protons of CH_2-COO-*t*-Bu (singlet at δ 4.43) to both C6 (δ 149.6) and C2 (δ 152.3), as well as CH(6) (singlet at δ 8.19) to the methylene carbon (δ 49.9).

Next, the Fmoc backbone was prepared by a modified procedure of Thomson et al. (14) (Scheme 3). An excess of ethylenediamine was alkylated with *tert*-butyl chloroacetate, followed by aqueous work up. The product, *tert*-butyl *N*-(2-aminoethyl) glycinate, was then reacted with Fmoc-NHS for 4 h, extracted and carefully acidified with 1 equiv. of HCl in ether (5 mol/L) to give the Fmoc backbone HCl salt (Scheme 3). In the condensation to the nucleobase-1-yl-acetic acid, the Fmoc backbone HCl salt was neutralized by extraction against sodium bicarbonate and used as the free base.

Condensation of **4** and **12** to the neutralized Fmoc backbone was achieved with DCC–HOBt, and subsequent acidolysis of the *tert*-butyl ester gave the target methyl orotate monomer **6** and uracil-5-methylcarboxylate monomer **14** (Scheme 4). Both the methyl orotate and uracil-5-methylcarboxylate monomers were used in the solid-phase peptide synthesis of oligomers.

Synthesis of PNA oligomers

Incorporation of the methyl orotate (*MO*) monomer into PNA hexamers was done using a Rink amide resin using standard conditions for Fmoc-based oligomerization chemistry. Hexamers were synthesized containing thymine and terminally, internally, or doubly substituted MO derivatives **8**–**10**. The methyl orotate monomer, and the subsequently incorporated methyl orotate unit, was found to be completely compatible with the solid-phase synthesis; no saponification, transesterification, or other loss of the methyl ester functional group was found.

The amide linkage to the resin allowed for reaction of resin bound oligomers **8**–**10** with hydroxide or an amine. Standard acidolysis with TFA–Et_3SiH released the oligomers from the resin to give methyl orotate **8**–**10**, orotic acid **11**–**13**, or orotamide **14**–**17** containing PNAs (Table. 2). Hydrolysis of resin-bound methyl orotate oligomers was performed using NaOH in THF–H_2O. The orotic acid oligomers were released from the resin by acidolysis and RP-HPLC showed one major peak with minimal byproducts. Aminolysis of methyl orotate allows for the introduction of various substituted amides, and incorporation of 3-(*N*,*N*-dimethylamino)propylamide or ethanolamide was accomplished by treating the resin with neat amine at 55 °C for 6 h, and cleavage form the resin was performed as described. For example, resin-bound oligomer **10** was converted to **16** as previously described (Fig. 2A), isolated as the only major product by RP-HPLC (Fig. 2B), and identified by mass spectrometry (Fig. 2C).

Synthesis of uracil-5-methylcarboxylate and uracil-5-carboxamide containing oligomers (**19**, **20**) proceeded in a similar fashion. The uracil-5-methylcarboxylate (*UM*) was introduced into the internal position of a hexamer Ac-TTT*UM*TTK-NH_2 (**19**) and converted to the 3-(*N*,*N*-

Hybridization studies of PNA containing C5 and C6 derivatives of uracil

The hybridization of methyl orotate, orotic acid, and orotamide substituted hexamers **8**–**17** and C5-substituted ester and amide **19** and **20** was studied by temperature-dependent UV absorbance. The binding stoichiometry for the modified oligomers containing C5 and C6 carboxamides with poly(rA) was determined by the method of continuous variation, commonly referred to as Job plots (15). This analysis revealed a 2:1 ratio, which is consistent with triplex formation (Fig. 3, shown for orotamide). Presumably, this triplex is composed of an antiparallel Watson–Crick (16) binding domain and a parallel Hoogsteen (17) binding domain as seen for covalently linked bisPNAs (10). The use of unlinked binding domains is useful in this case because an antiparallel orientation between the two domains is not enforced and the oligomers are free to adopt the most favourable binding arrangement. If the C6 derivatives had been found to benefit triplex formation, elucidation of the strand orientation would be more relevant (vide infra).

