Molecular modeling

The molecular modeling on compound **1** was performed using CaChe WorkSystem Pro Version 5. After having set a weak bond between the hydroxyl hydrogen and the N of the piperidine ring, an energy minimization experiment was performed in two steps. First, the "fastest procedure" (augmented MM3 parameters) was used, followed by the "standard procedure" (PM3 parameters). The energy-minimized conformation indicated strong H-bonding in the molecule (Fig. 2).

X-ray crystallography

Crystals of compound **9** were grown from a saturated dichloromethane–methanol (1:1) solution, while crystals of compound **11** were grown from saturated diethyl ether solu-

[a]Flack parameter 0.0 (1).
[b]$R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[c]$wR_2 = [\Sigma(w(F_o^2 - F_c^2)^2)/\Sigma w(F_o^2)^2]^{1/2}$, where $w = 1/[\sigma^2(F_o^2) + (0.0664P)^2 + (0.0000P)]$ (**9**) and $w = 1/[\sigma^2(F_o^2) + (0.1000P)^2 + (0.0000P)]$ (**11**), where $P = (\max(F_o^2, 0) + 2F_c^2)/3$.

tion. Crystals were mounted using a glass fiber. All measurements were made on a Rigaku AFC5R diffractometer with graphite monochromated Mo Kα radiation.

The data were collected at a temperature of –60 ± 1 °C to a maximum 2θ value of 60.2°. The structure was solved by direct methods (39) and expanded using Fourier techniques (40). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined using the riding model. The neutral atom scattering factors were taken from Cromer and Weber (41). Anomalous dispersion effects were included in F_{calcd} (42); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (43). The values for the mass attenuation coefficients are those of Creagh and Hubbell (44). All calculations were performed using the CrystalStructure crystallographic software package (45, 46) except for refinement, which was performed using SHELXL-97 (47).

The crystallographic data collection parameters, bond lengths, and bond angles for **9** and **11** are presented in Tables 1–3. The full details of the structure have been deposited.[3]

Results and discussion

One of the interests of this laboratory lies in the use of 2-tetralone–2-naphthol skeletons as versatile building blocks (48–50). Substituted 1-arylidene-2-tetralones (**A**) were prepared from 2-tetralone and appropriate aldehydes by palladium-catalyzed Knoevenagel-type condensation (37). Subsequently, 1-arylidene-2-tetralones reacted with piperidine to produce the compounds **1**–**4** instead of the expected aza-Michael adducts (**B** or **C**). Based on this observation, it appears highly probable that aza-Michael adducts (**B** or **C**) are unstable and that they collapse back to the starting materials if they are not trapped by aerial oxidation of the dihydronaphthalene ring to form stable and aromatic 1-(aryl-piperidin-1-ylmethyl)naphthalen-2-ols (**1**–**4**), as shown in Scheme 2. This rather unusual conversion, driven by the aromatization, was found to be slow and the best yield after a reaction time of 7 days was ~30%. Although the reactions suffer from rather long reaction times and low yields, this is a novel conversion.

Several attempts were made to expedite the reaction course by addition of oxidizing agents (viz., H_2O_2, MnO_2, DDQ, and O_2). No decline in the reaction time could be achieved; rather, undesired products and complex mixtures were obtained. No attempts were made to identify the undesired products. The results suggest that the first elementary step (formation of **B** or **C**, Scheme 2) is rate-limiting and the presence of oxidizing agents lead to undesired reactions with the starting materials. We are in the process of optimizing the conditions.

We prepared additional analogs (**1**–**11**, Table 4) by modifying a reported microwave-assisted procedure (26) for which we achieved an appreciable improvement in yields and reaction time (Scheme 3). Sharifi et al. (26) have reported the synthesis of related compounds on acidic alumina support under solvent-free conditions and microwave irradiation with an average yield of 64% in the reaction time range of 4–8 min, compared to an average yield of 75.1% and a reaction time of 1 min under our conditions. The irradiation time was split into two 30 s pulses with a nearly 30 s intervening gap to avoid superheating and charring the reaction contents. Our procedure involved solvent-free conditions and the use of only catalytic amounts of *p*-TSA, thus avoiding the use of excessive acidic alumina. Numerous trials of microwave-assisted reaction under solvent-free conditions using 2-nitrobenzaldehyde (for compound **4**) were not successful and violent splashing of the contents was noticed within the irradiation period of ~10 s; TLC did not indicate the formation of any product even after continued irradiation for up to 2 min. The use of solvent (DMF) and solid support (silica gel) under microwave irradiation did not change the outcome.

Although the Mannich bases of 2-naphthols with heterocyclic amines were reported in the past (24, 26, 27, 51), their

detailed NMR behavior has not been examined, to the best of our knowledge; some NMR peaks are reported in broad range (27). We consistently noted interesting NMR activities of the compounds under investigation, as they often gave poorly resolved heterocyclic proton and carbon peaks in their respective spectra at ambient temperature. We decided to systematically investigate this behaviour. Besides the indispensable use of NMR spectroscopy in structure elucidation, it remains a powerful technique for stereochemical analysis of organic molecules. From the point of view of conformational analysis, six-membered saturated carbocycles and heterocycles have been studied (52–55). A recent study on 1-(2-hydroxy-2,2-diarylethyl)piperidin-4-ones describes a new mechanism of N-inversion — a concerted H-bond dissociation – N inversion process (56). The piperidine ring is a common structural fragment of many alkaloids and, therefore, conformational analysis of these biologically active amines is necessary for the comprehension of the molecular mechanisms of their action.

The ^{1}H and ^{13}C NMR spectra obtained at ambient temperature (300 K) suffered from the broadening of several peaks suggesting dynamism in the piperidine conformation, making the interpretation ambiguous. Thus, we resorted to recording the NMR experiments at lower temperatures. As expected, the ^{1}H NMR spectrum of compound **1** at 273 K gave better resolved peaks. The peak at δ 14.1, integrating for one proton of -OH group at position 2 of the naphthalene ring, clearly indicated strong H-bonding with the N of the piperidine ring. In addition, most of the protons on the piperidine ring gave discrete peaks, making it obvious that the symmetry of the piperidine ring was lost. This observation was also supported by the ^{13}C NMR spectrum of compound **1** at 273 K, which not only resulted in better resolved peaks but also showed distinct peaks for each CH_2 of the piperidene ring. This was another indication that the magnetic equivalence of the two pairs of methylene carbons is destroyed by restricted rotation of the piperidine ring with two flanking aromatic rings and the H bond. The NMR experiments that were recorded in a temperature span of 50 °C (three each for ^{1}H and ^{13}C) clearly demonstrated an increase in molecular dynamics with the rise in temperature. The portion of NMR plots of compound **1** that were most affected by the temperature change is shown in Fig. 3. The five C peaks of nonsymmetric piperidine at 273 K converge into

three C peaks of symmetric piperidine at 323 K. A similar observation was made in the H spectrum at corresponding temperatures, albeit at the cost of resolution.

The molecular model shown in Fig. 2 also demonstrates the existence of a very strong H bond (calculated distance = 1.83 Å) and a consequent loss of symmetry. This is more evident in Fig. 3*b,* where methylene Cs on the right side of N are magnetically nonequivalent to those on the left side because of restricted rotation. At lower temperature, this system may be regarded as a hindered spirocyclic system. As the temperature is increased, the H bond is disrupted allowing rotation of the piperidine ring along the benzylic C—N axis with concurrent ring flipping and (or) N-inversion. Being rather fast for the NMR timescale, the convergence of a pair of piperidine methylene takes place with loss of resolution in the ^{13}C NMR. As seen in Fig. 3, as the two discrete piperidine -NCH_2, appearing at 51.83 and 54.77 ppm, observed at 273 K coalesce to a broad peak at ~53.30 ppm when recorded at 323 K, it can be qualitatively said that a temperature increase of 50 °C leads to approximately 800 conformational interchanges per second (based on the expression for the rotational rate constant at the coalescence point (57) ($k_{coal} = \pi\ (\Delta\nu)/\sqrt{2}$). Thus, at the coalescence temperature, the interchanging conformations have a lifetime of about 1.25 ms ($1/k_{coal}$). Contrary to this, for the C-3 and C-5 carbons of piperidine that are away from the crowded centre, a similar effect is achieved with a temperature increase of ~27 °C (k_{coal} ~ 75 s^{-1}). The ^{1}H NMR also shows this behaviour where peak broadening is more severe.

The HSQC experiment with shaped pulse recorded at 273 K resulted in the expected correlations (Fig. 4). In addition to the presence of piperidine methylenes (inverted

© 2006 NRC Canada

Fig. 4. HSQC with shaped pulse for inversion of compound **1** recorded at 273 K.

peaks), the HSQC experiment also showed the presence of at least eight magnetically nonequivalent protons on the piperidine ring. A pronounced disparity in the appearance of seemingly similar diastereotopic methylene (C2, C6 pair) protons was observed. The more deshielded protons on the two carbons are 0.65 ppm apart, while the more shielded ones are 0.20 ppm apart. Also, the amount of shielding and deshielding on the protons on these carbons is considerably disparate (1.23 vs. 0.78 ppm).

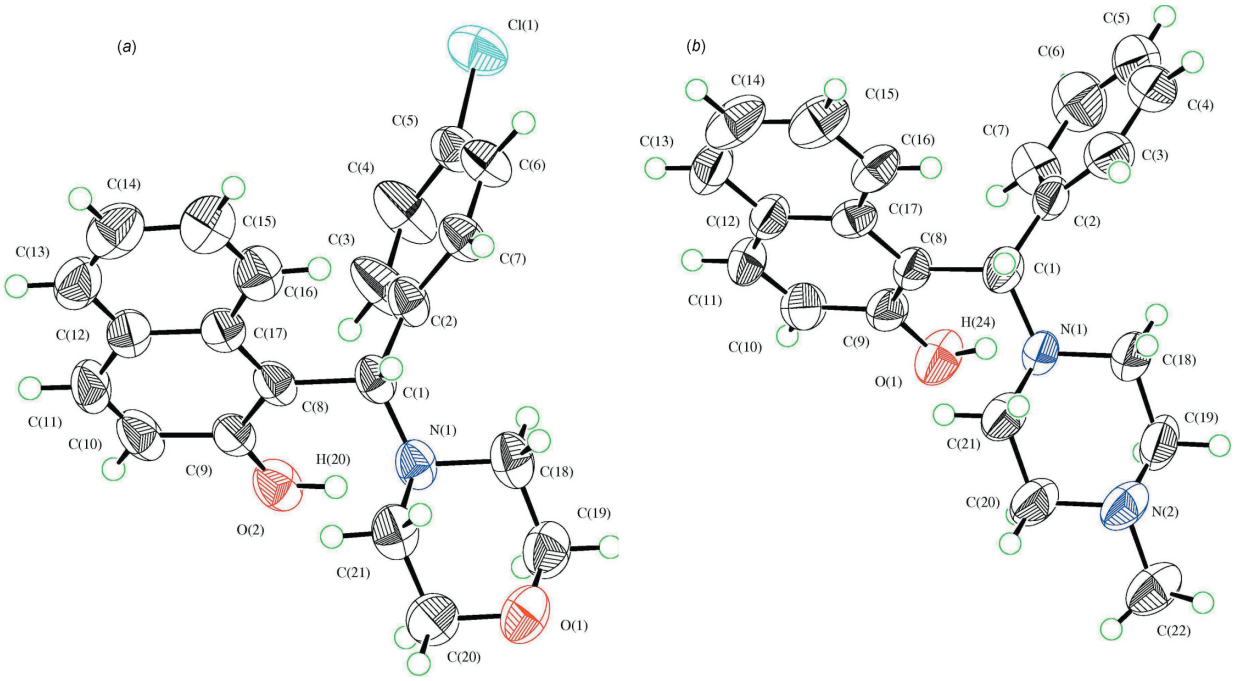
Similar NMR behaviour was consistently noticed for all the compounds (except compound **7**) irrespective of the heterocycle substituents. At 273 K, piperidinyl, morpholinyl, and *N*-methylpiperzinyl groups showed magnetic nonequivalence of all constituent carbons and hydrogens. Compound **7**, being devoid of an aryl group compared to others in the series, has significantly reduced crowding near the heterocyclic nitrogen atom and, therefore, the heterocyclic ring retains the symmetry even at 273 K.

Finally, X-ray crystal structures of compounds **9** and **11** were solved to compare the NMR solution- and solid-phase crystal conformations. The prominent feature of both compounds **9** and **11** is an internal hydrogen bond from the hydrogen atom of the OH group to N(1), the nitrogen of the piperidine or morpholine ring, which are bonded to C(1). It can be seen in Fig. 5 that the O—H bond approaches the piperidine or morpholine ring obliquely so that the C(18) and C(21) carbon atoms of this ring are not equivalent. This is a strong hydrogen bond; the observed H(20)—N(1) and H(24)—N(1) distances in **9** and **11** are 1.78 and 1.75 Å, respectively. This H-bonding also persists in solution as evidenced by the appearance of the hydrogen-bonded -OH peak at values >13 ppm in ^{1}H NMR. This H bond forms a six-membered cycle and restricts the free rotation of the heterocyclic ring along the benzylic C—N bond. A close inspection of the bond lengths and angles of the heterocyclic ring (shown in bold face in Tables 2 and 3) reveal that the ring is slightly distorted, compounding the magnetic nonequivalence of Hs and Cs on seemingly symmetric heterocyclic rings.

Conclusion

2-Naphthol Mannich bases with heterocyclic amines were synthesized using two different approaches. Variable-temperature NMR investigations proved helpful in resolving complicated NMR spectra of these rather simple molecules. Molecular modeling and X-ray crystallography supported the NMR results. These results can be explained by the loss of magnetic equivalence of certain heterocyclic Cs and Hs caused by restricted rotation of the heterocyclic ring when N is involved in strong H-bonding with phenolic -OH.

Acknowledgements



We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Nova Scotia Health Research Foundation (NSHRF) for their financial support. Ms. J. Beal is thanked for preliminary investigations. The Atlantic Region Magnetic Resonance Centre (ARMRC) and the Maritime Mass Spectrometry Laboratory (MMSL) at Dalhousie University are acknowledged for providing NMR and MS support, respectively. Dr. Michael Lumsden of ARMRC is thanked for technical suggestions.

Efficient stabilization of oligonucleotide duplexes through terpyridine metal complexes

Fabrice Freville, Nathalie Pierre, and Serge Moreau

Abstract: A large increase in the melting temperature of complementary oligonucleotides was obtained through the conjugation of terpyridine ligands at their nearby 5′ or 3′ ends and the addition of stoichiometric amounts of various transition metals. We describe here a short efficient synthetic route for the conjugation of terpyridine moieties and report new data on the stabilizing contribution of metal-assisted hybridization of oligonucleotides through UV-monitored melting temperature experiments.

Key words: oligonucleotides, metal complexes, terpyridine.

Résumé : Une augmentation importante de la température de fusion d'oligonucléotides complémentaires peut être obtenue par la conjugaison des ligands terpyridine à leurs extrémités adjacentes (5′ ou 3′) et l'addition de quantités stœchiométriques de divers métaux de transition. On décrit ici une courte voie de synthèse efficace pour la conjugaison des groupes terpyridine. On présente également de nouvelles données expérimentales sur l'effet stabilisant des métaux dans l'hybridation des oligonucléotides par des mesures de température de fusion soumises en spectroscopie UV.

Mots clés : oligonucléotides, complexes métalliques, terpyridine.

Introduction

We previously reported a high stabilization of complementary DNA strands association through the addition of a coordination link between the oligomers (1). Such a link was obtained using terpyridine moieties as chelating agents and serinol as a deoxyribose mimic to allow easy conjugation of the chelator to oligonucleotides at nearby 3′ and 5′ ends.

We report here a new way to access the efficient conjugation of terpyridine moieties on both 3′ and 5′ ends of oligonucleotides. To allow structural studies, we chose to use a pantolactone-based ribose mimic developed by Dioubankova et al. (2). This synthetic route was used to extend our studies on metal-assisted hybridization of oligonucleotides, providing an easy way to increase nucleic acid duplex stability.

Results

We chose to use two short complementary DNA sequences to evaluate the contribution of the metallic bridge on duplex stability. This data was obtained by UV-thermal denaturation experiments. The introduction of the terpyridine chelators at nearby 5′ and 3′ ends required the synthesis of a phosphoramidite monomer bearing the terpyridine moiety and a specific solid-supported reagent for 3′ conjugation.

Chemical synthesis

Taking into account the strategy develop by Dioubankova et al., we designed a new synthetic route involving pantolactone as a precursor for a nonnucleosidic monomer. The new monomer was derivatized as a phosphoramidite unit and used in a solid-supported terpyridine linker. The whole synthetic scheme is depicted in Fig. 1.

Pantolactone **1** was treated with an excess of 1,3 diaminopropane. The side chain aminogroup was transiently protected through trifluoroacetylation. The primary hydroxyl group was then selectively tritylated using 4,4′-dimethoxytrityl chloride, yielding compound **3**. **3** was purified by silica gel flash chromatography using a dichloromethane – ethyl acetate gradient. The overall yield from **1** was 68%. The N-protecting group was then removed by sodium carbonate treatment leading to **4** (yield of 74%). The terpyridine monomer **5** was obtained by the reaction with the *N*-hydroxysuccinimide ester **9** in high yield (82%), after chromatography over aluminum oxide using an ethyl acetate – hexane gradient. This monomer **5** was used either to synthesize the phosphoramidite **6** through phosphitylation with 2-cyanoethyl-*N*,*N*-diisopropylchloro phosphoramidite or to yield a solid-supported reagent **7** by reaction with succinylated LCAA-CPG. **6** was purified by reverse-phase chromatography and elution with neat acetonitrile (yield 43%). The overall yield from **1** was 17%. The solid-supported reagent **7** was obtained by known procedure (3). The loading range of the CPG reagent was found to be 25–35 μmol/g. The terpyridine moiety **8** was synthesized according to published procedures (4) and the *N*-hydroxysucciimide ester **9** was obtained in high yield (93%).

Duplex formation

To evaluate the stability of various metallic bridges be-

tween complementary oligomers, we designed specific strand combinations. Oligonucleotide sequences are gathered in Table 1, together with the MS analysis of TPY-conjugated strands by MALDI-Q-TOF in negative mode. We thus confirmed the chemical structure of modified oligomers with the monoisotopic peaks in the MS analysis. Using the previously mentioned linkers, the terpyridine chelator was introduced into the 3′ or 5′ ends of complementary

[c]Nd: not determined.

strands. Five different duplexes were studied, allowing comparisons between unmodified double-stranded oligomers and either mono- or bis-terpyridine conjugated oligonucleotides.

Thermal denaturation experiments were conducted in two different buffers. Data from nonmetalated species were obtained in a buffer containing EDTA to avoid contamination from traces of metal ions. As can be deduced from Table 2, the addition of at least 1 equiv. of Zn^{2+} ions (relative to duplex concentration) to the terpyridine-containing duplex IV resulted in a large increase in Tm (ΔTm = + 35.3 °C) in comparison with that of the unmodified duplex I. All other combinations of terpyridines moieties did not produce this stabilizing contribution. Duplexes II and III, although revealing some slight stabilization compared with I, did not reveal any stabilizing effect when compared with the data obtained from an unmetallated incubation medium (see column 2, Table 2). The presence of the two nearby terpyridine ligands is a prerequisite for the stabilization through added metal ions; duplex V, which exhibits noncontiguous terpyridine ligands, was not stabilized. The expected stoichiometry of the ligation reaction was obtained from a titration experiment with Zn^{2+} ions using the specific absorption band (320 nm) of the metalated terpyridine determined in a previous study (1) (Fig. 2).

Data from the nonmetalated buffer revealed a slight contribution from the terminal terpyridine in the stabilization of the duplexes (see column 2, Table 2). This stabilizing effect might arise from the formation of stacked aromatic pyridines on double-stranded oligonucleotide ends. The intercalation abilities of the terpyridine nucleus was discarded from previously observed data.

Fig. 2. Titration experiment showing the variation of the absorbance at 320 nm as a function of added $ZnCl_2$ (equiv. refers to the duplex concentration (1 μmol/L)).

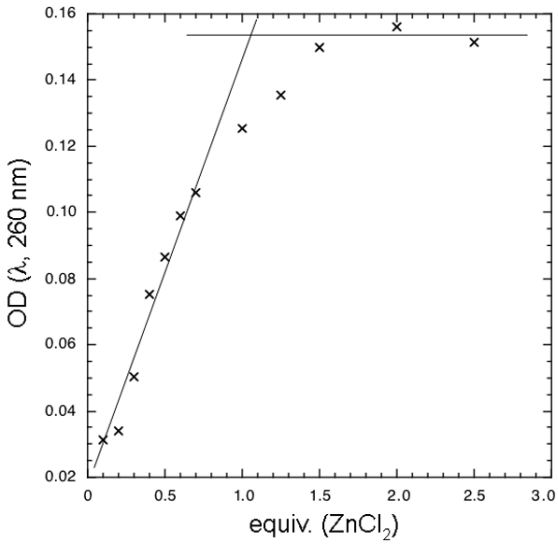

Table 2 also showed data from various chelating metals. All produced large increases in the Tm values of metalated duplexes; ΔTm from the unmodified duplex I ranged from 31 to 38.7 °C. The observed variations in the stabilizing contributions of the various chelated metals might arise from the coordination properties of the metals. All are known to form octahedral terpyridine complexes (5), however, other coordination numbers of 4 and 5 are also observed for copper (6,

© 2006 NRC Canada

7) and zinc–nickel complexes (8, 9). We cannot, therefore, exclude the occurrence of different coordination patterns in the metal-assisted hybridization of the oligonucleotides with coordination links between the nearby terpyridines varying from one to three.

Experimental section

General

Thin layer chromatography was performed on Merck silica gel 60F254 aluminum-backed plates. Flash chromatography refers to column chromatography performed with a Biotage system. NMR spectra were recorded with a Bruker Avance 300 spectrometer working at 300 MHz for ^{1}H, 75.45 for ^{13}C, and 121.49 for ^{31}P. The chemical shifts are expressed in ppm using TMS as internal standard (for ^{1}H and ^{13}C NMR data) and 85% H_3PO_4 as external standard for ^{31}P NMR data. Mass spectra (MALDI-Q-TOF, negative mode) were recorded on a Waters Ultima spectrometer. A special preparation technique was designed to analyse the TPY-modified oligonucleotides. The stainless steel target was first covered with a thin layer of matrix (0.5 μL of 2,4,6-trihydroxyacetophenone (THAP), 10 mg/mL in acetone) and this layer was washed with a saturated EDTA solution (2 × 1 μL) and water (2 × 1 μL). The oligonucleotides (0.5 μL of a 20 μmol/L solution in water) were then deposited on this matrix layer and allowed to dry. The final preparation step was the application of a second layer of matrix (0.5 μL of a 1:1 solution of THAP (30 mg/mL in ethanol) and 100 mmol/L aqueous ammonium citrate) that was allowed to dry at room temperature.

Chemical synthesis

Compound 3

A solution of (*R*)-(–)-pantolactone (1 g, 7.68 mmol) and 1,3-diaminopropan (1.67 mL, 38.42 mmol) in 6 mL EtOH was kept at 55 °C for 48 h, to which was added 13.7 mL (115.3 mmol) of ethyl trifluoroacetate. The mixture was kept at room temperature overnight, evaporated, then co-evaporated with toluene and dry pyridine. The residue was dissolved in dry pyridine (40 mL), cooled in an ice bath, and 4,4′-dimethoxytrityl chloride (2.86 g, 8.45 mmol) was slowly added. The reaction was stopped after 2 h by the addition of 0.5 mL of water and then diluted with 200 mL of $CHCl_3$. The organic phase was washed with 2.5% $NaHCO_3$ (3 × 60 mL), water (2 × 60 mL), and 20% NaCl (60 mL), then dried ($MgSO_4$). The residue was purified by flash chromatography using a stepwise gradient of EtOAC (0%–15%) in CH_2Cl_2–Et_3N (0.25%) to yield **3** as a colorless oil (3.14 g, 68%). ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 8.03 (t, 1H, N*H*COCF$_3$), 7.36–6.82 (m, 13H, H_{DMTr}), 6.66 (t, 1H, NHCOCH(OH), $^{3}J_{NH-CH_2}$ = 6 Hz), 4.07 (s, 1H, C*H*OH), 3.77 (s, 6H, OCH_3), 3.27 (m, 2H, C*H*$_2$NHCOCF$_3$), 3.16 (m, 3H, C*H*$_2$NHCO and CH_{2a}ODMTr), 3.01 (d, 1H, CH_{2b}ODMTr), 1.57 (m, 2H, $CH_2CH_2CH_2$), 1.12 (s, 3H, CH_{3a}), 1.02 (s, 3H, CH_{3b}). ^{13}C NMR (75.45 MHz, $CDCl_3$, ppm) δ: 173.8 (*C*ONH), 158.7 (*C*OCH$_3$), 157.5 (q, *C*OCF$_3$, $^{2}J_{C-F}$ = 36.5 Hz), 144.1–113.4 (7C, DMTr), 116.0 (q, CO*C*F$_3$, $^{1}J_{C-F}$ = 285.9 Hz), 86.8 (O*C*$_{DMTr}$), 77.8 (*C*HOH), 71.2 (*C*H$_2$ODMTr), 55.3 (OCH_3), 38.9 (*C*(CH$_3$)$_2$), 36.0 (*C*H$_2$NHCOCF$_3$) 35.4 (*C*H$_2$NHCO), 29.0 ($CH_2CH_2CH_2$), 22.0 (CH_{3a}), 20.9 (CH_{3b}).

Compound 4

Compound **3** (3 g, 5.9 mmol) was dissolved in MeOH (40 mL), then an aqueous solution of Na_2CO_3 (10%, 11 mL) was added. The reaction mixture was stirred overnight at 65 °C, evaporated, diluted with 200 mL of EtOAc, washed with 1.5% $NaHCO_3$ (3 × 150 mL), then dried (Na_2SO_4), evaporated, and co-evaporated with toluene (3 × 30 mL) and CH_2Cl_2 (2 × 30 mL) to yield 2.2 g of **4** (74% yield). This compound was used without further purification. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.36–6.82 (m, 14H, H_{DMTr} and NHCO), $^{3}J_{NH-CH_2}$ = 6 Hz), 4.08 (s, 1H, C*H*OH), 3.78 (s, 6H, OCH_3), 3.16 (m, 3H, C*H*$_2$NHCO and CH_{2a}ODMTr), 3.01 (d, 1H, CH_{2b}ODMTr), 2.62 (t, 2H, C*H*$_2$NH$_2$, $^{3}J_{H-H}$ = 6.6 Hz), 1.57 (m, 2H, $CH_2CH_2CH_2$), 1.12 (s, 3H, CH_{3a}), 1.02 (s, 3H, CH_{3b}). ^{13}C NMR (75.45 MHz, $CDCl_3$, ppm) δ: 172.4 (*C*ONH), 158.6 (*C*OCH$_3$), 144.1–113.4 (7C, DMTr), 86.4 (O*C*$_{DMTr}$), 77.1 (*C*HOH), 70.8 (*C*H$_2$ODMTr), 55.2 (OCH_3), 39.3 (CH_2NH_2), 39.0 (*C*(CH$_3$)$_2$), 36.4 (*C*H$_2$NHCO), 33.0 ($CH_2CH_2CH_2$), 22.0 (CH_{3a}), 20.9 (CH_{3b}).

Compound 5

4 was carefully dried by three co-evaporations with pyridine and then dissolved in anhydrous pyridine. The NHS ester **9** was added and the solution stirred at RT and monitored by TLC. The reaction medium was evaporated and purified by chromatography over aluminum oxide with a gradient of ethyl acetate in hexane (50%–80%) in the presence of 0.25% triethylamine (1.35 g, yield 82%). ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 8.68 (ddd, 2H, $^{3}J_{ortho}$ = 4.8 Hz, $^{4}J_{meta}$ = 1.8 Hz, and $^{5}J_{para}$ = 0.9 Hz, H6 and H6″), 8.62 (ddd, 2H, $^{3}J_{ortho}$ = 7.5 Hz, $^{4}J_{meta}$ = 1.0 Hz and $^{5}J_{para}$ = 0.9 Hz, H3 and H3″), 8.02 (s, 2H, H3′ and H5′), 7.85 (ddd, 2H, $^{3}J_{ortho}$ = 7.8 Hz, $^{3}J_{ortho}$ = 7.5 Hz, and $^{4}J_{meta}$ = 1.5 Hz, H4 and H4″), 7.41–6.85 (m, 15H, H_{DMTr}, H5 and H5′), 6.64 (t, 1H, $^{3}J_{H-H}$ = 6 Hz, NHCO), 6.52 (t, 1H, $^{3}J_{H-H}$ = 5.7 Hz, NHCO), 4.29 (t, 2H, $^{3}J_{H-H}$ = 5.9 Hz, CH_2CH_2O), 4.09 (s, 1H, C*H*OH), 3.80 (s, 6H, CH_3O), 3.19 (m, 5H, C*H*$_2$NHCO and CH_{2a}ODMTr), 3.02 (d, 1H, CH_{2b}ODMTr), 2.45 (t, 2H, $^{3}J_{H-H}$ = 7.2 Hz, CH_2CO), 2.22 (m, 2H, NHCH$_2$C*H*$_2$CH$_2$NH), 1.50 (m, 2H, CH$_2$C*H*$_2$CH$_2$), 1.07 (s, 3H, CH_{3a}), 1.00 (s, 3H, CH_{3b}). ^{13}C NMR (75.45 MHz, $CDCl_3$, ppm) δ: 172.8 (CONH), 172.2 (CONH), 166.9 (C4′), 158.5 (*C*OCH$_3$), 156.9 (C2′, C6′), 155.9 (C2,C2″), 148.9 (C6, C6″), 144.3–113.2 (12C, DMTr), 136.6 (C4, C4″), 123.7 (C5, C5″), 121.2 (C3, C3″), 107.4 (C3′, C5′), 86.4 (O*C*$_{DMTr}$), 77.3 (*C*HOH), 70.8 (*C*H$_2$ODMTr), 66.2 (O*C*H$_2$), 55.2 (OCH_3), 38.8 (*C*(CH$_3$)$_2$), 35.8 (*C*H$_2$NHCO) 35.6 (*C*H$_2$NHCO), 32.8 ($OCH_2CH_2CH_2CONH$), 29.6 (NHCH$_2$*C*H$_2$CH$_2$NH), 25.1 (NHCH$_2$*C*H$_2$CH$_2$O), 22.0 (CH_{3a}), 20.9 (CH_{3b}). MS (FAB$^-$) calcd.: 823.97; found: 822 (M – H)$^-$.

Compound 6

5 (1 g, 1.2 mmol) was dissolved in anhydr. CH_2Cl_2 (10 mL). Diisopropylethylamine (520 μL, 3 mmol) and 2-cyanoethyl diisopropylchlorophosphoramidite (1.8 mmol, 430 mg) were then added to the previous solution. The reaction was stopped after 1 h at RT with 500 mL of CH_3OH and diluted with 100 mL of EtOAc, washed with 2.5%

$NaHCO_3$ (200 mL), and then dried over Na_2SO_4. The residue was purified over reverse phase silica gel (Lichroprep RP-18 (40–63 μmol/L)) and eluted with CH_3CN–Et_3N (0.25%) to yield 534 mg of solid **5** (43%). ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 8.67 (d, 2H, $^3J_{ortho}$ = 4.2 Hz, H6 and H6″), 8.60 (d, 2H, $^3J_{ortho}$ = 7.8 Hz, H3 and H3″), 8.01 (s, 2H, H3′ and H5′), 7.85 (td, 2H, $^3J_{ortho}$ = 7.5 Hz, and $^4J_{meta}$ = 0.9 Hz, H4 and H4″), 7.41–6.85 (m, 15H, H_{DMTr}, H5 and H5″), 6.56 (t, 1H, $^3J_{H–H}$ = 6.0 Hz, NHCO), 6.43 (t, 1H, $^3J_{H–H}$ = 5.7 Hz, NHCO), 4.28 (t, 2H, $^3J_{H–H}$ = 6.0 Hz, $COCH_2CH_2CH_2O$), 4.09 (d, 1H, $^2J_{H–P}$ = 12.6 Hz, C*H*OP), 3.78 (s, 6H, CH_3O), 3.70–3.4 (m, 4H, CH_2NHCO), 3.4–2.9 (m, 6H, CH_2ODMTr, CH_2CH_2OP, NC*H*), 2.43 (m, 4H, $OCH_2CH_2CH_2CO$, $POCH_2CH_2CN$), 2.21 (m, 2H, $NHCH_2CH_2CH_2NH$), 1.55 (m, 2H, $OCH_2CH_2CH_2CO$), 1.11 (m, 15H, CH_3), 1.00 (s, 3H, CH_{3b}). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 171.4 (CONH), 170.0 (CONH), 167.0 (C4′), 158.6 ($COCH_3$), 157.1 (C2′, C6′), 156.1 (C2, C2″), 149.0 (C6, C6″), 145.2–112.9 (7C, DMTr), 136.7 (C4, C4″), 123.8 (C5, C5″), 121.3 (C3, C3″), 117.9 (CH_2CN), 107.4 (C3′, C5′), 85.8 (OC_{DMTr}), 77.3 (CHOP), 70.8 (CH_2ODMTr), 67.3 ($OCH_2CH_2CH_2CO$), 58.2 ($NCCH_2CH_2OP$), 55.2 (OCH_3), 43.4 (NCH), 38.8 ($C(CH_3)_2$), 35.9 (CH_2NHCO) 35.7 (CH_2NHCO), 32.8 ($OCH_2CH_2CH_2CONH$), 29.6 ($NHCH_2CH_2CH_2NH$), 25.1 ($COCH_2CH_2CH_2O$), 24.6 ($NCH(CH_3)_2$), 22.7 and 22.3 ($C(CH_3)_2$), 20.4 (CH_2CN). ^{31}P NMR (120 MHz, $CDCl_3$, ppm) δ: 156.0, 152.5. MS (FAB^-) calcd.: 1023.19 $(M – H)^-$; found: 1022 $(M – H)^-$.

Compound 7

A solution of succinic anhydride (300 mg, 3 mmol) and DMAP (80 mg, 0.66 mmol) in 10 mL of dry pyridine was added to 3000 mg of LCAA-CPG (500 Å) and the mixture was left at RT for 24 h with occasional swirling. After filtration, successive washes with 10 mL portions of pyridine, CH_2Cl_2, Et_2O, and drying, the succinylated LCAA-CPG was suspended in 4 mL of DMF pyridine (1:1 *v*/*v*); compound **5** (206 mg, 0.25 mmol), 1,3-diisopropylcarbodiimide (0.28 mL, 1.8 mmol)), and DMAP (20 mg) were added. The suspension was left for 48 h at RT. To block the remaining carboxylic groups, a solution of pentachlorophenol (100 mg) was added and the mixture was kept at RT for further 12 h. The support was filtered, resuspended in 5% *v*/*v* solution of piperidine (3 mL), reacted for 10 min, filtered again and washed successively with 10 mL portions of $CHCl_3$, CH_3OH, CH_3CN, and dried in vacuo. Loading was determined by treating a portion (5 mg) of **7** with 1 mL of 3% *w*/*v* CCl_3CO_2H in 1,2-dichloroethane and measuring the absorbance of DMTr cation at 504 nm (ε = 75 000 L mol^{-1} cm^{-1}). Loading found: 25–35 μmol/g.

Compound 9

Compound **8** (5.36 mmol, 2 g), obtained according to previously published procedures (4), was dissolved in dimethylformamide (40 mL), and *N*,*N*-diisopropylcarbodiimide (1.1 equiv., 5.9 mmol, 923 mL) and *N*-hydroxysuccinimide (1.1 equiv., 5.9 mmol, 678 mg) were added. The reaction was stirred at 40 °C overnight. The crude mixture was concentrated and crystallization from methanol yielded **9** (2.17 g, 93%).

Oligonucleotide synthesis

All oligonucleotides were synthesized on a 0.2 μmol scale with a Millipore Expedite 9809 synthesizer using conventional β-cyanoethyl phosphoramidite chemistry. The standard bases were dissolved in anhydrous acetonitrile (0.1 mol/L final concentrations). The modified phosphoramidites were dissolved in anhydrous acetonitrile and coupled manually with a coupling time of 15 min. The coupling efficiency was the same as that of unmodified amidites. All oligomers were synthesized "trityl off". The solid support was treated overnight at 55 °C with fresh concd. NH_4OH (1 mL). The crude oligomers were purified by electrophoresis on denaturated polyacrylamide gels (20%) and visualized by UV shadowing. The pure samples were desalted through reverse-phase set-pak cartridges (C18, Waters)

UV-monitored melting experiments

Purified oligonucleotides (each strand was 1 μmol/L) were diluted in 200 mL of the appropriate buffer. The mixture was boiled for 2 min and the hybridization was assured by low-temperature cooling of the sample. Melting experiments were performed with a Cary 1E UV–vis spectrophotometer with a temperature controller unit. Samples were kept at 5 °C for at least 30 min and then heated from 4 to 90 °C at a rate of 0.4 °C/min. The absorbance (λ = 260 nm) was measured every minute. The melting temperature was determined from the maxima of the first derivative. Two different buffers were used. The studies on the metalated species were performed in a buffer containing 10 mmol/L sodium phosphate (10 mmol/L, pH 7) and sodium chloride (150 mmol/L). The metal-free experiments were measured in an EDTA-containing buffer: EDTA (200 mmol/L), sodium phosphate (10 mmol/L, pH 7), and sodium chloride (150 mmol/L).

The synthesis of butene glycol ethers with aluminium triflate

Yvette M. Terblans, Michelle Huyser, Desmond A. Young, and Michael J. Green

Abstract: The use of aluminium triflate as a ring-opening catalyst for butene oxide (BuO) was evaluated in the presence of different alcohols such as methanol, ethanol, *n*-propanol, *n*-butanol, 2-propanol, 2-methyl-1-propanol, and 2-methyl-2-propanol. The reaction with methanol was studied kinetically by varying the temperature, catalyst concentration, and methanol – butene oxide molar ratio. These reactions yielded two major products (2-methoxy-1-butanol and 1-methoxy-2-butanol) in a approximate ratio of 1:1. It was noted that at low catalyst concentrations (<5 ppm), low temperatures (<90 °C), and a MeOH–BuO molar ratio of 8:1, the selectivity of the reaction could be kinetically manipulated to shift the product ratio towards 1-methoxy-2-butanol, the α-alkoxyalcohol. This result was confirmed by an experimental design program. Statistical calculations using the data from the experimental design identified a feasible region in which reactions with methanol could be carried out, which would lead to slightly higher selectivities to 1-methoxy-2-butanol. This region shows that the methanol – butene oxide ratio should be 8:1, the temperature between 80 and 85 °C, and the catalyst concentration between 3.9 and 5 ppm. These reaction conditions were used to carry out a test reaction with methanol and an extended series of alcohols. All the alcohols, except for 2-methyl-2-propanol, reacted with butene oxide under these conditions, with the selectivity to the α-alkoxyalcohol higher than to the β-alkoxyalcohol. To obtain a ring-opening reaction with 2-methyl-2-propanol, it was found that a higher catalyst concentration (approximately 10 ppm) and a lower alcohol – butene oxide ratio (6:1) at a temperature of 80 °C were necessary. This reaction led to a mixture of 1-*tert*-butoxy-2-butanol and 2-*tert*-butoxy-1-butanol with the selectivity to the α-alkoxyalcohol being somewhat higher because of the steric influence of the bulky *tert*-butoxy group.

Key words: aluminium triflate, alcohols, butene oxide, ring opening, α-alkoxyalcohol, β-alkoxyalcohol.

Résumé : On a évalué l'utilité du triflate d'aluminium comme catalyseur pour effectuer l'ouverture du cycle de l'oxyde de butène (BuO) en présence de divers alcools, dont le méthanol, l'éthanol, le *n*-propanol, le *n*-butanol, le 2-propanol, le 2-methyl-1-propanol et le 2-methyl-2-propanol. On a étudié la cinétique de la réaction avec le méthanol en faisant varier la température, la concentration de catalyseur et le rapport molaire méthanol – oxyde de butène. Ces réactions conduisent à la formation de deux produits principaux (le 2-méthoxybutan-1-ol et le 1-méthoxy-2-butanol) dans un rapport approximatif de 1 : 1. On a noté que, à de faibles concentrations de catalyseurs (<5 ppm), de faibles températures (<90 °C) et un rapport molaire MeOH–BuO de 8 : 1, la sélectivité de la réaction peut être manipulée d'une façon cinétique pour déplacer le rapport des produits en faveur du le 1-méthoxy-2-butanol, le α-alkoxyalcool. Ce résultat a été confirmé par un programme de modélisation expérimental. Des calculs statistiques à l'aide de données de modélisations expérimentales ont permis d'identifier une région appropriée dans laquelle les réactions avec le méthanol pourraient se produire pour conduire à des sélectivités légèrement supérieures en le 1-méthoxy-2-butanol. Ces calculs montrent que le rapport méthanol – oxyde de butène devrait être de 8 : 1, la température entre 80 et 85 °C et la concentration en catalyseur entre 3,9 et 5 ppm. On a utilisé ces conditions pour évaluer la réaction avec le méthanol et une série importante d'alcools. Dans ces conditions, tous les alcools réagissent avec l'oxyde de butène, à l'exception de l'alcool *tert*-butylique, et dans tous les cas la sélectivité favorise le α-alkoxyalcool par rapport au β-alkoxyalcool. Pour obtenir une réaction d'ouverture de cycle avec le 2-methyl-2-propanol, il est nécessaire d'utiliser une concentration en catalyseur plus élevée (environ 10 ppm) et un rapport alcool – oxyde de butène plus faible (6 : 1), à une température de 80 °C. Cette réaction conduit à un mélange de 1-*tert*-butoxy-2-butanol et de 2-*tert*-butoxy-1-butanol dans lequel la sélectivité en faveur du α-alkoxyalcool est légèrement supérieure en raison de l'influence stérique du groupe *tert*-butoxy.

Mots clés : triflate d'aluminium, oxyde de butène, ouverture de cycle, α-alkoxyalcool, β-alkoxyalcool.

Scheme 1. Ring opening of butene oxide with an alcohol.

Introduction

Ring-opening reactions of epoxides with alcohols, which have been successfully carried out for many decades, can be either base- or acid-catalyzed (1). In recent years the use of triflate salts (also known as trifluoromethane sulfonate salts) has become increasingly popular as catalysts for these reactions. The catalytic acitivity of rare earth triflates (e.g., $Eu(CF_3SO_3)_3$, $La(CF_3SO_3)_3$, $Lu(CF_3SO_3)_3$, $Nd(CF_3SO_3)_3$, $Sm(CF_3SO_3)_3$, $Sc(CF_3SO_3)_3$, $Y(CF_3SO_3)_3$, and $Ce(CF_3SO_3)_4$) has been investigated for the ring opening of epoxides by alcohols (2). Scandium triflate was found to be an exceptionally active catalyst for the ring opening of epoxides. $Yb(CF_3SO_3)_3$ has also been reported as a catalyst for intermolecular ring-opening reactions of epoxides with alcohols to give β-alkoxyalcohols in good to high yields with high regio- and stereo-selectivity (3).

Aluminium triflate is a Lewis acid that has been used as a catalyst in organic synthesis, for reactions including Friedel–Crafts acylation and alkylation (4, 5), the epoxidation of olefins with iodosylbenzene (6), the preparation of esters and lactones (7), as initiators for cationic polymerization (8), and as co-catalysts in the polymerization of olefins (9). Aluminium triflate has also been used as a catalyst for the ring-opening reactions of epoxides in the presence of alcohols and amines (10–12). Some work has also been carried out in which different epoxides and alcohols have been employed (13). In a recent study, we described the reaction of butene oxide with methanol, catalyzed by aluminium triflate (14). We now report on a kinetic study in which the effect of reaction variables (i.e., catalyst concentration, temperature, and reagent molar ratio) on the rate of conversion of butene oxide and selectivity to the major products (the α- and β-alkoxyalcohols) was investigated. The study was further expanded to include reactions with ethanol, *n*-propanol, *n*-butanol, 2-propanol, 2-methyl-1-propanol, and 2-methyl-2-propanol, with the aim of comparing the activity of $Al(CF_3SO_3)_3$ as a ring-opening catalyst of butene oxide in the presence of different alcohols (Scheme 1).

Due to the fact that $Al(CF_3SO_3)_3$ is a Lewis acid, its use as a ring-opening catalyst for butene oxide leads to the formation of both isomers of the corresponding butene glycol ether, i.e., α- and β-alkoxyalcohols. Previous studies have shown that the two isomers form in a molar ratio of close to one with the β-alkoxyalcohol in a slight excess compared with the α-alkoxyalcohol (10–12, 14). In a recent communication, three examples were provided in which the selectivity to the α-alkoxyalcohol is higher when using butene oxide and several others in the case of styrene oxide (13). In this study we show that it is possible to slightly increase the selectivity to the α-alkoxyalcohol with a simultaneous decrease in selectivity to the β-alkoxyalcohol by choosing the correct reaction conditions. Lower temperatures and catalyst concentrations were found to increase the selectivity to the α-alkoxyalcohol, whereas the opposite was observed for higher temperatures and increased catalyst concentrations. These results were verified by statistical calculations on data obtained from an experimental design program.

Experimental

Unless otherwise stated, all chemicals used in this study were purchased from Sigma-Aldrich and used without further purification. Aluminium triflate was prepared as described in the literature (12). Stock solutions of $Al(CF_3SO_3)_3$ (500 ppm) were prepared in each alcohol and the desired quantity thereof was weighed for every reaction. Kinetic reactions were carried out in a Parr autoclave. Gas chromatography was carried out using a Shimadzu GC-17A equipped with a flame ionization detector and a PONA capillary column (50 m × 0.21 mm × 0.5 μm). Each sample was weighed into a GC vial and *n*-heptane was used as an internal standard.

Typical experimental procedure for the ring opening of butene oxide

Methanol (192.25 g, 6 mol) and butene oxide (72.11 g, 1 mol) were combined in a 300 mL Parr reactor. On closing the reactor, it was flushed with nitrogen and evacuated to remove all air present. This flushing procedure was repeated three times.

A catalyst bomb was placed under vacuum prior to the run. The desired amount of the stock solution (2.644 g, 5 ppm) was weighed and transferred via a syringe to the bomb, which was then connected to the inlet of the autoclave. Next, a high-pressure nitrogen line was connected to the opposite side of the catalyst bomb after which stirring in the reactor commenced. The reactor was subsequently heated to 100 °C after which the catalyst solution was discharged into the reactor and a sample taken immediately (0 min) and weighed. The sample was weighed to determine the mass removed from the reactor. Further sampling from the reactor was carried out at the following intervals: 5, 10, 15, 20, 30, 60, and 120 min and each sample was weighed. Saturated NaOH–water solution (0.5 mL) was added to all samples to quench the reaction.

Results and discussion

Butoxylation of methanol

Catalyst concentration

In the first part of this study, the influence of catalyst concentration on the conversion of butene oxide and the selectivity to the major products (the α- and β-alkoxyalcohols) was studied over a range of catalyst concentrations. Included in this was the uncatalyzed reaction. The conversion of butene oxide is shown in Table 1. The data showed that the rate of conversion of the uncatalyzed reaction (0 ppm) was

Fig. 1. Ring-opened intermediate.

significantly slower than those of the catalyzed reactions. The increase in the rates from 0 to 1 ppm and to 5 ppm can clearly be seen; thus, as the catalyst concentration was increased, the rate of conversion also increased. However, hardly any difference was observed in the rate of conversion when the catalyst concentration was increased from 5 to 10 ppm. At these two catalyst concentrations, the rate of the reaction was very fast and the reactions were completed after approximately 10 min. The low catalyst concentration needed for a fast reaction is due to the fact that the Lewis acid ($Al(OCF_3SO_3)_3$) coordinates to the epoxide, which leads to further activation of the already active electrophile. It was also further demonstrated that the transfer of the $Al(OCF_3SO_3)_3$ from the ring-opened intermediate (Fig. 1) to the next butene oxide molecule is energetically favourable (14).

In these reactions two major products (the α- and β-alkoxyalcohols, 1-methoxy-2-butanol and 2-methoxy-1-butanol) were formed. By-products such as dimers, diols, and in some instances, trimers, were also formed during these reactions with a total yield of dimers, diols, and trimers of approximately 8%, selectivity to dimers of approximately 4%, selectivity to diols of approximately 1%, and selectivity to the trimers of approximately 3%. All products were identified using GC–MS. It was noticed that the higher the catalyst concentration, the higher the concentration of by-products.

The selectivities to the α- and β-alkoxyalcohols and yields of these products were calculated after 30 min of reaction time and are tabulated in Table 2. Upon considering the influence of the catalyst concentration on the selectivity to the products, it is observed that the selectivity to 1-methoxy-2-butanol was slightly higher than to 2-methoxy-1-butanol. However, as the catalyst concentration was increased above 2.5 ppm, the selectivity to the 2-methoxy-1-butanol was slightly higher than to 1-methoxy-2-butanol. This observation shows that as the catalyst concentration is increased, the formation of the sterically more hindered isomer becomes more facile.

Temperature

The second part of the study with methanol focused on the influence of reaction temperature on the rates of conversion, as well as the selectivity to the products. The conversion data are shown in Table 3.

The temperature data display a similar trend as the catalyst concentration data, i.e., the rate of conversion, increased as the reaction temperature was increased. The data also showed that the increase in the rate of conversion was not as significant when the temperature was increased from 100 to 120 °C, as was the case when it was increased from 60 to 80 °C and to 100 °C. This is due to the fact that the rates become very fast at the higher temperatures. It was also seen that the higher the temperature, the higher the concentration of by-products, i.e., dimers and trimers (total yield approximately 10%, selectivity to dimers approximately 7% and to trimers approximately 3%).

The selectivities to the alkoxyalcohols and the yields of these products were calculated after 30 min of reaction time. The data are shown in Table 4. It was observed that, although the ratio of the major products is approximately 1, at temperatures below 80 °C, the selectivity to 1-methoxy-2-butanol is slightly higher than to 2-methoxy-1-butanol, whereas the opposite is observed at temperatures above 80 °C. At 90 °C, the selectivity to 1-methoxy-2-butanol is

120	43.33	43.33	50.67	50.67

Note: $Al(CF_3SO_3)_3$ catalyst concentration = 5 ppm; MeOH–BuO = 6:1.

Table 5. Conversion of butene oxide with $Al(CF_3SO_3)_3$ at different methanol – butene oxide ratios.

	Conversion (mol%) of butene oxide					
Time (min)	MeOH–BuO (4:1)	MeOH–BuO (6:1)	MeOH–BuO (8:1)	MeOH–BuO (10:1)	MeOH–BuO (12:1)	Me–BuO (14:1)
5	76.69	59.18	57.44	55.53	56.75	57.03
10	100.00	94.39	96.57	96.37	96.20	92.55
15	100.00	100.00	100.00	100.00	100.00	100.00

Note: T = 100 °C; catalyst concentration = 5 ppm.

virtually equal to the selectivity to 2-methoxy-1-butanol. These observations correlate well with those already observed for the catalyst concentration. It was observed that as the temperature is increased, the formation of the sterically more hindered isomer becomes more facile; the same trend is observed for the catalyst concentration.

Reactant molar ratio

The last part of the study with methanol focused on the influence of the molar ratio of the reagents on the rates of conversion, as well as the selectivity to the alkoxyalcohol products. The conversion data are shown in Table 5. In this study the ratio of MeOH–BuO was varied from 4:1 to 14:1.

It was observed that as the ratio of MeOH–BuO is increased, the rate of the reaction decreases, since the transfer of the $Al(CF_3SO_3)_3$ from the ring-opened intermediate (Fig. 1) to butene oxide depends on the concentration of butene oxide in the reaction mixture. Since the increase in the MeOH–BuO ratio will lead to a lowering in butene oxide concentration, a drop in rate was observed as expected. It was observed that the lower the MeOH–BuO ratio, the higher the concentration of by-products such as dimers and trimers (total yield approximately 10%, selectivity to dimers approximately 7% and to trimers approximately 3%).

The selectivities to the alkoxy alcohols and the yields of these products were calculated after 30 min and the data are shown in Table 6.

The data show that at lower MeOH–BuO ratios, the selectivity to 2-methoxy-1-butanol is slightly higher, however, this slight excess decreases and the selectivity to 1-methoxy-2-butanol starts to increase. At a 14:1 ratio of MeOH–BuO, the selectivity to the two products is virtually the same. This is due to the fact that at lower MeOH–BuO ratios, the formation of the sterically hindered product 2-methoxy-1-butanol is more facile than at higher MeOH–BuO ratios.

Experimental design

All the results obtained from this kinetic study led us to formulate an experimental design program in which to optimize conditions that would lead to shifting the selectivity to the formation of more 1-methoxy-2-butanol and less 2-methoxy-1-butanol. All work done in the experimental design program can be found in the Supplementary material[2] to the publication. After all the data had been accumulated

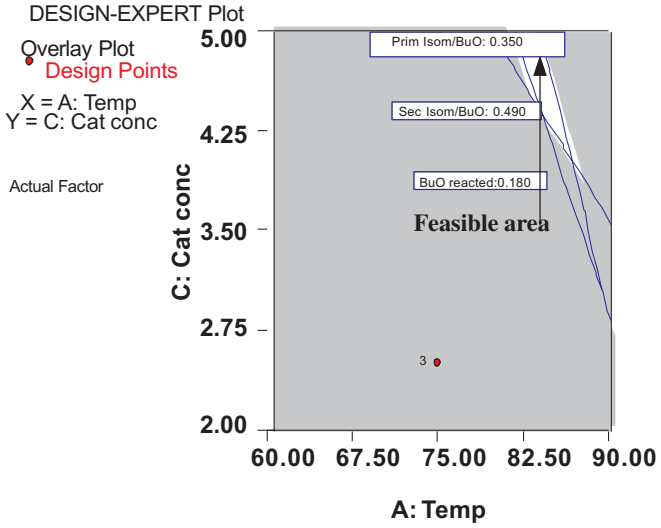
and the relevant calculations had been carried out to determine the selectivities to 1-methoxy-2-butanol and 2-methoxy-1-butanol, the data were statistically evaluated by fitting response surface models. A response surface model describes the response as a function of the influential variables and yields a regression model. The significance of the regression model is evaluated through an analysis of variance table. This was done for each time interval. As a similar result was obtained for each time interval, only the results obtained for the 5 min interval are discussed here; the rest of the statistical calculations can be found in the Supplementary material[2] to the publication.

The results obtained for the 5 min interval were evaluated to determine the simultaneous effect of the variables on the responses. An overlay plot (a three-point design plot) of the predicted trends from the models in Fig. 2 was used to determine this effect.

Figure 2 depicts the feasible region (white area demarcated by three blue lines) for temperature and catalyst concentration where the 1-methoxy-2-butanol – butene oxide ratio is greater than 0.45, the 2-methoxy-1-butanol – butene oxide ratio is smaller than 0.35, and the mass of butene oxide reacted is greater than 0.18 mol simultaneously. This feasible region is shown for a methanol – butene oxide ratio at its centre value (8:1). It is clear that the criteria are satisfied simultaneously for temperatures between 80 and 85 °C and catalyst concentrations between 3.9 and 5 ppm.

The statistical interpretation of the data indicates that for slightly higher selectivities to 1-methoxy-2-butanol and lower selectivities to 2-methoxy-1-butanol, lower temperatures and catalyst concentrations should be used. This would represent the feasible region as indicated by the overlay plot (T = 80–85 °C, catalyst concentration = 3.9–5 ppm, and MeOH–BuO ratio = 8:1).



Butoxylations of various alcohols

The results obtained from the methanol butoxylation reactions led to the expansion of the study to include other alcohols. The conditions identified for methanol were used to carry out reactions with ethanol, *n*-propanol, 2-propanol, *n*-butanol, 2-methyl-1-propanol, and 2-methyl-2-propanol, to test the activity of $Al(OCF_3SO_3)_3$ as an epoxide ring-opening catalyst in the presence of these alcohols. A reaction was also carried out with methanol at these reaction conditions, to verify that these were indeed suitable for slightly higher selectivities to 1-methoxy-2-butanol. The reaction conditions chosen were T = 80 °C, catalyst concentration = 4 ppm, and ROH–BuO = 8:1.

The conversion data obtained for the different alcohols are shown in Table 7.

The results show that an increase in the carbon chain length of the alcohol has an influence on the rate of the reaction: the longer the carbon chain, the lower the reaction rate. This was evident when the alcohol was changed from

n-BuOH	66.21	25.848 38	24.79	9.68	2.7:1
i-PrOH	59.37	16.890 77	16.63	4.73	3.5:1
i-BuOH	39.00	1.263 6	0	0	—
t-BuOH	0	0	0	0	—

$C_1 \rightarrow C_2 \rightarrow C_3 \rightarrow C_4$ *n*-alcohols. When the sterically more hindered alcohols (2-propanol, 2-methyl-1-propanol, and 2-methyl-2-propanol) were used, the rate decreased even further, up to the point where negligible reaction was observed when 2-methyl-2-propanol was used.

The selectivities to the alkoxyalcohols were calculated after 30 min of reaction time and are shown in Table 8. The yields of these products were also calculated at this time, as well as the ratio of the selectivity of the α-alkoxyalcohol to the the selectivity of the β-alkoxyalcohol (ratio Sel α : Sel β); these values are also shown in Table 8.

The nature of the alcohol plays a role on the product selectivity, clearly demonstrationg a greater selectivity for the α-alkoxyalcohol with increasing chain length and (or) steric bulk of the alcohol. No products were formed when using *tert*-butanol.

At these conditions, irrespective of the alcohol used, the reactions favoured the formation of the α-alkoxyalcohol above that of the β-alkoxyalcohol, in that more of the former and less of the latter were formed. The longer the carbon chain of the alcohol, the slower the rate of formation of the β-alkoxyalcohol. Results showed that even with methanol as the alcohol, 2-methoxy-1-butanol was only detected after 5 min. The ratio of 1-methoxy-2-butanol (the α-alkoxyalcohol) to 2-methoxy-1-butanol (the β-alkoxyalcohol) was, on average, 1.3. With an increase of one carbon atom in the chain length of the alcohol to ethanol, 2-ethoxy-1-butanol, the β-alkoxyalcohol was only detected after 10 min. The ratio of the two monomeric products (1-ethoxy-2-butanol to 2-ethoxy-1-butanol; α-alkoxyalcohol to β-alkoxyalcohol) was, on average, 1.9.

It should be noted that the reaction conditions used here were optimized for methanol as the alcohol and are not necessarily the optimum conditions when using the other alcohols. It was therefore decided to further investigate the reaction conditions for reaction with 2-methyl-2-propanol to determine whether any reaction will take place when $Al(CF_3SO_3)_3$ is used as the catalyst. If any reaction was observed, these conditions would also be used to carry out reactions with 2-propanol and 2-methyl-1-propanol.

The reaction conditions chosen were T = 80, 100, and 120 °C, catalyst concentration = 10 ppm, and *t*-BuOH–BuO = 6:1. The butene oxide conversion data are shown in Table 9. As expected, it was observed that as the temperature was increased, the reaction rate increased. Interestingly, at the higher catalyst concentration of 10 ppm and a lower *t*-BuOH–BO ratio of 6:1, a reaction between *t*-BuOH and BO was observed at 80 °C. Previously, the butoxylation reaction attempted at T = 80 °C, *t*-BuOH–BO = 8:1, and a catalyst concentration of 4 ppm showed no activity. Although the possibility of impurities in the feedstock acting as catalyst poisons cannot be ruled out at this stage, it has previously been indicated that higher catalyst concentrations are required with longer chain and bulkier alcohols (13).

Table 9. Conversion of BuO with *t*-BuOH at different temperatures.

	Conversion (mol%) of butene oxide		
Time (min)	80 °C	100 °C	120 °C
5	9.04	15.10	24.62
10	13.60	28.05	45.32
15	17.06	39.62	64.60
20	22.14	45.17	78.29
30	30.75	54.43	90.07
60	44.33	71.72	98.64
120	65.31	85.48	99.45

Note: $Al(CF_3SO_3)_3$ catalyst concentration = 10 ppm; *t*-BuOH–BuO = 6:1.

The selectivities to the major products, as well as their yields, were calculated after 30 min of reaction time. These results are shown in Table 10.

As the temperature was increased, the selectivity to the major products decreased. The ratio of the α-alkoxyalcohol to the β-alkoxyalcohol was approximately 2:1 at all three temperatures. This is expected as the sterically hindered alcohol (*t*-BuOH) would prefer to attach to the primary carbon (α-C) of butene oxide, rather than to the secondary carbon (β-C). This ratio is lower than expected (*n*-BuOH, 8:1) and can be rationalized as follows. The formed β-alkoxyalcohol is a primary alcohol and would react faster with the next molecule of BuO to produce dimers. Experimentally this is verified by large concentrations of the by-products such as dimers and trimers that are formed (yields between 15% and 20%). It can thus be concluded that an increase in the temperature leads to an increase in the conversion of the β-alkoxyalcohol to dimers and trimers.

As reactions with *t*-BuOH are generally known to be difficult because of the steric hinderance of the *tert*-butyl group, and as reaction conditions for the ring opening of butene oxide with *t*-BuOH were identified, it was decided to employ these reaction conditions in reactions with *i*-PrOH and *i*-BuOH, which have previously shown low activity. The influence of the different branched alcohols at the same set of reaction conditions on the rate of conversion of the butoxylation reaction is shown in Table 11.

Table 10. Selectivities to products at different temperatures with *t*-BuOH.

	1-*tert*-Butoxy-2-butanol		2-*tert*-Butoxy-1-butanol	
Temperature (°C)	Selectivity (%)	Yield (%)	Selectivity (%)	Yield (%)
80	62.20	19.13	26.80	8.24
100	59.50	32.39	27.50	14.97
120	51.00	45.94	29.90	26.93

Note: $Al(CF_3SO_3)_3$ catalyst concentration = 10 ppm; *t*-BuOH–BuO = 6:1.

Table 11. Conversion of BuO with different branched alcohols.

	Conversion (mol%) of butene oxide		
Time (min)	*t*-BuOH	*i*-BuOH	*i*-PrOH
5	15.10	33.89	35.67
10	28.05	53.06	49.96
15	39.62	70.50	71.80
20	45.17	77.91	82.47
30	54.43	86.42	88.02
60	71.72	95.84	96.53
120	85.48	99.09	99.65

Table 12. Selectivity to products with different branched alcohols.

	α-Alkoxyalcohol		β-Alkoxyalcohol	
Alcohol	Selectivity (%)	Yield (%)	Selectivity (%)	Yield (%)
t-BuOH	45.10	24.56	5.90	14.10
i-BuOH	52.1	45.026	33.90	29.30
i-PrOH	49.10	43.22	34.30	30.19

With *t*-BuOH, which is sterically more hindered than *i*-BuOH and *i*-PrOH, the rate of the butoxylation reaction with *t*-BuOH was slower. It was also observed that the rate with *i*-BuOH (a primary alcohol with branching) was similar to that with *i*-PrOH (a shorter chain secondary alcohol).

The selectivities to the major product and their yields were calculated at 30 min. These results are shown in Table 12.

For each of the three alcohols, the selectivity to the α-alkoxyalcohol (secondary alcohol) is higher than to the β-alkoxyalcohol (primary alcohol). This was also previously observed when the chain length of the alcohol was increased. The selectivity with *t*-BuOH was lower than for the other two alcohols, which correlates with the slower reaction rate, as the sterically more hindered alcohol will react slower. The selectivity for *i*-BuOH is higher than for *i*-PrOH, as the former alcohol is a primary alcohol and the latter a secondary alcohol. In all of these reactions, by-products were formed that are dimers and trimers.

Conclusion

The ring-opening reaction of butene oxide with different alcohols (methanol, ethanol, propanol, *n*-butanol, 2-propanol, 2-methyl-1-propanol, and 2-methyl-2-propanol) can easily be achieved in the presence of low concentrations of $Al(CF_3SO_3)_3$ as the catalyst. For short chain primary alcohols, e.g., methanol, ethanol, propanol, and *n*-butanol, very low catalyst concentrations (<5 ppm) and temperatures (<80 °C) are required to achieve this ring-opening reaction. For branched alcohols such as 2-propanol, 2-methyl-1-propanol, and 2-methyl-2-propanol, either slightly higher catalyst concentrations (approximately 10 ppm) or temperatures (approximately 120 °C) are required because of increased steric bulk and (or) hinderance.

It was also observed that the regioselectivity to the two major products (α- and β-alkoxyalcohols) can be kinetically manipulated to slightly favour either the one or the other, by changing the reaction conditions. For the reaction with methanol, it was observed that by choosing the correct reaction conditions, i.e., low catalyst concentrations and temperatures, the selectivity is slightly shifted to the α-alkoxyalcohol and vice versa. By using these conditions for the other alcohols, it was observed that the regioselectivity is shifted towards the α-alkoxyalcohol, except for 2-methyl-2-propanol where no reactivity was observed. However, by choosing the correct set of reaction conditions for 2-methyl-2-propanol to obtain activity (catalyst concentration of approximately 10 ppm and an alcohol–BuO molar ratio of 6), it was observed that the α-alkoxyalcohol is the preferred product. The same result is obtained when using 2-propanol and 2-methyl-1-propanol at the reaction conditions employed for 2-methyl-2-propanol.

Synthesis, characterization, and the molecular structures of two new kinds of stilbene

Yan-Hong Liu, Tong-Lai Zhang, Jian-Guo Zhang, Li Yang, Jin-Yu Guo, Wei Yu, Rui-Feng Wu, and Kai-Bei Yu

Abstract: We report in this study the synthesis, crystal culture, and single-crystal X-ray crystallography of two new kinds of double stilbene, which were readily prepared from trinitro-*p*-xylene and *p*-tolualdehyde in the presence of piperidine. We found that these triclinic crystals belong to the space group *P*-1. These compounds were also investigated using FT-IR, ^{1}H NMR, ^{13}C NMR, and MS spectroscopy techniques. The thermal decomposition processes of the compounds were tested by DSC and TG-DTG at a heating rate of 10 °C/min. These results indicate that the compounds have high heat-resistant stability.

Key words: polynitrostilbene, molecular structure, thermal decomposition.

Résumé : Dans ce travail, on rapporte la synthèse, la culture des cristaux, et la cristallographie par diffusion des rayons X de deux nouveaux types de double stilbène qui ont été facilement préparés par réaction du trinitro-*p*-xylène avec le *p*-tolualdéhyde en présence de pipéridine. On a trouvé que les cristaux tricliniques appartiennent au groupe d'espace *P*-1. On a aussi examiné ces produits par les techniques de spectroscopie infrarouge à transformée de Fourier, de RMN du^{1}H et du ^{13}C et par spectroscopie de masse. On a évalué les processus de décomposition thermique des composés par les techniques d'analyse calorimétrique différentielle (ACD) et de thermogravimétrie (TG) et de thermogravimétrie différentielle (TGD), à des taux de chauffage de 10 °C/min. Ces résultats indiquent que ces composés sont dotés d'une grande stabilité et d'une grande résistance à la chaleur.

Mots clés : polynitrostilbène, structure moléculaire, décomposition thermique.

[Traduit par la Rédaction]

Introduction

Nitro aromatic compounds, such as 2,4,6-trinitrotoluene (TNT), are well-known explosives that can be applied as energetic materials. These compounds have relatively high energy and good thermal stability and thus have been extensively studied (1–7). In previous papers, we reported the synthesis and properties of several new compounds of this kind, e.g., trinitro-*p*-xylene (TPX) and trinitro-trimethylbenzene (TNTM) (8, 9), which are more stable but less energetic than TNT. In this study, we present two other new kinds of stilbene that were synthesized by using TPX, *p*-tolualdehyde (PTD), and piperidine.

Stilbene is a type of compound whose structure contains C=C between phenyl rings (10–12), such as hexanitrostilbene (HNS), and is widely used in the medical and energetic materials industries. HNS is a heat-resistant explosive that has very low vapor pressure and high vacuum stability (13, 14). It is relatively insensitive to heat, spark, impact, and friction, yet it can be used widely as a heat-resistant booster charge for military applications.

During crude oil extraction, explosives are utilized for perforating the source rocks. As the average depths of the wells increase, as a consequence, the ambient temperatures in the wells increase. For these wells and for other applications requiring the explosive to withstand significant temperatures before initiation, heat-resistant explosives are of growing interest for the petroleum industry. Modern explosives have to withstand temperatures up to 260 °C for several hours without noticeable thermal decomposition (15).

We are interested in exploring some new heat-resistant explosives that have a similar structure to HNS, in which there exists a double stilbene bond and a piperidine ring that contains an aromatic nitrogen atom. To the best of our knowledge, this kind of structure has not been reported in the literature.

In this work, we cultured single crystals of the two compounds. The molecular and crystal structures were determined by X-ray single-crystal diffraction analysis. The thermal decomposition processes of the compounds were investigated to examine their thermal stability.

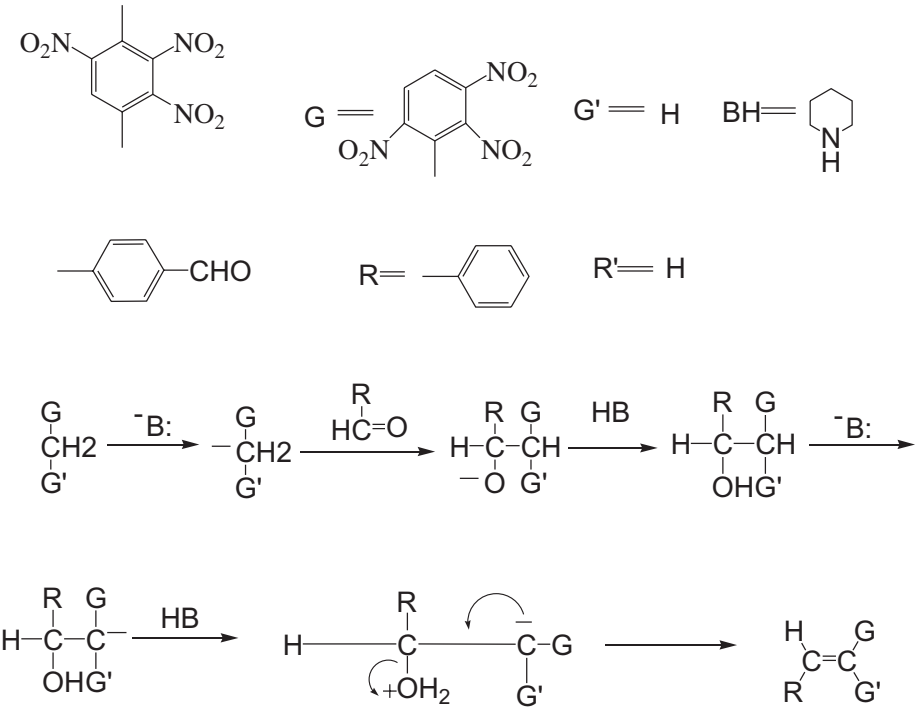
Results and discussion

Synthesis



Scheme 1 shows the equation of the synthesis of 1,4-di(*p*-methyl-styryl)2,3,6-trinitrobenzene (**A**) and 1,4-di(*p*-methyl-styryl)-2-piperidine-3,6-dinitrobenzene (**B**).

 doi:10.1139/V06-083 © 2006 NRC Canada

Scheme 1. The equation of the synthesis of **A** and **B**.

Scheme 2. The mechanism of reaction **A**.

The reactant TPX (CCDC number 25641) was synthesized and studied in a previous work (8).

The mechanism of the reaction is shown in Scheme 2. In this reaction the piperidine is used as the catalyst. When the proportion of the piperidine and TPX is more than 4:1, piperidine will react with the product as a nucleophilic reagent attached to C11 in the middle benzene ring, as shown in Scheme 3.

Crystal structure of the compounds

The X-ray single crystal structures of **A** and **B** were determined. The select bond lengths and bond angles are summarized in Tables 1 and 2. The unit structures of the molecules in the crystal lattice are illustrated in Fig. 1.

The data from Table 1 show that in structure **A** the left benzene ring is coplanar with the middle ring. The C8=C9 bond is in the same plane with the two phenyl rings, while the torsion angles of the C16=C17 bond between the middle benzene ring and the right benzene ring are 47.0° and 23.7°, respectively. The C=C bond (1.32 Å) is the shortest in this structure. Affected by the methyl and C=C bond, the endocyclic angles in the side benzene rings, C7-C2-C3 (117.3°), C6-C5-C4 (117.0°), C19-C18-C23 (117.7°), and C22-C21-C20 (116.7°) are smaller than the others (121°). The largest deviation between the inner angles and the stable benzene ring (120°) is 3.3°, which indicates that the two side benzene rings are stable. The C10—C11 and C13—C14 bonds are of normal length in the middle benzene ring; the C10—C15 and C12—C13 bonds (average length 1.40 Å) are found to be longer; and the C11—C12 (1.39 Å) bond is shorter. The C14—C15 (1.36 Å) is found to be the shortest among the benzene ring bonds because there is no

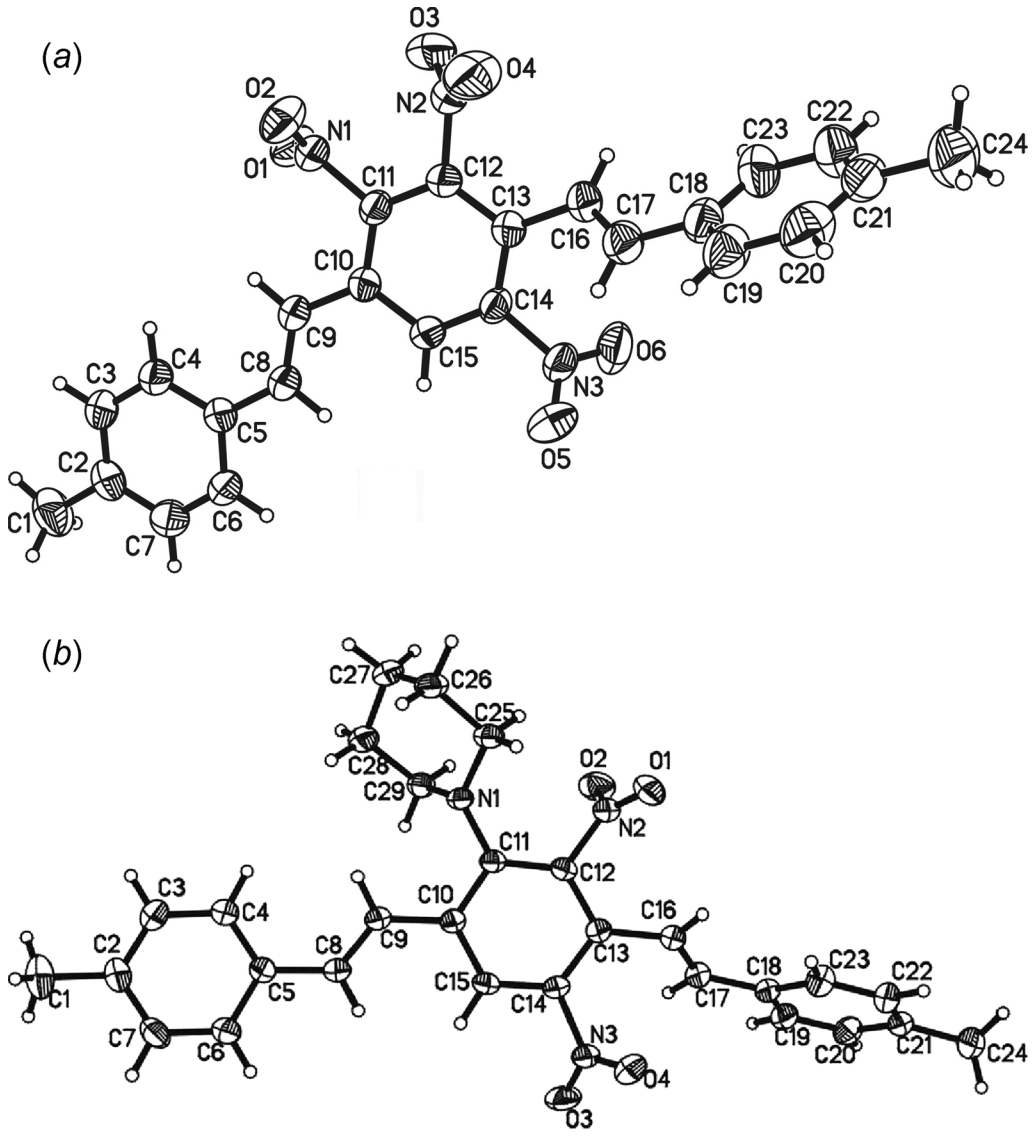
substituent at C15. The inner angles in the middle phenyl ring are about 123°, except for C15-C10-C11 (114.8°). The smaller bond angle of C15-C10-C11 may be caused by the conjugation of the C=C bond connected to C10. The other inner angles are larger than 120°, which indicates that there is some tension in the benzene and that the stability of the phenyl plane is weakened. The torsion angles about the C—N bonds are 60.9°, 50.7°, and 60.7° at C11, C12, and C14, respectively. N1 and N3 nitro groups have similar dihedral angles to the phenyl ring and rotate to the same face of the phenyl ring. The C—N bond length (N1—C11, 1.47 Å; N2—C12, 1.48 Å; N3—C14, 1.48 Å) is the largest and similar to the C—N length in TNT (14). The angles O-N-O and the two C-N-O average angle values are 125°, 118°, and 117°, respectively, so we can conclude that the N is sp^2 hybridized. The lengths and angles that contain the N are larger so we can predict that the C—N bond is easier to split than others. These results are similar to those for TPX (8) and TNT (16).



In structure **A**, there are two nitro groups in the ortho and para of the N1-nitro group, respectively, which make the density of the electric charge dispersal and the nucleophilic substitution easier for C11. Structure **B**, which results from the substitution of the nitro group at the N1 position of

structure **A** by a piperidine group, has a similar structure to **A**. From the data, we find that the results for the side benzene rings of structure **B** are basically the same as those of structure **A**. But there are some larger differences owing to the effect of the piperidine. Both C=C bonds are not coplanar to the benzene rings and the torsion angles C16-C17-C18-C23, C14-C13-C16-C17, C8-C9-C10-C15, and C4-C5-C8-C9 are 15.0°, 51.7°, 17.4°, and 22.0°.

Thermal behaviour

The results of DSC and TG-DTG analyses are shown in Figs. 2 and 3, which show TG and DTG curves, respectively. In the DSC curve, there is one aculeate endothermic peak and two exothermic peaks (see Fig. 2*a*). The temperatures at the peaks are 179, 238, and 530 °C. The second endothermic peak is wider than the first and corresponds to the second decomposition process. Correspondingly, the TG-DTG curve in Fig. 3*a* shows two processes of weight loss. The initial degradation temperature is 238 °C. In the first decomposition process, the largest mass loss rate is 9.0% per min at 252 °C. At 780 °C, the compound has not decomposed completely, with 30% residual mass. In Fig. 2*b*, there are two aculeate intense endothermic peaks, one sequential exothermic peak, and two exothermic peaks. The temperatures at the peaks are 191.6, 192.7, 209.5, and 272.6 °C. Compound **B** begins degrading at 253 °C and undergoes two obvious mass-losing processes. In the first decomposition process, the largest mass loss rate is 6.1% per min at 286 °C, with a total mass loss of 29.2% occurring in the range from 253 to 325 °C. During the second decomposition process, the largest mass rate is 5.5% per min at 599 °C, and at 683 °C the compound is completely decomposed. When the nitro group is substituted by piperidine, the initial degradation temperature becomes higher, probably because **B** has a larger formula weight than **A**. From the results, we find that the compounds have higher initial decomposition temperatures and higher heat resistances. The melting points of **A** and **B** are 179 and 192.7 °C, higher than TNT (80.9 °C), 1,3,5-trinitrobenzen (TNB, 121.2 °C), and TPX (141 °C). But the thermal abilities of these compounds do not compare with HNS, which has higher symmetry and more nitro groups. In the future, we will introduce more nitro groups to these compounds to improve their thermal abilities.

Conclusion

Polynitro dimethyldoublestilbene and piperidine substitutes have been prepared and characterized. In both crystal structures, there are two C=C bonds, three benzene rings, and two methyl-substituted groups. The difference between **A** and **B** is at the N1 position (at which **A** has a nitro group and **B** has a piperidine group). The two compounds have higher initial decomposition temperatures and higher heat-resisting abilities. But their thermal abilities do not compare to HNS. In the side benzene rings, there are eight unoccupied positions that could be substituted by other groups and that may produce some desired properties. So we expect that they could be used as heat-resistant explosives similar to HNS.

Experimental

General

The NMR spectra were determined using a Bruker AV400 MHz 400 spectrometer. ^{1}H NMR and ^{13}C NMR spectra were recorded for identification purposes in deuteriochloroform solutions at room temperature. All chemical shifts are reported in ppm downfield with tetramethylsilane as the internal marker. Infrared spectra were performed using a Bruker Equinox 55 FT-IR spectrometer (KBr pellet) in the range of 4000–400 cm^{-1}. Elemental analyses were carried out with a Flash EA 1112 fully automatic microanalyser. Mass spectra (MS) of the electronic impact positive ions were obtained using a GCT–MS Micromass spectrometer. Thermal properties of the compounds were measured using a differential scanning calorimeter (DSC), PerkinElmer Pyris-1 DSC, under a nitrogen atmosphere at a heating rate of 10 °C per min. A PerkinElmer Pyris-1 TG analyzer was used for thermogravimetric analysis. About 0.5 mg of the sample was held in a platinum pan, in a flow of dry oxygen-free nitrogen at 20 mL/min, and at a heating rate of 10 °C per min. The structures of the compounds were determined by single-crystal X-ray diffraction.

X-ray crystallography

The structure was solved by direct methods. Anisotropic displacement parameters were applied to all non-hydrogen atoms in full-matrix least-squares refinements based on F^2. The hydrogen atoms were set in calculated positions and refined as riding atoms with a common fixed isotropic thermal parameter.

© 2006 NRC Canada

All calculations were carried out using SHELXLS-98 (17). The conjugated and derivational effects of the nitro groups reduce the density of the electrons of the benzene ring. Crystallographic and refinement parameters are given in Table 3.[2]

Synthesis

1,4-Di(*p*-methyl-styryl)2,3,6-trinitrobenzene (A)

The general procedure for preparing **A** is as follows. 2,3,5-Trinitro-*p*-xylene (TPX) (0.02 mol), *p*-tolualdehyde (PTD) (0.042 mol), piperidine (3 mL), and benzene (100 mL) were placed in a dry 100 mL flask, equipped with a separate vessel of water and oil and a condenser. The reaction mixture was heated to reflux for 20 h. The mixture was cooled and ethanol was then added to the flask. The product was cooled in a refrigerator for 12 h. The mixture was filtrated and purified with acetone. The crystal was cultured in DMF, becoming pale yellow. Yield: 54%. IR (KBr, cm^{-1}): 3036, 2966, 2923, 1679, 1636, 1531, 1461, 1399, 1347, 1294, 1260, 1171, 1120, 1093, 1041, 979, 900, 804, 760, 725, 638, 550, 506. ^{1}H NMR ($CHCl_3$–TMS, *J* (Hz)) δ: 2.44–2.46 (d, 6H), 6.78–6.82 (d, 1H), 7.03–7.07 (d, 1H), 7.10–7.14 (d, 1H), 7.24–7.26 (d, 2H), 7.29–7.31 (d, 2H), 7.34–7.42 (t, 3H), 7.49–7.51 (d, 2H), 8.43 (s, 1H). ^{13}C NMR ($CDCl_3$–TMS, *J* (Hz), ppm) δ: 0.068, 21.33, 21.42, 114.32, 115.99, 123.38, 125.33, 126.04, 127.30, 127.65, 129.57, 129.82, 131.92, 132.08, 132.22, 138.75, 138.88, 140.14, 140.84, 142.71. Solubility prediction of anthracene in nonaqueous solvent mixtures using a combination of Jouyban–Acree and Abraham models

Abolghasem Jouyban, Maryam Khoubnasabjafari, and William E. Acree, Jr.

Abstract: The applicability of previously developed quantitative structure–property relationships was extended to predict the solubility of anthracene in nonaqueous binary and ternary solvent mixtures. The accuracy of the proposed methods was evaluated using 81 solubility data sets collected from the literature. The individual and mean percentage deviation (IPD and MPD) of experimental and computed solubilities were calculated as accuracy criteria. The computations were carried out using experimental and predicted mole fraction solubility of anthracene in monosolvent systems for binary and ternary solvent systems. The overall MPD of solubility prediction using experimental values in monosolvents varied from 5.2% to 4.2% and from 16.5% to 10.7% for binary and ternary solvents, using water to solvent and gas to solvent solvational parameters, respectively. The IPD distribution was better for the gas to solvent model. The corresponding ranges for the predicted solubility of anthracene in monosolvents were 47.9% to 28.1% and 23.9% to 22.5% for binary and ternary solvents, respectively, and IPD distribution was more favourable for the gas to solvent model. In general, the models derived from gas to solvent coefficients provided more accurate predictions and are recommended for practical applications.

Key words: solubility, prediction, cosolvency, anthracene, Abraham model, Jouyban–Acree model.

Résumé : On a étendu le domaine d'applicabilité des relations quantitatives structure–propriété développées antérieurement de façon à pouvoir prédire la solubilité de l'anthracène dans des mélanges de solvants non aqueux binaires et ternaires. On a évalué l'exactitude des méthodes proposées en faisant appel à 81 ensembles de données de solubilité tirés de la littérature. On a calculé le pourcentage de déviations individuelles (PDI) et moyennes (PDM) des solubilités expérimentales et calculées comme critère de l'exactitude. On a effectué les calculs en utilisant les fractions molaires expérimentales et calculées de solubilité de l'anthracène dans des systèmes à solvant unique pour les systèmes de solvant binaires et ternaires. Lorsqu'on utilise des paramètres de solvatation de l'eau au solvant et du gaz au solvant, les PDM globaux des valeurs prédites pour la solubilité en utilisant des valeurs expérimentales dans des solvants uniques varient respectivement de 5,2 % à 4,2 % et de 16,5 % à 10,7 % pour les solvants binaires et ternaires. La distribution des PDI est meilleure pour le modèle de gaz au solvant. Les plages correspondantes des valeurs prédites à partir de la solubilité de l'anthracène dans des solvants uniques varient respectivement de 47,9 % à 28,1 % et de 23,9 % à 22,5 % pour les solvants binaires et ternaires alors que la distribution PDI est plus favorable pour le modèle gaz à solvant. En général, les modèles dérivés de coefficients gaz à solvant conduisent à des prédictions plus exactes et on les recommande pour les applications pratiques.

Mots clés : solubilité, prédiction, cosolvant, anthracène, modèle d'Abraham, modèle de Jouyban–Acree.

[Traduit par la Rédaction]

Introduction

Anthracene is a low molecular weight polycyclic aromatic hydrocarbon (PAH), formerly known as a carcinogenic agent used for modelling purposes. However, later reports have stated that anthracene is not classifiable for its carcinogenicity to humans. Studies conclude that the toxicity of an oil appears to be a function of its diaromatic and triaromatic hydrocarbons, which include three-ring hydrocarbons. Acute toxicity of PAHs is rarely reported in humans, fish, or wildlife as a result of exposure to low levels of a single PAH compound. PAHs, in general, are more frequently associated with chronic risks. These risks include cancer and often are the result of exposures to complex mixtures of chronic-risk aromatics (such as PAHs, alkyl PAHs, benzenes, and alkyl benzenes), rather than exposures to low levels of a single compound. Anthracene is a very phototoxic compound, therefore, any of the water criteria that have been developed

for it using bioassays performed in the absence of UV light may be underestimating its true toxicity. The phototoxicity of PAHs was discovered when organisms that had survived laboratory exposures to PAHs died quickly after being moved into sunlight. Anthracene is ubiquitous in the aquatic environment. It has been detected in industrial effluents, in run-off waters, in surface water and sediments, in groundwater, and in drinking water. The industrial effluents that are most likely to contain PAHs, including anthracene, are wastewaters from the synthetic fuel industry. PAHs could be degraded using enzymatic reactions as has been reported in a recent paper (1), however, their poor solubility is a limiting factor and to overcome this limitation, researchers used mixed-solvent systems (1).

Solubility data of PAHs in mixed solvents is required for designing many industrial processes. In addition to experimental determinations, a number of mathematical models were developed for computation of the solubility. These include a quantitative structure–property relationship (QSPR) model recently proposed by our group to predict the solubility in binary and ternary solvent mixtures (2). Except for our study, we are not aware of any published work employing QSPRs or linear free energy relationships (LFERs) for describing the solubility of crystalline solutes in binary (or even higher-order multicomponent) solvent mixtures. QSPR and LFER correlations have been limited to single solvent systems. Katritzky et al. (3, 4) derived correlations that allow solubility predictions of about 500 substances in up to 69 diverse organic solvents using theoretical CODESSA-PRO descriptors. Each solute or solvent correlation employed a different set of molecular descriptors. Such correlations, while quite useful for solubility predictions in a single solvent, are not easily extendible to binary solvent mixtures as there is no convenient way to incorporate the binary solvent compositional dependence. Each individual solvent correlation uses a different set of solute descriptors. Acree, Abraham, and co-workers (5–8) have correlated the solubility behaviour of numerous crystalline nonelectrolyte solutes in a wide range of neat organic solvents, based on the Abraham solvation parameter model. The Abraham model uses a single set of solute descriptors for all partition and solubility processes. The additive terms in each derived Abraham correlation describe the various types of solute–solvent interactions, such as the interaction between the hydrogen bond acidity site(s) on the solute with the hydrogen bond basicity site(s) on the solvent.

The solubility of anthracene in nonaqueous mixed solvents has been extensively studied by our group (9–23). Details of previously published anthracene solubility data in binary and ternary solvent mixtures are listed in Tables 1 and 4, respectively. The experimentally determined data have been correlated using a solution model, i.e., the Jouyban–Acree model, which is proposed for correlating the solubility of PAHs in nonaqueous solvent mixtures (24, 25). The general form of the model is

$$[1] \qquad \ln X_m = f_1 \ln X_1 + f_2 \ln X_2 + f_1 f_2 \sum_{j=0}^{2} B_i (f_1 - f_2)^j$$

where X is the mole fraction solubility of the solute, f denotes the mole fraction of solvents 1 and 2 in the solvent mixture, subscripts m, 1, and 2 denote the mixed solvent and solvents 1 and 2, respectively, and B_i are the model constants, which are calculated using a no intercept least-squares analysis (26). The model can be readily extended to ternary solvent systems as follows

$$[2] \qquad \ln X_m = f_1 \ln X_1 + f_2 \ln X_2 + f_3 \ln X_3 + f_1 f_2 \sum_{i=0}^{2} B_i' (f_1 - f_2)^i + f_1 f_3 \sum_{i=0}^{2} B_i' (f_1 - f_3)^i + f_2 f_3 \sum_{i=0}^{2} B_i'' (f_2 - f_3)^i$$

where f_3 stands for the mole fraction of solvent 3 in the mixed solvent and B_i, B_i', and B_i'' are the sub-binary interaction terms. The main drawback of the Jouyban–Acree model is that it possesses a number of curve-fitting parameters and needs at least a number of experimental data points for training of the model. In a previous work, a QSPR model was proposed to estimate the numerical values of these model constants using Abraham's solvational parameters (27).

The Abraham solvational parameter model provides a convenient solubility prediction method for a wide variety of neat organic solvents. The basic models proposed for processes within condensed phases (water to solvent) and processes involving gas to condensed phase (gas to solvent) transfer are

$$[3] \qquad \log\left(\frac{C_S}{C_W}\right) = c + rR_2 + s\pi_2^H + a\sum \alpha_2^H + b\sum \beta_2^H + vV_X$$

$$[4] \qquad \log\left(\frac{C_S}{C_G}\right) = c + rR_2 + s\pi_2^H + a\sum \alpha_2^H + b\sum \beta_2^H + l \log L^{16}$$

where C_S and C_W are the solute solubilities in the organic solvent and water (in mol/L), respectively, C_G is the gas-phase concentration of the solute, R_2 is the excess molar refraction, π_2^H is dipolarity–polarizability of solute, $\sum \alpha_2^H$ denotes the solute's hydrogen bond acidity, $\sum \beta_2^H$ stands for the solute's hydrogen bond basicity, V_X is the McGowan volume of the solute, $\log L^{16}$ is the logarithm of the solute gas – hexadecane partition coefficent at 298.15 K, and c, r, s, a, b, v, and l are the model constants, which depend on the solvent system under consideration. The numerical values of the Abraham model constants were reported in previous works (5–8).

The solubilities of anthracene in 56 different binary solvent mixtures were used to compute the B_i terms of each binary solvent and the B_i terms were employed to build up a QSPR model using coefficients of the Abraham models of the solvents. The reported (27) QSPR models using water to solvent coefficients of the Abraham model for calculating B_i terms are

$$[7]\quad B_2 = -0.047 - 1.340(c_1 - c_2)^2 - 0.934(r_1 - r_2)^2 + 0.140(s_1 - s_2)^2 + 0.178(b_1 - b_2)^2 + 0.876(v_1 - v_2)^2$$

The corresponding equations for gas to solvent coefficients are

$$[8]\quad B_0 = 0.022 - 2.918(c_1 - c_2)^2 - 2.677(r_1 - r_2)^2 + 0.749(s_1 - s_2)^2 + 0.756(b_1 - b_2)^2 + 15.191(l_1 - l_2)^2$$

$$[9]\quad B_1 = 0.160 - 5.975(c_1 - c_2)^2 - 4.944(r_1 - r_2)^2 + 0.192(s_1 - s_2)^2 + 0.404(b_1 - b_2)^2 - 6.965(l_1 - l_2)^2$$

$$[10]\quad B_2 = -0.089 - 0.476(c_1 - c_2)^2 - 1.023(r_1 - r_2)^2 + 0.178(s_1 - s_2)^2 + 0.222(b_1 - b_2)^2 + 6.895(l_1 - l_2)^2$$

In eqs. [5]–[10], subscripts 1 and 2 denote solvents 1 and 2, respectively. The B_i terms, computed using eqs. [5]–[7] and [8]–[10], were used in eq. [1] and the solubility of anthracene in nonaqueous binary solvents was predicted employing experimental values of X_1 and X_2. The sub-binary interaction terms of the Jouyban–Acree model for ternary solvents, i.e., B_i, B_i', and B_i'', were computed using eqs. [5]–[7] and [8]–[10] and the Abraham's solvational coefficients of the corresponding solvents. To further reduce the required experimental data for solubility prediction, the numerical values of X_1 and X_2 were predicted using eqs. [11] and [12], then a full predictive version of the Jouyban–Acree model was proposed. By replacing numerical values of the descriptors, i.e., R_2, π_2^H, $\sum \beta_2^H$, V_X, and L^{16}, of anthracene taken from a previous paper (5), in eqs. [3] and [4], the solubilities (in mol/L) of anthracene in various organic solvents were calculated using

$$[11]\quad \log\left(\frac{C_S}{3.715\times10^{-7}}\right) = c + 2.290r + 1.340s + 0.280b + 1.454v$$

$$[12]\quad \log\left(\frac{C_S}{3.467\times10^{-10}}\right) = c + 2.290r + 1.340s + 0.280b + 7.568l$$

and converted to mole fraction solubilities using the density of neat solvents.

The aim of the present work is to check the applicability of the proposed QSPR model in predicting the solubility of anthracene in binary and ternary solvents. Anthracene data was choosen as the model system because of the vast amount of published experimental data. It is obvious that this approach could be employed for other solutes in mixed solvents.

Computational methods

The model constants of the Jouyban–Acree model were computed using eqs. [5]–[7] and [8]–[10] and the solubility of anthracene in binary and ternary solvents was predicted using eqs. [1] and [2], respectively. Using B_i values computed by the developed models, the only remaining unknown parameters needed to predict the solubility of a solute in binary and ternary solvent systems are the numerical values of the solute solubility in pure solvents, i.e., X_1, X_2, and X_3. To provide a predictive model (without any experimentally determined parameters), C_S values of anthracene in the solvents under consideration, computed using Abraham's models, were converted to the mole fraction solubilities using the density of the pure organic solvent. The computed X_1, X_2, and X_3 values were then used to predict the solubility in binary and ternary solvents using the Jouyban–Acree model. It is obvious that to convert C_S to mole fraction solubilities, we should use the density of saturated solutions, however, since that would require more experimental effort, we have used the density of pure organic solvents and ignored the effect of solute on the density of the solution.

The predicted B_i values were used to compute the solubility of anthracene in binary and ternary solvent mixtures and the mean percentage deviation (MPD) of observed and calculated solubilities were computed using

$$\mathrm{MPD} = \frac{100}{N}\sum \frac{|(X_m)_{cal.} - (X_m)_{obs.}|}{(X_m)_{obs.}}$$

where N is the number of data points. To check the variability of each solubility data point with the corresponding experimental value, individual percentage deviation (IPD) was also calculated using

$$\mathrm{IPD} = 100\,\frac{|(X_m)_{cal.} - (X_m)_{obs.}|}{(X_m)_{obs.}}$$

Computational results and discussion

Solubility prediction in binary solvents using experimental values of X_1 and X_2

The B_i terms, calculated using eqs. [5]–[7] and [8]–[10], and the experimental values of X_1 and X_2 were used to predict the solubility of anthracene in binary solvent mixtures and the MPD values are listed in Table 1. In this analysis, the only required information for predicting the solubility of anthracene in binary solvents are the numerical values of X_1 and X_2, i.e., two points for each binary solvent system, and there is no need to employ any experimental data from mixed-solvent systems. For B_i terms calculated using the water to solvent coefficients of Abraham's model (for details of the coefficients see Table 2), the minimum MPD (0.5%) was for 2-methyl-1-propanol + methyl *tert*-butyl ether, whereas the maximum MPD (19.2%) was for 2-butanol + acetonitrile solvent systems. The overall MPD (±SD) was 7.4 ± 5.2. In the next set of computations, B_i terms calculated using the gas to solvent coefficients of Abraham's model, i.e., eqs. [8]–[10] using the coefficients listed in Table 3, the minimum MPD (0.6%) was for 1-butanol + 1-propanol, whereas the maximum MPD (18.0%) was for 2-propanol + methyl *tert*-butyl ether solvent systems. The overall MPD (±SD) was 5.9 ± 4.3. The mean differences between the two numerical methods were not statistically significant (paired *t*-test, $p > 0.057$).

[a]Details of the numbers are the same as in Table 1.

In addition to the MPD criterion, we used the relative frequency of the IPDs of the predicted solubilities. The IPDs were sorted in three error ranges, i.e., ≤4% (comparable with experimental uncertainty (28)), 4%–30% (acceptable error range in pharmaceutical and chemical areas (29–31)), and >30% (unacceptable error range). These frequencies are shown in Fig. 1 for two solvational models using experimental X_1 and X_2 values. Using eq. [4], the probability of solubility prediction with error less than 30% was 0.994, whereas the corresponding probability for eq. [3] was 0.931. This finding reveals that despite the insignificant difference between MPDs of the two equations, the IPD distribution of

eq. [4] is better than that of eq. [3], and eq. [4] promises more accurate predictions and is recommended for predictive purposes.

Solubility prediction in binary solvents using predicted values of X_1 and X_2

The B_i terms, calculated using eqs. [5]–[7] and [8]–[10], and the predicted values of X_1 and X_2 were employed to predict the solubility of anthracene in binary solvent mixtures and the corresponding MPDs. This analysis was fully predictive and no experimental data was used in the prediction procedure. The results were also listed in Table 1. For B_i terms calculated using the water to solvent coefficients of Abraham's model, i.e., eqs. [5]–[7], and X_1 and X_2 calculated using eq. [11], the minimum MPD (9.9%) was for 1-propanol + acetonitrile, whereas the maximum MPD (263.5%) was for cyclohexane + 2-propanol solvent system. The overall MPD (±SD) was 47.9 ± 50.7. For B_i terms cal-

[c] X_1, X_2, and X_3 determined using eq. [12].

culated using the gas to solvent coefficients of Abraham's model, i.e., eqs. [8]–[10], and X_1 and X_2 calculated using eq. [12], the minimum MPD (4.3%) was for 1-butanol + acetonitrile, whereas the maximum MPD (92.2%) was for octane + 2-propanol solvent systems. The overall MPD (±SD) was 28.1 ± 22.3. The mean differences between the two numerical methods was statistically significant (paired *t*-test, $p < 0.0005$) as is shown in Fig. 2. The main reason for the relatively high MPD values for these analyses is the high prediction error for the predicted solubility of anthracene in monosolvent systems where the reported errors were 37.1% and 23.0%, respectively, for eqs. [11] and [12] (5). The next possible reason could be an error in solubility unit conversion from mol/L to mole fraction for which we used the density of pure solvent instead of the density of saturated solutions. The MPD differences for predicted solubilities in binary solvents were similar to those reported in a previous paper (5) for the solubility of anthracene in select organic solvents. The IPD distribution is shown in Fig. 1, in which the probability of solubility prediction using eq. [3] and its coefficients for IPD greater than 30% was 0.468 and the corresponding probability of eq. [4] was 0.270, revealing that eq. [4] is more accurate in comparison with eq. [3]. This finding was in agreement from earlier results using experimental X_1 and X_2 values.

Solubility prediction in ternary solvents using experimental values of X_1, X_2, and X_3

The B_i terms, calculated using eqs. [5]–[7] and [8]–[10], and experimental values of X_1, X_2, and X_3 were used to predict the solubility of anthracene in ternary solvent mixtures. The MPD values are listed in Table 4. In this analysis, the only required information for predicting the solubility of anthracene in ternary solvents is the numerical values of X_1, X_2, and X_3, i.e., three points for each ternary solvent system, and there is no need to employ any experimental data from mixed-solvent systems. For B_i terms calculated using the water to solvent coefficients of Abraham's model, i.e.,

Fig. 3. Relative frequencies of the IPDs for predicted solubilities in ternary solvents using two sets of solvational parameters of the Abraham model (experimental and predicted X_1, X_2, and X_3 values).

eqs. [5]–[7] (details of the coefficients are listed in Table 5), the minimum MPD (3.1%) was for dibutyl ether + 1-butanol + cyclohexane, whereas the maximum MPD (25.5%) was for 1,4-dioxane + 2-propanol + cyclohexane solvent systems. The overall MPD (±SD) was 10.7 ± 5.5. For B_i terms calculated using the gas to solvent coefficients of Abraham's model, i.e., eqs. [8]–[10] (details of the coefficients are listed in Table 6), the minimum MPD (1.8%) was for 1-butanol + 2-butanol + cyclohexane, whereas the maximum MPD (20.5%) was for 1,4-dioxane + 2-propanol + cyclohexane solvent systems and the overall MPD (±SD) was 9.3 ± 4.3. The mean differences between the two numerical methods were statistically significant (paired *t*-test, $p < 0.001$). The probability of solubility prediction within acceptable error range (<30%) using eqs. [3] and [4] was 0.972 and both equations showed similar IPD distributions, as shown in Fig. 3. However, it should be kept in mind that eq. [4] produced less MPD and also better results for IPD (≤4%).

Solubility prediction in ternary solvents using predicted values of X_1, X_2, and X_3

The B_i terms, calculated using eqs. [5]–[7] and [8]–[10], and predicted values of X_1, X_2, and X_3 using eqs. [11] and [12] were employed to predict the solubility of anthracene in ternary solvent mixtures and the corresponding MPDs. This analysis was fully predictive and no experimental data was used in the prediction procedure. The computed MPD values are listed in Table 4. For B_i terms calculated using the water to solvent coefficients of Abraham's model, i.e., eqs. [5]–[7] and X_1, X_2, and X_3 calculated using eq. [11], the minimum MPD (6.4%) was for 1,4-dioxane + 1-propanol + heptane, whereas the maximum MPD (74.8%) was for dibutyl ether + 2-methyl-1-propanol + cyclohexane solvent systems. The overall MPD (±SD) was 23.9 ± 18.8. For B_i terms calculated using the gas to solvent coefficients of Abraham's model, i.e., eqs. [8]–[10] and X_1, X_2, and X_3 calculated using eq. [12], the minimum MPD (9.9%) was for dibutyl ether + 2-methyl-1-propanol + cyclohexane, whereas the maximum MPD (33.0%) was for 1,4-dioxane + 2-butanol + 2,2,4-trimethylpentane solvent systems. The overall MPD (±SD) was 22.5 ± 7.1. The mean differences between the two numerical methods were not statistically significant (paired *t*-test, $p > 0.75$). Figure 3 shows that the probability of solubility prediction in ternary solvents within acceptable error range using fully predictive models with model constants derived from eqs. [3] and [4] were 0.740 and 0.788, respectively.

Conclusion

The QSPR models proposed in an earlier work provided accurate solubility predictions for anthracene dissolved in binary solvents using X_1 and X_2 values (and without these values) and the MPD values were within acceptable error range. The applicability of the methods was extended for predicting the solubility of anthracene in ternary solvents, which provided reasonably accurate predictions and could be used in solubility estimation methods that are widely required in the chemical and pharmaceutical industries. In the comparison between two solvational models and their coefficients for the solvents, the QSPR method derived from eq. [4] provided more accurate computations and is recommended for practical uses. We suspect that the superiority of the correlations derived from eq. [4] vs. those derived from

© 2006 NRC Canada

eq. [3] results from the fact that when the log P (e.g., eq. [3]) and log L (e.g., eq. [4]) correlations for the various organic solvents were developed, the log L equations generally had lower standard deviations and higher correlation coefficients. Often, different data sets were used in developing the two sets of correlations. In the case of highly water-insoluble organic compounds, the experimental uncertainty in the compound's aqueous solubility, needed in the indirect determination of the experimental log P value, undoubtedly contributed to a larger standard deviation for the Abraham eq. [3] correlations. It also should be added that the models discussed in this work were trained for mole fraction of solvents in the mixtures and that users should consider this point, since using volume and (or) weight fractions for expressing solvent composition will result in different model constants for eqs. [5]–[10]. As the results show, when employing solubility of anthracene in monosolvent systems, the proposed method provided accurate predictions. If solubility estimation with less accuracy is required, it is possible to use the fully predictive method proposed in this work.

NMR study of hydrogen bonding in methanol – carbon tetrachloride solutions

J.Q. Deng and R.H. Lipson

Abstract: The nuclear magnetic resonance (NMR) frequencies of the hydroxyl protons of methanol clusters in carbon tetrachloride were measured as a function of concentration between 245.4 and 320.2 K. The size of the methanol cluster (n) and the enthalpy and entropy of methanol self-association were obtained from nonlinear least-squares fittings to a model that assumed that only one dominant cluster was in equilibrium with the monomer at each temperature. The chemical shift measurements at 273 and 299.1 K fit best to theoretical curves calculated for a monomer–tetramer equilibrium. However, at higher and lower temperatures, the analyses indicate that the most dominant clusters are smaller and larger, respectively.

Key words: alcohol liquid solutions, structure, hydrogen bonding, thermodynamics of self-association, nuclear magnetic resonance.

Résumé : Opérant entre 245,4 et 320,2 K, on a mesuré les fréquences en résonance magnétique nucléaire (RMN) des protons hydroxyles d'agrégats de méthanol en fonction de sa concentration dans le tétrachlorure de carbone. On a évalué la taille (n) de l'agrégat de méthanol ainsi que ses enthalpie et entropie d'autoassociation sur la base d'ajustements non linéaires par la méthode des moindres carrés avec un modèle qui fait l'hypothèse que, pour chaque température, il n'existe qu'un seul agrégat dominant dans l'équilibre avec le monomère. Les valeurs expérimentales obtenues pour les mesures de déplacements chimiques à 273 et à 299,1 K s'ajustent bien aux courbes théoriques calculées pour un équilibre monomère–tétramère. Toutefois, à des températures plus élevées ou moins élevées, les analyses indiquent que les agrégats dominants sont respectivement plus petits et plus gros.

Mots clés : solutions liquides d'alcool, structure, liaison hydrogène, thermodynamique de l'autoassociation, résonance magnétique nucléaire.

[Traduit par la Rédaction]

Introduction

Liquid alcohols have been widely studied since the 1930s as model systems to understand the influence of hydrogen bonding and the alkyl chain on their physical properties. Despite a significant experimental effort to understand both neat liquid methanol (CH_3OH) and its solutions with relatively unreactive solvents such as carbon tetrachloride (CCl_4), the results have often been contradictory, particularly regarding the dominant cluster species at the microscopic level. This can be attributed primarily to the fact that most experimental techniques cannot directly image liquid structure at the molecular scale. An overview of previous studies on the structure of neat CH_3OH and CH_3OH–CCl_4 solutions (vide infra) reveals many uncertainties regarding the dominant cluster size in solution and at different temperatures. Therefore, CH_3OH–CCl_4 solutions were reexamined in this work by high-resolution NMR spectroscopy over a wide range of concentrations. In addition, measurements were carried out at four different temperatures (T = 245.4, 273, 299.1, and 320.2 K) to extract thermodynamic enthalpy and entropy of methanol self-association. This study was also undertaken to complement our recent work on the VUV laser – mass spectra of gas-phase methanol clusters (1).

Neat methanol

The role of hydrogen bonding in neat liquid methanol was first recognized by Zachariasen (2), who invoked this interaction to interpret his X-ray diffraction data. More recently, Magini et al. (3) provided X-ray diffraction data as evidence for extensive hydrogen-bonded chains, similar to that proposed in solid methanol (4). This conclusion agrees with that reached by Durov (5), who modeled methanol's thermodynamic, dielectric, and optical properties. His model indicates that methanol does not form small clusters, but instead, aggregates into long chains where the mean number of association at T = 293 K is n = 42. Tanaka et al. (6), however, using both X-ray and neutron diffraction data, concluded that the dominant species in neat methanol are clusters consisting of three or four hydrogen-bonded monomers. Yamaguchi et al. (7) revisited this problem using neutron diffraction and found the cluster size to be $n = 6.27 \pm 0.7$ at T = 193 K and $n = 5.5 \pm 1.0$ at T = 298 K. Sarkar and Joarder (8) argued that their X-ray diffraction data is strongly consistent with the presence of cyclic hexamers (n = 6). More recently, Saykally and co-workers (9) measured the room-temperature X-ray absorption spectrum of liquid methanol expanded in a

 doi:10.1139/V06-085 © 2006 NRC Canada

microjet, and using DFT calculations concluded that the bulk liquid is comprised of long chains ($n > 6$) and rings of hydrogen-bonded monomers.

The OH-stretching frequency of liquid methanol, monitored by IR (10) and Raman spectroscopy (11, 12), exhibits a structure that can be attributed to hydrogen bonding. Neat methanol exhibits three OH features, which in order of decreasing frequency are attributed to moieties that are nonbonded, those that interact weakly, and those that interact strongly, respectively. In essence, the last two bands arise essentially from weakly and strongly induced collective dipole moments; that is, from different degrees of clustering (13). The earlier Raman results (11) were interpreted in the framework of an electrostatic model, where it was concluded that the structure of liquid methanol is not chainlike but is instead a three-dimensional network featuring a mix of linear hydrogen bonds between two monomers, bifurcated hydrogen bonds among three monomers, and trifurcated hydrogen bonds among four monomers. The latter work (12) attributed the lowest frequency OH stretch to tetramers and higher aggregates.

A detailed statistical mechanical simulation of neat methanol at $T = 298$ K by Jorgensen (14) indicates that the liquid consists of long, winding hydrogen-bonded chains, where linear ($n = 2$) hydrogen bonding dominates. In contrast, semiempirical quantum calculations undertaken to understand the observed heat of vaporization indicate that methanol self-associates in pure liquids to form tetramers ($n = 4$) (15).

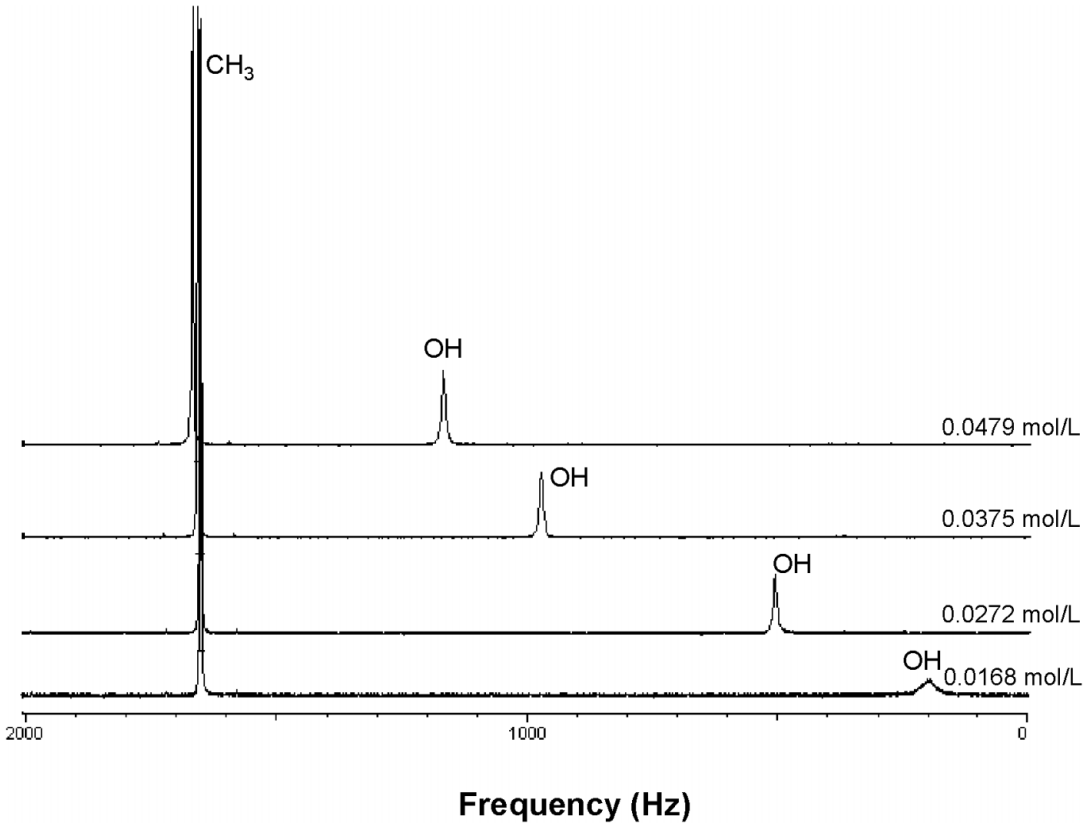
Methanol – carbon tetrachloride solutions

The physicochemical properties and supramolecular structure of MeOH–CCl_4 solutions have been reviewed and have been shown to be strong functions of solution concentration, temperature, and pressure (16). For example, methanol diffusion constants are inversely proportional to the degree of association and therefore, strongly concentration-dependent (17). Huyskens et al. (18) interpreted the dielectric studies of dilute methanol – carbon tetrachloride solutions in terms of cyclic alcoholic trimers ($n = 3$). Using similar techniques, Ibbitson and Moore (19) argued that linear dimers and trimers should be present when the mole fraction of methanol is ≤0.02. Light scattering, on the other hand, indicates cluster sizes between $n = 5$ and 6 (20). The methanol OH-stretching frequency in solution has also been investigated by vibrational spectroscopy (21–23). The IR spectra recorded by Bellamy and Pace (22) suggested that alcohols form open chain structures rather than cyclic compounds, and the hydrogen bonds linking trimers and higher polymers are significantly stronger than those for dimers. Fletcher and Heller (23) have presented evidence from IR spectra to support that the tetramer is the predominant polymeric species in solution.

NMR spectroscopy is well-suited to the study of alcohol solutions because hydrogen bonding decreases the electron cloud density around the H atom in the OH moiety. As a result, the nucleus becomes less screened from the applied magnetic field, which causes a shift to higher frequency in the observed resonance. The position of the OH proton resonance relative to those for the protons on the alkyl chain can therefore be taken as a measure of the extent of hydrogen bonding. Increases in temperature or dilution are expected to break the hydrogen-bonding network, causing the OH proton to become more shielded. In the limit of infinite dilution, the alcoholic proton chemical shift should approach that for a single uncomplexed monomer in the gas phase.

One of the earliest NMR studies of methanol in carbon tetrachloride was published by Saunders and Hyne (24) who covered concentrations down to 0.01 mol/L at a fixed temperature ($T = 294$ K). In their study, a model was developed to fit their data that assumed only one hydrogen-bonded species is in equilibrium with the monomer and a monomer–tetramer combination fit their data best. Symons and Thomas (25) compared IR and NMR spectra of CH_3OH in CCl_4 to show that hydrogen bonding remains complete down to below 0.1 mol fraction methanol, and that tetramers dominate at low temperature ($T = 183$ K). However, they also concluded that this model does not explain the room temperature data. Davis et al. (26) also reported an NMR study of MeOH in CCl_4, but their data covered a concentration range that excludes a large region (<0.04 mol/L) where the OH resonance frequency is still expected to change. They recognized that methanol polymers will exist at higher concentrations, but assignments were not provided. They also suggested that cyclic ring structures were expected to be particularly stable for clusters with $n \geq 4$. A recent NMR study (27) simply assumed that the most important equilibrium exists between monomers and tetramers in solution at room temperature. However, the emphasis in that study was the effect of high pressure on the NMR spectra. Specifically, chemical shifts were measured indicating the formation of new hydrogen bonds and (or) the strengthening of the existing interactions by bond length reduction.

Experimental



^{1}H NMR spectra were acquired on a Varian Inova 600 MHz spectrometer. Sigma-Aldrich HPLC grade methanol was distilled and placed under argon immediately prior to use. HPLC grade anhydrous carbon tetrachloride from Sigma-Aldrich was used without further purification. Working with neat methanol and solutions with molarities as low as ~0.0168 mol/L by volumetric dilution of liquid methanol, it was found that a concentration of 0.0168 mol/L was the lowest concentration that could still yield a spectrum with a good signal-to-noise ratio. Each sample was run in a NMR tube filled to the top with the solution to minimize contamination by moisture and to limit the amount of magnetic field shimming required. Prior to sample introduction, each NMR tube was cleaned with methanol and dried in a vacuum desiccator. Each tube was purged with Ar before filling. Once filled, the sample tubes were closed at the top and sealed with Parafilm.

The temperature of the sample was varied and calibrated to ~± 0.1 K using neat methanol NMR signals as a thermometer (28). Each sample was allowed to equilibrate for a minimum of 15 min to reach a stable temperature. At the lowest temperature ($T = 245.4$ K), at least 30 min were taken for stabilization to avoid a temperature gradient in the NMR tube, which might cause line broadening.

In this work, the peak center was taken as the resonance frequency for that signal. Each OH proton chemical shift

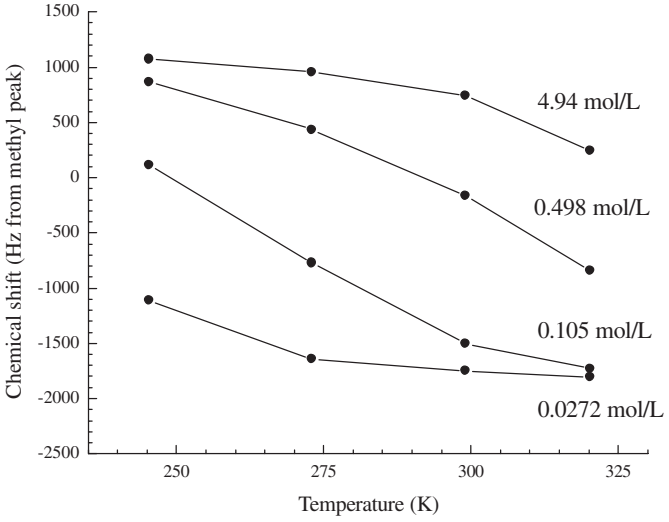
© 2006 NRC Canada

Fig. 1. Resonance frequency of the OH proton as a function of solution concentration at 245.4 K.

was measured relative to the methyl group resonance. A negative sign indicates that the hydroxyl resonance occurs at a lower frequency than the reference peak. Each reported shift is the average of at least three separate measurements. The precision of each chemical shift measurement lies within ±50 Hz and reflects the uncertainty in making solutions of identical concentration.

Results and discussion

Observations



The NMR spectra in Fig. 1 show the variation of the methanol OH signal frequency as a function of methanol – carbon tetrachloride mixture composition at 245.4 K. Increasing the methanol concentration increases the probability of hydrogen bonding, and as a result shifts the OH proton signal to higher frequencies. At low concentrations, when the probability of intermolecular hydrogen bond formation is greatly reduced, the resonance frequency of the OH proton should shift to lower values. The OH proton resonance for the lowest concentration mixture (0.0168 mol/L) studied in this work came at –1815.2 Hz or –3.02 ppm relative to the CH_3 peak at T = 320.2 K. This is consistent with the work of Chauvel and True (29), who reported an OH chemical shift in gaseous methanol of –3.39 ppm relative to CH_3 at T = 422 K. Therefore, it can be inferred that if the concentration of the methanol was sufficiently low, the measured chemical shift would correspond to a single methanol molecule.

Under the experimental conditions used to record the NMR spectra of methanol in Fig. 1, no coupling was observed between the hydroxyl hydrogen and the hydrogens belonging to the methyl group. Whether spin-spin splitting involving the hydroxyl hydrogen is observed or not depends on several factors including the resolution of the NMR spectrometer, the temperature, the purity of the sample, and the solvent used. Typically, spin coupling can only be observed in neat methanol at temperatures <223 K (30). Fine structure has been observed in ~0.068 mol/L methanol–benzene-d_6 solutions when the samples were very dry (30). The loss of spin coupling fine structure is a consequence of exchange of the methanol hydroxyl proton. At low concentrations in dry solvents, methanol can only exchange its proton with other methanol molecules. Thus, a loss of spin structure indicates that the hydrogen bonding is becoming important. As we do not see fine structure with solution concentrations <0.026 mol/L in this work, we conclude that despite precautions, our samples simply were not dry enough. Still, it is also evident in Fig. 1 that, at the lowest concentrations, the line width of the hydroxyl proton resonance is greater than that at higher concentrations. This is attributed to a decreasing exchange rate. At low concentrations, the methanol monomers and the hydrogen-bonded clusters experience different chemical environments, leading to the observed broadening.

The effect of increasing temperature is similar to lowering the solution concentration. An increased temperature causes hydrogen bonds to break shift the OH proton signal to lower frequencies (Fig. 2).

Analysis of self-association to determine dominant cluster size at T = 298 K

Different approaches to the analyses of hydrogen-bonding and association equilibria by NMR have been reviewed previously (31). Our analysis follows the procedure outlined below, which was first described by Saunders and Hyne (24) and Feeney and Walker (32). In their model, it is assumed that the solution is predominantly one cluster composed of n monomers, which obeys the following equilibrium.

$$[1] \qquad n(CH_3OH) \rightleftharpoons (CH_3OH)_n$$

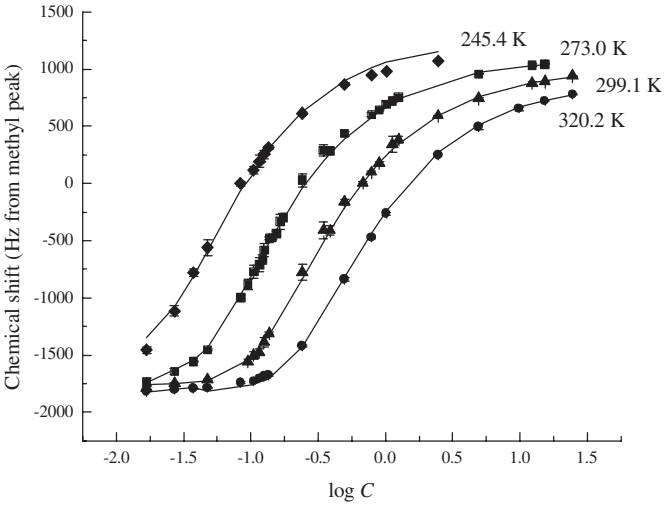
Let $[CH_3\ OH] = C_1$ and $[(CH_3OH)_n] = C_n$. The equilibrium constant (K_n) associated with rxn. [1] can then be written as

$$[2] \qquad K_n = \frac{C_n}{C_1^n}$$

In this analysis it is assumed that all hydroxyl groups in the same cluster contribute to the absorption at the same frequency. The model also assumes only one type of n-mer exists in solution, when in fact there could be a number of different geometric isomers. For an n-mer with n hydroxyl protons, the concentration of hydroxyl groups that absorb at the same frequency is given by nC_n or $nK_nC_1^n$. On the timescale of the experiment, the observed OH chemical shift is a weighted average of the chemical shifts of all the associated forms of the alcoholic compound.

The weighting factors are the fraction of the total number of hydrogen-bonded protons present in a given state at equilibrium. Thus, the transition frequency (ν) can be written as

$$[3] \qquad \nu = \frac{\nu_1 C_1 + 2\nu_2 K_2 C_1^2 + 3\nu_3 K_3 C_1^3 + \cdots}{C}$$



C is the total concentration of hydroxyl group in all clusters, which must equal the solution concentration; that is

$$[4] \qquad C = C_1 + C_2 + C_3 + ... = C_1 + 2K_2C_1^2 + 3K_3C_1^3 + ...$$

Table 1. Best-fit results for different n and K_n values at 299.1 K.

n	K_n (L^{n-1}/mol^{n-1})	ν_1 (Hz)	ν_n (Hz)	χ^2
2	4.0	–24691±5	1243±3	176.9
3	9.0	–1855±4	1063±2	21.0
4	30.7	–1757±4	1001±2	1.8
5	120.0	–1730±4	969±2	13.3

Fig. 3. Nonlinear least-squares fit of chemical shift (Hz) vs. log C, assuming a monomer–tetramer equilibrium at four different temperatures.

If only a single hydrogen-bonding equilibrium is significant and ν_n constant throughout the entire concentration range probed, then eqs. [3] and [4] simplify to

$$[5] \qquad \nu = \frac{\nu_1 C_1 + n\nu_n K_n C_1^n}{C}$$

where

$$[6] \qquad C = C_1 + nK_nC_1^n$$

Equation [5] was used as a fitting model with K_n set to an arbitrary value for a particular integer n at a given temperature to determine the characteristic chemical shifts of the monomer (ν_1) and n-mer (ν_n) by nonlinear least-squares fitting. Our experimental data were fit using four models: monomer–dimer, monomer–trimer, monomer–tetramer, and monomer–pentamer (n = 2, 3, 4, and 5 in eq. [5], respectively). In each case, K_n was varied until the χ^2 value of the fit was minimized.

Of all the fits done for the data at T = 299.1 K, the analysis obtained for n = 4 proved to be the best, inferring that tetramers are the predominant hydrogen-bonded species in solution. This agrees with the conclusion reached by Saunders and Hyne (24). The best-fit parameters for different values of n at 299.1 K are listed in Table 1.

Temperature studies

Figure 3 shows the fitted curves of chemical shift vs. log C as a function of temperature, assuming that the tetramer is the predominant hydrogen-bonded cluster in solution. The best-fit parameters are listed in Table 2. At very high dilu-

Table 2. Best-fit parameters assuming a monomer–tetramer equilibrium at different temperatures.

Temperature (K)	K_4 (L^3 mol^{-3})	ν_1 (Hz)	ν_4 (Hz)	χ^2
245.4	3550±150	–1494±21	1307±12	3.8
273.0	380±80	–1730±3	1102±1	1.8
299.1	31±3	–1757±4	1001±2	1.8
320.2	4.5±0.5	–1809±1	893.743±0.821	9.5

tion, the solution is assumed to be composed of only isolated methanol monomers surrounded by carbon tetrachloride. Although CCl_4 is expected to be relatively inert because it has no permanent dipole moment, the lone pairs of the chlorine atoms can interact weakly with the methanol hydroxyl proton. At each temperature except T = 245.4 K, the chemical shifts at high dilution are small and relatively unaffected by temperature as expected since they reflect an unchanging environment around the monomer. The change in ν_1 at the lowest temperature to higher frequencies suggests that the interaction between MeOH and CCl_4 is becoming more important. This low-temperature behavior is not unexpected given the small binding energy of MeOH and CCl_4 (2.6 kJ mol^{-1} at an uncorrelated Hartree–Fock level; 2.85 kJ mol^{-1} using B3LYP/6-31+G* density functional theory (30)). This binding energy, however, is considerably less than the interaction between two methanol monomers (22.7 kJ mol^{-1} at an uncorrelated Hartree–Fock level; 26.2 kJ mol^{-1} using B3LYP/6-31+G* density functional theory (30)), and illustrates the preference methanol has to self-associate.

As the concentration of methanol increases, the chemical shifts increase rapidly until they reach a plateau. The sharp increase in chemical shift is attributed to the strong preference of methanol monomers to hydrogen bond to other methanol molecules rather than to solvent molecules. In can be seen that the chemical shift of the tetramer (ν_4, listed in Table 2) is not a constant but decreases with increasing temperature. This change may be due in part to changes in the relative populations of linear and cyclic polymers in solution. A linear species has a free hydroxyl group. Since the average electronic shielding of a linear form is greater than a cyclic one, the chemical shift of a linear tetramer will be smaller than that for the cyclic isomer. In addition, the temperature variation of the tetramer proton might result from changes in the effective length of the H···O bond, which is influenced by low-frequency hydrogen-bond stretching vibrations and anharmonicity effects.

However, another important reason for a changing ν_4 chemical shift with temperature is the limitation of the analysis model itself. Based on the χ^2 values in Table 2, the monomer–tetramer model reproduces the shifts measured at 273.0 and 299.1 K well, but is less successful at higher and lower temperatures. At each temperature, a distribution of clusters is expected in solution. Thus, species other than the tetramer are expected to exist to a larger extent at higher and lower temperatures, which could affect the analyses. Since methanol – carbon tetrachloride solutions are composed of clusters of various sizes, then the average cluster size (n) may not necessarily correspond to an integer. Thus, the nonlinear least-squares fits were redone, but now allowing n to be a real number >1. In this way, better fits with smaller χ^2 values were obtained than those achieved using the monomer–tetramer model.

Table 3. Estimated ΔH values using ν_1 and ν_4 values obtained at different temperatures (C = 0.126 mol L^{-1}).

Temperature (K)	ν_1 (Hz)	ν_4 (Hz)	ΔH (kJ mol^{-1})
245.4	–1494	1307	–92.5±8.3
273.0	–1730	1102	–86.4±0.9
299.1	–1757	1001	–86.0±1.8
320.2	–1809	894	–86.7±4.9

At the lower temperature, the n value that gave the best fits was n = 4.3 (a change in χ^2 from 3.8 to 1.6), which implies that species larger than the tetramer are present in solution. Conversely, at higher temperatures, the best fit was obtained for n = 3.5 (a change in χ^2 from 9.4 to 3.2), indicating that smaller clusters are becoming the dominant species. It should be noted that the least-squares fits were not strongly sensitive to small changes in n, so it would be difficult to read more into the actual noninteger values of n other than the trends, which are the expected ones.

Thermodynamics of methanol association

Having equilibrium constants at different temperatures allows the enthalpy of association (ΔH) and the entropy of association (ΔS) to be determined since the Gibbs free energy change at a given temperature ($\Delta G = \Delta H - T\Delta S$) is related to K_n by

$$[7] \qquad \Delta G = RT \ln K_n$$

where R is the gas constant. Assuming that ΔH and ΔS are independent of temperature over the range of measurements, it is straightforward to show that

$$[8] \qquad \ln K_n = -\frac{\Delta H}{RT} + \frac{\Delta S}{R}$$

A van't Hoff plot of $\ln K_n$ vs. T^{-1} should then be linear with a slope of $-\Delta H/R$ and an intercept of $\Delta S/R$. Using the two equilibrium constants for T = 273.0 and 299.1 K yields a ΔH for tetramer association of –68.2 ± 8.4 kJ mol^{-1} and tetramer entropy of association of –200.2 ± 28.8 J mol^{-1} K^{-1}.

In the second approach (32), eqs. [5] and [6] were combined to yield

$$[9] \qquad K_n = \frac{(\nu - \nu_1)(\nu_n - \nu_1)^{n-1}}{nC^{n-1}(\nu_n - \nu)^n}$$

Assuming that ν_1 and ν_n are independent of temperature, then $(\nu_n - \nu_1)^{n-1}$ will also be a constant. It follows therefore that

[a]Dielectric study (see ref. 36).

$$[10] \quad \log K_n = \log \frac{(\nu - \nu_1)}{(\nu_n - \nu)^n} + B$$

where B is a constant. It is straightforward, using eqs. [10] and [8], to derive

$$[11] \quad \frac{1}{T} = -\frac{2.303R}{\Delta H} \log \frac{(\nu - \nu_1)}{(\nu_n - \nu)^n} + B''$$

where B'' is another constant. For a fixed total methanol concentration C, a plot of $1/T$ vs. $\log(\nu - \nu_1)/(\nu_n - \nu)^n$ should be linear with a slope of $-2.303R/\Delta H$. Using the frequencies ν_1 and ν_4 derived from chemical shifts measured at T = 273.0 K and C = 0.126 mol/L, such a plot yields a value of $\Delta H = -86.4 \pm 0.9$ kJ mol^{-1}. Table 3 gives the ΔH values obtained from similar plots using ν_1 and ν_4 values obtained at different temperatures. The values are quite consistent except when T = 245.4 K. The larger enthalpy change in this case is again attributed to the increased importance of methanol – CCl_4 interactions. Since we have shown that a monomer–tetramer model may not be completely valid at the highest and lowest temperatures considered in this work, an average ΔH of tetramer association of –86.2 ± 1.4 kJ mol^{-1} was calculated from the mid-temperature results alone.

Conclusion

A comparison of the thermodynamic data derived in this work with other experiments and solvents is presented in Table 4. Not surprisingly, the value of ΔS, corresponding to the entropy change for the formation of tetramers from monomers, is negative, indicating a more ordered solution. The sign of ΔH indicates that methanol self-association is an exothermic process.

The binding energy of the linear methanol dimer has been calculated using density functional theory to be –15.5 kJ mol^{-1} (33). If the methanol tetramer is linear and the three internal hydrogen-bond energies are additive, the resultant total binding energy would be –46.5 kJ mol^{-1}. Similarly, a cyclic structure with four hydrogen bonds would have a minimum binding energy of –62.0 kJ mol^{-1}. The enthalpy derived in this work is closer to the cyclic structure prediction.

Large differences between higher level calculations and the values above are attributed in part to cooperativity effects (34, 35). While the increase in binding energies for clusters above n = 4 follows an asymptotic approach to linear H bonds in larger systems, the particularly large cyclic tetramer binding energy of –113.84 kJ mol^{-1} (33) is attributed to cooperativity effects coupled with minimum ring strain (34). Still, this value is higher than experimental values determined for the gas-phase cluster from IR intensities (–75.3 kJ mol^{-1}) (34) and by heat capacity, vapor density, and thermal conductivity measurements (92.5–100.9 kJ mol^{-1}) (34), and the enthalpy obtained in this work. Interestingly, calculations place the binding energy of the linear chain configuration at –80.9 kJ mol^{-1}, the unequal branched chain at –61.4 kJ mol^{-1}, the equal branch chain at –69.8 kJ mol^{-1}, and the branch cycle at –83.5 kJ mol^{-1} (33). The enthalpy of association derived in this work lays closer to that expected for the linear chain and the branch cycle configurations. It must therefore be concluded that the actual dominant tetramer geometry in solution remains an open question, but it is most likely that the cluster adopts several forms.

One-electron oxidation of methionine peptides — Stability of the three-electron S—N(amide) bond

Patrick Brunelle, Christian Schöneich, and Arvi Rauk

Abstract: The possibility of sulfur–nitrogen (S—N) three-electron bond formation in a one-electron oxidized methionine peptide model was investigated computationally following the detection of such species in pulse radiolysis experiments (C. Schöneich, D. Pogocki, G.L. Hug, and K. Bobrowski. J. Am. Chem. Soc. **125**, 13700 (2003)). Geometry optimizations were carried out at the B3LYP/6-31G(d) level of theory. Relative free energies in aqueous solution at pH 7 were predicted for all intermediates with enthalpy evaluations at the CCSD(T)/6-31+G(d′) level and free energies of solvation predicted using a continuum model (CPCM). Both the initial oxidation product and the intermediate formed at higher pH were identified as cyclic S—N bonded species in which the intramolecular three-electron interaction is between the S atom and the π orbital of the amide group. TD-B3LYP calculations of the UV spectra support the assignments. A mechanism for the conversion to the most stable α-C-centered radical is proposed. The mechanism involves a novel deprotonation–reprotonation via an intermediate backbone-delocalized radical anion.

Key words: methionine oxidation, three-electron bonding, S—N bonding, B3LYP.

Résumé : À la suite de la détection d'espèces comportant des liaisons à trois électrons entre le soufre et l'azote (S—N) dans des expériences de radiolyse pulsée (C. Schöneich, D. Pogocki, G.L. Hug, and K. Bobrowski. J. Am. Chem. Soc. **125**, 13700 (2003)), on a fait appel à des calculs théoriques pour examiner la possibilité de formation d'un tel type de liaison lors de l'oxydation par un électron d'un peptide modèle de la méthionine. On a effectué les optimisations de la géométrie au niveau B3LYP/6-31G(d) de la théorie. On a pu faire des prédictions pour les énergies libres relatives en solution aqueuse, à un pH de 7, pour tous les intermédiaires avec des évaluations d'enthalpie au niveau CCSD(T)/6-31+G(d′) et les énergies libres de solvatation ont été faites utilisant un modèle continu, CPCM. On a établi que le produit d'oxydation initial ainsi que l'intermédiaire qui se forme à des pH plus élevés sont des espèces cycliques comportant des liaisons S—N dans lesquelles l'interaction intramoléculaire à trois électrons se situe entre l'atome de soufre et l'orbitale π du groupe amide. Des calculs de spectre UV faits au niveau TD-B3LYP sont en accord avec ces attributions. On propose un mécanisme pour la conversion vers le radical le plus stable centré sur le carbone-α. Le mécanisme implique une nouvelle réaction de déprotonation–reprotonation qui se fait par le biais d'un intermédiaire anion radical délocalisé sur le squelette.

Mots clés : oxydation de la méthionine, liaison à trois électrons, liaison S—N, B3LYP.

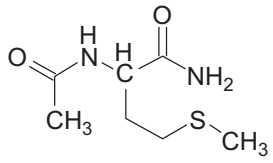
Introduction

Oxidation of methionine sulfur is an important feature of "oxidative stress" in biological systems (1–7), and may be a key step in the neurotoxicity of the β-amyloid peptide (Aβ) in Alzheimer's disease (8–10). The reduction potential of dimethyl sulfide radical cation is typical of a dialkyl sulfide, E° = 1.66 V vs. SHE (11, 12). Oxidation of aqueous methionine is an irreversible process. The reduction potential of 1 e oxidized zwitterionic methionine (Met) (exptl. at pH 7, $E^{\circ\prime} < 1.48$ V (13); calcd. $E^{\circ\prime} = 1.25$ V, $E^\circ = 1.66$ V (14)) is about the same as that of a typical dialkyl sulfide radical cation, and that of oxidized MetGly is modestly lower (1.42 ± 0.3 V) (15). It was confirmed by a recent ab initio investigation that intermediates with three-electron bonds between S and the -NH_2 group (S∴N) or -CO_2^- group (S∴O) of the Met amino acid are formed but do not result in a substantial lowering of the reduction potential (14). Both S∴O and S∴N bonds in Met derivatives and small organic sulfides have been proposed (15) and observed spectroscopically (16, 17) in pulse-radiolysis and flash photolysis experiments in aqueous solutions.



In a recent publication on the hydroxyl-radical-induced oxidation of *N*-acetylmethioninamide **2** (18), one of us presented experimental spectroscopic and kinetic evidence for the formation of a new sulfur–nitrogen 3 e bonded species, most likely **5a/5b**, in which an intramolecular 3 e bond (S∴N) was transiently formed between the S atom of a Met peptide and the N of a deprotonated amide group upon one-electron oxidation by hydroxyl radical after pulse radiolysis.

5a

5b

8

The putative structures **5a/5b** are the only asymmetric sulfide radical species detected 10 μs after the pulse at pH 5.4. The observed UV absorption was best fit with a broad band peaking at 390 nm, attributed to **5a/5b**. It was not possible at the time to distinguish **5a** from **5b**, or to characterize in more detail the nature of the S∴N bonding. As part of the present study, we provide an estimate of the S∴N bond strength in aqueous solution and in the gaseous phase and characterize it by the predicted UV spectrum in water.

Furthermore, some of the initially formed **5a/5b** are transformed into the α-C-centered radical **8**. This transformation is expected to be highly exothermic and can be formulated as a simple intramolecular hydrogen atom transfer (1,2- in the case of **5a**, or 1,3- for **5b**). However, such H-atom transfers typically encounter high activation barriers, and alternative routes involving elimination and addition of protons or H-atoms may be formulated. A secondary part of this study is to propose a mechanism for the transformation of **5a/5b** into **8**.

Methods

Ab initio calculations were performed with the Gaussian 98 (19) or Gaussian 03 (20) suites of quantum chemistry programs. Geometry optimization and frequencies for all species were carried out at the B3LYP/SB level of theory. Henceforth, we will use SB to represent the small basis set (6-31G(d)) and LB for the larger basis set (6-311+G(3df,2p)). All other basis sets will be given explicitly. A thorough investigation of the geometries of the related three electron bonded species in the gaseous phase and in solution found only minor differences in the two geometries (21). Zero point energies were obtained from the frequencies scaled by a factor of 0.9806 (22), while no scaling was applied for the calculation of entropies or the temperature dependence of the enthalpy ($H^{\circ}_{298K} - H^{\circ}_{0K}$). No attempts were made to locate all conformers for all species. The contribution to the entropy from the flexibility of the species was approximated as $R \ln(n)$, where n is an estimate of the number of significantly populated conformers (23). Values of n are given in Table S1 of the Supporting information.[2] To improve relative values of the enthalpy, energies were calculated at the B3LYP/LB, CCSD(T)/6-31+G(d′),[3] or CBS-RAD level (24) on the B3LYP/SB geometries. CBS-RAD is a high-level theoretical method for obtaining accurate thermochemical values for radicals to experimental accuracy. The CBS-RAD//B3LYP/SB method employed here was found to yield good reaction enthalpies and barriers for the addition of C-centered radicals to alkenes (25–27) and the β-scission reactions of alkoxy radicals (28). However, for reasons described in the following, relative energies of species involving 3 e S∴N bonds are more appropriately described at the CCSD(T) level. For consistency, all relative energies are cited at the CCSD(T) level.

Time-dependent density functional theory, with the B3LYP/6-311+G(d,p) description of the Hamiltonian (TD-B3LYP) (29) and the CPCM reaction field (30), is used to calculate the lowest UV transitions of selected species (20). In the case of cyclic structures containing a 3 e S∴N bond, spectra are very sensitive to the S—N separation. We show in the following that the CCSD(T)/6-31+(d′) level of theory yields the most reliable S—N separation. The CPCM procedure, as implemented in Gaussian, requires atom-centered spheres to describe the cavity in the solvent. The radii of atom-centered spheres were chosen so as to fill the volume defined by the gaseous-phase 0.001 e bohr^{-3} isodensity surface derived for a B3LYP/SB wave function (31, 32).

Orbitals were obtained from B3LYP/SB wave functions and shown at the contour level encompassing 60% of the electron.

Aqueous solvation

Solvation effects are modeled according to the conductor-like polarizable continuum model, as implemented in Gaussian 98 or Gaussian 03 as SCRF=CPCM with the cavity defined by an isodensity surface of the molecule, as described above. It is anticipated that calculation of the Gibbs free energy of solvation (ΔG_{SOLV}) in this manner will render inevitable errors to be more systematic and hence amenable to cancellation or to correction by reference to experiments. For entropy and free energy calculations in the gaseous and aqueous phases, a standard state of 1 mol L^{-1} is required. At 298.15 K, the change in volume from 24.6 L at 1 atm (1 atm = 101.325 kPa) to 1 L at 1 mol L^{-1} yields a change in the Gibbs free energy of +7.98 kJ mol^{-1}.

To reduce the errors in the calculated changes in Gibbs free energy of solvation for all the species involved in a reaction, values derived from experiment were adopted for the free energy of solvation of water ($G_{SOLV}(H_2O)$[4] = –26.4 kJ mol^{-1} and of the proton ($G_{SOLV}(H^+)$ =

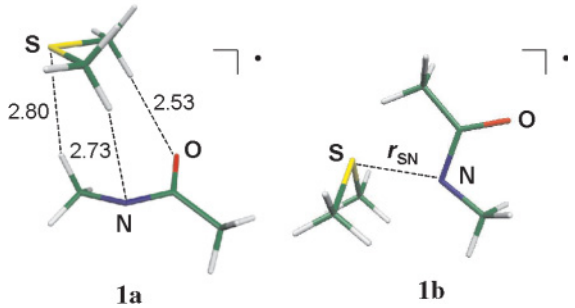
–1107 kJ mol^{-1} (33)). Values of pK_a are calculated from free energy changes for reactions involving loss of a proton.

Results and discussion

The present study aims to examine the thermodynamics of deprotonation–protonation equilibria of the Met dipeptide, *N*-acetylmethioninamide **2**, after one-electron oxidation to the sulfide radical cation (**2**$^{+\cdot}$) in aqueous solution. The nature of the bonding is of special interest. We begin by examining the simpler system comprised of dimethyl sulfide (DMS) and *N*-methylacetamide (NMA).



Dimethyl sulfide-*N*-methylacetamide (1, DMS-NMA)

The present methodology relies on structures determined at the B3LYP/SB level of theory. While this is the method of choice for many applications, it may suffer in the description of 3 e bonds (34). In previous work it was concluded that 3 e bonds between sulfur and oxygen (S.∴O) appear to be adequately described (14). For instance, the S.∴O bond between dimethylsulfide radical cation (DMS$^{+\cdot}$) and a water molecule was calculated to be too short by 0.1 Å at the B3LYP/SB level, compared with the CCSD(T)/6-31+G(d′) level. This may not be the case for S.∴N to divalent N as in amidyl radicals because of a larger disparity of sulfide and amide ionization potentials. A (σ,σ*) 3 e S.∴N bond may be described by resonance structures **a**–**c**.

$$\underset{\mathbf{a}}{S^{\bullet+}:N^{-}} \longleftrightarrow \underset{\mathbf{b}}{S.\therefore N} \longleftrightarrow \underset{\mathbf{c}}{S:\bullet N}$$

Such a bond between an oxidized DMS and deprotonated amide would ideally involve the nonbonding 3p orbital of the S and the in-plane sp^2-like orbital of the amide. Several unsuccessful computational attempts were made to obtain this type of bond between DMS$^{+\cdot}$ and the deprotonated amide, *N*-methylacetamide (NMA$^-$). Part of the problem arises from consideration of the wide disparity in the gaseous-phase ionization energies (IE) of a dialkyl sulfide compared with an anionic deprotonated amide. For example, IE(DMS) (calcd. CBS-RAD = 839 kJ mol^{-1}, expt. = 838 kJ mol^{-1} (35)) and IE(NMA$^-$) (calcd. CBS-RAD = 224 kJ mol^{-1}). Thus, the amidyl radical (NMA·) is predicted to be more stable than a DMS$^{+\cdot}$ by more than 600 kJ mol^{-1}. At least in the gaseous phase, a S.∴N bond will have most of the radical character on the nitrogen moiety (resonance structure **c**) and structure **a** should be a minor component. Aqueous solvation may alter this situation, since it will reduce IE(DMS) and raise IE(deprotonated amide). Description **c** requires that the amidyl radical be in the ^{2}A′ state, an electronically excited state of the amidyl radical whose ground state is ^{2}A″. Indeed, unconstrained optimization yields the structure **1a** shown in Fig. 1, which does not have a (σ,σ*) 3 e S.∴N bond, but rather a loose association of the parent DMS making three points of contact with the amidyl radical as shown. The amidyl radical does not optimize to a planar geometry; rather, the dihedral angle (CNCO) is 18°. However, since the planar C_s geometry is calculated to be only 0.4 kJ mol^{-1} higher at the CBS-RAD level, we will use symmetry designations a′ and a″ to denote σ and π radicals, respectively. To enforce a (σ,σ*) 3 e description of the S.∴N bond, we imposed C_s symmetry on the DMS amidyl radical complex (**1b** in Fig. 1) and varied the S—N separation (r_{SN}) over the range 2.2 to 3.7 Å in 10 steps, while optimizing all other variables at the B3LYP/SB level.

Fig. 1. Structures of complexes between dimethyl sulfide and *N*-methylacetamidyl radical. Optimized at the B3LYP/SB level (**1a**); structure with enforced C_S symmetry (**1b**).

At each of the distances, the energy was reevaluated at several higher levels: B3LYP/LB, MP2/CBSB3, CCSD(T)/6-31+G(d′), and CBS-RAD (no ZPE). MP2/CBSB3 and CCSD(T)/6-31+G(d′) are components of the CBS-RAD prescription. The results are shown in Fig. 2, plotted relative to the lowest energy points. At each point, at each level, the electronic state is ^{2}A′, i.e., the complex possesses a 3 e (σ,σ*) S.∴N bond.

The results displayed in Fig. 2 do not lend confidence in the ability of the various methods to describe the (σ,σ*) 3 e S.∴N(amide) bond. The MP2 and HF (not shown) procedures clearly favour unrealistically short bonds as was also found previously in the case of DMS$^{+\cdot}$/O$_2$ (36) and these results bias the CBS-RAD energies toward a shorter distance (2.35 Å). On the other hand, the B3LYP/SB-predicted S.∴N separation (2.95 Å) is too long compared to CCSD(T). This is corrected to a large extent with the larger 6-311+(G3df,2p) basis set (2.65 Å). We judge the CCSD(T) results to be the most reliable. The predicted S.∴N bond length is about 2.5 Å.

The energy of the ^{2}A′ complex at the CCSD(T) minimum is 49 kJ mol^{-1} higher than the CCSD(T)/6-31+G(d′) energy of **1a** (Fig. 1) at the B3LYP/SB-optimized geometry. Since the energy difference between σ and π radicals (i.e., ^{2}A′ and ^{2}A″ states) is greater than 70 kJ mol^{-1} based on a TD-B3LYP/6-311+G(d,p) calculation on the planar amidyl radical, the stabilization owing to the (σ,σ*) 3 e S.∴N bond in the gaseous phase must be approximately 20 kJ mol^{-1}. The most stable complex between DMS$^{+\cdot}$ and NMA$^-$, namely **1a**, is 11 kJ mol^{-1} more stable than the separated products but is predicted to dissociate to DMS and NMA· exergonically at 298 K (ΔG_g = –28 kJ mol^{-1} in the gaseous phase). The reaction is even more exergonic in solution (ΔG_{aq} = –44 kJ mol^{-1}).

The results for the DMS-NMA system (**1b**) indicate that the 3 e bond lengths of the complexes discussed in the following for oxidized **2** (optimized at B3LYP/SB) are likely to be too long. However, the S and N moieties are tethered together and cannot dissociate as in the case of **1a** or **1b**. We note also that the B3LYP bond-stretching potential for **1b** is very flat, and that the error in relative energy evaluations is likely to be less than 5 kJ mol^{-1} (the difference between the

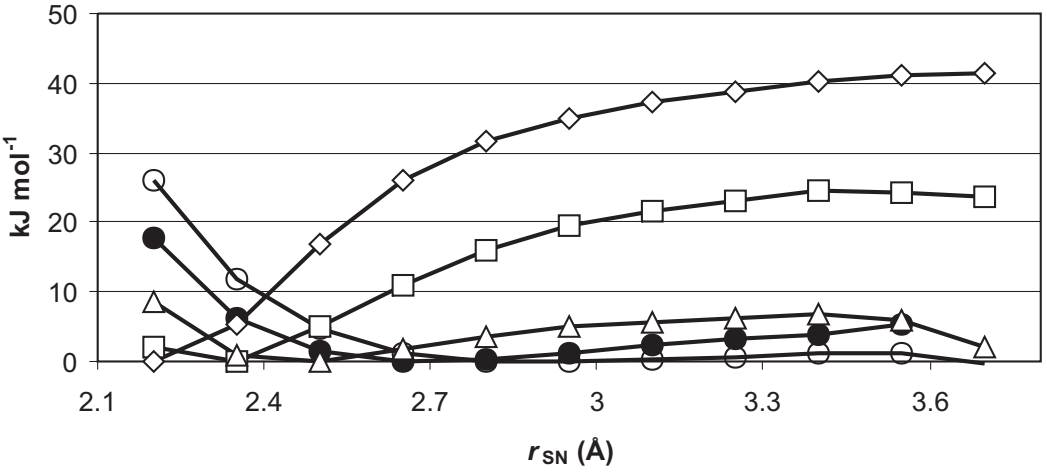
Fig. 2. Potential energy (kJ mol^{-1}) as a function of r_{SN} (Å) in **1b** at various levels of theory. B3LYP/SB (○), B3LYP/LB (●), CBS-RAD (□), MP2/6-31G(d′) (◇), and CCSD(T)/6-31+G(d′) (Δ).



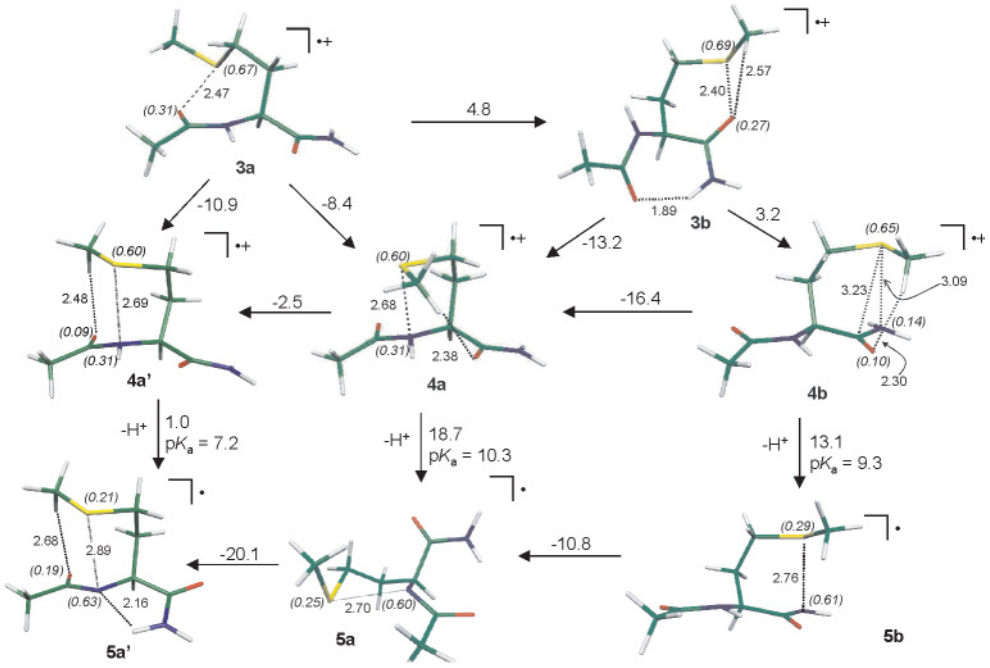


Fig. 3. Structures **3a**, **3b**, **4a′**, **4a**, and **4b** are primary species formed after one-electron oxidation of *N*-acetylmethioninamide **2**. Structures **5a′**, **5a**, and **5b** are primary N-H deprotonation products. Numbers on the arrows indicate the aqueous free energy change at pH 7 in the direction indicated by the arrow. Predicted pK_a values are also shown. Distances are in Å; numbers in italics and parentheses are spin populations.

B3LYP/LB and CCSD(T) energies even at the long distance of the B3LYP/SB minimum in Fig. 2).

Initial intermediates of one-electron oxidation of *N*-acetylmethioninamide (2)

N-Acetylmethioninamide (**2**) serves as a model of a midchain Met residue. One-electron oxidation of **2** yields four types of 3 e bonded intermediates as reported previously (14). The side chain is long enough to permit the S radical to make intramolecular three-electron bonds to the amide group on either side. Coordination may be either to the pro-R or pro-S face of the -CH_2-S-CH_3 plane. Each amide may be either a σ donor through the carbonyl O atom or a π donor, principally through the amide N atom. The oxygen-coordinated structures are similar in stability to the N-coordinated amide ones.

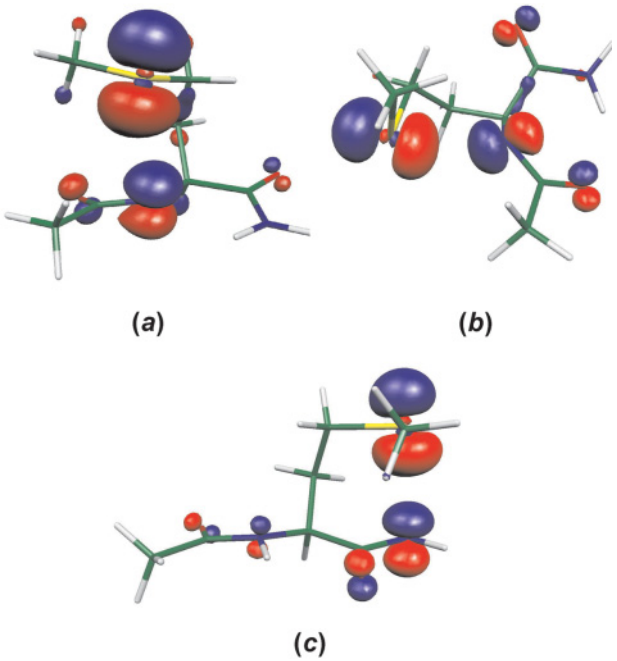
Of the structures previously examined (14), structure **3a** (Fig. 3) was found to be the most stable. Structure **3a** has a three-electron bond between the S and the carbonyl oxygen atom of the preceding (*i*–1) residue, forming a seven-membered ring. The S∴O distance is r_{SO} = 2.47 Å. Extensive spin delocalization is evident with 67% of the spin on S and 31% of the spin on O. The other S∴O structure (**3b**, Fig. 3) is 5 kJ mol^{-1} higher in energy than **3a**. The six-membered

© 2006 NRC Canada

ring of **3a** permits a shorter S∴O bond (r_{SO} = 2.40 Å). Structures analogous to **3a** and **3b** have been discussed previously by Pogocki et al. (21) who had found structures that were diastereomeric to, and less stable than, either **3a** or **3b**.

The energies of all structures were reevaluated at the CCSD(T)/6-31+G(d′) level. While **3a** and **3b** are unaffected, the S∴N bonded species are lower in energy at this level by about 10 kJ mol^{-1}. One of the S∴N coordinated structures (**4a**, Fig. 3) is 8 kJ mol^{-1} more stable than **3a**. The other (**4b**) is the least stable of the four (8 kJ mol^{-1} higher in energy than **3a**). The amide-coordinated S∴N distance is r_{SN} = 2.68 Å. Previously, we had not examined **4a′**, the diastereomeric form of **4a** in which the 3 e S∴N bond is to the opposite face of the C-S-C moiety. Structure **4a′**, shown in Fig. 3, is *more* stable than **4a** by 2.5 kJ mol^{-1} in aqueous solution. Deprotonation of the amide group from each of **4a** or **4a′** yields two distinctly different structures (see the following).

Deprotonation of midchain-oxidized methionine



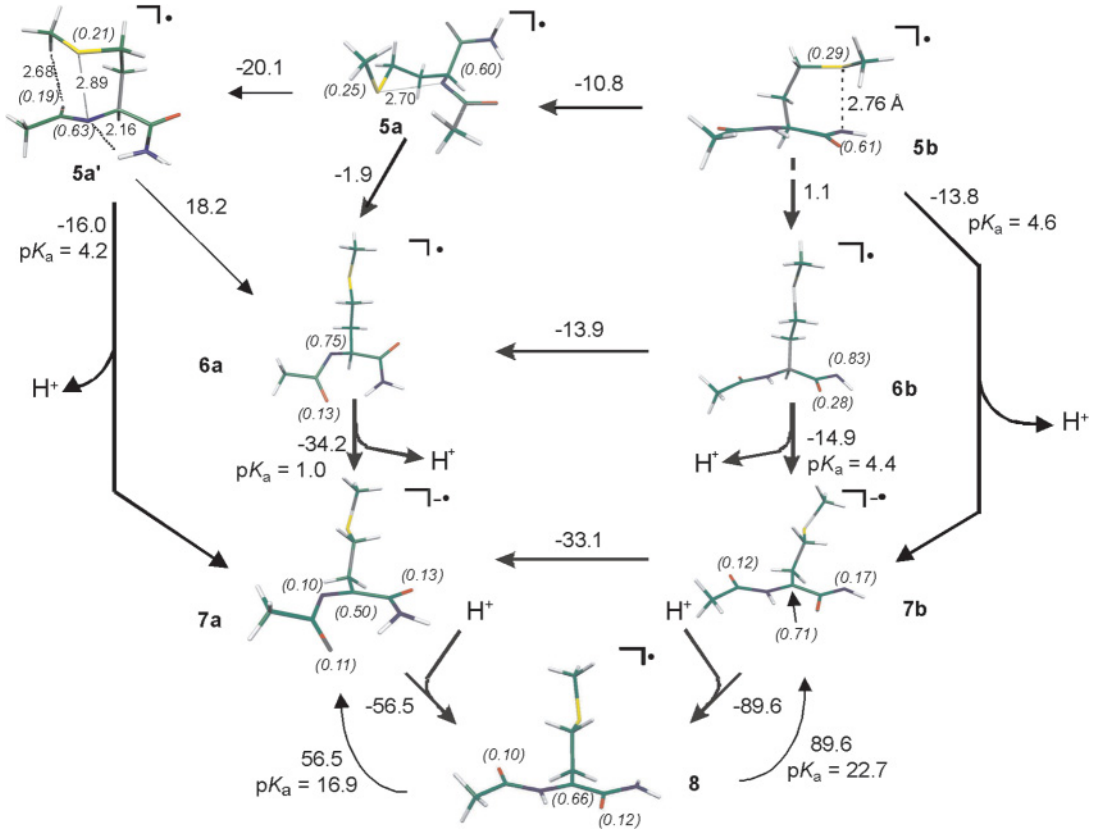
Deprotonation of **4a**, **4a′**, and **4b** yields the S∴N three-electron-bonded complexes **5a**, **5a′**, and **5b**, respectively (Fig. 3). Neither structure **5a′** nor **5b** has a bonding configuration that is entirely analogous to the model system (**1a**, Fig. 1) that was discussed previously as the most stable complex between an amidyl radical and a dialkylsulfide. The amidyl moiety in **5a′** or **5b** is the more stable π radical and makes two points of contact with the S-CH_3 moiety, but unlike **1a**, both **5a′** and **5b** have a loose 3 e S∴N bond (r_{SN} = 2.89 and 2.76 Å, respectively). Structure **5a** is conceptually different, having a 3 e (σ,σ*)-like S∴N bond entirely analogous to **1b** (Fig. 1). In the case of **5a**, the amidyl group is prevented from rotating into the more stable π-type 3 e interaction by the presence of a H-bond between N-H of the NH_2 group and the O of the acetyl group ($r_{O\cdots H}$ = 2.40 Å). A plot of the SOMO of **5a** is shown in Fig. 4*b*.

Structure **5a** is 11 kJ mol^{-1} less stable than **5a′** in the gaseous phase and less favourable solvation raises its aqueous free energy further to 19 kJ mol^{-1} above **5a′**. About 25% of the spin is on S, while 60% resides on N. The S—N distance is 2.70 Å, significantly shorter than the distance at the B3LYP/SB minimum of **1a** (Fig. 1), but quite similar to the B3LYP/LB potential curve for **1b** (Fig. 2).

In the case of the **5a′** and **5b** complexes, the three-electron bond is between the sulfur radical cation and the π system of the amidyl radical. This is clearly visible in the plots of the SOMO of **5a′** and **5b** shown in Figs. 4*a* and 4*c*. Different optimizations of **5b** were attempted to yield a 3 e (σ,σ*)-like S∴N bond with the lone pair on N^{i+1}, analogous to that in **5a**. However, they all reverted to structure **5b**. The S—N and S—O distances are 2.76 and 3.68 Å, respectively, in structure **5b**. Only 29% of the spin stays on S, while 61% of the spin is on N, indicating extensive oxidation of the negatively charged amido group.

The most stable amide deprotonation product of 1 e oxidized **2** is **5a′**. The direct precursor (**4a′**) has a calculated pK_a of 7.2. This value is higher than the pH range implied from spectroscopic observations (18). Reoptimization of the two species with a single water initially H-bonded to the carbonyl group lowers the energy of the cationic parent amide **4a′** relative to the neutral **5a′** by 7 kJ mol^{-1} at the B3LYP/LB level. However, continuum solvation favours the products by a small amount with the result that the calculated pK_a is lowered by one unit of pK_a at this level. If the effect of the explicit water of hydration is reflected at the CCSD(T)/6-1+G(d′) level, one might anticipate pK_a(**4a′**) ≈ 6. While we have not tested them explicitly, we expect similar results for the effect of explicit solvation on the acidity of **4a** and **4b** (Fig. 3). Thus, on the basis of calculated acidities of the initially formed products of the 1 e oxidation of **2**, only **4a′** has a pK_a sufficiently low to be a likely precursor to the species responsible for the 390 nm absorption required to fit the observed spectrum at pH 5.4 (18), and **5a′** is likely to be that species. We return to this point in the following when we compare computed UV spectra with that observed.

Fig. 4. SOMOs of (*a*) **5a′**, (*b*) **5a**, and (*c*) **5b**. The contour accounts for 0.6 e in each case.



Formation of the α-C-centered radical (8)

Several plausible intermediates in a sequence terminating in the most stable radical (**8**) are shown in Fig. 5. Opening up of the 3 e bonded ring of **5a** or **5a′** yields the extended amidyl π radical, **6a**, while **5b** leads to **6b**. Both processes are endergonic from **5a′** and **5b**, by 18 kJ mol^{-1} and 1 kJ mol^{-1}, respectively, but slightly exergonic from **5a**. The primary amidyl radical **6b** is 14 kJ mol^{-1} less stable than the secondary radical **6a**.

Perhaps surprisingly, loss of a proton from the α-C position of either **6a** or **6b** is an exergonic process, by 34 kJ mol^{-1} (pK_a = 1.0) and 15 kJ mol^{-1} (pK_a = 4.4), respectively, at pH 7. The stability of the product anionic π radicals (**7a** and **7b**) ensues from extensive π delocalization over seven heavy atoms, as well as increased solvation of the ionic products. This deprotonation has the effect of moving the radical from the amido group to the α-C position, where the radical is more stable. We note that **6a** and **6b** are not necessary intermediates. Deprotonation of **5a′** directly to **7a** is exergonic by 16 kJ mol^{-1} at pH 7, corresponding to pK_a =

© 2006 NRC Canada

Fig. 5. Mechanism to form the α-C radical from the S∴N three-electron bond. Numbers on the arrows indicate the aqueous free energy change at pH 7 in the direction indicated by the arrow. Predicted pK_a values are also shown. Distances are in Å; numbers in italics and parentheses are spin populations.

4.2 for the α-C-H proton of **5a′**. Likewise, deprotonation of **5b** directly to **7b** is exergonic by 14 kJ mol^{-1} at pH 7, corresponding to pK_a = 4.6 for the α-C-H proton of **5b**. Thus, **5a′**, **5a**, or **5b** should undergo loss of a proton from the α-C site to yield **7a** or **7b**.

Reprotonation at the amide N atom of **7a** and **7b** is even more exergonic (ΔG = –56 kJ mol^{-1} and –90 kJ mol^{-1}, respectively), yielding the neutral α-C radical (**8**) in both cases. A direct 1,2-hydrogen shift in **5a′** or **6a** was deemed impossible because of the orientation of the α-C—H bond. The 1,3-hydrogen shift enthalpic barrier in **6b** was calculated to be ~135 kJ mol^{-1}, which would make this 1,3-shift very unlikely on energetic grounds. This proposed mechanism explains the observation of a captodatively stabilized α-C radical after the one-electron oxidation of acetylmethioninamide **2** (18).

UV spectra of intermediates

The spectra of intermediates used to fit the UV spectrum measured 10 μs after the initial formation of **2**$^{+\cdot}$ are shown in Fig. 6. Of special interest is the origin of the broad absorption peaking at 390 nm, attributed to **5a/5b** (18).

Time-dependant DFT calculations of the seven lowest excited states, in the presence of the CPCM solvation field, were determined for all of the species discussed previously. We begin by a discussion of the nature of the electronic transitions expected of a 3 e (σ,σ*)-type S∴N(amide) bonded system, using **1b** as the prototypical example.

UV spectra of the 3 e (σ,σ)-type S∴N(amide) bond*

The electronic structure of the 3 e (σ,σ*)-type S∴N(amide) bond may be understood in terms of the orbital interaction diagram shown in Fig. 7. Two orbitals of each moiety are involved, the two lone pairs of the dialkyl sulfide (n_S and $3p_S$), the amidyl lone pair (n_N), and the second π orbital, shown as singly occupied in the amidyl radical. Only $3p_S$ and n_N interact significantly in C_s symmetry to give the σ_{SN} and σ^*_{SN} orbitals of the 3 e bond. As it happens, the first three electronic transitions shown on the right-hand side of Fig. 6 are as expected on the basis of orbital interaction theory (37).

A graphical depiction of the predicted UV spectrum of **1b** as a function of S—N distance is presented in Fig. 8. The lowest energy transition of **1b** at the CCSD(T) equilibrium distance (r_{SN} = 2.5 Å) is of a″ symmetry and corresponds to excitation of a β electron from the HOMO of the amidyl moiety (a π MO) into the β equivalent of the SOMO (σ^*_{SN}). The energy of the amidyl π MO is insensitive to the S—N separation, but the SOMO varies strongly, decreasing monotonically as the S—N distance increases. At r_{SN} = 2.5 Å, the lowest energy excitation occurs at 840 nm (1.48 eV) but is predicted to have zero oscillator strength.

The transition to the second excited state is of a′ symmetry and originates from excitation of a β electron from n_S, the nonbonded MO of the sulfide moiety not involved in 3 e bonding, to σ^*_{SN}. The n_S MO is also not very sensitive to r_{SN}, and the excitation energy parallels that of the first tran-

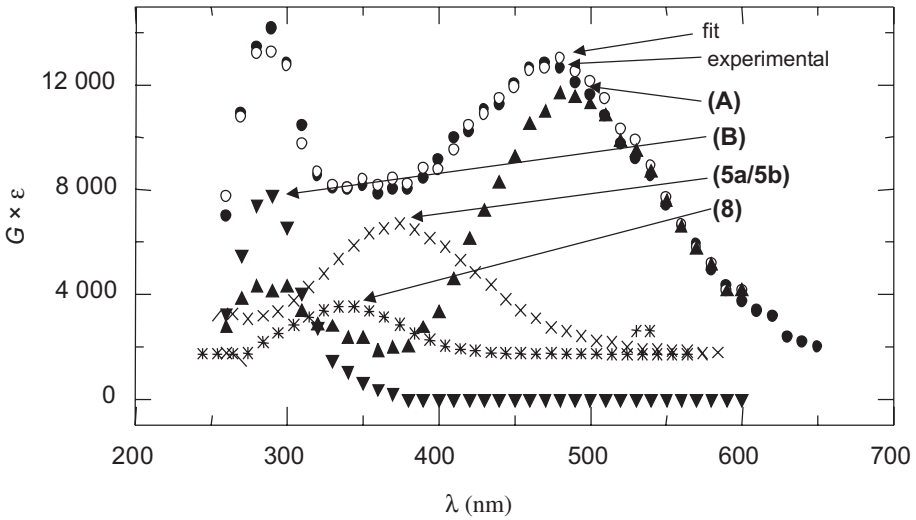
Fig. 6. Resolution of the spectral components in the transient absorption spectrum following HO· induced oxidation of **2** (2×10^{-4} mol/L) in N_2O saturated aqueous solutions at pH 5.4 taken 10 μs after the pulse (adapted from Fig. 3C of ref. 18). Components (**A**) and (**B**) were identified as [-S.∴S$^+$-] and [-C·HSCH$_3$/-CH$_2$SC·H$_2$] radicals, respectively.



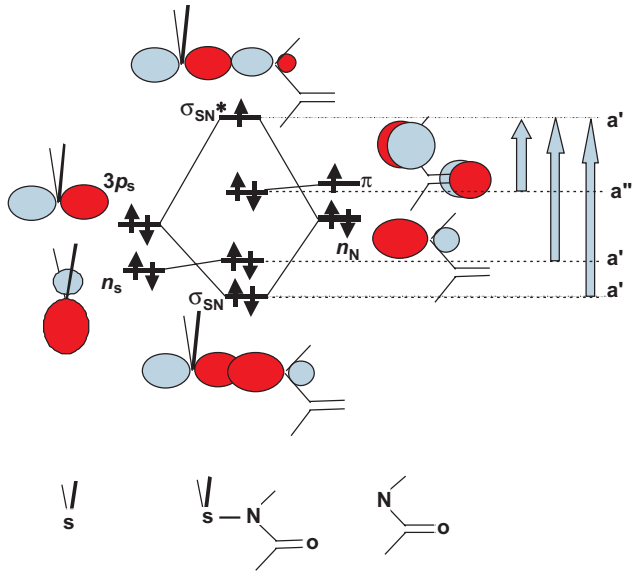


Fig. 7. Orbital interaction diagram of the bonding between DMS and NMA·, oriented so as to have C_S symmetry as in **1b**. The three lowest energy transitions are identified by the vertical arrows. MOs are labeled as a′ (σ type) or a″ (π type).

sition as r_{SN} increases. At r_{SN} = 2.5 Å, the second lowest excitation occurs at 440 nm (2.84 eV) and is predicted to have substantial oscillator strength (f = 0.13).

The transition to the third excited state is also of a′ symmetry and originates from excitation of a β electron from σ_{SN} to σ^*_{SN}. The σ_{SN} MO increases in energy as r_{SN} increases. As a consequence, the third excitation energy is very sensitive to r_{SN}. At r_{SN} = 2.5 Å, the third excitation occurs at 340 nm (3.62 eV) and is predicted to have even higher oscillator strength (f = 0.24).

As the next few higher energy transitions are predicted to have very low oscillator strength, the appearance of the longer wavelength UV spectrum of **1b** is dominated by the positions and intensities of the second and third transitions. The two transitions mix and exchange intensity as r_{SN} increases. The intensities are the same at r_{SN} = 2.65 and at 3.1 Å, the first band peaks at 700 nm and has almost all of the intensity.

The spectrum corresponding to the predicted minimum S—N distance (r_{SN} = 2.5 Å), if broadened, would correspond very well to the band with λ_{max} = 390 nm, attributed to **5a/5b** (Fig. 6) (18).

The predicted UV spectra of **5a**, **5a′**, and **5b** are shown in Fig. 9. Structure **5a** has a 3 e (σ,σ*)-type S.∴N bond (with optimized r_{SN} = 2.70 Å). Its predicted UV spectrum is entirely analogous to that expected from the model system **1b** at the same separation (Fig. 8). Assuming that the B3LYP procedure may yield too large a value for r_{SN}, structure **5a** was optimized with the constraint, r_{SN} = 2.5 Å. Such a structure is actually lower than the B3LYP/SB-optimized geometry by 3.0 kJ mol^{-1} at the CCSD(T)/6-31+G(d′)//B3LYP/SB level (by 0.3 kJ mol^{-1} at the B3LYP/LB//B3LYP/SB level). In the lower-symmetry environment, the first excitation at 680 nm has gained some intensity, compared with **1b** at the same 2.5 Å separation. However, the spectrum in the region 300–500 nm is entirely analogous to that of **1b**, and is an excellent match for the observed spectrum (Fig. 8). However, **5a** is predicted to be 20 kJ mol^{-1} less stable than **5a′**.

The most stable structure (**5a′**), which has a 3 e bond between the S and the amidyl π radical, is not modeled by **1a**. It is calculated to have a very long S—N separation (r_{SN} = 2.89 Å). The predicted spectrum for **5a′** at the B3LYP/SB geometry has its strongest absorption at 600 nm and virtually no absorbance at 390 nm. As in the case of **5a**, the r_{SN} of **5a′** was contracted in 0.1 Å steps to 2.5 Å. The total deformation energy between the optimized structure and that with r_{SN} = 2.5 Å is only 5 kJ mol^{-1}, indicating a very soft potential at the B3LYP level. The CCSD(T) energies of the r_{SN} = 2.5, 2.6, and 2.7 Å structures relative to the B3LYP-optimized structure are +4.4, +1.6, and +0.3 kJ mol^{-1}, respectively. Thus, a substantial shortening of the S—N separation at a higher level is not found in this case and the S—N separation is probably greater than 2.7 Å. The spectra

at each S—N separation are shown in Fig. 9*b*. The predicted spectrum varies strongly with r_{SN} in the same manner as was found for **1b**, and the origin of the transitions parallel those shown by the orbital interaction diagram in Fig. 7 and spectra in Fig. 8. The spectra corresponding to r_{SN} = 2.5 and 2.6 Å are both a very good match to the 390 nm band used in fitting the experimental spectrum (Fig. 6), but that at the lowest energy point (r_{SN} = 2.7 Å) has a maximum closer to 450 nm. As **5a′** is the most stable species from the kinetically favourable N-H deprotonation of the most stable

© 2006 NRC Canada

Fig. 10. TD-B3LYP predicted UV spectrum of (*a*) **3a** and (*b*) **4a′**. Optimized structure (black line); r_{SN} = 2.5 Å (purple line). primary oxidation product (**4a′**), we conclude that it is not a likely candidate for the 390 nm UV band, unless vibronic averaging or explicit solvation can lower the S—N separation into the range 2.5 Å < r_{SN} < 2.6 Å. In support of the latter possibility, we note that the single water of solvation mentioned previously in connection with the pK_a calculations of **5a′** lowers r_{SN} from 2.89 (no water) to 2.74 Å (one water) after optimization at the B3LYP/SB level.

Simulated UV absorption spectra of **3a** and **4a′**, the two most stable primary oxidation products, are shown in Fig. 10. In the original radiolysis study, the observed spectrum at 2 and 4 μs after the pulse and at low pH (pH 4) was fitted with a band peaking at 390 nm and attributed to a S∴O species, presumably **3a** (r_{SO} = 2.47 Å). Since the S∴O bond is already short, and since previous work has shown that S∴O bonds are satisfactorily described at the B3LYP/SB level, we have not computed the spectroscopic properties at distances other than r_{SO} = 2.47 Å. The simulated UV spectrum of **3a** is a composite of three transitions but dominated by a σ → σ* (second highest occupied MO to SOMO) excitation of a β electron, and peaking at 450 nm. On the basis of the computed spectrum of **3a**, and the fact that it is not the most stable primary oxidation product (see Fig. 3), it is unlikely that the 390 nm band required to fit the experimental spectrum is due to **3a**.

The UV spectrum of the most stable primary product (**4a′**), at three different values of r_{SN}, is shown in Fig. 10. The S—N stretching potential is very flat. The CCSD(T) energy of the structure at the shortest distance (r_{SN} = 2.5 Å) is 0.4 kJ mol^{-1} lower than at the B3LYP-optimized distance (r_{SN} = 2.7 Å). The UV spectrum at r_{SN} = 2.5 Å is a composite of two bands of similar intensity peaking at 330 and 400 nm, while that at r_{SN} = 2.6 Å is composed of two bands peaking at 350 and 440 nm. The summed spectrum is a very good match to the 390 nm band used to fit the observed spectrum at pH 4 (18) if the S—N separation of **4a′** were between 2.5 and 2.6 Å.

For completeness, the simulated aqueous spectra of the radical anions **6a** and **7a** are shown in Fig. 11. The presence of the amidyl radical anions (**6a** and **6b**) in the radiolysis experiment is unlikely for reasons discussed previously. Both species have significantly lower absorbance than the other species discussed, so that their detection would be unlikely in any case.

For the α-C-deprotonated radical anions (**7a** and **7b**, not shown), strong absorptions are calculated at 334 and 315 nm, respectively. However, these species are most likely not observable over the course of an experimental time frame because of the expected fast reprotonation step to form **8**.

Lastly, we show the simulated UV spectrum of the α-C-centered radical (**8**) in Fig. 12. As expected from the extended π system of this species, several long wavelength absorptions at 450, 370, 354, and 333 nm are predicted for this radical. However, all have low intensities, the largest being *f* = 0.015 for the 333 nm absorption. The first strong UV absorptions were calculated at 312 nm (*f* = 0.115) and 268 nm (*f* = 0.285). The spectroscopic properties of α-C-centered radicals have been well-characterized experimentally. For example, α-C-centered alanyl dipeptide radicals have an experimentally measured absorption with a maximum at ~350 nm (18). In the present case, the calculated UV absorption of **8** is to shorter wavelength than the experimentally assigned peak maximum, the discrepancy corresponding to an error of 0.9 eV in the excitation energy. We also carried out CIS calculations for the UV spectrum of

8 with the same basis set. The predicted strong absorptions were at even shorter wavelength and further from the experiment. We conclude that the excitations of the extended π radical system are not adequately described with a single determinantal starting point.

Conclusions

In a conformationally unconstrained system, a S∴N (3 e, σ,σ*) bond between a dialkylsulfide radical cation and a deprotonated amide is unstable. Extensive electron transfer takes place and the system adopts a loose π complex between an amidyl radical and a neutral dialkyl sulfide (Fig. 1). With geometric constraints that keep the S and N atoms in the proper orientation for a S∴N (3 e, σ,σ*) bond, a bond length (r_{SN} = 2.5 Å) is predicted at the CCSD(T)/6-31+G(d′) level. B3LYP/SB optimization yields a much longer value (r_{SN} = 2.9 Å). The UV spectrum is strongly dependent on the S—N separation.

The spectroscopic and pH-dependent behaviour of one-electron oxidized methionine dipeptide **2** was examined. The radical cation $\mathbf{2}^{+\cdot}$ preferentially adopts structure **4a′** (Fig. 3), with an intramolecular S∴N bond between the sulfide radical cation and the highest occupied π orbital of the first amide group. The acidity of the amide N-H of **4a′** is calculated to have a pK_a of 7, a value that may be too high by two units on the basis of the experiment. The length of the S∴N bond is predicted to be in the range 2.5 Å < r_{SN} < 2.6 Å based on CCSD(T) energies, and the match between the predicted UV spectrum and the absorbance at 390 nm used to fit the observed experimental spectrum (18) at low pH (pH 4). At pH > 5, after 10 μs, a new species generated by proton loss and also absorbing at 390 nm was invoked.

Species **5a′**, generated directly by deprotonation of **4a′**, is predicted to be the most stable deprotonated structure.

© 2006 NRC Canada

5a′ has an intramolecular S—N bond formed by interaction of the singly occupied π MO of the amidyl radical and the S atom. B3LYP optimization yields a long 3 e bond (r_{SN} = 2.89 Å). This value is reduced to 2.70 Å by inclusion of a single explicit water molecule. CCSD(T) calculation yields a similar value without explicit inclusion of the water molecule. With the additional water, it was not computationally feasible to scan shorter r_{SN} values at the CCSD(T) level. However, the results should be cumulative to bring the predicted UV transition into the vicinity of 390 nm, if **5a′** is responsible for the 390 nm absorption required to fit the observed spectrum (18). Structure **5a** (r_{SN} = 2.5 Å) is also predicted to absorb near 390 nm, but **5a** is calculated to be 20 kJ mol^{-1} less stable than **5a′** (Fig. 5).

The α-C-centered radical **8** of the Met dipeptide can be generated from **5a′** via two intermediate structures **6a** and **7a**, or directly via **7a**. The α-C—H bond of **5a′** is predicted to be moderately acidic: pK_a = 4.2 for loss of the α-C-H proton to yield **7a**. However, to achieve the skeletal geometry of **7a** from **5a′** requires rotation about the α-C—N bond (the Ramachandran angle, ϕ). This is more readily accomplished prior to loss of the proton from the α-C, while the α-C—N bond is a single bond. Rupture of the S∴N bond and rotation about the α-C—N bond of **5a′** yield **6a**, which is 18 kJ mol^{-1} less stable. The acidity of the α-C—H bond of **6a** is even higher (pK_a = 1). Loss of the α-C proton from **6a** directly yields **7a**. Reprotonation of **7a** at the N atom yields **8** in an exergonic process (ΔG_{aq} = –56 kJ mol^{-1} at pH 7).

Cucurbit[7]uril host–guest complexes with cationic bis(4,5-dihydro-1*H*-imidazol-2-yl) guests in aqueous solution

D. Saroja N. Hettiarachchi and Donal H. Macartney

Abstract: The host–guest interactions between cucurbit[7]uril and a series of novel cationic bis(4,5-dihydro-1*H*-imidazol-2-yl)arene and 1-(4,5-dihydro-1*H*-imidazol-2-yl)- and 1,3-bis(4,5-dihydro-1*H*-imidazol-2-yl)-adamantane guests have been investigated in aqueous solution using UV–vis and NMR spectroscopy, and electrospray mass spectrometry. With the exception of the 1,3-bis(4,5-dihydro-1*H*-imidazol-2-yl)adamantane (which binds externally to the CB[7]), these guests form very stable inclusion complexes with slow exchange on the ^{1}H NMR timescale. The direction and magnitude of the complexation-induced shifts (CIS) in the proton resonances of the guests are indicative of the residence of the hydrophobic core of the guest within the CB[7] cavity and the charged 4,5-dihydro-1*H*-imidazol-2-yl units outside the cavity adjacent to the carbonyl-lined portals of the host. The CIS values and the inclusion stability constants have been correlated with the nature of the guest core and with the distance between the charges on the terminal 4,5-dihydro-1*H*-imidazol-2-yl rings.

Key words: cucurbit[7]uril, host–guest complex, dihydroimidazolyl, inclusion stability constants.

Résumé : Faisant appel aux spectroscopies UV–vis et RMN ainsi qu'à la spectrométrie de masse par électronébulisation, on a étudié les interactions hôte–invité entre le cucurbit[7]urile {CB[7]} et une série de nouveaux invités cationiques bis(4,5-dihydro-1*H*-imidazoly-2-yl)arènes et 1-(4,5-dihydro-1*H*-imidazol-2-yl)- et 1,3-bis(4,5-dihydro-1*H*-imidazol-2-yl)-adamantanes. À l'exception du 1,3-bis(4,5-dihydro-1*H*-imidazol-2-yl)adamantane qui se lie d'une façon externe avec le CB[7], ces invités forment des complexes d'inclusion très stables qui ne présentent que des échanges lents à l'échelle de temps de la RMN du ^{1}H. La direction et l'amplitude des déplacements induits par la complexation (DIC) dans les résonances des protons des invités indiquent que la portion hydrophobe de l'invité réside à l'intérieur de la cavité du CB[7] et que les unités 4,5-dihydro-1*H*-imidazol-2-yles se trouvent à l'extérieur de la cavité, adjacentes aux portails de l'hôte alignés de groupes carbonyles. On a établi une corrélation entre les valeurs des DIC ou les constantes de stabilité et la nature de la portion hydrophobe de l'invité ou la distance entre les charges qui se trouvent sur les noyaux terminaux 4,5-dihydro-1*H*-imidazol-2-yles.

Mots clés : cucurbit[7]urile, complexe hôte–invité, dihydroimidazolyle, constantes de stabilité d'inclusion.

[Traduit par la Rédaction]

Introduction

The cucurbit[*n*]urils (CB[*n*], *n* = 5–10) are a family of macrocyclic host molecules (1–5) formed in the acid-catalyzed condensation reactions of glycoluril with paraformaldehyde. While this reaction, which yields primarily CB[6], was first reported in 1905 by Behrend et al. (6), the utility of these host molecules was not fully recognized until the work of Mock and co-workers on cucurbit[6]uril in the 1980s (7–10). More recently, improvements in the synthetic yields of the other members of the cucurbituril family, primarily CB[7] and CB[8] were independently reported by the research groups of Kim et al. (11) and Day et al. (12). Since these reports, there has been considerable interest in the guest–host chemistry of CB[7] and CB[8], and the use of these host molecules as reaction vessels for photochemical isomerizations and dimerizations (13–16), stabilizers for dyes (17, 18) and other molecules (19, 20), for solubilizing ferrocene (21, 22), and in the development of molecular shuttles, switches, and sensors (23–25).

The cucurbiturils CB[6], CB[7], and CB[8] have similarly sized hydrophobic cavities as the more well-studied α-, β-, and γ-cyclodextrins (CD), respectively, but differ in the nature and size of the portals to the cavities (4, 5). Nevertheless, a number of studies have dealt with the comparisons between the binding of guests to cucurbiturils and cyclodextrins and their respective effects on the chemistries of the guest molecules (22, 26, 27). The portals of the CB[*n*] cavities are lined with ureido carbonyl groups and provide a more restrictive entry to guest molecules than the corresponding CD hosts. The polar nature of the carbonyls, however, makes them attractive to cationic guest molecules, from simple metal ions (3) to protonated α,ω-diaminoalkanes (8). The CB[7] host (Scheme 1) has been shown to form very

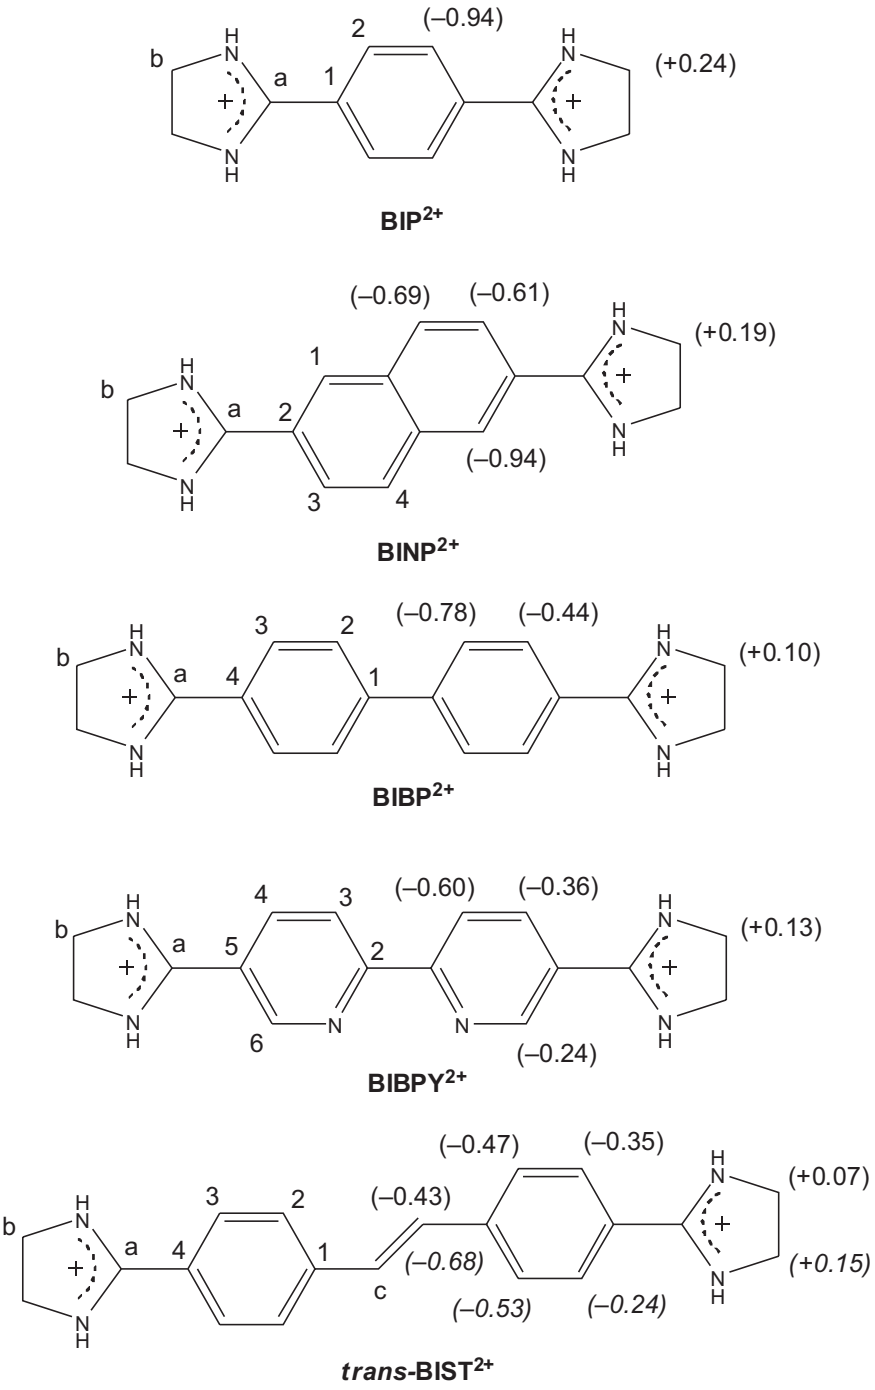
stable inclusion complexes with guests containing a diverse set of central units, including metalloferrocenes (21, 22), carboranes (28), aromatic rings (29–32), and adamantanes (32), particularly if these groups contain cationic substituents that can be aligned with the carbonyl-lined portals upon guest inclusion.

The CDs have two sets of protons on the internal surface of the cavity and changes in the chemical shifts of these provide evidence of inclusions of the guest molecules. The complexation-induced shifts (CISs) of the guest proton resonances, however, tend to be relatively small (33). While the cucurbiturils lack any protons inside the cavity, the CIS values for the guest protons located in the cavity tend to be quite large (upfield) and opposite in sign to those for protons located near the carbonyl portals. Mock and Shih (8) carried out a systematic study of the CISs of the methylene proton resonances of $H_3N(CH_2)_nNH_3^{2+}$ (n = 4–8) guests upon inclusion in CB[6]. There has not, however, been a similar study conducted on a series of related guests in complexes with CB[7]. In connection with their improved synthesis of CB[7], Kim's group (11) used the dicationic 2,6-bis(4,5-dihydro-1*H*-imidazol-2-yl)naphthalene guest to demonstrate the formation of guest–host inclusion complexes between aromatic guests and the larger CB[7], but did not report an inclusion stability constant. This guest has subsequently been employed in ab initio calculations of the energy-minimized structures of the 1:1 and 2:1 guest–host complexes with CB[7] (34) and CB[8] (35), respectively. These studies have indicated that the guest–host complexes are stabilized by hydrophobic interactions between the naphthalene group and the inside of the CB[*n*] cavity, and by ion–dipole and hydrogen bonding interactions between the dihydroimidazolyl rings and the carbonyl-rimmed portals of the CB[*n*] host molecule.

As the CB[7] cavity has a strong affinity for aromatic and adamantyl guests (32), we synthesized and characterized a series of novel cationic aromatic (Scheme 2) and adamantyl (Scheme 3) guests using the protonated (4,5-dihydro-1*H*-imidazol-2-yl) end groups. The advantage of these terminal groups is that the ethylene portion of the imidazole ring affords four equivalent protons to probe the environment of the ends of the guest molecule, in addition to the aromatic core. The guest–host inclusion stability constants with CB[7] were determined by using ^{1}H NMR chemical shift titrations and competitive binding experiments. The stability constants and CISs in the ^{1}H NMR resonances of the guests were correlated with the length of the guest (distance between positive charges) and the nature of the aromatic or aliphatic core.



Experimental section

Materials

CB[7] was prepared by a reported method (12). CB[8] (Sigma-Aldrich) and the α-, β-, and γ-cyclodextrins (Sigma-Aldrich, Cyclolab) were used as received. The guest compounds were prepared in accordance with the literature method of Kim et al. (11) by reacting the appropriate mono- or dicarboxyclic acids (Sigma-Aldrich) with a mixture of ethylenediamine and ethylenediamine dihydrochloride under argon gas. The ethylenediamine dihydrochloride was prepared prior to the experiment by adding ice-cold concd. HCl into an ethylenediamine solution until a white precipitate formed that was filtered and oven-dried for 12 h. The monocarboxylic acid (20 mmol) or dicarboxylic acid (10 mmol), ethylenediamine (20 mmol), ethylenediamine dihydrochloride (20 mmol), *p*-toluenesulfonic acid monohydrate (0.75 mmol), and ethylene glycerol (15 mL) were placed in a 50 mL round bottom flask and heated at reflux (190 °C) for 1–10 h (depending on the carboxylic acid used) under argon gas. The precipitates, which formed on cooling and from the removal of the solvent from the filtrate, were dissolved in 50 mL of distilled water (containing

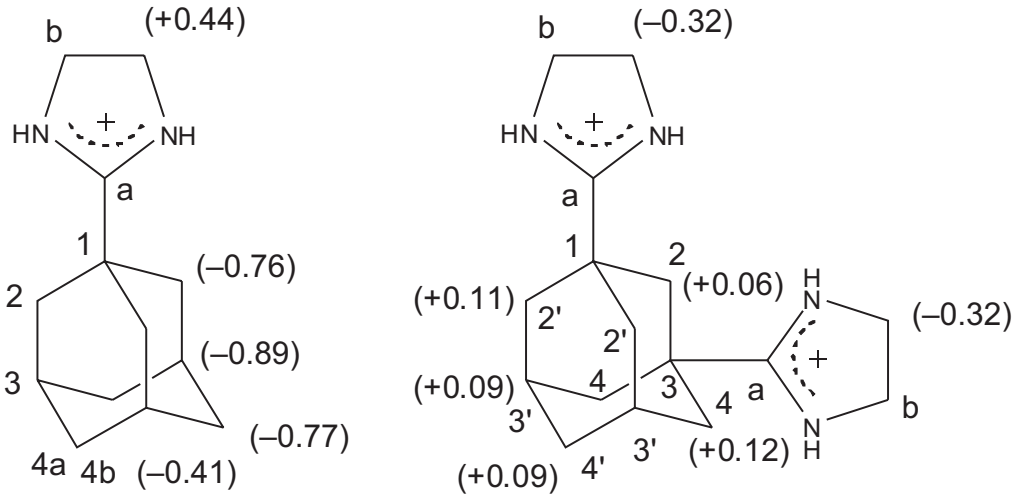
Scheme 2. Structures of the dicationic bis(4,5-dihydro-1*H*-imidazol-2-yl)arene guests with the proton labeling and the complexation induced chemical shifts changes (Δδ (ppm) in parantheses) of the ^{1}H NMR proton resonances of the guest upon formation of the 1:1 guest–host complex with cucurbit[7]uril. The Δδ values in italics for *trans*-BIST^{2+} refer to the corresponding *cis*-BIST^{2+} guest.



1.5 mL concd. HCl). The addition of 20 mL of 50% aq. NaOH into the mixture produced white or yellow precipitates, which were filtered, washed several times with distilled water, and dried under reduced pressure for several hours. Yields in the range of 68%–94% were obtained for the neutral guest compounds. The hydrochloride salts of the bis(dihydroimidazolyl) compounds were obtained as white or yellow solids by slowly adding a 10% HCl solution into a suspension of the product in methanol. The deposited precipitate was filtered and dried under vacuum.

Physical measurements

The NMR spectra were recorded on a Bruker Avance-400 instrument in D_2O (the residual solvent proton signal at 4.75 ppm served as the internal reference). Electrospray mass spectrometry measurements were obtained on a VG Quattro quadrupole mass spectrometer with an atmospheric pressure electrospray ionization source and a mass range for single-charged ions of 4000. Samples were prepared as solutions in distilled water containing the guest (2.5×10^{-3} mol/L) and CB[7] (0.015 mol/L). UV–vis spectra were recorded on a Hewlett-Packard 8452 diode array spectrome-

ter. Elemental analyses were preformed by Canadian Microanalytical Services Ltd., Delta, British Columbia.

The inclusion stability constants were determined from competitive binding studies monitored by ^{1}H NMR spectroscopy in D_2O at 25 °C, using the procedure of Isaacs and coworkers (32). The competitor primarily employed with the guests was sodium 3-(trimethylsilyl)propionate-2,2,3,3-d_4 (Sigma-Aldrich, $K_{CB[7]}$ = (1.82 ± 0.22) × 10^7 (mol/L)$^{-1}$ (32)), except for the BINP^{2+} guest, in which case (trimethylammonio)methylferrocene iodide (Sigma-Aldrich, $K_{CB[7]}$ = (3.31 ± 0.62) × 10^{11} (mol/L)$^{-1}$ (22, 32)) was used. For the weaker external binding of BIAD^{2+} to CB[7], a ^{1}H NMR chemical shift titration of the guest with CB[7] was performed in D_2O at 25 °C, with the data fit to a 1:1 binding model as described previously (33). Molecular modelling of the structures of the guest–host complexes was performed using Chem3D software (CambridgeSoft) with MM2 energy minimizations.

Results and discussion

The macrocyclic host molecule CB[7] forms very stable host–guest complexes with cationic guest molecules in aqueous solution. For organic guests, especially strong binding has been observed when the guest is comprised of a hydrophobic central core with positively charged substituents, which can be placed near the polar carbonyl groups that line the portals of the host. The dication guests formed by protonations of α,α′-diamino-*p*-xylene and 1,3-diaminoadamantane, for example, bind to CB[7] with stability constants of (1.84 ± 0.34) × 10^9 and (2.06 ± 0.33) × 10^8 (mol/L)$^{-1}$, respectively (32). The cationic guests synthesized in this study, as shown in Schemes 2 and 3, have variable hydrophobic aryl or adamantyl cores with 4,5-dihydroimidazol-2-yl end groups and would be expected to likewise form very stable inclusion complexes with CB[7].

The inclusion of the guests in the cavity of CB[7] is clearly seen by ^{1}H NMR spectroscopy (Fig. 1). The guest protons that reside within the hydrophobic cavity experience shielding and, therefore, upfield CISs in their resonances. The guest protons that are located near the ureido carbonyl groups rimming the portals are deshielded and the resonances move downfield, compared with the chemical shifts observed in the free guest. The ^{1}H NMR chemical shifts of the free guest and CB[7]-included guest protons are summarized in Table 1. The formation of 1:1 host–guest complexes is also supported by electrospray mass spectrometry. All of the complexes formed with the dicationic aromatic guests (M) exhibit peaks for the {M·CB[7]}$^{2+}$ species, while the adamantyl guests IAD$^+$ and BIAD^{2+} exhibit peaks for {M·CB[7]}$^+$ and {M·CB[7]-H}$^+$, respectively.

While Mock and Shih (8) carried out a systematic study

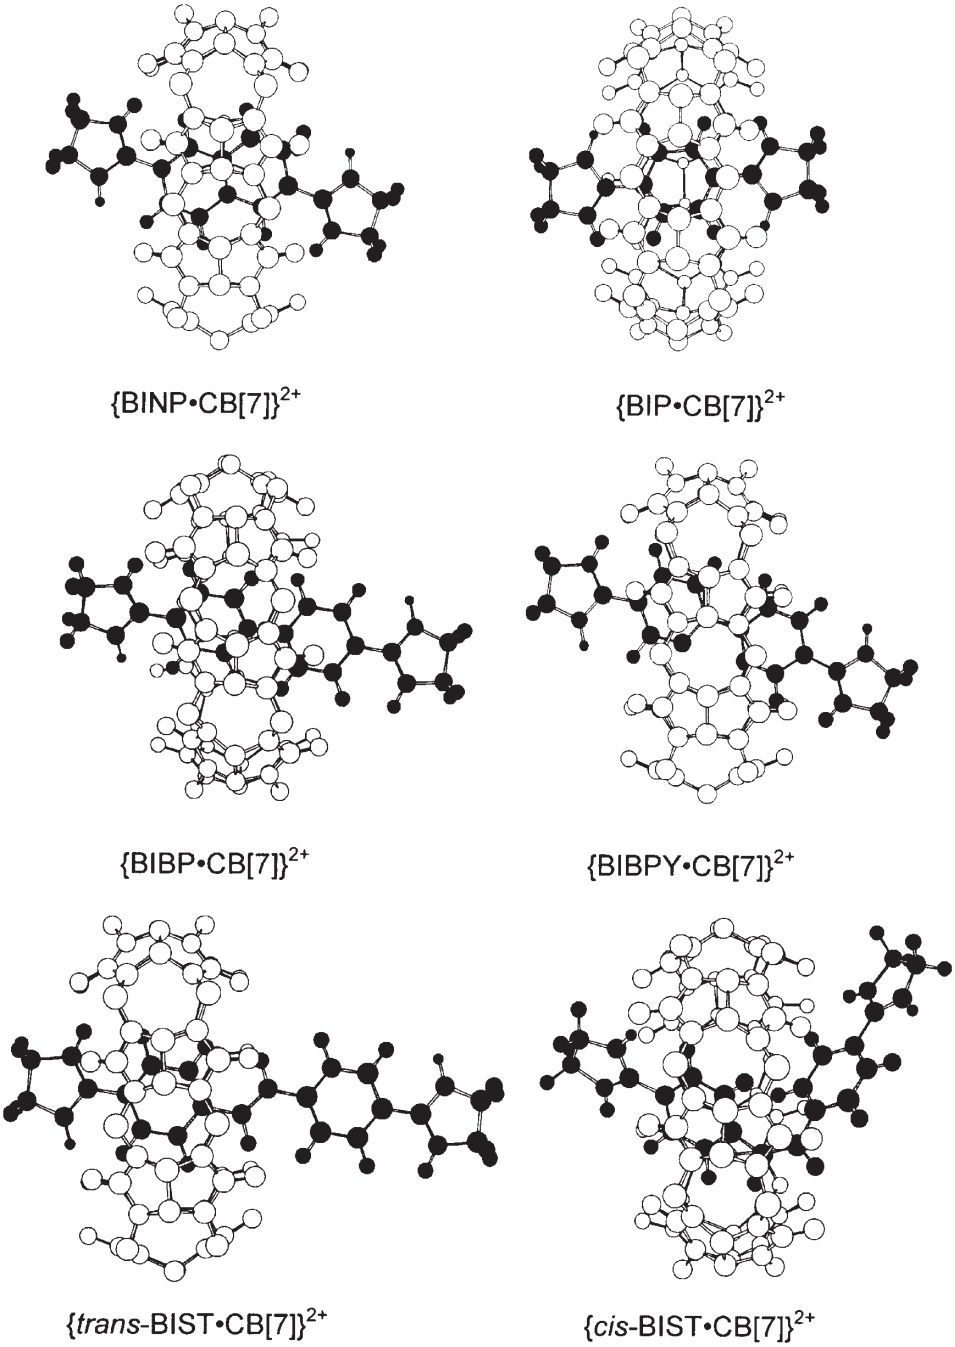
of the complexation-induced chemical shifts of the methylene protons of $H_3N(CH_2)_nNH_3^{2+}$ guests upon inclusion in CB[6], there had not been a similar study conducted on a series of related guests in inclusion complexes with CB[7]. The upfield chemical shift changes for the ^{1}H NMR resonances of the core aryl and adamantyl protons of the guests range from –0.24 to –0.94 ppm, a similar range of shifts as observed by Mock and Shih (8) for the methylene protons (up to –1.08 ppm) of the α,ω-alkyldiammonium guests included in the cavity of CB[6]. The CISs of highest magnitude for the ligands in this study are found for the protons near the centers of the aromatic cores of the guests. Even with the guests shuttling back and forth between orientations that place one of the positively charged dihydroimidazoyl rings near one of the portals, these central protons remain in the cavity. The lower magnitude shifts in the range are observed for the protons near the ends of the aromatic cores of the longer and (or) more weakly bound guests ($BIBPY^{2+}$ and *trans*-$BIST^{2+}$), which may spend proportionately more time near the portals or outside the cavity as the guests move back and forth along the axis of the cavity.

The further away that the cationic dihydroimidazolyl rings are from the portal carbonyl groups, on average, the less deshielding will be felt by the ethylene H_b protons on the ring. The largest CIS values for the H_b protons are observed for the shorter BIP^{2+} and $BINP^{2+}$ guests, while a much smaller value is exhibited by the more extended *trans*-$BIST^{2+}$. Using the distances between the C_a carbons on the rings as a measure of the extension of the guests (determined using Chem3D MM2 energy minimizations, see Fig. 2), a good correlation between the lengths of the guests (distances between the positive charges) and the CIS values for the H_b protons is established (see Fig. 3).



The inclusion of the dicationic guests in the cavity of CB[7] resulted in bathochromic shifts in the λ_{max}, with a lowering of the molar absorptivity coefficient for the π–π* transitions in the UV–vis spectra compared with the free guests (Table 2). This behaviour has also been observed with other dicationic guest molecules, such as methyl viologen (29, 30), 2,7-dimethyldiazapyrenium (31), and protonated 2-aminoanthracene (24). The bathochromic shifts are consistent with the solvatochromic behaviour of the aromatic guests within the CB[7] cavity, which has a less polar environment than the bulk aqueous solution (18, 36).

The stability constants for the host–guest inclusion complexes formed between CB[7] and the dicationic guests in this study (with the exception of the external binding of $BIAD^{2+}$, discussed later) are too large (>10^7 (mol/L)$^{-1}$) to be measured by conventional UV–vis spectrophotometric or ^{1}H NMR chemical shift titrations. The stability constants for the host–guest complexes formed between CB[7] and the cationic guests were thus determined by performing competitive binding studies, monitored by ^{1}H NMR spectroscopy, using guests whose stability constants with CB[7] had been reported previously (32). The 3-(trimethylsilyl)propionic acid-2,2,3,3-d_4 ($K_{CB[7]} = (1.82 \pm 0.22) \times 10^7$ (mol/L)$^{-1}$ (32)) was employed as the competitor for the BIP^{2+}, $BIBP^{2+}$, $BIBPY^{2+}$, *trans*-$BIST^{2+}$, and IAD^+ guests, while (trimethylammonio)methylferrocene iodide ($K_{CB[7]} = (3.31 \pm 0.62) \times 10^{11}$ (mol/L)$^{-1}$ (22, 32)) was used for the $BINP^{2+}$ guest.

The stability constants (Table 1) for the aromatic guests decrease in the order $BINP^{2+}$ > BIP^{2+} > *trans*-$BIST^{2+}$ > $BIBP^{2+}$ > $BIBPY^{2+}$. The trend is likely the result of several factors, including (*i*) the length of the aromatic core (distance between the positive charges), (*ii*) the fit of the aromatic core to the interior of the CB[7] cavity, and (*iii*) the hydrophobicity of the aromatic core. The highest stability constant is observed for the guest with the naphthyl core, suggesting that this guest optimizes the fit of the aromatic core with the CB[7] cavity and the cation–dipole and hydrogen bonding interactions between the dihydroimidazoyl groups and the portal carbonyl groups. The lowest stability constant among this set of guests is observed for $BIBPY^{2+}$. This is not unexpected as the introduction of the N hetero-

atoms into the bipyridine rings would reduce the hydrophobicity of the aromatic core and the stability constant compared with the biphenyl core of the $BIBP^{2+}$ guest.

The mono(IAD^{+}) and bis(dihydroimidazolyl) ($BIAD^{2+}$) substituted adamantane cations exhibit different modes of binding to CB[7] and CB[8]. For the monocation, the adamantyl portion binds tightly to the interior of CB[7] (Fig. 4), as reported previously for the protonated 1-aminoadamantane (32), with upfield shifts in the adamantyl proton resonances and a large downfield shift for the H_b protons on the dihydroimidazolyl ring. Contrary to the observation of binding of the 1,3-diaminoadamantane in the cavity of CB[7] (32), we observe that only external binding occurs with the $BIAD^{2+}$ dication. The 1,3-bis(4,5-dihydro-1*H*-imidazol-2-yl)adamantane ($BIAD^{2+}$) guest is too large to form a guest–host complex with CB[7], in which the adamantyl core is located in the cavity of the host. The H_b protons on the ring shift upfield (–0.32 ppm), while the adamantyl protons shift downfield (+0.06 to +0.12 ppm). These changes in the chemical shifts of the guest protons, upon the addition of CB[7], reveal that it is one of the dihydroimidazolyl rings that is located in the cavity, while

$[BINP]^{2+}$	246	6.41×10^4
$\{BINP\cdot CB[7]\}^{2+}$	250	4.53×10^4
$[BIP]^{2+}$	246	3.76×10^4
$\{BIP\cdot CB[7]\}^{2+}$	244	2.11×10^4
$[BIBP]^{2+}$	288	3.96×10^4
$\{BIBP\cdot CB[7]\}^{2+}$	290	2.98×10^4
$[BIBPY]^{2+}$	252	1.04×10^4
	300	1.67×10^4
$\{BIBPY\cdot CB[7]\}^{2+}$	258	8.40×10^3
	308	1.56×10^4
$[trans\text{-}BIST]^{2+}$	336	6.44×10^4
$\{trans\text{-}BIST\cdot CB[7]\}^{2+}$	344	4.29×10^4

the remainder of the guest is outside. The presence of only average resonances for the guest in the presence of a stoichiometric deficiency of CB[7] indicates that the guest is exchanging between the bound and unbound states rapidly on the NMR timescale.

A chemical shift titration and Job's plot of the $BIAD^{2+}$ with CB[7], as depicted in Fig. 5, confirms a 1:1 stoichiometry (maximum at $\chi^{BIAD} \approx 0.5$) and yields a stability constant of $(1.0 \pm 0.5) \times 10^4$ $(mol/L)^{-1}$. As indicated earlier, the protonated 1,3-diaminoadamantane guest forms a very stable complex with CB[7], in which the adamantyl core is located in the cavity. The smaller size of the ammonium group compared with the 4,5-dihydroimidazol-2-yl ring may account for the difference in the accessibility of the guest to the cavity. The addition of the larger CB[8] host to a solution of $BIAD^{2+}$, however, does result in the formation of an internal inclusion complex (Fig. 4), and the expected upfield shifts in the adamanyl proton resonances with downfield shifts in the H_b protons of the 4,5-dihydroimidazol-2-yl rings are observed.

A comparison of the binding behaviours of CB[7] with the CDs was undertaken in which the $[BIBP]^{2+}$ guest was mixed with slight stoichiometric excesses of α-, β-, and γ-CD and the ^1H NMR spectra compared to the inclusion complex formed with CB[7]. The $[BIBP]^{2+}$ guest undergoes inclusion complex formation with β- and γ-CD (but not the smaller α-CD cavity), exhibiting fast guest exchange on the NMR timescale. The larger ^1H NMR CIS values for the $[BIBP]^{2+}$ guest are observed for inclusion by β-CD, with its similar cavity size to CB[7].

The *trans*-$BIST^{2+}$ dication undergoes a photochemical isomerization to *cis*-$BIST^{2+}$ under UV irradiation in aqueous solution.[2] Inclusion of the *trans*-$BIST^{2+}$ guest in CB[7] also facilitates photoisomerization and eliminates photohydration side products. The resulting $\{cis\text{-}BIST\ B[7]\}^{2+}$ complex exhibits similar, but somewhat larger, chemical shifts of the guest protons upon inclusion in the CB[7] cavity. This is most likely the result of a more compact guest core within the CB[7] cavity.

We are currently investigating the CB[7] inclusion of other dicationic guest molecules with 4,5-dihydroimidazol-

2-yl and related cationic end groups, including the protonated forms of the water-soluble azo radical initiators azobis[2-(4,5-dihydro-1*H*-imidazol-2-yl)propane] and azobis(2-amidinopropane). Preliminary studies indicate that these initiators bind to CB[7] with comparable strength to the guests in the present study and that inclusion in the CB[7] cavity significantly stabilizes them with respect to unimolecular decomposition to carbon-centered radicals.

The volatilities and conductivities of ionic liquids — GC–MS methodology and preliminary studies of acetic acid – base systems

Ronald G. Treble, Keith E. Johnson, and Evangeline Tosh

Abstract: Gas chromatography – mass spectrometry studies of the headspaces above the binary systems pyridine (bp 115 °C) – acetic acid (bp 116 °C), 1-methylimidazole (bp 198 °C) – acetic acid, and triethylamine (bp 89 °C) – acetic acid show both components in the first case, acetic acid only in the second, and triethylamine only in the third. Negative deviations from Raoult's law are confirmed and proton transfer is evidenced by the downfield shift of the acidic proton as the addition of base proceeds. Specific conductances >2 mS cm^{-1} are found over wide composition ranges for all three systems with values >8 mS cm^{-1} at high (>2) mole ratios of acetic acid, suggesting the formation of acetatohydrogenate ionic liquids.

Key words: GC–MS, air, vapor pressure, conductivity, ionic liquids, acetic acid.

Résumé : Des études de spectrométrie de masse combinées à la chromatographie gazeuse des espaces de tête se trouvant au-dessus de systèmes binaires pyridine (p.é. 115 °C) – acide acétique (p.é. 116 °C), 1-méthylimidazole (p.é. 198 °C) – acide acétique et triéthylamine (p.é. 89 °C) – acide acétique montrent la présence des deux composants dans le premier cas, alors qu'on n'observe que la présence de l'acide acétique dans le second et que la triéthylamine dans le dernier. Des déviations négatives par rapport à la loi de Raoult ont été confirmées et on a mis en évidence un transfert de proton par le déplacement chimique vers les bas champs du proton acide au fur et à mesure de l'addition de la base. Pour les trois systèmes, on a observé des conductances spécifiques supérieures à 2 mS cm^{-1} sur un large spectre de composition, avec des valeurs supérieures à 8 mS cm^{-1} à des rapports molaires supérieurs à 2 d'acide acétique, ce qui suggère la formation de liquides ioniques acétatohydrogénates.

Mots clés : chromatographie gazeuse – spectrométrie de masse, air, tension de vapeur, liquides ioniques, acide acétique.

[Traduit par la Rédaction]

Introduction

Ionic liquids (ILs) consisting of organic cations and anions or organic cations and inorganic anions have presented chemists, particularly organic chemists, with a whole new range of solvents, catalysts, and reagents that can be used at ambient temperatures (RTILs) and upwards of 200–300 °C (1). These liquids are modest conductors of electricity (σ values in the mS cm^{-1} range) (2), have manageable fluidities, can have wide electrochemical windows, have modest dielectric constants (<30) (3, 4), and in many cases exhibit negligible vapor pressure (5) (reversibly decomposing anions are the exception and such behavior also applies to totally inorganic ILs such as alkali carbonates and heptachloroaluminates).

Deliberate measurements of the vapor pressures of ionic liquids are scant, but a foray into history is intriguing. Gardner in 1890 (6) observed that certain liquid mixtures of the bases pyridine, picoline, and triethylamine with the acids formic, acetic, and propionic, were maximum boiling azeotropes. Zawidzki in 1900 (7) presented measurements for the binary systems of pyridine with the above acids: large negative deviations from Raoult's law occurred, but both components were found in the vapor over a wide composition range. Gardner, Zawidzki, and later Dolezalek (8) suggested that compound formation took place and assigned molecular formulae or provided routines to evaluate stoichiometry. There seems to be no suggestion that the compounds were ionic. More recently, vapor pressure measurements were made on a chloroaluminate system (9), the distillation under reduced pressure of several dialkylimidazolium salts was reported (10), and the withstanding of UHV by an IL noted (5).

We reported recently on the use of gas chromatography – mass spectrometry (GC–MS) to study liquids and vapors in equilibrium with time intervals between gas and liquid sampling as low as 2.5 min (11). Among the applications of this technique we were able to (*i*) reproduce the classical vapor pressure data for the chloroform–acetone system (11),

(*ii*) determine the products of reaction of hydrocarbons with nonvolatile ionic liquids (12), and (*iii*) investigate the electroreduction of organic cations (13). The question arises as to *the temperatures at which various ionic liquids possess significant vapor pressure*. In this paper we discuss some preliminary results for acid–base systems. First, we describe the methodology for obtaining high-quality data on ambient-temperature air samples and then present a preliminary study of several ionic liquid systems. We also include some NMR data to establish whether or not proton transfer occurs to make salts in the liquid and some conductance data to evaluate any ionicity in the systems.

Experimental

Prior to sampling ionic liquid headspace fractions, ambient and fresh air samples were repeatedly analyzed. Data were correlated employing both full scan and selected ion monitoring modes to determine if any differences would dictate a preferred methodology.

All liquids employed in the binary mixtures that were used for the vapor pressure studies were first distilled and then run individually using GC–MS to determine purity. Preliminary full scan liquid fractions were also run to (*i*) first determine the relative retention times for the subsequent vapor phase studies and (*ii*) to produce the entire mass spectra, which then would allow for selection of "unique ions", if necessary, for employment of the selected ion monitoring mode. All GC–MS analyses were performed using a Finnigan Mat Incos 50 mass spectrometer system. The instrument consisted of a Hewlett-Packard 5890 gas chromatograph directly interfaced to an Incos 50 quadrupole mass spectrometer via a heated transfer line – capillary interface. The GC was configured with a splitless injection port and a DB-5MS fused-silica capillary column coated with a 0.25 μm film of stationary phase (15 m, 0.25 mm i.d., J & W Scientific, Folsom, California). As little as 0.05 mL of the headspace could be conveniently sampled and injected employing a latex-free 1 mL tuberculin disposable syringe (Becton Dickinson and Co., Franklin Lakes, New Jersey). An attempt was made to compare results of sampling precision using a gas-tight syringe. The additional sampling was performed employing a 0–500 μL 81256 Hamilton Samplelock™ syringe (Sigma-Aldrich Canada Ltd., Oakville Ontario).

The mass spectrometer was operated in the electron impact ionization mode with an electron energy of 70 eV. The ion source temperature was maintained at 180 °C for all analyses and the capillary interface transfer line was held at 250 °C. The headspace studies for the air samples were carried out with the gas chromatograph run at varied temperatures (isothermal), while the splitless injection port was held at 210 °C. Imperative to the headspace analyses was the requirement to acquire data while continuously making injections without having to reprogram the instrumentation. Prior to each run, the mass spectrometer was calibrated with perfluorotributylamine.

Headspace correlation studies of ionic liquids included the systems pyridine – acetic acid (sampling at 80 °C), 1-methylimidazole – acetic acid (sampling at 80 °C), and triethylamine – acetic acid (sampling at 23 °C). The gas chromatograph column was set at 60 °C isothermal for the triethylamine – acetic acid and the pyridine – acetic acid systems, producing satisfactory component resolution, while a 125 °C isothermal column temperature was required for the headspace analysis of the methylimidazole – acetic acid mixture. Our methodology employed 5 mL borosilicate vials with Teflon® septa in open cap screw tops (Chromatographic Specialties Inc., Brockville, Ontario). It is important to note that for all samples other than "air" employed for the precision studies, once the headspace was sampled, the syringe tip was not pulled out immediately from the sample vial septa; instead, it was allowed to remain with the plunger withdrawn for about 60–90 s in an attempt to approach a reasonable equilibrium. The vials containing the ionic liquid mixtures were kept in a continuously stirred hot water bath and supported by a Styrofoam collar.

^{1}H NMR spectra were obtained with a Bruker AC-200 MHz NMR with DMSO–d_6 as an external locking solvent.

Specific conductivities were measured by means of an Orion conductivity meter model 160 across a cell with platinum electrodes calibrated with 0.01 mol/L KCl solution. Approximate densities were obtained by weighing 1 mL portions in a volumetric flask.

Results and discussion

Reproducibility studies for ambient and fresh air components

Two separate modes of scanning were employed to monitor the relative amounts of nitrogen, oxygen, and argon. Both ambient (within the laboratory) and fresh air (outside the building) samples were subjected to full scan (5–50 amu) and selected ion monitoring (SIM). When the quadrapole mass filter was operated in the SIM mode, five ions were monitored for total relative amounts of nitrogen, oxygen, and argon (m/z for $z = +1$ were 28, 32, and 40; m/z for $z = +2$ were 14 and 16). For the full scan mode, these ions were also selected for the calculation of total relative amounts and results compared with those found in the SIM mode. The ability of the system to reliably identify the resolved total and selected ion chromatograms using electron impact ionization for any species is subject to certain criteria:

(*i*) peaks (all fragments) for identical species must appear at the same relative retention times (±0.02 min); (*ii*) the reconstructed ion chromatogram peaks of all ions monitored must have signal-to-noise ratios that are greater than 3:1.

Using the aforementioned criteria, carbon dioxide did not contribute to the envelope sampling.

Over 100 air samples were analyzed for the purpose of choosing (*i*) whether full scan or selected ion monitoring (SIM) should be employed and (*ii*) whether the technique could produce the required precision for relative proportions, regardless of volumes injected. It was found that although the SIM mode most certainly produces results with a magnitude greater sensitivity, the full scan mode worked extremely well with the required sensitivity with less noise for the required dynode voltage.

Table 1 depicts the precision afforded for 14 consecutively run random air samples at the indicated retention times (RT). All 14 samples were analyzed with full resolution in less

than 20 min. As can be seen in Table 1 for the total ion chromatograms (TIC), full scan mode, it is imperative that the 2+ ions for nitrogen and oxygen be included for the calculation of total relative amounts (14). Figure 1 shows the completely resolved, total ion chromatograms for random volumes of air sampled (volumes injected, 0.05–0.2 mL air). It can be clearly seen that although total peak areas are purposely quite varied (deliberate varied injection volumes), the respective standard deviations for all components monitored are very low. *The reproducibility studies for air were found to more than satisfy the requirements necessary for the subsequent partial-pressure studies on the selected ionic liquid mixtures.*

Ionic liquid systems

Analysis of 1-methylimidazole – acetic acid (mim–aa) mixtures

Five liquids containing mim–aa with varied mole fractions were analyzed employing the above technique. Because enhanced sensitivity was required for identification and integration of the respective species in the vapor phase, SIM was necessary. Initial studies on these systems included preliminary runs sampling every 2° or 3° from room temperature to 95 °C, in full scan and SIM modes. It was evident that the appearance of constituents (acetic acid) in the vapor phase could be seen at least 7 to 8 °C lower when employing the SIM mode. Also, in the initial studies of the mim–aa system as in the air composition analyses, the gas chromatograph was held at 60 °C. Selected subsequent samples were run at elevated, isothermal temperatures (125, 150, and 200 °C) to attain better chromatography only for the ionic liquid samples. Again, it was imperative in the integration of all peaks that the individual signals scanned qualify for a 3:1 signal-to-noise requirement.

Table 2 lists the various concentrations when the liquid was maintained at 80 °C for the mim–aa mixtures analyzed. It was discovered that for all five cases, the acetic acid was present in all headspace volumes (recorded in Table 2), whereas the 1-methylimidazole could not be detected even at the highest mole ratios for the mim constituent when the vials were heated as high as 95 °C and monitored in the single ion mode. Figure 2 includes the chromatograms and full scan mode for these mixtures. All five peaks observed (retention times, 2.5–12.5 min) are due to acetic acid in the headspace. Figure 3 is the mass spectrum (upper) and library search (lower) for the peak sampled between 3.01 and 3.03 min. Figure 4 shows the resulting respective chromatograms of headspace and liquid samples for the same mim–aa mixture where the mim concentration is the highest and the temperature was taken to 90 °C. It can be noted that the isolated single peak to the left is a result of the acetic acid in

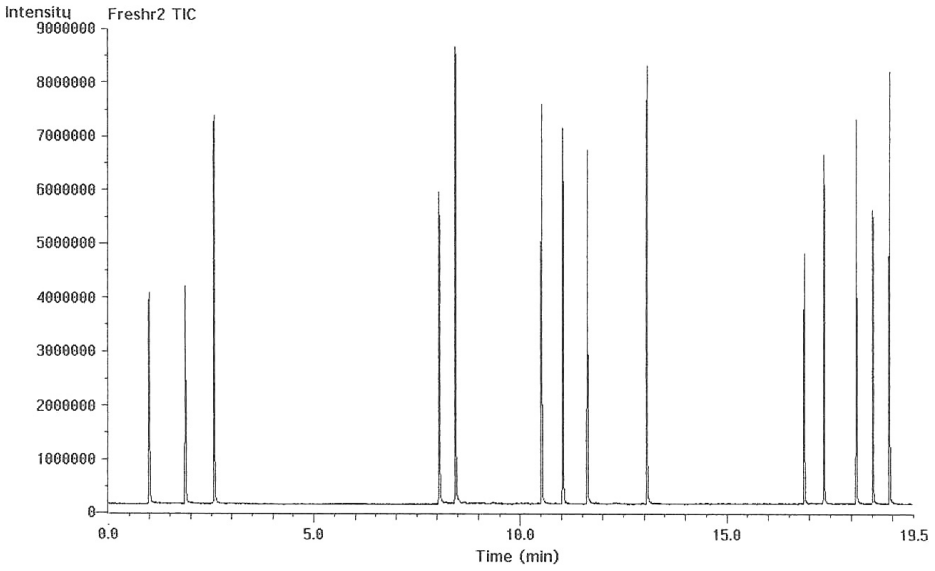

Fig. 2. Total ion chromatograms (full scan model) for mixtures of 1-methylimidazole and acetic acid. Peaks correspond to vials 1–5, Table 2.

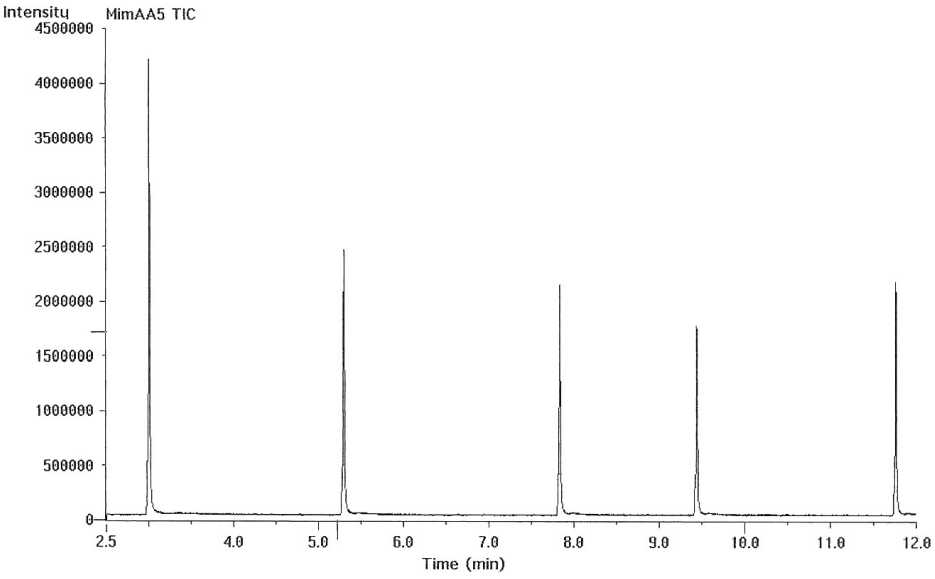

Table 2. Analysis of 1-methylimidazole – acetic acid (mim–aa) liquids at 80 °C.

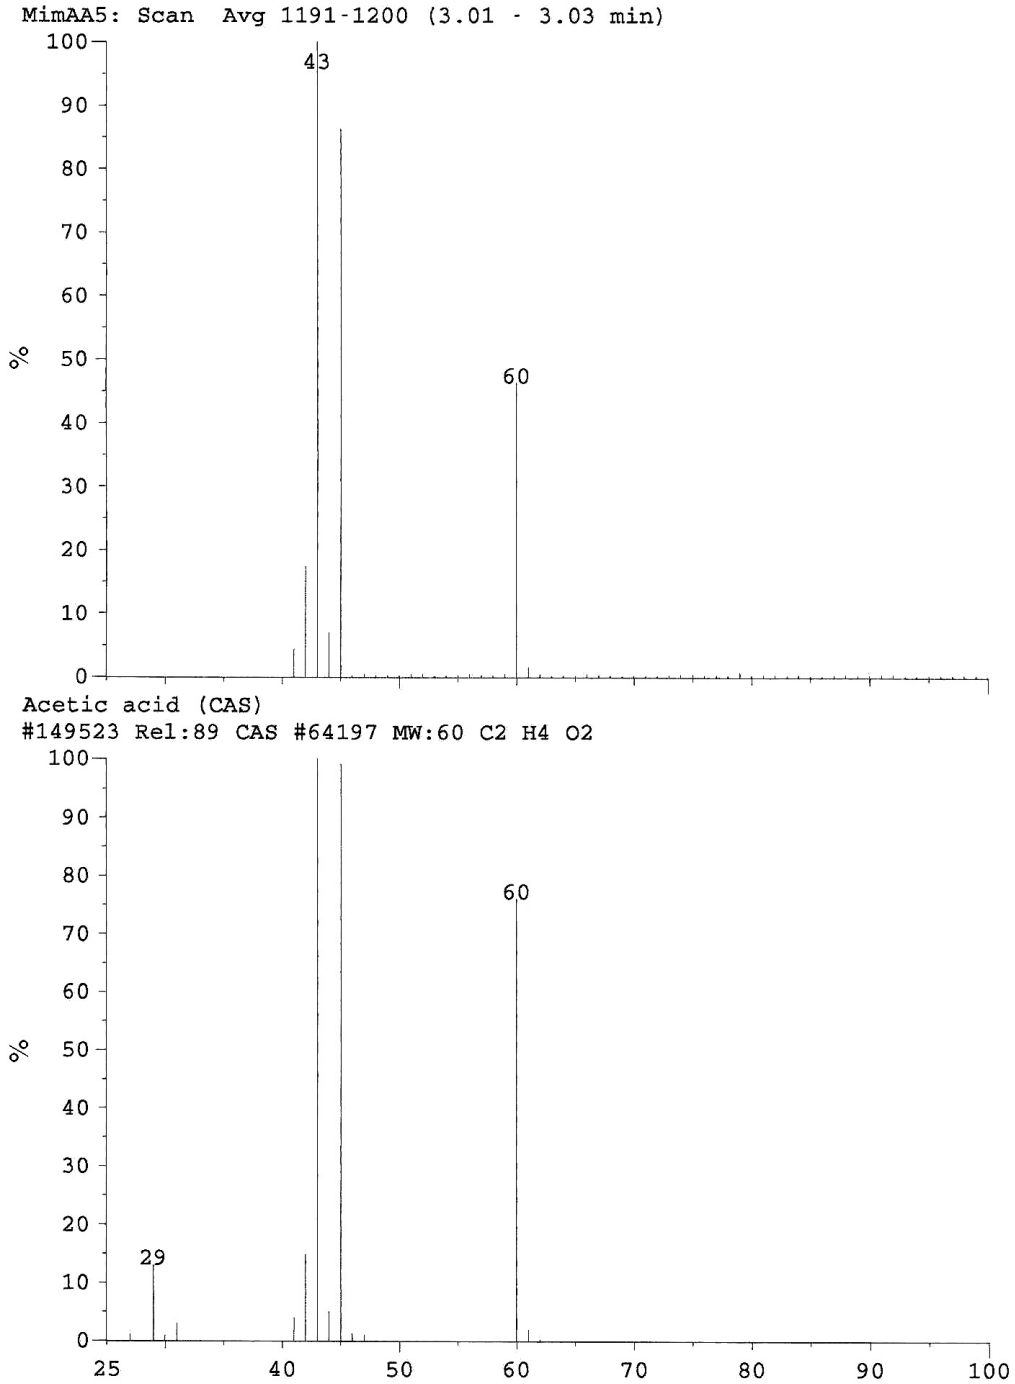
Vial	Acetic acid (mol)	1-Methylimidazole (mol)	Headspace acetic acid peak area (au)
1	0.0116	0.0226	378
2	0.0140	0.0213	330
3	0.0173	0.0188	403
4	0.0192	0.0180	461
5	0.0227	0.0149	737

the headspace volume and the two peaks to the right are a result of the acetic acid and the methylimidazole (extreme right) in the respective liquid portions (both sampled at 90 °C). The ratio of the acetic acid liquid to vapor was calculated for this concentration and was found to be 32.5:1.

The NMR signal of the carboxylic acid proton is shifted from 11.73 ppm vs. TMS to 13.92 and 14.42 ppm in 2:1 and 1:2 aa–mim mixtures, respectively. Conductivities across the system are shown in Fig. 5.



Correlation of the partial pressures of a pyridine – acetic acid (py–aa) mixture at 80 °C

An attempt was made to employ data received from headspace analyses of pyridine – acetic acid mixtures to correlate previously reported partial pressures of this binary mixture (7).

Table 3 is a tabulation of the integrated areas attained from the total ion chromatograms of seven separate 0.3 mL

headspace pyridine – acetic acid mixtures sampled at 80 °C using full scan monitoring.

A plot of the respective areas from Table 3 vs. the mole ratios yields a trend that is very similar to the previous work reported (7). Previous work indicated that for this system the partial pressures were exactly equivalent when the mole ratio was 0.50 for the respective species. Figure 6 shows the respective separate plots of headspace intensities vs. mole ratio acetic acid – pyridine.

The NMR signal for the carboxylic acid proton in the 1:5 aa–py system appears at 12.21 ppm. Conductivity data are shown in Fig. 5.

Examination of the triethylamine – acetic acid system

Headspace analyses of two separate mixtures of triethylamine – acetic acid were performed at room temperature. The impetus in the development of a method for analyzing this system was based upon a need to compare data received with that of the previously studied system, where the boiling point of the base (1-methylimidazole) was much higher. Ambient-temperature headspace samples of 0.3 mL were run on the GC–MS system for the 40% and 60% triethylamine mixtures. Gas chromatograph column temperatures were set at 60 and 125 °C isothermal and the mass spectrometer was operated using the full scan mode monitoring

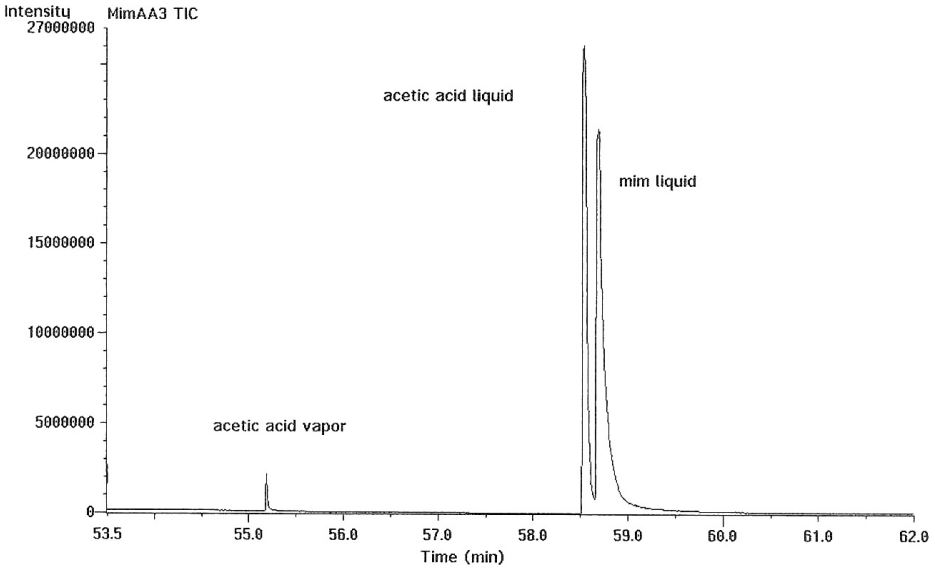

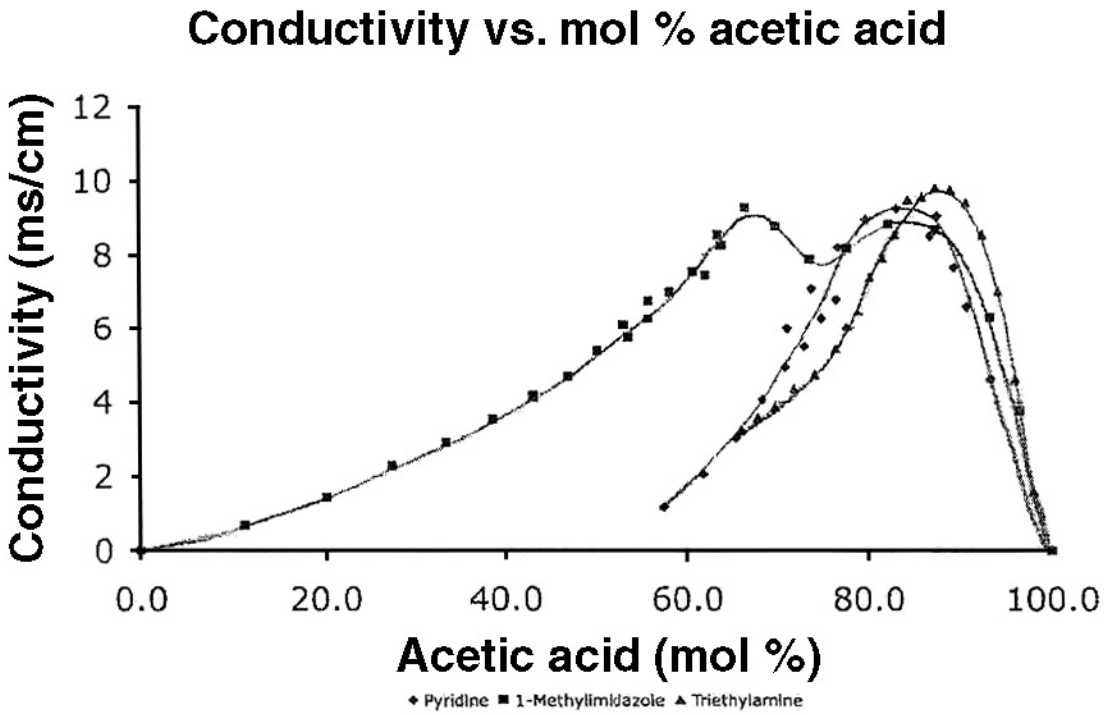

Fig. 5. Specific conductivity vs. mol % acetic acid for mixtures with three bases.

from 41 to 125 amu. Both headspace fractions were found to be entirely triethylamine, with barely traceable amounts of acetic acid present, using SIM (monitoring the molecular ion, 60 amu and the respective base peak, 43 amu). A completely miscible liquid was evident for the mixture containing 40% triethylamine. Following the headspace analysis, 0.05 μL of this 40% liquid mixture was sampled at room temperature and then injected and analyzed using the GC–MS system with full scan monitoring (last peak Fig. 7; retention times, 8.75–9 min). It was discovered that although we have a coeluting system, two distinct peaks could be seen emerging and confirmed and (or) attributed, respectively, to acetic acid (eluting first) and triethylamine. Matches confirmed with the library database (15) for the coeluting triethylamine (Fig. 8) were found to be in 97% agreement. The 60% triethylamine mixture visibly produced two distinct layers of about equal volumes with the top layer clear while the bottom layer was slightly discolored. Careful sampling (0.05 μL) and analysis of the bottom layer (same GC–MS conditions) resulted in the first peak in Fig. 7

(retention time, 3.75–4 min), producing exactly the same results as found for the 40% triethylamine mixture. Sampling of the clear top layer (second peak in Fig. 7, retention time, 7.9–8.1 min) showed triethylamine with a traceable amount of acetic acid. An additional species, which upon close examination of the chromatograms eluted, just prior to each headspace peak in Fig. 7, was found to be CO_2. Its origin was not apparent.[2]

The NMR signal of the carboxylic acid proton was shifted to 12.97 ppm for a 1:1 mixture.

[2] Pure acetic acid was repeatedly analyzed employing the aforementioned instrumental parameters to determine whether or not it contained dissolved carbon dioxide, which was detected in the previous acid–base headspace fractions. There was no evidence of residual carbon dioxide over and above that level associated with normal ambient air samples in the same acetic acid used in the headspace experiments. The headspace for all three pure bases was also analyzed in an attempt to determine where the residual CO_2 may be. It was found that for all three bases, residual CO_2 could not be detected. Additional attempts were made to analyze for residual methane that may also be present in the reported headspace fractions. No evidence of methane could be found in the samples analyzed.

Conclusions and prospects

For the 1-methylimidazole – acetic acid system, only the more volatile acetic acid was detectable in the headspace above the liquids even at 95 °C, while for the triethylamine – acetic acid system, only the more volatile triethylamine was observed. However, for the system derived from components with almost the same boiling points, pyridine (bp 115 °C) and acetic acid (bp 116 °C), *both* compounds were observed in the vapor except at the extremes of composition. Moreover, in the latter system, both compounds were obtained from mixtures in which their mole fractions were <0.5. If the 1:l compound is stable and has zero vapor pressure, then we would expect a v-shaped vapor pressure diagram.

The ^{1}H NMR data indicate that proton transfer does indeed occur from acetic acid to the different bases in the liquids, i.e., the compounds are ionized (16). It does not follow that the ion pairs are dissociated; that this occurs to a considerable extent is confirmed by the conductivity data. Values of specific conductivity in the mS cm^{-1} range are common for organic or semiorganic ionic liquids at ambient temperatures (2). Somewhat more surprising are the maxima in the conductivity–composition curves at high acetic acid mole ratios, although maximum boiling azeotropes have been observed for several carboxylic acid – base systems in the excess acid region (17). It appears that conjugate anions of the type H_nA_{n+1} are formed, similar to the halohydrogenates HCl_2^- and $H_2Br_3^-$, which we have described in pyridinium and 1-methylimidazolium ionic liquids (18, 19).

Do ionic liquids have a vapor pressure? The evidence, particularly from the pyridine – acetic acid system, is that they do. As the temperature is raised, we would expect the GC–MS technique to detect both components of the three systems we examined. No evidence of compound formation in the vapors was obtained, but this is in accord with the proton affinities (20) of acetate and the bases; the gas-phase equilibria should favor acetic acid.

$$\begin{array}{l} \mathrm{HA(l) + B(l) \rightarrow [BH^+][A^-](l) \rightarrow HA(g) + B(g)} \\ \qquad \downarrow\uparrow \\ \mathrm{\{[BH^+] + [A^-]\}(l)} \\ \mathrm{[A^-](l) + HA(l) \rightarrow [HA_2^-](l),\ etc.} \end{array}$$

Where the proton in the cation is replaced by an alkyl group, as in the familiar alkylpyridinium and dialkylimidazolium salts, vaporization of ion pairs (10) would be the only alternative to irreversible decomposition; lower conductivities, within this compound class, should then correspond to greater volatility.

$$\begin{array}{l} \mathrm{\{[RB^+] + [A^-]\}(l)\ \grave{A}\ \{[RB^+][A^-]\}(l)} \\ \qquad\qquad\qquad\qquad \mathrm{\grave{A}\ \{[RB^+][A^-]\}(g)} \\ \mathrm{[A^-](l) + HA(l)\ \grave{A}\ [HA_2^-](l),\ etc.} \end{array}$$

The product distribution in both of these situations is, of course, characterized by several equilibrium constants and disproportionations, such as $2[H_nA_{n+1}^-] \leftrightarrow [H_{n-1}A^-] + [H_{n+1}A_{n+2}^-]$, may be involved. In the cases of the aromatic bases, homoconjugate cation formation (21) may account for their miscibility at low base compositions, while the excess aliphatic base triethylamine appears as a separate phase (containing traces of acetic acid) from the primary salt phase.

One of the obstacles encountered in the GC–MS study was attempting to overcome and avoid contamination of the sampling syringe when in contact with any condensation on the underside of the vial septa, when the solution mixtures were taken somewhat above ambient temperatures. Future attempts at upgrading and refining this technique will eliminate condensation problems while incorporating a completely *closed temperature programmable sampling, vapor transfer, and gas-tight injection system*. The present methodology lends itself to a scope much larger and not confined to correlating vapor pressures. The present method without refinement is amenable to (1) rapid identification of any volatile species regardless of whether or not the chromatograms are completely resolved or what phase they are in, (2) possible isolation and identification of intermediates in the vapor phase for those reactions requiring time/temperature monitoring, (3) greatly enhanced sensitivity if necessary while employing SIM and (or) collective sampling techniques, and (4) immediate determination of relative proportions of constituents present in liquid and vapor phases.

Future work will include not only a more advanced study of vapor pressures associated with various ionic liquid mixtures at various temperatures *above and below ambient*, but also a study of (*i*) gas *saturation or storage capacities* and *ability to release* systems and (*ii*) analysis of various types of exhaust emissions (internal combustion engines, industrial gas plants, etc.).

Synthesis and thermolysis rate constants of diastereomeric oxadiazoline sources of acetoxy(methoxy)carbene — Reaction of acetoxy(methoxy)carbene with isocyanates

Wojciech Sokol and John Warkentin

Abstract: Oxidation of the methoxycarbonylhydrazone of *p*-methoxyacetophenone affords both the *cis*- and *trans*-2-acetoxy-2-methoxy-5-(*p*-methoxyphenyl)-5-methyl-Δ^3-1,3,4-oxadiazolines (also known as corresponding 2,5-dihydro-1,3,4-oxadiazoles) as well as methyl 1-acetoxy-1-(*p*-methoxyphenylethyl)diazenecarboxylate. The three isomers were separated and identified by spectroscopic means. Methyl 1-acetoxy-1-(*p*-methoxyphenylethyl)diazenecarboxylate is the major product from oxidation in dichloromethane. Oxidation in acetic acid did not afford the oxadiazolines but gave the diazenecarboxylate and, in addition, 1-(*p*-methoxyphenyl)ethyl acetate. Attempts to isomerize the diazenecarboxylate to the oxadiazolines by acid catalysis were not successful. Thermolysis of the oxadiazolines at 50.4 °C occurred with approximately the same rate constant (ca. 3.6×10^{-5} s^{-1}) to afford acetoxy(methoxy)carbene, which rearranges to methyl pyruvate by acetyl transfer. The carbene, which reacts with relatively unhindered isocyanates to transfer the methoxycarbonyl group to carbon and the acetyl group to nitrogen, can be considered an acyl anion equivalent in that reaction.

Key words: acetoxy(methoxy)carbene, diazene, oxadiazoline, isocyanate, (acetylamino)oxoacetate.

Résumé : L'oxydation de la méthoxycarbonylhydrazone de la *p*-méthoxyacétophénone conduit à la formation d'un mélange des 2-acétoxy-2-méthoxy-5-(*p*-méthoxyphényl)-5-méthyl-Δ^3-1,3,4-oxadiazolines *cis* et *trans* (aussi connues sous le nom des 2,5-dihydro-1,3,4-oxadiazoles correspondantes) accompagné de 1-acétoxy-1-(*p*-méthoxyphényléthyl)diazènecarboxylate de méthyle. On a séparé les trois isomères et on les a identifiés par des méthodes spectroscopiques. Le 1-acétoxy-1-(*p*-méthoxyphényléthyl)diazènecarboxylate de méthyle est le produit majeur de l'oxydation dans le dichlorométhane. L'oxydation dans l'acide acétique ne fournit pas d'oxadiazolines, mais conduit à la formation du diazènecarboxylate ainsi qu'à de l'acétate de 1-(*p*-méthoxyphényl)éthyle. On n'a pas réussi dans nos tentatives d'isomériser le diazènecarboxylate en oxadiazolines par catalyse acide. Les constantes de vitesse des thermolyses de chacune des oxadiazolines effectuées à 50,4 °C sont approximativement les mêmes, soit environ $3,6 \times 10^{-5}$ s^{-1}, et elles conduisent toutes les deux à la formation d'acétoxy(méthoxy)carbène qui se réarrange en pyruvate de méthyle par transfert d'un groupe acétyle. Le carbène, qui réagit avec les isocyanates non encombrées pour conduire à un transfert du groupe méthoxycarbonyle vers le carbone et du groupe acétyle vers l'azote, peut être considéré comme équivalent à un anion acyle dans cette réaction.

Mots clés : acétoxy(méthoxy)carbène, diazène, oxadiazoline, isocyanate, (acétylamino)oxoacétate.

[Traduit par la Rédaction]

Introduction

Generation of dimethoxycarbene from 2,2-dimethoxy-5-(*p*-methoxyphenyl)-5-methyl-Δ^3-1,3,4-oxadiazoline was reported recently (1). The *p*-methoxyphenyl substituent provided an extra methoxy signal in the ^{1}H NMR spectrum and it lowered the temperature for generation of the carbene from about 110 °C (for the 5,5-dimethyl analogue) to about 50 °C. We decided to make the isomeric 2-acetoxy-2-methoxy-5-(*p*-methoxyphenyl)oxadiazolines because acetoxy(methoxy)carbene (also known as (acetyloxy)methoxymethylene), which had been generated earlier at 110 °C (2), might have interesting properties, similar to those of acetoxy(methylthio)carbene that were reported in 2005, Scheme 1 (2). The diastereomers were separated and identified. We now report their spectra and rate constants for their thermolysis to carbonyl ylides that, in turn, fragment rapidly to acetoxy(methoxy)carbene. The carbene was intercepted with various isocyanates to afford methyl (acetylamino)oxoacetates.

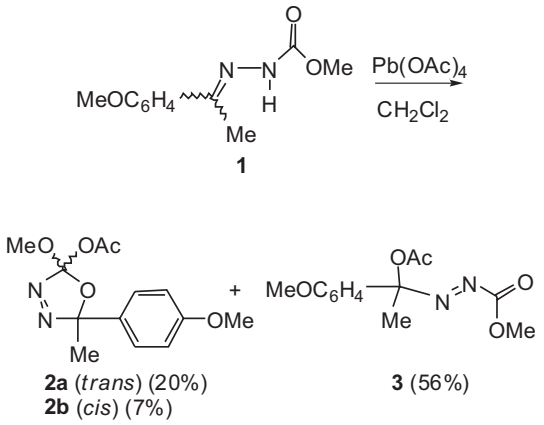
Results and discussion

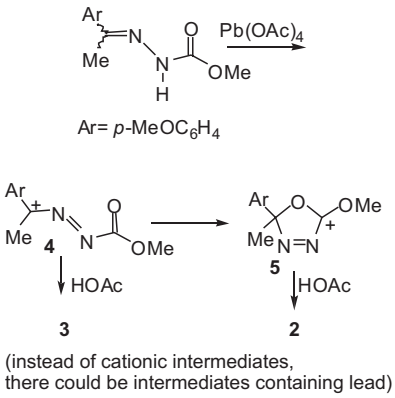


The isomeric oxadiazolines, **2a** and **2b** (also known as corresponding 2,5-dihydro-1,3,4-oxadiazoles), were prepared by oxidative cyclization (3) of a mixture of the (*E*)- and (*Z*)-methoxycarbonylhydrazones (**1**) of *p*-methoxy-

 doi:10.1139/V06-109 © 2006 NRC Canada

Scheme 1.

Scheme 2.



acetophenone with lead tetraacetate in dichloromethane. The products isolated were **2a** (20%), **2b** (7%), and a surprisingly large amount of an acyclic isomer **3** (ca. 56%) (Scheme 2). Oxidation in dry acetic acid did not produce **2** but gave **3** (28%) as well as 1-(*p*-methoxyphenyl)ethyl acetate (22%).

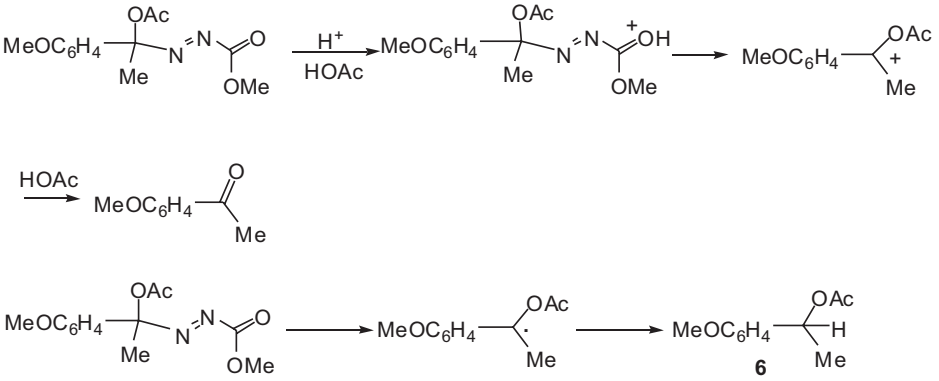
The formation of **3** as a major oxidation product (Scheme 2) suggests that there are cationlike precursors of the type **4** and **5** (Scheme 3). Exchange of acetoxy for methoxy, allyloxy (4), or other hydroxyl-containing groups under conditions of acid catalysis supports the intermediacy of ions such as **4** under exchange conditions. Probably, ion **4** does not cyclize easily to **5** because the stabilization afforded by the *p*-methoxyphenyl group is lost if the species cyclizes.

Cyclization in acetic acid was explored in the expectation that better solvation of cationlike intermediates would lessen the energy difference between **4** and **5**. Oxidation in acetic acid did not result in any oxadiazolines **2**. Attempts to isomerize **3** into a mixture of the diastereomers **2** by means of acid catalysis (CF_3CO_2H–CH_3CO_2H in CH_2Cl_2) did not succeed either. In the latter case, equal amounts of *p*-methoxyacetophenone and 1-(*p*-methoxyphenyl)ethyl acetate (**6**) (22%) were obtained. We suggest that those arise through the reactions shown in Scheme 4.

The ratio in which oxadiazolines **2a** and **2b** were formed by oxidation of **1** (Scheme 2) suggested that **2b** is more hindered and that it was expected to thermolyse more rapidly than **2a**. Oxadiazolines **2a** and **2b** are expected to undergo thermolysis by concerted 1,3-dipolar cycloreversion, to afford carbonyl ylides **7a**–**7d** (Scheme 5). The cycloreversion

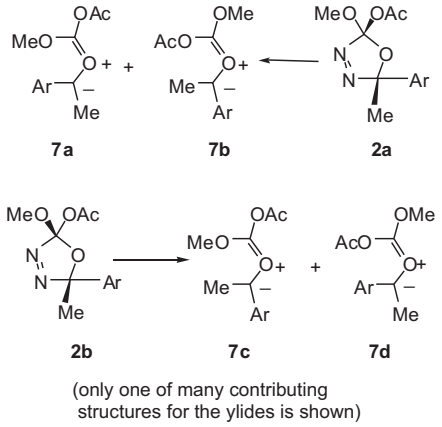
Scheme 3.

of an oxadiazoline is a disrotatory process, requiring that cis substituents at C-2 and C-5 rotate either both inward (endo) or both outward (exo) (5). Substituents in a trans relationship place one group endo and the other exo. Assuming that the aryl group has the largest steric requirement at C-5 and that polar effects are less important, one would predict that oxadiazoline **2a** would form ylide **7b** in preference to **7a**. Similarly, **2b** should form **7c** in preference to **7d** (Scheme 5). There was little hope of trapping those ylides, whose lifetimes are probably very short (6, 7), with barriers to fragmentation to carbene and ketone of only a few kcal mol^{-1} (1 cal = 4.184 J), but rate constants for thermolysis of the isomeric precursors could be measured. Those rate constants are a measure of the difference between ground-state and transition-state energies.



It turned out that **2b** does thermolyse faster than **2a** (3.74×10^{-5} s^{-1} vs. 3.49×10^{-5} s^{-1} in benzene at 50.4 °C). Isomer **2b** should have a higher ground-state energy than isomer **2a**, while the transition states for thermolysis of the isomers could be more nearly isoenergetic. Of course, the fact that **2b** could place both larger substituents exo (**7c**, Scheme 5) should favour its thermolysis additionally, but there would be a statistical penalty (a factor ≤ 2) involved in a restriction that favours outward rotation of the larger groups. The result suggests that the difference between the steric factors that operate in **2a** and **2b** is relatively small and probably partly compensated for by the statistical factor.

The putative carbonyl ylide intermediate shown in Scheme 5 has never been observed. Computations (7) on the dimethyl analog (rather than aryl methyl as in Scheme 2) indicate that the ylide is a real intermediate with a barrier to fragmentation to acetoxy(methoxy)carbene and ketone of about 2 to 3 kcal mol^{-1}. Although the aryl group of **7** could change that barrier, a change large enough to make the ylide trappable by conventional 1,3-dipolarophiles is hard to imagine. In an attempt to trap the ylide, thermolysis was carried out in neat phenyl isothiocyanate, which has been shown to trap carbonyl ylides (8). The ^1H NMR spectrum of the crude product showed *p*-methoxyacetophenone as the major product (>85%) with the characteristic pair of doublets at low field.



Evidence of the intermediacy of acetoxy(methoxy)carbene (**9**) (also known as (acetyloxy)methoxymethylene) came from two sources. First, it is known from both experiment (9) and theory (6) that the carbene rearranges to methyl

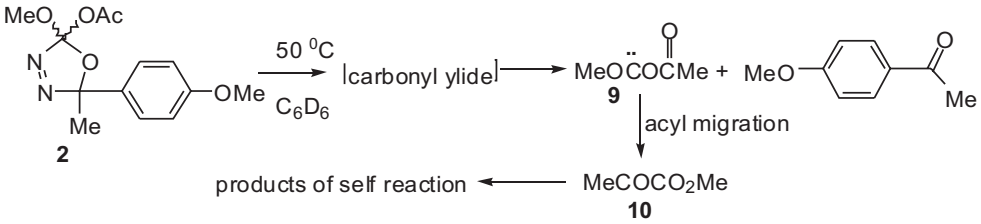
Scheme 4.

Scheme 5.

pyruvate (**10**). That product could be detected by ^{1}H NMR spectroscopy during kinetic runs in C_6D_6, but amounted to only 5% of the signal from *p*-methoxyacetophenone at 30% reaction and only about 2% when essentially all of the oxadiazoline had fragmented (Scheme 6). The reason for the low yield lies in the fact that methyl pyruvate is very self-reactive and does not survive the reaction conditions (10).

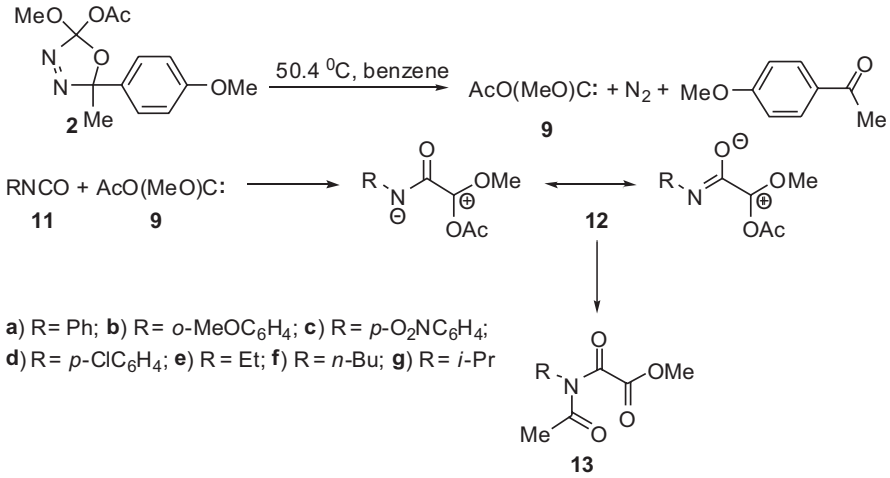
Rearrangement of acetoxy(methoxy)carbene to methyl pyruvate could be suppressed, but not eliminated, by an isocyanate (**11**) at high concentration. The pyruvate could always be detected (≤2%) among the crude reaction products. Eight isocyanates, with a variety of functional groups ranging from unhindered alkyl to hindered alkyl and from phenyl to variously substituted phenyls (Scheme 7) at nitrogen were treated with **2** at 50.4 °C. A liquid isocyanate (1 equiv. or more) was mixed with the liquid oxadiazolines **2** prior to degassing and heating. Homogeneous solutions resulted. A solid isocyanate, melting near 50 °C, and **2** gave a homogeneous solution immediately after the mixture had been heated to 50.4 °C. In the cases of aryl or alkyl isocyanates, except for *tert*-butyl isocyanate, reaction occurred to yield methyl (acetylamino)oxoacetates **12** (Scheme 7). Yields, not optimized, ranged from 48% for isopropyl isocyanate to 76% for phenyl isocyanate, after flash chromatography on silica. Product **12c** was obtained simply by washing the crude with ethyl acetate – hexane. Compound **12c** and other solid products from column chromatography were recrystallized from a benzene–hexane mixture. *tert*-Butyl isocyanate afforded many products (many OMe signals in the ^{1}H NMR spectrum), suggestive of extensive rearrangement of the carbene and subsequent reactions of methyl pyruvate. Although the isocyanate appeared to be unchanged (only one *tert*-butyl signal in the ^{1}H NMR spectrum), a low yield of the appropriate **12** (<5%) could not be excluded. Neat phenyl isothiocyanate mixed 1:1 with **2** also did not afford any of the expected product.

A possible mechanism for the reaction of **9** with isocyanates is shown in Scheme 7. Acetoxy(methoxy)carbene must be nucleophilic toward isocyanates. Although that carbene has not been placed on a nucleophilicity scale (11), it is probably ambiphilic toward alkenes. Trifluoroethoxy(methoxy)carbene is ambiphilic toward alkenes (12) and the acetoxy is only a little poorer than trifluoroethoxy as an electron donor (13). However, philicity depends on the partner; for example, acetic acid is acidic towards water and basic towards sulfuric acid.



A nucleophilic singlet carbene is expected to attack an isocyanate at the carbonyl carbon atom to generate zwitterion **12** or it could add to either double bond in a concerted process. However, the three-membered rings resulting from the latter process would have to undergo ring opening and acetyl transfer (2) to arrive at the product. Model α-lactams or iminooxiranes with *gem*-dialkoxy and carboxylate functions at the ring carbons, which could help to resolve the latter aspect, are unknown and there was no evidence for ring formation in the present case. On the other hand, there are many precedents for formation of zwitterionic intermediates in nonpolar solvents (14).

α-Lactams and iminooxiranes that could form by ring closure of **12** may well be unstable at 50 °C. Lengyel et al. (15) reported that α-lactams that are thermally unstable and chemically reactive afford 3-benzylamino products upon reaction with benzyl amine (Scheme 8). A possible explanation of that result is that such lactams open easily to zwitterions of the type **12**. Such an open form of an α-lactam was invoked by Ohshiro et al. (16) to account for the product from a reaction with a vinyl isocyanate (Scheme 9). There is also good evidence that *gem*-dialkoxycyclopropanes undergo thermal ring opening at moderate temperatures (17–20). In the present case, the negative charge of an intermediate is dispersed by conjugation, making it more likely that a three-membered-ring system (not shown in Scheme 7) would either not be formed or would open easily to **12**.



Phenyl isothiocyanate is known to be less reactive, by a

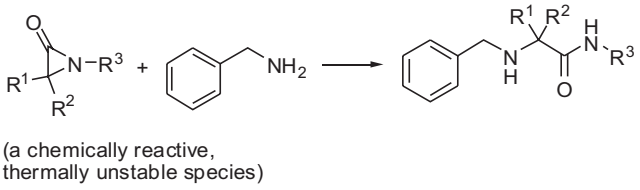


Scheme 6.

Scheme 7.

Scheme 8.

factor of 11, than phenyl isocyanate toward dimethoxycarbene at 140 °C (21). With a less nucleophilic carbene (acetoxy(methoxy)carbene) and a lower temperature (50.4 rather than 140 °C), the difference in reactivity between phenyl isocyanate and phenyl isothiocyanate could well be larger than 11. A product analogous to **12** (Scheme 7) was not obtained with phenyl isothiocyanate.

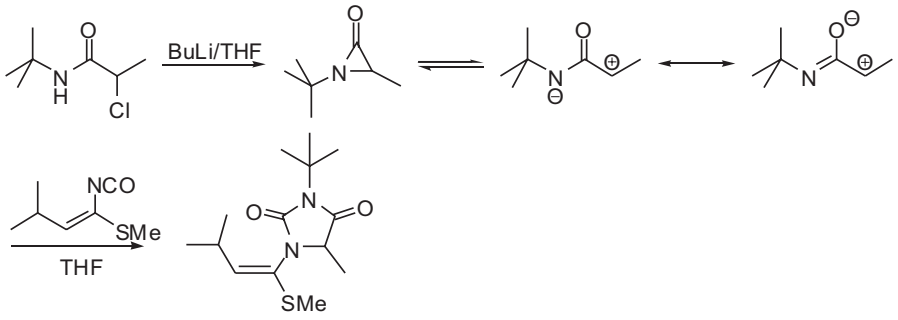
Summary

Diastereomeric oxadiazoline sources of acetoxy(methoxy)carbene were synthesized, separated, and fully characterized. Their thermolyses in benzene at 50.4 °C occurred with roughly equal rate constants (ca. 3.6×10^{-5} s^{-1}) and they afforded acetoxy(methoxy)carbene. The carbene reacted with various isocyanates to add the methoxycarbonyl group at carbon and the acetyl group at nitrogen. In its addition at carbon, the carbene behaved as an acyl anion equivalent.

Experimental

NMR spectra were taken with Bruker Avance 600 MHz and Bruker Avance 200 MHz instruments operating at frequencies given in each section. IR spectra came from a Bio Rad FTS 40 spectrometer and mass spectra were run with a Waters Micromass GCT instrument. Melting points were measured with a Uni-Melt Thomas Hoover capillary melting point apparatus. Yields were not optimized.

2-Acetoxy-2-methoxy-5-(*p*-methoxyphenyl)-5-methyl-Δ^3-1,3,4-oxadiazoline (2)



Lead tetraacetate (7.49 g, 16.05 mmol, 95% purity) was dissolved in dichloromethane (50 mL), the solution was cooled to about 0 °C, and the methoxycarbonylhydrazones of *p*-methoxyacetophenone (3.61 g, 16.24 mmol) were added in the solid state. After 0.5 h the temperature had risen to 25 °C and the mixture was stirred for an additional 4 h. It was filtered through a bed of Celite to afford a clear solution. The Celite cake was extracted with dichloromethane (2 × 25 mL) and the combined organic solution was washed twice with aqueous sodium bicarbonate (2 × 25 mL) and dried over $MgSO_4$. Evaporation of the solvent at room temperature left 4.84 g of crude product. The ^{1}H NMR spectrum of the mixture revealed the ratios of isomers **3**:**2a**:**2b** as 67.1:24.4:8.5. The products were purified by flash-chromatography on silica with diethyl ether – hexane (25:75) as eluent. Isolated were **3** (2.53 g, 9.02 mmol, 56%) and the diastereomers **2a** and **2b** (1.10 g, 3.91 mmol, 24.4%). Separation of the oxadiazolines was carried out by centrifugal chromatography with a Chromatotron® apparatus.

HRMS (CI, NH_3) m/z calcd. for $C_{13}H_{17}N_2O_5$: 281.1137 $(MH)^+$; found: 281.1159.

Assignments of the NMR signals are based on 2D correlation spectra. Gradient HMBC and gradient HSQC spectra were run in $CDCl_3$ with a Bruker AV 600 instrument. The relative configurations of substituents at C-2 and C-5 was established at the same time on the basis of a selective 1D NOESY experiment with a pulsed field gradient, with the pulse delay set at 5.0 s and the NOESY mixing time set at 0.6 s. Irradiation of the signal at 1.88 ppm caused enhancement of the signal at 7.44 ppm. Similarly, irradiation at 3.47 ppm caused strong enhancement at 2.15 and 7.44 ppm and weak enhancement at 6.87 ppm, while irradiation at 3.78 ppm caused signal enhancement at 6.87 ppm.

cis-2-Acetoxy-2-methoxy-5-(*p*-methoxyphenyl)-5-methyl-Δ^3-1,3,4-oxadiazoline (2b, minor diastereomer)

Pale yellow oil. IR (neat, cm^{-1}): 2993, 2955, 2843, 1776, 1612, 1515, 1445, 1372, 1306, 1253, 1080, 1031, 834. ^{1}H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 1.82 (s, 3H, CH_3), 2.00 (s, 3H, $COCH_3$), 3.62 (s, 3H, OCH_3), 3.78 (s, 3H, $C_6H_4OCH_3$), 6.87 (d, J = 8.9 Hz, 2H, CH_{Ar}), 7.40 (d, J = 8.9 Hz, 2H, CH_{Ar}). ^{1}H NMR (200.2 MHz, C_6D_6, ppm) δ: 1.41 (s, 3H, CH_3), 1.62 (s, 3H, CH_3), 3.22 (s, 3H, OCH_3), 3.35 (s, 3H, OCH_3), 6.70 (d, J = 8.9 Hz, 2H, CH_{Ar}), 7.52 (d, J = 8.9 Hz, 2H, CH_{Ar}). ^{13}C NMR (50.3 MHz, $CDCl_3$, ppm) δ: 21.28 ($COCH_3$), 26.53 (CH_3), 52.95 (OCH_3), 55.23 ($C_6H_4OCH_3$), 113.81 ($2CH_{Ar}$), 123.83 (C_{benzyl}), 126.32 ($2CH_{Ar}$), 129.67 (C_{Ar}), 134.98 (C_{ring}), 159.77 (C_{Ar}—O), 166.06 (CO). ^{13}C NMR (50.3 MHz, C_6D_6, ppm) δ: 20.62 (CH_3), 26.68 (CH_3), 52.53 (OCH_3), 54.7 (OCH_3), 114.10 ($2CH_{Ar}$), 123.86 (C_{benzyl}), 126.83 ($2CH_{Ar}$), 130.58 (C_{Ar}), 135.83 (C_{ring}), 160.21 (C_{Ar}—O), 165.42 (CO).

The relative configurations of substituents at C-2 and C-5 were established on the basis of selective 1D NOESY experiments with a pulsed field gradient, as described previously. Selective irradiation at 1.82 ppm caused signal enhancements at 3.62 and 7.44 ppm, while irradiation at 2.00 ppm caused strong enhancement at 7.40 ppm and medium enhancement at 3.62 ppm. Irradiation at 3.62 and 3.78 ppm caused enhancements of signals at 1.82 and 6.87 ppm, respectively.

Acyclic isomer 3

Lemon yellow oil. HRMS (CI, NH_3) m/z calcd. for $C_{13}H_{17}N_2O_5$: 281.1137 $(MH)^+$; found: 281.1130.

Thermolysis of oxadiazolines

A solution of **2b** (0.1837 mmol) and *tert*-butylbenzene (0.1021 mmol) in C_6D_6 (1 mL), in an NMR tube fitted with a ground glass joint, was degassed by means of three freeze–pump–thaw cycles before the tube was sealed and heated at 50.4 °C. Oxadiazoline **2a** (0.2498 mmol) and *tert*-butylbenzene (0.1512 mmol) were treated analogously. Every 3 h, ^{1}H NMR spectra were acquired with the tubes still sealed and with a pulse delay of 6 s to ensure complete relaxation. For **2b**, the signal at 1.41 ppm was integrated and compared with the signal of *tert*-butylbenzene at 1.20 ppm. For **2a**, the signal at 1.95 ppm was integrated and compared with the signal of *tert*-butylbenzene. Standard first-order treatment of the data gave $k_{\mathbf{2b}} = 3.74 \times 10^{-5}$ s^{-1} (seven points, $R2$ = 0.9914) and $k_{\mathbf{2a}} = 3.49 \times 10^{-5}$ s^{-1} (seven points, $R2$ = 0.9920).

Attempt to cyclize 3

A solution of **3** (0.32 g, 1.14 mmol) and trifluoroacetic acid (0.012 g, 0.105 mmol, 10 mol%) in acetic acid (25 mL) was stirred at room temperature for 9 days. The mixture was diluted with water (25 mL) and extracted with dichloromethane (3 × 15 mL). The solution in dichloromethane was then washed with aqueous sodium bicarbonate to remove acids and dried over $MgSO_4$. After flash chromatography on

© 2006 NRC Canada

silica with diethyl ether – hexane (25:75), *p*-methoxyacetophenone (0.038 g, 0.25 mmol, 22%), 1-(*p*-methoxyphenyl)ethyl acetate (0.049 g, 0.25 mmol, 22%), and unreacted **3** (0.178 g, 0.634 mmol, 55%) were obtained.

1-(*p*-Methoxyphenyl)ethyl acetate

Colourless oil. IR (neat, cm^{-1}): 2983, 2938, 2839, 1735, 1614, 1516, 1372, 1242, 1063, 1035, 832. ^1H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 1.50 (d, J = 6.5 Hz, 3H), 2.03 (s, 3H), 3.78 (s, 3H), 5.83 (q, J = 6.5 Hz, 1H), 6.86 (d, J = 8.7 Hz, 2H), 7.28 (d, J = 8.7 Hz, 2H). ^{13}C NMR (50.3 MHz, $CDCl_3$, ppm) δ: 21.33, 21.87, 55.17, 71.93, 113.74, 127.53, 133.64, 159.18, 170.32.

Thermolysis of oxadiazolines in the presence of isocyanates

All isocyanates except **11c** and **11d** are liquids at room temperature. The liquids except isopropyl isocyanate were freshly distilled before use. The isopropyl compound was used as received from Sigma-Aldrich. *p*-Chlorophenyl isocyanate and *p*-nitrophenyl isocyanate melted at 28–30.5 and 56–60 °C, respectively.

A mixture of **2** (1.00 mmol) and isocyanate (0.96–1.63 mmol), placed in an ampoule, was degassed by means of three freeze–pump–thaw cycles before the ampoule was sealed and heated at 50.4 °C for 41 h. A large excess of isocyanate was avoided after initial experiments with a two-fold excess indicated that a considerable amount of residual isocyanate hindered isolation of **12**. The crude reaction mixture was analysed by ^1H NMR spectroscopy before pure products were isolated as described.

Reaction of 2 with phenyl isocyanate

Heating **2** with 1.28 equiv. of *p*-chlorophenyl isocyanate gave **12a**, which was isolated by means of flash chromatography on silica with ethyl acetate – hexane (20:80) as eluent. Yield of colourless oil: 76%. IR (neat, cm^{-1}): 3064, 3018, 2958, 1750, 1729, 1706, 1597, 1439, 1370, 1343, 1273, 1235, 1140, 1046, 756, 733, 698. ^1H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 2.01 (s, 3H), 3.90 (s, 3H), 7.19–7.25 (m, 2H), 7.44–7.52 (m, 3H). ^{13}C NMR (50.3 MHz, $CDCl_3$, ppm) δ: 24.37, 52.90, 128.38, 129.84, 130.08, 135.67, 161.72, 162.52, 172.45. HRMS (CI, NH_3) m/z calcd. for $C_{11}H_{12}NO_4$: 222.0766 $(MH)^+$; found: 222.0760.

Reaction of 2 with *o*-methoxyphenyl isocyanate

Heating **2** with 1.63 equiv. of the isocyanate and flash chromatography of the crude products on silica with ethyl acetate – hexane (32:68) gave **12b** in 74% yield as pale yellow crystals, mp 115.5–118.5 °C. IR (NaCl, cm^{-1}): 3018, 2960, 2946, 1755, 1729, 1705, 1600, 1436, 1346, 1283, 1253, 1146, 1023, 754. ^1H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 1.99 (s, 3H), 3.84 (s, 3H), 3.91 (s, 3H), 7.00–7.09 (m, 2H), 7.16–7.21 (m, 1H), 7.39–7.48 (m, 1H). ^{13}C NMR (50.3 MHz, $CDCl_3$, ppm) δ: 23.48, 52.81, 55.86, 112.25, 121.36, 124.27, 129.68, 131.44, 155.01, 161.88, 162.34, 172.95. HRMS (CI, NH_3) m/z calcd. for $C_{12}H_{14}NO_5$: 252.0872 $(MH)^+$; found: 252.0875.

Reaction of 2 with *p*-nitrophenyl isocyanate

Heating **2** with 1.50 equiv. of *p*-nitrophenyl isocyanate gave a crude product that was not chromatographed, but was washed with ethyl acetate – hexane (35:65) to afford yellow crystals of **12c** (mp 107.0–110.0 °C) in 72% yield. IR (NaCl, cm^{-1}): 3118, 3082, 2955, 1752, 1732, 1710, 1597, 1530, 1352, 1271, 1236, 1141, 855, 750, 699. ^1H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 2.08 (s, 3H), 3.90 (s, 3H), 7.45 (d, J = 9.08 Hz, 2H), 8.37 (d, J = 9.08 Hz, 2H). ^{13}C NMR (50.3 MHz, $CDCl_3$, ppm) δ: 24.54, 53.18, 125.36, 129.93, 141.22, 148.42, 161.04, 162.11, 170.97. HRMS (CI, NH_3) m/z calcd. for $C_{11}H_{11}N_2O_6$: 267.0617 $(MH)^+$; found: 267.0609.

Reaction of 2 with *p*-chlorophenyl isocyanate

Heating **2** with 1.08 equiv. of the isocyanate gave, after flash chromatography and recrystallization from benzene–hexane (50:50), 57% of **12d** as white crystals melting at 115.5–117.5 °C. IR (NaCl, cm^{-1}): 3098, 3076, 2956, 1752, 1727, 1706, 1341, 1275, 1237, 1145, 1095, 1041, 832, 770, 720, 675, 635. ^1H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 2.03 (s, 3H), 3.90 (s, 3H), 7.17 (d, J = 8.75 Hz, 2H), 7.47 (d, J = 8.75 Hz, 2H). ^{13}C NMR (50.3 MHz, $CDCl_3$, ppm) δ: 24.44, 53.03, 129.86, 130.41, 134.17, 136.09, 161.49, 162.41, 171.98. HRMS (CI, NH_3) m/z calcd. for $C_{11}H_{11}NO_4Cl$: 256.0377 $(MH)^+$; found: 256.0339.

Reaction of 2 with ethyl isocyanate

Heating **2** with 1.37 equiv. of the isocyanate gave, after flash chromatography on silica with ethyl acetate – hexane (35:65) as eluent, product **12e** as a pale yellow oil in 55% yield. IR (neat, cm^{-1}): 2986, 2960, 1752, 1720, 1695, 1438, 1380, 1350, 1260, 1217, 1142, 1071, 1009, 781, 735, 635. ^1H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 1.20 (t, J = 7.1 Hz, 3H), 2.30 (s, 3H), 3.69 (q, J = 7.1 Hz, 2H), 3.81 (s, 3H). ^{13}C NMR (50.3 MHz, $CDCl_3$, ppm) δ: 13.66, 23.16, 39.02, 52.63, 161.93, 162.60, 172.47. HRMS (CI, NH_3) m/z calcd. for $C_7H_{12}NO_4$: 174.0766 $(MH)^+$; found: 174.0768.

Reaction of 2 with *n*-butyl isocyanate

Flash chromatography on silica with ethyl acetate – hexane (20:80) gave, after heating **2** with 0.96 equiv. of **11f** and 55% of **12f** as a colourless oil. IR (neat, cm^{-1}): 2963, 2877, 1754, 1724, 1701, 1464, 1437, 1379, 1349, 1282, 1233, 1202, 1145, 1078, 1019, 735, 638. ^1H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 0.89 (t, J = 7.2 Hz, 3H), 1.22–1.41 (m, 2H), 1.47–1.62 (m, 2H), 2.29 (s, 3H), 3.57–3.64 (m, 2H), 3.81 (s, 3H). ^{13}C NMR (50.3 MHz, $CDCl_3$, ppm) δ: 13.49, 19.84, 23.16, 30.65, 43.73, 52.60, 161.94, 162.81, 172.65. HRMS (CI, NH_3) m/z calcd. for $C_9H_{16}NO_4$: 202.1079 $(MH)^+$; found: 202.1040.

Reaction of 2 with isopropyl isocyanate

Heating **2** with 1.08 equiv. of **11g** gave **12g** by means of flash chromatography on silica, with ethyl acetate – hexane (28:72) as eluent. The product was obtained as a pale yellow oil in 48% yield. IR (neat, cm^{-1}): 3012, 2980, 2957, 1750, 1718, 1696, 1438, 1403, 1368, 1331, 1283, 1212, 1183, 1110, 1055, 1009, 770, 728, 638. ^1H NMR (200.2 MHz, $CDCl_3$, ppm) δ: 1.42 (d, J = 6.9 Hz, 6H), 2.29 (s, 3H), 3.79 (s, 3H), 4.16 (sept, J = 6.9 Hz, 1H). ^{13}C NMR (50.3 MHz,

Direct detection of methylphenylgermylene and 1,2-dimethyl-1,2-diphenyldigermene — Kinetic studies of their reactivities in solution

William J. Leigh, Ileana G. Dumbrava, and Farahnaz Lollmahomed

Abstract: Photolysis of 1,3,4-trimethyl-1-phenylgermacyclopent-3-ene (**5**) in hydrocarbon solvents containing isoprene, methanol, or acetic acid affords 2,3-dimethyl-1,3-butadiene (DMB) and the expected trapping products of methylphenylgermylene (GeMePh) in chemical yields exceeding 90%. The germylene has been detected in hexane solution by laser flash photolysis as a short-lived species (τ ~ 2 μs) exhibiting a UV–vis absorption spectrum centered at λ_{max} = 490 nm. It decays with second-order kinetics and a rate constant close to the diffusion-controlled limit, with the concomitant growth of a second longer-lived transient (λ_{max} = 420 nm) that is assigned to a mixture of (*E*)- and (*Z*)-1,2-dimethyl-1,2-diphenyldigermene (**4**). Absolute rate constants have been determined for the reactions of the germylene with primary and tertiary amines (*n*-$BuNH_2$ and Et_3N, respectively), acetic acid (AcOH), a terminal alkyne and alkene, isoprene, DMB, CCl_4, and the group 14 hydrides Et_3SiH and Bu_3SnH. GeMePh is slightly more reactive than $GePh_2$ towards all the reagents studied in this work; both are significantly less reactive than $GeMe_2$ toward the same substrates. Absolute rate constants for the reactions of **4** have also been measured or assigned upper limits in every case and are compared to previously reported values for tetraphenyl- and tetramethyl-digermene with the same reagents.

Key words: germylene, digermene, kinetics, laser flash photolysis, germirane, germirene, vinylgermirane, complex, UV–vis spectrum, insertion, addition.

Résumé : La photolyse du 1,3,4-triméthyl-1-phénylgermacyclopent-3-ène (**5**) dans des solvants hydrocarbonés contenant de l'isoprène, du méthanol ou de l'acide acétique conduit à la formation de 2,3-diméthylbuta-1,3-diène (DMB) et aux produits de piégeage attendus du méthylphénylgermylène (GeMePh) avec des rendements supérieurs à 90%. Faisant appel à la photolyse éclair au laser et opérant dans une solution d'hexane, on a détecté la présence du germylène sous la forme d'une espèce transitoire (τ d'environ 2μs) qui présente un spectre d'absorption UV–visible centré autour d'un λ_{max} de 490 nm. Sa décroissance présente une cinétique du second ordre et une constante de vitesse qui se rapproche de la limite d'un contrôle par la diffusion et qui est accompagnée de la croissance d'une deuxième espèce transitoire (λ_{max} = 420 nm) qui est attribuée à un mélange (*E*)- et (*Z*)-1,2-diméthyl-1,2-diphényldigermène (**4**). On a déterminé les constantes de vitesse absolues de la réaction du germylène avec des amines primaires et tertiaires (respectivement $BuNH_2$ et Et_3N), l'acide acétique (AcOH), un alcyne terminal, un alcène terminal, l'isoprène, le DMB, le CCl_4 et les hydrures du groupes 14, Et_3SiH et Bu_3SnH. Le GeMePh est légèrement plus réactif que le $GePh_2$ vis-à-vis tous les réactifs examinés dans ce travail; les deux sont toutefois beaucoup moins réactifs que le $GeMe_2$ par rapport aux même réactifs. Dans tous les cas, on a aussi mesuré ou attribué des valeurs limites supérieures pour les constantes de vitesses absolues de la réaction avec le composé (**4**) et on les a comparées aux valeurs rapportées antérieurement pour les réactions du tétraphényl- et du tétraméthyl-digermène avec les mêmes réactifs.

Mots clés : germylène, digermène, cinétique, photolyse éclair au laser, germirane, germirène, vinylgermirane, complexe, spectre UV–visible, insertion, addition.

[Traduit par la Rédaction]

Introduction

Germylenes are important intermediates in the thermal and photochemical reactions of germanium compounds (1), and the study of their synthesis and chemistry continues to be of considerable interest (2–6). Of particular fundamental and practical importance is the parent molecule, GeH_2, whose chemistry has been extensively studied in the gas phase by time-resolved kinetic methods.[2] Studies of several simple substituted derivatives by time-resolved spectroscopic methods in matrices and in solution have been reported,[3] but the solution-phase studies have been characterized by a particular lack of consistency in the spectroscopic properties and reactivities of these species (5). We have speculated that the problem is due to two main factors — the characteristic weakness of the lowest energy ($S_0 \rightarrow S_1$) electronic transition in divalent group 14 compounds and the pronounced complexity of the photochemistry of the particular organo-

germanium compounds (typically oligogermanes and oligosilagermanes) that have been employed as germylene precursors (7). As we have recently demonstrated (8), the combination of these factors can make transient germylenes relatively difficult to detect, even when they are the major products of photolysis.

We recently reported the first comprehensive kinetic studies of the reactivities of diphenyl- and dimethyl-germylene ($GePh_2$ and $GeMe_2$, respectively) in hydrocarbon solution, generating and monitoring them directly by laser flash photolysis of the 1,1-disubstituted germacyclopent-3-ene derivatives **1** and **2** (9–11). Trapping experiments showed that photolysis of these molecules proceeds very cleanly and with remarkably high efficiency in every case, producing the expected trapping products of the germylenes along with the corresponding conjugated dienes in chemical yields exceeding 90% and quantum yields on the order of 0.5. Absolute rate constants were reported for dimerization of the two species, which yields the transient digermene derivatives **3**, and for their reaction with a variety of representative substrates such as aliphatic amines, halocarbons (RX), aliphatic alkynes, dienes and alkenes, oxygen, acetic acid, and the group 14 hydrides R_3MH (M = Si, Ge, Sn; R = ethyl or *n*-butyl). Several of the reactions of these species were found to be reversible, such as the [2+1]-cycloaddition reactions with alkenes and dienes, and Lewis acid–base complexation with tertiary amines; they are nonetheless very fast, with forward rate constants on the order of 10^9–10^{10} $(mol/L)^{-1}$ s^{-1} in hexane at room temperature. The absolute rate constants measured for the reactions of $GeMe_2$ with the C—C unsaturated compounds and oxygen in solution (11) were found to agree quite well with earlier data reported by Walsh and coworkers (6, 12) for reactions with the same or similar substrates in the gas phase. The solution-phase data for the two germylenes showed $GeMe_2$ to be significantly more reactive than its phenylated counterpart in every reaction that was studied. Rate constants were also reported for the reactions of the digermenes **3a** and **3b** in several cases, providing the first indications of the effects of methyl vs. phenyl substitution on the reactivity of digermene derivatives toward various nucleophilic and electrophilic reagents.

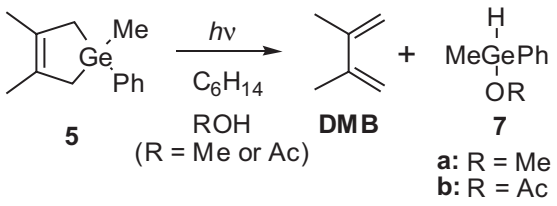
Reasonably precise determination of equilibrium constants for the (reversible) reactions with C=C bonds was possible only with $GePh_2$, which has a significantly higher extinction coefficient than $GeMe_2$ (thus affording stronger transient absorptions) and exhibits equilibrium constants that are in an ideal range to be measured under the conditions of our experiments. Furthermore, the (transient) products of these reactions could also be detected. We were less successful in characterizing the reactions of $GeMe_2$ with the same substrates; there were clear indications of reversibility, but the equilibrium constants are evidently significantly higher than those for $GePh_2$ and close to the upper limit measurable under the conditions of our experiments. While absolute rate constants for these reactions could be determined in a straightforward fashion, the weaker transient absorptions of the dialkylgermylene made it possible only to derive estimates of the equilibrium constants. The products also could not be detected, presumably because they do not absorb at sufficiently long wavelengths to enable detection with our methods.

Scheme 1.

Scheme 2.



In the present paper, we report the results of a time-resolved spectroscopic study of methylphenylgermylene (GeMePh) and (*E*)- and (*Z*)-1,2-dimethyl-1,2-diphenyldigermene (**4**, as a mixture of isomers) in hydrocarbon solution, generated by laser flash photolysis of 1,3,4-trimethyl-1-phenylgermacyclopent-3-ene (**5**, Scheme 1). This work represents the first step in a more extensive study of the effects of substituents (directly attached to germanium) on germylene and digermene reactivity, as well as an attempt to confirm and elaborate on some of the differences in the reactivity of $GeMe_2$ and $GePh_2$ towards the various substrates that have been examined so far. Our previous results for the other two germylenes lead to the expectation that the presence of a single phenyl group should provide a chromophore that would lead to stronger transient absorptions (thus enabling more precise kinetic measurements), facilitate the detection of transient products, and provide some moderation of reactivity (compared with $GeMe_2$) so that meaningful structure–reactivity relationships might eventually be derived.

Results

Steady state photolysis (254 nm) of a deoxygenated hexane solution of **5** (0.025 mol/L) containing isoprene (0.1 mol/L) led to the formation of 1,3-dimethyl-1-phenylgermacyclopent-3-ene (**6**) as the only detectable germanium-containing product at conversions below ca. 15% and an equal yield of 2,3-dimethyl-1,3-butadiene (DMB) (Scheme 2). The identity of **6** was established by GC coinjection of the crude photolysate with an authentic, independently synthesized sample of the compound. Similarly, photolysis of a cyclohexane-d_{12} solution of **5** (0.05 mol/L) containing methanol (MeOH, 0.5 mol/L) or acetic acid (AcOH, 0.095 mol/L), with periodic monitoring of the

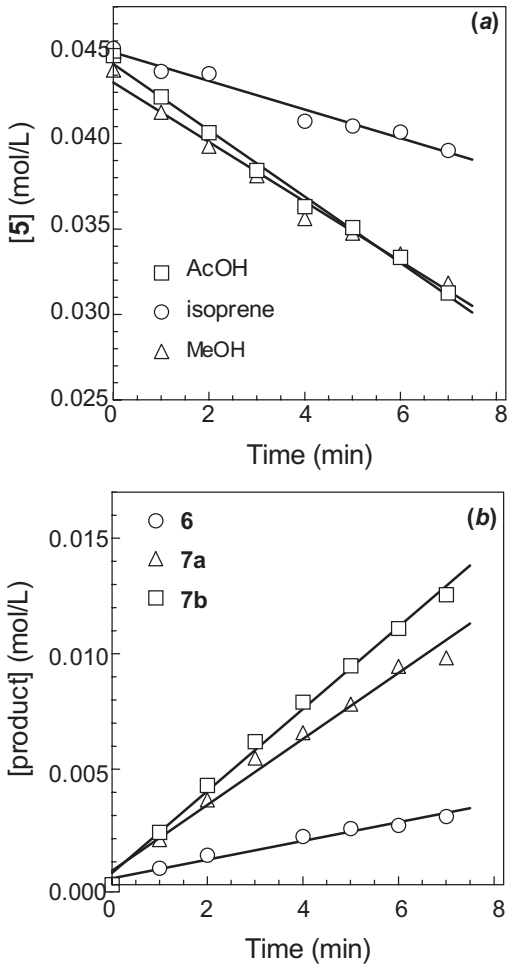

Scheme 3.

photolysates by ^{1}H NMR spectroscopy between 0% and ca. 25% conversion, afforded DMB and a single other product in each case. These were tentatively identified as methoxymethylphenylgermane and acetoxymethylphenylgermane (**7a** and **7b**, respectively, Scheme 3) on the basis of their ^{1}H NMR spectra. The results are consistent with formal [4+1]-cycloreversion to yield GeMePh and DMB as the predominant photochemical reaction pathway of **5**. The quantum yield was not rigorously determined, but qualitative comparisons of the rate of product formation in the MeOH-trapping experiment with those for **1a** (9) and **2a** (11) under the same conditions suggest that it is similar to the value of 0.55 that had been previously reported by us (9, 11) for the quantum yields for formation of $GePh_2$ and $GeMe_2$, respectively, from these compounds. A merry-go-round experiment was carried out, in which 0.045 mol/L solutions of **5** in cyclohexane-d_{12} containing MeOH (0.25 mol/L), AcOH (0.095 mol/L), and isoprene (0.094 mol/L) were irradiated in parallel, to assess any possible differences in reaction quantum yield with trapping agent. Concentration vs. time plots, showing the consumption of **5** and the formation of the products (**6**, **7a**, and **7b**), measured by ^{1}H NMR spectroscopy over the 0%–20% conversion range, are shown in Fig. 1. Correction of the isoprene concentration vs. time data for primary inner filter effects (because of coabsorption of the excitation light by the substrate) leads to the conclusion that product formation using the diene as trap (at ca. 0.1 mol/L) proceeds with roughly half the efficiency as in the experiments employing MeOH or AcOH as germylene scavengers. This corresponds to a $k_Q\tau$ value of ca. 10 $(mol/L)^{-1}$ for quenching of the reactive excited state of **5** by the diene, consistent with a lifetime of 10 ns or less assuming a quenching rate constant in excess of 10^9 $(mol/L)^{-1}$ s^{-1}.

Laser flash photolysis of continuously flowing deoxygenated solutions of **5** (ca. 0.0015 mol/L) in anhydrous hexane with the pulses from a KrF excimer laser (248 nm, ~25 ns, ~100 mJ) led to the formation of two transient species, one that appeared to be formed within ca. 50 ns of the onset of the laser pulse (λ_{max} = 490 nm) and another (λ_{max} = 415 nm) that grew to a maximum in concentration over the first ca. 4 μs after the pulse and then decayed to baseline over the next ca. 100 μs. Figure 2 shows transient absorption spectra recorded 95–200 ns and 3.4–3.6 μs after excitation, along with typical transient decay–growth profiles recorded at 510 and 410 nm, to the red and blue, respectively, of the absorption maxima of the two species, to isolate the transient decays as completely as possible without sacrificing appreciably in signal intensity. The decay of the first-formed species fits well to second-order kinetics (eq. [1]), affording

Fig. 1. Plots of concentration vs. time showing (*a*) the consumption of **5** and (*b*) the formation of trapping products from photolysis of **5** in cyclohexane-d_{12} containing AcOH (0.095 mol/L, □), MeOH (0.5 mol/L, Δ), and isoprene (0.094 mol/L, ○). The data from the latter have not been corrected for inner filter effects.

a decay constant of $k/\varepsilon_{510} = (1.6 \pm 0.1) \times 10^7$ cm s^{-1}. The behaviour is exactly analogous to that previously reported for **1a** and **1b** (9) and **2a** and **2b** (11) under similar conditions. We thus assign the two transients to GeMePh and its dimerization products, (*E*)- and (*Z*)-1,2-dimethyl-1,2-diphenyldigermene (**4**), respectively, (Scheme 1), which we assume are formed as a mixture of isomers.

$$[1] \qquad \Delta A_t = \Delta A_0 \,/\, (1 + 2k_{dim}(\Delta A_0/\varepsilon_\lambda l)t)$$

where ΔA_0 and ΔA_t are the transient absorbances at time = 0 and time = t after the laser pulse, ε_λ is the extinction coefficient at the monitoring wavelength, and l is the path length.

We next investigated the reactivities of the two species with various germylene scavengers (see Chart 1). Addition of AcOH, Bu_3SnH, CCl_4, or *tert*-butylacetylene (TBE) resulted in effects consistent with irreversible[4] scavenging of the germylene (9–11); the (germylene) absorption at 510 nm

[4] Any reaction with a (forward) rate constant of 10^9–10^{10} $(mol/L)^{-1}$ s^{-1} and an equilibrium constant greater than ca. 25 000 $(mol/L)^{-1}$ appears to be irreversible under the conditions of our experiments, to the extent that the reacting species decay completely to baseline with pseudo-first-order kinetics.

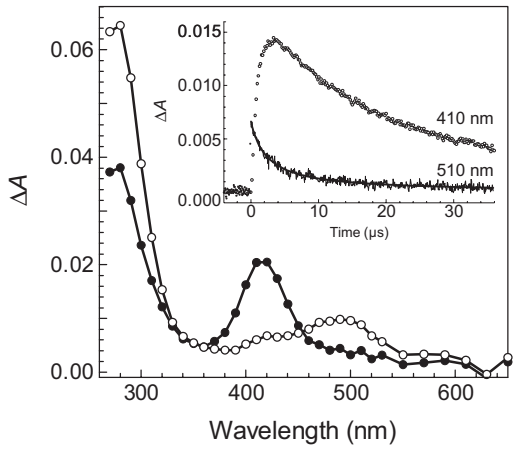
Fig. 2. Transient absorption spectra recorded 95–220 ns (○) and 3.4–3.6 μs (●) after the laser pulse from flash photolysis of a ca. 0.0015 mol/L solution of **5** in deoxygenated, anhydrous hexane. The inset shows representative transient decay and growth profiles recorded at 410 nm and 510 nm; the solid line in the latter is the fit of the data to second order decay kinetics



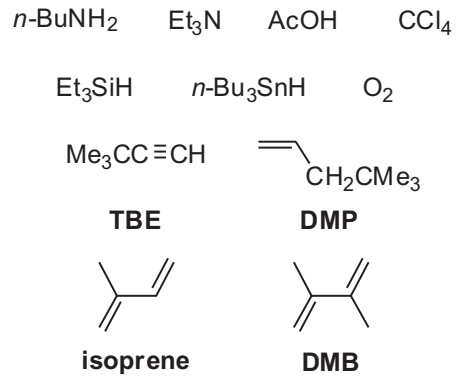


Chart 1.

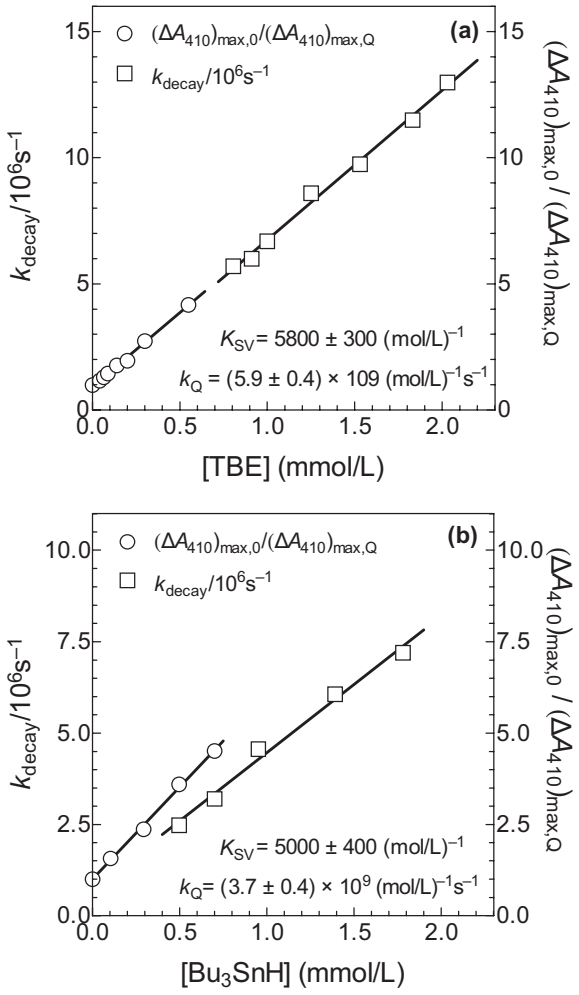
decayed at increased rates, completely to baseline, with clean first-order kinetics at concentrations above those required to reduce the peak digermene signal intensities to less than ca. 50% of their values in the absence of added reagent. As well, both the peak intensities and growth time of the absorptions because of **4** (measured at 410 nm) were reduced in proportion to the concentration of added scavenger. Plots of the pseudo-first-order rate constants for germylene decay (k_{decay}) vs. concentration were linear, consistent with the relationship of eq. [2],



$$[2] \qquad k_{decay} = k_0 + k_Q[Q]$$

where k_Q is the second-order rate constant for reaction of the species with the added reagent (Q) and k_0 is the (hypothetical) pseudo-first-order rate constant for decay in the absence of Q. Plots of the ratios of the peak transient absorbances due to **4**, in the absence and presence of scavenger at concentration [Q] ($\Delta A_{410,0}/\Delta A_{410,Q}$), were also linear in every case and were analyzed according to eq. [3],

$$[3] \qquad (\Delta A_{410})_{max,0}/(\Delta A_{410})_{max,Q} = 1 + K_{SV}[Q]$$

where K_{SV} is a proportionality factor reflecting the efficiency of the germylene scavenging reaction relative to

Fig. 3. Plots of k_{decay} (□) and $(\Delta A_{410})_{max,0}/(\Delta A_{410})_{max,Q}$ (○) vs. [Q] for scavenging of GeMePh by (*a*) 3,3-dimethyl-1-butyne (TBE) and (*b*) tri-*n*-butylstannane (Bu_3SnH). The solid lines are the linear least-squares fits of the data to eqs. [2] and [3], respectively. Decay and growth profiles for MePhGe and **4** were measured at 510 and 410 nm, respectively.

dimerization. Typical plots are shown in Fig. 3, from the experiments employing TBE and Bu_3SnH as scavengers. The absolute rate constants and K_{SV} values for reaction of GeMePh with the various reagents studied in this work are collected in Table 1. Also included in the table are the K_{SV}/k_Q ratios, calculated for each of the scavengers studied from the K_{SV} and k_Q values. Similar effects on the germylene and digermene absorptions to those noted above were observed in the presence of $BuNH_2$, even though its reaction with GeMePh is most likely reversible (vide infra).

In several cases, the reagent also had the effect of accelerating the decay of the digermene (**4**) signal over the concentration range where it could be detected, consistent with reaction of the scavenger with the digermene as well. The digermene decays followed reasonably good first-order kinetics in the presence of the scavenger, and plots of k_{decay} vs. [Q], according to eq. [2], were linear; the absolute rate constants obtained are also listed in Table 1. For those scavengers that did not exhibit distinctive effects on the digermene decay kinetics, upper limits of the rate constants were esti-

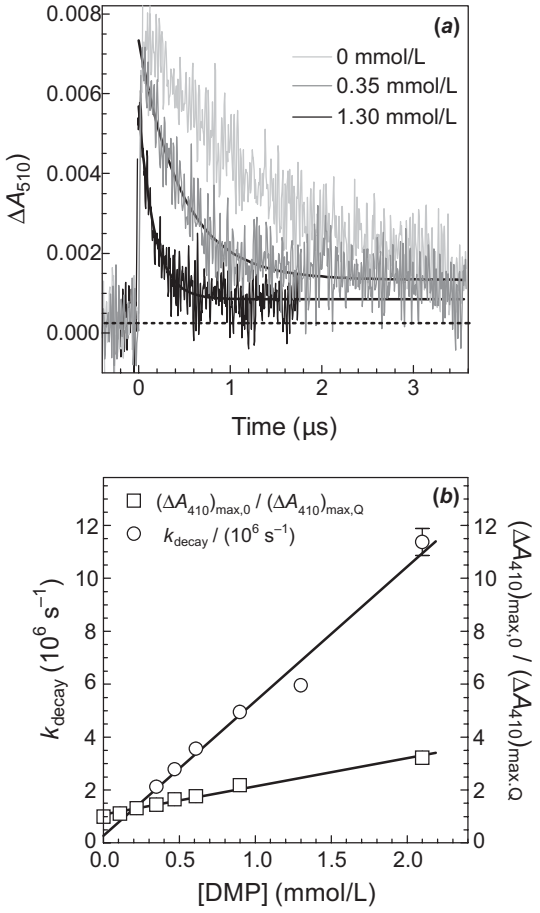
mated from the rate constant for decay of the signal at the highest scavenger concentration investigated, obtained by fitting the transient decay profiles to single exponential decay kinetics. These data are also listed in Table 1.

Addition of Et_3N, 4,4-dimethyl-1-pentene (DMP), isoprene, and DMB resulted in behaviour consistent with reversible scavenging of GeMePh, the main indication of which is a significantly less efficient reduction in the peak intensity of digermene absorption with increasing scavenger concentration; formation of the digermene could still be readily observed even at high enough substrate concentrations to reduce the lifetime of the germylene to the point where it could no longer be detected. This effect was common to all four substrates. Other anticipated effects varied with the substrate according to the magnitudes of the forward rate constant and equilibrium constant for the particular reaction. For example, addition of Et_3N caused the germylene signals to decay with clean first-order kinetics completely to the prepulse level at all concentrations throughout the 0.3–2 mmol/L range in added substrate, similar to the behaviour observed with the irreversible substrates; this is consistent with an equilibrium constant significantly in excess of ca. 25 000 (mol/L)$^{-1}$ (10), the approximate upper limit of the value measurable under the conditions of our experiment given a forward rate constant in the 10^9–10^{10} (mol/L)$^{-1}$ s^{-1} range. On the other hand, addition of DMP and isoprene caused the germylene signal to decay with bimodal kinetics within certain concentration ranges, consisting of a fast, approximately first-order decay followed by a much longer-lived residual absorption; the decay rate of the initial component increased while the residual absorption level and its decay rate both decreased with increasing substrate concentration. To illustrate this behaviour, Fig. 4*a* shows a series of germylene decay traces obtained in the presence of DMP. We associate the fast initial decay with the approach to equilibrium with the scavenging product and the residual absorption as being due to residual free germylene present at equilibrium and undergoing slow dimerization. This behaviour was evident over the full concentration range in which the germylene could be detected in the case of DMP (0.35–2.1 mmol/L), but only over the 0.1–0.5 mmol/L concentration range in the case of isoprene, with the decays proceeding completely to the prepulse level (within detection limits) at higher concentrations. This is consistent with a larger equilibrium constant for reaction with isoprene compared with that for DMP.



The germylene decay profiles in the experiments with DMP and isoprene were analyzed as single exponential decays to a nonzero residual absorption, as in our earlier study (10). Plots of the decay rate constants vs. scavenger concentration exhibited excellent linearity (see Fig. 4*b*), and analysis of the data according to eq. [4] afforded k_Q values of $(5.1 \pm 0.7) \times 10^9$ and $(8.0 \pm 0.4) \times 10^9$ (mol/L)$^{-1}$ s^{-1} for DMP and isoprene, respectively. The corresponding values of K_{SV}, obtained from analysis of the peak ΔA_{410} values due to digermene **4**, according to eq. [3], were 1060 ± 100 and 3800 ± 100 (mol/L)$^{-1}$. Plots of the ratios of the initial and residual germylene ΔA values, according to eq. [5], exhibited considerable scatter, mainly because of the rather low signal-to-noise that characterized the present series of experiments. It was thus not possible to determine the equilibrium constants with reasonable precision and reproducibility. Nevertheless, qualitative comparisons of the data to those previously published for $GePh_2$ (10) with the same substrates suggest the K_{eq} values to be in the range of 4000–8000 (mol/L)$^{-1}$ for DMP and 12 000–15 000 (mol/L)$^{-1}$ for isoprene.

$$[4] \qquad k_{decay} = k_{-Q} + k_Q[Q]$$

$$[5] \qquad (\Delta A_{510,0}/\Delta A_{510,res})_Q = 1 + K_{eq}[Q]$$

Fig. 4. (*a*) Absorbance vs. time profiles for GeMePh in deoxygenated hexane containing DMP (0, 0.35, and 1.30 mmol/L), monitored at 510 nm. The solid lines are the best fits of the data to single exponential decays. (*b*) Plots of k_{decay} and $(\Delta A_{410})_{max,0}/(\Delta A_{410})_{max,Q}$ vs. [DMP], showing the fits of the data to eqs. [4] and [3], respectively.

The data obtained with DMB as scavenger were very difficult to analyze accurately. Marked reductions in the strength of the germylene signals accompanied addition of the diene over the 0.5–3 mmol/L concentration range, yet effected only minor reductions in the strength of the digermene signals and consistent lengthening of their growth times with increasing concentrations. Typical data, corrected for inner filter effects because of coabsorption of the excitation light by the diene, are shown in Fig. 5. An initial fast component to the predominantly second-order germylene decay appeared to develop over the 0–0.8 mmol/L concentration range in added diene; it became distinctive enough to allow analysis between 1.0 and 2.0 mmol/L, but was too short-lived above 2.0 mmol/L to analyze accurately, leaving behind a much weaker residual second-order decay. This behaviour is again consistent with rapid reversible reaction, but with an equilibrium constant of less than ca. 1000 $(mol/L)^{-1}$ (13). A rate constant of $k_Q = (4 \pm 2) \times 10^9$ $(mol/L)^{-1}$ s^{-1} was estimated from the decay rate constants for the fast initial component of the bimodal decay profiles from several determinations (at shorter timescales) in the presence of 1.0–2.0 mmol/L DMB, analyzed in the same way as the data obtained with DMP, while a value of $K_{SV} = 175 \pm 25$ $(mol/L)^{-1}$ was obtained from analysis of the digermene peak signal strengths according to eq. [3].

Fig. 5. Growth and decay profiles for the signals due to (*a*) GeMePh and (*b*) **4** in the presence of DMB (0–2.76 mmol/L), and (*c*) plots of the relative peak signal intensities for the germylene (□) and digermene (○) absorptions vs. DMB concentration according to eq. [3].

As is evident from the raw data shown in Figs. 4 and 5, the strength of the germylene signals decreased noticeably with addition of reactive substrate in increasing concentrations; this was generally observed with all of the substrates studied, to an extent comparable to that shown in Fig. 4 with DMP as scavenger. It may be the result of the fact that

© 2006 NRC Canada

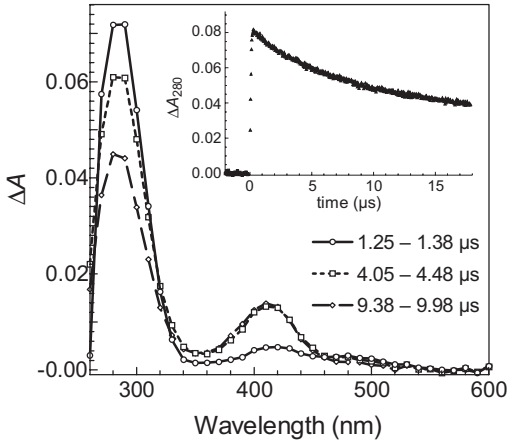
germylene formation appears to lag slightly behind the laser pulse; this is evident from the [DMP] = 0 trace of Fig. 4*a*, which suggests that the signal grows with a rise time of ca. 50 ns, significantly longer than the ca. 25 ns width of the laser pulse. This behaviour suggests that germylene formation is not a direct excited (singlet) state process, but rather ensues from a secondary intermediate. If this is true, then a reduction in germylene signal strength with increasing scavenger concentration would be expected, as reaction of the germylene with the scavenger becomes increasingly competitive with its formation. The effect on signal strength was much more pronounced in the experiments with isoprene and DMB as scavengers, suggesting an additional mechanism for quenching of the signals beyond that exhibited by the other scavengers. Plots of the relative peak transient absorbances at 510 nm vs. concentration (cf. eq. [3]) afforded Stern–Volmer constants of 1000 ± 150 $(mol/L)^{-1}$ and 650 ± 40 $(mol/L)^{-1}$ for isoprene and DMB (see Fig. 5*c*), respectively.

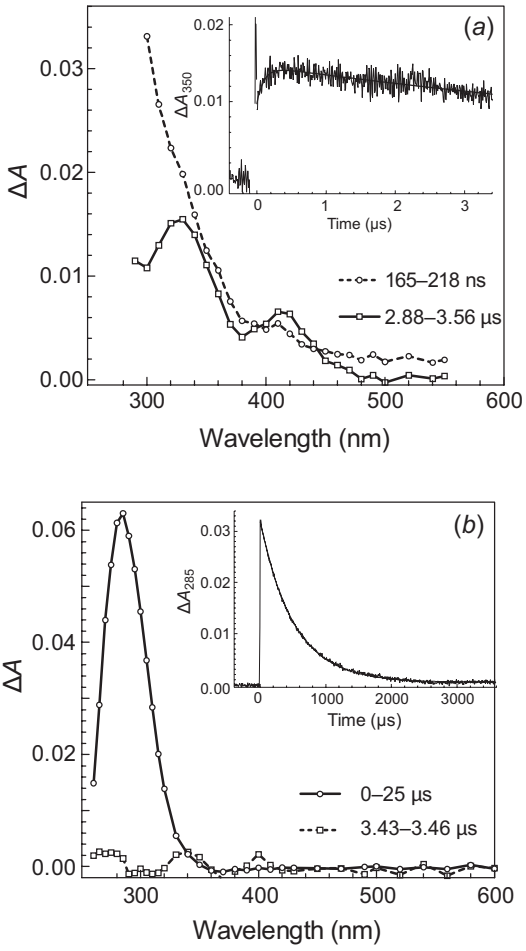
On the other hand, significant increases in the strength of the transient absorptions at 260–300 nm occurred with increasing DMB concentration; these absorptions, which are centered at ca. 285 nm and are superimposed on those formed in the absence of the scavenger (vide supra), decayed over a similar timescale as the weak germylene absorption at 510 nm at low diene concentrations. Figure 6 shows a series of transient absorption spectra recorded at various time intervals after the laser pulse for the solution containing 2.76 mmol/L DMB. Higher diene concentrations could not be investigated in this case because of coabsorption at the excitation wavelength by the diene.

New long-lived transient absorptions in the 270–350 nm range were also observed in the presence of the amines and the other C—C unsaturated compounds. The absorption maximum of the species that was formed in the presence of Et_3N (λ_{max} = 330 nm, Fig. 7*a*) was red-shifted sufficiently from the absorptions due to the free germylene and its oligomerization products to enable a growth in the signal to be detected at the upper end of the amine concentration range studied; the growth rate constant was found to be in reasonable agreement with that for decay of the germylene at the same amine concentration, consistent with the new species being formed by reaction of GeMePh with the amine. For example, a trace recorded at 350 nm with a solution of **5** containing 1.5 mmol/L Et_3N exhibited a growth rate constant of (10.5 ± 1.8) × 10^6 s^{-1}, which agrees reasonably well with the decay rate constant of k_{decay} = (6.5 ± 0.5) × 10^6 s^{-1}, measured for the germylene signal at 510 nm at the same amine concentration. We assign the species formed in the reaction to the Lewis acid–base complex **8a**. The analogous product (**8b**) is formed in the presence of $BuNH_2$ and exhibits its λ_{max} = 310 nm; however, the expected growth of its absorption could not be resolved because of overlap with other transient absorptions that are present in the short wavelength region at scavenger concentrations at which the germylene signal could still be detected. The same was true of the products formed in the presence of isoprene, DMP, and TBE, which absorb in the 270–285 nm range.

Transient decay profiles and spectra of the new products formed in the presence of isoprene, DMP, and TBE were re-

Fig. 6. Transient absorption spectra recorded at selected time intervals after the laser pulse for a solution of **5** (0.0015 mol/L) in deoxygenated hexane containing DMB (2.76 mmol/L). The inset shows a decay trace recorded at a monitoring wavelength of 280 nm.





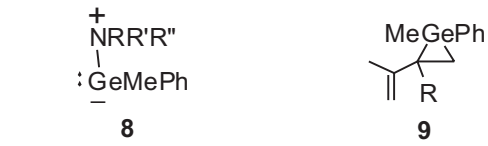


Fig. 7. Transient absorption spectra recorded by flash photolysis of a solution of **5** (ca. 0.0015 mol/L) in deoxygenated, anhydrous hexane containing (*a*) Et_3N (2.0 mmol/L) and (*b*) isoprene (20 mmol/L). The insets show growth and decay profiles recorded at 350 nm and 285 nm, respectively.

corded at relatively high (3.3–200 mmol/L) substrate concentrations to minimize contributions to the lifetimes from germylene dimerization or from overlapping transient absorptions because of GeMePh or its oligomerization products. It was possible to employ reasonably high substrate concentrations in the experiments with DMP, and the lifetime of the species formed from the alkene was found to be approximately independent of concentration over the 0.1–0.35 mol/L range. The species formed from isoprene absorbs with λ_{max} = 285 nm and decays with clean pseudo-first-order kinetics in the presence of 0.02 mmol/L diene (τ ~ 670 μs). The spectra and lifetimes of these species are similar to those observed previously from $GePh_2$ with the same substrates (10) and we tentatively assign them to the three-membered germanocycles **9a**–**11**. The species absorbing with λ_{max} ~ 285 nm in the transient spectra of Fig. 6 is similarly assigned to vinylgermirane **9b**. Table 2 contains a summary of the absorption maxima and lifetimes of the primary transient products formed from reaction of GeMePh with these compounds, while Fig. 7 shows examples of the spectra and decays obtained in the presence of Et_3N and isoprene.

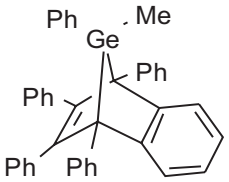
11

Saturation of a hexane solution of **5** with oxygen caused a ca. 40% drop in the peak absorbance due to digermene **4** compared with its value in deoxygenated solution, but had no discernible effect on the decay characteristics of the germylene signal. An upper limit of $k_{O_2} < 6 \times 10^7$ (mol/L)$^{-1}$ s^{-1} for quenching of GeMePh was thus obtained from the pseudo-first-order rate constant for decay of the germylene in O_2-saturated hexane (k_{decay} ~ 1×10^6 s^{-1}), using a value of 0.015 mol/L for the concentration of O_2 (14) and with the assumption that the decay of the germylene is dominated by its reaction with oxygen under these conditions. Modest reductions in the lifetime of the digermene were observed with increasing O_2 concentration, affording a value of k_{O_2} = (2.4 ± 0.3) × 10^7 (mol/L)$^{-1}$ s^{-1} from analysis of the digermene decays according to eq. [2].

Discussion



As we found previously for the related compounds **1** and **2** (9), steady state photolysis of **5** in the presence of MeOH (0.5 mol/L), AcOH (0.095 mol/L), or isoprene (0.1 mol/L) affords the expected trapping products of GeMePh in high yields, along with 2,3-dimethyl-1,3-butadiene (DMB). Qualitative comparisons of the rate of product formation in the MeOH-trapping experiment to those obtained in our earlier studies of **1a** and **2a**, which were carried out under the same conditions of lamp intensity and concentration, indicate similar quantum yields for germylene extrusion (Φ ~ 0.5) from the three compounds.

Table 2. UV absorption maxima and lifetimes of transient products from the reaction of GeMePh with amines and C—C unsaturated compounds in hexane at 23 °C.

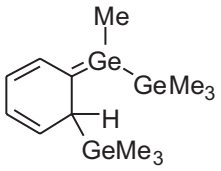
DMP	**10**	275	2.6 (350)
TBE	**11**	270	>2000 (3.3)

[a]Nd (not determined).

The UV–vis spectrum of GeMePh in a 3-methylpentane (3-MP) matrix at 77 K was reported in the late 1980s by two different groups; Ando et al. (15) generated the species by photolysis of the 1,4-germanonaphthalene derivative **12** and reported a UV spectrum exhibiting λ_{max} = 440 nm, while Mochida and co-workers (16) employed the photolysis of trigermane **13** and reported λ_{max} = 456 nm in 3-MP at 77 K and λ_{max} = 440 nm in cyclohexane solution at room temperature. The latter group also reported rate constants for reaction of the species in cyclohexane solution with DMB (k = 2.2×10^6 (mol/L)$^{-1}$ s^{-1}), Et_3SiH (k = 4.1×10^6 (mol/L)$^{-1}$ s^{-1}), and CCl_4 (k = 6.5×10^7 (mol/L)$^{-1}$ s^{-1}) (16). A transient exhibiting a similar UV absorption spectrum but much different reactivity toward DMB and CCl_4, from flash photolysis of poly(methylphenylgermylene) (**14**), was later assigned to GeMePh by the same group (17). The results reported in the present work using **5** as precursor differ significantly from those of the earlier studies, but are fully consistent with the spectroscopic and kinetic data reported by us recently for $GePh_2$ and $GeMe_2$ under similar conditions (9–11).

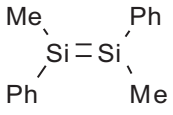
12

13



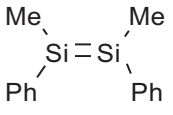
14
(*n* ~ 28)

For example, the long wavelength absorption maximum of the initially formed transient from laser photolysis of **5** (λ_{max} = 490 nm) lies between those of $GePh_2$ (λ_{max} = 500 nm, ε_{500} = 1850 dm^3 mol^{-1} cm^{-1} (9)) and $GeMe_2$ (λ_{max} = 470–480 nm (9, 11, 12), ε_{475} = 730 dm^3 mol^{-1} cm^{-1} (11)). The spectrum also shows a somewhat stronger absorption band centered at λ_{max} ~ 290 nm due to the $S_0 \rightarrow S_2$ transition, which is shifted ca. 10 nm to the blue of the corresponding band in the spectrum of $GePh_2$ (9). We note that the long wavelength absorption maximum of GeMePh is the same as that reported for the silicon homologue (SiMePh) in



© 2006 NRC Canada

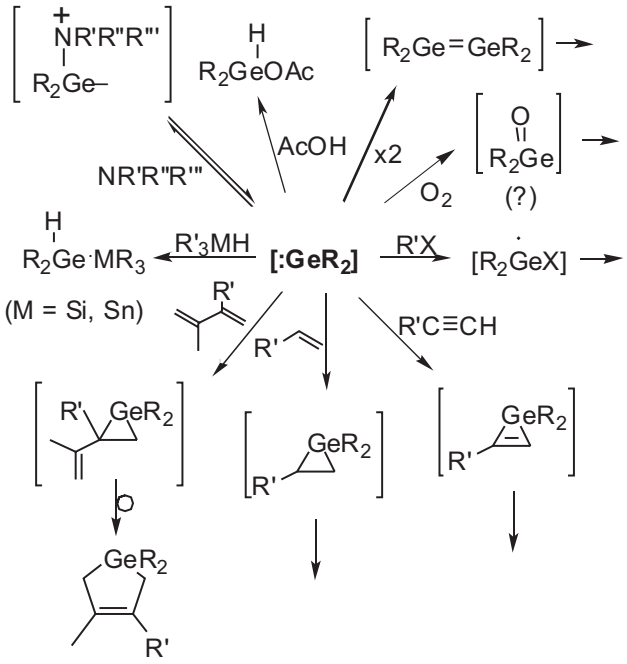
a hydrocarbon matrix at 77 K (λ_{max} = 490 nm (18)). Such similarities are also evident in the UV–vis spectra of $GeMe_2$ and $SiMe_2$ (λ_{max} = 453–465 nm (18, 19)), as well as those of $GePh_2$ and $SiPh_2$ (λ_{max} = 495 nm (18)). It thus seems clear that the transient absorptions assigned to GeMePh in the earlier time-resolved studies in solution, using **13** and **14** as precursors, must be due to other more strongly absorbing transient products; as we have shown previously for related systems (8), the likely candidates are conjugated germene derivatives and (or) germanium-centered radicals. For example, the conjugated germene derivative (**15**) that might be anticipated from photolysis of **13** can be predicted to exhibit an absorption maximum in the 430–450 nm range and exhibit moderate reactivity toward CCl_4 and DMB, based on analogies taken from related systems (7, 8, 20).



15

Similarly, the absorption maximum of the second-formed species (λ_{max} = 415 nm) falls between those of Ge_2Ph_4 (**3a**, λ_{max} = 440 nm (9)) and Ge_2Me_4 (**3b**, λ_{max} = 370 nm (9, 11, 21, 22)) and can thus be assigned with confidence to (*E*)- and (or) (*Z*)-1,2-dimethyl-1,2-diphenyldigermene (**4**, Scheme 1), formed most likely as a mixture of isomers. The spectra of (*E*)- and (*Z*)-**4** are also quite similar to those reported by Sekiguchi et al. (23) for the silicon homologues, (*E*)- and (*Z*)-1,2-dimethyl-1,2-diphenyldisilene [(*E*)- and (*Z*)-**16**, λ_{max} = 417 and 423 nm, respectively] in cyclohexane solution. An absorption maximum of λ_{max} = 420 nm was reported earlier for **16** in a 3-MP glass at 77 K, formed (presumably as a mixture of isomers) by dimerization of SiMePh (18).

***E*-16**



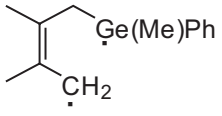
***Z*-16**

Absolute rate constants have been determined in this work for the reaction of GeMePh with a selection of representative germylene scavengers in hexane solution. The reactions studied include O-H insertion with AcOH, Lewis acid–base complexation with primary and tertiary amines, M-H insertions with trialkylhydridosilanes and -stannanes, reaction with terminal alkenes, alkynes, and conjugated dienes, chlorine atom abstraction from CCl_4, reaction with oxygen, and dimerization, as summarized in Scheme 4. While product studies specific to GeMePh have not been carried out in most instances, the course of these reactions are well established for $GeMe_2$ and other reactive germylenes (1, 10, 11, 24, 25) and all of them have direct analogies in silylene chemistry (26).

As we found in our earlier studies of $GePh_2$ and $GeMe_2$ (10, 11), two distinct types of kinetic behaviour are observed in the signals due to GeMePh and **4**, depending on whether

Scheme 4.

scavenging of the germylene is reversible or not. A reasonably reliable indicator of reversibility in the data is the K_{SV}/k_Q ratio, which (within certain limitations (11)) provides a normalized measure of the efficiency with which a given scavenger suppresses germylene dimerization as a result of its competing reaction with the digermene precursor (i.e., the germylene). The K_{SV}/k_Q ratio tends toward significantly smaller values (indicating lower scavenging efficiencies) for those substrates that react with the germylene reversibly compared with those for irreversible scavengers. Because K_{SV} is measured from the relative peak intensities of the signal due to digermene **4**, its magnitude is also affected by the reactivity of the digermene with the scavenger. This leads to artificially high values of the efficiency parameter, which become particularly significant when the reactivity of the digermene toward the scavenger is within a factor of ca. 5 of that of the germylene; the smaller the differential reactivity, the greater the distortion in the magnitude of K_{SV}, and K_{SV}/k_Q, from their true values. Thus, the K_{SV}/k_Q ratios for those reagents for which this differential reactivity is relatively small (e.g., $BuNH_2$, CCl_4, and O_2) can be expected to overestimate the efficiency (i.e., the rate relative to that of dimerization) of the scavenging reaction. For this reason, we have not attached an absolute value to the rate constant for scavenging of GeMePh by O_2 based on the K_{SV} value and report only the upper limit of the rate constant as defined by the lifetime of the germylene in O_2-saturated solution; similarly, the value estimated previously for the reaction of $GePh_2$ with O_2 ($k_{O_2} \sim 3 \times 10^7$ (mol/L)$^{-1}$ s^{-1}) (10) should also be considered an upper limit. In any event, it is clear from the data of Table 1 that those scavengers that react at least ca. three times faster with GeMePh than with **4** fall into two groups, those with $K_{SV}/k_Q \geq 0.9$ (AcOH, Bu_3SnH, O_2, CCl_4, and TBE) and those with $K_{SV}/k_Q < 0.5$ (Et_3N, isoprene, DMB, and DMP). The first group is comprised of those reagents that react with GeMePh irreversibly, while the second



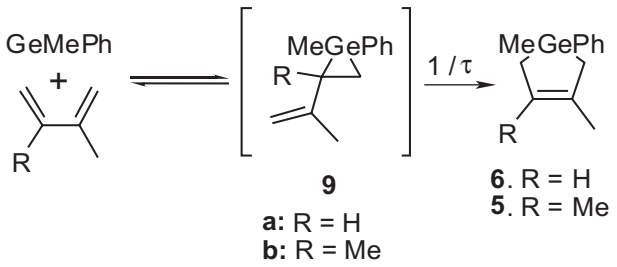
© 2006 NRC Canada

consists of the reversible scavengers. The K_{SV}/k_Q value for $BuNH_2$ would seem to suggest that it belongs in the group of irreversible scavengers, but as it reacts with digermene **4** only twice slower than it does with GeMePh, the K_{SV} value (and hence K_{SV}/k_Q) is likely to be significantly overestimated. This reaction is most likely reversible, like that with Et_3N (vide infra).

The absolute rate constants for the various reactions of GeMePh that have been studied in the present work are in most cases the same, within experimental error, as the corresponding values for $GePh_2$ (9, 10) and are consistently a factor of two to eight times smaller than those for reaction of $GeMe_2$ with the same substrates (11). The smallest variations throughout the series are exhibited by the rate constants for dimerization and Lewis acid–base complexation with the primary amine, which proceed within a factor of ca. 2 of the diffusional rate constant in hexane at 25 °C in all three cases (11). An estimate of $k_{dim} \sim 2 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1} for the rate constant for dimerization of GeMePh can be obtained from the measured second-order decay coefficient ($k/\varepsilon_{510} = (1.6 \pm 0.1) \times 10^7$ cm s^{-1}), assuming an extinction coefficient intermediate between those of $GePh_2$ ($\varepsilon_{max} \sim 1850$ dm^3 mol^{-1} cm^{-1}) (9) and $GeMe_2$ ($\varepsilon_{max} \sim 730$ dm^3 mol^{-1} cm^{-1}) (11). The results suggest that phenyl for methyl substitution has relatively small effects on the reactivity of simple germylenes toward this diverse set of reagents, but confirm the earlier conclusion that phenyl substitution has a distinct moderating effect on germylene reactivity (11). The present results indicate that most of the effect on the rate constant arises with substitution of the first alkyl substituent in $GeMe_2$ and replacing the second has much smaller consequences.

As might be expected, the equilibrium constants for the reversible reactions of GeMePh also appear to lie between those for $GeMe_2$ and $GePh_2$, although we have not been able to measure them with reasonable precision owing to the low signal-to-noise ratios that characterize the present experiments. Nevertheless, the equilibrium constants appear to be more sensitive to germylene substitution than the absolute rate constants for the forward component of the reaction. For example, the rate constants for reaction of the three germylenes with the alkene DMP vary by less than a factor of 2, while the equilibrium constants vary between $K_{eq} \sim 2500$ $(mol/L)^{-1}$ for $GePh_2$ (10) and $K_{eq} \sim 20\,000$ $(mol/L)^{-1}$ for $GeMe_2$ (11); these should be compared with the qualitative estimate of 4000–8000 $(mol/L)^{-1}$ for reaction of GeMePh with the same substrate. The estimated equilibrium constant for reaction of GeMePh with isoprene ($K_{eq} \sim 15\,000$ $(mol/L)^{-1}$) also falls within the range defined by $GePh_2$ and $GeMe_2$. The total range in K_{eq} exhibited by the reactions of DMP with the three germylenes corresponds to a range of ca. 1.3 kcal/mol (1 cal = 4.184 J) in standard free energy.

The two dienes have remarkably different effects on the germylene and digermene growth–decay profiles, which can be attributed primarily to a substantial difference in the equilibrium constants for the reactions of these substrates coupled with similar absolute rate constants for formation of the primary products. Interestingly, they also appear to quench the formation of the free germylene, to the extent that they cause significant reductions in the initial (peak) signal strengths of the GeMePh absorptions in laser flash photolysis experiments with these substrates. Apparent Stern–Volmer constants on the order of 1000 $(mol/L)^{-1}$ have been determined from analysis of the peak germylene absorbances as a function of diene concentration over the 0–3 mmol/L concentration range, which is consistent with diffusion-controlled quenching ($k \sim 2 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1}) of an intermediate possessing a lifetime of $\tau \sim 50$ ns. However, product studies indicate that product formation remains efficient in the presence of isoprene in concentrations as high as ca. 0.1 mol/L; compound **6**, the expected product of trapping of GeMePh by the diene, is formed in only modestly (ca. 2×) lower quantum yield than the corresponding products of trapping of the germylene by MeOH or AcOH. This indicates that whatever phenomenon is primarily responsible for the loss in signal strength in the flash photolysis experiments, it does not lead to a reduction in the yield of germylene-derived products; this effectively rules out energy-transfer quenching of an excited state of **5** as the process responsible for the effect. In this regard, it is noteworthy that in the absence of added scavengers the germylene signals appear to be characterized by a ca. 50 ns growth, which is discrete from the temporal characteristics of the laser pulse. This could be indicative of the involvement of an additional intermediate such as 1,5-biradical **17**, formed via Ge—C bond cleavage in the reactive excited state of **5**, which undergoes further fragmentation to yield GeMePh and DMB. Such a species would also be expected to undergo ring closure to yield **5** and **9b** competitively with fragmentation. The same temporal feature was also evident in our earlier studies of $GePh_2$ (generated from **1b**) (9) and $GeMe_2$ (generated from **2a**) (11), although the effects of added diene on the signal strengths were much less pronounced than in the present case. It is reasonable to expect that such a species might be reactive toward dienes, though again, the product studies demand that it must do so reversibly. Neumann and co-workers (27, 28) isolated products corresponding to the addition of two molecules of diene to $GeMe_2$ in their early studies of the reactions of $GeMe_2$ with aliphatic dienes; we have found no evidence for the formation of such products in the present instance, although the highest diene concentration we have employed in product studies is only 0.1 mol/L. Further work will be required to address the possible involvement of such intermediates in the photochemistry of 1-germacyclopent-3-ene derivatives and the reaction of the corresponding germylenes with dienes in a more conclusive way.



17

Addition of the dienes leads to the formation of new strongly absorbing transients exhibiting $\lambda_{max} = 285$ nm in both cases, which are assigned to the corresponding vinylgermirane derivatives **9a** and **9b**. The absorption spectrum and lifetime of the species formed from reaction of GeMePh with isoprene (**9a**, $\tau \sim 670$ μs, Fig. 7*b*) are quite close to those of the analogous product from reaction of

© 2006 NRC Canada

Scheme 5.

$GePh_2$ with the same diene (λ_{max} = 285 nm, τ ~ 500 μs) (10). It should be noted that the lifetime of the isoprene-derived product has been determined in the presence of sufficiently high diene concentrations to suppress digermene formation more or less completely, and where the decay of the species follows clean first-order kinetics. We thus tentatively associate the decay rate constant with that for further (unimolecular) rearrangement to yield the stable final product of the reaction (1, 27, 29), the corresponding germacyclopent-3-ene derivative **6** (Scheme 5). Unfortunately, the greater absorptivity of DMB at the laser excitation wavelength precluded experiments at sufficiently high diene concentrations to determine a lifetime for **9b** under comparable conditions. It is interesting to note that the relative equilibrium constants for formation of **9a** and **9b** from GeMePh indicate that **9b** is ca. 1.5 kcal/mol less thermodynamically stable than **9a**, with respect to cycloreversion back to the free germylene and the diene.

The intermediates formed in the reactions of GeMePh with the alkene (DMP) and alkyne (TBE) are also relatively long-lived and have been detected as discrete species with absorption maxima in the 270–285 nm range and lifetimes of ca. 2.6 ms or greater (see Table 2). The corresponding intermediates formed in the reactions of these substrates with $GePh_2$ exhibit similar absorption maxima (λ_{max} = 275 nm in both cases), but somewhat shorter lifetimes (τ ~ 1.2 and 600 ms, respectively) (10); the analogous products could not be detected from $GeMe_2$ under similar conditions, presumably because they absorb too far to the blue to be detectable under the conditions of our experiments (11). We similarly assign these products to the three-membered germanocycles **10** and **11**.

The significantly longer lifetimes of **9a**–**11** compared to those of the corresponding adducts from $GePh_2$ indicate that the greater degree of stabilization of the GeMePh adducts (as measured by the equilibrium constants for their formation) is also reflected in the rate constants for their further reaction. The processes responsible for the decay of the germirane (**10**) and germirene (**11**) at high substrate concentrations are unfortunately not clear; our earlier study of the reaction of DMP with $GePh_2$ indicated that it led to the formation of germanium-containing polymers, while the reaction with TBE produced a primary product that underwent further thermal or photochemical reaction under the conditions employed for its generation (10). Indeed, very few stable examples of such compounds are known (30–36), unlike the situation with the corresponding silicon analogues, which enjoy much greater thermodynamic stability (36–38). As mentioned previously, the reactions of $GeMe_2$ with alkenes, dienes, and alkynes are known to yield five-membered ring compounds derived from reaction of the germylene with two molecules of substrate, most likely via the intermediacy of the corresponding three-membered germanocycle (1, 27). We thus suspect that the relatively slow decay of these species is due to these secondary reactions, perhaps involving biradical intermediates formed by (single) Ge—C bond cleavage processes. In the case of **10** this process occurs with a rate constant of k ~ 500 s^{-1} in the presence of 0.1–0.35 mol/L alkene, roughly half that observed for the analogous species formed from reaction of $GePh_2$ with DMP under similar conditions (11). The process occurs roughly 10^3 times more slowly than cycloreversion to regenerate GeMePh and the alkene, based on an estimate derived from the estimated K_{eq} value and measured rate constant for the (forward) reaction of GeMePh with the alkene. The somewhat shorter lifetime observed for vinylgermirane **9a** is consistent with an additional contribution to its decay due to unimolecular isomerization, yielding **6**.

The reactions of GeMePh with $BuNH_2$ and Et_3N also result in the formation of detectable transient products, which can be identified as the Lewis acid–base complexes **8a** and **8b**, respectively. The equilibrium constants for formation of these complexes are in considerable excess of ca. 25 000 $(mol/L)^{-1}$, the approximate upper limit of K_{eq} for which residual germylene absorptions can be detected under the present experimental conditions. This was also found for the corresponding amine complexes with $GePh_2$ and $GeMe_2$ (10, 11), so it is not possible to comment on the relative stabilities of the amine complexes of this series of germylenes. Again, however, the rate constants for their formation are very similar. The only hint of a difference between the three germylenes in their reaction with amines is in the absorption spectra of the complexes, which are in both cases shifted significantly to the blue of those formed from $GePh_2$ (10), and significantly red-shifted compared with the complexes from $GeMe_2$ (11). Ando et al. (15) suggested that the positions of the absorption maxima of the complexes of amines, sulfides, phosphines, and ethers with a given germylene reflects their relative stabilities, in that they correlate broadly with Lewis base strength, shifting to the blue as the strength of the complex increases. This suggests that with a given amine, GeMePh forms the somewhat stronger Lewis acid–base complex and hence possesses somewhat higher Lewis acid strength than $GePh_2$. The opposite is true in regards to $GeMe_2$. For a given amine, the absorption maxima of the three germylene complexes vary to a much greater extent than those of the free germylenes. It is interesting to note that since the complex with $BuNH_2$ can be detected as a discrete, relatively long-lived intermediate, the formal H-migration process required to convert it to the putative N-H insertion product must be relatively slow. We previously reported that the reaction of $GePh_2$ with primary and secondary amines affords mainly polymeric material, and the germylamines derived from formal N-H insertion are formed in very low yields (10).

The effects of methyl vs. phenyl substitution on the reactivity of digermenes **3a**, **3b**, and **4** are somewhat greater and more varied than is the case with the corresponding germylenes. We have been successful in determining absolute rate constants for the reactions of **4** with four of the substrates studied ($BuNH_2$, AcOH, CCl_4, and O_2) and have determined

© 2006 NRC Canada

upper limits for the rate constants in the other cases. As mentioned earlier, we make the assumption that dimerization of GeMePh proceeds nonstereospecifically to yield a mixture of the (*E*)- and (*Z*)-isomers of the digermene, which seems reasonable enough considering that the reaction is fully diffusion-controlled. In most cases, the rate constants again fall between those of Ge_2Me_4 (**3b**) and Ge_2Ph_4 (**3a**), and since the mechanistic implications of these results have been discussed in some detail (11), they will not be elaborated on further here. The exception is the value for reaction with $BuNH_2$, which indicates somewhat greater reactivity for **4** compared with the tetraphenyl derivative. This is perhaps suggestive of a small steric effect on the rate of nucleophilic attack at the Ge=Ge bond in Ge_2Ph_4 (**3a**), which is thought to be the rate-determining step of the reaction (11).[5] It is also interesting to note that the rate constant for reaction with O_2 is ca. 30× lower than that reported (39) for the homologous disilenes, (*E*)- and *(Z)*-**16**, providing the first quantitative indication of the differences in reactivity of digermenes and disilenes of otherwise identical substitution. The reaction of disilenes and digermenes with oxygen has been reasonably well-studied and is known to yield the corresponding 1,2-dimetallaoxetane in both cases (40–42), presumably via the intermediacy of a triplet 1,4-(metalla-oxa)-biradical intermediate (43). Comparison of the rate constants for reaction of oxygen with the series of digermenes Ge_2Me_4 (**3b**, $k_{O_2} = 5.0 \times 10^7$ $(mol/L)^{-1}$ s^{-1}) (11), $Ge_2Me_2Ph_2$ (**4**, $k_{O_2} = 2.4 \times 10^7 (mol/L)^{-1}$ s^{-1}), and Ge_2Ph_4 (**3a**, $k_{O_2} = 4.8 \times 10^6$ $(mol/L)^{-1}$ s^{-1}) (10) indicates that phenyl for methyl substitution results in a consistent decrease in reactivity, spanning a factor of about 10 throughout the series. To our knowledge, there is little information available on the sensitivity of the rate constant to substituent for the reaction of O_2 with disilenes.

Similar trends in reactivity are evident in the rate constants for the reactions of **3a**, **4**, and **3b** with CCl_4 and AcOH (10, 11); the former is thought to proceed via initial chlorine atom abstraction to yield a (singlet) radical pair (44–46), while the latter most likely proceeds via 1,2-addition (of H-OAc) across the Ge=Ge bond, as is known for the reaction of alcohols with digermenes (9, 21) and disilenes (39, 47, 48). Interestingly, the opposite trend in reactivity is observed with the strong nucleophile, $BuNH_2$, for which the rate constants for the reactions with both **4** and Ge_2Ph_4 (**3a**) are ca. two orders of magnitude greater than that reported for Ge_2Me_4 (**3b**) (11). The difference in the reactivities of **3a** and **3b** toward this substrate is consistent with frontier molecular orbital control of the reaction, as the rate constants correlate with the relative LUMO energies of the two compounds (11).

Summary and conclusions

The direct detection and characterization of the reactivities of methylphenylgermylene (GeMePh) and (*E*)- and (*Z*)-1,2-dimethyl-1,2-diphenyldigermene (**4**), formed as a mixture by dimerization of the germylene, have been accomplished for the first time. The two species have been produced by photoextrusion of GeMePh from germacyclopent-3-ene derivative **5**, which affords GeMePh in >90% chemical yield and high quantum efficiency, based on the results of steady-state trapping experiments with methanol, acetic acid, and isoprene. The germylene is detectable as a weakly absorbing transient species with λ_{max} = 490 nm by laser flash photolysis of **5** in hexane solution, where it decays by diffusion-controlled dimerization to yield **4** (λ_{max} = 415 nm). The trends in the experimental UV–vis absorption spectra of $GeMe_2$, GeMePh, and $GePh_2$ mirror those in the spectra of the corresponding silylenes and similar correlations are found in the spectra of the corresponding digermenes and disilenes.

Absolute rate constants for reaction of GeMePh with several representative germylene scavengers have been measured, including primary and tertiary amines, acetic acid, triethylsilane, tri-*n*-butylstannane, O_2, CCl_4, two aliphatic dienes, and a terminal alkene and alkyne. With every reagent studied, GeMePh reacts with a similar absolute rate constant to that previously reported for $GePh_2$ under similar conditions and both germylenes are significantly less reactive than $GeMe_2$ toward the same substrates. Equilibrium constants falling between those determined earlier for $GeMe_2$ and $GePh_2$ have been estimated for the reversible reactions of GeMePh with amines, the alkene, and the dienes; the primary products of these reactions have also been detected as long-lived transient intermediates exhibiting similar UV–vis absorption spectra to the analogous products from $GePh_2$.

More detailed mechanistic studies of the photochemistry of arylgermacyclopent-3-ene derivatives and the reactions of transient germylenes and digermenes, including those with oxygenated substrates, are currently in progress in our laboratory.

Experimental

^1H and ^{13}C NMR spectra were recorded on Bruker AV 200 or AV 600 spectrometers in deuteriochloroform or cyclohexane-d_{12} solution and were referenced to the residual solvent proton and ^{13}C signals, respectively. Gas chromatographic analyses were carried out using a Hewlett-Packard 5890 gas chromatograph equipped with a conventional heated injector, a flame ionization detector, a Hewlett-Packard 3396A integrator, and a SPB-5 capillary column (25 m, 0.25 μm, Supelco, Inc.). Gas chromatographic – mass spectrometric (GC–MS) separations employed a Hewlett-Packard 5890 Series II gas chromatograph equipped with a HP-5971A mass selective detector and a SPB-5 capillary column (25 m, 0.25 μm, Supelco, Inc.). High-resolution electron impact mass spectra and exact masses were determined on a Micromass TofSpec 2E mass spectrometer. Exact masses were determined for the molecular ion (M^+), employing a mass of 12.000 000 for carbon-12. Column chromatography employed a 30 mm × 800 mm column using silica gel (120 g, acid-washed, 230–400 mesh ASTM, particle size 0.040–0.063 mm, Silicycle) and pentane as the eluant. Steady state photolyses employed a Rayonet® photochemical reactor (Southern New England Ultraviolet Co.,

[5] W.J. Leigh and L.A. Huck. To be published.

Branford, Connecticut) equipped with a merry-go-round apparatus and six RPR-2537 lamps (254 nm).

2,3-Dimethyl-1,3-butadiene, isoprene, phenylmagnesium bromide (3.0 mol/L solution in diethyl ether), methylmagnesium bromide (3.0 mol/L solution in diethyl ether), and magnesium were used as received from Sigma-Aldrich. Hexanes (Caledon Reagent) was dried by refluxing for several days under nitrogen with sodium–potassium amalgam followed by distillation, or by passage through activated alumina under nitrogen using a Solv-Tek solvent purification system (Solv-Tek, Inc., Berryville, Virginia). Diethyl ether (Caledon Reagent) and tetrahydrofuran (Caledon Reagent) were dried by the latter method. Each of the scavengers investigated in this work were obtained from commercial sources in the highest purity available. The amines were refluxed over solid KOH for 12 h and distilled, while triethylsilane (Et_3SiH) and tri-*n*-butylstannane (Bu_3SnH) were stirred at room temperature for 18 h over lithium aluminum hydride and distilled at atmospheric pressure (Et_3SiH) or under mild vacuum (Bu_3SnH). CCl_4 was refluxed over phosphorus pentoxide and distilled. 4,4-Dimethyl-1-pentene (DMP) was dried by passage through a silica gel column, while isoprene, DMB, and 3,3-dimethyl-1-butyne (TBE) were distilled at atmospheric pressure. 1,1-Dichloro-3,4-dimethylgermacyclopent-3-ene and 1,1-dichloro-3-methylgermacyclopent-3-ene were prepared as previously described (9, 49, 50). Deuterated solvents were used as received from Cambridge Isotopes Laboratories.

1,3,4-Trimethyl-1-phenyl-1-germacyclopent-3-ene (**5**) was synthesized by a procedure similar to that of Mazerolles and Manuel (51). In a flame-dried apparatus consisting of a 250 mL two-necked round-bottomed flask, reflux condenser, nitrogen inlet, addition funnel, and magnetic stirrer was prepared a solution of 1,1-dichloro-3,4-dimethyl-1-germacyclopent-3-ene (3.7 g, 0.016 mol) in anhydrous diethyl ether (80 mL) under nitrogen. The solution was cooled to 0 °C using an ice bath, and then a stirred solution of phenylmagnesium bromide (5.7 mL of a 3.0 mol/L solution in diethyl ether, 0.0171 mol) in dry diethyl ether (20 mL) was added dropwise over 1 h. The cooling bath was removed after 2 h and the white suspension was allowed to stir at room temperature for another 20 h. A solution of methylmagnesium bromide (6.3 mL of a 3.0 mol/L solution in diethyl ether, 0.019 mol) in anhydrous diethyl ether (20 mL) was then added dropwise over 1 h, and the reaction mixture was then stirred under reflux for a further 3 h. After cooling, the resulting yellow suspension was hydrolyzed with saturated aqueous ammonium chloride (40 mL) over 20 min, transferred to a separatory funnel, and the aqueous and organic fractions were separated. The aqueous fraction was extracted with diethyl ether (3 × 60 mL), and then the combined ether fractions were washed with distilled water (2 × 30 mL), 5% aqueous sodium bicarbonate (2 × 30 mL), dried with anhydrous magnesium sulfate (30 min), and filtered. The solvent was removed on a rotary evaporator to yield a yellow-green liquid (4.4 g). Distillation under vacuum (bp = 103–105 °C at 0.3 mm Hg, 1 mm Hg = 133.322 Pa) afforded **5** (3.78 g, 0.015 mol, 86%) as a colorless liquid. Further purification by column chromatography, using pentane as eluant, was performed until the purity of the compound was at least 99% according to GC analysis. The compound exhibited the following spectroscopic data: ^{1}H NMR ($CDCl_3$, 200 MHz) (52) δ: 0.56 (s, 3H), 1.74 (m, 10 H), 7.31–7.51 (m, 5H). ^{13}C NMR ($CDCl_3$) δ: –4.5, 19.4, 26.4, 128.0, 128.5, 130.9, 133.3, 143.9. MS *m/z*: 248 (65), 246 (45), 244 (35), 233 (38), 231 (28), 229 (20), 166 (70), 164 (43), 151 (100), 149 (85), 147 (80). Exact mass calcd. for $C_{13}H_{18}{}^{74}Ge$: 248.0620; found: 248.0617.

1,3-Dimethyl-1-phenyl-1-germacyclopent-3-ene (**6**) was prepared in similar fashion. A solution of 1,1-dichloro-3-methyl-1-germacyclopent-3-ene (2.0 g, 0.009 mol) in anhydrous diethyl ether (40 mL) was introduced into a flame-dried apparatus consisting of a two-necked round-bottomed flask (100 mL), reflux condenser, nitrogen inlet, addition funnel, and magnetic stirrer. After cooling to 0 °C, a solution of phenylmagnesium bromide (3.3 mL of a 3.0 mol/L solution in diethyl ether, 0.010 mol) in dry diethyl ether (20 mL) was added dropwise over 1.5 h with stirring. The cooling bath was removed after 2 h and the suspension was stirred at room temperature for another 15 h. A solution of methylmagnesium bromide (4.1 mL of a 3.0 mol/L solution in diethyl ether, 0.012 mol) in anhydrous diethyl ether (20 mL) was then added dropwise over 1.5 h, and the resulting mixture was stirred under reflux for a further 4 h. After cooling, the resulting yellow suspension was hydrolyzed with saturated aqueous ammonium chloride (40 mL) over 20 min and transferred to a separatory funnel, where the aqueous and organic fractions were separated. The aqueous fraction was extracted with diethyl ether (3 × 60 mL) and then the combined ether fractions were washed with distilled water (2 × 30 mL), 5% aqueous sodium bicarbonate (2 × 30 mL), dried with anhydrous magnesium sulfate (30 min), and filtered. The solvent was removed on a rotary evaporator to yield a yellow oil (2.3 g), which was purified by silica gel column chromatography with pentane as the eluting solvent. This afforded a colorless oil (1,9 g, 0.008 mol, 89%) in >99% purity, according to GC analysis, which was identified as **6** on the basis of the following spectroscopic data. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 0.58 (s, 3H), 1.23–1.80 (m, 7 H), 5.64 (s, 1H), 7.24–7.50 (m, 5H). ^{13}C NMR ($CDCl_3$) δ: –4.2, 14.2, 22.7, 31.7, 125.4, 128.1, 128.6, 130.9, 133.2, 140.3. MS *m/z*: 234 (35), 232 (25), 230 (18), 220 (67), 219 (36), 217 (15), 214 (10), 166 (40), 151 (100), 149 (85), 147 (50), 122 (20). Exact mass calcd. for $C_{12}H_{16}{}^{74}Ge$: 234.0464; found: 234.0446.

Steady state photochemical trapping experiments were carried out in quartz NMR tubes using 0.045 mol/L solutions of **5** in cyclohexane-d_{12} containing methanol (0.5 mol/L), acetic acid (0.095 mol/L), or isoprene (0.094 mol/L), monitoring the course of the reactions over the 0%–40% conversion range by ^{1}H NMR spectroscopy. The tubes were sealed with rubber septa and deoxygenated with a stream of dry argon for ca. 20 min prior to photolysis. The photolyses afforded equal yields of 2,3-dimethyl-1,3-butadiene (DMB; δ: 1.96, 4.88, 4.97) and a single additional major (>90%) product in each case. The identity of the isoprene adduct (**6**) was established by ^{1}H NMR spectroscopy, GC–MS, and GC coinjection of the crude photolysate with the authentic sample described above. The MeOH and AcOH adducts **7a** and **7b**, respectively, were identified on

the basis of comparisons of their ^{1}H NMR spectra to those of closely related compounds (9, 11, 53). Neither compound survived attempted GC separation without significant decomposition. Methoxymethylphenylgermane (**7a**): ^{1}H NMR (C_6D_{12}, 600 MHz) δ: 0.59 (d, 3H, J = 2.3 Hz), 3.45 (s, 3H), 5.68 (q, 1H, J = 2.3 Hz), 7.28 (m, 3H), 7.48 (m, 2H). Acetoxymethylphenylgermane (**7b**): ^{1}H NMR (C_6D_{12}, 600 MHz) δ: 0.79 (d, 3H, J = 2.3 Hz), 1.88 (s, 3H), 6.01 (q, 1H, J = 2.3 Hz), 7.28 (m, 3H), 7.58 (d, 2H).

Laser flash photolysis experiments employed the pulses from a Lambda Physik Compex 120 excimer laser, filled with F_2–Kr–Ne (248 nm, ~25 ns, 100 ± 5 mJ) mixtures and a Luzchem Research mLFP-111 laser flash photolysis system, modified as described previously (9). Solutions were prepared at concentrations such that the absorbance at the excitation wavelength (248 nm) was between ca. 0.7 and 0.9 and were flowed continuously through a thermostatted 7 × 7 mm Suprasil flow cell connected to a calibrated 100 mL reservoir, fitted with a glass frit to allow bubbling of nitrogen or argon gas through the solution for at least 30 min prior to and throughout the duration of each experiment. The glassware, sample cells, and transfer lines used for these experiments were stored in a 85 °C vacuum oven when not in use, and the oven was vented with dry nitrogen just prior to assembling the sample-handling system at the beginning of an experiment. Solution temperatures were measured with a Teflon-coated copper–constantan thermocouple inserted directly into the flow cell. Transient decay and growth rate constants were calculated by nonlinear least-squares analysis of the absorbance–time profiles using the Prism 3.0 software package (GraphPad Software, Inc., San Diego, California) and the appropriate user-defined fitting equations, after importing the raw data from the Luzchem mLFP software. Reagents were added directly to the reservoir by microliter syringe as aliquots of standard solutions. Rate constants were calculated by linear least-squares analysis of decay rate concentration data (five to seven points) that spanned as large a range in transient decay rate as possible. Errors are quoted as twice the standard deviation obtained from the least-squares analyses.

Acknowledgement

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support, the McMaster Regional Centre for Mass Spectrometry (Hamilton, Ontario) for mass spectrometric analyses, and Teck-Cominco Metals Ltd. (Vancouver, British Columbia) for a generous gift of germanium tetrachloride.

Tris(biimidazolato)chromium(III) as a building block for hydrogen-bonded supramolecular assemblies

Letitia M. Gruia, Fernande D. Rochon, and André L. Beauchamp

Abstract: The trischelate $[Cr(H_2biim)_3](NO_3)_3$ complex of 2,2′-biimidazole (H_2biim) was obtained by reacting $CrCl_3 \cdot 3THF$ with $[Ag(H_2biim)](NO_3)$ in methanol. In the solvent-free material, each ligand forms two N-H···O bonds to a nitrate ion and generates locally neutral $[Cr(H_2biim)_3](NO_3)_3$ units. A methanol solvate was also obtained in which intermolecular interactions involve optimal use of the hydrogen-bonding ability of the $[Cr(H_2biim)_3]^{3+}$ cations, NO_3^- anions, and methanol molecules. In both cases, there is no long-range regular organization of the complex units. Deprotonation of $[Cr(H_2biim)_3](NO_3)_3$ with $NaOCH_3$ yielded neutral $Cr(Hbiim)_3$. Its powder pattern is similar to that of $Ru(Hbiim)_3$, suggesting that it also consists of mutually perpendicular interlocked honeycomb sheets. Recrystallization by slow diffusion of diisopropyl ether into a methanol solution yielded a porous material of composition $Cr(Hbiim)_3 \cdot 2.6C_6H_{14}O$ in which superposed honeycomb sheets create infinite channels (~13 Å diameter) filled with disordered solvent molecules. A totally different structure is adopted by the solvate $Cr(Hbiim)_3 \cdot C_6H_6 \cdot 2H_2O$, where the benzene molecule is encapsulated in a cavity created by five complex molecules.

Key words: chromium, biimidazole, supramolecular, crystal structure, hydrogen bonding.

Résumé : Le complexe trischélate $[Cr(H_2biim)_3](NO_3)_3$ du 2,2′-biimidazole (H_2biim) a été obtenu par réaction de $CrCl_3 \cdot 3THF$ avec $[Ag(H_2biim)](NO_3)$ dans le méthanol. Dans les cristaux sans solvant, chaque ligand forme deux liaisons N-H···O avec un ion nitrate, ce qui crée localement des motifs neutres $[Cr(H_2biim)_3](NO_3)_3$. Un solvate méthanolique a également été isolé, dans lequel les interactions intermoléculaires font intervenir une utilisation optimale des liaisons hydrogène possibles entre les cations $[Cr(H_2biim)_3]^{3+}$, les anions NO_3^- et le méthanol. Dans les deux cas, il n'y a pas d'organisation régulière à grande échelle des motifs complexes. La déprotonation de $[Cr(H_2biim)_3](NO_3)_3$ avec $NaOCH_3$ a conduit au composé neutre $Cr(Hbiim)_3$. Son diagramme de poudre est semblable à celui de $Ru(Hbiim)_3$, ce qui laisse supposer qu'il est également constitué de feuillets hexagonaux mutuellement perpendiculaires, qui s'emboîtent les uns dans les autres. La recristallisation par diffusion lente d'éther diisopropylique dans une solution méthanolique a produit un matériau microporeux de composition $Cr(Hbiim)_3 \cdot 2.6C_6H_{14}O$, où des couches hexagonales superposées engendrent des canaux infinis (diamètre ~13 Å) occupés par des molécules de solvant désordonnées. Le solvate $Cr(Hbiim)_3 \cdot C_6H_6 \cdot 2H_2O$ adopte une structure complètement différente, dans laquelle le benzène est encapsulé dans une cavité créée par cinq molécules de complexe.

Mots clés : chrome, biimidazole, supramoléculaire, structure cristalline, liaison hydrogène.

Introduction

The assembly of molecular units by self-organization is one of the most important methods of developing new molecular materials with built-in features like porosity (1) or magnetism (2). One way to exert some control over the structure of the assembled product is to rely on hydrogen bonds. The strength and directionality of hydrogen bonding account for its significance and make it an extremely important interaction in supramolecular synthesis. The use of building blocks with such carefully positioned functionality can increase the odds of producing ensembles where the individual subunits are arranged in an expected way. This strategy has been used to produce a variety of architectures (3–6).

A particular organic target for the construction of such materials is the 2,2′-biimidazolate monoanion ($Hbiim^-$). This ligand can coordinate in a bidentate manner to metal centers (**1a**) and form a complementary hydrogen-bonding system using two sets of N-H donors and N acceptors (**1b**). A variety of inorganic molecular architectures in the solid state were obtained via these interactions. The resulting structural

units can be simple dimeric or oligomeric species without complementary interunit hydrogen bonds (zero-dimensional structure), 1-D hydrogen-bonded ribbons, 2-D hydrogen-bonded sheets, or 3-D cross-catenated networks (7–11).

The systematic study of Tadokoro and Nakasuji (8) on salts of the $[Ni(Hbiim)_3]^-$ unit revealed that the complex anion can either remain isolated or form extended multidimensional assemblies, depending on the countercations present. To cast some light on the intrinsic potential of trisbiimidazolate metal units for the development of controlled architectures, we turned to the uncharged $Cr(Hbiim)_3$ compound. The only Cr(III)-biimidazole complex structurally characterized so far is the mixed $[Cr(Hbiim)(H_2biim)_2]SO_4$ compound (11).

Experimental

Reactants and methods

The starting material ($CrCl_3$·3THF) was prepared following the procedure of Boudjouk and So (12). Biimidazole was prepared according to Fieselmann et al. (13) and recrystallized in boiling aq. NaOH (0.025 mol/L). $[Ag(H_2biim)](NO_3)$ was obtained by the published procedure (14). Solvents and all other chemicals were used as received.

FT-IR spectra (4000 and 250 cm^{-1}) were recorded as CsI pellets on a Nicolet Avatar 370 CsI spectrophotometer. Elemental analyses were run by the Laboratoire d'Analyse Élémentaire de l'Université de Montréal. Mass spectra were recorded in the FAB^+ mode from nitrobenzylic alcohol solutions at the Centre Régional de Spectrométrie de Masse de l'Université de Montréal. The X-ray powder diffraction study was carried out with a D500 Siemens diffractometer (Co Kα radiation, λ = 1.7902 Å) at the Laboratoire de Radiocristallographie de l'Université du Québec à Montréal. Magnetic susceptibility data on powdered samples were measured with a Faraday balance at the Université du Québec à Montréal. The diamagnetic corrections were estimated from Lewis and Wilkins (15).

Preparative work

$[Cr(H_2biim)_3](NO_3)_3$ (1)

$CrCl_3$·3THF (37.4 mg, 0.10 mmol) and $[Ag(H_2biim)](NO_3)$ (91.2 mg, 0.30 mmol) in methanol (20 mL) were refluxed in the dark for 3 h. The cooled mixture was filtered to remove precipitated AgCl. The filtrate was then evaporated under reduced pressure to a volume of 10 mL and kept in a refrigerator. Dark-red crystals were deposited after 48 h. μ_{eff} = 3.82 BM. FAB^+-MS *m/z:* 452 $[Cr(Hbiim)_3 + H]^+$. Anal. calcd. for $[Cr(H_2biim)_3](NO_3)_3$·(1/8)CH_3OH·(1/4)H_2O: C 33.55, H 2.95, N 32.38; found: C 33.48, H 2.77, N 32.26.

$Cr(Hbiim)_3$ (2)

$[Cr(H_2biim)_3](NO_3)_3$ (64.0 mg, 0.10 mmol) was suspended in methanol (5 mL). $NaOCH_3$ (3.27 mL of a 0.50% *w/v* methanol solution) was added slowly, and the orange suspension was stirred for 15 min. The mixture was concentrated under reduced pressure and filtered. The orange solid was washed with diethyl ether and dried in vacuo. μ_{eff} = 3.93 BM. FAB^+-MS *m/z*: 452 $[Cr(Hbiim)_3 + H]^+$. Anal. calcd. for $Cr(Hbiim)_3$·H_2O·(1/2)CH_3OH: C 45.77, H 3.95, N 34.62; found: C 45.83, H 3.69, N 34.67.

Once precipitated, the solid is difficult to redissolve. Vapor diffusion of benzene into the (wet) methanol filtrate gave a small amount of dark-orange crystals, which were identified by X-ray diffraction (see later) as the $Cr(Hbiim)_3$·C_6H_6·$2H_2O$ solvate (**2a**). Vapor diffusion of diisopropyl ether into the filtrate produced dark-orange crystals of the $Cr(Hbiim)_3$·$2.6C_6H_{14}O$ solvate (**2b**).

X-ray powder diffraction on $Cr(Hbiim)_3$

The pattern of a dried sample was indexed using the 16 strongest reflections with the dichotomy method implemented in DICVOL (16, 17). This procedure gave a unique solution, consisting of a monoclinic cell similar to that of $Ru(Hbiim)_3$ (9), with satisfactory figures of merit, $F(16)$ = 22.4 and $M(16)$ = 22.8 (18, 19). Further refinement of the unit cell parameters using the Le Bail method with FULLPROF (20) yielded the following values: a = 12.283(3) Å, b = 12.722(7) Å, c = 13.231(7) Å, and β = 95.77(3)°. Analysis via an alternate refinement method using the PowderCell program (21) led to similar conclusions. The structural data of $Ru(Hbiim)_3$ (replacing Ru by Cr) were first used and the model was refined by comparison with the experimental values. The cell parameters, the zero shift, the scale factor, the background (modeled by a ninth-order polynomial), and the coefficients of the reflection profiles (using the Pseudo-Voigt2 function) were refined. The final parameters were a = 12.225 Å, b = 12.720 Å, c = 13.288 Å, and β = 95.80°, with satisfactory agreement factors R_p = 23.7, R_{wp} = 32.9, and R_{exp} = 6.8.

Crystallographic measurements and structure determination

The single-crystal X-ray data of **1** and **2b** were obtained with a Bruker SMART diffractometer, equipped with a 2K CCD area detector, using Cu Kα radiation. They were collected in the 512 pixel × 512 pixel mode under the control of the SMART software (22). Narrow frames with ω scan widths of 0.30° were recorded, exposure time being 15 s per frame for **1** and 9 s for **2b**. The first 101 frames were remeasured at the end of data collection to monitor instrument and crystal stability. The data were integrated using the SAINT program (23) and the intensities were corrected for the Lorentz factor, polarization, air absorption, and absorption due to variation in the path length through the detector faceplate. SADABS (24) was used to calculate the absorption correction.

Crystals **1a** and **2a** were studied with an Enraf-Nonius CAD-4 diffractometer operating with Cu Kα radiation under the control of the CAD-4 software (25). The reduced cell was initially determined from 20–25 spots located on a preliminary rotation photograph and centered in the detector aperture. Accurate cell parameters were then determined from the positions of 25 high-angle reflections centered by the SETANG and DETTH procedures. A whole sphere of data was collected by the ω/2θ scan technique. Possible crystal decomposition was monitored by measuring five standard reflections every hour. The data were corrected for the effect of Lorentz and polarization and an absorption correction based on the crystal geometry was applied (26).

The SHELXTL package (27) was used for all calculations. The structures were solved by direct methods and ΔF map calculations. Non-hydrogen atoms were refined anisotropically using F^2 by full-matrix least-squares analysis. Hydrogens were fixed at idealized coordinates and allowed to ride on the supporting atoms during the refinement. They were assigned fixed isotropic thermal parameters U_{iso} = 1.2–1.5 × U_{eq} of the supporting atom. The final model was analyzed by means of the VOID routine of PLATON software (28) to check that no appreciable empty space remained in the structure. Crystal data are listed in Table 1 and CIF files are provided as Supplementary material.[2]

For **1**, the $\bar{3}m$ Laue symmetry and the systematic absences (hkl, $-h + k + l \ne 3n$; $h\bar{h}l$, $l \ne 2n$) were consistent with space groups $R3c$ and $R\bar{3}c$. The structure solved and refined normally in the centric $R\bar{3}c$ group. Positions were first found for the Cr atoms on equipoint 6a (32 local symmetry), surrounded by six "half-biimidazole" units in general position. The nitrate ions, in which one N—O bond lied on a twofold axis (18e), were then located from a ΔF map.

The $P4_2/n$ space group of **1a** was determined unambiguously from the 4/m Laue symmetry and systematic absences ($hk0$, $h + k \ne 2n$; $00l$, $l \ne 2n$). The Cr atom was found to lie on a crystallographic twofold axis (equipoint 4f) and the biimidazole ligands were readily identified. One of the nitrates (centered on N2) was located on a twofold axis (4e). The remaining nitrates and a lattice methanol molecule showed disorder. The latter nitrate adopted two slightly displaced orientations, but resolved positions could be defined for only one of the oxygens (O21/O21′, half occupancies). The C atom of the methanol molecule occupied a twofold axis (4e), whereas the OH group was disordered over two symmetry-equivalent sites about the axis (half occupancy imposed by symmetry).

For **2a**, space groups $P31c$ and $P\bar{3}1c$ were consistent with the observed $\bar{3}m$ Laue symmetry and systematic absences (hhl, $l \ne 2n$). The structure solved and refined normally in the centric $P\bar{3}1c$ group. The Cr(Hbiim)$_3$ unit was readily found, consisting of a Cr atom on equipoint 2c (32 local symmetry) surrounded by six "half-biimidazolate" units in

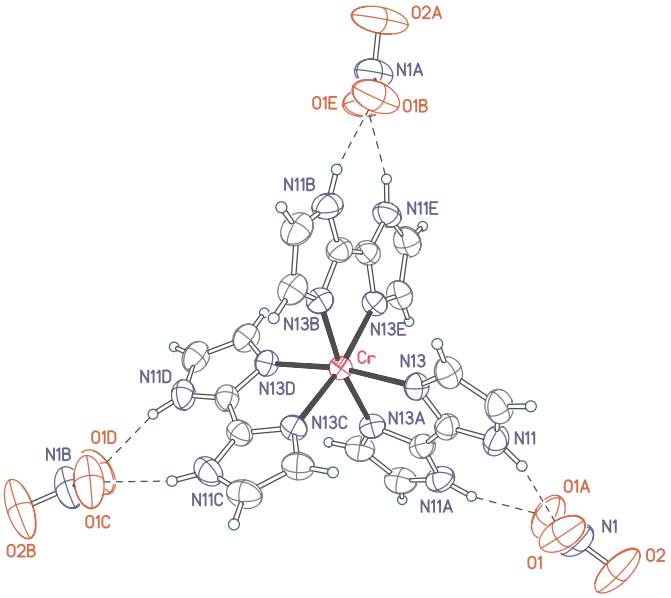
general position. A ΔF map then revealed the presence of lattice benzene molecules (one per complex) centered on equipoint 2d (32 symmetry), with the C (and H) atoms lying on crystallographic twofold axes (6h). Also, oxygens for lattice water molecules (two per complex) were aligned on the threefold axis (4e). In this high-symmetry environment, the N-H and O-H hydrogens had to be disordered. Since there was only one proton on each biimidazolate ligand, this proton had to be distributed statistically over the two uncoordinated N atoms. It was fixed at the idealized positions with half occupancy. For the water molecule, some electron density was found on the threefold axis (4e) at a reasonable position for hydrogen atom H1A, which was assigned only half occupancy, since another position generated by space group symmetry would be too close to be occupied simultaneously. Another small residual was detected in the ΔF map, near the line joining the water oxygen O1 and an uncoordinated biimidazolate N atom. This was considered as the position of the missing hydrogen (H1B), since the O1—H1B bond would make an angle of ~105° with O—H1A and ~121° with the two other symmetry-equivalent O—H1B bonds. An H1B atom was thus introduced along this direction at an idealized distance with half occupancy. This model provides the four water O1 atoms in the unit cell with eight hydrogens altogether, namely two H1A (half occupancy of fourfold equipoint 4c) and six H1B (half occupancy of 12-fold general equipoint). As will be discussed in the next section, this allowed full complementary hydrogen bonding to take place about the water molecule and uncoordinated biimidazolate N atoms.

Compound **2b** was found to be monoclinic (2/*m* Laue symmetry) and since only the centering systematic absence was noted ($hk0$, $h + l \neq 2n$), the space group could be *C*2, *Cm* or *C*2/*m*. The crystals did not diffract very well, especially at high angles, so these data were collected only up to $\theta = 55°$. Direct methods yielded a reasonable solution in the centric *C*2/*m* group. The eight Cr atoms were found to occupy two fourfold special positions (4g and 4h, respectively) on crystallographic twofold axes. They were each surrounded by biimidazolate units defining $Cr(Hbiim)_3$ molecules. Anisotropic refinement of these positions converged to $R = 0.16$. The ΔF map showed many weak peaks (<3 e/Å^3) in two large channels parallel to the *c* axis at (x, y) = (0, 1/2) and (1/2, 0), respectively. They were assumed to correspond to trapped solvent molecules. Extensive efforts were made to assemble these peaks into methanol or diisopropyl ether molecules, but without success. At this stage, the lower-symmetry space groups *C*2 and *Cm* were considered, but they did not solve the problem: the same structure was obtained for the complex, described by a greater number of parameters, and the very high correlations made refinement extremely unstable. Furthermore, no reasonable model could be unraveled for the solvent region in either case. Therefore, the *C*2/*m* model was retained. Since the solvent region could not be modelled with discrete fractional molecules, it was described via the SQUEEZE procedure implemented in the PLATON software (28). Analysis of the ordered model with the VOID routine of PLATON indicated that a volume of 4920 Å^3 occupied by 1205 electrons was available in the unit cell. Considering that a diisopropyl ether molecule contains 58 electrons and its volume is 235.5 Å^3 (based on a density of 0.720 g cm^{-3}), the presence of 20.8 molecules per cell would correspond to 1206 electrons and 4894 Å^3, which is very close to the above result. Methanol – diisopropyl ether mixtures were also considered, but they invariably led to poorer agreement. The contribution of the disordered solvent calculated by SQUEEZE was used to generate an adjusted set of intensity data bypassing the solvent contribution (29) and the ordered part of the structure was refined in space group *C*2/*m*. Two N-H protons with half occupancies were introduced at idealized positions to account for the fact that only one uncoordinated N atom of each biimidazolate ligand was protonated. Anisotropic refinement of the non-hydrogen atoms in the nonsolvent part of the structure converged normally to $R = 0.082$. Although this *R* factor is higher, it is considered to be quite satisfactory, considering the severe disorder present. The solvent composition deduced above was used to calculate the derived quantities in Table 1 and the Supplementary material.[2]

Results and discussion

Characterization of the cationic complex



The $[Cr(H_2biim)_3]^{3+}$ complex was obtained as the nitrate salt by reacting $CrCl_3 \cdot 3THF$ with 3 equiv. of $[Ag(H_2biim)](NO_3)$ in methanol. After filtering AgCl and reducing the volume of the solution, the compound was isolated in good yields. Upon cooling the methanol solution, two types of crystals were visible. Both were examined by X-ray diffraction, which confirmed the presence of the octahedral trischelate cation. The two types of crystals are actually the monomethanol solvate (**1a**) and the solvent-free material (**1**). The magnetic moment ($\mu = 3.82$ BM) is typical of discrete Cr(III) species. The FAB$^+$ mass spectrum shows a peak for the $[Cr(Hbiim)_3+H]^+$ species.

The IR data (4000–250 cm^{-1}) for H_2biim and the chromium complexes are provided in Table S-1.[2] The tentative assignments proposed for H_2biim are based on the detailed work of Bonsor et al. (30) on imidazole. Their assignments, which are largely supported by a normal coordinate analysis by Tatara et al. (31), were transferred to H_2biim. In principle, band splitting should occur throughout the spectrum since each imidazole ring should produce its own series of vibrations. However, splitting is observed only in a few cases. The ν, δ, and γ modes of the imidazole C2—H2 bond are replaced here by motions centered on the C2-C2′ junction, most of which are expected to occur at low frequency, except for the ν(C2-C2′) mode, which likely contributes significantly to the strong band observed at 1217 cm^{-1} in H_2biim.

In the spectrum of $[Cr(H_2biim)_3](NO_3)_3$, the nitrate ion gives a very strong and broad band at 1383 cm^{-1}. A small feature at 1036 cm^{-1} originates from lattice methanol. The most obvious perturbation for the ligand involves the very strong ν(N-H) band, which shifts from 2900 to ~3 000 cm^{-1} and loses most of its combination and (or) overtone fine structure. The easily detectable slightly broadened feature, observed at 1634 cm^{-1} in the complex, is probably due to a combination or overtone involving γ(N-H) and γ(C-H) modes observed between 700 and 900 cm^{-1}. Various other changes in position and (or) intensity are noted throughout

Fig. 1. The $[Cr(H_2biim)_3]^{3+}$ cation and the hydrogen-bonded nitrate ions (**1**). Ellipsoids correspond to 30% probability. In the numbering scheme, the first digit corresponds to ring number and the second digit to the position in the ring. Symmetry operations are (A) $-y, x - y, z$; (B) $-x + y, -x, z$; (C) $y, x, 1/2 - z$; (D) $x - y, -y, 1/2 - z$; (E) $-x, -x + y, 1/2 - z$.

the spectrum, the most characteristic being the replacement of the 1217 cm^{-1} band, believed to involve the C2-C2′ stretching, by a strong feature at 1177 cm^{-1}. A ring mode at 1143 cm^{-1} and a δ(C, N-H) band at 1072 cm^{-1} shift to 1134 and 1083 cm^{-1}, respectively, with substantially increased intensity. Two low-frequency bands at 505 and 449 cm^{-1}, respectively, where free H_2biim shows no absorption, are assigned to chelate ring deformation. Bands at 393 and 365 cm^{-1} are likely due to Cr-N stretching, these modes occurring at these same positions for $[Cr(bipy)_3]^{3+}$ (32) and other Cr^{3+}–bipyridine chelates (33).