The thermal stability (T_m) of triplex formation was evaluated near physiological ionic conditions (150 mmol/L NaCl, 10 mmol/L Na_2HPO_4, 1 mmol/L EDTA at pH 7.0). The hexamers were hybridized to poly(rA) or poly(dA) in a 2:1 ratio at a concentration of ~2 umol/L per nucleobase. The compounds were all well-behaved and showed a monophasic hyperchromic shift. The introduction of C6-modified residues into the hexamers (**8**–**17**) caused a drop in T_m in all cases as compared to an unmodified PNA control sequence (Ac-TTTTTTK-NH_2, **7**), as summarized in Table 2. Single modified residues located at the N terminus of the sequence (**8**, **11**, **14**) were better tolerated than at an internal position (**9**, **12**, **15**). The N-terminal modifications show a trend that can be rationalized predominately on electrostatic interactions. For instance, the introduction of an orotamide, with a pendant positively charged group, at the N terminus of the hexamers had only a weakly destabilizing effect. Complexes formed with hexamers containing an N-terminal methyl orotate (uncharged group) or orotic acid (negatively charged group) suffered a much greater destabilization. The greatest destabilization of complexes formed with both RNA or DNA contained the orotic acid insert, thus implying that electrostatic interactions are important. Single substitution internal to the sequence (**9**, **12**, **15**, **17**) and doubly substituted oligomers (terminal and internal: **10**, **13**, **16**) had a large detrimental effect. Such large effects for internal substitution suggest that the substituents exert a significant steric effect. For comparison, the internal substituted orotic acid hexamer **12** has a decrease in T_m that is comparable to the oligomers containing a mismatch: (Ac-TTT***C***TTK-NH_2, **18**, ΔT_m = −43 °C). Even the putative beneficial effect of a pendant positive charge (**15**, **16**) is insufficient to recover the binding affinity of the hexamers.

In stark contrast, our preliminary results show that the PNA containing an internal uracil-5-carboxamide stabilizes triple-helix formation with complementary RNA (Table 2, **20**). This result parallels those found in the chemistry of DNA and RNA, but in PNA the stabilization is larger in magnitude. The introduction of a single internal C5 carboxamide with a pendant positively charged group into an oligodeoxynucleotide has been shown to have a very modest effect on thermal stability (at 100 mmol/L NaCl) for duplexes formed with complementary DNA or RNA (18, 19), although larger effects were observed under low-salt conditions (20). The stabilization in these cases was attributed to increased base stacking through a five-membered ring formed by H bonding of the amide hydrogen with the C4 carbonyl of uracil and (or) by the pendant cationic charge (19). Other studies with oligonucleotides capable of forming triple helices demonstrated a destabilization of the complex when the polypyrimidine oligonucleotide possessed a single internal C5-carboxamide-modified uracil (18, 21). Granted, these are different sequence contexts and different structural backbones, thus comparisons between PNA and NA systems need to be made cautiously. In addition, for the triplex system described herein, each PNA strand carries a modification, so that each complex has a total of two modified residues; whereas the studies referenced on duplexes possess a single modified residue. However, it is noteworthy that the introduction of a single internal modification bearing a pendant positively charged group into the PNA strand is more stabilizing to the triplex formed than incorporation of a backbone modification based on lysine (22), but not as significant as a positively charged nucleobase analog that makes a specific H-bonding interaction with the complementary base — the so-called G-clamp (23). Such pendant positive charges incorporated into PNA via the nucleobases may benefit the binding affinity, sequence discrimination (24), accelerate hybridization and strand invasion (25–27), and favourably affect the intracellular accumulation (28) for in vivo applications.

In summary, we have described the synthesis of a methyl orotate and uracil-5-methylcarboxylate monomers that are effective convertible nucleobases, compatible with an on-resin conversion strategy. Incorporation of the esters into oligomers allows for aminolysis in high yield and purity. However the C6-modified PNA_2:NA triple helices do not tolerate this substitution, while the C5-carboxamide substitution stabilized triplex formation. We are extending these investiga-

© 2005 NRC Canada

tions to the duplexes formed between methyl orotate PNA sequences and DNA or RNA to determine if this substitution is tolerated better. Furthermore, the C5-substituted oligomers merit further investigation for the effect of various charged, lipophilic or hydrophilic groups on their hybridization properties.