Crystal structures of 1 and 1a

Both compounds are nitrate salts of the trischelate $[Cr(H_2biim)_3]^{3+}$, where the metal center has an octahedral coordination distorted by the small bite angle of H_2biim. In the solvent-free crystals **1**, the $[Cr(H_2biim)_3]^{3+}$ cation (Fig. 1) retains maximum symmetry (32 or D_3). Selected distances and angles are listed in Table 2. The Cr atom lies on a crystallographic threefold axis, whereas three twofold axes in a perpendicular plane bisect the C2—C2′ bond of each H_2biim ligand. The nitrate N1—O2 bonds also lie on these twofold axes. The remaining oxygens O1 form two symmetry-equivalent N-H···O1 hydrogen bonds with the ligand N-H groups. This crystal has the same structure as the Co(III) analogue (10).

The two five-membered rings of biimidazole are almost coplanar (N3-C2-C2′-N3′, torsion angle of –4.6°). Hydrogen bonding would be optimized if the nitrate anion and the biimidazole unit were coplanar, but the twist of the nitrate ion by 32.7(2)° about the twofold axis, because of molecular packing, does not appreciably weaken the hydrogen bonds, since the N···O1 separation is small (2.75 Å). The structural

units of Fig. 1 form columns parallel to the *c* axis at $(x, y) = (0,0)$, (1/3, 2/3), and (2/3, 1/3) (Fig. S-1).[2] The only particular interunit interaction involves the nitrate oxygen O2, nested between the H5 atoms of two adjacent molecules in different columns, with which it forms rather strong dipolar interactions (H5···O2 = 2.356 Å, C5-H5-O2 = 158°). Thus, in this compound, there is no long-range effect of hydrogen bonding on molecular packing.

In the methanol solvate $[Cr(H_2biim)_3](NO_3)_3{\cdot}CH_3OH$ (**1a**), the Cr^{3+} center retains the distorted octahedral coordination of **1** (Fig. 1). According to the geometrical data in Table 3, the only significant difference in the complex cation is a slightly greater twist about the central ligand bond, the N3-C2-C2′-N3′ torsion angles being –7.9° and –13.6° compared with –4.6° in **1**. The lattice contains methanol molecules, which can participate in hydrogen bonding without imposing strict directional constraints, and this lead to a totally different packing pattern (Fig. 2, stereoview S-2 available in the Supplementary material).[2] The complex cations form layers parallel to the *ab* plane at (z = 0 and 1/2) in which the methanol molecule is embedded. The interlayer region is occupied by the NO_3^- ions. In contrast with the solvent-free phase (**1**), the nitrates do not form a pair of hydrogen bonds to the same ligand but they tend to connect several adjacent molecules. All ligand N—H bonds participate in relatively strong N-H···O(nitrate) hydrogen bonds (N···O separation = 2.69–2.84 Å). The methanol molecule is disordered over two orientations about a crystallographic twofold axis and it forms an O-H···O bond (O···O = 2.84 Å) with O11 in one of the two adjacent nitrate ions.

Characterization of the neutral complexes

Neutralizing a suspension of the nitrate with 3 equiv. $NaOCH_3$ in methanol yields the deprotonated compound $Cr(Hbiim)_3$ as a poorly soluble orange solid. The compound has to be dried thoroughly to remove traces of solvent. Its

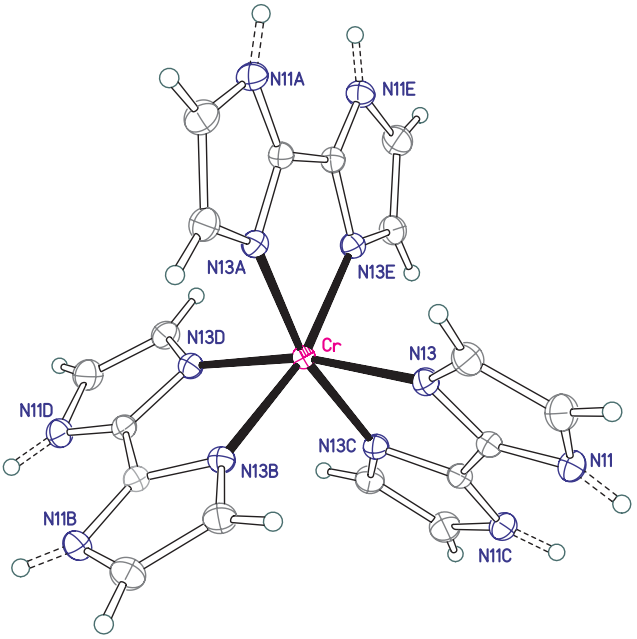
magnetic moment (μ_{eff} = 3.93 BM) is normal. The FAB^+ mass spectrum shows a peak for $[Cr(Hbiim)_3 + H]^+$.

Infrared data for $Cr(Hbiim)_3$ are compared with those of $[Cr(H_2biim)_3](NO_3)_3$ in Table S-1.[2] As expected, the strong nitrate band at ~1380 cm^{-1} has disappeared. The most characteristic spectral feature of the complex is a broad band at 1909 cm^{-1} in a featureless region for both the free ligand and $[Cr(H_2biim)_3](NO_3)_3$. Similar bands in the same region were reported for complexes of other metals containing biimidazole as the monoanion (8, 9, 34, 35) and were attributed to the 2γ(N-H) overtone on the basis of a study by Malarski and Sobczyk on imidazole (36). This assignment would imply that the fundamental γ(N-H) mode is near 950 cm^{-1}, and there is indeed a broad feature underlying other ligand vibrations in this region. The ν(N-H) vibration is shifted from 2900 to 2520 cm^{-1} in the complex. Several other differences are noted with respect to the above $[Cr(H_2biim)_3]^{3+}$ complex. In the sensitive 1000–1200 cm^{-1} region, the ν(C2-C2′) band is found at 1198 cm^{-1} and various shifts are noted. The chelate ring vibrations undergo small shifts to 523 and 460 cm^{-1}, whereas the ν(Cr-N) bands are not greatly affected (390 and 355 cm^{-1}).

In an attempt to replace all the N-H protons by Ag^+ ions, $[Cr(H_2biim)_3](NO_3)_3$ was reacted with Tollen's reagent (ammoniacal silver nitrate). Although the basic character of this concentrated ammonia solution neutralized one of the ligand protons, substitution of the second proton did not take place and $Cr(Hbiim)_3$ was isolated.

Fig. 2. View of the unit cell of $[Cr(H_2biim)_3](NO_3)_3 \cdot MeOH$ (**1a**) along the *b* axis.

Crystal structures of solvent-free Cr(Hbiim)$_3$ (2) and solvates 2a and 2b



Single crystals of $Cr(Hbiim)_3$ for X-ray work could not be grown, but a powder pattern was recorded on a thoroughly dried sample. Indexation based on the 16 strongest peaks yielded a monoclinic unit cell very similar to that reported by Tadokoro et al. (9) for $Ru(Hbiim)_3$. The experimental pattern for $Cr(Hbiim)_3$ is very similar to the one calculated by PLATON (28) from the unit cell and atom coordinates of $Ru(Hbiim)_3$ ($P2_1$, a = 12.243 Å, b = 12.643 Å, c = 13.207 Å, β = 92.74°, V = 2042 $Å^3$), suggesting that the Cr and Ru compounds are isostructural. Refinement of the cell parameters with FULLPROF (20) yielded the following values: a = 12.283(3) Å, b = 12.722(7) Å, c = 13.231(7) Å, β = 95.77(3)°, V = 2 057 $Å^3$. The unit cell of $Cr(Hbiim)_3$ is found to be slightly larger than that of $Ru(Hbiim)_3$, despite the fact that the six-coordinate radii of Cr^{3+} (0.76 Å) and Ru^{3+} (0.82 Å) are in the reverse order (37). Subtle packing effects could lead to this tiny difference, which lies, at any rate, near the limit of discrimination of the present study.

The crystal of **2a** contains neutral $Cr(Hbiim)_3$ molecules, together with one benzene and two water molecules per complex. The molecular unit (Fig. 3) has a distorted octahedral structure similar to that of the above $[Cr(H_2biim)_3]^{3+}$ cation, with the difference that there remains only one N-H proton per $Hbiim^-$ ligand, which is disordered statistically over the two rings. Distances and angles are given in Table 4. Any small geometrical differences between the protonated and the deprotonated rings are averaged, each uncoordinated N atom bears a half-proton, and the species exhibits an averaged structure with 32 (D_3) symmetry.

A view of the unit cell is provided in Fig. 4. Benzene and

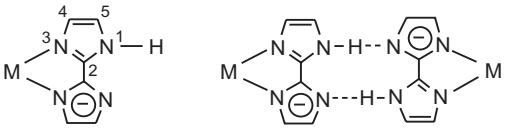
Fig. 3. The $Cr(Hbiim)_3$ molecule in **2a**. Ellipsoids correspond to 30% probability. Numbering scheme as in Fig. 1. The N-H proton (dashed bond) of each ligand is disordered statistically over two sites. Symmetry operations are (A) $1 - y, 1 + x - y, z$; (B) $-x + y, 1 - x, z$; (C) $1 - y, 1 - x, 1/2 - z$; (D) $-x + y, y, 1/2 - z$; (E) $x, 1 + x - y, 1/2 - z$.



complex molecules centered on a crystallographic threefold axis are repeated in alternance along this axis, which is parallel to the unit cell *c* direction. Although $Hbiim^-$ ligands are good candidates for complementary hydrogen bonding (Scheme 1*b*), the complexes are not directly hydrogen bonded to one another in the present structure, since all hydrogen bonds involve a participation of the lattice water molecules sitting on the *c* axis. The environment of the *c* axis, which is a crystallographic threefold axis, is depicted in Fig. 5. All N-H and O-H protons are disordered, but four hydrogen-bonding interactions take place around each water molecule and all imidazole rings are efficiently used. In one of the possible "snapshot" arrangements given in the figure, pairs of water molecules along the *c* axis form an O1-H1···O1 bond (O1···O1 = 2.76 Å). For the O1 atom acting as a donor, an O1-H1B···N11 bond is established with the deprotonated ring of a complex (O1···N11 = 2.75 Å). The corresponding rings in the two other threefold related complexes are protonated and act as donors in N11-H11···O1 interactions (N11···O1 = 2.75 Å). The D-H···A systems are all nearly linear and the angles around O1 are close to 110°. When O1 is an acceptor in the O1-H1A···O1 bond, its two hydrogens are of the H1B type and they participate in donor interactions to deprotonated imidazole rings in two complex molecules, while the ring in the third (threefold related) complex molecule is protonated and forms an N11-H11···O1 bond. A number of other instantaneous patterns can be generated by rotating the hydrogen-bonding pattern of either (or both) of the O1 atoms about the threefold axis or by allowing the O1-H1A···O1 bond to be directed up instead of down (inversion via the center of symmetry included in the $\bar{3}$ operation on *c*). In all cases, optimal use is made of the donor–acceptor abilities of the groups that are available to form efficient hydrogen bonds.

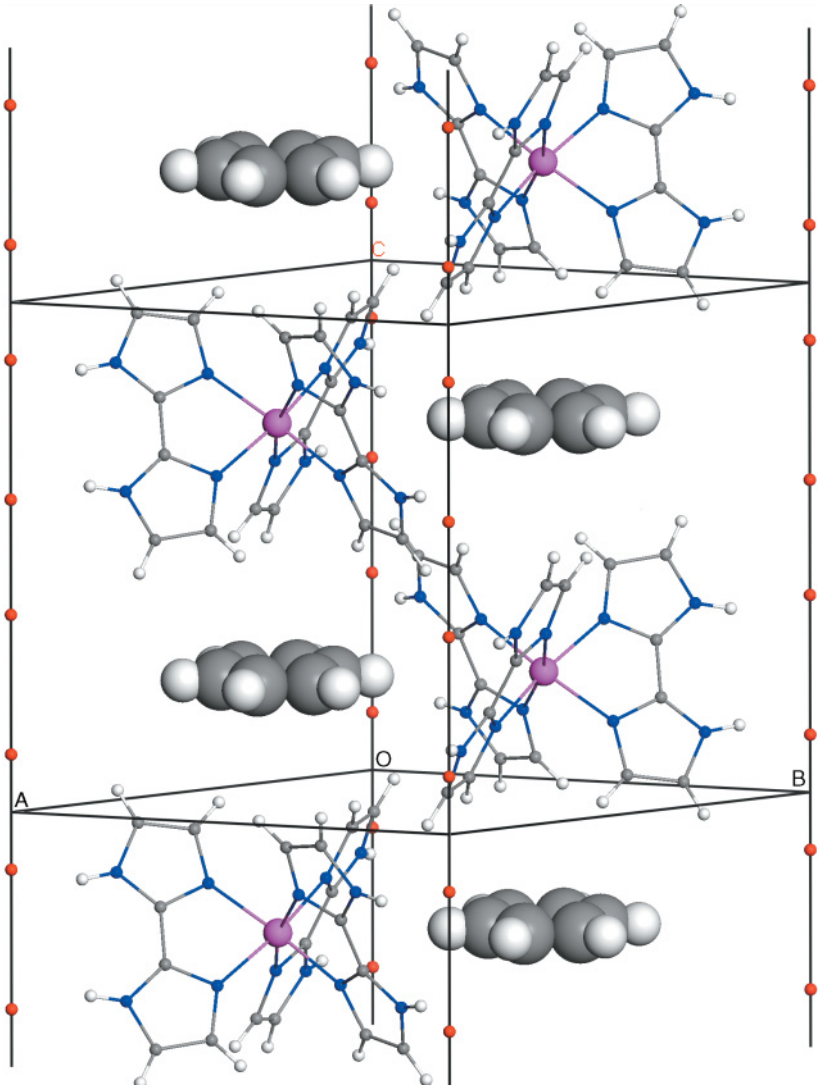
Scheme 1.

1a **1b**



The benzene molecule occupies a crystallographic site of 32 symmetry and the C—H bonds all lie on crystallographic twofold axes (Fig. 6). It sits in a cavity produced by three coplanar complex molecules repeated by the threefold axis through the middle of the benzene ring, together with two more complexes lying on this threefold axis, above and below. Local 32 symmetry implies that the benzene ring is perfectly planar with angles of 120° and identical C—C bond lengths. The observed C—C distance, 1.360(4) Å, is somewhat below the typical aromatic bond length (1.380 Å) (38), but this is probably an artefact of the relatively large thermal motion.

The crystal structure of **2b** also consists of discrete neutral $Cr(Hbiim)_3$ molecules. The asymmetric unit includes two independent molecules, but their structures are not significantly different. Distances and angles are provided in Table S-2.[2]

In this case, the molecules are associated via hydrogen bonding taking place directly between the ligands. The N—H bond and the free N atom are oriented so that a pair of complementary N-H···N bonds can be formed between any pair of ligands facing each other in different molecules; these interactions are strong (N···N separation of 2.67–2.80 Å) and the N-H···N angles (158°–167°) are favourable. In this racemic compound, each Δ enantiomer is surrounded by three Λ enantiomers and vice versa. This alternating sequence of Δ and Λ molecules allows the hydrogen bond pairs formed by a given molecule to take place roughly in

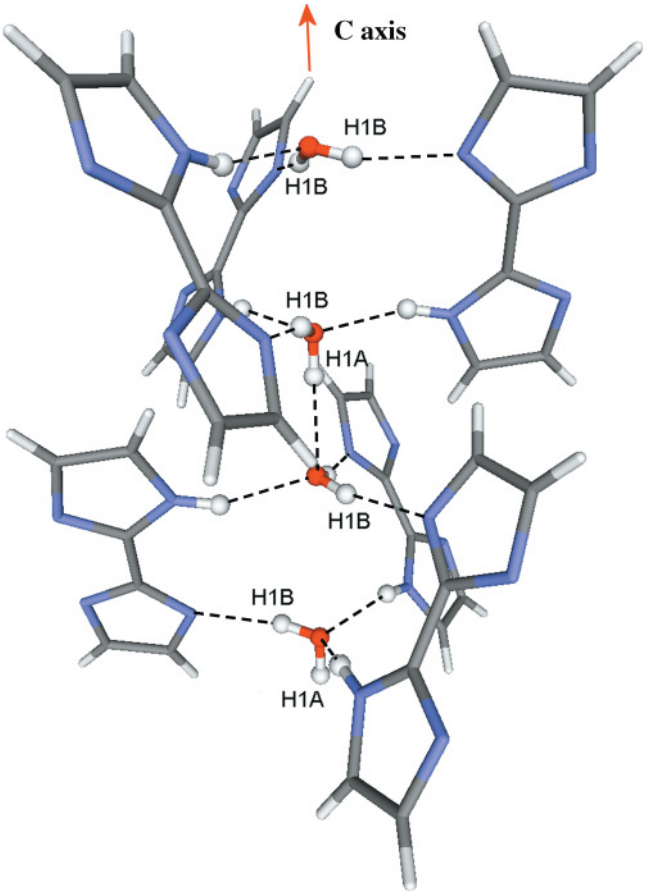
Fig. 4. Unit cell of $Cr(H_2biim)_3 \cdot C_6H_6 \cdot 2H_2O$ (**2a**). Benzene and complex molecules are stacked in alternance along the *c* axis (vertical in the figure). The spheres on the *c* axis represent the oxygen atoms of the water molecules (hydrogens not shown).

the same plane with its three neighbours, generating six-membered rings that propagate into a two-dimensional honeycomb sheet, parallel to the *ab* plane and superposed in the *c* direction (Fig. 7; perpendicular and parallel views of the sheet are provided in Figs. S-3 and S-4).[2] Intersheet contact involves only normal van der Waals interactions. The sheets do not lie exactly above one another, since the repetition by the *c* axis shifts the sheets in the *a* direction (monoclinic β angle of 108°). The fairly large hole in the middle of each hexagon in the honeycomb sheet is also displaced similarly. However, this does not create significant obstruction between the free regions of successive sheets, so that the lattice contains infinite channels parallel to *c* (Fig. 7), each of whose diameter is ~13 Å. The channels are filled with disordered diisopropyl ether molecules.

Geometry of chelated biimidazole



Despite the fact that the ligand is differently protonated in $[Cr(H_2biim)_3]^{3+}$ and $Cr(Hbiim)_3$, no drastic geometrical variations are detected (Tables 2–4 and S-2[2]). It should be mentioned that because the N-H proton is statistically disordered over the two rings in the neutral compound, ring geometry is averaged and any effect of deprotonation is obscured. The only substantial effect of deprotonation is detected on the internal angle C2-N1-C5 at the uncoordinated N atom, which is 108.0° for $[Cr(H_2biim)_3]^{3+}$ and 104.7° for $Cr(Hbiim)_3$. Reduction of ~3°–5° of C-N-C ring angles upon deprotonation is well-documented for related systems (39–41).

The mean Cr—N distance of 2.023 Å (range = 1.98–2.06 Å) is shorter than the values found in structures with various imidazole units (mean = 2.050 Å, range = 2.035–2.068 Å).[3] It is not clear why relatively large distances of 2.154(5)–2.216(5) Å have been observed for the sulphate salt of $[Cr(Hbiim)(H_2biim)_2]^{2+}$ (11). The N-Cr-N bite angle of ~80° is normal for metal ions of this size. No appreciable changes are noted on bond lengths or angles with respect to free 2,2′-biimidazole (43) or 1,1′-dimethyl-2,2′-biimidazole (44). As usually found for chelate formation, the internal

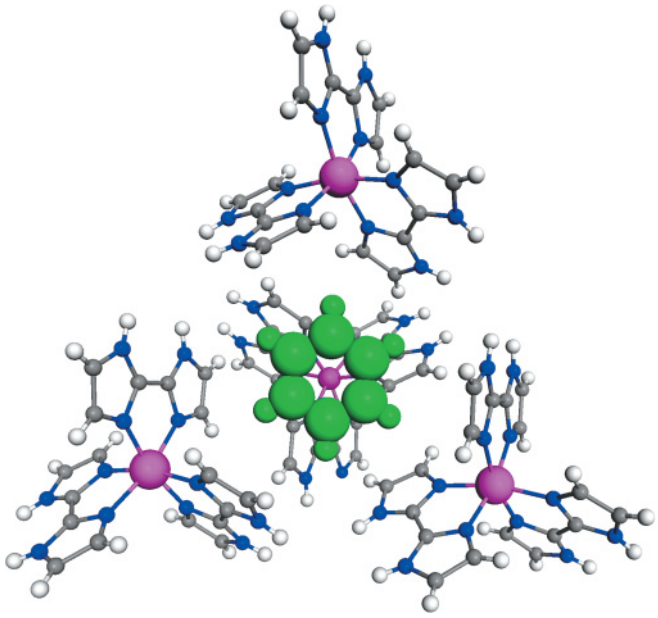
Fig. 5. Possible "instantaneous" hydrogen bonding around the *c* axis (crystallographic threefold axis) of **2a**. H1A and H1B are disordered as a result of the presence of other instantaneous patterns generated by the space group operations.



N3-C2-C2′ angles (mean = 116.2°) are much smaller than the external N1-C2-C2′ angles (mean = 133.8°). The metal atom does not lie exactly about the expected lone pair direction (mean values for Cr-N3-C2 and Cr-N3-C4 of 113.9° and 139.0°, respectively) and it is displaced significantly from the plane of the five-membered ring (mean Cr-to-plane distance = 0.15 Å). All these distortions, together with small relative twists of the rings about the C2—C2′ bond (mean = 5°, maximum = 14°), help chelate formation and contribute to absorbing the stress imposed by molecular packing.

Discussion

The structures of the octahedral trischelates $[Co(H_2biim)_3]^{3+}$ (10, 45) and $[M(H_2biim)_3]^{2+}$ (M = Fe, Co, and Ni) (46, 47) have been described. The solvent-free $[Cr(H_2biim)_3](NO_3)_3$ compound (**1**) reported here adopts the same structure as $[Co(H_2biim)_3](NO_3)_3$. Since both nitrogens are protonated on all ligands, these species can only act as hydrogen bond donors, and crystal organization in these materials depends on the counteranions. Each ligand in $[Cr(H_2biim)_3]^{3+}$ forms two N-H···O(nitrate) interactions and the complex cation is surrounded by nitrate anions, making full use of the hydrogen-bonding capability of the complex. No readily controlled long-range architecture develops, however. Since there is no partner for the third nitrate oxygen to form H-bonds, it participates in dipolar intermolecular interactions of low directionality with C-H protons. When precipitated in methanol, this solvent-free compact phase (**1**) cocrystallizes with a monomethanol solvate crystal (**1a**). Methanol is a good hydrogen bonding partner, but it does not impose strict directional constraints on molecule packing. Thus, although efficient use is made of the available donor and acceptor capabilities of the partners, no structural constraints are built in the methanol molecule and packing is controlled mainly by local packing efficiency.

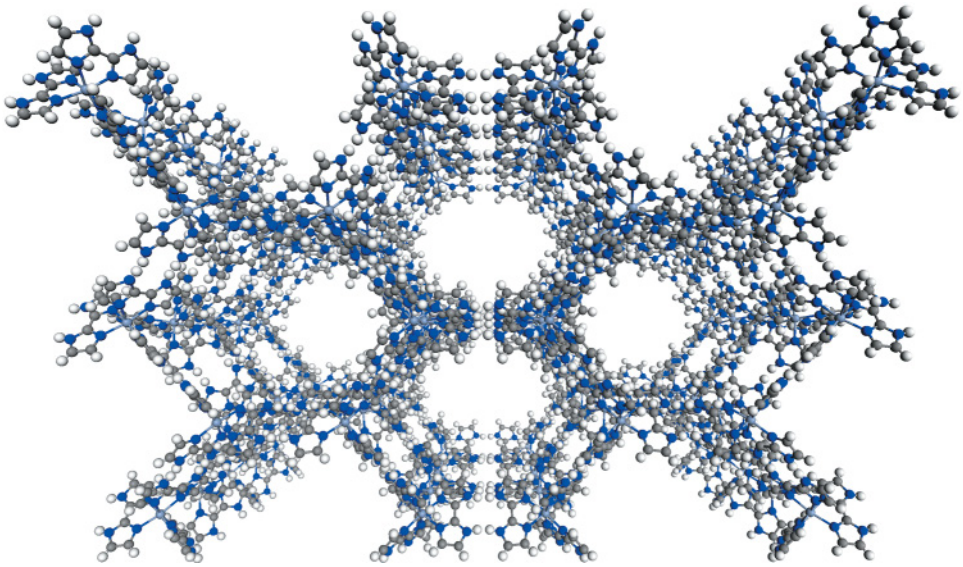


Fig. 6. Pocket containing the benzene molecule in $Cr(Hbiim)_3 \cdot C_6H_6 \cdot 2H_2O$ (**2a**) as viewed down the *c* axis. The pocket consists of three complex molecules related by a threefold axis and coplanar with the benzene molecule, with one molecule behind and an extra molecule in front (not shown).

The neutral $Cr(Hbiim)_3$ unit is a promising building block to create controlled superstructures. Kinetic inertness imparts to the Cr^{3+} centre a relatively long lifetime for architecture generation. The presence of one protonated and one deprotonated ring provides optimal hydrogen-bonding complementarity for each $Hbiim^-$ ligand. The formation of pairs of complementary N-H···N bonds has been observed in a number of cases (8). A series of $A[Ni(Hbiim)_3]$ salts were prepared, and depending on the A^+ cations present, the complex either remained isolated or formed extended uni- or multi-dimensional assemblies. A pattern encountered in these structures is the honeycomb sheet, based on rings of six $M(Hbiim)_3$ units connected via pairs of complementary N-H···N interactions. This pattern, which requires an alternance of Δ and Λ configurations around the ring, can be obtained only with racemic materials. When these honeycomb sheets are stacked with ring centers roughly above one another, they generate infinite channels, as observed for $[Ni(Hbiim)_3]^-$ salts with cations of the type $(K\text{-cryptate})^+$. A related framework has been obtained with $Co(Hbiim)_3$, the channels being filled in this case by methanol and methyl acetate molecules (48). On the other hand, for $Ru(Hbiim)_3$ (9), mutually perpendicular honeycomb sheets are inter-

© 2006 NRC Canada

Fig. 7. View of the solvent-filled channels parallel to the *c* axis of **2b**, running through the middle of the hexagons in the honeycomb sheets

locked to form a compact, solvent-free, three-dimensional framework.

With the present racemic $Cr(Hbiim)_3$ compound, both the compact solvent-free and the porous honeycomb-sheet solvated materials were isolated. The X-ray powder pattern shows that solvent-free $Cr(Hbiim)_3$ is structurally very close to the $Ru(Hbiim)_3$ solid described by Tadokoro et al. (9). Our $Cr(Hbiim)_3$·2.6diisopropyl ether solvate exhibits a structure similar to that of the the ethyl acetate – methanol solvate of $Co(Hbiim)_3$ (48). An unexpected material was obtained when crystallization of $Cr(Hbiim)_3$ took place in a wet atmosphere containing benzene. In this case, both the water and the benzene molecules play a determining role. The hydrogen-bonding ability of $Cr(Hbiim)_3$ was not expressed by direct intercomplex hydrogen bonding, but via properly positioned water molecules. Again, hydrogen bonding is optimized, since the number of hydrogen bond donors and acceptors in the three complex molecules surrounding any given pair of water molecules are perfectly complementary. The resulting layers leave exactly the amount of space necessary to host the benzene molecule.

In summary, $Cr(Hbiim)_3$ appears to be a robust building block and this Cr(III) centre is particularly attractive for the development of tailored magnetic compounds that have many applications in the field of materials science. The metal centre with its d^3 configuration could be coupled with other paramagnetic metal ions to produce molecular-based magnets of great interest. Compounds of Cr(III) with biimidazole ligands might be interesting building blocks for the design of homometallic, heterometallic, or other mixed-valent magnetic compounds. Although protonated and monodeprotonated biimidazole can form bridges between metal ions, the imidazole dianion ($biim^{2-}$) should be much more efficient. The complete deprotonation of H_2biim does not seem to take place very easily, but compounds of the types $[Cr(Hbiim)_2(biim)]^-$, $[Cr(Hbiim)(biim)_2]^{2-}$, or $[Cr(biim)_3]^{3-}$ seem to be very promising building blocks for the assembly of tailored designed uni- or multi-dimensional architectures.

Chemicals and energy from biomass

Lucian A. Lucia, Dimitris S. Argyropoulos, Lambrini Adamopoulos, and Armindo R. Gaspar

Abstract: Approximately 89 million metric tonnes of organic chemicals and lubricants are produced annually in the United States (T.M. Carole, J. Pellegrino, and M.D. Paster. Appl. Biochem. Biotechnol. **115**, 871 (2004)). The majority of these materials are fossil fuel based and may load the environment during use and at the end of their life cycle. Issues, such as disposal, pollution, and degradation, must be considered and weighed. As a result, the need to decrease pollution caused by petrochemical usage is currently impelling the development of green technologies. It is virtually inarguable that the dwindling hydrocarbon economy will eventually become unsustainable. The cost of crude oil continues to increase, while agricultural products see dramatic decreases in world market prices. These trends provide sufficient basis for renewed interest in the use of biomass as a feedstock and for the development of a carbohydrate-based economy as the logical alternative to fossil fuel resources.

Key words: biomass, biochemicals, natural products, bioenergy.

Résumé : Au cours d'une année, aux États-Unis d'Amérique, il se produit environ 89 millions de tonnes métriques de produits chimiques et de lubrifiants organiques. La majorité de ces produits sont obtenus à partir de combustibles fossiles et ils peuvent encrasser l'environnement durant leur cycle d'utilisation et de fin de vie. On doit donc considérer et pondérer des sujets tels que l'élimination, la pollution et la dégradation. En conséquence, la nécessité de diminuer la pollution qui est causée par l'usage des produits de l'industrie pétrochimique propulse le développement de technologies vertes. Il est pratiquement impossible de nier que l'économie basée sur les hydrocarbures ne pourra pas continuer. Le coût du brut continue d'augmenter alors que les prix des produits agricoles sur les marchés mondiaux font face à des réductions dramatiques. Ces tendances sont les bases du nouvel intérêt dans l'utilisation de la biomasse comme matière première ainsi que pour le développement d'une économie basée sur les hydrates de carbone comme alternative logique pour les ressources à base de combustibles fossiles.

Mots clés : biomasse, produits biochimiques, produits naturels, bioénergie.

[Traduit par la Rédaction]

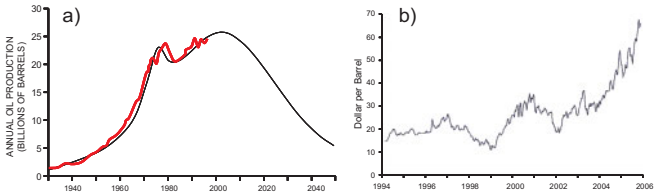
Petroleum — The current resource

Petroleum is the most chemically versatile and important of the fossil fuels, the so-called "biomass of earlier eras" (1). Petroleum is an indispensable resource, whose availability is integral to the functioning of our modern society. However, since the energy crises of the 1970s, the world realizes all too well that petroleum is a finite resource and its availability is limited. Taking into account production and existing reserves, Hubbert (see graph in Campbell (2)) has predicted a maximum peak for oil production (Fig. 1*a*, and see ref. 2) whose timing ominously coincides with current increasing petroleum prices. Yet, the price of petroleum tends to fluctuate, but is very intimately related to world events (Fig. 1*b* and see ref. 3).

In the United States, 40% of the total energy consumption is petroleum-based. This makes it perhaps the world's most important commodity, and obtaining it has been a factor in several military conflicts. Petroleum is primarily used as fuel oil (90% by volume), such as gasoline and diesel fuel. Nonfuel uses include chemical solvents, lubricating oils, and raw feedstock (naphtha and various refinery gases) for many sundry chemicals.

Biomass — The alternative resource

The National Renewable Energy Laboratory (Golden, Colorado) defines biomass as organic matter available on a renewable basis (4). Biomass includes forest and mill residues, agricultural crops and wastes, wood and wood wastes, animal wastes, livestock operation residues, aquatic plants, fast-growing trees and plants, and municipal and industrial wastes. In general, biomass can include anything that is not a fossil fuel that is bioorganic-based.



Biomass provides a naturally abundant resource that is not only cheap but also sustainable. The bioindustry presents an environmentally friendly alternative to the petroleum industry. The productive use of waste residues allows for lower emissions to the atmosphere, since CO_2 from biomass is considered neutral and could have ancillary benefits, such as providing a new source of economic growth for rural communities. Presently, the available biomass resources could provide as much as $6–10 \times 10^{15}$ Btu (1 Btu = 1.055 056 kJ)

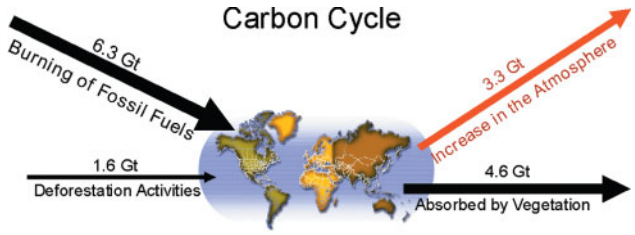
Fig. 1. (*a*) Hubbert's peak oil production. (*b*) Ten day moving average of prices (nominal, not adjustable for inflation) of NYMEX Light Sweet Crude.

of feedstock energy. This corresponds to the energy required to manufacture over 300×10^9 lb (1 lb = 0.453 592 37 kg) of organic chemicals (4).

There exists a real opportunity to discover new ways to produce novel and quality products within the context of sustainability issues that are beginning to permeate recent industrial thinking. In this context, issues such as producing biomaterials from renewable natural resources, are at the forefront. As fossil fuel feedstocks are irreversibly diminishing, environmental pressures are escalating, and the availability of inexpensive crude oil is coming to an end (5–7); thus, the evolution to renewable feedstocks for energy and chemicals seems inevitable (7, 8). The biomass technologies, therefore, have an opportunity to become competitive.



The combustion of fossil fuels contributes to carbon dioxide accumulation in the atmosphere. Its accumulation and deforestation activities are the main culprits behind radical climactic changes in the global environment (9). During the 1990s, annual greenhouse gas emissions to the atmosphere from the burning of fossil fuels was 6.3 Gt (in carbon units) (1 t = 1000 kg) and emissions from deforestation activities was an additional 1.6 Gt (10, 11). Furthermore, it has been estimated that the annual increase of CO_2 to the atmosphere is 3.3 Gt as carbon (12). The remaining 4.6 Gt is absorbed annually by the world's oceans and terrestrial vegetation (11). Figure 2 (see refs. 10–12) is a representation of the carbon cycle mass balance.

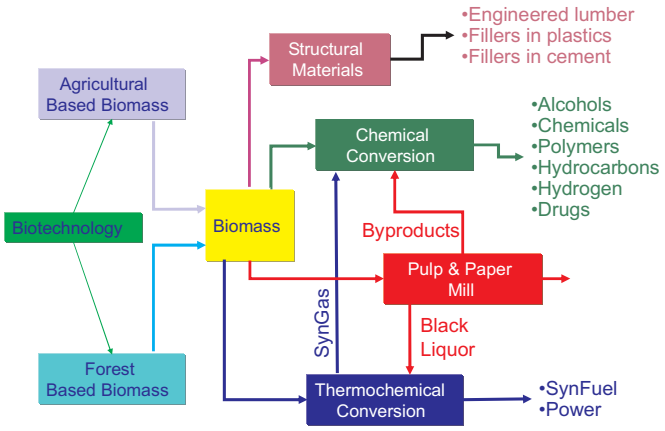
Bioproducts are industrial and consumer goods manufactured wholly or in part from renewable biomass. They are mainly created from primary resources, which are corn, wood, soybeans, and plant oils. The tremendous diversity of bioproducts, ranging from paper to solvents to pharmaceuticals, makes them an integral part of our lives.

Variations in the definition of what should be considered a bioproduct are responsible for disparities in the estimates of the annual usage of biomass in the manufacture of industrial and consumer products. The National Renewable Energy Laboratory estimated that about 21×10^9 lb of biomass were used in 2001 (4). On the other hand, the estimate by Energetics Inc. (Columbia, Maryland) was much more conservative, approximately 12.4×10^9 lb for 2001 (4).

The thousands of different industrial bioproducts produced today can be considered as stemming from sugar and starch, oils and lipids, gum, wood, and finally cellulose (4, 13–16). Annual production of industrial corn starch products is estimated to be 6500×10^6 lb, which corresponds to an estimated value of $2200 million US. Industrial ethanol production is estimated at 3.41×10^9 lb, with an estimated value of $961 million US. Oil- and lipid-based bioproducts include fatty acids and oils derived from soybeans, rapeseed,

Fig. 2. Mass balance of the carbon cycle during the 1990s.

or other oilseeds. Four hundred million pounds of glycerine, equivalent to $320 million US, are produced annually. Over 1200×10^6 lb of soy oil, peppermint, spearmint, and other plant oils produced annually have an estimated value of $550 million US. Gum and wood chemicals include tall oil, alkyd resins, rosins, pitch, fatty acids, turpentine, and other chemicals derived from trees. The annual production of these is approximately 3200×10^6 lb. The value of these is estimated at $890 million US. Cellulose derivatives, fibers and plastics, include products such as cellulose acetate (cellophane) and triacetate, cellulose nitrate, alkali cellulose, and regenerated cellulose. The primary sources of cellulose are bleached wood pulp and cotton linters. Cellulose derivatives have an annual production of 2140×10^6 lb. Their estimated value is $1400 million US.



The use of biomass for energy, materials, and chemicals parallels the concept of the biorefinery, as well as that of sustainability. A biorefinery is a facility that integrates biomass conversion processes and equipment to produce fuels, power, heat, and high-value chemicals from biomass. By-products, residues, and a portion of the produced fuels would be used to fuel the biorefinery itself. A biorefinery might produce transportation fuels (low-value product) in high volumes, high-value chemicals in low volumes, while generating electricity and process heat for its own use, and perhaps produce surplus electricity for sale into the power grid. The high-value products enhance profitability, the high-volume fuel helps meet national energy needs, and the power production reduces costs and avoids greenhouse gas emissions.

The pulp and paper industry has been practicing aspects of the biorefinery philosophy almost since its inception. Indeed, wood is converted into pulp for papermaking and black liquor (liquid phase containing the organic material from wood and the chemicals after the pulping process) is used in the recovery furnace for power and steam generation, while the tall oil is sold for conversion into high-value chemicals. However, one of the unifying themes in all of their biomaterials efforts is the redefinition of the pulp mill as a biorefinery, i.e., a conceptualized site that provides biobased resources and energy that are usually outside the scope of traditional functions. Figure 3 illustrates this concept using a flow diagram. The pulp and paper mill participates in the biorefinery concept by providing raw feedstock (by-products, such as hemicellulose, extractives) that may be chemically converted into a variety of fine chemicals, polymers, and other materials.

For example, Archer Daniels Midland Co. is a chemical company that has an expanded biorefinery in Decatur, Illinois. Their large corn wet-milling plant produces industrial enzymes, lactic acid, citric acid, amino acids, and ethanol.

© 2006 NRC Canada

Fig. 3. Flow diagram that represents the biorefinery concept in pulp, paper, agricultural residues, and related biomass.

Electricity and steam are obtained through an on-site cogeneration system.

Another company that has received a lot of attention for its biorefinery is Cargill Dow (17, 18). Their polylactide facility in Blair, Nebraska, currently relies on corn grain for glucose, which it converts to lactic acid. The plant capacity is 300×10^6 lb, and they project a possible market of 8×10^9 lb by 2020.

With the right technology, abundant biomass resources may be converted into valuable bioproducts and energy. Also, the development of low-cost enzymes and recombinant technologies allows for the engineering of exemplary microbes. These should also be examined in conjunction with chemicals derived from biomass, as they are an essential part of the biorefinery.

Biobased chemicals vs. parallel petrochemicals

Cellulosic biomass or lignocellulosics from plants can be a raw source of sugars for industrial processes. The use of this biomaterial presents several advantages. Theoretically, cellulose and lignin are a less expensive feedstock than petroleum. Moreover, its use would not affect food supplies and chemicals derived from lignocellulosics would have a lower impact on the environment than petrochemicals. Additionally, cellulosic biomass is considered carbon dioxide neutral since its burning does not add any carbon to the atmosphere, beyond what was required for the plant to grow. This makes it a very green, environmentally friendly alternative to fossil fuels.

Presently, only 5% of all global chemical sales are made up of green products derived from natural resources. Nevertheless, this market share has the potential to rise as high as 20% by 2010 and may reach two-third of the total global economy, if technological advances, low-cost enzymes, and new recombinant technologies are made available on a large scale. Consequently, the potential benefits of a bioindustry are enormous and alternate biobased routes for the synthesis of traditionally petrochemically derived products should be carefully examined.

The Pacific Northwest National Laboratory, North Richland, Washington, took part in a collaborative study with the National Renewable Energy Laboratory in an effort to identify the top-tier building block chemicals for biorefineries (19). The top twelve chemicals (Fig. 4) were selected based on their compatibility with existing petrochemical processing as well as their ease of synthesis. The compounds are 1,4 diacids (succinic, fumaric, and malice), 2,5-furandicarboxylic acid, 3-hydroxypropionic acid, aspartic acid, glucaric acid, glutamic acid, itaconic acid, levulinic acid, 3-hydroxybutyrolactone, glycerol, sorbitol, and xylitol–arabinitol. These molecules have six to twelve carbon atoms and multiple functional groups. Examining some of these is worthwhile in the effort to show different synthesis pathways for the same product, as well as product derivatives.

Different synthesis pathways for succinic acid

Succinic acid ($C_4H_6O_4$) occurs frequently in nature in animal tissues, vegetables and fruits, and in amber (20). Succinic acid and its salts may serve as building blocks for numerous chemical intermediates and end products (Fig. 5 and see ref. 21) in industries producing food and pharmaceutical products, surfactants, detergents, green solvents, and biodegradable plastics. Reaction with glycols gives polyesters, and specifically, esters formed by reaction with monoalcohols are important plasticizers and lubricants (22).

The total market for succinic acid is more than $400 million US per year (21). Currently, the food market is the only one using succinic acid produced by fermentation. For other uses, succinic acid is, to a large extent, produced petrochemically from butane through maleic anhydride. Succinic acid can be produced by hydrogenation of maleic acid, maleic anhydride, or fumaric acid with standard catalysts, such as Raney nickel, Cu, NiO, or CuZnCr, Pd-Al_2O_3, Pd-$CaCO_3$, or Ni-diatomite (22).

Succinic acid is a common metabolite for plants and microorganisms. It is derived through the fermentation of glucose and is a very green technology because it is CO_2 fixing. Succinate is formed from sugars or amino acids by propionate-producing bacteria, such as the genus *Propionibacterium*, gastrointestinal bacteria such as *Escherichia coli*, and rumen bacteria such as *Ruminococcus flavefaciens*.

For the rumen ecosystem, succinate is an important precursor for propionate, which after oxidation, provides energy and biosynthetic precursors to the animal. Rumen microorganisms are major cellulose-digesting anaerobes that produce acetic and succinic acids in the rumen (23). *Actinobacillus succinogenes* 130 Z is a ruminal anaerobic bacterium that is capable of producing very high concentrations of succinate from many different substrates, such as glucose, maltose, mannose, sucrose, cellobiose, and D-xylose (24).

Actinobacillus succinogenes uses the phosphoenolpyruviate (PEP) carboxykinase pathway to produce succinic acid (see Fig. 6 and ref. 25). Four key enzymes come into play, PEP carboxykinase, malate dehydrogenase, funarase, and fumarate dehydrogenase. The pathway used for succinic acid production, in which PEP carboxykinase fixes CO_2 and synthesizes oxaloacetate from phosphoenolpyruvate, is regulated by CO_2 levels. At low CO_2 levels (10 mol of CO_2 per 100 mol of glucose), *A. succinogens* produces mostly ethanol. At high CO_2 levels (100 mol of CO_2 per 100 mol of glu-

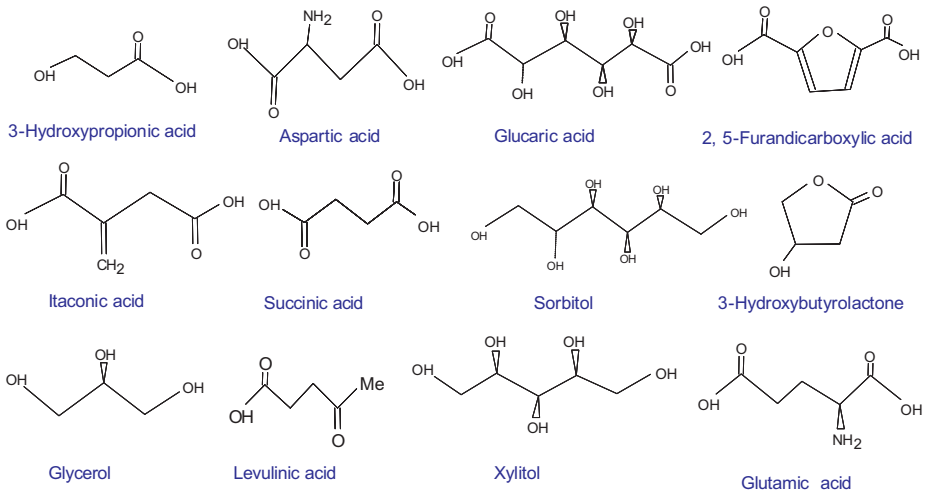

Fig. 5. Map of routes to succinic acid based products.

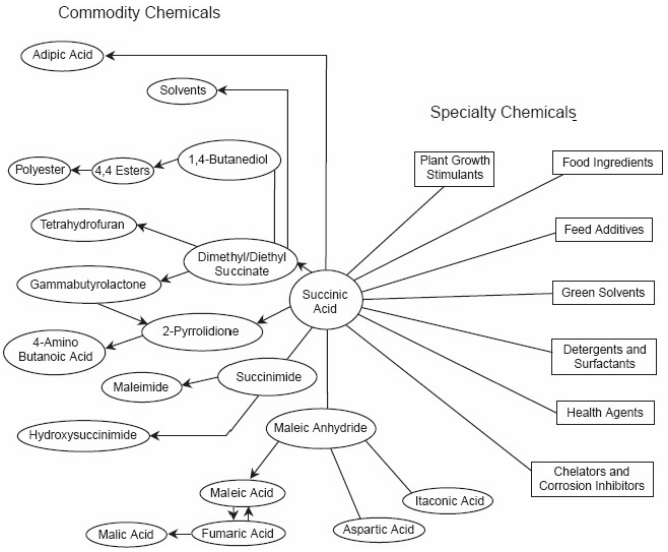

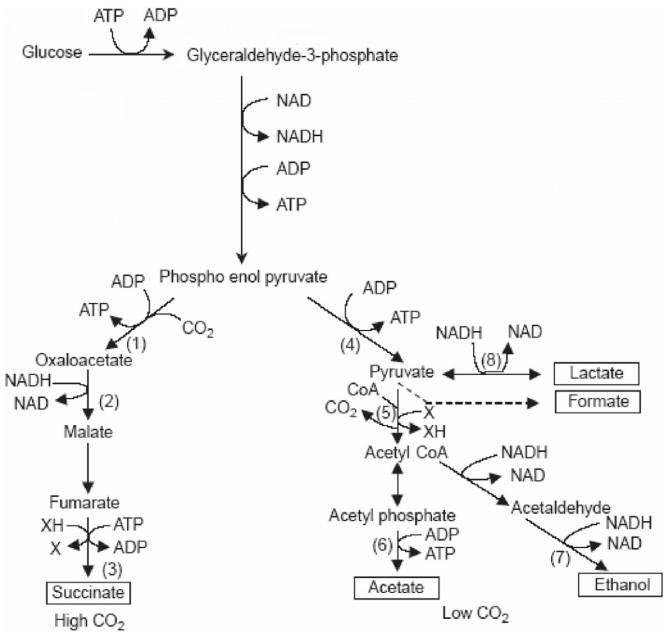

Fig. 6. Proposed catabolic pathway for glucose fermentation in *Actinobacillus succiniciproducens* and *A. succinogens.* Steps: (1) phosphoenolpyruviate carboxykinase, (2) malate dehydrogenase, (3) fumarate reductase, (4) pyruvate kinase, (5) pyruvate ferredoxin oxidoreductase, (6) acetate kinase, (7) alcohol dehydrogenase, (8) lactate dehydrogenase.

cose), succinate is the major product with only trace amounts of lactic acid or ethanol.

In actuality, the CO_2 concentration regulates the levels of the key enzymes in the pathway, thus determining what the majority product will be. At high CO_2 levels, phosphoenolpyruvate carboxykinase levels rise and alcohol dehydrogenase and lactate dehydrogenase are imperceptible. The CO_2 functions as an electron acceptor and PEP flows to succinate at high levels.

Most fermentation organisms are not tolerant of acidic conditions and the fermentation is usually neutralized to obtain a salt of succinic acid. This must then be separated, recovered, and reacidified to form free succinic acid. Significant research in microbial production of succinic acid has resulted in the development of a strain of *E. coli*, AFP111, which shows greatly improved productivity, and fermentation using this microorganism has been successfully tested at a commercial scale (4). Moreover, the development of a two-stage desalting and water-splitting electrodialysis system has facilitated the seperation, concentration, purification, and acidification of the product (26).

In 1992, fermentation production costs for succinic acid ranged from $1.50US to $2.00US per lb (4). Advances in fermentation and especially separation technology for the biobased route have reduced the potential production costs to about $0.50US per pound (21). Further improvements in separation and fermentation technologies could drop the production costs even more, enabling commodity scale production. This would allow for the expansion of current markets and for opportunities in new markets.

Different synthesis pathways for itaconic acid

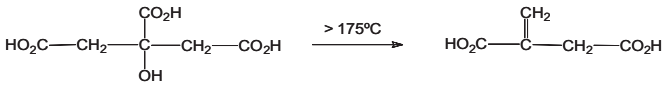
Itaconic acid (2-methylenebutanedioic acid) is an unsaturated dicarbonic acid. It can be regarded as an α-substituted

© 2006 NRC Canada

acrylic of methacrylic acid and may serve as a substitute for these petrochemical-based chemicals. On account of its two carboxyl groups, itaconic acid may easily be incorporated into polymers.

Currently, polymerized methyl, ethyl, or vinyl esters of itaconic acid are used as plastics, adhesives, and coatings. Also, it is used as a comonomer in rubberlike resins and in the manufacture of emulsion paints, where it improves the adhesion of the polymer. Acrylic lattices are supplemented with itaconic acid and used as nonwoven fabric binders. Furthermore, itaconic acid may have agricultural, pharmaceutical, and medicinal applications. It is used as a hardening agent in organosiloxanes for use in contact lenses. In addition, mono- and di-esters of partly substituted itaconic acid possess analgesic properties and some also present plant growth related activities.

The first synthesis of itaconic acid was by pyrolysis of citric acid and anhydride hydrolysis (S. Baup. Ann. Chim. Phys. **19**, 29 (1837)) (Fig. 7 and ref. 27). Similarly, chemical synthesis is mainly carried out by dry distillation of citric acid and treatment of the anhydride with water. However, use of itaconic acid has been limited because the petroleum route is still expensive. It cannot compete with the fermentation of carbohydrates by fungi as a source of itaconic acid. In fact, approximately 15 000 t of itaconic acid are produced annually by fermentation. Production rates do not exceed 1 g L^{-1} h^{-1} and production concentrations of 80 g L^{-1} (28). This makes itaconic acid an expensive product, whose use is therefore limited.



The biosynthesis of itaconic acid most probably happens through glycolysis, followed by the tricarboxylic acid cycle. Citric acid and aconitic acid are intermediates. Enzymatic decarboxylation of the latter allows for the formation of itaconic acid (Fig. 8 and ref. 28).

The most frequently used commercial application of itaconic acid is the cultivation of *Aspergillus terreus* with molasses. Molasses products are less expensive than other kinds of carbohydrates, but the cost of itaconic acid is still high because molasses contain many impurities that are not consumed by microorganisms. So, downstream processing and waste treatment therefore become expensive. Thus, alternate carbon sources are being examined. The best yields of itaconic acid are achieved with glucose or sucrose, but these are expensive raw materials. Raw starch materials show particular potential as a substitute to molasses. Itaconic acid was produced by *A. terreus* TN-484 in a medium containing raw corn starch (140 g L^{-1}) at pH 2.0, hydrolyzed with nitric acid at a concentration of more than 60 g L^{-1} in a 2.5 L air lift bioreactor (29).

Efforts are also being made in the selection of different microorganisms, such as various *Ustalgo* and *Candida* species. Furthermore, mutant microorganisms are also being produced and used to increase yields and biomass immobilization is being considered.

Finally, fermentation conditions are important and must be optimized. The itaconic acid fermentation is most favorable under phosphate-limited growth conditions at sugar concentrations between 100 and 150 g L^{-1}. During fermentation, the pH drops to 2.0 and itaconic acid becomes the main product. The temperature is normally kept at 37 °C, but certain mutated microorganisms may perform better at higher temperatures. Also, aerobic conditions are required and culture medium components, such as Fe, Mn, Mg, Cu, Zn, P, and N, must be carefully monitored.

Fig. 7. Thermal decomposition of citric acid.

The market for itaconic acid is still growing because of the possibilities of substituting it for acrylic and methacrylic acid in polymers. Moreover, its potential production from agricultural plant biomass makes it an attractive biofriendly alternative. It also provides a source of inexpensive raw feedstock. Efforts in effectively utilizing such waste, as well as the introduction of new technologies, are required for reducing itaconic acid production costs and market expansion.

Synthetic pathways for levulinic acid

Levulinic acid ($H_8C_5O_3$), also known as γ-ketovaleric acid, β-acetylpropionic acid, or 4-oxopentanoic acid, is a short chain fatty acid with a ketone carbonyl group and an acidic carboxyl group. These two highly reactive functional groups make it a highly versatile chemical capable of serving as a building block for other chemicals (Fig. 9 and ref. 30). Levulinic acid is the starting compound for many heterocycles. It can be used as a raw material for resins, plasticizers, textiles, animal feed, coatings, and antifreeze. It is an auxiliary in electroplating and levulinic acid esters are used in cosmetics.

Industrially, levulinic acid is prepared from wood processing and agricultural wastes. It basically hails from the transformation of hexose sugars in acidic media. The hexoses are obtained by the hydrolysis of cellulose at atmospheric pressure with strong acids, such as HCl and H_2SO_4, at 100 °C. The hydrolysate is then heated to 110 °C with 20% HCl and kept at this temperature for 1 day. Free halogens, as well as transition metals and anion-exchange resins, accelerate the process.

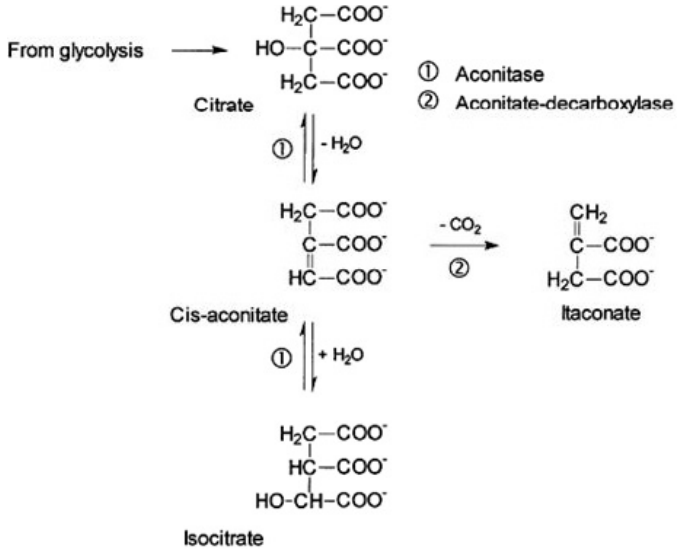
Initially, the intermediate compound 5-hydroxymethyl furfural is formed from the hexoses. This happens through a series of reactions (Fig. 10 and ref. 31). The first step is the enolization of D-glucose, D-mannose, or D-fructose in acidic media to give the enediol. Next, this compound is dehydrated to the enol form of 3-deoxyhexosulose. This substance then produces 3,4-dideoxyglycosulosene-3, which is converted to the dienediol that results in 5-hydroxymethylfurfural (31).

5-Hydroxymethylfurfural can then be converted to levulinic acid by addition of a molecule of water to the C2—C3 bond of the furan ring. The ring opens and an unstable tricarbonyl intermediate is formed, which is finally decomposed to formic and levulinic acids (Fig. 11 and ref. 31). Levulinic acid is isolated from the mixture with a yield of approximately 40% with respect to the hexose content (31). Furthermore, for each levulinic acid molecule generated, a formic acid molecule is also created and insoluble residues, including humics, are produced.

Furthermore, levulinic acid can be synthesized starting from furfuryl alcohol (Fig. 12 and ref. 31). Heating furfuryl alcohol in aqueous organic acids in the presence of hydrochloric acid allows an 80% yield of levulinic acid. The yield

© 2006 NRC Canada

Fig. 8. Biosynthesis of itaconic acid.



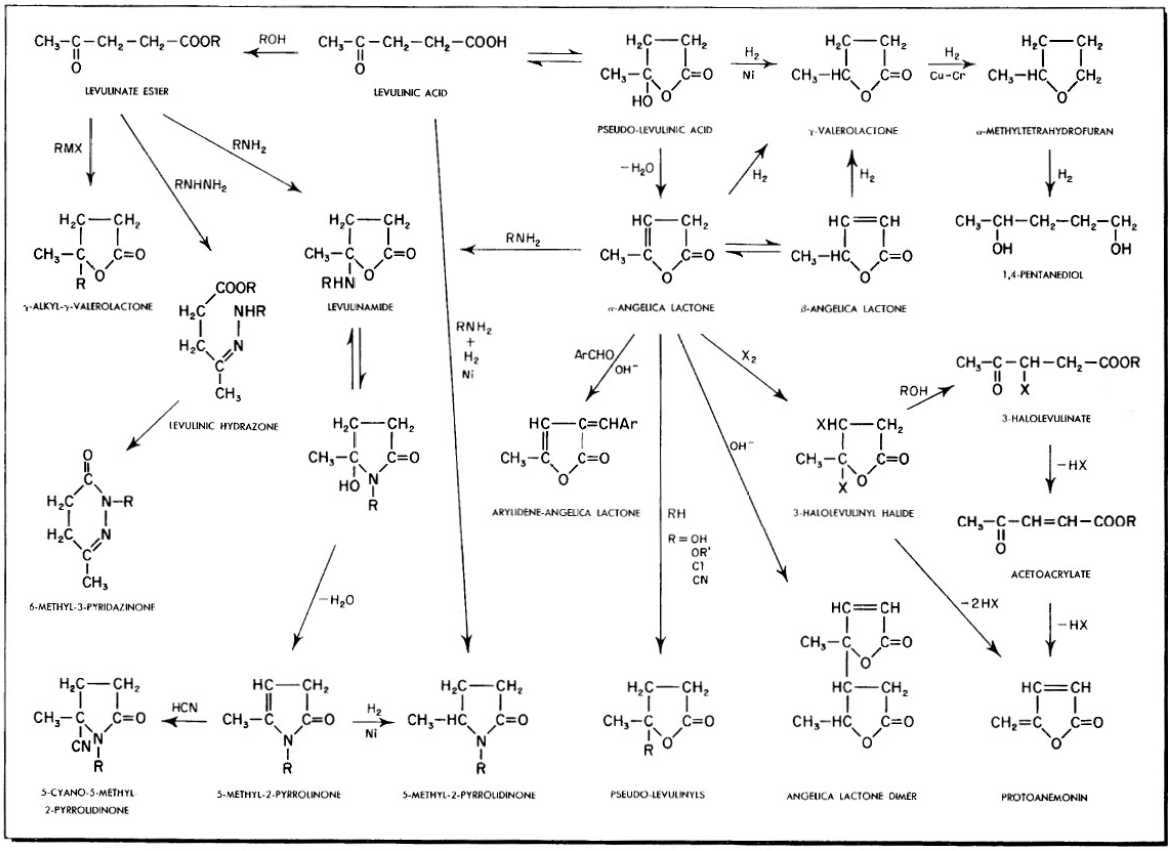


Fig. 9. Principal reactions of levulinic acid and relationships among its derivatives.

can be increased to approximately 90% when the reaction is performed in boiling ethyl methyl ketone.

Moreover, the oxidation of 5-methylfurfural with 28% H_2O_2 at 60 °C in the presence of HCOOH produces levulinic acid, as well as 4-oxopent-2-enoic acids (Fig. 13 and ref. 31). Levulinic acid can also be formed in high yields from the reaction of 4-(diphenylmethylsilyl)butyrolactone with MeMgI.

Levulinic acid can also be prepared from biomass, such as rice, straw, paper, and cotton (32). In this case, biomass is reacted at 40–240 °C for 1–96 h in the presence of 5%–90% sulfuric acid. Another substrate that can be used for levulinic acid production is sorghum grain. It has low cash value when sold as a feed grain and is a major source of carbohydrates. Pentosans, starch, and cellulose make up 80%–85% of the sorghum grain. Flour made from this grain at a 10%

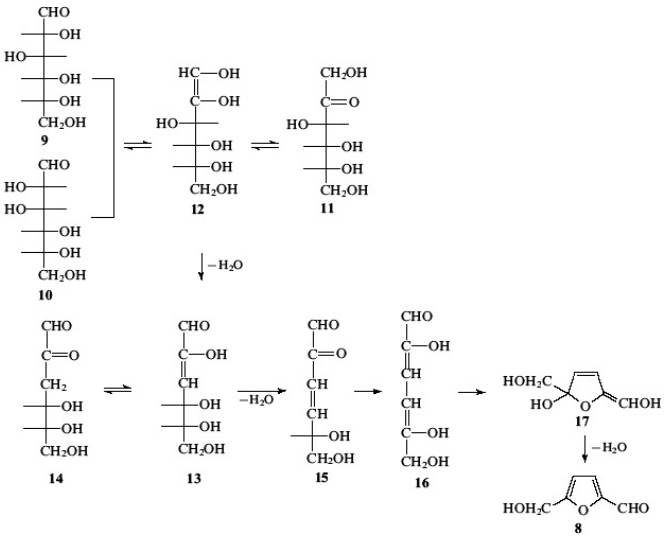
Fig. 10. 5-Hydroxymethylfurfural (**8**) obtained from D-glucose (**9**), D-mannose (**10**), or D-fructose (**11**).



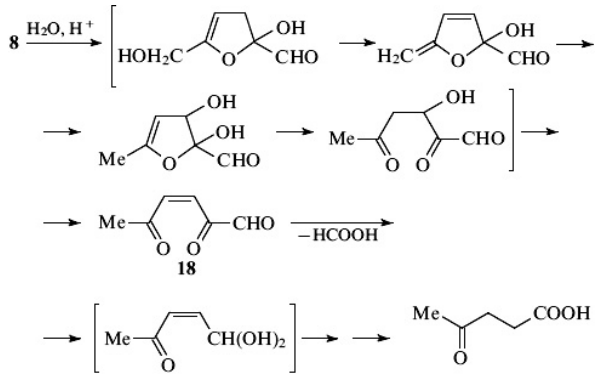


Fig. 11. 5-Hydroxymethylfurfural to levulinic acid.

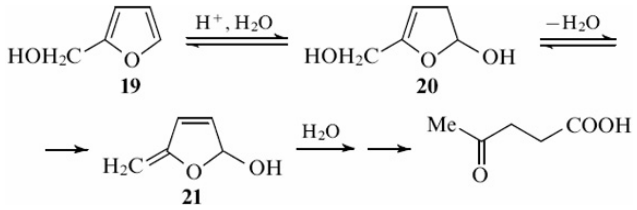
loading and blended with 8% sulfuric acid gives a yield of approximately 33% levulinic acid at 200 °C (33).

Finally, a two-step dilute mineral acid hydrolysis is available, the Biofine process (34), to break down biomass containing lignocellulose into intermediate chemicals. It was developed by BioMetics Inc. (Camarillo, California), with funding from the US Department of Energy. This high-temperature, dilute acid hydrolysis process fractionates lignocellulosic biomass into platform chemicals. The primary fractions of the process are levulinic acid, formic acid, furfural, and a bone dry char. The char residue contains approximately 11 000 Btu per lb and is a suitable feedstock for gasification.

BioMetics has operated a small commercial demonstration unit in New York State for four years and has just completed the first large-scale commercial facility in Italy. This large-scale facility will produce levulinic acid for monomer use, oxygenated diesel esters, and formic acid based solvents. The char residue will be converted to synthesis gas that will be burned in a gas engine to generate electricity. Approximately 0.5 lb of levulinic acid is produced per lb of cellulose processed (4). Currently, levulinic acid has a worldwide market of about 1.0×10^6 lb per year at a price of

Fig. 12. Levulinic acid from furfuryl alcohol (**19**).



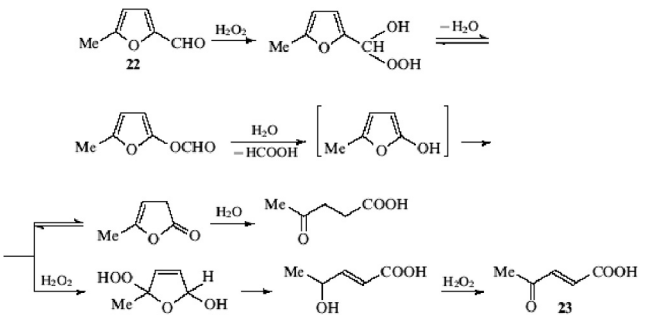


Fig. 13. Oxidation of 5-methylfurfural (**22**) to levulinic acid.

$4US–$6US per lb (35). Large-scale commercialization of the Biofine process could produce levulinic acid for as little as $0.32 per lb (35), spurring increased demand.

In parallel with the process development program, BioMetics has an ongoing program aimed at expanding commercial markets for the chemical derivatives of levulinic acid in cooperation with New York State, Rensselaer Polytechnic Institute (Troy, New York), the National Renewable Energy Laboratory, the Pacific Northwest National Laboratory, and major chemical companies.

This effort has allowed for the development of a one-step catalytic process facilitating the conversion of levulinic acid to methyl tetrahydrofuran (MTHF) approved for P-series alternative fuel formulations (36). Also, it has provided a low cost route to the herbicide and plant growth regulator, δ-aminolevulinic acid. New polycarbonate resin formulations using diphenolic acid are being examined and a new oxygenated diesel additive (ethyl levulinate) that reduces particulate matter emission has been developed.

The Biofine process allows for the manufacture of many high-value chemical and fuel products from cheap lignocellulosic biomass. This process is fast and continuous and is capable of utilizing a wide range of biomass feedstocks. Moreover, the gasification of the char covers the entire energy needs of the plant, making it self-sufficient. Finally, the process can be retrofitted into existing plants.

Levulinic acid is a compound that has many industrial applications. Its efficient preparation from biomass has many avenues. Its efficient extraction from decomposition products of natural materials would prove to be worthwhile for both industry and the environment.

Sample reactions for high-value chemicals

As opposed to many synthetic chemicals, forest-based and agricultural biomaterials are readily renewable, inexpensive, and environmentally benign. Despite a significant amount of recent research for augmenting the industrial use of readily

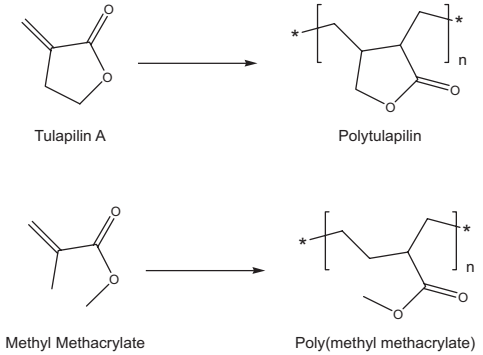
Fig. 14. Shown in the top structure is the natural product extract, tulapilin A (A–α-methylenebutyrolactone), found in tulips, and in the lower structure is its synthetic analogue, methyl methacrylate. Notice the strong chemical structural similarity in both the monomer and polymer.



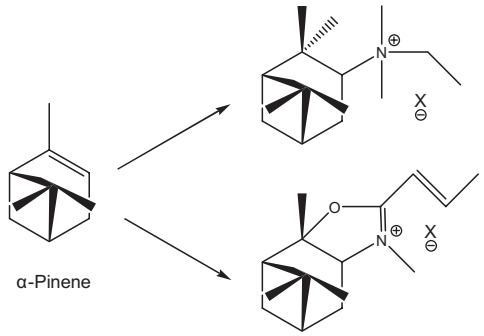


Fig. 15. Structure of α-pinene, a natural extractive from pine trees, which can be converted to two distinct chiral ionic liquids.

available carbohydrates as raw materials (37–42) (e.g., car moldings, cosmetics, food, and additives), the systematic exploitation of this vast resource, as already indicated, is still in its infancy. Since clean air pressures are mounting and while the availability of cheap and abundant fossil fuel becomes increasingly questionable, as seen in the current climate, it is likely that any economic advantages for a petrochemical-based economy will literally evaporate within the next 50 years.

For example, DuPont has determined that once the price point at which an extract from plants, tulipalin A (A–α-methylenebutyrolactone) shown in Fig. 14, becomes competitive with its commercial analogue, methyl methacrylate (MM), the natural material will be used commercially for polymer applications (43). MM is a feedstock that is used for polymerization to manufacture a number of plastics, moldings, and related materials. Its natural analogue (tulapilin A) produces a polymer whose durability and refractive index rival that of MM (43). Remarkably, DuPont has also found that limonene, a citrus tree extractive, mimics the chemistry of 4-vinyl-1-cyclohexene in that it can be used as an anchoring point for the introduction of alkoxylsilanes for exterior coatings (43).

An early example of a biobased green solvent is a new class of chiral ionic liquids that can be derived from α-pinene, an extract from pine trees, as shown in Fig. 15. Ionic liquids are salts that are liquid at or near room temperature. As such, they are composed of an anion and a cation, like any salt, but they do not have the high melting points typical of such species. Since the combination of organic cations and anions is virtually limitless, several classes of ionic liquids have actually been reported, with more and more such systems being continually discovered.

Energy derived from biomass

Since antiquity, biomass has been used by humanity as a source of energy, mainly for heating. Nowadays, new developing energy technologies are broadening the use of biomass well beyond simple combustion for heating. The conversion processes used on biomass feedstock allow the generation of steam and electric power, as well as a wide range of energy products, such as ethanol, biodiesel, fuel gas, and chemical intermediates and products. The conversion of biomass feedstock into energy products are well-established technologies, with enhanced improvements in the last decades. This subject was reviewed by Paisley (44).

Steam and electric power

Biomass has been used for simple heating by direct combustion, which by nature is a very low efficient operation (~7% for an open fireplace and ~15% for a fireplace with convective tubes) (45). Efficiency improvements are realized by larger scale combustion processes in boilers or furnaces, thus improving heat recovery, and therefore, overall efficiency.

Boiler applications further provide the opportunity to generate electrical power from the incoming biomass. The biomass is burned to generate steam, which is then used to turn a turbine to generate electric power. The majority of the biomass-based power plants are found in the pulp and paper industry. Woody residues from the wood raw material and the black liquor, a by-product from the pulping process, are consumed to generate the necessary power for plant operations. When black liquor is burned for energy recovery, the pulping chemicals are recovered and recycled, thus further reducing the costs.

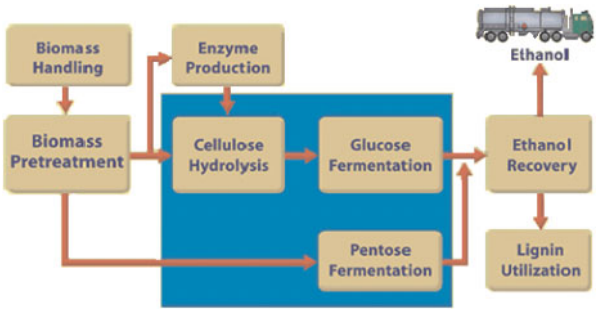
Biomass-based combined heat and power (CHP) systems provide the primary energy for large segments of the population in many European countries, mainly Scandinavian and northern countries. These systems typically combust biomass to produce high-pressure steam for further electric power generation. Lower-pressure steam is then extracted from the turbine system and used for district heating.

Ethanol

Ethanol production is known historically from the manufacture of alcoholic beverages, such as wines and beers. It is produced through natural fermentation of the starch and sugars present in different forms of biomass by biological organisms. Nowadays, grains of wheat or corn (biomass materials) are typically the primary source for the production of ethanol as fuel, which can be blended with other fuels such as gasoline (46, 47). Other sources for ethanol

© 2006 NRC Canada

production that are also in use are straw, sugar cane, sugar beet, and wood (48).



Large-scale production of ethanol makes use of the fermentation process as well. In a first stage, biomass material, such as corn kernel or other starchy grain, is milled through a dry or wet milling mode. The fermentation then takes place by mixing the resulting flour (biomass polysaccharides) in water with yeast. The mixture is heated at ~30 °C to initiate the fermentation reactions under an anaerobic environment, and the process takes ~1 to 2 days for completion. After fermentation, the ethanol is filtered and then distilled to increase its concentration from 10% to 95%. The concentrated ethanol is then blended with petroleum-based fuels to the desired concentration.

Ethanol can also be produced from cellulosic biomass such as agricultural residues, forestry residues, waste paper, yard wastes, portions of municipal residues, and industrial residues (49). The long-chain polysaccharide materials are initially treated with acid or enzymes to cleave the glycosidic bonds. The acid recovery system can be a complex process. Research is being performed to find ways to reduce the acid levels while maintaining high conversion levels. The resulting small fractions can then readily be fermented to ethanol. In parallel, small fractions of biomass can be used to grow fungi and other organisms to produce enzymes (cellulase), which hydrolyze cellulose (in pretreated biomass) to glucose. Figure 16 (see ref. 49) presents a scheme for the production of ethanol from cellulosic biomass (49). There are a variety of technologies that combine two or all three of the hydrolysis and fermentation steps within the shaded box.

US ethanol production has grown significantly in recent years. In 2004, a record 3.41×10^9 gal (1 gal Am. = 3.79 L) of ethanol were produced — an incredible 109% increase from 2000 (50). But ethanol plants also produce other products. Depending on the type of facility, a number of other coproducts result from ethanol production, adding even more value to corn feedstocks and to the economy. Dry mill facilities also produce distillers dried grain with solubles (DDGS) and carbon dioxide. Ethanol wet mills can also produce corn gluten meal feed, sweeteners, and corn oil. These coproducts and by-products from cellulosic biomass ethanol production can be used to produce value-added chemicals, contributing to the economy of fuel production from biomass. On the other hand, ethanol can also be used as a chemical intermediate in the production of other organic chemicals.

Oxygenated transportation fuels, such as the ethanol–gasoline blends, can benefit environmental conditions. Mixtures of up to 10% ethanol, referred to as E10, can be utilized in most gasoline engines with no modification. More concentrated blends, namely the E85 and E95 blends (85% and 95% ethanol, respectively) require specifically designed engines, referred to as "flexible fuel" engines, to perform properly. These flexible fuel engines can run on either gasoline or high-concentration ethanol blends. Automobile manufacturers are producing more vehicles that can use these high ethanol blends each year, thus increasing demand. The spark-ignition Otto-cycle engines used in today's automobiles, even in their early stages of development, were designed to operate with ethanol-containing fuels. Henry Ford designed the early Model T to use ethanol as a major fuel source. Such plans were subsequently changed when storage and transportation difficulties, combined with high corn prices at the time caused the supply of ethanol-containing blends to be reduced.

Fig. 16. Basic steps in production of ethanol from cellulosic biomass.

Biodiesel

Biodiesel is a fuel that can be made from renewable resources such as vegetable oils or animal fats. It is usually produced from soy or canola oil. Other possible resources are recycled fryer oils. Through a transesterification process, the oils are converted into biodiesel. The latter can be used as pure fuel or blended at any level with petrodiesel for use by diesel engines. Biodiesel is designated B100 and meets the requirements of ASTM D6751 (51).

Biodiesel comprises of a mix of monoalkyl esters of long-chain fatty acids. A lipid transesterification reaction is used to convert the base oil to the desired biodiesel. The most common process uses methanol to produce methyl esters, although ethanol can also be used to produce an ethyl ester biodiesel. In the production of biodiesel, the triglicerides in the oils and fats are reacted with methanol (or ethanol) to make methyl esters (or ethyl esters) and glycerol as a by-product. The process uses a catalyst, typically NaOH or KOH, to enhance the reaction rates. Some oils may have to undergo some pretreatment before reaction with methanol to avoid the formation of high concentrations of free fatty acids. The reactions take place at low temperatures (~65 °C) and at modest pressures (2 atm, 1 atm = 101.325 kPa). Biodiesel is further purified by washing and evaporation to remove any remaining methanol. The oil (87%), alcohol (9%), and catalyst (1%) are the inputs in the production of biodiesel (86%), the main output. Other by-products include glycerine (9%), alcohol (4%), and fertilizer (1%). Nothing is wasted in biodiesel production (52).

Biodiesel can be a direct substitute for petrodiesel, either as neat fuel (B100 or BD100) or as an oxygenate additive at any concentration, blended with diesel. Typically, the biodiesel that is primarily utilized is the B20 blend (20% biodiesel and 80% petrodiesel). Pure biodiesel or blends can be used in any compression-ignition (diesel) engine. B20 earns credits for alternative fuel under the US Energy Policy Act of 1992. Ranges as low as 2% (BD2 or B2), have shown lubricity benefits (53). In 2004, almost 30×10^6 gal of commercially produced biodiesel were sold in the US, up from less than 0.5×10^6 gal in 1999 (54). Because of increasing pollution control requirements and tax relief, the US market is expected to grow to 1 or 2×10^9 gal by 2010.

© 2006 NRC Canada

Looking back, Rudolf Diesel had successfully presented his engine powered by peanut oil (biofuel) at the World's Fair in Paris, France, in 1900, where he received the "Grand Prix" (highest prize). He believed that the utilization of biomass fuel was the real future of this engine. In a prophetic 1912 speech, Rudolf Diesel said, "the use of vegetable oils for engine fuels may seem insignificant today, but such oils may become, in the course of time, as important as petroleum and the coal–tar products of the present time" (55).

Conclusions

In retrospect, the petroleum age has served the growth of civilization quite well. However, it has also become an albatross to further growth, given its intrinsic deficiencies for environmental compatibility, sustainability, and micro- and macro-economics. As Rudolph Diesel so astutely intimated, we are now at the nexus of a major crossroads in the future of humanity with respect to the production of chemicals, materials, and energy. The only real solution that is viable and necessary is the efficient and intelligent use of biomass as derived from plant and animal residues. Capturing the chemical and material value of bioderived succinic, itaconic, and levulinic acids, as indicated in this review, will provide the world with freedom from the economic and geopolitical uncertainties associated with petroleum dependency. In addition, tapping into biobased fuel sources, such as ethanol and biodiesel, expands that horizon considerably by supporting environmental stewardship by their renewable nature and carbon neutrality. North Carolina State University realizes the importance of achieving this biomass age and is therefore poised by virtue of its faculty, research mission, and resources to promote it and thereby improve the world.

Synthesis and characterization of [M^{II}(bqb)] (M = Co, Ni, Cu), [N(*n*-Bu)$_4$][Co^{III}(bqb)(CN)$_2$], and [N(*n*-Bu)$_4$][Co^{III}(bqb)(N_3)$_2$] containing deprotonated *N*,*N*′-bis(2-quinolinecarboxamide)-1,2-benzene (bqb) — X-ray crystal structures of [Ni^{II}(bqb)] and [N(*n*-Bu)$_4$][Co^{III}(bqb)(N_3)$_2$]

Soria Meghdadi, Mehdi Amirnasr, Vratislav Langer, and Alison Zamanpoor

Abstract: Cobalt(II), nickel(II), copper(II), and two cobalt(III) complexes of a new dianionic ligand, bqb, [H_2bqb = *N*,*N*′-bis(2-quinolinecarboxamide)-1,2-benzene] have been synthesized and characterized by elemental analyses, IR, and ^{1}H NMR spectroscopy. The crystal and molecular structures of the [Ni(bqb)] (**2**) and [N(*n*-Bu)$_4$][Co^{III}(bqb)(N_3)$_2$] (**5**) complexes were determined by X-ray crystallography. Complex **2** crystallizes in the monoclinic space group *C*2/*c* with a distorted square-planar structure including two short Ni—N (1.848 Å) and two long Ni—N (1.958 Å) bonds. The structure consists of sheets formed in the plane parallel to the *b* axis and diagonal to vectors ***a*** and ***c*** by intermolecular hydrogen bonds. Complex **5** crystallizes in the monoclinic space group *C*2 with a distorted octahedral structure. The [N(*n*-Bu)$_4$]$^+$ ion is disordered at the C3A and C4A atoms of one Bu. The IR and ^{1}H NMR spectra of the complexes are also discussed.

Key words: N_4-dianionic amido ligand (bqb), (bqb) complexes of Co(II), Ni(II), Cu(II), and Co(III), azide, cyanide, X-ray crystal structures.

Résumé : On a réalisé la synthèse de complexes du cobalt(II), du nickel(II), du cuivre(II) et de deux complexes du cobalt(III) avec un nouveau ligand dianionique, bqb, [H_2bqb = *N*,*N*‘-bis(quinoléine-2-carboxamide)-1,2-benzène] et on les a caractérisés par analyses élémentaires, spectroscopies IR et RMN du ^{1}H. Faisant appel à la diffraction des rayons X, on a déterminé les structures cristallines et moléculaires des complexes [Ni(bqb)] (**2**) et [N(*n*-Bu)$_4$][[Co^{III}(bqb)(N_3)$_2$] (**5**). Le complexe **2** cristallise dans le groupe d'espace monoclinique *C*2/*c* avec une structure plan carré déformée comportant deux liaisons Ni—N courtes (1,848 Å) et deux liaisons Ni—N longues (1,958 Å). La structure est formée de feuillets alignés dans un plan parallèle à l'axe b et à la diagonale des vecteurs ***a*** et ***c*** par des liaisons hydrogènes intermoléculaires. Le complexe **5** cristallise dans le groupe d'espace monoclinique *C*2 avec une structure octaédrique déformée. L'ion [N(*n*-Bu)$_4$]$^+$ est désordonné au niveau des atomes C3A et C4A d'un des Bu. On discute aussi des spectres IR et RMN du ^{1}H des complexes.

Mots clés : ligand amido N_4-diatomique (bqb), complexes (bqb) du Co(II), du Ni(II), du Cu(II) et du Co(III), azide, cyanure, structures cristallines par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

The coordination chemistry of the dianionic organic amide ligands has been of great interest because of their role in biologically important coordination compounds (1–5). Structural modification of these ligands by altering the diamine backbone or by the introduction of suitable substituents in the pyridine nuclei makes the ligands attractive for stabilizing metals in high formal oxidation states (6–10), influencing the reactivity of metal centers (5, 8, 11), designing

Scheme 1.

sensitive and selective tools for specific analytical applications (12, 13),[2] and for providing catalysts with significant catalytic activity (8, 14).

Vagg and co-workers (15, 16) developed a series of acyclic tetradentate ligands with two central amide groups and two terminal pyridine groups. These and other related ligands act as chelating agents to form monomeric, dimeric, and polymeric complexes with transition-metal ions (17–19). The deprotonated anionic ligand is a strong σ donor that usually acts as a planar tetradentate N_4 ligand in the structure of square planar, square pyramidal, or octahedral complexes.

As part of our continued interest (17) in the transition-metal chemistry of dianionic bis(amide) in-plane ligands, we herein describe the synthesis and spectroscopic characterization of Co(II), Ni(II), Cu(II), and Co(III) complexes with the new bis(amide) ligand bqb(2-) [H_2bqb = *N*,*N*-bis(2-quinolinecarboxamide)-1,2-benzene] (Scheme 1). We have recently used the ligand for the construction of a Ho(III)-selective electrode (13), and we have obtained promising results using the [Co^{II}(bqb)] complex as a sensor for the potentiometric determination of cyanide.[2]

Contrary to [Co^{II}(bpb)], H_2bpb = *N*,*N*-bis(2-pyridinecarboxamide)-1,2-benzene, which is fairly reactive towards oxidative addition of σ donor amines like pyrrolidine (17), the reactivity of [Co^{II}(bqb)] towards addition of σ donor amines under oxidative conditions to produce *trans*-[Co^{III}(bqb)(amine)$_2$]$^+$ is substantially reduced. However, *trans*-[Co^{III}(bqb)(X)$_2$]$^-$ complexes are prepared in high yields in the presence of π acceptor ligands such as CN^- and N_3^-, under a vigorous stream of air. The X-ray crystal structures of [Ni(bqb)] (**2**) and [N(*n*-Bu)$_4$][Co^{III}(bqb)(N_3)$_2$] (**5**) complexes are also reported.

Experimental

All chemicals were used as supplied by Merck and Fluka without further purification. Solvents were either of reagent or spectroscopic grade and were dried by conventional procedures. 1,2-Phenylenediamine was recrystallized from hot ethanol prior to use.

Physical measurements

Elemental analyses were performed using a Heraeus CHN-O-RAPID elemental analyzer. IR spectra (KBr pellet) were obtained on a Shimadzu 435 spectrophotometer. ^{1}H NMR spectra were obtained on a BRUKER ACP-500 spectrometer at 500 MHz. Proton chemical shifts δ are reported in parts per million (ppm) relative to an internal standard of Me_4Si.

Synthesis

N,N′-*Bis[(2-quinolinecarboxamide)-1,2-benzene] (H_2bqb)*

To a solution of 1.038 g (0.006 mol) quinaldic acid in 5 mL pyridine was added a solution of 0.324 g (0.003 mol) of 1,2-diaminobenzene in 5 mL pyridine and the resulting yellow solution was stirred at 40–45 °C for 10 min. Triphenyl phosphite (1.57 mL, 0.006 mol) was then added dropwise and the reaction mixture was stirred at 90–100 °C for 4 h. The resulting dark red solution was left undisturbed at room temperature for 24 h until needlelike red crystals appeared. To this was then added 20 mL of ethanol resulting in a bulk of crystalline product that was filtered and washed with cold ethanol. The ligand was recrystallized from methanol. Yield: 1.193 g, 95%. IR (KBr, cm^{-1}) ν_{max}: 3320 (m, N-H), 1690 (s, C=O), 1590 (s, C=C), 1530 (s, C-N). ^{1}H NMR (500 MHz, $CDCl_3$, assignment as in Scheme 1) δ 10.61 (br s, 2H, H_{amidic}), 8.45 (d, 2H, H_a), 8.37 (d, 2H, H_b), 8.03 (2H, AA′XX′, J_m = 3.5 Hz, J_o = 9.5 Hz, H_h), 7.89 (dd, 2H, H_f), 7.85 (dd, 2H, H_c), 7.60 (m, 4H, $H_{d,e}$), 7.37 (2H, AA′XX′, J_m = 3.5 Hz, J_o = 9.5 Hz, H_i). Anal. calcd. for $C_{26}H_{18}N_4O_2$ (418.45): C 74.63, H 4.34, N 13.39; found: C 74.45, H 4.34, N 13.37.

[Co(bqb)(DMF)] (1)

A solution of 1.250 g (0.003 mol) of H_2bqb in 5 mL DMF was added dropwise to a solution of 0.747 g (0.003 mol) of cobalt(II) acetate tetrahydrate in 5 mL DMF. The resulting orange-brown solution was left undisturbed to give needlelike crystals. The crystals were isolated by filtration, washed with cold DMF, and dried in vacuo. Yield: 1.580 g, 96%. IR (KBr, cm^{-1}) ν_{max}: 1665 (s, C=O), 1590 (s, C=C), 1540 (s, C-N). Anal. calcd. for $C_{29}H_{23}N_5O_3Co$ (548.46): C 63.51, H 4.23, N 12.77; found: C 62.20, H 4.19, N 12.39.

[Ni(bqb)] (2)

A solution of 1.250 g (0.003 mol) of H_2bqb in 5 mL DMF was added dropwise to a solution of 0.747 g (0.003 mol) of nickel(II) acetate tetrahydrate in 5 mL DMF. The resulting deep green solution was left undisturbed to give dark green crystals, suitable for X-ray crystallography. The crystals were isolated by filtration, washed with cold DMF, and dried in vacuo. Yield: 1.383 g, 97%. IR (KBr, cm^{-1}) ν_{max}: 1630 (s, C=O), 1590 (s, C=C), 1575 (s, C-N). Anal. calcd. for $C_{26}H_{16}N_4O_2Ni$ (475.12): C 65.73, H 3.39, N 11.79; found: C 64.76, H 3.52, N 11.76.

[Cu(bqb)] (3)

A solution of 1.250 g (0.003 mol) of H_2bqb in 5 mL DMF was added dropwise to a solution of 0.599 g (0.003 mol) of copper(II) acetate monohydrate in 5 mL DMF. The resulting

brown solution was left undisturbed to give dark brown crystals. The crystals were isolated by filtration, washed with cold DMF, and dried in vacuo. Yield: 1.368 g, 95%. IR (KBr, cm^{-1}) ν_{max}: 1610 (s, C=O), 1590 (s, C=C), 1560 (s, C-N). Anal. calcd. for $C_{26}H_{16}N_4O_2Cu$ (479.98): C 65.03, H 3.36, N 11.67; found: C 64.60, H 3.52, N 11.73.

[N(n-Bu)$_4$][Co^{III}(bqb)(CN)$_2$ (4)

To a solution of 0.250 g (0.001 mol) of cobalt(II) acetate tetrahydrate in 10 mL of DMF was added dropwise a solution of 0.420 g (0.001 mol) H_2bqb in 10 mL DMF. The resulting orange-brown solution was stirred for 2 h to give a microcrystalline red-brown precipitate. A solution of 0.260 g (0.004 mol) KCN in 10 mL DMF was then added to the reaction mixture and air was bubbled through it for 12 h. The reddish-brown suspension gradually dissolved, generating a cherry-red clear solution. The final solution was filtered and a solution of 0.640 g (0.002 mol) [N(*n*-Bu)$_4$]Br in 5 mL DMF was added to the filtrate. The resulting solution was stirred for 5 min and the solvent removed under vacuum. The cherry-red solid was redissolved in acetone and filtered. Cherry red crystals of the complex were obtained by diffusion of Et_2O vapour into the filtrate. Yield: 0.732 g, 78%. IR (KBr, cm^{-1}) ν_{max}: 1610 (s, C=O), 1590 (s, C=C), 1560 (s, C-N), 2120 (m, C≡N). ^{1}H NMR (500 MHz, $(CD_3)_2CO$, assignment as in Scheme 1) δ 8.75 (2H, AA′XX′, J_m = 3.5 Hz, J_o = 9.5 Hz, H_h), 8.71 (d, 2H, H_a), 8.16 (d, 2H, H_b), 8.10 (dd, 2H, H_f), 7.88 (dd, 2H, H_c), 7.57 (m, 2H, H_e), 7.09 (m, 2H, H_d), 6.91 (2H, AA′XX′, J_m = 3.5 Hz, J_o = 9.5 Hz, H_i), 3.34 (m, 8H, H_m), 1.73 (m, 8H, H_n), 1.36 (m, 8H, H_p), 0.91 (m, 8H, H_r)]. Anal. calcd. for $C_{44}H_{52}N_7O_2Co$ (769.86): C 68.65, H 6.81, N 12.74; found: C 67.00, H 6.75, N 12.70.

[N(n-Bu)$_4$][Co^{III}(bqb)(N$_3$)$_2$ (5)

This complex was prepared by a procedure similar to that for **4**, except that NaN_3 (0.260 g, 0.004 mol) was used as the source of N_3^- ligand. The final dark red solid was redissolved in acetone and filtered. Dark red crystals of the complex, suitable for X-ray crystallography, were obtained by slow diffusion of ethyl acetate vapour into the filtrate at 0 °C. These crystals were isolated by filtration, washed with a mixture of cold ethyl acetate – acetone (9:1, *v*/*v*), and dried in vacuo. Yield: 0.706 g, 88%. IR (KBr, cm^{-1}) ν_{max}: 1610 (s, C=O), 1590 (s, C=C), 1560 (s, C-N), 2000 (m, N_3). ^{1}H NMR (500 MHz, $(CD_3)_2CO$, assignment as in Scheme 1) δ 8.88 (2H, AA′XX′, J_m = 3.5 Hz, J_o = 9.5 Hz, H_h), 8.70 (d, 2H, H_a), 8.28 (d, 2H, H_b), 8.09 (dd, 2H, H_f), 7.99 (dd, 2H, H_c), 7.55 (m, 2H, H_e), 7.05 (m, 2H, H_d), 6.92 (2H, AA′XX′, J_m = 3.5 Hz, J_o = 9.5 Hz, H_i), 3.37 (m, 8H, H_m), 1.75 (m, 8H, H_n), 1.38 (m, 8H, H_p), 0.91 (m, 8H, H_r)]. Anal. calcd. for $C_{42}H_{52}N_{11}O_2Co$ (801.87): C 62.91, H 6.54, N 19.21; found: C 61.90, H 6.71, N 19.56.

X-ray crystallography

Data were collected on a Siemens SMART CCD diffractometer, equipped with a LT-2A low-temperature device, using graphite-monochromated Mo Kα (λ = 0.710 73 Å) radiation. A full sphere of reciprocal lattice was scanned by 0.3° steps in ω with a crystal to detector distance of 3.97 cm. Preliminary orientation matrices were obtained from the first frames using SMART (20). The frames were integrated using the preliminary orientation matrices that were updated every 100 frames. Final cell parameters were obtained by the refinement of the positions of 8192 (for both **2** and **5**) reflections with $I > 2\sigma(I)$, after integration of all the frames using SAINT (20). The data were empirically corrected for absorption and other effects using SADABS (21). The structures were solved by direct methods and refined by the full-matrix least-squares method on F^2 data using SHELXTL (22). All non-H atoms were refined anisotropically. The structure of **5** is a racemic twin. One of the Bu chains of tetrabutyl ammonium ion was found to be disordered with occupancy factors of 0.530(9) and 0.470(9), respectively. The H atoms were constrained to idealized geometries and refined isotropically. The crystallographic and refinement data are summarized in Table 1.

Results and discussion

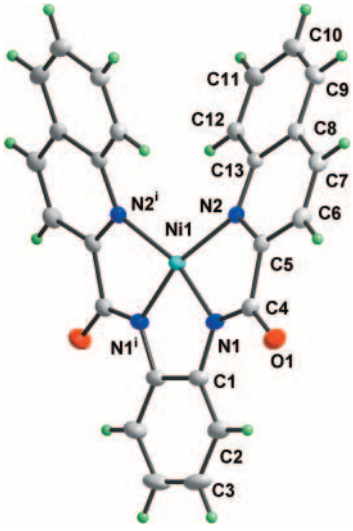
Synthesis

H_2bqb was prepared by the condensation of quinaldic acid and 1,2-diaminobenzene in pyridine in the presence of triphenyl phosphite. The product, as a red crystalline material, was characterized by CHN analysis, IR, UV–vis, and ^{1}H NMR spectroscopy.

The syntheses of mononuclear Co(II), Ni(II), Cu(II), and two Co(III) complexes (**1**–**5**) of the new dianionic ligand bqb(2-) are outlined in Scheme 1. The [M(bqb)] complexes (**1**–**3**) were prepared by the reaction of equimolar quantities of the ligand and the corresponding metal acetate in DMF. The [N(*n*-Bu)$_4$][Co(bqb)(X)$_2$] complexes (**4** and **5**) were synthesized by the air oxidation of [Co(bqb)], prepared in situ, in the presence of the corresponding X ligand in DMF. A vigorous stream of air was passed through the reaction mixture for a period of 12 h, during which the reddish-brown suspension dissolved. Cherry-red crystals of **4** and dark red crystals of **5** were obtained in good yields (78%–88%).

The [Co^{II}(bqb)] complex is sparingly soluble in any solvent and contrary to [Co^{II}(bpb)] (17), its reactivity towards the addition of σ donor amines like piperidine, pyrrolidine, and morpholine under oxidative conditions to produce *trans*-[Co^{III}(bqb)(amine)$_2$]$^+$ is substantially reduced. Preliminary electrochemical results indicate that [Co^{II}(bqb)] is less readily oxidized than [Co^{II}(bpb)], which is in accord with the stronger π accepting character of bqb, with two extra fused phenyl rings, as compared with bpb.[2]

Structure of [Ni(bqb)] (2)



Complex **2**, as illustrated in Fig. 1, crystallizes with the Ni atom placed at a twofold axis with a square-planar structure slightly distorted towards a tetrahedron as evidenced by the N1-Ni1-N2^i and N1^i-Ni1-N2 bond angles of 163.63(6)°. The Ni atom is on the mean plane defined by the amido and pyridine nitrogen atoms, which deviate alternatively above and below the mean plane as follows: N1, –0.185(2) Å; N1^i, +0.185(2) Å; N2^i, +0.142(2) Å; and N2, –0.142(2) Å. Ni atoms are apically attacked by symmetry related O1 atoms at a distance of 3.210(2) Å. The chelate molecules stack with their molecular plane parallel to the *b* axis and diagonal to vectors ***a*** and ***c*** (Fig. 2) and are stabilized in this plane by weak intermolecular hydrogen bonds. The shortest Ni···Ni separation of 5.4869(2) Å (perpendicular to the stack) is

significantly larger than the sum of the van der Waals radii of the Ni atoms (3.20 Å) (23). Selected bond lengths and angles are listed in Table 2. The Ni—N(amide) bond length of 1.848(1) Å agrees well with those reported (1.82–2.02 Å) for other deprotonated Ni—N(amide) bonds (17, 24–26) and is significantly shorter than the Ni—N(py) bond length of 1.958(1) Å. It is also shorter than the Ni—N(amine) bond length of 1.930(6) Å in $[Ni(C_9H_{24}N_4)](ClO_4)_2$ (27). This is in accord with the fact that the deprotonated amide nitrogen is a very strong σ donor. The Ni—N(py) bond length of 1.958(1) Å is also typical (1.952–2.004 Å) (17, 24, 28).

Structure of $[N(n\text{-}Bu)_4][Co(bqb)(N_3)_2]$ (5)

Complex **5**, as illustrated in Fig. 3, crystallizes with an octahedral structure. There are two crystallographically independent Co complexes, both located at the twofold axis. The octahedral polyhedron around Co(III) is slightly distorted, with the bqb ligand ($N_2N'_2$) occupying the equatorial positions and the two azides occupying the axial sites. Selected bond lengths and angles are listed in Table 3. The Co (amide) bond lengths of 1.871(2) Å for the first complex and 1.876(2) Å for the second, and the bond lengths of Co—N(py), 2.001(2) and 1.988(2) Å, are symmetric and compare well with the corresponding bond lengths reported for other deprotonated Co—N(amide) and Co—N(py) bonds (17, 28, 29). The deprotonated mode of coordination of the amide nitrogens is also evident from the absence of the amidic proton

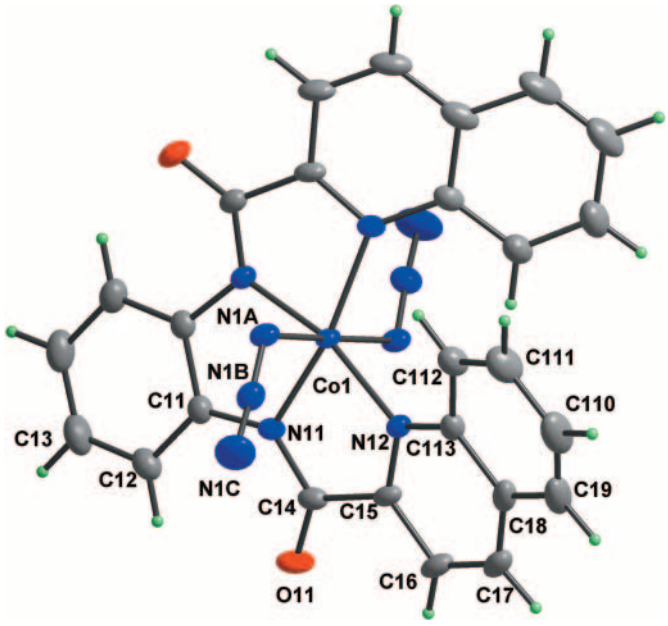

Fig. 2. The molecules form sheets in the plane, parallel with the *b* axis and diagonal to vectors ***a*** and ***c***, by weak intermolecular hydrogen bonds.

signal from the ^{1}H NMR spectrum of complex **5** (vide infra). The Co—N_3 bond length is 1.969(2) Å for both complexes, which is in good agreement with the Co—N_3 bond length of 1.959(3) Å in *trans*-[Co(3,2,3-tet)$(N_3)_2$]ClO_4, where 3,2,3-tet = 1,10-diamino-4,7-diazadecane (30).

All angles around the Co centers deviate significantly from 90°, indicating a rectangular distortion. The ligand–cobalt–ligand bond angles in the equatorial planes consist of one angle that is larger than 90 (N12^i-Co1-N12 = 111.9(1)°, N22-Co2-N22^{ii} = 110.0(1)°) and three that are smaller than 90° (N11^i-Co1-N11 = 84.5(1)°, N11^i-Co1-N12^i = N11-Co1-N12 = 81.96(8)° for the first complex and N21-Co2-N21^{ii} = 85.6(1)°, N21-Co2-N22 = N21^{ii}-Co2-N22^{ii} = 82.5(1)° for the second complex). This indicates that there might be some strain in the coordination sphere due to the rigid geometry of the ligand. The trans N1A-Co1-N1A^i unit with a bond angle of 177.2(1)° is almost linear, as is N2A^{ii}-Co2-N2A at 178.8(1)°. The four equatorial N-donor atoms deviate alternatively above and below the mean plane (N11^i +0.070(2) Å, N11 –0.070(2) Å, N12^i –0.053(1) Å, N12 +0.053(1) Å) for the first complex and (N21 +0.109(2) Å, N21^{ii} –0.109(2) Å, N22 –0.085(1) Å, and N22^{ii} +0.085 Å) for the second complex. The internal coordinates of the azide anions are 1.191(3) Å, 1.149(3) Å, and 175.9(3)° for the first complex and 1.205(3) Å, 1.153(3) Å, and 177.0(3)° for the second complex, as compared to 1.192(4) Å, 1.150(4) Å, and 175.4(4)° and 1.173(4) Å, 1.147(5) Å, and 176.7(5)° reported for *trans*-[Co(3,2,3-tet)$(N_3)_2$]ClO_4 (30). The so-called covalent azides are linear and asymmetric, possessing unequal N—N bond lengths (31). In ionic azides

Fig. 3. Atom-numbering scheme for the first complex $[Co(bqb)(N_3)_2]^-$ anion. Displacement ellipsoids are drawn at the 30% probability level.

both N—N bonds are of equal length and close to 1.17 Å (32). The variation of the long N—N bond is an indication of the degree of covalent character of the coordinate bond, being 1.24 Å in highly covalent structures. In the present

case, the long N—N bond length of 1.191(3) Å signifies some covalent character in the Co—N$_3$ bonds. The shortest distance between Co atoms is 10.205(1) Å.

Spectral characterization

The main features of the IR spectrum of the H$_2$bqb ligand are (*i*) the vibration due to the amidic NH that appears as a sharp band at 3320 cm^{-1}, (*ii*) the strong band at 1690 cm^{-1} owing to amidic C=O stretching vibration, and (*iii*) the C—N stretching vibration of medium intensity appearing at 1530 cm^{-1}. The absence of ν(N-H) (3320 cm^{-1} band) in the IR spectra of the complexes confirms that the bqb ligand is coordinated in its deprotonated form. The ν(C-N) is shifted to higher frequencies relative to the free H$_2$bqb (1530 cm^{-1}), ranging from 1540 cm^{-1} in **1** to 1560 cm^{-1} in **5**. Correspondingly, the ν(C=O) is shifted to lower frequencies relative to the free H$_2$bqb (1690 cm^{-1}), ranging from 1665 cm^{-1} in **1** to 1610 cm^{-1} in **5**, which is in agreement with the data reported for related complexes (33). A planar conformation involving maximum delocalization would be achieved on deprotonation, leading to an increase in the double-bond character of the amidic C—N bond and a simultaneous decrease in the double-bond character of the C—O bond in this mode of coordination. This is also evident from the amidic C—N bond lengths in **2** (1.345(2) Å) and **5** (1.325(3) and 1.341(3) Å), which are close to the C=N bond lengths of the py ring of the coordinated bqb (1.347 Å in **2** and 1.333 Å in **5**) given in

O21-C24-N21	128.4(3)
O21-C24-C25	121.4(3)
N21-C24-C25	110.0(2)
N22-C25-C24	116.3(2)
C26-C25-C24	122.1(2)

Note: Symmetry codes (i) –*x*, *y*, 1 –*z*, (ii) 1 – *x*, *y*, – *z*.

Tables 2 and 3. The C—O bond lengths of 1.243(2) Å in **2** and of 1.240(3) and 1.243(3) Å in **5** are also longer than the isolated C=O bonds. A comparison of the C—N and C=O bond lengths of 1.475(11) and 1.196(5) Å, respectively, reported for 1-aza-2-adamantanone (34), with 1.545(11) and 1.124(12) Å, respectively, reported for the amides (35), would be convincing.

The hexacoordinate geometry of **5** is evident from the X-ray structure analysis (Fig. 3). A hexacoordinate trans structure for complex **4** can be inferred based on the similarity of the ^{1}H NMR spectra of this complex with that of **5**. There are three main features in the ^{1}H NMR spectra of the complexes. (*i*) The absence of the amidic (δ 10.61 ppm) proton signal confirms that the equatorial amide ligand is coordinated in its deprotonated form. (*ii*) The expansion, toward downfield chemical shifts, of the aromatic proton signals range. These signals in the spectrum of the free H_2bqb ligand are located between 7.37 and 8.45 (Δδ 1.08 ppm), while in the spectra of the complexes they lie between 6.91 and 8.88 (Δδ 1.87 ppm), showing a common pattern in the two complexes (Fig. 4). These signals have been assigned by comparison with the spectra of closely related complexes [18]. The appearance of one signal set for each type of proton in $(CD_3)_2CO$ solution conform with the symmetric conformation of the equatorial ligand. (*iii*) The aliphatic protons of the [N(*n*-Bu)$_4$]$^+$ appear in the 3.37–0.91 ppm range. The NMR data are in agreement with the existence of a diamagnetic *trans*-[Co(bqb)X$_2$]$^-$ anion in both complexes, confirmed by the X-ray crystal structure of [N(*n*-Bu)$_4$][Co(bqb)(N$_3$)$_2$] (**5**).

Conclusion

We have reported the synthesis and characterization of two series of complexes, [M^{II}(bqb)] and [N(*n*-Bu)$_4$][Co^{III}(bqb)X$_2$], with the new bqb ligand. The substitution level in the pyridyl rings has a significant effect on the structure of the complexes and on the reactivity of the central metal ion towards other ligands. The fused phenyl rings in the structure of bqb, as compared with that of bpb, increases the π accepting character of bqb. Consequently, the reactivity of Co^{II} in [Co^{II}(bqb)] towards σ donor ligands

© 2006 NRC Canada

(such as amines) is lowered and only σ donor and π acceptor ligands such as CN^- and N_3^- with strong π accepting character are suitable for addition to the axial positions in an oxidative process.[3]

Microwave-assisted N-nitroarylation of some pyrimidine and purine nucleobases

Ali Khalafi-Nezhad, Abdolkarim Zare, Abolfath Parhami, Mohammad Navid Soltani Rad, and Gholam Reza Nejabat

Abstract: An efficient procedure for the synthesis of some *N*-nitroaryl derivatives of nucleobases via microwave-assisted N-nitroarylation of nucleobases in the presence of SiO_2 and Cs_2CO_3 in DMSO, as the homogenizing solvent, is described. In this method, some pyrimidine and purine nucleobases are nitroarylated regioselectively in moderate to high yields and short reaction times.

Key words: microwave, N-nitroarylation, pyrimidine, purine, SN_{Ar}.

Résumé : On a mis au point une méthode efficace de synthèse de quelques dérivés *N*-nitroaryles de nucléobase en procédant à la N-nitroarylation des nucléobases, assistée par les micro-ondes, en présence de SiO_2 et de Cs_2CO_3 dans le DMSO comme solvant homogénéisant. Dans cette méthode, on a pu réaliser la nitroarylation régiosélective de nucléobases de la pyrimidine et de la purine avec des rendements allant de moyens à élevés et de faibles temps de réaction.

Mots clés : microonde; N-nitroarylation; pyrimidine; purine; SN_{Ar}.

[Traduit par la Rédaction]

Introduction

In recent years, there has been a growing interest in the synthesis of bioactive compounds in organic chemistry (1). One important class of these compounds is modified N-substituted nucleobases (nucleoside analogues) including acyclic (2), carboacyclic (3), carbocyclic (4), aza (5), and thionucleosides (6). The majority of nucleosides are known because of their nucleobase linkages with acyclic or cyclic side chains; however, there are a few reports of chemical synthesis as well as chemotherapeutic characterization for *N*-aryl derivatives of pyrimidines and purines (7–16). The *N*-aryl nucleobases have been found to be of particular interest in a variety of biological studies. Several N9-arylpurines are agonists or antagonists for various receptors such as adenosine receptors (7) and corticotropin-releasing hormone receptors (8) and for enzymes like xanthine oxidase (9), adenosine deaminase (10), and guanosine deaminase (11). Other bioactivities are reported, including antitumor activity (12), antimicrobial activity (13), and plant growth stimulating effects (14). These compounds are usually prepared by multistep reactions (15). Moreover, there are a few reports of the synthesis of these compounds via N-arylation of nucleobases with arylboronic acids or diaryliodonium salts in the presence of coupling agents (16). These methods are associated with one or more of the following drawbacks: long reaction time, low reaction yield, and reaction difficulty. Indeed, to the best of our knowledge, there are no reports of N1-nitroarylation of pyrimidines or N9-nitroarylation of purines via nucleophilic aromatic substitution (SN_{Ar}).

Microwave-assisted organic reactions have been used as an useful technique in organic synthesis (17). Microwave irradiation often leads to large reduction in reaction times, increased yields, easier workups, and may enhance the regio- and stereo-selectivity of reactions (17).

In an extension of our previous studies on the synthesis of nucleoside derivatives (18), we describe here an efficient, rapid, and operationally simple method for regioselective N-nitroarylation of nucleobases via SN_{Ar}. In this method, various pyrimidine and purine nucleobases were nitroarylated with activated nitroaryl halides in the presence of SiO_2 and Cs_2CO_3 in DMSO, as the homogenizing solvent, under microwave irradiation (Schemes 1 and 2).

Results and discussion

To initially optimize reaction conditions, the synthesis of compound **1a** was selected as a model reaction (Scheme 1); thus, a well-ground mixture of uracil (1 mmol), 1-chloro-2,4-dinitrobenzene (1.3 mmol), and Cs_2CO_3 (1 mmol) in DMSO (1 mL) was irradiated in a microwave oven (200 W, max. 160 °C) for 8 min; however, a low yield of product was obtained, even with increased reaction time and microwave power (Table 1). Yields improved remarkably when support was added to the reaction mixture. By testing different supports in the reaction, silica gel showed the best results (Table 1).

To select the appropriate base for the N-nitroarylation reaction, the influence of various bases was investigated on the

7	NBu_3	4	18

[a]Isolated yield.

described model reaction. The results are summarized in Table 2. As shown in Table 2, higher yields and shorter reaction times were observed when Cs_2CO_3 was applied. Therefore, Cs_2CO_3 was the base of choice for all reactions.

In another study, the effect of different solvents in the presence of SiO_2 and Cs_2CO_3 was examined (Table 3). As is clear from Table 3, the use of DMSO gave the best results. Thus, DMSO was applied as an homogenizing solvent in our reaction.

Interestingly, in our method, pyrimidine and purine nucleobases were regioselectively nitroarylated at the N-1 and N-9 positions, respectively. The sites of N-nitroarylation in both pyrimidine and purine nucleobases were indicated by ^1H and ^{13}C NMR spectral analysis. Several reports from the literature also confirmed this site of N-substitution (18*a*, 18*b*, 19).

Table 3. The influence of various solvents on the reaction of uracil with 1-chloro-2,4-dinitrobenzene in the presence of SiO_2 and Cs_2CO_3 under microwave irradiation (200 W, max. 160 °C).

Entry	Solvent	Time (min)	Yield[a] (%)
1	DMSO	2	84

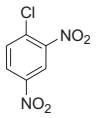
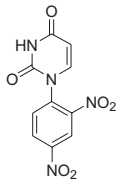
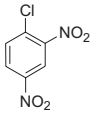
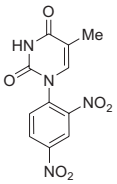
Table 4. Comparative synthesis of compounds **1f** and **1g** using conventional heating (Δ, 160 °C) vs. the microwave method (400 W, max. 160 °C).

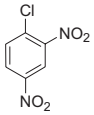
	Time (min)		Yield[a] (%)	
Compound	Δ	MW	Δ	MW
1f	200	3.5	49	62
1g	180	3	68	77

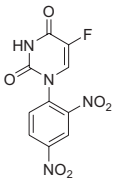


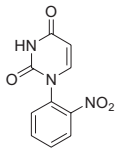


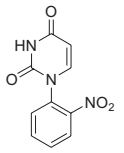


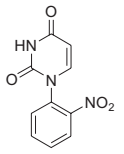


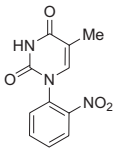


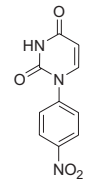












[a]Isolated yield.

To realize the capability and efficiency of microwave heating compared with conventional heating in our reaction, we also synthesized compounds **1g** and **1f** via N-nitroarylation of uracil with nitroaryl halides in the presence of SiO_2 and Cs_2CO_3 in DMSO under thermal conditions (160 °C) (Table 4). As Table 4 indicates, the microwave method is more efficient. Furthermore, the syntheses of compounds **1g** and **1f** were examined in solvent-free conditions (microwave and thermal); lower yields and longer reaction times were obtained in comparison with in-solution conditions.

To investigate the versatility and scope of our method, the reaction was examined with various nucleobases and

[a]Isolated yield.

gate the effect of leaving groups (halogens) at nitroaryl halides on the reaction, we examined the reaction of nucleobases with 2-nitroaryl fluoride, chloride, and bromide. As was expected, the reaction of nucleobases with 2-nitroaryl fluoride is the most efficient (Table 5, entries 4–6, 12, and 13). The higher reactivity of 2-nitroaryl fluoride is attributed to the higher electronegativity of the fluorine atom that increases positive charge on the ipso carbon. In this method, purine nucleobases were also nitroarylated regioselectively at the N-9 position in good to high yields (Table 5, entries 11–15). The presence of -NH_2 or -Cl substituents on C-6 of the purines gave similar results (Table 5, entries 11 and 15). Moreover, hypoxanthine was N-nitroarylated at N-9 in good yield (Table 5, entry 14). The biological evaluations of the named compounds are under investigation.

In summary, we have developed an efficient, clean, and rapid method for N-nitroarylation of different nucleobases via nucleophilic aromatic substitution. This new method afforded N1-nitroaryl pyrimidines and N9-nitroaryl purines as

biologically interesting compounds in short reaction times and reasonable yields.

Experimental

All chemicals were supplied by either Merck or Fluka. Solvents were purified and dried according to the reported methods and stored over molecular sieves (20). The progress of the reactions was followed with TLC, using silica gel SILG-UV 254 plates. Silica gel 60 (0.063–0.200 mm, 70–230 mesh ASTM) was used for column chromatography and support. All reactions were carried out using a CEM MARS 5™ microwave oven. IR spectra were run on a Shimadzu FT-IR-8300 spectrophotometer (ν_{max} in cm^{-1}). The ^1H NMR (250 MHz) and ^{13}C NMR (62.5 MHz) were run on a Bruker Avance DPX-250 FT-NMR spectrometer. Mass spectra were recorded on a Shimadzu GC–MS QP 1000 EX apparatus. Microanalyses were performed on a PerkinElmer 240-B microanalyzer. Melting points were recorded on a Büchi B-545 apparatus in open capillary tubes and are uncorrected.

General procedures for the preparation of compound 1a

A well-ground mixture of compounds consisting of nucleobase (2 mmol), 1-chloro-2,4-dinitrobenzene (0.52 g, 2.6 mmol), Cs_2CO_3 (0.65 g, 2 mmol), and SiO_2 (0.70 g) in anhydr. DMSO (2 mL) was poured into a microwave vessel and irradiated in a microwave oven for an appropriate time and at an appropriate power level (Table 5). The microwave was programmed to give a maximum internal temperature of 160 °C. Afterward, the reaction mixture was cooled to room temperature and poured into ice water (20 mL), the solids were filtered, and the filtrate was extracted with ethyl acetate. The solvent was evaporated and the the residue was combined with solids. This mixture was purified by column chromatography on silica gel with EtOAc–*n*-hexane (1:1) to give **1a** as a pale yellow solid, mp 225–227 °C. IR (KBr, cm^{-1}): 3435, 3042, 1688, 1657, 1608, 1283. ^1H NMR (DMSO-d_6, ppm) δ: 5.87 (d, 1H, J = 7.9 Hz, H_5 of uracil), 7.89 (d, 1H, J = 7.9 Hz, H_6 of uracil), 8.02 (d, 1H, J = 8.7 Hz, H_6 of aromatic ring), 8.71 (d, 1H, J = 8.7 Hz, H_5 of aromatic ring), 8.83 (s, 1H, H_3 of aromatic ring), 11.78 (s, 1H, NH, exchangeable with D_2O). ^{13}C NMR (DMSO-d_6) δ: 103.1, 120.6, 129.2, 131.4, 136.0, 143.6, 144.9, 146.9, 149.5, 163.3. MS *m*/*z*: 278 (M^+). Anal. calcd. for $C_{10}H_6N_4O_6$: C 43.18, H 2.17, N 20.14; found: C 42.99, H 2.36, N 20.26.

1-(2,4-Dinitrophenyl)-5-methyl-1*H*-pyrimidine-2,4-dione (1b)

Column chromatography on silica gel and eluting with EtOAc–*n*-hexane (1:1) gave a pale yellow solid, mp 228–230 °C. IR (KBr, cm^{-1}): 3437, 3056, 1694, 1652, 1591, 1289. ^1H NMR (DMSO-d_6, ppm) δ: 2.00 (s, 3H, CH_3), 7.98 (s, 1H, H_6 of thymine), 8.15 (d, 1H, J = 8.8 Hz, H_6 of aromatic ring), 8.83 (d, 1H, J = 8.8 Hz, H_5 of aromatic ring), 8.97 (s, 1H, H_3 of aromatic ring), 11.93 (s, 1H, NH, exchangeable with D_2O). ^{13}C NMR (DMSO-d_6) δ: 11.8, 110.9, 120.6, 129.1, 131.1, 136.1, 139.1, 144.9, 146.7, 149.5, 163.9. Protein mass measurement combined with mass spectrometric sequencing of protein digests for detection and characterization of protein modifications[1]

Chengjie Ji, Zhengping Wang, and Liang Li

Abstract: A method for the characterization of modifications of low molecular weight proteins (<20 kDa) extracted from a microorganism based on the use of multiple separation tools and mass spectrometric techniques is described. In this method, intact proteins from cell extracts are first separated and fractionated by liquid chromatography (LC). Individual fractions are then analyzed by matrix-assisted laser desorption ionization (MALDI) mass spectrometry (MS) to provide intact protein mass information. The fractions are further characterized by using trypsin digestion and LC electrospray ionization (ESI) MS/MS analysis of the resultant peptides to identify the proteins. Gel electrophoresis of a fraction is also carried out to estimate the molecular masses of the proteins. The gel bands are identified by in-gel digestion and peptide mass mapping and sequencing using MALDI-MS and MALDI-MS/MS. The combined information generated from these experiments is interpreted for detecting and characterizing modified proteins. This method has been developed and applied to the analysis of posttranslational modifications (PTMs) of low-mass proteins (5–20 kDa) extracted from a relatively well-characterized microorganism, *Escherichia coli*. Using this method, not only previously reported PTMs involving acetylation, methylation, oxidation, and the removal of signal peptides, but also two novel PTMs, namely loss of N-terminal Met-Thr-Met (MTM) and hydroxylation of arginine, were identified. It is envisaged that this method should be applicable to other relatively simple microorganisms for the discovery of new PTMs.

Key words: top-down proteomics, protein modification, HPLC, gel electrophoresis, tandem mass spectrometry.

Résumé : On a mis au point une méthode de caractérisation des modifications des protéines de faible poids moléculaire (< 20 kDa) extraites d'un microorganisme; elle est basée sur l'utilisation de multiples techniques de séparation et de spectrométrie de masse. Dans cette méthode, les cellules intactes telles qu'extraites des cellules sont d'abord soumises à une séparation, puis elles sont soumises à un fractionnement par chromatographie liquide (CL). Afin d'obtenir des informations relatives à la masse des protéines intactes, les fractions individuelles sont alors analysées par spectrométrie de masse avec ionisation par désorption laser assistée par la matrice. Les fractions sont ensuite caractérisées d'une façon plus poussée en faisant appel à une digestion à l'aide de trypsine et à de la SM/SM avec ionisation par électronébulisation des peptides qui en résultent pour identifier les protéines. On a aussi effectué une électrophorèse sur gel d'une fraction pour évaluer les masses moléculaires des protéines. On a identifié les bandes du gel en procédant à une digestion dans le gel et à une cartographie de masse des peptides et une détermination de la séquence à l'aide de SM-MALDI et de SM/SM. On a interprété les informations combinées générées à l'aide de ces expériences pour détecter et caractériser les protéines modifiées. On a développé cette méthode et on l'a appliquée à l'analyse de modifications post-translationnellle (MPT) de protéines de faibles masses moléculaires (5–20 kDa) extraites d'un microorganisme relativement bien caractérisé, *Escherichia coli*. Utilisant cette méthode, on a pu identifier des MPT qui avaient été rapportée antérieurement, telles l'acétylation, la méthylation, l'oxydation et l'enlèvement des peptides signaux, ainsi que deux nouvelles MPT, à savoir la perte du groupe Met-Thr-Met (MTM) N-terminal et l'hydroxylation de l'arginine. On croit que cette méthode devrait pouvoir être appliquée à d'autres microorganismes relativement simples pour découvrir de nouvelles MPT.

Mots clés : protéomiques descendantes, modification de protéine, chromatographie liquide à haute performance (CLHP), électrophorèse sur gel, spectrométrie de masse en tandem.

Fig. 1. Schematic representation of the strategy used for the detection and characterization of protein modifications. Proteins identified by tandem MS/MS in each HPLC fraction were assigned to those apparent masses observed in the MALDI-MS spectrum of the same fraction.

Introduction

Posttranslational modifications (PTMs) of proteins are chemical processing events by proteolytic cleavage or addition of a modifying group to one or more amino acid residues that alter a protein's properties after its translation. PTMs include phosphorylation, glycosylation, acetylation, methylation, sulfation, disulfide bond formation, deamidation, ubiquitination, and nitration of tyrosine (1). Most proteins undergo co- and (or) post-translational modifications. Knowledge of these modifications is extremely important because they may alter the proteins' physical and chemical properties, such as folding, conformational distribution, stability and activity, and consequently change the function of the proteins and their interaction with other proteins. Moreover, the modification itself can act as an added functional group. Examples of the biological effects of protein modifications include phosphorylation for signal transduction, ubiquitination for proteolysis, and attachment of fatty acids for membrane anchoring and association. Consequently, the analysis of proteins and their posttranslational modifications is particularly important for the study of many different types of diseases including cancer, neurodegenerative diseases, and diabetes.

Despite the major role of PTMs in biological functions, large-scale study still remains a great challenge because of a lack of suitable analytical methods (1). Mass spectrometry (MS) plays an increasingly important role in characterizing protein PTMs. Recent applications of MS to the identification of PTMs have ranged in scale from the study of single purified proteins (2–4) to the search for one type of modification on all the proteins or proteome in a sample (5–8), and to scanning for all modifications on a proteome-wide scale (9). Considering the complexities involved in identifying all the modifications on a single protein, proteome-wide scanning is, at present, not comprehensive. Nevertheless, large amounts of biologically useful information can be generated. To determine the sites of modification, maximum protein sequence coverage is desirable. For this purpose, in the bottom-up proteomic approach, peptide mass mapping using two or more different enzymes, such as trypsin, Asp-N, or Glu-C, can be employed. Protein modifications are then identified from the measured masses and fragmentation spectra using manual or computer-assisted interpretation (10). In the top-down proteomic approach, intact protein mass is accurately measured and compared to that calculated from the database sequence of the identified protein. Some amino acid sequence information of the intact protein can also be deduced. For example, multiple-charged intact protein ions generated by electrospray ionization (ESI) can be dissociated and the resulting product ion spectra are interpreted for the characterization of protein modifications (11–14).

While using the bottom-up or top-down approach alone can generate useful information on protein modifications, recent studies have indicated that these two approaches are complementary to each other and the combination of the two techniques can provide more detailed characterization of modified proteins (15–19). In this study, we present a method for the characterization of PTMs of low-mass proteins (5–20 kDa) extracted from a relatively simple microorganism by combining separation tools with intact protein mass measurement and protein digest analysis based on ESI and matrix-assisted laser desorption ionization (MALDI) MS. This method is applied for the analysis of a number of low-mass proteins from an *Escherichia coli* cell extract.

Results and discussion

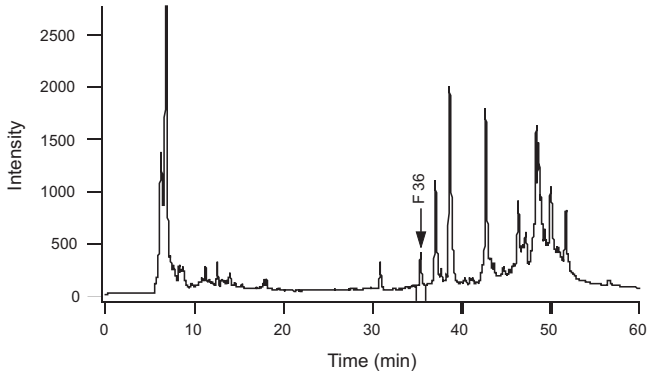

Figure 1 shows the work flow developed for the characterization of PTMs of low-mass proteins observed in MALDI-MS spectra. The proteins in the cell extracts of *E. coli* were

© 2006 NRC Canada

separated by HPLC. For this relatively simple microorganism, one-dimensional HPLC separation was used, while for more complex organisms with large sizes of proteome, multidimensional HPLC is likely needed to simplify the protein mixture. The apparent molecular masses of low-mass proteins in each HPLC fraction were detected using MALDI-MS. Then, the proteins in each selected HPLC fraction were identified using two different tandem MS experiments. First, proteins in the selected fraction were digested in solution by trypsin. The resulting peptide mixture was separated by capillary column HPLC using a gradient of acetic acid – acetonitrile. Individual peptide ions were automatically selected for collision-induced dissociation (CID) MS/MS followed by database searching using the SEQUEST (20) software. Second, proteins in each selected HPLC fraction were separated by one-dimensional SDS polyacrylamide gel electrophoresis (PAGE). Following electrophoretic separation, individual low-mass gel bands were digested in situ by trypsin. Peptides were then extracted from the gel and each peptide mixture was analyzed by MALDI-MS and MALDI-MS/MS, followed by database searching using the MASCOT (21) software. Finally, the identified proteins in each selected fraction were assigned to the apparent masses observed in the MALDI mass spectrum and any possible PTMs were assigned by comparing the theoretical mass of the identified protein in the public database with the observed mass in the MALDI-MS analysis.

Figure 2 shows the chromatogram of cell extracts of *E. coli* 47076. Since the major components eluted between 35 and 52 min, efforts were concentrated on those fractions. The apparent molecular masses observed in MALDI-MS spectra of HPLC fractions collected between 35 and 52 min, which had signal-to-noise ratios over 5, are listed in Table 1. Some proteins appeared in two consecutive fractions because we collected the fractions based on time intervals instead of the UV absorbance peak. For example, the proteins with *m/z* 8327 and 9080 were observed in fractions 36 and 37 and the molecular weights for those proteins are the same in the consecutive fractions. For proteins that appeared in several consecutive fractions, Table 1 only lists their initial fraction. The possible matched proteins in the SWISS-PROT and TrEMBL databases, searched using the sequence retrieval system (SRS), are listed in the third column in Table 1. It should be noted that the technique described here is not suitable for detecting deamidation, which only generates 1 Da mass difference, not readily differentiated by low-resolution intact mass measurement. Most of the apparent molecular masses observed in MALDI-MS spectra have more than one match in the public proteome database. Accession numbers and names of proteins identified by combining the LC–ESI-MS/MS and MALDI-MS/MS experiments, which correspond to those observed in MALDI mass spectra, are listed in the fifth and sixth columns in Table 1. Each of these proteins was identified by at least two peptides with significant matches. In the ESI-MS/MS experiments, peptides are considered to be identified only when they pass the following criteria: for the 1+ charge state, $X_{corr} \geq 2.0$ for fully tryptic peptides and $X_{corr} \geq 3.0$ for partially tryptic peptides; for the 2+ charge state, $X_{corr} \geq 2.4$ for fully tryptic peptides and $X_{corr} \geq 3.5$ for partially tryptic peptides; for the 3+ charge state, $X_{corr} \geq 3.7$ for fully tryptic peptides and $X_{corr} \geq 4.5$ for partially tryptic peptides. All criteria have a ΔC_n value of ≥ 0.1. In the MALDI-MS/MS experiments, peptides are considered to be identified only when the first assigned peptide with score is above the identity threshold score. Table 1 shows that nine of the identified proteins have masses that are different from those in the public proteome database. This is because some of the proteins in the public proteome database are posttranslationally modified in vivo or processed in vitro during the sample preparation process.

Fig. 2. Chromatogram of cell extracts of *E. coli*. Note that F36 indicates the fraction collected between 36 min and 37 min.

Protein truncation is one of the PTMs. Protein fragments have been identified by Edman sequencing of gel-separated *E. coli* proteins (22, 23). The N-terminal sequence tags of these fragments matched the predicted internal region of the genes in the *E. coli* preparation, in vivo events, or translation products initiated at the internal sites of the genes. None of these putative cleavage sites matches with any known *E. coli* protease recognition sequences, although little is known of the target specificity of *E. coli* proteases (24–26). In this work, efforts toward the identification of protein fragments by MS/MS will be discussed. Using a program called Paws (27), mass searching was attempted to correlate the identified proteins in Table 1 with the unidentified low-mass species in the MALDI mass spectrum. By entering a peptide mass, Paws will search over an entire protein sequence to determine if any stretch of the sequence has a mass that matches with the input mass. If the observed mass in MALDI-MS matched with a part of the sequence covered by the identified peptide sequences, the low-mass species observed in MALDI was considered as a fragment of the specific protein. Mass information from one-dimensional gel electrophoresis was used to achieve a conclusive identification.

As an example, in fraction 36, the observed molecular mass of 10 386 Da ($M + H^+$) is a fragment of outer membrane protein A (OMPA, accession number P02934) instead of those matched by SRS. Figure 3(*A*) shows the MALDI spectrum of the tryptic digests of the indicated gel band as shown in Fig. 4. Peptides matched with OMPA are labeled with an asterisk in Fig. 3(*B*). OMPA was identified based on the fragmentation patterns of four peptides. Figure 3(*C*) shows one representative MS/MS spectrum. This protein has the following amino acid sequence:
MKKTAIAIAVALAGFATVAQAAPKDNTWYTGAKLGWS

The bold characters show the sequence coverage of the MS/MS results. The molecular mass of this protein is 37 292 Da, which was not found in the MALDI spectrum (Fig. 3(*A*)). Simple calculation shows that the underlined protein sequence has the molecular mass of 10 386.7 Da, matching a major component in Fig. 3(*A*). This molecular mass information matches the molecular mass estimate of the gel. There is also a disulfide bond formed between two cysteines inside the underlined sequence. Therefore, the final molecular mass ($M + H^+$) of the underlined sequence is 10 385.7 Da, which is very close to that observed in the MALDI mass spectrum. This was confirmed by the identification of an unexpected tryptic peptide PKDGSVVVLGYTDR (Fig. 3(*D*)). Thus, the apparent molecular mass of 10 386 Da corresponds to the fragment from OMPA. This was done by MASCOT searching without any enzyme type constraint. Seven y ions and seven b ions matched with the in silico fragmentation pattern, showing a strong correlation between the MS/MS spectrum and the identified peptide sequence. The fragmentation of this protein most likely occurred during protein extraction and isolation because of acid-labile cleavage of an amino acid bond between Asp (D) and Pro (P). It is found that in dilute acidic conditions, aspartyl peptide bonds tend to be more rapidly hydrolyzed than other aminoacyl peptide bonds, particularly for aspartyl proline bonds (28). This is due to the neighbouring group effects caused by the proximity of the side-chain carboxyl group of the amino acid residue Asp to the α-carboxyl peptide bond. On the basis of this notion, the fragmentation of this protein most likely occurred during protein extraction and isolation, since dilute TFA aqueous solution was used in both steps.

Fig. 4. Proteome map of HPLC fraction 36 of *E. coli* cell extracts.

The most common PTM of the proteins in *E. coli* involves loss of the N-terminal methionine. For cytoplasmic proteins, the amino-terminal processing model (29, 30) predicts that the truncation of N-terminal Met residue by methionine aminopeptidase depends on the side-chain length of the second amino acid. This modification occurs most often in cases where the amino acid next to this methionine has a short side chain. Sterically large side chains are believed to prevent proteins from docking in the methionine aminopeptidase active site. When the second amino acid is Ala, Cys, Gly, Pro, Ser, Thr, or Val, the initiator Met is excised. Violations of the model were observed by Edman sequencing of the gel-separated *E. coli* proteins (23) and it was believed that protein structures other than the second amino acid residue were involved in the excision specificity. It has been shown (23) that all initial Met residues are removed when the second residue is Ala or Ser, and none of the Met

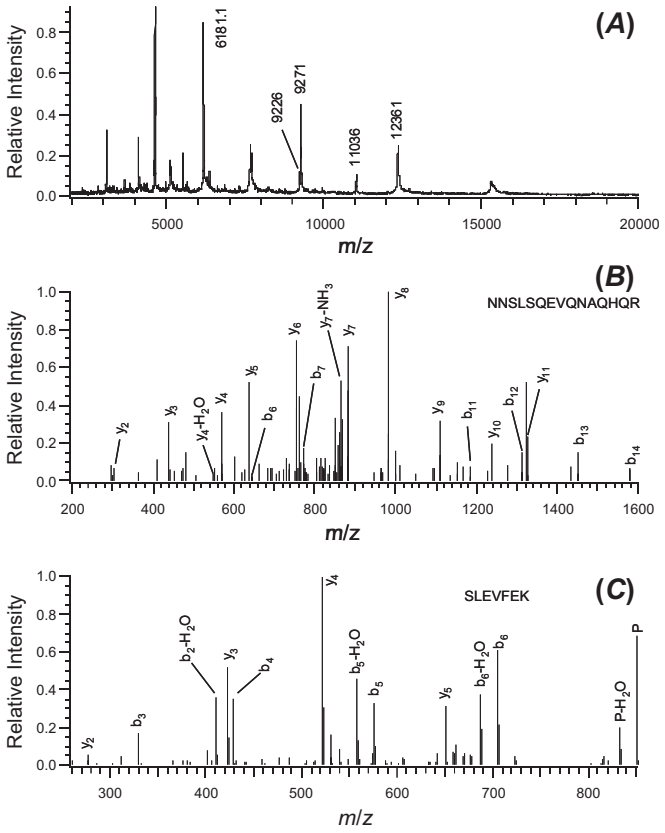
Fig. 5. Hydroxylation of arginine in 50S ribosomal protein L16 observed in MALDI-MS. (*A*) MALDI-MS spectrum of HPLC fraction 50 of *E. coli* cell extracts. (*B*) LC–MS/MS spectrum of the peptide sequence NNSLSQEVQNAQHQR. (*C*) LC–MS/MS spectrum the peptide sequence SLEVFEK.



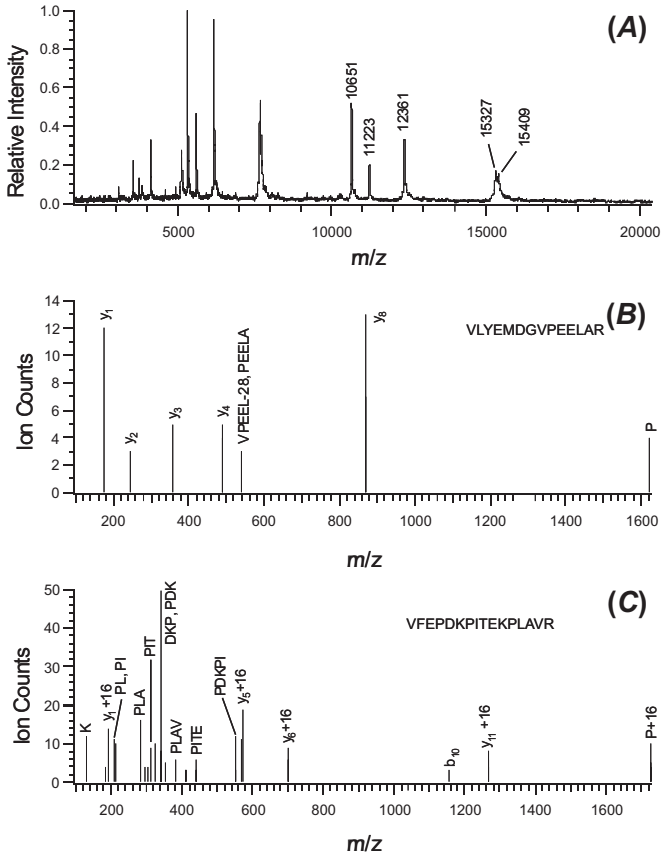


Fig. 6. Loss of MTM in hypothetical protein YIIU_ECOLI observed in MALDI-MS. (*A*) MALDI-MS spectrum of HPLC fraction 49 of *E. coli* cell extracts. (*B*) MALDI-MS/MS spectrum of the peptide sequence VLYEMDGVPEELAR. (*C*) MALDI-MS/MS spectrum of the peptide sequence VFEPDKPITEKPLAVR.

is removed when Val is in the second position. The excision of Met is variable when the second residue is Thr, Gly, or Pro. It is very easy for the integration host factor α-subunit protein precursor (accession number P06984), observed in the MALDI spectrum of fraction 49, to lose the first methionine in its sequence because the amino acid in the second position is alanine, which has a small side chain.

The removal of signal peptides from protein precursors is another common PTM of the proteins in *E. coli*. Proteins located in the periplasm and outer membrane region are expected to have a signal sequence that helps direct their transport across the inner membrane (29, 31). The signal peptide generally has a positively charged amino-terminal region, a central hydrophobic region, and a carboxy-terminal region. *Escherichia coli* signal peptides are 15–30 amino acids long and they are removed from the protein precursors (i.e., the gene expression products) by the signal peptidase (Lep) after transport through the membrane (29). Therefore, the mature protein has a molecular mass 1500–3000 Da lower than predicted from the genome. The proteins with masses of 9740, 9064, and 11 978 Da listed in Table 1 were identified to correspond to HDEA (accession number P26604), HDEB (accession number P26605), and YGIW (accession number P52083) with the removal of their signal peptides. Additionally, the removal of the signal peptides from HDEA, HDEB, and YGIW was confirmed previously by Link et al. (23) via N-terminal Edman degradation following separation of these proteins by 2D gel electrophoresis.

Loss of MTM (methionine, threonine, methionine) from an amino terminus is a novel PTM observed in this study. In fraction 50, none of the proteins identified by LC–ESI-MS/MS matched with the molecular mass of 9271 Da observed in the MALDI mass spectrum (Fig. 5(*A*)). One possible reason was that this molecular mass corresponded to a posttranslationally modified protein. Thus, SEQUEST database searching was done on LC–ESI-MS/MS spectra without an enzyme type constraint. Four y ions and four b ions matched with the in silico fragmentation pattern of the peptide SLEVSEK (Fig. 5(*C*)). This peptide sequence is a partial sequence of hypothetical protein YIIU (accession number P32164). YIIU was identified based on the fragmentation patterns of three peptides. Figure 5(*B*) shows one representative MS/MS spectrum. YIIU_ECOLI has the following sequence: MTM**SLEVFEK**LEAK**VQQAIDTITL-LQMEIEELKEKNNSLSQEVQNAQHQR**EELERENNH LKEQQNGWQER**LQALLGR**MEEV.

The bold sequence represents coverage by the MS/MS results. Using the Paws program, it was found that the underlined protein sequence has an average molecular mass of

© 2006 NRC Canada

9271 Da, matching one major component in the MALDI-MS spectrum of HPLC fraction 50. This means that the apparent mass of 9271 Da observed in MALDI MS is YIIU_ECOLI with the loss of MTM at the N-terminus.

Several other PTMs, including methylation, oxidation, and acetylation, are also detected and listed in Table 1. In fraction 49, none of the proteins identified by LC–ESI-MS/MS and MALDI-MS/MS matched with the molecular mass of 15 327 Da observed in the MALDI mass spectrum (Fig. 6(*A*)). It was reported that 50S ribosomal protein L16, which has a nominal molecular mass of 15 281 Da based on the genome sequence, was seen to have an apparent mass of 15 326 Da, 45 Da higher, in its MALDI mass spectrum (32). 50S Ribosomal protein L16 was identified based on the fragmentation patterns of four peptides. Figure 6(*B*) shows one representative MS/MS spectrum. The N-terminal methionine of this protein has been reported as being methylated (33). The original sequencing of this subunit also indicated that the arginine residue at position 81 was modified in some way. Subsequent work by Brosius and Chen (33) suggested it was hydroxylated. This is confirmed by MALDI-MS/MS on the selected parent peptide ion of 1726.01 Da (VFPDKPITEKPLAVR, Fig. 6(*C*)), which correlates to 1710.00 Da and the addition of 16 Da because of hydroxylation of an arginine residue at position 81 of the sequence of 50S ribosomal protein L16. When the MS/MS spectrum of the parent ion of 1726.0 Da was searched on MASCOT, there were no significant matches. After 16 Da was added to arginine, the spectrum matched with the product ion of peptide VFPDKPITEKPLAVR. These two modifications still yield a protein that is 15 Da lighter than the observed mass, suggesting that another methylation or hydroxylation is present. Efforts to confirm this were unsuccessful because another peptide that had a molecular mass 16 or 14 Da higher than the theoretical mass could not be found. This example illustrates that only partial information on the modification of this protein can be produced using the method described. Other complementary techniques are needed to generate the additional information required for the complete characterization of this protein. These techniques may include intact protein sequencing by mass analysis of polypeptide ladders (MAP) after controlled hydrolysis of the modified protein (34) and top-down sequence analysis from the product ion spectra of the intact protein generated in ESI Fourier transform (FT) MS. Work in these directions is underway.

Finally, the sensitivity of the method was evaluated using a protein standard, cytochrome *c*. It was found that the lowest total amount used for intact protein mass measurement, LC fractionation, gel electrophoresis, and subsequent in-gel digest analysis was about 6.5 ng (525 fmol) of cytochrome *c*.

Conclusions

We have presented a method for characterizing protein modifications of low-mass proteins extracted from a microorganism using a combination of HPLC protein fractionation, intact protein mass measurement, LC–ESI-MS/MS of peptides produced from trypsin digestion of individual protein fractions, and gel electrophoresis of protein fractions followed by MALDI-MS and MALDI-MS/MS. Using the described method, not only previously reported PTMs involving acetylation, methylation, oxidation, and the removal of signal peptides, but also two novel PTMs, namely loss of N-terminal Met-Thr-Met (MTM) and hydroxylation of arginine, were observed. In this study, 37 low-mass proteins were observed in the MALDI mass spectra of HPLC fractions of *E. coli* cell extracts and 28 of them were identified. Among the identified proteins, nine were modified, resulting in mass shifts between the theoretical masses and the apparent masses in MALDI-MS. While the current method was developed and applied to the analysis of PTMs of proteins extracted from a relatively well-characterized microorganism, it is envisaged that this method should be applicable to other microorganisms for the discovery of new PTMs of low-mass proteins (<20 kDa). For higher mass proteins, mass resolution and mass measurement accuracy of intact proteins need to be improved, which can be done by using ESI-MS. For more complex organisms with large sizes of proteome, multidimensional HPLC separation of intact proteins, instead of the one-dimensional separation used in this work, is likely required.

Experimental section

Chemicals and reagents

HPLC grade acetone, methanol, acetonitrile (ACN), 2-propanol, and glacial acetic acid were from Fisher Scientific Canada (Edmonton, Alberta). Water used in all experiments was obtained from a Milli-Q Plus purification system (Millipore Corp., Bedford, Massachusetts). Bovine trypsin, cytochrome *c*, trifluoroacetic acid (TFA), and α-cyano-4-hydroxycinnamic acid (HCCA) were from Sigma-Aldrich-Fluka (Oakville, Ontario). HCCA was purified by recrystallization from ethanol (95%) at 50 °C prior to use. Tris(hydroxymethyl)aminomethane (electrophoresis purity grade) and Coomassie Blue G250 staining solution were purchased from Bio-Rad Laboratories (Hercules, California).

Cell growth and protein extraction

Escherichia coli (ATCC 47076) cells were ordered from the American Type Culture Collection (ATCC). Cells were grown in Luria Broth (LB) (BBL, Becton Dickinson, Franklin Lakes, New Jersey) at 37 °C with constant shaking and harvested at 72 h. The cells were then washed with sterile water, lyophilized, and stored at –20 °C before extraction. *Escherichia coli* extracts were prepared by a solvent suspension method as described previously (35). In brief, proteins were extracted by probe tip sonication using 0.1% TFA as extraction solvent. About 100 mg of lyophilized *E. coli* sample was suspended in 5 mL of 0.1% TFA solution in a 15 mL centrifuge tube. For sonication, a Branson Sonifier 450 (VWR Scientific, Bridgeport, New Jersey), with the duty cycle set to 75% and the output control set to 5, was used. The *E. coli* cell suspension was sonicated for 1 min with the tube on ice and then centrifuged at 13 000 g. Supernatant (i.e., the clear solution above the cell debris) was then transferred into fresh 1.5 mL vials. The extracts were filtered using a Microcon-3 (Millipore Corporation, Billerica, Massachusetts) with 3000 Da molecular mass cutoff and then concentrated to ~0.5 mL by SpeedVac (Thermo Electron Corporation, Waltham, Massachusetts).

Fractionation of proteins from the soluble *E. coli* whole cell lysates by RP-HPLC

Solvent delivery and separations were performed on an Agilent (Palo Alto, California) HP1100 HPLC system. The solvents used for reversed-phase HPLC were water (**A**) and acetonitrile (**B**) with 0.1% (*v*/*v*) TFA in both phases. The gradients were 2%–20% **B** in 10 min, 20%–40% **B** in 30 min, 40%–55% **B** in 5 min, 55%–65% **B** in 10 min, and 65%–90% **B** in 10 min. After the column was equilibrated for 30 min with 100% mobile phase **A**, 70 μL of bacterial extract was separated on a 250 mm × 4.6 mm i.d. C_8 column (5 μm particles with 300 Å pore size, Grace Vydac, Hesperia, California) at a flow rate of 500 μL/min. One minute fractions were collected with a Gilson FC 203B fraction collector (Gilson, Middleton, Wisconsin) and then concentrated to about 10 μL by SpeedVac.

In-solution digestion

Each of the selected HPLC fractions was adjusted to pH 8.5 with 1 mol/L NH_4HCO_3 and ~0.8 μg of trypsin was then added to each. Digestion was performed at 37 °C for ~2 h.

LC–ESI-MS/MS

Peptides in the in-solution protein digest of each HPLC fraction were desalted using commercial C18 μZiptips from Millipore prior to LC–ESI tandem mass spectrometry analysis. LC–ESI-MS/MS was performed on an LCQ Deca quadrupole ion trap mass spectrometer equipped with a dynamic nanospray source (ThermoFinnigan, San Jose, California). The dynamic nanospray source was coupled to a Surveyor HPLC system (ThermoFinnigan, San Jose, California). The flow from the pump was reduced from 300 to 1 μL/min by using a splitting tee and a length of restriction tubing made from fused silica. All separations were performed on a 150 μm × 15 cm i.d. capillary column, packed with 5 μm 218MS (C_{18}) beads (Grace Vydac). A 2 μL sample solution was injected for each run. The HPLC gradient was 5%–10% **B** in 2 min, 10%–45% **B** in 38 min, 45%–65% **B** in 10 min, and followed by 65%–85% **B** in 5 min (solvent **A**, 0.5% acetic acid in water; **B**, 0.5% acetic acid in acetonitrile, *v*/*v*). The nanospray tip used was a 50 μm i.d. tip from New Objective (Woburn, Massachusetts). During the HPLC separation, the ion trap repetitively surveyed the full scan MS over the *m*/*z* range of 400–1800 and executed data-dependent MS/MS scans. MS/MS spectra were acquired using a relative collision energy of 30% (LCQ instrumental settings). An isolation width of 2 *m*/*z* units was used and recurring ions were dynamically excluded after two MS/MS spectra were obtained. Interpretation of the resulting MS/MS spectra was performed by the SEQUEST software. The *E. coli* proteome database created from a nonredundant protein database, which was downloaded from NCBI (36), was used for database searching.

1D SDS PAGE

Proteins in each of the selected HPLC fractions were also separated using Tris-Tricine 10%–20% gradient Ready Gels (Bio-Rad Laboratories, Hercules, California). The premixed running buffer composition of the Tris–Tricine–SDS was as follows: 100 mmol/L Tris, 100 mmol/L Tricine, and 0.1% SDS. The sample buffer was composed of 200 mmol/L Tris-HCl, 2% SDS, 40% glycerol, and 0.04% Coomassie G-250. Gel electrophoresis was performed at a constant voltage of 100 V. For some fractions, to increase the sample quantity, the same fractions from two separate runs were combined for 1D SDS-PAGE mini-gel separation. Proteins in the gel bands were visualized by staining with Coomassie Blue G-250.

In-gel digestion

Low-mass gel bands of interest were excised and subjected to tryptic digestion according to the published digestion protocol (37). Reduction was performed at 56 °C for at least 30 min in 10 mmol/L DTT in 100 mmol/L NH_4HCO_3. Alkylation was performed in the dark at room temperature for 30 min in 55 mmol/L iodoacetamide in 100 mmol/L NH_4HCO_3. Sufficient 12.5 ng/μL trypsin in 50 mmol/L NH_4HCO_3 was added to cover the gel piece. Trypsin digestion was performed overnight (~12 h) at 30 °C. Sequential extraction of peptides from the gel was done twice with 0.25% TFA – 20% ACN, twice with 0.25% TFA – 50% ACN, and once with 0.25% TFA – 80% ACN. The extracts were pooled and the organic solvent removed by SpeedVac.

MALDI-MS

MALDI-MS results were obtained using a Bruker Reflex III MALDI time-of-flight (TOF) mass spectrometer (Bremen, Leipzig, Germany) equipped with a SCOUT 384 multiprobe inlet and a 337 nm nitrogen laser operated with a 3 ns pulse. Spectra were acquired in positive ion mode with delayed extraction using reflectron mode. The sample spot was scanned with the laser beam under video observation and spectra were acquired by averaging 300–500 individual laser shots and processed with the Bruker supporting software. The spectra were then reprocessed using the Igor Pro software package (WaveMetrics, Lake Oswego, Oregon). Each spectrum was normalized to the most intense signal in the mass range displayed.

For LC off-line MALDI analysis, each HPLC fraction was concentrated by a factor of 50 times to ~10 μL before mixing with matrix for analysis. A two-layer method was used for MALDI sample preparation (38). HCCA was used as a matrix. About 1 μL of 100 mmol/L HCCA in acetone–methanol (130:45, *v*/*v*) was applied to the MALDI plate to quickly form the first layer. For the second layer, the sample solution was mixed at a volume ratio of 1:2 with saturated HCCA in formic acid–2-propanol–water (1:2:3, *v*/*v*/*v*). About 1 μL of the second layer solution was then applied onto the first layer and allowed to dry. On-spot washing of the MALDI sample with water was performed to remove any salts. Quasi-internal mass calibration was done as follows to improve the accuracy. Once the sample spot was dried, about 0.5 μL of a mixture of standard protein solution with second layer HCCA matrix solution was spotted adjacent to the sample spot. The spectrum was collected from the sample spot first. After the intensity of the signal reached a certain level, the plate was moved and the laser beam was aimed at the standard. Finally, a spectrum, including peaks from both sample and standard, was recorded. Singly, doubly, and triply charged peaks from cytochrome *c* were used to make this quasi-internal calibration. For MALDI-MS on digests from in-gel tryptic digestions, the

© 2006 NRC Canada

spectra were internally calibrated with trypsin autolysis peptide peaks and matrix peaks.

MALDI-MS/MS

MALDI-MS/MS spectra of the selected peptide peaks from the MALDI-MS spectra of in-gel tryptic digests were acquired on an Applied Biosystems/MDS-Sciex QSTAR Pulsar QqTOF instrument equipped with an orthogonal MALDI source employing a 337 nm nitrogen laser (Concord, Ontario). The instrument was operated in positive ion mode and collisional-induced dissociation (CID) of peptides was achieved with argon as the collision gas. Spectra were acquired and processed using Sciex supplied software and reprocessed with Igor Pro software for presentation.

Database search

Possible matches in the public proteome database with the apparent masses observed in MALDI-MS were searched as previously described (39). The SWISS-PROT and TrEMBL (40) databases were searched using the SRS. The molecular mass measured by MALDI-MS was entered into the information field, along with the organism *E. coli*. Proteins were accepted as possible matches only if the database molecular masses matched with the experimental masses to within ±0.05%.

Mass spectral data interpretation

Known contaminant peak masses were eliminated from each MALDI-MS spectrum. The sample peaks were determined by comparing the peaks from a sample to the peaks from a blank piece of gel. Only sample peaks were considered for database searching. Artificial modifications of peptides by electrophoresis, such as acrylamide adducts to cysteine or oxidation of methionine, were also considered for the database search. Both peptide mass figure printing (PMF) and the peptide sequencing results were searched for protein identification using the MASCOT search program and the UCSF Protein Prospector Database (41). The obtained partial sequence information for each peptide was used to confirm, discard, or correct the previously obtained results from PMF.

Characterization of Au and Pd nanoparticles by high-temperature TGA–MS

Weijuan Jia, Jessica McLachlan, Jiayan Xu, Seyed M. Tadayyon, Peter R. Norton, and S. Holger Eichhorn

Abstract: Noble metal nanoparticles (NPs) prepared by a surfactant-free single-phase solution method have been proposed to contain fewer ionic contaminants than similar NPs prepared by a two-phase method. Reported herein is the possible contamination of Au and Pd NPs, prepared by a surfactant-free single-phase method, with Li_2CO_3 and other Li salts. High-temperature thermal gravimetric analysis measurements coupled with mass spectrometry (TGA–MS) up to 1100 °C were employed to determine the relative amounts of ionic contaminants since protecting thiolate groups and inorganic contaminants were removed in separate weight loss events. Assignment of the different weight loss events was supported by MS analysis of the evolved gases. TGA–MS also revealed the presence of larger amounts of oxidized sulfur species in the Pd NPs. High-resolution transmission electron microscopy (HRTEM), UV–vis, IR, elemental analysis (EA), and X-ray photoelectron spectroscopy (XPS) measurements complemented the characterization of the NPs. The amount of ionic contaminants crucially depended on the workup conditions, and quenching of the reaction mixture with ethanol was found to be essential for the formation of Li_2CO_3. Workup procedures that avoid the formation of TGA–MS detectable ionic contaminants are proposed along with purification steps for contaminated NPs.

Key words: gold, palladium, nanoparticles, TGA, mass spectrometry, ionic contamination.

Résumé : Il a été suggéré que les nanoparticules de métaux nobles (NP) préparées par une méthode impliquant une solution en une phase sans agent de surface contiennent moins de contaminants ioniques que des particules semblables préparées par une méthode en deux phases. Dans ce travail, on rapporte des résultats qui suggèrent que les nanoparticules d'or ou de palladium préparées par une méthode en une seule phase sans agent de surface pourraient avoir été contaminées par du Li_2CO_3 ou d'autres sels de lithium. On a fait appel à des mesures d'analyse gravimétrique thermique à haute température couplées à la spectrométrie de masse (ATG–SM) jusqu'à 1100 °C pour déterminer les quantités relatives de contaminants ioniques puisque les groupes protecteurs thiolates et les contaminants inorganiques avaient été enlevés dans des manipulations séparées de pertes de poids. Les attributions de pertes de poids aux différentes manipulations sont en accord avec l'analyse par spectrométrie de masse des gaz qui se dégagent. La méthode ATG–SM a aussi révélé la présence de plus grandes quantités d'espèces de soufre oxydé dans les nanoparticules de Pd. La microscopie électronique par transmission à haute résolution, les spectroscopies UV–vis et IR, les analyses élémentaires et les mesures de spectroscopie photoélectronique des rayons X ont permis d'ajouter un complément à la caractérisation des nanoparticules. La quantité de contaminants ioniques dépend d'une façon cruciale sur les conditions du traitement conclusif et on a trouvé que la désactivation du mélange réactionnel avec de l'éthanol est essentielle pour la formation du carbonate de lithium. On propose des méthodes pour le traitement conclusif qui évitent la formation de contaminants ioniques détectables par ATG–SM ainsi que des étapes de purification pour les nanoparticules contaminées.

Mots clés : or, palladium, nanoparticules, analyse thermogravimétrique, spectrométrie de masse, contamination ionique.

[Traduit par la Rédaction]

Introduction

Noble metal nanoparticles (NPs) have become important building blocks in nanoscience (1) They can be prepared by a wide range of different physical and chemical methods, of which the preparations by wet chemistry have proved versatile and straightforward. Stable and soluble thiolate-protected metal NPs have been prepared by convenient two- (2) and single-phase (3) solution methods. Their average sizes and size distributions crucially depend on the reaction conditions (4).

Thiolates are usually considered to be the only molecules attached to the surface of noble metal NPs because of their relatively strong interactions. Other molecules and ions,

however, may compete for a place at the high-energy and large-area surface during the synthesis and workup or may be trapped in the organic layer of the protecting groups. The presence of such contaminants has seldom been reported as their detection is difficult, especially at low concentrations. NMR studies of long-chain alkyl thiol protected Au NPs prepared by the two-phase method revealed contamination by ionic phase transfer agents, such as tetraalkylammonium bromide (5). Soxhlet extraction has been shown to successfully remove the phase transfer agent but it is the experience of both our and other groups (5*a*) that excessive extraction of the NP powders with organic solvents also removes thiolate groups and that the yields of soluble particles decrease drastically.

Rowe et al. (6) proposed that metal NPs prepared by a surfactant-free single-phase method contain smaller amounts of ionic contaminants than similar Au NPs prepared by a two-phase method. This assumption, however, was based solely on the differences in the ionic conduction of these NPs. No spectroscopic or other analytical evidence was provided.

The identification and quantification of ionic impurities is essential as they might affect the solubility (5) and stability of the NPs, as well as their optical and electronic properties (7). It is expected that the type and quantity of contaminants crucially depend on the reaction and workup conditions as well as the type of thiol ligand. Large dendritic ligands, for example, have been shown to effectively entrap solvent molecules and phase transfer agents (8).

The methods that are typically applied in the characterization of metal NPs are restricted in their ability to detect contaminants. Standard solution NMR (9) only monitors hydrogen- and carbon-containing molecules and may be limited by the relatively low solubility of many NPs (often <1 mg/mL) as well as line-broadening of groups that are close to the metal surface. IR spectroscopy (10) is a convenient and sensitive method if the contaminants give rise to strong and characteristic absorptions that do not overlap with the absorptions of the NPs, but a quantification of the contaminants by IR is difficult. XPS (11) is the most straightforward method for the detection of unexpected elements and elements in unexpected chemical environments but, again, quantification is complicated by a limited penetration depth (approximately 1 to 2 nm, depending on the element and the electron energy channel) and the increasing attenuation of the photoelectron yield with increasing size of the organic ligands. XRD (12) and TEM (13) only detect contaminants that are present as particles, preferentially crystalline, of about 1 nm in diameter or larger. Low-temperature TGA (<700 °C) (4*a*, 14) has been routinely employed for the quantification of organic vs. metal content, but weight losses above 500 °C have not been discussed, though are occasionally observed (3*b*).

Herein, we introduce high-temperature TGA–MS as a convenient method for the identification and possible quantification of contaminants that also ensures a more accurate determination of the thiolate to gold ratios. Au and Pd NPs protected by octane-1-thiol (Au-C8), dodecane-1-thiol (Au-C12 and Pd-C12), octadecane-1-thiol (Au-C18), and 2-phenylethanethiol (Au-C2Ph and Pd-C2Ph) were prepared by a surfactant-free one-phase method in THF first described by Ulman and co-workers (3*b*, 3*c*). All NPs were characterized by TEM, UV–vis, TGA–MS, and XRD. Some particles were also examined by IR, XPS, and elemental analysis.

Experimental

The following compounds were used, 1-Octanethiol (Sigma-Aldrich, 98.5+%), 1-dodecanethiol (Sigma-Aldrich, 98+%), 1-octadecanethiol (Sigma-Aldrich, 98%), 2-phenylethanethiol (Sigma-Aldrich, 98%), lithium triethylborohydride (Super-Hydride® Sigma-Aldrich, 1.0 mol/L in THF), hydrogen tetrachloroaurate(III) hydrate (Strem Chemicals Inc., Newburyport, Massachsetts, 99.9%), and palladium(II) acetate (Sigma-Aldrich, 99.9%). THF was freshly distilled from sodium under nitrogen or run through activated Al_2O_3 columns using an Innovative Technology Inc. (Newburyport, Massachsetts) solvent purification system. Ethanol was first dried over $MgSO_4$ and then over a molecular sieve (4 Å). All other solvents were of ACS grade and used as received.

Transmission electron microscopy (HRTEM) was performed by Fred Pearson at McMaster University (Hamilton, Ontario) on a JEOL 2010F FEG TEM/STEM at 200 kV. Dilute solutions of NPs in THF were filtered through a 0.02 μm filter, dropped onto a carbon-coated copper grid, and the solvent was allowed to evaporate. Reported size distributions are based on the measurements of at least 200 particles per sample. Thermal gravimetric analysis with mass spectrometric detection of evolved gases was conducted on a Mettler Toledo TGA SDTA 851e that was attached to a Pfeiffer Vacuum Thermostar™ mass spectrometer (1–300 amu) via a thin glass capillary. Helium (99.99%) was used to purge the system at a flow rate of 60 mL/min. Samples were held at 25 or 30 °C for 20 or 30 min before being heated to 1000 °C at rates of 5 or 10 °C/min. A mass range from 16–240 *m*/*z* was constantly scanned for low-resolution measurements. High-resolution scans were conducted at a scan rate of 2 °C/min and specific *m*/*z* values were monitored at a high frequency. UV–vis spectra of solutions in THF (spectroscopic grade) were recorded on a Varian Cary 50. Powder XRD measurements were run on a Bruker D8 Discover diffractometer, equipped with a GADDS 2D detector, and operated at 40 kV and 40 mA. Cu Kα1 radiation (λ = 1.541 87 Å) was used and the initial beam diameter was 0.5 mm. All samples were sealed in Charles Supper Company (Natick, Massachusetts) 1.0 mm glass capillaries and run at θ angles of 18°, 50°, and 80°, each for 120 min. Spectra were combined and evaluated in EVA and plotted with Origin.

Crude and acid-washed samples of Au-C8 and Au-C12 were cast from DCM solution onto silicon wafers for FTIR and XPS investigations. One set of wafers with crude NPs was also heated to 500 °C in a stream of He for 30 min. FT-IR measurements were performed on a Bruker Vector 22. XPS measurements were conducted on a self-built system that consisted of an Al Kα X-ray source (1486.6 eV, unmonochromated) and a VG Scientific CLAM2 concentric hemispherical electron analyzer in a vacuum chamber (base pressure 2×10^{-10} torr, 1 torr = 133.322 4 Pa). The Au($4f_{7/2}$) peak of clean gold metal served as the energy standard (84.0 eV) and photoelectrons were analyzed at 50 eV pass energy with a resolution of about 1 eV for survey scans over

© 2006 NRC Canada

the entire binding energy range. An energy increment of 0.1 eV was used for regional scans over the photoelectron peaks of interest. Ten to fifteen scans were collected for each region, depending on the signal-to-noise ratio.

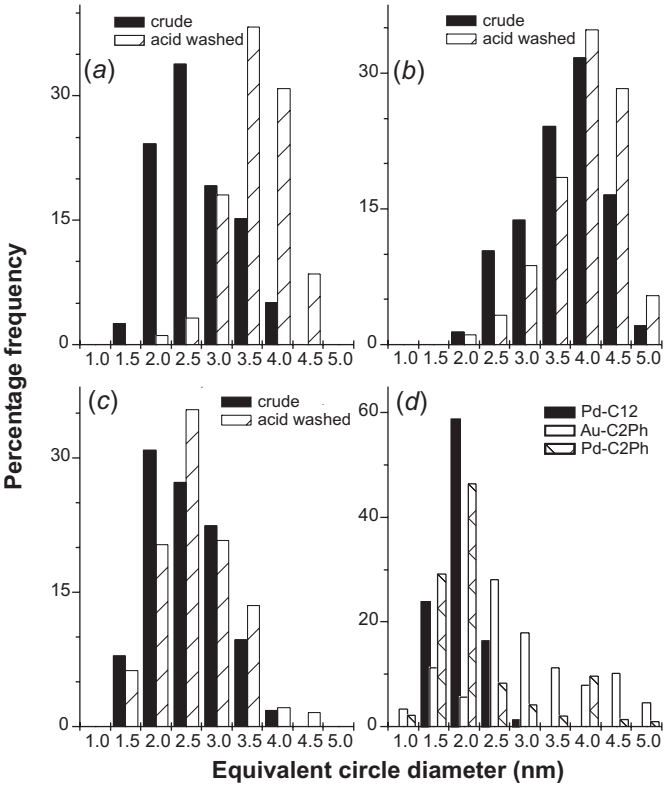
Synthesis and purification

Hydrogen tetrachloroaurate(III) hydrate (0.306 g, 1 mmol) or palladium(II) acetate (0.224 g, 1 mmol) were dissolved in 15 mL of dry THF and stirred under Ar for 15 min. Thiol (2.53 equiv.) was added and the mixture was stirred for another 30 min. Super-Hydride® (15 equiv., 1 mol/L solution in 15 mL of THF, 15 mmol of Super-Hydride®) was added within 30 min (0.75 mL/min) via a syringe pump and the mixture was stirred for another 2 h before being quenched by the addition of dry ethanol (30 mL). The sample was refrigerated for 12 h to fully precipitate all NPs, which were collected on a 0.2 μm PTFE membrane filter and washed with ethanol (95%). THF (10 mL) was used to wash the NPs through the filter and they were again precipitated from the filtrate by the addition of ethanol (60 mL). The final precipitate was collected on a PTFE membrane filter and dried in vacuum (4 mbar, 1 bar = 100 kPa) for 24 h.

The following yields of crude NPs, based on the initial amount of metal salt and the average composition of the NPs derived from TGA and TEM, were obtained: Au-C8 (81%), Au-C12 (72%), Au-C18 (89%), Au-C2Ph (72%), Pd-C12 (86%), Pd-C2Ph (72%).

Alternative workup procedures

A fraction of the Au-C8 reaction mixture was transferred into 10 mL Beckman polyallomer centrifuge tubes and run in a Beckman Coulter (Fullerton, California) Optima™ MAX E ultracentrifuge at 45 000 r/min (140 000*g*) at 12 °C for 20 min. The solvent was decanted off and the pellet was again dissolved in dry THF and centrifuged. This procedure was repeated two more times before the pellet was washed with deionized water and ethanol (95%) and dried in vacuum (4 mbar) for 24 h.



Quenching under Ar

One fraction of Pd-C2Ph was precipitated from the THF reaction mixture by the addition of dry ethanol under Ar. The precipitate was then filtered off under air (0.45 μm PTFE membrane filter) and the NPs were washed with 95% ethanol as described previously.

Acid-wash

Fractions of crude NPs that were isolated by precipitation from ethanol were dissolved in THF (10 mL) and precipitated by the addition of a 1:1 mixture of ethanol and aqueous hydrochloric acid (0.1 mol/L). This procedure was repeated until the filtrate reached a pH of 6 or lower (usually after the second precipitation). Acetic acid and 1 mol/L NH_4Cl (aq) were also tested for 0.1 mol/L HCl (aq) but the carbonate salts were not removed.

Fig. 1. Size distributions of (*a*) Au-C8, (*b*) Au-C12, (*c*) Au-C18, and (*d*) Au-C2Ph and Pd NPs derived from TEM measurements (TEM images are provided in the Supplementary information, Figs. S1–S5).[2]

Results and discussion

TEM and XRD characterization

The average sizes and size distributions of the NP cores were determined by TEM analysis (Fig. 1 and Supplementary information (SI), Figs. S1–S5).[2] Pd-C12 consisted of the smallest NPs (2.0 nm) with the narrowest size distribution (1.5–3.0 nm) (15). Au-C8 and Au-C18 both had an average size of 2.5 nm (1.5–4.0 nm), while the largest NPs were obtained for Au-C12 with an average size of 3.5 nm (2.0–5.0 nm). Au-C2Ph and Pd-C2Ph showed broader size distributions than those of alkyl thiolate protected NPs with average sizes of 2.9 nm (1.0–5.0 nm) and 2.3 nm (1.0–5.0 nm), respectively. All observed sizes and size distributions are in a typical range for nonfractionated NPs prepared by single- or two-phase solution methods in the presence of thiols (3*b*, 3*c*, 4*a*).

Acid wash treatment with 0.1 mol/L HCl (aq) for the removal of basic impurities caused a minor increase in average sizes (<0.5 nm) of Au-C12 and Au-C18, whereas a considerable increase in average size (>1.0 nm) was observed for Au-C8 (Fig. 1). No TEM pictures were taken of acid-washed Au-C2Ph as it quickly increased in size according to UV–vis

[a]These values represent the organic loss corrected for the inorganic contamination by subtracting the inorganic weight losses from the total weight.
[b]These calculated values, based on the assumption that only CO_2 contributes to the inorganic second losses, are multiplied by 0.273 to give the C contribution in *wt %*, which was added to the value of the first loss.
[c]The average number of gold atoms per NP based on the TEM derived average size and a *FCC* packing.
[d]The average number of thiolate groups attached to a NP based on N_{metal} and organic loss values.
[e]The ratio between the average number of surface gold atoms per NP, based on the TEM derived radii, N_{metal}, and $N_{thiolates}$.
[f]This sample still contained excess octadecane thiol. It was removed from the crude sample by extraction with acetone–ethanol (1:1).
[g]The third loss of 8.5 *wt %*, observed above 900 °C in high-resolution TGA, was disregarded.

and the Pd NPs were even less stable in these conditions and coagulated to bulk material.

Assuming an *FCC*-like crystal structure for Au and Pd NPs as suggested by XRD, the average number of metal atoms per NP might be calculated from the average diameters of the NPs determined by TEM (15). Average diameters of 2.0 nm (Pd-C12), 2.3 nm (Pd-C2Ph), 2.5 nm (Au-C8,-C18), 2.9 nm (Au-C2Ph), and 3.5 nm (Au-C12) are equivalent to about 281, 427, 466, 728, and 1280 gold atoms per NP, respectively. Similarly, the average percentage of gold atoms at the surfaces of the NPs was calculated to be 54%, 48%, 47%, 42%, and 35%, respectively. These numbers, together with the average contents of metal and organic groups as determined by TGA, were used for the calculation of the average compositions of the NPs (Table 1, part 5).

Wide-angle XRD of the Au NPs revealed the typical peaks of an *FCC*-like gold core (12), while the Pd NPs appeared to be predominantly amorphous as no diffraction peaks of the Pd cores were observed (SI, Figs. S13–S15)[2] (16). The diffraction pattern of crude Au-C2Ph showed an unusual set of sharp peaks between $2\theta = 20°$ to 35°, which were identified as diffractions of Li_2CO_3 crystallites. The same peaks, but of much lower intensity, were found in the pattern of crude Au-C8. The small sharp peaks between $2\theta = 20°$ to 25° in the diffraction pattern of Au-C18 did not match the pattern of Li_2CO_3 and were likely caused by partial crystallization of the aliphatic side chains. No diffraction peaks of Li_2CO_3 were observed in the crude samples of Au-C12, AuC18, or the Pd NPs, although they contained Li_2CO_3 as confirmed by TGA–MS and IR analyses. It is assumed that Li_2CO_3 was present as too small a crystallite to give sufficiently intense diffraction peaks. All acid-washed NPs were free of Li_2CO_3 based on XRD, TGA–MS, and IR.

TGA–MS analysis

Two distinct weight losses were observed by TGA (Fig. 2). The first loss, between 100 and 400 °C, was caused mainly by the desorption and decomposition of the thiolate monolayer (3*b*, 4*a*, 4*c*), while the previously unreported second weight loss, between 650 and 900 °C, was mainly caused by the decomposition of the contaminant Li_2CO_3. TGA–MS measurements on a reference sample of Li_2CO_3 gave identical results (SI, Fig. S11)[2], and Li_2CO_3 was also identified by XRD and IR in the samples with high content (Au-C8 and Au-C2Ph). LiCl would have been completely removed in the same temperature range as Li_2CO_3 but no chlorine related ion peaks (*m*/*e* = 35 and 37) were observed by MS in any of the NPs, nor was Cl detected by XPS. Li_2O, another possible contaminant, is stable up to 1100 °C and consequently not detectable by TGA–MS.

All weight loss curves of the Au NPs levelled out at temperatures above 900 °C and bulk gold was left in the crucibles, based on visual inspection. Pd NPs that were heated to 1000 °C did not generate bulk palladium with a shiny metal-

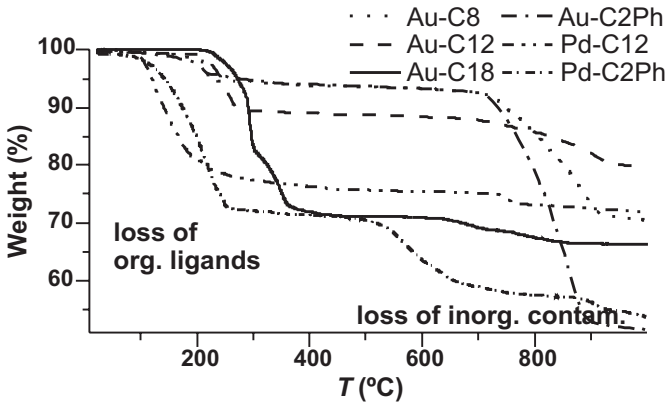
Fig. 2. TGA curves of crude NPs.



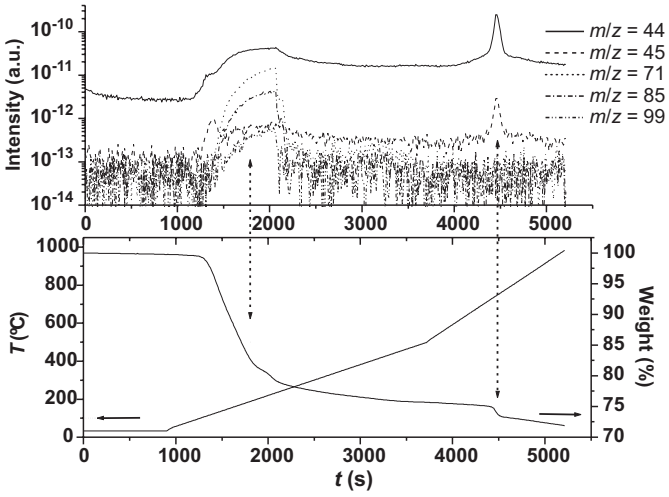


Fig. 3. TGA–MS measurement of Pd-C12. MS curves of only a small number of significant *m/e* values are shown for clarity.

lic surface but rather with a dull black appearance. High-resolution measurements on Pd NPs discussed later confirmed another weight loss above 900 °C that originated from the removal of oxidized sulfur species.

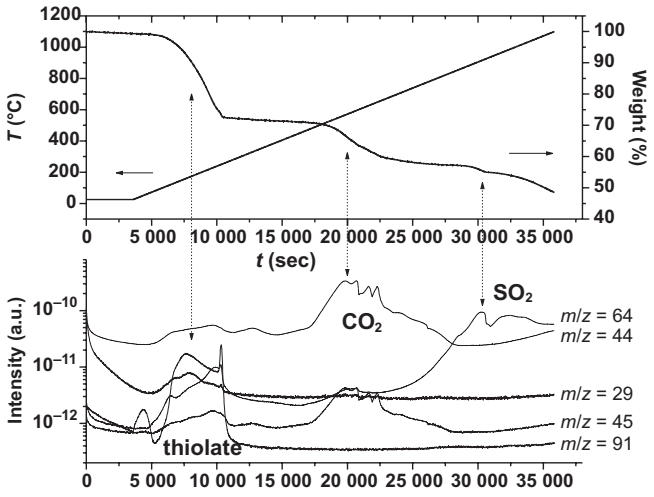
The thermal stability of the thiol monolayer, based on the onset temperatures of the first weight loss, decreased in the order Au-C18 > Au-C12 > Au-C8 > Au-C2Ph > Pd-C2Ph > Pd-C12. This suggests a decrease in thermal stability with decreasing chain lengths, which has also been observed by others (6, 9*b*), and a generally lower thermal stability of the Pd NPs. The amount of Li_2CO_3 in the Au NPs, based on the second weight loss in TGA, increased with decreasing thermal stability of the thiol monolayer. Thiols with longer alkyl chains seem to exclude ionic contaminants more effectively, which might be explained by the formation of more dense, partially crystalline, monolayers (10*a*, 17). Pd NPs, on the other hand, contained the least thermally stable thiolate monolayers and the lowest weight % of Li_2CO_3.

MS analysis of the TGA exhaust gas confirmed the loss of the organic ligands between 100 and 400 °C as increased intensities for masses of typical aliphatic fragment ions (e.g., 71, 85, and 99) were observed (Fig. 3 and SI, Figs. S8–S10).[2] The second weight loss, between 600 and 900 °C, coincided with the loss of other fragments than those from the thiol ligands, according to MS. Large increases in intensities were observed for *m/e* values of 28 (CO), 44 (CO_2), and 45 (CO_2H), which are typical decomposition products of carbonate salts. Temperature range and fragment ions in MS matched the reference spectrum of Li_2CO_3.

No second weight loss was observed in the TGA graphs of the acid-washed Au NPs, indicating a complete removal of Li_2CO_3 and possibly other contaminants (SI, Fig. S6)[2] (18). A comparison of the first weight losses between acid-washed and crude samples shows that the *wt %* losses of organic ligands were very similar when the *wt %* of the second losses were subtracted from the total weights of the crude samples (Table 1). Thermally, however, only CO_2 is assumed to be removed, leaving Li_2O (38% of the weight) behind. This discrepancy may be explained by other contaminants in the crude samples that were removed in the first weight loss below 500 °C and also by the acid wash procedure. This assumption is supported by the observation that intensities of ions, such as 28 (CO) and 44 (CO_2), also peaked at about 150 °C in the TGA–MS spectra of the crude samples, but no such peaks were observed for the acid-washed samples. The absence of oxidized carbon species in the acid-washed samples was also verified by XPS, as discussed later.

MS analysis of the evolved gases also revealed a considerable contribution from SO_2 (*m/e* = 64) and SO for Pd NPs, while it was small for the Au NPs and did not contribute to a significant weight loss (<0.5 *wt %*). The loss of SO_2 peaked twice in a high-resolution measurement of Pd-C2Ph up to 1100 °C (Fig. 4). One portion was removed with the aliphatic side chains between 100 and 300 °C, according to MS; the second loss occurred well after the loss of CO_2 at temperatures above 900 °C. Thiols have been shown to more easily oxidize on palladium than on gold surfaces (19), which would explain the loss of larger amounts of SO_2 in the MS of Pd NPs. This additional high-temperature loss of about 8 *wt %* complicates the calculation of the organic content based on TGA as a third weight loss process must be considered. Interesting, however, is the observation that considerable amounts of oxidized sulfur species remain on the metal surface at temperatures up to 900 °C. In contrast, the sulfur of the alkyl thiolates is fully removed with the organic groups at a temperature of 500 °C, according to the TGA–MS and XPS measurements discussed later.

UV–vis spectroscopy



All crude Au-NPs showed surface plasmon absorption peaks between 518 and 533 nm (SI, Fig. S12).[2] These are typical values for particles with gold cores in the 2–6 nm diameter range (18). The absorption maxima for the crude and acid-washed samples were almost identical for Au-C8 (520 and 518 nm, respectively), Au-C12 (524 and 523 nm, respectively), and Au-C18 (both at 530 nm). A large shift was observed for Au-C2Ph (518–533 nm), which suggested a significant increase in average particle size. No distinct maxima were observed for the surface plasmon bands of the Pd NPs in THF and chloroform solutions. Values between 225 and 302 nm have been reported in the literature for Pd NPs of average sizes between 3 and 4 nm (3*b*, 3*c*).

IR and XPS measurements

Crude and acid-washed samples of Au-C8 and Au-C12 were cast from DCM solution onto silicon wafers and one

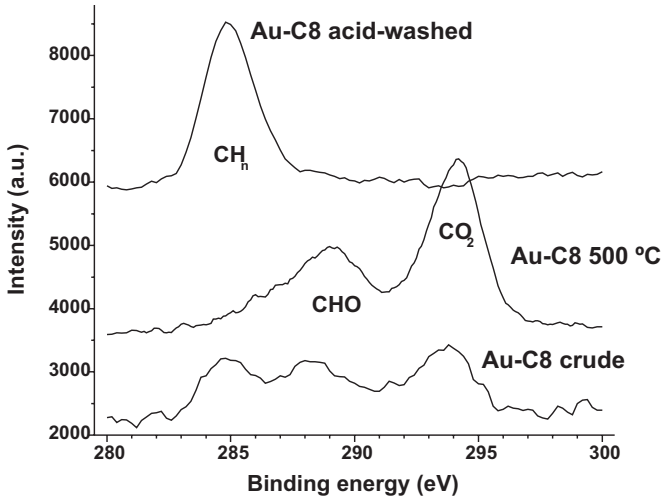
Fig. 4. High-resolution TGA–MS data for Pd-C2Ph (run at 2 °C/min).



set of wafers with crude NPs was also heated to 500 °C in a stream of He for 30 min. The IR spectra of the crude and heated samples were dominated by strong absorptions at 1500, 1435, and 880 cm^{-1}, but these peaks were absent in the acid-washed samples (SI, Fig. S16).[2] These three absorptions were also found in the reference IR spectrum of Li_2CO_3. The C-H stretching bands of the aliphatic side chains at around 2900 cm^{-1} were present in the crude and acid-washed samples, while they were missing in the heated samples. These results independently verified the presence of Li_2CO_3 in the crude samples, the selective removal of the aliphatic side chains below 500 °C, and the complete removal of Li_2CO_3 by the acid wash procedure.

XPS measurements on the same six samples revealed the presence of Au, C, S, O, and Li, whereas no other elements such as N, Cl, or B were detected. The relative intensities of the elements changed depending on the treatment. A drastic decrease in the relative content of O was observed for the acid-washed samples, but the O content increased in the crude samples that were heated to 500 °C. This finding was surprising as the samples were first purged with He for 30 min and then heated under a flow of He. Possible explanations include the reaction of the organic material with the silicon oxide surface (e.g., reduction by sulfur species) or, less likely, remaining small amounts of molecular oxygen in the sample or purge gas. A detection of the silicon oxide surface owing to incomplete coverage by the decomposed NPs can be excluded since no increase in the intensity of the Si (2p) signal was observed.

The intensities of the S (2p) signals between 163 and 164 eV drastically decreased in the heated samples and the maxima were shifted to much higher binding energies between 168 and 170 eV, which could be explained by the formation of small amounts of oxidized sulfur. The lithium signal was very weak because of its small atomic sensitivity factor, which made quantitative comparisons difficult, but the lithium content was about the same in the crude and heated samples and lower in the acid-washed samples.

Detailed studies of the carbon signal identified at least four different species in the crude samples of which three matched the values for CH, CHO/CHOH, and CO_2 (Fig. 5).

Fig. 5. XPS of the C (1s) binding energies in Au-C8 samples on silicon wafers. Three samples are compared, a crude sample, an acid-washed sample, and a crude sample that was heated at 500 °C in a stream of He.

The acid-washed samples only contained CH species while the heated crude samples only contained oxidized carbon. Two single peaks were observed for Au $4f_{7/2}$ and Au $4f_{5/2}$ with maxima at 83.85 and 87.35 eV, and agree with values reported by others (11).

Elemental analysis and calculation of average compositions

The compositions of Au-C8, -C12, and -C18 were also studied by EA (C, H, N) for comparison. Crude samples gave carbon–hydrogen contents of 9.86:0.70 *wt %*, 10.24:1.18 *wt %*, and 26.55:4.64 *wt %*, respectively. The calculated H:C ratios for pure alkyl chains are 0.18 (C_8), 0.17 (C_{12}), and 0.17 (C_{18}) and the values found for the crude samples were lower with 0.07 (Au-C8), 0.12 (Au-C12), and 0.14 (Au-C18). These values are comparable to the TGA results if the inorganic loss is considered to be predominantly CO_2 (see Table 1) and suggest a high content of carbon bond to other elements than hydrogen. EA also confirms an increase in the content of non-hydrocarbon carbon with decreasing chain lengths that was observed by TGA. The acid-washed samples gave decreased carbon and increased hydrogen contents for Au-C8, -C12, and -C18 of 5.07:0.81 *wt %*, 8.55:1.36 *wt %*, and 29.31:5.06 *wt %*, respectively. Calculated H:C ratios of 0.16, 0.16, and 0.17, respectively, were now close to the theoretical values for alkyl chains given earlier. This confirms a close to complete removal of non-hydrocarbon carbon and is consistent with XPS and TGA–MS results.

A comparison of the C, H content based on EA with the C, H, S content based on TGA also gave comparable values. The TGA values are approximate numbers based on two simplifications: the first weight loss is solely caused by the removal of the thiolate ligands and the second weight loss is exclusively due to the loss of CO_2 (Table 1). TGA values were 4%–20% larger than the EA-derived values, which is in the range of the expected sulfur contribution depending on the length of the alkyl chains. Only the crude sample of Au-

© 2006 NRC Canada

C18 gave a slightly higher C, H content by EA than by TGA.

TGA and EA data, in combination with structural information obtained by HRTEM and XRD, were used for the calculation of the average compositions of NP samples (Table 1). Estimated surface gold to thiolate ratios were in the typical range of 1.5–2.6 for Au-C18 and Au-C12, respectively. The lower ratio for Au-C18 could be explained by a previously reported decrease in the ratio with decreasing particle size (4*a*), but may also reflect a larger number of surface sites being occupied by inorganic contaminants in Au-C12. Au-C8 gave an unusually large value of 4.5, which suggests a considerable replacement of thiolates by inorganic contaminants, such as Li_2CO_3, at the metal surface. Au-C8 of gold core sizes of 300–400 gold atoms prepared by the two-phase method was reported to lose 19.7% of its weight below 500 °C, which would account for a surface gold to thiolate ratio of about 2.0 (9*b*).

Removal of the lithium salts by the acid wash treatment gave stable, although not very soluble, Au-C8 NPs of even larger surface gold to thiolate ratios and slightly increased ratios were also calculated for the acid-washed samples of Au-C12 and Au-C18. Based on these results, it may be concluded that the lithium salts are capable of replacing thiolates at the metal surface but the majority are incorporated as smaller or larger crystallites into the organic layers of individual NPs as well as into larger aggregates of NPs. However, the surface gold to thiolate ratios of neither crude nor acid-washed gold NPs were lowered significantly by their treatments with thiols at room temperature.

Alternative workup procedures

One fraction of the Au-C8 reaction mixture was not quenched with ethanol but the NPs were separated by ultracentrifugation and then washed with water and ethanol. TGA measurements of these NPs revealed an increase of the first weight loss to 27 *wt %* in comparison with the crude Au-C8 sample, possibly because of an incomplete removal of excess thiols and disulfides, but no second weight loss (SI, Fig. S7).[2] This sample did not contain any Li_2CO_3 or LiCl, but the presence of lithium ions cannot be excluded based on TGA–MS.

In a different experiment, a fraction of the Pd-C2Ph reaction mixture was quenched with dry ethanol under argon, which may have avoided the initial carbonate formation, but filtration of the NPs in air generated the same amount of carbonate as in the crude sample discussed earlier. Workup and handling of the NPs strictly under CO_2 and water-free conditions was not tested as it was assumed that LiOEt would still be trapped in the particles and eventually converted to Li_2CO_3 upon exposure to air.

These experiments suggest that the formation of Li_2CO_3 requires the quenching of the reaction mixture with ethanol–alcohol and subsequent exposure to air. It is likely that excess $LiB(Et)_3H$ reacts with dry ethanol to form LiOEt that is subsequently converted to LiOH when exposed to water. LiOH eventually reacts with CO_2 to form Li_2CO_3. Separation by ultracentrifugation is a possible but tedious alternative workup that avoids the contamination with Li_2CO_3.

Hydrophobic NPs appear to be best purified by liquid–liquid extraction methods and precipitated with polar aprotic solvents (5*a*, 6). Much lower Li_2CO_3 contents were observed in NPs that were dissolved in toluene and extracted with 0.01 mol/L HCl (aq) before precipitation by the addition of acetonitrile. Both Au and Pd NPs were stable in these conditions, and a small amount of thiol may be added to the toluene phase to compensate for ligand loss because of excessive extractions. However, treatment of contaminated NPs with an excess of thiol in the THF and toluene solutions did not result in any removal of Li_2CO_3 at room temperature.

Additional Comments

Previously, only the content of organic ligands and the thermal stability of Au and Pd NPs were determined by TGA measurements up to 500–700 °C. Measurements up to 1100 °C, collected herein, provide valuable additional information on the composition of NPs as inorganic contaminants, as well as the fact that oxidized sulfur and carbon species may be detected in separate weight loss events. Parallel MS analysis of the evolved gasses was essential for determining the structures of removed fragments and for concluding what structures contributed to each of the observed weigh losses.

High-temperature TGA–MS analysis revealed a complex composition of the NPs presented herein. They contained inorganic salts, such as Li_2CO_3, in addition to the expected thiolate ligands and their relative contents could be quantified by TGA as the organic ligands were removed below 500 °C, while the CO_2 loss of Li_2CO_3 occurred above 600 °C. TGA–MS could also distinguish between the evaporation of the original thiolate ligands and their oxidized species. All this information may be collected from a 2 mg sample in one measurement.

TGA–MS also has its limitations since nonvolatile contaminants, such as Li_2O, cannot be detected by this method and other techniques are required for their detection. XPS, IR, and XRD were used here to detect nonvolatile components and to verify the conclusions drawn from the TGA–MS analysis. Quantifications of the content of certain groups and (or) compounds based on TGA are only accurate if their weight losses occur at different temperatures. Events that occur at similar temperatures may be further separated by optimizing the heating program. Still, overlapping events may be recognized by MS, but unfortunately, quantification of the intensities observed in the MS data is not straightforward.

The second significant outcome of this study is the possible contamination of metal NPs with inorganic salts. This is likely to be a specific problem of surfactant-free single-phase methods as any generated inorganic salts have low solubility in the organic solvent. Once contaminated, only aggressive acidic conditions may remove the inorganic contaminants, but two-phase workup conditions have been demonstrated to prevent the contamination right from the beginning.

It is unlikely that Li_2CO_3 played a significant role in controlling the growth of the NPs as they were not detected in the sample purified by ultracentrifugation that otherwise produced NPs of similar size but higher organic content. However, the lower solubility and larger calculated surface gold to thiolate ratios of the contaminated NPs suggested that the lithium salts are capable of replacing thiolate ligands at the

© 2006 NRC Canada

gold surface, although most of these contaminants must have been incorporated in the organic layer of the thiolates. It is assumed that the surface bond Li salts are not fully removed by the acid treatment and account for the remaining Li ion content observed by XPS. This may also explain why their thiolate content cannot be increased by exposure to excess thiol and a replacement of larger amounts of Li_2CO_3 in the crude NPs by excess thiol in solution at room temperature was also unsuccessful.

Conclusions

TGA–MS has been demonstrated to be a powerful tool for the characterization of Au and Pd NPs. Measurements up to 1100 °C revealed complex weight loss patterns and identified oxidized sulfur and carbon species that must be considered for calculations of organic ligand to gold ratios. NPs prepared by a surfactant-free single-phase method contained Li_2CO_3 as a major contaminant when the reaction mixture was quenched with alcohols. The content of Li_2CO_3 was quantified by TGA–MS, which also appeared to be more sensitive than XRD and IR. Contaminated Au-NPs, passivated with thiolates of C_{12} or longer alkyl chains, remained mostly unaffected when purified by extractions with dilute acids, but Au-NPs with shorter alkyl groups and Pd-NPs increased in size or even coagulated to bulk metal. Incorporation of Li_2CO_3 was avoided by precipitating them in an ultracentrifuge or by liquid–liquid extraction and the initial application of aprotic solvents for precipitation.

4-Aminophenyldiphenylphosphinite (APDPP), a new heterogeneous and acid scavenger phosphinite — Conversion of alcohols, trimethylsilyl, and tetrahydropyranyl ethers to alkyl halides with halogens or *N*-halosuccinimides

Nasser Iranpoor, Habib Firouzabadi, and Mohammad Gholinejad

Abstract: A new heterogeneous phosphinite, 4-aminophenyldiphenylphosphinite (APDPP), is prepared and used for the efficient conversion of alcohols, trimethylsilyl ethers, and tetrahydropyranyl ethers to their corresponding bromides, iodides, and chlorides in the presence of molecular halogens or *N*-halosuccinimides. The amino group in this phosphinite acts as an acid scavenger and removes the produced acid. A simple filtration easily removes the phosphinate by-product.

Key words: 4-aminophenyldiphenylphosphinite, alcohol, trimethylsilyl ether, tetrahydropyranyl ether, alkyl halide.

Résumé : On a préparé un nouveau phosphinite hétérogène, le phosphinite de 4-aminophényle et de diphényle, et on l'a utilisé pour la conversion efficace d'alcools et d'éthers triméthylsyles ou tétrahydropyranyles en bromures, chlorures et iodures correspondants en présence d'halogènes moléculaires ou de *N*-halogénosuccinimides. La groupe amino de ce phosphinite agit comme piège et permet d'enlever l'acide qui est produit. Une filtration simple permet d'enlever la phosphinate obtenu comme sous-produit.

Mots clés : phosphinite de 4-aminophényle et de diphényle, alcool, éther triméthylsilyle, éther tétrahydropyranyle, halogénure d'alkyle.

[Traduit par la Rédaction]

Introduction

The very useful application of tertiary phosphines as oxophiles has been widely studied in organic synthesis. Conversion of alcohols into alkyl halides using triphenylphosphine, one of the most popular phosphines under Mitsunobu conditions, or in the presence of molecular halogens has been widely studied (1–12). Isolation of the phosphine oxide by-product is considered a drawback of using homogeneous phosphine reagents. To simplify the workup procedure for the removal of phosphine oxides, the use of a limited number of heterogeneous phosphines is reported. The use of polymer-supported triphenylphosphine has the usual problem of lower efficiency of the polymeric reagents compared with monomeric ones (6*a*, 13–17). Tris{4-(1*H*,1*H*-perfluorooctyloxy)phenyl]phosphine has been reported as another heterogeneous phosphine (18). Using diphos-1,2-bis(diphenylphosphino)ethane as an interesting source of phosphines for this purpose still suffers from the problem that only 75% of diphos oxide can be removed under optimized conditions (19). Recently, we prepared a silica-based inorganic phosphine reagent (silphos) and applied it to the conversion of alcohols into their corresponding alkyl halides (17). Another drawback of using phosphines in conjunction with molecular halogens for the preparation of alkyl halides from alcohols is the production of HX in the reaction mixture, which may cause problems for acid-sensitive functional groups.

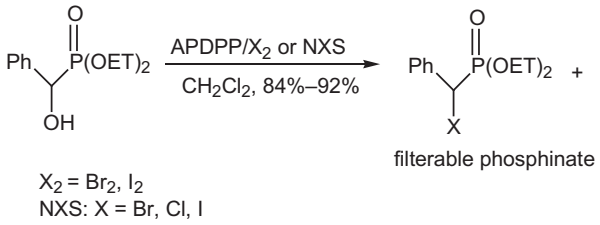
Results and discussion

In this work, we introduce 4-aminophenyldiphenylphosphinite (APDPP) as a new heterogeneous monomeric phosphinite reagent. In the presence of molecular halogens, this reagent efficiently converts alcohols into alkyl halides. The presence of an amino group makes this reagent an efficient acid scavenger and removes the HX produced from the reaction mixture. A simple filtration separates the ammonium salt of the produced phosphinate and leaves the pure product.



We successfully applied this easily prepared heterogeneous phosphinite to the conversion of different classes of alcohols to alkyl halides in the presence of molecular bromine, iodine, and *N*-halosuccinimides (NXS, X = Cl, Br, I) in dichloromethane at room temperature (Scheme 1).

 doi:10.1139/V06-120 © 2006 NRC Canada

Scheme 1.

Scheme 2.

The optimized molar ratios of benzyl alcohol – APDPP – halogen were found to be 1:1.2:1.2 for bromination and 1:1.5:1.5 for iodination reactions. Primary, secondary, and tertiary alcohols were converted into their corresponding alkyl bromides and iodides in excellent yields using these optimized conditions (Table 1). The HX produced in this reaction reacts with the amino group of the reagent and its phosphinate is easily removed by filtration. To extend the applicability of this reagent, we replaced the molecular halogens with *N*-halosuccinimides (NXS, X = Cl, Br, I) as safer sources of halogens for the conversion of alcohols to their corresponding halides. Here again, the produced phosphinate is insoluble and can be removed by filtration.

α-Functionalized phosphonates are important organophosphorous compounds in biology, pharmacology, and organic chemistry. A few methods for the conversion of diethyl α-hydroxyphosphinates into their corresponding diethyl α-halophosphinates have been reported in the literature (20, 21*a*–21*c*). Among these methods, the use of PPh_3–Br_2 in the presence of pyridine as an acid scavenger has been also reported (21*a*).

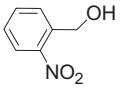
We successfully applied APDPP to the conversion of diethyl α-hydroxyphosphinates into their corresponding diethyl α-halophosphinates in the presence of molecular halogens or *N*-halosuccinimides (Scheme 2, Table 1, entries 13 and 14). The presence of an acid scavenger amino group in the structure of APDPP for the conversion of diethyl α-hydroxyphosphinates into their corresponding diethyl α-halophosphinates eliminates the use of toxic pyridine, as reported in the literature (21*a*). The results of this study are tabulated in Table 1.

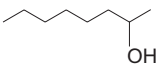
In continuation of this work, we used this new phosphinite reagent for the efficient conversion of trimethylsilyl and tetrahydropyranyl ethers to their corresponding alkyl halides in conjunction with molecular halogens or *N*-halosucinimides under heterogeneous conditions (Scheme 1). The conversion of trimethylsilyl and tetrahydropyranyl ethers to their corresponding alkyl halides with this reagent occurs at room temperature with high to excellent yields. The results are shown in Tables 2 and 3.

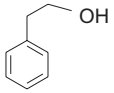
To show the stability of acid-sensitive compounds during the course of the reaction, we converted benzyl alcohol to its bromide and iodide in the presence of equimolar amounts of 2-phenyl-1,3-dioxolane as a highly acid-sensitive compound. The conversion of benzyl alcohol to its halides occurred quantitatively, but the 2-phenyl-1,3-dioxolane remained intact. Similarly, addition of styrene oxide to a mixture of benzyl alcohol, APDPP, and Br_2 in CH_2Cl_2 did not show the formation of any product from the ring opening of styrene oxide. These results show that the acid produced in the course of the reaction of alcohols with APDPP and halogens can be removed by the amino group of the reagent before affecting the acid-sensitive groups.

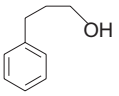
In summary, the present investigation has demonstrated the applicability of APDPP as a new heterogeneous phosphinite for the efficient conversion of alcohols, trimethylsilyl ethers, and tetrahydropyranyl ethers to their corresponding alkyl halides. α-Hydroxyphosphonates can also be converted heterogeneously into their α-halophosphonates without the need to use an additional base such as pyridine. In addition, the stability, heterogeneous nature, easy preparation, and acid-scavengering properties are considered other advantages of using APDPP for these transformations.

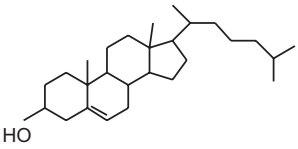
Experimental

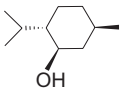


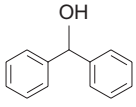


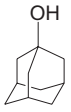












Chemicals were either prepared in our laboratory or obtained from Fluka (Buchs, Switzerland) and Merck (Darmstadt, Germany) chemical companies. IR spectra were recorded on a PerkinElmer 781 spectrometer. NMR spectra were recorded on an Avance DPX 250 MHz spectrometer. GC analyses were recorded on a Shimadzu GC-14A. Mass spectra were run on Shimadzu GC-Mass-QP 1000 EX at 70 eV.

Preparation of 4-aminophenyldiphenylphosphinite (APDPP)

To a flask containing *t*-BuOH (15 mL) was added potassium (0.43 g, 11 mmol), which was stirred slowly until the potassium was completely consumed. 4-Aminophenol (1.09 g, 10 mmol) was added and the solution was stirred with a mechanical stirrer for 30 min at room temperature. To the resulting dark syrup, chlorodiphenylphosphine (1.9 mL, 10 mmol) was added dropwise for a period of 10 min at room temperature. The reaction was completed after 5 min. The obtained product was washed with 30 mL of water to remove the produced KCl. The filtered cake was washed with diethyl ether (2 × 20 mL) and dried under vacuum at room temperature. 4-Aminophenyldiphenylphosphinite was obtained as a milky white solid (0.27 g, 93%). IR (KBr): 3340 (w), 3250 (w), 2915 (m), 2361 (m), 1498 (s), 1434 (m), 1281(w), 1213 (m), 865 (m), 690 (s), 511 (m). ^{1}H NMR (DMSO, 250 MHz, ppm) δ: 4.5 (b, 2H, NH_2), 6.4–6.5 (AA′BB′, pattern, 4H), 7.1–7.74 (complex, 10H). EI-MS (70 eV) *m/e*: 293 (2.07%), 292 (4.08%), 201 (53.4%), 183 (100%), 152 (13.9%), 107 (16%), 77 (26%), 51 (14%). Anal. calcd. for $C_{18}H_{16}NOP$: C 73.71, H 5.50, N 4.78; found: C 73.35, H 5.36, N 4.65.

Note: The molar ratios of $ROSiMe_3$–APDPP–Br_2, $ROSiMe_3$–APDPP–I_2, and $ROSiMe_3$–APDPP–NXS are 1:1.2:1.2, 1:1.5:1.5, and 1:2:2, respectively.

Typical procedure for the conversion of benzyl alcohol to benzyl bromide using APDPP–Br_2.

To a flask containing APDPP (0.35 g, 1.2 mmol) was added Br_2 (0.06 mL, 1.2 mmol) at room temperature in CH_2Cl_2 (7 mL) and stirred. Then benzyl alcohol (0.1 mL, 1 mmol) was added. The progress of the reaction was monitored by TLC and GC analysis. Benzyl alcohol was completely converted to benzyl bromide immediately. The reaction mixture was filtered to remove the produced insoluble phosphinate and enough powdered sodium thiosulfate was added to the solution, with vigorous stirring, to react with excess bromine. After filtration, the solvent was evaporated under vacuum in a rotary evaporator. For further purification, the product was washed over a silica gel pad (2 cm thick) using *n*-hexane – ethyl acetate as eluent. Benzyl bromide was obtained as a colourless liquid (0.16 g, 95% yield), bp 195 to 196 °C (lit. value (22) bp 196–198 °C).

Typical procedure for the conversion of benzyl alcohol to benzyl bromide with APDPP–*N*-bromosuccinimide.

To a two-necked flask containing APDPP (0.58 g, 2 mmol) and benzyl alcohol (0.1 mL, 1 mmol) in reflux dichloromethane (10 mL) was added dropwise a solution of *N*-bromosuccinimide (0.35 g, 2 mmol) in CH_2Cl_2 (10 mL) for a 1.5 h period. After the addition, GC analysis of the reaction mixture indicated when the reaction was complete. The reaction mixture was then filtered to remove the insoluble phosphinate and enough powdered sodium thiosulfate was added, with vigorous stirring, to remove any bromine produced. After filtration, the solvent was evaporated under vacuum in a rotary evaporator. The purification of the product was achieved using chromatography over a silica gel pad using *n*-hexane – ethyl acetate as eluent. Benzyl bromide was obtained as colourless liquid (0.16 g, 90% yield).

Typical procedure for the conversion of 1-octanol to 1-iodooctane using APDPP–I_2

To a flask containing a stirring mixture of APDPP (0.44 g, 1.5 mmol) in dichloromethane (20 mL) was added I_2 (0.38 g, 1.5 mmol) at room temperature. After 5 min, 1-octanol (0.15 mL, 1 mmol) was added. GC analysis showed completion of the reaction after 20 min. After removal of the produced phosphinate by filtration, enough powdered sodium thiosulfate was added, with vigorous stirring, to react with the unreacted iodine. After filtration, the solvent was evaporated under vacuum in a rotary evaporator. For further purification, the product was washed over a silica gel pad (2 cm thick) using *n*-hexane as eluent to give 1-iodooctane

(0.18 g, 93% yield, bp 226 to 227 °C (lit. value (22) bp 225 to 226 °C).

Typical procedure for the conversion of benzyltrimethylsilyl ether to benzyl bromide using APDPP–Br_2

To a flask containing a stirring mixture of APDPP (0.35 g, 1.2 mmol) was added Br_2 (0.06 mL, 1.2 mmol) at room temperature in dichloromethane (15 mL), after which benzyltrimethylsilyl ether (0.18 g, 1 mmol) was also added. TLC monitoring of the reaction showed completion of the reaction after 1 min. After filtration of the reaction mixture, enough powdered sodium thiosulfate was added, with vigorous stirring, to react with the unreacted bromine. The reaction mixture was filtered and the solvent was evaporated under vacuum in a rotary evaporator. The product was chromatographed on a short silica gel pad (2 cm thick) using *n*-hexane as eluent. Benzyl bromide was produced (0.12 g, 95% yield).

Typical procedure for the conversion of benzyltetrahydropyranyl ether to benzyl iodide by APDPP–I_2

To a stirring mixture of APDPP (0.44 g, 1.5 mmol) and I_2 (0.38 g, 1.5 mmol) in CH_2Cl_2 (10 mL) was added benzyltetrahydropyranyl ether (0.18 g, 1 mmol) at room temperature. After 30 min, TLC and GC analysis indicated that the reaction was complete. The reaction mixture was filtered and the unreacted iodine was removed by the addition, with vigorous stirring, of enough powdered sodium thiosulfate. The mixture was then filtered and the resulting solution was evaporated. To purify the product, it was passed through a short column of silica gel using *n*-hexane – ethyl acetate as eluent. Benzyl iodide was obtained (0.2 g, 95% yield). It was identified by comparison with a known sample.

Typical procedure for the conversion of diethyl α-hydroxybenzylphosphinate to diethyl α-bromobenzylphosphinate using APDPP–Br_2

To a flask containing a stirring mixture of APDPP (2 mmol, 0.58 g) was added Br_2 (2 mmol, 0.1 mL) in CH_2Cl_2 (7 mL) at room temperature. Then, diethyl α-hydroxyphosphinate (0.24 g, 1 mmol,) was added. After 6 h, the reaction mixture was filtered to remove the insoluble phosphinate and enough powdered sodium thiosulfate was added to the solution, with vigorous stirring, to react with the unreacted bromine. After filtration, the product was washed over a silica gel pad (2 cm thick) using *n*-hexane – ethyl acetate (4:1) as eluent to give α-bromophosphinate (0.275 g. 90% yield). ^{1}H NMR ($CDCl_3$, 250 MHz, ppm) δ: 1.08 (t, 3H, $^3J_{HH}$ = 7.1 Hz, 2-OCH_2CH_3), 1.26 (t, H, $^3J_{HH}$ = 7.1 Hz, 2-OCH_2CH_3), 3.79–4.00 (m, 2H, 2-OCH_2CH_3), 4.03–4.17 (m, 2H, 2-OCH_2CH_3), 4.79 (d, 1H, $^2J_{PH}$ = 12.5 Hz, -CH), 7.25–7.28 (m, 3H, -C_6H_5), 7.47–7.49 (m, 2H, -C_6H_5). ^{13}C NMR ($CDCl_3$, TMS, 62.9 MHz) δ: 16.57 (d, $^3J_{CP}$ = 5.8 Hz, 2-OCH_2CH_3), 16.78 (d, $^3J_{CP}$ = 5.8 Hz, 2-OCH_2CH_3), 41.85 (d, $^1J_{CP}$ = 159.2 Hz, -CH), 64.46 (d, $^2J_{CP}$ = 4.2 Hz, 2-OCH_2CH_3), 64.57 (d, $^2J_{CP}$ = 4.2 Hz, 2-OCH_2CH_3), 129.05–129.95, 134.94, 134.99 (-C_6H_5). MS (70 eV) *m/e*: 307 [M^+], 227 [M – Br], 90 [227 – P(O)$(OEt)_2$]. Anal. calcd. for $C_{11}H_{16}BrO_3P$ (%): C 43.00, H 5.21; found: C 43.10, H, 5.30.

Typical procedure for the preparation of diethyl α-iodobenzylphosphinate from diethyl α-hydroxybenzylphosphinate using APDPP–NIS

A two-necked flask, equipped with a dropping funnel and a reflux condenser, was charged with APDPP (0.67 g, 2.3 mmol) and α-hydroxybenzylphosphinate (0.24 g, 1 mmol) in CH_2Cl_2 (10 mL) in reflux condition. Then a solution of *N*-iodosuccinimide (2.3 mmol) in CH_2Cl_2 (10 mL) was added dropwise for a 1.5 h period. TLC monitoring showed the completion of the reaction after 10 h. After filtration of the reaction mixture, the residue was chromatographed on a silica gel column, using *n*-hexane – ethyl acetate (4:1) as eluent, to give α-iodobenzylphosphinate (0.31 g, 87% yield). ^{1}H NMR ($CDCl_3$, TMS, 250 MHz, ppm) δ: 3.80–4.08 (m, 2H, 2-OCH_2CH_3), 4.18–4.27 (m, 2H, 2-OCH_2CH_3), 4.98 (d, 1H, $^2J_{PH}$ = 13.4 Hz, -CH), 7.28–7.31 (m, 3H, -C_6H_5), 7.56–7.59 (m, 2H, -C_6H_5). ^{13}C NMR ($CDCl_3$, TMS, 62.9 MHz, ppm) δ: 15.41 (d, $^1J_{CP}$ = 139.9 Hz, -CH), 16.57 (d, $^3J_{CP}$ = 5.9 Hz, 2-OCH_2CH_3), 16.7 (d, $^3J_{CP}$ = 5.9 Hz, 2-OCH_2CH_3), 64.42 (d, $^2J_{CP}$ = 8.6 Hz, 2-OCH_2CH_3), 64.55 (d, $^2J_{CP}$ = 8.6 Hz, 2-OCH_2CH_3), 128.95–130.04 (-C_6H_5). MS (70 eV) *m/e*: 354 [M], 226 [M – Br], 89 [226 – P(O)$(OEt)_2$]. Anal. calcd. for $C_{11}H_{16}IO_3P$ (%): C 37.29, H, 4.52; found: C 37.5, H, 4.48.

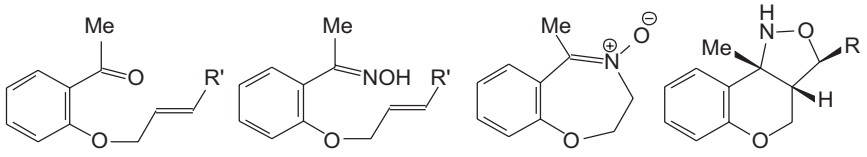
DISCUSSION / DISCUSSION

Discussion of "Efficient, microwave-assisted intramolecular 1,3-dipolar cycloadditions of oximes and *N*-methylnitrones derived from *o*-alkenylmethoxyacetophenones"[1]



Frances Heaney and Linda Doyle

The following discussion note arises in defence of comments and assertions made upon our work (1) in the paper entitled "Efficient, microwave-assisted intramolecular 1,3-dipolar cycloadditions of oximes and *N*-methylnitrones derived from *o*-alkenylmethoxy-acetophenones", published in the *Canadian Journal of Chemistry* (2). Ishar and co-workers (2) include in their publication a number of inaccuracies and contradictions of our previously published work (1), the details of which are outlined in the following paragraphs.

Firstly, the inaccuracies. The abstract of the paper begins "Contrary to literature reports oximes (**2a**, **2b**) are transformed to nitrones, which undergo regio- and stereoselective intramolecular 1,3-dipolar cycloadditions, both on microwave heating under solvent free conditions and refluxing in toluene, to afford novel cycloadducts (**5a**, **5b**); the oxazepine *N*-oxide (**3a**) reported to be formed in 98% yield was obtained only as a minor product (~10%)." The final sentence of the introductory paragraph continues in the same vane, stating "Recently, it has been reported that the oximation of *o*-allyloxy-acetophenone and -benzophenone (**1**) affords *E*-oximes (**2**), which are quantitatively converted to dipoles (**3**, Scheme 1) on refluxing in xylene for 14 h (5)." The implication being that our cited work (1) included results on the behaviour of oximes **2**, i.e, **2a**–**2c**. This is in error, our publication concerned only the reaction of oxime **2a**, it did not include any data on **2b** or **2c**.

Secondly, the contradictions. The reaction of **2a** described in the publication by Ishar and co-workers (2) involves heating in toluene at 110 °C for 72 h, whilst our cited work (1) refers to thermal reaction of **2a** following 14 h heating in refluxing xylene (140 °C). Within the Results and discussion section of this paper (2), the authors contradict our work (1) no less than four times. The changes in experimental conditions, in terms of both reaction temperature (30 °C lower) and reaction duration (58 h longer) between that reported by Ishar and co-workers (2) and our cited work (1) are of sufficient magnitude to make it completely unreasonable for Ishar and co-workers to conclude that the result of their reaction contradicts our cited result. Indeed, following the publication of the paper by Ishar and co-workers, a researcher in our laboratory, not previously involved with the initial reactions of **2a**, repeated our reported work (1); thus, we can confirm that **2a** transforms (xylene, 140 °C, 14 h) smoothly to **3a** in excellent yield as we previously described (1).

The publication of the paper by Ishar and co-workers has publicly and inaccurately discredited our work on the important topic of the relationship between oxime geometry and reactivity. Moreover, this paper has already been cited by respected researchers in our field (3) and we welcome the opportunity to clarify our position with regard to the reaction of oxime **2a**.

DISCUSSION / DISCUSSION

Reply to the discussion by Heaney and Doyle on "Efficient, microwave-assisted intramolecular 1,3-dipolar cycloadditions of oximes and *N*-methylnitrones derived from *o*-alkenylmethoxyacetophenones"[1]

M.P.S. Ishar

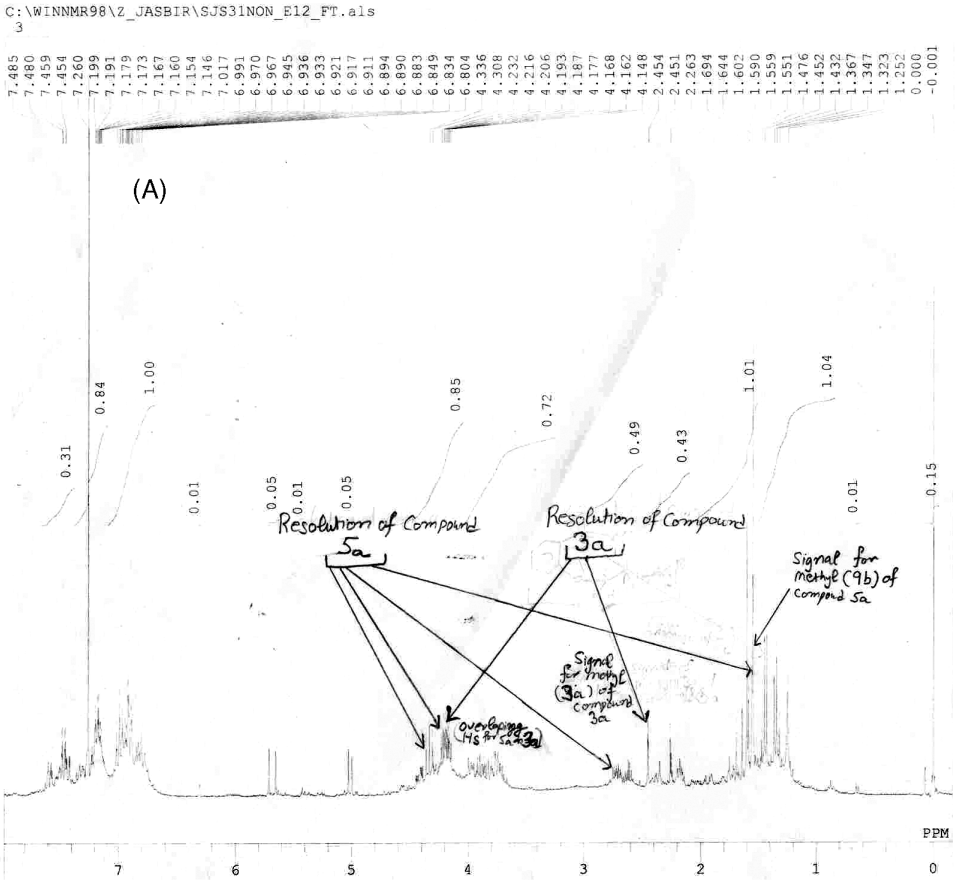
This relates to the objections raised by Dr. Heaney and Linda Doyle regarding the use of the phrase "Contrary to literature reports" in our publication (1), which according to her has discredited their work (2).

I would like to make clear that our aim was never to discredit anyone's work. However, we had to contradict any over generalization, which was contrary to our observations.

We performed the reaction for the oximes under microwave heating because under these conditions the oximes are known to undergo a proton shift to generate nitrones in situ that can be trapped intramolecularly through 1,3-dipolar cycloadditions. As the observed outcome was in contradiction with the thermal transformations of related oximes reported by Heaney and O'Mahony (2), to compare our result with the thermal transformation, we carried out the corresponding thermal reactions by refluxing the oximes in toluene, wherein we obtained 1,3-dipolar cycloadducts as the major products in some cases. Therefore, we had no option but to contradict the literature reports.

If one goes through the abstract of the paper (2) by Heaney and O'Mahony, it reads "Thermally induced cyclization of *anti*-alkenyl oximes *E*-**7a**,**b** and *E*-**17a**,**b** affords cyclic α-alkoxycarbonylnitrones **8** and the 6,7-bicyclic nitrones **18**, respectively." This statement clearly generalizes the thermal behavior of similar oximes and no mention is made of reaction conditions. Heaney and O'Mahony have further asserted that the reaction outcome is related to the configuration (geometry) of oximes and that these oximes are configurationally stable under reaction conditions (refluxing xylene). However, in their Discussion, Heaney and Doyle have attributed the difference in reaction outcomes to possible differences in reaction conditions and reaction times, which is in contradiction with their own hypothesis that these oximes are configurationally stable under these reaction conditions (in refluxing xylene); we used a lower reaction temperature (refluxing toluene).

We have now repeated this reaction. The ^{1}H NMR spectra of the crude products obtained by refluxing oxime **2a** (**17a** in their case) in both toluene (72 h, spectrum A) and xylene (72 h, spectrum B) are presented here. It is obvious that intramolecular 1,3-dipolar cycloadducts are formed as the major products under both conditions and the nitrone **3a** derived from intramolecular alkylation is the minor product in both cases, although relative yields may be different; the spectra of the pure products, i.e., **5a** (spectrum D) and **3a** (spectrum E) are also presented for comparison. The ^{1}H NMR spectrum (C) obtained after refluxing oxime **2a** in xylene for 14 h is also presented. In this case, it is apparent that unreacted oxime **2a** is the major component, whereas Heaney and O'Mahony (2) reported the formation of nitrone **3a** (**18a** in their case) in excellent yield under the same conditions of temperature and time. Obviously, there is a great difference between our result and the results reported by Heaney and O'Mahony (2).



Even if it is accepted that the mode of transformation is specific to the configuration of the oxime, then the assertion that oximes are configurationally stable may not be correct or oxime **2a** does not preferably exist in the *E* form. Alternatively, the configuration is not important and the mode of transformation is temperature-dependent. Oxime **2a** gave the same spectral data as reported for **17a** by Heaney and O'Mahony (2), although they did not report the melting point and the crude solid obtained on trituration is used as such; however, they reported the assignment of the configuration of the oxime by ^{1}H nOe measurements. Interestingly, in one case, i.e., *o*-cinnamyloxyacetophenone oxime **3c** (in

our paper, ref. 1), we obtained exclusive formation of a nitrone from intramolecular alkylation, thereby indicating that the nature of the alkene moiety dictates the mode of transformation.

It is true that only one example, i.e., oxime **17a** in their case (2) and **2a** in our paper (1) is identical. The generalization, if proved wrong in one case, can be rejected. Therefore, there is nothing wrong in using the phrase "Contrary to literature reports". Again, we would like to mention here again that our aim is not to discredit anyone's work, but to advance the understanding of the subject.

Stereoselective debromination and selective reduction of *vic*-dibromides with nickel boride

Jitender M. Khurana, Bhaskar M. Kandpal, Gagan Kukreja, and Purnima Sharma

Abstract: A simple procedure is reported for the stereoselective debromination of *vic*-dibromides with nickel boride at ambient temperature. Debromination with concomitant reduction of *vic*-dibromides to give dihydro products in a one-pot reaction is also reported. α,β-Dibromoketones can also be converted to their corresponding alcohols.

Key words: debromination, *vic*-dibromides, stereoselective, reduction, *E*-alkenes.

Résumé : On a mis au point une méthode simple de débromuration stéréosélective de dibromures *vicinaux* impliquant l'utilisation du borure de nickel à la température ambiante. On rapporte aussi la réaction monotope de débromuration avec réduction concomitante des dibromures *vicinaux* qui conduit à la formation des produits dihydrogénés. On peut aussi transformer les α,β-dibromocétones en alcools correspondants.

Mots clés : débromuration, dibromures *vicinaux*, stéréosélective, réduction, *E*-alcènes.

[Traduit par la Rédaction]

Introduction

The protection–deprotection of olefins via bromination and debromination (1) has been studied and different reagents and reaction conditions exist for debrominating *vic*-dibromides (2–9). Solvolytic stereoselective debromination has also been reported by DMF (10) and HMPA (11) without the aid of any reagents. The efficiency of a reagent greatly depends upon its selectivity and compatibility with other functionalities present in the substrate. Nickel boride is a versatile reducing agent reported to bring about a number of transformations, e.g., reduction, deoxygenation, desulfurization (12). It is known to behave differently under different reaction conditions and therefore we decided to explore its application for the debromination and (or) reduction of *vic*-dibromides.

Results and discussion

This is the first report on (*i*) stereoselective debromination of *vic*-dibromides to olefins and (*ii*) debromination with concomitant reduction of *vic*-dibromides in a one-pot reaction with nickel boride by changing the stoichiometric ratios and the solvent. Chalcone dibromides (benzylideneacetophenone dibromides/benzalacetophenone dibromides) also undergo chemoselective debromination to chalcones or undergo debromination with concomitant reduction to selectively give either dihydrochalcones or tetrahydrochalcones in methanol in one-pot reactions by changing the stoichiometric ratios.

A variety of stilbene dibromides and other *vic*-dibromides (Table 1, runs 1–16), soluble in tetrahydrofuran, undergo quantitative debromination with nickel boride generated in situ from nickel chloride and sodium borohydride using a molar ratio of 1:2:6 (substrate–$NiCl_2$–$NaBH_4$) in THF to give the corresponding alkenes (eq. [1]). The reactions were complete in 30–120 min at ambient temperature as monitored by TLC. Chalcone dibromides and other α,β-dibromoketones did not undergo complete debromination under these conditions. Smooth debromination of different chalcone dibromides and other α,β-dibromoketones, which were soluble in methanol, was successfully achieved to afford the corresponding chalcones or enones (Table 2, runs 17–28) in quantitative yields using a molar ratio of 1:5:2 (substrate–$NiCl_2$–$NaBH_4$) in methanol at ambient temperature for 15–60 min (eq. [1]). The carbonyl, carboxylic, carbmethoxy, highly sensitive furan and benzopyrone rings remained unaffected under these conditions. Even steroidal derivatives could be readily debrominated. The debrominations are stereoselective as (*E*)-stilbene was obtained from *meso*- and *dl*-stilbene dibromides, and fumaric acid was obtained from *meso*- and *dl*-α,β-dibromosuccinic acids. The possibility of any isomerization of (*Z*)-stilbene to (*E*)-stilbene or maleic acid to fumaric acid has been ruled out by independent reactions of (*Z*)-stilbene and maleic acid with nickel boride under identical conditions. The debrominations were undoubtedly due to the involvement of nickel boride generated in situ as starting *meso*-stilbene dibromide was recovered unchanged when treated with nickel chloride or sodium borohydride separately.

43	$CH_3CHBrCHBrCOOCH_3$ (**Ip**)	15	81
44	 (**Iq**)	15	85

Note: Fifty millilitres of solvent were used per gram of substrate. Molar ratio is 1:3:9 (substrate–$NiCl_2$–$NaBH_4$).

We also report herein the debromination with concomitant reduction of *vic*-dibromides with nickel boride generated in situ. Since the activity, selectivity, and the physical and chemical properties of nickel boride depend on its method of preparation, and the amount of H_2 adsorbed in the crystal lattice of nickel boride depends upon the metal–boron ratio (12), the stoichiometric ratios of substrate–$NiCl_2$–$NaBH_4$ were varied to achieve the goal. *vic*-Dibromides (**Ia**–**Ii**, **Ik**–**Iq**) can be debrominated and reduced concomitantly in a one-pot reaction with nickel boride using a molar ratio of 1:3:9 in methanol to give the corresponding reduced product (Table 3, runs 29–44) in high yields (eq. [2]). Reactions of *meso*- and *dl*-stilbene dibromides using molar ratios of 1:2:6 or 1:1:3 of substrate – nickel chloride – sodium borohydride in methanol resulted in the formation of a mixture of (*E*)-stilbene and bibenzyl, implying that the reductions must be proceeding via the corresponding alkenes. The acid and ester groups were unaffected under these conditions.

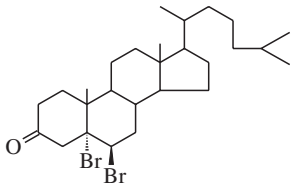
[2] $$\underset{\textbf{Ia–Ii, Ik–Iq}}{RCHBr\text{-}CHBrR'} \xrightarrow[MeOH,\ rt]{NiCl_2,\ NaBH_4} \underset{\textbf{Va–Vi, Vk–Vq}}{RCH_2CH_2R'}$$

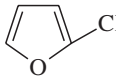
Chalcone dibromides and other α,β-dibromoketones gave corresponding alcohols (eq. [3]) rather than ketones under these conditions (Table 4, runs 45–53). Reactions of chalcone dibromide using molar ratios of 1:1:3 or 1:2:6 were incomplete and showed the presence of chalcone, dihydrochalcone, and tetrahydrochalcone. Selective debromination and reduction of the double bond could not be achieved under these conditions without affecting the carbonyl group. However, selective debromination was achieved using a molar ratio of 1:10:15 (substrate–$NiCl_2$–$NaBH_4$). High yields of dihydrochalcones were obtained under these conditions in methanol at ambient temperature (eq. [4]) (Table 5, runs 54–58). *p*-Bromochalcone dibromide (**IIIf**) also underwent competitive aryl debromination under these conditions.

[3] $$\underset{\textbf{IIIa–IIIe, IIIg–IIIj}}{RCHBr\text{-}CHBrC(=O)\text{-}R'} \xrightarrow[MeOH,\ rt]{NiCl_2,\ NaBH_4} \underset{\textbf{VIa–VIe, VIg–VIj}}{RCH_2CH_2\text{-}CH(OH)\text{-}R'}$$

[4] $$\underset{\textbf{IIIa–IIIe}}{RCHBr\text{-}CHBrC(=O)\text{-}R'} \xrightarrow[MeOH,\ rt]{NiCl_2,\ NaBH_4} \underset{\textbf{VIIa–VIIe}}{RCH_2CH_2\text{-}C(=O)\text{-}R'}$$

We conclude that nickel boride is an efficient and versatile reagent for debromination of *vic*-dibromides to the corresponding (*E*)-olefins and for debromination with concomitant reduction to give dihydro products at ambient temperature. Chalcone dibromides and other α,β-dibromoketones undergo debromination with complete reduction to give alcohols or undergo debromination with selective reduction to give dihydrochalcones.





Experimental

General procedure for reactions of stilbene dibromides with $NiCl_2$ and $NaBH_4$ (molar ratio 1:2:6, Table 1) in THF

In a typical general procedure, *meso*-stilbene dibromide (1 g, 2.94 mmol) was dissolved in THF (75 mL) in a 250 mL round-bottomed flask mounted over a magnetic stir-

Note: Forty millilitres of methanol were used per gram of substrate. Molar ratio is 1:10:15 (substrate–$NiCl_2$–$NaBH_4$).
[a]A mixture of dihydrochalcone (56%) and *p*-bromodihydrochalcone (28%) was obtained.

rer. $NiCl_2$ (1.39 g, 5.88 mmol) was added followed by the addition of $NaBH_4$ (0.67 g, 17.64 mmol) while vigorously stirring the solution. The progress of the reaction was monitored by TLC using petroleum ether as eluent. The reaction was found to be complete in 30 min. The reaction mixture was filtered through a Celite pad (~1 in, 1 in = 25.4 mm) and washed with THF (2 × 10 mL). The combined filtrate was reduced to half and diluted with water (~150 mL). The product was extracted with ethyl acetate (3 × 15 mL). The combined extract was dried over anhydr. $MgSO_4$, filtered, and concentrated on a rotary evaporator to afford a white solid, which was identified as (*E*)-stilbene (0.5 g, 96%) with a mp of 112 °C (lit. value (13*a*) mp 114 °C) as demonstrated by the mixed mp, IR, and NMR spectra.

General procedure for reactions of chalcone dibromides with $NiCl_2$ and $NaBH_4$ (molar ratio 1:5:2, Table 2) in methanol

In a 100 mL round-bottomed flask mounted over a magnetic stirrer was placed a mixture of chalcone dibromide (1 g, 2.71 mmol), methanol (30 mL), and $NiCl_2$ (3.22 g, 13.55 mmol). $NaBH_4$ (0.206 g, 5.43 mmol) was added with continuous stirring. Disappearance of starting material was monitored by TLC using petroleum ether – benzene (50:50) as eluent. The reaction was complete after 45 min. The reaction mixture was filtered through a Celite pad (~1 in) and washed with methanol (2 × 15 mL). The combined filtrate was diluted with water (~150 mL) and extracted with ethyl acetate (3 × 15 mL). The combined extract was dried over anhydr. $MgSO_4$, filtered, and concentrated on a rotary evaporator to yield chalcone (0.508 g, 90%), confirmed with a mp of 55 °C (lit. value (13*b*) mp 56–58 °C) as demonstrated by the mixed mp, IR, and NMR spectra.

Reactions of stilbene dibromides with $NiCl_2$ and $NaBH_4$ (molar ratio 1:3:9, Table 3) in methanol

A mixture of *meso*-stilbene dibromide (1 g, 2.94 mmol), methanol (50 mL), and $NiCl_2$ (2.090 g, 8.82 mmol) was placed in a 100 mL round-bottomed flask and fitted with a reflux condenser and a guard tube. $NaBH_4$ (1.005 g, 26.46 mmol) was carefully added with continuous stirring. The progress of the reaction was monitored using petroleum ether as an eluent. The starting material disappeared in 10 min. The reaction was worked up as in previous proce-

© 2006 NRC Canada

dures. The product obtained was identified to be 1,2-diphenylethane (0.48 g, 92%) by IR and NMR spectra.

Reactions of chalcone dibromides with $NiCl_2$ and $NaBH_4$ (molar ratio 1:3:9, Table 4) in methanol

Chalcone dibromide (1 g, 2.71 mmol), $NiCl_2$ (1.926 g, 13 mmol), and methanol (40) mL were placed in a 100 mL conical flask fitted with a condenser. The flask was mounted over a magnetic stirrer. Sodium borohydride (0.929 g, 24.39 mmol) was added very cautiously while vigorously stirring the solution. The progress of the reaction was monitored by TLC using petroleum ether – benzene (50:50) as eluent. The starting material disappeared after 15 min and then the reaction was worked up as in previous procedures. The product obtained was identified to be tetrahydrochalcone (0.50 g, 91%) by IR and NMR spectra.

Reaction of chalcone dibromide with $NiCl_2$ and $NaBH_4$ (molar ratio 1:10:15, Table 5) in methanol

Chalcone dibromide (1 g, 2.71 mmol), $NiCl_2$ (6.422 g, 27.1 mmol), and methanol (40 mL) were added to a 100 mL round-bottomed flask fitted with a reflux condenser. The reaction mixture was stirred at room temperature and $NaBH_4$ (1.54 g, 40.65 mmol) was added very cautiously. The progress of the reaction was monitored by TLC using petroleum ether – benzene (50:50) as eluent. The starting material disappeared completely after 30 min and the reaction was worked up as in previous procedures. Dihydrochalcone (0.49 g, 87%) was isolated and identified with a mp of 70 to 71 °C (lit. value (13*c*) mp 72–75 °C) as demonstrated by IR, and NMR spectra.

In the case of aliphatic and cyclic *vic*-dibromides, because of high solubility in water, the reaction mixture was filtered through a Celite pad and washed with methanol or THF (2 × 15 mL). The combined extract was dried over anhydr. $MgSO_4$, filtered, and concentrated on a rotary evaporator. The product was extracted by triturating with dry ether.

Theoretical study on six-fold coordinated silicon in silicophosphate compounds

Hassan Rabaâ and Fatima Bkiri

Abstract: Extended Hückel tight-binding (EHTB) calculations were performed on silicophosphate compounds with six-coordinated silicon. Speculative structures related to silicon coordination in SiP_2O_7 are reported. To account for the particular structural distortion caused by the presence of SiO_6 in the silicon pyrophosphate, it is important to examine how the stability and the band gap of the extended structure of SiP_2O_7 are affected. Different theoretical tools are used (EHTB, ab initio Hartree–Fock, and density functional theory DFT-B3LYP). To obtain detailed descriptions of the incorporation of hexacoordinated silicon in this material, the band structures in SiP_2O_7 and $[P_2O_7]^{4-}$ were analyzed. It seems that the diffuse orbitals of silicon and the high energy of the Si 3p orbital lead to higher energy coordination and contribute to the breaking of the P-O-P bridge and the forming of a Si-O-P entity in this material. In addition, to provide more evidence of the existence of the octahedral silicon coordination in SiP_2O_7 (**1**), two model clusters $[P_4Si_2O_{23}H_{18}]$ (**2**) and $[P_4Si_2O_{19}H_{10}]$ (**3**) involving silicon atoms in octahedral and tetrahedral sites were investigated using Hartree–Fock and DFT theories. A remarkable agreement between calculated and experimental bond lengths for Si—O and P—O is obtained using the DFT calculation. The model cluster **2** corroborates the structural change in the Si-O-P and P-O-P fragments seen in **1**. The IR vibrational frequencies are calculated for both model clusters and are predicted to shift towards lower frequencies in the octahedral Si sites, which is consistent with experimental data.

Key words: silicophosphate, SiO_6, band structure, tight-binding calculations, Hartree–Fock, DFT, B3LYP, model cluster, IR frequencies.

Résumé : On a effectué des calculs étendus de Hückel à liaison serrée (EHTB) sur des silicophosphates comportant un silicium hexacoordiné. On rapporte les structures proposées pour la coordination du silicium dans le SiP_2O_7. Pour tenir compte de la distorsion particulière de la structure provoquée par la présence du SiO_6 dans le pyrophosphate de silicium, il est important d'examiner comment la stabilité et la bande interdite de la structure étendue du SiP_2O_7 sont affectées. On a étudié divers outils théoriques (calculs ab initio de Hartree–Fock, EHBT et théorie de la densité fonctionnelle, DFT-B3LYP). Dans le but d'obtenir des descriptions détaillées de l'incorporation du silicium hexacoordiné dans ce composé, on a analysé les structures de bande du SiP_2O_7 et du $[P_2O_7]^{4-}$. Il semble que les orbitales diffuses du silicium et l'énergie élevée de l'orbitale Si (3p) conduisent à une énergie de coordination plus élevée et qu'elles contribuent à une rupture du pont P-O-P et à la formation de l'entité Si-O-P dans ce produit. De plus, dans le but d'obtenir plus d'information sur l'existence d'une coordination octaédrique du silicium dans le SiP_2O_7 (**1**), et faisant appel aux théories de Hartree–Fock et de la densité fonctionnelle, on a étudié deux agrégats modèles $[P_4Si_2O_{23}H_{18}]$ (**2**) et $[P_4Si_2O_{19}H_{10}]$ (**3**) impliquant des atomes de silicium dans des sites octaédriques et tétraédriques. Avec la théorie de la densité fonctionnelle, on a obtenu un accord remarquable entre les valeurs calculées et expérimentales des liaisons Si—O et P—O. L'agrégat modèle **2** permet de corroborer le changement structural des fragments Si-O-P et P-O-P observés dans le produit **1**. On a calculé les fréquences vibrationnelles en infrarouge pour les deux composés modèles et ces calculs permettent de prédire un déplacement vers des fréquences plus basses pour les sites de silicium octaédrique, ce qui est en accord avec les données expérimentales.

Mots clés : silicophosphate, SiO_6, structure de bande, calculs.

[Traduit par la Rédaction]

Introduction

Silicophosphate compounds have been the subject of intensive study for their important applications (1–5). These materials have good reactivity and easy resorbance for natural bone in animals (1). For example, a calcium silicophosphate ceramic was tested for use in orthopaedic implants (3). High-silica glasses containing P_2O_5 have been recognized as promising materials for optical fibre communications (2). Vitreous ionic conducting materials have also been investigated as electrolytes in high-density solid-state alkaline batteries (6–8).

The addition of oxides such as Li_2O, Na_2O, or K_2O to the SiO_2–P_2O_5 binary system regulates the degree of SiO_6 formation and stimulates the copolymerisation of silicate compounds by forming a metaphosphate group and pyro-

phosphate linked by SiO_4 tetrahedra and SiO_6 octahedra (5–11). Molecular mechanics (12) and ab initio studies (13) on alkali phosphates have also been reported. The authors optimized different small clusters that contain the P-O-P unit with different alkali atoms (13*a*).

Silicon pyrophophosphate is of special interest because of the similarity of P and Si coordination environments. For example, phosphates and silicates exhibit similar crystalline structures based on $[PO_4]^{3-}$ and $[SiO_4]^{4-}$ tetrahedral units (11–20). Moreover, it is experimentally interesting to see how the low-temperature structure phases of SiP_2O_7 (**1**) differ from the high-temperature ones (14 and15). Eight crystal phases exist for **1** including the monoclinic and cubic structures that were prepared at high temperature. From an experimental viewpoint, several attempts to characterize **1** have been reported utilizing solid state NMR (9) and X-ray powder diffraction (20). The characterization of the structure and nature of the P-O-Si bond fragment in **1** remains a difficult task (12–20).

The first aim of this work is to study the electronic structural changes induced by a six-coordinate silicon atom in the silicon pyrophosphate phase obtained at low temperature. An understanding of the band structure of **1** using an extended Hückel tight-binding (EHTB) approach (21 and 22) is required. Our theoretical investigation focuses on the detailed description of the Si—O and P—O bonds of the SiO_6 building blocks with respect to binding energy, orbital overlap, and the band widths of the Si and P atoms in **1**. The second aim is to understand the changes that occur in this material using two cluster models $[P_4Si_2O_{23}H_{18}]$ (**2**) (Si in octahedral site) and $[P_4Si_2O_{19}H_{10}]$ (**3**) (Si in tetrahedral site) within an ab initio Hartree–Fock framework and also employing density functional theory, i.e., B3LYP. Finally, we analyze IR vibrational frequencies by comparing calculated frequencies with experimental data.

Computational details

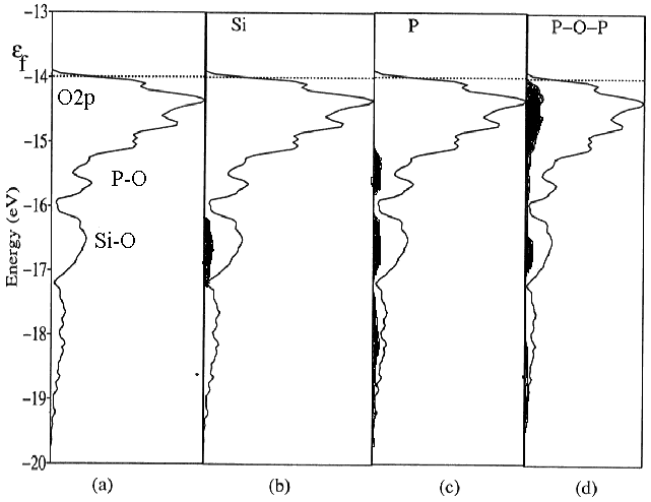
The first part of this work focuses on the structure–property relationship of **1** by studying the one-electron band structure determined from a tight-binding approximation based on the extended Hückel method (EHTB) (21). The methodology is described in detail elsewhere and has been found to be quite satisfactory in describing a wide range of organic and inorganic structural problems (22). Both periodic (YAeHMOP, yet another extended Hückel molecular orbital package) (23) and molecular (CACAO, computer-aided composition of atomic orbitals) extended Hückel (24) software were used. The parameters employed in our YAeHMOP calculation are listed in Table 1. The off-diagonal elements of the Hamiltonian matrix were evaluated with the Wolfsberg–Helmholtz formula (26). Numerical integrations over the symmetry-unique section of the Brillouin zone of the three-dimensional structure were performed using a set of 36 k-points. DOS and COOP signify density of states and crystal orbital overlap population, respectively. The positive and negative regions shown in the COOP curves represent the bonding and antibonding zone between atoms. The *x* axes in Figs. 1 and 2 correspond to the DOS peaks. Their total integration fixes the main bonding encountered in the corresponding bands and is estimated generally between 0% and 100%.

Table 1. Parameters used in the EHTB calculations with a weighted H_{ij} approximation.

Atoms	Orbital	H_{ij} (eV)	ξ
P	3s	–18.6	1.75
	3p	–14.0	1.30
O	2s	–32.3	2.275
	2p	–14.8	2.275
Si	3s	–17.3	1.383
	3p	–9.20	1.383

Note: H_{ij} = orbital energy, ξ = Slater exponent. The k-points are generated according to the geometrical methods of Ramirez and Böhm (25).

Fig. 1. DOS of **1** from EHTB calculations. (*a*) Total DOS of **1**. Shaded areas represent the projection of individual atoms in, (*b*) silicon, (*c*) phosphorus, and (*d*) bridging oxygens in P-O-P. For clarity, the antibonding bands are not plotted. The same scaling factor is used for all plots. (X axes correspond to DOS peaks).



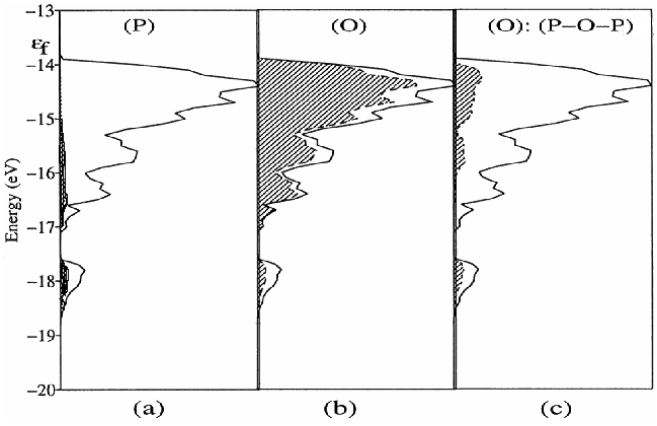


Fig. 2. DOS of 4 from EHTB calculations. The contributions of individual atoms are shown in shaded areas: (a) phosphorus (b) total of oxygens, and (c) bridging oxygens in P-O-P.

The second part concerns the model cluster using ab initio Hartree–Fock calculations in the Gaussian 98 package (27). The choice of this method was made for several reasons. For one, it was used in different theoretical investigations and in

© 2006 NRC Canada

cluster modeling by several authors (13). In addition, our model clusters **1** and **2** represent the real unit cell in pyrophosphate and metaphosphate compounds, respectively. Thus, two model clusters with four- and six-coordinate silicon are investigated, **2** and **3**, respectively. The cluster geometries were optimized at the Hartree–Fock (HF) level with the standard 6-31G* basis set for H, O, Si, and P atoms. Hydrogen atoms were used to terminate the dangling bonds that would otherwise result in open valences. To account for the electron correlation effects, supplementary calculations with DFT (27) using the same basis quoted above were undertaken for both clusters. Harmonic frequencies were calculated to determine the stationary points and the active band in the infrared spectra.

Results and discussion

Crystal structure of 1

Different speculations about powder structure resolution and coordination of SiO_6 in the crystal structure of SiP_2O_7 have been reported (5 and 6, 14 and 15). We begin by analyzing the crystal structure of **1**, synthesized at low temperature, according to the X-ray powder diffraction obtained by Clearfield and co-workers (20) (Fig. 3). It belongs to the hexagonal space group $P6_3$. The Si and P atoms are, respectively, octahedrally and tetrahedrally coordinated with oxygen atoms. The layers in **1** are held together by a linear P-O-P angle. From Fig. 3, it is clear that an oxygen atom that binds to any silicon is shared by six pyrophosphate groups. In other words, each pyrophosphate group binds to six different silicon atoms.

In Table 2, the important bond lengths and bond angles of **1** are summarized (20). The averages of the P—O_b (O_b, bridging oxygen, corresponds to O_2 in Table 2) and P=O_t (O_t, terminal oxygen, corresponds to O_1 and O_3) bond lengths are 1.56 Å and 1.49 Å, respectively. We observe that the PO_4 tetrahedral units possess three phosphorus–oxygen bonds (P—O_1, P—O_3, and P—O_2), two longer and one shorter. Moreover, a careful investigation of the data presented in Table 2 and a comparison of other compounds with tetrahedral silicon (4), shows an important structural change in **1** induced by the presence of the six-coordinated silicons; some Si—O bonds are elongated (1.77–1.70 Å vs. 1.62 Å) while P—O bonds are shortened (1.48 Å vs. 1.60 Å). The variation in the range of O-Si-O angles from 81° to 102° involves the distortion away from an ideal octahedron. Moreover, the P-O-P angle is equal to 180°. In accounting for such a structural change in this material (28–35), it was interesting to examine variation, stability, band gap, and binding energy by using tight-binding calculations in the extended structure of **1** or the cluster model.

Tight-binding calculations

We begin by exploring the EHTB-derived band structure of **1** Figures 1*a*–1*d* show, respectively, a plot of the total DOS for **1** with different DOS projections for Si and P atoms and the bridging oxygen atoms within the P-O-P fragment. In Fig. 1, we choose an energy window from –13 to –20 eV that represents the most important zone of P—O and Si—O bonding analysis including the band gap and the Fermi level (ε_f).

Fig. 3. Polyhedral representation of **1** as derived from ref. 20. The tetrahedra are PO_4 and the octahedra are SiO_6. The small red circles are O while the P-O-P bonds form linear bridges between the layers. The crystals belong to the hexagonal space group $P6_3$, with projection in the *ac* plane.

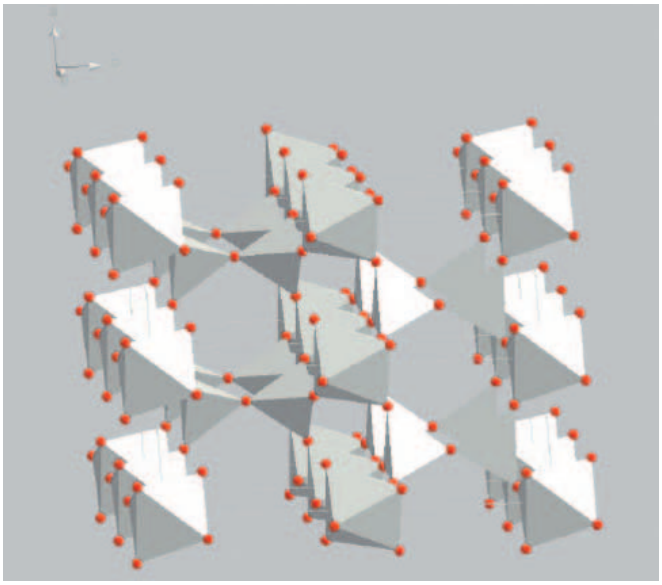

Table 2. Summary of the important bond lengths and angles for **1** from ref. 20.

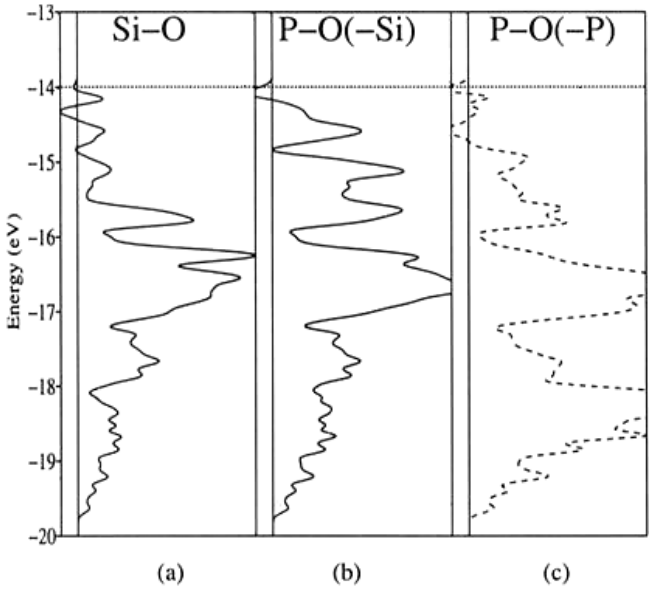

Bond lengths (Å)	
Si—O_1	1.77(1)
Si—O_3	1.70(2)
P_1—O_2	1.58(2)
P_1—O_3	1.48(1)
P_2—O_2	1.53(2)
P_2—O_1	1.48(1)
Bond angles (°)	
P_1-O_1-Si	152(2)
P_2-O_3-Si	141(1)
O_1-Si-O_1	81(1)
O_1-Si-O_3	86(1)
O_1-Si-O_3	102(1)
O_3-Si-O_3	93(1)
O_3-P_1-O_3	115(1)
O_3-P_1-O2	103(1)
P_2-O_2-P_1	180

Note: O_1 and O_3 are O_t and O_2 is O_b.

As a first observation of Fig. 1, it is clear that **1** displays a large band gap (3.5 eV), consistent with an insulator material. Just below the Fermi level (ε_f) at –13.7 eV, a large band formed by the lone pairs of terminal atoms with a small admixture of P (P—O bonds) appears. From –16.0 to –19.6 eV, the band contains a small contribution from silicon atoms, enough to show the presence of Si—O bonds. In this DOS portion, the dispersion of the silicon band reveals (Fig. 1*b*) a large Si—O interaction involving the diffuse orbital of silicon property and represents the interaction of Si-O_6 in the silicophophate.

© 2006 NRC Canada

Fig. 4. Average COOP plots for **1**. The contribution of each bond is shown: (*a*) P—O, (*b*) P—O (—Si) with an oxygen linked to the silicon atoms, and (*c*) P—O (—P) with an oxygen linked to the phosphorus atoms.

In Fig. 4, the COOP curves confirm this Si—O bond interaction. We show the binding of Si—O in SiO_6 and two types of P—O bonds, one related to a P-O-P linkage and another to a Si-O-P linkage. In addition, we notice a large Si—O and Si-O-P bonding contribution with an interesting overlap of silicon and oxygen concentrated in the region from –16.0 to –19.6 eV. The overlap averages of Si—O and P—O are 0.30 and 0.50, respectively. Meanwhile, the average silicon and phosphorus atomic charges are 2.77 and 2.44, respectively, showing a big difference between the silicon and phosphorus environments in terms of the silicon octahedral and phosphorus tetrahedral sites. In addition, the charges of O_b in P-O_b–P and Si-O_b–P, are equal to –1.22 and –0.99, respectively, indicating that the bridging oxygen charges in the Si-O-P bridges are more delocalized than in the P-O-P units. A similar extended Hückel calculation also shows the presence of a silicon molecular orbital (MO) at high energy around –15 eV (36).[2] Thus according to this analysis, the silicon orbitals should contribute significantly to the stability of **1** by an important interaction with the six surrounding atoms of oxygen and the latter probably explains the crystallization of **1** with six-fold coordinated silicon.

However, to understand the six-fold silicon coordination in **1** let us analyze the DOS and silicon binding energy of the hypothetical sublattice $[P_2O_7]^{-4}$ (**4**) obtained by removing the silicon atoms from the extended structure of **1**. We calculated the density of state of **4** (Fig. 2) and observed a higher-energy part of the valence band that is characterized by the O(2p) nonbonding levels of **4**. Below this band, another band has O(2s) oxygen and phosphorus P(3p) bonding character. The Fermi level moves down to around –13.8 eV in **4.** This shift is largely due to the removal of Si—O interactions in **4**. Also, the P—O band around –18 eV is less dispersed than in **1** (–17 to –20 eV). The difference in curve shape (Figs. 1 and 2) comes from the formation of the incoming Si—O bonds and P=O destruction. In addition, the computed binding energy of the hexacoordinated silicon (Si-O_6) in **1** was estimated at 1.1 eV. But this energy is insufficient to give a more stable compound at ambient temperature and explains the difficulty in synthesizing a hexacoordinated silicon. Moreover, the hypervalency (diffuse orbital) of Si atoms should also strongly modify the environment of phosphorus by breaking P=O bonds and forming Si—O bonds because of the closer energy level between oxygen and silicon atoms (37).

Table 3. Ab initio HF optimized bond lengths and angles of **2** (Si in octahedral sites, linear chains) and **3** (Si in tetrahedral sites, linear chains).

	2	**3**
Average bond lengths (Å)		
Si—O_b	1.893	1.612
Si—O_t	1.782	1.649
P=O_n	—	1.541
P—O_b	1.599	1.619
P—O_t	1.639	1.656
O—H	0.926	0.946
Average bond angles (°)		
O-Si-O	87.0	110
Si-O_b-P	121.4	146

P-O-P	158.1	140

Model clusters

Ab initio calculation

Besides the extended Hückel calculations, our aim is to complete our previous electronic analysis of the hexacoordinated silicon with an ab initio methodology (HF) using two model clusters **2** and **3**. The models were chosen for the following reasons: **2** represents a model of the pyrophosphate chain (a linear chain with Si atoms in octahedral sites) while **3** models the linear chain usually found in metaphosphates (a linear chain with silicon in tetrahedral sites). As a first result, the middle column in Table 3 lists the optimized bond lengths and angles of **2**. The optimized cluster is presented in Fig. 5. In comparing the structures of **1** and **2,** we observe an increase of the Si—O (1.89 Å) and P—O_b bond lengths (1.64 Å) in **2**, which indicates a substantial change in bond and dihedral angles. In addition, the mean angle of O-Si-O is closer to 87° in **2** and involves distortion away from an ideal octahedron of SiO_6, in agreement with the X-ray data of **1.**

The computed P-O-P angle of 158° is not surprising because different studies have found P-O-P angles ranging from 140° to 180° (29). This can also be interpreted in terms of the change in the π bonding character of the P—O bond, which depends on the average π bonding in the cluster. The lone pair orbital of oxygen (O_b) is substantially stabilized by

[2] Rabaâ. Unpublished work.

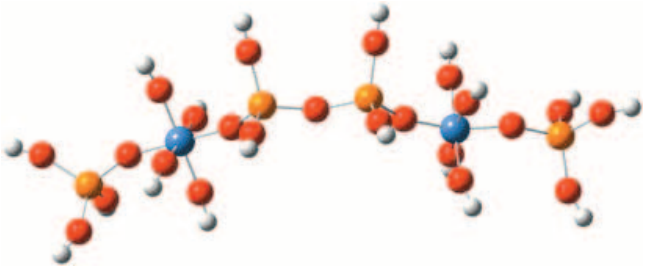
Fig. 5. Ab initio HF optimized structure of **2** with Si atoms in the octahedral site. The red circles represent oxygen atoms, blue circles represent silicon, big yellow circles represent phosphorus, and small gray circles represent hydrogen. P-O-P and Si-O-P angles are 158° and 121°, respectively.



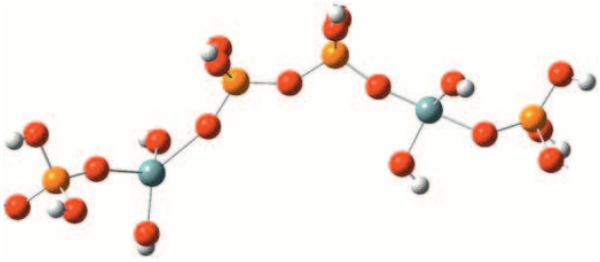


Fig. 6. Ab initio HF optimized structure of **3** with Si in tetrahedral coordination. The red circles represent oxygen atoms, blue circles represent silicon, yellow circles represent phosphorus, and small gray circles represent hydrogen. P-O-P and Si-O-P angles are 147° and 146°, respectively.

mixing with the $\sigma^*_{P\text{-}O}$ acceptor orbital and induces the linearity of P-O-P angles.

To complete our analyses, we compared the hexa- and tetra-coordinated silicon electronic structures. Thus, a new cluster **3** with silicon in the tetrahedral site was calculated. The optimized geometry of **3** is shown in Fig. 6.

The right column of Table 3 shows the calculated P—O_b, P—O_t, Si—O_b, and Si—O_n (O_n, nonbridging) bonds, which are equal to 1.612 Å, 1.649 Å, 1.619 Å, and 1.656 Å, respectively. The P=O bond is equal to 1.54 Å. Our calculations confirm a relative shortening of the Si—O and P—O bonds in **3** and a decrease of the P-O-P bond angles (146°). O'Keeffe et al. (34) reported similar values for the optimized distances of P—O and P=O in **4**, 1.65 Å and 1.57 Å, respectively.

DFT calculation

The previous model was also simulated using the B3LYP hybrid functional (27), which takes the electric correlation effects into account. The geometries of both model clusters **2** and **3** were optimized. A comparison of DFT and HF calculations reveals that the optimization of **2** and **3** in DFT converge to shorter bond lengths for Si—O and P—O and smaller bond angles for O-Si-O and Si-O-P (Table 4). Again, we observe a large difference between Si tetrahedral and octahedral sites in agreement with HF calculations. The conclusion of these calculations is that cluster **2** exhibits a structure similar to the unit cell of **1** and demonstrates the existence of SiO_6 bonding in accordance with the powder diffraction structure of **1** (20).

Infrared vibrational frequencies

We were quite interested in computing the infrared vibrational frequencies of the model clusters **2** and **3** and comparing them with the experimental IR data of **1**, which is available both for the cubic and monoclinic structures (38 and 39). For example, the IR spectra of several varieties of **1** are given by Ferraro et al. (38). Four crystalline polymorphs having the space groups $P2_1/n$, $P2_1/c$, $Pa3$ as well as one tetragonal and one vitreous phase are described. All IR spectra displayed strong lines at 500, 700, 1050, and 1200 cm^{-1} for the crystals. Selected computed IR frequencies of **2** and **3** are listed in Table 5 and compared with experimental data.

Table 4. DFT optimized bond lengths and angles of **2** (Si in octahedral sites, linear chains) and **3** (Si in tetrahedral sites, linear chains).

	2	**3**
Average bond lengths (Å)		
Si—O_b	1.807	1.656
Si—O_t	1.727	1.639
P=O_n	—	1.483
P—O_b	1.578	1.593
P—O_t	1.610	1.594
O—H	0.991	0.997
Average bond angles (°)		
O-Si-O	93.7	109.3
Si-O_b-P	129.1	146.4
P-O-P	121.2	134.3

The first calculation for **2** gives a band at 1245 cm^{-1}, assigned primarily to the P—O stretching because of the large overlap between O and P. The bands localized from 1133 to 1095 cm^{-1} are assigned to the P—O vibrational frequencies. The bands localized at 888 cm^{-1} are assigned to the coupled P—O and Si—O vibrational frequencies. Moreover, the band ranging from 893 to 875 cm^{-1} is assigned to P=O in **3.** The vibration frequencies in **2** within the range 800–809 cm^{-1} are assigned to Si—O_t and confirm the existence of hexacoordinated silicon. In contrast, in **3** the large band located between 923 to 909 cm^{-1} is assigned to tetrahedral silicon. In addition, the peaks at 708 cm^{-1} in **2** and 826 cm^{-1} in **3** are assigned to coupled Si—O and P—O stretching vibrations. Those at 708 and 826 cm^{-1} are attributed to P-O-P, respectively in **2** and **3.** The frequency at 515 cm^{-1} corresponds to pure bonding modes of the bridging oxygens in Si-O-Si in **2** while their signals frequency in **3** is equal to 557 cm^{-1}. As expected in **2**, the Si—O stretching vibrations involving the SiO_6 octahedral units and Si-O-P appear at much lower wave numbers (331 cm^{-1}).

Conclusion

We computed the band structure of **1** using an extended Hückel tight-binding calculation giving the DOS and the COOP and showing the principal interaction of P-O-P and

Si-O-P linkage. Furthermore, we demonstrated that the crystal structure possesses a relative stability and large overlapping of Si-O_6 because of a large dispersion in the silicon pyrophosphate. The distortion seen in the parent compound **1** should be attributed to the presence of hexacoordinated silicon in this material and the diffuse character of Si atoms. From ab initio molecular and DFT calculations on model clusters, we confirmed that the hexacoordinated silicon in **2** imparts a structural change in bond lengths and bond angles in accordance with the crystal data of **1** Also, the vibrational frequency involving the octahedral Si—O stretching motions in **2** appears at lower wavenumbers, corroborating the experimental data.

Regio- and stereo-selectively kinetic resolution of four stereoisomers of 1-phenylbutan-1,3-diol by *Candida rugosa* lipase

Yi-Hui Chen, S. Joly, Pin-Mei Huang, and Kuangsen Sung

Abstract: Regio- and stereo-selective *Candida rugosa* lipase (CRL)-catalyzed acetylations of (±)-*syn*-1-phenylbutan-1,3-diols ((±)-*syn*-**1**) generated two monoacetates, (+)-*syn*-**2** and (–)-*syn*-**3**, whereas that of (±)-*anti*-**1** produced a monoacetate, (+)-*anti*-**3,** and an unreacted (–)-*anti*-**1**.

Key words: Candida rugosa lipase, kinetic resolution, 1,3-diols.

Résumé : Les acétylations régio- et stéréo-sélectives catalysées par la lipase *Candida rugosa* de (±)-*syn*-1-phénylbutane-1,3-diol, (±)-*syn*-**1**, conduisent à la formation de deux monoacétates, les (+)-*syn*-**2** et (–)-*syn*-**3**, alors que celles du (±)-*anti*-**1** conduisent à la formation d'un seul monoacétate, le (+)-*anti*-**3**, et qu'on retrouve du (–)-*anti*-**1** qui n'a pas réagi.

Mots clés : lipase *Candida rugosa*, résolution cinétique, 1,3-diols.

[Traduit par la Rédaction]

Introduction

Enzymes are unique and efficient catalysts for the preparation of many chiral molecules. Their reactions are environment-friendly and have a practical work-up with low costs (1*a*–1*d*). Lipases are one of the most commonly used enzymes in asymmetric synthesis. They have resolved racemic carboxylic acids and alcohols (1*e*), and demonstrated chemoselective O-acylation in aminoalcohols (1*f*) and regioselective O-acylation of nonequivalent hydroxy groups (1*g*).

The subunit 1,3-diol is present in several natural products and biologically active compounds, such as polyenemacrolide antibiotics (2). Some stereo-selective syntheses of chiral 1,3-diols have been developed in the last two decades (2*e*, 3–5). The 1,3-diols are known to protect ketones and aldehydes (6), so chiral 1,3-diols have the potential to become a chiral auxiliary in asymmetric synthesis. In spite of the fact that the lipases have often been employed for the resolution of several secondary alcohols (1), they have not been extensively used for the resolution of the 1,3-diols. It was reported that 1,3-diarylpropan-1,3-diols were resolved by *Candida rugosa* lipase (CRL) (4). Dynamic kinetic resolution of 1,3-diols was carried out by *Candida antarctica* lipase B (CAL-*B*) (5). We were interested in CRL-catalyzed resolution of an unsymmetrical 1,3-diol, 1-phenylbutan-1,3-diol (**1**) (see Scheme 1), with vinyl acetate as an acyl donor. The substrate **1**, with one large phenyl group and one small methyl group at either end, consists of four stereoisomers and has two nonequivalent chiral secondary alcohol groups. Clearly, it opens up several attractive prospects such as regio-selectivity with the two nonequivalent hydroxyl groups and stereo-selectivity with each of the two hydroxyl groups.

Results and discussion

Kinetic resolution of (±)-*syn*-**1** was carried out by CRL with vinyl acetate as an acyl donor and generated two monoacetates, (+)-*syn*-**2** and (–)-*syn*-**3**, along with some unreacted (±)-*syn*-**1**. (Scheme 1). NMR spectroscopy showed that no diacetate product has been found in this reaction. For (+)-*syn*-**2** and (–)-*syn*-**3,** intramolecular transesterification has not been observed in vinyl acetate or in $CDCl_3$ after a period of 24 h. However, it was observed in the presence of CRL, silica gel, aluminum oxide, methanol, and aqueous acetonitrile. Consequently, to minimize this intramolecular transesterification, we tried to derivatize (+)-*syn*-**2** and (–)-*syn*-**3** with phenyl isocyanate. However, the corresponding carbamate isomers were difficult to separate by column chromatography and preparative HPLC. The next strategy we chose was the oxidation of (+)-*syn*-**2** and (–)-*syn*-**3** with pyridinium chlorochromate (PCC) right after this enzymatic reaction. The oxidation products, (+)-**4** and (–)-**5**, could be purified by column chromatography. Oxidation of the mixture of (+)-*syn*-**2** and (–)-*syn*-**3** at a ratio of 1:2.3 by PCC generated the mixture of (+)-**4** and (–)-**5** at a ratio of 1:2.6, indicating that very little intramolecular transesterification occurred during the oxidation. The isomer ratios were determined by ^{1}H NMR spectroscopy with $CDCl_3$ as a solvent. Thus, information regarding approximate enantiomeric excess (ee) values and configurations of (+)-*syn*-**2** and (–)-*syn*-**3** can be obtained from those of (+)-**4** and (–)-**5**.

 doi:10.1139/V06-131 © 2006 NRC Canada

Scheme 1.

The ee values of (+)-**4** have been determined by chiral HPLC,[2] and the ee values of (–)-**5** have been determined by NMR chiral shift reagent of (+)-Eu(hfc)$_3$. To confirm the configuration of (+)-**4**, it was synthesized by another reported procedure (7a). According to the chiral HPLC analysis, (+)-**4** indirectly produced from this enzymatic reaction is exactly the same as the one prepared by the reported procedure (7a), indicating that its configuration is (*R*) and the configuration of (+)-*syn*-**2** should be (*R*,*R*). According to the optical rotation and chiral HPLC analysis,[3] reduction of (+)-*syn*-**2** and (–)-*syn*-**3** with $LiAlH_4$ generated (+) and (–)-*syn*-**1**, respectively. The configurations of (+)-*syn*-**1** and (–)-*syn*-**1** are (*R*,*R*) and (*S*,*S*), respectively, (3*b–d*, 3*h*). Therefore, the configuration of (+)-*syn*-**2** is (*R*,*R*) and the configuration of (–)-*syn*-**3** is (*S*,*S*).

Two possible mechanisms operated in the kinetic resolution of (±)-*syn*-**1**. The first is enzymatic acetylation of one hydroxyl group of (±)-*syn*-**1**, followed by intramolecular transesterification to the other hydroxyl group. The second mechanism is that the enzymatic acetylation occurred in both one hydroxyl group of one enantiomer of (±)-*syn*-**1** and the other hydroxyl group of the other enantiomer. If this kinetic resolution had followed the former mechanism, the configurations of (+)-*syn*-**2** enantiomers would have been the same as those of (–)-*syn*-**3**. As previously stated, the reduction of (+)-*syn*-**2** and (–)-*syn*-**3** with $LiAlH_4$ generated opposite enantiomers of (±)-*syn*-**1**, respectively, implying that this kinetic resolution follows the latter mechanism and the enzymatic acetylation reactions are regio- and stereoselective.

As shown in Table 1, enzymatic acetylation of (±)-*syn*-**1** with CRL and vinyl acetate for 3 h produced (+)-*syn*-**2** with an ee >99% and a yield of 36%, and (–)-*syn*-**3** with an ee of 69% and a yield of 49%. When the reaction ran for a longer time, ee values of both (+)-*syn*-**2** and (–)-*syn*-**3** decreased, indicating that the highly regio- and stereo-selective acetylations of (±)-*syn*-**1** carried out by CRL and vinyl acetate were deteriorated by intramolecular transesterifications. For example, treatment of a mixture of (+)-*syn*-**2** and (–)-*syn*-**3** at a ratio of 8.1:1 with CRL and vinyl acetate for 24 h generated *syn*-**2** and *syn*-**3** at a ratio of 1:1.6; whereas, treatment of another mixture of (+)-*syn*-**2** and (–)-*syn*-**3** at a ratio of 1:39 with CRL and vinyl acetate for 24 h produced *syn*-**2** and *syn*-**3** at a ratio of 1:4.6. Each of the products, *syn*-**2** and *syn*-**3**, has much worse optical purity than the corresponding starting materials (+)-*syn*-**2** and (–)-*syn*-**3**. In addition, no

Table 1. Kinetic resolution of (±)-*syn*-**1** by CRL and vinyl acetate at 25 °C.

		(+)-*syn*-**2**		(–)-*syn*-**3**	
Time (h)	Solvent and reagent (mL)	Yield (%)[a]	ee (%)[b]	Yield (%)[a]	ee (%)[c]
2	Vinyl acetate (2.5)	30	>99	45	69
3	Vinyl acetate (2.5)	36	>99	49	62
6	Vinyl acetate (2.5)	32	93	58	45
4	*i*-Pr_2O (2.0), vinyl acetate (0.5)	17	66	53	45

[a]The yields were based on ^{1}H NMR analysis of the reaction mixtures right after the enzymatic reactions.
[b]This was determined indirectly on (+)-**4** by chiral HPLC analysis.
[c]This was determined indirectly on (–)-**5** by NMR chiral shift reagent (+)-Eu(hfc)$_3$.

Scheme 2.

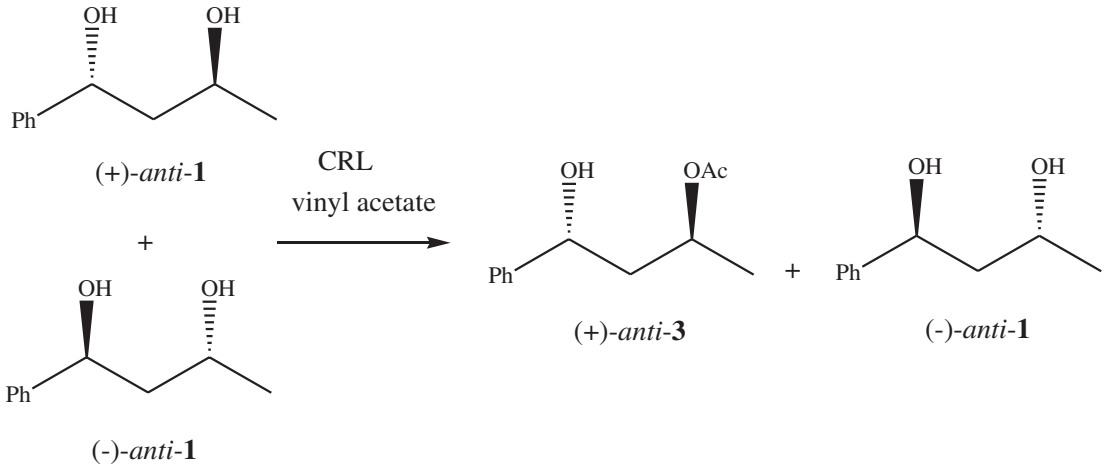

Table 2. Kinetic resolution of (±)-*anti*-**1** by CRL and vinyl acetate at 25 °C.

		(+)-*anti*-**3**		(–)-*anti*-**1**	
Time	Solvent (mL)	Yield (%)[a]	ee (%)[b]	Yield (%)[a]	ee (%)[b]
20 min	Vinyl acetate (2.5)	49	94	51	74
6 h	Vinyl acetate (2.5)	57	71	43	>99
18 h	Vinyl acetate (2.5)	59	48	41	>99
24 h	Vinyl acetate (2.5)	60	35	40	>99

[a]The yields were based on ^{1}H NMR analysis of the reaction mixtures right after the enzymatic reactions. The reaction conversion is the same as the yield of *anti*-**3**.
[b]This was determined on its diacetate derivative by chiral HPLC analysis. E = 72 at 20 min, according to the equation $E = \{\ln[1 - c(1 + ee_p)]/\ln[1 - c(1 - ee_p)]\}$ (7*a*).

hydrolyzed product, (±)-*syn*-**1**, was observed in these two reactions. When the mixtures of (+)-*syn*-**2** and (–)-*syn*-**3** were stirred in ethyl acetate – hexane containing silica gel or in aqueous acetonitrile for 24 h, similar results were found. Based on these experimental results, we suggest the presence of intramolecular transesterification equilibria between (+)-*syn*-**2** and (+)-*syn*-**3** and between (–)-*syn*-**2** and (–)-*syn*-**3** in vinyl acetate with CRL, ethyl acetate – hexane containing silica gel, or aqueous acetonitrile. The equilibria lie far to (±)-*syn*-**3**. This explains the low ee values for both products, (+)-*syn*-**2** and (–)-*syn*-**3**, in the CRL-catalyzed acetylations of (±)-*syn*-**1** at a longer reaction time, especially for the product of (–)-*syn*-**3**.

As shown in Scheme 2, kinetic resolution of (±)-*anti*-**1** with CRL and vinyl acetate generated monoacetate (+)-*anti*-**3** and unreacted (–)-*anti*-**1**. The results are shown in Table 2. As the reaction time increases, the ee value of (+)-*anti*-**3** decreases but the ee value of the unreacted (–)-*anti*-**1** increases, indicating that the CRL-catalyzed acetylation occurs at the 3-hydroxyl group of both (+)-*anti*-**1** and (–)-*anti*-**1** and one is much faster than the other. The kinetic resolution of (±)-*anti*-**1** is best stopped after 20 min. Intramolecular transesterification of (±)-*anti*-**3** was too slow to be observed in presence of vinyl acetate, $CDCl_3$, CRL, silica gel, aluminum oxide, methanol, or aqueous acetonitrile. The configuration of the unreacted (–)-*anti*-**1** with an ee of >99% was determined to be (1*S*,3*R*) by comparing its optical rotation with the reported data (3*d*, 3*g*, 3*h*). The ee values of the CRL-catalyzed acetylation products, (+)-*anti*-**3** and (–)-*anti*-**1**, were determined by chiral HPLC analysis[4] of their

[4]Chiral HPLC analysis for diacetate of (+)-*anti*-**3** and (–)-*anti*-**1**: Chiralcel OD-RH column; mobile phase: water/i-PrOH/acetonitrile = 6:3:1; flow rate: 0.24 mL/min; detection UV wavelength: 257 nm; retention time: 39.5, 46.0 min.

diacetate derivatives that were prepared by reaction with acetic anhydride and pyridine. According to the chiral HPLC analysis[4] of their diacetate derivatives, the configurations of (+)-*anti*-**3** and (–)-*anti*-**1** are opposite. The configuration of (–)-*anti*-**1** was determined to be (1*S*,3*R*), so the configuration of (+)-*anti*-**3** is (1*R*,3*S*) and the optical rotation is exactly opposite to that of the known (–)-anti-**3** (5*b*).

In conclusion, we have developed kinetic resolutions for four stereoisomers of 1-phenylbutan-1,3-diol by CRL. These chiral 1,3-diols have potential to be chiral auxiliaries in asymmetric synthesis.

Experimental

General

All the reagents were obtained from commercial suppliers and used as received. The 1,3-diols, (±)-*syn*-**1**, and (±)-*anti*-**1** were prepared according to the literature (8). *Candida rugosa* lipase (Type VII, 700–1500 unit/mg solid) was purchased from Sigma Chemical Co. (St. Louis, MO, USA).

CRL-catalyzed acetylation of (±)-*syn*-1, followed by oxidation with PCC

To a solution of (±)-*syn*-**1** (50 mg, 0.3 mmol) in 2.5 mL of vinyl acetate, CRL (51 mg) was added. The mixture was stirred at room temperature for some time. The reaction was stopped by filtration of the mixture, and the filtrate was concentrated by a rotary evaporator. The ratios of the products, (+)-*syn*-**2**,(–)-*syn*-**3**, and the unreacted diol (±)-*syn*-**1** were determined by ^{1}H NMR spectroscopy. The ee value of the unreacted diol (±)-*syn*-**1** was determined by chiral HPLC.[3] The residue was dissolved in 5 mL of dichloromethane, and this solution was added to a solution of PCC (120 mg, 0.556 mmol) in 5 mL of dichloromethane. The reaction was stirred for 2 h. Then the reaction mixture was diluted with 30 mL of diethyl ether and passed through a short pad of silica. After evaporation of the solvent, the crude reaction mixture was purified by column chromatography with a mobile phase of 10% ethyl acetate in hexane to yield (+)-**4** and (–)-**5** as colourless oily liquid. Their characterizations agreed with those reported (7*a*–7*d*). The enantiomeric excess of (+)-**4** was determined by chiral HPLC analysis.[2] The enantiomeric excess of (–)-**5** was determined by the ^{1}H NMR spectroscopy in the presence of 25 mg of chiral shift reagent (+)-Eu(hfc)$_3$.

syn-3-Hydroxy-1-phenylbutyl acetate (*syn*-2)

IR ($CDCl_3$, cm^{-1}): 1730 (C=O). ^{1}H NMR ($CDCl_3$) δ: 1.19 (d, J = 6.0 Hz, 3H, CH_3), 1.83–1.89 (m, 1H, CH), 2.05 (s, 3H, CH_3), 2.10–2.17 (m, 1H, CH), 3.70 (m, 1H, CH), 5.91 (t, J = 7.2 Hz, 1H, CH), 7.26–7.37 (m, 5H, PhH). ^{13}C NMR ($CDCl_3$) δ: 21.26, 23.81, 45.35, 65.18, 74.41, 126.59, 128.01, 128.48, 140.21, 170.24. 3-Oxo-1-phenylbutyl acetate (4)

^{1}H NMR ($CDCl_3$) δ: 2.02 (s, 3H, CH_3), 2.14 (s, 3H, CH_3), 2.92 (dd, J = 8.7, 5.0 Hz, 1H, CH), 3.00 (dd, J = 8.7, 5.0 Hz, 1H, CH), 6.18 (m, 1H, CH), 7.26–7.34 (m, 5H, PhH). Its characterization agreed with that reported in the literature (7*d*).

4-Oxo-4-phenylbutan-2-yl acetate (5)

^{1}H NMR ($CDCl_3$) δ: 1.37 (d, J = 6.4 Hz, 3H, CH_3), 1.99 (s, 3H, CH_3), 3.03 (dd, J = 6.4, 16.5 Hz, 1H, CH), 3.42 (dd, J = 6.4, 16.5 Hz, 1H, CH), 5.41–5.50 (m, 1H, CH), 7.41–7.59 (m, 3H, PhH), 7.93–7.97 (m, 2H, PhH). Its characterization agreed with that reported in the literature (7*c*).

CRL-catalyzed acetylation of (±)-*anti*-1

To a solution of (±)-*anti*-**1** (50 mg, 0.3 mmol) in 2.5 mL vinyl acetate, CRL (50 mg) was added. The reaction mixture was stirred at room temperature for some time. The reaction was stopped by filtration of the enzyme, and the filtrate was concentrated by rotary evaporator. The residue was purified by column chromatography with a mobile phase of 20% ethyl acetate in hexane to yield (+)-*anti*-**3** and (–)-*anti*-**1**. The optical rotation of (–)-*anti*-**1** was measured to be $[\alpha]^{26}_D$ –51.8° (*c* 0.96, $CHCl_3$, >99% ee), which is close to the literature data (3*d*, 3*g*, 3*h*). Characterization of (+)-*anti*-**3** is the same as that found in the literature (5*b*). The conversion was determined from the ^{1}H NMR spectrum of the reaction mixture. Derivatization of (+)-*anti*-**3** and (–)-*anti*-**1** was achieved by treating them with acetic anhydride (1 mmol) and pyridine (1.2 mmol) at room temperature for 24 h. The reaction mixture was neutralized with dilute hydrochloric acid, followed by extraction with diethyl ether. The ether solution was dried over anhydrous sodium sulfate. After evaporation of the ether, the residue was purified by column chromatography, followed by analysis with chiral HPLC.[4]

(+)-*anti*-4-Hydroxy-4-phenylbutan-2-yl acetate ((+)-*anti*-3)

$[\alpha]^{26}_D$ +11.3° (*c* 1.015, $CHCl_3$, 94% ee). IR ($CDCl_3$, cm^{-1}): 1715 (C=O). ^{1}H NMR ($CDCl_3$) δ: 1.26 (d, J = 6.4 Hz, 3H, CH_3), 1.87–1.91 (m, 2H, CH_2), 2.04 (s, 3H, CH_3), 2.96 (s, 1H, OH), 4.61–4.66 (m, 1H, CH), 5.17–5.23 (m, 1H, CH), 7.23–7.36 (m, 5H, PhH). ^{13}C NMR ($CDCl_3$) δ: 20.63, 21.21, 46.00, 68.33, 70.23, 125.59, 127.40, 128.40, 143.95, 171.59. HR-MS (EI) *m*/*z* calcd. for $C_{12}H_{16}O_3$: 208.1099; found: 208.1092.

Buffer capacity in multiple chemical reaction systems involving solid phases

Ilie Fishtik and Igor Povar

Abstract: The buffer capacity of a chemical species in a multiple chemical reaction system is discussed in terms of a special class of stoichiometrically unique reactions referred to as response reactions (RERs). More specifically, it is shown that the buffer capacity may be partitioned into a sum of contributions associated with RERs. This finding provides a deeper understanding of the factors that determine the buffer capacity. In particular, the main contributions to the buffer capacity come from the RERs involving the most abundant species. Concomitantly, the RERs approach provides a simple stoichiometric algorithm for the derivation and analysis of the buffer capacity that may be easily implemented into a computer software.

Key words: buffer capacity, response reaction, heterogeneous system, stoichiometric coefficient.

Résumé : La capacité d'une espèce chimique à agir comme tampon dans un système à multiples réactions chimiques est discuté en termes d'une classe spéciale de réactions à stoechiométrie unique appelées réactions de réponse (RER). D'une façon plus spécifique, on démontre que la capacité à agir comme tampon peut être divisée en une somme de contributions associées aux réactions de réponse. Cette conclusion permet de mieux comprendre les facteurs qui déterminent la capacité à agir comme tampon. En particulier, les contributions principales à cette capacité proviennent des réactions de réponse impliquant les espèces les plus abondantes. D'une façon concomitante, l'approche par les réactions de réponse fournit un algorithme stoechiométrique simple qui permet de dériver et analyser la capacité à agir comme tampon et qui peut être facilement appliqué par le biais d'un programme informatique.

Mots clés : capacité à agir comme tampon, réaction de réponse, système hétérogène, coefficient stoechiométrique.

Introduction

Buffer capacity is an important concept in many areas of science: analytical chemistry, geochemistry, biochemistry, medicine, water treatment, environment, and so forth. Initially, it was introduced to characterize the response of an acid–base system to changes in pH (1). Later on, the buffer capacity was extended to redox (2) and complex formation reactions (3–5) as well as reactions involving solid phases (6–8). Recently, several simple and elegant treatments of the buffer capacity have been presented (9, 10). The derivation of the buffer capacity formulae in multiple reaction systems may be performed in a straightforward manner using the simple rules of differentiation of implicit functions (11, 12). Alternatively, the buffer capacity may be easily evaluated employing numerical methods. In the meantime, by its very essence, it is clear that the buffer capacity is a particular case of a more general theoretical approach known as sensitivity analysis. As is well known, sensitivity analysis is a means to study the system's response to various perturbations. Within this approach, the buffer capacity may be treated as the sensitivity of the system with respect to a change in the concentration of a particular species.

A recent general study of the sensitivity of equilibrium multiple chemical reaction systems with respect to different perturbations revealed that the system's response may be partitioned into a sum of contributions. These contributions were associated with a special class of stoichiometrically unique reactions referred to as response reactions (RERs) (13, 14). This finding was shown to provide a deeper insight into the nature of chemical interactions in multiple chemical reaction systems. In particular, within the RERs formalism, the buffer capacity may be partitioned into certain stoichiometric and compositional factors associated with RERs. Consequently, these factors may be evaluated explicitly (15). As a result, one may select the RERs that dominate the buffer capacity of a complex system. Concomitantly, the RERs approach provides a simple stoichiometric algorithm for computer generation of the buffer capacity in complex systems starting from a list of species. In heterogeneous multiple chemical reaction systems, the RERs approach requires a substantial modification. The purpose of this work

is to point out the particularities of the RERs approach to the analysis of buffer capacity as applied to heterogeneous multiple chemical reaction systems.

Notation and definitions

We consider the general case of a heterogeneous multiple chemical reaction system comprising n chemical species B_1, B_2, ..., B_n. For simplicity, we assume that the system obeys an ideal behavior, that is, pure condensed phases (activity is one), dilute water solutions (activity of water is one), and ideal gas phases.

Let C_k^0 and $[B_k]$ ($k = 1, 2, ..., n$) be the initial and equilibrium concentrations of the species, respectively. The buffer capacity of the species B_k is defined as

$$[1] \qquad \beta_k = \left(\frac{\partial C_k^0}{\partial \ln[B_k]} \right)_{C_{k \neq i}}$$

This definition is slightly different from the conventional one in that we use the natural logarithm rather than the ten-based logarithm. Obviously, these two definitions differ by a factor of 2.303.

Let the species B_1, B_2, ..., B_n consist of s elements E_1, E_2, ..., E_s, where "elements" means any stoichiometrically appropriate atomic, molecular, or ionic set that may be used to construct the species, i.e.,

$$[2] \qquad B_1 = \varepsilon_{11}E_1 + \varepsilon_{21}E_2 + \ldots + \varepsilon_{s1}E_s$$

$$B_2 = \varepsilon_{12}E_1 + \varepsilon_{22}E_2 + \ldots + \varepsilon_{s2}E_s$$

$$B_n = \varepsilon_{1n}E_1 + \varepsilon_{2n}E_2 + \ldots + \varepsilon_{sn}E_s$$

Here ε_{li} ($l = 1, 2, ..., s$, $i = 1, 2, ..., n$), is the number of elements E_l in the species B_i. Let the rank of the formula matrix $\boldsymbol{\varepsilon}$ be

$$[3] \qquad \text{rank } \boldsymbol{\varepsilon} = \text{rank} \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \cdots & \varepsilon_{1s} \\ \varepsilon_{21} & \varepsilon_{22} & \cdots & \varepsilon_{2s} \\ \cdots & \cdots & \cdots & \cdots \\ \varepsilon_{n1} & \varepsilon_{n2} & \cdots & \varepsilon_{ns} \end{bmatrix} = s$$

From chemical stoichiometry, it is known that the number m of the stoichiometrically independent reactions is $m = n - \text{rank}\varepsilon = n - s$.

Response reactions (RERs)

A reaction involving no more than rank $\boldsymbol{\varepsilon} + 1 = s + 1$ species is called a response reaction (RER). Let the $s + 1$ species involved in a RER be $B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_{i_{s+1}}$ where i_1, i_2, …, i_s, i_{s+1} is an $(s + 1)$-tuple set of integers satisfying the condition $1 \leq i_1 < i_2 < \ldots < i_{s+1} \leq n$. A RER is denoted by $\rho(B_{i_1}, B_{i_2}, \ldots, B_{i_{s+1}})$ and its general equation is given by

$$[4] \qquad \rho(B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_{i_{s+1}}) = \begin{vmatrix} \varepsilon_{i_1,1} & \varepsilon_{i_2,2} & \cdots & \varepsilon_{i_1,s} & B_{i_1} \\ \varepsilon_{i_2,1} & \varepsilon_{i_2,2} & \cdots & \varepsilon_{i_2,s} & B_{i_2} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \varepsilon_{i_s,1} & \varepsilon_{i_s,2} & \cdots & \varepsilon_{i_s,s} & B_{i_s} \\ \varepsilon_{i_{s+1},1} & \varepsilon_{i_{s+1},2} & \cdots & \varepsilon_{i_{s+1},s} & B_{i_{s+1}} \end{vmatrix} = 0$$

Thus, a complete set of RERs may be generated by selecting all of the possible combinations of $(s + 1)$ species from the total of n. Consequently, the number of RERs N is

$$[5] \qquad N = \binom{n}{s+1} = \frac{n!}{(s+1)!(n-s-1)!}$$

Clearly, the stoichiometric coefficients in the RERs are not necessarily equal to the smallest integers. If so, every RER $\rho(B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_{i_{s+1}})$ may be presented as

$$[6] \qquad \rho(B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_{i_{s+1}}) = \gamma(\rho_0)\,\rho_0(B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_{i_{s+1}})$$

Here, $\rho_0(B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_{i_{s+1}})$ is a RER in which the stoichiometric coefficients are the smallest integers while $\gamma(\rho_0)$ is a constant. The constant $\gamma(\rho_0)$ is a fundamental stoichiometric characteristic of a RER and is called the stoichiometric factor of a RER. It is not the absolute value of $\gamma(\rho_0)$ that counts but the ratios of $\gamma(\rho_0)$ for different RERs. Thus, for a complete set of RERs we choose the values of $\gamma(\rho_0)$ as the smallest integers. Furthermore, in all quantitative applications (formulae) of RERs, the stoichiometric factors appear as $\gamma^2(\rho_0)$. Because the sign of $\gamma(\rho_0)$ is not important, the directionality of the RERs is also arbitrary.

Although the RERs are linearly dependent, they have the remarkable property of being *stoichiometrically unique*, in that they only depend upon a given list of species. In other words, for a given set of species, one arrives at the same set of RERs no matter how they are derived.

For our purposes,we need to consider all of the RERs involving a certain species B_k ($k = 1, 2, \ldots, n$). The respective subset of RERs may be selected from a complete set of RERs by fixing one of the species, for example, $B_{i_{s+1}} = B_k$. Hence, the subset of RERs involving a given species B_k is simply $\rho(B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_k)$, where i_1, i_2, … , i_s is an s-tuple set of integers satisfying the conditions $1 \leq i_1 < i_2 < \ldots < i_s \leq n$ and i_1, i_2, …, $i_s \neq k$, we introduce further two quantities that characterize a RER $\rho_0(B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_k)$, namely,

$$[7] \qquad \pi_k(\rho_0) \equiv [B_{i_1}][B_{i_2}] \ldots [B_{i_s}]$$

$$[8] \qquad g_k(\rho_0) \equiv \frac{\nu_{i_1}{}^2(\rho_0)}{[B_{i_1}]} + \frac{\nu_{i_2}{}^2(\rho_0)}{[B_{i_2}]} + \ldots \frac{\nu_{i_s}{}^2(\rho_0)}{[B_{i_s}]}$$

These relations contain contributions coming from all species involved in a RER except species B_k.

Remark

Generally, the enumeration of RERs may be performed without reference to the activity of the species. For the special case of systems involving dilute aqueous solutions and pure condensed phases, the RERs need to be defined in a special way. Namely, the water and pure condensed phase

© 2006 NRC Canada

species are always among the $(s + 1)$ species that are involved in a RER $\rho_0(B_{i_1}, B_{i_2}, \ldots, B_{i_s}, B_{i_{s+1}})$. Because the activity of water and pure condensed phases is equal to one, these species should be disregarded in eqs. [7] and [8].

Buffer capacity in terms of RERs

We are now in a position to formulate the following result

$$[9] \qquad \beta_k = [B_k] + \frac{1}{\Delta_k} \sum_{\rho_0} \gamma^2(\rho_0)\, \nu_k{}^2(\rho_0)\, \pi_k(\rho_0)$$

$$[10] \qquad \Delta_k = \frac{1}{m} \sum_{\rho_0} \gamma^2(\rho_0) g_k(\rho_0)\, \pi_k(\rho_0)$$

Here, the summation runs over all RERs involving the species B_k. The proof of eqs. [9] and [10] follows the same lines as that used in our previous work and, therefore, is not given here. Obviously, the buffer capacity is a sum of two terms. The first term may be regarded as the own buffer capacity of the species B_k, e.g., the buffer capacity of a system containing no other species but B_k. The second term is a contribution coming from chemical reactions and may be regarded as reaction buffer capacity. In turn, the reaction buffer capacity of a multiple chemical reaction system may be partitioned into contributions coming from a subset of RERs involving the species B_k. The remarkable feature of this result is that the contributions of the RERs to the reaction buffer capacity may be evaluated explicitly. As indicated by eq. [9], the reaction buffer capacity depends on two factors. One of them is purely stoichiometric, i.e., it reflects the stoichiometric structure of the system. Namely, the contribution of the system's stoichiometry to the reaction buffer capacity is expressed through the stoichiometric factors $\gamma(\rho_0)$ and stoichiometric coefficients $\nu_k(\rho_0)$ of RERs. The other factor that determines the reaction buffer capacity is a compositional one, i.e., a function of the species concentrations, and is given explicitly by $\pi_k(\rho_0)$. Normally, the compositional factor is the dominant one. Because $\pi_k(\rho_0)$ is equal to the product of species concentrations involved in a RER, we immediately conclude that the most important contributions to the buffer capacity should be expected from the RERs involving the most abundant species.

The partition of the reaction buffer capacity into a sum of contributions associated with RERs concomitantly provides a simple algorithm for the computer generation of the analytical expressions of the buffer capacity. This algorithm includes the following steps. First, starting from a list of species, i.e., the formula matrix (eq. [3]), a complete set of RERs along with their stoichiometric factors $\gamma(\rho_0)$ is generated according to eqs. [4] and [6]. A subset of RERs involving a given species B_k ($k = 1, 2, \ldots, n$) is further selected from the complete set of RERs. The functions $\pi_k(\rho_0)$ and $g_k(\rho_0)$ are next generated according to eqs. [7] and [8]. The final equation for the buffer capacity is obtained by summing the contributions coming from RERs according to eqs. [9] and [10].

Examples

Buffer capacity with respect to H^+ in carbonate system

This system comprises $n = 8$ species: $CaCO_3$(s), H_2O(l), H^+(aq), Ca^{2+}(aq), CO_2(aq), HCO_3^-, CO_3^{2-}, and CO_2(g). An appropriate set of "elements" may be selected such as Ca^{2+}, C^{4+}, H^+, and O^{2-} resulting into the following formula matrix

$$\boldsymbol{\varepsilon} = \begin{array}{c} \begin{matrix} Ca^{+2} & C^{4+} & H^+ & O^{2-} \end{matrix} \\ \begin{bmatrix} 1 & 1 & 0 & 3 \\ 0 & 0 & 2 & 1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 2 \\ 0 & 1 & 1 & 3 \\ 0 & 1 & 0 & 3 \\ 0 & 1 & 0 & 2 \end{bmatrix} \end{array} \begin{matrix} CaCO_3 \\ H_2O \\ H^+ \\ Ca^{2+} \\ CO_2(g) \\ HCO_3^- \\ CO_3^{2-} \\ CO_2(g) \end{matrix}$$

Obviously, this selection of the elements is not unique; however, it results in a formula matrix whose rank is equal to the number of elements, i.e., rank $\boldsymbol{\varepsilon} = s = 4$. Thus, the number of linearly independent reactions is equal to $m = n - \text{rank}\varepsilon = 8 - 4 = 4$ while a RER in this system involves no more than rank $\boldsymbol{\varepsilon} + 1 = 4 + 1 = 5$ species. The assumption that $CaCO_3$ is a pure solid phase and the activity of H_2O is equal to one requires these species to be involved in every RER. The other three species involved in a RER need to be selected from the remaining species H^+(aq), Ca^{2+}(aq), CO_2(aq), HCO_3^-, CO_3^{2-}, and CO_2(g). Here, we consider only the buffer capacity with respect to H^+; therefore, we need to generate a complete set of RERs involving H^+. Thus, each RER will involve two more species from the remaining five species: Ca^{2+}(aq), CO_2(aq), HCO_3^-, CO_3^{2-}, and CO_2(g). There are $5!/(3!/2!) = 10$ ways to select two species from a total of five, whereas the number of RERs involving concomitantly $CaCO_3$, H_2O and H^+ is equal to 10. For example, the five species, $CaCO_3$, H_2O, H^+, Ca^{2+} and CO_2(aq), define the following RER $\rho(CaCO_3, H_2O, H^+, Ca^{2+}, CO_2(aq))$. Applying eq. [4] to the formula matrix we obtain

$$\rho(CaCO_3,\ H_2O,\ H^+,\ Ca^{2+},\ CO_2(aq)) = \begin{vmatrix} 1 & 1 & 0 & 3 & CaCO_3 \\ 0 & 0 & 2 & 1 & H_2O \\ 0 & 0 & 1 & 0 & H^+ \\ 1 & 0 & 0 & 0 & Ca^{2+} \\ 0 & 1 & 2 & 3 & CO_2(aq) \end{vmatrix} = -\,CaCO_3 + H_2O - 2H^+ + Ca^{2+} + CO_2(aq) = 0$$

Fig. 1. Overall reaction buffer capacity (dashed line) and individual contributions coming from various RERs (lines 1–5) for carbonate sustem discussed in Example 1. The total carbonate concentration is 0.1 mol/L. Equilibrium constants from ref. (6). 1. $CaCO_3(s) + 2H^+ = Ca^{2+} + CO_2(aq) + H_2O$, and $CaCO_3(s) + 2H^+ = Ca^{2+} + CO_2(g) + H_2O$; 2. $CaCO_3(s) + H^+ = Ca^{2+} + HCO_3^-$; 3. $HCO_3^- + H^+ = CO_2(aq) + H_2O$; 4. $HCO_3^- + H^+ = CO_2(g) + H_2O$; 5. $CO_3^{2-} + H^+ = HCO_3^- + H_2O$.

Clearly, the stoichiometric coefficients in this RERs are equal to the smallest integers and, consequently, the stoichiometric factor is equal to $\gamma(\rho_0) = 1$. To determine the contribution of this RER to the buffer capacity we need to further evaluate the functions $\pi_{H^+}(\rho_0)$ and $g_{H^+}(\rho_0)$. For the above RER these functions are

$$\pi_{H^+}(\rho_0) = [Ca^{2+}][CO_2(aq)]$$

$$g_{H^+}(\rho_0) = \frac{1}{[Ca^{2+}]} + \frac{1}{[CO_2(aq)]}$$

Continuing this procedure over the remaining RERs, we ultimately arrive at a complete set of RERs that, along with their stoichiometric and compositional factors, is presented in Table 1. Notice, the stoichiometric coefficients of H^+ in two RERs, namely, RERs 3 and 7 are equal to zero and consequently, the contributions to the buffer capacity with respect to H^+ coming from these RERs vanish. The buffer capacity with respect to H^+ is readily derived according to eqs. [9] and [10] and using the information presented in Table 1. The final result is

$$\beta_{H^+} = [H^+] + [OH^-] + \frac{1}{\Delta_{H^+}}(4[Ca^{2+}][CO_2(aq)] + [Ca^{2+}][HCO_3^-] + 4[Ca^{2+}][CO_2(g)] + [CO_2(aq)][HCO_3^-] + 4[CO_2(aq)][CO_3^{2-}] + [HCO_3^-][CO_3^{2-}] + [HCO_3^-][CO_2(g)] + 4[CO_3^{2-}][CO_2(g)])$$

where

$$\Delta_{H^+} = [Ca^{2+}] + [CO_2(aq)] + [HCO_3^-] + [CO_3^{2-}][CO_2(g)]$$

Here, the species concentrations are the equilibrium ones; hence, they may be evaluated by finding the equilibrium position in the system. Also, the units of $[CO_2]$ are mol/L. For ideal systems, the volumetric concentration of CO_2 may be converted to partial pressure via

$$[CO_2] = \frac{P_{CO_2}}{RT}$$

A numerical evaluation of the overall reaction buffer capacity along with contributions coming from individual RERs is presented in Figure 1. Clearly, the carbonate dominates the buffer capacity at low pH via the reactions:

$$CaCO_3(s) + 2H^+ = Ca^{2+} + CO_2(aq) + H_2O$$

$$CaCO_3(s) + 2H^+ = Ca^{2+} + CO_2(g) + H_2O$$

$$CaCO_3(s) + H^+ = Ca^{2+} + HCO_3^-$$

At a higher pH, the effect of carbonate rapidly decreases and the buffer capacity is controlled by reactions involving only aqueous and gas phase species:

$$HCO_3^- + H^+ = CO_2(aq) + H_2O$$

$$HCO_3^- + H^+ = CO_2(g) + H_2O$$

$$CO_3^{2-} + H^+ = HCO_3^- + H_2O$$

Table 2. A complete list of RERs and their stoichiometric factors in the system kaolinite–anorthite aqueous solution.

RERs	$\gamma(\rho_0)$
1. ρ_0 ($Al_2Si_2O_5(OH)_4$, $CaAl_2Si_2O_8$, H_2O, H^+, Ca^{2+}, Al^{3+}) = $- Al_2Si_2O_5(OH)_4 - Ca^{2+} + CaAl_2Si_2O_8 + H_2O + 2H^+ = 0$	2
2. ρ_0 ($Al_2Si_2O_5(OH)_4$, $CaAl_2Si_2O_8$, H_2O, H^+, Ca^{2+}, H_4SiO_4) = $- Al_2Si_2O_5(OH)_4 - Ca^{2+} + CaAl_2Si_2O_8 + H_2O + 2H^+ = 0$	2
3. ρ_0 ($Al_2Si_2O_5(OH)_4$, $CaAl_2Si_2O_8$, H_2O, H^+, Al^{3+}, H_4SiO_4) = $- Al_2Si_2O_5(OH)_4 - 6H^+ + 2Al^{3+} + 2H_4SiO_4 + H_2O = 0$	1
4. ρ_0 ($Al_2Si_2O_5(OH)_4$, $CaAl_2Si_2O_8$, H_2O, Ca^{2+}, Al^{3+}, H_4SiO_4) = $- 4Al_2Si_2O_5(OH)_4 - 3Ca^{2+} + 3CaAl_2Si_2O_8 + 2Al^{3+} + 2H_4SiO_4 + 4H_2O = 0$	2

Kaolinite–anorthite aqueous solution

This system comprises $n = 7$ species: $Al_2Si_2O_5(OH)_4$ (kaolinite), $CaAl_2Si_2O_8$ (anorthite), H_2O, H^+, Ca^{2+}, Al^{3+}, and H_4SiO_4. An appropriate set of elements for this system may be selected as Ca^{2+}, Al^{3+}, Si^{4+}, H^+, and O^{2-}. In this case, the rank formula matrix

$$\boldsymbol{\varepsilon} = \begin{array}{c} \begin{matrix} Ca^{2+} & Al^{3+} & Si^{4+} & H^+ & O^{2-} \end{matrix} \\ \begin{bmatrix} 0 & 2 & 2 & 4 & 9 \\ 1 & 2 & 2 & 0 & 8 \\ 0 & 0 & 0 & 2 & 1 \\ 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 4 & 4 \end{bmatrix} \end{array} \begin{matrix} Al_2Si_2O_5(OH_4) \\ CaAl_2Si_2O_8 \\ H_2O \\ H^+ \\ Ca^{2+} \\ Al^{3+} \\ H_4SiO_4 \end{matrix}$$

is equal to the number of elements, i.e., rank $\boldsymbol{\varepsilon} = s = 5$ and the number of linearly independent reactions is $m = n - s = 7 - 5 = 2$. A RER in this system is, therefore, defined by $s + 1 = 5 + 1 = 6$ species. The assumption that kaolinite and anorthite are pure solid phases while the aqueous solution is dilute implies that kaolinite, anorthite, and water should be involved in all of the RERs. The other three species need to be selected from the remaining four species, i.e., H^+, Ca^{2+}, Al^{3+}, and H_4SiO_4. Thus, we have a total of 4!/(3!/1!) = 4 RERs. The latter may be readily generated using eq. [4]. For example, the RER ρ ($Al_2Si_2O_5(OH)_4$, $CaAl_2Si_2O_8$, H_2O, H^+, Ca^{2+}, Al^{3+}) is given by

$$\rho(Al_2Si_2O_5(OH)_4, CaAl_2Si_2O_8, H_2O, H^+, Ca^{2+}, Al^{3+}) = \begin{vmatrix} 0 & 2 & 2 & 4 & 9 & Al_2Si_2O_5(OH)_4 \\ 1 & 2 & 2 & 0 & 8 & CaAl_2Si_2O_8 \\ 0 & 0 & 0 & 2 & 1 & H_2O \\ 0 & 0 & 0 & 1 & 0 & H^+ \\ 1 & 0 & 0 & 0 & 0 & Ca^{2+} \\ 0 & 1 & 0 & 0 & 0 & Al^{3+} \end{vmatrix} = 2Al_2Si_2O_5(OH)_4$$

$$- 2CaAl_2Si_2O_8 - 2H_2O - 4H^+ + 2Ca^{2+} + 0Al^{3+} = 0$$

Clearly, the stoichiometric numbers in this RER may be factorized by a factor of two. Hence, requiring the stoichiometric coefficients in the RER to be the smallest integers, we have to introduce a stoichiometric factor $\gamma(\rho_0)$ equal to two, i.e.,

$$\rho(Al_2Si_2O_5(OH)_4, CaAl_2Si_2O_8, H_2O, H^+, Ca^{2+}, Al^{3+}) = 2\rho_0(Al_2Si_2O_5(OH)_4, CaAl_2Si_2O_8, H_2O, H^+, Ca^{2+}, Al^{3+})$$

where

$$\rho_0(Al_2Si_2O_5(OH)_4, CaAl_2Si_2O_8, H_2O, H^+, Ca^{2+}, Al^{3+}) = -Al_2Si_2O_5(OH)_4 - Ca^{2+} + CaAl_2Si_2O_8 + H_2O + 2H^+ = 0$$

A complete set of RERs for this system along with their stoichiometric factors is presented in Table 2. Based on this complete set of RERs, one can easily derive the buffer capacity for all of the aqueous species. As an example, consider the buffer capacity for H^+. From the complete set of RERs, we select the subset of RERs involving H^+. Next, for every RER we evaluate the functions $\pi_{H^+}(\rho_0)$ and $g_{H^+}(\rho_0)$. These calculations are summarized in Table 3. Substituting the values of $\gamma(\rho_0)$, $\nu_{H^+}(\rho_0)$, $\pi_{H^+}(\rho_0)$ and $g_{H^+}(\rho_0)$ into eqs. [9] and [10] and summing over the three RERs gives

Table 3. Contributions to the buffer capacity with respect to H^+ in the kaolinite–anorthite aqueous solution.

RERs	$\gamma(\rho_0)$	$\nu_{H^+}(\rho_0)$	$\pi_{H^+}(\rho_0)$	$g_{H^+}(\rho_0)$
1. ρ_0 ($Al_2Si_2O_5(OH)_4$, $CaAl_2Si_2O_8$, H_2O, H^+, Ca^{2+}, Al^{3+}) = – $Al_2Si_2O_5(OH)_4$ – Ca^{2+} + $CaAl_2Si_2O_8$ + H_2O + $2H^+$ = 0	2	2	$[Ca^{2+}][Al^{3+}]$	$\frac{1}{[Ca^{2+}]}$
2. ρ_0 ($Al_2Si_2O_5(OH)_4$, $CaAl_2Si_2O_8$, H_2O, H^+, Ca^{2+}, H_4SiO_4) = – $Al_2Si_2O_5(OH)_4$ – Ca^{2+} + $CaAl_2Si_2O_8$ + H_2O + $2H^+$ = 0	2	2	$[Ca^{2+}][H_4SiO_4]$	$\frac{1}{[Ca^{2+}]}$
3. ρ_0 ($Al_2Si_2O_5(OH)_4$, $CaAl_2Si_2O_8$, H_2O, H^+, Al^{3+}, H_4SiO_4) = – $Al_2Si_2O_5(OH)_4$ – $6H^+$ + $2Al^{3+}$ + $2H_4SiO_4$ + H_2O = 0	1	–6	$[Al^{3+}][H_4SiO_4]$	$\frac{4}{[Al^{3+}]} + \frac{4}{[H_4SiO_4]}$

Table 4. Buffer capacity with respect to aqueous species in the kaolinite–anorthite aqueous solution.

Species	Buffer capacity
H+	$[H^+] + [OH^-] + 4[Ca^{2+}] + \frac{9[Al^{3+}][H_4SiO_4]}{[Al^{3+}] + [H_4SiO_4]}$
Ca^{2+}	$[Ca^{2+}] + 1/4[H+] + 9/4\ \frac{[Al^{3+}][H_4SiO_4]}{[Al^{3+}] + [H_4SiO_4]}$
Al^{3+}	$[Al^{3+}] + \frac{[H^+][H_4SiO_4] + 4[Ca^{2+}][H_4SiO_4]}{[H^+] + 4[Ca^{2+}] + 18[H_4SiO_4]}$
H_4SiO_4	$[H_4SiO_4] + \frac{[H^+][Al^{3+}] + 4[Ca^{2+}][Al^{3+}]}{[H^+] + 4[Ca^{2+}] + 18[Al^{3+}]}$

$$\beta_{H^+} = [H^+] + [OH^+] + 4[Ca^{2+}] + \frac{9[Al^{3+}][H_4SiO_4]}{[Al^{3+}] + [H_4SiO_4]}$$

The meaning of each term in this equation is evident. Namely, the first two terms are associated with the presence of H^+ and water dissociation while the last two terms are associated with the reactions

$$Al_2Si_2O_5(OH)_4 + Ca^{2+} = CaAl_2Si_2O_8 + H_2O + 2H^+$$

$$Al_2Si_2O_5(OH)_4 + 6H^+ = 2Al^{3+} + 2H_4SiO_4 + H_2O$$

Similarly, one can derive the buffer capacity for the remaining aqueous species. The buffer capacity with respect to all aqueous species is given in Table 4.

Pyrite–O_2 aqueous solution

This system comprises (n = 8) species: FeS_2(s), $Fe(OH)_3$(s), H_2O(l), H^+(aq) SO_4^{2-}(aq), Fe^{2+}(aq), Fe^{3+}(aq), and O_2(aq). An appropriate set of elements for this system is:

$$\boldsymbol{\varepsilon} = \begin{array}{c} \begin{matrix} Fe & S & H & O & e \end{matrix} \\ \begin{bmatrix} 1 & 2 & 0 & 0 & 0 \\ 1 & 0 & 3 & 3 & 0 \\ 0 & 0 & 1 & 2 & 0 \\ 0 & 0 & 1 & 0 & -1 \\ 0 & 1 & 0 & 4 & 2 \\ 1 & 0 & 0 & 0 & -2 \\ 1 & 0 & 0 & 0 & -3 \\ 0 & 0 & 0 & 2 & 0 \end{bmatrix} \end{array} \begin{matrix} FeS_2 \\ Fe(OH)_3 \\ H_2O \\ H^+ \\ SO_4^{2-} \\ Fe^{2+} \\ Fe^{3+} \\ O_2 \end{matrix}$$

It is easy to show that rank $\boldsymbol{\varepsilon}$ = 5 and m = 8 – 5 = 3. A RER in this system is thus defined by rank $\boldsymbol{\varepsilon}$ + 1 = 5 +1 = 6 species. Two of the species comprising the system, namely, FeS_2 and $Fe(OH)_3$, are assumed to be pure condensed phases, while the activity of H_2O is assumed to be unity. This means that these three species should be involved in every RER. The remaining three species need to be selected from H^+, SO_4^{2-}, Fe^{2+}, Fe^{3+}, and O_2. Thus, the number of RERs in this system is equal to 5!/(3!/2!) = 10. For instance, the RER ρ (FeS_2, $Fe(OH)_3$,H_2O, H^+, SO_4^{2-}, Fe^{2+}) is given by

Table 5. A complete set of RERs for the pyrite–O_2 aqueous solution.

RERs	$\gamma(\rho_0)$
1. $\rho_0(FeS_2, Fe(OH)_3, H_2O, H^+, SO_4^{2-}, Fe^{2+}) = -FeS_2 - 14Fe(OH)_3 - 26H^+ + 2SO_4^{2-} + 15Fe^{2+} + 34H_2O = 0$	1
2. $\rho_0(FeS_2, Fe(OH)_3, H_2O, H^+, SO_4^{2-}, Fe^{3+}) = -Fe(OH)_3 - 3H^+ + 3Fe^{3+} + 3H_2O = 0$	15
3. $\rho_0(FeS_2, Fe(OH)_3, H_2O, H^+, SO_4^{2-}, O_2) = -4FeS_2 - 15O_2 - 14H_2O + 4Fe(OH)_3 + 8SO_4^{2-} + 16H^+ = 0$	1
4. $\rho_0(FeS_2, Fe(OH)_3, H_2O, H^+, Fe^{2+}, Fe^{3+}) = -Fe(OH)_3 - 3H^+ + 3Fe^{3+} + 3H_2O = 0$	2
5. $\rho_0(FeS_2, Fe(OH)_3, H_2O, H^+, Fe^{2+}, O_2) = -4Fe^{2+} - O_2 - 10H_2 + 4Fe(OH)_3 + 8H^+ = 0$	2
6. $\rho_0(FeS_2, Fe(OH)_3, H_2O, H^+, Fe^{3+}, O_2) = -Fe(OH)_3 - 3H^+ + 3Fe^{3+} + 3H_2O = 0$	8
7. $\rho_0(FeS_2, Fe(OH)_3, H_2O, SO_4^{2-}, Fe^{2+}, Fe^{3+}) = -3FeS_2 - 16Fe(OH)_3 - 26Fe^{3+} + 45Fe^{2+} + 6SO_4^{2-} + 24H_2O = 0$	1
8. $\rho_0(FeS_2, Fe(OH)_3, H_2O, SO^{2-}_4, Fe^{2+}, O_2) = -4FeS_2 - 4Fe(OH)_3 - 13O_2 + 8Fe^{2+} + 8SO_4^{2-} + 6H_2O = 0$	2
9. $\rho_0(FeS_2, Fe(OH)_3, H_2O, SO_4^{2-}, Fe^{3+}, O_2) = -12FeS_2 - 4Fe(OH)_3 - 45O_2 + 16Fe^{3+} + 24SO_4^{2-} + 6H_2O = 0$	1
10. $\rho_0(FeS_2, Fe(OH)_3, H_2O, Fe^{2+}, Fe^{3+}, O_2) = -12Fe^{2+} - 3O_2 - 6H_2O + 4Fe(OH)_3 + 8Fe^{3+} = 0$	2

Table 6. Contributions to the buffer capacity with respect to H^+ in the pyrite–O_2 aqueous system.

RERs	$\gamma(\rho_0)$	$\nu_{H^+}(\rho_0)$	$\pi_{H^+}(\rho_0)$	$g_{H^+}(\rho_0)$
1. $\rho(FeS_2, Fe(OH)_3, H_2O, H^+, SO_4^{2-}, Fe^{2+}) = -FeS_2 - 14Fe(OH)_3 - 26H^+ + 2SO_4^{2-} + 15Fe^{2+} + 34H_2O = 0$	1	–26	$[SO_4^{2-}][Fe^{2+}]$	$\frac{4}{[SO_4^{2-}]} + \frac{225}{[Fe^{2+}]}$
2. $\rho(FeS_2, Fe(OH)_3, H_2O, H^+, SO_4^{2-}, Fe^{3+}) = -Fe(OH)_3 - 3H^+ + 3Fe^{3+} + 3H_2O = 0$	15	–3	$[SO_4^{2-}][Fe^{3+}]$	$\frac{9}{[Fe^{3+}]}$
3. $\rho(FeS_2, Fe(OH)_3, H_2O, H^+, SO_4^{2-}, O_2) = -4FeS_2 - 15O_2 - 14H_2O + 4Fe(OH)_3 + 8SO_4^{2-} + 16H^+ = 0$	1	16	$[SO_4^{2-}][O_2]$	$\frac{64}{[SO_4^{2-}]} + \frac{225}{[O^2]}$
4. $\rho(FeS_2, Fe(OH)_3, H_2O, H^+, Fe^{2+}, Fe^{3+}) = -Fe(OH)_3 - 3H^+ + 3Fe^{3+} + 3H_2O = 0$	1	–3	$[Fe^{2+}][Fe^{3+}]$	$\frac{9}{[Fe^{3+}]}$
5. $\rho(FeS_2, Fe(OH)_3, H_2O, H^+, Fe^{2+}, O_2) = -4Fe^{2+} - O_2 - 10H_2O + 4Fe(OH)_3 + 8H^+ = 0$	2	8	$[Fe^{2+}][O_2]$	$\frac{16}{[Fe^{2+}]} + \frac{1}{[O^2]}$
6. $\rho(FeS_2, Fe(OH)_3, H_2O, H^+, Fe^{3+}, O_2) = -Fe(OH)_3 - 3H^+ + 3Fe^{3+} + 3H_2O = 0$	8	–3	$[Fe^{3+}][O_2]$	$\frac{9}{[Fe^{3+}]}$

$$\rho(FeS_2,\ Fe(OH)_3,\ H_2O,\ H^+,\ SO_4^{2-},\ Fe^{2+}) = \begin{vmatrix} 1 & 2 & 0 & 0 & 0 & FeS_2 \\ 1 & 0 & 3 & 3 & 0 & Fe(OH)_3 \\ 0 & 0 & 1 & 2 & 0 & H_2O \\ 0 & 0 & 1 & 0 & -1 & H^+ \\ 0 & 1 & 0 & 4 & 2 & SO_4^{2-} \\ 1 & 0 & 0 & 0 & -2 & Fe^{2+} \end{vmatrix}$$

$$= -7FeS_2 + 4Fe(OH)_3 - 34H_2O + 22H^+ + 14SO_4^{2-} + 3Fe^{2+} = 0$$

The stoichiometric coefficients in this RER are equal to the smallest integers, therefore, $\gamma(\rho_0) = 1$. A complete list of RERs for this system along with their stoichiometric factors is given in Table 5. The complete set of RERs may now be used to build up the buffer capacity expressions for all aqueous species. To do this, we need to select the RERs involving a certain species and evaluate the functions $\pi_k(\rho_0)$ and $g_k(\rho_0)$. For instance, the buffer capacity for H^+ may be derived based on the data presented in Table 6. Summing the contributions coming from these RERs according to eqs. [9] and [10] gives

$$\beta_{H^+} = [H^+] + [OH^+] + \frac{1}{\Delta_{H^+}}(676[SO_4^{2-}][Fe^{2+}] + 2025[SO_4^{2-}][Fe^{3+}] + 256[Fe^{2+}][O_2]$$
$$+ 36[Fe^{2+}][Fe^{3+}] + 256[Fe^{2+}][O_2] + 576[Fe^{2+}][O_2])$$

© 2006 NRC Canada

Table 7. Buffer capacity with respect to aqueous species in the pyrite–O_2 aqueous solution.

Species	Buffer capacity
H^+	$[H^+] + [OH^-] + \frac{3(676[SO_4^{2-}][Fe^{2+}] + 2025[SO_4^{2-}][Fe^{2+}] + 256[SO_4^{2-}][O_2] + 36[Fe^{2+}][Fe^{3+}] + 256[Fe^{2+}][O_2] + 576[Fe^{2+}][O_2])}{(2475[SO_4^{2-}] + 44[Fe^{2+}] + 704[O_2])}$
SO_4^{2-}	$[SO_4^{2-}] + \frac{3(4[H^+][Fe^{2+}] + 64[H^+][O_2] + 36[Fe^{2+}][Fe^{3+}] + 256[Fe^{2+}][O_2] + 576[Fe^{3+}][O_2]}{(2475[H^+] + 3337[Fe^{2+}] + 4726[Fe^{3+}] + 768[O_2])}$
Fe^{2+}	$[Fe^{2+}] + \frac{3(225[H^+][SO_4^{2-}] + 64[H^+][O_2] + 2025[SO_4^{2-}][Fe^{3+}] + 256[SO_4^{2-}][O_2] + 576[Fe^{2+}][O_2]}{(6075[SO_4^{2-}] + 136[Fe^{3+}] + 1728[O_2])}$
Fe^{3+}	$[Fe^{3+}] + \frac{3(2025[H^+][SO_4^{2-}] + 36[H^+][Fe^{2+}] + 576[H^+][O_2] + 676[SO_4^{2-}][Fe^{2+}] + 256[SO_4^{2-}][O_2] + 256[Fe^{2+}][O_2]}{(6075[SO_4^{2-}] + 136[Fe^{2+}] + 1728[O_2]}$
O_2	$[O_2] = \frac{3(225[H+][SO_4^{2-}] + 4[H^+][Fe^{2+}] + 676[SO_4^{2-}][Fe^{2+}] + 2025[SO_4^{2-}][Fe^{3+}] + 36[Fe^{2+}][Fe^{3+}])}{(794[H^+] + 768[SO_4^{2-}] + 768[Fe^{2+}] + 1728[Fe^{3+}])}$

where

$$\Delta_{H^+} = \frac{1}{3}(2475[SO_4^{2-}] + 44[Fe^{2+}] + 704[O_2])$$

The buffer capacity for other aqueous species may be derived in a similar manner. The results are summarized in Table 7.

Discussion and concluding remarks

The buffer capacity in multiple chemical reaction systems is a complex function of the equilibrium composition. Explicit equations for the buffer capacity may be easily derived by differentiating the equilibrium conditions with respect to species concentrations. However, for complex, multiple chemical reaction systems, this procedure results in cumbersome expressions that lack a clear physicochemical meaning. In this work, we showed that the buffer capacity may be partitioned into a sum of contributions coming from RERs. This partition allows an easy way to generate analytical expressions for the buffer capacity based on a purely stoichiometric analysis. Concomitantly, this partition may be used to determine the reactions that contribute dominantly to the buffer capacity.

A DFT study of spherands containing five anisyl groups — Highly preorganized to bind the alkali metal

Shabaan A.K. Elroby, Kyu Hwan Lee, Seung Joo Cho, and Alan Hinchliffe

Abstract: Although anisyl units are basically poor ligands for metal ions, the rigid placements of their oxygens during synthesis rather than during complexation are undoubtedly responsible for the enhanced binding and selectivity of the spherand. We used standard B3LYP/6-31G** (5d) density functional theory (DFT) to investigate the complexation between spherands containing five anisyl groups, with CH_2–O–CH_2 **(2)** and CH_2–S–CH_2 **(3)** units in an 18-membered macrocyclic ring, and the cationic guests (Li^+, Na^+, and K^+). Our geometric structure results for spherands **1**, **2**, and **3** are in good agreement with the previously reported X-ray diffraction data. The absolute values of the binding energy of all the spherands are inversely proportional to the ionic radius of the guests. The results, taken as a whole, show that replacement of one anisyl group by CH_2–O–CH_2 **(2)** and CH_2–S–CH_2 **(3)** makes the cavity bigger and less preorganized. In addition, both the binding and specificity decrease for small ions. The spherands **2** and **3** appear beautifully preorganized to bind all guests, so it is not surprising that their binding energies are close to the parent spherand **1**. Interestingly, there is a clear linear relation between the radius of the cavity and the binding energy (R^2 = 0.999).

Key words: spherands, preorganization, density functional theory, binding energy, cavity size.

Résumé : Même si les unités anisyles sont d'une façon inhérente de mauvais ligands pour les ions métalliques, les placements rigides de leur atome d'oxygène au cours des synthèses plutôt que durant la complexation sont sans aucun doute plus responsables pour l'augmentation de la fixation et de la sélectivité du sphérand. On a fait appel à la théorie de la densité fonctionnelle B3LYP/6-31G** (5d) standard pour étudier la complexation entre des espèces cationiques invitées (Li^+, Na^+ et K^+) et des sphérands macrocycliques à dix-huit membres comportant cinq groupes anisyles avec des unités CH_2–O–CH_2 **(2)** et CH_2–S–CH_2 **(3)**. Les résultats pour la structure géométrique des sphérands **1**, **2** et **3** sont en bon accord avec les données de diffraction des rayons X trouvées dans la littérature. Les valeurs absolues pour l'énergie de liaison de chacun des sphérands est inversement proportionnelle au rayon ionique des molécules invitées. Pris dans leur ensemble, les résultats montrent que le remplacement d'un groupe anisyle par des unités CH_2–O–CH_2 **(2)** et CH_2–S–CH_2 **(3)** fait que la cavité est agrandie et moins préorganisée. De plus, la fixation et la spécificité diminuent toutes les deux avec les petits ions. Les sphérands **2** et **3** semblent bien préorganisés pour se lier à toutes les molécules invitées; il n'est donc pas surprenant que les énergies de fixation des sphérands **2** et **3** soient proches de celle du sphérand fondamental **1**. Il est intéressant de noter qu'il existe clairement une relation linéaire entre le rayon de la cavité et l'énergie de liaison (R^2 = 0,999).

Mots clés : sphérands, préorganisation, théorie de la densité fonctionnelle, énergie de liaison, rayon de la cavité.

Introduction

Supramolecular chemistry and the quantification of noncovalent interaction offer the basis for novel approaches in medicine, host–guest chemistry (1), chromatography (2), and biocatalysis (3). The development of artificial receptors capable of forming complexes with specific guests (4–6) is important to the progress of supramolecular host–guest chemistry.

In host–guest complexation, the concave surface of a host complements the convex surface of a guest. Similarly, the receptor sites of enzymes frequently contain rigid cavities whose internal surfaces complement the convex surfaces of substrates or inhibitors.

The spherands, exemplified by **1** (Chart 1), are a specific type of cavitands. Unlike the chorands (crowns) or cryptands, they contain rigid cavities formed during their syntheses rather than during their complexation. The spherands' preorganization results in the highest binding and selectivity yet observed for the alkali metal ions (7). There is a vast chemical literature describing studies of the binding proper-

ties for the host–guest complexation ion involving such spherands.

The syntheses, characterization, and binding properties of four new spherands were reported by Cram and co-workers (8). These spherands contain five meta-linked anisyl binding sites incorporated in an 18-membered macrocyclic ring. The 18-membered macrocycles were completed with conformationally mobile CH_2–O–CH_2 and CH_2–S–CH_2 units. The crystal structure of the spherands indicated that the anisyl groups' CH_3O possess an up-down-up-down-up-down conformation when proceeding clockwise around the ring. All six oxygens' unshared electron pairs line forming an elongated spherical cavity preorganized to bind the smaller alkali metal cations (9).

To our knowedge, ab initio studies concerning the spherands compounds are very rare, presumably because of the large size of these hosts. Furthermore, ab initio studies in the gas phase would give a zero-order, yet valuable, opportunity to understand the intrinsic factors affecting the complexation without including the effects of solvation.

To understand the complexation of spherands, we have undertaken a density functional theory (DFT) study of spherands containing five anisyl groups and their complexes with Li^+, Na^+, and K^+ ions. The results can be compared with the results obtained experimentally. Hosts **2** and **3** are spherands in which one anisyl group is replaced by one group of CH_2–O–CH_2 or CH_2–S–CH_2, respectively. The main purpose of the present work is to provide accurate theoretical information on the structures of spherands **2** and **3** and their metal complexes and to analyze how the presence of CH_2–O–CH_2 or CH_2–S–CH_2 modifies the binding capacities relative to spherand **1**.

Computational method

All DFT calculations were carried out using the G03 suite of programs (10). We used the standard B3LYP/6-31G** (5d) model (11). All structures were fully optimized. Because the crystal structure of the analogous macrocycle (4-$MeC_6H_2OMe)_6$ shows D_{3d} symmetry, the OMe–spherands $(C_6H_3OMe)_6$ are thought to be of D_{3d} symmetry (9). Basis set superposition error corrections (BSSEC) (12) were used to obtain more reasonable binding energies. All the calculations were done using KIST teraflops Linux cluster.

Result and discussion

In spherand **1**, the acyclohexmetaphenylene system provides a framework that holds the oxygens of six methoxyl groups in a perfect octahedral arrgement by their attachment to six convergent positions of the aryl group. In the present work, we studied the effect of replacement of one anisyl group by CH_2–O–CH_2 (**2**) and CH_2–S–CH_2 (**3**) on the binding energies and the preorganization toward Li^+, Na^+, and K^+ guests. Because of the importance of Li^+, Na^+, and K^+ in physiological chemistry, the ability of hosts to differentiate between these ions in complexation is interesting.

Spherands **2** and **3** were examined for their differential binding properties toward the alkali metal and compared to spherand **1**. In both molecules, the five anisyl CH_3O groups and one CH_2–O–CH_2 and CH_2–S–CH_2 group possess an up-down-up-down-up-down conformation proceeding clockwise around the ring (18).

We defined the binding energy (E_{BE}) of the complexation (eq. [1]) as the measure of the enthalpic contribution to the thermodynamic stability of the host–guest complex:

$$[1] \qquad E_{BE} = E_{complex} - (E_{host} + E_{guest})$$

All binding energies, with and without the BSSEC, are listed in Table 1. Amongst the hosts of this study, those containing 18-membered rings (**1–3**) exhibit both the highest binding energy values and, generally, demonstrate the most discrimination between the guest ions studied.

Clearly, the absolute value of binding energy is inversely proportional to the ionic radius. As expected, Li^+ was found to be the strongest guest to **1**. Spherand **1** complexed Li^+ with a binding energy of 134.16 kcal/mol, which is 29 and 71.4 kcal/mol greater than those of **1**·Na^+ and **1**·K^+, respec-

Note: The average diameter of the resulting cavities was calculated by averaging the distances between the three sets of oxygen pairs most distant from one another (e.g., oxygens at 2 and 8, at 4 and 10, and at 6 and 12 o'clock).
[a] Experimental data from ref. 8.

tively. Spherand **2** complexed Li^+ with a binding energy of 129.63 kcal/mol which is 58.96 kcal/mol greater than the binding energy value for **2**·K^+(60 kcal/mol). As expected from the DFT calculations, host **1** is more preorganized and strongly binding than hosts **2** and **3**. The spherands **2** and **3** and their complexes are shown in Fig. 1, and the set of geometric parameters are gathered in Table 2 along with some experimental results. It is interesting to note how the diameter of sphere changes.

The DFT calculations predicted that the distance between the sulfur at 12 o'clock and the oxygen at 6 o'clock (see Chart 1) was 5.869 and 5.449 Å which is in good agreement with the experimental data (18). The calculations also predicted the distance between the oxygen at 12 o'clock and the oxygen at 6 o'clock to be 5.445 Å which is very close to the O12–O6 distance of 5.447 Å obtained from X-ray studies (18).

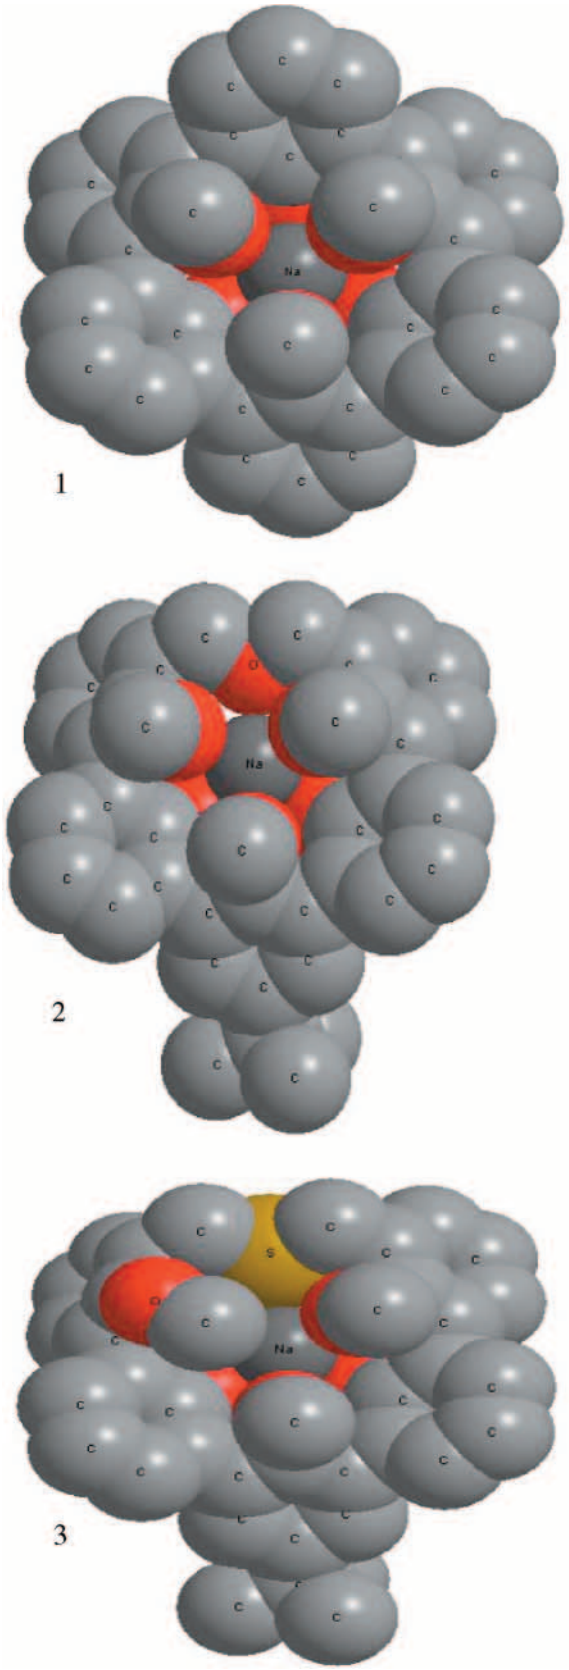
The predicted O2–O8 distances in hosts **2** and **3** of 5.202 and 5.117 Å differ from the experimentally derived values of 4.084 and 3.843 Å, respectively; this is within the experimental error margin. The experimental data show that O2 is below the mean plane thus accounting for the differences in the theoritical and experimental data.

The average diameter of the resulting cavities was calculated by averaging the distances between the three sets of oxygen pairs most distant from one another (e.g., oxygens at two and eight, at four and 10, and at six and 12 o'clock). The spherical diameter of **1** is 4.46 Å. It is interesting to note the changes in the diameter of the sphere that comprises six oxygen atoms. When complexed with Li^+, it shrinks slightly to 4.31 Å, while it enlarges to 4.59 and 5.20 Å with Na^+ and K^+, respectively. The contraction of **1** upon Li^+ complexation indicates the electrostatic attraction between Li^+ and its surrounding oxygen atoms. In conclusion, **1** stretched to accommodate K^+ and Na^+ and contracted to complex Li^+.

The cavity diameters in free **2** and **3** were 5.15 and 5.28 Å, respectively as compared with 5.470 and 5.709 Å in the case of K^+ complexes. Thus, spherand **2** and **3** appear beautifully preorganized to bind all guests and it is not surprising that their binding energies are close to that of the host **1**.

© 2006 NRC Canada

Fig. 1. The Na^+ complexes structures of the spherands studied. All H atoms are removed to improve visualization.



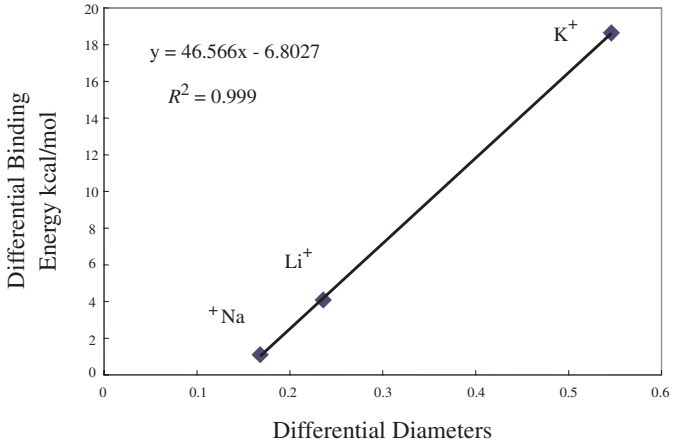


Fig. 2. The correlation between differential diameter and differential binding energy of hosts **2** and **3** complexes.

The diameter of the cavity of **2** in spheraplexes **2**·Na^+ and **2**·K^+ was 4.75 Å and 5.47 Å, respectively, compared with 5.149 Å in the case of free **2**. Thus, **2** stretched to accommodate K^+ and contracted to complex Li^+. Our calculations suggest that only the four OCH_3 oxygens and CH_2–O–CH_2 or CH_2–S–CH_2 can contact K^+ in **2**·K^+ and **3**·K^+, which correlates with the lower binding for these spheraplexes of 60.66 and 56.57 kcal/mol, respectively. The much lower binding energy with **2** and **3** compared with **1** is attributed to the fact that the presence of the respective CH_2–O–CH_2 and CH_2–S–CH_2 units in **2** and **3** not only expands the cavity but also introduces a flexibility into the 18-membered macroring, thus providing measurable binding for Na^+ and Li^+. The respective values for **2** and **3** complexing these ions are as follows: Li^+, 129.63 and 128.53 kcal/mol; Na^+, 105.59 and 86.96 kcal/mol. Thus, host **2** binds Na^+ better than host **3.** The cavity of **3** is larger than that of **2** because of the longer bonds in CH_2–S–CH_2 as compared to CH_2–O–CH_2. The softer character of S compared to O means bond angle deformations involving S are less costly than those involving O.

The effect of complexation of **2** and **3** on their geometric parameters is apparent from the comparisons in Table 2. Some structural parameters of the three complexes of the alkali metal ions are also listed in Table 2. The Na^+ ion in **3**·Na^+ exhibits a strong interaction compared to the host **3**. The average Na^+–O distances for **2**·Na and **3**·Na^+ are 2.39 and 2.59 Å, respectively. Comparisons of Na^+–O average distances in **2**·Na^+ and **3**·Na^+ with the standard value of 2.35 Å (19) show that Na^+ has stronger interactions with host **2** than host **3**. Because of constraints, the cavity of **3** is unable to contract enough to allow all six of its oxygen atoms to legate the Na^+ at the same time as K^+ ion. This is demonstrated by the fact that the diameter of **3**·Na^+ is 5.296 Å, much greater than normal, but in **2**·Na^+ the diameter is 4.75 Å, lower than normal. Thus, the O12–Ar dihedral angle (12–A–B–C) expands in **2**·Na^+ by 3.3° and shrinks in **3**·Na^+ by 2.2°. Also, we see a strong correlation between the differential diameter and differential binding energy of the complexes of hosts **2** and **3**. Figure 2 illustrates this relation and gives a good fitting equation with R^2 = 0.999. A comparison of the geometric parameters of the parent spherand

© 2006 NRC Canada

complexes with those of **2** and **3** is instructive. The Na^+–O distance in spherand **1** complexes is 2.296 Å, which is less than the standard value of 2.35 Å.

Comparisons of the Na^+–O distance of spherand **1** complexes with the standard value of 2.35 Å[3] and average distance of spherands **2** and **3** complexes show that spherand **1** has stronger interactions with all metal ions than hosts **2** and **3** (see Table 1).

Conclusion

This work reports results for the binding properties of spherands **2** and **3** based on the B3LYB/6-31G** (5d) level of theory. Results for the structures are compared with available X-ray diffraction data of spherands. A good agreement is observed between theoretical predictions and experimental data for hosts **2** and **3**. The results taken as a whole show that as the number of anisyl units increases, the cavity becomes smaller and more preorganized. Also, binding and specificity increase for the small ions, and the rates of equilibration among spherand, guest, and spheraplex decrease. Systems that contain five and six self-organizing anisyl groups are less specific for Li^+ over Na^+ and K^+ passing from **1** to **3**, respectively. Also, spherands **2** and **3** appear beautifully preorganized to bind all guests, so it is not surprising that their binding energies are close to that of the host **1**.

Microwave-assisted synthesis of β-$Co(OH)_2$ and Co_3O_4 nanosheets via a layered precursor conversion method

Zhen-Hua Liang, Ying-Jie Zhu, Guo-Feng Cheng, and Yue-Hong Huang

Abstract: Single crystalline β-$Co(OH)_2$ nanosheets have been synthesized from a layered precursor cobalt(II) acetate hydroxide by microwave heating. The average thickness of β-$Co(OH)_2$ nanosheets is ~10 nm, with particle sizes up to 360 nm. The layered precursor was prepared using $Co(CH_3COO)_2{\cdot}4H_2O$, ethylene glycol, and H_2O in some cases by microwave heating. Co_3O_4 nanosheets have been synthesized by hydrothermal oxidation of the layered precursor cobalt(II) acetate hydroxide using H_2O_2.

Key words: nanosheets, microwave, cobalt hydroxide, cobalt oxide.

Résumé : On a réalisé la synthèse de nanofeuillets de β-$Co(OH)_2$ monocristallins en chauffant à l'aide de microondes une couche de son précurseur, l'hydroxyde de l'acétate de cobalt(II). L'épaisseur moyenne des nanofeuillets de β-$Co(OH)_2$ varie d'environ 10 nm jusqu'à 360 nm. La couche de précurseur a été préparée en chauffant, à l'aide de microondes, un mélange de $Co(OCOCH_3)_2{\cdot}4H_2O$, d'éthylèneglycol et (ou) d'eau. Les nanofeuillets de Co_3O_4 ont été synthétisés en procédant à une oxydation hydrothermique à l'aide de H_2O_2 de la couche d'hydroxyde de l'acétate de cobalt(II) précurseur.

Mots clés : nanofeuillets, microonde, hydroxyde de cobalt, oxyde de cobalt.

[Traduit par la Rédaction]

Introduction

The properties of nanostructured materials are dependent on the shape of building blocks. Although many examples have been demonstrated, controlling the shape of building blocks is still a great challenge. In the past decade, one-dimensional nanostructures such as nanorods, nanowires, and nanotubes have been intensively studied because of their novel properties and potential applications (1). Two-dimensional nanosheets possess interesting properties because of their high anisotropy and ultrathin thickness (2, 3). Nanosheets are considered as ideal systems for the investigation of dimensionally confined transport phenomena and as the ideal bases upon which to build functional devices.Therefore, it would be interesting to develop new methods for the synthesis of nanosheets of a variety of compounds.

Recently, cobalt hydroxide $Co(OH)_2$ has attracted increasing attention (4–6) because of its electric and magnetic applications. When added to nickel oxide electrodes, β-$Co(OH)_2$ can improve the electrochemical performance by enhancing the electrode conductivity and chargeability (7–10). There have been some reports on the synthesis of β-$Co(OH)_2$ nanostructures (11–13).

Co_3O_4 with a spinel structure is an important magnetic p-type semiconductor. Co_3O_4 has received considerable attention because of its diverse applications in fields such as solar selective absorber (14–15), catalysis (16, 17), batteries (18, 19), solid-state sensors (20, 21), magnetic materials (22, 23), and electrochromic devices (24). Different nanostructures of Co_3O_4 such as nanoparticles (25), nanocubes (26, 27), and nanotubes (28) have been reported. Recently, the preparation of Co_3O_4 nanoplatelets by thermal decomposition of $Co(OH)_2$ nanoplatelets was also reported (29).

The layered precursor conversion method is an effective method for the preparation of nanosheets of metal oxides such as CuO (30). In this paper, we demonstrate that powders of β-$Co(OH)_2$ single crystalline nanosheets can be synthesized by a simple microwave-assisted layered precursor conversion method. The application of microwave heating in synthetic chemistry is a fast-growing research area, and microwave heating has been accepted as a promising heating method. As a result, this has opened up the possibility of realizing reactions in a very short time. Co_3O_4 nanosheets have been synthesized by hydrothermal oxidation of the layered precursor cobalt(II) acetate hydroxide using H_2O_2.

Experimental

Chemicals and synthesis

Cobalt acetate $Co(CH_3COO)_2{\cdot}4H_2O$, H_2O_2 (Shanghai Chemical Reagents Company, Shanghai), and ethylene glycol (EG, Shanghai Lingfeng Chemical Reagents Co., Ltd.,

Shanghai) were of analytical grade and used as purchased without further purification. Deionized water was used as the solvent in all experiments. In a typical experiment for the preparation of the precursor, 0.5 g of $Co(CH_3COO)_2{\cdot}4H_2O$ was dissolved in 20 mL of ethylene glycol (EG) and 0.4 mL of H_2O was added. The resulting solution was microwave heated to 170 °C and held at this temperature for 5 min. The microwave oven used was a focused single-mode microwave synthesis system (Discover, CEM, Matthews, USA). The microwave synthesis system was equipped with a water-cooled condenser outside the microwave cavity and a magnetic stirring system. After the solution was cooled to room temperature, the pink product (precursor) was centrifuged and washed with absolute ethanol. The precursor was redispersed in 20 mL of deionized water, microwave-heated to 100 °C, and held at 100 °C for 20 min. The product (sample 1) was separated by centrifugation, washed twice with deionized water, and dried in vacuum. Other samples were prepared by a procedure similar to that of sample 1, but under different conditions. Co_3O_4 was synthesized using the following procedure: the precursor and 20 mL deionized water were added in a 40 mL Teflon-lined stainless steel autoclave, then 1 mL 1 mol/L H_2O_2 was added while stirring. The autoclave was sealed, heated to 140 °C and maintained at this temperature for 12 h. Then, it was allowed to cool to room temperature. The black product was separated by centrifugation, washed with deionized water, and dried in vacuum.

Instruments and characterization

X-ray powder diffraction (XRD) patterns were recorded using a Rigaku D/max 2550V X-ray diffractometer with high-intensity Cu Kα radiation (λ = 1.54178 Å) and a graphite monochromator. TEM micrographs were taken with JEOL JEM-2010, JEOL JEM-200CX, selected area electron diffraction (SAED) patterns, and HITACHI H-800 transmission electron microscope.

Results and discussion

Cobalt acetate $Co(CH_3COO)_2{\cdot}4H_2O$ could dissolve in an EG solution and hydrolyze at elevated temperatures. The partially hydrolyzed product, cobalt acetate hydroxide, formed during the microwave heating process. The formation process of the cobalt acetate hydroxide may be described by the following reaction:

$$Co(CH_3COO)_2{\cdot}4H_2O + nH_2O \rightarrow Co(CH_3COO)_{2-x}(OH)_x{\cdot}yH_2O + xCH_3COOH$$

The presence of a small amount of water in EG is favorable for the formation of the layered precursor because it is a hydrolysis process. EG acts as a solvent with a high boiling point of ~198 °C, allowing the hydrolysis reaction to occur at a relatively high temperature.

Figure 1*a* shows the XRD pattern of the precursor cobalt(II) acetate hydroxide. It is typical of a layered structure, with an interlayer spacing of 8.4 Å. The sharp peak at a small angle and broad and asymmetric peaks at high angles indicate that the precursor was a lamellar compound with a brucite structure. Such features can be explained on the basis of stacking order of brucite-like sheets. This behavior was observed for α-$Co(OH)_2$ and layered hydroxide cobalt acetate (31, 32). Figure 1*b* shows that sample 1 consists of well-crystallized β-$Co(OH)_2$ with a hexagonal structure. No peaks due to α-$Co(OH)_2$ were observed in the XRD pattern.

Fig. 1. XRD patterns of the products: (*a*) the precursor, (*b*) β-$Co(OH)_2$ nanosheets, and (*c*) Co_3O_4 nanosheets.

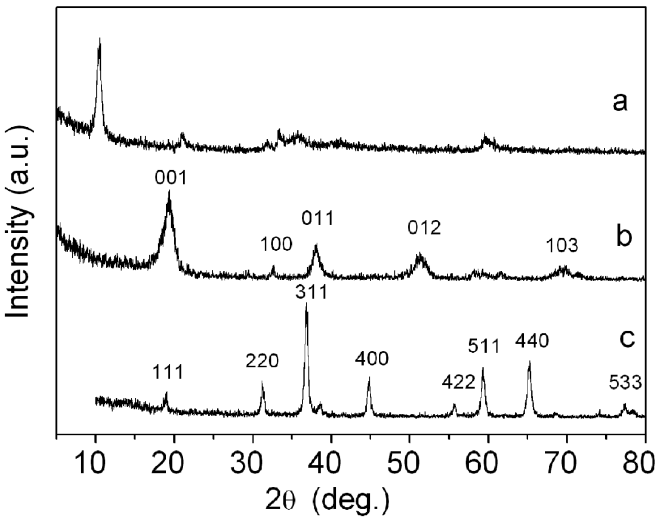

Figure 2 shows TEM micrographs of four samples of $Co(OH)_2$ nanosheets. Figures 2*a* and 2*b* show TEM micrographs of sample 1. One can see hexagonally shaped β-$Co(OH)_2$ nanosheets with angles of 120° between adjacent edges and with particle sizes up to 360 nm. We suggest that the surface of the nanosheets is parallel to the (0001) planes of the hexagonal β-$Co(OH)_2$. An SAED pattern of an individual nanosheet in Fig. 2*b* shows that the nanosheet was single-crystalline. In addition to the nanosheets, small particles were also observed. Figures 2*c* and 2*d* show TEM micrographs of sample 2 prepared under the same conditions as sample 1 except that the microwave heating time for the preparation of the precursor was 10 min instead of 5 min. In addition to hexagonal nanosheets, irregular and circular nanosheets with sizes in the range of 200–360 nm were observed. The sizes of nanosheets in sample 2 increased compared with those in sample 1.

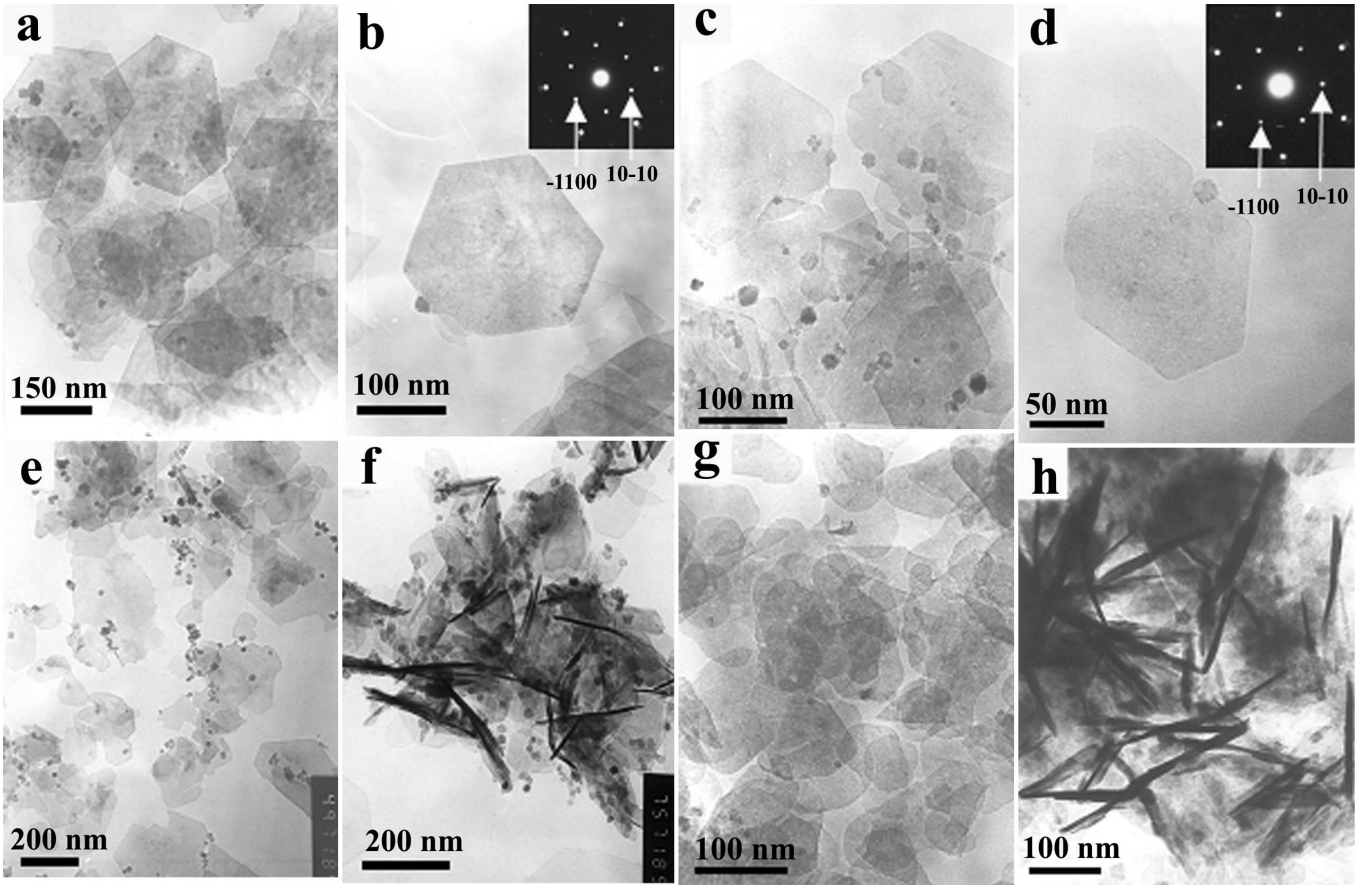

Figures 2*e* and 2*f* show the TEM micrographs of sample 3 prepared under the same conditions as sample 1 except that no water was added in EG. The product consisted of irregularly shaped nanosheets with sizes in the range of 120–300 nm and some having 120° angles between their adjacent edges. In a few cases, some curled nanostructures were also observed (Fig. 2*f*) because of the thin nanosheets. The average thickness of β-$Co(OH)_2$ nanosheets was about 10 nm, estimated from either the curled nanostructures or the standing nanosheets.

Figures 2*g* and 2*h* show the TEM micrographs of sample 4 prepared under the same conditions as sample 3 except that the microwave heating time for the preparation of the precursor was 10 min. It is interesting that the product consisted of circular nanosheets with diameters up to 150 nm. Figure 2*h* shows the curled nanostructures with lengths up to 300 nm. The average thickness of nanosheets was about 10 nm, estimated from the curled nanostructures.

Our experimental results show that the layered precursor

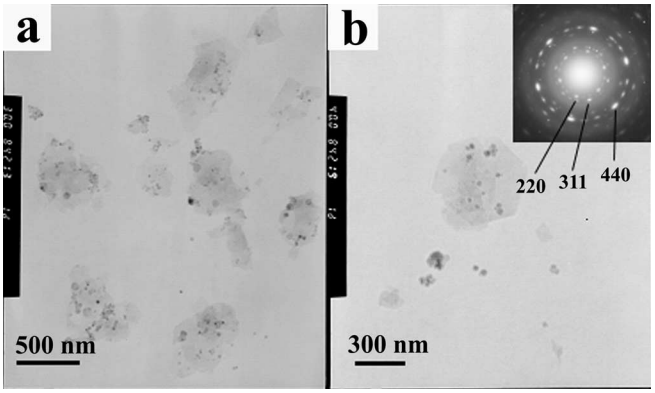
Fig. 2. TEM micrographs of four β-$Co(OH)_2$ samples: (*a*) and (*b*) sample 1; (*c*) and (*d*) sample 2; (*e*) and (*f*) sample 3; (*g*) and (*h*) sample 4. The insets of (*b*) and (*d*) are SAED patterns of an individual nanosheet by focusing electron beam along [0001] zone axis.



cobalt acetate hydroxide had an important effect on the morphology of β-$Co(OH)_2$. The presence of water in EG favored the formation of nanosheets with a hexagonal shape (sample 1). An increase in the microwave heating time for the preparation of the layered precursor resulted in the formation of irregularly shaped nanosheets (sample 2) instead of hexagonal nanosheets (sample 1). When EG was used as the only solvent without adding water, no hexagonal nanosheets were obtained, yet many curled nanostructures were observed.

The spinel Co_3O_4 with a cubic structure rarely forms sheet-like morphology by a direct synthesis method. We have successfully synthesized Co_3O_4 nanosheets by the hydrothermal oxidation of the layered precursor using H_2O_2. XRD pattern of the product (Fig. 1*c*) shows that it was a single phase of Co_3O_4 with a cubic structure (JCPDS 80-1545). No peaks from $Co(OH)_2$ were observed by XRD. The conversion from the layered precursor to Co_3O_4 nanosheets was achieved by a partial oxidation of Co^{2+} to Co^{3+} by H_2O_2. From TEM micrographs of the Co_3O_4 sample (Fig. 3), one can observe the formation of Co_3O_4 nanosheets.

Conclusion

In summary, we have successfully synthesized β-$Co(OH)_2$ nanosheets from a layered precursor cobalt(II) acetate hydroxide by the microwave heating method. The average thickness of β-$Co(OH)_2$ nanosheets is ~ 10 nm, with particle size up to 360 nm. The layered precursor was prepared using $Co(CH_3COO)_2{\cdot}4H_2O$, ethylene glycol, and H_2O in some cases by microwave heating. Co_3O_4 nanosheets were synthesized by the hydrothermal oxidation of the layered precursor cobalt(II) acetate hydroxide using H_2O_2. We expect that the layered precursor conversion method may be extended to synthesize nanosheets of other kinds of metal hydroxides and oxides.

Solvent-free synthesis of 5-oxo-5,6,7,8-tetrahydro-4*H*-benzo-[*b*]-pyran derivatives under microwave irradiation

Xue Yuan Hu, Xue Sen Fan, Xin Ying Zhang, Gui Rong Qu, and Yan Zhen Li

Abstract: Several benzo-[*b*]-pyran derivatives were prepared via microwave irradiation under solvent-free conditions in the presence of $InCl_3 \cdot 4H_2O$. The advantages of this method include simple operational process, environmental benignancy, and high efficiency. Moreover, the catalyst can be recovered and reused effectively for at least six times.

Key words: benzo-[*b*]-pyran derivatives, indium trichloride, microwave irradiation.

Résumé : On a préparé plusieurs dérivés du benzo[*b*]pyrane par irradiation à l'aide de micro-ondes, dans des conditions sans solvant et en présence de $InCl_3 \cdot 4H_2O$. Cette méthode présente l'avantage d'être écologique, très efficace et de comporter un processus opérationnel simple. De plus, le catalyseur peut être récupéré et réutilisé d'une façon efficace au moins six fois.

Mots clés : dérivés du benzo-[*b*]-pyrane, trichlorure d'indium, irradiation à l'aide de microonde.

[Traduit par la Rédaction]

Introduction

Currently, research on the tetrahydropyran skeleton is of great interest in organic synthesis because the tetrahydropyran ring occurs in a number of natural products (1). Tetrahydropyran derivatives have also been extensively studied because they possess a wide range of biological activities and pharmacological properties, such as anticancer (2) and antihypertensive activities (3). Many procedures have been reported for the preparation of such compounds (4*a*); one of them is the condensation of α,β-unsaturated ketones with 5,5-dimethyl-1,3-cyclohexandione promoted by various catalysts. In this regard, anhydrous zinc chloride was recently utilized to catalyze this reaction to produce the substituted benzo-[*b*]-pyran derivatives. However, this method gives a low yield over a long reaction time (4*b*). A combination of glacial acetic acid and phosphoric anhydride could efficiently catalyze this reaction (4*c*), but the use of strongly acidic compounds is undesirable in view of green chemistry and may exclude some acid-sensitive substrates. Therefore, it is desirable to develop more efficient and greener synthetic methods for the preparation of benzo-[*b*]-pyran derivatives.

Recently, indium halides have emerged as mild Lewis acids imparting high regio- and chemo-selectivity in a variety of chemical transformations such as the Diels–Alder reaction (5), rearrangement reaction (6), Friedel–Crafts acylation reaction (7), Mukaiyama aldol reaction (8), Mannich-type reaction (9), and Biginelli reaction (10). Compared with conventional Lewis acids, indium halides possess advantages such as water stability, recyclability, and simplicity in operation. On the other hand, microwave-assisted organic syntheses have attracted considerable interests in recent years (11) because they offer several environmental and economic benefits, e.g., avoiding use of expensive and (or) toxic solvents, saving energy and time, and easier work-up after the reactions are completed. As part of our program aimed at developing environment-friendly methodologies for organic synthesis, we describe a simple, green, and efficient method for the synthesis of benzo-[*b*]-pyran derivatives. Treatments of chalcones (**1**) with 5,5-dimethyl-1,3-cyclohexandione (**2**) in the presence of $InCl_3 \cdot 4H_2O$ under microwave irradiation produced the corresponding 5-oxo-5,6,7,8-terahydro-4*H*-benzo-[*b*]-pyran derivatives (**3**) (Scheme 1) in excellent yields.

Results and discussion

At the outset of this study, we examined the condensation process by employing 1,3-diphenyl-propenone **(1a)** (Scheme 2) and **2** as model substrates. A summary of the optimization experiments is provided in Table 1. When **1a** (1 mmol) was treated with **2** (1 mmol) in the presence of a catalytic amount of $InCl_3 \cdot 4H_2O$ (10 mol%) under the microwave irradiation power of 495 W for 10 min, the desired

Table 1. $InCl_3·4H_2O$-catalyzed synthesis of **3a** under different reaction conditions.

Entry	Microwave power (W)	Amount of $InCl_3·4H_2O$ (mol%)	Reaction time (min)	Isolated yields (%)
1	698	10	5	—
2	495	10	10	54
3	300	10	13	86
4	300	20	13	85
5	300	5	20	67
6	300	2.5	25	50
7	300	0	25	41

product **3a** was obtained with a moderate yield (54%), together with some unidentified by-products (Table 1, entry 2). However, no product could be obtained, and almost all the materials involved were carbonized when the reaction was carried out under a much higher irradiation power (698 W) (Table 1, entry 1). Under lower irradiation power (300 W), a much higher yield (86%) (Table 1, entry 3) was realized by treating the mixture of **1a** and **2** together with $InCl_3·4H_2O$ (10 mol%) for 13 min. On the other hand, the effect of the amount of $InCl_3·4H_2O$ on the output of this reaction was also investigated and the optimum concentration was determined to be 10 mol% (Table 1, entries 3–7). It should also be noted that the absence of $InCl_3·4H_2O$ would result in a much lower yield even over a longer reaction period (Table 1, entry 7).

With this exhilarating result, we extended this method to a variety of substituted chalcones to investigate its scope and generality.The results are listed in Table 2. A wide range of chalcones could react with **2** to give **3** with good yields (Table 2, entries 1–11). It is noted that the electronic property of the aromatic ring of chalcone affects the rate of this condensation process. In general, a shorter reaction time was needed with substrates bearing electron-withdrawing groups on the aromatic rings (Table 2, entries 2, 5–9). Substrates bearing electron-donating groups can also produce the corresponding products with satisfactory yields. However, a longer period was needed to complete the reaction (Table 2, entries 4, 10).

In view of green chemistry, recovery and reuse of the catalyst are highly preferable. To test this possibility, water was added to the reaction mixture upon completion of the reaction, and the product was extracted with ethyl acetate. The catalyst remaining in the aqueous phase was recovered by removing water under reduced pressure. Its reusability was investigated by using **1a** and **2** again as the model substrates. The corresponding product could be obtained with good yield even in the sixth round by using the catalyst recovered from the fifth round (Table 3, entry 6).

To compare conventional heating with solvent-free microwave irradiation for the synthesis of **3a**, a mixture of **1a** and **2** was dissolved in several organic solvents and the solution was refluxed using a classic heating method (oil bath in this case) in the presence of 10 mol% $InCl_3·4H_2O$. When the mixture of **1a** and **2** was refluxed in anhydrous ethanol for 5 h, no **3a** was formed (Table 4, entry 2). Although **3a** could be obtained with other solvents, a much longer reaction time was needed and the yield was much lower. Therefore, solvent-free microwave irradiation is more efficient compared with conventional heating in terms of reaction time and yield.

In conclusion, we have presented a new method for the preparation of benzo-[*b*]-pyran derivatives in the presence of $InCl_3·4H_2O$ under microwave irradiation. This simple and reproducible technique produces various benzo-[*b*]-pyran de-

rivatives in a few minutes with excellent yields without the involvement of toxic materials or the formation of undesirable side products. Moreover, the catalyst can be recovered conveniently and reused efficiently. With all these advantages, this method provides an attractive alternative for the preparation of benzo-[*b*]-pyran derivatives.

Experimental

Melting points were measured by a Kofler micromelting point apparatus and were uncorrected. Infrared spectra were recorded on a Bruker Vector 22 spectrometer in KBr with absorption in cm^{-1}. ^1H NMR spectra were determined on a Bruker AC 400 spectrometer as $CDCl_3$ or DMSO solutions. Chemical shifts (δ) were expressed in ppm downfield from the internal standard tetramethylsilane, and coupling constants *J* were given in Hz. Mass spectra were obtained by a HP5989B mass spectrometer.

General procedure for the preparation of 5-oxo-5,6,7,8-tetrahydro-4*H*-benzo-[*b*]- pyran derivatives

Chalcones **1** (1 mmol), 5,5-dimethyl-1,3-cyclo-hexanedione **2** (1 mmol), and $InCl_3·4H_2O$ (0.1 mmol) were mixed without solvent in a 10 mL open flask and placed in a domestic microwave oven. The mixture was irradiated at 300 W for a certain period of time, as required to complete the reaction (monitored by TLC). Upon completion, the reaction mixture was cooled down to room temperature. Water was added, and the mixture was extracted with ethyl acetate. After the organic layer was dried (Na_2SO_4) and concentrated, the residue was recrystallized from a mixture of ethyl acetate and hexane to give 3 (Table 2). All the products were fully characterized by IR, ^1H NMR, and MS. The catalyst remaining in the aqueous phase was recovered for reuse by removing water under reduced pressure.

Table 4. Comparison between the conventional heating and solvent-free microwave irradiation (MWI) for the synthesis of compound **3a**.

Entry	Solvents	Heating methods	Reaction time (min)	Isolated yields (%)
1	None	MWI	13	86
2	Ethanol	Reflux	300	—

Chemoenzymatic synthesis of the chiral herbicide: (*S*)-metolachlor

Liangyu Zheng, Suoqin Zhang, Fang Wang, Gui Gao, and Shugui Cao

Abstract: A chemoenzymatic approach for the production of (*S*)-metolachlor, one of the most widely used herbicides, has been developed. The starting material (*S*)-*N*-(2-ethyl-6-methylphenyl)alanine was obtained by the use of lipase-catalyzed hydrolytic kinetic resolution. Under the optimal conditions, the good activity and excellent enantioselectivity of lipase B from *Candida antarctica* (CAL-B, $E > 100$) are achieved in diethyl ether – water (15% *v*/*v*), which is about 9.7-fold more enantioselective than that in a pure buffered aqueous solution ($E = 12.1$). After a simple extraction procedure is used to separate the acid product from the remaining ester, the remaining ester is racemized, providing the basis for the continuous resolution process. Then (*S*)-metolachlor is synthesized by a simple chemical method using the enantiomerically pure (*S*)-acid.

Key words: (*S*)-metolachlor, herbicide, CAL-B, (*S*)-*N*-(2-ethyl-6-methylphenyl)alanine, resolution.

Résumé : On a mis au point une approche chimioenzymatique à la production du (*S*)-métolachlore, un des herbicides les plus utilisés. Le produit de départ, la (*S*)-*N*-(2-éthyl-6-méthylphényl)alanine, a été préparé en faisant appel à une résolution par hydrolyse cinétique catalysée par une lipase. Dans des conditions optimisées, la meilleure activité et l'excellente énantiosélectivité de la lipase B provenant de la *Candida antartica* (CAL-B, $E > 100$) sont obtenues en opérant dans un mélange d'éther éthylique et d'eau (15% *v*/*v*), une énantiosélectivité qui est environ 9,7 fois plus élevée que dans une solution aqueuse pure ($E = 12,1$). Après avoir utilisé une simple procédure d'extraction pour éliminer le produit acide et récupérer de l'ester résiduel, ce dernier peut être racémisé et servir dans un processus continue de résolution. La synthèse du (*S*)-métolachlore est ensuite complétée par une méthode chimique simple en utilisant l'acide (*S*) énantiomériquement pur.

Mots clés : (*S*)-métolachlore, herbicide, CAL-B, (*S*)-*N*-(2-éthyl-6-méthylphényl)alanine, dédoublement.

[Traduit par la Rédaction]

Introduction

As optically pure single enantiomers are often more specific targets and have fewer side effects than their corresponding racemates, there is a real driving force for the production of new drugs and agrochemicals with high optical purity (1). The herbicide metolachlor (*N*-(1′-methyl-2′-methoxyethyl)-*N*-chloroacetyl-2-ethyl-6-methylaniline) has been widely used for over 20 years with a main strength in the control of weeds following pre-emergence application. In addition, weed resistance has not been developed, making metolachlor an important option in weed-management strategies (2). Metolachlor comprises four stereoisomers, the isomerism of which is based on a combination of a chiral center in the aliphatic side chain and a chiral axis between the phenyl group and the nitrogen atom. Although the four stereoisomers differ in their ability to inhibit the growth of weeds, it is reported that the herbicidal activity is mainly influenced by the chiral center, the (*S*)-enantiomers (Fig. 1) providing higher herbicidal activity than the (*R*)-enantiomers (3). Consequently, it is recognized that enriching the isomeric ratio in favor of the (*S*)-enantiomer will increase the biological activity of the herbicide. Thus, providing excellent weed control at rates substantially lower than those for racemic metolachlor and showing a reduced risk of environmental contamination. Therefore, it is necessary to develop a new catalyst system to allow the production of enantiomercially enriched (*S*)-metolachlor on a commercial scale.

(*S*)-*N*-(2-ethyl-6-methylphenyl)alanine ((*S*)-**2**) is an important precursor in the synthesis of (*S*)-metolachlor, which is currently produced by chemical synthesis in large quantities (4). The chemical method presently used requires drastic reaction conditions that may cause racemization, decomposition, or side reactions. The high energy consumption required for a long reaction time at a high temperature is unfavorable especially for industrial processes (5). As alternative to such processes, a highly active biocatalyst could be used in a very efficient manner. Among various commercial enzymes, lipases are attractive in terms of availability, the fact that there is no need of cofactors, high stability, and activity in organic media (6–8). The resolution of racemates by enzyme is still the most important approach in the industrial synthesis of optically pure compounds (9,10), as it is often

Fig. 1. Structure of (*S*)-metolachlor.

the most economical and convenient way to prepare enantiomerically pure compounds. The main disadvantage of a resolution process compared with an enantioselective synthesis is that the maximum theoretical yield is 50%. Therefore, racemization of the unwanted enantiomer is of critical importance for economically and environmentally acceptable resolutions. A combination of classical resolution processes with racemization to give asymmetric transformations will be necessary to keep up with the advances in asymmetric synthesis (11).

Herein, we first report a practical lipase-catalyzed hydrolytic kinetic resolution of (*S*)-**2**, the key intermediate for (*S*)-metolachlor. To obtain the higher enantiomercially pure (*S*)-acid, the catalytic properties of different lipases are compared, the conditions of lipase-catalyzed hydrolysis are optimized, and the remaining ester is racemized. Then, (*S*)-metolachlor is synthesized by a chemical method based on (*S*)-**2**.

Experimental

Materials

Pseudomonas sp. lipase (PSL) and *Candida cylindracea* A.Y. lipase (AYL) were purchased from Amano Pharmaceutical Co., Ltd. (Nagoya, Japan). *Candida antarctica* lipase B (CAL-B) was kindly donated by Novo Nordisk Industries (Guangzhou, China). *Porcine pancreatic* lipase (PPL) was purchased from Shanghai Dongfeng biochemical reagent Co., Ltd. (Shanghai, China). *Candida lipolytic* lipase (CLL) was provided by Wuxi enzyme preparation plant (Wuxi, China). *Penicillium expansum* lipase (PEL) was provided by Nantong Pharmaceutical Co., Ltd. (Nantong, China). The authenticity of compounds prepared during the study was confirmed by spectroscopic analysis, including 300 MHz NMR (Mercury-300B, VARIAN, Palo Alto, USA), and GC–MS (Saturn 220, VARIAN, Palo Alto, USA). Reactions were routinely monitored on silica gel plates (Qingdao Haiyang Chemical Co., LTD., Qingdao, China) using UV light for detection of the spots. Optical rotation was measured with a WZZ-1S digital automatic polarimeter (Shanghai, China). All the organic solvents were reagent grade and used without further purification. Other reagents were all analytical grade or better.

Determination of conversion and enantiomeric excess (ee_p)

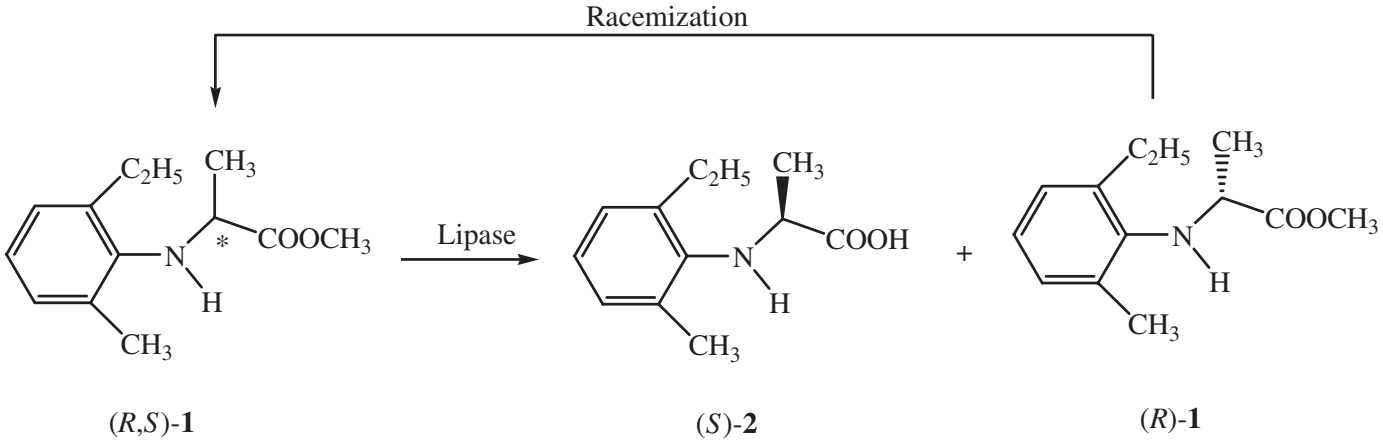
The analysis of the reaction mixtures and the determination of enantiomeric excesses of (*S*)-**2** were performed by capillary zone electrophoresis (P/ACE MDQ, Beckman, Fullerton, USA) with a 59 cm (49 cm to detector) × 50 μm i.d. eCAP^{TM} neutral capillary (Beckman, Fullerton, USA). The conversion of the reaction was determined by using 100 mmol/L triethylamine – acetic acid buffer (TEAA, pH = 5.5) as the background electrolyte. The enantiomeric excess of (*S*)-**2** was successfully analyzed in the buffer by using 40 mmol/L 2,6-di-*O*-methyl-β-cyclodextrin (DM-β-CD, Beckman, Fullerton, USA) as a buffer additive. The analysis was performed with an applied voltage of –20 kV, and the absorbance was recorded at 200 nm.

Enantiomeric ratio (*E*) of the hydrolysis of racemic *N*-(2-ethyl-6-methylphenyl) alanine methyl ester was calculated from the conversion (c) and enantiomeric excess (ee_p) of (*S*)-**2**, using the equation

$$E = \ln[1 - c(1 + ee_p)]/\ln[1 - c(1 - ee_p)]$$

where $ee_p = (c_S - c_R)/(c_S + c_R)$, where c_S and c_R are concentrations of the (*S*)- and (*R*)-enantiomers, respectively (12). The absolute configuration of the enantiomers was established by comparison of the measured optical rotation with the literature data (4).

Preparation of (*R*,*S*)-*N*-(2-ethyl-6-methylphenyl) alanine methyl ester: (*R*,*S*)-1



The reaction mixture of 2-ethyl-6-methylaniline (8.4 mL, 60 mmol), $NaHCO_3$ (5.5 g, 65 mmol), and methyl 2-bromopropionate (180 mmol) was stirred under nitrogen atmosphere and slowly heated to 120–125 °C in 1 h. Then, the dark reaction mixture was continually kept at the same temperature for 18 h with stirring. After cooling, the reaction mixture was transferred into 30 mL of ice water and extracted with ethyl acetate. The ethyl acetate fractions were dried over anhydrous Na_2SO_4 and concentrated in a rotary evaporator at 40 °C. After normal work-up, the resulting ester was purified by column chromatography on silica gel using ethyl acetate – petroleum ether (1:5) as the eluant to furnish the corresponding ester. *N*-(2-ethyl-6-methylphenyl) alanine methyl ester (8.9 g, 67.2% yield): ^{1}H NMR ($CDCl_3$) δ: 7.02–6.96 (m, 2H, aromatic H), 6.88–6.83 (t, 1H, J = 7.2 Hz, aromatic H), 3.96–3.94 (q, 1H, J = 6.9 Hz, $CHCH_3$), 3.81 (s, 1H, NH), 3.66 (s, 3H, OCH_3), 2.69–2.66 (m, 2H, CH_2CH_3), 2.30 (s, 3H, aromatic CH_3), 1.38–1.35 (d, 3H, J = 6.9 Hz, CH_2CH_3), 1.26–1.21 (t, 3H, J = 7.5 Hz, $CHCH_3$).GC–MS *m*/*z* (%): 221(M^+, 25), 162 (100), 133 (30), 77 (11); GC: 98% area.

Biocatalytic hydrolysis of (*R*,S)-1 in aqueous buffer with organic compound

CAL-B (200 mg) and (*R*,*S*)-**1** (2.2 g, 10 mmol) were added to the aqueous phosphate buffer (100 mmol/L, pH 8.0) containing diethyl ether (15% *v*/*v*) 100 mL. The mixture was stirred at 25 °C and the pH was maintained using 0.1 mol/L NaOH solution. When the hydrolysis reached 49% conversion, a saturated solution of $NaHCO_3$ (100 mL) was added to the reaction mixture. The mixture was then extracted with ether (3 × 100 mL) to remove the unchanged ester. The aqueous mixture was then acidified to pH 5.5 with 0.1 mol/L HCl and was extracted again with ether (3 × 100 mL) to remove the acid product. Acid extracts were

Scheme 1. Lipase-catalyzed hydrolysis of (*R*,*S*)-**1** and chemical racemization.

dried over anhydrous Na_2SO_4 and evaporated to give (*S*)-**2** (1.0 g, ee_p > 98%).

Racemization of (*R*)-*N*-(2-ethyl-6-methylphenyl) alanine methyl ester: (*R*)-1

The solution of (*R*)-**1** (1.0 g, 4.5 mmol) in toluene (5 mL) was added to a mixture of *n*-butyraldehyde (0.32 g, 4.5 mmol) and benzoic acid (0.22 g, 1.8 mmol) under nitrogen atmosphere. After refluxing for 3 h, the mixture was cooled to room temperature and washed with 5% Na_2CO_3 (3×5 mL) and H_2O (5 mL). The organic layer was separated, dried over anhydrous Na_2SO_4, and concentrated under reduced pressure. The resulting products were purified by silica gel chromatography using ethyl acetate – petroleum ether (1:5) as the eluant to produce the corresponding (*R*, *S*)-**1** (0.9 g, 90% yield, *R*:*S* = 50:50).

Preparation of (*S*)-*N*-(1′-methyl-2′-hydroxyethyl)-2-ethyl-6-methylaniline: (*S*)-3

To a stirred solution of $NaBH_4$ (0.9 g, 23 mmol) in anhydrous THF (20 mL) under nitrogen atmosphere, a solution of (*S*)-**2** (ee_p > 98%, 1.9 g, 9 mmol) in anhydrous THF (10 mL) was added dropwise. Then, the concentrated H_2SO_4 (0.7 mL) was added slowly below 20 °C. The reaction mixture was stirred at room temperature overnight, and the reaction was quenched by slow addition of methanol (20 mL). After concentrating the mixture in vacuo, 5 mol/L sodium hydroxide (10 mL) was added, and the reaction mixture was heated under reflux for 3 h. The crude mixture was filtered and extracted with $CHCl_3$ (3 × 20 mL). The organic layer was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to give (*S*)-**3** (1.6 g, 92% yield): $[\alpha]^{20}_D$ +6.8° (*c* 2.0%, methanol), 97.1% ee_p based on $[\alpha]^{20}_D$ +7° (*c* 1.941%, methanol) reported in literature (4). GC–MS *m*/*z* (%): 193.1 (M^+, 13.2), 162.2 (100); GC: 90% area.

Preparation of (*S*)-*N*-(1′-methyl-2′-hydroxyethyl)-*N*-chloroacetyl-2-ethyl-6-methylaniline: (*S*)-4

To a solution of (*S*)-**3** (1.6 g, 8.3 mmol) and Na_2CO_3 (0.88 g, 8.3 mmol) dissolved in benzene (10 mL) under nitrogen atmosphere, chloroacetyl chloride (0.94 g, 8.3 mmol) was slowly added at 15–20 °C with efficient stirring. The reaction mixture was then stirred for 3 h at room temperature and filtered. The filtrate was washed with 10% HCl, 10% Na_2CO_3, and saturated NaCl. The organic phase was dried over anhydrous Na_2SO_4, and subsequent concentration under reduced pressure afforded the yellow oil (*S*)-**4** (2.1 g, 95% yield): $[\alpha]^{20}_D$ +11.6°(*c* 1.1%, methanol), 96.6% ee_p based on $[\alpha]^{20}_D$ +12° (*c* 1.166%, methanol) reported in literature (4). GC–MS *m*/*z* (%): 269.2 (M^+, 12), 162.2 (100), 133.1 (21); GC: 92% area.

Preparation of (*S*)-*N*-(1′-methyl-2′-methoxyethyl)-*N*-chloroacetyl-2-ethyl-6-methylaniline: (*S*)-5

The reaction mixture of (*S*)-**4** (2.0 g, 7.4 mmol), 2,2-dimethoxypropane (1.69 g, 14.8 mmol), and *p*-toluenesulfonic acid (0.26 g, 1.1 mmol) dissolved in methanol (5 mL) was heated under reflux for 36 h. After cooling the reaction mixture to room temperature, methanol was evaporated under reduced pressure. The residue was taken up in ethyl acetate (10 mL), and the solution was washed with 10% Na_2CO_3 and water. The organic layer was dried over anhydrous $MgSO_4$ and concentrated in vacuo. The residual oil was purified by column chromatography on silica gel using ethyl acetate – petroleum ester (1:6) as the eluant to furnish the corresponding (*S*)-metolachlor, (*S*)-**5** (1.4 g, 66% yield): $[\alpha]^{20}_D$ –8.2 ± 1° (*c* 2.1%, *n*-hexane), 91.1% ee_p based on $[\alpha]^{20}_D$ –9.0 ± 1° (*c* 2.073%, *n*-hexane) reported in literature (4). ^1H NMR ($CDCl_3$), δ: 7.24–7.13 (m, 3H, aromatic H), 4.22 (m, 1H, $CHCH_3$), 3.94 (dd, *J* = 4.2 and 9.4 Hz) and 3.75 (dd, *J*= 4.2 and 9.4 Hz) for one diastereomeric proton of $CHCH_2OCH_3$), 3.62–3.61 (s, 2H, CH_2Cl), 3.51 (dd, *J* = 4.2 and 9.4 Hz) and 3.49 (dd, *J* = 4.2 and 6.5 Hz) for one diastereomeric proton of $CHCH_2OCH_3$, 3.27–3.26 (d, 3H, OCH_3), 2.62–2.54 (m, 2H, CH_2CH_3), 2.26 (s, 1H, aromatic CH_3), 2.24 (s, 2H, aromatic CH_3), 1.28–1.23 (t, 3H, *J* = 7.5 Hz, CH_2CH_3), 1.17–1.14 (q, 3H, *J* = 7.0 Hz, $CHCH_3$). GC–MS *m*/*z* (%): 284 (M^+, 60), 252 (38), 250 (100), 218 (47), 178 (25), 162 (37), 73 (60); GC: 98% area.

Results and discussion

In a general experimental procedure, readily accessible racemic methyl ester **1** was used as a substrate in the identification of a suitable lipase for the enantioselective hydrolysis (Scheme 1), and the screening results were listed in Table 1. The lipase CAL-B was very active, and 48.2% of

Note: Reaction conditions: substrate: 0.5 mmol; CAL-B: 10 mg; organic compound/phosphate buffer (100 mmol/L, pH= 8.0, 5.0 mL) 1:9; temperature: 25 °C.

(*R*,*S*)-**1** was hydrolyzed only after 2 h at 37 °C; however, it displayed poor enantioselectivity (*E* = 10.6) towards the (*S*)-enantiomer of the acid. The *E* value of >100 and enantiomeric excess (ee_p) of >98% were obtained by lipase PSL and PPL, but they preferably produced the (*R*)-acid and needed longer reaction time. Other enzymes investigated in this work gave both low conversion and enantioselectivity, making them practically useless. As a result of its higher activity and stereospecificity towards the (*S*)-enantiomer, the lipase CAL-B was chosen from the enzymes screened for further study.

Initially we investigated the influence of the microenvironment on the CAL-B-catalyzed resolution and found that the enantioselectivity of CAL-B was still too low for a large-scale preparation (data not shown). This may be ascribed to the ability of CAL-B to catalyze the hydrolysis of both (*R*)- and (*S*)-enantiomers of substrate, thus leading to the low enantioselectivity of enzyme. According to this assumption, if we take measures to enantioselectively inhibit the reaction rate of CAL-B-catalyzed hydrolysis, and as a result, the (*S*)-enantiomer becomes overwhelmingly the faster reacting enantiomer, the enantioselectivity of CAL-B may be enhanced.

The strategy of enantioselective inhibition by adding an organic compound to the reaction medium to enhance the selectivity of lipase had previously been reported by our group (13). So, in this study, organic compounds with different hydrophobicities (log *P*) (14, 15) were added to the reaction system to observe their effect on CAL-B-catalyzed hydrolysis (Table 2). In all experiments, the biocatalytic system shows the same stereopreference for (*R*,*S*)-**1** giving (*S*)-acid. Also, the addition of organic compounds generally enhanced the enantioselectivity of CAL-B compared with that in a pure buffered medium, despite a decrease in enzyme activity.

According to the previously mentioned results, it is worthy to note that the use of diethyl ether and *n*-hexane as additives is preferred (*E* = 19.0 and 20.1, respectively). Herein, the effects of diethyl ether and *n*-hexane amounts on the activity and enantioselectivity of CAL-B were studied. The additive amount of the organic compound is an important parameter worthy of careful optimization because it may have a strong influence on enzyme activity and enantioselectivity. When diethyl ether was added to the reaction medium, the maximum *E* value of CAL-B was obtained at 15% (*v*/*v*) (*E* > 100, Fig 2), which was approximately 9.7-fold more enantioselective than that in the pure buffered medium. For *n*-hexane, the results differed and the maximum enantioselectivity of CAL-B was stabilized at the additive amount ranging from 10 to 15% (*v*/*v*) (*E* = 20.1, Fig 3). The conversion ratios of reactions for various amounts of organic compounds were also measured and it was found that the ratio decreased with an increase of additive amount of organic compound. Based on these results, we presume that diethyl ether is a stronger and more (*R*)-selective inhibitor than *n*-hexane.

After CAL-B-catalyzed hydrolysis finished under the optimized conditions, the enantiomercially pure (*S*)-**2** (>98% ee_p) and the remaining ester (*R*)-**1** were extracted with ether. The two compounds can be separated easily by partitioning in ether or water. This simple extraction–partition procedure is especially convenient and suitable for a large-scale operation. The remaining ester can be recycled by chemical racemization, which is achieved through treatment with a mixture of *n*-butyraldehyde and benzoic acid dissolved in toluene (Scheme 1). The aldehyde-catalyzed racemization of

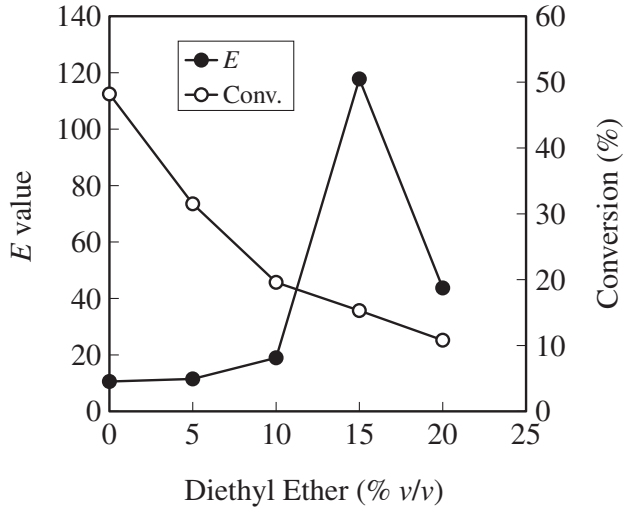

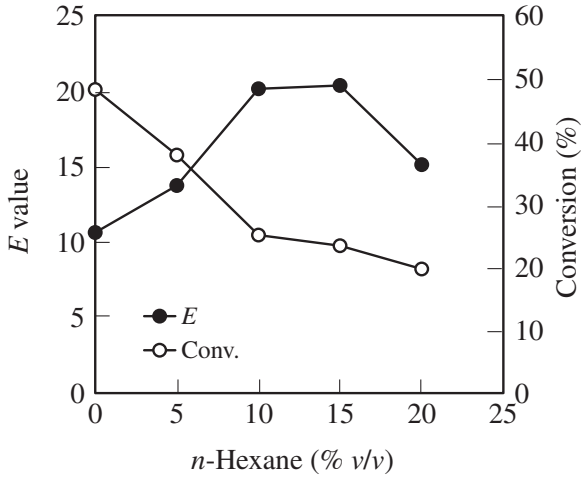

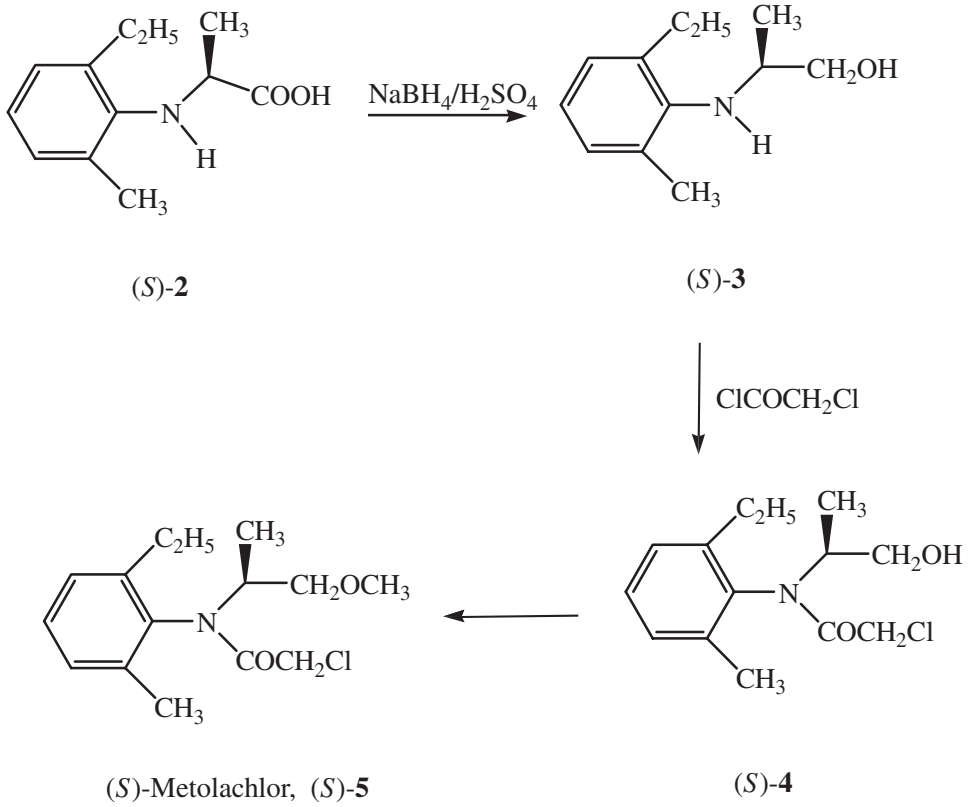

Fig. 3. Effect of different volume fractions of *n*-hexane on the conversion and enantioselectivity of CAL-B-catalyzed hydrolysis of (*R*,*S*)-**1**.

Scheme 2. Synthesis of (*S*)-metolachlor from enzymatically prepared (*S*)-**2**.

amino acids and derivatives is the most prominent example of how to derive a functional group connected to a chiral center and affect optical stability. Herein, we also investigated the effects of other aldehydes including formaldehyde, acetaldehyde, propionaldehyde, *n*-valeraldehyde, and benzaldehyde on the racemization, and found that the experimental results were similar. However, considering the economic factor and the boiling point of the aldehyde, we selected *n*-butyraldehyde as the racemic reagent. Very similar results were also reported by Park et al. (6).

The chemical synthesis of (*S*)-metolachlor was then carried out using enantiomercially pure (*S*)-**2** as a substrate via a number of pathways, which included reduction, chloroacetylation, and etherification (Scheme 2). The reduction of (*S*)-**2** to (*S*)-**3** is conveniently carried out in an inert solvent. Suitable reducing agents are lithium aluminium hydride and

© 2006 NRC Canada

sodium borohydride, but the selectivity of lithium aluminium hydride towards the functional group of the compound is poor and it is rather expensive. Thus, it is preferable to use sodium borohydride in the form of a complex, especially as a sodium borohydride – tetrahydrofuran complex. The conversion of (*S*)-**3** into (*S*)-**4** is carried out in an inert solvent by the reaction with a chloroacetylating agent, such as chloroacetyl chloride, in the presence of a base. Suitable bases may be alkali metal carbonates, triethylamine, and pyridine. Suitable inert solvents may be hydrocarbons, such as hexane, cyclohexane, benzene, toluene, and chlorobenzene. In this work, Na_2CO_3 and benzene were selected as the base and inert solvent, respectively. The reaction was carried out at a low or moderately elevated temperature. The etherification of the 2-hydroxy group of (*S*)-**4** was carried out by heating the reaction mixture, dissolved in methanol, in the presence of a strong acid at a reflux temperature. A strong acid suitable for the reaction is *p*-toluenesulfonic acid. Then (*S*)-metolachlorwas obtained with the optical purity of 91.1% ee_p. Compared with racemic metolachor, (*S*)-metolachlor has a markedly superior herbicidal action against weeds without increasing phytotoxicity towards cultivated plants.

Conclusion

We successfully developed a chemoenzymatic procedure for the synthesis of enantiomerically pure (*S*)-metolachlor. We took advantage of the higher activity and excellent enantioselectivity of lipase CAL-B, chemical racemization of the remaining ester, and chemical reactions including reduction, chloroacetylation, and etherification. The method is easy to perform with standard equipment and can be widely applied. At the same time, we found that organic compounds strongly influenced the selectivity of CAL-B. Diethyl ether, in particular, was found to achieve the highest enantioselectivity of CAL-B ($E > 100$) in the hydrolysis of (*R*,*S*)-**1**. Further work in this area, including the repeated use of enzymes to decrease the enzymatic cost and scale-up results of the process, is being done in our laboratory and will be reported soon.

A new and efficient one-pot solid-supported synthesis of 1,2,4,6-tetraaryl-1,4-dihydropyridines

Anil K. Verma, Summon Koul, Tej K. Razdan, and Kamal K. Kapoor

Abstract: 1,2,4,6-Tetraaryl-1,4-dihydropyridines were obtained by the one-pot reaction of chalcones and substituted anilines on the surface of Bi(III)nitrate-Al_2O_3. The reaction seems to proceed via β-oxygenation of Bi(III) enolised chalcones followed by Michael addition and heteroannulation with simultaneous retro aldol disproportionation. The presence of the ring-activating groups at ortho and para positions in the aniline seems to be essential for the reaction.

Key words: 1,2,4,6-tetraryl-1,4-dihydropyridines, chalcones, substituted anilines, Bi(III) nitrate-alumina catalyst.

Résumé : On a réalisé la synthèse de 1,2,4,6-tétraaryl-1,4-dihydropyridines par le biais d'une réaction monotope de chalcones avec des anilines substituées à la surface d'un catalyseur de nitrate de Bi(III)-Al_2O_3. La réaction semble impliquer une β-oxygénation des sels de Bi(III) des chalcones énolisées, suivie d'une addition de Michael et d'une héteroannelation accompagnée d'une dismutation simultanée rétroaldolique. Il semble que la présence de groupes activants dans les positions ortho et para de l'aniline soit essentielle à la réalisation de la réaction.

Mots clés : 1,2,4,6-tétraaryl-1,4-dihydropyridines, chalcones, anilines substituées, catalyseur de nitrate de Bi(III)-alumine.

[Traduit par la Rédaction]

Introduction

1,4-Dihydropyridine derivatives participate actively in biochemical oxidoreductase (1) and transaminase (2) reactions. They serve as key intermediates in the biogenesis of indole alkaloids (3) as well as the synthesis of several naturally occurring bioactive alkaloids (4) and substituted pyridines (5). These products are primarily potent calcium antagonists (6) and the activity is dictated by the stereochemistry at C-4 (7). The compounds also exhibit a wide range of other therapeutic properties such as antioxidant (8), antimutagenic (9), antidiabetic (10), hepatoprotective (11), antiaddictive (12), bronchodilating (13), herbicidal (14), and anticancer (15) activity. Therefore, the synthesis of 1,4-dihydropyridine derivatives continues to be a subject of fruitful research. These products, especially the calcium channel regulators, are synthesized chiefly by Hantzsch synthesis (14) or its modifications and by the reduction of pyridine derivatives or pyridinium salts. Several reviews (16) have exhaustively dealt with the synthesis, chemistry, pharmacology, and industrial utility of 1,4-dihydropyridine derivatives.

Our interest in the synthesis of 1,2,4,6-tetraaryl-1,4-dihydropyridines originated from the presumption that because of the planarity of the 1,4-dihydropyridine nucleus (17) these products may display the photodynamic activity akin to the symmetrical 2,4,6-triarylthiopyrylium, selenopyrylium, and telluropyrylium photosensitizers, which have been recommended for cell-specific cancer therapy (18). Moreover, since most of the known syntheses (16) of 1,4-dihydropyridine derivatives are multistage laborious processes and involve harsh or environmentally hazardous reaction conditions, together with the fact that the alkyl and the aryl primary amines have not gained popularity in their synthesis, we opined that a new and straightforward catalytic method, employing aryl primary amine as one of the substrates, was needed for the synthesis of 1,2,4,6-tetraaryl-1,4-dihydropyridines. Herein, we report a simple, convenient, and cost-effective one-pot solid-supported synthesis of these compounds from chalcones and substituted anilines using the hitherto unexplored Bi(III) nitrate-Al_2O_3 reagent.

Results and discussion

Although Bi(III) nitrate is easily available in pure form and has negligible toxicity (19) and high stability in air and moisture, its catalytic efficacy has not been thoroughly explored. This led us to evaluate the possible catalytic utility of Bi(III) nitrate immobilized on neutral alumina in the synthesis of the title products. The catalyst was selected on the assumption that Bi(III) ions, being moderately acidic (20) in nature, could bind efficiently to the surface of neutral alumina, prevent its restructuring, synergise its catalytic activity (21), and initiate a reaction under mild conditions. The catalyst was prepared by adsorbing Bi(III) nitrate·$5H_2O$ (5% *w*/*w*) on neutral alumina and activation of the air-dried mixture in a hot air oven at 110 ± 5 °C, for six hours. The catalyst was reactivated each time before use.

The chalcone substrates **1a**–**1k** were prepared from the appropriate benzaldehyde and acetophenone by classical

Claisen–Schmidt condensation (22). Subsequent reactions of **1a**–**1k** with *o*-phenylenediamine, **2a**, (2:1 mol/L), and Bi(III) nitrate-Al_2O_3 (Scheme 1), in the proportion by weight of chalcones, were carried out in a thermostatically controlled hot air oven at 130 ± 5 °C, for 4 to 5 h. The resulting product mixtures were isolated with chloroform and separated by column chromatography to yield the major products **3a**–**3k** (56%–76%) (Table 1) and the minor products **4a**–**4k** (8%–10%). These reactions also afforded the aldehyde (5%–6%) from which **1a**–**1k** were prepared. The compounds **3a**–**3k** and **4a**–**4k** were analysed by spectral methods, HREI-MS, IR, ^{1}H NMR, ^{13}C NMR and DEPT 135°. The spectra established the structures of **3a**–**3k** as 1,2,4,6-tetraaryl-1,4-dihydropyridine derivatives (Scheme 1). The expanded peak segregated ^{1}H NMR spectra of the products showed a characteristic one proton triplet (J = 3.8 Hz) near δ 5.37 because of the α proton (5*a*, 23) at C-4, δ_C 54.7, coupled to the protons at C-3 and C-5, δ 6.80–7.1 (d, J = 3.9 Hz, 2H), δ_C 145.2, of the dihydropyridine nucleus. The IR absorption band at υ_{max} 3455 cm^{-1} and a broad singlet near δ 7.23 (2H) in the ^{1}H NMR spectra revealed the presence of a free amino group in the compounds. The ^{13}C NMR signals were assigned on the basis of DEPT 135 experiments. The mass spectra of **3a**–**3k** exhibited fragmentations typical of 1,4-dihydropyridines (24) and displayed abundant ion peaks corresponding to the loss of an aryl radical from the C-4 of the

molecular ion. The base peak fragment ion at *m/z* 246 resulted from the loss of the second aryl radical from the C-2 or C-6 position of the (M^+ – $Ar^·$) fragment ion. Except for compounds **3f** and **3k**, which possessed two monosubstituted aryl rings at positions 2 and 6 of the 1-(2-aminophenyl)-1,4-dihydropyridine nucleus, and compound **3a**, which possessed unsubstituted phenyl rings at positions 2,4, and 6 of the nucleus, all products had a lone substituted phenyl ring at position 4 of the nucleus.

The ^{1}H NMR spectra of the minor products **4a**–**4k** displayed resonance signals near δ 3.0 (dd, *J* = 8.2, 11.5 Hz, H_a-6), 3.20 (dd, *J* = 4.1, 11.5 Hz, H_b-6), 5.10 (dd, *J* = 4.1, 8.2 Hz, H-7), and 3.80–3.90 (s, br, 1H, NH) typical of benzo-1,4-diazepines. These compounds were known and their spectral data and melting points were consistent with the literature (25).

To generalize this reaction and assess the influence of the ring-activating and ring-deactivating substituents in anilines on the percentage yield of the products, chalcone **1b** was reacted separately but under identical conditions with *ortho*-, *meta*-, and *para*-hydroxyaniline **2b**–**2d**, bromoaniline **2e**–**2g**, nitroaniline **2h**–**2j**, and aniline **2k** (Scheme 2). Aniline, *o*-

Scheme 3. Probable mechanism for formation of 1,2,4,6-tetraaryl-1,4-dihydropyridine.

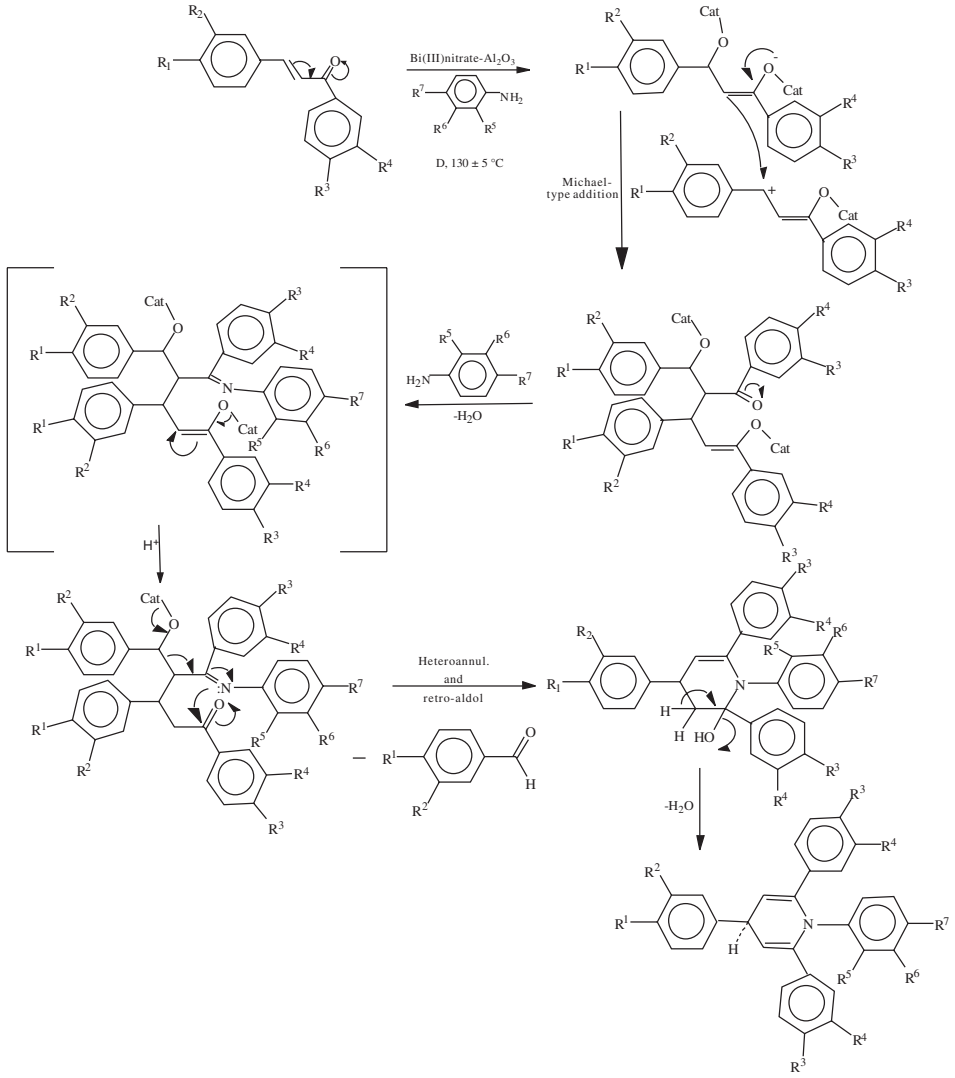

Table 2. Yield of the products of **1b** with different anilines **2b**–**2h**.

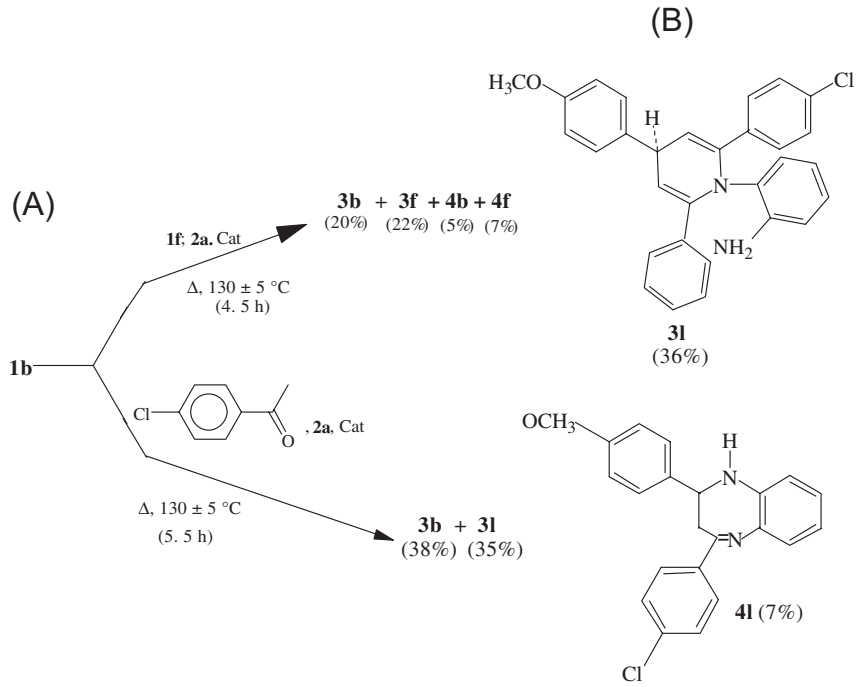
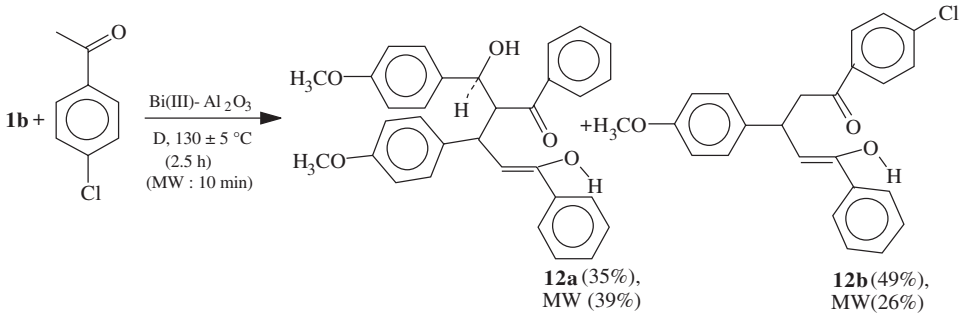
Product	Oven yield (%)	MW yield (%)	MW time (min)
5	65.6	68.2	20
6	22.5	26.0	26
7	72.0	74.3	25
8	73.4	75.4	18
9	19.5	19.8	25
10	76.5	78.5	20
11	32.5	33.0	20



nitroaniline, and *p*-nitroaniline failed to afford the desired 1,2,4,6-tetraaryl-1,4-dihydropyridines while *meta*- nitroaniline afforded the product **11**, albeit in low yield (Table 2). The ring-activating groups in anilines seem to favour the reaction and formed compounds **5**–**10** with the percentage yield in the expected order of para > ortho > meta substituted anilines (Table 2).

Since crystalline bismuth nitrate exists as $Bi(NO_3)_3{\cdot}5H_2O$ and alumina also chemisorbs water readily (25) and retains some of it even after activation at 110 ± 5 °C, the mechanism of the reaction may be rationalised as involving β-oxygenation of the Bi(III) nitrate activated chalcone enolate, which may then undergo a Michael addition to a second α,β-unsaturated ketone (Scheme 3) to form a 1,5-diketone enolate adduct. Subsequent heteroannulation with substituted anilines via condensation and retro-aldol disproportionation (26) may form 2-hydroxy-1,2,4,6-tetraaryl-1,2,3,4-tetrahydropyridine derivatives, which may undergo dehydration to yield 1,2,4,6-tetraaryl-1,4-dihydropyridines. This mechanism is supported by the fact that the products obtained from 4-substituted chalcones, like **3b**, possessed only one substituted phenyl group at position 4-4 of the 1-(2-aminophenyl)-1,4-dihydropyridines nucleus.



To substantiate the proposed mechanism, cross-reactions of chalcones **1b** and **1f** and also **1b** and *p*-chloroacetophenone (1:1 mol/L) with equimolar amounts of **2a** and 5% Bi(III) nitrate-Al_2O_3, in proportion by weight of the substrates, were carried out at 130 ± 5 °C (Scheme 4). The reaction of **1b**, **1f**, and **2a** yielded **3b** (20%), **3f** (22%), **3l** (36%),

© 2006 NRC Canada

Scheme 4. Cross reaction of **1b**.

Scheme 5. Reaction of **1b** and *p*-chloroacetophenone in the absence of aniline derivatives.

4b (5%), and **4f** (7%). The reaction involving **1b**, *p*-chloroacetophenone, and **2a** gave **3b** and **3l** in nearly equal proportions and **4l** (13%).

We attempted the reaction of equimolar quantities of **1b**, *p*-chloroacetophenone, and equal mass of Bi(III)nitrate-Al_2O_3 at 130 ± 5 °C (Scheme 5) in the absence of arylamines. The reaction afforded two products, **12a** and **12b**, which were separated by column chromatography and identified by spectral methods as 2-(4-methoxyphenyl)hydroxymethyl-3-(4-methoxy)phenyl-1,5-diphenylpentan-4-en-5-ol-1-one (**12a**) and 1-(4-chloro)phenyl-3-(4-methoxy)phenyl-5-phenylpentan-4-en-5-ol-1-one (**12b**) (Scheme 5). The ^{1}H NMR, ^{13}C NMR and DEPT 135 spectra for **12a** and **12b** showed the presence of a carbonyl group, δc 197.3, and an enol hydroxyl, δ 12.9 (s br, exch. D_2O, 1H). The spectra of **12a** revealed the absence of a methylene carbon whose presence in **12b** was evident from the resonance signals at δ 2.69 (d, J = 4.5 Hz, 2H) in its ^{1}H NMR spectrum and δ_C 25.3 in its ^{13}C NMR and DEPT 135 spectra. The spectra of **12a** showed the presence of a secondary hydroxyl displaying resonance signals at δ 2.80 (s br, exch. D_2O, 1H) and 5.01 (d, J = 3.6 Hz, 1H, -CH-OH), δ_C 83.2. These signals were absent in the spectra of **12b**. These observations were consistent with the proposed mechanism and indicated that the retro-aldol disproportionation is probably triggered by the heteroannulation of the Michael adduct with substituted anilines, especially the anilines having a ring-activating group at the ortho or para position.

The reaction is sensitive to temperature with the optimum temperature being 130 ± 5 °C. The reaction failed to proceed in solution or when neat Al_2O_3 or Bi(III) nitrate were used as the reagent. We repeated all the reactions in a domestic microwave (2450 MHz) using 60% power and followed the procedure of Mukhopadhyay et al. (27), which allows the temperature to remain at ca. 130 °C. The reactions were completed in 19–26 min without any appreciable improvement in the yield of the 1,2,4,6-tetraaryl-1,4-dihydropyridines (Tables 1 and 2).

Conclusion

In conclusion, we have devised a new one-pot environmentally benign and general solid-supported catalytic method for the synthesis of 1,2,4,6-tetraaryl–1,4-dihydropyridines

© 2006 NRC Canada

from the easily accessible chalcones and substituted anilines using Bi(III) nitrate immobilized on Al_2O_3 as a reagent. An advantage of this method is the low toxicity (19) and the antiulcerative (28) properties of bismuth compounds. Further studies on the scope and limitations of immoblized Bi(III) nitrate in organic transformations are under way.

Experimental

General

Melting points are uncorrected and were determined on Perfit melting point apparatus. IR, on KBr discs, were taken on a Brucker 4800 IR spectrometer. ^{1}H NMR (200 MHz) and ^{13}C NMR (50.3 MHz) were recorded in DMSO or $CDCl_3$ using a Brucker Ac DPX-200 spectrometer; some spectra were recorded on Varian Gemini 300 MHz instrument. HREI-MS were recorded on JEOL D-300 mass spectrometer at 70 eV. TLC was performed on 0.5 mm thick plates using BDH silica gel-G adsorbent. Column chromatography was performed on silica gel (BDH, mesh size 60–120) using graded solvent systems of petroleum ether (40–60 °C), petroleum ether – $CHCl_3$ and $CHCl_3$–EtOAc. Microwave irradiations were carried out in a domestic microwave oven (LG Model No. MS-255R, No. 4140W1A347A) with frequency 2450 MHz and R_f output of 900W.

Preparation of catalyst

Bi(III) nitrate·$5H_2O$ (2.5 g) was dissolved in 50% MeOH (150 mL) and the solution was added to neutral alumina (50 g) and stirred for 12 h at room temperature. The mixture was air dried and then heated at 110 ± 5 °C in a thermostatic hot air oven for 6 h. The activated Bi(III) nitrate-Al_2O_3 mixture was cooled in a dessicator and preserved. The catalyst was reactivated at 110 ± 5 °C for 0.5 h each time before use.

Preparation of chalcones 1a–1k

Chalcones **1a**–**1k** were prepared from the appropriate benzaldehyde and acetophenone by the well known procedure for Claisen–Schmidt condensation (22). Chalcones were purified by CC on silica gel using petroleum ether – CH_2Cl_2 (9:1, 7:3, and 1:1 *v*/*v*, 40–60 °C) followed by crystallization from $CHCl_3$ –MeOH.

General procedure for the preparation of 3a–3k, 5–11 and cross-reactions of 1b

The solution of chalcone **1a**–**1k** (2×10^{-3} mol/L) and *o*-phenylenediamine **2a** (1×10^{-3} mol/L) in chloroform (10 mL) were adsorbed on a Bi(III) nitrate-Al_2O_3 mixture in proportion by weight of the chalcones. The solvent was evaporated in air and the air-dried solid mixture was charged into a stoppered flask. The flask was heated in a thermostatically controlled hot air oven and maintained at 130 ± 5 °C. Simultaneously, separate experiments were conducted to monitor the reaction by comparative TLC of the ethylacetate extracts of the aliquots drawn out from the reaction flask at 0.5 h intervals, using petroleum ether – CH_2Cl_2 (9:1, 7:3, and 3:7 *v*/*v*, 40–60 °C) as solvent systems. The plates were developed by spraying with Ce(IV) ions and heating at 110 ± 5 °C for 10 min when dark purple spots of the Ce(IV) complexes of 1,2,4,6-tetraaryl-1,4-dihydropyridines and yellow spots of the 1,4-benzodiazepines were observed against a white background. On completion of the reaction (4–5 h) the product mixtures were extracted with hot $CHCl_3$ in a soxhlet extractor, freed from the solvent, and separated by CC, using petroleum ether – CH_2Cl_2 (40–60 °C) graded solvent systems. Twenty milliliter fractions were collected and TLC identical fractions were pooled. The solvent was distilled and the residue was purified by crystallization from $CHCl_3$ – petroleum ether (40–60 °C) and $CHCl_3$–MeOH. This gave **3a**–**3k** as major product and **4a**–**4k** (25) as the minor product (Table 1). In addition to these compounds, minor quantities of aldehydes from which **1a**–**1k** were prepared were also obtained. Compounds **5**–**11** (Scheme 3) were prepared by reacting **1b** (2×10^{-3} mol/L) and 2-aminophenol (**2b**), 3-aminophenol (**2c**), 4-aminophenol (**2d**), 2-bromoaniline (**2e**), 3-bromoaniline (**2f**), 4-bromoaniline (**2g**), and 3-nitroaniline (**2h**) (1×10^{-3} mol/L), respectively, with Bi(III) nitrate-Al_2O_3 in proportion by weight of the substrates using the previously described procedure. The same procedure was adopted in the reaction of **1b** (1×10^{-3} mol/L), **1f** (1×10^{-3} mol/L), and Bi(III) nitrate-Al_2O_3 and a mixture of **3b**, **3f**, **3l**, **4b**, and **4f** were obtained (Scheme 4). The mixture was separated by CC as described earlier. A similar procedure was used in the reaction of **1b** (1×10^{-3} mol/L), *p*-chloroacetophenone (1×10^{-3} mol/L), and Bi(III) nitrate-Al_2O_3 (Scheme 4) when a mixture of **3b**, **3l**, and **4l** was recovered by adopting the previously described procedure for the isolation, separation, and purification of the compounds.

Preparation of 12a and 12b

To a mixture of **1b** (0.238 g, 1×10^{-3} mol/L) and *p*-chloroacetophenone (0.15 g, 1×10^{-3} mol/L) dissolved in $CHCl_3$ (10 mL) was added the reagent Bi(III)nitrate-Al_2O_3 (0.388 g). The mixture was dried in air and heated in a thermostatically controlled hot air oven at 130 ± 5 °C. A separate experiment was simultaneously conducted to monitor the reaction by TLC of the chloroform extract of the aliquots drawn from the reaction mixture at 0.5 h intervals. On completion of the reaction (2.5 h) the products were isolated with chloroform and filtered, and the filtrate was washed with water and dried over anhydr. $MgSO_4$. TLC (silica gel G, solvent C_6H_6) of the product mixture showed the presence of two products **12a** and **12b**, which were separated by CC (silica gel), using petroleum ether – benzene (1:1) and benzene and were crystalized from chloroform–methanol.

General procedure for microwave irradiation

The solid mixtures of chalcones, anilines, and Bi(III)nitrate- Al_2O_3 in the same proportions as were used during the reactions carried out in a thermostatically controlled hot air oven were heated in a domestic microwave (2450 MHz) using 60% power (540 W) using the procedure of Mukhopadhyay et al. (27), which permits the control of temperature at 130 °C. The reactions were monitored by TLC as described earlier. The reactions were completed within 18–26 min (Tables 1 and 2). The products were extracted and purified as before and were identified by co-TLC, mp, and mmp as **3a**–**3k**, **3l**, **4a**–**4k**, **4l**, **5**–**11**, **12a**, and **12b**.

Isomerization of 4-amino-6,7-diphenylbicyclo[2.2.2]octan-2-ones

Werner Seebacher, Robert Saf, Reto Brun, Marcel Kaiser, and Robert Weis

Abstract: Under strongly basic conditions (6*SR*,7*SR*)-4-amino-6,7-diphenylbicyclo[2.2.2]octan-2-ones isomerized regioselectively in position 6 giving their (6*RS*,7*SR*) analogues. The structure of the new products was established with the aid of NMR experiments.

Key words: aminobicyclo[2.2.2]octanones, isomerization, structure elucidation.

Résumé : Faisant appel à des bases fortes, les (6*SR*,7*SR*)-4-amino-6,7-diphénylbicyclo[2.2.2]octan-2-ones peuvent être isomérisées d'une façon régiosélective en position 6 pour conduire à la formation de leurs analogues (6*RS*,7*SR*). Les structures des nouveaux produits ont été déterminées à l'aide de la résonance magnétique nucléaire.

Mots clés : animobicyclo[2.2.2]octanones, isomérisation, élucidation de structures.

[Traduit par la Rédaction]

Introduction

Previously, we reported the formation of 4-aminobicyclo-[2.2.2]octan-2-ones **1a**–**1d** from the reaction of ammonium thiocyanates and benzylidene acetone (1, 2). Those compounds were used as starting materials for derivatives with antiplasmodial and antitrypanosomal activity (3–5). So far, structural modifications have been restricted to different substitutions of the aromatic rings, of the amino nitrogen, and in ring positions 1 and 2. To synthesize new derivatives with a substituent in ring position 3 of compounds **1a**–**1d**, we subjected the above-mentioned ketones to strong alkaline conditions for preliminary deprotonation experiments (Fig. 1). During these investigations, we observed transformations to new products. The yields of these reactions were improved by modification of the reaction conditions and structural evidence of the new compounds was achieved by use of NMR experiments.

Results and discussion

For deprotonation, we treated the 4-aminobicyclo-[2.2.2]octan-2-one **1a** with sodium *tert*-butylate in *tert*-butanol at 145 °C and observed the formation of a new compound. After 3 h, ca. 35% of **1a** was transformed into the new product. The rest of the mixture contained unchanged **1a**. No formation of side products was observed in the ^{1}H NMR spectra of the mixture. Longer reaction periods (overnight) or higher reaction temperature (200 °C for 4 h in an autoclave) did not increase the yield of the new product. Higher yields were obtained when the conversion was done without solvent at 200 °C. The reaction mixture contained up to 80% of the isomerized product, leaving 20% unchanged starting material. Still, no side products were detectable. Compounds **1b**–**1d** were converted in the same way. The new products were separated from **1** and purified by repeated recrystallization of their hydrochlorides. From NMR experiments it was evident that a symmetric molecule was formed. In ^{1}H NMR spectra the signals for the protons in positions 5 and 8 appeared as two, instead of four, separated signals as in compounds **1**. Therefore, we assumed that one of the symmetric ketones **2** or **3** had been formed, which is only possible by a change of the configuration in position 6 or 7. The protons 5-H′ and 8-H′ resonate at a higher field because of the shielding of the aromatic rings. Those protons show NOEs to aromatic protons as well as to the protons in position 3, ruling out structure **3** and furnishing the evidence of structure **2** (Fig. 1).

Muir and Stothers (6) proposed the following mechanism for homoenolization reactions of bicyclic compounds without enolizable protons in the α-position at 185 °C using *t*-BuO$^-$/*t*-BuOH. Proton abstraction from the bicyclo-[2.2.2]octan-2-one (**4**) was reported to give the tricyclic β-enolate (**5**) as an intermediate. When the bond between positions 2 and 6 is cleaved (**a**), compound **4** was re-formed, whereas splitting of the the bond between positions 1 and 2 (**b**) led to the bicyclo[3.2.1]octan-6-one (**6**) (Scheme 1).

Nickon et al. (7) proved that homoenolate ions can be generated in ketones with enolic protons and also that chiral centers β to a carbonyl can be epimerized via such ions. Therefore, deprotonation in position 6 of compounds **1** is expected to give β-enolates **7** as intermediates, which should undergo conversion to mixtures of **1** and **8**. However, the bicyclo[2.2.2]octane ring system was re-formed by selective addition of a proton in position 6, giving mixtures of bicyclo[2.2.2]octanes **1** and **2** that have reverse configurations in position 6 (Scheme 2). There are two possible rea-

Scheme 1.

4 **5** **6**

sons why isomers **3** did not emerge from **7**. Either the proton in position 7 is not accessible by the used base or compounds **3** cannot be formed because of the sterical interaction of the two phenyl rings. Besides, the expected conversion of **7** to bicyclo[3.2.1]octanes (**8**) by cleavage of the bond between positions 1 and 2 was not observed in ^1H NMR spectra of the reaction mixtures. This could be due to better resonance stabilization of the benzylic anion, which is formed from **7** prior to the formation of compounds **2**.

Using this method, a complete conversion of compounds **1** to their isomers **2** is not possible. This was demonstrated by the reaction of **2d** with potassium *tert*-butylate. In this case, 15% of **1d** were formed showing that the isomerization is a balanced reaction.

Furthermore, we verified the essential role of the oxo group of compound **1a** in the isomerization process. We removed the oxo group of **1a** via a Wolff–Kishner reduction giving **9a** (8). When the latter was treated with *t*-BuOK at 200 °C, no isomerization was observed ruling out a simple proton abstraction in the benzyl position as an initial step of the isomerization. This observation established the formation of β-enolates in the proposed mechanism.

The antiplasmodial properties of the new ketones **2** were determined in an in vitro assay as described (3) and compared with those of ketones **1**. The results are presented in Table 1. A distinct increase of the activity against *Plasmodium falciparum* strain K1 of compounds **2** compared with compounds **1**, due to isomerization in position 6, is worthy of note. Compound **2c** exhibits the highest antiplasmodial activity and at the same time the lowest toxicity of this series.

Conclusion

(6*SR*,7*SR*)-6,7-diphenylbicylo[2.2.2]octan-2-ones **1** isomerized under strong alkaline conditions regioselectively to their (6*RS*,7*SR*) analogues. The mechanism of their formation contains a tricyclic enolate. The new compounds **2** show a distincly higher antiplasmodial activity compared with compounds **1**. Therefore the (6*RS*,7*SR*) analogues of the most active derivatives of compounds **1** will be synthesized.

Experimental

General

Melting points were obtained on a digital melting point apparatus Electrothermal IA 9200 and are uncorrected. IR spectra were obtained using a PerkinElmer 2000 FT IR spectrometer system. UV–vis were obtained using a PerkinElmer Lambda 17 UV spectrometer. NMR spectra were obtained using a Varian Inova 400 (300 K) with 5 mm tubes and TMS resonance as internal standard. ^1H and ^{13}C resonances were assigned using $^1H,^1H$ and $^1H,^{13}C$ correlation spectra. HMBC spectra were optimized for 8 Hz. For NOE measurements, oxygen was carefully removed by bubbling Ar through the solutions. ^1H and ^{13}C resonances are numbered as given in the formulas. Assignments marked with an asterisk are interchangeable. MS was measured using a Varian MAT 711 spectrometer with 70 eV electron impact and a Kratos profile spectrometer with 70 eV electron impact. GC-MS measurements were done with a Hewlett-Packard HP-6890 with 70 eV electron impact. Microanalyses were obtained by a EA 1108 CHNS–O apparatus (Carlo Erba) at the Microanalytical Laboratory at the Institute of Physical Chemistry, Vienna. Materials used for column chromatography (CC): silica gel 60 (Merck, 70–230 mesh), pore diameter 60 Å; thin-layer chromatography (TLC): TLC plates (Merck, silica

Synthesis of (6*SR*,7*SR*)-(±)-4-amino-6,7-diphenylbicyclo-[2.2.2]octan-2-ones 1a–1d

The synthesis of compounds **1a**–**1d** from acyclic starting material is described previously (1, 2).

Synthesis of (6*RS*,7*SR*)-(±)-4-amino-6,7-diphenylbicyclo-[2.2.2]octan-2-ones 2a–2d

Method A: Ketones **1** were dissolved in dry *tert*-butanol and potassium *tert*-butylate was added. The mixture was refluxed overnight at 145 °C and then cooled to room temperature. Brine was added and the resulting solution was extracted 4 times with ether. The combined organic layers were washed with water, dried over sodium sulfate, filtered, and the solvent evaporated. The residue contained 35% of the isomerization product and 65% of the starting product (^{1}H NMR) and was dissolved in the minimum amount of EtOH, treated with 10 mL of concd HCl, and evaporated. This process was repeated once more. Small amounts of the hydrochloride of the isomerization product were isolated by repeated crystallization from ethyl acetate – EtOH.

Method B: Ketones **1a**–**1d** were mixed with potassium *tert*-butylate and heated to 200 °C for 3 h. After cooling to room temperature, the dark red solid residue was dissolved in the minimum amount of EtOH and brine was added. The mixture was extracted 4 times with ether, the organic phases were combined, washed with water, and dried over sodium sulfate. After filtration from the solid, the solvent was evaporated in vacuo. The residue contained 80% of the isomerization product and 20% of the starting material. For further purification, the residue was dissolved in EtOH and 10 mL of concd HCl were added and the solvents evapo-

rated. The treatment of the residue with hydrochloric acid was repeated and the solvent evaporated. The residue was dissolved in a mixture of EtOH – ethyl acetate and the hydrochloride of the pure isomerization product crystallized. The bases were set free by treatment of the hydrochloride with 2N NaOH and repeated extraction with ether. The combined organic phases were washed with water, dried over sodium sulfate, filtered, and the solvent evaporated. The resinous residue was dried under reduced pressure.

(6*RS*,7*SR*)-(±)-4-Dimethylamino-6,7-diphenylbicyclo-[2.2.2]octan-2-one 2a

Method A: 3.5 g (11 mmol) of **1a** in 32 g of dry *tert*-butanol with 4.9 g (44 mmol) of potassium *tert*-butylate gave 300 mg (7.7%) of the hydrochloride of **2a**.

Method B: 4.8 g (15 mmol) of **1a** with 6.5 g (53 mmol) of potassium *tert*-butylate gave 2.97 g (56%) of the hydrochloride of **2a**.

Melting point (HCl) 261 °C. UV–vis (HCl, CH_3OH, nm) λ (logε): 210 (4.169). Biology

IC_{50} values are given in Table 1.

© 2006 NRC Canada

Antimalarial activity of compounds 1a–1d and 2a–2d

Antiplasmodial activity was determined using the K1 strain of *P. falciparum* (resistant to chloroquine and pyrimethamine). A modification of the [^{3}H]-hypoxanthine incorporation assay was used (9). Briefly, infected human red blood cells in an RPMI 1640 medium with 5% Albumax were exposed to serial drug dilutions in microtiter plates for 48 h. Viability was assessed by measuring the incorporation of [^{3}H]-hypoxanthine by liquid scintillation counting 24 h after the addition of the radiolabel. The counts were expressed as percentage of the control cultures, sigmoidal inhibition curves were drawn, and IC_{50} values calculated. The standard was artemisinine.

Activity of compounds 1a–1d and 2a–2d against *Trypanosoma b. rhodesiense* and cytotoxicity

Minimum essential medium (50 μL) supplemented according to Baltz et al. (10) with 2-mercaptoethanol and 15% heat-inactivated horse serum was added to each well of a 96-well microtiter plate. Serial drug dilutions were added to the wells. Then, 50 μL of trypanosome suspension (*T.b.rhodesiense* STIB 900) was added to each well and the plate incubated at 37 °C under a 5% CO_2 atmosphere for 72 h. Alamar Blue (10 μL) was then added to each well and incubation continued for a further 2–4 h. The plate was then read with a Millipore Cytofluor 2300 using an excitation wavelength of 530 nm and an emission wavelength of 590 nm (11). Fluorescence development was expressed as percentage of the control and IC_{50} values were determined. Melarsoprol served as the standard. Cytotoxicity was assessed using the same assay and L-6 cells using mefloquine as standard.

A simple and facile solventless procedure for the cyclization of 2′-amino- and 2′-hydroxy-chalcones using silica-supported sodium hydrogen sulphate as heterogenous catalyst

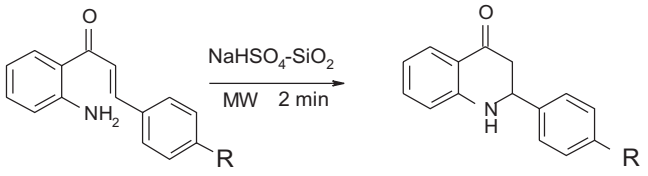
K. Hemanth Kumar and P. T. Perumal

Abstract: A simple environmentally friendly method for the cyclization of 2′-amino- and 2′-hydroxy-chalcones under solventless conditions using silica-supported sodium hydrogen sulphate has been reported.

Key words: 2′-aminochalcones, 2′-hydroxychalcones, silica gel, sodium hydrogen sulphate, quinolones and flavanones.

Résumé : On a mis au point une méthode simple et écologique de cyclisation des 2′-amino- et 2′-hydroxychalcones dans des conditions sans solvant en présence de sulfate acide de sodium déposé sur de la silice qui agit comme catalyseur.

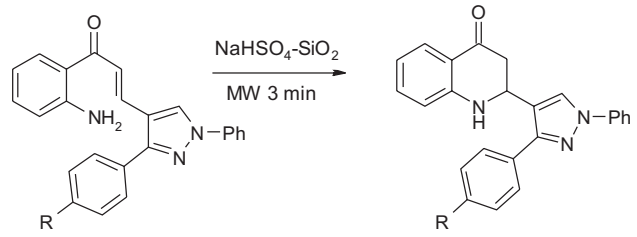
Mots clés : 2′-aminochalcones, 2′-hydroxychalcones, gel de silice, sulfate acide de sodium, quinoléones, flavones.



[Traduit par la Rédaction]

Introduction

Substituted tetrahydroquinolones and flavanones display various pharmacological activities (1, 2) and can be prepared (3, 4) by acid or base catalyzed reactions. Many of these procedures involve the use of corrosive reagents such as orthophosphoric acid, acetic acid, or strong alkali. Furthermore, many of them are of limited synthetic scope because of lower yields, extended reaction time, and the amount of catalyst or solvent used. In recent years, there has been increasing interest in solid-supported reagents coupled with microwave irradiation owing to the benefits of enhanced reaction rates, improved yields, cleaner reaction profiles, greater selectivity, and operational simplicity (5).



In continuation of our studies on the synthesis of heterocyclic compounds with medicinal potential from 2′-aminochalcones (6) and 2′-hydroxychalcones (7), we report an efficient and simple method for the synthesis of tetrahydroquinolones and flavanones through the cyclization of the corresponding chalcones using silica-supported sodium hydrogen sulphate under solventless conditions. The catalyst $NaHSO_4$-SiO_2 can be easily prepared (8), safely handled and removed from the reaction mixture, is inexpensive, and works under heterogeneous conditions.

Scheme 2.

R = Cl, H, OMe, OEt

Results and discussion

2′-Aminochalcone was uniformly mixed with silica gel (finer than 200 mesh), preimpregnated with $NaHSO_4$, transferred into a glass vial, and irradiated by microwaves until (2 min) the reaction was complete (TLC). The reaction mixture was directly charged on a small silica gel column and eluted with a mixture of ethyl acetate – hexane (1:9) to afford the product 2-aryltetrahydro-4-quinolone in excellent yield (Scheme 1). To extend the scope of the reaction, a wide range of substituted and structurally diverse 2′-aminochalcones were subjected to similar conditions (Scheme 2). The reactions proceeded in a similar fashion

and substituted tetrahydro-4-quinolones were obtained in good yields (Table 1). The reaction rates and yields were dramatically enhanced by microwave irradiation.

Flavanones form a large and important group of naturally occurring secondary metabolites and are important intermediates for the synthesis of biologically active flavones and isoflavones (9). The conventional methods for the cyclization of 2′-hydroxychalcones involve prolonged time and the use of corrosive reagents such as sulphuric acid, hydrochloric acid, and strong alkalis (10), furnishing flavanones in not more than 50% yields. Hence, we attempted to synthesize flavanones by using $NaHSO_4$ on silica gel under solvent-free conditions as a mild catalyst for the cyclization of 2′-hydroxychalcones (Scheme 3), which fur-

Scheme 3.

nished the flavanones in good yields (Table 2). Here too, the use of microwave irradiation significantly enhanced the reaction rates as well as the yields.

Conclusion

In conclusion, the present procedure catalyzed by $NaHSO_4$ impregnated with silica gel provides an efficient and rapid synthesis of tetrahydroquinolones and flavanones by the cyclization of the corresponding 2′-aminochalcones and 2′-hydroxychalcones. The notable advantages of this procedure are (*i*) operational simplicity, (*ii*) fast and clean reaction, (*iii*) high yield, and (*iv*) safe and inexpensive catalyst. We believe that this procedure will provide a better scope and a more practical alternative to the existing procedures for the synthesis of tetrahydroquinolones and flavanones.

Experimental

2′-Amino- and 2′-hydroxy-chalcones were prepared using appropriate aldehyde and corresponding *o*-substituted acetophenones by earlier reported procedures (11, 12). 2-Amino- and 2-hydroxy-acetophenones (Sigma-Aldrich) were used as purchased. Sodium hydrogen sulphate and aromatic aldehydes were obtained from E-Merck (India) Ltd. Melting points were determined in capillary tubes and are uncorrected. Analytical TLC was performed on precoated plastic sheets of silica gel G/UV-254 of 0.2 mm thickness (Macherey-Nagel, Germany). FT-IR spectra were taken as KBr pellets on a PerkinElmer Spectrum RXI FT-IR spectrophotometer. ^{1}H NMR (500 MHz) and ^{13}C NMR (125 MHz) spectra were recorded in $CDCl_3$ solution with TMS as an internal standard. Column chromatography was performed on silica gel (60–120 mesh, SRL, India).

Cyclization of 2′-amino- or 2′-hydroxy-chalcones under microwave irradiation — Typical procedure A

The chalcone (1 mmol) was added to 2 g of silica gel (100–200 mesh activated by heating for 8 h at 150 °C before

© 2006 NRC Canada

use) impregnated with sodium hydrogen sulphate (2 g). The whole mixture was stirred for 5 min for uniform mixing and was then transferred to a glass tube and inserted in an alumina bath (100 g, 60 GF254, Fisher Scientific bath 6.8 cm diameter) inside the microwave oven. The compound was irradiated in a domestic microwave oven (BPL, India) at 650 W for the appropriate time. On completion, the reaction mixture was directly charged on a small silica gel column and eluted with a mixture of ethyl acetate – hexane (1:9 for quinolones, 2:8 for flavanones) to afford the corresponding products in high yields. The results are summarized in Tables 1 and 2.

Cyclization of 2′-amino- or 2′-hydroxy-chalcones by conventional means — Typical procedure B

The chalcone (1 mmol) was added to 2 g of silica gel (100–200 mesh activated by heating for 8 h at 150 °C before use) impregnated with sodium hydrogen sulphate (2 g). The whole mixture was stirred for 5 min for uniform mixing and was then transferred to a 100 mL RB flask and kept in a water bath for the appropriate time. On completion, the reaction mixture was directly charged on a small silica gel column and eluted with a mixture of ethyl acetate – hexane (1:9 for quinolones, 2:8 for flavanones) to afford the corresponding products in high yields. The results are summarized in Tables 1 and 2.

Experimental and theoretical study of the electrochemical behavior of N-protonated dopamine at Nafion multiwalled carbon nanotubes (MWNTs) modified glassy carbon (GCE) electrode

Yuanzhi Song and Yang Song

Abstract: The electrochemistry of N-protonated dopamine (DAH^+) was studied by cyclic voltammetry (CV) at a glassy carbon electrode modified by Nafion multiwalled carbon nanotubes (MWNTs) in phosphate buffers (pH 5.50) and the results show that the standard electrode potential of half reaction for $DAH^+_{(O)},H^+/\ DAH^+_{(R)}$ is 0.74 V. Calculations are performed using DFT B3LY/6-31G(d,p) for nine conformers of N-protonated dopamine ($DAH^+_{(R)}$) and three conformers of oxidized N-protonated dopamine ($DAH^+_{(O)}$). The energies of solvation and sum of electronic and thermal free energies of $DAH^+_{(R)}$, $DAH^+_{(O)}$, *p*-benzoquinone (*p*-BQ), and *p*-hydroquinone (*p*-HQ) are calculated at same level. The theoretical weighted average of the standard electrode potential (0.732 V) for $DAH^+_{(O)},H^+/\ DAH^+_{(R)}$, using the transformed Gibbs free energies of the stable $DAH^+_{(R)}$ and $DAH^+_{(O)}$ with a *p*-BQ, H^+/*p*-HQ reference electrode, is consistent with the experimental one of 0.74 V.

Key words: dopamine, DFT, cyclic voltammetry, standard electrode potential.

Résumé : Opérant dans des solutions tamponnées (pH de 5,50) de phosphate, on a étudié l'électrochimie de la dopamine N-protonée (DAH^+) en faisant appel à la voltampérométrie cyclique au niveau d'une électrode de carbone vitreuse modifiée par des nanotubes de carbone à plusieurs épaisseurs de Nafion; les résultats montrent que le potentiel d'électrode standard de la demie réaction pour $DAH^+_{(O)}/DAH^+_{(R)}$ est de 0,74 V. On a effectué des calculs de théorie de la fonctionnelle de densité au niveau B3LY/6-31G(d,p) pour neuf conformères de la dopamine N-protonée ($DAH^+_{(R)}$) et trois conformères de la dopamine N-protonée ($DAH^+_{(O)}$) et on a calculé au même niveau les énergies de solvatation et la somme des énergies libres électroniques et thermiques de dopamine N-protonée $DAH^+_{(R)}$, $DAH^+_{(o)}$, de la *p*-benzoquinone (*p*-BQ) et de la *p*-hydroquinone (*p*-HQ). Il existe une bonne corrélation entre la valeur expérimentale de 0,74 V et le potentiel d'électrode standard moyen théorique (0,7372 V) pour la réaction $DAH^+_{(O)},H^+/DAH^+_{(R)}$ lorsqu'on utilise les énergies libres de Gibbs transformées pour les formes stables du $DAH^+_{(R)}$ et du $DAH^+_{(O)}$ avec un électrode de référence *p*-BQ,H^+/*p*-HQ.

Mots clés : dopamine, théorie de la fonctionnelle de densité, voltampérométrie cyclique, potentiel d'électrode standard.

Introduction

Dopamine (DA) is very important catecholamine neurotransmitter in the mammalian central nervous system and is often electrochemically monitored in vivo with microfibre electrodes. The oxidation of these compounds is interesting and this process occurs in the human body. Catecholamine drugs are also used to treat hypertension, bronchial asthma, organic heart disease, and are used in cardiac surgery and myocardial infarction (1, 2). In addition, the N-protonated form is a preferred candidate for the formation of a drug-receptor complex through a reinforced electrostatic interaction (3).

Conformational studies of dopamine have been performed using experimental NMR techniques (4) and theoretical quantum chemical calculations (5, 6). No information could be obtained from these studies regarding the orientation of the catechol ring because of the rapid rotation of the aminoethyl chain.

An understanding of the electrochemical reactions of dopamine is necessary to develop a method for studying their physiological function and to aid in the diagnosis of some diseases. In clinical medicine, it is often desirable to develop an electroanalytical method to study electron transfer processes. Numerous observations of the electrochemical behaviour of dopamine and its analogs such as epinephrine have been made by many research groups (7–13). Figure 1 illustrates the reaction scheme for the case of DAH^+ at an electrode.

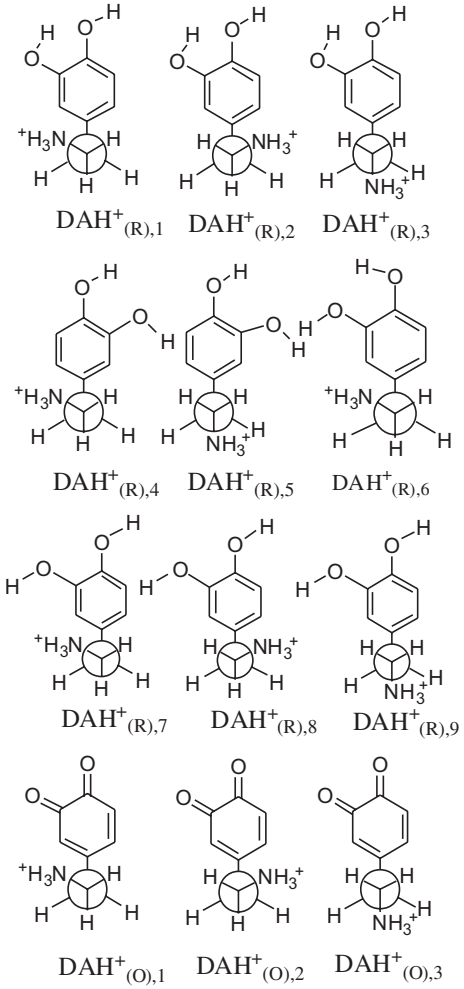
Fig. 1. Reaction scheme for the electrochemical oxidation of $DAH^+_{(R)}$.

Based on the studies mentioned earlier, this article describes the CV of N-protonated dopamine (pH 5.50) at a glassy carbon electrode modified by Nafion multiwalled carbon nanotubes (Nafion-MWNTs) and discusses the electrochemical properties using quantum chemistry.

DFT using hybrid functionals has emerged as very powerful theoretical method to investigate electrochemical properties (14–19). Thus, we selected the B3LYP method, using 6-31G(d,p), to study the geometries of $DAH^+_{(R)}$ and its oxidized forms ($DAH^+_{(O)}$) and to compute the standard electrode potential for $DAH^+_{(O)}$,H^+/$DAH^+_{(R)}$.

Experimental



Chemicals and reagents

The phosphate buffer solution was made from 0.1 mol/L of NaH_2PO_4 and adjusted to the desired pH by adding 1 mol/L NaOH or HNO_3 solution. DA and Nafion solutions were from Sigma-Aldrich. All solutions were prepared with double-distilled water. The MWNTs were from Central Normal University (China). The MWNTs were depurated following the literature method (20). The MWNTs (50 mg) were dispersed in 50 cm^3 of concentrated nitric acid (68%, analytical grade), heated for 24 h, and left to stand for a further 24 h at room temperature. Then, the solution mixture was filtered with a PTFE membrane disc filter (1 μm pore size) under vacuum, followed by several washings with double-distilled water until neutralized. The MWNTs on the membrane disc were dried in an oven at 60 °C for 12 h. The prepared sample is named acid-treated MWNTs. The peaks of 1735 and 1690 cm^{-1} of the sample in the FTIR spectrum revealed that the carboxylic acid groups were present on the surface of acid-treated MWNTs.

Electrode preparation

A cylindrical glassy carbon electrode (GCE), 3 mm in diameter and 50 mm in length, was used for the preparation of the modified electrode as follows. The GCE was prepared by polishing to a mirrorlike appearance, first with fine wet emery papers (grain size 4000) and then with 1.0 mm and 0.3 mm alumina slurry on micro cloth pads (Buehler, Lake Bluff, IIlinois). After the initial polishing, the GCEs were resurfaced using 0.05 mm alumina slurry. The GCEs were sonicated in water twice, then in a 1:1 (*v*/*v*) isopropyl alcohol – acetonitrile (IPA + MeCN) mixture for 10 min each, respectively. The polished and cleaned GCE surface was modified with a 10 uL solution (1mg MWNTs, 5 mL of 1% Nafion in ethanol). To compare with the CV of an electrode modified with MWNTs, a polished and cleaned GCE surface was also modified with a 10 uL solution of the mixture (5 mL of 1% Nafion).

Fig. 2. The initial geometry of $DAH^+_{(R)}$ and $DAH^+_{(O)}$.

Instrumentation

A polarograph (Jiangsu Electrochemistry Analysis Instrument Corp., China) with MEC-12B analytical software was used to test electrochemical behaviour. A conventional three-electrode cell system was used. Silver chloride in 3 mol/L KCl solution, a platinum wire, and the GCE modified with MWNTs were used as the reference, auxiliary, and working electrodes, respectively. All CV experiments were carried out at a temperature of 25 °C.

Calculation methods

According to their molecular structure and symmetry, the initial geometries of nine conformers for $DAH^+_{(R)}$ and three conformers for $DAH^+_{(O)}$, shown in Fig. 2, are optimized. Both $DAH^+_{(R)}$ and $DAH^+_{(O)}$ exhibit conformational equilibrium by the rotation of an amine group about the C–C bond in the side chain. Furthermore, the asymmetrical substitution of the phenol ring provides possible further conformations for $DAH^+_{(R)}$. There is an antipode corresponding to each isomer and the energy of each isomer shown in Fig. 2 will be same for its antipode. Therefore, we need not study the antipode.

All the calculations were performed by using the DFT method B3LYP (21) with the split-polarized 6–31(d,p) using

the Gaussian 03 suite of programs (22). Optimized geometries of $DAH^+_{(O)}$ and $DAH^+_{(R)}$ were calculated with no geometrical restriction. All optimized geometries were further examined through vibrational frequency analysis. The energies of solvation of $DAH^+_{(O)}$ and $DAH^+_{(R)}$ at 298.15 K and 1 atm (1 atm = 101.325 kPa) were calculated by the polarized continuum (overlapping spheres) model (PCM) of Tomasi and co-workers (23–25) for analytic energies at the same levels. *p*-Benzoquinone (*p*-BQ) and *p*-hydroquinone (*p*-HQ), as reference electrodes, are also calculated at same level.

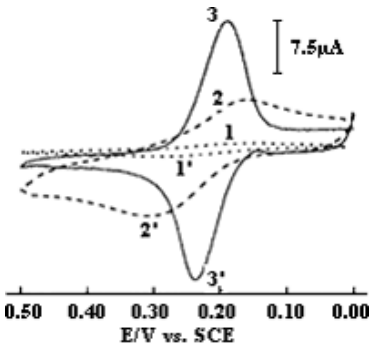
Results and discussion

Electrochemical investigation of dopamine at the modified GCE

The standard electrode potential E^0 of half reaction for reversible redox couple with CV is calculated as (26)

$$[1] \qquad E^0 = (E_{pa} + E_{pc})/2$$

where E_{pa} and E_{pc} represent oxidation potential and reduction potential, respectively.



As shown in Fig. 3, for the phosphate buffer (0.1 mol/L, pH 5.50) no redox peak appears for the bare GCE. When $DA_{(R)}$ (1.0×10^{-4} mol/L) was added to the solution and the first CV scan toward the positive direction was performed, a pair of redox peaks appeared at about 0.200 V (E_{pc}) and 0.245 V (E_{pa}) for the Nafion- MWNTs-GCE, as well as 0.161 V (E_{pc}) and 0.300 V (E_{pa}) for the Nafion-GCE, respectively. In comparison, the peak currents at the modified electrode are much greater than those at the bare GCE. This means that the electrochemical behavior of DA can be improved by this modified electrode. Moreover, this electrochemical response has good stability as the peaks remain unchanged after 10 consecutive CV scans. The conditional potential of $DAH^+_{(O)}$,H^+/ $DAH^+_{(R)}$, estimated from the average values of the anodic and cathodic peak potentials *E* (26), $(E_{pa} + E_{pc})/2$, were 0.222 V and 0.230 V vs. Ag/AgCl, corresponding to the Nafion-MWNTs-GCE electrode and the Nafion-GCE, respectively. DAH^+ is undergoing two-electron oxidation during the two processes occurring at the modified electrode.

The standard electrode potential ($E^0{}_1$) vs. Ag/AgCl is written as

$$[2] \qquad E = E^0{}_1 + 0.059\text{l g}[H^+] \text{ (1 atm, 25 °C)}$$

then

Fig.3. The cyclic voltammogramms dopamine (1.0×10^{-4} mol/L) in phosphate buffer (pH 5.50). 1,1′ at bare GCE; 2,2′ at Nafion modified GCE (Nafion-GCE); 3,3′ at 3 Nafion multiwalled carbon nanotubes modified GCE (Nafion-MWNTs-GCE). Scanning rate = 50 mV/s.

$$[3] \qquad \text{at pH} = 5.50,\ E^0{}_1 = 0.551 \text{ V (1 atm, 25 °C)}$$
for Nafion-MWNTs-GCE

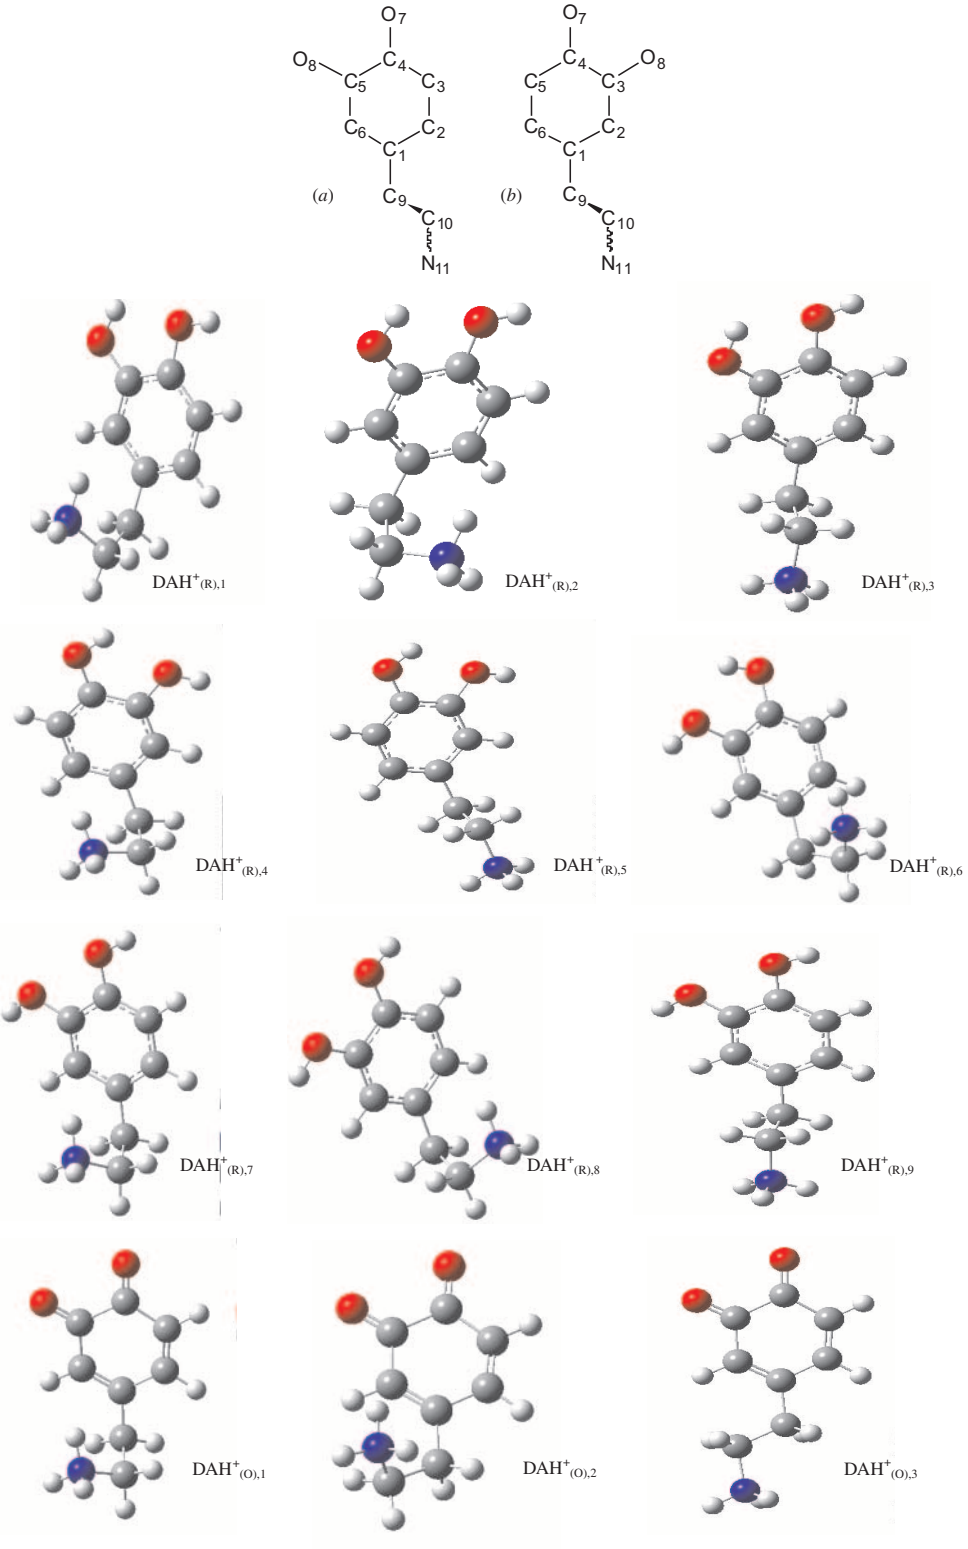
$$[4] \qquad \text{at pH} = 5.50,\ E^0{}_1 = 0.549 \text{ V (1 atm, 25 °C)}$$
for Nafion-GCE

The standard electrode potential $E^0{}_2$ vs. the normal hydrogen electrode (NHE) is given as

$$[5] \qquad E^0{}_2 = E^0{}_1 + E_{Ag/AgCl(3M\ KCl)}$$

$$[6] \qquad E_{Ag/AgCl(3M\ KCl)} = E^0{}_{AgCl/Ag} - 0.059\text{l g}[Cl^-] = 0.222 \text{ V} - 0.059\text{l g}[3] = 0.194 \text{ V (1 atm, 25 °C)}$$

where $E^0{}_{AgCl/Ag}$ represents the standard electrode potential for Ag/AgCl (27). Therefore, $E^0{}_2$ is calculated as



$$[7] \qquad E^0{}_2 = 0.517 \text{ V} + 0.194 \text{ V} = 0.74 \text{ V (1 atm, 25 °C)}$$
for Nafion-MWNTs-GCE

$$[8] \qquad E^0{}_2 = 0.525 \text{ V} + 0.194 \text{ V} = 0.74 \text{ V (1 atm, 25 °C)}$$
for Nafion-GCE

In a comparison with literature results (7–9), Table 1 shows the standard electrode potential as calculated earlier, indicating that the standard electrode potential for the reversible redox couple of DAH^+ at Nafion-GCE and Nafion-MWNTs-GCE with CV is in agreement with that at the different modi-

fied electrodes and that the error in standard electrode potential is due to the irreversible reaction with CV.

Geometry of DAH^+

The geometries were optimized using BLYP/6–31G(d,p) and the numeration of atoms in both $DAH^+_{(R)}$ and $DAH^+_{(O)}$ shown in Fig. 4. The structure (Fig. 4*b*) of the two conformers, $DAH^+_{(R),4}$ and $DAH^+_{(R),5}$, is different from that of the others (Fig. 4*a*). All atoms of the benzene ring with OH atoms in both $DAH^+_{(O)}$ and $DAH^+_{(R)}$ are nearly planar.

The bond lengths and bond angles of both $DAH^+_{(R)}$ and $DAH^+_{(O)}$ optimized with B3LYP/6–31G(d,p) are listed in

Table 2. From Table 2, it can be seen that the bond lengths and bond angles of each isomer in both $DAH^+_{(R)}$ (except $C_4C_5C_8$, $C_3C_4C_7$, and $C_6C_5C_8$) and $DAH^+_{(O)}$ (except $C_2C_1C_9$ and $C_6C_1C_9$) are in a good agreement with that of other isomers. However, the dihedral angles of $C_2C_1C_9C_{10}$, $C_6C_1C_9C_{10}$, and $C_1C_9C_{10}N_{11}$ in both $DAH^+_{(R)}$ and $DAH^+_{(O)}$ conformers change markedly. From Table 2, the bond lengths of C_5C_8, C_4C_7, and C_2C_3 in $DAH^+_{(O)}$ are shorter than those in $DAH^+_{(R)}$ because of two carbonyls, however the bond lengths of C_1C_2, C_3O_4, and C_5O_6 in $DAH^+_{(O)}$ are longer than those in $DAH^+_{(R)}$. So, the bond angles of $C_2C_1C_9$, $C_6C_1O_9$, $C_1C_2C_3$, and $C_4C_5C_6$ as well as the dihedral angles of $C_2C_1C_9C_{10}$, $C_6C_1C_9C_{10}$, and $C_1C_9C_{10}C_{11}$ also change markedly with the changes in bond lengths.

Calculated standard electrode potential

The theoretical calculation of standard electrode potential for N-protonated dopamine versus *p*-BQ,H^+/*p*-HQ can be written as

[9] $DAH^+_{(O),g} + 2e^- + 2H^+_g = DAH^+_{(R),g}$

[10] $p\text{-}BQ_g + 2H^+_g + 2e^-_g = p\text{-}HQ_g$

where $DAH^+_{(O),g}$, $DAH^+_{(R),g}$, $p\text{-}BQ_g$, and $p\text{-}HQ_g$ represent $DAH^+_{(O)}$, $DAH^+_{(R)}$, *p*-BQ, and *p*-HQ in the gas state, respectively.

[11] $DAH^+_{(O),g} + p\text{-}HQ_g = DAH^+_{(R),g} + p\text{-}BQ_g$

The transformed Gibbs free energy of [11] is written as

[12] $$\Delta rG^0{}_1\ (298.15\ \text{K}) = G^0{}_{DAH^+(R),g} + G^0{}_{p\text{-}BQg} - G^0{}_{DAH^+(O),g} - G^0{}_{p\text{-}HQg}$$

where G^0 represents standard Gibbs free energies at 298.15 K and 1 atm, which is calculated using the Gaussian 03 package.

The redox reaction in solution is designed as (Fig. 5) where $\Delta rG^0{}_{aq,DAH^+(O)}$, $\Delta rG^0{}_{aq,DAH^+(R)}$, $\Delta rG^0{}_{aq,p\text{-}HQ}$, and $\Delta rG^0{}_{aq,p\text{-}BQ}$ are energies of solvation of $DAH^+_{(O)}$, $DAH^+_{(R)}$, *p*-HQ, and *p*-BQ in water at 298.15 K and 1 atm, respectively.

[13] $$\text{If } \Delta rG^0{}_2 = \Delta rG^0{}_{aq,DAH^+(R)} + \Delta rG^0{}_{aq,p\text{-}BQ} - \Delta rG^0{}_{aq,DAH^+(O)} - \Delta rG^0{}_{aq,p\text{-}HQ}$$

then the standard transformed Gibbs energy of reaction in solution is written as

[14] $\Delta rG^0\ (298.15\ \text{K, 1 atm}) = \Delta rG^0{}_1 + \Delta rG^0{}_2$

The standard electrode potential (E^0) of half reaction for $DA_{(O)}$,H^+/ $DA_{(R)}$ is calculated as

[15] $$\Delta rG^0\ (298.15\ \text{K, 1 atm}) = -nF\ (E^0 - E^0{}_{p\text{-}BQ,H^+/\,p\text{-}HQ})$$

where F is the Faraday constant (96.485 C/mol), n is number of electrons transferred, $E^0{}_{p\text{-}BQ,H^+/\,p\text{-}HQ}$ (0.699 V (27)) represents the standard electrode potential of half reaction for *p*-BQ,H^+/*p*-HQ.

The electron energies (ε_0), zero point energies (E_{ZPE}), total energies E_t ($\varepsilon_0 + E_{ZPE}$), relative energies (ΔE) in gas state compared with the lowest total energies, Gibbs free energies

[a]Hartree

Fig. 5. Design of redox reaction of $DAH^+_{(R)}$ in solution, where g and aq denote gas and solution, respectively.

in water ($G^0_{aq} = G^0 + \Delta rG^0_{aq}$), relative Gibbs free energies in water ΔG^0_{aq}, G^0, ΔrG^0_{aq}, ΔrG^0_1, ΔrG^0_2, and $E^0_{DAH^+(O),H^+DAH^+(R)}$ are shown in Table 3. From Table 3, the most stable $DAH^+_{(R)}$ and $DAH^+_{(O)}$ in the gas state are $DAH^+_{(R),1}$ and $DAH^+_{(O),1}$, respectively. However, the lowest Gibbs free energies in water (G^0_{aq}) are ascribed to $DAH^+_{(R),9}$ and $DAH^+_{(O),3}$ because of the energies of solvation, respectively. The standard electrode potential calculated by $DAH^+_{(R),9}$ and $DAH^+_{(O),3}$ is 0.735 (V), which is in good agreement with the experimental value of 0.74 (V) at pH 5.50. From Table 3, it is found that the calculated standard electrode with a combination of stable $DAH^+_{(R),5}$, $DAH^+_{(R),9}$, and $DAH^+_{(O),3}$ is very close to our experimental value. However, there are more deviations from the theoretical values with a other combinations.

According to the Boltzmann distribution, the molecular number of excited states, N_i, the molecular number of ground states, N_o, the quantum number of the excited state at same energy level, $g_i = 2$, the quantum number of the ground state at same energy level, $g_o = 2$, Boltzmann constant, k, temperature, T (298.15 K), and the Gibbs free energy difference of the excited state, and the ground state for each molecule, ΔG_{aq}, are related by the equation (28)

$$[16] \quad N_i/N_o = g_i/g_o \exp(-\Delta G_{aq}/kT)$$

The N_i/N_o values of $DAH^+_{(R),1}$, $DAH^+_{(R),2}$, $DAH^+_{(R),3}$, $DAH^+_{(R),4}$, $DAH^+_{(R),5}$, $DAH^+_{(R),6}$, $DAH^+_{(R),7}$, and $DAH^+_{(R),8}$, shown in Table 3, are 5.403×10^{-4}, 2.121×10^{-3}, 0.153, 3.087×10^{-3}, 0.926, 4.677×10^{-3}, 5.429×10^{-3}, and 4.367×10^{-3}, respectively. The N_i/N_o values of $DAH^+_{(O),1}$ and $DAH^+_{(O),2}$ are 3.273×10^{-3} and 1.574×10^{-3}, respectively.

Suppose

$$[17] \quad N_o + \sum N_i = N_o + (5.403 \times 10^{-4}) \times N_o + (2.121 \times 10^{-3}) \times N_o + 0.153N_o + (3.087 \times 10^{-3}) \times N_o + 0.926N_o + (4.677 \times 10^{-3}) \times N_o + (5.429 \times 10^{-3}) \times N_o + (4.367 \times 10^{-3}) \times N_o = 1000$$

then $N_o = 476.4$. The distribution coefficients (a_R) of $DAH^+_{(R),1}$, $DAH^+_{(R),2}$, $DAH^+_{(R),3}$, $DAH^+_{(R),4}$, $DAH^+_{(R),5}$,

$DAH^+_{(R),6}$, $DAH^+_{(R),7}$, $DAH^+_{(R),8}$, and $DAH^+_{(R),9}$, shown in Table 3, are 2.574 0^{-4}, 1.010×10^{-3}, 0.0729, 1.471×10^{-3}, 0.4411, 2.228×10^{-3}, 2.586×10^{-3}, 2.080×10^{-3}, and 0.4764, respectively. The distribution coefficient (*a*) of $DAH^+_{(O),1}$, $DAH^+_{(O),2}$, and $DAH^+_{(O),3}$, calculated similarly, shown in Table 3, are 3.257×10^{-3}, 1.566×10^{-3}, and 0.995, respectively. These results indicate that the redox reaction ascribes mainly to $DAH^+_{(R),5}$, $DAH^+_{(R),9}$, and $DAH^+_{(O),3}$.

We calculated the weighted average of the standard electrode potential E^0 as

[18] $$E^0 = \sum E^0_{i,j} \times a_{Ri} \times a_{Oj} = 0.732 \text{ (V)}$$

This result is in excellent agreement with the experimental value of 0.74 V and thus we believe that our theoretical calculation is reliable.

Conclusion

The geometries of $DAH^+_{(O)}$ and $DAH^+_{(R)}$ are optimized at the B3LYP/6–31G(d,p) level and nine conformers of $DAH^+_{(R)}$ and three conformers of $DAH^+_{(O)}$ are obtained. The predicted weighted average of standard electrode potentials (0.732 V) are in best agreement with experimental data (0.74 V at pH 5.50). This method is very useful in predicting unknown standard potentials of such compounds because the theoretical method is very simple and inexpensive.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

CIC Medal Award Lecture — Molecular keystones: Lessons from bioorganic reaction mechanisms[1]

Ronald Kluger

Abstract: The work of the author is reviewed in terms of "keystone molecules" that serve as figurative points of support to understand the interactions of smaller molecules within biological macromolecules. The review emphasizes lessons learned in carboxylation of biotin, reactions of cyclic phosphates, the uses of acyl phosphate monoesters, and the mechanism of decarboxylation of thiamin-derived intermediates.

Key words: CIC medal, biotin, ATP, mechanisms, cyclic phosphates, thiamin, acyl phosphates, catalysis.

Résumé : Ce rapport résume les travaux de l'auteur en fonction de molécules "clés de voûte" qui servent d'une façon figurative de support pour comprendre les interactions de molécules plus petites dans les macromolécules biologiques. Cette revue met en relief les leçons tirées de la carboxylation de la biotine, des réactions des phosphates cycliques, des utilisations des monoesters des phosphates d'acyle et du mécanisme de décarboxylation des intermédiaires dérivés de la thiamine.

Mots clés : médaille de l'ICC, biotine, ATP, mécanismes, phosphates cycliques, thiamine, phosphates d'acyle, catalyse.

[Traduit par la Rédaction]

Introduction

I was delighted to be designated the 2006 recipient of the CIC Medal; the Institute has been a central part of my scientific life. I gave the medal address as part of the Canadian Chemistry Conference in June 2006. This paper summarizes much of the talk and makes some clarifications while omitting some sections that do not follow an intelligible script. I organized the presentation around specific organic molecules that relate to mechanisms in biological chemistry. My objectives as a scientist result from approaching complex problems with the tools afforded by finding the right molecule to answer a question or target a larger system. I chose the phrase "molecular keystones" to describe species that are the basis of conceptual developments and built the talk around each of these as a section. The term "molecular keystone" has also been used to describe a structural role for a small molecule within a larger species (1).

In general, we chose molecular keystones as the simplest synthetic molecule containing the reacting functionality of a more complex biomolecule. This includes molecules designed to mimic biological interactions on a small scale and those that formed a basis for extended mechanism-based molecular design.

My interest in doing this work was the result of a perspective that goes back to my earliest days as a university student. I began doing organic chemistry research in my second undergraduate year at Columbia University in New York. Gilbert Stork hired me to work in his research group on projects that were odds and ends — preparing materials for others to use in their complex syntheses as well as changing the oil in the vacuum pumps. I was chosen for this from the many students taking introductory organic chemistry midway through the course. My teaching assistant was an undergraduate who had been with Stork and was leaving for graduate studies at mid-year. He designated me as his replacement. Of course, at the time I had no idea who Gilbert Stork was or how fortunate I was. The 3 years I spent in that lab were wonderful; Professor Stork's attitude was inspiring and amusing. I quickly became an expert at changing the pump oil and making the highly mutagenic precursor used at the time for making diazomethane. The department obtained its first routine NMR machine (a Varian-A60), and it was an immediate hit. But the only deuterated solvent that could be purchased was deuterium oxide. So I was given a project: make deuterochloroform so members of the Stork group could use it as a solvent for the new NMR. The synthesis was in a collection, "Organic Syntheses with Isotopes" (2) and seemed straightforward: combine chloral and sodium deuteroxide in deuterium oxide with anhydrous chloral. I could purchase chloral but not sodium deuteroxide. Stork

Received 28 July 2006. Accepted 5 September 2006. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 31 October 2006.

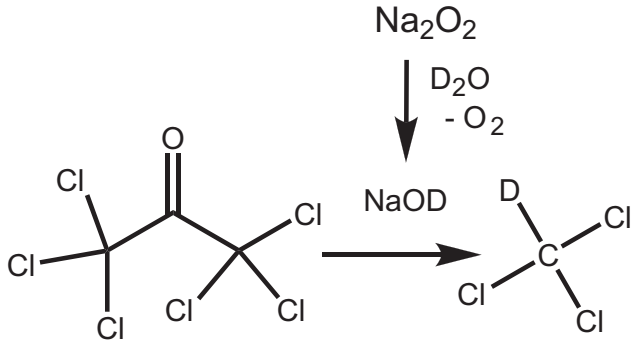
[1]Based on the CIC medal address.

 doi:10.1139/V06-149 © 2006 NRC Canada



and I discussed the obvious and dangerous route involving adding pieces of sodium to deuterium oxide. The by-product is deuterium gas, which reacts just as hydrogen does, potentially combining explosively with oxygen. This process also loses an equivalent of deuterium from the solvent for each equivalent of deuteroxide produced. I recalled a high school chemistry experiment in which oxygen is generated from sodium peroxide and water, with sodium hydroxide as a by-product. I suggested that I try making sodium deuteroxide from sodium peroxide and deuterium oxide, and I was encouraged to try it. It worked well and cleaving chloral worked well. We had a lot of deuterochloroform. However, chloral is very wet and usually a hydrate. So I tried hexaxchloroacetone instead. This chemical is a powerful tear gas but is anhydrous. There was none in the department, so I called City Chemical in lower Manhattan. They had it in stock. I took the subway to their location, bought a gallon bottle of practical grade hexachloroacetone (it was inexpensive) and rode back to Columbia on the subway with my starting material. I was happy to finance my own research. I then made kilos of deuterochloroform. The word quickly spread throughout the department, and we were giving away many bottles of the solvent. The NMR was instantly busy. Professor Stork was very pleased and he encouraged me in my desire to describe the procedure in a journal article — an experience that I found exciting (Scheme 1).

It appeared in the *Journal of Organic Chemistry* during my third year as an undergraduate (3). My skill at making deuterochloroform did not remain in demand for long. Merck, Sharp and Dohme Isotopes (MSD) of Dorval, Quebec, started selling it for a low price soon after. Several years later a friend of mine interviewed there for a job. Recalling my deuterochloroform story, he asked how they made theirs. The answer was that they follow an unpatented procedure that had appeared in the *Journal of Organic Chemistry* a few years before, a fact I confirmed with Irwin Lesk of MSD when I met him after my arrival in Toronto. Just a year ago, I received a note from a professor in Wales who said he thought a student of his had a new and efficient synthesis of deuterochloroform. Then he had been referred to me and to my old article. He said that his method was not as good, and he had tried to learn how Aldrich currently made theirs. They wouldn't tell him. I called the technical department of Cambridge Isotope Labs and asked how they made their deuterochloroform. The answer was satisfying: by cleaving hexachloroacetone with sodium deuteroxide. When I asked how they came to do it that way, the answer was that they had always done it that way.

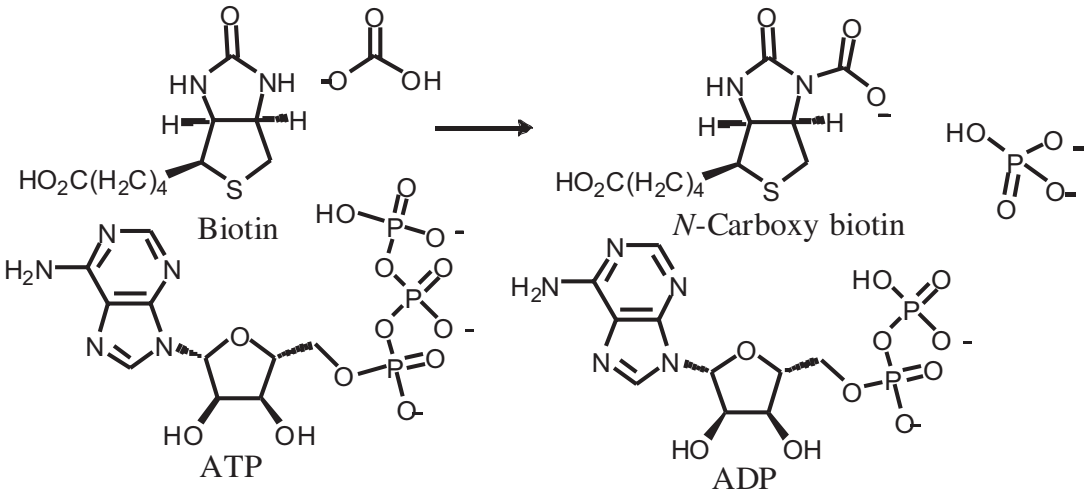
While I was at Columbia I also had the pleasure of taking a course in organic reaction mechanisms with Ronald Breslow and later asked for advice about what to do in organic chemistry. His response was that while it is satisfying to make molecules, it is even more satisfying to use them to test ideas. This was inspiring and has been my guiding principle. Professor Stork told me as I left that since I had learned how to make molecules in the time I was with him, I should do something that would use that as a background and that I should take advantage of opportunities to use mathematical applications to study reactions in more detail.

My graduate education involved studies of cyclic peptides with Elkan Blout and phosphate reaction mechanisms with

Scheme 1.

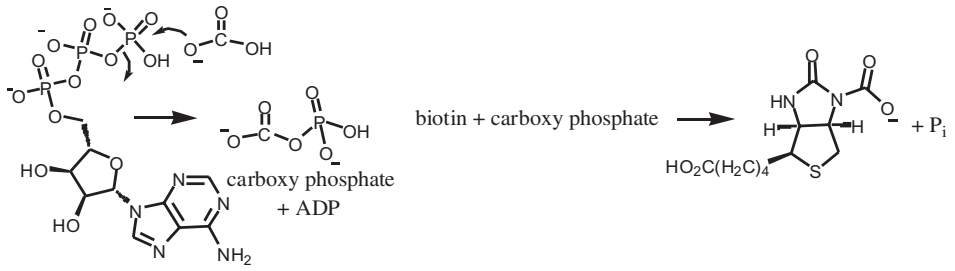
Frank Westheimer. I was a postdoc with Bob Abeles at Brandeis and learned to work on enzyme mechanisms. Regrettably, I was off to my first job at the University of Chicago only a short time after I started with Bob Abeles. This was because I had an interview at Chicago while I was still a student for a job I hadn't applied for. After a short time in Chicago, I moved to Toronto where I have had a most exciting and pleasant time with excellent students and colleagues. Some of the molecular keystones from my career in Toronto will be the focal points of the remainder of this review.

N-Carboxybiotin



Biological processes involving synthesis are often associated with the hydrolysis of the terminal phosphate of ATP to give ADP and inorganic phosphate. The hydrolysis reaction is exergonic. Somehow, the energetically favored hydrolysis through the intervention of enzymes becomes the driving force for an apparently unrelated chemical synthetic process. Lipmann set these out in terms of the artifice of "high energy phosphate bonds" (4). One notable case is the formation of dicarboxylic acids from monocarboxylic acids and bicarbonate. Enzymes that catalyze the reaction do this in solution and accomplish this at the expense of ATP hydrolysis, using biotin as a cofactor. Lynen showed that the involvement of ATP hydrolysis is in an initial stage when bicarbonate and biotin react to form *N*-carboxybiotin. Oxygen from bicarbonate is transferred to the phosphate that is cleaved from ATP (5). Thus, the formation of *N*,1′-carboxybiotin creates a single chemical bond while dehydrating bicarbonate along with ATP hydrolysis (6).

The role of ATP in the process is direct; if bicarbonate is uniformly labeled with ^{18}O, a labeled oxygen atom appears in the phosphate that results from the reaction that produces *N*-carboxybiotin (5). Kinetic and isotope-exchange studies indicated that the reaction requires all components and that there are no partial exchange reactions. The overall process is summarized in Scheme 2.



There are three reactants and three products, and no intermediate has been isolated. The lack of exchange is consistent with a fully concerted reaction of all three, but there is nothing chemically reasonable about any transition state that would be implied. The alternative is to break the process into more steps and to propose intermediates that have not been detected. The first two-step mechanism that was proposed involves the initial reaction of ATP and bicarbonate to give the mixed anhydride of carbonic and phosphoric acids,

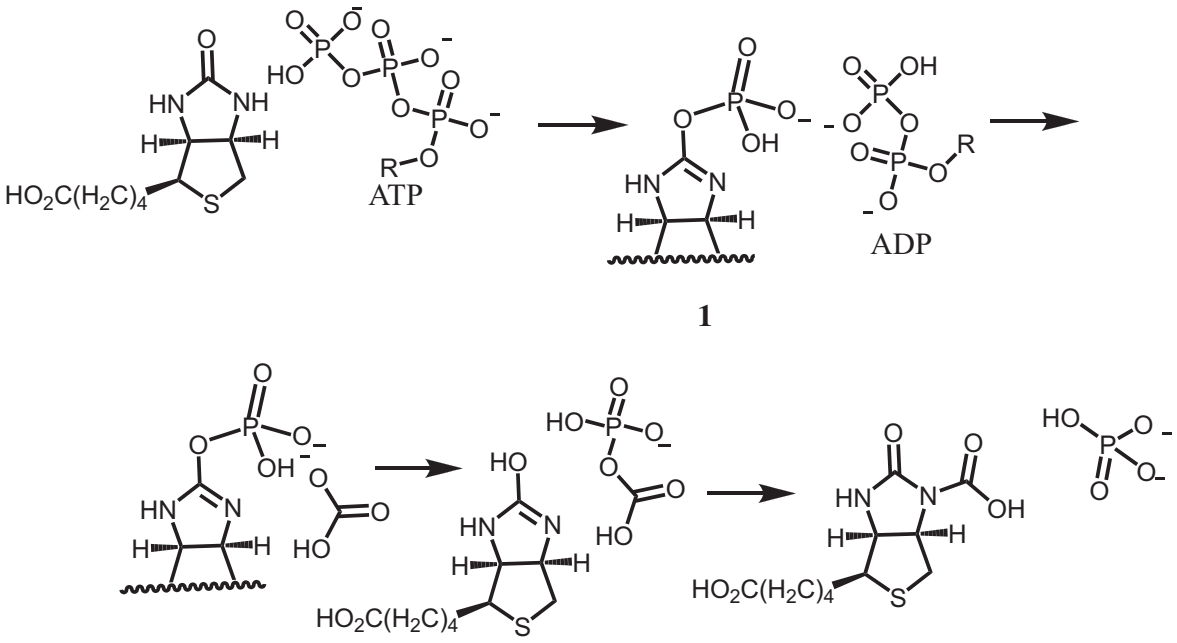
Scheme 2.

Scheme 3.

carboxy phosphate and ADP (7). This reacts with the nitrogen of the conjugate base of biotin to give *N*-carboxybiotin (Scheme 3).

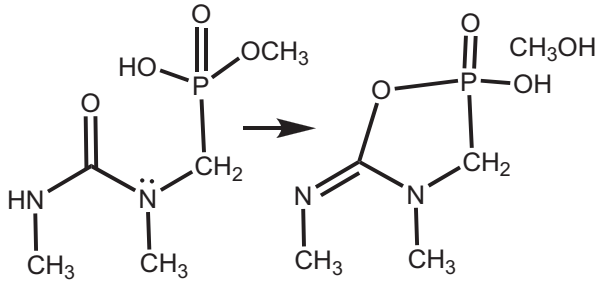
In this mechanism, carboxy phosphate is formed in the first step and transfers its carboxyl group to biotin in the second step. This mechanism is found in textbooks and accommodates much of the data. It is consistent with later studies on the stereochemical course at the terminal phosphate of ATP (8). Yet, the intermediate has never been observed and the there are aspects that are questionable in terms of chemical reactivity. In a study of half esters of carbonic acid, it was reported that carboxy phosphate is too unstable to produce synthetically, with an expected half-life in the millisecond time scale (9). Jencks proposed that upon formation, carboxy phosphate would convert to unsolvated carbon dioxide, which would react rapidly with the conjugate base of biotin. However, others suggested that the conjugate base of biotin would react with carboxy phosphate, since carbon dioxide does not react with biotin (10). Another problem in that case is that carboxy phosphate is a poorer electrophile than bicarbonate. Despite the shortcomings, it is normally the only mechanism presented when this system is reviewed. The fact that a mechanism is widely cited does not mean that it is correct. In Popper's view, hypotheses can only be tested by negation or risky prediction: consider all the possibilities and do experiments that challenge them. So, with biotin carboxylation, we should seek all possibilities and then challenge them with experiments.

An alternative two-step mechanism is the addition of biotin to ATP to form *O*-phosphobiotin (Scheme 4, structure **1**) (11). If the urea oxygen of biotin reacts with ATP, the intermediate is a functional analogue of the addition product from DCC and a phosphate. This could react with bicarbonate to generate carboxy phosphate adjacent to the reacting nitrogen. The steps are consistent with all the experimental information. To get an adjacent attack, the addition product would undergo pseudorotation at the phosphorus, leading to a mechanism with the same overall stereochemistry as reported.



This raises the question of whether the urea is sufficiently nucleophilic to attack the phosphorus and displace the leaving group. By joining the two species to minimize the entropy barrier, Paul Davis and Prakash Adawadkar showed that such a reaction is very likely to occur rapidly. Hydrolysis of the phosphonate ester with an adjacent urea is very rapid, indicative of the formation of a cyclized covalent intermediate (Scheme 5) (12).

We have so far presented two mechanisms involving an initial reaction of two of the three reactant species. There is one remaining combination involving two initial reactants: bicarbonate reacts with biotin and the addition product reacts with ATP. A reaction through this combination is shown in Scheme 6.



The addition of the conjugate base of biotin to bicarbonate should occur more readily than the addition to carboxy phosphate. Such a reaction had been established in an excellent model by Kirby and co-workers (13). In the next step, the remaining reactant, ATP, is the subject of nucleophilic substitution to produce a second addition intermediate and ADP. Loss of phosphate generates *N*-carboxybiotin. In this

© 2006 NRC Canada

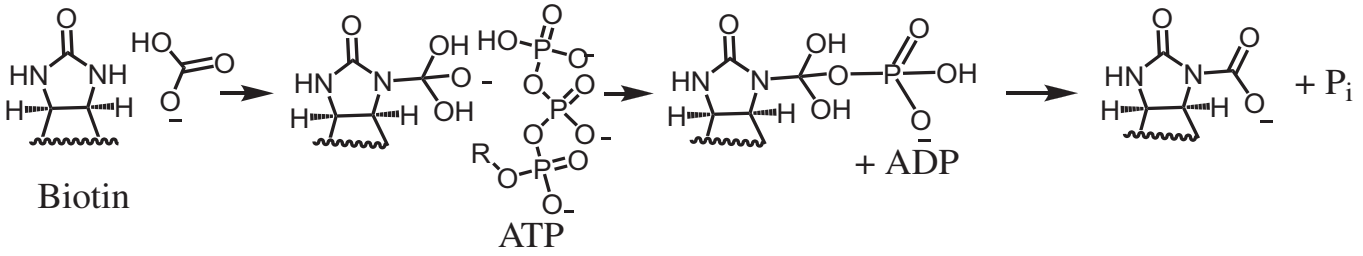
Scheme 4.

Scheme 5.

mechanism, ATP is cleaved only when the addition to bicarbonate has occurred. The initial oxyanion addition product is a stronger base than bicarbonate. Will such a reaction occur at phosphorus (14)? Scott Taylor produced a phosphate ester derived from acetoin that reacts rapidly via just such a pathway (Scheme 7) (15).

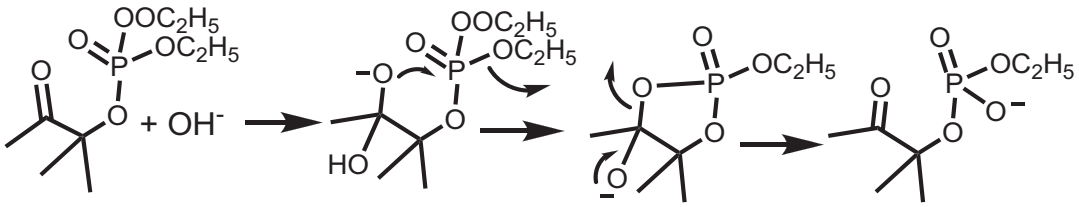
This established that if biotin were to add to bicarbonate, the resulting product would be reactive toward ATP. The addition product is the same as would be formed in the reaction of biotin with carboxy phosphate, but it avoids the generation of such an unstable species that could simply consume ATP and give off CO_2. The matter of which mechanism is correct for an enzyme has yet to be established, although many authors believe it has. It is good to note that in Silverman's text (16), all the possibilities remain as possibilities.

Methyl ethylene phosphate



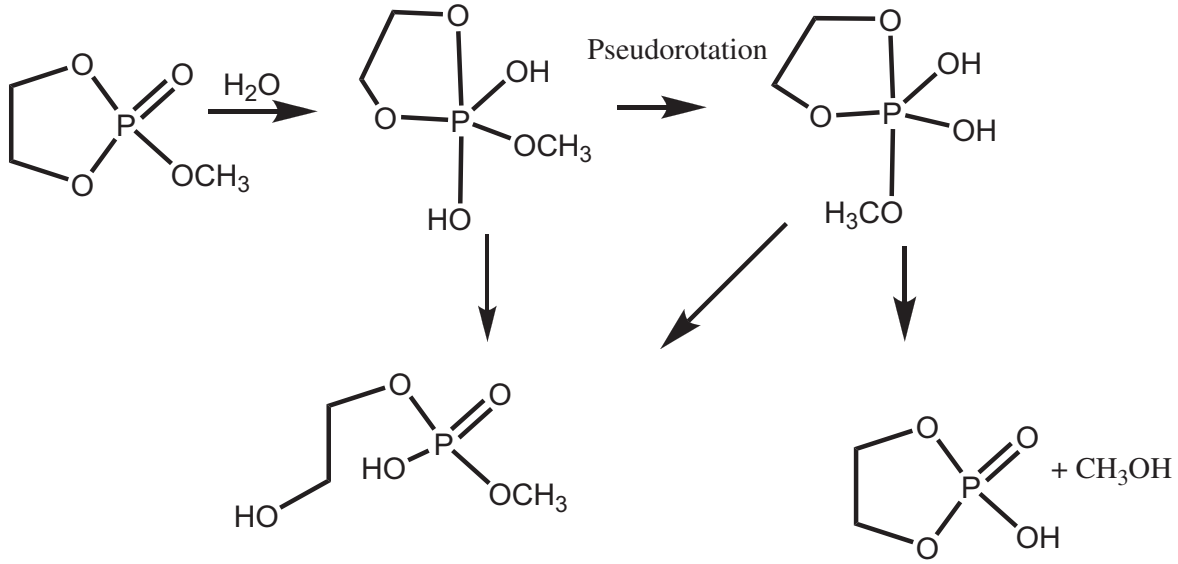
The hydrolysis of the ester linkages in RNA is catalyzed by ribonuclease enzymes from many sources. The immediate product of chain cleavage is the formation of a 2′,3′-cyclic derivative of the 5′-nucleotide from which the remaining chain continues. The cyclic ester is much more reactive than the open-chain material. The cyclic material undergoes relatively rapid spontaneous hydrolysis. Why is the cyclic species so much more reactive? Westheimer determined that the heat of hydrolysis of the cyclic ester, methyl ethylene phosphate (MEP), exceeds that of the comparable acyclic ester by about 5 kcal/mol (17, 18). The 5-coordinate phosphorus intermediate formed upon the addition of water to MEP is a high energy species and should closely resemble the transition states that lead to its formation and decomposition. Molecular mechanics computations suggested that the ring strain is negligible in the intermediate because of the change in hybridization of the bonding orbitals in the higher coordination state (19, 20). The kinetic acceleration of the reaction is about 10^6 in the observed first-order rate constant. The reduced strain in the transition state corresponds to about half the acceleration, although there are undocumented reports of strain up to 9 kcal/mol in MEP (21). This raises the question: if the strain accounts for only half the acceleration, what is the source of the rest (19)?

In Scheme 8, hydrolysis of MEP is shown to lead to two distinct sets of co-existing products. One product is ethylene phosphate in which the original ring is retained. Thus, it is clear that the acceleration can occur due to ring strain without the need for the ring to be cleaved. The formation of EP requires the pseudorotation of the intermediate because the attack and departure require the leaving–attacking groups to be in apical positions while the small ring must span an apical and an equatorial position (22). The yield of EP and methanol as a fraction of total products is expressed as the percent exocyclic cleavage. Analysis of the relationship of pH of hydrolysis to products showed that pseudorotation competes with other processes and can be rate-limiting for exocyclic cleavage (23). In alkaline solutions (Scheme 9), the electronegativity of the ionized hydroxyl in the intermediate supports direct expulsion of the ring as a leaving group and there is no exocyclic cleavage.



Exocylic cleavage occurs in neutral and in dilute acid solutions but not in dilute base solutions. In more concentrated

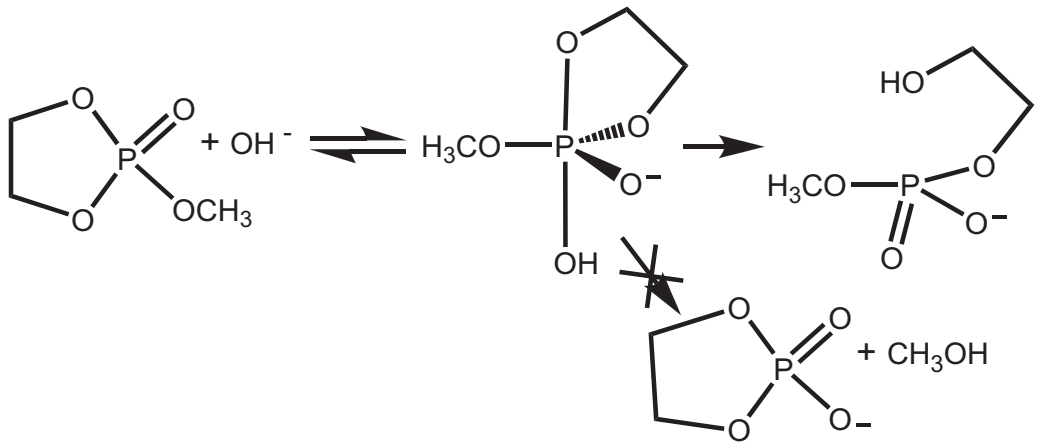
© 2006 NRC Canada



Scheme 6.

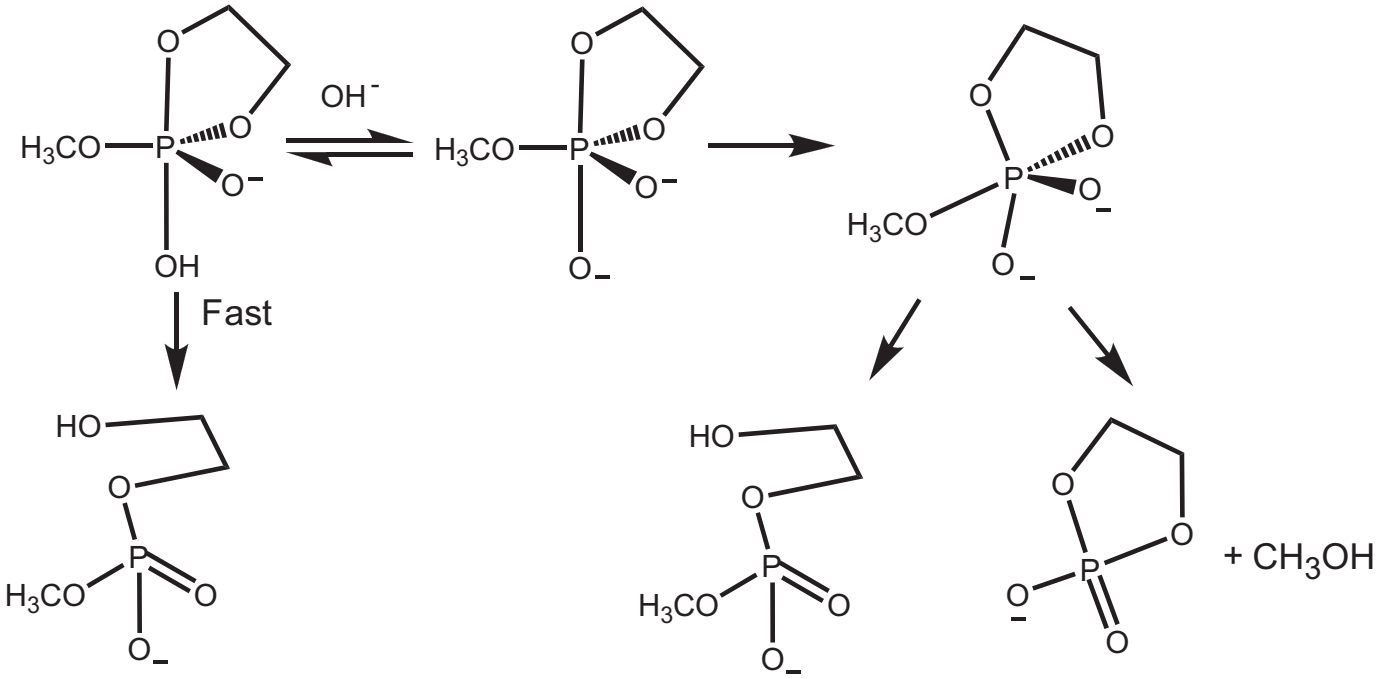
Scheme 7.

Scheme 8.



solutions of hydroxide, exocyclic cleavage increases in proportion to the concentration of added base. Because the overall reaction is first-order in hydroxide, the additional cleavage is second-order in base. This can be explained by the formation of the dianion, which forces a pseudorotation to accommodate its anionic oxygens in equatorial positions (Scheme 10).

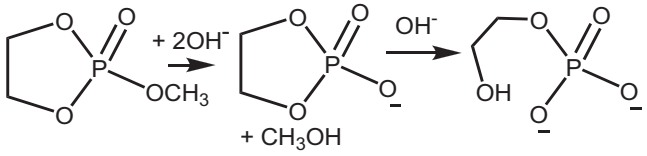
Gorenstein developed a theory (24) that extended Lehn's application (25) of the Deslongchamps anti-periplanar lone pair hypothesis (ALPH) (26) to account for the increased reactivity of cyclic phosphates; leaving groups anti-periplanar to the greatest number of nonbonding lone pairs of electrons on oxygen will react fastest because of the nature of specific orbital interactions (27). However, the results that led to the mechanism in Scheme 10 appear to contradict that suggestion. The dianionic five-coordinate phosphorus intermediate that has undergone pseudorotation contains more lone electron pairs anti-periplanar to the ring O–P bond, yet the product distribution includes an increasing amount of exocyclic cleavage, which would violate the firm prediction from the Gorenstein version of ALPH.



Our observations and explanation preceded the theoretical work by almost a decade. The results were based on careful analysis of methanol produced under both concentrated and dilute reaction conditions (to avoid possible polymerization of the product (28)) and with extrapolation to the time of mixing of the reactants. Thus, it seemed that the theory was not correct on this fundamental point. I noted this in correspondence with David Gorenstein whose paper reported that there is no exocylic cleavage in the hydrolysis of ethyl ethylene phosphate in strongly basic solutions confirming the predictions of ALPH but contradicting our own work (29). To my dismay, in 1983, Frank Westheimer contacted me and said that he had received a preprint of a paper from Gorenstein and Taira reporting results of using a rapid-quench method and ^{31}P NMR to re-examine the products of

© 2006 NRC Canada

Scheme 9.



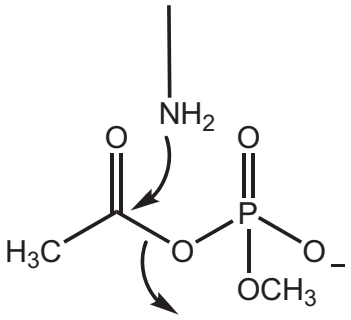
Scheme 10.

the reaction of MEP in a strongly basic solution (30). They concluded that our report in 1969 (31) was incorrect; that there is no exocyclic cleavage and, therefore, their ALPH theory is correct. He told me that it was my responsibility to reinvestigate that work and find out where I went wrong or he would do it. The Taira–Gorenstein publication appeared with these results: "We also now find no exocyclic cleavage (0 ± 3%) for methyl ethylene phosphate between pH 8 and 15. Even in 5 mol/L NaOH, a rapid freeze/acid quench (after less than 2 s of reaction) led to 100% endocyclic cleavage". The product analysis is based exclusively on ^{31}P NMR spectra, and the conclusion is based on the apparent absence of a signal for 2-hydroxyethyl phosphate, the product that would result from the further hydrolysis of the immediate product of exocyclic cleavage, ethylene phosphate (Scheme 11).

There is no mention of the signal of ethylene phosphate, which should be the product of interest from this method if a quench is used to stop any further reaction. Why would they not mention it? The rapid freeze – acid quench method is not

Scheme 11.

described in this paper but is presented in an earlier paper and applied to a similar compound, ethyl ethylene phosphate: "A 50 μL sample of 0.155 mol/L ethyl ethylene phosphate in dry dioxane was added to 0.49 mL of 5.0 mol/L NaOH at room temperature, and the solution was quickly frozen in an acetone/dry ice bath. To the almost frozen solution, was carefully added 66.6 μL of 36 N H_2SO_4. The pH of the solution was adjusted to about 9 with a Tris buffer solution. Up to this point everything was carried out within a minute. Some inorganic precipitate was filtered through a ni-



© 2006 NRC Canada

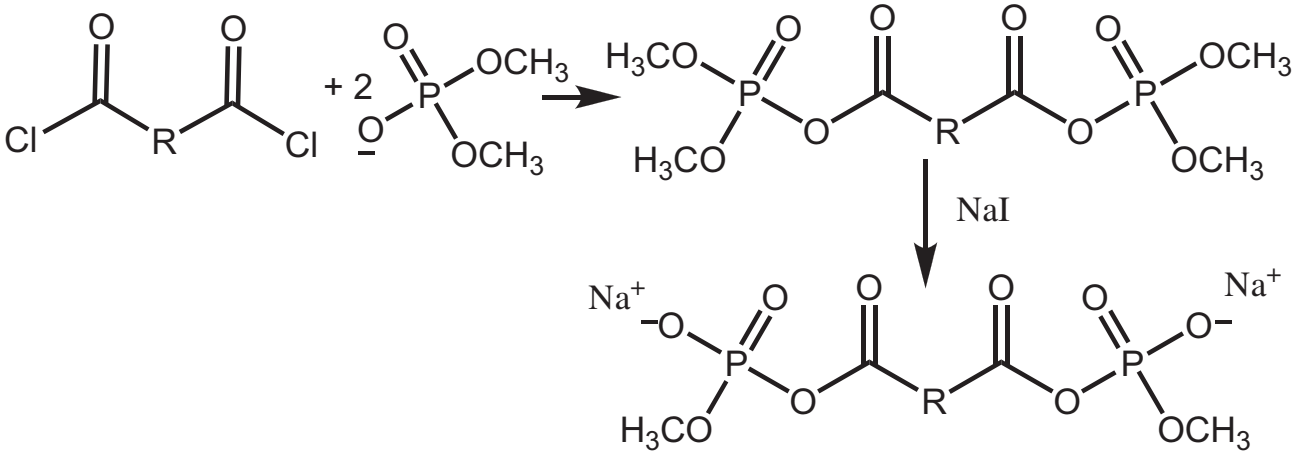
tric acid and EDTA solution treated disposable pipet plugged with EDTA-treated cotton and Chelex-100 (Bio-Rad) ion exchange resin". Gorenstein's graduate student, Kazunari Taira, also reported these results in his Ph.D. thesis. He wrote "I remember the day I asked Dr. Gorenstein frankly, 'Do you mind if I try to disprove your stereoelectronic theory by examining Westheimer's system in more detail?' He answered 'No, of course not. I just want to know the truth. Go ahead!!' I am glad that I have gotten the results which are consistent with the stereoelectronic theory, which constitutes my thesis" (32).

I asked Greg Thatcher, who was a graduate student in my lab in Toronto at the time, to duplicate the Gorenstein–Taira experiments and to analyze the products more completely. Greg synthesized MEP and attempted the quench reaction. It did not work at all as had been reported. Concentrated sulfuric acid flows very slowly from a pipet and reacts violently with concentrated sodium hydroxide, giving a massive solid of sodium sulfate with no liquid remaining (sodium sulfate forms hydrates). We changed the quench to use concentrated hydrochloric acid and worked as fast as possible. The results were the same as without a quench. Methanol is clearly present and can be seen and quantified in the ^{1}H NMR. Ethylene phosphate is easily seen in the ^{31}P NMR and in the amounts one would expect from the methanol produced (33). After running many controls (multiple synthetic routes, concentration dependence of every species), we concluded that whatever results were reported by Gorenstein and Taira were suspect and our original observation was correct; there is substantial exocyclic cleavage from MEP in a strong base, and this means that ALPH fails this test. Therefore, the question remains as to whether strain alone accounts for the increased rate of hydrolysis of cyclic phosphates.

While our results showed that it is not ALPH that accelerates the reaction, the actual difference in heats of reaction of comparable cyclic and acyclic phosphates remained uncertain. If the value is what was originally reported, 5 to 6 kcal mol, there is a significant additional factor beyond strain. If the value is a larger, then there isn't. Scott Taylor joined my group and took on this problem. He measured rates of reaction at various temperatures to obtain activation parameters for the hydrolysis of cyclic and acyclic esters. He used adiabatic precision calorimetry, taking advantage of newly developed computer interfacing to control the experiment and deal with the data. He first measured and compared the activation parameters for hydrolysis of MEP and related acyclic esters (34). The acceleration in MEP relative to the acyclic ester is entirely due to a lower enthalpy of activation; entropies of activation were identical. Therefore, there is no advantage in the cyclic compound from its restricted conformational space. Scott's precise calorimetry also confirmed that the originally reported value of strain energy of about 5 kcal/mol for MEP is correct (34). So, strain accounts only for about half of the enhanced reactivity of cyclic phosphates. Analyzing the reaction in terms of these results leads to the necessary conclusion that the transition state of the cyclic reaction is lower in energy than the transition state of the acyclic reaction. The explanation based on strain assumed that the cyclic ground state is higher in energy than in the acyclic case, but the transition states were of the same energy. This alteration makes sense on steric grounds; addition to a four-coordinate center is sterically demanding, and the five-coordinate intermediate (and thus transition state) is very crowded. By joining two of the coordinated groups into a ring, the crowding is dramatically relieved and the strain is increased. The combination quantitatively accounts for the nonenzymic reactivity of the cyclic phosphate intermediate in RNA hydrolysis.

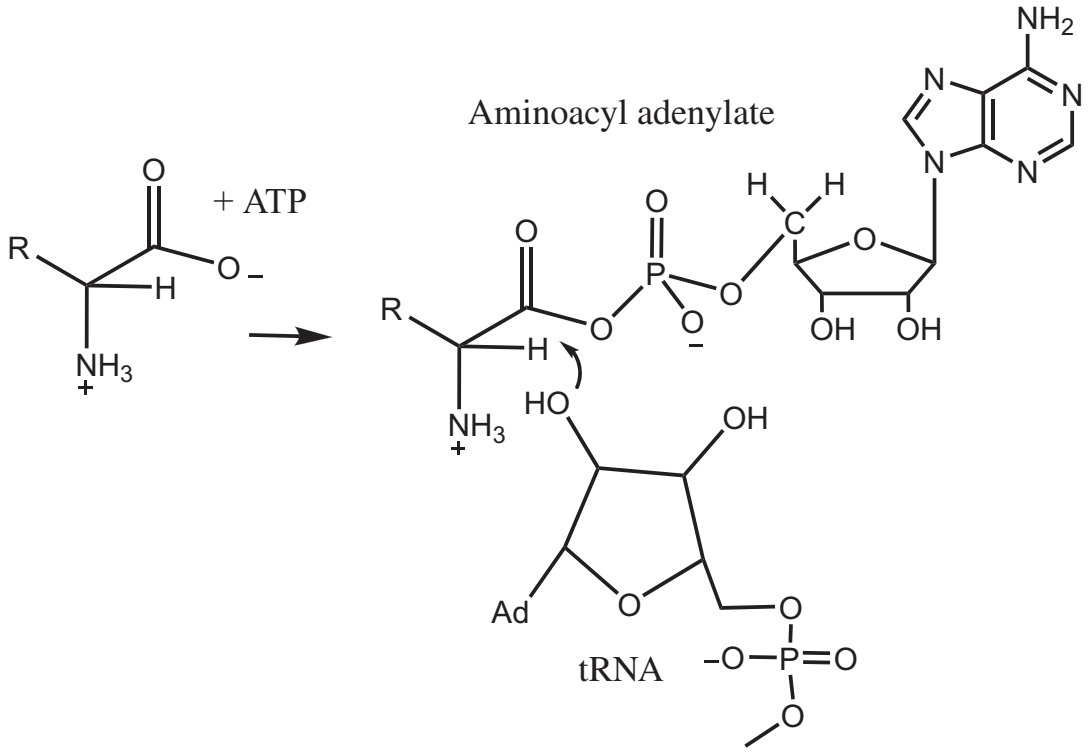
Scheme 12.

Methyl acetyl phosphate and acyl phosphate monoesters



Carboxylic acids are not reactive in substitution reactions in neutral solution. Nature often activates carboxylic acids for substitution in enzymic reactions with ATP to give mixed anhydrides of AMP and the carboxylic acid. These intermediates are acyl adenylates. When we began our work in the area, there was no reliable route to acyl phosphate monoesters. Wing-Cheong Tsui developed the first reliable route to the simplest member of this class of materials, methyl acetyl phosphate (MAP) (Scheme 12) (35).

MAP was designed to react with amino groups in enzyme active sites that bind anionic groups and adjacent carbonyl groups (36). The reactivity of MAP is ideal for that purpose. Its half life for hydrolysis in neutral water is over 100 h at room temperature, but it reacts very rapidly with amines to form an amide. It is interesting that MAP is a reactive anionic electrophile; the functional group is divided into an electrophilic part and an anionic part. The electrophilic part makes it an acylating agent, while the anionic part produces the overall charge. We used that observation to give the original report a catchy title "Methyl Acetyl Phosphate. A Small Anionic Acetylating Agent" (35). Soon after the publication appeared, I was contacted by Professor James Manning, he had been working on the reactions of anionic acylating agents with hemoglobin. The protein contains a polycationic site that associates with 2,3-diphosphoglycerate (DPG), which is a penta-anion. Association of DPG with hemoglobin red blood cells causes a lowering in the oxygen affinity of hemoglobin, permitting the red blood cells to deliver oxygen efficiently. Manning and Ueno used our MAP and showed that it acetylated groups in the DPG-binding site of hemoglobin (37).



The idea that acyl phosphate monoesters will modify hemoglobin in the DPG-binding site became well established, and the potential for treatment of sickle cell disease was also noted. Soon after that, it occurred to me that a bifunctional version of MAP might serve to introduce a specific chemical cross-link into hemoglobin, which would then serve as a cir-

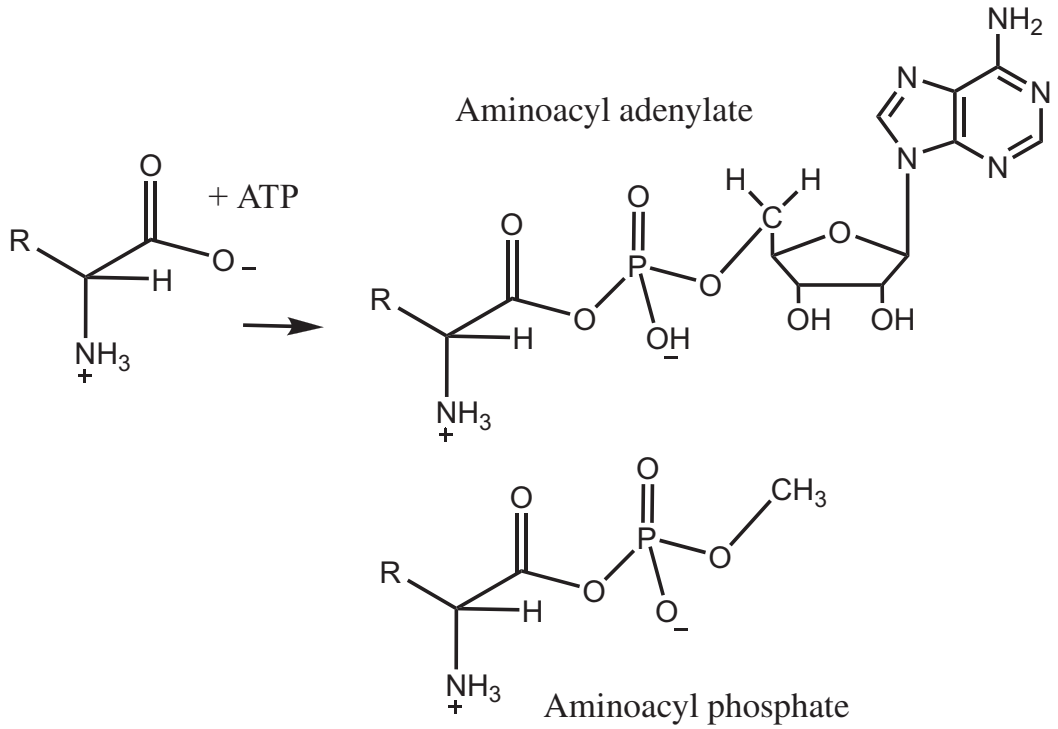
© 2006 NRC Canada

Scheme 13.

Scheme 14.

culating oxygen carrier, a potential replacement for red blood cells in transfusions. The general strategy for synthesis of these species was developed by Stephen Bearne, Andrew Grant, and Marcel Trachsel (Scheme 13) (38). This was carried further by Jolanta Wodzinska (39) and others and has reached its current state from the work of Nik Goruianov (40, 41) and Amer Alagic (42).

This method permits the efficient synthesis of simple and complex materials, including derivatives of triacids and tetra-acids. Many of these compounds react efficiently with hemoglobin, producing stable and specifically cross-linked species whose properties are easily investigated. A key discovery came from measuring the oxygen-binding and dissociation curves for a number of cross-linked hemoglobins with varying cross-links lengths. We have provided several summary reviews (42, 43). Our work has now been extended to create arrays of cross-linked hemoglobins, with linkages between cross-linked tetramers as well as conjugates of hemoglobin and other molecules.



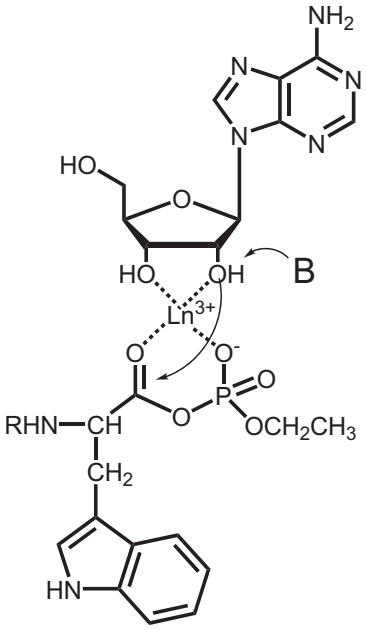
Aminoacyl phosphate monoesters

Amino acids are activated for ester formation in biochemical reactions within the cell by an initial reaction with the α-phosphoryl (Scheme 14) with catalysis and specificity provided by aminoacyl tRNA synthetases. In a second step on the same enzyme, the amino acid is transferred to the 3′-terminal hydroxyl group of the cognate tRNA

The intermediate is an aminoacyl adenylate (44), which is an aminoacyl phosphate monoester, a more complex version of the general class of acyl phosphate monoesters described earlier. The possibility of using a synthetically produced

© 2006 NRC Canada

Scheme 15.



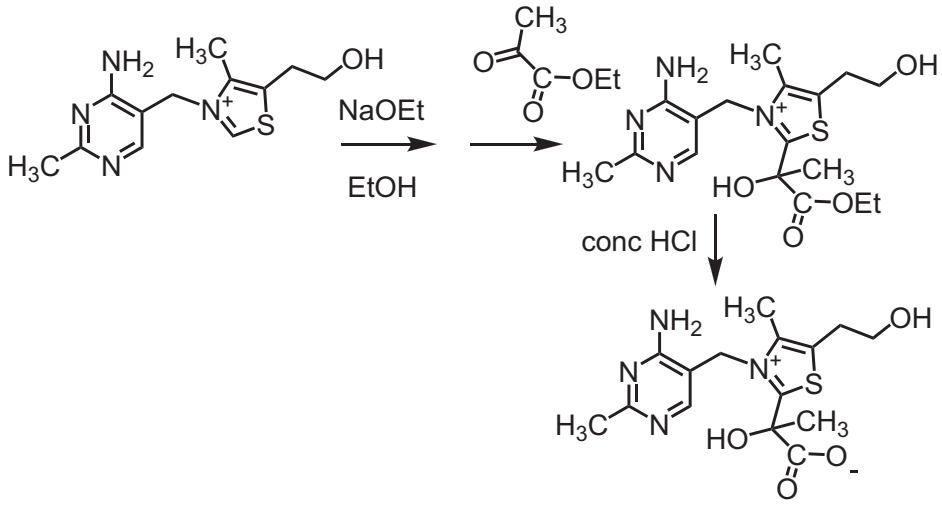
aminoacyl tRNA to alter the composition of a protein produced by a ribosome was proposed by Hecht (45) and actively pursued by him as well as by Schultz (45). Their methods involved rather complex syntheses, cleaving and reconnecting the tRNA. Because enzymes promote the synthesis by a route that simply brings the reactants together, we sought a way to take advantage of the aminoacyl phosphate ester to achieve similar results (Scheme 15).

The inherent reactivity of amines and acyl phosphate monoesters with one another led to the use of an amino-protecting group to prevent such reactions. The first examples were prepared by Neil Branda as an undergraduate project.

The normal nonenzymic reaction patterns of acyl phosphates are not suitable for the purpose of selective acylation of tRNA. These molecules react rapidly with amines and very slowly with oxygen-centered nucleophiles, as evidenced by their very slow spontaneous hydrolysis. We suspected that metal ions could serve as Lewis acid catalysts to enhance the reactivity of the carbon of the carboxyl center by coordination to the carbonyl oxygen and to the phosphate. However, this would also enhance the hydrolysis if successful. We found that a series of divalent metal ions did promote the hydrolysis, but there was no indication of enhanced reactivity with respect to alcohols (46). The structure of tRNA presents some built-in distinctions among the many hydroxyl groups within the chain compared with those of the ribosyl group at the 3′-terminus. Those within the chain are next to anionic phosphates, which would repel the anionic acyl phosphate. The terminal hydroxyls are the only diol in the macromolecule. Derived from ribose, the 2′ and 3′ groups are *cis*, and set up to form a chelate. By using a metal ion that can form a bis-bidentate chelate of the nucleotide diol and the aminoacyl phosphate, we might induce the desired reaction by proximity (Scheme 16).

Lisa Cameron discovered that lanthanide ions can very

Scheme 16.



likely be used to achieve the desired specific result. They promote the base-catalyzed addition of methanol or water to acyl phosphates. Diols are acylated much more rapidly and at lower concentrations (47, 48). The work has recently been extended to the reactions of nucleotides and dinucleotides by Amber Asad and to tRNA with aminoacyl phosphates by Svetlana Tzvetkova.

α-Lactylthiamin

One of the major focuses of my research from the begin-

© 2006 NRC Canada

Scheme 17.

ning of my independent career has been the reactivity of the thiamin diphosphate (TDP) addition products in enzymes and how this reactivity compares to nonenzymic reactivity. Breslow had solved the basic puzzle of thiamin catalysis in 1957 by establishing that the C2 position of a thiazolium is a relatively acidic carbon acid (49). Nucleophilic addition of the carbanion from C2 of TDP to the keto group of 2-keto acids gives an intermediate that is set up for decarboxylation. The existence of such specific and reactive coenzyme-derived intermediates presented a unique opportunity to calibrate the effects of a protein on the reactivity of an intermediate. My presentation touched very briefly on this area because it had been the focus of another talk in the Enzyme Mechanisms symposium. The treatment here is especially brief to reflect that.

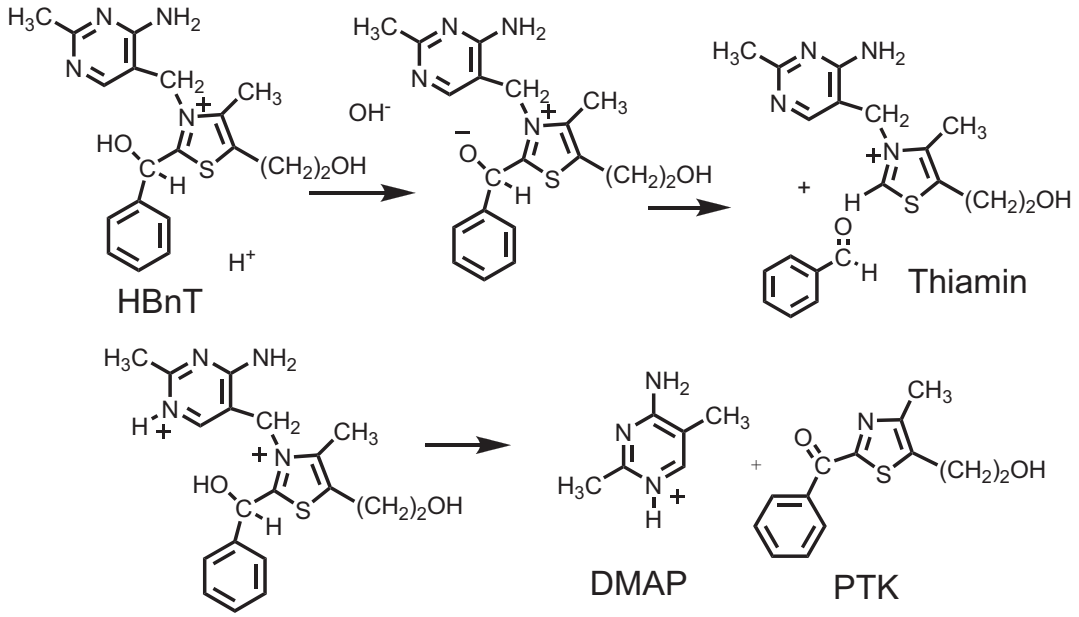
α-Lactylthiamin is a somewhat simplified analogue of the intermediate formed from TDP and pyruvate, α-lactylthiamin diphosphate, in enzymes that catalyze the decarboxylation of 2-ketoacids. Tim Smyth developed the first synthesis of α-lactylthiamin as well as α-lactylthiamin diphosphate (Scheme 17) (50). Jik Chin measured the nonenzymic reactivity while Smyth studied the interactions with the enzyme (51). We found that the enzyme activates the decarboxylation process by a factor of about 10^6 compared with the reaction of the intermediate itself. Furthermore, the enzyme binds the intermediate tightly, so addition of the synthetic intermediate is blocked. David Pike made the phosphonate analogues of pyruvate and found that they would be excellent inhibitors if they joined with TDP to form an impotent intermediate: one that is not able to do anything but reverse its addition (52).

2-1-(Hydroxybenzyl)thiamin

Washabaugh reported that the conversion of 2-1-(hydroxybenzyl)thiamin (HBnT) to benzaldehyde and thiamin is general-base catalyzed (53). I examined the molecule and its possible reaction pathways but could find none that would result in a mechanism that gives observed kinetics of general-acid catalysis. John Lam and C.-S. Kim studied the reaction and found that the products were not the expected benzaldehyde and thiamin but rather fragmentation products from a process Oka observed from the combination of benzaldehyde and thiamin in basic ethanol, giving a substituted phenyl thiazole ketone (PTK) and a dimethyl amino pyrimidine (DMAP) (Scheme 18) (54, 55). PTK absorbs strongly at 328 nm so it is readily observed by UV–vis spectroscopy.

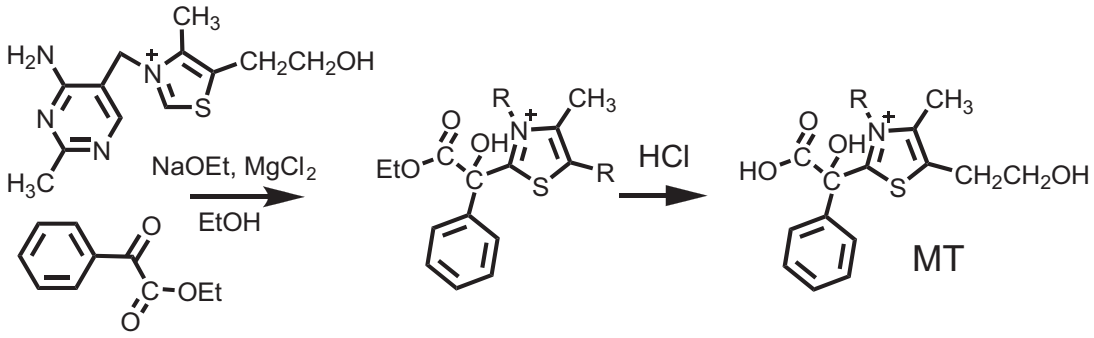
Ian Moore studied the kinetic patterns of these reactions and found that the fragmentation step is very fast, with a first-order rate constant of about 10^4 s^{-1} (56). This is about 100 times larger than k_{cat} of the enzyme benzoylformate decarboxylase, which functions through the diphosphate of HBnT as an intermediate. How does the enzyme promote decarboxylation and suppress fragmentation?

α-Mandelylthiamin



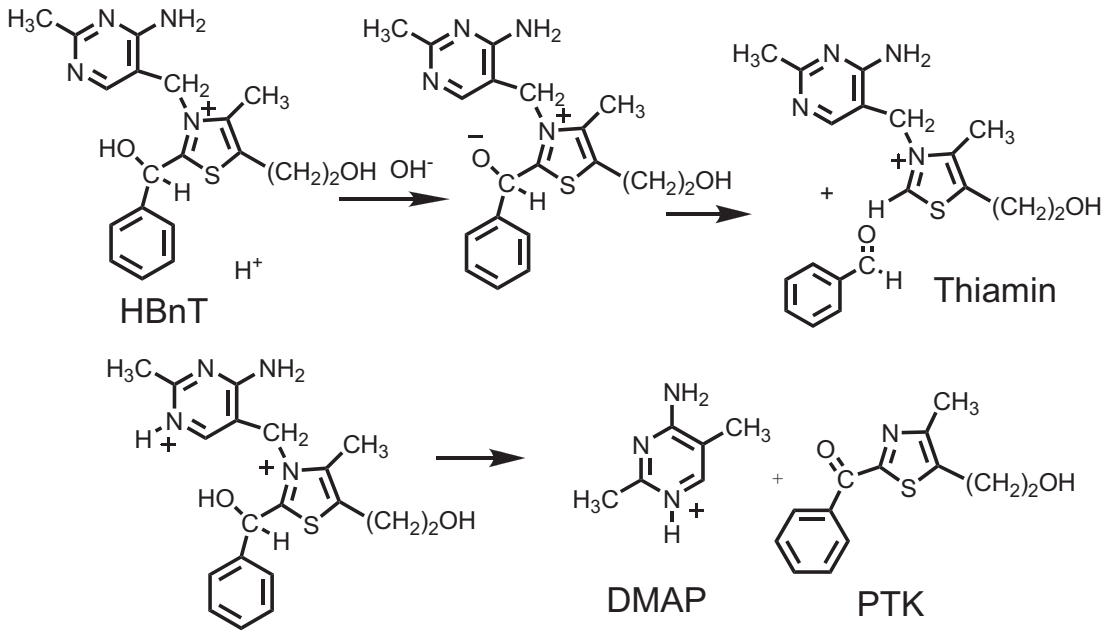
The enzymic precursor to HBnTDP is the compound α-mandelyl-TDP. Its inherent reaction patterns should answer important questions as to how the enzyme affects its reactivity. Qingyan (Jane) Hu developed a synthesis of the very elusive α-mandelylthiamin through a combination of determination and careful assessment of reactivity (Scheme 19) (57).

The rate of decarboxylation of MT is about 10^6 times less than the enzyme's k_{cat} and it undergoes rapid fragmentation after decarboxylation (Scheme 20) (58).



How does the enzyme enhance decarboxylation and prevent fragmentation of its similar intermediate? Jane studied the effects of buffers on product distribution, because Brønsted acids are expected to protonate the decarboxylation product and, thus, suppress fragmentation. Surprisingly, she discovered that the conjugate acid of pyridine accelerates the decarboxylation process, while other Brønsted acids that are not pyridine derivatives do not provide catalysis. There is no obvious place to add a proton to enhance the rate of bond-breaking in the decarboxylation step. When we looked up what is known about decarboxylation, we came across the work of Jiali Gao describing the theoretical analysis of decarboxylation related to another enzyme. The theory indicated that carbon dioxide in association with a carbanion will result in the reformation of the C–C bond, with a very low energy barrier. Separation of carbon dioxide is limited

© 2006 NRC Canada



Scheme 18.

Scheme 19.

Scheme 20.

© 2006 NRC Canada

by its diffusion rate. Because a reaction with no barrier has a rate constant of about 10^{13} s^{-1}, while diffusion of carbon dioxide has a rate constant of about 10^{8} s^{-1}, there is a possibility for catalysis if a proton could be added prior to the departure of carbon dioxide after the C–C bond is broken. Because HBnT contains a benzene ring, pyridine could associate with HBnT by π-stacking and provide a proton without having to travel into the complex as it will be pre-associated. An enzyme could readily achieve similar catalysis by transferring protons from nearby groups to the nascent carbanion (59). The presence of two essential catalytic histidines at the active site of the enzyme is consistent with this (60).

Concluding remarks

The molecular keystones provide a point of strength and a point for departure. By using simple molecules as a starting point and analyzing complex environments, we continue to see that the methods and concepts of organic chemistry have unlimited prospects in the biochemical world. Once again I thank those who attended my talk and now add my thanks to those who have read this account.

Acknowledgements

My work has primarily and continuously been supported by the Natural Sciences and Engineering Research Council of Canada (NSERC) through operating and discovery grants, collaborative health research projects, and strategic projects. Mike Smith invited me to be a founding member of The Protein Engineering Networks of Centres of Excellence, and that period not only helped with funding but also gave me many new scientific interactions. I thank the students whose work has been mentioned and those who are specifically cited as well. All their contributions helped enormously. I thank those in the scientific community of Canada who have always been available to answer my naïve questions about reaction mechanisms, in particular, Peter Guthrie, Jerry Kresge, and the late John Bunting, to whom I dedicated my talk. I thank the CSC and CIC for keeping chemistry in Canada alive as a national interest and for giving me this recognition. Finally, I thank my family for accepting my abnormal interest in molecules with a smile.

Synthesis and insulin-sensitizing activity of (*S*)-2-ethoxy-3-phenylpropanoic acid derivatives

Xiao-hua Cai and Bing Xie

Abstract: A series of (*S*)-2-ethoxy-3-phenylpropanoic acid derivatives were synthesized and their insulin-sensitizing activities were evaluated in 3T3-L1 cells. Compounds **1b** ($EC_{30} = 9.43 \times 10^{-3}$ μmol/L), **1d** ($EC_{30} = 7.45 \times 10^{-3}$ μmol/L), **1e** ($EC_{30} = 6.22 \times 10^{-3}$ μmol/L), and **1f** ($EC_{30} = 7.76 \times 10^{-3}$ μmol/L) exhibited more potent insulin-sensitizing activity than rosiglitazone ($EC_{30} = 2.06 \times 10^{-2}$ μmol/L).

Key words: (*S*)-2-ethoxy-3-phenylpropanoic acid derivatives, type 2 diabetes, insulin-sensitizing agents.

Résumé : On a réalisé la synthèse d'une série de dérivés de l'acide (*S*)-éthoxy-3-phénylpropanoïque et on a évalué leur activité de sensibilisation à l'insuline à l'aide de cellules 3T3-L1. Les composés **1b** ($EC_{30} = 9{,}43 \times 10^{-3}$ μmol/L), **1d** ($EC_{30} = 7{,}45 \times 10^{-3}$ μmol/L), **1e** ($EC_{30} = 6{,}22 \times 10^{-3}$ μmol/L), et **1f** ($EC_{30} = 2{,}06 \times 10^{-2}$ μmol/L) présentent une plus grande activité sensibilisatrice de l'insuline que la rosiglitazone ($EC_{30} = 2{,}06 \times 10^{-2}$ μmol/L).

Mots clés : dérivés de l'acide (*S*)-éthoxy-3-phénylpropanoïque, diabète de type 2, agents de sensibilisation de l'insuline.

[Traduit par la Rédaction]

Introduction

Type 2 diabetes is a complex metabolic disorder that affects between 6% and 20% of the populations in industrial societies. It is characterized by insulin resistance, hyperglycemia, and defects in insulin secretion and is usually associated with dyslipidemia, hypertension, and obesity (1–4). The peroxisome proliferator-activated receptors (PPARα, PPARγ, PPARδ) belong to the nuclear receptor superfamily and function as ligand-activated transcription factors (5).These receptors play a key role controlling the expresssion of genes involved in lipid and carbohydrate metabolism in various tissues. Interest in the PPARs has increased with the discovery of insulin sensitizers (e.g., TZD, pioglitazone, and rosiglitazone), which are potent and selective PPARγ agonists used in the treatment of type 2 diabetes. However, the success of these drugs has been hampered by cases of liver toxicity and side-effects such as fluid retention and weight gain (6). This has prompted the search for non-TZD ligands with different characteristics compared with the glitazones.

We were interested in developing a series of non-thiazolidinedione insulin-sensitizing activities, which might surmount the hepatic toxicity problems associated with the known non-thiazolidinedione. A few (*S*)-2-ethoxy-3-phenylpropanoic acid derivatives could increase insulin-sensitizing activities and have been reported to be useful in the treatment of hyperglycemia and hyperlipidemia. Of them, ragaglitazar (7) is in phase III and tesaglitazar (8) is in phase II clinical trials. Ragaglitazar (DRF-2725) has a binding affinity of 0.98 μmol/L at hPPARα and 0.092 μmol/L at hPPARγ and transactivates PPARα and PPARγ with EC_{50} values of 3.2 and 0.57 μmol/L, respectively. Ragaglitazar also displays good in vivo antidiabetic activity in db/ob mice and is reported to have 77% oral bioavailability in Wistar rats. Ragaglitazar was co-licensed by Novo Nordisk and completed phase II clinical trials. However, the clinical development of ragaglitazar has been terminated because of an incidence of bladder tumors in rodents. Our ongoing efforts to find a drug substance in the non-TZD class. As we know, molecular structures of many drugs contain bisphenyl moieties; therefore, using the dual PPARα/γ ragaglitazar as a structural template combined with the structural characteristics of rosiglitazone (Scheme 1), we demonstrate that insulin-sensitizing agents can be designed by using (*S*)-2-ethoxy-3-phenylpropanoic acid as the acidic moiety and bisphenyl as the lipophilic moiety of the molecule. A few bisphenyl-containing compounds **1a**–**1f** were designed and synthesized, and their insulin-sensitizing activities were evaluated with 3T3-L1 cells in vitro.

Chemistry

Compounds **1a**–**1f** were synthesized as outlined in Scheme 2. Intermediate **8** was prepared starting from diaryl methanol by chlorination, condensation with 2-methylaminoethanol, and mesylation (7). Then, **8** condensed with

traction with ethyl acetate (20 mL × 4). The extracted liquid was washed with water, dried over magnesium sulfate, and concentrated. The residue was purified by silica gel column chromatrography (petroleum ether – ethyl acetate, 10:1) to afford a colorless liquid **7a**: 1.06 g (44%). IR (KBr, cm^{-1}) ν_{max}: 3401, 3060, 3026, 2965, 2879, 2847, 1598, 1492, 1452, 1268, 1080, 1017, 759, 746, 706. ^1H NMR (600 MHz, $CDCl_3$) δ 2.18 (s, 3H), 2.56 (t, *J* = 7.2 Hz, 2H), 3.64 (t, *J* = 7.2 Hz, 2H), 4.50 (s, 1H), 7.21 (t, *J* = 7.2 Hz, 2H), 7.32 (t, *J* = 7.6 Hz, 4H), 7.39 (d, *J* = 7.2 Hz, 4H). ESI-MS *m/z* (%): 243 ($[M + H + 1]^+$, 8), 242 ($[M + H]^+$, 67).

1a

A mixture of ethyl (*S*)-2-ethoxy-3-(4-hydroxyphenyl)propionate **(9)** (0.357 g, 1.5 mmol), mesylate of **7a** (0.481 g, 1.5 mmol), potassium carbonate (0.828 g, 6 mmol), and toluene (15 mL) was refluxed for 12 h. After completion (monitored by TLC), the reaction mixture was poured into ice water and the toluene layer was separated while the aqueous layer was extracted with toluene. The combined organic layer was washed with water and concentrated under reduced pressure to afford an oil, which was dissolved in methanol (20 mL). Then, 2 mol/L sodium hydroxide (1.5 mL) aqueous solution was added slowly to the solution at room temperature. The reaction mixture was stirred for 8 h. The progress of the reaction was monitored by TLC. After completion of the hydrolysis, the reaction mixture was diluted with water (40 mL) and washed with ether to remove the impurities. The aqueous layer was adjusted to pH 2.5–3.0 with dilute hydrochloric acid and extracted with ethyl acetate (20 mL). The combined organic solution was washed with water and concentrated under reduced pressure to give a colorless solid **1a**: 0.558g (86%). IR (KBr, cm^{-1}) ν_{max}: 3430, 3028, 2973, 2923, 2870, 2783, 1730, 1612, 1583, 1512, 1454, 1241, 1178, 1115, 1021, 924, 827, 746, 706. ^1H NMR (600 MHz, $CDCl_3$) δ 1.20 (t, *J* = 6.8 Hz, 3H, OCH_2CH_3), 2.30 (s, 3H, NCH_3), 2.83 (s, 2H, NCH_2CH_2O-), 2.95 (dd, *J* = 14.4, 7.6 Hz, 1H, CH_2CH), 3.09 (dd, *J* = 14.4, 4.2 Hz, 1H, CH_2CH), 3.46–3.51 (m, 1H, OCH_2CH_3), 3.56–3.61 (m, 1H, OCH_2CH_3), 4.06–4.09 (m, 3H, NCH_2CH_2O, CH_2CH), 4.51 (s, 1H, $CHNCH_3$), 6.79 (d, *J* = 8.4 Hz, 2H), 7.13 (d, *J* = 8.4 Hz, 2H), 7.19 (t, *J* = 7.2 Hz, 2H), 7.29 (t, *J* = 7.6 Hz, 4H), 7.45 (d, *J* = 7.2 Hz, 4H). ^{13}C NMR (150 MHz, CDCl3,) δ 15.1, 37.5, 41.5, 53.8, 66.3, 67.0, 75.9, 79.8, 114.3, 127.0, 128.1, 128.4, 130.5, 142.8, 157.9, 172.8. ESI-MS *m/z* (%): 435 ($[M + H + 1]^+$, 27), 434 ($[M + H]^+$, 100), 433 ($[M^-]$, 28), 432 ($[M - H]^-$, 100); HRESI-MS *m/z* (%): 456.2147 ($[M + Na]^+$, calcd. for 456. 2145).

Insulin-sensitizing assay

All compounds were screened for insulin-sensitizing activity by measuring the triglyceride accumulation resulting from insulin-regulated differentiation of 3T3-L1 cells (9). Confluent 3T3-L1 cells were incubated in 5% fetal calf serum with isobutylmethylxanthine (0.5 mmol/L) and dexamethasone (1 μmol/L) for 48 h. Cultures were then incubated in Dulbecco's modified Eagle's medium – 2% fetal calf serum for 4 days with insulin (10 ng/mL) and the test compounds. Cellular triglycerides were extracted with 2-propanol and assayed by the enzymatic method using a commercially available kit (MPR2 Triglycerides GPO-PAP, Boehringer Mannheim, Mannheim, Germany). The marketed insulin-sensitizing drug rosiglitazone was selected as a positive control. All compounds activities in Table 1 are given as a percentage of rosiglitazone response for insulin-sensitizing activity at 1 μmol/L concentration, and the EC_{30} values (effective concentration for 30% enhancement of insulin-induced triglyceride accumulation in 3T3-L1 cells) of some compounds are also given.

Discussions

As indicated in Table 1, compounds **1b**, **1d**, **1e**, and **1f** exhibited more potent insulin-sensitizing activity than rosiglitazone according to their EC_{30} values. The primary structure–activity relationship study of these compounds indicated that the substituents at the *p*-position of the bisphenyl moiety play a key role in the potency of their activity, and the eletron-donating or aryl substituents (**1b**, **1d**, **1e**, and **1f**) lead to enhancement of the activity, whereas eletron-withdrawing substituents reduce the activity (**1c**).

Conclusion

In summary, we discovered a novel class of (*S*)-2-ethoxy-3-phenylpropanoic acid derivatives, which possesses potent insulin-sensitizing activity. This could be used as a lead structure in the search of non-thiazolidinedione insulin-sensitizing agents.

Synthesis and evaluation of methyl 2-methoxycarbonyl-3-phenylpropionate derivatives as a new type of angiotensin converting enzyme inhibitors

Xiao-hua Cai, Bing Xie, and Hui Guo

Abstract: Methyl 2-methoxycarbonyl-3-phenylpropionate derivatives were prepared, and their inhibitory activities for angiotensin converting enzyme (ACE) were evaluated. Compounds **5b** (IC_{50} = 0.0039 μmol/L), **5d** (IC_{50} = 0.0027 μmol/L), **5e** (IC_{50} = 0.0021 μmol/L), and **5f** (IC_{50} = 0.0052 μmol/L) exhibited more potent ACE inhibitiory activity than the control drug Captopril® (IC_{50} = 0.0075 μmol/L).

Key words: hypertension, 2-methoxycarbonyl-3-phenyl propionate derivative, ACE inhibitor.

Résumé : On a préparé des dérivés du 2-méthoxycarbonyl-3-phénylpropionate de méthyle et on a évalué leurs activités inhibitrices pour l'enzyme de conversion de l'angiotensine (ECA). Les composés **5b** (IC_{50} = 0,0039 μmol/L), **5d** (IC_{50} = 0,0027 μmol/L), **5e** (IC_{50} = 0,0021 μmol/L), et **5f** (IC_{50} = 0,0052 μmol/L) présentent des activités inhibitrices vis-à-vis l'ECA qui sont supérieures à celle du médicament de contrôle, le Captopril® (IC_{50} = 0,0075 μmol/L).

Mots clés : hypertension, dérivés du 2-méthoxycarbonyl-3-phénylpropionate de méthyle, inhibiteur de l'ECA.

Introduction

Hypertension is a major risk factor for the development of cardiovascular diseases and mortality in Western countries (1). Although some of these risk factors can be unchanged, one factor that can be controlled and has the greatest impact on the etiology of stroke is high blood pressure (2). There are several classes of agents that have been used in the treatment of hypertension (3). Angiotensin I converting enzyme (ACE, EC 3.4.15.1), is responsible for hypertension by producing vasoconstrictor angiotensin II and degrading vasodilator, bradykinin. Therefore, inhibition of ACE is considered to be an important therapeutic approach for controlling hypertension. Initial interest in ACE inhibitors began with the discovery of snake venom peptides that could compete well with angiotensin I, the natural substrate of ACE (4, 5). With the model development of catalytic structure of ACE, specific inhibitors that bind more precisely to the enzyme active site were developed (6). Certain functional foods containing ACE inhibitory compounds have exhibited the ability to act as alternative treatment for hypertension (7). Even though the clinical ACE inhibitors are remarkably effective as antihypertensive drugs, they often cause adverse side effects or some of them are difficult to be synthesized (8). Therefore, the development of new ACE inhibitors is still important.

Methyl 2-methoxycarbonyl-3-phenylpropionate derivatives, such as JTP-20993 (9) and compound **1** (10) (Scheme 1), are PPARα/γ agonists used in the treatment of hyperglycemia and hyperlipidemia. Initially, we wish to design and synthesize some methyl 2-methoxycarbonyl-3-phenylpropionate derivatives (**5a**–**5f**) containing bisphenyl in the lipophilic moiety of the molecules and to investigate their PPARα/γ agonistic activity. Accidently, all the compounds showed ACE inhibitory activities.

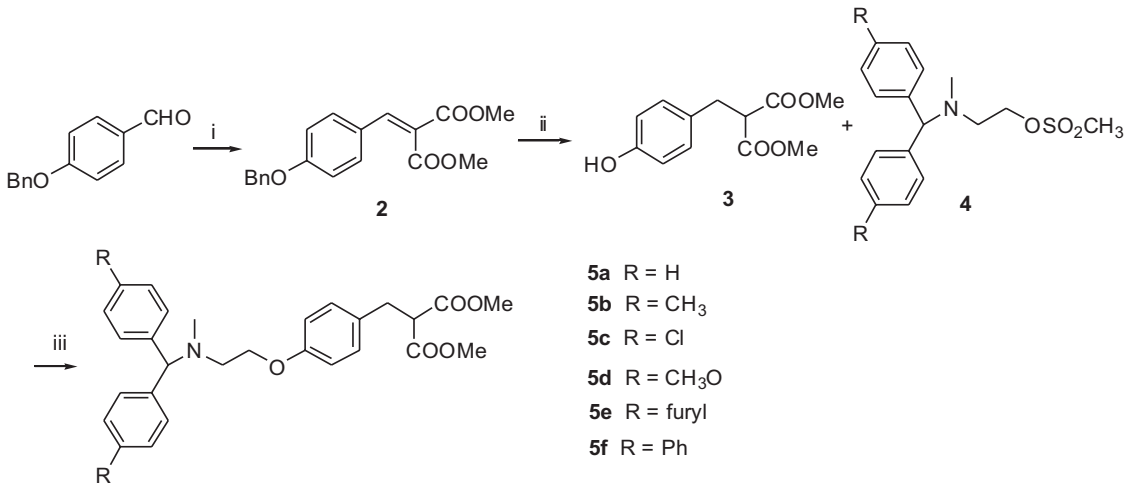
Chemistry



Compounds **5a**–**5f** were synthesized as outlined in Scheme 2. 4-Benzoxybenzaldehyde was condensed with dimethyl malonate using catalytic quantity of pipiridinium acetate to give 2-(4-benzyloxybenzylidene)malonic acid dimethyl ester (**2**), which was hydrogenated with 5% Pd–C and produced methyl 3-(4-hydroxyphenyl)-2-methoxycarbonylpropionate (**3**). Compound **3** was condensed with compound (**4**) to afford the desired products **5a**–**5f**. Compound 4 was prepared starting from diaryl ketones by reduction (11), chlorination, and condensation with 2-methylaminoethanol followed by mesylation (12) (Scheme 3).

1173, 1155, 1104, 1026, 829, 772. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 3.15 (d, *J* = 7.9 Hz, 2H, C*H*$_2$CH), 3.64 (t, *J* = 7.9 Hz, 1H, CH_2CH-), 3.70 (s, 6H, OC*H*$_3$), 5.89 (br s, 1H, O*H*), 6.72 (d, *J* = 8.2 Hz, 2H), 7.03 (d, *J* = 8.2 Hz, 2H). ESI-MS *m*/*z* (%): 277 ([M + K]$^+$, 17), 261([M + Na]$^+$, 97), 237 ([M – H]$^-$, 66).

8a

Thionyl chloride (2.38 g, 20 mmol) was added dropwise to a solution of **6a** (1.84g, 10 mmol) and benzene (15 mL) and the mixture was refluxed for 12 h. The solution was concentrated under reduced pressure to give brown oil **7a**. 2-Methylaminoethanol (4 mL) was added to **7a** and the mixture was heated to 100 °C for 8 h. After the reaction completion (monitored by TLC), water (50 mL) was added to the reaction mixture that was then extracted with ethyl acetate (20 mL × 4). The organic layer was washed with water, dried over magnesium sulfate, and concentrated. The residue was purified by silica gel column chromatrography (petroleum ether – ethyl acetate, 10:1) to afford **8a**: 1.06 g (44%) as a colorless liquid. IR (KBr, cm^{-1}) ν_{max}: 3401, 3060, 3026, 2965, 2879, 2847, 1598, 1492, 1452, 1268, 1080, 1017, 759, 746, 706. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 2.18 (s, 3H), 2.56 (t, *J* = 7.2 Hz, 2H), 3.64 (t, *J* = 7.2 Hz, 2H), 4.50 (s, 1H), 7.21 (t, J = 7.2 Hz, 2H), 7.32 (t, *J* = 7.6 Hz, 4H), 7.39 (d, *J* = 7.2 Hz, 4H). ESI-MS *m*/*z* (%): 243 ([M + H + 1]$^+$, 8), 242 ([M + H]$^+$, 67).

5a

The mixture of **3** (2 mmol), mesylate of **8a** (**4a**, 2 mmol), potassium carbonate (8.28 g, 6 mmol), and toluene (20 mL) was refluxed for 10 h. The progress of the reaction was monitored by TLC. After completion, the reaction mixture was poured into ice water and the toluene layer was separated while the aqueous layer was extracted with toluene. The combined organic layer was washed with water and concentrated under vacuum. The residue was purified by silica gel column chromatography (petroleum ether – EtOAc, 6:1) to give **5a**: 0.787 g (85%) as a colorless liquid. IR (KBr, cm^{-1}) ν_{max}: 3060, 3027, 2953, 2848, 2782, 1753, 1737, 1612, 1512, 1492, 1452, 1436, 1343, 1244, 1178, 1152, 1023, 926, 828, 760, 747, 708. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 2.28 (s, 3H, NC*H*$_3$), 2.80 (t, *J* = 6.0 Hz, 2H, NC*H*$_2$CH$_2$O), 3.16 (d, *J* = 7.8 Hz, 2H, C*H*$_2$CH), 3.63 (t, *J* = 7.8 Hz, 2H, CH$_2$C*H*), 3.71 (s, 6H, OC*H*$_3$), 4.06 (t, *J* = 6.1 Hz, 2H, NCH$_2$C*H*$_2$O), 4.48 (s, 1H, C*H*NCH$_3$), 6.77 (d, *J* = 8.6 Hz, 2H), 7.09 (d, *J* = 8.6 Hz, 2H), 7.19 (t, *J* = 7.6 Hz, 2H), 7.28 (t, *J* = 7.6 Hz, 4H), 7.44 (d, *J* = 7.6 Hz, 4H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 34.0, 41.5, 52.5, 53.8, 53.9, 66.3, 75.9, 114.5, 126.9, 128.0, 128.4, 129.7, 129.8, 142.9, 157.7, 169.3. ESI-MS *m*/*z* (%): 485 ([M + Na + 1]$^+$, 8.5), 484 ([M + Na]$^+$, 27), 462 ([M + H]$^+$, 25); HRESI-MS *m*/*z* (%): 484.2116 ([M + Na]$^+$, calcd. for $C_{28}H_{31}NNaO_5$: 484.2094).

ACE inhibitory assay

ACE inhibitory activity was determined spectrometrically following the reported procedure using hippuryl-*L*-histidyl leucine (HHL) as the substrate (13, 14). Appropriate solutions of HHL, inhibitor, and ACE were obtained by dissolving them in 50 mmol/L sodium borate buffer (pH 8.3) and a mixture containing 50 mL of inhibitor and 50 μL of ACE solution (25 mU/mL) was preincubated for 10 min at 37 °C. For ACE activity determination, 150 μL of 4.15 mmol/L HHL was added to the mixture followed by incubation for 30 min at 37 °C, and the reaction was terminated by addition of 250 μL of 1 mol/L HCl. The hippuric acid formed by the action of ACE was extracted into 500 μL of ethyl acetate. After centrifugation for 10 min, 200 μL of supernatant was separated from the upper layer and subjected to evaporation at room temperature under vacuum for 2 h. Distilled water (1.0 mL) was added to dissolve the hippuric acid, and the absorbance of the solution at 228 nm was monitored by a spectrophotometer. The sample added before mixing with ACE was used as a blank, while the sample replaced by the same volume of distilled water was treated as a control. The inhibitory ratio (%) of ACE was calculated as (C-A)/(C-B) × 100%, where A is A_{228} of the inhibitor, B is A_{228} of the blank, and C is A_{228} of the control. Captopril® was used as a positive control for ACE inhibitor.

Table 1. ACE inhibitory activity of **5a**–**5f**.

Compound	IC_{50} (μmol/L)
5a	0.0083
5b	0.0039
5c	0.0132
5d	0.0027
5e	0.0021
5f	0.0052
Captopril®	0.0075

Discussion

The ACE inhibitory activity of these compounds is summarized in Table 1, Captopril® was used as a positive control. Compounds (**5a**–**5f**) show ACE inhibitory activity, and the inhibitiory activities of compounds **5b** (IC_{50} = 0.0039 μmol/L), **5d** (IC_{50} = 0.0027 μmol/L), **5e** (IC_{50} = 0.0021 μmol/L), and **5f** (IC_{50} = 0.0052 μmol/L) were higher than that of the control drug Captopril® (IC_{50} = 0.0075 μmol/L). The primary structure–activity relationship study indicated that the substituents at the *p*-position of the bisphenyl moiety play a key role in determining the potency of ACE inhibitory activity, and the eletron-donating or aryl substituents at the *p*-position of the bis(diphenyl) moiety enhanced the activity (**5b**, **5d**, **5e**, and **5f**), whereas eletron-withdrawing substituents reduced the activity (**5c**).

Conclusion

We developed a new type of potent ACE inhibitory compounds. These results encouraged the continued synthesis and evaluation of compounds in the chemical series with the purpose of increasing in vitro potency.

Theoretical study of one- and two-photon absorption properties of olefin-linked paracyclophane oligomers

Xiang-Biao Zhang, Ji-Kang Feng, Ai-Min Ren, and Chia-Chung Sun

Abstract: The electronic structures and the one- and two-photon absorption (TPA) properties of two series of the olefin-linked paracyclophane (pCp) oligomers have been studied using AM1 and ZINDO-SOS methods. The relationship between the TPA cross sections and the molecular chain length is obtained. The maximum TPA cross section increases in proportion to N^{α} (N denotes the number of repeat units) and the values of α depend on different molecular structures. The olefin-linked pCp oligomers, which have good transparency and large TPA cross sections, are promising candidates for TPA materials.

Key words: two-photon properties, paracyclophane oligomer, AM1, ZINDO-SOS.

Résumé : Faisant appel aux méthodes AM1 et ZINDO-SOS, on a fait une étude théorique des structures électroniques et des propriétés d'absorption d'un photon et de deux photons (ADP) de deux séries d'oligomères de paracyclophane (pCp) reliés par des oléfines. On a pu établir la relation entre les sections droites de l'ADP et la longueur de la chaîne moléculaire. L'augmentation de la valeur maximale de la section droite de l'ADP est proportionnelle à N^{α} où N correspond au nombre d'unités alors que les valeurs de α dépendent des diverses structures moléculaires. Les oligomères de pCp liés par des oléfines, qui présentent une bonne transparence et des sections droites d'ADP, sont des candidats offrant beaucoup de possibilités comme matériaux d'ADP.

Mots clés : propriété à deux photons, oligomère de paracyclophane, méthode AM1, méthode ZINDO-SOS.

[Traduit par la Rédaction]

Introduction

New two-photon absorption (TPA) materials are under intense investigation because of their potential use in emerging applications such as upconverted lasing (1–3), optical power limiting (4–6), three-dimensional (3D) microfabrication (7–9), and photodynamic therapy (10). Extensive studies have revealed that some basic structural motifs are important with respect to TPA-active molecular construction (11, 12). Molecular structures containing a π center with electron donors or acceptors on the terminal sites of the conjugation systems are expected to exhibit good TPA response (12, 13). Particularly, the conjugation length, π electron center, and chemical functional groups at the end of electron conjugation are recognized as three important factors for structure–property optimization (11, 14). Quadrupolar molecules still receive considerable attention (10, 12, 13), though many recent studies have focused on octupolar and multibranched structures (15–18).

Typical organic nonlinear optical systems, based on intramolecular charge transfer (ICT) from a donor toward an acceptor moiety through a π system, require a compromise in properties (19). Most strategies to increase the degree of ICT require greater conjugation length. Although greater ICT typically leads to a greater nonlinearity in the optical response, the increased conjugation leads to a lower transparency in the spectral region of interest, limiting the potential usefulness of the material. Paracyclophane-based molecules may afford advantages in this tradeoff by generating a strong NLO response while providing favourable displacement of the region of transparency. Zyss et al. (20) investigated the NLO properties of substituted paracyclophane and pointed out that the paracyclophane core leads to significant ICT while preserving transparency. Our group have designed a series of paracyclophane derivatives and studied their TPA properties (21). The results showed that the paracyclophane core, as a multidimensional tunneling barrier, remarkably increases the TPA cross section of molecules. Bartholomew et al. (22, 23) have studied 3D nonlinear optical chromophores based on (2.2)paracyclophane (pCp) and have pointed out that the interplay between through-bond ICT and through-space ICT processes gives rise to large quadratic hyperpolarizability values. However, for practical application of such materials, they have to be incorporated into polymer to form thin films (24). An ideal approach for this would be to design the polymer structure in such a way as to allow maxi-

mum utilization of monomeric or oligomeric TPA properties. The polymers containing pCp repeat units have been experimentally synthesized (25–27). In this paper, to provide useful information for the practical application of the pCp polymers, two series of the olefin-linked paracyclophane oligomers (see Fig. 1) have been designed and their electronic structures and TPA properties have been comparatively studied. The structure–property relationship of these molecules has been established.

Computational methods

The TPA process corresponds to simultaneous absorption of two photons. The TPA efficiency of an organic molecule, at optical frequency $\omega/2\pi$ can be characterized by the TPA cross section $\delta(\omega)$. It can be directly related to the imaginary part of the second hyperpolarizability $\gamma(-\omega; \omega, \omega, -\omega)$ (28),

$$[1] \qquad \delta(\omega) = \frac{8\pi^2\hbar\omega^2}{n^2c^2} L^4 \operatorname{Im}\gamma(-\omega; \omega, \omega, -\omega)$$

where $\hbar$ is Planck's constant divided by 2π, ω is the photon frequency, c is the speed of light, and n is the refractive index of the medium. L corresponds to the local-field factor. In the calculations presented here, n and L are set to 1 (isolated molecule in vacuum).

The sum-over-states (SOS) expression to evaluate the components of the second hyperpolarizability $\gamma_{\alpha\beta\gamma\delta}$ can be deduced using perturbation theory. By considering a Taylor expansion of energy with respect to the applied field, the $\gamma_{\alpha\beta\gamma\delta}$ Cartesian components are given by (29, 30)

$$[2] \quad \gamma_{\alpha\beta\gamma\delta}(-\omega_\sigma; \omega, \omega, -\omega) = \hbar^{-3} \sum \mathrm{P}_{1,2,3} \left\{ \sum_K{}' \sum_L{}' \sum_M{}' \left[\frac{\langle 0|\mu_\alpha|K\rangle\langle K|\overline{\mu_\beta}|L\rangle\langle L|\overline{\mu_\gamma}|M\rangle\langle M|\mu_\delta|0\rangle}{(\omega_K - i\Gamma_K/2 - \omega)(\omega_L - i\Gamma_L/2 - \omega_2 - \omega_3)(\omega_M - i\Gamma_L/2 - \omega_3)} \right.\right.$$
$$+ \frac{\langle 0|\mu_\beta|K\rangle\langle K|\overline{\mu_\alpha}|L\rangle\langle L|\overline{\mu_\gamma}|M\rangle\langle M|\mu_\delta|0\rangle}{(\omega_K + i\Gamma_K/2 + \omega_1)(\omega_L - i\Gamma_L/2 - \omega_2 - \omega_3)(\omega_M - i\Gamma_M/2 - \omega_3)} + \frac{\langle 0|\mu_\beta|K\rangle\langle K|\overline{\mu_\gamma}|L\rangle\langle L|\overline{\mu_\alpha}|M\rangle\langle M|\mu_\delta|0\rangle}{(\omega_K + i\Gamma_K/2 + \omega_1)(\omega_L + i\Gamma_L/2 + \omega_1 + \omega_2)(\omega_M - i\Gamma_M/2 - \omega_3)}$$
$$\left. + \frac{\langle 0|\mu_\beta|K\rangle\langle K|\overline{\mu_\gamma}|L\rangle\langle L|\overline{\mu_\alpha}|M\rangle\langle M|\mu_\delta|0\rangle}{(\omega_K + i\Gamma_K/2 + \omega_1)(\omega_L + i\Gamma_L/2 + \omega_1 + \omega_2)(\omega_M + i\Gamma_M/2 + \omega_\sigma)} \right] - \sum_K{}' \sum_L{}' \left[\frac{\langle 0|\mu_\alpha|K\rangle\langle K|\mu_\beta|0\rangle\langle 0|\mu_\gamma|L\rangle\langle L|\mu_\delta|0\rangle}{(\omega_K - i\Gamma_K/2 - \omega_\sigma)(\omega_K - i\Gamma_K/2 - \omega_1)(\omega_L - i\Gamma_L/2 - \omega_3)} \right.$$
$$+ \frac{\langle 0|\mu_\alpha|K\rangle\langle K|\mu_\alpha|0\rangle\langle 0|\mu_\gamma|L\rangle\langle L|\mu_\delta|0\rangle}{(\omega_K - i\Gamma_K/2 - \omega_1)(\omega_L + i\Gamma_L/2 + \omega_2)(\omega_L + i\Gamma_L/2 - \omega_3)} + \frac{\langle 0|\mu_\beta|K\rangle\langle K|\mu_\alpha|0\rangle\langle 0|\mu_\gamma|L\rangle\langle L|\mu_\delta|0\rangle}{(\omega_K + i\Gamma_K/2 + \omega_1)(\omega_K + i\Gamma_K/2 + \omega_\sigma)(\omega_L + i\Gamma_L/2 - \omega_2)}$$
$$\left.\left. + \frac{\langle 0|\mu_\beta|K\rangle\langle K|\mu_\alpha|0\rangle\langle 0|\mu_\gamma|L\rangle\langle L|\mu_\delta|0\rangle}{(\omega_K + i\Gamma_K/2 + \omega_1)(\omega_L + i\Gamma_L/2 + \omega_2)(\omega_L - i\Gamma_L/2 - \omega_3)} \right] \right\}$$

ΔE_{H-L}	6.378 02	6.054 21	5.775 46	5.805 16	5.697 23	5.714 07	5.663 53	5.689 80

Note: Energy values are given in eV.

In this formula, α, β, γ, and δ refer to the molecular axes; ω_1, ω_2, and ω_3 are optical frequencies; and $\omega_\sigma = \omega_1 + \omega_2 + \omega_3$ is the polarization response frequency; $\Sigma P_{1,2,3}$ indicates a sum over the terms obtained by the six permutations of the pairs (ω_1/μ_β) and (ω_3/μ_δ); *K*, *L*, and *M* denote excited states and 0 denotes the ground state; $|K\rangle$ is an electronic wavefunction with energy $\hbar\omega_K$ relative to the ground electronic state; μ_α is the αth (= x, y, z) component of the dipole operator, $\langle K|\bar{\mu}_\alpha|L\rangle = \langle K|\mu_\alpha|L\rangle - \langle 0|\mu_\alpha|0\rangle\delta_{KL}$; the primes on the summation over the electronic states indicate exclusion of the ground state. Γ_K is the damping factor of excited state *K* and in the present work all damping factors Γ are set 0.14 eV. To compare the calculated δ value with the experimental value measured in solution, the orientationally averaged (isotropic) value of γ is evaluated. It is defined as,

$$[3] \qquad \langle\gamma\rangle = \frac{1}{15}\sum_{i,j}(\gamma_{iijj} + \gamma_{ijij} + \gamma_{ijji})$$

Substituting the imaginary part of $\langle\gamma\rangle$ into eq. [1], an expression for $\delta(\omega)$ is obtained that can be used to compare with the experimental value.

Generally, the position and relative strength of the two-photon response are predicted using the following simplified form of the SOS expression (31),

$$[4] \qquad \delta \propto \frac{M_{0k}^2 M_{kn}^2}{(E_{0k} - E_{0n}/2)^2\Gamma} + \frac{M_{0n}^2 \Delta\mu_n^2}{(E_{0n}/2)^2\Gamma}$$

where M_{ij} is the transition dipole moment from state *i* to *j*; E_{ij} is the corresponding excitation energy; the subscripts 0, *k*, and *n* refer to the ground state S_0, the intermediate state S_k, and the TPA final state S_n, respectively; and $\Delta\mu_n$ is the dipole moment difference between S_0 and S_n, which is zero in centrosymmetric molecules. So for centrosymmetric molecules, eq. [4] becomes

$$[5] \qquad \delta \propto \frac{M_{0k}^2 M_{kn}^2}{(E_{0k} - E_{0n}/2)^2\Gamma}$$

In this paper, taking into account the sizes of the molecules, all the geometries of the molecules are optimized with Austin Model 1 (AM1) method (32), which has been successfully applied to calculate many molecular structures (11). The properties of electronic excited states were then obtained by 196 single electron excitation and 54 double electron excitation configuration interactions (SDCI) using the ZINDO program. Furthermore, the transition energies and transition dipole moments that are needed to predict TPA were also provided. Then, using eqs. [1-3], the second hyperpolarizability γ and TPA cross section $\delta(\omega)$ were calculated, including the contributions of 200 lowest-lying excited states.

Results and discussions

Molecular geometries and electronic structures

The chemical structures of the studied molecules are shown in Fig. 1. As shown in Fig. 1, these molecules can be classified into two groups: **meso-*n*** (***n* = 1–5**) and **rac-*n*** (***n* = 0–7**). In the **meso-*n*** (***n* = 0–5**) repeat unit, the pCp cores are positioned in an "up/down" steplike configuration with one pCp above the plane of the ethylene linkage and the other pCp below the plane. In the **rac-*n*** (***n* = 1–7**) repeat unit, the pCp cores adopt an "up/up" configuration, in which both pCp cores are above the plane of the ethylene linkage. All the molecular geometries have been calculated with the AM1 method using the Gaussian 03 program suite. At the AM1 level in the studied molecules, the plane of the ethylene linkage is distorted about 30° from the adjacent phenyl rings in the pCp core and the ring strain distorts the phenyl rings in the pCp core. The distance between the bridgehead carbons on the opposing rings is about 2.7 Å while the distance between the nonbridging carbons is about 3.1 Å, which are in agreement with the experimental values of 2.78 and 3.09 Å (33). The middle two pCp cores in **rac-*n*** (***n* = 0, 2, 4, 6**) form a nearly perpendicular configuration with a dihedral angle of about 80°.

Tables 1 and 2 summarize the energies of the highest occupied molecular orbitals (HOMO), the lowest unoccupied molecular orbitals (LUMO), as well as the HOMO–LUMO energy gaps (ΔE_{H-L}) of **meso-*n*** (***n* = 0–5**) and **rac-*n*** (***n* = 0–7**), respectively. As can be seen in Table 1, in **meso-*n*** (***n* = 0–5**), the HOMO energy increases with ***n***, the molecular length, from –6.362 eV for **meso-0** to –6.288 eV for **meso-5**. Conversely, the LUMO energy decreases with the molecular length from –0.063 eV for **meso-0** to –0.192 eV for **meso-5**. In **rac-*n*** (***n* = 0–7**), the HOMO energy increases in the order of **rac-0** (–6.379 eV) < **rac-1** (–6.285 eV) < **rac-3**

Note: (H→L) denotes the single excitation from HOMO to LUMO.

Fig. 2. Energy gaps (ΔE) between HOMO and LUMO for the oligomers under study vs. the reciprocal numbers of repeat units ($1/N$).

(–6.192 eV) < **rac-2** (–6.175 eV) < **rac-5** (–6.158 eV) < **rac-7** (–6.145 eV) < **rac-4** (–6.140 eV) < **rac-6** (–6.125 eV). It can be seen that while ***n*** is even or odd, the HOMO energy increases as the molecular length increases. The LUMO energy in **rac-*n*** (***n* = 0–7**) decreases in the order of **rac-0** (–0.002 eV) > **rac-1** (–0.232 eV) > **rac-3** (–0.387 eV) > **rac-2** (–0.4 eV) > **rac-4** (–0.443 eV) > **rac-5** (–0.444 eV) > **rac-7** (–0.455 eV) > **rac-6** (–0.461 eV). As shown in Fig. 2, the HOMO–LUMO energy gaps of **meso-*n*** and **rac-*n*** (***n*** is even or odd) are inversely proportional to the number of the repeat units N (N = n + 1) and can be predicted with the following equations:

$$\text{L1: } \Delta E_{H-L} = 6.058\ 81 + 0.242\ 83/N \text{ (for } \textbf{meso-}\boldsymbol{n}\text{)}$$

$$\text{L2: } \Delta E_{H-L} = 5.557\ 87 + 0.990\ 48/N \text{ (for } \textbf{rac-}\boldsymbol{n}\text{, } \boldsymbol{n} \text{ even)}$$

$$\text{L3: } \Delta E_{H-L} = 5.522\ 94 + 0.8486\ 4/N \text{ (for } \textbf{rac-}\boldsymbol{n}\text{, } \boldsymbol{n} \text{ odd)}$$

Observing the slopes of L1, L2, and L3 (Fig. 2), one can see that the slope of L2 is greater than the slope of L3 and L1 has the smallest slope, which indicates that the **rac-*n*** (***n*** odd) reach a saturation limit for ΔE_{H-L} vs. the reciprocal of the number of repeat units more easily than the **rac-*n*** (***n*** even), and that the **meso-*n*** reach saturation most easily. The intercepts 6.058 81, 5.557 87, and 5.522 94 may be assigned to the HOMO–LUMO energy gaps of the infinite **meso-*n*** and **rac-*n*** (***n*** even and odd), respectively, corresponding to the HOMO–LUMO energy gaps of the corresponding polymers, respectively. The decrease of ΔE_{H-L} with the increase in the repeat units indicates that as the number of repeat units increases the electron conjugated scope enlarges, which is a favourable factor for the increase of TPA cross section of the molecule.

One-photon absorption

On the basis of the optimized molecular structures determined by the AM1 method, we calculated the OPA spectra of all the oligomers using the ZINDO program. Tables 3 and 4

show the maximum OPA wavelengths (λ^{O}_{max}), the corresponding oscillator strengths, and the transition natures for the **meso-*n*** (***n* = 0–5**) and the **rac-*n*** (***n* = 0–7**), respectively. To examine the calculation method, we chose 4,4′-bis (dimethylamino)stilbene (molecule **M** in Table 3) as a comparison sample. As shown in Table 3, the calculated results are in agreement with experimental values. There are two absorption bands in the OPAs of the studied molecules, one at 400–450 nm and another at 320–370 nm. For the molecules **meso-*n*** (***n* = 0–5**), the absorption of the low-energy bands is weaker so that we focus on the absorption of the high-energy bands. In Table 3, **meso-0** to **meso-5** exhibited the maximum absorptions at 330.7, 352.2, 343.5, 340.5, 332.7, and 319.1 nm, respectively. Apparently, the **meso-1** has the largest red-shifted wavelength of 352.2 nm. Subsequently, the absorption is blue-shifted as the molecular length increases, which is correlated to the energy level increase of the absorption state. The oscillator strength increases with the molecular length from 0.425 for **meso-0** to 1.915 for **meso-5**, but **meso-3** is an exception and its oscillator strength (2.019) is largest among the studied molecules. Compared with the molecule **meso-*n*** (***n* = 0–5**), the absorption of **rac-*n*** (***n* = 0–5**) is red-shifted. It can be seen in Table 4 that for the molecules **rac-*n*** (***n*** even), the low- and high-energy absorptions of **rac-2** are red-shifted by 12.2 and 36.8 nm relative to **rac-0**, respectively. Subsequently, the absorptions are blue-shifted from 454.9 and 365.9 nm for **rac-2** to 435.5 and 352.1 nm for **rac-6**. For the molecules **rac-*n*** (***n*** odd), the low- and high-energy absorptions of **rac-3** are red-shifted by 7.9 and 13.7 nm relative to **rac-1**, respectively. Subsequently, the absorptions are blue-shifted from 449.9 and 366.2 nm for **rac-3** to 428.7 and 346.7 nm for **rac-7**. The oscillator strength of the low-energy absorption of the **rac-*n*** increases with the molecular length. While ***n*** is even or odd, the oscillator strength reaches a saturation for **rac-2** and **rac-3**, respectively, and then decreases with the molecular length.

Two-photon absorption

Using eqs. [1–3], we calculated the third-order nonlinear susceptibilities γ and the TPA cross sections δ of the oligomers **meso-*n*** (***n* = 0–5**) and **rac-*n*** (***n* = 0–5**). Tables 5 and 6 summarize the maximum TPA wavelengths (λ^{T}_{max}), the maximum TPA cross sections (δ^{T}_{max}), the imaginary parts of third-order nonlinear susceptibilities (Imγ), and the transition natures. The curves of the TPA cross sections δ vs. the energies of the photons are plotted in Fig. 3. It should be noted that the TPA and OPA of the **meso-*n*** (***n* = 0–5**) have different final states because of the centrosymmetric structures of the molecules, while the TPAs of the **rac-*n*** (***n* = 0–5**) are more or less accompanied by OPA because they are noncentrosymmetric molecules. As shown in Tables 5 and 6, our calculated TPA cross sections and wavelengths are in agreement with experimental values. The maximum TPA

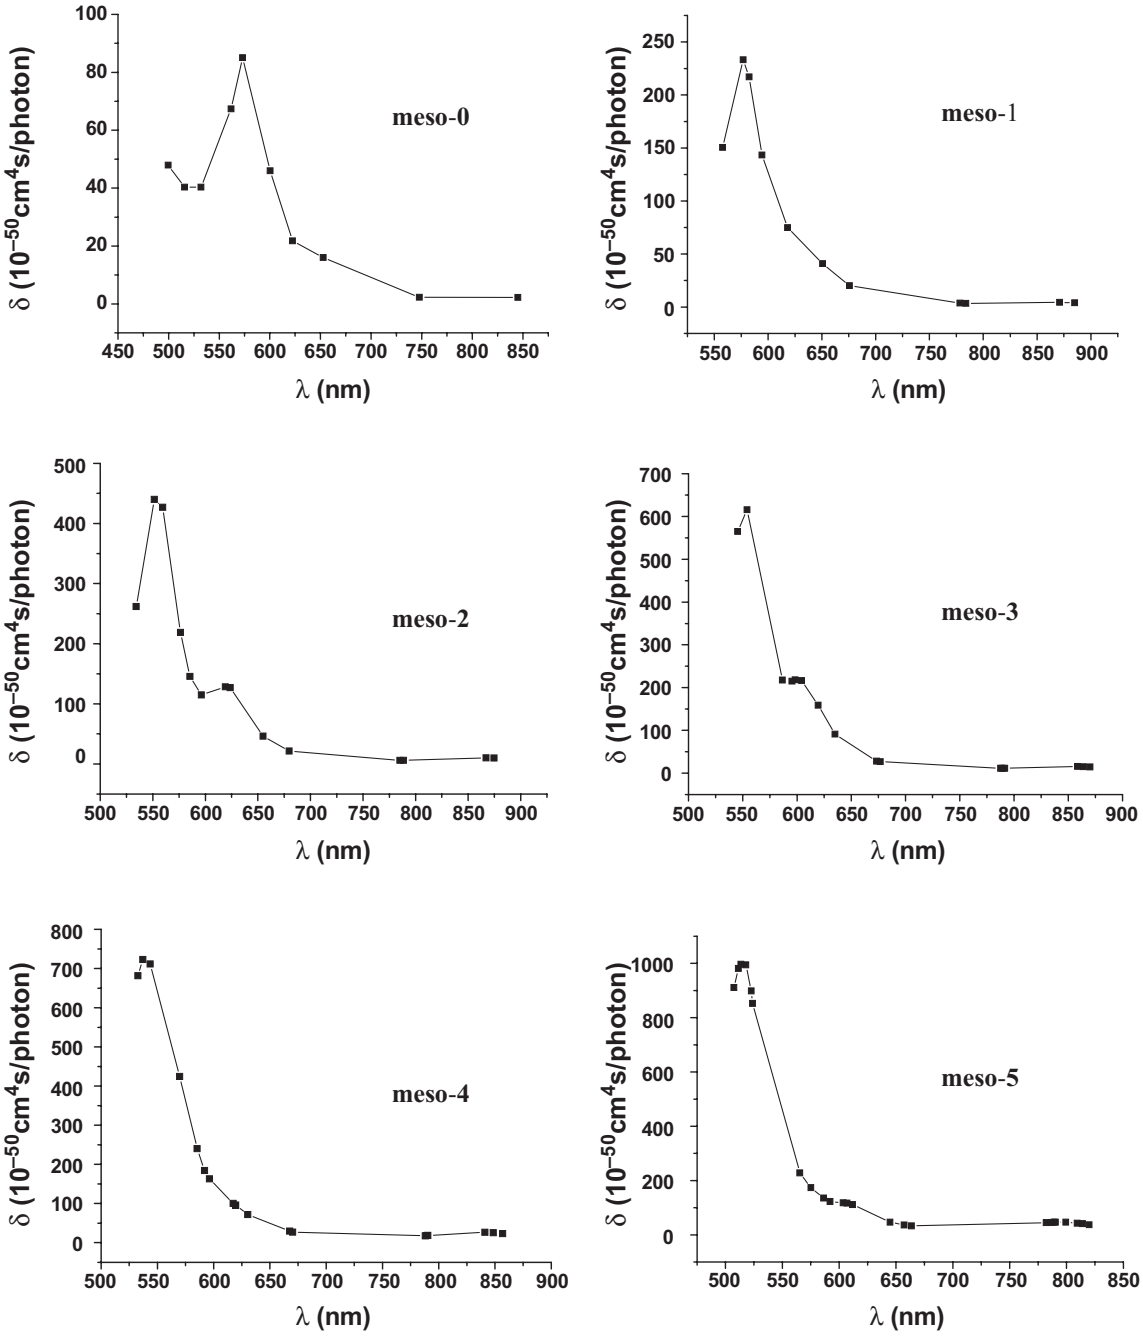
rac-4	608	$S_0 \rightarrow S_{21}$	2406.23	539.92	0.37 (H-6→L+9)
rac-5	606.4	$S_0 \rightarrow S_{24}$	3028	675.45	0.34 (H-8→L+8)

Note: (H-3→L+1) denotes the single excitation from HOMO-3 to LUMO+3.

peaks of the **meso-*n*** (***n* = 0–5**) and **rac-*n*** (***n* = 0–5**) are positioned at 510–580 nm and 570–630 nm, respectively. The molecules **meso-0** and **meso-1** have almost the same TPA positions (573 nm for **meso-0** and 576.8 nm for **meso-1**, respectively). Subsequently, the TPA position of the **meso-*n*** (***n* > 1**) are blue-shifted as the molecular length increases from 576.8 nm for **meso-1** to 513.6 nm for **meso-5**. For the **rac-*n*** (***n*** even or odd), the absorption reaches saturation for **rac-2** or **rac-3** and then slightly blue-shifts as the molecular length increases.

As shown in Tables 5 and 6, the TPA cross sections of the **meso-*n*** and **rac-*n*** increase as the molecular length increases. The enhancement of the TPA cross sections of the **meso-*n*** and **rac-*n*** with the molecular length can be expressed as $\delta_{TPA}(N) = N^{\alpha}\,\delta_{TPA}$ ($N = 1$). To obtain the values of α, we plotted $\lg\delta_{TPA}(N)$ vs. $\lg N$ according to $\lg\delta_{TPA}(N) = \alpha\lg N + \lg\delta_{TPA}(N = 1)$ (Fig. 4) and the linear equations are as follows:

$$\text{L3: } \lg\delta_{TPA}(N) = 1.356\,71 \times \lg N + 1.951\,97 \quad \text{(for } \textbf{meso-}\boldsymbol{n}\text{)}$$



$$\text{L4: } \lg\delta_{TPA}(N) = 2.135\,55 \times \lg N + 1.872\,69 \quad \text{(for } \textbf{rac-}\boldsymbol{n}\text{)}$$

The equations show that α values for the **meso-*n*** and **rac-*n*** are 1.356 71 and 2.135 55, respectively. The calculated equations can be used to predict the values of the TPA cross sections of the **meso-*n*** and **rac-*n*** with different repeat units. We can find from the slope of two straight lines that the slope of L4 is greater than that of L3, indicating the enhancement of the TPA cross section of **rac-*n*** with the molecular length is greater than that of **meso-*n***. P. Najechalski et al. (35) give an approximate explanation of this relationship using the exciton model combined with the three-state expression of the TPA cross section.

In OPAs of **meso-*n***, the high-energy absorption has greater oscillator strength, indicating that the high-energy absorption state can be regarded as the intermediate state of the TPA of the **meso-*n***. For the **rac-*n***, the oscillator strength of the low-energy absorption increases with the molecular length; for ***n* > 2**, the low-energy absorption state becomes the intermediate state of TPA of the **rac-*n***. Though **rac-0** to **rac-5** are noncentrosymmetric molecules, we still use eq. [5] to explain the change of their TPA cross sections because of the smaller dipole moment difference between S_0 and $S_n(\Delta\mu_n)$. According to eq. [5], the excitation energies of the intermediate states (S_k) and the final states (S_n) of TPAs of the **meso-*n*** (***n* = 0–5**) and **rac-*n*** (***n* = 0–5**) and the transition dipole moments of $S_0 \rightarrow S_k$ and $S_k \rightarrow S_n$ (M_{ok} and M_{kn}) are collected in Figs. 5*a* and 5*b*. From eq. [5], it can be found that the TPA cross section is proportional to the squares of M_{ok} and M_{kn} and is inversely proportional to the square of the energy detuning term ($E_{ok} - E_{0n}/2$). As shown in Fig. 5*a*, the increase of TPA cross sections from **meso-0** to **meso-1** is mainly due to the decrease of the excitation energy of the intermediate states E_{0k} (3.75 eV for **meso-0** and 3.52 eV for **meso-1**). For **meso-2** to **meso-5**, the excitation energies of

© 2006 NRC Canada

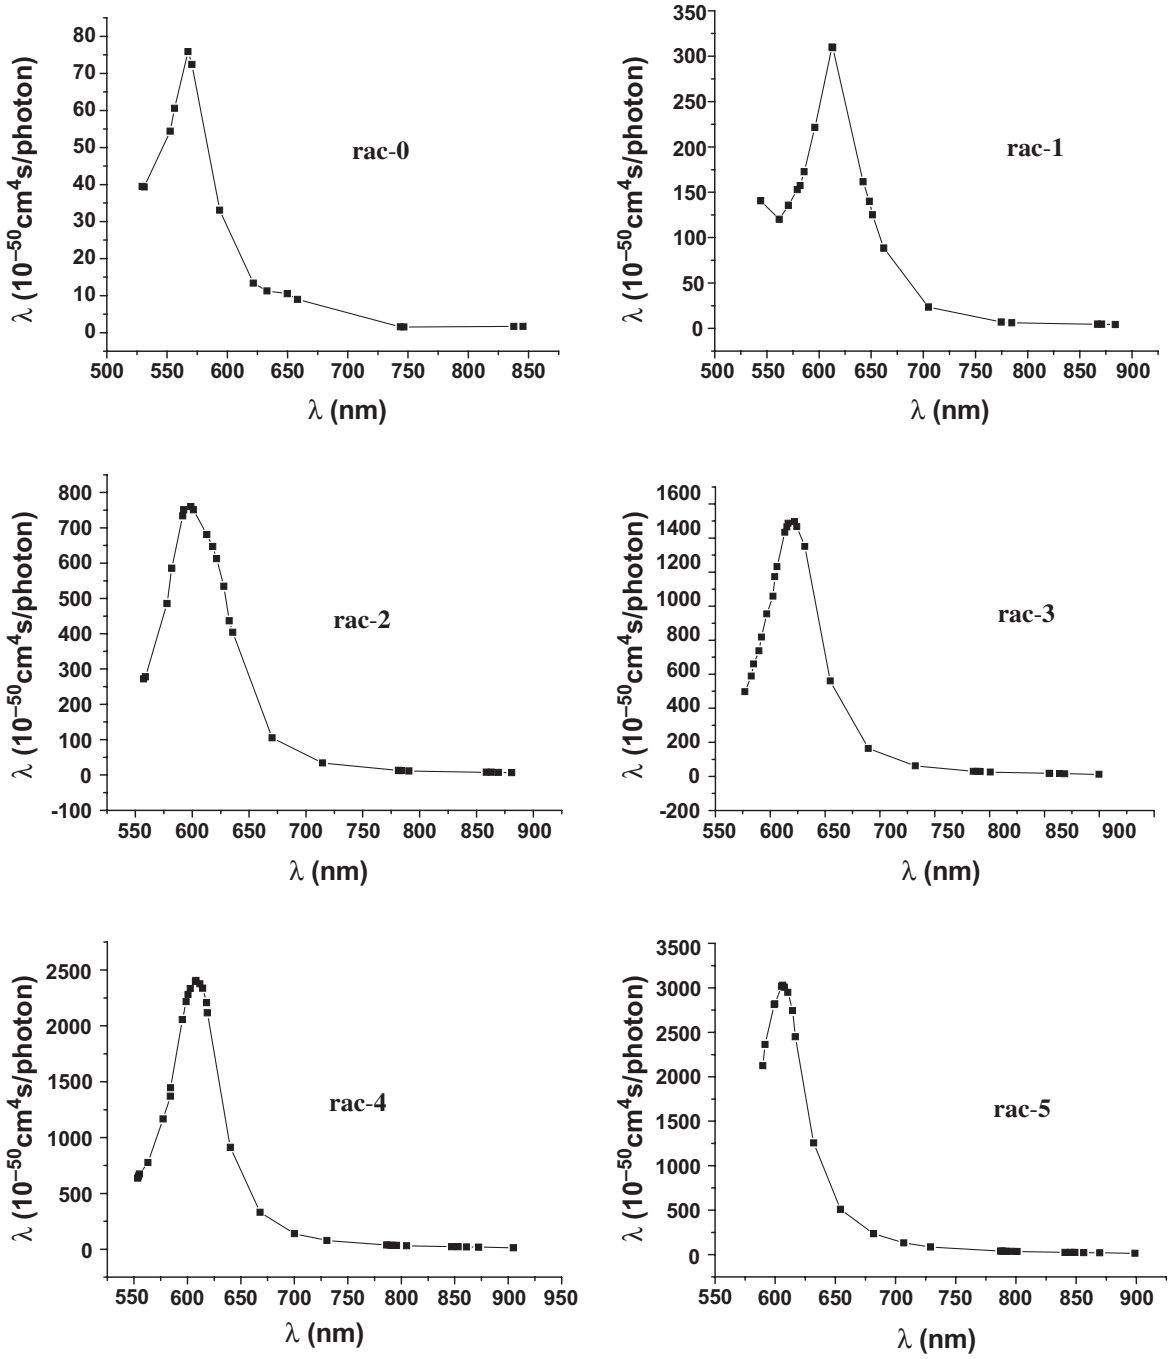


Fig. 3. The OPA and TPA spectra of the oligomers under study.

the intermediate states gradually increase (3.52, 3.60, 3.64, 3.73, and 3.88 eV for **meso-1**, **meso-2**, **meso-3**, **meso-4**, and **meso-5**, respectively). The enhancement of TPA cross section of the **meso-*n*** is mainly ascribed to the increased transition dipole moments M_{0k} (from 6.5 D for **meso-1** to 11.4 D for **meso-5**) and M_{kn} (from 4.8 D for **meso-1** to 12.0 D for **meso-5**). Though the **meso-3** has the largest M_{0k} (12.1 D) and M_{kn} (13.2 D), its TPA cross section is smaller than that of **meso-4** and **meso-5**. This is correlated to the smaller excitation energy of the TPA final state E_{0n} of **meso-3** compared with **meso-4** and **meso-5**. We can see from Fig. 5*b* that the excitation energies of the intermediate states of **rac-2** to **rac-5** are far smaller than that of **rac-0** and **rac-1**, so that **rac-*n*** (***n* > 1**) will have the smaller values of ($E_{0k} - E_{0n}/2$), which are the main reason for the remarkable enhancement of TPA cross sections for **rac-0** or **rac-1** to **rac-*n*** (***n* > 1**). From **rac-2** to **rac-5**, the transition dipole moments M_{0k} and M_{kn} increase with the molecular length and lead to the increased TPA cross sections. As shown in Tables 5 and 6, in comparison with the **meso-*n***, the **rac-*n*** have larger TPA cross sections because of the smaller excitation energy of the intermediate state.

Fig 3 (*concluded*).

It can be seen from Tables 3–6 that the studied ethylene-linked pCp oligomers have good transparency λ^{O}_{max} (< 460 nm) and large TPA cross sections that are proportional to N^{α} (α = 1.35671 for **meso-*n*** and α = 2.13555 for **rac-*n***, respectively). The TPA cross sections of **meso-5** and **rac-5** reach 997.07 GM (1 GM = 1×10^{-50} cm^4 sec) and 3028 GM, respectively. Their maximum OPA wavelengths are 399.7 and 449.4 nm, respectively. Therefore, the olefin-linked paracyclophane oligomers are promising TPA materials in terms of transparency and large third-order nonlinear responses.

Conclusions

In this paper, the electronic structures and the OPA and TPA properties of the olefin-linked paracyclophane oligomers have been studied by using AM1 and ZINDO methods. The results show that the HOMO–LUMO energy gaps of the olefin-linked paracyclophane oligomers are inversely proportional to the molecular length. And a power law $\delta_{TPA}(N) = N^{\alpha}$ δ_{TPA} (α = 1.35671 for the **meso-*n*** and 2.13555 for **rac-*n***) has been obtained. The enhancement of the TPA cross sections

is related to the increase of the transition dipole moments between the ground state and the intermediate state as well as between the intermediate state and the TPA final state and the decrease of the energy detuning term. The olefin-linked paracyclophane oligomers have good transparency and large TPA cross sections and, therefore, are promising TPA materials.

Ionization potentials of nitriles — Photoelectron spectra of succinonitrile and glutaronitrile

Heidi M. Muchall and Nick H. Werstiuk

Abstract: The He(I) photoelectron spectra of succinonitrile (**1**) and glutaronitrile (**2**), both with extensive overlap of ionization bands in the low-energy region, are reported. To assign ionizations, we studied the conformational behaviour and resulting ionization energy dependence of **1** and **2** computationally with the B3LYP/6-31+G(d) model chemistry based on the fact that it reliably reproduces the ionization potentials of eleven mono- and di-nitriles, both saturated and unsaturated. The correlation of proton affinities with observed ionization potentials of **1**, **2**, and malononitrile establishes the orbital sequence of four C≡N π orbitals followed by two nitrogen lone pair orbitals as the highest occupied molecular orbitals for all three compounds.

Key words: photoelectron spectrum, ionization potential, conformational dependence, nitrile, DFT.

Résumé : On a déterminé les spectres photoélectroniques He(I) du succinonitrile (**1**) et du glutaronitrile (**2**) qui présentent tous les deux un recouvrement important des bandes d'ionisation dans la région de basse énergie. Pour attribuer les ionisations, en se basant sur le fait qu'ils permettent de reproduire fidèlement les potentiels d'ionisation de onze mono- et di-nitriles, tant saturés qu'insaturés, on a fait appel à des calculs théoriques au niveau B3LYP/6-31+G(d) pour effectuer une étude du comportement conformationnel des composés **1** et **2** et de la dépendance d'énergie d'ionisation qui en résulte. La corrélation des affinités protoniques avec les potentiels d'ionisation observés pour les composés **1**, **2** et pour le malonitrile permettent d'établir que, pour les trois composés, la séquence orbitalaire des orbitales moléculaires hautes occupées sont les quatre orbitales π du C≡N, suivies par les orbitales de deux orbitales de paires célibataires de l'azote.

Mots clés : spectre photoélectronique, potentiel d'ionisation, dépendance conformationnelle, nitrile, théorie de la théorie de la fonctionnelle de densité.

[Traduit par la Rédaction]

Introduction

This study was prompted by a request for the ionization potentials (IPs) of succinonitrile (**1**), which were needed for a comparison with those from 1,2-dicyanocyclopropanes (1). As explained in the following, the interpretation of the photoelectron (PE) spectrum of **1**, as well as that of glutaronitrile (**2**), turned into the comprehensive study reported here.

Two major problems have been reported with respect to the assignment of ionizations in nitriles. Firstly, Koopmans' theorem (2) seems to break down when model chemistries do not include electron correlation, which affected earlier analyses that made use of semiempirical or Hartree–Fock methods (3). Secondly, hole-mixing effects are reported to potentially further complicate the assignment of ionization events, even though the valence region seems to be little affected (4).

We expected to be able to make use of the methodology that we developed for the reliable calculation of ionization potentials of carbenes (5). The first ionization potential can be readily obtained as the difference in energy between a molecule and its radical cation at the geometry of the molecule (first vertical IP, $IP_{v,1}$) or the optimized radical geometry of the cation (first adiabatic IP, $IP_{a,1}$). Once the difference between the $IP_{v,1}$ and the energy of the highest occupied molecular orbital (HOMO) is added onto the energies of all occupied molecular orbitals, "calculated IPs" are obtained that can be compared to those obtained from a PE spectrum. Because the correlation between the two sets of IPs is usually of high accuracy, with both slopes and correlation coefficients of a linear regression close to 1.0, the calculated values are of tremendous aid in the interpretation of a PE spectrum in the case of multiple overlapping bands. A goal of this study was, therefore, to evaluate whether the low-energy ionizations of nitriles could be calculated reliably at the B3LYP/6-31+G(d) level of theory, as this model chemistry is highly efficient. Numerous PE spectra of nitriles are published and available for comparison with computational data and we chose nitriles **3**–**13** for our study because of their widely varying electronic structures.

In the following, we first evaluate the B3LYP/6-31+G(d) model chemistry for the determination of the low-energy ionization potentials of eleven nitriles, **3**–**13**, whose PE spectra are available in the literature. Next, the PE spectra of **1** and **2** are reported for the first time (to the best of our

 doi:10.1139/V06-141 © 2006 NRC Canada

knowledge) and the assignment of their ionization bands is discussed with particular emphasis on the molecular flexibility and its implications. Finally, the matter of the relative position of π and n type ionizations in the dinitrile series, malono- (**13**), succino- (**1**), and glutaronitrile (**2**), is addressed.

Experimental and computational details

The He(I) photoelectron spectra were recorded on a locally built instrument (6). Linearity of the scale was ensured through calibrations with iodomethane (9.54 and 10.16 eV) (7) and nitrogen (15.60 eV) (7) performed prior to the experiments. To remove water from succinonitrile and glutaronitrile (both purchased from Sigma-Aldrich), samples were pumped in the PE spectrometer at elevated probe temperatures (50–60 °C) and the process was followed by monitoring the PE spectra until the prominent ionization of water at 12.62 eV (7) had disappeared and no further change between subsequent spectra was discernible. The final spectra (averages of 20 scans) were also run with a probe temperature of 50–60 °C with nitrogen as an internal calibrant as well as make-up gas (8) to increase the pressure and improve the signal-to-noise ratio.

All calculations were performed using the Gaussian 98 (9) or Gaussian 03 (10) suite of programs. Geometries of the (protonated) nitriles were fully optimized with the Becke3 (11) – Lee, Young, and Parr (12) hybrid density functional (B3LYP) with the 6-31+G(d) basis set; only indicated torsional angles were frozen in the torsional analyses. All minima were confirmed by harmonic vibrational frequency analyses and wave functions were checked for stability. Synthetic spectra were generated with a Fortran program PESPEC (13). The temperature was set to 300 K and ionization potentials are convoluted with a Gaussian line-shape with a full width at half height of 0.2. Molecular orbitals were plotted using GaussView 3.0 (14). All energies, total and otherwise, used in the calculation of ionization potentials and proton affinities are given in Table S1 in the Supplementary Information.[2]

Results and discussion

Ionization potentials of nitriles 3–13

We decided to use the already published PE spectra of eleven mono- and di-nitriles, saturated and unsaturated, to evaluate our methodology for the calculation of ionization potentials (5). The prominent low-energy ionizations from n and π orbitals of **3**–**13** and ionizations from the onset of the σ-region reported in the literature are given in Table 1. We have calculated the first vertical ionization potentials ($IP_{v,1}$) of **3**–**13**. These are also given in Table 1 together with the calculated orbital energies ε and calculated IPs (obtained as explained in the introduction and in a footnote in Table 1).

As can be seen from Table 1, our calculated values for $IP_{v,1}$ are within 0.5 eV of the experimental values and in many cases the deviation is significantly less. Overall there is a very good agreement between experimental and calculated $IP_{v,1}$ with a correlation coefficient R^2 of 0.9664.

Individual plots of calculated vs. experimental IP_v for mononitriles **3**–**5** (10 data points) and alkenes **6**–**9** (25 data points) suggest that two of the values reported in the literature should be revised. In Fig. 1*a*, the fifth ionization for propionitrile (**5**), reported at 14.25 eV (7) and indicated with the symbol ×, is more likely to be at 13.8 eV and a close re-examination of the PE spectrum seems to confirm this. This suggested shift, pointed out by the arrow in Fig. 1*a*, improves the correlation coefficient from 0.9781 to 0.9884. In Fig. 1*b*, the third ionization for alkene **9**, reported at 13.35 eV (indicated with the symbol ×) (15), should probably be at a smaller value. While the onset of the second band in the PE spectra of alkenes **6**–**8** is sharp and starts from the baseline, there seems to be a shoulder on the low-energy side of the second band in the PE spectrum of **9**, indicating a somewhat broader ionization band under the one given at 12.77 eV (15). We suggest that the third ionization should then be located at 12.8 eV instead, which improves the correlation coefficient from 0.9684 to 0.9818.

In Fig. 2, we show the plot of calculated vs. experimental IP_v with the previously mentioned revised values for nitriles **3**–**13**. With a slope of close to one and an intercept near

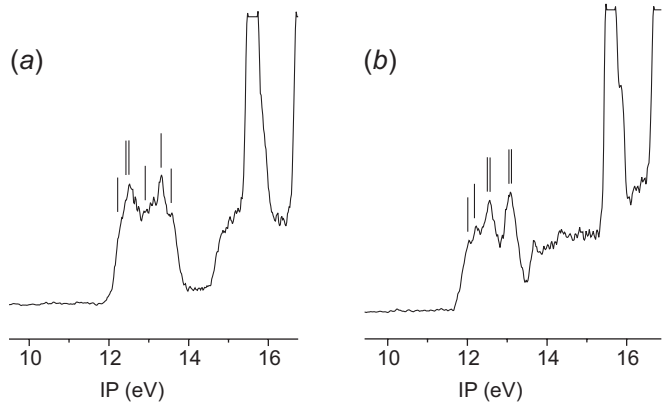
zero, this correlation demonstrates that our choice of model chemistry reliably reproduces the vertical ionization potentials of nitriles. Neither a larger basis set (6-311+G(2d,p)) nor a switch to the Perdew–Burke–Ernzerhof (PBE0) (18) functional with either basis set produced a significant improvement over the results presented here (we performed calculations on selected nitriles only; the results for $IP_{v,1}$ are given in Table S2 in the Supplementary Information).[2]

Photoelectron spectra of 1 and 2

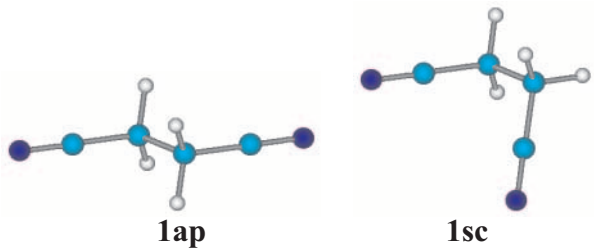
The recorded photoelectron spectra of **1** and **2** are reported in Fig. 3. Owing to the relatively low vapour pressure of both **1** and **2** even at 50–60 °C, nitrogen was used as a make-up gas during the acquisition of the spectra. The intense first ionization of nitrogen at 15.6 eV is cut off arbitrarily in both spectra in Fig. 3. Both spectra exhibit extensive overlap of multiple ionization bands in the low-energy region (below 15 eV for **1** and below 13.5 eV for **2**) and an interpretation of the spectra is only possible with the help of computational results. Accordingly, the assignment of the observed bands for **1** and **2** is performed in the following sections, taking the calculated ionization potentials and conformational flexibility of the molecules into account. The resulting interpretation in terms of low-energy ionization bands of **1** and **2** is given in Tables 2 and 3 and as vertical bars in Fig. 3.



Interpretation of the PE spectra of 1 and 2

While nitriles **3**–**13** do not possess conformational flexibility (apart from methyl group rotations that are irrelevant for our purposes), **1** and **2** can exist in several conformations and this can affect the appearance of the PE spectra if the conformers are close in energy and their orbital energies differ sufficiently (19, 20).

Succinonitrile (1)



The conformations of **1** have been studied computationally with ab initio methods as early as 1978 (21), with even earlier work on its torsional potential (22). For **1**, a 1,2-disubstituted ethane, two low-energy conformations can be identified, antiperiplanar **1ap** and synclinal **1sc**. While **1sc**

Fig. 3. He(I) photoelectron spectra of (*a*) succinonitrile (**1**) and (*b*) glutaronitrile (**2**). The N_2 (make-up gas) signal at 15.6 eV is cut off. Assigned band positions are given by vertical bars.

(C–C–C–C torsional angle is 69° with B3LYP/6-31+G(d), 75° from experiment (23)) is the form present in the solid below –43.7 °C (24, 25), in the gas phase we calculate a destabilization with respect to **1ap** of 1.2 kcal/mol (B3LYP/6-31+G(d) based on either electronic energies or Gibbs free energies, 1 cal = 4.184 J) in line with an early prediction (25). We find a similar destabilization of 1.1 kcal/mol with B3LYP/6-311+G(2d,p) and PBE0/6-311+G(2d,p) model chemistries, thus confirming that the smaller basis set is adequate for the description of **1**. The energy difference leads to an equilibrium population of 78% **1ap** and 22% **1sc** (combined amount for the two indistinguishable conformers +sc and –sc) at 300 K, which is in excellent agreement with the 74% **ap** equilibrium at 170 °C found by electron diffraction in the gas phase (23).

Table 2 gives the calculated orbital energies and ionization potentials of **1ap** and **1sc** and it is obvious that even a small amount of **1sc** in the equilibrium should influence the appearance of the PE spectrum of **1**. To assess the IP dependence on the change in torsional angle that converts **1ap** into **1sc**, we have performed a relaxed potential energy scan twisting the C–C–C–C torsional angle through 180° and optimizing the rest of the molecule. The plot is shown in Fig. 4 for the first six calculated IPs (energies for HOMO to HOMO–5 shifted so that the HOMO energy for a torsional angle equals its first vertical ionization potential), which correspond to ionizations from the characteristic nitrile π and n orbitals. Orbital energies and calculated IPs for the different torsional angles are given in Table S3 in the Supplementary Information.[2] Figure 4 demonstrates the predicted significant changes in IPs upon twisting of **1**. Plots of the molecular orbitals of the C_{2h}-symmetrical **1ap** are given in Fig. 5; the order of the orbitals is the same in **1sc**. HOMO to HOMO–3

are π type orbitals with additional coefficients on the linking CH_2 groups; HOMO–4 and HOMO–5 are the two lone pair combinations, n_N^+ and n_N^-. Ionizations arising from HOMO–1 and HOMO–2, the two out-of-plane orbitals π^-_{CNoop} and π^+_{CNoop}, as well as those from n_N^+ and n_N^- show only a small splitting that could be attributed to through-bond interactions in the molecular orbitals. On the other hand, ionizations from HOMO and HOMO–3, the two in-plane orbitals π^+_{CNip} and π^-_{CNip}, exhibit a somewhat constant splitting of about 0.4 eV throughout the torsion.

The fitted potential for the torsion in **1** is shown in Fig. 6*a* and we have simulated the PE spectrum of **1**, given in Fig. 6*b*, based on this potential and the six IPs given in Fig. 4. A comparison between the experimental and the simulated spectrum shows good agreement in the low-energy part and it can be seen that six ionizations lie under the first two broad bands in the experimental spectrum of **1** (Fig. 3*a*). As well, the simulated spectrum suggests that the first ionization in Fig. 3*a* should not be attributed to the maximum of the first band (12.5 eV) but rather to a shoulder on its low-energy side at 12.3 eV. The first adiabatic IP (IP_a) of **1** is at 11.9 eV (Fig. 3*a*) and so the experimentally determined energy gap between first IP_a and IP_v of 0.4 eV matches the calculated one (the IP_a calculated for **1ap** from 0–K enthalpies is 11.52 eV).

The final band assignment for the ionizations of **1** is given in Table 2 and their position as vertical bars in Fig. 3*a*. As a final note, and keeping in mind that the discrimination in count rate between high- and low-energy electrons is different for the two spectrometers used, our spectrum of **1** resembles that of *trans*-1,2-dicyanocyclopropane (**14**) (1) with one fundamental exception. The major difference is caused by the stabilization of HOMO and HOMO–1 of **1** as compared to these orbitals in **14** by 0.8 and 0.5 eV, respectively, because in **14** π_{CN} coefficients on the two nitrile groups are combined with two high-lying Walsh orbitals of the cyclopropyl group, ω_S and ω_A. The stabilization of the two orbitals in **1** leads to a shift of the first two ionizations towards higher potentials and the subsequent extensive overlap

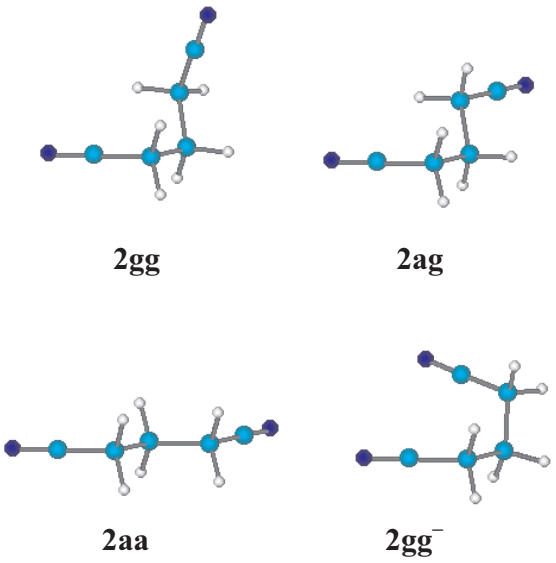
of bands in the spectrum of **1** that is not present in the spectrum of **14**.



Glutaronitrile (2)

For **2**, a 1,3-disubstituted propane, there are two torsional angles and conformations can be described as antiperiplanar (a) or synclinal/gauche (g) for either substituent (26) or using the trans (T) and gauche (G) notation in the older literature (27). The four possible conformers for **2** from B3LYP/631+G(d) electronic energies are **2gg** (global minimum), **2ag** (+0.4 kcal/mol), **2aa** (+1.0 kcal/mol), and **2gg**$^{-}$ (+3.8 kcal/mol). From these relative stabilities, with a statistical weight of two for a **gg** and four for an **ag** conformer, at 300 K the equilibrium is composed of 48% **2gg**, 47% **2ag**, and 5% **2aa**. The conformer **2gg**$^{-}$ is too high in energy to contribute significantly.[3] An approximately equimolar mixture of **2gg** and **2ag** was also reported from an electron diffraction study at 448 K in the gas phase, but evidence for the presence of a small amount of **2aa** was not found (28).

The MO sequence in the C_2-symmetrical **2gg** is π^{+}_{CNip} (a symmetry), π^{-}_{CNoop} (b symmetry), π^{-}_{CNip} (b), π^{+}_{CNoop} (a), n_N^{-} (b), n_N^{+} (a). Pictures of the orbitals are similar to those given in Fig. 5. Some of these combinations are lost in **2ag** and π and n orbitals are localized on the individual CN groups, π^{+}_{CN}, π_{CN}, π_{CN}, π^{-}_{CN}, n_N, n_N. Table 3 shows that orbital energies for the two conformers are very similar. To simulate the PE spectrum of **2**, two torsional angles would have to be considered, a CN–C–C–C that converts **2gg** into **2ag** and another for conversion of **2gg** into **2aa**. We have checked the orbital energy dependence on the CN–C–C–C torsional angle that relates the two major contributors, **2gg** and **2ag**. Not surprisingly, we find the dependence to be sim-

[3] As **2gg** and **2ag** are approximately equal in energy, their equilibrium composition is about 1:1. This does not change when Gibbs free energies are considered even though **2ag** is now more stable by 0.1 kcal/mol.

© 2006 NRC Canada

ilar to that in **1** but less pronounced (plot not shown). For these reasons we have not simulated the PE spectrum of **2**.

With its onset (IP_a) at 11.7 eV and its maximum (IP_v) at 12.0 eV (Fig. 3*b*), the slope of the first ionization band is similar to that in the spectrum of **1**. Unlike for **1**, though, the adiabatic first IP for **2** is more difficult to assess computationally. A radical cation with a geometry close to that of **2gg** does not exist at the B3LYP/6-31+G(d) level and removal of an electron from **2gg** and geometry optimization leads to the transition state for a double hydride transfer instead. The calcd. IP_a for **2ag** (for which the optimized radical cation is a proper minimum) is 11.04 eV and with calculated IP_v values of 11.45 for **2gg** and 11.36 eV for **2ag**, the width-at-half-height of the first ionization band should be as is found experimentally. Overall, because of the similar IPs of **2gg** and **2ag** the presence of a second major conformer, be it **2gg** or **2ag**, is not detectable. Because **2aa** only contributes 5% to the equilibrium, its presence would only be noticeable if its first ionization potential were considerably lower than those of **2gg** and **2ag**. Table 3 shows that this is not the case. The final band assignment for the ionizations of **2** is given in Table 3 and their position as vertical bars in Fig. 3*b*.

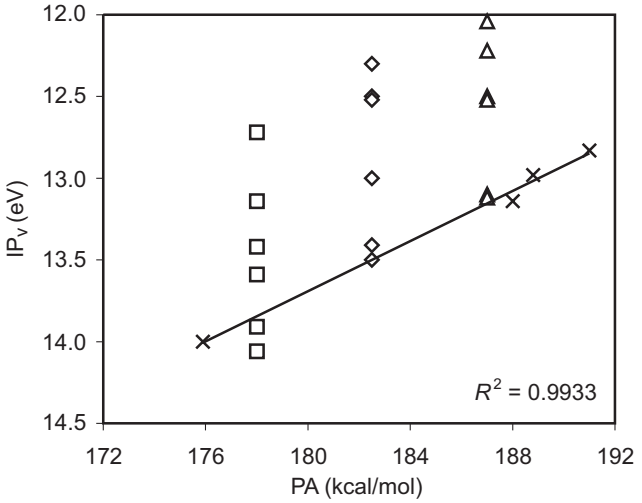
Lone pair ionizations in dinitriles 1, 2, and 13

The question of which are the lone pair ionizations in **1** and **2** is easier to answer than in malononitrile (**13**), for which several orbital sequences have been given (4, 17, 29, 30). For **1**, the two n_N ionizations are degenerate at a C–C–C–C torsional angle of 90° (Fig. 4) and so the orbital energy dependence confirms the assignment given in Fig. 5. For **2**, the two functional groups are far enough apart that they show hardly any interaction and consequently the energy gap between π and n ionizations (0.7 eV calculated for **2gg**) is similarly pronounced as those in the mononitriles **4** and **5** (0.9 eV calculated). In contrast, the reported order of orbitals and peak assignments for the first six ionization bands in **13** varies from π, π, n_N^+, n_N^-, π, π (29) to π, π, π, n_N^+, n_N^-, π (17) to π, π, π, π, n^-, n^+ (4); i.e., the potentials for the lone pair ionizations are progressively increased.

Staley et al. (30) have shown a linear correlation between the proton affinity (PA) of a nitrile and its n_N ionization potential. While the data points for most mononitriles investigated (among these **3**–**6**) fall close to the correlation line, the two IPs for the dinitrile **13** (n_N^+ and n_N^-) are 6 and 10 kcal/mol too small when the original orbital sequence from Stafast and Bock (29) is used (30). This, among other reasons, led to a reassignment of the orbital order (17). We decided to use a similar correlation that would include **1** and **2** to confirm the orbital sequences we determined earlier. Calculating the proton affinity as the difference between the 0–K enthalpies of the neutral and protonated molecules (for our purposes we can ignore temperature effects (31)), we find a good linear correlation ($y = 1.419x - 82.83$, values in kcal/mol, $R^2 = 0.9945$, raw data are given in Table S4 in the Supplementary information)[2] between calculated and experimental PAs for the mononitriles **3**–**6**. From this, our calculated PAs for **1ap** (176.2 kcal/mol) and **2gg** (182.6 kcal/mol) give estimated experimental PAs of 182.5 and 187.0 kcal/mol, respectively. With these values, Fig. 7 allows the confirmation of the assigned lone pair ionizations in **1** and **2**. It shows good linear correlation between the experimental n_N ionization potential (Table 1) and the experimental PA of nitriles **3**–**6** (30). Superimposed are the first six ionization potentials of **1** and **2** at their estimated experimental PAs. Clearly, IPs around 13.5 eV for **1** and around 13.2 eV for **2** lie close to the regression line, confirming our assignment of these IPs to n_N orbitals. In addition, Fig. 7 seems to support the orbital assignment of Cambi and von Niessen for **13**, with four π orbitals followed by two n_N orbitals (4). At an experimental PA of 178.0 kcal/mol, the fifth ionization, attributed to the higher-lying lone pair combination, lies close to the correlation line. The orbital sequence of **13** is thus in perfect agreement with that given above for both **1** and **2**.

Conclusions

We have presented the He(I) photoelectron spectra of succinonitrile (**1**) and glutaronitrile (**2**). Even though the low-energy regions of both spectra exhibit extensive overlap of bands, it is possible to assign individual bands with the aid of calculated ionization potentials. Both **1** and **2** exhibit four π orbitals followed by two nonbonding orbitals as the six highest occupied molecular orbitals. This orbital sequence was also established for the related malononitrile.



Finally, for nitriles of varying electronic structure (mono- and di-nitriles, either saturated or unsaturated), the B3LYP/6-31+G(d) model chemistry allows vertical ionization potentials to be reproduced reliably. A violation of Koopmans' theorem for dinitriles is not found with this density functional theory method.

Electrochemically formed passive layers on titanium — Preparation and biocompatibility assessment in Hank's balanced salt solution

Baodong Zhao and Gregory Jerkiewicz

Abstract: Uniform and crack-free passive layers on Ti are prepared using AC voltage in 7.5 wt.% aq. $NH_4{\cdot}BF_4$ at 25 °C. The passive layers possess coloration (wide spectrum of colors) that depends on the experimental conditions. The biocompatibility of such prepared passive layers is evaluated using corrosion science and analytical techniques. Their corrosion behavior, Ti-ion release, surface roughness, and wettability in Hank's Balanced Salt Solution (HBSS) at 37 °C are the main focus of this work. Open-circuit potential and polarization measurements demonstrate that the corrosion potential (E_{corr}) of the passive layers becomes more positive than that of the untreated Ti. The value of E_{corr} increases as we increase the AC voltage (V_{AC}). Their corrosion rate (CR) is lower than that of the untreated Ti, and they reduced the Ti-ion release level from 230 to 15 ppb. An increase in the AC voltage frequency (f) leads to a slightly higher level of the Ti-ion release (~50 ppb). Surface profilometry, optical microscopy, and scanning electron microscopy (SEM) analyses show that prolonged exposure of the passive layers to HBSS results in changes to their surface topography. The passive layers prepared by the application of AC voltage are rougher and more hydrophilic than the untreated Ti. Our methodology of preparing biocompatible passive layers on Ti might be applied as a new surface treatment procedure for Ti implants.

Key words: titanium, metal surface treatment, surface roughness, corrosion, metal ion release, contact angle.

Résumé : Utilisant un voltage de courant alternatif dans une solution aqueuse à 7,5% (p/p) de $NH_4{\cdot}BF_4$, à 25 °C, on a préparé des couches passives uniformes et sans fissure sur du titane. Les couches passives possèdent des colorations qui s'étalent sur un large spectre de couleur et qui dépendent des conditions expérimentales. On a évalué la biocompatibilité des couches passives préparées de cette façon en faisant appel à la science de la corrosion et des techniques analytiques. Les orientations principales de cette étude sont le comportement de corrosion, la libération d'ion de titane, la rugosité de leur surface et la capacité de mouillage dans une solution de sel balancée de Hanck (SSBH) , à 37 °C. Le potentiel en circuit ouvert et les mesures de polarisation démontrent que le potentiel de corrosion (E_{corr}) des couches passives devient plus positif que celui du titane qui n'a pas été traité. La valeur de E_{corr} augmente avec une augmentation du voltage du courant alternatif (V_{CA}). Leur vitesse de corrosion (VC) est inférieure à celle du titane qui n'a pas été traité et le niveau de libération du titane est réduit de 230 à 15 ppb. Une augmentation de la fréquence (f) du voltage du courant alternatif conduit à un niveau légèrement supérieur de libération de l'ion titane (~50 ppb). Des analyses de profilométrie de surface, de microscopie optique et de microscopie électronique à balayage (MEB) montrent que des expositions prolongées des couches passives à une SSBH conduit à des changements de la topographie de la surface. Les couches passives préparées par l'application d'un voltage de courant alternatif sont plus rugueuses et plus hydrophiles que le titane qui n'a pas été traité. Il est possible que notre méthodologie de préparation de couches passives biocompatibles puisse trouver une application dans le développement d'une nouvelle façon de produire des implants au titane.

Mots clés : titane, traitement de la surface métallique, rugosité de la surface, corrosion, libération d'ion métallique, angle de contact.

Introduction

Titanium of commercial purity (CP) and its alloys are widely used as biomedical materials and find applications in bone and joint replacement, orthopedic treatment, dental implants, cardiovascular devices, external prostheses, and surgical instruments because of their suitable chemical, physical, and biological properties (1). The biological response of the human body to implant materials is directly related to their interfacial properties. Corrosion resistance, metal-ion release, surface roughness, and wettability are

 doi:10.1139/V06-142 © 2006 NRC Canada

among the most important properties that need to be considered in the fabrication and surface treatment of new biomaterials. The two main factors that determine the biocompatibility of a material are the host reaction induced by the material and the material's degradation in the body environment (2). Corrosion of the implanted metal by the body fluids changes its mechanical and interfacial properties and results in the release of undesired metal ions. The latter may interfere in physiological processes and subsequently induce rejection reactions, such as toxicity and allergy (3, 4). This is why metallic implants are selected based on their corrosion resistance or their ability to form a protective passive film. It was reported that in some cases large amounts of Ti compounds are found in tissues surrounding the implant device (5, 6), in spite of its good corrosion resistance. Suitable surface modification procedures are indispensable prior to the application of Ti or Ti-based alloys as implants, and surface treatment and biocompatibility evaluation of these materials have been a subject of extensive research (5–18).

The oxide layer that covers Ti is very stable and determines the corrosion behavior of Ti implants and their high tissue compatibility. Surface treatment procedures modify the composition, morphology, and thickness of the oxide layer; thus, they subsequently influence the corrosion behavior of such treated implants. It is the oxide's uniformity and chemical stability that are predominant factors in the protection of implants against biological corrosion. The corrosion resistance of implants does not only depend on the oxide's thickness (15).

Several different surface treatment methods have been used to improve the corrosion resistance and biocompatibility of Ti and Ti-based alloys. Thermal treatment involves heating at an elevated temperature, and oxides formed under such conditions lack uniformity or deform and subsequently cause swelling or cracking of the oxide layer due to the differing thermal expansion coefficients of Ti and its oxide. These phenomena are of major concern in the design and preparation of biocompatible passive layers. Electrochemical techniques have advantages over other surface treatment methods. They can be applied at the ambient temperature and form passive layers that are highly adhesive, uniform, and crack-free. In addition, typical electrochemical instrumentation and procedures are relatively simple and facilitate the formation of compact passive layers within seconds or minutes. Moreover, electrochemical methods allow one to easily control the oxide thickness.

Our previous work (19, 20) indicated that brightly and uniformly colored passive layers on Ti can be obtained by the application of AC (alternating current) voltage in aqueous $NH_4{\cdot}BF_4$. The coloration and thickness of these passive layers can be controlled by varying the concentration and pH of the electrolyte, adjusting the separation between electrodes, selecting the passivation time, and tuning the magnitude of the applied AC voltage. We examined the morphology, chemical composition, and electrochemical characteristics of the colored Ti passive layers using scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS), and electrochemical techniques. We concluded that the coloration of the passive layers originated from iridescence; thus, depended on their thickness. We also reported a linear relation between the oxide thickness (that is in the 50–310 nm range) and the applied AC voltage (V_{AC}, from 10 to 60 V_{AC}). XPS measurements showed that Ti^{z+} (z varies from 4 to 2 depending on the layer depth), O^{2-}, and F^- were the main constituents of the passive layers. We also determined that the colored passive layers on Ti were more corrosion resistant than Ti in 1.0 mol/L aq. H_2SO_4.

In this paper, we report new results that show how the frequency of the AC voltage affects the visual properties, thickness, and morphology of the passive layers. We analyze the influence of different pretreatments (such as etching, micro-sandblasting, and polishing) on their surface morphology, and study their biocompatibility by evaluating their biocorrosion behavior, Ti-ion release, surface roughness, and wettability in Hank's Balanced Salt Solution (HBSS) at 37 °C. Finally, we compare these results with those obtained for the untreated Ti.

Experimental

Preparation of Ti specimens

We used disc- and wire-shaped titanium specimens. The disc specimens were used to study the surface morphology and wettability, and to examine the Ti-ion release in immersion tests; whereas the wire specimens were used for electrochemical characterization that primarily involved monitoring the open-circuit potential and recording polarization curves. The disc specimens were prepared from a Ti foil (Johnson-Matthey, Ward Hill, MA, USA, 99.7% Ti, 0.0875% Fe, 0.1225% O, 0.0015% N, 0.0095% C, 0.0023% H) and were 13.0 mm in diameter and 0.89 mm in thickness; their geometric surface area was 3.0 cm^2. They were spot-welded to a Ti wire of 0.81 mm in diameter (Johnson-Matthey, Ward-Hill, MA, USA, 99.7% Ti, 0.031% Fe, 0.012% C, 0.009% N, 0.054% O, 0.0047% H) for electrical contact. The Ti wire was insulated with shrinkable Teflon and sealed at the connection point using epoxy resin. The wire-shaped specimens were prepared from a Ti wire (Johnson-Matthey, Ward Hill, MA, USA, composition as above) of 0.81 mm in diameter. They were connected to a copper wire using a special electrical connector and sealed at the connection point using epoxy resin. The Cu wire was insolated and never left in contact with the electrolyte. The Ti wire was cut to a length of 10.0 mm, and the cut surface was mechanically polished with 2400 grade silicon carbide grinding paper using a mechanical polisher (Struers, Copenhagen, Denmark) to obtain a flat end. These wire specimens were pretreated according to the following procedure: (*i*) degreasing in acetone under reflux for 2 h to remove any organic impurities and rinsing with Nanopure water (Millipore, Molshem, France); (*ii*) etching for 5 min in a HNO_3–HF solution, or (*ii′*) micro-sandblasting with 90 μm aluminum oxide using a Macro Cab (Danville Engineering, Inc., San Ramon, CA, USA) micro-sandblaster, or (*ii″*) mechanical polishing (in the case of Ti discs only) with 4000 grade silicon carbide grinding paper; and (*iii*) rinsing with Nanopure water, sonicating for 5 min in an ultrasonic bath (Branson, Danbury, CT, USA), and drying in the air.

© 2006 NRC Canada

Formation of passive layers

Titanium disc- and wire-shaped specimens, prepared according to the previous procedure, were placed in a single-compartment electrochemical cell containing 7.5 wt.% aq. $NH_4{\cdot}BF_4$ at 25 °C, and were passivated using either AC or DC voltages. The AC voltage was applied using a variable AC power supply (3KVA AC Power Source Model 3001iM, 0–300 V, 16–500 Hz, California Instruments, San Diego, CA, USA), while the DC voltage was applied using a DC power supply (Kepco, Flushing, NY, USA, 0–125 V). The counter electrode was a Pt foil (Johnson-Matthey, Ward Hill, MA, USA, 99.99%) in the case of wire-shaped specimens and a Ti foil (Johnson-Matthey, Ward Hill, MA, USA, 99.7% Ti) in the case of disc-shaped specimens. The separation between the Ti specimen and the counter electrode was ~10 cm, which was sufficient to allow for effective circulation of the electrolyte between the electrodes and for removal of the gases generated during the passivation. The passivation time was 10 s. To obtain uniform oxide thickness and coloration of the Ti specimens, the passivation was performed at well-controlled temperature conditions, i.e., the temperature was maintained at 25 °C using water circulation (Haake, Thermal Electron Corporation, Waltham, MA, USA) and the electrolyte was rigorously stirred using a magnetic stirrer. Following the passivation, the Ti specimens were rinsed with Nanopure water and sonicated for 5 min in an ultrasonic bath. This procedure ensured good reproducibility of the experimental results.

Surface morphology analysis

The uniformity of the surface coloration and the morphology of the colored Ti passive layers were examined by means of optical microscopy (SEIWA Optical, Correct Metallurgical Microscope, SDM-TR, Tokyo, Japan) and scanning electron microscopy (MICROLAB 310-F, Thermo Electron Co., East Grinstead, West Sussex, England). The average surface roughness (R_a) of the specimens prior to and after the passivation as well as after the immersion test was measured using a stylus surface profiler (Dektak8, Veeco, Veeco Tucson Inc., Tucson, AZ, USA). In the case of the surface profilometry data, we report a mean R_a value of at least 10 reproducible individual measurements.

Potentiodynamic polarization test

Potentiostatic polarization tests were carried out using a Princeton Applied Research (PAR) 263A Potentiostat and a standard three-compartment electrochemical cell. The PAR PowerCorr electrochemical software package was used to control the experimental parameters, and to collect and process the data. Platinum gauze served as a counter electrode, and its surface area was at least five times that of the working electrode to minimize any polarizability effects. A saturated calomel electrode (SCE) was used as a reference electrode. The electrolyte used in the tests was HBSS, that is, a simulated body fluid of the following composition: NaCl: 8.00 g L^{-1}; KCl: 0.40 g L^{-1}; $NaHCO_3$: 0.35 g L^{-1}; KH_2PO_4: 0.06 g L^{-1}; Na_2HPO_4: 0.0475 g L^{-1}; glucose: 1.00 g L^{-1}; and pH: 7.4 (13). The electrolyte was held at a constant temperature of 37 °C by immersing the cell in a Haake water bath. We followed the ASTM G5 standard test method in our measurements (21). The electrolyte was deaerated with ultra-high purity (UHP) N_2 for at least 1 h before immersing the test specimen in it, and the purging was maintained during the test. The open circuit potential, i.e., the corrosion potential (E_{corr}) of the test specimen, was continuously recorded for 1 h, starting immediately after the specimen's immersion. Potentiodynamic polarization transients were recorded by conducting a forward scan from a potential that was 0.25 V below E_{corr} up to an upper limit of 3.00 V vs. SCE at a scan rate of 0.166 mV s^{-1}. Tafel extrapolation was done in the ±0.25 V range of E_{corr} (E_{corr} – 0.25; E_{corr} + 0.25) in accordance with the procedure described by S. Hrapovic and co-workers (20); the anodic and cathodic Tafel parameters (β_A and β_C, respectively) were determined. The polarization resistance (R_P) was determined on the basis of potentiodynamic polarization resistance curves in the potential range (E_{corr} – 0.20; E_{corr} + 0.20) (21–24). Then, the corrosion current density (i_{corr}) in μA cm^{-2} and the corrosion rate (CR) in μm $year^{-1}$ at E_{corr} were calculated using the PowerCorr software. This program uses the Stern–Geary equation, the relation between CR and i_{corr}, the values of β_A, β_C, R_P, equivalent weight (EW) in g, the surface area, and the density of the test specimen (eqs. [1–3]).

$$[1] \qquad I_{corr} = \frac{\beta_A \beta_C}{2.3 R_P (\beta_A + \beta_C)}$$

$$[2] \qquad CR = \frac{3.27 i_{corr} EW}{d}$$

$$[3] \qquad EW = \frac{1}{N_{EQ}} = \frac{1}{\sum_i \left(\frac{f_i n_i}{a_i} \right)}$$

where d is the metal or alloy density in g cm^{-3}, N_{EQ} is the total number of equivalents, f_i is the mass fraction, a_i is the atomic weight, and n_i is the number of electrons exchanged. According to the AMS standards (24), the value of EW for Ti is 16 under reducing acid conditions and 12 under oxidizing conditions. These values are determined based on the assumption that the corrosion rate is uniform across the entire Ti surface. Finally, in these measurements, all i_{corr} values are reported with respect to the geometric surface area of the specimens. The E_{corr}, R_P, and CR values are the mean values of at least three reproducible individual measurements with a maximum uncertainty of 10%.

Immersion test and the Ti-ion release analysis

The disc-shaped specimens (3.0 cm^2) were placed in test tubes each containing 40.0 mL of HBSS and sealed with a silicone stopper. The specimens were suspended in the solution by using an insulated Ti wire attached to the silicone stopper to avoid any contact of the specimens with the test tube. The test tubes were immersed in a Haake water bath maintained at 37 °C. The specimens were taken out of the test tubes after 2 weeks, and a 2.0 mL aliquot of concentrated nitric acid was added to each tube to maintain low pH and to prevent any precipitation of insoluble Ti compounds. An inductively coupled plasma mass spectrometer (ICP-MS, Renaissance, LECO, St. Joseph, MI, USA) was used to measure the amount of Ti ions released during the immersion test. The detection limit of Ti was 0.5 ppb.

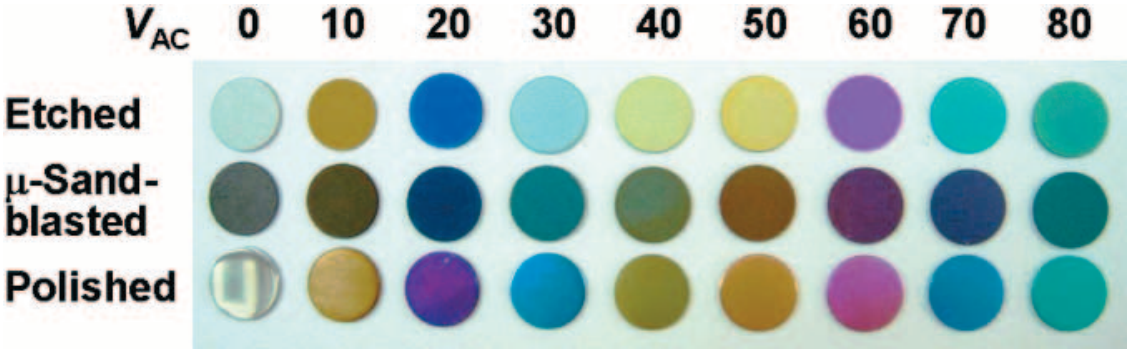

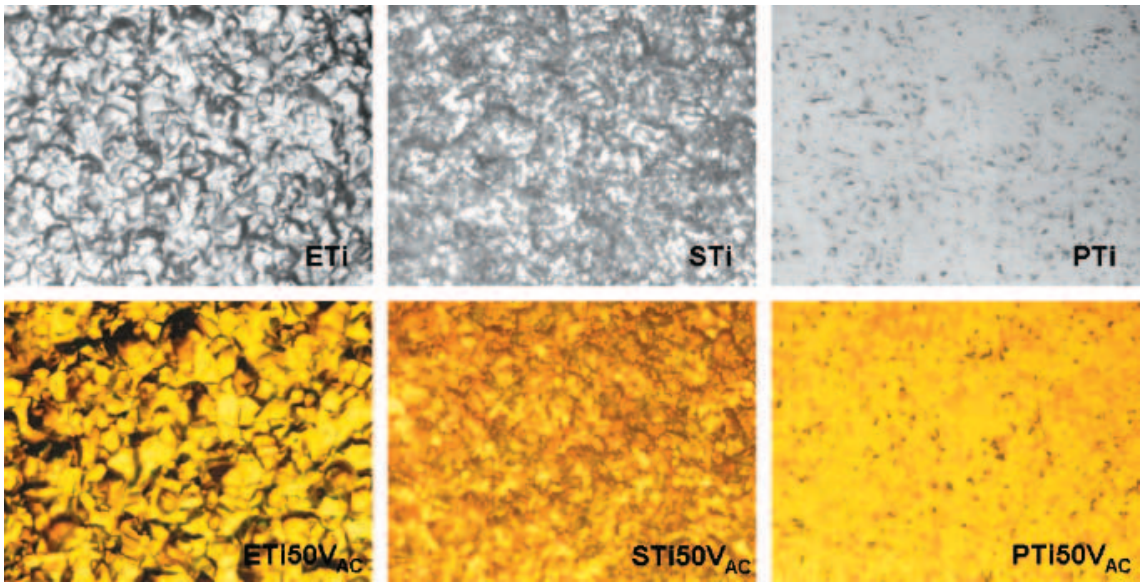

Fig. 2. Surface morphology of the etched, micro-sandblasted, and polished Ti (ETi, STi, and PTi, respectively) and their passive layers formed at 50 V_{AC} ($ETi50V_{AC}$, $STi50V_{AC}$, and $PTi50V_{AC}$, respectively) examined by optical microscopy at a magnification of 400×; the $NH_4 \cdot BF_4$ concentration is 7.5 wt.%, the polarization time is 10 s, and the AC frequency is 60 Hz.

Static contact angle (SCA) measurement

Static contact angle measurements were performed at the room temperature (22 °C ± 1) using a video contact angle system (VCA Optima, AST Products, Inc., Billerica, MA, USA). A 1.5 μL droplet of HBSS was placed on the specimen surface and the contact angle was analyzed. We report an average of at least 10 reproducible individual measurements.

Results and discussion

Influence of pretreatment, AC and DC voltage, and AC frequency on the visual properties and morphology of passive layers on Ti

Figure 1 shows the coloration of passive layers formed at different V_{AC} values up to 80 V_{AC} and at f = 60 Hz on Ti pretreated using three methods, i.e., chemical etching, micro-sandblasting, and mechanical polishing. In the first column, we show etched, micro-sandblasted, and polished Ti specimens without any electrochemical treatment (0 V_{AC}); they serve as respective references. We observe that the AC polarization of the Ti specimens at $10 \leq V_{AC} \leq 80$ V_{AC} results in a wide spectrum of bright, uniform, well-defined colors; the coloration varies in the following order (from the lowest to the highest value of V_{AC}): brown, blue, light blue, yellow, golden yellow, purple, olive green, and turquoise. Similar colors were obtained in the case of micro-sandblasted and mechanically polished specimens. However, the colors of the micro-sandblasted specimens were different in shade and less bright than those of either polished or etched specimens; the polished specimens revealed a shiny finish. The different colors and shades provide a wide range of choices for biomedical and decorative applications if a visual aspect is required, as in the case of orthodontic archwires or dental implants placed under the gum skin. Figure 2 shows the surface morphology of etched (E), micro-sandblasted (S), and mechanically polished (P) Ti specimens prior to and after the formation of a passive layer at 50 V_{AC}. The micrographs were obtained by means of optical microscopy at a 400× magnification. The results reveal that the passive layers are uniform and free of any cracks or flakes that could be observed using optical microscopy. The passive layers grow in registry with the underlying metal. Thus,

Table 1. Average surface roughness (R_a) in μm.

		Ti sample passivated at		
Specimen	Ti	10 V_{AC}	30 V_{AC}	50 V_{AC}
Polished	0.048 ± 0.008	—	—	0.13
Micro-sandblasted	0.89 ± 0.05	—	—	0.94
Etched	1.30 ± 0.03	1.43 ± 0.06	1.50 ± 0.06	1.58 ± 0.05
Etched and exposed to HBSS for 2 weeks	1.46 ± 0.06	1.52 ± 0.06	1.63 ± 0.05	1.71 ± 0.05

surface morphology of the passive layers resembles that of the corresponding untreated Ti specimen although the surface roughness slightly increases (see a later section dealing with surface profilometry studies). The etched specimens reveal a clearly discernible grain structure that comprises crystals and grain boundaries. In all cases, the coloration of each grain is uniform and identical to that of the adjacent grains. The micro-sandblasted Ti specimens show smaller features because of the micro-erosion caused by the 90 μm alumina particles; their morphology does not reveal any well-defined crystals or grain boundaries that are observed in the case of etched specimens. Clearly, the surface of the etched specimens is rougher than that of micro-sandblasted or polished specimens, and this observation is corroborated by the surface profilometry analysis (the values of the average surface roughness are reported in Table 1). We observed that the average surface roughness increases in the following order: mechanically polished Ti (0.048 μm), micro-sandblasted Ti (0.89 μm), and chemically etched Ti (1.30 μm). We also measured the surface roughness of three specimens that were pretreated as described previously and subsequently passivated at 50 V_{AC} (60 Hz). The results indicated that the passivation increased the surface roughness compared with non-passivated but identically pretreated specimens. The values of the average surface roughness increased in the following order: mechanically polished Ti (0.13 μm), micro-sandblasted Ti (0.94 μm), and chemically etched Ti (1.58 μm). We observed that this order is the same for the untreated and passivated Ti specimens.

We also analyzed the effect of the magnitude of V_{AC} on the surface roughness. This series of experiments was carried out using etched Ti specimens that were passivated at 10, 30, and 50 V_{AC}. The results revealed that the average surface roughness increased from 1.30 μm for Ti to 1.58 μm for the passive layer formed at 50 V_{AC} (Table 1). Figures 3*a* and 3*b* show three-dimensional surface profiles for an etched Ti specimen prior to and after passivation at 50 V_{AC}, respectively. The possibility of increasing and controlling the surface roughness of Ti specimens is of interest in the surface treatment of biocompatible materials. Specifically, roughened surfaces increase bone-implant contact, promote tissue and bone ingrowth, and create the interlock between the bone and implants, thus improving the bone-healing process (25). Because chemical etching and passivation provide the roughest Ti samples, we selected this pretreatment in our further tests.

It was important to evaluate whether passive layers on Ti of similar visual properties could be prepared by the application of DC voltage in the same electrolyte. Therefore, we applied both AC (f = 60 Hz) and DC voltage of the same magnitude to prepare passive layers on Ti (the other experimental parameters were the same). Figure 4 shows the passive layers prepared at several V_{AC} and V_{DC} values that ranged from 10 to 80 V_{AC} or V_{DC}. The results reveal that DC polarization also led to uniformly colored passive layers; however, their colors are different from those prepared using AC voltage. We observe that the color obtained at 30 V_{DC} is similar to that obtained at 20 V_{AC}; the other "V_{DC} – V_{AC} pairs of values" that gave the same surface coloration are as follows: 40 V_{DC} – 30 V_{AC}, 50 V_{DC} – 40 V_{AC}, 60 V_{DC} – 50 V_{AC}, 70 V_{DC} – 60 V_{AC}, and 80 V_{DC} – 70V_{AC}. We observe that, in general, a higher V_{DC} is required to obtain the same coloration as that achieved using an AC voltage (with other parameters being the same). This observation may at first seem counterintuitive, but it is the nature of the AC and DC voltage, properties and composition of the oxide layers, and associated electrochemical processes that determine the growth mechanism of passive layers and their thickness. As a passive layer on Ti develops at a given anodic V_{DC}, it imposes a barrier to the charge transfer (anodically formed ox-

Fig. 3. Three-dimensional surface profiles of (*a*) the etched Ti (R_a = 1.30 μm) and (*b*) its passive layer formed at 50 V_{AC} (60 Hz) (R_a = 1.58 μm).

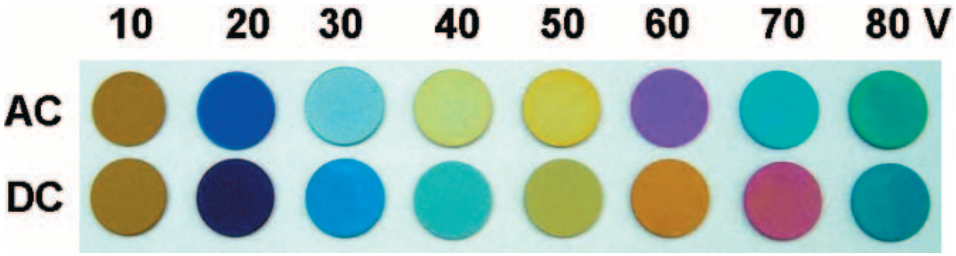
Fig. 4. Relation between the coloration of the passive layers formed on etched Ti and the applied AC or DC voltage; the $NH_4{\cdot}BF_4$ concentration is 7.5 wt.%, the polarization time is 10 s, and AC frequency is 60 Hz.



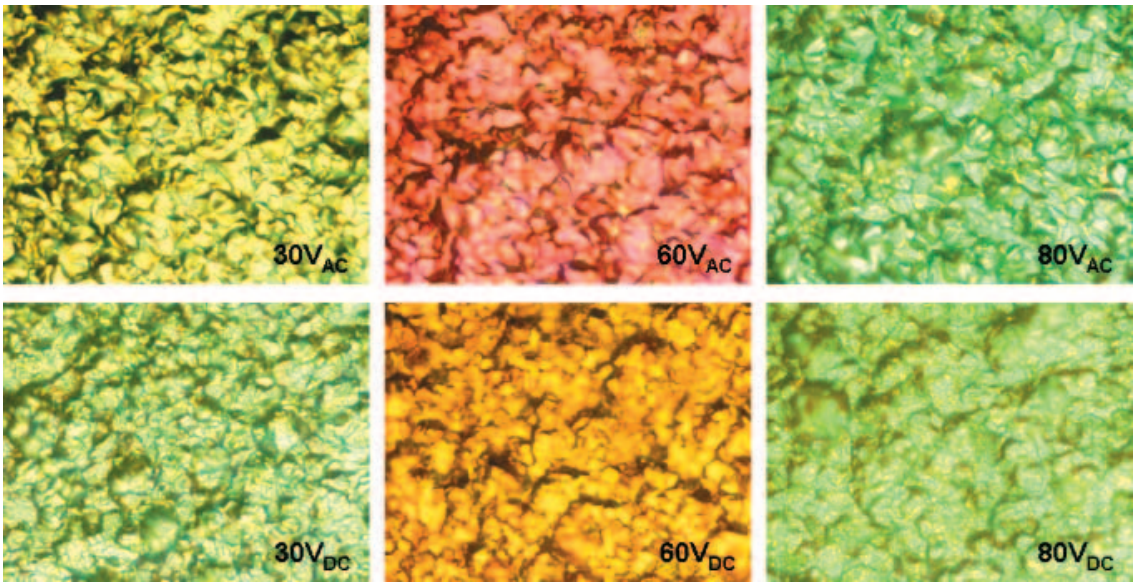


Fig. 5. Surface morphology of the passive layers formed on etched Ti using different V_{AC} (60 Hz) and V_{DC} values examined by optical microscopy at a 400× magnification; $NH_4{\cdot}BF_4$ concentration is 7.5 wt.% and the polarization time is 10 s.

ide layers have semiconducting properties), thus making the interface a less efficient electronic conductor. This translates into a gradual decrease of the oxidation current, which is eventually reduced to a very small value; thus, the passive layer grows to a limiting thickness for a given V_{DC} (26). In the case of AC polarization, we repetitively apply anodic and cathodic voltages whose magnitude is a sinusoidal function of time (the number of the anodic and cathodic voltages applied per unit time equals the AC frequency, f). Clearly, anodic and cathodic voltages result in oxidation (oxide formation and oxygen generation) and reduction (partial oxide reduction and hydrogen generation) reactions. If the anodically formed oxide is partially reduced, then its electronic properties are modified. In the case of Ti, the AC polarization results in the formation of a passive layer that contains Ti_2O_3 sandwiched between Ti and a thin surface layer of TiO_2 (19, 20). At present, we are unable to quantify the amount of Ti oxides that was reduced during cathodic transients of AC polarization because a specialized experimental setup is being constructed (this will be reported in a subsequent paper).

Figure 5 shows surface micrographs for the chemically etched and then passivated Ti specimens obtained using optical microscopy at a magnification of 400×; the applied AC and DC voltages were 30, 60, and 80 V_{AC} and V_{DC}, respectively. The results demonstrate that the DC polarization-formed passive layers are uniformly colored and are free of cracks or flakes. The morphology of the DC voltage-formed passive layers closely resembles that of the AC voltage-formed ones.

Another parameter that affects the growth of passive layers on Ti, and their coloration and thickness, is the frequency (f) of the applied AC voltage. Figure 6 presents 36 specimens that show the surface coloration for a set of V_{AC} and f values, namely, $10 \leq V_{AC} \leq 60$ V_{AC} and $16 \leq f \leq 500$ Hz. These results reveal that a wider spectrum of colors is created and the surface coloration becomes more uniform as f decreases; the most visually appealing specimens are those obtained at the lowest value of f (here, $f = 16$ Hz). Elsewhere, we showed that there is a well-defined relationship between the passive layers' coloration and thickness (20). According to those results and the data presented in Fig. 6, we may conclude that for a given V_{AC}, the thickness of the passive layers decreases as we increase f. Clearly, in the case of $f = 500$ Hz, we do not observe any passive layer formation up to $V_{AC} = 30$ V_{AC}. This observation is consistent with our proposal that a cathodic transient can reduce oxidized Ti species formed during a very short anodic transient

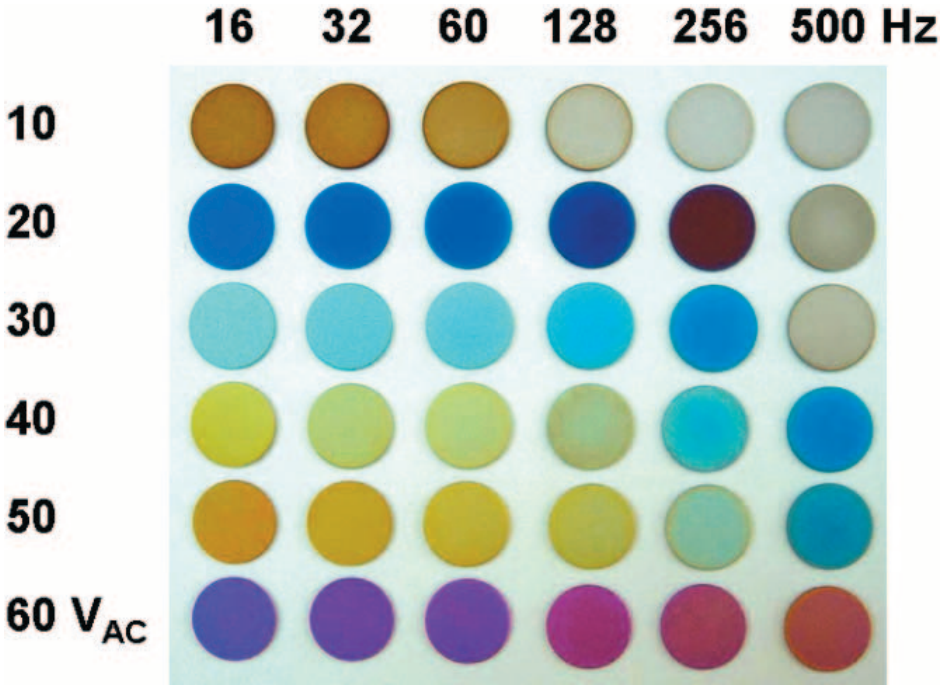
Fig. 6. Relation between the coloration of the Ti passive layers, the applied AC voltage, and its frequency; the $NH_4{\cdot}BF_4$ concentration is 7.5 wt.% and the polarization time is 10 s.



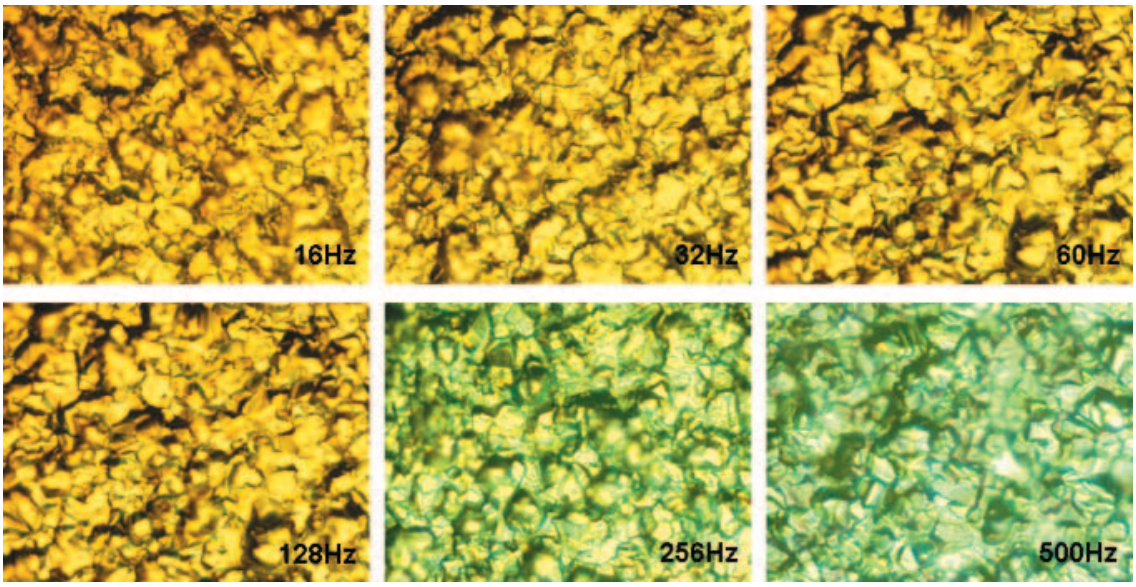


Fig. 7. Surface morphology of the passive layers formed on etched Ti at 40 V_{AC} and at different frequencies (16–500 Hz) examined by optical microscopy at a magnification of 400×; $NH_4{\cdot}BF_4$ concentration is 7.5 wt.% and the polarization time is 10 s.

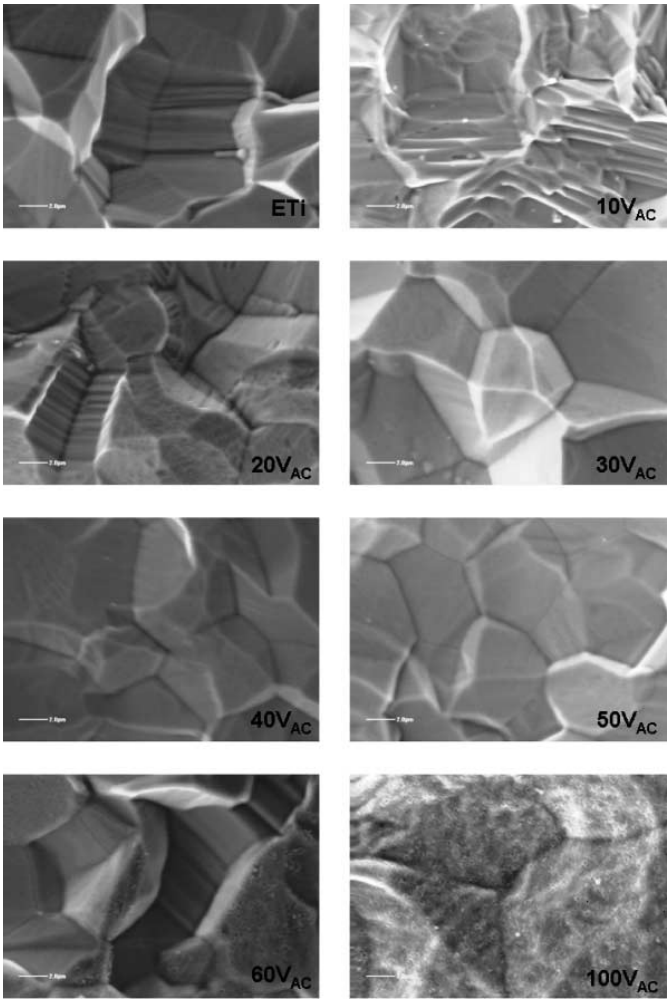

(here, 1 ms). For instance, in the case of V_{AC} = 10 V_{AC}, there is hardly any noticeable formation of a passive layer for 128 ≤ f ≤ 500 Hz. In the case of V_{AC} = 60 V_{AC}, the passive layer is the thickest for f = 16 Hz and the thinnest for f = 500 Hz. Consequently, the thickest passive layers are obtained at the highest V_{AC} and the lowest f value. Figure 7 shows surface micrographs obtained at a 400× magnification for passive layers formed at 40 V_{AC} and at six different values of f, namely, 16, 32, 60, 128, 256, and 500 Hz. In all cases, the passive layers have a uniform coloration and are free of cracks or flakes. Their surface morphology is similar, and there are no specific features that could be assigned to the frequency variation; their topography resembles that of the etched Ti (see Fig. 2).

Figure 8 shows SEM micrographs for disc-shaped Ti specimens at a magnification of 6000× that were prepared by the application of 10, 20, 30, 40, 50, 60, and 100 V_{AC} (60 Hz); the first micrograph refers to the etched Ti (ETi) and serves as a reference. The results indicate that the passive layers grow in registry with the underlying substrate and

Fig. 8. SEM micrographs for the disc-shaped etched Ti (ETi) and seven passive layers formed at 10, 20, 30, 40, 50, 60, and 100 V_{AC} (60 Hz) examined at a magnification of 6000×; the $NH_4{\cdot}BF_4$ concentration is 7.5 wt.% and the polarization time is 10 s.

there are only small changes in the surface morphology caused by the passive layer formation. We observe that in the case of the etched Ti and the specimens passivated at $10 < V_{AC} \leq 50$ V_{AC}, the morphology of each grain is uniform. However, the specimen prepared at 60 V_{AC} reveals sub-micrometre circular pores that become even more pronounced and denser in the case of passivation at 100 V_{AC}. We relate these features to the non-uniformity and (or) electrical breakdown that took place when an AC voltage of 60 V_{AC} or more was applied.

During the specimen preparation, we observed that the passive layers were not always uniform and that the applied AC voltage also resulted in a gas generation that occurred concurrently with the passive layer formation. To achieve uniform passivation, the electrolyte had to be efficiently cooled because the application of high voltages resulted in high currents and consequently in resistive heating of the electrolyte and a rise in its temperature. We also observed that the Ti disc became red-hot when polarized at very high V_{AC} values (≥60 V_{AC}) despite rigorous cooling. Such high localized temperatures (at the Ti surface) can affect the adhesion of the passive layers, as we explain in the following statements. The passive layer is formed at a localized high temperature, and as the process terminates, the specimens subsequently cool down to the ambient temperature. Because Ti and its oxides have different thermal expansion coefficients, the metal and the oxides contract in a different way (with a possible crack development), thus affecting their adhesion. Another factor that needs to be considered is the electrical breakdown that was manifested by audible cracking and (or) visible sparking at the electrode surface (26, 27). It is reported by James and Straumanis that the application of $V_{DC} \geq 60$ V_{DC} in 20% aqueous H_2SO_4 at 20 °C causes an electric breakdown of the anodic passive layer on Ti (26). Our results are consistent with those reported because we observed that the electrical breakdown of the passive layers occurred each time we heard cracking or observed sparking. We observed the same phenomena when using the wire-shaped Ti electrodes, but they manifested themselves already at voltages ≥ 50 V_{AC} and the sparking occurred only at the wire tip (regions of greater current density). In the following sections, we discuss the evaluation of the corrosion behavior, metallic ion release, and wettability of the Ti passive layers. The data reported next refer to the Ti specimens that were chemically etched and passivated using AC voltage for one frequency, namely, $f = 60$ Hz.

Corrosion behavior in HBSS

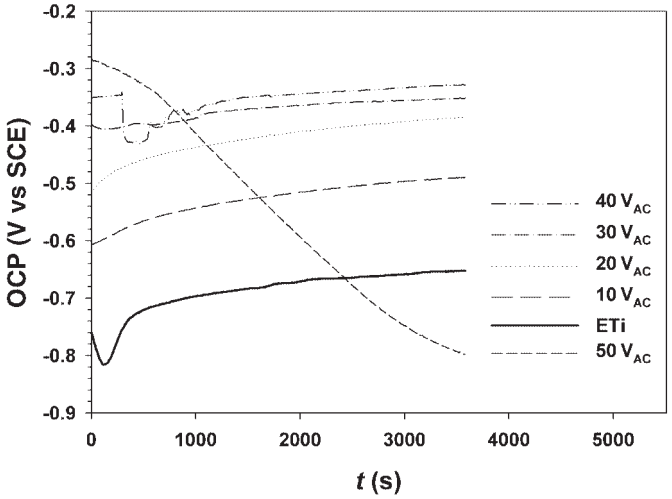
We studied the corrosion behavior of the passive layers by recording polarization curves in HBSS over a wide potential range, typically from E_{corr} –0.25 V to +3.00 V. A typical polarization curve consists of the following regions, starting from the most negative to the most positive potential: hydrogen generation, active, active–passive transition, passive, and transpassive with concurrent oxygen generation (20). An analysis of the polarization curves allows us to identify these regions (not all polarization curves reveal all of them) and to determine important corrosion parameters, such as the corrosion current density (i_{corr}) at corrosion potential (E_{corr}), critical potential (E_{cr}), critical current density (i_{cr}), passive current density (i_{pass}), and breakdown potential (E_b). The value of i_{corr} allows us to calculate the material's corrosion rate (CR) using eq. [2]. The value of E_{corr} is a measure of the material's stability, and the more positive E_{corr}, the more stable the material; the i_{corr} and CR are measures of the material's tendency to undergo corrosion. The value of i_{corr} is used to calculate CR and represents the amount of material that is lost because of corrosion per unit time, typically per year in corrosion studies. The higher the value of i_{corr}, the greater the material's loss (13).

Corrosion potential measurements and polarization curves for Ti specimens

Figure 9 shows the variation of the open circuit potential (OCP) with time in HBSS at 37 °C for etched Ti (ETi) and for passive layers on etched Ti formed at 10, 20, 30, 40, and 50 V_{AC} (60 Hz). The shape of the OCP versus time profile for the etched Ti indicates that it develops a passive layer upon contact with HBSS. In the case of the passive layers formed at 10, 20, 30, and 40 V_{AC}, we observe a continuous

© 2006 NRC Canada

Fig. 9. Variation of the open circuit potential (OCP) with time in HBSS at 37 °C for the etched Ti (ETi) and five passive layers formed at 10, 20, 30, 40, and 50 V_{AC} (60 Hz).



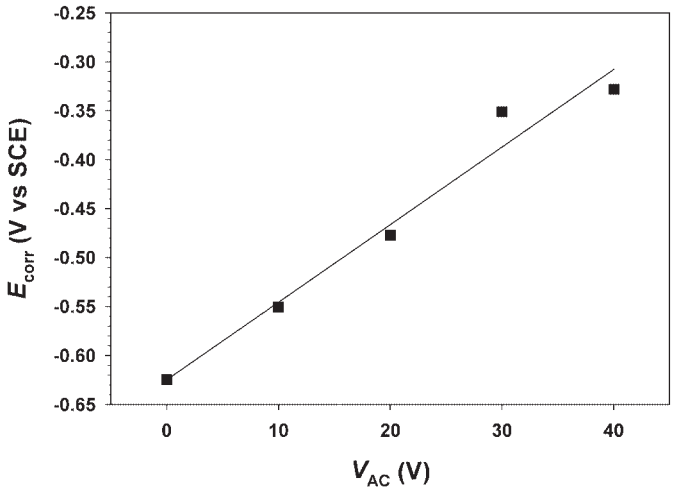


Fig. 10. Relation between the corrosion potential (E_{corr}) and the applied AC voltage (V_{AC}) for the etched Ti and four passive layers formed at 10, 20, 30, and 40 V_{AC} (60 Hz) in HBSS at 37 °C.

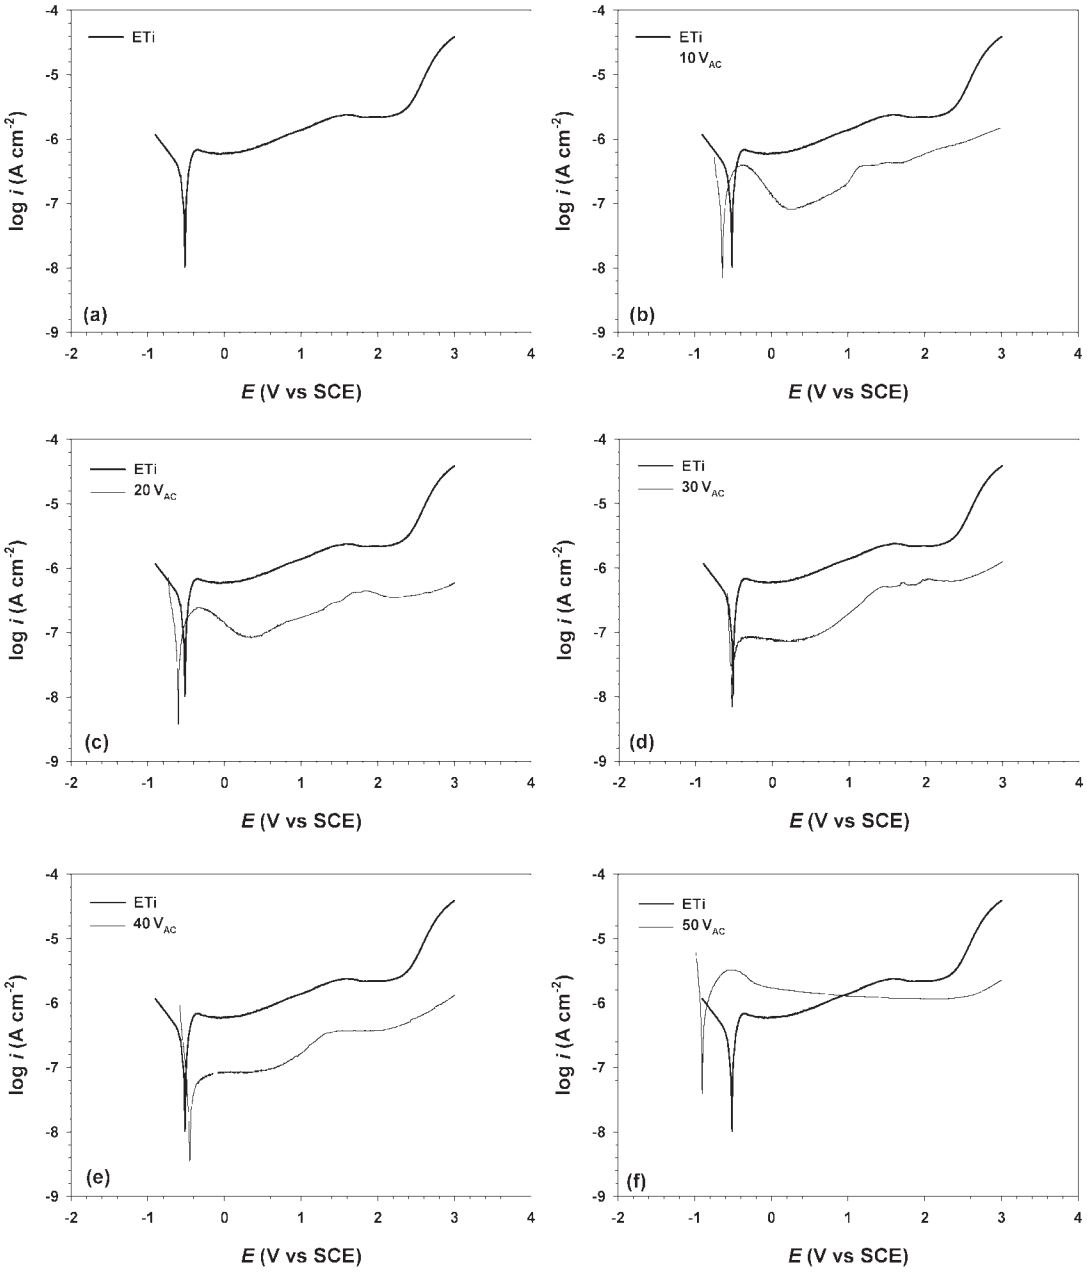

increase of OCP which indicates that the existing passive layers became more stable. These curves tend to a steady-state potential after 1 h of immersion in HBSS; the limiting OCP is referred to as the corrosion potential (E_{corr}). Figure 10 shows a relationship between E_{corr} and V_{AC} for V_{AC} up to 40 V_{AC}; we observe a linear rise of E_{corr} which indicates that the passive layers are more stable than the etched Ti. The curve for the passive layer prepared at 50 V_{AC} (Fig. 9) shows a different trend. At the onset, OCP is higher than all the other values; however, it decreases monotonously and reaches a value of –0.798 V versus SCE after 1 h. This value is more negative than any other value reported in Fig. 9 and still does not seem to tend to a steady-state value (consequently, we do not report E_{corr} for this passive layer). The decrease of OCP for the layer formed at 50 V_{AC} from –0.284 to –0.798 V points to its rapidly deteriorating corrosion resistance (see the discussion of the non-uniformity of the passive layers and their electrical breakdown).

Figure 11*a* shows a polarization curve for an etched, wire-shaped Ti specimen recorded in HBSS at 37 °C at a scan rate (*s*) of 0.166 mV s^{-1}; the potential range is (E_{corr} –0.25 to +3.00 V). The transient reveals the following features: (*i*) hydrogen generation and active region from –0.90 to –0.35 V; (*ii*) active–passive transition at the critical potential (E_{cr}) of –0.35 V; (*iii*) a passive region from –0.35 to +2.40 V; and (*iv*) a transpassive region beyond +2.40 V. The magnitude of the current density in the transpassive region is well below the value of 5 mA cm^{-2} that would be expected if pitting corrosion were to be present (28). Therefore, we may conclude that our experimental conditions do not trigger the development of pits, even in the transpassive region where the oxygen evolution takes place; we do not observe any breakdown potential either (6, 29). This polarization curve serves as a reference in the subsequent evaluation of the corrosion behavior of the passive layers in the same environment. Figures 11*b*–11*f* show polarization curves for the passive layers formed at 10, 20, 30, 40, and 50 V_{AC}, respectively, (f = 60 Hz). The transients for the passive layers formed at 10–40 V_{AC} reveal the following new features: (*i*) the shape of the polarization curves for the passive layers resembles that of Ti, but the current density values are lower; (*ii*) the critical potential (E_{cr}) that refers to the active–passive transition is in the –0.35 to –0.10 V range; (*iii*) the critical current density (i_{cr}) decreased from 0.686 μA m^{-2} for the etched Ti to 0.085 μA cm^{-2} for the passivated layer formed at 40 V_{AC}; the i_{cr} values decrease as V_{AC} rises; (*iv*) the passive current density (i_{pass}) decreased by approximately one order of magnitude upon the formation of the passive layers, thus from ~10^{-6} (for etched Ti) to 10^{-7} A cm^{-2} (for passive layer formed at 40 V_{AC}), which means that the corrosion rate of Ti decreases almost 10 times after the AC polarization; (*v*) the extent of the passive region for the passive layers is wider than that for the etched Ti. These results and, in particular, the passive region's extent and the passive current density value show that the growth of the passive layer on Ti accomplished by AC voltage improves its corrosion resistance. The passive layer formed at 50 V_{AC} reveals different characteristics; its E_{cr} (–0.52 V) is more negative and i_{cr} (3.277 μA cm^{-2}) is higher than the corresponding values for the etched Ti. In addition, i_{pass} is up to an order of magnitude higher than the analogous values for the other passive layers.

Figures 12 and 13 show the polarization resistance (R_P) and the corrosion rate (CR) values at E_{corr} for the etched Ti and the passive layers formed on Ti wires at 10, 20, 30, and 40 V_{AC}. We observe that the R_P values increase linearly with increasing V_{AC}, indicating that the passive layers are more corrosion-resistant than the etched Ti. We also observe that the higher the V_{AC} value, the more corrosion resistant the specimen. The trend of CR values confirms that the passive layers increase the corrosion resistance of Ti. The corrosion rate in HBSS drops from 1.12 μm $year^{-1}$ for the etched Ti to 0.30 μm $year^{-1}$ for the passive layer formed at 40 V_{AC}, i.e, by a factor of ~3. The passive layer formed at 50 V_{AC} has an R_P of 41.2 kΩ cm^2, a value that is lower than that for the etched Ti (190.9 kΩ cm^2). Its CR of 6.23 μm $year^{-1}$ is much higher than that of the etched Ti (1.11 μm $year^{-1}$). These re-

Fig. 11. Polarization curve for the etched Ti (ETi) and five sets of two polarization curves, one for ETi and one for a passive layer formed at a given V_{AC} value (10, 20, 30, 40, and 50 V_{AC}; f = 60 Hz). The polarization curves were recorded in HBSS at 37 °C at a scan rate s = 0.166 mV s^{-1}.

sults point to the non-uniformity and electrical breakdown of the passive layer formed at 50 V_{AC}.

Figure 14 shows four pictures, each containing two specimens, that demonstrate changes in the surface coloration of the etched Ti (ETi) and three passive layers (20, 40, and 50 V_{AC}, f = 60 Hz) prior to (left) and after (right) recording polarization curves in HBSS. The etched Ti and the passive layers formed at 20 and 40 V_{AC} are uniform and reveal only a minor change in the coloration brought about by the corrosion test. However, the passive layer formed at 50 V_{AC} shows significant changes in the coloration and its uniformity, which are assigned to the corrosion of the electrically broken-down passive layer. Figure 15 shows SEM micrographs for etched Ti (ETi) and three passive layers (30, 40, and 50 V_{AC}, f = 60 Hz) after recording polarization curves in HBSS. The etched Ti and the passive layers formed at 30 and 40 V_{AC} are free of damage after the corrosion test, but the passive layer formed at 50 V_{AC} shows damage at the specimen's tip. The passive layer formed at 50 V_{AC} is more prone toward corrosion-induced damage.

Titanium-ion release in HBSS

Figure 16 shows the Ti-ion release level as a function of the applied V_{AC} for the disc-shaped Ti specimens after immersion in HBSS at 37 °C for 2 weeks. The data show that the amount of the released Ti-ion decreases from 230

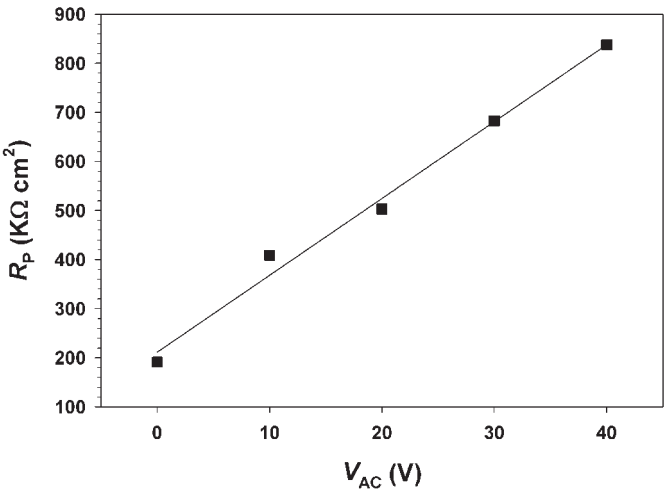

Fig. 13. Relation between the corrosion rate (CR) and the applied AC voltage (V_{AC}) for the etched Ti and four passive layers formed at 10, 20, 30, and 40 V_{AC} in HBSS at 37 °C.

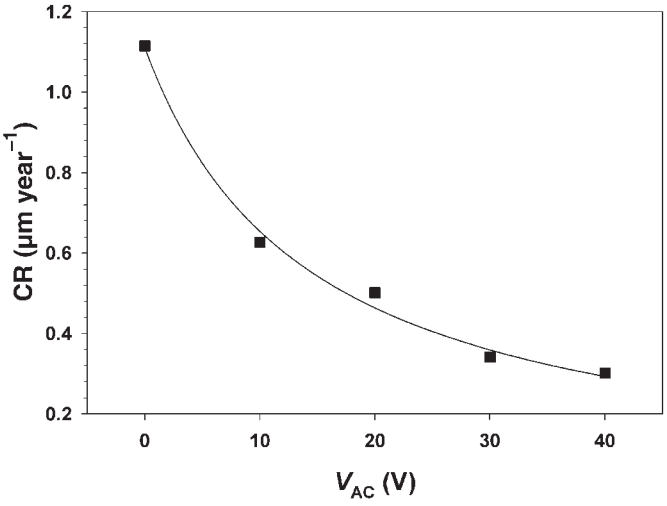

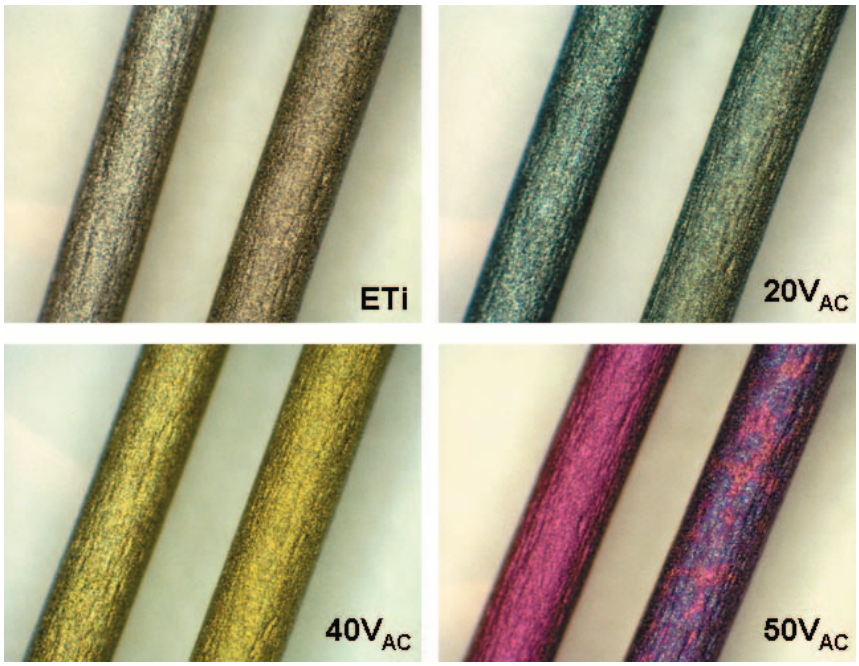

Fig. 14. Comparison of the surface morphology of the wire-shaped etched Ti (ETi) and three passive layers formed at 20, 40, and 50 V_{AC} (60 Hz) examined by optical microscopy at a magnification of 30× prior to (left) and after (right) recording polarization curves in HBSS at 37 °C.

(etched Ti, represented as 0 V_{AC}) to 15 ppb (passive layer formed at 50 V_{AC}); the results reveal that the higher the applied V_{AC} value, the lower the Ti-ion release level. The results presented in Figs. 13 and 16 and obtained using two different experimental approaches follow each other, therefore, demonstrating that the corrosion rate and the Ti-ion release data are in very good agreement. Figure 17 shows the Ti-ion release level as a function of the AC frequency ($16 \leq f \leq 500$ Hz) for the passive layer formed at 30 V_{AC} in comparison to the etched Ti (square symbol in Fig. 17). The data show that the Ti-ion release level for the etched Ti is much higher than for the AC voltage-treated specimens. They also reveal that a gradual increase of f from 16 to 500 Hz increases the Ti-ion release from 46 to 53 ppb, thus about 15%. Knowledge of the Ti-ion release allows us to calculate the corrosion rate. The outcome of such calculations shows that the amount of released Ti-ion ranges from 0.22 μg cm^{-2} d^{-1} for the etched Ti to 0.01 μg cm^{-2} d^{-1} for the passive layer formed at 50 V_{AC} (60 Hz); these results are in good agreement with the data reported in ref. 11. Figure 18 shows SEM micrographs for the etched Ti (ETi) and the passive layers formed at 20, 40, and 50 V_{AC} (60 Hz) after the Ti-ion release test obtained at a magnification of 6000×; the specimens were disc-shaped. These micrographs

Fig. 15. SEM micrographs for wire-shaped etched Ti (ETi) and three passive layers formed at 30, 40, and 50 V_{AC} (60 Hz) after recording polarization curves examined at a magnification of 500×.

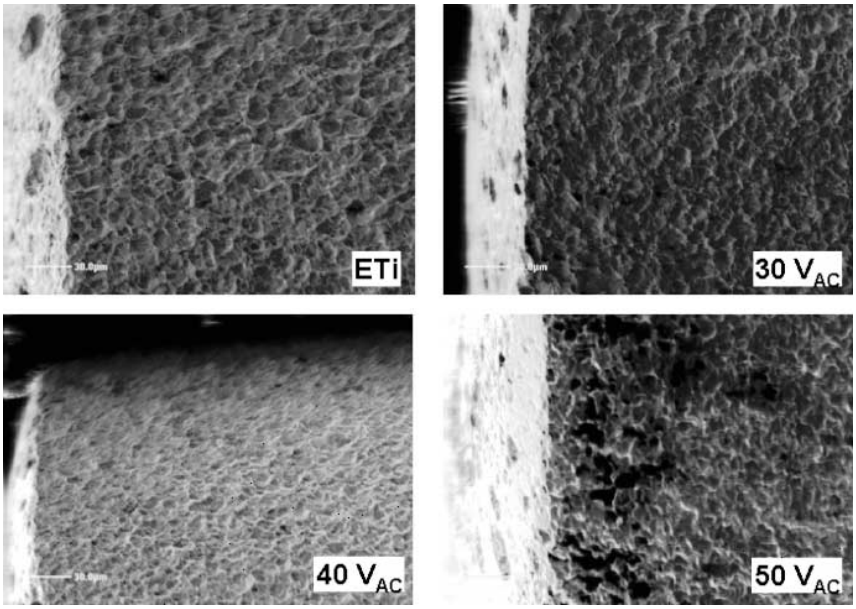

Fig. 16. Relationship between the Ti-ion release and the applied AC voltage (V_{AC}) for the etched Ti and five passive layers formed at 10, 20, 30, 40, and 50 V_{AC} (60 Hz); the specimens were immersed in 40 mL of HBSS at 37 °C for 2 weeks; the surface area of each specimen was 3.00 cm^2.

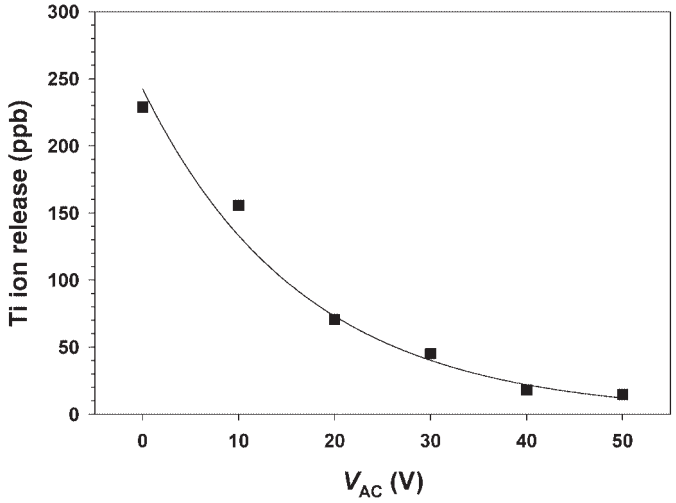

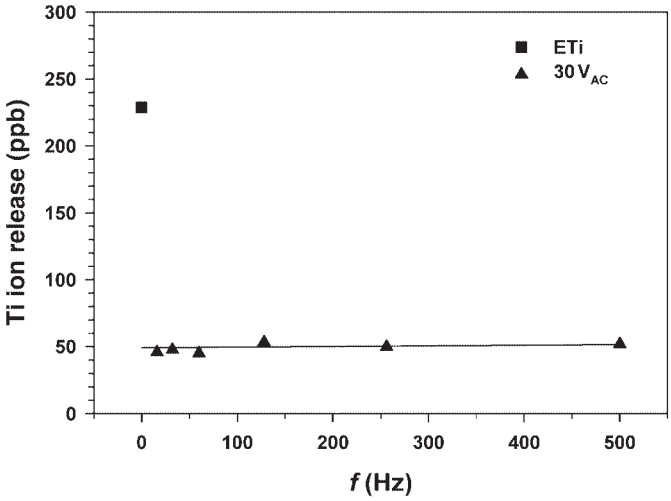

Fig. 17. Relationship between the Ti-ion release and the frequency (f) of the applied AC voltage (30 V_{AC}) for the etched Ti (ETi) and six passive layers formed at six different frequencies (16, 32, 64, 128, 256, and 500 Hz); the specimens were immersed in 40 mL of HBSS at 37 °C for 2 weeks; the surface area of each specimen was 3.00 cm^2.

reveal only small morphology changes that are assigned to the increase of surface roughness; all specimens are uniform and free of any other morphological features such as cracks or flakes. We also analyzed the surface roughness of these specimens after the Ti-ion release test (Table 1) using surface profilometry. The results reveal that the surface of all the specimens becomes rougher after the immersion test because of corrosion in HBSS.

Static contact angles

Table 2 shows the values of the static contact angle formed between HBSS and several Ti specimens, namely, the etched Ti and the passive layers formed at 10, 30, and 50 V_{AC}. The results reveal that the contact angle decreases upon the formation of passive films by up to 5° for the highest value of V_{AC}. Although the variation of the contact angle is small in magnitude, it still indicates that the passive layers on Ti slightly increase the surface wettability of Ti in HBSS; thus, the Ti surface becomes more hydrophilic.

Conclusions

(1) Uniform and crack-free passive layers were formed on Ti surface by applying AC or DC voltage in aqueous

Fig. 18. SEM micrographs for the etched Ti (ETi) and three passive layers formed at 20, 40, and 50 V_{AC} (60 Hz) after an immersion test in HBSS at 37 °C for 2 weeks.

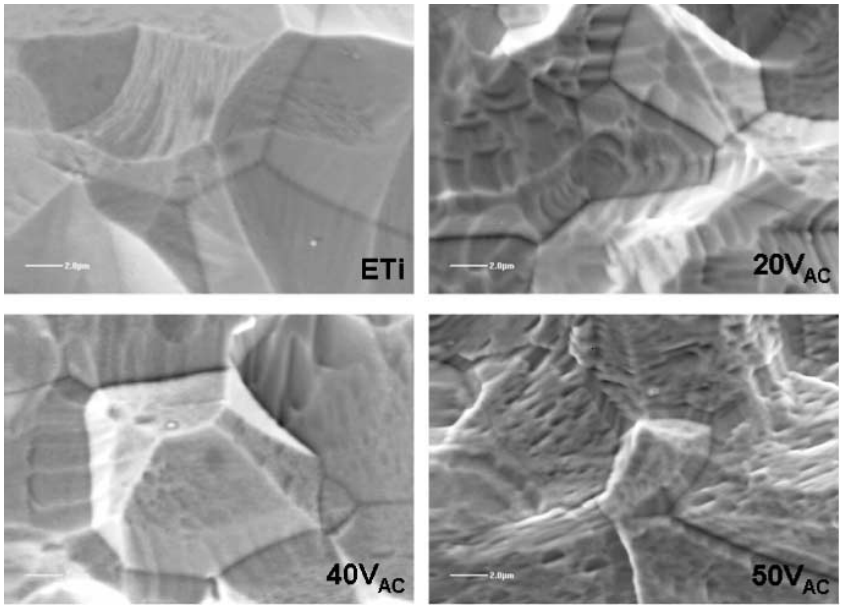

Table 2. Contact angle in HBSS.

Sample	Contact angle (°)
Etched Ti	67.7 ± 0.5
Passive layer formed at 10 V_{AC}	64.3 ± 0.4
Passive layer formed at 30 V_{AC}	63.5 ± 0.4
Passive layer formed at 50 V_{AC}	62.4 ± 0.5

$NH_4{\cdot}BF_4$. Their coloration and thickness could be modified by adjusting the experimental parameters.

(2) Higher DC voltages were required to prepare passive layers of similar coloration and thickness as those obtained using AC.

(3) The colored passive layers grew in registry with the underlying Ti substrate and no cracks or flakes were observed.

(4) The surface modification of Ti accomplished by the formation of passive layers made the surface rougher and slightly more hydrophilic.

(5) The passive layers revealed an enhanced corrosion resistance in HBSS at 37 °C when compared with the untreated Ti. These passive layers reduced the corrosion rate of Ti in HBSS by a factor of 3.

(6) The passive layers effectively reduced the Ti-ion release level in HBSS at 37 °C by a factor of 15; the higher the applied V_{AC}, the lower the Ti-ion release level.

The photochemistry of ring-substituted cinnamyl acetates

S.A. Fleming, L. Renault, E.C. Grundy, and J.A. Pincock

Abstract: The photochemistry of the (*E*)-cinnamyl acetates ((*E*)-1-aryl-3-propenyl acetates, **8a**–**8e**) with substituents H, 4-CH_3O, 3-CH_3O, 4-CF_3, and 3-CF_3, respectively, was examined in both cyclohexane and methanol solvents. Alkene isomerization (*E* to *Z*) occurred more efficiently than other reactions and evidence is presented that this process occurs from the excited triplet state. In a slower process, 1,3-migration of the acetoxy group led to the rearranged 3-aryl-3-propenyl acetate isomers (**9a**–**9e**) as the major pathway, particularly in cylohexane. In methanol, the isomeric ethers 3-aryl-3-methoxypropene (**14**) and 1-aryl-3-methoxypropene (**15**) were formed by reaction of methanol with the photochemically generated cation. The combined yield of **14** and **15** (95% and 5%, respectively) was quantitative for the 4-methoxyphenyl compound (**8b**). Independent irradiations of the isomers **9a**–**9c** demonstrated that the ethers **14** and **15** were primary photoproducts from **8** and not secondary photoproducts from **9**. Fluorescence quantum yields and excited singlet state lifetimes indicated that the reactions, other than the *E* to *Z* isomerization, are from the excited singlet state.

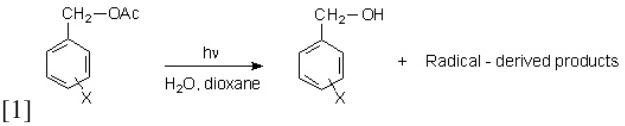
Key words: cinnamyl acetates, photochemistry, *E*/*Z* isomerization, photocleavage, fluorescence.

Résumé : Opérant tant dans le cyclohexane que dans le méthanol comme solvants, on a étudié la photochimie des acétates de (*E*)-cinnamyle (acétates de (*E*)-1-aryl-3-propényle, **8a**–**8e**) portant des substituants H, 4-OCH_3, 3-OCH_3, 4-CF_3, et 3-CF_3. L'isomérisation de l'alcène (*E* à *Z*) est la réaction qui se produit de la façon la plus efficace par rapport aux autres et on présente des données qui montrent que cette réaction se produit à partir de l'état triplet excité. Dans un processus plus lent, particulièrement dans le cyclohexane, la voie réactionnelle principalement provoque un réarrangement avec migration-1,3 du groupe acétoxy qui conduit aux acétates de 3-aryl-3-propényle isomères (**9a**–**9e**). Dans le méthanol, les éthers isomères 3-aryl-3-méthoxypropène (**14**) et 1-aryl-3-méthoxypropène (**15**) se forment par réaction du méthanol avec le cation généré photochimiquement. Le rendement combiné des composés **14** et **15** (95 % et 5 %) est quantitatif pour le composé 4-méthoxyphényle (**8b**). Des irradiations indépendantes des isomères **9a**–**9c** ont démontré que les éthers **14** et **15** correspondent aux photoproduits primaires des composés **8** et non pas des photoproduits secondaires des composés **9**. Les rendements quantiques de fluorescence et les temps de vie de l'état excité singulet indiquent que les réactions, à l'exception de l'isomérisation *E* à *Z*, se font à partir de l'état singulet excité.

Mots clés : acétates de cinnamyle, photochimie, isomérisation *E*/*Z*, photoclivage, fluorescence.

[Traduit par la Rédaction]

Introduction



For some time, we have been interested in the effect that substitutents on aromatic rings have on photochemical processes. In particular, we have examined the photocleavage reactions of arylmethyl systems with leaving groups ($ArCH_2$-LG), the competition between radical and ion-derived products in polar nucleophilic solvents like alcohols, Scheme 1, and the pathway for their formation (1–3).

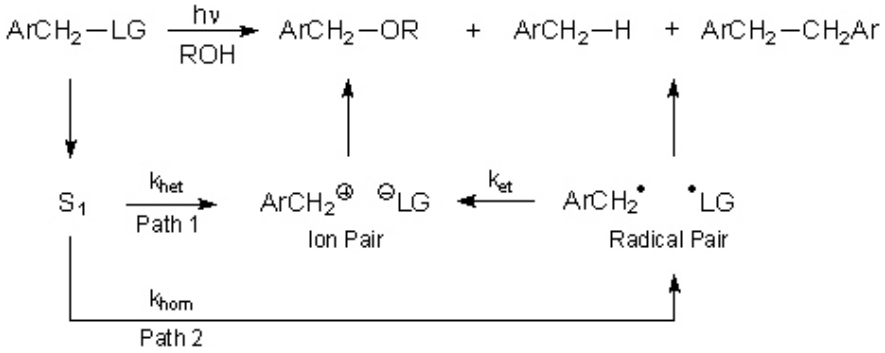
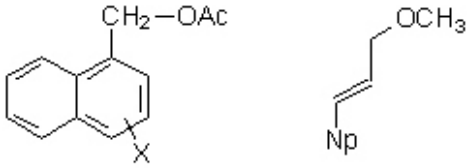
The initial report of the "meta effect" for these reactions by Zimmerman and coworkers (4, 5) presented the observation that 3-methoxybenzyl acetate (**1b**) gives a higher chemical (29%–35%) and quantum yield (0.13) of formation of the ion-derived alcohol product than 4-methoxybenzyl acetate (**1a**) ("minor" amount and 0.016, respectively) on photolysis in aqueous dioxane (eq. [1]). This observation is contrary to expectations on the basis of ground state stability of the corresponding cations, the 4-methoxybenzyl cation being considerably more stable than the 3-methoxy substituted one.



[1]

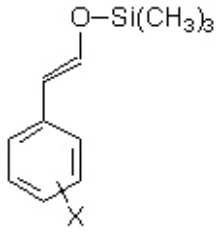
1a: X = 4-OCH_3
1b: X = 3-OCH_3



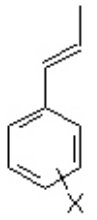
As outlined in Scheme 1, two quite different mechanistic proposals have been advanced to explain this observation.

 doi:10.1139/V06-140 © 2006 NRC Canada

Scheme 1.

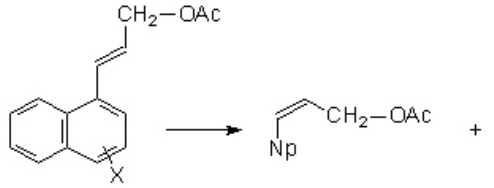


Path 1, as initially proposed and reinforced by more recent computational results by Zimmerman (6, 7) assumes that the ion pair is formed directly from the first excited singlet state, S_1, of the substrate and that the 3-methoxybenzyl cation is formed more efficiently than the 4-methoxy substituted one. Path 2, as developed by us, assumes that the ion pair is formed by redox electron transfer from an initially formed radical pair; direct formation of the ion pair from S_1 is, at most, a minor process. The yield of the ion pair is then determined by k_{et}, the rate constant for electron transfer that converts the radical pair to the ion pair and therefore by the driving force as determined by the reduction potential of the acyloxy radical and the oxidation potential of the arylmethyl radical. Results for substituted benzyl and 1- naphthylmethyl acetates **1**, **2** have been particularly important in developing this mechanism (1).



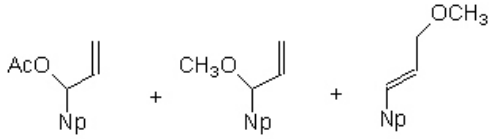
2a: X = 4-OCH_3
2b: X = 3-OCH_3

7



10b: X = 4-OCH_3
10c: X = 3-OCH_3
10d: X = 4-CF_3
10e: X = 3-CF_3

11a: X = H



More recently, Rao et al. (8) reported on the photochemistry[2] of (*E*)-1-naphthylallyl acetates (**3**) for X = H, 4–CH_3 and 4–OCH_3 (eq. [2]) in hexane, methanol, and acetonitrile. In hexane, *E* to *Z* isomerization was the major process observed although low yields of the rearranged acetate **5** were reported for **3b** and **3c**. In acetonitrile, the efficiencies of conversion were similar but the major product was now the rearranged acetate **5** for all three cases. In methanol, the major photosolvolysis product for all three was the methyl ether **6** with yields of 30% from **3a**, 36% from **3b**, and 80% from **3c**. The ether **7**, resulting from direct substitution, was not observed. Remarkably, the 4-methoxy substrate **3c** reacted considerably more efficiently than either of the other two in methanol (conversion after 30 min of 40%, 43%, and 95% for **3a**, **3b**, and **3c**, respectively). No products obviously derived from radical intermediates were reported for any of the three substrates, even in cyclohexane as solvent, although the rearranged acetates **5** could be so formed.

[2]

3a: X = H
3b: X = 4-CH_3
3c: X = 4-OCH_3

4

5 **6** **7**

We have observed (9) a similar high yield (74% of the methyl ether) of ion-derived product for the photolysis in methanol of the 4-methoxy-1-naphthyl substrate **2a**, compared with the corresponding 3-methoxy derivative **2b** (31%).

We now report on the photochemistry in both cyclohexane and methanol of the cinnamyl acetates **8a**–**8e** (eq. [3]).

[a]C = cyclohexane, M = methanol.

These compounds were chosen to examine both the "meta effect" for a system with extended conjugation relative to the prototypical benzyl acetates **1** and the connection between the arylmethyl compounds **1** and **2** and those with more extended allylic conjugation, **3** and **8**. The CF_3-substituted cases were included to examine the contrast in reactivity with substrates having electron-withdrawing substituents.

[3]

Results and discussion

Synthesis and photolysis experiments

The synthesis of the (*E*)-1-aryl-3-propenyl acetates **8a**–**8e** was performed as described in the literature (10). The corresponding commercially available cinnamic acids were converted to their ethyl esters, reduced with DIBAL, and the resulting alcohols were esterified by reacting with acetyl chloride. The acetates (100 mg in 100 mL of solvent) were irradiated at 25 °C in a Rayonet apparatus equipped with 254 nm lamps. The reaction progress was monitored by GCMS and product ratios (by GC and ^{1}H NMR) are reported in Table 1 after 1 hour of irradiation. Dark control experiments in methanol resulted in no alkene isomerization or solvolysis for any of the compounds **8**. For photolysis of all substrates, the mass balance for volatile products was low (e.g., typical of most cases only 55% after 85% conversion of **8a** in methanol). The nonvolatile products are assumed to be oligomers formed from the arylallyl radical and ionic intermediates. This suggestion is supported by the observation of broad structureless signals in the aromatic and aliphatic region of the ^{1}H NMR spectra of crude reaction mixtures. Therefore, the values of product yields in Table 1 have been normalized to 100%. On the basis of product yields, the most reactive compound in both cyclohexane and methanol is the 4-methoxy one, similar to the previous observations (8) for the 1-naphthyl derivatives **3** (eq. [2]).

A main photoproduct for each of the substrates was the isomeric 3-aryl-3-propenyl acetate (**9**). Although they could be isolated by chromatography from the photolysis mixtures, **9a**–**9c** were also prepared by the reaction of vinylmagnesium bromide with the appropriate substituted benzaldehyde followed by quenching with acetyl chloride.

Photophysical properties of 8a–8e and the siloxanes 10b–10e in cyclohexane and methanol

The photophysical properties of the esters **8** in both cyclohexane and methanol are reported in Table 2 along with those for the corresponding siloxanes **10**, which serve as useful models because they have the same chromophore but are photochemically unreactive to C–O bond cleavage. The siloxanes **10b**–**10e** were available in our laboratory because they had been prepared for a related project on the photochemistry of dicinnamyl siloxanes. Another good model for the chromophore of the esters are 1-arylpropenes, which have been studied previously; literature values for the spectra of 1-phenylpropene **11a** are also included in Table 1.

The UV absorption spectra of compounds **8**, **10**, and **11** are as expected on the basis of the reported values for 1-arylpropenes (11, 12) with a longer wavelength lower intensity band with vibrational structure for the S_0 to S_1 transition and a higher intensity broad structureless band for the S_0 to S_2 transition at shorter wavelength. As an example, for cinnamyl acetate **8a** in methanol the bands observed are at 291 nm (ε = 780 $(mol/L)^{-1}$ cm^{-1}) and 282 nm (ε = 1190 $(mol/L)^{-1}$ cm^{-1}) for the S_1 transition and 252 nm (ε = 16 100

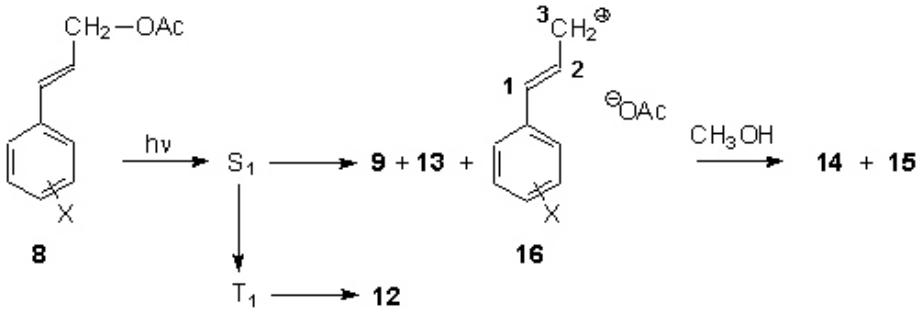
(mol/L)$^{-1}$ cm^{-1}) for the S_2 transition. The irradiation experiments were done at 254 nm into the S_2 transition and only those bands are reported in Table 1. This band is shifted to longer wavelength (263 nm) and higher molar absorptivity (ε = 22 200 (mol/L)$^{-1}$ cm^{-1}) by the conjugating 4-methoxy substituent **8b** but affected only slightly by the other substituents. The change in solvent from cyclohexane to methanol also has little effect. A comparison of the absorption bands and the molar absorptivities for the esters **8** and the siloxanes **10** indicates that, as expected, the chromophores are essentially the same for the two.

In contrast, the quantum yields of fluorescence (Φ_f) for the methoxy substituted esters **8b** and **8c** are considerably lower than for the corresponding siloxanes **10b** and **10c**, particularly in methanol. This quantum yield is defined by eq. [4], where k_f and k_t are the rate constants for fluorescence and the total rate of decay for the excited singlet state, respectively. The rate constant k_t (the reciprocal of τ_S) is defined by eq. [5], where k_{ic}, k_{isc}, and k_r are the rate constants for internal conversion, intersystem crossing, and reaction, respectively. The decreases in Φ_f are a consequence of the fact that the excited singlet states of the esters have a pathway, C–O bond cleavage, for deactivation that competes with fluorescence but is unavailable for the silanes. In agreement with this concept, the excited singlet state lifetimes (τ_s) are also considerably shorter for the esters. The parallel decrease in the quantum yield of fluorescence and singlet state lifetime means that k_f remains nearly constant, again indicating the similarity of the excited states of the esters and the model siloxanes. This similarity is also apparent for the trifluoromethyl substituted compounds **8d** and **8e**, but now the Φ_f and τ_s values suggest that excited state C–O bond cleavage is a relatively inefficient process in both cyclohexane and methanol.

$$[4] \qquad \Phi_f = k_f / k_t = k_f \tau_s$$

$$[5] \qquad 1 / \tau_s = k_t = k_f + k_{isc} + k_{ic} + k_r$$



Photolysis of esters 8 in cyclohexane

Although the main goal of this study was to examine the ion-derived products formed by photosolvolysis of the cinnamyl esters, the results in cyclohexane provide important information on other mechanisms. Several observations and trends are worth noting. First, from percent conversion vs. time plots, *E* to *Z* isomerization occurs more rapidly than other photochemical processes to give mixtures enriched in the *Z* isomer. This result is apparent from the photolysis yield results shown in Table 1 for those substrates that are not completely consumed after one hour of irradiation. Further product formation then occurs from this equilibrated mixture, which is rich in the *Z* isomer. Because the secondary photochemistry must compete with the more rapid isomerization process, the photoreactions are relatively inefficient.

On the basis of results by Lewis and Zuo (11) for *(E)*- and (*Z*)-1-phenylpropene, which have an analogous chromophore

Scheme 2.

to the unsubstituted cinnamyl acetate **8a**, the *E* isomer should have a high barrier (~9 kcal/mol, 1 cal = 4.184 J) in the excited singlet state for rotation about the C=C double bond. At room temperature, the dominant mode of the excited singlet state decay should be intersystem crossing and isomerization would then occur by a barrierless process in the triplet manifold. In contrast, the *Z* isomer should have a lower barrier (~4 kcal/mol) for excited singlet state rotation and this process would be the dominant mode for its decay at room temperature.

Attempts to confirm that the triplet state of **8a** did undergo *E* to *Z* isomerization were unsuccessful because of rapid reaction of the sensitizers, either benzophenone or xanthone with the solvent cyclohexane. However, a previous report (13) on the triplet sensitization of the photochemistry of cinnamyl acetate **8a** in acetonitrile indicated that only isomerization occurred to give a ratio of 35% *E* and 65% *Z*. A very small amount (2.5%) of the rearranged isomer **9a** was also reported but it was ascribed to direct absorption of the incident light by **8a** rather than by the sensitizer.

Second, the predominate product for the irradiations in cyclohexane is the 3-aryl-3-propenyl acetate **9** that results from a 1,3-shift of the acetoxy group (eq. [3]). This observation is similar to that reported recently (8) for the formation of the products **5** on photolysis in hexane of the 1-(1-naphthyl)-3-propenyl acetate derivatives **3** (eq. [2]). However, in contrast to the high yields observed in the current study (94% for **8b**; X = 4-CH_3O, for example, the compound where this process is the most efficient) the yields reported for the naphthyl derivatives are very low (3% for **3c**; X = 4-CH_3O). Because these products are being formed in cyclohexane where ionic intermediates are unlikely to be formed, the mechanism for their formation must be by a radical or concerted pathway similar to a photo-Claisen rearrangement.

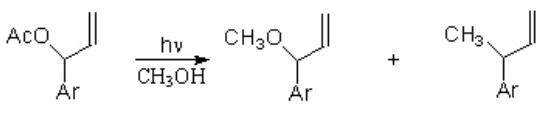
The other major product of the photolyses in cyclohexane is **13**, another deconjugated isomer of the starting material but formed by a 1,3-hydogen shift and as a mixture of *E* and *Z* isomers. The yield is highest (27%) for the 4-trifluoromethyl substrate **8d**. Again, this process does not likely involve ion pairs.

An important point to make here is that no products resulting from radical coupling were obtained. In the photochemistry of both benzyl and 1-naphthylmethyl acetates, products (ethylbenzene and ethylnaphthalene derivatives) resulting from the loss of carbon dioxide from the acetyloxy radical followed by coupling of the methyl radical with the arylmethyl radical are always observed (1). The lack of analogous products for the photolysis of **8** suggests that the formation of the rearranged isomers **9** and **13** in cyclohexane as solvent occurs by a concerted process without discrete intermediates.

Photolysis of esters 8 in methanol

Photolysis of each of the substrates **8** in methanol resulted in the formation of the ion-derived products **13** and **14** along with, in most cases, those obtained in cyclohexane irradiations. However, for the 4-methoxy compound **8b** the ethers **13** and **14** are the only products observed with a high selectivity for unconjugated isomer **14**. The evidence that these products are derived from the excited singlet state is provided by a sensitized irradiation in methanol for **8a**. Xanthone, as opposed to benzophenone, was chosen as the sensitizer on the basis of the fact that its triplet state is not efficiently quenched by methanol (14). Irradiation using a Pyrex filter, conditions that led to no reaction in the absence of xanthone, resulted in efficient *E* to *Z* isomerization. No other products were detected indicating that the excited triplet state of **8a** does not react by C–O bond cleavage in contrast to direct irradiations, which proceed through the excited singlet state. As discussed previously, this proposal is supported by the decreases in Φ_f and τ_f for **8a** (Table 1) relative to the *(E)*-1-phenylpropene **11a**.

None of the compounds irradiated in methanol, as in cyclohexane, gave observable quantities of radical coupling products. Therefore, the observed photochemistry is consistent with three possible mechanisms: (*i*) heterolytic cleavage of the C–O bond from S_1 to form the ion pair directly, (*ii*) homolytic cleavage from S_1 followed by electron transfer that is faster than decarboxylation of the acetyloxy radical, and (iii) bimolecular reaction of methanol with S_1 to form **14** (S_N2') or **15** (S_N2). The second would require that electron transfer be more than an order of magnitude faster than 10^9 s^{-1}, the rate of decarboxylation of the acetyloxy radical (15) and therefore faster than previously determined rates for benzyl systems (1). The third also seems unlikely because, to our knowledge, convincing evidence for this possibility in photosolvolysis reactions has not been reported. The first possibility, direct heterolytic cleavage from S_1, is therefore most probable. This suggestion is supported by the greater efficiency of reaction for the methoxy substituted compounds, which should favour cation formation relative to those with trifluoromethyl substituents.



By reaction of the solvent at the aryl-substituted end C1 of the allylic cation, Scheme 2, the photosolvolysis products primarily give the unconjugated ether **14**. The same observation was made for the 1-naphthylmethyl derivatives **3**

© 2006 NRC Canada

(eq. [2]) with **6** formed in preference to **7**. Moreover, irradiation of the conjugated ether **15a** in methanol did not result in formation of the unconjugated isomer **14a**. If the two isomers were equilibrating photochemically then **14a**, with the weaker chromophore, would have been the major one in the mixture. Finally, because the conjugated isomers **15** will be more stable than the unconjugated ones **14**, any explanation for the preference for **14** must be a kinetic rather than a thermodynamic one.

This selective regiochemistry could simply be the result of the distribution of the positive charge in the cationic intermediate **16**. However, calculated positive charges (Mulliken, with attached hydrogens summed into the carbons) by Gaussian 03 (B3LYP, 6-31G(d), optimized geometry) (16) for **16** gave values (X, charge at C1, charge at C3) that were significantly higher at C3 than C1: **16a** (H, 0.091, 0.200), **16b** (4-methoxy, 0.055, 0.155), **16c** (3-methoxy, 0.081, 0.192), **16d** (4-trifluoromethyl, 0.098, 0.214), **16e** (3-trifluoromethyl, 0.099, 0.215). This result leads to a prediction opposite to that observed. However, examination of the LUMO, a pure π orbital dominated by contributions from the AO's at C1 and C3 so that it resembles an allyl system, was more satisfactory. The values for **16** were (X, contribution from $2p_x + 3p_x$ at C1, contribution from $2p_x + 3p_x$ at C3, difference): **16a** (H, 0.710, –0.614, 0.096), **16b** (4-methoxy, 0.694, –0.579, 0.115), **16c** (3-methoxy, 0.0.723, –0.617, 0.105), **16d** (4-trifluoromethyl, 0.718, –0.616, 0.102), **16e** (3-trifloromethyl, 0.725, –0.620, 0.105). Therefore, the LUMO is dominated by the contribution from C1 for all substituents, the largest difference being for the 4-methoxy compound where the selectivity is also high for reaction at C1 to give **14** (95%) over C3 to give **15** (5%) (Table 1). A similar observation that LUMO coefficients are better than positive charge distribution at predicting the regioselectivity of cation reactivity with methanol has been reported previously for photosolvolysis reactions (17). The asymmetry of the allyl fragment in the cations **16** is also apparent from the calculated bond lengths. The C1–C2 bond is significantly longer (1.420 ± 0.002) than that for C2–C3 (1.358 ± 0.0023), this difference being essentially independent of substituent.

The possibility that the methyl ethers **14** and **15** were formed as secondary photoproducts from the initially formed rearranged esters **9** was also independently tested by studying the photochemistry of **9**. As indicated in Table 2 and as expected, the esters **9a**–**9c** absorbed at similar wavelengths to **8a**–**8c**, but the molar absorptivity of compounds **9** was more than one order of magnitude lower. Therefore, competitive photochemistry of **9** is unlikely because it cannot be absorbing a significant percentage of the photons until very high conversion. Moreover, the rearranged acetate **9b** was not even observed in the photolysis of **8b** in methanol. The other interesting observation from the photochemistry of compounds **9** is that the products were exclusively the unconjugated ethers **14** and the radical coupling products **17** (eq. [6]). As discussed above, these latter products were not observed as photoproducts in methanol from compounds **8**. This implies that the excited states of **8** and **9** behave quite differently, the latter being comparable to normal benzylic ester photochemistry.

[6] 

9 **14** **17**

For irradiation of the 3- or 4-trifluoromethyl substituted compounds **8d** and **8e** in methanol, photosolvolysis is not the major pathway. In both cases the major photoproducts are the rearranged acetates **9** and **13**, the former being preferred. This result is consistent with a less efficient heterolytic cleavage because the electron-withdrawing groups do not assist with the bond breaking process. As discussed previously, this conclusion is supported by their small changes in fluorescence quantum yield and excited singlet state lifetime (Table 1) relative to the siloxanes **10d** and **10e**. The reversed polarity of the excited states as a consequence of the electron-withdrawing groups may also explain the preference for 1,3-hydrogen and 1,3-acetoxy migrations to give compounds **9** and **13**, respectively.

Conclusions

The photochemistry of the *(E)*-cinnamyl acetates is similar to that of benzylic esters in that processes involving C–O bond cleavage occur, including photosolvolysis in methanol. These processes from the excited singlet state are in competition with the more efficient intersystem crossing followed by *E* to *Z* isomerization from the triplet state. In contrast to benzylic systems, where 3-methoxy derivatives react considerably more efficiently than the 4-methoxy substituted ones in polar protic solvents, both methoxy compounds give high yields of photosolvolysis for the cinnamyl derivative. In fact, the 4-methoxy compound gives essentially 100% yield of ion-derived ethers in methanol.

In both cyclohexane and methanol, no evidence for radical-derived products was obtained. The rearranged acetates appear to be derived from concerted 1,3-hydrogen or acetoxy migrations.

Experimental

Materials and instruments

All NMR spectra were obtained in $CDCl_3$ using a Bruker 250 MHz instrument unless otherwise noted. High resolution mass spectrometry (HRMS) was performed on a CEC 21-110B sector instrument using electron impact ionization. Solvent extractions were dried with magnesium sulfate. Toluene was distilled from CaH. Ethyl acetate and hexane were flash distilled prior to chromatography. All other solvents were used without further purification. Solvents used for photochemical experiments were obtained commercially as HPLC grade. Column chromatography was performed using 60–250 mesh silica gel under flash conditions. Chiral chromatography was performed on a Varian Star #1 instrument using a Chiracel AD-RH column eluted with methanol–water.

Irradiations

A solution of ~100 mg of the appropriate compound in 100 mL of methanol or cyclohexane was purged with nitrogen and then irradiated in a Rayonet photochemical reactor using 16 lamps (75 W, 254 nm). The temperature was con-

© 2006 NRC Canada

trolled (±1 °C) by circulating water in an immersion tube. Reaction progress was monitored by GC followed by NMR analysis after solvent evaporation. For sensitized reactions in methanol, ~250 mg of **8a** and xanthone (3.6×10^{-4} mol/L, A = 2.3 at 340 nm) in 280 mL of solvent was irradiated in the well of a 450 W Hanovia lamp using a Pyrex filter. In the absence of the sensitizer, no reaction occurred under these conditions.

GC method

GCMS analyses were done a PerkinElmer Autosystem using a Supelco 30 mm × 0.25 mm MDN-5S 5% phenyl methylsiloxane column, film thickness 0.50 µm, temperature programmed as follows: 60 °C for 1min, 20 °C/min to 240 °C, 240 °C for 10 min.

Absorbance measurements

Absorbance spectra were recorded at 1 nm resolution using a Cary 100 UV–vis spectrometer thermostated at 25 °C.

Fluorescence measurements

All samples were degassed by three freeze-pump-thaw cycles and then thermostated at 25 °C. Fluorescence intensity measurements were done using a PTI-210M fluorescence spectrometer with dual Model 101 monochromators, a 75W Xenon lamp, and a Model 814 photomultiplier detector. Corrected spectra were obtained.

Singlet lifetimes were measured by monitoring fluorescence decay using a PRA time-correlated single photon counting apparatus with a hydrogen flash lamp with pulse width of about 1.8 ns. The cell compartment was thermostated at 25.0 °C with circulating water from a constant temperature bath.

General synthetic procedure for substituted (*E*)-cinnamyl acetates 8

(E)-Cinnamyl acetate **8a** is commercially available. For the other acetates, the commercially available substituted *(E)*-cinnamic acid was converted to its respective ester by refluxing in 100% ethanol in the presence of a catalytic amount of *p*-toluenesulfonic acid for 24–36 h. The isolated ester was then treated with 3 equiv. of diisobutyl aluminum hydride (DIBAL) in toluene in an ice bath. The reaction was allowed to stir for 2 h. The reaction was quenched with aq HCl (5%) and extracted with ether. The organic layer was washed with aq HCl (5%), water, brine, and then dried. The resulting alcohol was purified by recrystallization or chromatography to give the known X-substituted cinnamyl alcohols: X = 4-methoxy (18), X = 3-methoxy (19), X = 4-trifluoromethyl (20), X = 3-trifluoromethyl (21). Treatment of the alcohol with excess acetyl chloride in benzene then purification by chromatography yielded the substituted *(E)*-cinnamyl acetate.

4-Methoxycinnamyl acetate 8b

^{1}H NMR δ 7.32 (d, 2H, *J* = 8.5 Hz), 6.85 (d, 2H, *J* = 8.7 Hz), 6.60 (d, 1H, *J* = 16 Hz), 6.15 (dt, 1H, *J* = 16 and 6.2 Hz), 4.69 (d, 2H, *J* = 6.5 Hz), 3.80 (s, 3H), 2.01 (s, 3H). ^{13}C NMR (62.5 MHz) δ 171.1, 159.8, 134.2, 129.1, 128.0, 121.0, 114.2, 65.5, 55.4, 21.2. HRMS calcd. for $C_{12}H_{14}O_3$: 206.0943; found: 206.0939. The literature reference for the synthesis provides no spectral data (22).

3-Methoxycinnamyl acetate 8c

^{1}H NMR δ 7.25 (m, 1 H), 6.95 (d, 1H), 6.92 (bs, 1H), 6.83 (dd, 1H), 6.63 (d, 1H), 6.27 (dt, 1H), 4.73 (dd, 2H), 3.81 (s, 3H), 2.10 (s, 3H). ^{13}C NMR (62.5 MHz) δ 171.0, 160.1, 137.8, 134.3, 129.8, 123.8, 119.5, 114.0, 112.1, 65.2, 55.4, 21.2. The literature reference for the synthesis provides no spectral data (10).

4-Trifluoromethylcinnamyl acetate 8d

^{1}H NMR δ 7.57 (d, 2H, *J* = 7 Hz), 7.47 (d, 2H, *J* = 8 Hz), 6.67 (d, 1H, *J* = 16 Hz), 6.37 (dt, 1H, *J* = 16 and 6 Hz), 4.75 (d, 2H, *J* = 6 Hz), 2.11 (s, 3 H). ^{13}C NMR (62.5 MHz) δ 170.8, 139.9 (q, *J* = 1 Hz), 132.4, 129.9 (q, *J* = 32 Hz), 126.9, 126.2, 125.7 (q, *J* = 3.6 Hz), 124.3 (q, *J* = 270 Hz), 64.7, 21.0. HRMS calcd. for $C_{12}H_{11}F_3O_2$: 244.0711; found: 244.0714 (23).

3-Trifluoromethylcinnamyl acetate 8e

^{1}H NMR δ 7.7–7.4 (m, 4H), 6.67 (d, 1H, *J* = 16 Hz), 6.36 (dt, 1H, *J* = 16 and 6 Hz), 4.35 (d, 2H, *J* = 6 Hz), 2.11 (s, 3 H). ^{13}C NMR (62.5 MHz) δ 170.9, 137.1, 132.5, 131.2 (q, *J* = 32.3), 129.8 (q, *J* = 1.3), 129.2, 125.5, 124.7 (q, *J* = 3.7), 124.2 (q, *J* = 271), 123.4 (q, *J* = 4.0), 64.7, 21.0. HRMS calcd. for $C_{12}H_{11}F_3O_2$: 244.0711; found: 244.0713.

General synthetic procedure for substituted 3-aryl-3-propenyl acetates 9a–9c

The aldehyde (9.5 mmol) in 100 mL of anhydrous ether was cooled in an ice bath and 8.5 mL (8.5 mmol) of vinyl magnesium bromide was added. The reaction mixture was stirred for 3 h followed by the addition of acetyl chloride (2.4 mL, 38 mmol) followed by further stirring for 20 h. The reaction mixture was then poured into aq NaOH (5%) and extracted with ether. The extract was washed with water and saturated brine and then dried with magnesium sulfate. The crude ester was then purified by column chromatography with yield approximately 75%. Spectral data agreed with those reported previously: X = H (24), X = 4-methoxy (25), X = 3-methoxy (26).

Characterization of photoproducts from irradiation of the cinnamyl esters 8

The following compounds were isolated from photolysis mixtures by separation using column chromatography. Spectra were compared with those from the literature. Other photoproducts were not obtained in pure form but were identified by GCMS and analysis of ^{1}H NMR of mixtures.

3-(4-Trifluoromethylphenyl)-3-propenyl acetate 9d (26)

^{1}H NMR δ7.62 (d, 2H, *J* = 8.5 Hz), 7.46 (d, 2H, *J* = 8.5 Hz), 6.28 (bd, 1H, *J* = 6 Hz), 5.98 (ddd, 1H, *J* = 17, 10.3 and 6 Hz), 5.30 (m, 2H, =CH_2), 2.13 (s, 3H). GCMS *m/z* (rel. intensity): 244 (1), 202 (11), 165 (49), 164 (19), 145 (29, 133 (31), 116 (24), 115 (100), 75 (14), 69 (25), 63 (13).

3-(3-Trifluoromethylphenyl)-3-propenyl acetate 9e

185 (12), 184 (20), 165 (38), 164 (19), 145 (22), 133 (24), 116 (202), 115 (100), 69 (12).

3-Methoxy-3-phenylpropene 14a (27)

^{1}H NMR δ 7.5–7.2 (m, 5H), 5.93 (ddd, 1H, *J* = 17, 10.4 and 6.8 Hz), 5.23 (m, 2H, =CH_2), 4.61 (bd, H, *J* = 6.8 Hz), 3.43 (s, 3H). GCMS *m/z* (rel. intensity): 148 (1), 116 (30), 115 (86), 91 (53), 89 (15), 77 (68), 63 (38), 62 (20), 51 (100).

3-Methoxy-3-(4-methoxyphenyl)propene 14b (28)

^{1}H NMR δ 7.24 (d, 2H, *J* = 8.7 Hz), 6.88 (d, 2H, *J* = 8.7 Hz), 5.93 (ddd, 1H, *J* = 17.3, 10.2 and 6.5 Hz), 5.23 (m, 2H, =CH_2), 4.57 (bd, H, *J* = 6.5 Hz), 3.79 (s, 3H), 3.30 (s, 3H). GCMS *m/z* (rel. intensity): 178 (89), 177 (28), 163 (14), 151 (44), 148 (17), 147 (100), 146 (94), 135 (32), 132 (15), 131 (69), 117 (15), 116 (13), 115 (45), 104 (18), 103 (97), 102 (26), 91 (51), 89 (14), 78 (24), 77 (67), 76 (15), 65 (20), 63 (30), 55 (230, 51 (34).

3-Methoxy-3-(3-methoxyphenyl)propene 14c (26)

^{1}H NMR δ 7.3–6.7 (m, 4H), 5.92 (ddd, 1H, *J* = 16.7, 10.7 and 6.5 Hz), 5.27 (dt, 1H, *J* = 16.7 and 1.5 Hz), 5.19 (bd, 1H, *J* = 10.7 Hz), 4.59 (bd, H, *J* = 6.5 Hz), 3.80 (s, 3H), 3.33 (s, 3H). GCMS *m/z* (rel. intensity): 178 (75), 177 (18), 163 (19), 151 (32), 148 (15), 147 (63), 146 (100), 135 (22), 131 (50), 117 (12), 115 (32), 104 (13), 103 (63), 102 (15), 91 (28), 78 (13), 77 (30), 63 (15), 51 (12).

3-Methoxy-3-(3-trifluoromethylphenyl)propene 14e

^{1}H NMR δ 7.6–7.4 (m, 4H), 5.88 (m, H), 5.26 (m, 2H), 4.66 (bd, H, *J* = 7.1 Hz), 3.36 (s, 3H). GCMS *m/z* (rel. intensity): 218 (1), 189 (15), 73 (13), 165 (96), 164 (18), 147 (50), 145 (56), 141 (97), 133 (59), 117 (23), 116 (23), 115 (100), 109 (10), 91 (12), 89 (16), 75 (23), 69 (60), 63 (33), 55 (19), 51 (22), 50 (21).

(E)-3-Methoxy-1-(3-methoxyphenyl)propene 15c

^{1}H NMR δ 7.23 (t, 1H, *J* = 7.8 Hz), 6.98 (d, 1H, *J* = 7.8 Hz), 6.92 (d, 1H, *J* = 1.5 Hz), 6.81 (dd, 1H, *J* = 8 and 1 Hz), 6.58 (bd, 1H, *J* = 15.8 Hz), 6.27 (dt, 1H, *J* = 15.8 and 6 Hz), 4.09 (dd, 2H, *J* = 6 and 1 Hz), 3.81 (s, 3H), 3.39 (s, 3H).

(Z)-3-Methoxy-1-(3-methoxyphenyl)propene 15c

^{1}H NMR δ: 7.25 (t, 1 H, *J* = 8.5 Hz), 6.84–6.76 (m, 3 H), 6.57 (d, 1 H, *J* = 12 Hz), 5.84 (dt, 1 H, *J* = 12 and 6.5 Hz), 4.19 (d, 2 H, *J* = 6.3 Hz), 3.81 (s, 3 H), 3.36 (s, 3H).

(E)-3-(4-Trifluoromethylphenyl)-1-propenyl acetate 13d

^{1}H NMR δ: 7.55 (d, 2H, *J* = 8 Hz), 7.31 (d, 2H, *J* = 8 Hz), 7.20 (dt, 1H, *J* = 13 and 1.5 Hz), 5.50 (dt, 1H, *J* = 13 and 7.5 Hz), 3.39 (bd, 2H, *J* = 7.5 Hz), 2.07 (s, 3H).

(Z)-3-(4-Trifluoromethylphenyl)-1-propenyl acetate 13d

^{1}H NMR δ 7.55 (d, 2H, *J* = 8 Hz), 7.31 (d, 2H, *J* = 8 Hz), 7.19 (dt, 1H, *J* = 6.5 and 1.7 Hz), 5.07 (dt, 1H, *J* = 7.7 and 6.5 Hz), 3.55 (bd, 2H, *J* = 7.7 Hz), 2.13 (s, 3H). The two last isomers have not been previously reported but their spectra match (*E*)- and (*Z*)-3-phenyl-1-propenyl acetate (29).

The recognition and sensing of anions by a novel phenanthroline-bridged diamide

Yan-Hong Qiao, Hai Lin, and Hua-Kuan Lin

Abstract: A novel neutral anion recognition receptor **1** with the additional capability of selectively sensing anionic guest species has been synthesized and examined for its anion-binding abilities by UV–vis absorption spectroscopy. The results of nonlinear curve fitting and Job plot indicate that **1** forms 1:1 stoichiometric complexes with fluoride, chloride, bromide, iodide, and acetate, respectively. Their UV–vis absorption spectra in DMSO indicate the presence of anions such as F^-, Cl^-, Br^-, I^-, and AcO^- with high affinity ability and selectivity toward F^-, and also show dramatic colour changes from colourless to yellow in the presence of TBAX (1×10^{-5} mol/L, X= F^-, Cl^-, Br^-, I^-, and AcO^-). Receptor **1** has almost no affinity abilities for $H_2PO_4^-$ and OH^-.

Key words: phenanthroline-bridged diamide, synthesis, UV–vis spectrum, anion recognition.

Résumé : On a réalisé la synthèse d'un nouveau récepteur (**1**) qui peut reconnaître un anion neutre tout en possédant aussi la capacité de détecter la présence d'espèces invitées anioniques et, faisant appel à la spectroscopie UV-vis, on a étudié ses capacités à se lier aux anions. Les résultats d'un ajustement de courbe non linéaire et une courbe de Job indiquent que le composé **1** forme des complexes de stoechiométrie 1:1 respectivement avec les ions fluorure, chlorure, bromure, iodure et acétate. Leurs spectres d'absorption UV–vis dans le DMSO montrent qu'ils répondent avec une possibilité d'affinité élevée à la présence des anions tels que F^-, Cl^-, Br^-, I^- et AcO^-, avec sélectivité à la présence de F^- et avec un changement dramatique de couleur, d'incolore à jaune en présence de TBAX (1×10^{-5} mol/L, X = F^-, Cl^-, Br^-, I^- et AcO^-). Le récepteur **1** n'a pratiquement pas de possibilité d'affinité pour le $H_2PO_4^-$ ou le OH^-.

Mots clés : diamide à pont phénanthroline, synthèse, spectre UV–vis, reconnaissance d'anions.

[Traduit par la Rédaction]

Introduction

The development of neutral receptors for the recognition of anions has attracted much attention in organic as well as inorganic chemistry during recent years (1–11). There are a number of reasons for the sudden growth in this new area. Anions are ubiquitous throughout biological systems. Inorganic anions such as fluoride, chloride, bromide, iodide, dihydrogenphosphate, acetate, or hydroxide ion play an important role in energy transduction in organisms and control metabolic processes via participation in enzymatic reactions. They carry genetic information (DNA is a polyanion). The majority of enzyme substrates and cofactors are anionic. Anions also play roles in the areas of medicine and catalysis. Anions are larger than isoelectronic cations (12) and therefore have a lower ratio of charge to radius. This means that electrostatic binding interactions of anions are less effective than for the smaller cations. The design of anion receptors is particularly challenging. The design and synthesis of fluorescent or colorimetric sensors (13–18) are of vital importance because of their potential applications. In general, the performance of a chemosensor can be improved either by (*i*) increasing its selectivity through the preorganization of the receptor or (*ii*) through the improved signal transduction (read-out) that leads to a reliable substrate specific response. Aromatic scaffolds for amide groups are common motifs in anion receptors. The effectiveness of such building blocks was shown by Crabtree and coworkers with isophthalamide (11) and dipicolinic bisamide (19), followed by Gale et al. with pyrrole derivatives (20, 21). We decided to extend this family of aromatic building blocks to phenanthroline derivatives. In this note, we report the result of an anion recognition study of our novel *N*,*N*-(*p*-nitro-phenyl)-1,10-phenanthroline-2,9-dimethanamide receptor (Scheme 1).

Experimental

Reagents

All anions, in the form of tetrabutylammonium salts, were purchased from Sigma-Aldrich Chemical Co., stored in a desiccator under vacumm containing self-indicating silica,

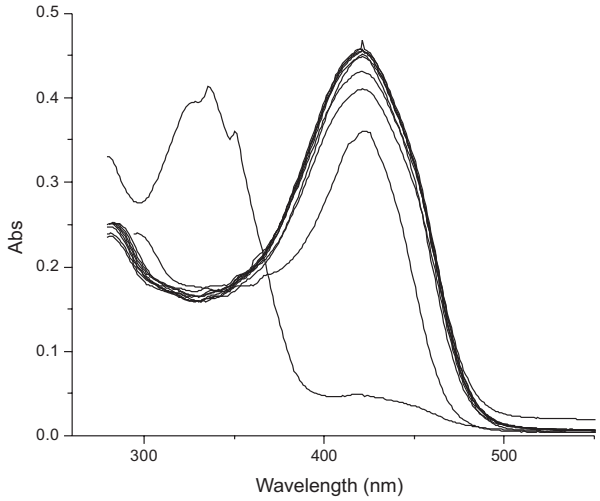
Scheme 1.

used without any further purification, and dried with P_2O_5 in a vacumm desiccator at 353 K for 24 h prior to use. Dimethyl sulfoxide was dried with calcium hydride and distilled at reduced pressure prior to use. Unless stated otherwise, AR grade chemicals were purchased and used without further purification. The 1,10-phenanthroline-2,9-dicarboxylic acid was prepared according to the known method (22).

Instruments

Elemental analyses for C, H, and N were carried out on a PerkinElmer 240C element analyzer at the Institute of Elemento-Organic Chemistry, Nankai University. The ^{1}H NMR spectra were recorded using a Varian UNITY-plus 400 MHz spectrometer at the State Key Laboratory of Functional Polymer Materials for Absorption and Separation, Nankai University. UV–vis absorption spectra were performed on a General 1900 spectrophotometer. The spectrophotometer was standardized.

Synthesis



N,N′-(p-*nitro-phenyl)-1,10-phenanthroline-2,9-dimethanamide (1)*

The receptor *N*,*N*′-(*p*-nitro-phenyl)-1,10-phenanthroline-2,9-dimethanamide (**1**) was prepared by a method similar to that in the literature (23). To 1,10-phenanthroline-2,9-dicarboxylic acid (1.1 g, 4 mmol) was added thionyl chloride (25 mL) and the mixture refluxed for 6 h. The solution was concentrated under reduced pressure to dryness. The residue was added to 4-nitro-phenylamine (1.12 g, 8.1 mmol) in dry dichloromethane (50 mL) followed by the addition of triethylamine (2.5 mL). The solution was stirred for 72 h at room temperature, poured into sodium bicarbonate – deionized water, filtered, and washed with water to give a white solid, which was recrystallized from DMF to yield 0.68 g of **1** (yield 34.3%). ^{1}H NMR (DMSO-d_6) δ: 11.86 (s, 2H, NH), 8.87 (d, 2H, phen-H), 8.64 (d, 2H, phen-H), 8.45 (m, 8H, phenyl-H), 8.31 (d, 2H phen-H). Anal. calcd. for $C_{26}H_6N_6O_6.H_2O$: C 59.32, H 3.42, N15.97; found: C 59.79, H 3.88, N 15.86.

Anion titration of 1

Spectrophotometric titrations were performed on solutions of compound **1** (1.0×10^{-5} mol/dm^3) in DMSO (redistilled before use). Typically, increasing concentrations (0–10 equiv.) of a standard fresh tetrabutylammonium salt solution of the required anion F^-, Cl^-, Br^-, I^-, AcO^-, $H_2PO_4^-$, and OH^- were added, respectively, and the UV-vis absorption of the samples were recorded.

Fig. 1. UV–vis spectrum of **1** (1.0×10^{-5} mol/dm^3) in the presence of fluoride in DMSO. The equiv. of the fluoride anion are: 0, 0.05, 0.1, 0.2, 0.5, 0.8, 1, 2, 3, 4, and 5.

Results and discussion

Figure 1 shows the changes in the UV–vis spectra of **1** at a concentration of $1 \times 1.0\ 0^{-5}$ mol /dm^3 in DMSO upon addition of the fluoride anion. When the fluoride anion was introduced to the solution of **1**, a new absorption peak was observed at 422 nm and the absorbances at 336 and 351 nm were significantly decreased. Similar phenomena were observed when Cl^-, Br^-, I^-, or AcO^- were added to the solution of **1**. A satisfactory result was achieved when nonlinear curve fitting (absorbance at 422 nm against the fluoride anion equivalent) confirmed that **1** and fluoride anion formed a 1:1 complex, as shown in Fig. 2.

A continuous variation method was used to determine the stoichiometric ratios of the receptor **1** and the fluoride anion guest. Figure 3 shows a Job plot of the difference between the observed absorbance and the absorbance of the free receptor **1** (422 nm with the molar fraction of host {[H] / ([H] + [G])}) for a series of solutions in which the total concentration of host and fluoride anion guest was constant (2.0×10^{-5} mol /dm^3), while the molar fraction of the host was continuously varyied (24). The result illustrates that the receptor–anion complex concentration approaches a maximum when the molar fraction of the host {[H] / ([H] + [G])} is about 0.50, meaning that the receptor formed a 1:1 complex with the fluoride anion. In the same way, it was deduced that the receptor **1** and other halide anions (Cl^-, Br^-, and I^-) also formed 1:1 complexes. Though the shape of the acetate anion is different from the halide anions, the Job plot (Fig. 4) still proved that it would bind to the receptor in 1:1 stochiometry, as in the fluoride case.

For a complex of 1:1 stoichiometry, the relation in eq. [1] could be derived easily, as reported formerly (25), where *X*

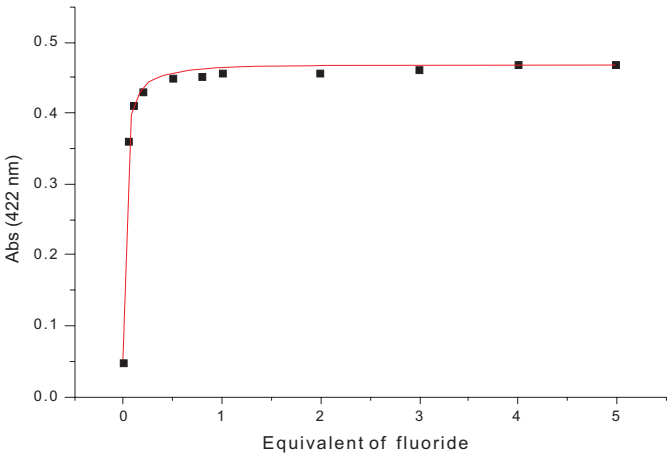
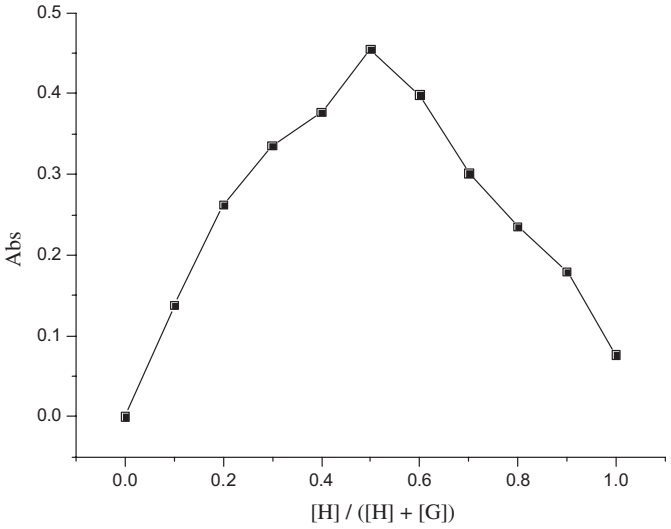
Table 1. Association constants (K_{ass}) of receptor **1** with anions in DMSO.

Anion	Fluoride	Chloride	Bromide	Iodide	Acetate	Phosphate	Hydroxy
K_{ass} ((mol/L)$^{-1}$)	5.64×10^6	3.33×10^5	1.89×10^5	1.24×10^4	1.96×10^5	Nd	Nd

Note: Nd indicates that the spectra showed little or no change with the addition of the anion so that the affinity constant cannot be determined using the spectra.

Fig. 2. Nonlinear curve at 422 nm vs. equiv. of fluoride anion. The correlation coefficient (R^2) of the nonlinear curve fit is 0.99809.





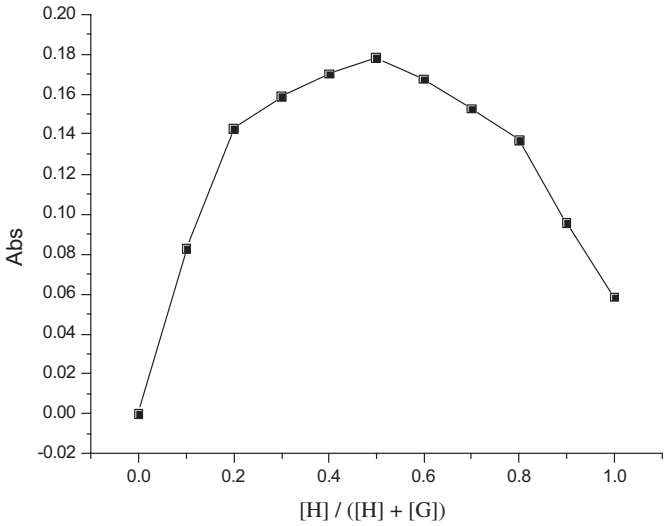


Fig. 3. Job plot of receptor **1** with fluoride anion at 422 nm. The total concentration of the host and guest was 2.0×10^{-5} mol/dm^3.

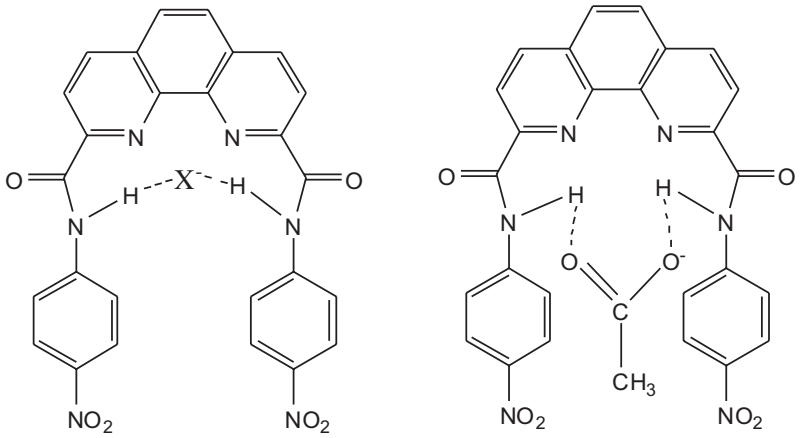
is the absorption intensity, and c_H or c_G is the concentration of the host or the anion guest, respectively.

$$[1] \quad X = X_0 + (X_{lim} - X_0)\{c_H + c_G + 1/K_{ass} - [(c_H + c_G + 1/K_{ass})^2 - 4c_Hc_G]^{1/2}\}/2c_H$$

Fig. 4. Job plot of receptor **1** with acetate anion at 423 nm. The total concentration of the host and guest was 2.0×10^{-5} mol/dm^3.



The affinity constants determined by UV–vis titration, summarized in Table 1, illustrate that the receptor can bind anions in the order $F^- > Cl^- > AcO^- > Br^- > I^- > H_2PO_4^- \sim OH^-$. In particular, receptor **1** can recognize fluoride anions with higher selectivity (over 10 times) than other halide anions, which is better than some fluorogenic receptors or colorimetric sensors reported previously (13–18). This indicates that the selective recognition for halide anions is related to the size of the anions.

Conclusion

In summary, a neutral anion receptor **1**, bearing diamide binding sites, was synthesized. The receptor **1** forms 1:1 complexes with anions. The receptor **1**, with a cleft forming a rigid cavity with two rigid arms, binds preferably with anions through effective hydrogen bonding. The sensitivity for the recognition of halide anions is related to the size of the anions. The cleft between the hydrogen of NH in receptor **1** is able to bind well to small anions, such as fluoride. Acetate (a triangular anion) is too big to enter the cleft, but binds via two O's with the two H's of NH on the cavity plane of receptor **1**. The proposed binding mode of receptor **1** is shown in Scheme 2. The receptor **1** selectively binds F^-, Cl^-, Br^-, I^-, and AcO^-, in particular the fluoride anion, with high affinity. Upon the addition of anions (F^-, Cl^-, Br^-, I^-, or AcO^-) to a solution of **1**, the response shows dramatic colour changes from colourless to yellow and selectivity toward F^-.

Catalyzed β scission of a carbenium ion II — Variations leading to a general mechanism

Qingbin Li and Allan L.L. East

Abstract: The β-scission mechanisms of catalytically chemisorbed carbenium ions are further investigated using density functional theory computations and explicit-contact modelling, but with slightly larger catalyst fragment models than in our previous work. Some variations are seen, including the existence of formal one-step and three-step (rather than two-step) mechanisms. The activation barriers are most affected by the basicity of the catalyst model than by any other characteristics: the stronger the base, the greater the barrier. A general mechanism for β scission is presented, as are the specific mechanisms for all the step variations observed from computations to date.

Key words: C–C bond fission, β scission, carbenium ion, catalysis, chloroaluminate, mechanism.

Résumé : Faisant encore appel à des calculs de théorie de la densité fonctionnelle, on a étudié à nouveau les mécanismes de scission-β d'ions carbénium catalytiquement chimisorbés en faisant de la modélisation de contact explicite et en examinant des modèles de fragments de catalyseur légèrement supérieurs à ceux examinés antérieurement. On a observé des variations, y compris l'existence des mécanismes formels à une et à trois étapes, plutôt que deux étapes. La basicité du modèle du catalyseur est le facteur qui affecte le plus les paramètres d'activation; plus la base est forte, plus grande est la barrière. On présente un mécanisme général pour les scissions β ainsi que des mécanismes spécifiques pour toutes les variétés d'étapes qui ont été observées jusqu'à maintenant à partir des calculs.

Mots clés : scission d'une liaison C–C, scission β, ion carbénium, catalyse, chloroaluminate, mécanisme.

[Traduit par la Rédaction]

Introduction

Catalyzed β scission of the secondary carbenium ion *s*-$C_5H_{11}^+$ on small aluminum-containing anions ($AlH_2(OH)_2^-$ and $AlHCl_3^-$) has been computationally studied by us recently (1). That study filled the holes left by earlier studies of aluminum oxide catalysis of β scission (2–4) and demonstrates qualitative differences in the mechanism due to the different strengths of basicity of the two anions. We have also published β-scission steps found for the larger *s*-$C_6H_{13}^+$ ion on $AlHCl_3^-$ (5).

Real catalytic systems involve condensed phases and are much more difficult to model. Two examples of current interest are solid aluminosilicate zeolites and chloroaluminate ionic liquids. To date, calculations using periodic boundary conditions (6) have been forced to use approximate transition-state-finding algorithms (7) and await improvements. Continuum dielectric models have been problematic for proton-transfer phenomena and may be more so for ionic liquids, although new improvements look promising (8–10).

In this current study, we obtained more B3LYP computational results of minimum-energy pathways for β scission of secondary carbenium ions, initially chemisorbed to various anions. Five systems were studied, $C_5H_{11}^+$ on $Al(OH)(OSiH_3)_3^-$, $C_5H_{11}^+$ on $Al_2Cl_7^-$, $C_6H_{13}^+$ on $Al_2Cl_7^-$, $C_6H_{13}^+$ with a two-fragment catalyst model $AlCl_4^-$ + $AlHCl_3^-$, and $C_6H_{13}^+$ with a three-fragment catalyst model $AlCl_4^-$ + $AlHCl_3^-$ + Na^+. These systems are still poor mimics of real zeolite or ionic liquid systems. However, that is not the point. First, these systems allow us to explore how transition states and mechanisms may change as the models get larger without having to compromise on the accuracy in energy and transition-state calculations. Second, and most importantly, with these 22 new transition states added to the 12 found in our first paper and the 10 relevant ones from ref. 5, we feel we have enough examples to be able to present a truly proper discussion of the β scission of a secondary carbenium ion.

Methods, models, and terminology

Calculations were performed to locate transition states (and the intermediates that they connect) for the β scission of chemisorbed 2-pentenium and 2-hexenium ions, catalyzed by various catalyst models in explicit contact. All computational methods and procedures are the same as before (1), based on the density functional theory model B3LYP (11, 12) with the 6-31G(d,p) basis set (13) and using the PQS 3.0 (14) and Gaussian 98-03 (13) codes. The energies reported have no ZPVE corrections attached, both for consistency with ref. 1 and to maintain focus on the underlying potential energy surface (PES).

For a more zeolite-like aluminosilicate fragment, the 18-atom cluster $Al(OH)(OSiH_3)_3^-$ containing four tetrahedral atoms (denoted T4 model, T=Si, Al), was employed.

 doi:10.1139/V06-143 © 2006 NRC Canada

Compared with the T1 model $AlH_2(OH)_2^-$ used in our previous study (1), the T4 model can better represent the surface of a zeolite, having three surface oxygen atoms and each of these bonded to a silicon atom to make the electron density near the Al and the basicity of the oxygen atoms more realistic. This T4 model has been used in other quantum chemical studies as a zeolite mimic. For example, Svelle et al. used T4 to investigate methylation of methylbenzenes and alkenes by halomethanes and methanol over acidic zeolites (15, 16) and the dimerization of linear alkenes over acidic zeolites (4). Arstad et al. (17, 18) studied the methylation, ethylation, and iso-propylation of methylbenzenes on T4 zeolites. Moreover, Rozanska et al. (19, 20) showed that the relative order of the activation energies of isomerization and transalkylation reactions of toluene and xylenes is conserved when comparing results obtained from T4 with results from larger models using periodic boundary conditions and plane wave basis sets.

For a chloroaluminate ionic liquid fragment, $Al_2Cl_7^-$ was chosen as a first extension over the previously used $AlHCl_3^-$. This choice was motivated by the work in the Johnson group (21). Using B3LYP/6-31G(d,p), Hunter thoroughly examined ionic liquid ion cluster systems involving $AlCl_3$, pyridine (Pyr), and HCl in various ratios and the resulting energies suggested that $PyrH^+$, $Al_2Cl_7^-$, and $AlCl_4^-$ were the predominant species in these mixtures, with extra HCl units complexed to the anions (22).

Further extension of an ionic liquid model was explored using two- and three-fragment catalysis models. The two-fragment model employed both $AlHCl_3^-$ and $AlCl_4^-$ placed on either side of the hydrocarbon and was first tried in an exploration of intermediates (ref. 5, Fig. 9). Since this model produces an overall –1 charge for the system, a three-fragment overall-neutral model was also tested, simply by adding a Na^+ spectator ion to the model. These models were designed to explore the possibility of a lowering of the β-scission barrier by providing a more flexible product chemisorption site option.

As before, we refer to the conversion from chemisorbed to physisorbed structures as ascension and the opposite as descension. We will use single and double slashes to denote chemisorbed and physisorbed complexes, respectively, (eg. $C_6H_{13}^+/AlHCl_3^-$ vs. $C_6H_{13}^+//AlHCl_3^-$). Our atom-numbering convention will be to count the carbon atoms as C_1, C_2, C_3, C_4, and C_5, or for hexane cracking to C_6, such that the C_2 atom is initially bound to the O_1 or Cl_1 atom of the catalyst in the chemisorbed state. A common abbreviation we use is PCP^+ for protonated dialkylcyclopropane, the prevalent form of a physisorbed or gas-phase secondary carbenium ion.

Results

The Cartesian coordinates of the 22 new transition states are provided as Supplementary Material, for purposes of reproducibility.[2] Specific bond distances are not reported in this paper because the important ones hardly differ from the values reported earlier, found with smaller Al-O and Al-Cl anion models (1). The structural results are presented in this section; the energies are left for the Discussion section.

One-fragment catalyst models $T4^-$ and $Al_2Cl_7^-$

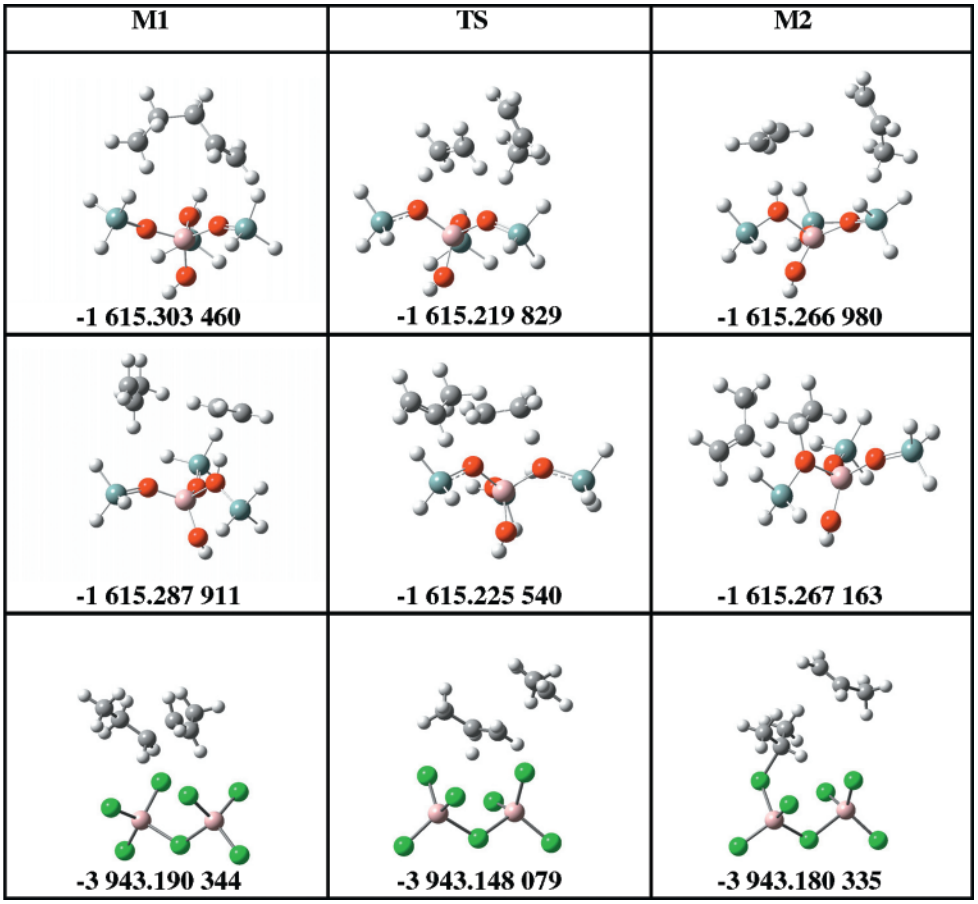
Seven transition states (and the minima they connect) were found for the reaction $C_5H_{11}^+ \rightarrow C_2H_5^+ + C_3H_6$ on the T4 zeolite catalyst fragment $Al(OH)(OSiH_3)_3^-$. Five of the seven steps are qualitatively the same as those observed with the T1 model (ref. 1, Figs. 1, 3, and 5). Images of the two qualitatively new steps appear in Fig. 1. The first one (top row), a physi-to-physi β scission, is in comforting agreement with Svelle et al. (4), who observed it with this T4 model and a smaller (6-31G(d)) basis set. Hence, β scission of chemisorbed $C_5H_{11}^+/T4^-$ first rises to physisorbed $C_5H_{10}//T4$, but then could step to either chemisorbed $C_2H_5^+$ or physisorbed C_2H_4. The second row of Fig. 1 shows an extra descension step for the C_2H_4 product, so that we can consider this physi-to-physi β-scission route as a step in a complete chemi-to-chemi mechanism (see Discussion).

Two transition states were found for the two-step scission of $C_6H_{13}^+$ on $AlCl_4^-$. They are no different qualitatively than the two steps found earlier on $AlHCl_3^-$ (1).

Five transition states were found for the reactions $C_5H_{11}^+ \rightarrow C_2H_5^+ + C_3H_6$ (two) and $C_6H_{13}^+ \rightarrow C_3H_7^+ + C_3H_6$ (three) on the $Al_2Cl_7^-$ fragment. Four are qualitatively the same as the two-step "2Cl" (involving two Cl atoms) pathways observed previously for both these carbenium ions on $AlHCl_3^-$ (1, 5). Images for the qualitatively new step appear in the bottom row of Fig. 1. In this step, a physi-to-chemi β-scission step, the physisorbed ion-pair $C_6H_{13}^+//Al_2Cl_7^-$ intermediate undergoes scission, isomerization (p-$C_3H_7^+$ to s-$C_3H_7^+$), and descension (to a chemisorbed s-$C_3H_7^+$ fragment). These three processes are concerted (all in the one step) but not fully synchronous, as the descension occurs in the later part of the step. A similar-looking transition state exists in the $AlHCl_3^-$ fragment pathway (5), but there the forward direction resulted in a proton transfer to the catalyst (generating $HCl{\cdot}AlHCl_2$) rather than to a neighbouring C atom. This discrepancy in product may be due to catalyst basicity or the orientations chosen. In any event, the higher barrier associated with this step (see Discussion) suggests that this isomerization step during β scission will be rare.

Two-fragment catalyst model $AlHCl_3^-$ + $AlCl_4^-$

Figure 2 shows 3D images of the stationary-point geometries obtained for the β scission $C_6H_{13}^+ \rightarrow C_3H_7^+ + C_3H_6$ catalyzed by separated $AlHCl_3^-$ + $AlCl_4^-$ fragments. This model system has an overall charge of –1.



The top two rows of Fig. 2 show the two-step path, as seen with single-fragment catalysis. Here, $AlHCl_3^-$ was chosen as the chemisorbing fragment with $AlCl_4^-$ acting as a spectator fragment physisorbed near the reaction center.

In the third row, concerted one-step chemi-to-chemi β scission is observed, analogous to a one-step mechanism seen before (ref. 1, Fig. 9). Here in Fig. 2, $AlCl_4$ is the chemisorbing fragment with $AlHCl_3^-$ as the physisorbed spectator ion. The ascension of chemisorbed C2 from Cl1 occurs in concert with the S_N2-like migration of the C4 atom

Fig. 1. B3LYP/6-31G(d,p) stationary points for the three qualitatively new steps observed for carbenium ion scission on single anion fragment models. Top row: physi-to-physi scission of 1-pentene on the T4 zeolite catalyst fragment. Middle row: descension of ethene to a chemisorbed ethenium ion. Bottom row: a one-step scission/isomerization/descension of $C_5H_{11}^+$ to C_3H_6 and a chemisorbed *s*-$C_3H_7^+$ fragment on $Al_2Cl_7^-$.

from C3 to Cl2. Subtleties in orientation of the initial structure likely control whether the β scission will be one-step or two-step, since the simpler $AlHCl_3^-$ single-fragment model also exhibited both possibilities (1).

In the last row of Fig. 2, we see another concerted one-step chemi-to-chemi β scission, but here the hydrocarbon migrates from one catalyst fragment ($AlCl_4^-$) to the other ($AlHCl_3^-$). This was the qualitatively new step we hoped to find with the two-fragment catalyst model.

Three-fragment catalyst model $Na^+ + AlHCl_3^- + AlCl_4^-$

Figure 3 shows 3D images of the stationary-point geometries obtained for β scission ($C_6H_{13}^+ \rightarrow C_3H_7^+ + C_3H_6$) in the presence of Na^+ as well as $AlHCl_3^-$ and $AlCl_4^-$ ions. The Na^+ was added to have a neutral charge model system for comparison to the negatively charged model of the previous section. Several choices for the location of the Na^+ ion were tested before settling on one particular choice.

The first two rows show the usual two-step mechanism seen in all chloroaluminate models, here having $AlCl_4^-$ as the chemisorbing fragment and $Na^+ \cdot AlHCl_3^-$ as a spectator complex. The only noteworthy item concerns the first minimum, which shows a peculiar rotation of the tight $Na^+ \cdot AlHCl_3^-$ complex that places the Na^+ near the hydrocarbon.

In the following two rows of Fig. 3, two different one-step chemi-to-chemi β scissions are presented. Unlike the ones in Fig. 2, however, *both* these examples involve a migration from one anion to another, the first from $AlCl_4^-$ to $AlHCl_3^-$ and vice versa for the second. To complicate matters, the addition of Na^+ to the model has created more variety of possible structures, including a saltlike catalyst surface (Fig 3., bottom row). This suggests that the use of three ions in explicit-contact modelling is still a poor model for mimicking liquid-phase transition states.

Discussion

β scission — The general mechanism and its finer details

Our convention considers the reactant and products to be chemisorbed because chemisorbed states are the lower-energy "storage states" of carbenium ions in the presence of oxide and chloride sites. This convention also allows a direct relationship between the reaction activation energy and the strength of the conjugate base of the original Bronsted catalyst (see later).

Given this convention, the general β-scission mechanism is shown in Fig. 4 and consists of three mechanistic components, ascension of the hydrocarbon (A), C–C bond scission

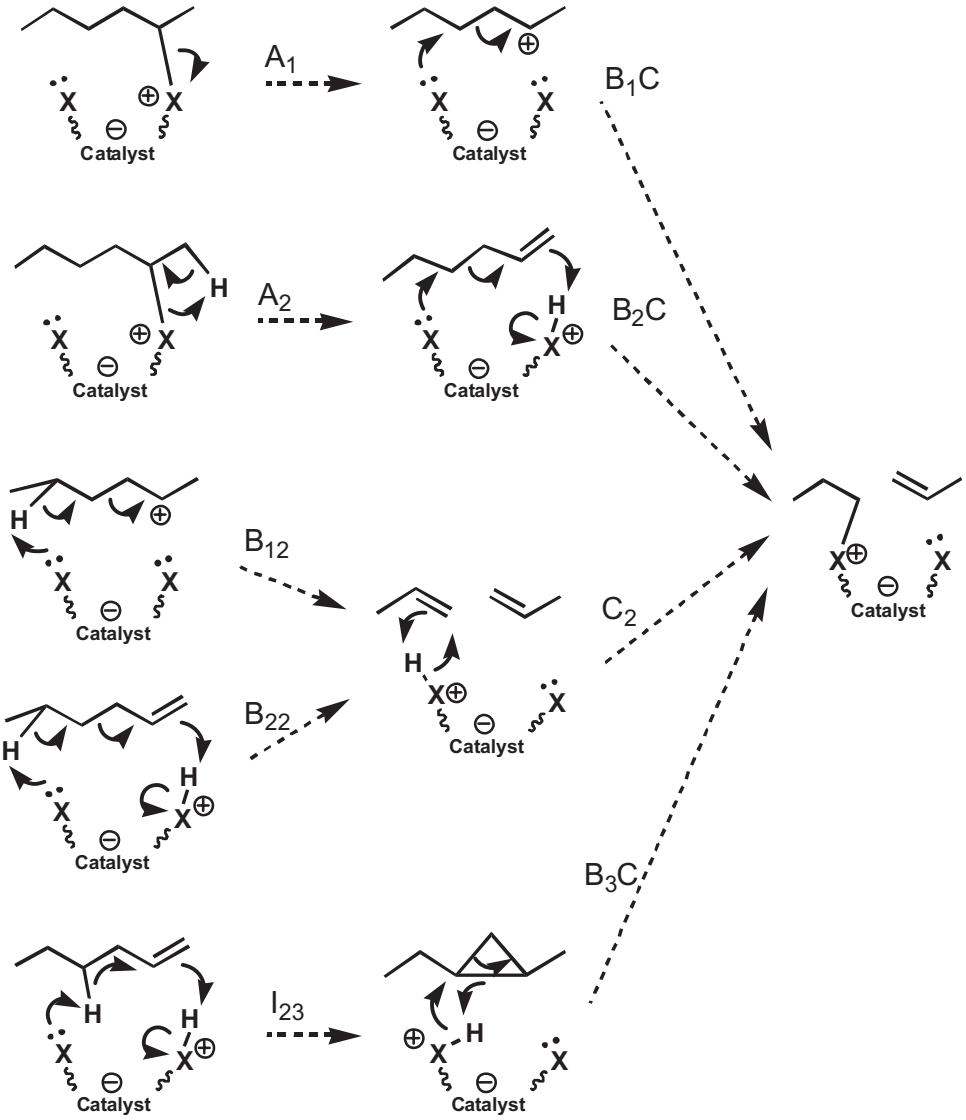
(B), and descension of the resulting primary carbenium ion product (C). In paper I (1), we found the mechanism to be two-step, with ascension to a higher-energy intermediate occurring as a separate step, followed by a concerted scission and descension step. From the work in this paper, we discover that the mechanism could also be one-step or even three-step, depending on catalyst and conformer orientation. Hence, we use the labels "ABC", "A,BC", and "A,B,C" to denote one-step, two-step, and three-step mechanisms.



In addition, Paper I showed that there is some variation in the nature of the physisorbed intermediates. We will denote these here with subscripts, 1 for carbenium ions (PCP^+), 2 for alkenes, and 3 for cyclopropanes. Hence, A_1 will denote

Fig. 4. The general β-scission mechanism from chemisorbed reactant to chemisorbed product. The three components of the mechanism we call ascension (A), scission (B), and descension (C). The mechanism could be one-step, two-step, or three-step, depending on the degree of concertedness of these components.

Fig. 5. The various reaction steps seen to date in two-step and three-step β-scission mechanisms from B3LYP calculations using hexenium ion as the example. A, B, C are defined in Fig. 4, while I refers to an isomerization. The subscript labels refer to the type of physisorbed intermediate: 1, carbenium ion (PCP^+); 2, alkene; 3, dialkylcyclopropane.

ascension to a physisorbed PCP^+ ion and B_1C will denote concerted scission and descension of this PCP^+ ion. Fig. 5 shows the mechanism for each variation of the steps observed so far.

The B3LYP/6-31G(d,p) relative energies for present and previously published β-scission results are presented in Tables 1 (AlO-containing catalysts) and 2 (AlCl-containing catalysts). Several things are worth commenting on here. First, there is almost no difference in energetics between $C_5H_{11}^+$ and $C_6H_{13}^+$ β scission and there should be no qualitative differences in mechanism either; the A_2 ascensions found with $C_6H_{13}^+/AlHCl_3^-$ also likely exist with $C_5H_{11}^+/AlHCl_3^-$. Second, note the higher energy barriers for both A and BC steps on AlO-containing catalysts vs. AlCl-containing ones. Third, note the qualitative change in intermediates with AlCl-based catalysts; the intermediates can be carbenium ions (note the subscript 1's), unlike the ones with small AlO-based catalysts in which the intermediates are exclusively neutral (subscript 2's and 3's). This was emphasized in paper I and still holds true with the slightly larger catalyst fragments studied here. Fourth, note that the physisorbed carbenium ions of the AlCl-based systems are precariously stable, with barriers of less than 1 kcal mol^{-1} (1 cal = 4.184 J) to returning to the original chemisorbed state.

Single-fragment catalysis

There is a direct relationship between the overall activation barrier for the complete chemi-to-chemi β scission and the strength of the Lewis base sites on the catalyst. A simple indicator of the Lewis base strength of these sites is their proton affinity (PA): the higher the PA, the more basic the nucleophilic site must be. In our tables, we call this calculated PA the conjugate-base proton affinity (CBPA) to remind the reader that the original catalyst for C–C bond cracking is assumed to be a Bronsted acid that has been de-

[a]Structural images of these steps are presented in Fig. 1.

activated to its conjugate-base anion form before the β-scission reaction occurs. This consideration is not a moot one because these conjugate-base "catalyst fragments" actually inhibit, rather than accelerate, the β-scission reaction: the more basic the fragment, the more energy is required to rise from the chemisorbed state to the rate-determining transition state (which, in all cases, is an ion-pair complex). This apparent anomaly arises only when considering the β-scission reaction alone, for when the complete cracking of a neutral hydrocarbon is considered, these bigger barriers seen with stronger conjugate bases are actually bigger barriers in overall reactions with weaker acids.

Table 3 summarizes the overall ΔE and E_a values for complete chemi-to-chemi β scission on single-fragment catalysts, together with the CPBA values of the catalysts. The reaction energy is 20–22 kcal mol^{-1}, independent of catalyst. However, the activation barriers vary systematically with basicity of the catalyst, roughly following the linear relation E_a = CBPA/2 – 100. Curiously, an equally simple relation between the base strength and the E_a for simple ascension could not be found.

Aluminum chloride catalysis — Multiple-fragment models

For the two-fragment $AlHCl_3^-$ + $AlCl_4^-$ model (Table 2, 6th section), the first two rows describe the now familiar two-step β scission involving a single fragment ($AlHCl_3^-$ in this case with $AlCl_4^-$ as a spectator ion). The energies are closer to those of $Al_2Cl_7^-$ catalysis than $AlHCl_3^-$ catalysis. One-step chemi-to-chemi β scission was also found, analogous to the one-step scission on $AlHCl_3^-$ with no spectator anion, but with the two-fragment model the energies are closer to that of the two-step $Al_2Cl_7^-$ catalysis. Both of these two-fragment mechanisms give an overall ΔE of 20.5 kcal mol^{-1}, changing little from single-fragment models. The fourth row is the migratory two-fragment step we desired with ascension from $AlCl_4^-$ and descension of the product $C_3H_7^+$ onto $AlHCl_3^-$. The E_a dropped only from 30 to 29 kcal mol^{-1}, indicating little benefit to a two-fragment process. The noticeable decrease in ΔE, from 20.5 to 16.3 kcal mol^{-1}, is merely due to the change of the chemisorption host from a weaker base ($AlCl_4^-$) to a stronger one ($AlHCl_3^-$).

A further step in mimicking an ionic liquid might be to add a cation, making the entire model neutrally charged as it is in our single-fragment modelling. With Na^+ added to the $AlHCl_3^-$ side of the hydrocarbon, we again found the two-step mechanism (involving chemisorbed structures solely with $AlCl_4^-$). Interestingly, the energies for this (Table 2, 7th section) look more similar to those of $AlCl_4^-$ catalysis than those from two-fragment modelling with Na^+ absent. We tried to find two-fragment paths, but these revealed dramatic effects of the Na^+ ion. Saltlike structures of the inorganic ions were seen to offer 8–13 kcal mol^{-1} energy stabilization for the intermediates M1 and M2, for both one-step chemi-to-chemi paths. Such structures are more like solids than liquids and reveal the difficulties in trying to mimic ionic liquids in this way.

Conclusions

β scission, considered here to start and finish with carbenium ions chemisorbed to a catalyst, involves three fundamental components, which are ascension, bond scission, and descension. The lowest-energy pathways on AlO- and AlCl-containing catalyst fragments, as computed with B3LYP/6-31G(d,p), are generally two-step mechanisms, with ascension to a physisorbed intermediates preceding the concerted scission-plus-descension second step. A nearly linear relationship exists between the overall barrier height and the proton affinity of the anion catalyst fragment (the conjugate-base of the hypothetical original Bronsted-acid catalyst).

The extension of an AlO-containing catalyst model from $AlH_2(OH)_2^-$ to $Al(OH)(OSiH_3)_3^-$ reduces the catalyst basicity

but not enough to change qualitative aspects of the reaction. The physisorbed intermediates are neutral-pair complexes of either alkene or disubstituted cyclopropane with catalyst, with two-step or three-step mechanisms observed to date. The overall barrier for β scission from the chemisorbed state is lowered from 67 to 59 by using the larger and less basic anion model.

Chloroaluminate catalysis of the β-scission reaction is also hardly changed qualitatively with moderate extension of the models. The physisorbed intermediates that lead to C–C scission are ion-pair $PCP^+//Al_xCl_y^-$ complexes present with each catalyst model, which are always bound by less than 1 kcal mol^{-1} relative to descension to a chemisorbed state. Hence, the formally two-step A_1,B_1C mechanisms might kinetically appear little different from the one-step chemi-to-chemi β-scission paths, which have been found in both

single-fragment and multiple-fragment modelling. Finally, a truly liquid state proved difficult to mimic with multiple ions, which tended to form saltlike (crystalline) complexes on one side of the hydrocarbon.

Some oxidation products of lycoctonine revisited

Doaa Abdelrahman, Michael Benn, Ryan Hellyer, Masood Parvez, and Oliver E. Edwards

Abstract: The structure of a chromic acid oxidation product of the norditerpenoid alkaloid lycoctonine (**1**) was established as hydroxylycoctonal (**3**) by spectrometric analyses and X-ray crystallography of its reduction product, hydroxylycoctonine (**5**); the structure of lycoxonine, a chromic acid oxidation product of the lactam, lycoctonam (**7**), was similarly confirmed as *N*-ethyl-4,7,8-trihydroxy-1α,6β,14α,16β-tetramethoxy-19-oxoaconitane (**8**). Reduction of lycoxonine with lithium aluminium hydride gave the 1,14-di-*O*-methyl ether (**12**) of the bisnorditerpenoid alkaloid delbine (**9**).

Key words: norditerpenoid, bisnorditerpenoid, alkaloids, lycoctonine, lycoctonam, hydroxylycoctonal, lycoxonine. 1,14-di-*O*-methyldelbine, semisynthesis.

Résumé : Faisant appel à des analyses spectroscopiques et à la diffraction des rayons X sur son produit de réduction, l'hydroxylycoctonine (**5**), on a établi que le produit d'oxydation à l'aide de l'acide chromique de l'alcaloïde norditerpénoïde lycoctonine (**1**) correspond à l'hydroxylycoctonal (**3**); de la même manière, on a établi que la lycoxonine, un produit d'oxydation chromique de la lactame, lycoctoname (**7**), correspond au *N*-éthyl-4,7,8-trihydroxy-1α,6β,14α,16β-tétraméthoxy-19-oxoaconitane (**8**). La réduction de la lycoxonine à l'aide d'hydrure double de lithium et d'aluminium conduit à l'éther 1,14-di-*O*-méthyle (**12**) de l'alcaloïde bisnorditerpénoïde, delbine (**9**).

Mots clés : norditerpénoïde, bisnorditerpénoïde, alcaloïdes, lycoctonine, lycoctoname, hydroxylycoctonal, lycoxonine, 1,14-di-*O*-méthyldelbine, semisynthèse.

[Traduit par la Rédaction]

Introduction

We report here the solutions to two long-standing puzzles in the chemistry of the alkaloid lycoctonine.

Initially described in 1886 as a constituent of *Aconitum lycoctonum* L (1), lycoctonine (**1**) is also the parent aminopolyol core of various ester-alkaloids present in this and other species of *Aconitum* and *Delphinium*. About 50 years ago, during the work directed at establishing the structures of these alkaloids, several of which are pharmacologically active, the oxidation products of lycoctonine received much attention (2–5) and it was X-ray crystallography of one such derivative at the National Research Council (NRC) in Ottawa (6) that first established the norditerpenoid skeleton that characterizes them. However, at that time the techniques for separations and spectrometric characterizations that are now routinely employed were unavailable and several products were left poorly characterized. We have had occasion to reexamine two such substances with the results that we now describe.

Results and discussion

The first of these compounds had been encountered as a side product during the preparation of the aldehyde lycoctonal (**2**) by the oxidation of **1** with sodium dichromate in acetic acid. This procedure afforded **2** as crystalline hydrate in about 55% yield along with another base (**3**), which resisted crystallization but gave a crystalline perchlorate salt (**4**).

When it was isolated in 1959, the only data collected for this salt were an elemental analysis and an IR spectrum that contained an intense carbonyl-stretch absorption band. Recently, reinvestigation of this product revealed the presence of an aldehyde attached to a quaternary centre, as shown by NMR signals (δ_H 9.20 (1H, s) and δ_C 201.5 (*d*) ppm, cross-correlated in a HMQC spectrum). Additionally, the ^{1}H NMR spectrum contained signals for an ethyl and four methoxyl groups, while the ^{13}C NMR spectrum contained a total of 25 resonances (shown by DEPT-90 and 135 spectra to be due to 5 methyls, 6 methylenes, 10 methines, and 4 quaternary carbons). This implied that all the carbons of **1** were present in the product. Also notable were the presences in the ^{13}C NMR spectrum of a methine resonance at δ_C 183.9, which cross-correlated in HMQC spectra with a proton signal at δ_H 8.79 (1H, br s), and a quaternary carbon at δ_C 210.4 ppm. Strikingly, when **4** was converted to the free base (**3**) these signals disappeared, although that of the aldehyde (now δ_C 203.4, δ_H 9.44 ppm) remained. As before, the free base (**3**) was shown to be comprised of 5 methyls, 6 methylenes, 10 methines, and 4 quaternary carbons. When compared with the ^{13}C NMR data for **1** it was seen that a quaternary-

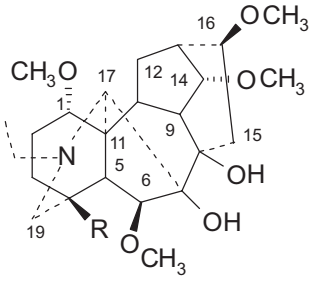
 doi:10.1139/V06-144 © 2006 NRC Canada

carbon resonance ascribed to C-7 had moved downfield from 88.3 to 96.0 ppm, although the resonance ascribed to C-8 showed little difference (77.3 ppm in **3**, 77.5 ppm in **1**).

These findings recalled hydroxylycoctonine (**5**), an unfortunately named compound prepared by the oxidation of lycoctonine with silver(I) oxide (2, 3), lead(IV) acetate (7), or potassium ferricyanide (2). Upon treatment with strong acid this forms ring-opened immonium ion salts (**6**), which, upon basification in aqueous media, hydrate and recyclise to **5** (8, 9). Thus, our observations were consistent with **3** being hydroxylycoctonal, the aldehyde of **5,** and **4** being the corresponding ring-opened immonium ion salt. That this was correct was demonstrated by the sodium borohydride reduction of **3** to provide in high yield a crystalline dihydro product, whose structure was proven to be hydroxylycoctonine (**5**) by X-ray crystallography and comparison with authentic material.

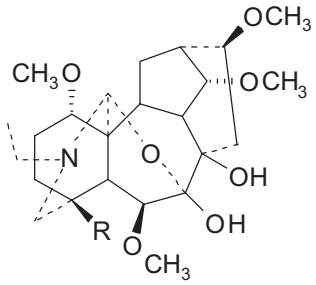
The formation of hydroxylycoctonal (**3**) in the Cr(VI) oxidation of lycoctonine (**1**) can be rationalized in terms of the formation of a chromate ester at C-7, the fragmentation of which affords an immonium ketone that upon work-up yields the hydroxybase. We did not observe hydroxylycoctonine (**5**) among the products of our oxidation of lycoctonine, which suggests that hydroxylycoctonal (**3**) is mainly, if not entirely, formed as an overoxidation product of lycoctonal (**2**) rather than by oxidation of the primary alcohol function of **5**.

In contrast to its behaviour with chromic acid, oxidation of lycoctonine with permanganate in neutral, weakly acidic, or alkaline solution affords the lactam, lycoctonam, 19-oxolycoctonine (**7**), a matter to which we will return. Suginome et al. (5) reported that the further oxidation of this product with chromic acid gave another neutral substance, lycoxonine, isolated as a crystalline hydrate together with formic acid. Microanalyses, including Zeisel and Hertzig–Meyer procedures, suggested that lycoxonine had the elemental composition $C_{24}H_{37}NO_8$ and contained an *N*-ethyl and four methoxyl groups. When heated with acetyl chloride or acetic anhydride, lycoxonine hydrate yielded a monoacetyl anhydro compound, which could be deacetylated to afford anhydrolycoxonine. These observations were taken to indicate that the di-tertiary 7,8-diol system of lyoctonam was still present in lycoxonine, i.e., the anhydro compound was formed via a pinacolic rearrangement. Largely on the basis of this information, Suginome proposed that lycoxonine had the structure (**8**) (5).



Relatively recently, this bisnorditerpenoid skeleton has been encountered in some *Delphinium* alkaloids, e.g., delbine (**9**), isolated from *Delphinium bonvalottii* Franchet (10). As Suginome's lycoxonine appeared to afford a semisynthetic entry to such alkaloids, we reinvestigated its preparation and structure.

The immediate precursor, lycoctonam (**7**), was originally prepared by adding solid potassium permanganate to a solution of lycoctonine in aqueous acetone containing acetic acid to prevent the reaction mixture becoming strongly alkaline as potassium hydroxide is generated (3). Suginome et al. (5) reported better yields when the acetic acid was omitted, but when we repeated their procedure, which involves leaving the reaction mixture overnight, we found that diacetone alcohol was formed in considerable amount, complicating the work-up. Subsequently, the NRC group showed that norditerpenoid alkaloids carrying a 6-methoxyl substituent were rapidly oxidized by a solution of potassium permanganate in aqueous acetone with the outcome determined by the orientation of the methoxyl; a β geometry steered the products towards lactams. Lycotonam (**7**) was obtained from lycoctonine (**1**) by this procedure in very high yield within 4 min (11). We found that a similarly fast and efficient nonaqueous oxidation was obtained by adding benzyltriethylammonium permanganate (12) in dichloromethane to lycoctonine in the same solvent. When benzyltriethylammomium chloride was used as a phase-transfer catalyst in a two-phase water–dichloromethane system with lycoctonine and potassium permanganate, the result was the same. The catalyst is known to be unstable in an alkaline solution and this induced us to try the two-phase oxidation without it. After a brief induction period the oxidation was complete within a few minutes. Following the destruction of excess reagent and manganese dioxide with dilute sulfuric acid and sodium metabisulfite, the only product isolated upon removal of the dichloromethane was **7**, formed in the same high yield as in the procedure of Achmatowicz et al. (11). The work–up of the two-phase reaction is simpler than that of the homogeneous aqueous acetone oxidation and it became our preferred route for conversion of **1** to **7**.



As Strassner and Houk have commented (13), although potassium permanganate is a venerable reagent remarkably little is known about the mechanistic details of the oxidations that it performs. In those oxidations that produce manganese(IV) oxide a three-electron reduction process is involved, indicating a multistep process, as with oxidations involving the reduction of Cr(VI) to Cr(III). For the oxidation of hydrocarbons there is evidence that the initial step involves hydrogen atom abstraction by the permanganate anion (14). In the oxidations of amines in nonaqueous media, the amide oxygen derives from the reagent and it seems reasonable to suppose that this is generally true. The selectivity seen in the oxidation of tertiary amines can then be rationalized either by an initial hydrogen atom transfer from a site adjacent to nitrogen (which would stabilize the resultant radical more than that obtained by abstraction from some other site) to give a radical pair that collapses ("oxygen rebound") to form a manganate(V) ester in a process similar to that proposed for the oxidations of hydrocarbons with permanganate (13, 14), or via an initial one-electron transfer from nitrogen to permanganate anion followed by a hydrogen atom transfer to generate an immonium ion and a manganate(V) anion that combine to yield the ester. Direct evidence that the H transfer step is rate-controlling is provided by the observation of a substantial kinetic isotope effect in the hexadecyltrimethylammonium permanganate oxidation of α-deuterated benzylamines in dichloromethane (15).

The manganate ester might fragment reversibly to the immonium ion pair or irreversibly to form an amide and an Mn(III) species, which then reacts with permanganate to form Mn(IV) dioxide and a manganate(VI) ion. Amide formation dominates in the case of lycoctonine (**1**), but the intermediacy of an immonium ion has been invoked (16) to account both for the N-dealkylations sometimes observed when the permanganate oxidation of other diterpenoid alkaloids is conducted in aqueous media (trapping of water gen-

erates a carbinolamine, which then decomposes to aldehyde and secondary amine) and for the fact that intramolecular cyclisation to a carbinolamine-ether may occur when when a hydroxyl group is in suitable proximity to the nitrogen (via its trapping by the immonium ion).

Suginome et al. (5) did not specify the ratio of chromic acid to lycoctonam used for their preparation of lycoxonine but when we used a 3:4 ratio of lycoctonam to chromium trioxide (in accordance with eq. [1]) we obtained a neutral crystalline product in about the same yield as they had reported.

[1] $3R_3CCH_2OH + 4CrO_3 + 12\ H^+ \rightarrow 3R_3COH + 3HCOOH + 4Cr^{3+} + 6H_2O$

The ^1H and ^{13}C NMR spectra of our product were in accord with the structure proposed for lycoxonine. In particular, there were only 24 ^{13}C resonances of which 3 could be attributed to tert alcohols and there was no longer one corresponding to the carbon of a hydroxymethylene group. The matter was clinched by X-ray crystallography, which revealed the structure of our product to indeed be **8**, as proposed by Suginome (5).

No explanation was suggested for the formation of **8**; however, carbon–carbon bond fission accompanying chromium(VI) oxidations of alcohols are precedented (17, 18). The mechanism of the reaction appears to involve a homolytic process induced by chromium(IV), evidence for which includes the inhibition of the cleavage reaction by oxalic acid (18). When we carried out the oxidation of

© 2006 NRC Canada

lycoctonam in aqueous acetone in the the presence of oxalic acid, as described by Müller and Blanc (19), there was nearly complete suppression of lycoxonine formation, the major products now being lycoctonamal (**10**) and lycoctonamic acid (**11**) together with recovered lycoctonam (**7**). As another experiment revealed that chromic acid oxidized lycoctonamal to lycoctonamic acid, rather than lycoxonine, we excluded the possibility that **8** was formed via a Baeyer–Villiger type cleavage involving a chromate ester of hydrated lycoctonamal and conclude that it is, as in other such cases, the result of chromium(IV) oxidation of the alcohol **7.**

Lithium aluminum hydride reduction of lycoxonine then afforded **12**, which corresponds to the 1,14-di-*O*-methyl ether of delbine. Variations in the extent of the degree of methoxylation are commonly observed in the norditerpenoid alkaloids so although **12** has not yet been isolated from a plant source we predict that it will be ultimately be discovered as a natural product.

Experimental

General procedures

NMR spectra were collected using a Bruker DRX 400 spectrometer (400 MHz ^{1}H, 100 MHz ^{13}C) in $CDCl_3$, using residual $CHCl_3$ (δ_H 7.25 ppm) and the centre line of the $CDCl_3$ multiplet (δ_C 77.0 ppm) as internal references. Sodium 3-(trimethylsilyl)propionate-2,2,3,3-d_4 was used as reference for solutions in D_2O. Melting points were measured with a Leitz hot-stage microscope and are uncorrected. Analytical and preparative TLC were carried out using Merck silica gel 60 F254 on glass plates (5 cm × 20 cm × 0.25 mm and 20 cm × 20 cm × 0.25 mm respectively), using I_2/silica gel powder (20) to detect spots and locate bands by the dusting of PTLC plate edges. Column chromatography was performed using Woelm neutral alumina, activity III. Lycoctonine (**1**) was isolated by saponifying methyllycaconitine obtained from *Delphinium glaucum* growing locally in the foothills of the Rocky Mountains (21). It was obtained as the crystalline hydrate, mp 112 to 113 °C, with ^{1}H and ^{13}C NMR spectra as recorded in the literature (22).

Hydroxylycoctonal (3)

(*a*) Lycoctonine (5 g) was dissolved in acetic acid (150 mL) and divided into 10 aliquots. To each of these was added a 5% (*w*/*v*) solution of $Na_2Cr_2O_7{\cdot}5H_2O$ in acetic acid (2.3 mL) over a period of 3 h. After another 4 h, by which time all of the oxidant appeared to have been reduced, the aliquots were combined and the bulk of the solvent removed under reduced pressure. The dark green residual solution was diluted with 1.5 mol/L aq. H_2SO_4 and extracted with $CHCl_3$ (5 × 30 mL). The combined $CHCl_3$ extracts were backwashed with 0.5 mol/L aq. H_2SO_4 (30 mL) and water (30 mL). Sufficient ice was added to the combined aqueous extract and washings to chill the mixture to below RT. Concentrated aqueous ammonia (ca. 17 mol/L) was added dropwise until the mixture was alkaline (pH 10–12, indicator paper) and the solution was then extracted with $CHCl_3$ (7 × 30 mL). The combined $CHCl_3$ extracts were dried (MgSO4) and the solvent removed to give a pale yellow glass (4.7 g). This was taken up in a little hot MeOH (ca. 3 mL) and hot water was added dropwise until permanent turbidity was just apparent. Crystals of lycoctonal (**2**) slowly separated and after the suspension had been kept overnight at RT, these were collected by filtration and air-dried (2.44 g). An additional amount of crystals (0.31 g) was obtained by evaporation of the mother liquors, redisolving the residue in MeOH, and adding H_2O as before. Total yield ca. 55% (2.75 g), mp 90–93 °C. ^{1}H NMR δ_H: 9.46 (1H, s), 3.58 (3H, m), 3.39 (3H, s), 3.32 (3H, s), 3.25 (3H, s), 3.17 (1H, m), 3.1–2.8 (6H, m), 2.78 (1H, d, J = 12.4 Hz), 2.58 (1H, dd, J = 9.0 and 15.3 Hz), 2.41 (1H, dd, J = 4.6 and 14.3 Hz), 2.32 (1H, dd, J = 4.6 and 16.1 Hz), 2.1 (2H, br m), 2.05–1.8 (3H, m), 1.63 (2H, m), 1.5 (1H, m), 1.05 (3H, t, J = 7.1 Hz). ^{13}C NMR δ_C: 203.7d, 91.9d, 88.5s, 83.8d, 83.6d, 82.6d, 77.6s, 64.7d, 59.3q, 57.8q, 56.3q, 56.0q, 50.9t, 49.9t, 49.7s, 48.8d, 48.4s, 46.0d, 43.3d, 38.1d, 33.5t, 29.9t, 29.0t, 25.2t, 14.0q.

Attempts to obtain more crystalline material by further concentration of the mother liquors was unsuccessful so these were taken to dryness under reduced pressure and the residue distributed between aqueous citric acid – sodium dihydrogen phosphate buffer (pH 6.6, 30 mL) and benzene (30 mL). The benzene extract was re-extracted with the buffer solution (pH 6, 30 mL) and both aqueous extracts were backwashed with benzene (30 mL). The combined benzene extracts and washings were then washed with 1 mol/L aq. NH_4OH, dried ($MgSO_4$), and evaporated to give a colourless glass (0.66 g). This was dissolved in MeOH (2 mL) and treated with a solution of 70% aq. $HClO_4$ (0.25 mL) in MeOH (2 mL) until pH 2 to 3 (indicator paper) to yield crystalline hydroxylycoctonal perchlorate (**4**) (0.22 g). Melting point 208–210 °C. IR (KBr, cm^{-1}) ν_{max}: 3998 br s, 2933s, 2830s, 1731s. ^{1}H NMR (D_2O) δ_H: 9.20 (1H, s), 8.79 (1H, br s), 4.4–4.0 (6H, m), 3.64 (4H, m), 3.47 (3H, s), 3.41 (3H, s), 3.33 (3H, s), 3.21 (3H, s), 2.97 (1H, m), 2.77 (1H, d, J = 9.8 Hz), 2.66m (1H, m), 2.54 (3H, m), 1.96 (1H, d, J = 16.8 Hz), 1.95–1.7 (2H, m), 1.59 (3H, t, J = 7.2 Hz), 1.45 (1H, m), 1.12 (1H, m). ^{13}C NMR δ_C: 210.4s, 201.5d, 183.9d, 89.8d, 87.0d, 82.2s, 81.7d, 81.6d, 61.5t, 61.1q, 60.7q, 60.6q, 59.4q, 56.3t, 53.4s, 50.3s, 44.0d, 42.7d, 42.2d, 37.9d, 35.0t, 32.8t, 31.5t, 26.3t, 16.0q.

Hydroxylycoctonal (**3**) was obtained from the salt by suspending it in 1 mol/L aq. Na_2CO_3 followed by extraction with $CHCl_3$. Removal of the solvent from the dried ($MgSO_4$) $CHCl_3$ extracts gave the free base as a colourless glass, which resisted crystallization. IR ($CHCl_3$, cm^{-1}) ν_{max}: 1725. ^{1}H NMR δ_H: 9.44 (1H, s), 4.83 (1H, s), 3.66 (1H, t, J = 4.5 Hz), 3.40 (3H, s), 3.39 (3H, s), 3.30 (3H, s), 3.25 (3H, s), 3.20 (1H, m), 3.04 (1H, dd, J = 6.2 and 10.9 Hz), 3.0 (1H, br d, J = 12.6 Hz), 2.85 (1H, dq, J = 7.1 and 12.9 Hz), 2.7–2.5 (4H, m), 2.38 (1H, m), 2.17 (1H, m), 2.05 (1H, dq, J = 7.1 and 12.9 Hz), 2.0–1.8 (3H, m), 1.7–1.5 (4H, m), 1.08 (3H, t, J = 7.1 Hz). ^{13}C NMR δ_C: 203.4d, 96.0s, 88.7d, 87.1d, 85.9d, 84.4d, 82.5d, 78.0s, 60.6q, 57.8q, 56.8q, 56.4q, 49.5s, 48.4t, 49.0d, 47.1t, 44.9d, 44.0d, 42.4s, 38.1d, 33.0t, 29.8t, 29.5t, 23.9t, 12.9q. HR EI-MS *m*/*z* for $C_{25}H_{39}NO_8$: 481.2698; req. 481.2676.

(*b*) To a magnetically stirred solution of lycoctonine hydrate (500 mg) dissolved in AcOH (7.5 mL) was added a 5% (*w*/*v*) solution of $Na_2Cr_2O_7{\cdot}5H_2O$ in AcOH (1.5 mL). After 1 h, more oxidant (1 mL) was added and after a further 3 h a

© 2006 NRC Canada

little more (0.2 mL). The mixture was allowed to stir for a total of 5 h and then poured into H_2O (50 mL) containing $Na_2S_2O_5$ (25 mg). The solution was acidified (pH 1, indicator paper) with 3 mol/L aq. H_2SO_4 and extracted with $CHCl_3$ (3 × 20 mL) to removed neutral byproducts, then made alkaline with Na_2CO_3 (s) (pH 9 to 10, indicator paper) and extracted with $CHCl_3$ (3 × 25 mL). After removal of solvent, the combined dried (Na_2SO_4) $CHCl_3$ extracts gave the basic products as a colourless glass (411 mg). TLC ($CHCl_3$–MeOH, 7:1 *v/v*) revealed 3 major components, R_F 0.15, 0.51, and 0.70. A portion of the mixture (ca. 20 mg) was subjected to PTLC on a 20 cm × 20 cm × 0.25 mm plate of Merck silica gel 60 F254, using the same solvent system. The individual components were then examined by NMR. This resulted in the following identifications: R_F 0.10, lycoctonine (**1**) (5 mg); R_F 0.45, lycoctonal (**2**) (13 mg); and R_F 0.70, hydroxylycoctonal (**3**) (4 mg).

Sodium borohydride reduction of hydroxylycoctonal — Formation of hydroxylycoctonine (5)

The free base (404 mg) obtained by chloroform extraction of a solution of the perchlorate salt in water, which was basified with aq. 1 mol/L Na_2CO_3, was dissolved in MeOH (15 mL) and $NaBH_4$ (100 mg) was added in 3 equal portions at 10 min intervals. After a further 30 min, the reaction mixture was diluted with H_2O (45 mL) and the resultant milky alkaline solution was extracted with $CHCl_3$ (5 × 10 mL). The combined dried ($MgSO_4$) $CHCl_3$ extracts were evaporated to a colourless glass (424 mg), which crystallized from moist ether and recrystallized from acetone–hexanes in plates. Melting point 123–125 °C. That this product was hydroxylycoctonine (**5**), despite the difference in mp observed here and the value of 150–153 °C reported for the anhydrous compound (2, 7), was established by X-ray crystallography as well as the following data. ^{1}H NMR δ_H: 4.83 (1H, s), 4.11 (1H, br s, exchanged by D_2O), 3.81 (1H, br s, exchanged by D_2O), 3.67 (1H, t, J = 4.5 Hz), 3.67 (3H, s), 3,57 (1H, br s), 3.54 (1H, d, J = 7 Hz), 3.41 (3H, s), 3.31 (3H, s), 3.24 (3H, s), 3.00 (1H, dd, J = 6.1 and 11.1 Hz), 2.83 (1H, dq, J= 7.1 and 12.9 Hz), 2.78 (1H, dd, J = 8.5 and 15.0 Hz), 2.71 (1H, t, J = 4.8 Hz), 2.58 (1H, dq, J = 7.1 and 12.9 Hz), 2.5–2.3 (4H, m), 2.2–2.1 (1H, m), 2.1–1.9 (3H, m), 1.7–1.5 (6H, m), 1.06 (3H, t, J = 7.1Hz). ^{13}C NMR δ_C: 96.4s, 89.5d, 86.5d, 85.8d, 84.4d, 82.5d, 77.6s, 68.5t, 59.7q, 57.8q, 56.6q, 65.4q, 50.2t, 49.3d and 49.3t, 44.5d, 43.9d, 42.8s, 38.2s, 37.6d, 33.2t, 32.3t, 29.5t, 24.8t, 12.9q. HR EI-MS *m/z* found for highest mass ion $C_{25}H_{41}NO_8$: 483.2834; req. 483.2832. Crystal data: $C_{25}H_{41}NO_8{\cdot}H_20$; MW = 501.60; monoclinic; space group $P2_1$; cell dimensions a = 7.842(2), b = 10.170(3), c = 15.656(4) Å, and β = 99.79(2)°; V = 1230.4(6) Å^3; Z = 2; dx = 1.354 Mg/m^3; μ = 0.102 mm^{-1}; F(000) = 544; λ (mo Kα) = 0.71073 Å; T = 173(2) K; R = 0.065 (for 3717 $I > 2.0\sigma(I)$); and wR = 0.99 (all data); goodness of fit S = 1.04. The absolute structure could not be established by the Flack method.[2]

Lycoctonam (7)

To lycoctonine (**1**) (1.14 g, 2.35 mmol) in CH_2Cl_2 (30 mL) was added a solution of powdered $KMnO_4$ (502 mg, 3.18 mmol) in H_2O (5 mL) and the mixture was stirred vigorously (magnet) for 30 min. Excess oxidant was destroyed by adding $Na_2S_2O_5$ to the stirred mixture until all of the MnO_2 had dissolved and a clear two-phase system remained. The organic layer was separated and the aqueous phase was extracted with CH_2Cl_2 (2 × 15 mL). The organic layers were combined, dried (Na_2SO_4), and the solvent evaporated in vacuo yielding lycoctonam (**7**) in quantitative yield as a near colourless oil, which set to a solid white cake of crystals on addition of drop of water. Melting point 98–100 °C (lit. value (3) 95 °C for the dihydrate). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 3.38 (d, J = 2.1 Hz, 6H, MeO), 3.32 (s, 3H, MeO), 3.17 (s, 3H, MeO), 1.07 (t, J = 7.1 Hz, 3H, NEt). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 173.6s, 91.1d, 85.8s, 83.4d, 81.9d, 81.2d, 76.4s, 66.8t, 63.1d, 58.5q, 57.7q, 56.2q, 55.0q, 50.7d, 48.0s, 47.0s, 44.7d, 43.2t, 42.6d, 37.3d, 33.1t, 28.6t, 28.4t, 24.4t, 11.9q.

Lycoxonine (8)[3]

To lycoctonam (**7**) (2.055 g, 4.283 mmol) in 0.5 mol/L aqueous sulfuric acid (57 mL) was added chromium trioxide (1.14 g, 11.4 mmol) in 0.5 mol/L aq. H_2SO_4 (11.5 mL) with stirring. The resulting solution was left to stir for 48 h and then extracted with $CHCl_3$ (3 × 100 mL). The organic extracts were washed with H_2O–ammonia (4:1, 1 × 40 mL) and brine (1 × 80 mL) and the solvent was evaporated in vacuo. Chromatographic separation (on alumina) of the obtained crude oil, with 0.5% MeOH–$CHCl_3$ as eluent, afforded lycoxonine (**8**) (247.1 mg, 25.7%) as a white crystalline solid, shown by X-ray crystallography to be chloroform solvate. Melting point 98–91 °C (lit. value (8) 80–83 °C for a hydrate). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 3.44 (s, 3H, MeO), 3.36 (s, 3H, MeO), 3.23 (s, 3H, MeO), 1.14 (t, J = 7.3 Hz, 3H, NEt). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 172.6s, 90.4d, 86.0s, 83.5d, 82.2d, 81.4d, 76.6s, 74.9s, 63.8d, 58.7q, 58.0q, 56.4q, 55.5q, 53.0t, 49.0s, 45.8d, 43.3t, 43.0d, 38.0d, 34.4t, 32.9t, 27.8t, 27.1t, 12.3q. Crystal data: $C_{24}H_{37}NO_8{\cdot}CHCl_3$; MW = 586.91; orthorhombic; space group $P2_12_12_1$; cell dimensions a = 9.273(2), b = 16.111(4), and c= 18.218(5) Å; V = 2721.7(12) Å^3; Z = 4; dx = 1.432 Mg/m^3; μ = 0.39 mm^{-1}; F(000) = 1240; λ (mo Kα) = 0.71073 Å; T = 170(2) K; R = 0.046 (for 5260 $I > 2.0\sigma(I)$); wR = 0.136 (all data); goodness of fit S = 1.04.

These data can be obtained, free of charge, via http://www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

[3] Chemical Abstracts Services has assigned the name aconitane to the hexacyclic ring system, which characterizes many of the norditerpenoid alkaloids of *Aconitum* and *Delphinium*, as exemplified by lycoctonine (**1**) (23). Lycoxonine is then semisytematically named as *N*-ethyl-4,7,8-trihydroxy-1α,6β,14α,16β-tetramethoxy-19-oxoaconitane.

The absolute structure was established by the Flack method.[2]

Co-oxidation of lycoctonam and oxalic acid — Preparation of lycoctonamal (10)

Lycoctonam hydrate (350 mg, 0.70 mmol) and oxalic acid dehydrate (690 mg, 5.48 mmol) were dissolved with stirring (magnet) in 60% (*v*/*v*) aqueous acetone containing concd. H_2SO_4 (40 μL). To the stirred homogeneous solution, cooled in ice water, was added dropwise from a syringe over 20 min a solution of CrO_3 (195 mg, 1.95 mmol) in H_2O (220 μL). There was rapid production of a purple solution and concomitant gas evolution. The syringe was rinsed into the reaction mixture with 60% aqueous acetone (ca. 200 μL) and stirring continued for a further 3 h. The mixture was diluted with water (ca. 30 mL) and extracted with CH_2Cl_2 (3 × 20 mL). The combined CH_2Cl_2 extracts were washed with H_2O (5 mL) and then with aq. NH_4OH (NH_4OH–H_2O, 1:5 *v*/*v*, 2 × 5 mL) and water (3 mL). The combined aq. NH_4OH and final H_2O washes were acidified to pH 1 (indicator paper) with 3M aq. H_2SO_4 and extracted with CH_2Cl_2 (3 × 5 mL). Evaporation of the dried (Na_2SO_4) CH_2Cl_2 extract remaining after the aq. NH_4OH washes yielded the neutral fraction (**N**) as a colourless foam (299 mg), while the CH_2Cl_2 extracts obtained after acidification of the aq. NH_4OH washes similarly yielded the acidic products (**A**) as a white crystalline solid (43 mg).

TLC (Al_2O_3, MeOH–$CHCl_3$ 1:50) of the neutral fraction (**N**) revealed two components, R_f 0.56 and 0.38, the slower running corresponding to recovered lycoctonam (**7**). Flash chromatography of the material (on Woelm neutral Al_2O_3 grade III, 23 cm × 1.2 cm), eluting with $CHCl_3$–MeOH (50:1 *v*/*v*, collecting 25 mL fractions), resulted in the rapid elution of lycoctonamal (**10**) obtained, after removal of solvents under reduced pressure, as a colourless glass (220 mg). ^{1}H NMR δ_H: 10.22 (1H, s), 4.12 (1H, dq, *J*= 7.2 and 14.4 Hz), 4.03 (1H, br s), 3.65 (1H, t, *J* = 4.5 Hz), 3.41 (3H, s), 3.38 (1H, d, *J* = 1.6 Hz), 3.36 (3H, s), 3.27 (1H, d, *J* = 3 Hz), 3.34 (3H, s), 3.21 (3H, s), 3.06 (1H, dq, *J* = 7.2 and 14.4 Hz), 2.92 (1H, dd, *J* = 4.6 and 6.8 Hz), 2.56 (1H, dd, *J* = 8.9 and 15.5 Hz), 2.42 (1H, br t, *J* = 4.6 Hz), 2.19 (1H, d, *J* = 1.1 and 3.1 Hz), 2.1 (3H, m), 1.95 (3H, m), 1.74 (1H, dd, *J* = 8.9 and 15. 5 Hz), 1.5 (4H, m), 1.4 (1H, m), 1.13 (3H, t, *J* = 7.2 Hz). ^{13}C NMR δ_C: 204.7d, 168.7s, 94.3d, 85.8s, 83.6d, 82.2d, 81.0d, 76.9s 62.9d, 60.7s, 59.9q, 57.9q, 56.4q, 55.5q, 49.2d 47.7s, 44.9d, 43.6t, 42.8d, 37.7d, 33.2t, 29.7t, 28.6t, 24.5t, 11.9q. No lycoxonine could be detected in this material by TLC, ^{1}H NMR, or ^{13}C NMR. ES MS *m*/*z*: 502 (M + Na) with MS-MS on this ion revealing its fragmentation to an ion *m*/*z*: 474 (likely loss of CO or C_2H_4). HR EI-MS highest mass ion *m*/*z* calcd. for $C_{23}H_{33}NO_8$: 451.2186, 451.2206 (M – C_2H_4).

Lycoctonam (**7**) (71 mg) was eluted in later fractions and identified by ^{1}H and ^{13}C NMR.

The acidic material (**A**) was similarly identified as lycoctonamic acid (**11**). ^{1}H NMR δ_H: 4.13 (1H, br s), 4.10 (1H, dq, *J* = 7.2 and 14.4 Hz), 3.64 (1H, t, *J* = 4.5 Hz), 3.54 (1H, d, *J* = 4.9 Hz), 3.44 (3H, s), 3.38 (3H, s), 3.33 (3H, s), 3.25 (1H, d, *J* = 2.9 Hz), 3.18 (3H, s), 3.12 (1H, m), 3.10 (1H, dq, *J* = 7.2 and 14.4 Hz), 2.94 (1H, br t, *J* = 4.6 and 6.9 Hz), 2.54 (1H, dd, *J* = 8.9 and 15.4 Hz), 2.43 (1H, d, *J* = 2.0 Hz), 3.40 (1H, dd, *J* = 4.6 and 6.9 Hz), 2.17 (1H, m), 2.12 (1H, m), 1.73 (1H, *J* = 7.1 and 15.4 Hz), 1.54 (1H, m), 1.12 (3H, t, *J* = 7.2 Hz). ^{13}C NMR δ_C: 173.1s, 172.0s, 94.5d, 86.0s, 82.0d, 83.3d, 82.0d, 80.2d, 76.7s, 63.9d, 60.0d, 57.7q, 56.2q, 55.5q, 55.4q, 49.1s, 47.3s, 44.5t, 44.3d, 42.5d, 37.4d, 33.0t, 32.5t, 28.6t, 23.9t, 11.5q.

Chromic acid oxidation of lycoctonamal — Formation of lycoctonamic acid (11)

To a stirred solution of lycoctonamal (**10**) (27 mg) in 0.5 mol/L aq. H_2SO_4 (3 mL) was added CrO_3 (9 mg) and the mixture was stirred at RT overnight. A few crystals of $Na_2S_2O_5$ were added to destroy excess oxidant and the mixture was extracted with $CHCl_3$ (3 × 3 mL). The combined $CHCl_3$ extracts were washed with aq. Na_2CO_3 (2 × 2 mL), then dried (Na_2SO_4) and evaporated to yield a trace of neutral materials (2 mg), which was not lycoxonine (by ^{1}H and ^{13}C NMR). Acidification of the Na_2CO_3 extracts with concd. aq. HCl (to pH 1, indicator paper) followed by extraction with $CHCl_3$ (3 × 2 mL) and removal of solvent from the combined dried (Na_2SO_4) extracts gave the acidic products (18 mg) as a white solid. The ^{1}H and ^{13}C NMR spectra revealed it to be lycoctonamic acid (**11**).

1,14-Di-*O*-Methyldelbine (12)

To freshly powdered $LiAlH_4$ (212.6 mg, 5.607 mmol) in anhydr. THF (7.4 mL) was added lycoxonine (**8**) (132.6 mg, 283.9 μmol) in THF (3.2 mL). The reaction mixture was stirred and boiled under reflux. After 6 h, the reaction mixture was cooled to RT and H_2O (300 μL) was added followed by 15% *w*/*w* sodium hydroxide – H_2O (600 μL). The mixture was filtered and the granular residue of white inorganic material was washed with $CHCl_3$ (5 mL). The combined filtrate and washings were evaporated in vacuo and then partitioned between $CHCl_3$ (3 mL) and 0.5 mol/L aq. H_2SO_4 (3 mL). The $CHCl_3$ phase was re-extracted with 0.5 mol/L aq. H_2SO_4 (2 × 3 mL). The combined aq. H_2SO_4 extracts were bacified to pH 10 (indicator paper) with aq. NH_4OH and extracted with $CHCl_3$ (4 × 5 mL). The combined $CHCl_3$ extracts were combined and the solvent removed in vacuo affording 1,14-di-*O*-methyldelbine (**12**) (101.6 mg, 79%) as a golden oil. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 4.20 (s, 1H, OH), 4.06 (s, 1H, H-6), 3.39 (s, 6H, MeO), 3.31 (s, 3H, MeO), 3.22 (s, 3H, MeO), 1.02 (t, *J* = 7.1 Hz, 3H, NEt). ^{13}C NMR (ppm) δ_C: 89.9d, 88.8s, 83.9d, 83.8d, 82.7, 77.6s, 70.0s, 64.0d, 58.3q, 57.8t, 57.7q, 56.2q, 56.1q, 56.0d, 50.6s, 50.4t, 45.9d, 43.4d, 38.3d, 37.5t, 33.3t, 28.7t, 27.0t, 14.1q.

Ruthenium(III) acetylacetonate [$Ru(acac)_3$] — An efficient chemoselective catalyst for the tetrahydropyranylation (THP) of alcohols and phenols under solvent-free conditions

Ravi Varala and Srinivas R. Adapa

Abstract: A catalytic amount of ruthenium(III) acetylacetonate (2 mol%) [$Ru(acac)_3$] enables solvent-free tetrahydropyranylation of different types of alcohols and phenols at ambient temperature in moderate to excellent yields. Notably, selective monoprotection of diols can be achieved chemoselectively. Furthermore, the catalyst could be recovered and reused if necessary.

Key words: tetrahydropyranyl ethers, protecting groups, ruthenium(III) acetylacetonate, alcohols, thiols.

Résumé : L'addition de quantités catalytiques (2 mol %) d'acétylacétonate de ruthénium(III) [$Ru(acac)_3$] permet d'effectuer un tétrahydropyranylation sans solvant de divers types d'alcools et de phénols, à la température ambiante, avec des rendements allant de modérés à excellents. Il est à noter que la monoprotection sélective de diols peut être réalisée chimiosélectivement. De plus, si cela est nécessaire, le catalyseur peut être récupéré et réutilisé.

Mots clés : oxydes de tétrahydropyranyle, groupes protecteurs, acétylacétonate de ruthénium(III), alcools, thiols.

[Traduit par la Rédaction]

Introduction

The choice of the protection and deprotection strategy in a synthetic sequence is inevitable owing to the chemoselective transformations in the presence of various functional groups (1). Tetrahydropyran (THP) ethers are one of the most widely used protecting groups employed during a multistep organic synthesis because of their low cost, easy removal under mild acidic conditions, and stability in various reaction conditions such as strong bases, Grignard reagents, hydrides, redox reagents, alkylating, acylating agents, and catalytic hydrogenation (2). Furthermore, tetrahydropyranyl ethers are synthetically useful as building blocks for the synthesis of biologically important compounds such as nucleosides, carbohydrates, steroids,and alkaloids. They can also be used in perfume formulations (3). A variety of protonic as well as Lewis acid catalysts, including amberlyst, zeolites, montmorillonite K-10, sulfuric acid on silica gel, $ZnCl_2$, tetrabutylammonium bromide, PTSA, $BF_3{\cdot}Et_2O$, $ZrCl_4$, I_2, $In(OTf)_3$, $NbCl_5$, $InCl_3$, $PdCl_2(CH_3CN)_2$, lithium perchlorate – diethyl ether, TBATB, $Bi(OTf)_3$, $La(NO_3)_3{\cdot}6H_2O$, $Fe_2(SO_4)_3{\cdot}xH_2O$, $VO(OAc)_2$, $AlCl_3{\cdot}6H_2O$, and $CeCl_3{\cdot}7H_2O$ – NaI, have been developed for tetrahydropyranylation of hydroxy functions (4). However, several reported methods are associated with drawbacks including long reaction times under reflux, high catalyst to substrate ratios, the use of large amounts of solid support (which eventually results in the generation of large amount of toxic waste, harsh and acidic conditions), the use of expensive and toxic reagents or solvents, and incompatability with other acid-sensitive functional groups. Despite a number of precedents, a solvent-free and catalytically efficient practical alternative for this very important transformation is highly desirable and subject to further improvement.[2]

Recently, we reported CuBr-catalyzed chemoselective thioacetalization of carbonyl compounds (5). As part of our ongoing research program to develop novel synthetic methodologies, particularly carbon–carbon and carbon–heteroatom bond formations (6), we herein present our preliminary results using an efficient ruthenium(III) acetylacetonate [$Ru(acac)_3$]-catalyzed solvent-free tetrahydropyranylation of hydroxy and thiol functions. The procedure, based on the Lewis acid catalytic activity of [$Ru(acac)_3$], represents an environmentally benign alternative to current chemical processes that use water-intolerant Lewis acids.

The screening of a few acetylacetonates allowed us to select [$Ru(acac)_3$] as the versatile catalyst to affect this transformation (Table 1).

Among the reagents tested, the addition product of

Note: All reactions were carried out by stirring mixtures of **1** (1 mmol), DHP (1.1 mmol), and a catalyst for the appropriate times.
[a]Isolated yields.

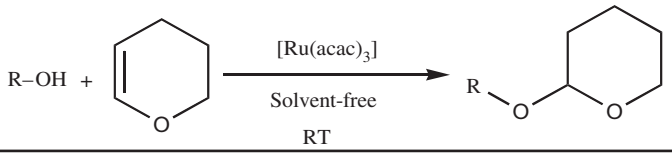
$[Ru(acac)_3]$ was obtained in >99% yield in 30 min at ambient temperature by using solvent-free conditions (Table 1, entry 4). Next, our efforts focused on achieving the optimum conditions for tetrahydropyranylation of *n*-butanol (**1**) as a model hydroxy compound in the presence of $[Ru(acac)_3]$ as Lewis acid. The results are summarized in Table 2. From the results obtained, we noted that the optimum concentration of 2 mol% of $[Ru(acac)_3]$ is sufficient to carry forward the reaction. The reaction is found to be sluggish when carried out using even stoichiometric – 0.5 equiv. of catalyst amounts. Among the various solvents tested for the THP protection of **1**, toluene and DCM did not furnish the expected product (Table 2, entries 3, 7), whereas other solvents gave moderate to good yields of the addition product. We have also adopted a solvent-free procedure, and to our surprise, the reaction can be carried out in a shorter time with almost quantitative yield (Table 2, entry 9). This allowed us to adopt a simple work-up procedure by employing ether to dissolve the organic material and not the catalyst, which could be easily removed by filtration.

With optimized experimental conditions for the reaction between *n*-butanol (**1**) and DHP, this process was investigated for a wide range of aromatic and aliphatic alcohols and phenols. The results are listed in Table 3.

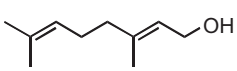
One of the important features of this protocol for the formation of THP ethers is that absolute anhydrous conditions are not required. The reaction conditions are mild enough not to induce any isomerization of the double bonds of allylic systems (Table 3, entries 2, 4–6, 8). The reactions are reasonably fast, which holds well even with hindered alcohols like geranial and menthol (Table 3, entries 8–9). We investigated the substrate scope and tolerance of electronically divergent alcohols including those that contain sensitive functionalities, for example, epoxy (Table 3, entry 17), C=C, C≡C (Table 3, entries 3, 7), NO_2 (Table 3, entry 32), and Cl (Table 3, entry 33). Another remarkable feature of this method is the chemoselective monotetrahydropyranylation of symmetrical 1,*n*-diols (Table 3, entries 14–16, with 7–8% of di-THP ethers), which is a difficult transformation to accomplish via conventional methods. A primary alcohol has been selectively protected in the presence of a secondary alcohol (Table 3, entry 14). Benzylic alcohols are also smoothly tetrahydropyranylated when reacting with DHP (Table 3, entries 10, 28) to give the corresponding THP ethers in good yields. Furthermore, alcohols bearing the hydroxy group bonded to a carbon stereogenic centre (Table 3, entries 9, 16, 18) can be protected, giving adducts with a complete retention of configuration. However, low diastereoselectivity is observed.

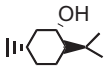
We also investigated the electronic effects on the phenol moiety in the THP protection reaction (Table 3, entries 19–27, 29–33). No apparent difference in the rate of reactivity was observed in the presence of electron donating and withdrawing groups on the aromatic ring. However, no or less reaction occurred between entries 20–23 and 3,4-dihydro-2*H*-pyran. Interestingly, *p*-hydroxy benzaldehyde and *o*-aminophenol (Table 3, entries 27, 30) did not react as expected, even after stirring for 2 days.

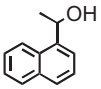
The efficiency and generality of the present $[Ru(acac)_3]$-catalyzed protocol can be realized at a glance by comparing our results for the chosen model substrates with those of some recently developed procedures (Table 4). The reactions have been compared with respect to the reaction times, mol% of the catalyst used, and the yields.

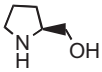


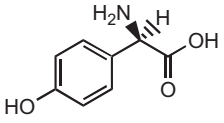
In conclusion, we have developed a mild, efficient, and highly selective methodology for the tetrahydropyranylation of alcohols using $[Ru(acac)_3]$ as a catalyst (2 mol%). Notable features of the protocol include clean and simple reaction conditions, nonaqueous work-up, and environmentally benign reagents. This work widens the scope of using transition metal salts and complexes in organic synthesis because of the nontoxic nature of the catalyst. We believe that this work will be a valuable addition to modern synthetic methodologies.











Typical experimental procedures

The hydroxy compound (1–33, 1.0 mmol), 3,4-dihydro-2*H*-pyran (1.1 mmol), and $[Ru(acac)_3]$ (2 mol%) were placed successively in a flask. After stirring, the reaction mixture was treated with Et_2O (2 × 10 mL), and the catalyst was removed by filtration. The filtrate extracts were concentrated under reduced pressure, and the crude product was then purified by silica gel chromatography (hexane – ethyl acetate). All the obtained tetrahydropyranyl ethers were characterized by IR, ^1H NMR spectroscopy, and mass spectrometry, and

Monometallic, homo-, and hetero-bimetallic complexes of a siloxy-bis(phosphinimide) ligand

Gema Martinez and Douglas W. Stephan

Abstract: Deprotonation of $Me_3SiNP(t\text{-}Bu)_2Me$ with BuLi generates $[Me_3SiNP(t\text{-}Bu)_2CH_2Li]$ (**1**), which reacts with $(Me_2SiCl)_2O$ to give the new siloxyl-bis(phosphinimine) ligand $[Me_3SiNP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (**2**). This ligand reacts with 1 or 2 equiv. of $CpTiCl_3$ to give $[CpTiCl_2NP(t\text{-}Bu)_2CH_2SiMe_2OCH_2SiMe_2P(t\text{-}Bu)_2NSiMe_3]$ (**3**) and $[CpTiCl_2NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (**4**), similar to the species $[CpNbCl_3NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (**5**) and $[CpTiCl_2NP(t\text{-}Bu)_2(\mu\text{-}O\text{-}(CH_2SiMe_2)_2)\text{-}P(t\text{-}Bu)_2NCpNbCl_3]$ (**6**). Subsequent alkylations of these metal-halide derivatives afforded the analogous permethylated analogs **7**–**10**, respectively. Reaction of **8** with $B(C_6F_5)_3$ generates $[(CpTiMe_2NP(t\text{-}Bu)_2CH_2SiMe_2)(CpTiMeNP(t\text{-}Bu)_2CH_2SiMe_2)O][MeB(C_6F_5)]$ (**11**). Benzylation of **4** give the species $[CpTiBz_2NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (**12**), which reacts subsequently with $NC(2,6\text{-}Me_2C_6H_3)$ to give a 1:1 mixture of the diastereoisomers of $[CpTiBz(N{=}C(CH_2Ph)(2,6\text{-}Me_2C_6H_3))NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ **13a** and **13b**. These synthetic routes are described and the implications considered. X-ray structural data for compounds **2**, **4**, **8**, and **10** are reported.

Key words: phosphinimide ligands, bimetallic species, heterobimetallic compounds.

Résumé : La déprotonation du $Me_3SiNP(t\text{-}Bu)_2Me$ à l'aide de BuLi génère du $[Me_3SiNP(t\text{-}Bu)_2CH_2Li]$ (**1**) qui réagit avec du $(Me_2SiCl)_2O$ pour conduire à la formation du nouveau ligand siloxyl-bis(phosphinimine) $[Me_3SiNP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (**2**). Ce ligand réagit avec un ou deux équivalents de $CpTiCl_3$ pour conduire à la formation des complexes $[CpTiCl_2NP(t\text{-}Bu)_2CH_2OCH_2SiMe_2P(t\text{-}Bu)_2NSiMe_3]$ (**3**) et $[CpTiCl_2NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (**4**) et de la même manière aux espèces $[CpNbCl_3NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (**5**) et $[CpTiCl_2NP(t\text{-}Bu)_2(\mu\text{-}OCH_2Me_2)_2P(t\text{-}Bu)_2CpNbCl_3]$ (**6**). Des alkylations subséquentes ces halogénures métalliques conduisent aux analogues perméthylés **7**–**10** respectivement. La réaction du composé **8** avec du $B(C_6F_5)_3$ fournit le complexe $[CpTiMe_2NP(t\text{-}Bu)_2CH_2SiMe_2)(CpTiMeNP(t\text{-}Bu)_2CH_2SiMe_2)O][MeB(C_6F_5)]$ (**11**). La benzylation du composé **4** fournit l'espèce $[CpTiBz_2NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (**12**) qui peut réagir subséquemment avec le $NC(2,6\text{-}Me_2C_6H_3)$ pour conduire à un mélange 1:1 des diastéréoisomères **13a** et **13b** du $[CpTiBz(N{=}C(CH_2Ph)(2,6\text{-}Me_2C_6H_3))NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$. On rapporte les voies de synthèses de ces composés et les implications considérées des données relatives aux structures de composés **2**, **4**, **8** et **10** déterminées par diffraction des rayons X.

Mots clés : ligands phosphinimide, espèces bimétalliques, composés hétérobimétalliques.

[Traduit par la Rédaction]

Introduction

The utility of monometallic early metal phosphinimide complexes of the general form $CpTi(NPR_3)X_2$ and $(R_3PN)_2TiX_2$ in olefin polymerization has been established (1–4). Such complexes have been shown to result in high activity single-site polymerization catalysts under commercially relevant conditions. In efforts to both develop new catalysts as well as glean a deeper understanding of the structure–reactivity relationships, considerable effort has been put into the synthesis and study of a variety of new phosphinimide derivatives. Much of the work on such phosphinimide-based complexes to date has been recently reviewed (5).

One avenue for examination that has drawn some recent attention has been the effort to prepare and utilize bis(phosphinimide) ligands (Scheme 1). One motivation involves the analogy between bis(phosphinimide) complexes and ansa-metallocene systems. However, the synthesis of such compounds has proved challenging. Bochmann and coworkers (6) have shown that bis(diphenylphosphinimino)ethane affords bimetallic bis(phosphinimide) complexes as well as chelate complexes (**A**) in which the ligand backbone is metallated (**B**). In the related bis(phosphinimino)methane chemistry, Cavell and coworkers (8–10) have described related bimetallic species (**C**) (7) as well as a number of species in which double activation of the central carbon of the ligand gives rise to reactive carbene derivatives (**D**). Bimetallic Ti-phosphinimide complexes have also been recently obtained by Fryzuk and coworkers (11) from the oxidation of a phosphine during dinitrogen cleavage chemistry (**E**). Contrived synthesis of bis(phosphinimide) ligands derived from $p\text{-}C_6H_4(CH_2PR_2)_2$ have been used to prepare bimetallic titanium derivatives (**F**), while more recently we (12) and

Scheme 1. Examples of known Ti bis(phosphinimine) and bis(phosphinimide) complexes.

others (13, 14) showed that the phosphinimines derived from *m*-$C_6H_4(CH_2PR_2)_2$ and $CH_2(CH_2P$*t*-$Bu_2)_2$ provide access to chelate complexes (**G**, **H**) (Scheme 1). In this paper, we explore the potential of a new siloxy-bis(phosphinimide) ligand in the synthesis of monometallic as well as bimetallic complexes. In addition, this ligand is employed to prepare a rare example of heterobimetallic phosphinimide complexes.

Experimental

General data

All preparations were done under an atmosphere of dry O_2-free N_2 employing both Schlenk line techniques and an MBraun or Vacuum Atmospheres inert atmosphere glove box. Solvents were purified employing a Grubbs type solvent purification system manufactured by Innovative Technologies. All organic reagents were purified by conventional methods. ^{1}H, ^{31}P{^{1}H}, ^{11}B{^{1}H}, and ^{13}C{^{1}H} NMR spectra were recorded on Bruker Avance-300 and 500 spectrometers. All spectra were recorded in C_6D_6 at 25 °C unless otherwise noted. Trace amounts of protonated solvents were used as reference and chemical shifts are reported relative to $SiMe_4$. ^{31}P{^{1}H} and ^{11}B{^{1}H} NMR spectra were referenced to external 85% H_3PO_4 and $BF_3{\cdot}Et_2O$, respectively, and are reported in ppm. Additionally, to make the correct assignation for each signal in ^{1}H and ^{13}C NMR, all complexes were characterized by HMQC and DEPT. Combustion analyses were performed in-house employing a PerkinElmer CHN Analyzer. The species $Me_3SiNP(t\text{-}Bu)_2Me$ was prepared by literature methods (5). $(Me_2SiCl)_2O$ was purchased from the Sigma-Aldrich Chemical Co.

Generation of [$Me_3SiNP(t\text{-}Bu)_2CH_2Li$] 1

This intermediate reagent was generated and used in situ by reaction of a THF solution of $Me_3SiNP(t\text{-}Bu)_2Me$ with a stoichiometric amount of *n*-BuLi and used in situ. ^{31}P{^{1}H} NMR δ: 58.9.

Synthesis of [$Me_3SiNP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ 2

A solution of $(Me_2SiCl)_2O$ (0.38 g, 1.97 mmol) in THF (10 mL) was added to a solution of the lithium salt **1** (1.00 g, 3.95 mmol) in THF (20 mL) at RT. The mixture was stirred for 18 h. The solvent was removed under vacuum and the residue extracted with hexanes (30 mL). The solvent was removed under vacuum to produce **2** as a microcrystalline white solid. Yield 1.97 g, 3.16 mmol, 80%. ^{1}H NMR δ: 0.35 (s, 18H, $SiMe_3$), 0.47 (s, 12H, $SiMe_2$), 1.07 (d, $^3J_{PH}$ = 14 Hz, 36H, *t*-Bu), 1.13 (d, $^3J_{PH}$ = 14 Hz, 4H, CH_2). ^{13}C{^{1}H} NMR δ: 3.4 (s, $SiMe_2$), 4.9 (s, $SiMe_3$), 13.6 (d, $^1J_{PC}$ = 60 Hz, CH_2), 27.7 (s, *t*-Bu), 37.3 (d, $^1J_{PC}$ = 60 Hz, *t*-Bu). ^{31}P{^{1}H} NMR δ: 27.7. EA calcd. for $C_{28}H_{70}Si_4ON_2P_2$: C 53.79, H 11.29, N 4.48; found: C 53.71, H 11.04, N 4.63. X-ray quality crystals were obtained from hexanes at –30 °C.

Synthesis of [$CpTiCl_2NP(t\text{-}Bu)_2CH_2SiMe_2OSiMe_2CH_2P(t\text{-}Bu)_2NSiMe_3$] 3

To a solution of **2** (3.00 g, 4.78 mmol) in toluene (15 mL) was added $CpTiCl_3$ (0.70 g, 3.19 mmol) at 25 °C. The mixture was stirred for 7 h. The volume of the solution was reduced under vacuum and the residue was washed with pentane (30 mL) and dried under vacuum to give a yellow crystalline solid. Yield 1.75 g, 2.39 mmol, 75%. ^{1}H NMR ($CDCl_3$, 25 °C) δ: –0.03 (s, 9H, $SiMe_3$), 0.31 (s, 6H, $SiMe_2$), 0.42 (s, 6H, $SiMe_2$), 1.10 (d, $^3J_{PH}$ = 14 Hz, 2H, CH_2), 1.15 (d, $^3J_{PH}$ = 15 Hz, 18H, *t*-Bu), 1.17 (d, $^3J_{PH}$ = 13 Hz, 2H, CH_2), 1.39 (d, $^3J_{PH}$ = 15 Hz, 18H, *t*-Bu), 6.46 (s, 10H, Cp). ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) δ: 4.0 (s, $SiMe_2$), 4.6 (s, $SiMe_2$), 5.6 (s, $SiMe_3$), 12.3 (d, $^1J_{PC}$ = 50 Hz, CH_2), 12.3 (d, $^1J_{PC}$ = 58 Hz, CH_2), 28.3 (s, *t*-Bu), 28.4 (s, *t*-Bu), 38.2 (d, $^1J_{PC}$ = 58 Hz, *t*-Bu), 40.2 (d, $^1J_{PC}$ = 54 Hz, *t*-Bu), 116.3 (s, Cp). ^{31}P{^{1}H} NMR δ: 21.1, 41.0. EA calcd. for $C_{30}H_{60}Cl_2N_2P_2OSi_3Ti$: C 49.37, H 8.29, N 3.84; found: C 49.24, H 8.57, N 3.64.

Synthesis of [$CpTiCl_2NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ 4

To a solution of **2** (2.00 g, 3.19 mmol) in toluene (50 mL) was added $CpTiCl_3$ (1.40 g, 6.39 mmol) at 25 °C. The re-

© 2006 NRC Canada

sulting suspension was stirred for 18 h. The volume of the solution was reduced under vacuum to cause the formation of a solid that was washed with hexanes (40 mL) and dried under vacuum to give a yellow crystalline solid. Yield 2.33 g, 2.62 mmol, 89%. ^{1}H NMR ($CDCl_3$, 25 °C) δ: 0.49 (s, 12H, $SiMe_2$), 1.17 (d, $^3J_{PH}$ = 13 Hz, 4H, CH_2), 1.38 (d, $^3J_{PH}$ = 15 Hz, 36H, *t*-Bu), 6.45 (s, 10H, Cp). ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) δ: 3.5 (s, $SiMe_2$), 11.0 (d, $^1J_{PC}$ = 49 Hz, CH_2), 27.2 (s, *t*-Bu), 39.1 (d, $^1J_{PC}$ = 54 Hz, *t*-Bu), 115.4 (s, Cp). ^{31}P{^{1}H} NMR δ: 43.5. EA calcd. for $C_{32}H_{62}Cl_4Si_2ON_2P_2Ti_2$: C 45.40, H 7.35, N 3.31; found: C 45.20, H 7.15, N 2.99. X-ray quality crystals were obtained by slow evaporation of a toluene solution.

Synthesis of [CpNbCl$_3$NP(*t*-Bu)$_2$CH$_2$SiMe$_2$]$_2$O 5

To a solution of **2** (0.50 g, 0.79 mmol) in THF (30 mL) was added $CpNbCl_4$ (0.48 g, 1.59 mmol). The resulting suspension was stirred at 25 °C for 18 h. The volume of the solution was reduced under vacuum to cause the formation of a yellow solid that was washed with hexanes (20 mL) and dried under vacuum to give **5** as a microcrystalline solid. Yield 0.66 g, 0.65 mmol, 82%. ^{1}H NMR ($CDCl_3$, 25 °C) δ: 0.53 (s, 12H, $SiMe_2$), 1.45 (d, $^3J_{PH}$ = 16 Hz, 36H, *t*-Bu), 1.51 (d, $^3J_{PH}$ = 15 Hz, 4H, CH_2), 6.59 (s, 10H, Cp). ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) δ: 4.8 (s, $SiMe_2$), 10.0 (d, $^1J_{PC}$ = 47 Hz, CH_2), 28.6 (s, *t*-Bu), 40.59 (d, $^1J_{PC}$ = 50 Hz, *t*-Bu), 118.5 (s, Cp). ^{31}P{^{1}H} NMR δ: 65.5. EA calcd. for $C_{32}H_{62}Cl_6Si_2ON_2P_2Nb_2$: C 38.14, H 6.20, N 2.78; found: C 37.96, H 6.56, N 2.75.

Synthesis of [CpTiCl$_2$NP(*t*-Bu)$_2$CH$_2$SiMe$_2$OSiMe$_2$CH$_2$P(*t*-Bu)$_2$NCpNbCl$_3$] 6

To a solution of **3** (0.50 g, 0.68 mmol) in THF (30 mL) was added $CpNbCl_4$ (0.20 g, 0.68 mmol) at 25 °C. The reaction suspension was stirred at 25 °C for 18 h and slowly became a yellow solution. The volume of the solvent was reduced under vacuum to give a yellow solid that was washed with a mixture of toluene and hexanes in proportion 3 to 1 (3 × 40 mL) and dried under vacuum. Yield 0.53 g, 0.57 mmol, 85%. ^{1}H NMR ($CDCl_3$, 25 °C) δ: 0.49 (s, 6H, $SiMe_2$), 0.53 (s, 6H, $SiMe_2$), 1.22 (m, 4H, CH_2), 1.39 (d, $^3J_{PH}$ = 15 Hz, 18H, *t*-Bu), 1.46 (d, $^3J_{PH}$ = 16 Hz, 18H, *t*-Bu), 6.44 (s, 5H, Cp), 6.61 (s, 5H, Cp). ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) δ: 3.6 (s, $SiMe_2$), 3.9 (s, $SiMe_2$), 9.2 (d, $^1J_{PC}$ = 47 Hz, CH_2), 11.2 (d, $^1J_{PC}$ = 49 Hz, CH_2), 27.4 (s, *t*-Bu), 27.6 (s, *t*-Bu), 40.5 (d, $^1J_{PC}$ = 54 Hz, *t*-Bu), 40.1 (d, $^1J_{PC}$ = 50 Hz, *t*-Bu), 115.5 (s, Cp), 117.6 (s, Cp). ^{31}P{^{1}H} NMR δ: 41.2, 66.3. EA calcd for $C_{32}H_{62}Cl_5Si_2ON_2P_2NbTi$: C 41.46, H 6.74, N 3.02; found: C 41.26, H 6.66, N 2.95.

Synthesis of [CpTiMe$_2$NP(*t*-Bu)$_2$CH$_2$SiMe$_2$OSiMe$_2$CH$_2$P(*t*-Bu)$_2$NSiMe$_3$] 7

To a suspension of **3** (0.50 g, 0.68 mmol) in hexanes (30 mL) was added 3.0 mol/L MeMgCl in THF (0.50 mL, 1.50 mmol) at 25 °C. The reaction mixture was stirred for 18 h. The light yellow solution was filtered and the solvent removed under vacuum to give a yellow microcrystalline solid that was washed with cold pentane (2 mL). Yield 0.38 g, 0.55 mmol, 82%. ^{1}H NMR δ: 0.44 (s, 9H, $SiMe_3$), 0.57 (s, 12H, $SiMe_2$), 0.71 (s, 6H, TiMe), 1.17 (d, $^3J_{PH}$ = 14 Hz, 18H, *t*-Bu), 1.17 (d, $^3J_{PH}$ = 14 Hz, 2H, CH_2), 1.27 (d, $^3J_{PH}$ = 14 Hz, 18H, *t*-Bu), 1.27 (d, $^3J_{PH}$ = 14 Hz, 2H, CH_2), 6.30 (s, 10H, Cp). ^{13}C{^{1}H} NMR δ: 3.2 (s, $SiMe_2$), 3.4 (s, $SiMe_2$), 5.0 (s, $SiMe_3$), 12.1 (d, $^1J_{PC}$ = 49 Hz, CH_2), 13.5 (d, $^1J_{PC}$ = 63 Hz, CH_2), 27.1 (s, *t*-Bu), 27.3 (s, *t*-Bu), 37.4 (d, $^1J_{PC}$ = 59 Hz, *t*-Bu), 38.9 (d, $^1J_{PC}$ = 56 Hz, *t*-Bu), 42.5 (s, TiMe), 110.2 (s, Cp). ^{31}P{^{1}H} NMR δ: 25.9, 27.3. EA calcd. for $C_{32}H_{66}N_2P_2OSi_3Ti$: C 55.79, H 9.66, N 4.07; found: C 55.22, H 9.70, N 4.01.

Synthesis of [CpTiMe$_2$NP(*t*-Bu)$_2$CH$_2$SiMe$_2$]$_2$O 8

To a suspension of complex **4** (0.10 g, 0.12 mmol) in hexanes (20 mL) was added 3.0 mol/L MeMgCl in THF (0.16 mL, 0.50 mmol). The reaction mixture was stirred for 18 h. The light yellow solution was filtered and the solvent removed under vacuum to produce a yellow solid that was washed with cold pentane (2 × 2mL) and dried under vacuum. Yield 0.06 g, 0.08 mmol, 66%. ^{1}H NMR δ: 0.50 (s, 12H, $SiMe_2$), 0.65 (s, 12H, TiMe), 1.11 (d, $^3J_{PH}$ = 12 Hz, 4H, CH_2), 1.15 (d, $^3J_{PH}$ = 15 Hz, 36H, *t*-Bu), 6.21 (s, 10H, Cp). ^{13}C{^{1}H} NMR δ: 3.9 (s, $SiMe_2$), 12.5 (d, $^1J_{PC}$ = 49 Hz, CH_2), 27.6 (s, *t*-Bu), 38.9 (d, $^1J_{PC}$ = 55 Hz, *t*-Bu), 42.6 (s, TiMe), 111.5 (s, Cp). ^{31}P{^{1}H} NMR δ: 36.3. EA calcd. for $C_{36}H_{84}Si_2ON_2P_2Ti_2$: C 56.53, H 9.75, N 3.66; found: C 56.13, H 9.23, N 3.55. X-ray quality crystals were obtained from pentane at –30 °C.

Synthesis of [CpNbMe$_3$NP(*t*-Bu)$_2$CH$_2$SiMe$_2$]$_2$O 9

To a suspension of complex **5** (0.22 g, 0.21 mmol) in hexanes (20 mL) was added 3.0 mol/L MeMgCl in THF (0.50 mL, 1.30 mmol). The reaction mixture was stirred for 18 h. The light yellow solution was filtered and the solvent removed under vacuum to produce a yellow solid that was washed with cold pentane (2 × 2 mL) and dried under vacuum. Yield 0.15 g, 0.17 mmol, 81%. ^{1}H NMR δ: 0.42 (s, 12H, $SiMe_2$), 1.01 (s, 18H, NbMe), 1.04 (d, $^3J_{PH}$ = 14 Hz, 36H, *t*-Bu), 1.05 (d, $^3J_{PH}$ = 14 Hz, 4H, CH_2), 5.62 (s, 10H, Cp). ^{13}C{^{1}H} NMR δ: 3.7 (s, $SiMe_2$), 11.8 (d, $^1J_{PC}$= 49 Hz, CH_2), 27.5 (s, *t*-Bu), 34.0 (s, NbMe), 38.7 (d, $^1J_{PC}$ = 55 Hz, *t*-Bu), 107.1 (s, Cp). ^{31}P{^{1}H} NMR δ: 39.6. EA calcd. for $C_{38}H_{80}Si_2ON_2P_2Nb_2$: C 51.57, H 9.11, N 3.17; found: C 51.96, H 8.86, N 2.75.

Synthesis of [CpTiMe$_2$NP(*t*-Bu)$_2$CH$_2$SiMe$_2$OSiMe$_2$CH$_2$P(*t*-Bu)$_2$NCpNbMe$_3$] 10

A 3.0 mol/L THF solution of MgMeCl (0.95 mL, 2.80 mmol) was added at 25 °C to a suspension of **6** (0.50 g, 0.53 mmol) in hexanes (30 mL). The reaction mixture was stirred for 18 h. After filtration the solvent was removed under vacuum and the residue was extracted with pentane (20 mL). The solvent was removed from the filtrate under vacuum to produce **12** as a microcrystalline yellow solid. Yield 0.30 g, 0.36 mmol, 68%. ^{1}H NMR δ: 0.41 (s, 6H, $SiMe_2$), 0.50 (s, 6H, $SiMe_2$), 0.62 (s, 6H, TiMe), 0.93 (d, $^3J_{PH}$ = 14, 2H, CH_2), 1.01 (d, $^3J_{PH}$ = 14 Hz, 18H, *t*-Bu), 1.03 (s, 9H, NbMe), 1.16 (d, $^3J_{PH}$ = 14, 2H, CH_2), 1.19 (d, $^3J_{PH}$ = 14 Hz, 18H, *t*-Bu), 5.63 (s, 5H, Cp), 6.20 (s, 5H, Cp). ^{13}C{^{1}H} NMR δ: 3.7 (s, $SiMe_2$), 3.8 (s, $SiMe_2$), 11.7 (d, $^1J_{PC}$ = 48 Hz, CH_2), 12.3 (d, $^1J_{PC}$ = 49 Hz, CH_2), 27.4 (s, *t*-Bu), 27.6 (s, *t*-Bu), 35.1 (s, NbMe), 38.6 (d, $^1J_{PC}$ = 56 Hz, *t*-Bu), 38.9 (d, $^1J_{PC}$ = 56 Hz, *t*-Bu), 42.6 (s, TiMe), 107.0 (s, Cp), 111.4 (s, Cp). ^{31}P{^{1}H} NMR δ: 39.4, 25.7. EA calcd.

for $C_{37}H_{77}Si_2ON_2P_2NbTi$: C 53.87, H 9.41, N 3.40; found: C 53.66, H 9.33, N 3.25. X-ray quality crystals were obtained by slow evaporation of pentane.

Generation of [(CpTiMe$_2$NP(*t*-Bu)$_2$CH$_2$SiMe$_2$OSiMe$_2$CH$_2$P(*t*-Bu)$_2$)TiCpMe][MeB(C$_6$F$_5$)] 11

An equimolar mixture of **8** (34.00 mg, 0.04 mmol) and $B(C_6F_5)_3$ (0.022 g, 0.04 mmol) was charged into a Teflon-valved NMR tube and BrC_6D_5 was added at 25 °C. Complex **11** was highly sensitive to air and moisture and only characterized by NMR techniques. ^{1}H NMR (BrC_6D_5, 25 °C) δ: –0.04 (s, 3H, TiMe), 0.14 (s, 6H, $SiMe_2$), 0.31 (s, 6H, $SiMe_2$), 0.55 (s, 6H, TiMe), 0.99 (m, 4H, CH_2). 1.02 (d, $^3J_{PH}$ = 14 Hz, 18H, *t*-Bu), 1.03 (d, $^3J_{PH}$ = 14 Hz, 18H, *t*-Bu), 5.99 (s, 10H, Cp). ^{13}C{^{1}H} NMR (BrC_6D_5, 25 °C) δ: 3.3 (s, $SiMe_2$), 3.4 (s, $SiMe_2$), 11.3 (d, $^1J_{PC}$ = 50 Hz, CH_2), 26.6 (s, *t*-Bu), 26.8 (s, *t*-Bu), 37.6 (d, $^1J_{PC}$ = 51 Hz, *t*-Bu), 38.3 (d, $^1J_{PC}$ = 54 Hz, *t*-Bu), 42.1 (s, TiMe), 49.3 (s, TiMe), 113.2 (s, Cp). ^{19}F NMR (BrC_6D_5, 25 °C) δ: –132.1 (d, F_o), –164.4, (t, F_p), –166.8 (t, F_m). ^{11}B{^{1}H} NMR (BrC_6D_5, 25 °C) δ: –14.9. ^{31}P{^{1}H} NMR (BrC_6D_5, 25 °C) δ: 39.5, 39.6.

Synthesis of [CpTiBz$_2$NP(*t*-Bu)$_2$CH$_2$SiMe$_2$]$_2$O 12

A 2 mol/L THF solution of BzMgCl (0.25 mL, 0.49 mmol) was added at 25 °C to a solution of complex **4** (0.10 g, 0.12 mmol) in Et_2O (20 mL). The resulting suspension was stirred for 18 h. The orange solution formed was filtered. After removal the solvent under vacuum the residue was washed with hexanes (2 × 20 mL) and dried under vacuum to give an orange solid. Yield 0.08 g, 0.07 mmol, 65%. ^{1}H NMR δ: 0.48 (s, 12H, $SiMe_2$), 1.10 (d, $^3J_{PH}$ = 13 Hz, 4H, CH_2), 1.11 (d, $^3J_{PH}$ = 15 Hz, 36H, *t*-Bu), 2.69 (d, J_{HH} = 10 Hz, 4H, $TiCH_2$), 2.82 (d, J_{HH} = 10 Hz, 4H, $TiCH_2$), 5.95 (s, 10H, Cp), 6.92 (m, 4H, H_p Ph), 7.03 (m, 8H, H_o Ph), 7.24 (m, 8H, H_m Ph). ^{13}C{^{1}H} NMR (C_6D_6, 25 °C) δ: 4.2 (s, $SiMe_2$), 13.2 (d, $^1J_{PC}$ = 48 Hz, CH_2), 27.8 (s, *t*-Bu), 38.7 (d, $^1J_{PC}$ = 55 Hz, *t*-Bu), 71.7 (s, $TiCH_2$), 114.2 (s, Cp), 121.2 (s, C_p Ph), 126.4 (s, C_o Ph), 128.6 (s, C_m Ph), 153.7 (s, C_{ipso} Ph). ^{31}P{^{1}H} NMR δ: 36.3. EA calcd. for $C_{60}H_{80}Si_2ON_2P_2Ti_2$: C 67.40, H 8.48, N 2.61; found: C 67.11, H 8.37, N 2.81.

Synthesis of [CpTiBz(N=C(CH$_2$Ph)(2,6-Me$_2$C$_6$H$_3$))NP(*t*-Bu)$_2$CH$_2$SiMe$_2$]$_2$O 13

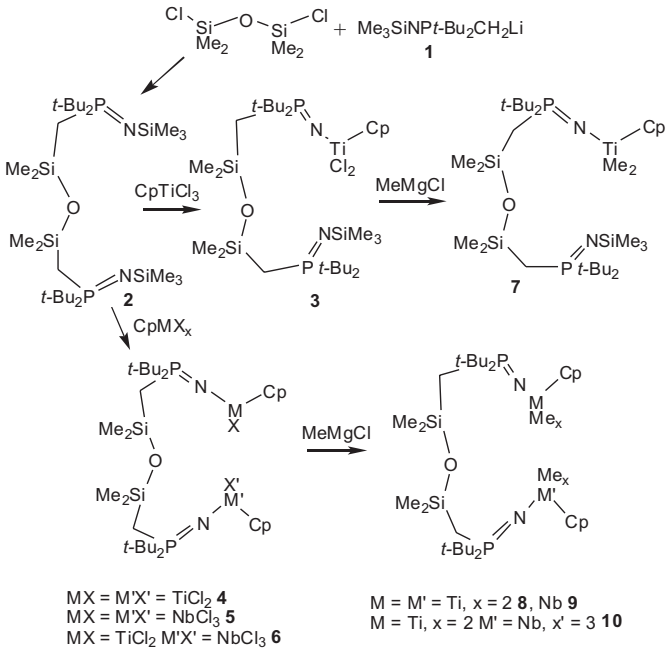
To an orange solution of **12** (0.40 g, 0.52 mmol) in toluene (20 mL) was added NC(2,6-$Me_2C_6H_3$) (0.13 g, 1.04 mmol). The mixture was stirred for 1 h at 25 °C. After removal of the solvent under vacuum the residue was washed with hexanes (10 mL) and dried under vacuum to give complex **5** as a mixture of two diastereomers **13a** and **13b** (assignments to the two isomers are denoted with [a] and [b]). Yield 0.34 g, 0.25 mmol, 68%. ^{1}H NMR δ: 0.50[a]/0.51[b] (s, 6H, $SiMe_2$), 0.55[a]/0.56[b] (s, 6H, $SiMe_2$), 1.07[a]/1.08[b] (d, $^3J_{PH}$ = 14 Hz, 18H, *t*-Bu), 1.10[a]/1.11[b] (d, $^3J_{PH}$ = 14 Hz, 18H, *t*-Bu), 1.13[a,b] (m, 4H, CH_2), 1.53[a,b] (s, 3H, $Me_2C_6H_3$), 2.20[a,b] (s, 3H, $Me_2C_6H_3$), 3.04[a,b] (d, J_{HH} = 8 Hz, 2H, $TiCH_2$), 3.13[a,b] (d, J_{HH} = 7 Hz, 2H, $TiCH_2$), 3.72[a,b] (d, J_{HH} = 14 Hz, 2H, CH_2Ph), 3.79[a,b] (d, J_{HH} = 14 Hz, 2H, CH_2Ph), 5.82/[a]5.83[b] (s, 10H, Cp), 6.80–7.20[a,b] (m, 26H, $Me_2C_6H_3$ and C_6H_5). ^{13}C{^{1}H} NMR δ: 4.5[a,b] (s, $SiMe_2$), 14.8[a,b] (d, $^1J_{PC}$ = 44 Hz, CH_2), 19.2[a,b] (s, $Me_2C_6H_3$), 20.1[a,b] (s, $Me_2C_6H_3$), 28.0[a]/28.2[b] (s, *t*-Bu), 37.6[a]/38.2[b] (d, $^1J_{PC}$ = 56 Hz, *t*-Bu), 44.8[a,b] (s, CH_2Ph), 52.9[a]/53.1[b] (s, $TiCH_2$), 109.3[a]/109.6[b] (s, Cp), 125.7[a,b], 126.1[a,b], 127.1[a,b], 127.8[a,b], 128.8[a,b], 128.9[a,b], 129.5[a,b], 130.5[a,b], (s, C_p, C_o, C_m, Ph), 137.1[a,b] (s, C_{ipso} CH_2Ph), 147.1[a,b] (s, C_{ipso} $TiCH_2Ph$), 157.0[a,b] (s, N=C). ^{31}P{^{1}H} NMR δ: 26.5. EA calcd. for $C_{78}H_{108}Si_2ON_4P_2Ti_2$: C 70.36, H 8.18, N 4.21; found: C 70.25, H 8.11, N 4.11.

X-ray data collection and reduction

Crystals were manipulated and mounted in capillaries in a glove box, thus maintaining a dry O_2-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer. The data

© 2006 NRC Canada

were collected in a hemisphere of data in 1448 frames with 10 s exposure times. The observed extinctions were consistent with the space groups in each case. The data sets were collected for the range $4.5° < 2\theta < 45–50.0°$. The intensities of reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and XPREP processing packages. An empirical absorption correction based on redundant data was applied to each data set. Subsequent solution and refinement was performed using the SHELXTL solution package.



Structure solution and refinement

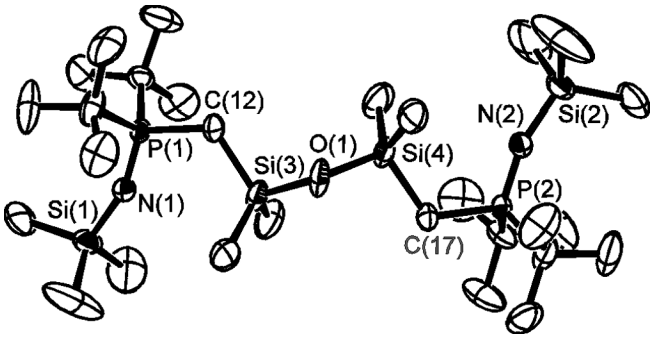
Non-hydrogen atomic scattering factors were taken from the literature (15). The heavy atom positions were determined using the SHELXTL direct methods routine. The remaining non-hydrogen atoms were located from successive Fourier map difference calculations. The refinements were carried out by using full-matrix least-squares techniques on *F*, minimizing the function $\omega (F_o\text{-}F_c)^2$ where the weight ω is defined as $4F_o^2/2\sigma (F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of each refinement, all non-hydrogen atoms were assigned anisotropic temperature factors. In the case of **10**, the cell parameters suggested the possibility of an alternative refinement using a monoclinic cell. All attempts to refine models in higher symmetry space groups provided unsatisfactory refinements. Thus, it was concluded that the correct space group was indeed the reported triclinic cell. In all cases, hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded, assuming a C–H bond length of 0.95 Å. H atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the C atom to which they are bonded. The H atom contributions were calculated but not refined. The locations of the largest peaks in the final Fourier map difference calculation as well as the magnitude of the residual electron densities in each case were of no chemical significance. Addition details are provided in the Supplementary data.[2]

Results and discussion

Deprotonation of a P-bound methyl group has been shown in the past to be a straightforward manner for the generation of a carbon-based P-containing nucleophile (16). In this fashion, the reaction of $Me_3SiNP(t\text{-}Bu)_2Me$ with BuLi was employed to generate solutions of the lithium salt $[Me_3SiNP(t\text{-}Bu)_2CH_2Li]$. Subsequent reaction of this reagent with $(Me_2SiCl)_2O$ afforded, after suitable work-up, the new siloxyl-bis(phosphinimine) ligand $[Me_3SiNP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ **2** in 80% isolated yield (Scheme 2). This species gives rise to a single $^{31}P\{^1H\}$ NMR signal at 27.7 ppm and the expected ^1H and $^{13}C\{^1H\}$ NMR resonances. X-ray quality crystals were obtained from hexanes at

Scheme 2. Synthesis of compounds **1**–**10**.

–30 °C. The crystallographic structure (Fig. 1) confirmed the above formulation and revealed the new average C–Si bond length of 1.865(4) Å, while the N–Si distances averaged 1.653(4) Å. The central Si–O bond length was found to be 1.631(3) Å, while the Si–O–Si angle was 144.7(2)°.



Initial attempts to utilize this ligand **2** involved reactions with MCl_4 (M = Ti, Zr). In these cases, refluxing conditions gave complex mixtures of products. ^{31}P NMR resonances attributed to $HNP(t\text{-}Bu)_2Me$, $Me_3SiNP(t\text{-}Bu)_2Me$, and $OP(t\text{-}Bu)_2Me$ were consistent with ligand fragmentation. In constrast, the ligand precursor **2** reacts cleanly and stoichiometrically with $CpTiCl_3$. Reaction of **2** with 1 equiv. of $CpTiCl_3$ proceeded smoothly at 25 °C in toluene to give a yellow crystalline solid **3** in 75% yield. The $^{31}P\{^1H\}$ NMR spectrum of **3** gave rise to two resonances at 21.1 and 41.0 ppm. These data together with the ^1H and ^{13}C NMR data were consistent with the formulation of **3** as $[CpTiCl_2NP(t\text{-}Bu)_2CH_2SiMe_2OCH_2SiMe_2P(t\text{-}Bu)_2NSiMe_3]$ (Scheme 2).

In an analogous manner, the reaction of **2** with 2 equiv. of $CpTiCl_3$ proceeded to give a yellow crystalline solid **4** in 89% yield. The $^{31}P\{^1H\}$ NMR resonance for **4** is shifted downfield to 43.5 ppm. The simplicity of the ^1H NMR spectrum is notable; resonances at 6.45, 1.38, 1.17, and 0.49 ppm are attributable to cyclopentadienyl, methylene, *t*-Bu, and Me protons respectively. The corresponding resonances are observed in the $^{13}C\{^1H\}$ NMR spectrum. These assignments support the notion of reactions of both ends of the ligand with Ti. This results in the formulation of **4** as bimetallic

Fig. 1. ORTEP drawing of **2**; 30% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Selected distances (Å) and angles (°) are Si(1)–N(1) 1.659(3), Si(2)–N(2) 1.668(3), Si(3)–O(1) 1.640(3), Si(3)–C(12) 1.863(4), Si(4)–O(1) 1.630(3), Si(4)–C(17) 1.865(4), P(1)–N(1) 1.535(3), P(2)–N(2) 1.526(3), Si(4)–O(1)–Si(3) 144.8(2).

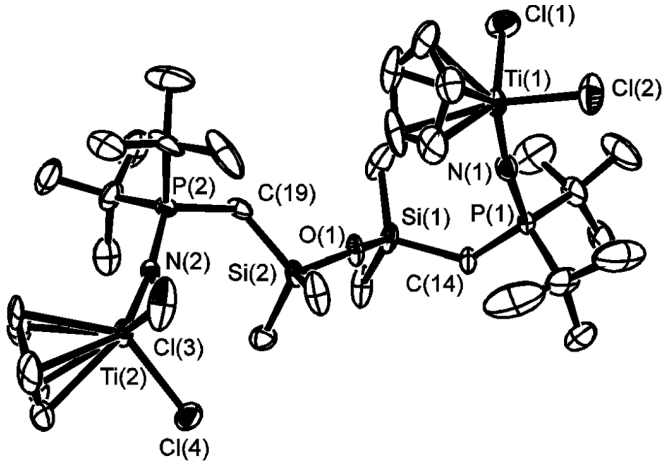
species $[CpTiCl_2NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$. Recrystallization of **4** from toluene gave well-formed crystals for X-ray diffraction studies. The crystallography confirmed the bimetallic nature of **4** (Fig. 2). The Ti–Cl distances averaged 2.315(4) Å with Cl–Ti–Cl averaging 100.9(1)°. The *Ti*-phosphinimide linkages are typical, with average Ti–N and N–P bond lengths of 1.767(6) Å and 1.620(6) Å, respectively. The corresponding Ti–N–P angles were found to be 171.2(4)° and 167.7(3)°. The central Si–O linkage gave rise to an average Si–O distance of 1.649(4) Å and an Si–O–Si angle of 149.3(3)°.

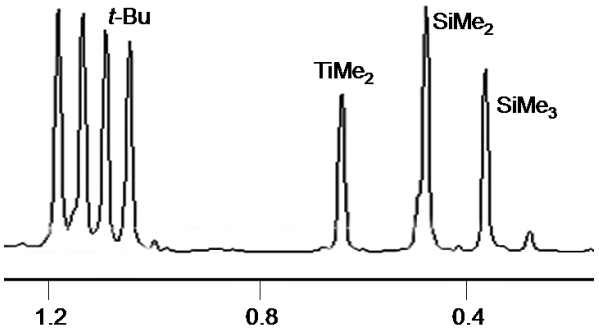
In an analogous synthetic method, the ligand **2** was reacted with 2 equiv. of $CpNbCl_4$ at 25 °C to give a yellow solid **5** in 82% yield. The resulting $^{31}P\{^1H\}$ NMR resonance for **5** was observed at 65.5 ppm while the ^1H resonance at 6.59 ppm was attributed to the cyclopentadienyl ligands. These data were consistent with the formulation of **5** as diniobium complex$[CpNbCl_3NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (Scheme 2).

In a similar fashion, the species **3** reacts with $CpNbCl_4$ to give a yellow solid **6** in 85% yield formulated as the heterobimetallic complex $[CpTiCl_2NP(t\text{-}Bu)_2\{\mu\text{-}O\text{-}(CH_2SiMe_2)_2\}P(t\text{-}Bu)_2NCpNbCl_3]$. The $^{31}P\{^1H\}$ NMR of **6** showed two resonances at 41.2 and 66.3 ppm while the ^1H NMR spectrum showed resonances attributable to cyclopentadienyl ligands at 115.5 and 117.6 ppm (Scheme 2). It is also noteworthy that attempts to react **4**–**6** with an additional equivalent of the siloxyl-bis(phosphinimine) ligand **2** failed to give either isolable macrocyclic or oligomeric products.

Subsequent alkylations of these metal halide derivatives **3**–**5** were probed. In the case of **3**, alkylation was effected by reaction with MeMgCl in THF to give an 82% yield of a yellow microcrystalline solid **7**. The $^{31}P\{^1H\}$ NMR spectrum of **7** gave rise to two resonances at 25.9 and 27.3 ppm. The ^1H NMR of **7** shows the ligand resonances as well as signals at 0.71 and 6.30 ppm, attributable to Ti-bound methyl and cyclopentadienyl groups. The presence of two sets of resonances at 0.44 and 0.57 ppm, attributable to $SiMe_2$ fragments, and at 1.17 and 1.27 ppm, arising from the $P(t\text{-}Bu)_2$ groups, were consistent with the monosubstitution of the ligand (Fig. 3). These data confirm the formulation of **7** as $[CpTiMe_2NP(t\text{-}Bu)_2CH_2SiMe_2OSiMe_2CH_2\ P(t\text{-}Bu)_2NSiMe_3]$.

Fig. 2. ORTEP drawing of **4**; 30% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Selected distances (Å) and angles (°) are Ti(1)–N(1) 1.767(6), Ti(1)–Cl(2) 2.315(2), Ti(1)–Cl(1) 2.323(2), Ti(2)–N(2) 1.767(5), Ti(2)–Cl(3) 2.306(2), Ti(2)–Cl(4) 2.316(2), P(1)–N(1) 1.611(6), P(2)–N(2) 1.628(5), Si(2)–O(1) 1.649(4), Si(2)–O(1) 1.649(4), N(1)–Ti(1)–Cl(2) 103.86(19), N(1)–Ti(1)–Cl(1) 102.82(19), Cl(2)–Ti(1)–Cl(1) 101.18(10), N(2)–Ti(2)–Cl(3) 102.15(18), N(2)–Ti(2)–Cl(4) 105.21(17), Cl(3)–Ti(2)–Cl(4) 100.78(9), P(1)–N(1)–Ti(1) 171.2(4), P(2) N(2)–Ti(2) 167.7(3), Si(1)–O(1)–Si2 149.3(3).





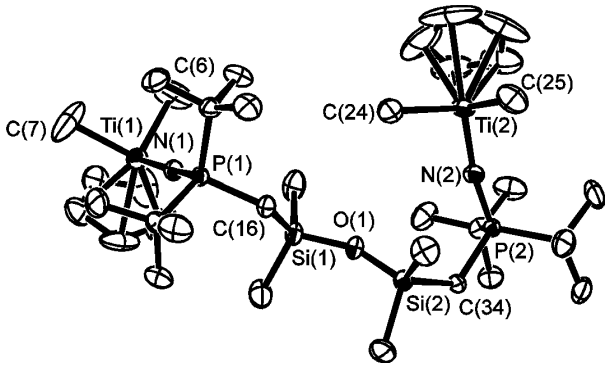


Fig. 3. Methyl region of the ^1H NMR spectrum of **7**.

In a similar fashion, akylation of **4** afforded the new species **8** in 73% yield. The compound **8** is soluble in aromatic and hydrocarbon solvents and gives rise to a $^{31}P\{^1H\}$ NMR resonance at 36.3 ppm as well as a ^1H NMR signal at 0.65 ppm, attributable to the Ti-bound methyl groups. The resulting formulation of **8** as $[CpTiMe_2NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ was subsequently confirmed by X-ray crystallography (Fig. 4). The metric parameters for **8** showed Ti–N distances of 1.802(3) and 1.805(3) Å, slightly longer than that seen in **4**. The corresponding P–N distances were shorter in **8** than those in **4**, averaging 1.585(3) Å, while the Ti–N–P angles in **8** were in a similar range to those in **4** being 170.98(19)° and 169.93(19)°. These metric differences were consistent with the replacement of the chlorine atoms by the electron-donating methyl groups. The Ti–C distances in **8** range from 2.114(5) to 2.136(5) Å, while the C–Ti–C angles were found to be 97.8(3)° and 95.3(2)°. The Si–O bonds in **7** were found to be only slightly shorter than those

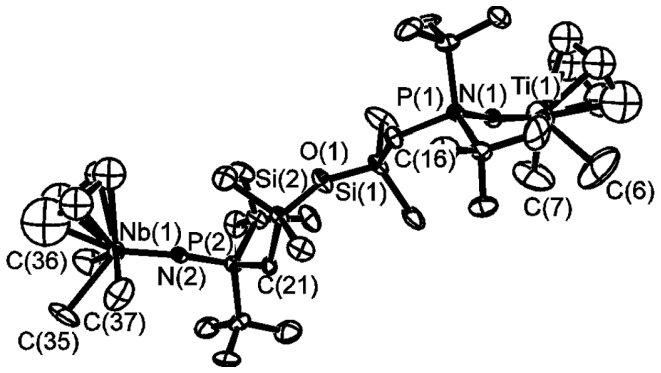
Fig. 4. ORTEP drawing of **8**; 30% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Selected distances (Å) and angles (°) are Ti(1)–N(1) 1.802(3), Ti(1)–C(6) 2.126(6), Ti(1)–C(7) 2.128(6), Ti(2)–N(2) 1.805(3), Ti(2)–C(24) 2.114(5), Ti(2)–C(25) 2.136(5), Si(1)–O(1) 1.628(2), Si(2)–O(1) 1.625(3), P(1)–N(1) 1.586(3), P(2)–N(2) 1.583(3), N(1)–Ti(1)–C(6) 103.29(17), N(1)–Ti(1)–C(7) 103.2(2), C(6)–Ti(1)–C(7) 97.8(3), N(2)–Ti(2)–C(25) 103.51(18), C(24)–Ti(2)–C(25) 95.3(2), P(1)–N(1)–Ti(1) 170.98(19), P(2)–N(2)–Ti(2) 169.93(19), Si(2)–O(1)–Si(1) 155.10(18).



in **4**, being 1.628(2) and 1.625(3) Å, while the Si–O–Si angle is slightly larger at 155.10(18)°.

Alkylation of **5** with excess MeMgCl was also readily accomplished in a hexane suspension. The yellow product **9** was obtained in 81% yield and gave rise to a new $^{31}P\{^{1}H\}$ NMR signal at 39.6 ppm. The ^{1}H NMR spectrum revealed resonances at 1.01 and 5.62 ppm, attributable to Nb-bound methyl and cyclopentadienyl ligands, respectively. These data affirmed the formulation of **9** as $[CpNbMe_3NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ (Scheme 2). In a similar fashion, the full methylation of **6** resulted in the formation of a yellow crystalline solid **10**. Isolation afforded an overall yield of 68%. Two resonances were observed in the $^{31}P\{^{1}H\}$ NMR spectrum at 39.4 and 25.7ppm. Similarly, the ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra reflected the dissymmetry of the molecule and confirmed the formulation of **10** as $[CpTiMe_2NP(t\text{-}Bu)_2CH_2SiMe_2OSiMe_2CH_2P(t\text{-}Bu)_2NCpNbMe_3]$. X-ray quality crystals were obtained by slow evaporation of a pentane solution. The dissymmetry of the molecule is reflected in the crystallographic data (Fig. 5). The Nb–N distance was found to be 1.850(8) Å, slightly longer than the corresponding Ti–N distance of 1.804(9) Å. Interestingly, the corresponding P–N distances are not distinct, both being 1.58(1) Å. This Nb–N is similar to that found in $NbCl_3(NPR_3)_2$ (R = Ph 1.827(4) (17), i-Pr 1.835(7) (18)). The corresponding metal–C distances were found to be 2.192(12), 2.236(14), and 2.249(14) Å for Nb and 2.097(17) and 2.25(2) Å for Ti. The remaining metric parameters of the ligand are similar to those seen above with a Si–O–Si angle of 150.7(5)°.

Reactivity of the bimetallic species was briefly probed. The complex **8** was shown to react with 1 equiv. of $B(C_6F_5)_3$ in BrC_6D_5. The resulting product **11** exhibits two $^{31}P\{^{1}H\}$ NMR signals at 39.5 and 39.6 ppm. ^{1}H NMR data for **11** shows signals at –0.04 and 0.55 ppm in a 1:2 ratio, which were attributed to Ti-bound methyl groups. These data support the formation of inequivalent Ti centers, although only one resonance at 5.99 ppm was attributable to the cyclopentadienyl ligands. ^{19}F resonances at –132.1, –164.4, and –166.8 ppm, together with the $^{11}B\{^{1}H\}$ resonance at –14.9 ppm, were consistent with the formation of the free anion $[MeB(C_6F_5)]$ and the formulation of **11** as $[(CpTiMe_2NP(t\text{-}Bu)_2CH_2SiMe_2)(CpTiMeNP(t\text{-}Bu)_2CH_2SiMe_2)O][MeB(C_6F_5)]$. It is noteworthy that monometallic cations exhibit a downfield shift of the $^{31}P\{^{1}H\}$ resonance relative to that of monometallic precursors $CpTi(NPR_3)Me_2$ (19). In the case of **11**, the similarity of the two $^{31}P\{^{1}H\}$ NMR signals and the symmetry of the ^{1}H NMR spectrum suggests the possibility of cyclic structure (Scheme 3 (a)) where the ^{1}H NMR resonance at –0.04 ppm is attributable to the bridging methyl group. Further spectral data collected at –30 °C yielded no further structural information for this very sensitive product. Repeated attempts to isolate X-ray quality crystals of this product were unsuccessful and thus precluded the unambiguous confirmation of this structural proposition. Attempts to probe the related chemistry of **10** afforded complex mixtures of products, suggesting that methyl abstraction from either Ti or Nb results in the formation of mixture of methyl-bridged oligomers. However, this proposition could not be confirmed.

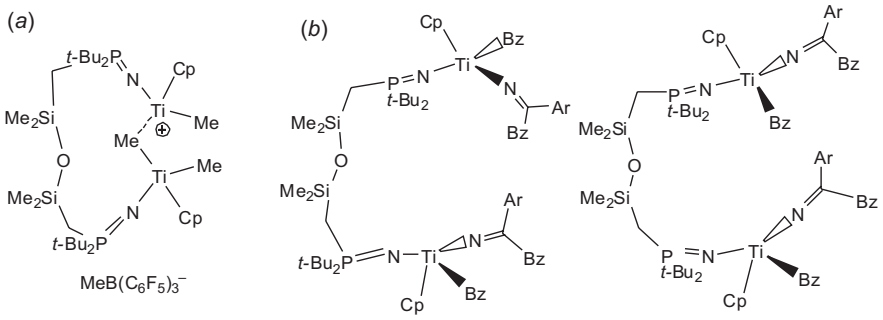


Fig. 5. ORTEP drawing one of the two molecules in the asymmetric unit of **10**; 30% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Selected distances (Å) and angles (°) are Nb(1)–N(2) 1.850(8), Nb(1)–C(37) 2.192(12), Nb(1)–C(36) 2.236(14), Nb(1)–C(35) 2.249(14), Ti(1)–N(1) 1.804(9), Ti(1)–C(7) 2.097(17), Ti(1)–C(6) 2.25(2), P(1)–N(1) 1.575(9), P(1)–C16 1.803(10), P(2)–N(2) 1.574(8), Si(1)–O(1) 1.616(7), Si(1)–C17 1.846(13), Si(1)–C16 1.863(11), Si(1)–C18 1.876(14), Si(2)–O(1) 1.624(7), N(2)–Nb(1)–C(37) 92.6(5), N(2)–Nb(1)–C(36) 95.8(5), C(37)–Nb(1)–C(36) 135.5(8), N(2)–Nb(1)–C(35) 122.9(7), C(37)–Nb(1)–C(35) 70.0(8), C(36)–Nb(1)–C(35) 68.8(8), N(1)–Ti(1)–C(7) 107.0(7), N(1)–Ti(1)–C(6) 102.2(9), C(7)–Ti(1)–C(6) 77.9(12), P(1)–N(1)–Ti(1) 169.0(6), P(2)–N(2)–Nb(1) 173.5(5), Si(1)–O(1) Si(2) 150.7(5).

Compound **4** was also alkylated with BzMgCl to give the species $[CpTiBz_2NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ **12** in 65% yield as an orange solid. The $^{31}P\{^{1}H\}$ NMR spectrum of **12** was observed as a singlet at 36.3 ppm. The ^{1}H NMR data showed the expected resonances including two doublets at 2.69 and 2.82 ppm attributable to the metal-bound methylene groups. The corresponding $^{13}C\{^{1}H\}$ resonance was seen at 71.7 ppm. Compound **12** was shown to react with 2 equiv. of $NC(2,6\text{-}Me_2C_6H_3)$ upon stirring for 1 h at 25 °C in toluene. Work-up afforded a new species **13** in 68% yield, which gave rise to a single new $^{31}P\{^{1}H\}$ resonance at 26.5 ppm.

© 2006 NRC Canada

Scheme 3. (*a*) Proposed structures of **11** and (*b*) diastereomers of 13.

The ^{1}H and $^{13}C\{^{1}H\}$ NMR data are consistent with the formation of a 1:1 mixture of diastereoisomers formulated as $[CpTiBz(N{=}C(CH_2Ph)(2,6\text{-}Me_2C_6H_3))NP(t\text{-}Bu)_2CH_2SiMe_2]_2O$ **13a** and **13b** (Scheme 3(b)). The chirality results from the insertion of the nitrile into one of the Ti-Bz groups on each of the Ti centers of **13**. As an example, this is evidenced by the observation of benzylic ^{1}H resonances observed at 3.04, 3.13, 3.72, and 3.79 ppm as well as peaks at 5.82 and 5.83 attributable to the cyclopentadienyl rings.

In summary, the new bis(phosphinimide) siloxy-based ligand described herein affords synthetic pathways to linked phosphinimide mono- and bi-metallic complexes as well as heterobimetallic species. The chemistry of related phosphinimide compounds continues to be the subject of study in our laboratories.

Regioselectivity of glycoluril-directed Claisen condensations — A kinetic and mechanistic study of substituent effects in the nucleophilic acyl group

Mei Chen, Katie Won, Robert S. McDonald, and Paul H.M. Harrison

Abstract: The Claisen-like condensation of a series of 1-arylacetyl-6-acetyl-3,4,7,8-tetramethylglycolurils (Ar = Ph, *p*-$OMeC_6H_4$, and *p*-ClC_6H_4) was studied in preparative experiments and by analysis of kinetic data. The reactions proceeded in virtually quantitative yield and were highly regioselective: the corresponding *N*-(2′-aryl-3′-ketobutanoyl)-3,4,7,8-tetramethylglycolurils were obtained in all cases, with none of the 4′-aryl regioisomers being detected. Clean bimolecular kinetics were observed for each conversion using UV spectroscopy. Reaction rates followed the order Ar = *p*-$OMeC_6H_4$ < Ph < *p*-ClC_6H_4. The results are explained by a mechanism in which the deprotonation of the substrates is rate-limiting; thus, deprotonation of the arylacetyl groups is favoured. The ensuing enolate reacts rapidly in the C–C bond-forming step.

Key words: glycoluril, biomimetic, Claisen condensation, regioselectivity, kinetics, mechanism, substituent effects.

Résumé : On a étudié la condensation de type Claisen d'une série de 1-arylacétyl-6-acétyl-3,4,7,8-tétraméthylglycoluriles (Ar = Ph, *p*-$MeOC_6H_4$ et *p*-ClC_6H_4) dans des expériences préparatives ainsi que par l'analyse de données cinétiques. Les réactions se produisent avec des rendements pratiquement quantitatifs et un grande régiosélectivité; dans tous les cas, on a obtenu les *N*-(2′-aryl-3′-cétobutanoyl)-3,4,7,8-tétraméthylglycoluriles et on n'a pas pu détecter la présence du régioisomère 4′-aryle. Pour chacune des conversions, en faisant appel à la spectroscopie UV, on a observé une cinétique bimoléculaire propre. Les vitesses des réactions sont dans l'ordre Ar = *p*-$MeOC_6H_4$ < Ph < *p*-ClC_6H_4. Les résultats sont expliqués par un mécanisme dans lequel la déprotonation des substrats correspond à l'état cinétiquement limitante; la déprotonation des groupes arylacétyles est donc favorisée. L'énolate qui en résulte réagit rapidement dans l'étape de formation de la liaison C–C.

Mots clés : glycourile, biomimétique, condensation de Claisen, régiosélectivité, cinétique, mécanisme, effets de substituants.

Introduction

The Claisen condensation is one of the fundamental C–C bond forming reactions in organic chemistry (1). However, remarkably, the mechanism of this process has not been extensively explored by kinetics experiments despite a number of studies of the related aldol and Claisen–Schmidt reactions (2). This may be in part a result of problems associated with the characteristics of enolates, such as self association and variation of metal coordination, which can give rise to complex kinetic schemes (3).

Although there are reports of catalysts that circumvent the problem of regioselectivity, the modest yields and mixtures of the products obtained in many crossed-Claisen condensations have discouraged the use of this method in synthesis (4). Nonetheless, many natural processes, e.g., the formation of acetoacetyl-coenzyme A from two moles of acetyl-CoA by acetoacetyl-CoA thiolase, proceed through highly efficient Claisen-like mechanisms (5). A related reaction in vivo, which occurs during the biosynthesis of polyketides and fatty acids, is the Claisen-like decarboxylative condensation of malonate and acyl units attached to the fatty acid synthase (FAS) or polyketide synthase (PKS) (6).

Some time ago, we developed an efficient intramolecular Claisen-like condensation between two acyl groups, that were pre-assembled onto 3,4,7,8-tetramethylglycoluril (**1a**) (7) or its dithio congener (**1b**) (8) (Scheme 1); this process allows efficient and selective monoacylation to afford, e.g., **2a**, then a second acylation to give, e.g., **3a** ensues under

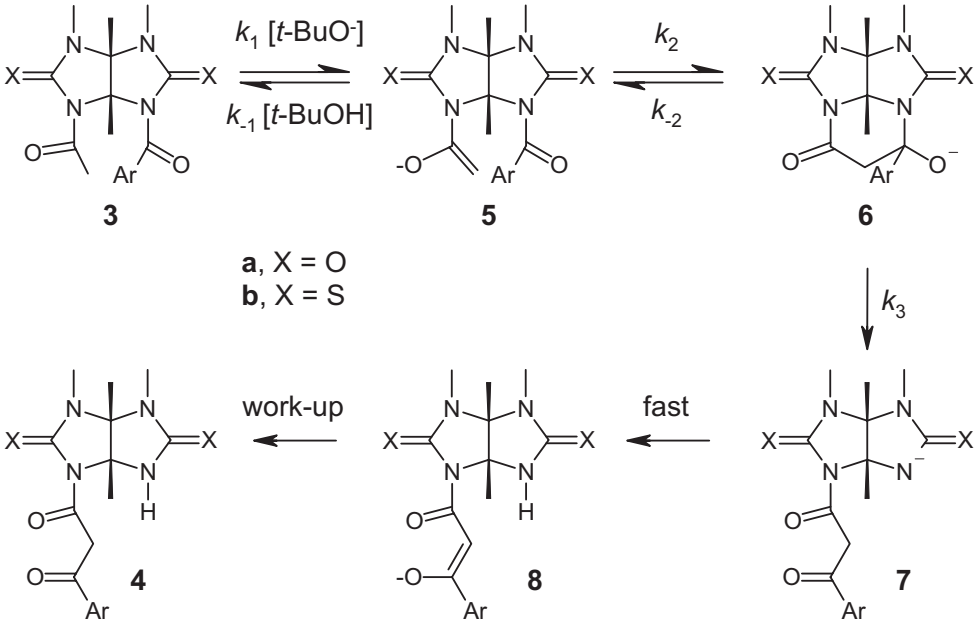
more forcing conditions. The condensation between the acetyl and aroyl moieties to give the β-ketoacyl derivatives, which mimics some features of FAS and PKS, was shown to proceed efficiently in >95% yield; thus, **3a** gives, e.g., **4a** (9). The methodology is amenable to an iterative approach to the chemical synthesis of fatty acids and polyketides in a sequence of reactions that mimics several features of the biosynthesis of this important class of natural products. The regioselectivity of the condensation reaction was examined in preparative experiments (7, 8); although the regioselectivity could be altered and even reversed by altering the glycoluril, the results generally showed a preference for deprotonation at the smaller of two acyl groups. However, the mechanistic origin of the observed regioselectivity was unclear. Because an understanding of regiocontrol is important in designing improved methodology based on the glycoluril, we initiated a program to explore the mechanism of the reaction.

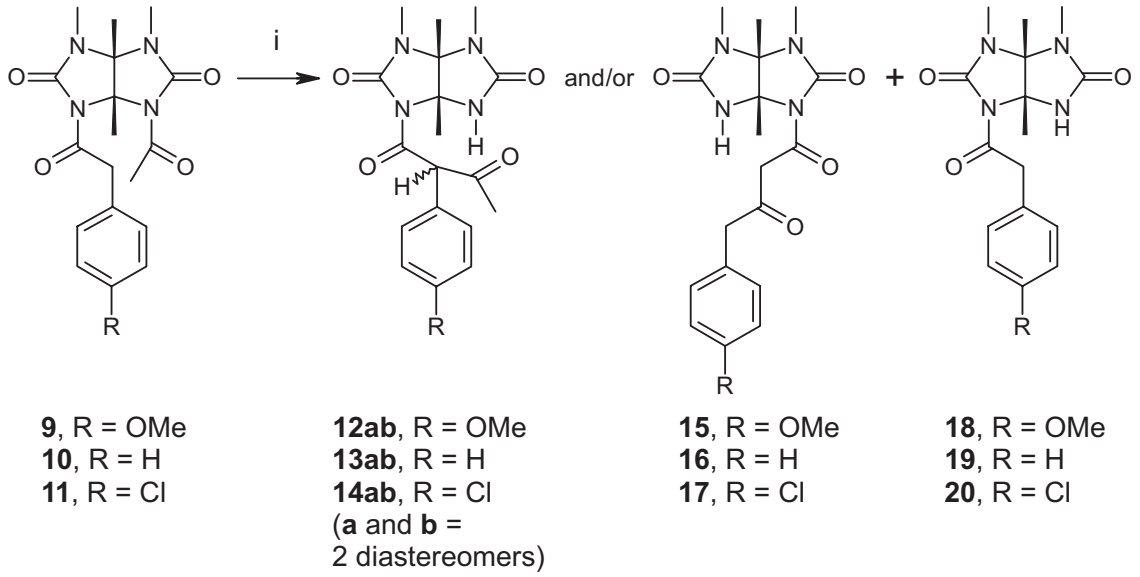
In previous work, we demonstrated that the progress of this Claisen-like condensation could be monitored readily by UV spectroscopy. The kinetics of this reaction were explored for acetyl aroyl glycolurils (e.g., **3a**) (10) and their dithio congeners (e.g., **3b**) (11); the results showed that substituents on the aroyl moiety influenced the overall rate of condensation, with electron-withdrawing groups accelerating the process. These and other results, from deuterium isotope effects in the acetyl methyl group, support a mechanism in which initial deprotonation of substrate (step 1, k_1) is partially reversible, and is followed by nucleophilic attack of the ensuing enolate (**5**) onto the acceptor aroyl moiety, which behaves as the electrophile in this case (step 2, k_2) (Scheme 2). Depending on the aroyl substituent and the glycoluril structure, step 1 or step 2 were shown to be the rate-limiting steps. The collapse of tetrahedral intermediate **6** via **7** to **8** was assumed to be fast, based on precedents found in the literature (12). The conjugated enolate **8** is the species observed as the final product in the kinetics experiments in the UV cell; neutral products **4** are formed during acidic work-up in preparative experiments.

We were intrigued to determine whether substituents on the nucleophilic donor acyl moiety might influence the rate of condensation, as opposed to the previously studied effects on the electrophilic acyl acceptor unit. We expected that knowledge of this influence would shed mechanistic light on the origin of regioselectivity in the condensation process. Therefore, we prepared a series of acetyl arylacetyl glycoluril derivatives (**9**–**11**) for further kinetic analysis. However, prior to performing the kinetics experiments, it was unclear whether these compounds would condense with the desired regioselectivity, i.e., would these reactions proceed under thermodynamic or kinetic control, and, if the latter, would deprotonation occur at the phenylacetyl group to give **12**–**14**, or at the acetyl moiety to give **15**–**17** (Scheme 3)? Therefore, we first investigated the regiochemical outcome of these condensations in preparative experiments and then used kinetics to explain the observed regiochemistry. The results of these experiments are described herein.



Results

Compounds **9**–**11** were readily prepared by treatment of monoacetylglycoluril **2a** with the appropriate acid chloride. Each compound was then treated with potassium *tert*-butoxide in a preparative experiment. The condensation products were isolated and purified.



NMR analysis of these samples showed, in all three cases, a pair of closely related products in a ratio of approx.1:2 (**12**–**14a**, **12**–**14b**, respectively). A trace impurity was detected in all cases; however, this did not correspond to the regioisomeric condensation products **15**–**17**, which were clearly absent from the spectra, but rather to the arylacetylglycolurils (**18**–**20**) in which the acetyl group had been cleaved from the starting material, presumably by solvolysis. Notably, each proton NMR spectrum showed two singlets at about 5.8 ppm, which were tentatively assigned to H-2′ in the two diastereomeric forms of **12**–**14** (Table 1), along with a pair of singlets at 2.1 ppm, which by chemical shift comparison with previous condensation products could be assigned to methyl groups C-4′ in the two diastereomers. Further purification and NMR examination, including COSY, HSQC, and HMBC experiments, confirmed each structure unambiguously. The results of these experiments for the side-chain part-structure of **13** are shown in Fig. 1; a full spectral assignment for **13** is given in Table 1. NMR data for **12** and **14** were essentially identical to that for **13**, except in the aryl group. Mass spectral data further confirmed the structures; each sample exhibited a prominent fragment ion at *m*/*z* [M – 42] corresponding to the loss of CH_2CO, a fragmentation that is possible for **12**–**14**, but not for regioisomers **15**–**17**. Intriguingly, there was no evidence for

Scheme 3. Intramolecular Claisen-like condensations of acetyl arylacetyl glycolurils **9–11** to give the observed products **12–14** as a mixture of diastereomers **a** and **b**. Regioisomers **15–17** were not observed. Reagent: KO*t*-Bu, THF, 0 °C to RT; for kinetics experiments: 50:50 *tert*-BuOH – THF, 25 °C, then KO*t*-Bu.

enolization of any of the three condensation products, despite the observation of enol contents up to ~50% in other β-ketoacylglycolurils that we prepared in previous work (7–11).

Nonetheless, when a dilute solution of condensation products **12–14** in THF–*tert*-butanol was treated with excess potassium *tert*-butoxide in a quartz UV cell, substantial spectral changes occurred. For example, a new strong absorbance peak centred at 309 nm was observed in the base-treated solution of **13** (Fig. 2, panels B vs. D), indicating the formation of the enolate by deprotonation of the condensation product. The spectrum of the starting diacylglycoluril **10** was recorded in the same solvent (Fig. 2, panel A), and then the sample was treated with KO*t*-Bu. After completion of reaction, the spectrum in panel C was recorded. In this case, the spectrum resembles that of panel D, indicating that KO*t*-Bu induced the conversion of **10** to **13**. Similar results were obtained for conversion of **9** to **12** and **11** to **14**.

Next, the yield for the conversion in the cell was estimated. The extinction coefficient for the enolate of product **13** was calculated from the UV spectrum, assuming complete deprotonation. This coefficient was then used to determine the concentration of condensation product that had been formed by the base treatment of **10**. Comparing this concentration with the known starting concentration of **10** in the spectrometer cell gave an estimate of the yield of the conversion of **10** to **13** in the cell, namely 81%. A similar

Fig. 1. Structure of diastereomers (**13a** and **13b**) showing the numbering sequence. Critical connectivities identified within the β-ketoacyl group are shown: magenta = COSY; red = weaker, long-range correlation observed in the COSY spectrum; cyan = HMBC; green = weaker, 4-bond correlation observed by HMBC. 1-bond heteronuclear shift correlations were also observed for each protonated carbon, but are not shown for clarity. Each correlation was observed in both of the diastereomers (**a** and **b**).

calculation for the conversion of **9** to **12** gave a value of 86% (Table 2). Although the errors in these calculations are estimated to be ~10% (largely due to errors in weighing the two substrates), it is apparent that in each case the condensation reaction within the UV cell proceeds in high yield and with at least predominantly the same regioselectivity as was observed in the preparative experiments. Therefore, the dramatic change in conditions (temperature, solvent, and concentrations) between the preparative and the kinetics experiments does not alter the reaction outcome.

The kinetics of each reaction was observed through monitoring the conversion of each substrate into product, i.e., at the λ_{max} of the product enolate determined as described above. In the presence of excess base, the reaction progress curves were readily observed and could be fit to pseudo first-order kinetics, giving a pseudo first-order rate constant k_{obs}, as we described previously (7). Next followed a series of experiments using **9** and **10** as substrates in which the [KO*t*-Bu] was varied. Both plots of k_{obs} vs. base concentration were linear, indicating that the processes were first-order in base. Therefore, the apparent second-order rate constant, k_{app}, could be determined for each substrate, either from the slope of the plots, or by dividing measured k_{obs} values by base concentration. The results are summarized in Table 2, along with an estimate of error in k_{app} from three replicate experiments. Also shown is k_{rel}, the rate constant relative to that for **9**, from a separate series of experiments with each substrate in which the same stock solution of base was used. This latter treatment removes errors in the estimation of the base concentration between different base stock solutions and gives values which allow for a better comparison between the three analogues. Although the results vary

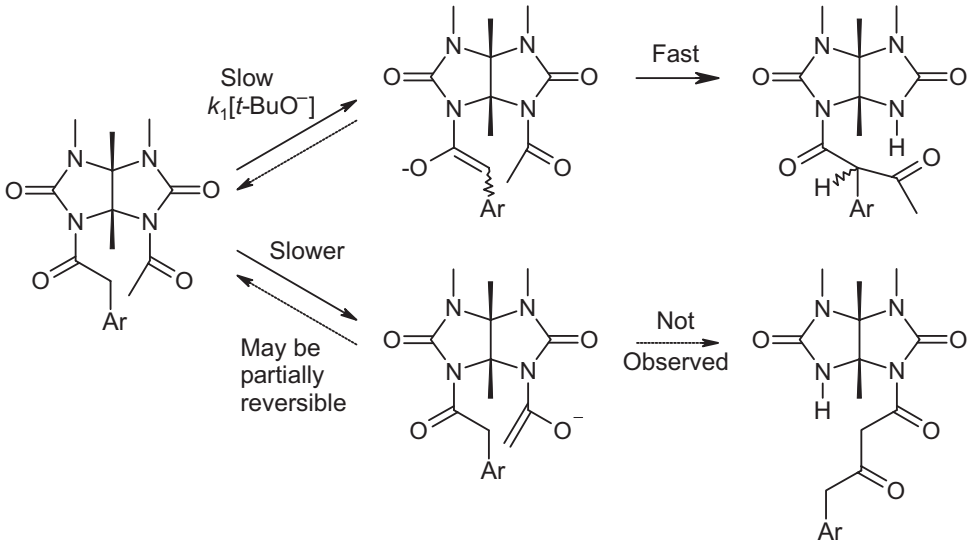
quantitatively depending on the method of determination, in all cases the qualitative order of reactivity was **9 < 10 < 11**.

Discussion

At the outset of this investigation, we had shown in preparative experiments that the glycolurils **1a** and **1b** acted as efficient auxiliaries to allow high-yield Claisen-like condensations between two acyl groups. The present results extend these observations. Although the yields for attachment of the arylacetyl moieties to the glycoluril were not optimized, the key C–C bond forming reaction, i.e., the condensation step, proceeds with the same high efficiency observed in previous cases, giving isolated yields of 80–96%. It is also noteworthy that these yields are not reduced by dilution, even under the highly diluted conditions of the kinetics experiments. The chemical yields were shown by UV spectroscopy to be in excess of 80%.



Furthermore, previous synthetic experiments in which the two acyl groups were not equivalent showed that the condensation process was moderately regioselective, e.g., in a competition between an acetyl and a butanoyl group attached to **1**, the dominant product was that in which the acetyl group was deprotonated, and the butanoyl group acted as the electrophilic partner in the condensation. Because it was unclear which of the regioisomers would predominate for **9–11**, we initially explored the condensation reaction in preparative experiments. The results illustrate an unprecedented level of regiocontrol, with clean conversion to condensation products **12–14** and no detectable amounts of regioisomers **15–17** being formed (Scheme 4). Thus, the reactions are highly selective in favour of deprotonation at the arylacetyl group, with nucleophilic attack of the ensuing enolates onto the carbonyl group of the acetyl moieties. This is clearly the case even with electron-donating groups in the aromatic ring. All three compounds studied gave products of the same regiochemical orientation. Together with the high chemical yield, these results illustrate the ruggedness of the glycoluril methodology and bode well for further applications in synthesis.

Despite the prior and current observations of regioselectivity in this system, the mechanistic origin of this effect remained speculative. We formerly discussed the possibility that the deprotonation of acetyl butanoyl glycoluril was under kinetic control, and thus the easiest formed enolate, i.e., that of the acetyl moiety, would dominate. However, we also noted that the process could be controlled by the condensation step (step 2). In this case, the deprotonation could be reversible, but the enolate that reacts fastest in step 2 (i.e., presumably also the acetyl enolate on steric grounds) would lead to the dominant product. Finally, the process could be under overall thermodynamic control, with the relative stability of the two regioisomeric enolate products determining their ratio. These possibilities could not be readily distinguished from the preparative experiments but are important to resolve to make logical predictions in applying this methodology in synthesis.

We investigated the mechanism of the condensation reaction using kinetics experiments. The glycoluril system provided clean, bimolecular kinetics, and this was also observed for each compound in the present study. Thus, there is no need to take into account the association of the enolate in the present case, allowing for simpler interpretation of the data. This lack of apparent association may be the result of the low enolate concentration in the present experiments: the

Scheme 4. Proposed kinetic scheme for the intramolecular Claisen-like condensations of **9–11** to give **12–14**.

enolate reacts as soon as it is formed. A variety of previous results indicated that either step 1, i.e., deprotonation of substrate, or step 2, i.e., the key C–C bond forming step, could control the rate of the overall reaction (Scheme 2). Notably, if step 1 is endothermic and rate-limiting, then $k_{app} = k_1$, while a pre-equilibrium with step 2 as the rate-limiting step has kinetics of the same order but a different value for k_{app}, i.e., $k_{app} = (k_1k_2 / k_{-1})/[t\text{-BuOH}]$. These different situations are reflected in different substituent effects, deuterium kinetic isotope effects, and deuterium exchange.

However, all substrates reported in kinetics experiments to date were either symmetric (two acetyl groups) or had an acetyl and an aroyl group. In these cases, there is only one possible product, and so the issue of regioselectivity and its control had not been explored. Therefore, we wished to extend the kinetics approach to explore a system that could potentially lead to two regioisomeric condensation products; to measure the rates of reaction for quantitative comparison with the known systems; to determine what step(s) control(s) the rate and, therefore, the regiochemical outcome; and to provide a facile method to explore whether reaction conditions can be varied to control the regiochemical outcome.

We selected the acetyl arylacetyl glycolurils **9–11** for kinetic exploration, reasoning that the anticipated conjugation of the aryl moieties with the enolates of one regioisomeric condensation product (**12–14**) would give rise to UV absorption at a substantially different wavelength than that for the enolates of regioisomers **15–17**, where the aryl unit is isolated from the enolate component. Furthermore, the aryl moiety allows the introduction of substituents at the remote *p*-position to explore electronic effects on the reaction rate.

While deprotonation at the arylacetyl moiety should be favoured because of the greater thermodynamic stability of the resonance-stabilized enolate over the unstabilized enolate formed by deprotonation of the acetyl moiety (Scheme 4, step 1), this stabilized enolate might also be expected to react more slowly in the condensation step (Scheme 4, step 2). Furthermore, if the deprotonation were to occur under kinetic control, it is less obvious which enolate would be favoured. Sterically, the acetyl moiety is more accessible, but the aryl group might also stabilize the transition state leading to deprotonation at the phenylacetyl group.

In the control experiments, we compared the UV spectra of the observed enolates produced from the kinetics experiments with those obtained from deprotonation of the authentic, synthetic products. They were qualitatively identical, and a quantitative comparison of the spectra showed that the kinetics experiments were forming the same regioisomer as the synthetic work, in a yield of at least 80–90%. Therefore, the measured rate constants represent those for the dominant reaction, i.e., for the formation of **12–14**.

As seen in Table 2, all three rate constants k_{app} for the acetyl arylacetyl glycolurils are 10-fold to 20-fold larger than that for the diacetyl analogue (8.6 L mol^{-1} s^{-1} (11)); therefore, the presence of the aryl group accelerates the overall reaction. It follows that the observed regioselectivity results from an overall rate *acceleration* relative to the diacetyl analogue because of the presence of the aryl moiety and *not* from a reduction in the rate of condensation of the acetyl enolate (i.e., it is not due to a smaller rate constant for step 2 (Scheme 2, k_2) for the acetyl enolate than for the phenylacetyl enolate, Scheme 4). The latter effect might reasonably have accounted for selectivity because the nucleophilic attack of the acetyl enolate onto the phenylacetyl group might be expected to suffer from steric effects compared with the corresponding reaction of the diacetyl compound. The observed rate acceleration also argues against the reaction proceeding through initial fast formation of **15–17**, followed by thermodynamic rearrangement to **12–14**. Because deprotonation at the acetyl group would be the obligatory first step, this process would be expected to proceed at an overall rate comparable to or slower than that for the diacetylglycoluril. Therefore, the regioselectivity is determined kinetically.

A comparison of the three rate constants for **9**, **10**, and **11** is also revealing: the values for k_{app} are larger with an electron-withdrawing group (*p*-Cl) and smaller with an electron-donating group in the aryl ring. These observations are consistent with the stabilization of the negative charge in the key rate-determining transition state, and imply that step 1,

© 2006 NRC Canada

i.e., the deprotonation of the substrate, is important in determining the overall rate of reaction (Scheme 4). The results are not consistent with a rate-determining step 2 for the reaction of the aryl enolate, where an inverse effect of substituent would be expected, but rather are best described in terms of a rate-limiting deprotonation followed by a rapid intramolecular C–C bond forming step. Assuming that the deprotonation of the acetyl group of **9**–**11** proceeds at approximately the same rate as for the diacetyl analogue, then the regioselectivity of the condensation can be estimated from the relative rates after allowing for the two acetyl groups in the diacetyl compound. This gives a predicted selectivity, ranging from 21:1 for **9** to 42:1 for **11**, consistent with the high level of selectivity observed in the preparative experiments.

We note that the reactions described herein can proceed through either an *E* or a *Z* enolate and that there is a number of diastereomeric transition states for step 2. The present results do not shed light on these issues, and it must be noted that the rate constants are overall constants for each step irrespective of whether the reaction proceeds through a single stereoisomeric path or multiple ones. We hope to investigate the cryptic stereochemistry of this process through further experiments.

In summary, the results show that the condensation reaction under the conditions used in the kinetics experiments proceeds by slow enolate formation at the phenylacetyl group to give a stabilized enolate, a process that is nonetheless fast compared with deprotonation at the acetyl moiety. The enolate is still capable of rapid intramolecular attack onto the acetyl carbonyl group in step 2. The high rate of this step, compared with the acetyl aroyl glycolurils where step 2 is at least partially rate-determining, may be due to the higher electrophilicity of the acetyl moiety compared with the aroyl carbonyl group. Thus, step 1 is the rate-determining step, but we cannot yet establish unambiguously whether this is a kinetic or an equilibrium effect, i.e., whether $k_2 > k_{-1}[t\text{-BuOH}] > k_1$ or $k_{-1}[t\text{-BuOH}] > k_2 > k_1$. Further work to explore the latter issue, as well as whether other factors can alter the rate-determining step, including a study of the temperature dependence of the reaction rates, are in progress. The results will be reported soon.

Conclusion

The crossed-Claisen-like condensation of an arylacetyl and an acetyl group is promoted by the attachment of these moieties to the N1 and N6 positions of 3,4,7,8-tetramethylglycoluril. The process proceeds rapidly under mild conditions to give exclusively the regioisomer resulting from the deprotonation at the arylacetyl group. Kinetics experiments show that the first deprotonation step is rate-determining and that the origin of the regioselectivity lies in the ease of deprotonation of the phenylacetyl versus the acetyl moiety. Because the C–C bond forming step is fast, the relative rates of this step leading to each regioisomer do not influence the overall regiochemical outcome of the reaction.

Experimental

General

General conditions for the preparation and characterization of the glycoluril derivatives were as previously described. THF was distilled from sodium–benzophenone. *tert*-Butanol was purchased from Fisher (Nepean, ON, Canada). Potassium *tert*-butoxide was obtained from Alfa Aesar (Ward Hill, MA, USA). All glassware was oven-dried prior to use for all the reactions. All air- and moisture-sensitive reagents were transferred by syringe. NMR spectra were recorded on Bruker AM-600 and Bruker AM-200 spectrometers. IR spectra were recorded on a Biorad FTS-40 spectrophotometer. Mass spectra were determined on a Finnigan 4500 mass spectrometer. UV spectroscopy was performed on a Cary 300 spectrophotometer with the temperature controlled to 25 °C. Quartz UV cells bearing a screw cap and a septum were obtained from Aldrich (Oakville, ON, Canada); they were dried by evacuation over phosphorus pentoxide in a desiccator.

General procedure for kinetic determinations

Stock solutions of each predried acetyl (substituted) phenylacetyl glycoluril and the condensation product were prepared by the dissolution of a carefully determined mass (~2.5 mg) in 1:1 *v*/*v* anhydrous THF–*tert*-butanol in a volumetric flask (5 mL). The resulting solutions (0.3 mL) were further diluted with 2.4 mL of the stock solvent in a quartz UV cell equipped with a magnetic stir bar and a septum. The reference cell contained 1:1 *v*/*v* anhydrous THF–*tert*-butanol. After equilibration of the temperature to 25 °C within the spectrophotometer, the UV spectrum was recorded in scanning mode. The resulting solutions had concentrations of 9.11×10^{-5} to 13.96×10^{-5} mol/L.

The base solution was prepared with potassium *tert*-butoxide (~25 mg) in the same stock solvent in a volumetric flask (25 mL). The kinetic measurements were recorded by monitoring the absorbance at λ_{max} at 25 °C after adding 0.3 mL of the base solution by syringe to the substrate solution in the UV cell with rapid stirring. The observed rate constant, k_{obs}, was determined for each compound by the spectrometer computer after the kinetic data were fit to a pseudo first-order kinetic plot. Then the apparent second-order rate constant, k_{app}, was obtained by dividing the corresponding value by the calculated base concentration. Values of k_{app} and k_{rel} were also determined from plots of k_{obs} vs. [Base] and from experiments using the same base solution, respectively, as described in the text.

General procedure for preparation of acetyl (substituted) phenylacetyl glycolurils 9–11

To a solution of acetyl-3,4,7,8-tetramethylglycoluril (**2a**) in anhydrous THF (8 mL per mmol **2a**), which had been cooled to 0 °C, 1.2 equiv. of lithium bis(trimethylsilyl)-amide (1.0 mol/L solution in tetrahydrofuran) was added by syringe. The mixture was stirred for 30 min. Then (substituted) phenylacetyl chloride (1.1–1.5 equiv.) was added, and stirring was continued for 1 h at 0 °C. After quenching the reaction mixture with 1 mol/L $NaHSO_4$ aqueous solution (1.5 mL per mmol **2a**), most of the THF was removed on the rotary evaporator and the aqueous residue was extracted

three times with $CHCl_3$. The combined organic layers were washed with an equal volume of sodium bicarbonate and then water and saturated sodium chloride in sequence, dried over Na_2SO_4, filtered, and concentrated. The product was purified by flash chromatography on silica gel using ethyl acetate as the eluent.

Acetyl 4-methoxyphenylacetyl glycoluril (9)

Compound **2a** (1.5 g, 6.3 mmol) and 4-methoxyphenylacetyl chloride (1.44 mL) gave 300 mg (12%) of **9**; mp 150–152 °C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε): 213, 275 (17 738, 3069); when treated with excess KO*t*-Bu: λ_{max} = 213, 310 (12 146, 6170). IR ($CHCl_3$ cast, cm^{-1}): 2938, 2839 (C–H str.), 1728 (C=O), 1613, 1514, 1406, 1368, 1247, 1115, 1093, 1033, 952, 822. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.20 (d, *J* = 7 Hz, 2H, ArH), 6.84 (d, *J* = 7 Hz, 2H, ArH), 4.33 (d, *J* = 16 Hz, 1H, $OCCH_2$), 3.81 (d, *J* = 16 Hz, 1H, $OCCH_2$), 3.77 (s, 3H, OCH_3), 2.94 (s, 6H, $2NCH_3$), 2.46 (s, 3H, $OCCH_3$), 1.91 (s, 3H, CH_3), 1.45 (s, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 172.18 (C=O), 170.46 (C=O), 158.53 (urea, C=O), 153.13 (urea, C=O), 130.90, 126.49, 113.87 (aryl, 2 signals overlapped), 80.76, 77.95 (C bridgehead), 55.31 (OCH_3), 43.19 (CH_2), 26.87 (2C), 26.17, 19.15, 14.66. EI-MS *m*/*z*: 388, 295, 282, 225, 168, 149, 148, 121, 120, 78, 43. HR-MS calcd. for $C_{19}H_{24}N_4O_5$: 388.1747; found: 388.1736.

Acetyl phenylacetyl glycoluril (10)

Compound **2a** (2.8 g, 11.7 mmol) and phenylacetyl chloride (2.1 mL) gave 340 mg (8%) of **10**; a yield of 38% was obtained using *n*-BuLi as the base; mp 51–54 °C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε): 212, 259 (13 446, 1807); when treated with excess KO*t*-Bu: λ_{max} = 212, 309 (12 328, 6888). IR ($CHCl_3$ cast, cm^{-1}): 3031 (Ar–H str.), 2932 (C–H str.), 1732 (C=O), 1406, 1373, 1254, 1116, 1094. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.26 (m, 5H, C_6H_5), 4.38 (d, *J* = 16 Hz, 1H, $OCCH_2$), 4.05 (d, *J* = 16 Hz, 1H, $OCCH_2$), 2.90 (s, 6H, $2NCH_3$), 2.44 (s, 3H, $COCH_3$), 1.88 (s, 3H, CH_3), 1.41 (s, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 171.61 (C=O), 170.30 (C=O), 152.94 (2 urea C=O), 134.37, 129.75, 128.28, 126.71 (aryl), 80.60, 77.81 (C bridgehead), 43.90 (CH_2), 26.72 (2C), 26.02, 18.98, 14.47. EI-MS *m*/*z*: 358, 323, 316, 284, 245, 244, 225, 199, 168, 140, 126, 125, 118, 91, 90, 56. HR-MS calcd. for $C_{18}H_{22}N_4O_4$: 358.1641; found: 358.1638.

Acetyl 4-chlorophenylacetyl glycoluril (11)

Compound **2a** (3 g, 12.5 mmol) and 4-chlorophenylacetyl chloride (2 mL) gave 300 mg (6%) of **11**; mp 126–128 °C. UV (50:50 THF – *t*-BuOH) λ_{max} (nm) (ε): 215 (22 757); when treated with excess KO*t*-Bu: λ_{max} = 212, 311 (15 614, 7918). IR ($CHCl_3$ cast, cm^{-1}): 2920, 2851 (C–H str.), 1729 (C=O), 1653, 1559, 1492, 1406, 1345, 1116, 1093, 1017, 809. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.26–7.14 (m, 4H, ArH), 4.35 (d, *J* = 17 Hz, 1H, $OCCH_2$), 3.99 (d, *J* = 16 Hz, 1H, $OCCH_2$), 2.92 (s, 6H, $2NCH_3$), 2.44 (s, 3H, $OCCH_3$), 1.88 (s, 3H, CH_3), 1.45 (s, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 171.47 (C=O), 170.40 (C=O), 153.00 (urea, 2C=O), 132.96, 132.70, 131.36, 128.48 (aryl), 80.68 (2C, C bridgehead), 43.46 (CH_2), 26.86 (2C), 26.06, 19.11, 14.63. EI-MS *m*/*z*: 392, 350, 307, 279, 240, 199, 163, 154, 152, 118, 86, 84. HR-MS calcd. for $C_{18}H_{21}N_4O_4Cl$: 392.1251; found: 392.1247.

General procedure for preparative condensations of acetyl (substituted) phenylacetyl glycolurils 9–11 giving 12a–12b, 13a–13b, 14a–14b

The acetyl (substituted) phenylacetyl glycoluril was dissolved in anhydrous THF and the mixture was cooled to 0 °C. Then, potassium *tert*-butoxide (2 equiv.) in THF was added to the solution by syringe, and the mixture was stirred for 20 min at 0 °C. The reaction mixture was quenched with 1 mol/L $NaHSO_4$, then the organic solvents were removed using a rotary evaporator, and the residue was extracted with $CHCl_3$. The extracts were dried over Na_2SO_4, filtered, and concentrated. The product was purified by flash chromatography on silica gel using ethyl acetate as the eluent.

N^1-[2′-(4″-Methoxy)-phenyl-3′-oxo-butanoyl]-3,4,7,8-tetramethylglycoluril (diastereomers 12a, 12b)

Compound **9** (100 mg, 0.26 mmol) in THF (20 mL) with potassium *tert*-butoxide (58 mg) gave 80 mg (80%) of a mixture of **12a** and **12b**. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε): 214, 275 (10 515, 1957); when treated with excess KO*t*-Bu: λ_{max} = 213, 310 (11 233, 7198). IR ($CHCl_3$ cast, cm^{-1}): 3337 (N–H), 2922 (C–H str.), 1718 (C=O), 1512, 1458, 1413, 1387, 1251, 1111, 1035, 929. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 7.19 (d, *J* = 9 Hz, 0.67H, ArH of **12a**), 7.16 (d, *J* = 9 Hz, 1.33H, ArH of **12b**), 6.92 (d, *J* = 8.4 Hz, 1.33H, ArH of **12b**), 6.91 (d, *J* = 9 Hz, 0.67H, ArH of **12a**), 6.02 (s, 0.33H, NH of **12a**), 5.84 (s, 0.33H, COCHCO of **12a**), 5.83 (s, 0.67H, NH of **12b**), 5.67 (s, 0.67H, COCHCO of **12b**), 3.81 (s, 3H, OCH_3), 3.00 (s, 3H, NCH_3), 2.91 (s, 1H, NCH_3 of **12a**), 2.86 (s, 2H, NCH_3 of **12b**), 2.17 (s, 2H, CH_3CO of **12b**), 2.14 (s, 1H, CH_3CO of **12a**), 1.78 (s, 2H, CH_3 of **12b**), 1.63 (s, 1H, CH_3 of **12a**), 1.56 (s, 3H, CH_3 of **12b**), 1.55 (s, sh, CH_3 of **12a**). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 202.96 (C=O of **12b**), 201.81 (C=O of **12a**), 168.95 (C=O), 159.68 (urea, C=O of **12a**), 159.62 (urea, C=O of **12b**), 157.10 (urea, C=O of **12a**), 156.94 (urea, C=O of **12b**), 153.13 ($COCH_3$), 131.44, 131.40 (Ar), 123.35 (Ar of **12a**, CCHCO), 123.33 (Ar of **12b**, CCHCO), 114.28 (Ar), 78.80, 78.67 (C bridgehead), 65.11 (COCH of **12b**), 64.81 (COCH of **12a**), 55.27 (OCH_3), 28.78 ($COCH_3$), 27.10 (NCH_3), 26.62 (NCH_3 of **12a**), 26.42 (NCH_3 of **12b**), 19.92 (CH_3 of **12a**), 19.03 (CH_3 of **12b**), 15.92 (CH_3 of **12a**), 15.73 (CH_3 of **12b**). EI-MS *m*/*z*: 388, 347, 346, 326, 279, 214, 213, 202, 190, 155, 148, 128, 85, 69, 57, 43. HR-MS calcd. for $C_{19}H_{24}N_4O_5$: 388.1747; found: 388.1710.

N^1-(2′-Phenyl-3′-oxo-butanoyl)-3,4,7,8-tetramethylglycoluril (diastereomers 13a, 13b)

Compound **10** (130 mg, 0.36 mmol) in THF (20 mL) with potassium *tert*-butoxide (81 mg) gave 120 mg (92%) of a mixture of **13a** and **13b**. UV (50:50 THF – *t*-BuOH) λ_{max} (nm) (ε): 214, 259 (14 167, 925); when treated with excess KO*t*-Bu: λ_{max} = 213, 309 (10913, 8554). IR ($CHCl_3$ cast, cm^{-1}): 3431, 3354 (N–H), 3007 (Ar–H str.), 2924, 2852 (C–H str.), 1734 (C=O), 1599, 1455, 1353, 1263, 1112, 1035, 991, 962, 867. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 7.30–7.40 (m, 3H, ArH), 7.20–7.29 (m, 2H, ArH), 6.07 (s, 0.33H, NH of **13a**), 5.89 (s, 0.33H, COCHCO of **13a**), 5.88 (s,

IN MEMORIAM \ NÈCROLOGIE

Professor David A. Armstrong

David Anthony Armstrong, FCIC, passed away suddenly at his home in Calgary on July 24, 2006 in his 76th year. He is survived by his wife, Ruth, three children, and one grandchild. With his passing, the University of Calgary and the scientific community have lost a highly respected member, a kind mentor, a true gentleman, and a good friend.

He was born in Barbados on August 27, 1930 and studied at McGill University, completing a B.Sc. (Honours Chemistry) degree in 1952. He completed his Ph.D. degree in physical chemistry at McGill in 1955 with research on the kinetics of active nitrogen reactions, under the supervision of Professor C. A. Winkler. During his undergraduate years he was introduced to western Canada through a student exchange program, spending the year 1950-51 at the University of Alberta. From 1955 to 1957 he was Brotherton Research Lecturer at the University of Leeds in England and did research on the radiation chemistry of water with Professor F. S. Dainton. Following a two-year NRC postdoctoral fellowship with Professor J. W. T. Spinks at the University of Saskatchewan, he joined the staff of the University of Alberta, Calgary as an Assistant Professor in 1958. He was promoted to Associate Professor in 1963 and to Professor in 1968.

He was a key figure in the small group of academics who developed the foundations for the Department of Chemistry

Le 24 juillet 2006, **David Anthony Armstrong**, MICC, est décédé soudainement chez lui, à Calgary, un mois avant son 76e anniversaire. Il laisse dans le deuil sa conjointe Ruth, ses trois enfants et un petit enfant. À l'Université de Calgary et dans le milieu scientifique, son départ marque la perte d'un homme très respecté, d'un mentor apprécié, d'un vrai gentleman et d'un bon ami.

M. Armstrong est né à la Barbade le 27 août 1930. Il a étudié à l'Université McGill, où il a obtenu un baccalauréat spécialisé en chimie en 1952. Il a terminé son doctorat en chimie physique à McGill en 1955. Ses recherches, sous la supervision du professeur C. A. Winkler, portaient sur la cinétique des réactions de l'azote actif. Durant ses études de premier cycle, il a fait la découverte de l'ouest du Canada en participant à un échange d'étudiants, qui lui a permis d'étudier à l'Université de l'Alberta en 1950-1951. Bénéficiaire d'une bourse de recherche Brotherton de l'Université de Leeds, en Angleterre, de 1955 à 1957, il a étudié la radiolyse de l'eau avec le professeur F. S. Dainton. Après avoir obtenu une bourse de recherche postdoctorale du CNRC pour travailler deux ans avec le professeur J. W. T. Spinks à l'Université de la Saskatchewan, il s'est joint au personnel de l'Université de l'Alberta, à Calgary, à titre de professeur adjoint, en 1958. Il est devenu professeur agrégé en 1963, et professeur en 1968.

M. Armstrong était au cœur du petit groupe d'universitaires qui ont jeté les fondations du Département de chimie de

© 2006 NRC Canada

at the University of Calgary, which was established in 1966. He served as Head of the Department of Chemistry during its formative years and also as Dean of the Faculty of Science at the University of Calgary from 1984 to 1989. He retired in 1991 and was awarded emeritus status; he was appointed as a Faculty Professor in 1994. In 2000, he was named to the Order of the University of Calgary for his contributions to the development of the University. His continuing recent research in radiation chemistry and chemical kinetics focused on the radical reactions that occur during oxidative damage in living cells and on reactions between electrons and clusters of molecules.

The international recognition of his research led to a number of Visiting Scientist appointments at research institutions in Canada, Europe, Australia, and China. He also held a Visiting Professor appointment at the University of Notre Dame.

In 1998, the *Polish Radiation Research Society* awarded the Marie Skłodowska-Curie Medal to him for his contributions to radiation chemistry. He was appointed to the Research and Development Advisory Panel of Atomic Energy of Canada Ltd. and the IUPAC Chemistry Task Group on Radical Reduction Potentials, continuing his active participation until his death.

A total of 13 graduate theses were completed under his supervision (including the first Ph.D. thesis completed at the University of Alberta, Calgary in 1963) and 18 postdoctoral fellows and research associates worked in his laboratory over the years. His research was presented in 96 invited lectures and conference papers and in more than 160 refereed journal articles.

Peter J. Krueger, FCIC

l'Université de Calgary, établi en 1966. D'ailleurs, il a été directeur de ce département durant les premières années de sa mise sur pied, puis doyen de la Faculté des sciences de l'Université de Calgary, de 1984 à 1989. En 1991, il a pris sa retraite et a reçu le titre de professeur émérite. Par la suite, il a été nommé professeur à la Faculté (titre honorifique) en 1994. En 2000, il a été nommé à l'ordre de l'Université de Calgary pour sa contribution au développement de l'Université. Ses recherches récentes en chimie sous rayonnement et en cinétique chimique portaient principalement sur les réactions des radicaux dans les cellules vivantes soumises à un stress oxydatif et sur les réactions entre des électrons et des agrégats de molécules.

La reconnaissance internationale de ses recherches lui a valu plusieurs nominations à titre de chercheur invité dans des établissements de recherche du Canada, d'Europe, d'Australie et de Chine. Il était aussi professeur invité à l'Université de Notre Dame.

En 1998, la *Polish Radiation Research Society* lui a remis la médaille Marie Skłodowska-Curie pour sa contribution à la chimie sous rayonnement. Il a été nommé au Comité consultatif de recherche et développement d'Énergie atomique du Canada limitée et au groupe de travail sur les potentiels de réduction des radicaux de l'Union internationale de chimie pure et appliquée, et y est demeuré actif jusqu'à son décès.

Treize étudiants des cycles supérieurs ont rédigé leur mémoire ou leur thèse sous sa supervision. De ce nombre, on trouve le premier titulaire d'un doctorat décerné par l'Université de l'Alberta, à Calgary, en 1963. En outre, 18 boursiers de recherche postdoctorale et associés de recherche ont travaillé dans son laboratoire au fil des ans. Par ailleurs, M. Armstrong a présenté ses recherches dans le cadre de 96 conférences et communications sur invitation, et plus de 160 articles de revue à comité de lecture.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2005 Alfred Bader Award Lecture Diaminopimelate and lysine biosynthesis — An antimicrobial target in bacteria[1,2]

John C. Vederas

Abstract: The development of bacterial resistance to current antibiotic therapy has stimulated the search for novel antimicrobial agents. The essential peptidoglycan cell wall layer in bacteria is the site of action of many current drugs, such as β-lactams and vancomycin. It is also a target for a number of very potent bacterially produced antibiotic peptides, such as nisin A and lacticin 3147, both of which are highly posttranslationally modified lantibiotics that act by binding to lipid II, the peptidoglycan precursor. Another set of potential targets for antibiotic development are the bacterial enzymes that make precursors for lipid II and peptidoglycan, for example, those in the pathway to diaminopimelic acid (DAP) and its metabolic product, L-lysine. Among these, DAP epimerase is a unique nonpyridoxal phosphate (PLP) dependent enzyme that appears to use two active site thiols (Cys73 and Cys217) as a base and an acid to deprotonate the α-hydrogen of LL-DAP or meso-DAP from one side and reprotonate from the other. This process cannot be easily duplicated in the absence of the enzyme. A primary goal of our work was to generate inhibitors of DAP epimerase that would accurately mimic the natural substrates (meso-DAP and LL-DAP) in the enzyme active site and, through crystallographic analysis, provide insight into mechanism and substrate specificity. A series of aziridine-containing DAP analogs were chemically synthesized and tested as inhibitors of DAP epimerase from *Haemophilus influenzae*. Two diastereomers of 2-(4-amino-4-carboxybutyl)aziridine-2-carboxylic acid (AziDAP) act as rapid irreversible inactivators of DAP epimerase; the AziDAP analog of LL-DAP reacts selectively with the sulfhydryl of Cys73, whereas the corresponding analog of meso-DAP reacts with Cys217. AziDAP isomers are too unstable to be useful antibiotics. However, mass spectral and X-ray crystallographic analyses of the inactivated enzymes confirm that the thiol attacks the methylene group of the aziridine with concomitant ring opening to give a DAP analog bound in the active site. Further crystallographic analyses should yield useful mechanistic insights.

Key words: enzyme mechanism, enzyme inhibition, antibiotics, aziridines, amino acids.

Résumé : Le fait que les bactéries aient développé de la résistance aux antibiotiques actuels a stimulé la recherche de nouveaux agents antimicrobiens. La paroi cellulaire essentielle des bactéries qui est formée de peptidoglycane est le site d'action de plusieurs médicaments actuels, y compris les β-lactames et la vancomycine. C'est aussi la cible d'un certain nombre de peptides antibiotiques très puissant produits par des bactéries, telles la nisine A et la lacticine 3147 qui sont toutes les deux des antibiotiques fortement modifiés d'une façon post-translationnelle qui agissent en se liant au lipide II, le précurseur du peptidoglycane. Un autre ensemble de cibles potentielles pour le développement d'antibiotiques sont les enzymes bactériens qui fabriquent des précurseurs du lipide II ou du peptidoglycane, dont ceux qui se retrouvent dans la voie conduisant à l'acide diaminopimélique (ADP) et à son produit de métabolisme, la L-lysine. Dans cette catégorie, l'épimérase de l'ADP est un enzyme unique qui ne dépend pas du phosphate de pyridoxyal (PLP) et qui semble utiliser les deux sites thiols actifs (Cys73 et Cys217) comme acide et base pour déprotoner l'hydrogène α des LL-ADP et méso-ADP à partir d'un côté pour le reprotoner de l'autre. Il n'est pas possible de réaliser ce processus en l'absence d'un enzyme. Un des objectifs primaires de notre travail a été de générer des inhibiteurs de l'épimérase d'ADP qui pourraient imiter correctement les substrats naturels (méso-ADP et LL-ADP) dans le site enzymatique actif et, par le biais d'études cristallographiques, pourraient nous donner une idée sur le mécanisme et sur la spécificité du substrat. On a réalisé la synthèse d'une série d'analogues de l'ADP contenant une aziridine et on les a

testés comme inhibiteurs de l'épimérase d'ADP provenant du *Haemophilus influenzae*. Deux diastéréoisomères de l'acide 2-(4-amino-4-carboxybutyl)aziridine-2-carboxylique (AziADP) agissent comme inactivateurs irréversibles rapides de l'épimérase d'ADP; l'analogue AziADP du LL-ADP réagit d'une façon sélective avec le groupe sulfhydryle du site Cys73 alors que l'analogue correspondant du méso-ADP réagit avec celui du site Cys217. Les isomères du AziADP sont trop instables pour être utiles comme antibiotiques. Toutefois, les spectres de masse et les analyses par diffraction des rayons X des enzymes inactivés confirment que le thiol attaque le groupe méthylène de l'aziridine avec une ouverture de cycle concomitante qui conduit à la formation d'un analogue ADP lié au site actif. Des études cristallographiques ultérieures devraient permettre d'obtenir un nouvel éclairage sur le mécanisme.

Mots clés : mécanisme enzymatique, inhibition enzymatique, antibiotiques, aziridines, acides aminés.

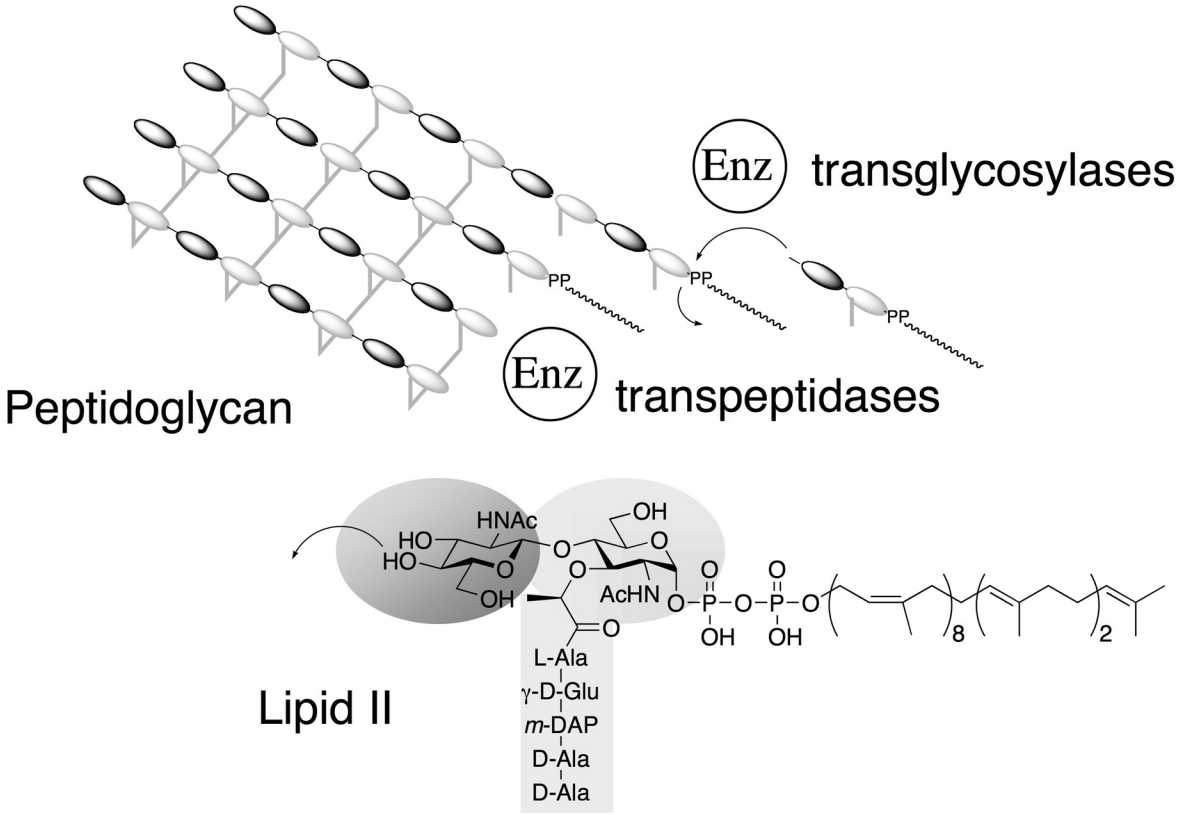
[Traduit par la Rédaction]

Introduction

Resistance to common antibiotics was observed shortly after their introduction into clinical practice in the late 1940s and early 1950s, and has become a serious and costly problem in health care. Although it is well-understood that overuse of antibiotics produces resistance, it is estimated that currently about half of the 100 million prescriptions per year written by office-based physicians in the United States are unnecessary because they are prescribed for the common cold and other viral infections, against which antibiotics are not active (1). The approximate direct cost of antibiotic resistance may be more than $3 billion annually with an associated indirect cost of perhaps 10 times that amount (2). Another concern that exacerbates this problem is that the market for antibiotics is a fragile one. Unlike medicines for chronic conditions, such as high cholesterol or high blood pressure, that are taken daily for long periods of time, antibiotics are only taken for a short time and only when a patient suffers particular diseases. Thus, the profitability of this class of medications is limited and it has become even more limited because the costs and standards for regulatory approval match those for the more profitable drugs that see daily use.

Formation of peptidoglycan, the netlike cell wall layer in bacteria, is a primary target for many antibiotics, including the β-lactams (e.g., penicillins, cephalosporins) as well as vancomycin and related glycopeptides (3). Interestingly, lipid II, the monomer unit that is polymerized to form peptidoglycan, is also a target for antimicrobial agents (Fig. 1). The topical peptide antibiotic bacitracin inhibits utilization and processing of its lipid portion (4), whereas a number of lantibiotics (lanthionine-containing peptides), such as nisin A, bind to it (5). Nisin A (Fig. 2), which is approved for use as a food preservative, uses lipid II as a docking molecule not only to inhibit peptidoglycan formation, but also to create pores in bacterial cell membranes. Although nisin A is many orders of magnitude more potent than conventional antibiotics, its instability at neutral pH and its tendency to be inactivated by Michael addition of ubiquitous thiols, such as glutathione, to its dehydroamino acid residues precludes its therapeutic use in mammals (6). Fortunately, lacticin 3147, a very potent two-peptide lantibiotic consisting of A1 and A2 peptides and certain other lantibiotics, appears to be much more stable and may be useful in such applications (7, 8).

Lipid II in Gram-negative bacteria contains a *meso*-diaminopimelic acid (meso-DAP) residue that acts as a cross-linking amino acid in peptidoglycan via attack at the penultimate D-alanine amide bond of a nearby pentapeptide moiety (Fig. 3) (9). In most Gram-positive bacteria, the DAP moiety is replaced by its metabolic product, L-lysine, which serves the analogous function. For some time, we and others have been interested in targeting the DAP pathway to L-lysine (Fig. 4), which occurs in bacteria and higher plants, for possible development of new antibiotics (10). The DAP pathway is absent in mammals, which require L-lysine in their diet as an essential amino acid. Hence, it is likely that specific inhibitors of the bacterial enzymes in this metabolic route could be potent antimicrobial agents against bacteria resistant to conventional antibiotics and would be nontoxic to humans and animals. Limited antibiotic activity has already been demonstrated for an heterocyclic analog of DAP that inhibits DAP dehydrogenase (11).



DAP epimerase and its properties

DAP epimerase is an enzyme of particular interest because of its unusual mechanism, although it may not be the best target for antibiotic development as it appears late in the pathway and its function may be circumvented (12). The enzyme reversibly interconverts LL-DAP and meso-DAP without the use of cofactors, metals, or keto or imine intermediates (13). Although a number of enzymes racemize amino acids using pyridoxal phosphate (PLP) (14, 15), DAP epimerase belongs to the class of PLP-independent racemases, which includes aspartate racemase (16), glutamate racemase (17, 18), and proline racemase (19). Based on early work by Albery and Knowles (19), Wiseman and Nichols (13) proposed that DAP epimerase uses two cysteines in the active site (Fig. 5) as an acid and a base to remove the α-proton and reprotonate from the opposite side. During this process, a primary kinetic isotope effect is observed and the α-hydrogen exchanges with solvent via the thiol (13, 20). DAP epimerase is highly specific and does not transform the DD-isomer of DAP or any isomer of lanthionine (the 3-thia analog of DAP). All substrate carboxyl and amino groups of DAP must be present for successful binding and neither the D- or L-isomers of lysine or α-aminopimelic acid are substrates or effective inhibitors (21).

This type of epimerization is not a trivial process and the half-life for such a transformation in the absence of enzyme is estimated to be in excess of 1500 years (22). Several major obstacles block this reaction in the absence of enzyme. The most important is the inherent lack of acidity of the α-hydrogen in a free α-amino acid compared with the much

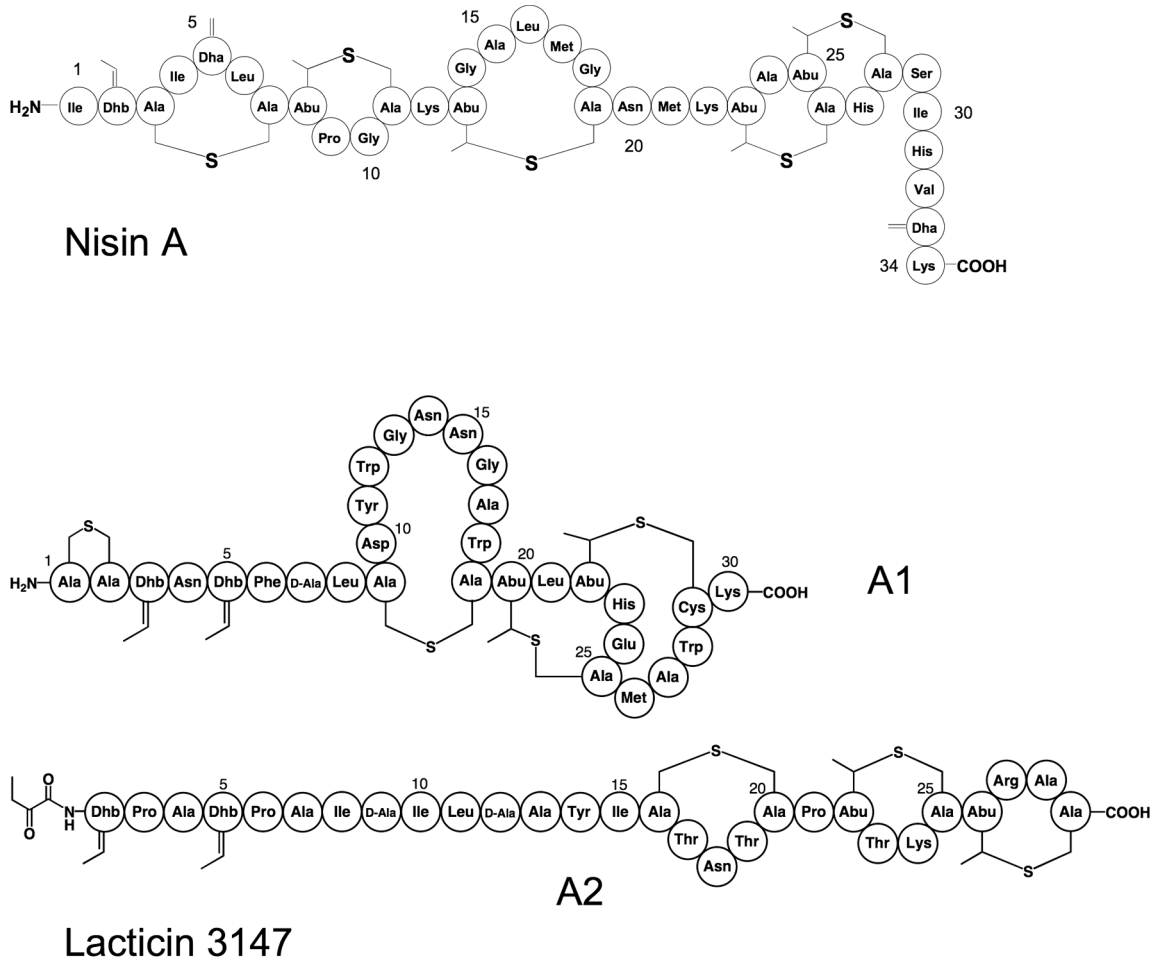
Fig. 1. Simplified schematic of the formation of peptidoglycan from lipid II. In Gram-positive bacteria, *m*-DAP is usually replaced by L-lysine.

more acidic hydrogens on the carboxyl oxygen in a fully protonated amino acid or on the ammonium group in the zwitterionic form. The pK_a of the α-hydrogen has been estimated to be 34 for the deprotonated anionic amino acid, about 29 for the zwitterionic form, and 21 for the corresponding fully protonated version (23). Thus, a free base in solution will rapidly take a proton first from the carboxyl oxygen and then from the ammonium group, at which point removal of the α-hydrogen requires an extremely strong base. A second major problem is that the free thiol of a cysteine residue typically has a pK_a of ca. 10 and, as a result, the corresponding thiolate is a poor base for deprotonation at the α-carbon.

Nevertheless, the formation of an α-anion in the epimerization process could be confirmed by elimination of hydrogen fluoride from pure β-fluoro-DAP stereoisomers (24). Interestingly, the loss of HF proceeds very rapidly from isomers **1** and **3**, but diasteromers **2** and **4** epimerize reversibly and only slowly undergo elimination of hydrogen fluoride (Fig. 6).

These results indicate not only that anionic character forms at the α-carbon, but also that the substrate, which is normally conformationally mobile, is rigidly held in the enzyme active site so as to orient the cleaving bonds at the α- and β-carbons synperiplanar or antiperiplanar in the rapidly eliminating isomers. Subsequent experiments with β-fluoro-DAP stereoisomers **1** and **2**, using site-specific mutants Cys73Ala and Cys217Ala, demonstrate that Cys73 is the base that removes the α-proton from LL-DAP, whereas Cys217 performs the analogous function on meso-DAP (25).



A major breakthrough in the understanding of this unusual enzyme was the elucidation by Blanchard and co-workers (26) of the crystal structure (2.7 Å) of an inactive form of DAP epimerase from *Haemophilus influenzae* in which Cys73 and Cys217 formed a disulfide. This was subsequently refined by Roper and co-workers (27) to 1.75 Å. The monomeric enzyme (274 amino acid residues) displays an unusual pseudo twofold symmetry axis around the central cleft that forms the putative active site. Unfortunately, unambiguous modeling of DAP isomers as substrates in the active site is not readily accomplished using this inactive disulfide structure. Subsequent crystallographic structures of related PLP-independent racemases such as aspartate racemase (16) and glutamate racemase (17, 28), also do not permit definitive placement of substrate (29) in the active sites in such a way as to elucidate the catalytic mechanism. Thus, a primary goal of our work was to generate inhibitors of DAP epimerase that would accurately mimic the natural substrates (meso-DAP and LL-DAP) in the enzyme active site and provide mechanistic insight through crystallographic analysis.

Synthesis of AziDAP isomers

In 1990, Higgins and co-workers (30) reported that a crude mixture of all possible diastereomers of 2-(4-amino-4-carboxybutyl)aziridine-2-carboxylic acid (AziDAP), generated by heating a mixture of α-halomethyl DAP isomers, caused irreversible inactivation of DAP epimerase (Fig. 7). Enzymatic digestion of the inactivated enzyme indicated that Cys73 had been alkylated by the inhibitor through an attack

© 2006 NRC Canada

Fig. 2. Structures of nisin A and lacticin 3147 (a two-component antibiotic consisting of A1 and A2 peptides).

by the thiol on the methylene of the aziridine ring in AziDAP. Subsequently, an elegant study by Tanner and Miao (31) employed an aziridino analog of glutamic acid to inactivate the PLP-independent glutamate racemase. A diastereomeric mixture of oxa analogues of AziDAP was also found to irreversibly inactivate DAP epimerase, probably by thiol opening of the epoxide moiety (32). We reasoned that the synthesis of pure AziDAP isomers **5** and **6**, corresponding to the natural substrates LL-DAP and meso-DAP, respectively, would provide probes that could give crystallographic pictures of the DAP epimerase active site with a bound substrate analog. These would have a stereochemically locked DAP skeleton. Although the AziDAP isomers **5** and **6** are quite small molecules, their synthesis provides a considerable challenge because of high reactivity of the aziridine ring under acidic conditions. This sensitivity is exacerbated by the presence of five internal nucelophiles (four carboxyl oxygens and the distal amino group). In addition, complete stereochemical purity at well-separated centers is required. We also embarked on the synthesis of the DAP derivatives **7** and **8**, having an internal aziridine moiety, to test their ability to analogously inactivate DAP epimerase.

Analog **8** could be prepared by aziridination of an α,β-unsaturated amide bearing a chiral auxiliary. We had earlier reported (33) the diastereoselective aziridination of *N*-enoylbornane[10,2]sultams by *N*-aminophthalimide mediated by lead tetraacetate. This reaction subsequently proved feasible with oxoalkenyloxazolidinone (34) and camphor auxilliaries (35). Hence, we targeted an analogous route with the use of 3-amino-2-ethyl-3,4-dihydroquinazolin-4-one (**15**) to provide the stereoselective synthesis of the internal aziridine moiety to be followed by deprotection using N—N bond reduction with metal in ammonia. As shown (Fig. 8), reaction of the chiral phosphonate ester with *N*,*N*-di-Boc glutamate semialdehyde (**9**) gives exclusively the *trans*-alkene. One Boc protecting group could then be cleaved with TFA to generate the desired precursor **10** for aziridination. Lead tetraacetate aziridination with quinazolin-4-one at –40 °C gives a diastereomeric ratio of 9:1. The major isomer **11** is readily isolated by recrystallization. Although the absolute stereochemistry of this aziridine could not be directly confirmed by X-ray crystallography, it is known that addition to *N*-enoylbornane[10,2]sultams occurs by syn attack from the re face of the α-carbon (33). Removal of the Boc group, base hydrolysis, and reductive cleavage of the N—N bond with Li and ammonia affords the target **8**. With stereochemically pure **8** available, we also synthesized a 1:1 mixture of **8** and its diastereomer **7** to test for irreversible in-

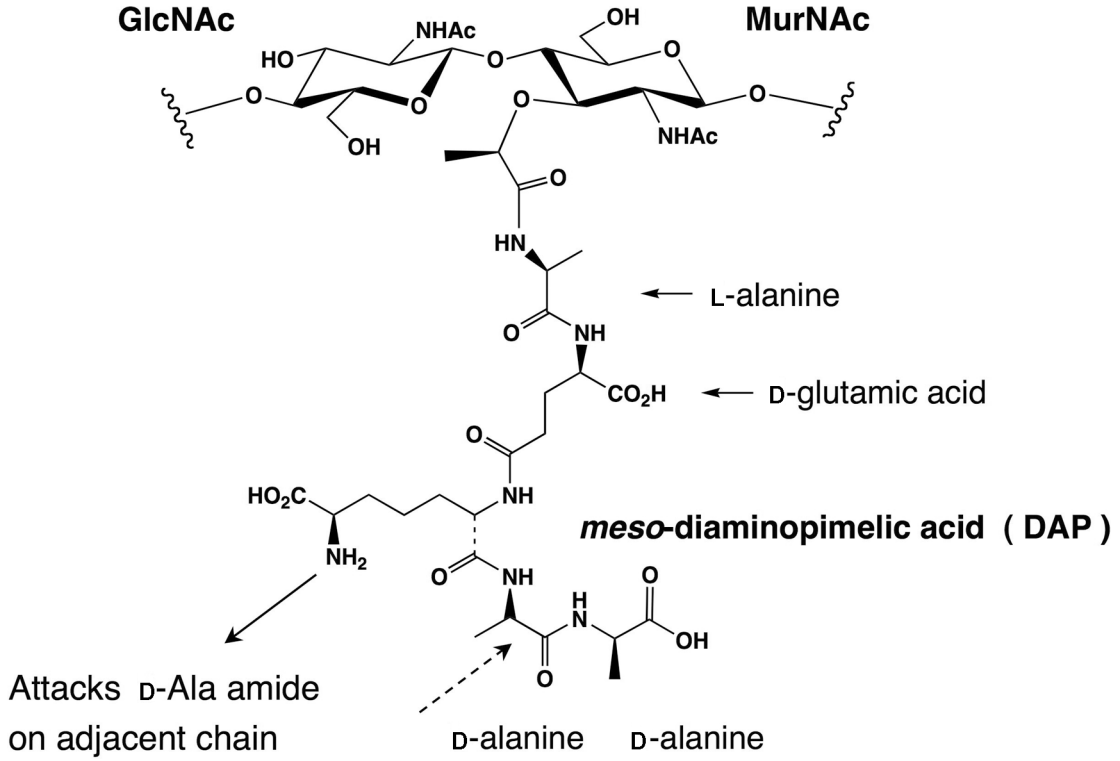

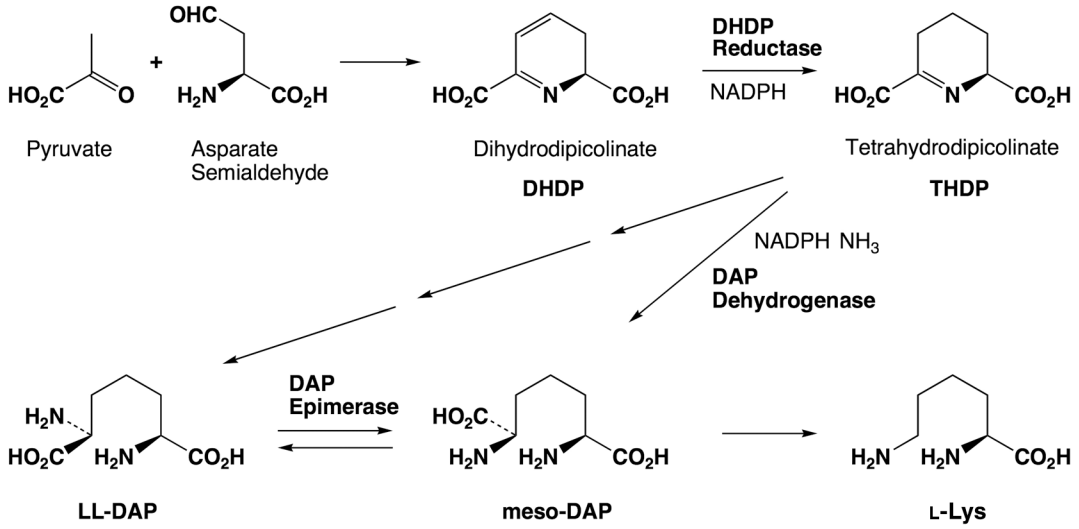

Fig. 4. Diaminopimelate pathway to L-lysine in bacteria. Most bacteria use the route via LL-DAP, but some Gram-positive bacteria employ a shortcut to meso-DAP via DAP dehydrogenase.

activation of DAP epimerase. This mixture was made by by nonstereospecific aziridination of the dimethyl ester **12** followed by analogous deprotection (Fig. 8).

Numerous approaches for synthesis of stereochemically pure **5** and **6** were tried, and the most successful method involved the tethering of a chiral aziridinating moiety via an ester linkage (36, 37) to the unsaturated amino acid framework to allow intramolecular reaction. The required unsaturated α-aminopimelic ester **16** was constructed by photolysis of the Barton ester of *N*-Cbz-L-glutamic acid α-methyl ester with methyl α-thiophenol methylacrylate to give a 68% yield over three steps (Fig. 9) (38). The chiral aziridinating portion, (*R*)-aminoquinazolin-4(3*H*)-one (**18**), was then coupled to the monoacid **17**, which was made by saponification of **16** and selective monoesterification using methanol and polymer-bound PTSA (39). Although the tethering of the aziridinating agent to form **20** works reasonably well using DCC–DMAP, several cycles of flash chromatography are re-

quired to remove the unwanted urea by-product. In contrast, resin-bound *N*-benzyl-*N*-cyclohexylcarbodiimide reagent (PS-DCC) (40) permits facile purification after coupling of acid **17** to the (*S*)-aminoquinazolin-4(3*H*)-one (**19**) to give **22** in 51% yield. Intramolecular aziridination of **22** progresses rapidly upon treatment with lead tetraacetate at 0 °C to give the target **23** with complete diastereoselectivity (>99:1 dr). NOE studies confirm the stereochemical outcome of this reaction. In particular, there is a strong (3%) NOE interaction of the hydrogen on the stereogenic centre bearing the methyl group across the face of the 10-membered ring with the methylene hydrogens of the side chain (Fig. 10). Preparation of the diastereomeric aziridine **21** under analogous conditions is slightly less selective (98:2 dr), but the minor diastereomer can be removed by careful column chromatography to give a >99:1 dr. Interestingly, the diastereomeric compounds **21** and **23** can be distinguished by ^{13}C NMR spectroscopy despite the relatively wide separation of the stereogenic centres. Hydrolysis of the fully protected AziDAP **23**, using lithium hydroxide or sodium hydroxide, results in decomposition. Fortunately, sodium carbonate (41) in methanol–water allows quantitative generation of the salt of the diacid. Subsequent deprotection with sodium or lithium in ammonia at –78 °C gives AziDAP isomer **6** as the major product along with ε-methyl-α-aminopimelic acid in a 5.6:1 ratio. This undesired product is formed as a 1:1 mixture of diastereomers at the carbon bearing the methyl. It may result from reductive aziridine ring cleavage to generate an anion α to the carboxylate followed by elimination of nitrogen and further reduction of the resulting conjugated olefin. Separation of the crude reaction mixture using preparative TLC under basic conditions gives

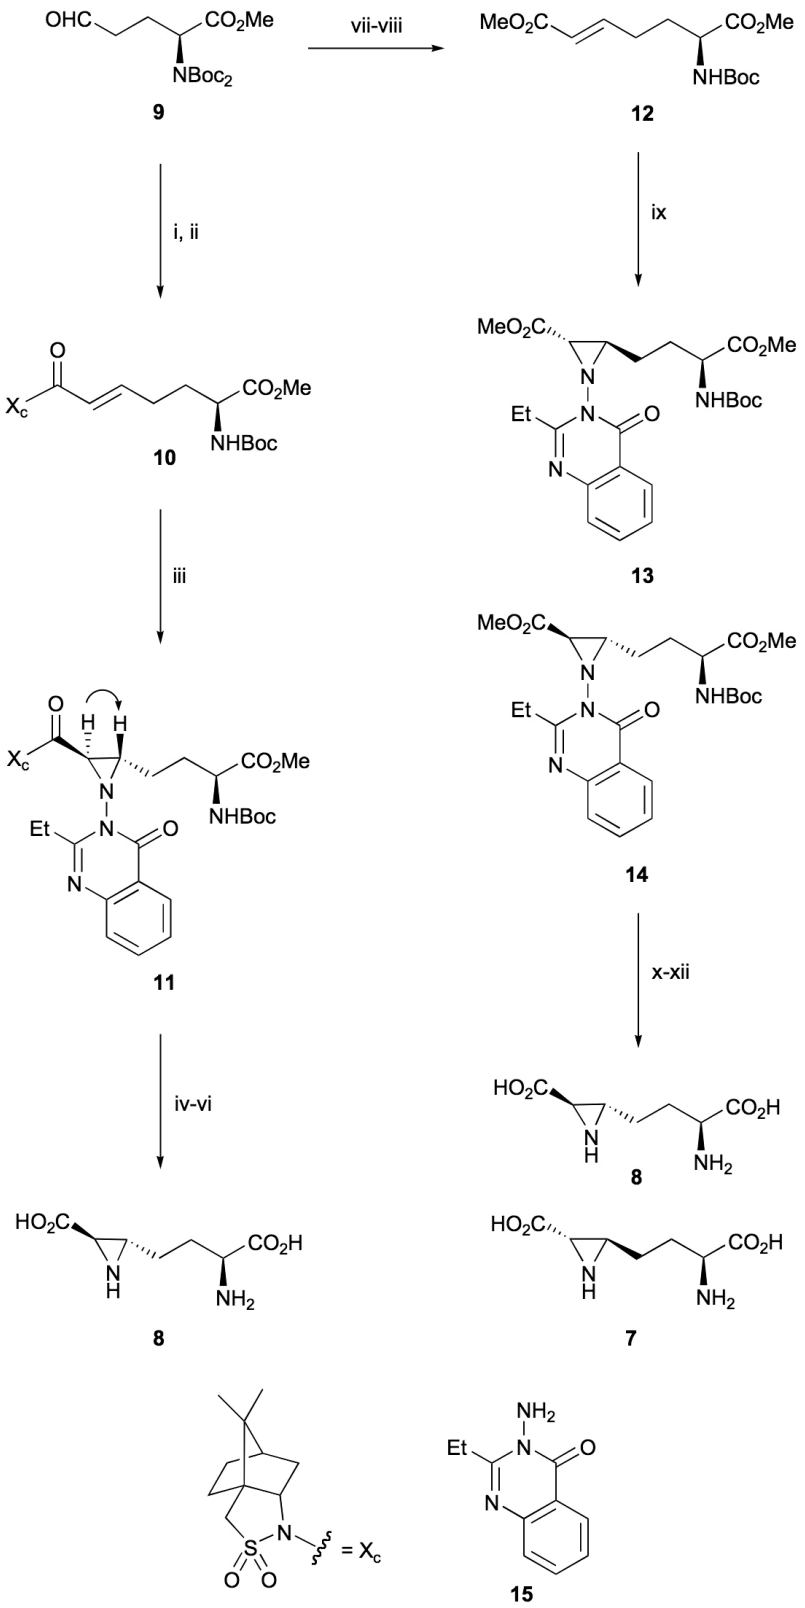
Fig. 7. Inactivation of DAP epimerase by a mixture of AziDAP isomers and synthetic targets.



a low isolated yield (23% for AziDAP **6**). Pure AziDAP **5** could be prepared in improved yield (30%) by direct reduction, without preliminary HPLC purification of the diacid salt. AziDAP isomers **5** and **6** are extremely sensitive compounds that are stable in a strong base, but decompose quickly under acidic or neutral conditions. The multiple internal nucleophiles (four carboxylate oxygens and the distal amino group) promote rapid intramolecular aziridine ring opening. As solid carboxylate salts, **5** and **6** decompose somewhat more slowly at room temperature, with half-lives of about 2 weeks. They are stable for longer periods only under cryogenic (–80 °C) conditions, but this propensity to decompose in aqueous media precludes evaluation of their antimicrobial activity in bacterial cultures.

Interaction of DAP epimerase from *H. influenzae* with AziDAP isomers

As mentioned previously, Higgins and co-workers (30) reported that a crude mixture of all possible diastereomers of AziDAP caused irreversible inactivation of DAP epimerase with covalent modification of Cys73 in the enzyme active site. Exposure of cloned and overexpressed (*Eschrichia coli*) DAP epimerase from *H. influenzae* (25) to **5**, **6**, **7**, and **8** demonstrates that the compounds with the internal aziridine ring (**7** and **8**) are weak reversible inhibitors (IC_{50} for **8** is 2.88 mmol/L) that do not bind permanently in the active site. In contrast, the AziDAP isomers **5** and **6** rapidly and irreversibly inactivate the enzyme at low concentration and show both time and concentration dependence. The covalent attachment of both isomers to the enzyme can be demonstrated by electrospray mass spectroscopy. Because of the instability of these compounds in aqueous media, it is not possible to obtain accurate kinetic constants, an observation already reported by the Higgins group with the isomeric mixture (30). Earlier studies (25) suggested that pure LL-AziDAP **5** should result in selective attachment to Cys73 of DAP epimerase, whereas DL-AziDAP **6** would react with Cys217. Inactivation of DAP epimerase with individual AziDAP isomers, followed by treatment with thermolysin and trypsin, generates fragments that afford excellent sequence coverage (89%) by MS–MS and allow separate examination of both active site cysteines. The reaction of **5** with Cys73 of the enzyme is readily demonstrated by this approach. In contrast, analysis of DAP epimerase inhibited with a large excess (10- to 100-fold) of AziDAP **6** reveals that in addition to the expected alkylation of Cys217, attack also occurs at Cys73 to a certain extent. In principle, it is possible that a single diasteroisomer of AziDAP (i.e., 29) reacts with both cysteines. However, the excess of inhibitor **6** could possibly be contaminated by very small amounts (<1.0%) of the other AziDAP diastereomer **5**, which is not easily detectable and could act on the DAP epimerase. The use of such a large excess of inhibitor was initially prompted

by the desire to completely and rapidly inactivate the enzyme for crystallographic studies prior to its facile aerobic oxidation to form the internal disulfide between Cys73 and Cys217.

Fortunately, X-ray crystallography studies by our collaborators, Professor Michael James and Dr. Bindu Pillai (Department of Biochemistry, University of Alberta), on DAP epimerase separately inhibited with the individual AziDAP isomers showed that LL-AziDAP **5** bound exclusively to Cys73 and that DL-AziDAP **6** attached only to Cys217. In both cases, inactivation proceeds as predicted by attack of the thiolate on the aziridine methylene. Although these three-dimensional structures will be the subject of a separate report (submitted for publication), the key features essential for the unusual catalysis are readily evident. As one of the active site thiols in DAP epimerase has a considerably reduced pK_a (6 to 7) (20), the two cysteines are likely to exist as a thiolate–thiol pair prior to substrate binding. Binding of AziDAP and ring opening by the thiolate gives an analog of the substrate–enzyme complex in which the α-hydrogen of the corresponding DAP substrate is replaced by a methylene group. The enzyme–inactivator complex shows a significant domain shift, compared with the inactive disulfide version of the enzyme (26, 27), to enclose the DAP analog, similar to what has been very recently reported for glutamate racemase with D-glutamate in the active site (42). This creates a very tight-fitting pocket for binding the substrate, which is lined with hydrophobic side chains and also has a series of hydrogen bond donors and acceptors to recognize and interact with the substrate–inhibitor carboxyl and amino functionalities. As expected, the carboxylate attached to the α-carbon that undergoes epimerization is fully hydrogen bonded to allow electron delocalization. The amino group at the α-carbon is also protonated and α-helices near the carboxylate assist dispersion of negative charge. Finally, relatively rigid binding of substrate–inhibitor with exclusion of solvent, and location of the thiolate base close to the α-hydrogen with separation from the carboxyl and amino groups, enables catalysis with minimal movement. The crystallographic details will be reported in a forthcoming publication (43).

Acknowledgements

I am deeply grateful to the Canadian Society for Chemistry for selecting me to receive the Alfred Bader Award. I would particularly like to acknowledge the continuing contributions that Alfred Bader has made in supporting scientific endeavours internationally, not only through generous donations to national societies and universities, but also by his career-long efforts to make useful laboratory chemicals routinely available. Co-workers and collaborators cited in the references are gratefully acknowledged for their dedicated work in this project. I especially thank John Blanchard (Albert Einstein College of Medicine, Yeshiva University), Michael James, Bindu Pillai, Paul Semchuk, and Maia Cherney (Department of Biochemistry, University of Alberta), and Andrew Sutherland and Christopher Diaper of our group. This research has been supported by the Natural Sciences and Engineering Research Council of Canada (NSERC), Merck Frosst Canada, the Canada Research Chair in Bioorganic and Medicinal Chemistry, and the Alberta Heritage Foundation for Medical Research.

Mechanism of cyclopropanol to cyclopropanol isomerization mediated by Ti(IV) and a Lewis acid[1]

Charles P. Casey and Neil A. Strotman

Abstract: Isomerization of *trans*-3-deutero-*r*-1-methyl-*cis*-2-phenylcyclopropan-1-ol (**1-trans-d**) to three isomeric cyclopropanols was facilitated by reaction with a mixture of Ti(O-*i*-Pr)$_4$ and $BF_3{\cdot}OEt_2$. The more Lewis acidic Cl_2Ti(O-*i*-Pr)$_2$ catalyzed this reaction in the absence of $BF_3{\cdot}OEt_2$. This cyclopropanol to cyclopropanol rearrangement involves reversible ring opening to a β-titanaketone. When the major species in solution prior to quenching was a titanium cyclopropoxide, a 40:40:10:10 mixture of cyclopropanols **1-trans-d**:**1-cis-d**:**2-trans-d**:**2-cis-d** was obtained; this is close to the equilibrium ratio of the titanium cyclopropoxides. When a catalytic quantity of Ti(O-*i*-Pr)$_4$ and a large excess of cyclopropanol was used, quenching gave a 29:29:21:21 mixture; this is closer to the equilibrium ratio of the cyclopropanols than the cyclopropoxides. Extrapolation to 0% and to 100% cyclopropoxide gave equilibrium constants for both cyclopropanols (K_{eq} = [**2**]/[**1**] = 1.3) and cyclopropoxides (K_{eq} = [**2-Ti**]/[**1-Ti**] = 0.18). A mechanism for these isomerization processes that involves ring opening and (or) ring closing with both retention and inversion of configuration at the carbon bearing phenyl is proposed.

Key words: cyclopropanol, titanium isopropoxide, Kulinkovich hydroxycyclopropanation.

Résumé : L'isomérisation du *trans*-3-deutéro-*r*-1-méthyl-2-phénylcyclopropan-1-ol (**1-trans-d**) en trois cyclopropanols isomères est facilitée par une réaction avec un mélange de Ti(O-*i*-Pr)$_4$ et de $BF_3{\cdot}OEt_2$. Le Cl_2Ti(O-*i*-Pr)$_2$, un acide de Lewis plus acide, catalyse cette réaction sans $BF_3{\cdot}OEt_2$. Ce réarrangement d'un cyclopropanol en un autre implique une ouverture de cycle réversible en β-titanacétone. Quand l'espèce principale en solution avant le captage le cyclopropylate de titane, on obtient un mélange 40 : 40 : 10 : 10 des cyclopropanols **1-trans-d** : **1-cis-d** : **2-trans-d** : **2-cis-d**, une proportion qui se rapproche du rapport à l'équilibre des cyclopropylates de titane. Quand on utilise une quantité catalytique de Ti(O-*i*-Pr)$_4$ avec un large excès de cyclopropanol, le piégeage conduit à un mélange 29 : 29 : 21 : 21 qui est plus près du rapport d'équilibre des cyclopropanols que de celui des cyclopropylates. Une extrapolation à des quantités égales à 0 % et à 100 % de cyclopropylate permet d'obtenir les constantes d'équilibre tant pour les cyclopropanols ($K_{éq}$ = [**2**]/[**1**] = 1,3) que pour les cyclopropanolates ($K_{éq}$ = [**2-Ti**]/[**1-Ti**] = 0,18). On propose un mécanisme pour ces processus d'isomérisation qui impliquent des ouvertures et des fermetures de cycle impliquant des rétentions et des inversions de configuration au niveau du carbone portant le noyau phényle.

Mots clés : cyclopropanol, isopropylate de titane, hydroxycyclopropanation de Kulinkovich.

[Traduit par la Rédaction]

Introduction

The Kulinkovich hydroxycyclopropanation, discovered in 1989, allows for the one-step preparation of polysubstituted cyclopropanols from esters, Grignard reagents, and Ti(O-*i*-Pr)$_4$ (Scheme 1) (1). Advances in this methodology have resulted in the employment of catalytic quantities of titanium (2), highly diastereoselective (3), and enantioselective (4) variants of this reaction and a widely broadened substrate scope.

This reaction is believed to involve a Ti(II)-alkene complex (**B**), formed via alkane loss from an unstable dialkyl-Ti(IV) intermediate (**A**) (Scheme 2). In the presence of an added alkene, exchange occurs, leading to increased product diversity. Reductive coupling of the alkene and the ester carbonyl by Ti(II) leads to metallacycle **C**. This metallacycle fragments with alkoxide loss to give β-titanaketone (**D**). Attack of the nucleophilic carbon bound to titanium on this γ-carbonyl moiety results in ring closure to form cyclopropoxide.

We recently demonstrated that the final step of the Kulinkovich hydroxycyclopropanation reaction involves frontside attack of the carbon–titanium bond on the γ-carbonyl to form a cyclopropoxide (Scheme 3) (5). Deuterium labelling revealed that the carbon bound to titanium retained its configuration throughout this process to give *trans*-3-

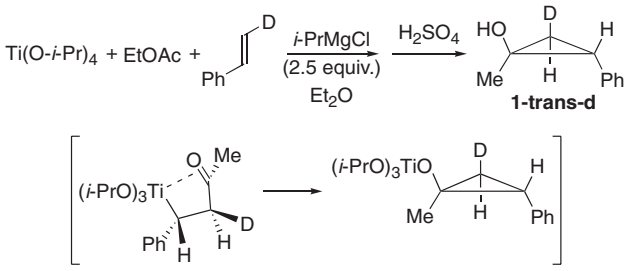


Scheme 2.

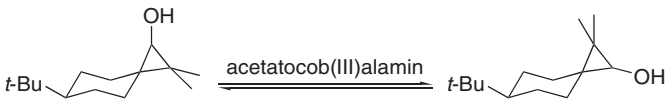
deutero-*r*-1-methyl-*cis*-2-phenylcyclopropan-1-ol (**1-trans-d**)[3] as the only observed product (5, 6).

We wondered whether introduction of a Lewis acid into this reaction, prior to cyclopropoxide formation, might result in a different ring closure mechanism. It seemed likely that the carbonyl oxygen would bind more tightly to an electron deficient Lewis acid, such as BF_3, than intramolecularly to the electron rich alkyltitanium triisopropoxide unit (Scheme 4). This would inhibit coordination of the carbonyl oxygen to titanium and would cause the alkyltitanium species to adopt a less sterically demanding transition structure. This opens the possibility that ring closure might occur with inversion of configuration at the carbon bound to titanium. An analogous transition structure, in addition to being involved in iron- (7), tin- (8), and zirconium-mediated (5) cyclopropane formation, was consistent with the inversion of configuration that we observed at the carbon–titanium bond in de Meijere's cyclopropylamine synthesis (5, 9) (Scheme 4). The addition of BF_3 during the Kulinkovich reaction produced additional cyclopropanol isomers. Here, we report an

Scheme 3.

unusual cyclopropanol to cyclopropanol rearrangement, catalyzed by Ti(O-*i*-Pr)$_4$ and $BF_3{\cdot}OEt_2$, that is responsible for the observation of additional isomers (10).[4] This isomerization is shown to require reversible ring opening of a cyclopropoxide. Moreover, two different mechanisms for the reversible ring opening are required; one involves retention and the other involves inversion of configuration at the carbon bound to titanium in the ring-opened intermediate.

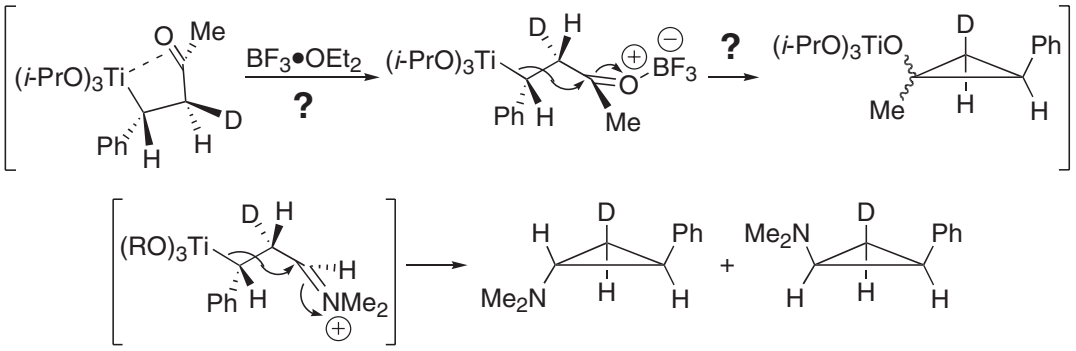
Results



To test our hypothesis that a Lewis acid could affect a different ring closure mechanism in the Kulinkovich hydroxycyclopropanation, we modified the cyclopropanation procedure (3*d*). In the original Kulinkovich procedure, 2.5 equiv. of *i*-PrMgCl were added to a solution of Ti(O-*i*-Pr)$_4$, EtOAc, and *trans*-β-deuterostyrene in refluxing ether over a 1 h period. However, in our variation, the Grignard reagent was added over 5 min at 0 °C, followed by the addition of 2.5 equiv. of $BF_3{\cdot}OEt_2$ and stirred for 1 h (Scheme 5).

Formation of two deuterium-scrambled cyclopropanols in the presence of BF_3

In contrast to the reaction in the absence of $BF_3{\cdot}OEt_2$, which produced only a single cyclopropanol (**1-trans-d**), the addition of $BF_3{\cdot}OEt_2$ led to the formation of three additional isomeric cyclopropanols: *cis*-3-deutero-*r*-1-methyl-*cis*-2-phenylcyclopropan-1-ol (**1-cis-d**), *trans*-3-deutero-*r*-1-methyl-*trans*-2-phenylcyclopropan-1-ol (**2-trans-d**), and *cis*-3-deutero-*r*-1-methyl-*trans*-2-phenylcyclopropan-1-ol (**2-cis-d**). ^{1}H NMR spectroscopy of the crude product mixture showed the formation of **1-trans-d** and **1-cis-d** (δ 2.31) and **2-trans-d** and **2-cis-d** (δ 1.98) in 37% and 19% yields, respectively. ^{2}H NMR spectroscopy showed a 1:1:0.46:0.46 mixture of **1-trans-d**:**1-cis-d**:**2-trans-d**:**2-cis-d**. A mixture of **1-trans-d** and **1-cis-d** was isolated as a white solid (35%) by



[3] The stereochemistry of cyclopropanes is specified using the IUPAC reference system where *r*- is used to specify the reference substituent.

[4] This isomerization from one cyclopropanol to another is very unusual. We found only two other reports containing evidence of a cyclopropanol to cyclopropanol rearrangement. Kasatkin and Sato (3*b*) observed a temperature dependence on the cis/trans product ratio of cyclopropanols generated from homoallyl esters, Ti(O-*i*-Pr)$_4$, and 2 *i*-PrMgBr. When the reaction mixture was allowed to equilibrate at room temperature for 1.5 h before quenching, the trans product was favored greatly with a 95:5 trans:cis ratio, compared with a 41:59 ratio obtained without this equilibration period. In a second example, acetatocob(III)alamin catalyzed the equilibrium isomerization of a spiro-fused cyclopropanol in a maximum of 29% yield (eight other products from oxidation of the cyclopropanol were also seen).

Scheme 4.

Scheme 5.

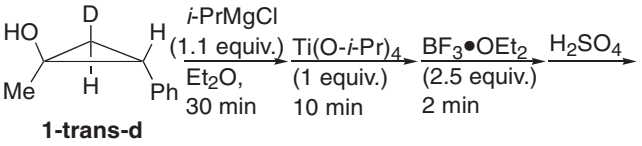
recrystallization. Since *r*-1-methyl-*trans*-2-phenylcyclopropan-1-ol (**2**) could not be obtained by crystallization, it was eventually isolated by preparative TLC (see the following).

The ^{1}H NMR spectrum of recrystallized **1-trans-d** and **1-cis-d** was similar to that of the undeuterated analog *r*-1-methyl-*cis*-2-phenylcyclopropan-1-ol (**1**) except that the two cyclopropyl protons at C-3 (δ 1.21 and 0.97) each gave integrations of 0.5H and each showed coupling only to the benzylic proton. Proton-decoupled ^{2}H NMR spectroscopy showed peaks at δ 1.21 and δ 0.98 of equal integration corresponding to a 1:1 mixture of **1-trans-d** and **1-cis-d**. ^{13}C NMR spectroscopy showed the cyclopropyl carbon bearing the deuterium at δ 18.9 (J_{CD} = 24 Hz) as a 1:1:1 triplet. The absence of a larger central peak or any overlapping quintet indicated that no d_0 or d_2 analog was present.

In a similar experiment, preparative TLC led to the isolation of **2**, which was free of **1**. However, the 1:1 mixture of **2-trans-d**:**2-cis-d** also contained ~30% decomposition products.[5] The ^{1}H NMR chemical shifts were consistent with those previously reported for compound **2** (11). The proton decoupled ^{2}H NMR spectrum of the impure mixture of **2-trans-d** and **2-cis-d** showed equal integrations for the peaks at δ 1.05 and δ 1.18, corresponding to deuterium on C-3 of the cyclopropane.

While this BF_3 modification of the Kulinkovich procedure is clearly of no synthetic utility, it suggests the interesting possibility that an unusual cyclopropanol to cyclopropanol isomerization might be occurring. The formation of cyclopropanols **1** and **2** and the 1:1 ratio of deuterium on C-3 of each cyclopropanol strongly suggested that some type of equilibration process had occurred. It seemed highly unlikely that a 1:1 ratio of retention:inversion at the carbon–titanium bond had occurred in the formation of each cyclopropanol. We suspected that isomerization might have occurred *after* cyclopropanol formation, possibly by reversible ring opening.

To determine whether the majority of cyclopropane was formed stereospecifically prior to the addition of BF_3, we conducted an analogous experiment in which 2.5 equiv. of *i*-PrMgCl were added to Ti(O-*i*-Pr)$_4$, EtOAc, and *trans*-β-deuterostyrene at 0 °C over 5 min and then quenched with acid and water. In this experiment, with no BF_3·OEt_2 added, a 57% NMR yield of **1-trans-d** was obtained. There was no evidence of other cyclopropanol isomers detected by either ^{1}H or ^{2}H NMR spectroscopy in the crude product mixture. This demonstrated that rapid ring closure (<5 min at 0 °C) to form cyclopropoxide had occurred before Lewis acid addition and that BF_3·OEt_2 was involved in the isomerization of the cyclopropoxide rather than in the initial ring closure step.



Cyclopropanol to cyclopropanol isomerization with *i*-PrMgCl, Ti(O-*i*-Pr)$_4$, and BF_3·OEt_2

We next tested whether pure cyclopropanol **1-trans-d** (5) could undergo cyclopropanol to cyclopropanol rearrangement. Deprotonation of the cyclopropanol **1-trans-d** with 1.1 equiv. of *i*-PrMgCl was followed by the sequential addition of 1.0 equiv. of Ti(O-*i*-Pr)$_4$ and 2.5 equiv. of BF_3·OEt_2 and quenching with H_2SO_4 (Scheme 6). When the reaction was quenched after 2 min, ^{1}H NMR spectroscopy showed both **1** and **2** and integration vs. an internal standard showed quantitative recovery of cyclopropanols. Integration of the ^{2}H NMR peaks for the CHD resonances of **1** and **2** at δ 1.22,

[5] The low recovered yields were due to decomposition on the silica gel as well as incomplete separation of TLC bands.

Scheme 6.

1-trans-d:1-cis-d:2-trans-d:2-cis-d
38:38:12:12

0.98, 1.04, and 1.18 indicated a 38:38:12:12 mixture of **1-trans-d**:**1-cis-d**:**2-trans-d**:**2-cis-d**.[6]

At longer times before H_2SO_4 quenching (>60 min), the ratio of deuterated cyclopropanols remained the same, but the yield of recovered cyclopropanols decreased.

Several recrystallizations from pentane at –78 °C of a mixture obtained from isomerization of **1** led to the isolation of a mixture of pure cyclopropanols greatly enriched in **2**. When this 25:75 mixture of **1**:**2** was subjected to our standard isomerization conditions, a 71:29 mixture of **1**:**2** was obtained (Scheme 7). The observation of the same ratio of isomers of **1**:**2** starting from either **1** or **2** demonstrates that equilibrium between the salts of **1** and **2** was reached.

Attempts to isomerize *cis*-2-butyl-*r*-1-methylcyclopropanol (2), bearing a butyl group in place of the phenyl in **1**, failed under our standard conditions and gave only starting material. This indicates that only a bond to a benzylic carbon can cleave during rearrangement.

Cyclopropanol to cyclopropanol isomerization with *i*-PrMgCl and $Cl_2Ti(O\text{-}i\text{-}Pr)_2$

The isomerization of **1-trans-d** did not occur in the presence of $Ti(O\text{-}i\text{-}Pr)_4$ or BF_3 alone; only the starting cyclopropanol was recovered. Our hypothesis was that both a titanium salt and a Lewis acid were required for isomerization. This hypothesis suggested that the more electron deficient $Cl_2Ti(O\text{-}i\text{-}Pr)_2$ might be used alone to serve this dual purpose.

Deprotonation of **1-trans-d** with *i*-PrMgCl, addition of 2 equiv. $Cl_2Ti(O\text{-}i\text{-}Pr)_2$, and quenching after 30 min led to incomplete equilibration and observation of an 85:8:3:3 ratio of **1-trans-d**:**1-cis-d**:**2-trans-d**:**2-cis-d** (Scheme 8). When the reaction mixture was quenched after 3.5 h, more extensive isomerization to a 46:34:10:10 ratio was seen. This ratio is similar to the equilibrium ratio seen in the $Ti(O\text{-}i\text{-}Pr)_4$–$BF_3$ mediated isomerization. Although $Cl_2Ti(O\text{-}i\text{-}Pr)_2$ proved a competent catalyst for this isomerization, it facilitated rearrangement much more slowly.

Equilibrium formation of titanium cyclopropoxides

We wondered whether irreversible deprotonation of the cyclopropanol by *i*-PrMgCl was necessary for the $Ti(O\text{-}i\text{-}Pr)_4$–$BF_3$ catalyzed isomerization. We first examined the equilibrium for cyclopropanol exchange with $Ti(O\text{-}i\text{-}Pr)_4$. The ^{1}H NMR spectrum of a solution of equimolar amounts of $Ti(O\text{-}i\text{-}Pr)_4$ and cyclopropanol **1** in $Et_2O\text{-}d_{10}$ showed an equilibrium mixture of titanium alkoxides (Scheme 9). No change in the NMR spectrum of this solution was seen over 80 min, indicating that equilibrium had been rapidly achieved. In addition, no isomerization to the cyclopropoxide of **2** (**2-Ti**) and no ring opening of the cylopropanol was observed. The cyclopropanol **1** and titanium cyclopropoxide **1-Ti** were differentiated by their benzylic proton resonances at δ 2.22 and 2.45, respectively; $Ti(O\text{-}i\text{-}Pr)_4$ and *i*-PrOH were distinguished by their CHO proton resonances at δ 4.52 and 3.87, respectively.[7] At equilibrium, the benzylic protons at δ 2.45 and 2.22 integrated to 89:11 when equimolar amounts of **1** and $Ti(O\text{-}i\text{-}Pr)_4$ were used (K_{eq} = ~65). Apparently, deprotonation of the cyclopropanol by a Grignard reagent is not required to generate titanium cyclopropoxides without deleterious side reactions.

While NMR spectroscopy allowed ready distinction between cyclopropanol and cyclopropoxides, it did not provide a way to distinguish between the various $Ti(O\text{-}i\text{-}Pr)_n(OR)_{4-n}$ species. To determine whether multiple cyclopropoxy units bind to a single titanium center, we studied the equilibrium between cyclopropanol and cyclopropoxides at high ratios of cyclopropanol:titanium by ^{1}H NMR spectroscopy (Table 1).

In all cases, more cyclopropoxide was seen than predicted by statistics, indicating that **1** is more acidic than isopropanol. Multiple cyclopropoxy groups can clearly bind to titanium. There does not appear to be any significant difference in the selectivity of cyclopropoxide binding to the various $Ti(O\text{-}i\text{-}Pr)_n(OR)_{4-n}$ species.

Cyclopropanol to cyclopropanol isomerization with $Ti(O\text{-}i\text{-}Pr)_4$ and $BF_3{\cdot}OEt_2$

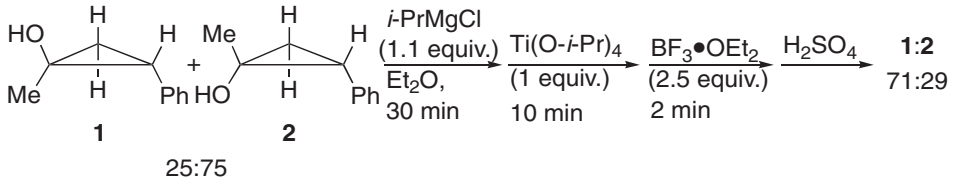
1-trans-d was combined with 1.0 equiv. of $Ti(O\text{-}i\text{-}Pr)_4$ followed by 2.5 equiv. of $BF_3{\cdot}OEt_2$ and the reaction was quenched after 2 min. NMR spectroscopy showed the ratio of **1-trans-d**:**1-cis-d**:**2-trans-d**:**2-cis-d** was 40:40:10:10 (Scheme 10). This shows that $Ti(O\text{-}i\text{-}Pr)_4$ and $BF_3{\cdot}OEt_2$ are sufficient for cyclopropanol to cyclopropanol isomerization and that prior irreversible deprotonation by a Grignard reagent is not necessary.

Both $Ti(O\text{-}i\text{-}Pr)_4$ and $BF_3{\cdot}OEt_2$ are required for isomerization. No isomerization of **1-trans-d** was seen with $Ti(O\text{-}i\text{-}Pr)_4$ alone. Similarly, $BF_3{\cdot}OEt_2$ alone did not catalyze cyclopropanol epimerization although a small amount of decomposition (<10%) of **1-trans-d** was seen.

This equilibrium ratio of products is approximately representative of the relative energies of the cyclopropoxides of **1** and **2** (**1-Ti** and **2-Ti**), since little of the free cyclopropanols exists at equilibrium. This indicates that a $(i\text{-PrO})_3$TiO- unit is more sterically bulky than a methyl group, making the titanium alkoxide **1-Ti** with phenyl cis to methyl slightly more stable than the titanium alkoxide **2-Ti** with phenyl cis to $(i\text{-PrO})_3$TiO-.

Using only a catalytic amount of $Ti(O\text{-}i\text{-}Pr)_4$ should allow direct measurement of the equilibrium ratio of **1**:**2** rather than the equilibrium ratio of the titanium alkoxides **1-Ti**:**2-**

[6] The ratio of cyclopropanols **1** and **2** varied between 83:17 and 72:28 and showed no relationship to reaction time. This variation between runs may be due to the exact ratio of titanium:magnesium employed and the extent of precipitation of magnesium salts. The identity of the metal would affect the relative energies of the cyclopropoxides **1** and **2**.



[7] The resonance at δ 4.52 corresponds to $Ti(O\text{-}i\text{-}Pr)_4$ as well as $(RO)Ti(O\text{-}i\text{-}Pr)_3$ (**1-Ti**).

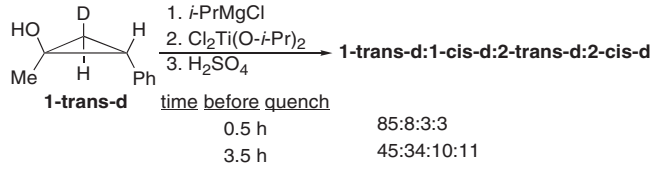
Table 1. Percent of material present as titanium cyclopropoxide as a function of ratio of **1** : Ti(O-*i*-Pr)4.

1 : $Ti(O\text{-}i\text{-}Pr)_4$	% as **1-Ti**	Expected statistical (% as **1-Ti**)	Theoretical maximum (% as **1-Ti**)
1.0:1	89	80	100
4.0:1	62	50	100
10:1	36	29	40

Scheme 7.



Ti, since most of the material would be in the protonated form. When **1-trans-d** was combined with 0.10 equiv. of $Ti(O\text{-}i\text{-}Pr)_4$ followed by 0.25 equiv. of $BF_3{\cdot}OEt_2$ and quenched after 1 h, the ratio of **1-trans-d**:**1-cis-d**:**2-trans-d**:**2-cis-d** was 30:30:20:20 (Scheme 10). Allowing the same reaction to proceed for 3 h before quenching gave an almost identical ratio 29:29:21:21, demonstrating that equilibrium had been reached after 1 h. To obtain a closer approximation of the equilibrium amounts of cyclopropanols, we attempted to further decrease the amount of $Ti(O\text{-}i\text{-}Pr)_4$. However, catalyst deactivation, indicated by incomplete isomerization of **1-trans-d** to **1-cis-d** even at long reaction times, was seen below 0.1 equiv. of $Ti(O\text{-}i\text{-}Pr)_4$ and 0.25 equiv. of $BF_3{\cdot}OEt_2$.

Equilibrium ratios of cyclopropanols and of cyclopropoxides are both involved in determining the ratios of cyclopropanols upon quenching (Scheme 11). When a 1:1 ratio of cyclopropanol–$Ti(O\text{-}i\text{-}Pr)_4$ was employed (Scheme 10), 89% of the material is present as a titanium cyclopropoxide (Table 1) and the observed 80:20 ratio of **1**:**2** obtained on quenching mainly reflects the equilibrium ratio of cyclopropoxides. When a 10:1 ratio of cyclopropanol:$Ti(O\text{-}i\text{-}Pr)_4$ was employed (Scheme 10), 64% of the material is present as a free cyclopropanol (Table 1) and the observed 58:42 ratio of **1**:**2** obtained on quenching has an increased contribution from the equilibrium ratio of cyclopropanols. The greater equilibrium amount of **2** seen at lower titanium levels indicates that the equilibrium ratio of cyclopropanols **1**:**2** must be substantially less than that of the corresponding cyclopropoxides. The ratio of **1**:**2** obtained upon quenching is the weighted average of the ratios of **1**:**2** and **1-Ti**:**2-Ti** existing in solution. At high titanium concentrations, the equilibrium in Scheme 11 is shifted toward cyclopropoxides **1-Ti** and **2-Ti**, whereas at low titanium concentrations this equilibrium is shifted toward cyclopropanols **1** and **2**.

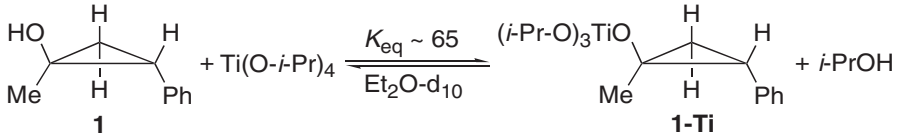
A linear plot of **1** (in %) in the quench vs. cyclopropoxides **1-Ti** and **2-Ti** (in %) in the solution being quenched was obtained (Fig. 1). [8,9]Extrapolation of the plot to 100% cyclopropoxides gives the percentage of **1-Ti** at equilibrium (**1-Ti**:**2-Ti** = 85:15; K_{eq} = [**2-Ti**]/[**1-Ti**] = 0.18; ΔG = 1.0 kcal mol^{-1} (1 cal = 4.184 J)). Similarly, extrapolation of the plot to 0% cyclopropoxides gives the percentage of free alcohol **1** at equilibrium (**1**:**2** = 43:57; K_{eq} = [**2**]/[**1**] = 1.3, ΔG = –0.17 kcal mol^{-1}).

Scheme 8.

These equilibration studies show that cyclopropoxide **1-Ti** is more stable than **2-Ti**, indicating that an $O\text{-}Ti(OR)_3$ group is more sterically bulky than a methyl group. In contrast, equilibration showed that the free cyclopropanol **2** is more stable than **1**, reaffirming that an OH group has less steric bulk than a methyl group. The order of decreasing steric bulk is : $O\text{-}Ti(OR)_3$ > Me > OH.

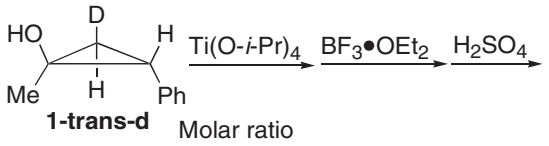
Since both cyclopropoxide **2-Ti** and cyclopropanol **2** are present in substantial amounts at equilibrium, the formation of cyclopropanol **1** as the only product of the Kulinkovich hydroxycyclopropanation[9] must be a kinetic phenomenon.

Discussion



Cyclopropanol to cyclopropanol rearrangements, such as the one reported here, are very unusual (10). Normally, cyclopropanols undergo rearrangement to ketones and epimerization is not observed. For example, DePuy (12) observed that **1** undergoes ring-opening isomerization in protic solvents to 4-phenylbutan-2-one by different stereospecific pathways in acidic and basic solution. Ring opening of **1** un-

[8] This analysis does not take into account any effect of BF_3 on the cyclopropoxide:cyclopropanol ratio, the cyclopropanol:cyclopropanol ratio, or the cyclopropoxide:cyclopropoxide ratio. ^1H NMR spectroscopy of a mixture of cyclopropanol with $Ti(O\text{-}i\text{-}Pr)_4$ and $BF_3{\cdot}OEt_2$ was unable to resolve any relevant resonances.



[9] Supplementary material provides a derivation of the equation for the plot of the percentage of **1** in quench vs. the percentage of cyclopropoxides **1-Ti** and **2-Ti**. Supplementary data for this article are available on the journal Web site (http://canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. Scheme 11.

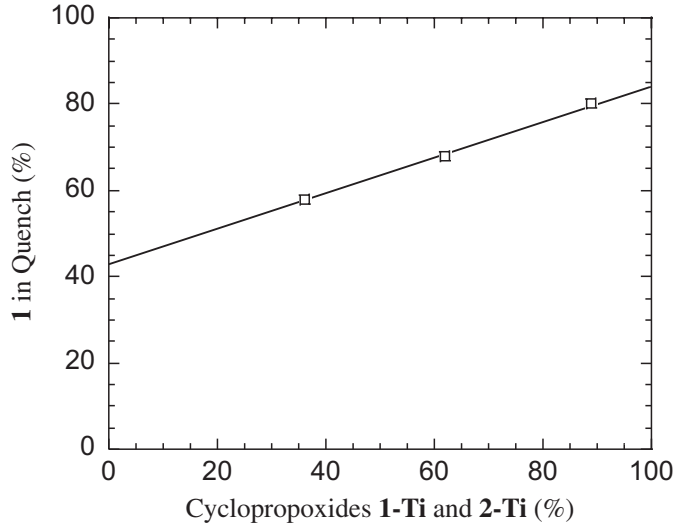
der basic conditions in 1:1 dioxane–D_2O occurred "almost instantaneously" to give 4-phenylbutan-2-one with inversion of configuration, corresponding to corner protonation of the cyclopropane (Scheme 12). Under acidic conditions in 1:1 dioxane:D_2O, slower ring opening of **1** gave a 40:60 mixture of 4-phenylbutan-2-one–3-phenylbutan-2-one; 4-phenylbutan-2-one was formed with exclusive retention of stereochemistry, corresponding to edge protonation of the cyclopropane.

It is interesting that while ring opening of **1** occurs rapidly in the presence of base in 1:1 dioxane–D_2O, we did not observe any ring opening of titanium cyclopropoxide **1-Ti** in the presence of alcohols in Et_2O or CH_2Cl_2. Apparently, titanium alkoxides are more covalent and stable than "free" alkoxide ions. The kinetic stability of titanium cyclopropoxides was confirmed by the calculation of a large barrier (28.8 kcal mol^{-1}) for the ring opening of *cis*-1,2-dimethylcyclopropoxytitanium trimethoxide (6).

Mechanism of cyclopropanol to cyclopropanol isomerization with $Ti(O\text{-}i\text{-}Pr)_4$ and BF_3OEt_2

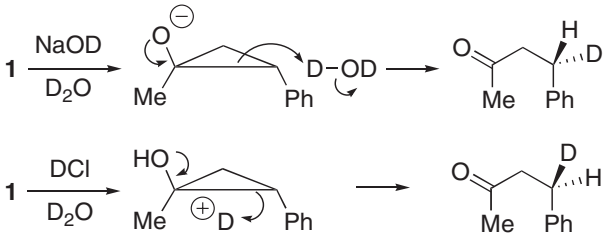


Any valid mechanism must account for three key observations (13).[10] (*i*) BF_3 is required as a Lewis acid for isomerization; titanium cyclopropoxides are stable in its absence. (*ii*) A 2-phenyl substituent on the cyclopropanol ring is required; *cis*-2-butyl-*r*-1-methylcyclopropanol, bearing a butyl group in place of the phenyl, did not isomerize. This suggests that breaking a bond to the carbon bearing the phenyl group is involved in the isomerization. (*iii*) Since all possible diastereomers of the deuterated cyclopropanol are obtained, at least two of the three ring carbons must undergo epimerization.

[10]At one point we considered the possibility that this apparent scrambling of the deuterium stereochemistry was occurring by deprotonation by an alkoxide α to the carbonyl in the ring-opened intermediate. However, this would lead to d_0 and d_2 products, which is inconsistent with our ^{13}C NMR results showing only d_1 compounds. The possibility of the phenyl substituent being β to titanium and α to the carbonyl has been excluded based on (*i*) computational results (6), (*ii*) analogy with quenching studies of the reaction of ketones (*a*) or imides (*b*) with alkenes, and (*iii*) our quenching experiment with a nitrile and alkene.

© 2006 NRC Canada

Fig. 1. 1 (in %) in quench vs. cyclopropoxides **1-Ti** and **2-Ti** (in %).

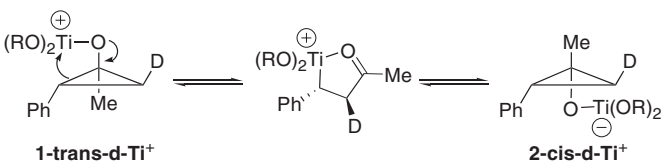


Kasatkin and Sato (3*b*), who observed a temperature dependence on the cis/trans product ratio of cyclopropanols generated from homoallyl esters, Ti(O-*i*-Pr)$_4$, and 2*i*-PrMgBr, attributed this apparent cyclopropoxide isomerization to reversible dissociation of the TiO—C(cyclopropyl) bond. However, the involvement of cyclopropyl cations in our rapid cyclopropanol to cyclopropanol isomerizations can be excluded. While reversible Lewis acid mediated cleavage of the cyclopropyl C—O bond might lead to interconversion of **1** and **2**, this process alone cannot alter the relative stereochemistry of phenyl and deuterium. Although reversible ring opening of the cyclopropyl cation to an allyl cation could, in principle, have isomerized phenyl relative to deuterium, cyclopropyl ring opening is highly exothermic (ΔH°_{expt} = –30 kcal mol^{-1}) (14) and is irreversible. Moss and Chu (15) recently generated the 2-phenyl-1-methylcyclopropyl cation in question and found that ring opening to allyl chlorides was competitive with ion pair collapse to a chlorocyclopropane. In addition, we demonstrated that **1-trans-d** is not isomerized by $BF_3{\cdot}OEt_2$ or Ti(O-*i*-Pr)$_4$ alone.

It is possible to directly convert any one of the four cyclopropoxide diastereomers to each of the other three by distinct processes (Scheme 13).

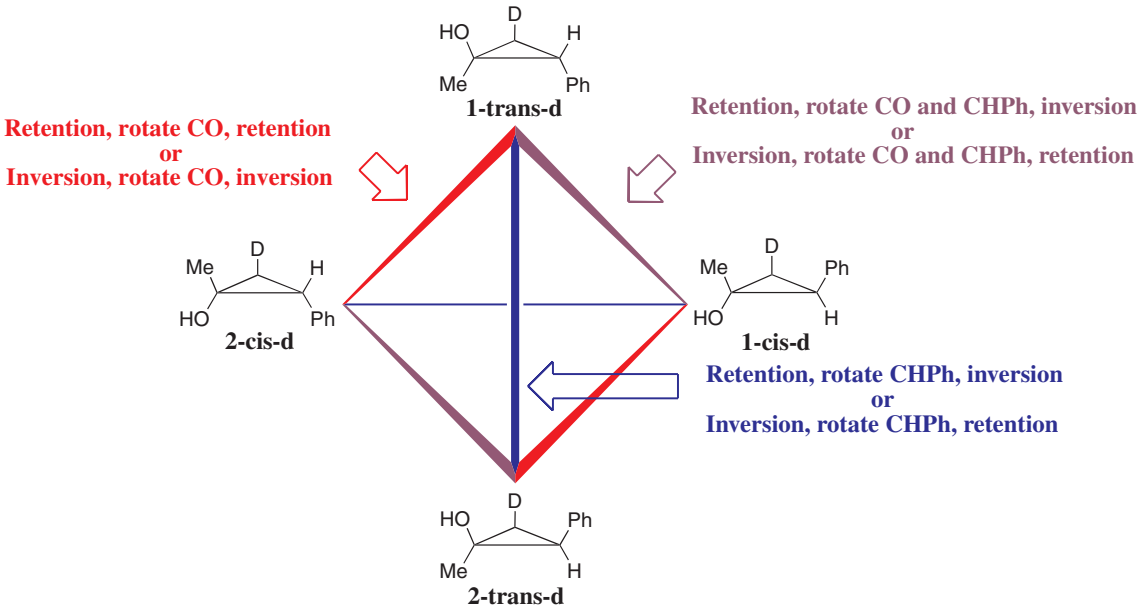
All of the interconversions begin with an electrophilic attack on the cyclopropoxide. The electrophile could be

Scheme 12.



$Ti(OR)_3^+$, generated by the reaction of BF_3 with $Ti(OR)_4$, or another reactive titanium species.[11] Our proposed mechanism for these cyclopropanol isomerization reactions involves two different stereochemistries for the attack of the electrophile on the cyclopropoxide and two different stereochemistries for the microscopic reverse, cyclopropanol ring closing. Electrophilic attack on the cyclopropane bond linking the -OTi and phenyl-bearing carbons leads to retention of configuration at the carbon bearing the phenyl group (Scheme 14); this process is analogous to edge protonation of a cyclopropane. Electrophilic attack on the backside of the same cyclopropane bond leads to inversion of configuration and is analogous to corner protonation of a cyclopropane. The microscopic reverse of this process is responsible for the inversion of configuration at the titanium center in the formation of cyclopropylamines in the de Meijere reaction (5). In both cases, the bond linking the -OTi and phenyl-bearing carbons is attacked and a stabilized benzylic titanium species is generated.

The processes shown in Scheme 14 epimerize the CHPh ring carbon via cyclopropanol ring opening by the backside attack of the electrophile on the phenyl-bearing carbon (inversion of configuration at this carbon), rotation about the C—CHPhTi bond, and frontside ring closure with retention of configuration. Reversing the order of these processes to frontside ring opening with retention, rotation about the C—CHPhTi bond, and backside ring closure with inversion, produces the same result. This corresponds to the processes shown in blue in Scheme 13 that interconverts **1-trans-d** with **2-trans-d** and **1-cis-d** with **2-cis-d**.



The processes shown in Scheme 15 epimerize the CMeOTi ring carbon by electrophilic cyclopropanol ring opening, rotation about the TiOMeC—C bond, and ring closure with the same stereochemistry as the ring opening. There are two different pathways, one involving ring open-

[11]It is also possible that cationic titanium cyclopropoxide **1-trans-d-Ti$^+$**, generated by BF_3 abstraction of an isopropoxy group from **1-trans-d-Ti**, can ring open in an intramolecular fashion involving only a single titanium. Migration of the benzylic carbon to the highly electrophilic cationic titanium center during cleavage of the carbon–carbon bond should be more favorable than carbon migration to a neutral titanium center. This could explain why isomerization to other cyclopropanols via ring opening is not observed in the Kulinkovich hydroxycyclopropanation, but is made accessible with the addition of BF_3. This suggests that production of only **1-Ti** through the Kulinkovich hydroxycyclopropanation is a kinetic phenomenon, and that when BF_3 is present, ring closure to **1-Ti** is made reversible. Even if only a very small fraction of ring closures lead to **2-Ti**, successive ring closure and ring-opening cycles would eventually lead to a an equilibrium mixture of **1-Ti** and **2-Ti**. Epimerization of the benzylic carbon requires the involvement of two titanium centers.

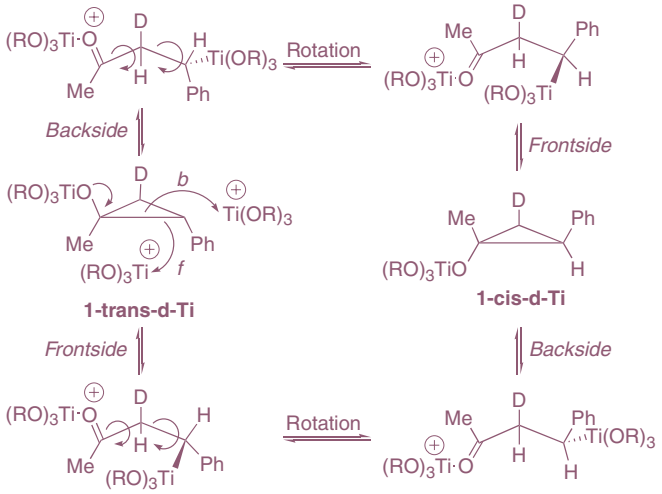
Scheme 14.

Scheme 15.

ing and ring closing with inversion of configuration and the other involving ring opening and ring closing with retention. These are the red processes in Scheme 13 that interconvert **1-trans-d** with **2-cis-d** and **1-cis-d** with **2-trans-d**.

The processes shown in Scheme 16 simultaneously epimerize both the CHPh and the CMeOTi ring carbons by electrophilic cyclopropanol ring opening, rotation about both the C—CHPhTi and TiOMeC—C bonds, and ring closure with the opposite stereochemistry. Microscopic reversibility requires equal rates for the processes of retention-double, rotation–inversion, and inversion-double rotation–retention. These are the purple processes in Scheme 13 that interconvert **1-trans-d** with **1-cis-d** and **2-trans-d** with **2-cis-d**.

The isomerizations of **1-trans-d** catalyzed by $Ti(O\text{-}i\text{-}Pr)_4$ and $BF_3{\cdot}OEt_2$ occur so rapidly that only fully equilibrated mixtures are seen. Therefore, it is not possible to tell whether any one of the three processes in Scheme 13 occurs more rapidly than another. In the slower isomerization catalyzed by *i*-PrMgCl and $Cl_2Ti(O\text{-}i\text{-}Pr)_2$ (Scheme 8), all three isomerized cyclopropanes formed at rates proportional to their equilibrium distributions. Therefore, it seems likely that the three processes of Scheme 13 all occur at similar rates.



It should be noted that the processes shown in Schemes 14–16 all involve ring opening, rotation, and ring closing. Two of these processes require that ring opening and ring closing occur with opposite stereochemistries. An alternative would be to have the ring opening and closing occur with only a single stereochemistry and to invert the -CHPhTi center by transmetallation. Normally, transmetallation occurs with retention of stereochemistry, but there are examples where inversion has been demonstrated (16).

Conclusions

We have demonstrated a rapid $Ti(O\text{-}i\text{-}Pr)_4$–$BF_3{\cdot}OEt_2$ catalyzed isomerization of cyclopropanols involving epimeriza-

© 2006 NRC Canada

Scheme 16.

tion at two cyclopropyl carbons. This double epimerization requires reversible opening of the cyclopropyl ring to a β-titanaketone and is consistent with two competing stereochemistries for ring closing and opening. Equilibrium constants between epimeric cyclopropoxides and between epimeric cyclopropanols were determined by measuring the effects of catalyst concentration on product ratios.

Experimental section

Kulinkovich hydroxycyclopropanation employing $BF_3{\cdot}OEt_2$

i-PrMgCl (4.2 mL, 2.0 mol/L solution in Et_2O, 8.4 mmol) in Et_2O (5 mL) was added dropwise over 5 min to a 0 °C solution of Ti(O-*i*-Pr)$_4$ (0.99 mL, 3.5 mmol), EtOAc (0.33 mL, 3.4 mmol), and *trans*-β-deuterostyrene (0.71 g, 6.7 mmol) in Et_20 (15 mL). After stirring for 1 min, $BF_3{\cdot}OEt_2$ (1.06 mL, 8.4 mmol) was added and the reaction mixture was allowed to warm to room temperature over 1 h. The reaction mixture was poured into a 10% aq. H_2SO_4 solution (20 mL) and was extracted with Et_2O (3 × 15 mL). The Et_2O extract was washed with a satd. aq. $NaHCO_3$ solution (20 mL) and H_2O (20 mL) and was dried ($MgSO_4$). Solvent was removed by rotary evaporation to give a colorless oil. ^{1}H NMR spectroscopy showed the formation of **1-trans-d** and **1-cis-d** (37%) and of **2-trans-d** and **2-cis-d** (19%), based on integration vs. THF added after workup as an internal standard. Recrystallization from pentane gave a 1:1 mixture of **1-trans-d** and **1-cis-d** (177 mg, 35%).

In a similar experiment, a 1:1 mixture of **1-trans-d** and **1-cis-d** (62 mg, 12%) was obtained by preparative TLC (silica gel, 10:1 pentane–ether, R_f = 0.2) along with a 1:1 mixture of **2-trans-d** and **2-cis-d** (R_f = 0.3) as an impure mixture with decomposition products. The ^{1}H NMR spectrum of this mixture of **2-trans-d** and **2-cis-d** was consistent with the chemical shifts previously reported for unlabelled cyclopropanol **2** (11).

For a 1:1 mixture of **1-trans-d** and **1-cis-d**: ^{1}H NMR (300 MHz, CD_2Cl_2) δ: 7.28 (t, *J* = 7.5 Hz, 2H), 7.21–7.13 (m, 3H), 2.31 (br d, *J* = 9.3 Hz, 1H, CHPh), 2.13 (br s, 1H, OH), 1.21 (d, *J* = 10.2 Hz, 0.5 H, CHD), 1.16 (s, 3H, Me), 0.97 (d, *J* = 6.6 Hz, 0.5 H, CDH). ^{2}H{^{1}H}NMR (76.7 MHz, CH_2Cl_2) δ: 1.21 (s, 1.00D), 0.98 (s, 1.01D). ^{13}C{^{1}H}NMR (75 MHz, CD_2Cl_2) δ: 139.4, 128.9 (2C), 128.7 (2C), 126.4, 57.8, 31.2, 20.9, 18.9 (t, J_{HD} = 24 Hz). HRMS (EI) calcd. for $C_{10}H_{11}D^{\cdot+}$ ($M^{\cdot+}$): 149.0950; found: 149.0950.

For a 1:1 mixture of **2-trans-d** and **2-cis-d**: ^{2}H {^{1}H} NMR (76.8 MHz, CH_2Cl_2) δ: 1.18 (s, 1.00D), 1.05 (s, 1.02D).

Isomerization of cyclopropanols 1 and 2 *with* deprotonation by a Grignard reagent

A solution of cyclopropanol **1** (25.0 mg, 0.168 mmol) in Et_2O (0.8 mL) was added by syringe over 1 min to a stirred solution of *i*-PrMgCl (92 μL, 2.0 mol/L solution in Et_2O, 0.18 mmol) in Et_2O (1.5 mL). After stirring for 30 min, Ti(O-*i*-Pr)$_4$ (47.8 mg, 0.168 mmol) in Et_2O (0.5 mL) was added. After 10 min, $BF_3{\cdot}OEt_2$ (53 μL, 0.42 mmol) was added and the reaction mixture was stirred for ~2 min before quenching. The mixture was cooled to ~5 °C and cold 10% aq. H_2SO_4 (4 mL) was added. This mixture was extracted with Et_2O (3 × 2 mL) and the combined Et_2O extracts were washed with satd. aq. $NaHCO_3$ (2 mL) and H_2O (3 mL) and dried over 4Å molecular sieves. Evaporation of the solvent gave a 4:1 mixture of cyclopropanols **1** and **2**, which were shown to be >95% pure by ^{1}H and ^{2}H NMR spectroscopy.

When the isomerization of **1** was performed on a 100 mg scale, recrystallization from pentane at –30 °C allowed separation of pure crystalline **1**. Successive crystallizations of the mother liquor at –78 °C gave a mixture of **2** and **1** in a 75:25 ratio that was free of any additional impurities.

For cyclopropanol **2** (11): ^{1}H NMR (500 MHz, CD_2Cl_2) δ: 7.31 (t, *J* = 7.4 Hz, 2H), 7.19–7.26 (m, 3H), 1.98 (dd, *J* = 9.5, 7.0 Hz, 1H, CHPh), 1.72 (br s, 1H, OH), 1.54 (d, *J* = 0.6 Hz, 3H, Me), 1.19 (tq, *J* = 6.6, 0.6 Hz, 1H, CH*H*), 1.05 (dd, *J* = 9.5, 5.9 Hz, 1H, C*H*H). ^{13}C {^{1}H} NMR (126 MHz, CD_2Cl_2) δ: 138.6, 129.0 (2C), 128.6 (2C), 126.4, 57.1, 30.8, 26.2, 20.4. NOESY 1D ^{1}H NMR (500 MHz, CD_2Cl_2): The methyl protons at δ 1.54 were pulsed and integrated for –3.000H, the resonance at δ 1.98 for the benzylic hydrogen cis to the methyl group integrated as +0.035H (3.5%), the resonance at δ 1.05 for the proton on C-3 cis to the methyl group integrated as +0.020H (2.0%), and the resonance at δ 1.18 for the proton on C-3 trans to the methyl group integrated as +0.004H (0.4%).

Isomerization of cyclopropanols 1 and 2 *without* deprotonation by a Grignard reagent

$BF_3{\cdot}OEt_2$ (53 μL, 0.42 mmol) was added to a solution of **1** (25.0 mg, 0.168 mmol) and Ti(O-*i*-Pr)$_4$ (47.8 mg, 0.168 mmol) in Et_2O (2.3 mL). After 2 min, the solution was cooled to 5 °C and quenched by the addition of cold 10% aq. H_2SO_4 (4 mL). This mixture was extracted with Et_2O (3 × 2 mL) and the combined Et_2O extracts were washed with satd. aq. $NaHCO_3$ (2 mL) and H_2O (3 mL) and dried over 4 Å molecular sieves. Evaporation of the solvent gave a quantitative yield of a 4:1 mixture of cyclopropanols **1** and **2**, which were shown to be >97% pure by ^{1}H and ^{2}H NMR spectroscopy.

Reaction of 1-trans-d with $BF_3{\cdot}OEt_2$ in the absence of Ti(O-*i*-Pr)$_4$

$BF_3{\cdot}OEt_2$ (53 μL, 0.42 mmol) was added to a solution of **1** (25.0 mg, 0.168 mmol) in Et_2O (0.8 mL). After 2 min, the

© 2006 NRC Canada

solution was cooled to 5 °C and quenched by the addition of cold 10% aq. H_2SO_4 (4 mL). This mixture was extracted with Et_2O (3 × 2 mL) and the combined Et_2O extracts were washed with satd. aq. $NaHCO_3$ (2 mL) and H_2O (3 mL) and dried over 4 Å molecular sieves. Evaporation of the solvent gave an oily solid that was >90% **1-trans-d** by ^1H and ^2H NMR spectroscopy and contained no other cyclopropanols.

Measurement of cyclopropanol–Titanium cyclopropoxide equilibria

In an NMR tube, cyclopropanol **1** (25 or 50 mg) was combined with Ti(O-*i*-Pr)$_4$ (1.0, 0.25, or 0.10 equiv.) in Et_2O-d_{10} (0.65 mL). Equilibrium was established immediately and spectra of the samples taken directly after the addition or after 20 min showed no differences. Peaks for the methine proton of the isopropanol and titanium isopropoxide were visible at δ 3.9 and 4.5, respectively.[12] The peaks for the benzylic protons of cyclopropanol **1** and the titanium cyclopropoxides of **1** gave resonances at δ 2.22 and 2.5, respectively. The percentage of **1** in the cyclopropanol form relative to the percentage in the titanium cyclopropoxide form was determined from the relative integrations of these two peaks (Table 1).

6. It has been demonstrated elsewhere (3*a*, 3*d*, 4) and observed in our lab that the Kulinkovich hydroxycyclopropanation yields exclusively cyclopropanol isomer **1**, bearing phenyl cis to methyl and does not give any of isomer **2**, where phenyl is trans to methyl. The origin of this stereochemical preference has been addressed computationally. Y.-D. Wu and Z.-X. Yu. J. Am. Chem. Soc. **123**, 5777 (2001).

Tetraazaoctaphyrin — A biimidazole-containing expanded porphyrin[1]

Jonathan L. Sessler, Bobbi L. Rubin, Marcin Stępień, Thomas Köhler, G. Dan Pantos, and Vladimir Roznyatovskiy

Abstract: A series of expanded porphyrins, incorporating biimidazoles and bipyrroles within their macrocyclic framework, has been synthesized. Insights into the complex conformational characteristics of these systems were obtained from two-dimensional NMR spectroscopic studies. The relative energy values for the various asymmetric structures inferred from these analyses were compared using DFT molecular modeling calculations.

Key words: macrocycles, expanded porphyrins, imidazoles, pyrroles, biimidazoles, supramolecular chemistry, heterocycles.

Résumé : On a réalisé la synthèse d'une série de porphyrines agrandies qui incorporent des biimidazoles et des bipyrroles dans le squelette de leur macrocycle. Sur les bases des études de spectroscopie RMN bidimensionnelle, on a extrait des donnés qui permettent de mieux comprendre les caractéristiques conformationnelles complexes de ces systèmes. On a comparé les valeurs relatives d'énergie de diverses structures asymétriques déduites de ces analyses à celles obtenues par des calculs de modélisation moléculaire sur la base de la théorie de la fonctionnelle de densité.

Mots clés : macrocycles, porphyrines agrandies, imidazoles, pyrroles, biimidazoles chimie macromoléculaire, hétérocycles.

[Traduit par la Rédaction]

Introduction

A new subdiscipline of porphyrin chemistry, involving the synthesis and study of large oligopyrrole macrocycles, so-called expanded porphyrins, was instigated by the serendipitous discovery of sapphyrin by Woodward and co-workers in the mid 1960s (1). In the decades since that time, the field of expanded porphyrin chemistry has grown into a large and vibrant subfield of macrocyclic chemistry (2). Expanded porphyrins have been studied in the context of molecular recognition with anionic, cationic, and neutral substrates (3). Part of what is driving this research is the promise that these systems show in various practical applications, ranging from drug development to anion recognition (4–7). Work in this area has also been inspired by less prosaic motivations, including the synthetic challenge of constructing new oligopyrrolic macrocycles and their inherent aesthetic appeal.

Most known expanded porphyrins, with the exception of Schiff-base macrocycles, have been constructed from pyrrole and its closely related heterocyclic analogues, furan, thiophene, and selenophene. Recently, efforts have shifted towards incorporating imidazoles and biimidazoles into porphyrin-like structures. Youngs et al. (8) reported the synthesis of a series of cyclophane complexes, or porphyrinoids, which contained imidazoliums incorporated into the skeletal framework of the macrocycle. In 2003, the research groups of Allen (9) and Nonell (10) separately reported the first biimidazole-based porphycene analog, imidacene. There have also been a number of reports that describe the incorporation of imidazole or imidazolium cations into other macrocyclic structures (11–14). These systems show great promise in both anionic and cationic recognition and are made especially interesting because they are potentially capable of recognition both inside and outside the skeletal framework. In spite of this promise, biimidazoles, as opposed to imidazoles, have yet to be incorporated into expanded porphyrin-type frameworks. We report here the first example of such a system, namely 3,6,21,24-tetraaza[32]octaphyrin(1.0.1.0.1.0.1.0).

Results and discussion

The synthesis of tetraazaoctaphyrin target **3** was carried out in a single step via the condensation of biimidazole **1** with bis-α-free bipyrrole **2** under dilute conditions (Scheme 1). Biimidazole **1a** was prepared according to the literature and **1b** was synthesized using an extension of this same basic methodology (10). Bipyrroles **2a**–**2c** were synthesized according to the literature (15, 16).[4] The condensation of biimidazole **1** with bipyrrole **2** was performed in a

 doi:10.1139/V06-068 © 2006 NRC Canada

methanol–tetrahydrofuran (THF) mixture using trifluoroacetic acid (TFA) as the acid catalyst. After column chromatographic work-up over silica gel, tetraazaoctaphyrins **3a**–**3e** were obtained in yields ranging from 26% to 69%, depending on the substrates used. The compounds obtained in this way are unstable when exposed to oxygen and decompose over time. Thus, they were stored in a freezer under a blanket of argon. Under these conditions, little decomposition was seen for a period of 1 week. Elemental analysis was used as a means of characterization and repeatedly resulted in total carbon, hydrogen, and nitrogen counts of 95%–96% of the theoretical values. XPS analysis revealed the presence of silicon and oxygen, which is supported by a singlet near 0 ppm observed in the ^{1}H NMR spectra of **3a**–**3e**, attributable to a dimethyl siloxane compound. Efforts to remove the impurity included recrystallization, trituration, and extraction, but unfortunately all proved unsuccesful. If, however, the carbon, hydrogen, and nitrogen percentage is normalized to 100% and compared with a theoretical percentage of the same elements, thus accounting for the amount of impurity in these percentages, the experimental results fall within acceptable error values (i.e., $\Delta < 0.20\%$). In an additional experiment, the solvent was passed through a blank column under identical conditions and the siloxane was identified in the eluate by XPS and ^{1}H NMR spectroscopy, thus establishing the silica gel as the likely source of the impurity.

The UV–vis absorption spectrum of **3b**, the prototypical tetraazaoctaphyrin chosen for detailed study, is characterized by a Soret-type band at 299 nm and a Q-type band at 633 nm (Fig. 1). These features, particularly the latter long-wavelength absorption band, are considered diagnostic of an extended conjugated system (17). Dilute solutions of tetraazaoctaphyrin **3** in methylene chloride are blue and fluoresce red (Fig. 2). For the fluorescence emission experiments, excitation was performed at 578 nm, while the emission maximum was observed at 670 nm.

The one-dimensional ^{1}H NMR spectrum of **3b** recorded in dichloromethane-d_2 is shown in Fig. 3. It is apparent from an inspection of this spectrum that the solution structure of **3b** does not exhibit the fourfold symmetry implied by the representation of the macrocycle given in Scheme 1. The actual conformation has only twofold symmetry, which can be inferred from the doubled number of peaks in the aromatic and alkyl regions. The signal at 9.87 ppm integrates to two protons and most likely corresponds to a pyrrole NH proton. When studied as a solution in DMSO-d_6, an additional peak with the same integral intensity can be observed at 10.8 ppm. In dichloromethane-d_2, this signal is broadened by exchange and cannot be observed. Such a solvent dependence is typically found for imidazole NH protons. Based on these findings, the signal is assigned as an imidazole NH; however, its exact placement on the biimidazole unit could not be determined. Chemical shifts of the NH and meso protons indicate an absence of overall macrocyclic aromaticity.

The doubled spectral pattern, indicative of symmetry lowering, is also seen for the other tetraazaoctaphyrin derivatives. It should, however, be noted that the doubled signals assigned to the dominant species present in solution are often accompanied by ones ascribable to an impurity, which gives rise to a single set of peaks. The admixture inferred on this basis cannot be separated by chromatography (all samples yield a single peak on the HPLC chromatogram). While the identity of the additional species could not be ascertained, it is thought that it may correspond to a different symmetrical conformation for each of the different derivatives of **3**.

Fig. 1. Absorbance (—) and fluorescence spectra (----) of **3b** in CH_2Cl_2.

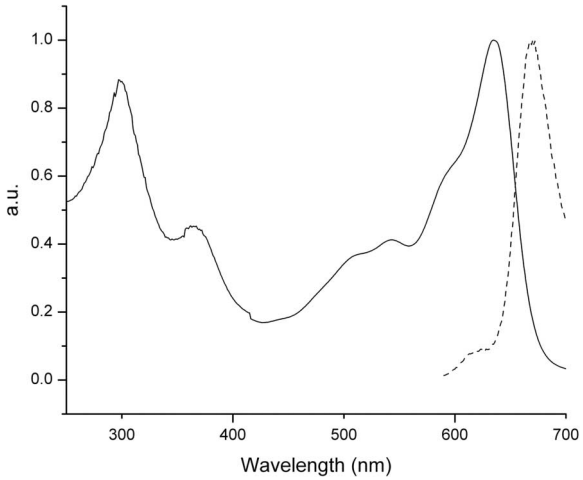

Fig. 2. Dilute solution tetraazaoctaphyrin **3b** in methylene chloride in the absence (left) and presence (right) of an illuminating black light (365 nm).

The assignment of the signals presented in Fig. 3 follows the labeling pattern given in Scheme 2. These assignments were deduced using two-dimensional NMR spectroscopy (COSY and ROESY maps). Figure 4 shows representative expansions of the COSY spectrum, used to establish connectivity within the aryl rings and alkyl chains. There is a significant crowding of signals in the alkyl region, which was resolved on the COSY map. Further insight into the structure and conformation of **3b** was gained from an analysis of the ROESY spectrum (Fig. 5).

Based on selected ROE cross-peaks, it was possible to assign unequivocally each of the signals to one of the two

nonequivalent subunits 1 and 2 (Scheme 3). Each of the subunits contains one pyrrole ring and one imidazole ring linked by a meso-bridging carbon atom. In addition, four special ROE correlations provided the information necessary to determine the arrangement of constituent rings in each subunit. The meso signal of subunit 1 ($meso_1$, 7.04 ppm) correlates with the ortho signal of the adjacent aryl ring ($ortho_1$, 7.59 ppm, peak A in Fig. 5), as well as with one of the ethyl CH_3 signals (β-Et1, 1.04 ppm, peak C). In the other subunit, the meso signal ($meso_2$, 6.95 ppm) only correlates with the respective ethyl group (β-Et2, 1.21 ppm, peak D) and shows no cross-peak to the ortho signal ($ortho_2$, 7.72 ppm). However, the latter yields an unexpected correlation with the pyrrolic NH (peak B). This latter correlation can be rationalized by assuming a "kinked" conformation for subunit 2, in which the meso CH fragment is turned away from the aryl ring (Scheme 3).

Macrocycle **3** should contain two subunits of type 1 and two of type 2 combined in such a way that the entire structure exhibits twofold symmetry. The four arrangements that meet the above criterion are shown in Fig. 6. In arrangements A and B, the sequence of subunits in the ring is 1–2–1–2, whereas, in arrangements C and D, the sequence is 1–1–2–2. Furthermore, the aryl rings pointing towards the inside of the macrocycle are positioned on the same side of the macrocyclic plane (in arrangements A and C) or on the opposite sides (B and D). As a result, we obtain four distinct conformers, two of which are chiral (A and D).

Inspection of the molecular models leads to the inference that arrangement B is the least congested of the four conformers and hence the one with the lowest energy. This conclusion is supported by DFT calculations performed at the TZ2p atomic level. Optimized geometries and relative

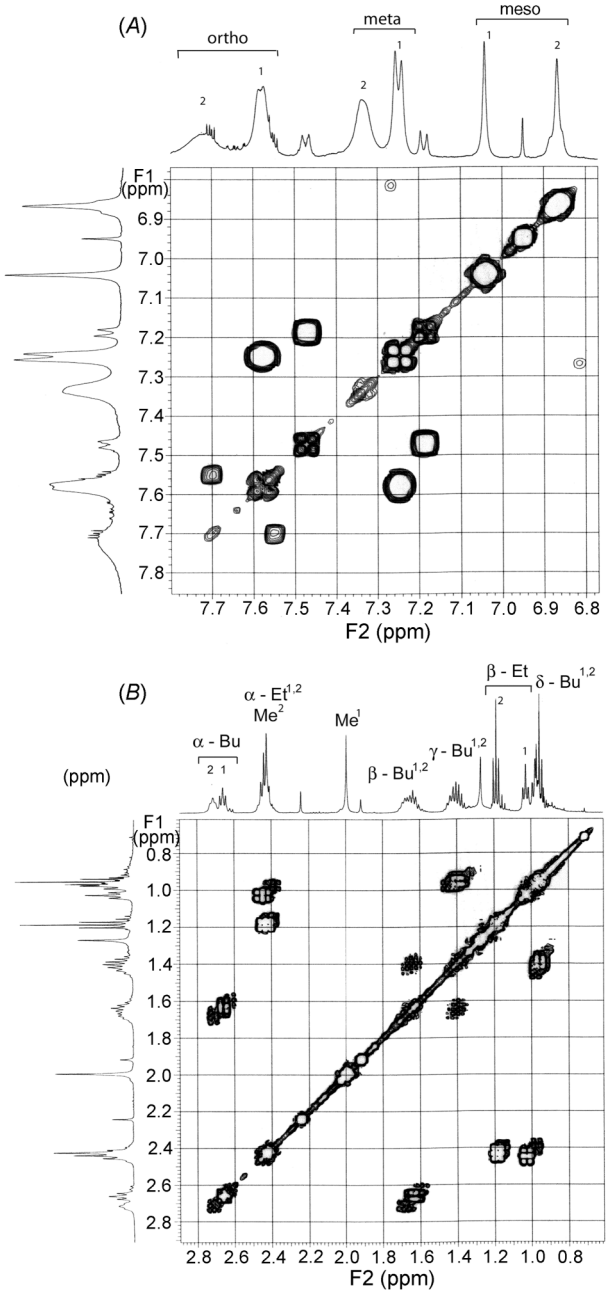
Fig. 4. ^{1}H COSY spectrum of **3b** (500 MHz, CD_2Cl_2, 298 K). Parts (*A*) and (*B*) show expansions of the aromatic and aliphatic regions, respectively. Peaks corresponding to the symmetrical form are not labeled.



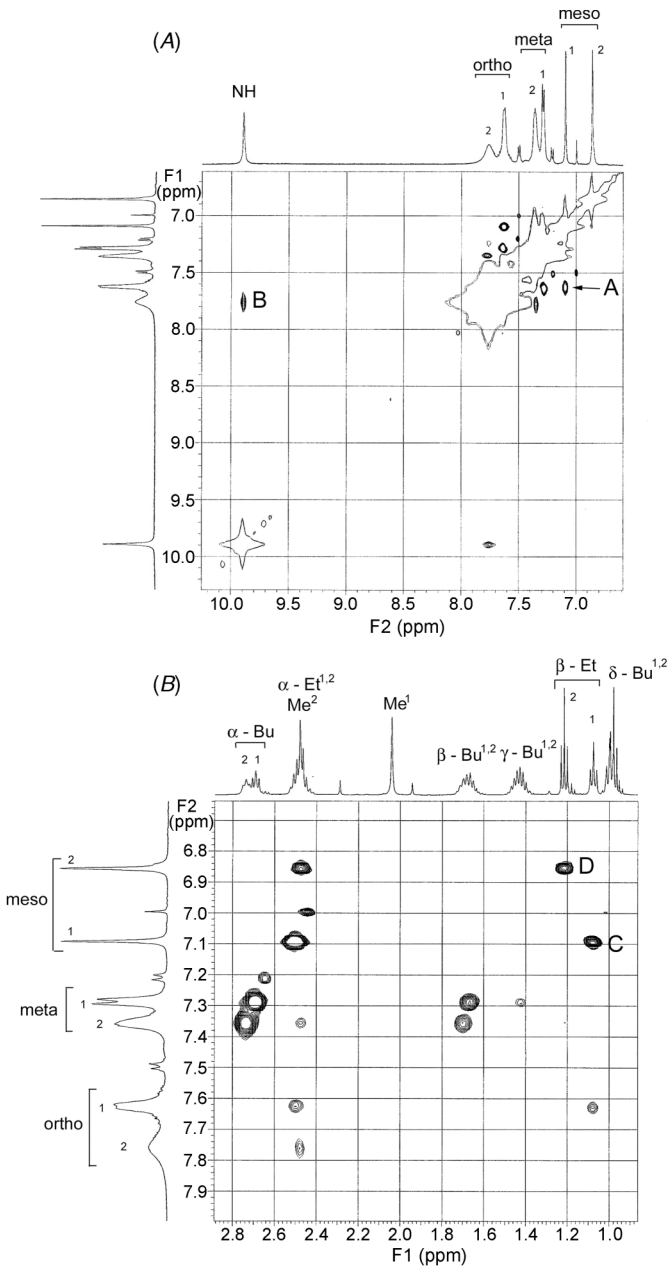


Fig. 5. ^{1}H ROESY spectrum of **3b** (500 MHz, CD_2Cl_2, 298 K). Parts (*A*) and (*B*) show the expansions of aromatic–aromatic and aliphatic–aromatic regions, respectively. The spectrum is phased to give positive ROE crosspeaks.

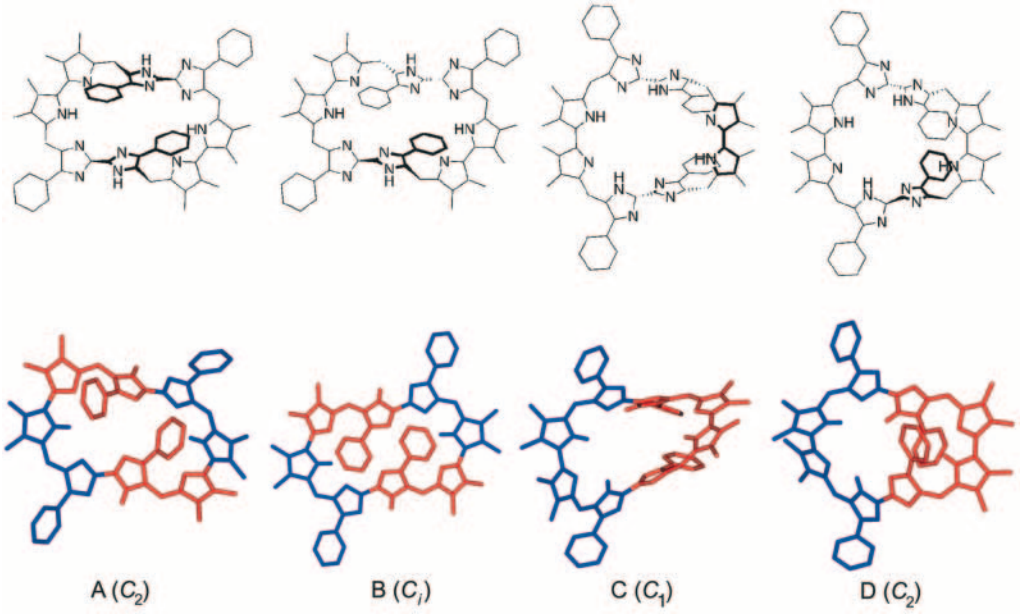
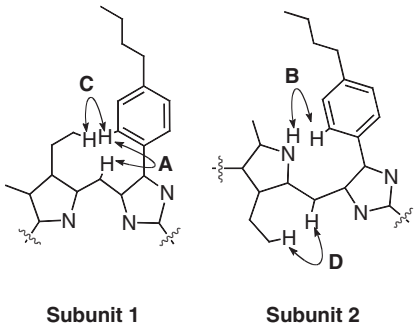


energy values are given in Table 1. Conformer B is the most stable, closely followed in energy by conformer D (Fig. 6); not surprisingly, conformations A and C are higher in energy, likely reflecting the cis arrangement of the phenyl rings within the cavity. Additionally, conformer C, expected to have a symmetry plane (C_s symmetry), collapsed upon optimization into a completely nonsymmetrical geometry.

The conformation of **3** observed in solution appears to be rigid. No exchange cross-peaks in the room temperature ROESY and NOESY spectra have been observed between topologically equivalent signals (e.g., meso$_1$ and meso$_2$); nor has any exchange been noted between the major asymmetrical form and the symmetrical admixture mentioned earlier. In point of fact, the lines remain sharp even at 130 °C in DSMO-d_6. However, significant broadening is observed at room temperature for the ortho and meta signals of the aryl rings (Fig. 3). This broadening is most readily interpreted in terms of the aryl moieties being in an unsymmetrical environment and undergoing slow rotation, conclusions that are consistent with the nonplanar conformation noted above.



Interestingly, the conformation proposed for **3** has no apparent precedent among the structures of octaphyrins

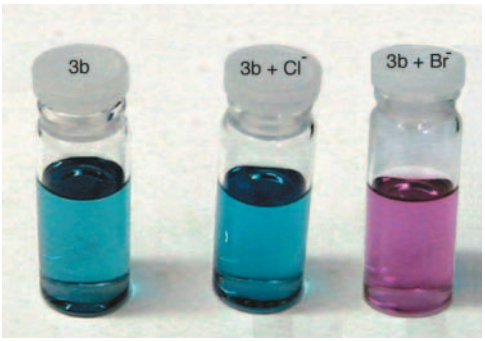
reported to date. For [32]octaphyrin(1.0.1.0.1.0.1.0), reported by Vogel and co-workers (18), a D_2-symmetrical figure eight conformation with transoid bipyrrole subunits located at the figure eight intersection was observed in the crystal structure. A similar conformation was conjectured for a closely related macrocycle obtained by Setsune et al. (19). Another type of figure eight conformation was observed for [36]octaphyrin(1.1.1.1.1.1.1.1), reported by Furuta, Osuka and co-workers. (20), and for its thiophene analogue obtained by Spruta and Latos-Grażyński (21). However, the presence of four imidazole rings in system **3** and a different substitution pattern (aryl groups at the β-pyrrole positions) may explain why this new macrocycle adopts a conformation different from that of its all-pyrrole analogue (18).

Conclusion



The design and synthesis of a novel expanded porphyrin has been described. The series of tetraazaoctaphyrins **3a**–**3e** were formed from the condensation of biimidazole dialdehydes **2a** and **2b** with bis-α-free bipyrroles **2a**–**2c**. The high density of NH functionality makes these systems of potential interest as anion receptors. Initial qualitative tests of this postulate have been performed on tetraazaoctaphyrin **3**. We have found that the neutral host (**3b**) undergoes a naked-eye detectable color change in the presence of fluoride, bromide

Table 1. Minimization energy values for molecular arrangements A–D.

Arrangement	Energy (kcal/mol)	Relative energy
A	–321 084.01	16.76
B	–321 067.25	0
C	–321 053.80	13.45
D	–321 064.63	2.62

Note: 1 cal = 4.184 J.

(Fig. 7), cyanide, hydroxyde, acetate, nitrate, dihydrogenphosphate anions (studied in the form of their respective tetrabutylammonium salts). On the other hand, no change in the spectral properties of **3b** was noted upon addition of chloride, iodide, hypochlorate, nitrite, benzoate, and hydrogensulfate anions. Such observations lead us to propose that this or other neutral biimidazole-incorporated expanded porphyrins may emerge as useful anion sensors.

Experimental

General information

All reagents and solvents were purchased from Sigma-Aldrich Corporation, Fischer Scientific, or Fluka and used without further purification with the following exceptions. Dichloromethane was dried by distillation under argon over calcium hydride. Dimethylformamide was dried by passage through two columns of molecular sieves. Tetrahydrofuran (THF) was dried by passage through two columns of activated alumina. Toluene was dried by passage through two columns of activated alumina. *N*-Bromosuccinimide was recrystallized from boiling water. For column chromatography, silica gel (Scientific Adsorbents Inc., particle size 32–63 μm) was used as the immoble phase.

*1-((2-(Trimethylsilyl)ethoxy)methyl)-2-(1-((2-(trimethylsilyl)ethoxy)methyl)-5-formyl-4-*p*-tolyl-1*H*-imidazol-2-yl)-4-*p*-tolyl-1*H*-imidazole-5-carbaldehyde*

4,4′-Dibromo-1,1′-bis[(trimethylsilyl)ethoxymethyl]-2,2′-biimidazole-5,5′-dicarbaldehyde (10) (1.68 mmol) and *p*-methylphenyl boronic acid (3.36 mmol) were degassed for 20 min in 9.2 mL of 2 mol/L sodium carbonate and 4 mL of ethanol by purging the solution with argon. Palladium tetrakistriphenylphosphine (10% mol) was added and the reaction was heated to reflux for 7 h using an oil bath. The reaction flask was removed from the oil bath, cooled, and the mixture was diluted with ethyl acetate, dried with sodium sulfate, filtered, and concentrated in vacuo to give an oil. Column chromatography was performed using silica gel as the solid support, eluting initially with hexanes and slowly increasing the polarity to 20% ethyl acetate in hexanes. Desired fractions were combined, concentrated in vacuo, and dried to give an off-white solid in 89% yield. ^{1}H NMR ($CDCl_3$, 400 MHz) δ: –0.13 (m, 9H), –0.08 (m, 9H), 2.02 (s, 3H), 2.42 (s, 3H), 3.58 (m, 4H), 4.10 (m, 4H), 6.31 (s, 2H), 6.37 (s, 2H), 7.30 (d, J = 8.0 Hz, 4H), 7.61 (d, J = 7.6 Hz, 4H), 9.88 (s, 1H), 9.96 (s, 1H). ^{13}C NMR δ: 14.17, 17.86, 21.35, 60.39, 66.41, 127.14, 127.55, 128.75, 128.95, 129.29, 120.49, 129.525, 139.71, 141.16, 154.49, 171.17, 181.00. HR-MS (CI^+) m/z ($M + H^+$) calcd. for $C_{22}H_{18}N_4O_2$: 371.1508; found: 371.1521.

*2-(5-Formyl-4-*p*-tolyl-1*H*-imidazol-2-yl)-4-*p*-tolyl-1*H*-imidazole-5-carbaldehyde (1a)*

The previous compound (0.457 mmol) was dissolved in 10 mL ethanol. Ten milliliters of 10% HCl was added and the reaction was heated to reflux for 1 h using an oil bath. The flask was removed from the oil bath, cooled, and the solution was carefully neutralized with 10% aqueous sodium carbonate. At this juncture, a solid precipitated out of solution. It was filtered and washed with ice-cold water, and dried under vacuum to give the desired compound in the form of a white solid in 78% yield; mp 160–180 °C. ^{1}H NMR (400 MHz, DMSO-d_6) δ: 2.37 (s, 6H), 7.33 (d, J = 7.6 Hz, 4H), 7.79 (d, J = 8.4 Hz, 4H), 9.88 (s, 2H). ^{13}C NMR (500 MHz, DMSO-d_6) δ: 21.00, 125.30, 126.81, 128.73, 128.97, 129.30, 129.58, 129.72, 133.12, 139.25, 140.01, 182.60. HR-MS (CI^+) m/z ($M + H^+$) calcd. for $C_{22}H_{18}N_4O_2$: 371.1508; found: 371.1521.

General procedure for the preparation of tetraazaoctaphyrin derivatives (3)

Biimidazole dialdehyde **1** (0.184 mmol) was dissolved in 200 mL of dry 2:1 methanol–THF containing 1 mL of TFA. Bipyrrole **2** (0.184 mmol) was separately dissolved in 40 mL of the same solvent ratio and placed in an addition funnel. The bipyrrole solution was added dropwise to the biimidazole solution over 30 min and after several hours of stirring at room temperature, an additional 1 mL of TFA was added to the reaction. Stirring was continued overnight with the reaction left open to the atmosphere. After 12 h, the deep blue-black solution was concentrated in vacuo to give a deep purple oil, which was taken to dryness on the vacuum line to remove any residual trifluoroacetic acid. Column chromatography was performed twice over silica gel, eluting initially with methylene chloride before the polarity of the eluent was slowly increased to 3% methanol in methylene chloride. The desired fractions were combined and concentrated in vacuo to give a lustrous blue-black solid. The material was then redissolved in methylene chloride, washed with 5% aqueous sodium bicarbonate, dried over sodium sulfate, filtered, concentrated in vacuo to a blue-black solid, and dried under vacuum. The solid was triturated with distilled pentane to remove any remaining grease. The desired tetraazaoctaphyrin was obtained as a blue-black lustrous solid.

Elemental analysis was pursued as a means of characterization and repeatedly resulted in carbon, hydrogen, and nitrogren counts of 95%–96% of the theoretical values. XPS analysis revealed the presence of 3.14% silicon in the sample of **2.5b**. Taking into account this silicon percentage, the calculated impurity reveals 1.40 equiv. of the siloxane for each equivalent of the host **2.5b**. Anal. calcd. for $C_{84}H_{92}N_{12}\cdot 1.4SiO_2(CH_3)_2$: C 74.72, H 7.20, N 12.05; found: C 74.71, H 7.09, N 12.22. Efforts to remove the impurity included recrystallization, trituration, and extraction, but unfortunately all proved unsuccesful.

*2,7,20,25-Tetra-*p*-butylphenyl-11,12,15,16,29,30,33,34-octaethyl–3,6,21,24-tetraaza[32]octaphyrin(1.0.1.0.1.0.1.0) (3a)*

The compound was obtained from the condensation of biimidazole **1b** (10) with bipyrrole **2b** (16)[4] in 69% yield, following the general procedure given above. Molecular modelling studies

Molecular modelling studies were performed using semi-empirical calculations at the PM3 level, using HyperChem® V7.1, for preoptimization. Density functional theory (DFT) calculations were then performed using PRIRODA-04 (22). A PBE functional that includes the electron density gradient was used. The TZ2p atomic basis sets of grouped Gaussian functions were used to solve the Kohn–Sham equations. The criterion for convergence was to reach a difference in energy gradient between two sequential structures below 0.01 kcal/mol/Å (1 cal = 4.184 J). A PDB file for each optimized structure is included in the Supplementary information.[5]

Toward the total synthesis of lophotoxin — New methodologies and synthetic strategies[1]

Peter Wipf and Michel Grenon

Abstract: Our recent progress toward the synthesis of the furanocembranolide lophotoxin (**1**) is disclosed. Strategies for the stereoselective incorporation of the C_{13} stereocenter by a catalytic desymmetrization of a cyclic *meso*-anhydride, as well as a novel 1,6-addition reaction of organocuprates to unsaturated [1,3]dioxin-4-ones are discussed. Preliminary results on the development of a rhodium-catalyzed asymmetric 1,6-addition reaction are also mentioned. Finally, modifications of a previously reported transition-metal-catalyzed cyclization reaction involving α-propargyl β-keto esters allow furan ring formation either under thermal conditions or by microwave irradiation.

Key words: 1,6-addition, organocuprates, catalytic desymmetrization, furan cyclization, microwave.

Résumé : Nos plus récents progrès concernant la synthèse totale du furanocembranolide lophotoxine (**1**) sont décrits. Des stratégies pour l'incorporation stéréosélective du substituant en C_{13} par la désymétrisation catalytique d'un anhydride cyclique *meso*, ainsi qu'une nouvelle réaction d'addition 1,6-conjuguée d'organocuprates sur des [1,3]dioxin-4-ones insaturées sont discutées. Des résultats préliminaires sur le dévelopement d'une réaction d'addition 1,6-conjugée asymétrique catalysée par le rhodium sont aussi mentionnés. Finalement, la modification d'une réaction de cyclisation catalysée par un métal de transition et mettant en jeu l'α-propargyl β-céto ester permet la formation d'un furane soit sous certaines conditions thermiques ou par irradiation aux micro-ondes.

Mots clés : addition 1,6-, organocuprates, désymétrisation catalytique, cyclisation de furane, microonde.

Introduction

Lophotoxin (**1**) is a member of the furanocembranolides (1), a growing class of natural products that comprise a number of highly functionalized cyclic diterpenes (Fig. 1). This compound is found in a number of marine invertebrates (gorgonian octocorals) located in tropical and subtropical waters (2). Lophotoxin acts as a potent neurotoxin by binding selectively and irreversibly to the Tyr^{190} residue present in the α-subunit of nicotinic acetylcholine receptors, leading to respiratory depression, paralysis, asphyxia, and ultimately death (3). SAR studies have demonstrated that the key structural elements responsible for this unique biological activity can be attributed to the C_7–C_8 epoxide and the lactone oxygens, allowing for a direct structural correlation of the pharmacophore in **1** with acetylcholine (4).

The presence of a 2,3,5-trisubstituted furan ring adjacent to a trans-trisubstituted epoxide, along with an epoxidized butenolide imbedded in a strained 14-membered macrocycle are the most prominent structural features of this molecule. In addition to the interesting biological activity displayed by this compound, the synthetic challenge offered to organic chemists has prompted a number of research groups to develop strategies aimed at the total synthesis of lophotoxin (5, 6) and other furanocembranolides (7–10).

Our research group has been interested in this class of molecules for a few years and we have recently disclosed a method to construct the 2-alkenyl-3,5-trisubstituted furan (**2**) from the simple acyclic α-propargyl β-keto ester (**3**) (Fig. 1) (11). This method is based on a general strategy for the construction of five-membered heterocycles (12) and features the use of a palladium catalyst and an inorganic base to induce the 5-exo-dig cyclization and concomitant aromatization to the furan ring. High levels of selectivity for the (*Z*)-isomer **2** were obtained as a result of the facial-selective protonation of an allene intermediate. With the furan in hand, the vinylsilane moiety was further elaborated to the C_{19} methyl group attached to the trans-trisubstituted epoxide in lophotoxin.

Some issues that were not addressed in our previous communication concern the installation of the C_{13} acetate group as well as a method to introduce the C_1 isopropenyl group in a stereoselective way. Previous synthetic work by others has either exploited the chiral pool (8, 9), a diastereoselective alkylation (5), or an intramolecular Nozaki–Hiyama–Kishi reaction (7) to introduce the isopropenyl group, whereas the

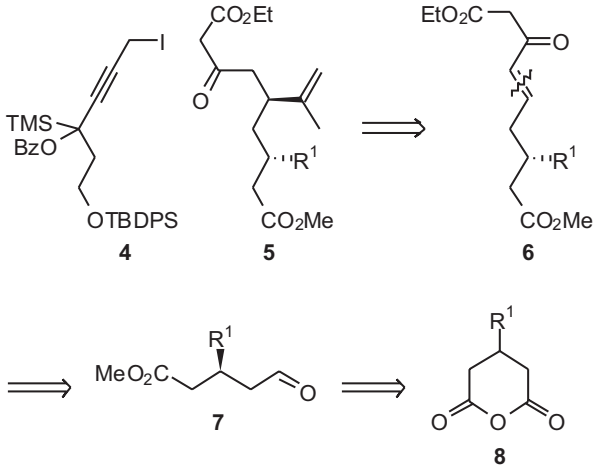
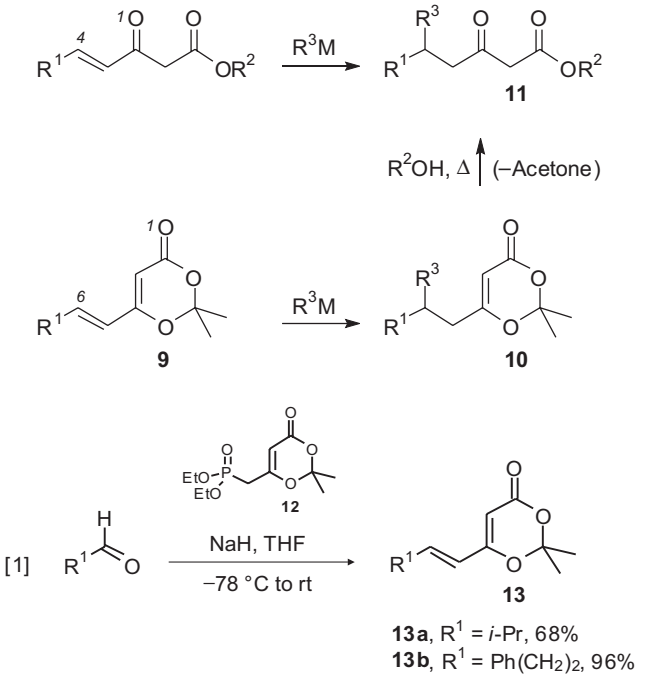
Fig. 1. Lophotoxin and the structures of synthetic intermediates.

configuration of the C_{13} substituent was not addressed (5, 6) or of no concern (7–9). In this paper, we wish to report on our findings for the stereoselective introduction of these two stereogenic carbons. A modification of our initial set of conditions, which uses microwave irradiation for the furan cyclization reaction, is also disclosed.



Results and discussions

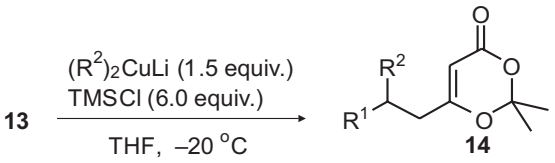
β-Keto esters, such as **3**, are rapidly constructed by an alkylation reaction with propargylic iodide (**4**) (11) (Scheme 1). Segment **5** would need to be constructed in a stereocontrolled fashion. Further simplification of **5** provides **6**, which can be assembled from aldehyde **7** and an appropriate phosphonate by a Horner–Wadsworth–Emmons olefination. Finally, the highly symmetrical nature of aldehyde **7** led us to consider the use of a catalytic desymmetrization reaction of cyclic *meso*-anhydride (**8**) with an alcohol (13) to create the stereocenter at C_{13}.



We initially envisioned that a conjugate 1,4-addition of an isopropenyl group to the unsaturated β-keto ester would be a straightforward means to introduce the C_1 side chain in **6**. However, owing to the ease of enolization of this particular type of substrate, we opted for an indirect route in which the 1,3-dicarbonyl unit would be revealed at a later stage (Scheme 2). We further anticipated that confinement of the β-keto ester to a [1,3]dioxin-4-one ring system, such as in **9**, would solve the problem, however, instead of a conjugate 1,4-addition, this required an extended 1,6-additon reaction. Thermolysis of adduct **10** in the presence of an alcohol (R^2OH) would then provide a number of different β-keto esters **11**, and an even greater number of derivatives could be obtained if other heteronucleophiles such as thiols or amines were to be used instead.

To test the feasibility of this route, [1,3]dioxin-4-ones (**13**) were prepared from phosphonate (**12**) (14) and either isobutyraldehyde or hydrocinnamaldehyde according to a literature procedure (15) and used as model substrates (eq. [1]).

Scheme 1. Strategy for the incorporation of the C_{13} stereogenic carbon center.



Scheme 2. Strategy for the incorporation of the C_1 stereogenic carbon center.

After some optimization of the reaction conditions, it was found that the addition of these extended Michael acceptors to solutions of Gillman-type organocuprates (R_2CuLi) containing chlorotrimethylsilane (16) at low temperature cleanly afforded the desired 1,6-addition products in high yields (Table 1). A small survey of different organocuprates revealed that simple alkyl groups were readily added (Table 1, entries 1–4), as were aromatic (Table 1, entries 5 and 6) and even silicon-based groups (17) (Table 1, entries 7 and 8). The addition of sterically encumbered organocuprates such as $(t\text{-Bu})_2CuLi$ also proceeded to afford the 1,6-addition adduct, albeit in low yields (Table 1, entries 9 and 10). However, the low yields observed were not because of a lack of reactivity during the 1,6-addition, but rather the result of a

nonselective protonation step of the intermediate extended silyl enol ether formed after the 1,6-addition. No reaction occured when less reactive sp-hybridized organocopper reagents (RC≡CCu) or organocuprates [$(RC{\equiv}C)_2CuLi$] were used. It should be pointed out that in all cases studied using these sets of conditions, no adducts derived from 1,4- or 1,2-addition were isolated (18).

Having established that the extended conjugate addition reaction was possible, we next turned our attention toward the preparation of fragment **5** for our synthesis of lophotoxin. As we discussed previously, we planned on introducing the stereocenter at C_{13} by a catalytic desymmetrization reaction on cyclic *meso*-anhydrides **8** (Scheme 3). These were conveniently prepared according to a literature procedure (19) from commercially available diethyl 3-hydroxyglutarate by protection of the free hydroxyl group as a silyl ether to give **15**, followed by exhaustive saponification and dehydration of the resulting disodium acid salt with acetic anhydride. The TBDMS-protected cyclic anhydride **8a** was obtained as an off-white solid upon recrystallization of the crude material after the dehydration step, whereas the TBDPS-protected anhydride **8b** had to be filtered rapidly over a pad of silica gel pretreated with acetic anhydride to remove silanes before recrystallization was successful.[3]

Although there are a number of reported procedures to effect the desymmetrization of the cyclic anhydride **8a** (20–22), we opted for a method recently developed by Deng and co-workers (23) that employs modified cinchona alkaloids, initially adapted for the catalytic asymmetric dihydroxylation of alkenes (24) (Table 2). Using substoichiometric amounts (30 mol%) of $(DHQD)_2AQN$ in the presence of an excess of methanol at low temperature, Deng and co-workers (23) converted cyclic *meso*-anhydrides **8** (R^1 = Me, *i*-Pr) to acids **16** in good yields and high values of ee (Table 2, entries 1 and 2). When these optimized conditions were applied to the TBDMS-protected cyclic anhydride **8a**, a similar conversion to the desired acid was obtained (Table 2, entry 3). Longer reaction times resulted in higher conversions (Table 2, entry 4), however extensive desilylation of the product in both cases precluded the use of this substrate. Fortunately, when the TBDPS-protected cyclic anhydride **8b** was submitted to the desymmetrization reaction, conversions of 75%–85% were obtained, and more importantly, ^{1}H NMR analysis of the crude mixture indicated that no desilylation of **16** had occurred (Table 2, entry 5). An aliquot of the crude acid, accumulated from seven desymmetrizations under identical conditions, was reduced to the corresponding alcohol and treated with dil. HCl to provide the cyclic lactone **18** (Scheme 4) (25). Comparison of the chiral HPLC trace of this material with the racemic material prepared using quinuclidine as the organocatalyst (Table 2, entry 7) showed that the desymmetrization reaction occurred with a high level of enantioselectivity (95% ee). Finally, conducting the desymmetrization of **8b** at a higher temperature (–20 °C, Table 2, entry 6) resulted in a com-

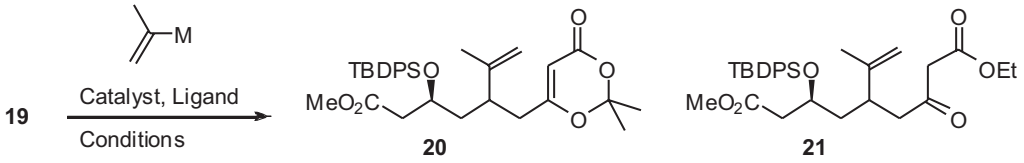
Scheme 4. Preparation of furan cyclization precursor **22**. Reagents and conditions: (*a*) BH_3·DMS, THF, rt, 15–17 h; (*b*) 10% HCl, rt, 1 h (38% from **8b**); (*c*) satd. aq. $NaHCO_3$, rt, 20 min (71% from **8b**); (*d*) TPAP (5 mol%), NMO, 4 Å MS, MeCN–CH_2Cl_2 (1:9), 30 min; (*e*) **12**, NaH, THF, –78 °C to rt, 1 h (49%, two steps); (*f*) CuI, 2-lithiopropene, TMSCl, THF, –20 °C, 16 h (94%, 1:1 dr); (*g*) EtOH, toluene, Δ; (*h*) NaH, **4**, THF, 0 °C to rt (77%, two steps).

plete conversion to the acid, albeit with lower selectivity (88% ee).

With an efficient and stereoselective solution for introducing the protected alcohol at C_{13}, we proceeded with our synthesis of fragment **5**. Reduction of the acid function in **16** with the borane – dimethyl sulfide complex followed by basic aqueous work up gave the alcohol **17** in good overall yield from cyclic *meso*-anhydride **8b**. Ley–Griffith oxidation of this alcohol to the aldehyde (26) followed by a Horner–Wadsworth–Emmons olefination with the stabilized phosphonate **12** (15) provided the 1,6-addition precursor **19** as a single isomer. Using 3 equiv. of the organocuprate derived from 2-lithiopropene, addition to the extended Michael acceptor occurred smoothly to provide **20** in high yield as a 1:1 mixture of diastereomers. Thermolysis of the [1,3]dioxin-4-one ring with ethanol in refluxing toluene revealed the β-keto ester (**21**) (see Table 3) that was then alkylated with the previously reported iodide **4** (11) to give the furan cyclization precursor **22** in good yield as a mixture of stereoisomers.



We were not surprised by the lack of stereocontrol obtained for the 1,6-addition of the organocuprate to [1,3]dioxin-4-one (**19**) (Scheme 4). By analogy to the diastereoselective 1,4-addition of copper-based organometallic reagents to Michael acceptors possessing a stereogenic center at the δ position under substrate control (27), we anticipated low levels of selectivity for the 1,6-addition. This gave us the opportunity to develop a catalytic asymmetric variant of the 1,6-addition reaction, and since stoichiometric copper-based reagents were effective, we initially screened for copper catalysts (Table 3). These studies proved quite disappointing; indeed, using conditions optimized for the catalytic asymmetric 1,4-addition of diorganozincs to enones (28), no reaction occurred and the starting material was recovered unchanged (Table 3, entry 1). The addition of chlorotrimethylsilane had no effect on the outcome of the reaction and even the use of Et_2Zn, which is often employed as a nucleophile in catalytic asymmetric conjugate additions, failed as well.

Over the past decade, rhodium catalysts have received increasing attention as alternatives to copper catalysts for the catalytic asymmetric 1,4-addition reaction, especially since the pioneering work by the research groups of Miyaura and Hayashi (29). However, a serious concern arises when considering the experimental conditions employed; most of the procedures involve heating at elevated temperatures in a binary solvent mixture composed of water and a cosolvent. We feared that thermal fragmentation of the [1,3]dioxin-4-one ring would lead to the α,β-unsaturated methyl ketone derived from **19** by a sequence that involves addition of 1 equiv. of water to an acyl ketene intermediate, followed by intramolecular decarboxylation of the resulting β-keto acid. As shown in Table 3 (entry 2), these concerns were confirmed when an addition of lithium 2-propenylborate in the presence of 1 equiv. of water (30) resulted in hydrolysis of **19** and isolation of the α,β-unsatured ester (65%).

Recent findings by Feringa and co-workers (31) and Genêt and co-workers (32) have shown that potassium organotrifluoroborates (RBF_3K), a class of air- and moisture-stable organometallic reagents, can be used as substitutes for boronic acids in the rhodium-catalyzed asymmetric 1,4-addition to enones using phosporamidites or

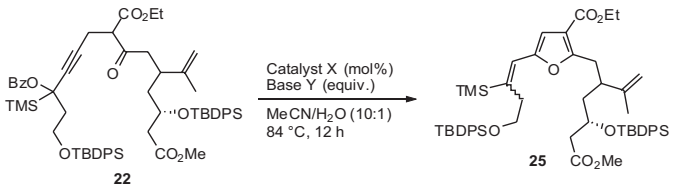
L_2 (Carreira's diene)

bidentate phosphines as chiral ligands. Of particular interest to us was the fact that these reactions can be performed in the absence of water (pure EtOH) and at lower temperatures (70 °C) (31), so that addition could occur before any significant cleavage of the [1,3]dioxin-4-one ring could take place. Gratifyingly, on our first try with Monophos™ (**L_1**, see bottom of Table 3) in a heated ethanolic solution, we obtained a mixture of 1,6-addition products **20** and **21** in a moderate combined yield, albeit in low diastereoselectivity (Table 3, entry 3). We then turned our attention to chiral bidentate phosphine ligands such as (*R*)-Binap, (*R*,*R*)-Me-Duphos, and (*S*,*S*)-Chiraphos, however, the use of these ligands seemed to considerably diminish the activity of the catalytic system and only starting material was recovered.



Another class of promising chiral ligands for the catalytic asymmetric 1,4-addition are chiral dienes (33), which have been disclosed recently by Hayashi et al. (34) and Carreira and co-workers (35). We chose to prepare Carreira's diene (see **L_2**, bottom of Table 3) from commercially available carvone. After heating **19** with the organotrifluoroborate in the presence of a rhodium catalyst, we were able to isolate the addition products **20** and **21** in a moderate combined yield as a 4:1 mixture of isomers (Table 3, entry 4) (36). Performing the reaction with a different neutral rhodium catalyst, $\{[RhCl(eth)_2]_2\}$ gave similar results (64% combined yield, 3.1:1 dr), whereas lower temperatures (57–60 °C) resulted in lower conversions.[4] We also attempted the reaction with the acetate-protected derivative **24** (Table 3, entry 5) as well as the free-hydroxyl derivative **23**, however, no increase in selectivity was observed with the former and the latter appeared to be unreactive.

Since we were unable to prepare the 1,6-addition products **20** and (or) **21** with high levels of stereoselectivity, we decided to resume our synthesis of lophotoxin with the 1:1 mixture of diastereomers obtained in high yield from the organocuprate addition (Scheme 4). The stage was now set for the key cyclization step that would produce the 2,3,5-trisubstituted furan ring and stereoselectively generate the olefin with the appropriate geometry, all in a single transition-metal-catalyzed event. Unfortunately, treatment of the α-propargyl β-keto ester **22** under our previously optimized conditions (11) gave only trace amounts of furan **25** (Table 4, entry 1). Although the starting material had been completely consumed, as judged by ^{1}H NMR analysis, no identifiable products could be isolated from the crude reaction mixture. After a number of unsuccessful attempts, we decided to conduct control experiments and we were quite surprised to see that treatment of **22** with only K_2CO_3, present under otherwise identical reaction conditions, resulted in rapid desilylation (TMS group) of the starting material (ca. 1 h, Table 4, entry 2). In light of this result, we decided to screen for other catalyst–base combinations and we were pleased to see that the use of $Pd(PPh_3)_4$ and $NaOAc{\cdot}3H_2O$ provided a reasonable yield of furan **25** as a 6.8:1 mixture of isomers (Table 4, entry 3). The addition of more base (Table 4, entry 4) or the use of related bases (Table 4, entries 5

[4] Comparable diastereomeric ratios (3.9:1) were obtained.

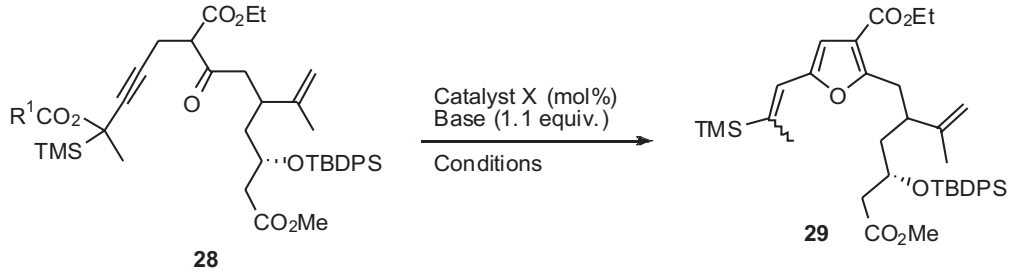
and 6) led to almost identical results, as did the combination of $NaOAc{\cdot}3H_2O$ and an organic base (Entry 7).

Comparison of the ^1H NMR spectra of **25** with our previously described furan **2** (Fig. 1) indicated that the major isomer formed during the reaction was the undesired (*E*)-isomer.[5] To verify the olefin configuration, we converted the vinylsilane moiety to the corresponding iodide and performed a Negishi cross-coupling reaction with dimethylzinc that yielded furan **26** (eq. [2]). A 1D-nOe analysis allowed us to assign the stereochemistry of the major isomer as **(*Z*)-26** since an nOe enhancement was observed between the hydrogen atoms of the newly introduced methyl group and the hydrogen atom of the alkene, establishing that the TMS group in **25** was located *trans* to the furan ring.

Our inability to gain access to **(*Z*)-25** forced a reconsideration of our strategy to close the macrocyclic ring in lophotoxin. Instead of relying on the furan cyclization reaction to set the stereochemistry as shown in **(*Z*)-25** and then attach the C_{19} methyl group, we decided to prepare furan **(*E*)-29** (Table 5) that already had an attached C_{19} methyl group and to use the vinylsilane moiety for further transformations. In addition to being more convergent, this approach gave us the opportunity to focus on a different bond disconnection in which C_8 and C_9 would be joined together by a transition-metal-catalyzed intramolecular cross-coupling reaction. In any event, we prepared the α-propargyl β-keto esters **28** from β-keto ester **21** and the appropriate halides **27** (eq. [3]).



When substrate **28a** (R^1 = Ph) was subjected to the original cyclization conditions, virtually no furan was formed and the starting material decomposed (Table 5, entry 1). Using the modified set of conditions [$Pd(PPh_3)_4$–$NaOAc{\cdot}3H_2O$] we were pleased to see that cyclization had occured, although we were alarmed by the much lower isolated yield (Table 5, entry 2). Another product, possibly arising from migration of the benzoate group across the alkyne, was recovered from this reaction in ca. 32% yield. Since the benzoate might be too readily eliminated, we prepared the pivaloate derivative **28b** (R^1 = *t*-Bu) and were relieved to see that under the new set of conditions, the desired furan **29** was formed once again in moderate yield (Table 5, entry 3). To decrease the reaction times and possibly minimize side reactions, we next turned our attention to the use of microwave irradiation to promote the cyclization reaction. Gratifyingly, heating **28b** for only 40 min in the microwave under otherwise identical reaction conditions led to furan **29** in a comparable yield and high selectivity (Table 5, entry 4). While screening for other transition-metal catalysts, we were pleased to find that the allylpalladium chloride dimer was also an effective catalyst for the cyclization. In this case, both pivalate and benzoate derivatives could be used and the furan was obtained in acceptable yields (Table 5, entries 5 and 6). Although the (*E*/*Z*) selectivity was severely diminished, isomerization of the furan mixture with a catalytic amount (5–10 mol%) of $(PhSe)_2$ in THF at reflux produced pure **(*E*)-29** in high yield (Table 5, entry 5). With a more practical route to this furan in hand, we are currently exploring a strategy that involves further modification of the protected β-hydroxy ester fragment followed by an intramolecular transition-metal-

[5] The ^1H NMR chemical shift of the TMS group is particularly diagnostic. Indeed, in **2** the TMS group has a δ of 0.11 ppm, whereas the major isomer in **25** has a δ of 0.00 ppm and the minor isomer has a δ of 0.09 ppm.

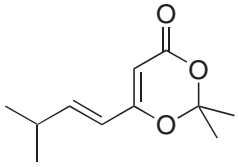
catalyzed cross-coupling reaction with the vinylsilane moiety. These results will be disclosed in due course.

Conclusion



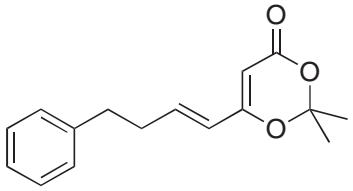
We have shown that a catalytic desymmetrization reaction using a modified cinchona alkaloid allows for the stereoselective incorporation of the C_{13} substituent present in lophotoxin from a simple prochiral cyclic anhydride. A newly developed, highly regioselective 1,6-addition reaction of organocuprates to unsaturated [1,3]dioxin-4-ones provided a means to introduce the C_1 isopropenyl group, and encouraging preliminary results have established that a rhodium-catalyzed asymmetric 1,6-addition reaction provides moderate levels of diastereocontrol. Problems encountered with the transition-metal catalyzed furan cyclization reaction have led to modifications of our original thermal procedure and to the development of a microwave-assisted variant. We are currently applying these modifications toward the total synthesis of lophotoxin and other members of the furanocembranolide family of natural products.

Experimental

General methods

All moisture-sensitive reactions were performed under an atmosphere of N_2 and glassware was flame-dried under vacuum prior to use. Et_2O and THF were dried by distillation over Na–benzophenone. Distilled hexane and ethyl acetate were used for chromatographic purifications. Toluene and CH_2Cl_2 were purified by filtration through activated alumina. TMSCl was distilled over CaH_2 and kept in a dessicator. $(DHQD)_2AQN$ was prepared according to a literature procedure (24). Unless otherwise stated, all other reagents and solvents were used as received. Analytical thin layer chromatography (TLC) was performed on precoated silica gel 60 F-254 plates (particle size 0.040–0.055 mm, 230–400 mesh) and visualization was accomplished with a 254 nm UV light and (or) by staining with a basic $KMnO_4$ solution (1.5 g of $KMnO_4$ and 1.5 g of K_2CO_3 in 100 mL of a 0.1% aq. NaOH solution). NMR spectra were recorded at 300 MHz and 76 MHz for ^1H NMR and ^{13}C NMR, respectively, using a Bruker AVANCE 300 MHz spectrometer at 21 °C in $CDCl_3$ unless stated otherwise. Chemical shifts (δ) are reported as follows: chemical shift, multiplicity (singlet (s), doublet (d), triplet (t), quartet (q), quintet (qn), hextet (hex), multiplet (m), broad (b)), coupling constants, and integration. IR spectra were obtained on a Nicolet AVATAR 360 FT-IR ESP spectrometer. Mass spectra were obtained on a Micromass Autospec double focusing instrument. Optical rotations were measured on a PerkinElmer 241 polarimeter. Microwave reactions were run on a CEM Discover instrument.

2,2-Dimethyl-6-(3-methylbut-1-enyl)[1,3]dioxin-4-one (13a)



To a solution of phosphonate **12** (1.11 g, 3.99 mmol) in THF (20 mL) cooled to 0 °C was added NaH (192 mg of a 60% mineral dispersion, 4.80 mmol). The ice bath was removed and the reaction mixture was stirred at rt for 30 min, cooled to –78 °C, and treated with isobutyraldehyde (400 μL, 4.4 mmol). The solution was allowed to gradually warm to rt and stirred for 1 h. One drop of satd. aq. $NaHCO_3$ was added and the mixture was stirred for 5 min (to complete the deprotonation step). After adding satd. aq. $NaHCO_3$ (50 mL), the reaction was transferred to a separatory funnel and extracted with Et_2O (3 × 50 mL). The organic layers were combined, dried (Na_2SO_4), filtered,

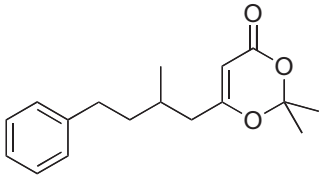
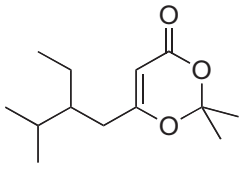
concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 532 mg of **13a** (68%) as a colourless oil. R_f 0.26 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2963, 2872, 1731, 1653, 1592, 1391, 1374, 1273, 1206, 1018. ^1H NMR ($CDCl_3$) δ: 6.54 (dd, J = 15.6, 6.8 Hz, 1H), 5.85 (dd, J = 15.6, 1.4 Hz, 1H), 5.26 (s, 1H), 2.46 (hexd, J = 6.8, 1.4 Hz, 1H), 1.72 (s, 6H), 1.08 (d, J = 6.8 Hz, 6H). ^{13}C NMR ($CDCl_3$) δ: 163.5, 161.8, 148.5, 119.6, 106.0, 93.1, 31.1, 24.8 (2), 21.3 (2). HR-MS (EI) *m/e* calcd. for $C_{11}H_{16}O_3$: 196.1099; found: 196.1102.

2,2-Dimethyl-6-(4-phenylbut-1-enyl)[1,3]dioxin-4-one (13b)



To a solution of phosphonate **12** (1.95 g, 7.01 mmol) in THF (50 mL) cooled to 0 °C was added NaH (240 mg of a 60% mineral dispersion, 6.00 mmol). The ice bath was removed and the reaction mixture was stirred at rt for 30 min, cooled to –78 °C, and treated with hydrocinnamaldehyde (730 μL, 5.0 mmol). The solution was allowed to gradually warm to rt and stirred for 1 h. One drop of satd. aq. $NaHCO_3$ was added and the mixture was stirred for 5 min (to complete the deprotonation step). After adding satd. aq. $NaHCO_3$ (50 mL), the reaction was transferred to a separatory funnel and extracted with Et_2O (4 × 50 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 1.23 g of **13b** (96%) as a colourless oil. R_f 0.20 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2999, 2941, 1725, 1653, 1592, 1390, 1274, 1205, 1020. ^1H NMR ($CDCl_3$) δ: 7.34–7.18 (m, 5H), 6.61 (dt, J = 15.5, 7.1 Hz, 1H), 5.93 (dt, J = 15.6, 1.4 Hz, 1H), 5.25 (s, 1H), 2.82–2.76 (m, 2H), 2.58–2.50 (m, 2H), 1.72 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 163.1, 161.9, 141.2, 140.6, 128.4 (2), 128.2 (2), 126.1, 122.9, 106.2, 93.4, 34.6, 34.4, 24.9 (2). HR-MS (EI) *m/e* calcd. for $C_{16}H_{18}O_3$: 258.1256; found; 258.1254.

6-(2,3-Dimethylbutyl)-2,2-dimethyl[1,3]dioxin-4-one (14a)

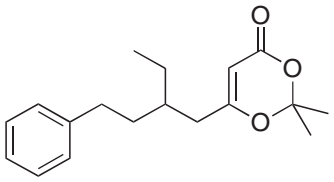


To a suspension of CuI (143 mg, 0.751 mmol) in THF (2.5 mL) cooled to –78 °C was added dropwise a solution of MeLi in Et_2O (1.6 mol/L, 940 μL, 1.5 mmol). The cold bath was removed and the mixture was stirred at rt for 30 min. The resulting colourless solution was then cooled to –78 °C and TMSCl (380 μL, 3.0 mmol) was added. After stirring for ca. 5 min, a solution of **13a** (98.8 mg, 0.503 mmol) in THF (1.5 mL, 1.0 mL rinse) was added. The mixture was stirred at –78 °C for 30 min, then at –20 °C for ca. 18 h. The reaction was stopped by adding satd. aq. $NaHCO_3$ (30 mL) at –20 °C, then warmed to rt, transferred to a separatory funnel, and extracted with Et_2O (4 × 30 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 97 mg of **14a** (91%) as a colourless oil. R_f 0.36 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2961, 2876, 1735, 1633, 1390, 1272, 1205, 1013. ^1H NMR ($CDCl_3$) δ: 5.23 (s, 1H), 2.29 (dd, J = 14.1, 5.0 Hz, 1H), 1.96 (dd, J = 14.1, 9.4 Hz, 1H), 1.75–1.70 (m, 1H), 1.70 (s, 3H), 1.69 (s, 3H), 1.65–1.59 (m, 1H), 0.91 (d, J = 6.8 Hz, 3H), 0.87 (d, J = 6.8 Hz, 3H), 0.86 (d, J = 6.8 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 171.7, 161.2, 106.1, 94.0, 38.5, 36.0, 31.8, 25.2, 24.7, 19.8, 17.7, 15.0. HR-MS (ESI–POS) *m/e* calcd. for $C_{12}H_{20}O_3Na$: 235.1310 [M + Na]; found: 235.1299.

2,2-Dimethyl-6-(2-methyl-4-phenylbutyl)[1,3]dioxin-4-one (14b)

Following the previous procedure for the 1,6-addition of Me_2CuLi, [1,3]dioxin-4-one **13b** (124 mg, 0.480 mmol) gave 101 mg (77%) of **14b** as a colourless oil. R_f 0.29 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2998, 2929, 1732, 1633, 1390, 1272, 1204, 1014. ^1H NMR ($CDCl_3$) δ: 7.32–7.27 (m, 2H), 7.22–7.15 (m, 3H), 5.22 (s, 1H), 2.73–2.67 (m, 1H), 2.63–2.57 (m, 1H), 2.28 (dd, J = 14.2, 6.1 Hz, 1H), 2.07 (dd, J = 14.2, 7.9 Hz, 1H), 1.86 (hex, J = 6.4 Hz, 1H), 1.73–1.67 (m, 1H), 1.67 (s, 3H), 1.66 (s, 3H), 1.56–1.47 (m, 1H), 1.02 (d, J = 6.7 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.8, 161.1, 141.9, 128.3 (2), 128.2 (2), 125.8, 106.1, 94.2, 41.0, 38.3, 33.1, 30.1, 25.0, 24.9, 19.3. HR-MS (ESI–POS) *m/e* calcd. for $C_{17}H_{22}O_3Na$ [M + Na]: 297.1467; found: 297.1447.

6-(2-Ethyl-3-methylbutyl)-2,2-dimethyl[1,3]dioxin-4-one (14c)



To a suspension of CuI (143 mg, 0.751 mmol) in THF (2.0 mL) cooled to 0 °C was added dropwise a 0.39 mol/L solution of EtLi in benzene–cyclohexane (90:10, 3.8 μL, 1.5 mmol) and the mixture was stirred at 0 °C for 30 min. The resulting dark black solution was then cooled to –78 °C and TMSCl (380 μL, 3.0 mmol) was added. After stirring for ca. 5 min, a solution of **13a** (97.6 mg, 0.497 mmol) in THF (1.5 mL, 1.0 mL rinse) was added. The mixture was stirred at –78 °C for 30 min, then at –20 °C for ca. 17 h. The reaction was stopped by adding satd. aq. $NaHCO_3$ (30 mL) at –20 °C, then warmed to rt, transferred to a separatory funnel, and extracted with Et_2O (3 × 30 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under

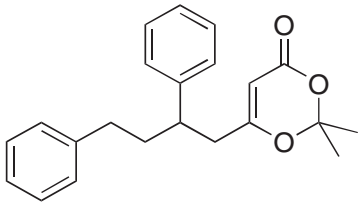
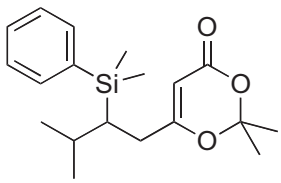
reduced pressure, and purified by chromatography on SiO_2 to afford 99 mg of **14c** (88%) as a colourless oil. R_f 0.35 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2961, 2876, 1735, 1632, 1464, 1389, 1272, 1205, 1015. ^1H NMR ($CDCl_3$) δ: 5.24 (s, 1H), 2.21 (dd, *J* = 14.4, 6.0 Hz, 1H), 2.06 (dd, *J* = 14.4, 7.7 Hz, 1H), 1.82–1.72 (m, 1H), 1.69 (s, 6H), 1.53–1.42 (m, 1H), 1.42–1.17 (m, 2H), 0.89 (t, *J* = 7.5 Hz, 3H), 0.88 (d, *J* = 7.3 Hz, 3H), 0.86 (d, *J* = 7.0 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 172.3, 161.3, 106.1, 94.0, 42.8, 34.9, 28.6, 25.1, 24.9, 22.8, 19.0, 18.6, 11.6. HR-MS (EI) *m/e* calcd. for $C_{10}H_{16}O_2$: 168.1150 [M – CH_3COCH_3]; found: 168.1148.

6-(2-Ethyl-4-phenylbutyl)-2,2-dimethyl[1,3]dioxin-4-one (14d)



Following the previous procedure for the 1,6-addition of Et_2CuLi, [1,3]dioxin-4-one **13b** (131 mg, 0.507 mmol) gave 134 mg (92%) of **14d** as a colourless oil. R_f 0.28 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2998, 2935, 1731, 1631, 1455, 1390, 1272, 1204, 1014. ^1H NMR ($CDCl_3$) δ: 7.32–7.26 (m, 2H), 7.22–7.14 (m, 3H), 5.23 (s, 1H), 2.67–2.57 (m, 2H), 2.26–2.19 (m, 2H), 1.73–1.60 (m, 3H), 1.67 (s, 3H), 1.65 (s, 3H), 1.49–1.36 (m, 2H), 0.92 (t, *J* = 7.4 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 171.2, 161.2, 142.0, 128.3 (2), 128.2 (2), 125.8, 106.2, 94.2, 37.7, 36.1, 34.7, 32.7, 25.5, 25.0, 24.9, 10.4. HR-MS (EI) *m/e* calcd. for $C_{18}H_{24}O_3$: 288.1725; found: 288.1727.

2,2-Dimethyl-6-(3-methyl-2-phenylbutyl)-[1,3]dioxin-4-one (14e)

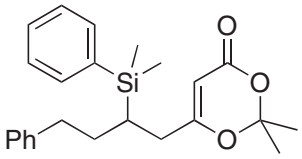


To a suspension of CuI (143 mg, 0.751 mmol) in THF (2.5 mL) cooled to 0 °C was added dropwise a solution of PhLi (1.0 mol/L) in cyclohexane–Et_2O (70:30, 1.5 mL, 1.5 mmol). After stirring at 0 °C for 30 min, the mixture was cooled to –78 °C, at which point a dense precipitate formed. TMSCl (380 μL, 3.0 mmol) was added and after ca. 5 min a solution of **13a** (99.2 mg, 0.506 mmol) in THF (1.5 mL, 1.0 mL rinse) was added. The mixture was stirred at –78 °C for 30 min, then at –20 °C for ca. 18 h. The reaction was stopped by adding satd. aq. $NaHCO_3$ (30 mL) at –20 °C, then warmed to rt, transferred to a separatory funnel, and extracted with Et_2O (4 × 30 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 110 mg of **14e** (79%) as a colourless oil. R_f 0.31 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2960, 2873, 1731, 1633, 1454, 1390, 1272, 1204, 1014. ^1H NMR ($CDCl_3$) δ: 7.29–7.24 (m, 2H), 7.22–7.17 (m, 1H), 7.10–7.06 (m, 2H), 5.05 (s, 1H), 2.76 (dd, *J* = 14.2, 4.3 Hz, 1H), 2.73–2.66 (m, 1H), 2.52 (dd, *J* = 14.2, 11.1 Hz, 1H), 1.84 (apparent hex, *J* = 6.8 Hz, 1H), 1.51 (s, 3H), 1.32 (s, 3H), 0.98 (d, *J* = 6.7 Hz, 3H), 0.77 (d, *J* = 6.7 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.7, 161.2, 141.4, 128.4 (2), 128.1 (2), 126.6, 106.2, 94.5, 49.5, 36.9, 33.6, 25.4, 24.0, 20.6, 20.1. HR-MS (EI) *m/e* calcd. for $C_{14}H_{16}O_2$: 216.1150 [M – CH_3COCH_3]; found: 216.1150.

6-(2,4-Diphenylbutyl)-2,2-dimethyl[1,3]dioxin-4-one (14f)

Following the previous procedure for the 1,6-addition of Ph_2CuLi, [1,3]dioxin-4-one **13b** (128 mg, 0.496 mmol) gave 110 mg (66%) of **14f** as a colourless oil. R_f 0.24 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 3027, 2999, 2939, 2858, 1728, 1632, 1495, 1454, 1390, 1272, 1204, 1014. ^1H NMR ($CDCl_3$) δ: 7.36–7.31 (m, 2H), 7.29–7.23 (m, 3H), 7.21–7.15 (m, 3H), 7.12–7.07 (m, 2H), 5.07 (s, 1H), 2.97–2.89 (m, 1H), 2.60 (dd, *J* = 14.5, 6.4 Hz, 1H), 2.56–2.40 (m, 3H), 2.05–1.88 (m, 2H), 1.53 (s, 3H), 1.46 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 169.8, 161.0, 142.6, 141.6, 128.6 (2), 128.29 (2), 128.26 (2), 127.5 (2), 126.8, 125.8, 106.3, 94.5, 42.3, 40.7, 38.1, 33.3, 25.0, 24.6. HR-MS (EI) *m/e* calcd. for $C_{19}H_{18}O_2$: 278.1307 [M – CH_3COCH_3]; found: 278.1303.

6-[2-(Dimethylphenylsilanyl)-3-methylbutyl]-2,2-dimethyl[1,3]dioxin-4-one (14g)



To a suspension of CuI (143 mg, 0.751 mmol) in THF (1.0 mL) cooled to –20 °C was added dropwise a solution of $PhMe_2SiLi$ in THF (0.40 mol/L, 3.8 μL, 1.5 mmol), and the mixture was stirred at –20 °C for 4 h. TMSCl (380 μL, 3.0 mmol) was added and the mixture was stirred for ca. 5 min after which a solution of **13a** (95.4 mg, 0.486 mmol) in THF (1.5 mL, 1.0 mL rinse) was added. The reaction mixture was stirred at –20 °C for ca. 15 h, stopped by adding satd. aq. $NaHCO_3$ (30 mL) at –20 °C, then warmed to rt, transferred to a separatory funnel, and extracted with Et_2O (4 × 30 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 97 mg of **14g** (60%) as a colourless oil. R_f 0.42 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2998, 2957, 2872, 1732, 1630, 1427, 1389, 1271, 1205, 1111, 1016. ^1H NMR ($CDCl_3$) δ: 7.54–7.47 (m,

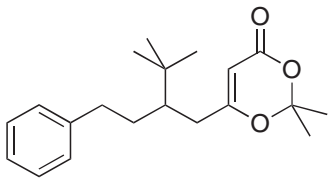
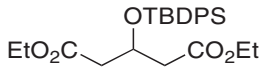
2H), 7.39–7.33 (m, 3H), 5.17 (s, 1H), 2.30–2.22 (m, 2H), 1.98–1.92 (m, 1H), 1.63 (s, 3H), 1.60 (s, 3H), 1.31–1.26 (m, 1H), 0.95 (d, J = 6.9 Hz, 3H), 0.88 (d, J = 7.0 Hz, 3H), 0.36 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 172.6, 161.2, 138.3, 133.7 (2), 129.0, 127.8 (2), 106.1, 93.5, 31.4, 29.8, 28.7, 25.2, 24.6, 22.0, 21.3, –2.2, –3.1. HR-MS (EI) *m/e* calcd. for $C_{18}H_{25}O_3Si$: 317.1573 [M – CH_3]; found: 317.1557.

6-(2-(Dimethyl(phenyl)silyl)-4-phenylbutyl)-2,2-dimethyl-4H-1,3-dioxin-4-one (14h)



Following the previous procedure for the 1,6-addition of $(PhMe_2Si)_2CuLi$, [1,3]dioxin-4-one **13b** (129 mg, 0.499 mmol) gave 121 mg (61%) of **14h** as a colourless oil. R_f 0.26 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2999, 2950, 2859, 1729, 1629, 1389, 1272, 1204, 1112, 1014. ^{1}H NMR ($CDCl_3$) δ: 7.53–7.48 (m, 2H), 7.42–7.36 (m, 3H), 7.28–7.23 (m, 2H), 7.20–7.16 (m, 1H), 7.05–7.01 (m, 2H), 5.19 (s, 1H), 2.61–2.53 (m, 1H), 2.53–2.46 (m, 1H), 2.38 (dd, J = 14.9, 4.5 Hz, 1H), 2.16 (dd, J = 14.9, 9.6 Hz, 1H), 1.83–1.75 (m, 1H), 1.67–1.59 (m, 1H, hidden under two s), 1.65 (s, 3H), 1.64 (s, 3H), 1.32–1.25 (m, 1H), 0.363 (s, 3H), 0.360 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 171.9, 161.0, 141.8, 137.2, 133.8 (2), 129.3, 128.3 (2), 128.1 (2), 127.9 (2), 125.8, 106.2, 93.8, 35.2, 34.3, 31.9, 25.1, 24.7, 22.1, –4.1, –4.2. HR-MS (EI) *m/e* calcd. for $C_{24}H_{30}O_3Si$: 394.1964; found: 394.1953.

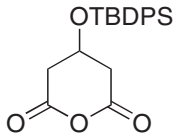
6-(2-Isopropyl-3,3-dimethylbutyl)-2,2-dimethyl[1,3]dioxin-4-one (14i)



To a suspension of CuI (143 mg, 0.751 mmol) in THF (2.5 mL) cooled to –78 °C was added dropwise a solution of *t*-BuLi in pentane (1.4 mol/L, 1.1 µL, 1.5 mmol). The mixture was stirred at –78 °C for 30 min and then TMSCl (380 µL, 3.0 mmol) was added. After stirring for ca. 5 min, a solution of **13a** (101 mg, 0.515 mmol) in THF (1.5 mL, 1.0 mL rinse) was added. The mixture was stirred at –78 °C for 30 min, then at –20 °C for ca. 15 h. The reaction was stopped by adding satd. aq. $NaHCO_3$ (30 mL) at –20 °C, then warmed to rt, transferred to a separatory funnel, and extracted with Et_2O (3 × 30 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 22 mg of **14i** (17%) as a colourless oil. R_f 0.53 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2960, 1733, 1630, 1389, 1271, 1205, 1016. ^{1}H NMR ($CDCl_3$) δ: 5.29 (s, 1H), 2.22 (d, J = 5.6 Hz, 2H), 2.11–2.06 (m, 1H), 1.69 (s, 6H), 1.50 (td, J = 5.7, 1.9 Hz, 1H), 0.93–0.92 (m, 12H), 0.87 (d, J = 6.8 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 174.1, 161.5, 106.1, 93.2, 49.9, 34.9, 30.4, 28.6 (3), 27.7, 25.2, 25.0, 24.4, 18.3. HR-MS (EI) *m/e* calcd. for $C_{15}H_{27}O_3$: 255.1960 [M + H]; found: 255.1964.

6-(3,3-Dimethyl-2-phenethylbutyl)-2,2-dimethyl[1,3]dioxin-4-one (14j)

Following the previous procedure for the 1,6-addition of $(t\text{-Bu})_2CuLi$, [1,3]dioxin-4-one **13b** (130 mg, 0.503 mmol) gave 68 mg (43%) of **14j** as a colourless oil. R_f 0.33 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 3026, 2960, 1732, 1630, 1454, 1389, 1272, 1204, 1014. ^{1}H NMR ($CDCl_3$) δ: 7.32–7.25 (m, 2H), 7.22–7.13 (m, 3H), 5.32 (s, 1H), 2.74–2.67 (m, 1H), 2.58–2.51 (m, 1H), 2.47 (dd, J = 15.0, 4.2 Hz, 1H), 2.07 (dd, J = 15.0, 7.5 Hz, 1H), 1.90–1.82 (m, 1H), 1.71 (s, 6H), 1.53–1.48 (m, 1H), 1.46–1.37 (m, 1H), 0.91 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 172.7, 161.2, 142.1, 128.4 (2), 128.2 (2), 125.9, 106.2, 93.8, 45.1, 35.9, 35.6, 33.9, 33.4, 27.5 (3), 25.3, 24.9. HR-MS (EI) *m/e* calcd. for $C_{17}H_{22}O_2$: 258.1620 [M – $(CH_3)_2CO$]; found: 258.1616.



3-(tert-Butyldiphenylsilanyloxy)pentanedioic acid diethyl ester (15, R^1 = OTBDPS)

To a solution of imidazole (1.36 g, 20.0 mmol) in CH_2Cl_2 (20 mL) at rt was added TBDPSCl (2.47 mL, 9.50 mmol). After stirring for 10 min at rt, a solution of diethyl 3-hydroxyglutarate (2.04 g, 10.0 mmol) in CH_2Cl_2 (5, 2, and 1 mL rinses) was added to the white suspension. The reaction was stirred at rt for 16 h after which it was stopped by the addition of water (25 mL) and diluted with Et_2O (125 mL). The mixture was then transferred to a separatory funnel, extracted, the layers separated, and the organic layer was washed with brine (25 mL). The aqueous layers were combined and extracted with Et_2O (50 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 4.05 g of **15** (96%) as a white solid; mp 44–46 °C. R_f 0.48 (20% EtOAc–hexane). FT-IR (KBr, cm^{-1}): 2966, 1740, 1378, 1268, 1227, 1145, 1107, 1026. ^{1}H NMR ($CDCl_3$) δ: 7.70–7.66 (m, 4H), 7.47–7.35 (m, 6H), 4.55 (qn, J = 6.0 Hz, 1H), 4.08–3.97 (m, 4H), 2.60 and 2.54 (AB of ABX, J = 15.2, 6.3 and 15.2, 5.9 Hz, 4H), 1.19 (t, J = 7.1 Hz, 6H), 1.03 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 170.8 (2), 135.8 (4), 133.5 (2), 129.7 (2), 127.6 (4), 67.2, 60.3 (2), 41.8 (2), 26.8 (3), 19.2, 14.1 (2). HR-MS (EI) *m/e* calcd. for $C_{24}H_{31}O_5Si$: 427.1941 [M – CH_3]; found: 427.1931.

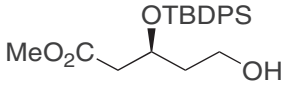
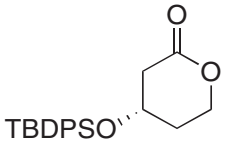
3-[(*tert*-Butyldiphenylsilyl)oxy]pentanedioic anhydride (8b, R^1 = OTBDPS)



To a solution of diester **15** (8.85 g, 20.0 mmol) in MeOH (30 mL) was added NaOH pellets (2.00 g, 50.0 mmol) and the mixture was stirred vigorously at rt for 38 h. The resulting yellowish suspension was concentrated under reduced pressure and kept under high vacuum. The flaky solid was then crushed into smaller pieces, suspended in a mixture of benzene (40 mL) and Ac_2O (30 mL) and heated to reflux for 1.5 h. During this time, the colour changed to a deep purple. After cooling to rt, the reaction was stopped by the addition of brine (200 mL) and the mixture was transferred to a separatory funnel with $CHCl_3$ (400 mL). After extraction, the layers were separated and the organic layer was washed with satd. aq. $NaHCO_3$ (3 × 200 mL). The organic layer was then dried ($MgSO_4$), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 [pretreated with hexane containing 1% Ac_2O, solvent gradient from pure hexane (+1% Ac_2O) to 20% EtOAc–hexane (+1% Ac_2O)] to afford 3.40 g of **8b** (46%) as a white solid. Recrystallization from a hot mixture of hexane–EtOAc (20:1) provided white needles; mp 107 to 108 °C (hexane–EtOAc 20:1). R_f 0.27 (20% EtOAc–hexane containing 1% Ac_2O). FT-IR (KBr, cm^{-1}): 2932, 1817, 1765, 1429, 1348, 1262, 1191, 1111, 1070, 1044. ^{1}H NMR ($CDCl_3$) δ: 7.71–7.56 (m, 4H), 7.55–7.35 (m, 6H), 4.31 (qn, *J* = 3.2 Hz, 1H), 2.86 (dd, *J* = 16.0, 3.6 Hz, 2H), 2.58 (dd, *J* = 16.0, 2.4 Hz, 2H), 1.05 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 165.3 (2), 135.8 (4), 132.4 (2), 130.6 (2), 128.3 (4), 62.9, 38.9 (2), 26.9 (3), 19.2. HR-MS (EI) *m/e* calcd. for $C_{17}H_{15}O_4Si$: 311.0740 [M – C_4H_9]; found: 311.0744.

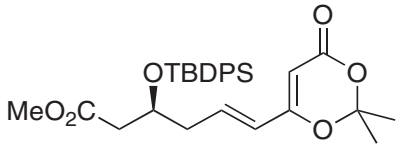
(S)-((3-*tert*-Butyldiphenylsilyl)oxy)pentanedioic acid monomethyl ester (16)



To a previously dried flask containing cyclic anhydride **8b** (1.09 g, 2.96 mmol) was added Et_2O (100 mL). The solution was cooled to –40 °C, $(DHQD)_2AQN$ (760 mg, 0.887 mmol) was added and the mixture was stirred for about 20 min. MeOH (1.20 mL, 29.6 mmol) was then added and the reaction was stirred at –40 °C for 70–72 h, stopped by the addition of 10% aq. HCl (90 mL) at –40 °C, and allowed to warm to rt. After transferring to a separatory funnel, the mixture was extracted, the layers were separated, and the aqueous layer was reextracted with EtOAc (2 × 100 mL). The organic layers were combined, dried (Na_2SO_4), filtered, and concentrated under reduced pressure to provide 1.25 g of the crude acid **16** as a pale yellow oil. ^{1}H NMR ($CDCl_3$) δ: 7.70–7.65 (m, 4H), 7.48–7.35 (m, 6H), 4.51 (qn, *J* = 6.1 Hz, 1H), 3.56 (s, 3H), 2.69–2.53 (m, 4H), 1.03 (s, 9H). The ^{1}H NMR spectra was identical with the one reported in ref. 25. This material was combined with other crude desymmetrized material to provide 7.29 g of product. The catalyst was recovered by basifying the acidic aqueous layer with KOH pellets (a yellow precipitate formed). The aqueous layer was then extracted with Et_2O until the organic layer remained colourless. The organic layers were combined, dried (Na_2SO_4), filtered, and concentrated under reduced pressure. The recovered catalyst was purified by chromatography on SiO_2 with 5% MeOH–$CHCl_3$ containing 0.5% aq. NH_4OH before being reused.

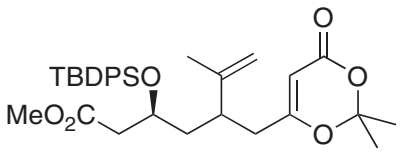
(S)-3-((*tert*-Butyldiphenylsilyl)oxy)-5-hydroxypentanoic acid, methyl ester (17)

To a solution of crude acid **16** (7.29 g, 19.8 mmol) in THF (100 mL) at rt was added a solution of BH_3·DMS in THF (2.0 mol/L, 30 mL, 60 mmol) and the mixture was stirred for 15 h. The reaction was stopped by slowly adding satd. aq. $NaHCO_3$ (350 mL) and stirred vigorously for 20 min. The mixture was then transferred to a separatory funnel and extracted with Et_2O (3 × 300 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 5.41 g of **17** (71%) as a colourless oil. ^{1}H NMR ($CDCl_3$) δ: 7.74–7.65 (m, 4H), 7.48–7.37 (m, 6H), 4.38 (qn, *J* = 5.9 Hz, 1H), 3.70–3.61 (m, 2H), 3.54 (s, 3H), 2.55 (d, *J* = 6.4 Hz, 2H), 1.86–1.80 (m, 1H), 1.78–1.72 (m, 1H), 1.62 (bt, *J* = 5.5 and 5.2 Hz, 1H), 1.06 (s, 9H). The ^{1}H NMR spectra was identical with the one reported in ref. 25.



(S)-3-((*tert*-Butyldiphenylsilyl)oxy)-5-hydroxypentanoic acid lactone (18)

To a solution of crude acid **16** (115 mg, 0.287 mmol) in THF (2.0 mL) at rt was added a solution of BH_3·DMS in THF (2.0 mol/L, 430 μL, 0.86 mmol) and the mixture was stirred for 17 h. The reaction was stopped by slowly adding 10% HCl (3.5 mL) and stirred vigorously for 1 h. The mixture was then transferred to a separatory funnel and extracted with Et_2O (3 × 5 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 38 mg of **18** (38%) as a colourless oil. $[\alpha]_D$ –12.3 (*c* 7.55, $CHCl_3$). ^{1}H NMR ($CDCl_3$) δ: 7.67–7.62 (m, 4H), 7.50–7.37 (m, 6H), 4.63 (ddd, *J* = 11.3, 8.6, 4.5 Hz, 1H), 4.28–4.18 (m, 2H), 2.59 (d, *J* = 4.9 Hz, 2H), 1.94–1.75 (m, 2H), 1.08 (s, 9H). The ^{1}H NMR spectra was identical with the one reported in ref. 25. The enantiomeric excess was determined by chiral HPLC (Chiralcel OD) using *i*-PrOH–hexane (1.0%) at a flow rate of 1.0 mL/min (R_t minor = 22.8 min, R_t major = 24.5 min).

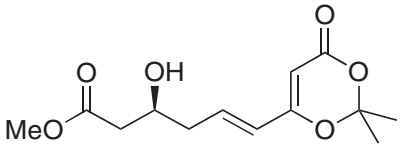


© 2006 NRC Canada

3-(tert-Butyldiphenylsilanyloxy)-6-(2,2-dimethyl-6-oxo-6H-[1,3]dioxin-4-yl)hex-5-enoic acid methyl ester (19)

To a stirred solution of alcohol **17** (5.41 g, 14.0 mmol) in a mixture of CH_2Cl_2 (63 mL) and CH_3CN (7 mL) at rt was added NMO (2.46 g, 21.0 mmol) and 4 Å molecular sieves (7.0 g). TPAP (246 mg, 0.700 mmol) was added in three portions over a period of 20 min and the resulting mixture was stirred for 30 min at rt. The dark black mixture was then filtered over Celite with CH_2Cl_2 and the filtrate was concentrated under reduced pressure. The resulting oil was rapidly purified by chromatography on SiO_2 with EtOAc–hexanes (20%) to afford 4.23 g of the corresponding aldehyde (79%) as a colourless oil. A solution of phosphonate **12** (4.28 g, 15.4 mmol) in THF (100 mL) cooled to 0 °C was treated with 95% NaH (317 mg, 13.2 mmol). The cold bath was removed and the mixture was stirred at rt for 20 min. After cooling to –78 °C, a solution of the aldehyde (4.23 g, 11.0 mmol) in THF (5 mL, 5 mL rinse) was added, the bath was removed, and the reaction was allowed to gradually warm to rt and was stirred at that temperature for 1 h. One drop of satd. aq. $NaHCO_3$ was added and the mixture was stirred for 5 min (to complete the deprotonation step). After adding additional satd. aq. $NaHCO_3$ (300 mL), the mixture was transferred to a separatory funnel and extracted with Et_2O (3 × 300 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 3.50 g of **19** (49% from alcohol) as a colourless oil. $[\alpha]_D$ 58.0 (*c* 0.21, $CHCl_3$). R_f 0.33 (30% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2932, 2858, 1728, 1655, 1592, 1428, 1390, 1274, 1206, 1111, 1020. ^1H NMR ($CDCl_3$) δ: 7.76–7.60 (m, 4H), 7.52–7.33 (m, 6H), 6.44 (dt, *J* = 15.5, 7.5 Hz, 1H), 5.78 (d, *J* = 15.6 Hz, 1H), 5.18 (s, 1H), 4.29 (qn, *J* = 6.0 Hz, 1H), 3.57 (s, 3H), 2.54 (A of ABX, J_{AB} = 15.2, J_{AX} = 6.4 Hz, 1H), 2.48–2.36 (m, 3H), 1.67 (s, 6H), 1.04 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 171.3, 162.7, 161.9, 137.4, 135.81 (2), 135.78 (2), 133.4, 133.3, 129.8 (2), 127.6 (4), 125.2, 106.2, 93.8, 69.5, 51.5, 41.7, 40.2, 26.8 (3), 24.9 (2), 19.2. HR-MS (EI) *m/e* calcd. for $C_{25}H_{27}O_6Si$: 451.1577 [M – C_4H_9]; found: 451.1575.

(3S)-Methyl 3-(tert-butyldiphenylsilyloxy)-5-((2,2-dimethyl-4-oxo-4H-1,3-dioxin-6-yl)methyl)-6-methylhept-6-enoate (20)

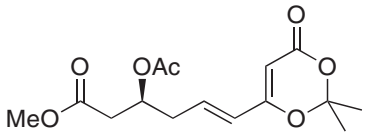


A solution of *t*-BuLi in pentane (1.2 mol/L, 33 mL, 40 mmol) cooled to –78 °C was diluted with THF (33 mL) and 2-bromopropene (1.78 mL, 20.0 mmol) was added dropwise. The mixture was stirred at –78 °C for 30 min, then at 0 °C for 30–45 min. To a suspension of CuI (1.10 g, 5.78 mmol) in THF (20 mL) cooled to –78 °C was added the solution of 2-lithiopropene (39 mL, 12 mmol). The dark black mixture was stirred at –78 °C for 30 min and then TMSCl (3.0 mL, 24 mmol) was added. After stirring for ca. 5 min, a solution of **19** (981 mg, 1.93 mmol) in THF (6.0 mL, 2 × 2.0 mL rinse) was added. The mixture was stirred at –78 °C for 30 min, then at –20 °C for ca. 16 h. The reaction was stopped by adding satd. aq. $NaHCO_3$ (100 mL) at –20 °C, then warmed to rt, transferred to a separatory funnel, and extracted with Et_2O (4 × 100 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 999 mg of **20** (94%) as a colourless oil. R_f 0.38 (30% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2933, 2858, 1732, 1633, 1428, 1390, 1272, 1205, 1111, 1015. ^1H NMR ($CDCl_3$) δ: 7.75–7.62 (m, 4H), 7.51–7.34 (m, 6H), 5.08 and 5.05 (s, 1H), 4.66–4.62 (m, 1H), 4.54 and 4.41 (br s, 1H), 4.14–4.03 (m, 1H), 3.59 and 3.54 (s, 3H), 2.65–2.26 (m, 3H), 2.11–1.97 (m, 2H), 1.67–1.47 (m, 2H), 1.65 and 1.64 (s, 3H), 1.60 and 1.58 (s, 3H), 1.49 and 1.21 (s, 3H), 1.04 and 1.02 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 171.6 [171.3], 170.0 [169.8], 161.16 [161.09], 144.4 [144.3], 135.9 (8), 133.9 [133.7], 133.6 [133.5], 129.8 (4), 127.6 (8), 113.9 [113.3], 106.3 (2), 94.2 [94.1], 68.6 [68.4], 51.41 [51.36], 42.6 [41.2], 40.8 [40.7], 40.8 [40.4], 37.8 [37.4], 26.9 (3) [26.8 (3)], 25.40 [25.36], 25.0 [24.9], 19.3 [19.2], 17.6 [17.3]. HR-MS (ESI–POS) *m/e* calcd. for $C_{32}H_{42}O_6NaSi$: 573.2648 [M + Na]; found: 573.2642.

Rhodium-catalyzed asymmetric 1,6-addition of potassium isopropenyl organotrifluoroborate to 19 in the presence of Carreira's diene

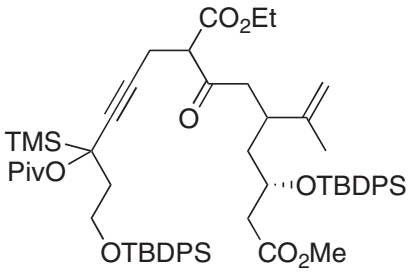
To a dry sealed tube was added the diene ligand (3.6 mg, 0.014 mmol), $Rh(acac)(eth)_2$ (3 mg, 0.01 mmol), and EtOH (0.5 mL) and the mixture was stirred at rt for 15 min. A solution of **19** (117 mg, 0.230 mmol) in EtOH (0.75 mL, 0.75 mL rinse) was then added, followed by potassium isopropenyl organotrifluoroborate (37) (102 mg, 0.689 mmol). The reaction mixture was stirred at 82 °C for 24 h, cooled to rt, and treated with satd. aq. $NaHCO_3$ (15 mL). The mixture was transferred to a separatory funnel and extracted with Et_2O (3 × 15 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 27.2 mg (21%) of **20** and 47.5 mg of **21** (38%).

6-(2,2-Dimethyl-6-oxo-6H-[1,3]dioxin-4-yl)-3-hydroxyhex-5-enoic acid methyl ester (23)



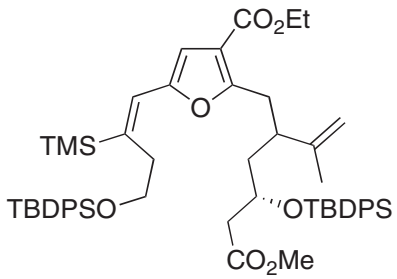
To a solution of **19** (234 mg, 0.460 mmol) in THF (5.5 mL) in a plastic tube was added HF·pyridine (600 µL, 23 mmol) and the mixture was stirred vigorously at rt for 3 days. The reaction was stopped by dropwise addition to

© 2006 NRC Canada



satd. aq. $NaHCO_3$ (75 mL). After adding solid $NaHCO_3$ to the aqueous solution, the mixture was transferred to a separatory funnel and extracted with Et_2O (4 × 30 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 34 mg (15%) of starting material **19** and 101 mg of **23** (81%) as a colourless oil. $[\alpha]_D$ 5.9 (*c* 2.38, CH_2Cl_2). R_f 0.17 (50% EtOAc–hexane). FT-IR (neat, cm^{-1}): 3454, 2999, 2952, 1728, 1651, 1592, 1392, 1276, 1204, 1067, 1020. ^1H NMR ($CDCl_3$) δ: 6.59 (dt, *J* = 15.6, 7.6 Hz, 1H), 6.01 (d, *J* = 15.6 Hz, 1H), 5.28 (s, 1H), 4.23–4.13 (m, 1H), 3.74 (s, 3H), 3.10 (d, *J* = 3.6 Hz, 1H), 2.54 (A of ABX, J_{AB} = 16.7, J_{AX} = 3.4 Hz, 1H), 2.51–2.40 (m, 3H), 1.72 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 172.8, 162.7, 161.9, 137.2, 125.1, 106.4, 93.9, 66.9, 51.8, 40.6, 39.4, 24.9 (2). HR-MS (EI) *m/e* calcd. for $C_{13}H_{16}O_5$: 252.0998 [M – H_2O]; found: 252.0999.

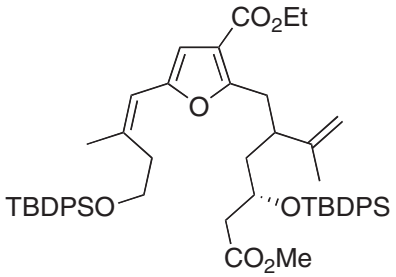
(S,E)-Methyl 3-acetoxy-6-(2,2-dimethyl-4-oxo-4H-1,3-dioxin-6-yl)hex-5-enoate (24)



To a solution of **23** (51.2 mg, 0.189 mmol) in pyridine (1.56 mL, 19.3 mmol) was added Ac_2O (910 μL, 9.6 mmol) and the mixture was stirred at rt for 6.5 h. After concentrating under reduced pressure, the resulting mixture was purified by chromatography on SiO_2 to afford 56.4 mg (95%) of **24** as a colourless oil. $[\alpha]_D$ 11.9 (*c* 1.96, CH_2Cl_2). R_f 0.37 (50% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2999, 2954, 1732, 1656, 1594, 1438, 1376, 1244, 1020. ^1H NMR ($CDCl_3$) δ: 6.45 (dt, *J* = 15.5, 7.5 Hz, 1H), 5.98 (dt, *J* = 15.6, 1.3 Hz, 1H), 5.36–5.27 (m, 1H), 5.28 (s, 1H), 3.69 (s, 3H), 2.64 (A of ABX, J_{AB} = 15.8, J_{AX} = 7.3 Hz, 1H), 2.59–2.52 (m, 2H), 2.04 (s, 3H), 1.71 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 170.3, 170.1, 162.5, 161.9, 135.6, 125.8, 106.5, 94.3, 68.8, 51.9, 38.2, 37.0, 25.0, 24.9, 20.9. HR-MS (EI) *m/e* calcd. for $C_{13}H_{16}O_5$: 252.0998 [M – CH_3CO_2H]; found: 252.0998.

(7S)-Dimethyl 2-(4-(benzoyloxy)-6-(tert-butyldiphenylsilyloxy)-4-(trimethylsilyl)hex-2-ynyl)-7-(tert-butyldiphenylsilyloxy)-3-oxo-5-(prop-1-en-2-yl)nonanedioate (22)

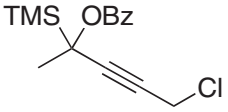
To a solution of [1,3]dioxin-4-one **20** (999 mg, 1.81 mmol) in toluene (20 mL) was added EtOH (530 μL, 9.1 mmol). The solution was heated at reflux for ca. 1.5 h until TLC analysis showed complete consumption of the starting material. The solution was then concentrated under reduced pressure and kept under high vacuum. The crude β-keto ester was redissolved in THF (20 mL) and cooled to 0 °C. The septum was temporarily removed to allow the quick introduction of 98% NaH (52 mg, 2.2 mmol) and the mixture was stirred at 0 °C for ca. 20 min. Afterwards, a solution of iodide **4** [prepared from the corresponding chloride (1.86 g, 3.30 mmol) and NaI (679 mg, 4.53 mmol) in refluxing acetone (15 mL)] in THF (6.0 mL, 6.0 mL rinse) was added and the reaction was gradually warmed to rt, while maintaining the flask in the cold bath. After stirring overnight, the reaction mixture was concentrated under reduced pressure and filtered over a pad of SiO_2 with EtOAc–hexane (20%). This material was then purified by chromatography on SiO_2 to afford 1.50 g of **22** (77%, two steps) as a colourless oil. Since this α-propargyl β-keto ester exists as a mixture of up to four different diastereomers, it was not characterized.



Ethyl 5-((E)-4-(tert-butyldiphenylsilyloxy)-2-(trimethylsilyl)but-1-enyl)-2-((4S)-4-(tert-butyldiphenylsilyloxy)-6-methoxy-6-oxo-2-(prop-1-en-2-yl)hexyl)furan-3-carboxylate (25)

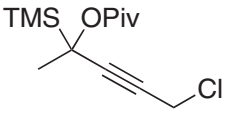
A solution of α-propargyl β-keto ester **22** (76.0 mg, 0.0713 mmol) in a mixture of MeCN (1.0 mL) and H_2O (100 μL) was subjected to three freeze–pump–thaw cycles. Afterwards, $NaOAc{\cdot}3H_2O$ (10.7 mg, 0.0784 mmol) and $Pd(PPh_3)_4$ (12 mg, 0.010 mmol) were added and the mixture was stirred at 87 °C for 2 h. After cooling to rt, the crude mixture was filtered over a pad of SiO_2 with 20% EtOAc–hexane and concentrated under reduced pressure. This material was then purified by chromatography on SiO_2 to afford 33.2 mg of **25** (49%, 6.8:1 mixture of (*E*)–(*Z*)-isomers) as a colourless oil. R_f 0.28 (10% EtOAc–hexane). FT-IR (neat, cm^{-1}): 3071, 2931, 2857, 1741, 1716, 1590, 1428, 1388, 1230, 1111. ^1H NMR ($CDCl_3$) δ: 7.75–7.59 (m, 8H), 7.46–7.31 (m, 12H), 6.75 and 6.71 (s, 1H), 6.45 and 6.42 (s, 1H), 4.58 and 4.46 (brs, 1H), 4.46 and 4.41 (brs, 1H), 4.32–4.20 (m, 2H), 4.18–4.03 (m, 1H), 3.71–3.61 (m, 2H), 3.55 and 3.49 (s, 3H), 2.94–2.72 (m, 4H), 2.61–2.33 (m, 2H), 1.75–1.48 (m, 3H), 1.57 and 1.21 (s, 3H), 1.33 and 1.30 (t, *J* = 7.2 Hz, 3H), 1.063 and 1.056 (s, 9H), 1.00 (s, 9H), –0.003 and –0.004 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 172.0 [171.5], 163.8 [163.7], 160.0 [159.7], 151.1 [151.0], 145.7 [144.9], 140.04 [139.99], 135.94, 135.88, 135.8, 135.6, 135.2, 134.8, 134.2, 133.8, 133.62, 133.58, 129.5, 127.7, 127.6, 127.5, 127.4, 126.6 [126.4], 115.6, 112.85 [112.80], 110.0, 69.0 [68.9], 62.5, 60.1, 51.33 [51.27], 43.2, 43.0, 42.5 41.0, 40.1, 39.6, 34.7, 32.4 [32.3], 26.9, 26.8, 26.5, 19.2, 19.1, 19.0, 18.0, 16.9, 14.33 [14.28], 0.14, –1.8.

© 2006 NRC Canada



Ethyl 5-((Z)-4-(*tert*-butyldiphenylsilyloxy)-2-methylbut-1-enyl)-2-((4S)-4-(*tert*-butyldiphenylsilyloxy)-6-methoxy-6-oxo-2-(prop-1-en-2-yl)hexyl)furan-3-carboxylate (26)

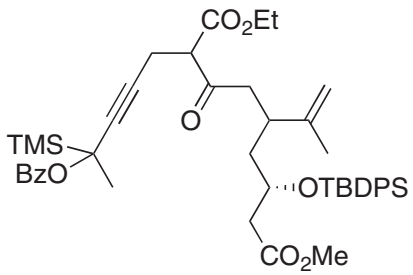
To a solution of I_2 (105 mg, 0.414 mmol) in THF (0.5 mL) was added pyridine (50 μL, 0.62 mmol) followed by $AgClO_4$ (85 mg, 0.41 mmol). The mixture was stirred at rt for 15 min, then a solution of furan **25** (97.4 mg, 0.103 mmol) in THF (1.0 mL, 2 × 0.5 mL rinse) was added. After stirring at rt for 19 h, the crude reaction mixture was filtered over a pad of Celite with Et_2O (25 mL). The solution was transferred to a separatory funnel and extracted with a mixture of 10% aq. $Na_2S_2O_3$ (10 mL) and satd. aq. $NaHCO_3$ (10 mL). The layers were separated and the aqueous layer was extracted again with Et_2O (2 × 10 mL). The combined organic layers were dried (Na_2SO_4), filtered, and concentrated under reduced pressure to afford 113 mg of crude vinyl iodide. The iodide was redissolved in THF (1.0 mL) and subjected to two freeze–pump–thaw cycles. The degassed solution was then cooled to 0 °C and $Pd(PPh_3)_4$ (6.0 mg, 0.0052 mmol) was added, followed by a 2.0 mol/L solution of Me_2Zn in toluene (160 μL, 0.32 mmol). The cold bath was removed and the reaction was stirred at rt for ca. 17 h, stopped by adding H_2O (5 mL), and transferred to a separatory funnel. The aqueous layer was extracted with Et_2O (3 × 5 mL), the organic layers were combined, washed with brine (10 mL), dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 57.5 mg of **26** (63%, 4.7:1 mixture of (*Z*)–(*E*)-isomers) as a colourless oil. R_f 0.28 (10% EtOAc–hexane). FT-IR (neat, cm^{-1}): 3071, 2931, 2857, 1740, 1715, 1600, 1428, 1385, 1227, 1111. ^1H NMR ($CDCl_3$) δ: 7.74–7.61 (m, 8H), 7.45–7.33 (m, 12H), 6.47 and 6.45 (s, 1H), 6.02 and 6.00 (s, 1H), 4.54 and 4.43 (brs, 1H), 4.43 and 4.37 (brs, 1H), 4.31–4.20 (m, 2H), 4.16–4.04 (m, 1H), 3.87–3.79 (m, 2H), 3.55 and 3.50 (s, 3H), 2.98–2.77 (m, 2H), 2.77–2.59 (m, 2H), 2.55–2.35 (m, 2H), 1.86 and 1.85 (s, 3H), 1.71–1.50 (m, 3H), 1.56 and 1.09 (s, 3H), 1.32 and 1.30 (t, J = 7.2 Hz, 3H), 1.041 and 1.038 (s, 9H), 1.01 and 1.00 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 172.0 [171.5], 163.93 [163.90], 159.2 [158.9], 151.05 [150.97], 145.8 [145.0], 137.43 [137.38], 135.91, 135.88, 135.81, 135.6, 135.2, 134.8, 134.2, 133.9, 133.7, 133.6, 133.5, 129.5, 127.7, 127.6, 127.5, 127.4, 115.37 [115.24], 115.15 [115.08], 112.7, 107.7 [107.6], 69.0 [68.9], 62.3, 60.0, 51.31 [51.25], 43.3, 43.0, 42.4, 41.0, 40.3, 39.7, 36.6, 32.3 [32.2], 26.9, 26.8, 26.5, 25.2, 19.2, 19.1, 18.4, 18.0, 17.0, 14.4 [14.3].



5-Chloro-2-(trimethylsilyl)pent-3-yn-2-yl benzoate (27a)

A solution of *n*-BuLi (1.6 mol/L, 4.4 mL, 7.0 mmol) in Et_2O (40 mL) was cooled to –78 °C and treated with propargyl chloride (540 μL, 7.5 mmol). After stirring at

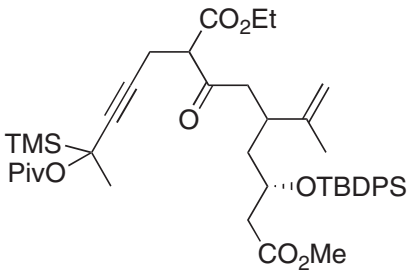
–78 °C for 20 min, acetyltrimethylsilane (720 μL, 5.0 mmol) was added dropwise. The mixture was stirred at –78 °C for 30 min and benzoyl chloride (870 μL, 7.8 mmol) was added. The reaction was allowed to gradually warm up to rt, while maintained in the cold bath and stirred overnight. The reaction was stopped by adding H_2O (50 mL) and the mixture was transferred to a separatory funnel. After extraction, the organic layer was separated and the aqueous layer was extracted once more with Et_2O (50 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 1.2 g of **27a** (80%) as a yellow-orange oil. For the full spectral characterization of this compound, see ref. 11.



5-Chloro-2-(trimethylsilyl)pent-3-yn-2-yl pivalate (27b)

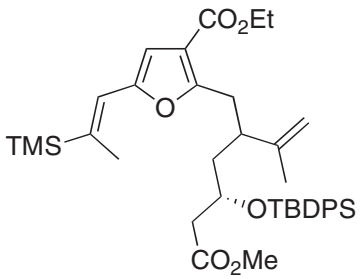
A solution of *n*-BuLi (1.6 mol/L, 8.8 mL, 14 mmol) in Et_2O (80 mL) cooled to –78 °C was treated with propargyl chloride (1.09 mL, 15.0 mmol). After stirring at –78 °C for 20 min, acetyltrimethylsilane (1.43 mL, 9.98 mmol) was added dropwise. The mixture was stirred at –78 °C for 30 min and trimethylacetyl chloride (1.85 mL, 15.0 mmol) was added. The reaction mixture was allowed to gradually warm up to rt, while maintained in the cold bath and stirred overnight. The reaction was stopped by adding H_2O (100 mL) and transferred to a separatory funnel. After extraction, the organic layer was separated and the aqueous layer was extracted once more with Et_2O (100 mL). The organic layers were combined, dried (Na_2SO_4), filtered, concentrated under reduced pressure, and purified by chromatography on SiO_2 to afford 1.59 g of **27b** (58%) as a yellow-orange oil. R_f 0.22 (5% EtOAc–hexane). FT-IR (neat, cm^{-1}): 2970, 1737, 1479, 1367, 1262, 1144, 1060. ^1H NMR ($CDCl_3$) δ: 4.24 (s, 2H), 1.62 (s, 3H), 1.19 (s, 9H), 0.19 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 177.1, 87.6, 82.4, 67.2, 39.2, 31.3, 27.1 (3), 21.1, –4.2. HR-MS (EI) *m/e* calcd. for $C_{13}H_{23}O_2SiCl$: 274.1156; found: 274.1154.

(7S)-1-Ethyl 9-methyl 2-(4-(benzoyloxy)-4-(trimethylsilyl)pent-2-ynyl)-7-(*tert*-butyldiphenylsilyloxy)-3-oxo-5-(prop-1-en-2-yl)nonanedioate (28a)



Following the same procedure as for the preparation of α-propargyl β-keto ester **22**, the alkylation of β-keto ester **21**

© 2006 NRC Canada



[prepared from [1,3]dioxin-4-one **20** (422 mg, 0.765 mmol)] with the iodide derived from **27a** (406 mg, 1.38 mmol) gave 580 mg (95%, two steps) of **28a** as a colourless oil. Since this α-propargyl β-keto ester exists as a mixture of up to four different diastereomers, it was not characterized.

(7S)-1-Ethyl 9-methyl 7-(tert-butyldiphenylsilyloxy)-3-oxo-2-(4-(pivaloyloxy)-4-(trimethylsilyl)pent-2-ynyl)-5-(prop-1-en-2-yl)nonanedioate (28b)

Following the same procedure as for the preparation of α-propargyl β-keto ester **22**, the alkylation of β-keto ester **21** [prepared from [1,3]dioxin-4-one **20** (387 mg, 0.703 mmol)] with the iodide derived from **27b** (349 mg, 1.27 mmol) gave 350 mg (64%, two steps) of **28b** as a colourless oil. Since this α-propargyl β-keto ester exists as a mixture of up to four different diastereomers, it was not characterized.

Ethyl 2-((4S)-4-(tert-butyldiphenylsilyloxy)-6-methoxy-6-oxo-2-(prop-1-en-2-yl)hexyl)-5-((E)-2-(trimethylsilyl)prop-1-enyl)furan-3-carboxylate (29)

In a microwave tube, a solution of **28b** (84.3 mg, 0.108 mmol) in THF (500 μL) was subjected to three freeze–pump–thaw cycles. To the degassed solution was then added allylpalladium chloride dimer (3.0 mg, 0.0082 mmol) and dppf (9.0 mg, 0.016 mmol) and the mixture was stirred vigorously at rt for ca. 5 min (during this time a voluminous precipitate formed). The microwave tube was then heated with stirring in the microwave reactor for 20 min (100 °C, 300 W) and then cooled to rt. The crude, wine-red reaction mixture was filtered over a pad of SiO_2 with 20% EtOAc–hexane. This material was then purified by chromatography on SiO_2 to afford 43.5 mg of **29** (59%) as a colourless oil. The diastereomeric mixture of furans was dissolved in THF (500 μL) and $(PhSe)_2$ (1.0 mg, 0.0032 mmol) was added. The solution was heated at 70 °C for 16 h in a sealed tube, then cooled to rt, and concentrated under reduced pressure. This material was purified by chromatography on SiO_2 to afford 36.8 mg of pure ***E*-29** (50% from **28b**) as a colourless oil. R_f 0.55 (20% EtOAc–hexane). FT-IR (neat, cm^{-1}): 3072, 2954, 2857, 1742, 1715, 1597, 1428, 1229, 1111. ^1H NMR ($CDCl_3$) δ: 7.73–7.60 (m, 4H), 7.45–7.31 (m, 6H), 6.55 and 6.54 (s, 1H), 6.44 and 6.37 (apparent q, J = 1.5 and 1.6 Hz, 1H), 4.59 and 4.48 (bs, 1H), 4.46 and 4.43 (bs, 1H), 4.31–4.19 (m, 2H), 4.18–4.04 (m, 1H), 3.56 and 3.50 (s, 3H), 3.00–2.75 (m, 2H), 2.63–2.36 (m, 2H), 2.01 and 2.00 (d, J = 1.6 and 1.6 Hz, 3H), 1.75–1.49 (m, 3H), 1.56 and 1.16 (s, 3H), 1.34 and 1.31 (t, J = 7.1 and 7.1 Hz, 3H), 1.00 (s, 9H), 0.14 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 171.9 [171.5], 163.9 [163.8], 159.4 [159.1], 151.83 [151.79], 145.7 [145.1], 140.2 [140.0], 135.92 (2) [135.88 (2)], 135.85 (2) [135.77 (2)], 134.2 [133.8], 133.6 (2), 129.6 (3), 129.5, 127.5 (6), 127.4 (2), 124.3 [124.2], 115.5 (2), 112.8 [112.6], 109.74 [109.71], 69.0 [68.8], 60.0 (2), 51.3 [51.2], 43.0 [42.9], 42.5 [41.0], 40.1 [39.6], 32.3 (2), 26.9 (3) [26.8 (3)], 19.2 (2), 18.0 [17.1], 17.1 (2), 14.34 [14.28], –2.3 (6). HR-MS (ESI–POS) *m/e* calcd. for $C_{39}H_{54}O_6NaSi_2$: 697.3357 [M + Na]; found: 697.3303.

Synthesis of a hindered C_2-symmetric hydrazine and diamine by a crisscross cycloaddition of citronellal azine[1]

Barry B. Snider, James F. Grabowski, Roger W. Alder, Bruce M. Foxman, and Lin Yang

Abstract: Crisscross cycloaddition of citronellal azine (**6**) with 2 equiv. of TFA and powdered 3 Å molecular sieves in CH_2Cl_2 at reflux for 22 h afforded 37% of the desired C_2-symmetric hydrazine **7** and 5%–10% of diastereomer **8** in which one of the 6–5 ring fusions is cis. Methylation of the hydrazine of **7** and reduction of the resulting salt (**9**) with Li in NH_3 cleaved the N—N bond to give secondary tertiary amine **10** in 97% yield. Eschweiler–Clarke methylation afforded the C_2-symmetric bis tertiary amine **11** in 69% yield. Racemic products were obtained in initial attempts at asymmetric catalysis using **7** or **11** as asymmetric bases, using bistertiary amine **11** as a ligand analogous to sparteine for alkyllithiums, or using the lithium amide from secondary tertiary amine **10** as an asymmetric base. Apparently, the proton is buried in the core of **11**, leaving a hydrophobic surface; the free counterion is not an asymmetric catalyst. Diamine **11** may be too hindered to complex to *s*-BuLi. Tertiary amine **11** (pK_{a1} = 24.7) is more basic than DBU (pK_a = 24.3) in CH_3CN, in good agreement with theory.

Key words: crisscross cycloaddition, azine, dipolar cycloaddition, calculation of pK_a.

Résumé : La cycloaddition croisée de l'azine du citronellal (**6**) à l'aide de 2 équivalents d'acide trifluoroacétique et de tamis moléculaires 3 Å en poudre, dans du CH_2Cl_2 au reflux, pendant 22 heures, conduit à la formation de l'hydrazine (**7**) de symétrie C_2 recherchée avec un rendement de 37 % ainsi qu'à environ 5 % à 10 % du diastéréomère **8** dans lequel la fusion des cycles à cinq et à six chaînons est cis. La méthylation de l'hydrazine **7** et la réduction du sel **9** qui en résulte avec du Li dans de l'ammoniac permet de clivé la liaison N—N pour conduire à la formation de l'amine secondaire tertiaire **10** avec un rendement de 97 %. Une méthylation de Eschweiler–Clarke fournit la bisamine tertiaire de symétrie C_2 (**11**) avec un rendement de 60 %. On n'a obtenu que des produits racémiques dans les essais initiaux de catalyse asymétrique en utilisant les bases asymétriques **7** ou **11**, en utilisant la bisamine tertiaire **11** comme ligand analogue à la spartéine pour les alkyllithiens ou en utilisant l'amide de lithium dérivé de l'amine secondaire tertiaire **10** comme base asymétrique. Il semble que le proton est enfoui à l'intérieur du composé **11** qui ne laisse qu'une surface hydrophobe; le contre-ion libre n'est pas un catalyseur asymétrique. Il est possible que la diamine **11** soit trop encombrée pour se complexer au *s*-BuLi. L'amine tertiaire **11** (pK_{a1} = 24,7) est plus basique que la DBU (pK_a = 24,3) dans le CH_3CN, ce qui est en bon accord avec la théorie.

Mots clés : cycloaddition croisée, azine, cycloaddition dipolaire, calcul de pK_a.

[Traduit par la Rédaction]

Introduction

Both inter- and intra-molecular crisscross cycloadditions of azines with two alkenes are well-known as routes to 1,5-diazabicyclo[3.3.0]octanes, which are tetralkylhydrazines embedded in the ring fusion of a bicyclo[3.3.0] ring system (see Scheme 1) (1, 2). In an intermolecular example, the azine of hexafluoroacetone (**1**) reacted with 2 equiv. of methyl acrylate in benzene at 80 °C for 8 days to give 64% of adduct **2** and minor amounts of regio- and stereo-isomers (2*b*). Reaction of 2-allyloxy-1-naphthalenecarboxaldehyde (**3**) with 0.5 equiv. of hydrazine dihydrochloride in EtOH at

Scheme 2. Crisscross cycloaddition of azine **6**.

reflux for 4 h provided the azine, which underwent a crisscross cycloaddition to give **4** in 61% yield (2*a*, 2*c*). We were intrigued by the possibility of using this reaction with the azine of a readily available chiral aldehyde, such as citronellal, to obtain a chiral C_2-symmetric product that might be of value as an asymmetric catalyst. C_2-Symmetric diamines have been widely used in asymmetric synthesis (3), as has sparteine, which is not C_2-symmetric (4). The intramolecular cycloaddition of citronellal phenylhydrazone has been reported, although the stereochemistry of the product has not been well-characterized (5). Kobayashi et al. (6) have also explored asymmetric cycloadditions of related unsaturated acylhydrazones.

Results and discussion

Crisscross cycloaddition of 6

Initial attempts at forming the azine **6** of (*R*)-citronellal (**5**) with hydrazine dihydrochloride under various conditions afforded complex mixtures of azine **6**, hydrazones, hemiacetals, hemiaminals, and (or) the ene adduct, isopulegol. Eventually we found that treatment of neat (*R*)-citronellal (**5**) with 0.5 equiv. of anhydrous hydrazine for 10 min at 0–25 °C afforded azine **6** quantitatively as a 100:20:1 mixture of *E*,*E*-, *E*,*Z*-, and *Z*,*Z*-isomers, respectively, as determined by analysis of the chemical shift of the CH=N protons (7).

Heating a solution of azine **6** with 2 equiv. of TFA and powdered 3 Å molecular sieves in CH_2Cl_2 at reflux for 22 h afforded 37% of the desired C_2-symmetric hydrazine **7** and 5%–10% of diastereomer **8** in which one of the 6–5 ring fusions is cis (see Scheme 2). Lower yields were obtained without molecular sieves, with either more or less TFA, with other acids or $BF_3{\cdot}Et_2O$, or by combining azine formation and crisscross cycloaddition in a single step.

The structures of both **7** and **8** were established by spectroscopic analysis and X-ray structure determination. The ^{13}C NMR spectrum of **7** has only 10 different carbons, establishing that the molecule is symmetrical. The ^1H NMR spectrum of **7** is also simple. H_{4a} and H_{10a} both absorb at δ 2.65 as a ddd (J = 11.0, 11.0, 3.7 Hz). The 11.0 Hz coupling constant between both H_{4a} and H_{12a} and H_{10a} and H_{6a} establishes that the ring fusions are trans with antiperiplanar hydrogens. The cycloaddition should proceed preferentially to give products with the methyl groups attached to C_3 and C_9 equatorial, permitting the assignment of **7** as the major product.

The ^{13}C NMR spectrum of the minor product **8** has 20 different carbons. H_{4a} absorbs at δ 2.17 as a ddd (J = 11.0, 11.0, 3.1 Hz). The 11.0 Hz coupling constant between H_{4a} and H_{12a} establishes that the ring fusion is trans. H_{10a} absorbs at δ 3.01 as a ddd (J = 8.5, 8.5, 5.5 Hz), establishing that the other ring fusion is cis. Assuming that the cycloaddition gave only products with equatorial methyl groups, the minor product must be **8**.

Crystallographic analysis[3]

Figures 1 and 2 show the structures of **7** and **8** determined by X-ray crystallographic analysis. The orientation of the lone pairs in the core 1,5-diazabicyclo[3.3.0]octanes is quite different in the two adducts. In the major adduct **7**, the lone pairs are syn with a calculated torsion angle of 12° (see Scheme 3). The numbering corresponds to that used for the crystallographic data. The nitrogens are pyramidal and are 0.45 and 0.44 Å above the plane formed by the three substituents. In the minor adduct **8**, the lone pairs are anti with a calculated torsion angle of 177°. The molecule is flattened with the nitrogens only 0.11 and 0.23 Å above the plane formed by the three substituents. In syn isomers such as **7**, the torsion angles C_1-N_1-N_2-C_{11} (117.8°) and C_{17}-N_1-N_2-C_7 (141.4°) are much less than 180° and differ significantly. In anti isomers, such as **8**, the torsion angles C_1-N_1-N_2-C_{11} (169.3°) and C_{17}-N_1-N_2-C_7 (174.7°) are both close to 180°. In syn isomers such as **7**, the torsion angle between the lone pairs (12°) is calculated to be the average of C_1-N_1-N_2-C_7 (12.2°) and C_{17}-N_1-N_2-C_{11} (11.4°). In anti isomers such as **8**, the torsion angle between the lone pairs (177°) is calculated

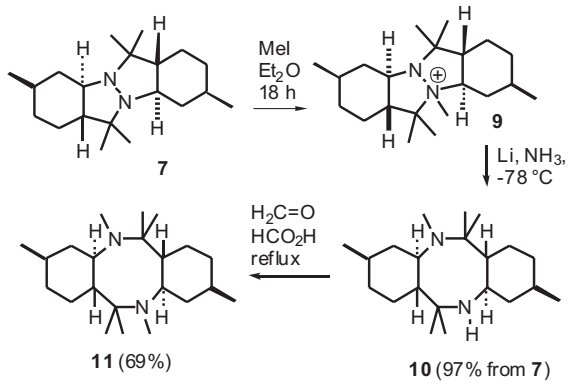
Scheme 3. 1,5-Diazabicylo[3.3.0]octane cores of **7** and **8** showing lone pair torsion angles.

to be 180° minus half the difference between C_1-N_1-N_2-C_7 (23.9°) and C_{17}-N_1-N_2-C_{11} (18.5°).

A search of the Cambridge Structural Database (CSD) found structures of seven 1,5-diazabicyclo[3.3.0]octanes whose CSD refcodes, lone pair torsion angles, and out of plane distances, respectively, are listed in the following. Five of these have syn lone pairs comparable to **7**: BETGOW, 48.3°, 0.45 Å, 0.45 Å (2*b*); BETGUC, 23.8°, 0.35 Å, 0.35 Å (2*b*); BETHAJ, 23.2°, 0.35 Å, 0.35 Å (2*b*); FEDYAP, 44.8°, 0.54 Å, 0.56 Å (2*i*); and WIWFAJ, 36.6°, 0.52 Å, 0.52 Å (2*g*). The other two have anti lone pairs comparable to **8**: LEKHIS, 179.8°, 0.44 Å, 0.43 Å (2*e*); and LEKHIS, 175.3°, 0.46 Å, 0.42 Å (2*e*).



Preparation of 10 and 11

Hydrazines are less basic than amines (8) and are sensitive to oxidation. We therefore explored the reductive cleavage of **7** to give a bis secondary amine. Although hydrazines have been reduced hydrogenolytically (9) or by dissolving metal reductions (10), initial attempts to reduce **7** by either method were unsuccessful. Apparently, steric hindrance and the electron-donating alkyl substituents retard the reduction. We activated the system toward reduction by methylation (11). A solution of **7** was treated with excess (10 equiv.) MeI in ether for 18 h at 25 °C to give **9** (see Scheme 4). Slow addition of a THF solution of **9** to excess Li in NH_3 at –78 °C afforded secondary tertiary amine **10** in 97% yield from **7**. It is important to make sure that excess Li is present because $LiNH_2$ acts as a nucleophile to convert **9** back to **7** with the formation of $MeNH_2$. Eschweiler–Clarke methylation (12) of **10** with formic acid and aqueous formaldehyde at reflux for 19 h afforded the C_2-symmetric tertiary amine **11** in 69% yield.

Evaluation of 7, 10, and 11 as catalysts

We now turned our attention to exploring the use of hydrazine **7** and amines **10** and **11** for asymmetric catalysis. Methanolysis of *cis*-1,2-cyclohexanedicarboxylic anhydride in ether (13) was very slow with **7** as the catalyst and very rapid with **11** as the catalyst. In both cases racemic product was obtained. Attempted deprotonation of *N*-Boc pyrrolidine with *s*-BuLi and **11**, analogously to that reported with *s*-BuLi and sparteine (14) was unsuccessful. Attempted asymmetric deprotonation of cyclohexene oxide with LDA and **10** as described by Asami for other chiral secondary tertiary amines (15) gave racemic 2-cyclohexen-1-ol. The nitrogens of **11** are very basic and quite hindered. The NMR spectrum of diamine **11** in CD_3OD is identical to that of the monotrifluoroacetate salt indicating that the free amine is fully converted to the ammonium methoxide. Apparently, the proton is buried in the core leaving a hydrophobic surface and the reactive methoxide is not an asymmetric catalyst.

Scheme 4. Conversion of hydrazine **7** to amines **10** and **11**.

Diamine **11** may be too hindered to complex to *s*-BuLi. It is also possible that the distance between and (or) alignment of the lone pairs make **11** a poor ligand for Li. The presence of the two geminal dimethyl groups makes the nitrogens very hindered so that **11** is not effective as an asymmetric catalyst or ligand.

Determination of the pK_a of 11 in MeCN

Cyclic diamines are much more basic than simple amines because there is lone pair repulsion in the free diamine and the ammonium salt is stabilized by a strong intramolecular hydrogen bond. 1,4-Dimethyl-1,4-diazacyclooctane has a pK_{a1} in H_2O of 11.9 (15). We determined the pK_{a1} of **11** relative to DBU (**12**) in CD_3CN by adding 0.4 equiv. of TFA to a CD_3CN solution of 1 equiv. of DBU and 1 equiv. of **11**. The NMR spectrum showed three species. Amine **11** (0.72 equiv.) and **11-H$^+$** (0.28 equiv.) are observed as separate species that equilibrate slowly on the NMR timescale as has been previously observed for other polyamines (16). DBU is observed as a single rapidly equilibrating species that is 14% protonated by comparison with values for DBU and DBU-H$^+$. We established that this mixture was at equilibrium by adding the components in various orders. These data establish that **11** is more basic than DBU by 0.4 pK_a units. Using a value of 24.3 for the pK_a of DBU in CH_3CN (17), the pK_{a1} of **11** is 24.7. A similar experiment in DMSO showed that only DBU was protonated, indicating that DBU (pK_a = 13.9, ref. 17) is much more basic than **11** in DMSO.

Calculation of the pK_a of 11

Calculation of proton affinities (PA), gas-phase basicities (GB), and solution pK_a values have been extensively developed in recent years and might help us understand the basicity of **11**. Liptak and Shields (18) have shown that it is possible to calculate absolute aqueous pK_a values with chemical accuracy and their methods have been applied with considerable success to calculate pK_a values in several solvents for one special class of strong neutral bases, the diaminocarbenes, by Magill et al. (19). Unfortunately, the most reliable methods (e.g., CBS-QB3) are far too computationally intensive to be applied to molecules the size of **11**. Magill and Yates' (20) recent results suggest that two good options for larger species are (*a*) CBS-4M and (*b*) B3LYP/6-311+G** and method (*b*) has been used here. This procedure uses geometries, zero point energies, and thermal and entropy corrections from the well-established B3LYP/6-

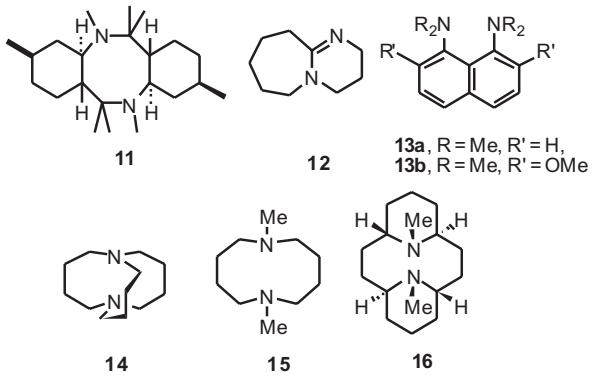
Table 1. Calculated (B3LYP/6-311+G**//B3LYP/6-31G*) PA and pK_a values for amines **11**–**15**.

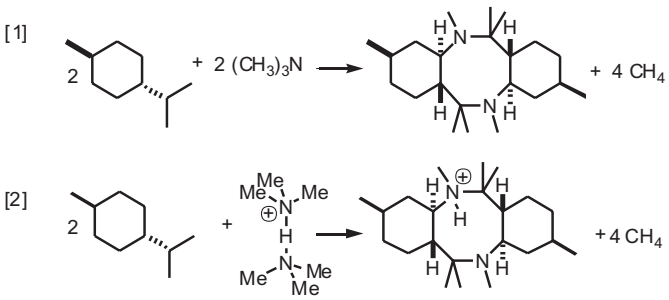
Diamine	Gas-phase PA (kJ mol^{-1})	pK_a (MeCN)[a]	pK_a (DMSO)[b]	$\Delta E(1)$ (kJ mol^{-1})	$\Delta E(2)$ (kJ mol^{-1})
11	1074	24.4	14.7	98	59
12	1052	23.9	12.1		
13a	1028	18.1	8.5		
13b	1089	23.2	11.1		
14	1046	23.5	14.0	1	–9
15	1078	28.3	18.7	42	–6
16	1105	30.4	20.9	43	–23

[a]Relative to Me_3N, pK_a = 17.61.
[b]Relative to Me_3N, pK_a = 8.4.



31G* level of theory. pK_a values have been calculated relative to the pK_a values for Me_3NH^+ of 17.61 in MeCN and 8.4 in DMSO, as described previously (21).

DFT calculations were performed with the Jaguar program package (22), using Becke's three-parameter exchange functional (23) with the correlation functional of Lee et al. (B3LYP) (24). All species were characterized by full geometry optimization with the standard 6-31G* basis set, and minima were characterized by analytical frequency calculations. Single point calculations were then carried out with the 6-311+G** basis set. Calculations simulating the solvents MeCN and DMSO employed the Poisson–Boltzmann continuum solvent model as implemented in the Jaguar program, with the assumption that geometries, zero point energy, and thermodynamic parameters could be transferred from the gas-phase calculations. These procedures lead to pK_a values of 11.9 (H_2O), 18.1 (MeCN), and 8.5 (DMSO) for the original proton sponge **13a** compared with experimental values of 12.1 (25), 18.62 (17*a*), and 7.5 (26, 27), respectively. The pK_a value of **13b** in DMSO is calculated to be 11.1 (experimental value, 11.5, ref. 28). While the general level of agreement in MeCN seems relatively good, it is worth noting that the calculated pK_a difference between **13b** and **15** in DMSO is 3.9, compared with a measured value of only 0.4 (15, 21).



Monte Carlo multiple minimum conformational searches (29, 30) were carried out to find low energy conformations for diamine **11** and the monoprotonated ion, using the MMFFs force field in MacroModel (31, 32). One conformation was clearly preferred for the ion, with a strong N···H-N$^+$ bond (2.66 Å distance between nitrogens; N···H-N angle, 140.9°). The cyclohexane rings are in the expected chair form, and the eight-membered ring is in a twist boat form. The conformational situation for diamine **11** was less clear and therefore, five low energy structures from a MacroModel search for the diamine were submitted to B3LYP/6-31G* calculation. The preferred structure was found to have the same conformation as the protonated ion, with the nitrogen atoms separated by 2.90 Å; this structure was used for the PA and pK_a calculations.

PA and pK_a values for amines **11**–**16** (see Chart 1) are listed in Table 1. The gas-phase PA results should be regarded as rather reliable. They show that diamine **11** is a substantially stronger base than the flexible 10-membered ring diamine **14**, in spite of having a hydrogen bond that is further from the linear ideal. This presumably reflects greater strain relief on protonation.

Chart 1. Structures of amines whose calculated PA and pK_a values are shown in Table 1.

Scheme 5. Theoretical eqs. [1] and [2] used for assessing strain relief in calculations of PA and pK_a values.

As described previously (21), a convenient way to assess this strain relief is by comparison of the calculated energy changes associated with eqs. [1] and [2] in which the strained diamine and protonated ion are formally constructed from unstrained components (see Scheme 5). The B3LYP/6-31G* computed vales for $\Delta E(1)$ and $\Delta E(2)$ are shown in Table 1. The value of $[\Delta E(1) - \Delta E(2)]$ for **11** (39 kJ mol^{-1}) is considerably greater than for **14** and approaches that for **15**, but is still much smaller than that for **16** (66 kJ mol^{-1}). We conclude that this strain relief is the major factor that determines the PA of these diamines. The increased strain in diamine **11**, when compared with its protonated ion, will be partly due to lone pair – lone pair repulsion, but forcing the nitrogen atoms to move to 2.90 Å, compared with 2.66 Å in the protonated ion, necessarily increases the strain elsewhere in the molecule.

There is much more uncertainty about the calculated pK_a values, since these rely on the performance of the solvation

© 2006 NRC Canada

model. In fact, the calculated pK_a values in MeCN for **11** and **12** are in reasonable agreement with the experimental relative pK_a data. Note that the calculations suggest that, in this solvent, **11** has a rather low pK_a value considering its PA, and is nearer to **14** than **15** in calculated pK_a. This of course reflects a relatively high (calculated) solvation energy for the diamine. There is no simple way of assessing whether this is correct, but we note that diamine **11** has a larger purely hydrophobic surface than the other diamines being used for comparison. While the calculated pK_a values in MeCN are in (possibly fortuitously) quite good agreement with experiment, the calculated values in DMSO are in poor agreement. We can offer no simple explanation, beyond noting that results for DMSO, using the Poisson–Boltzmann continuum solvent model, as implemented in the Jaguar program, have been less satisfactory than for MeCN, as noted earlier.

Conclusion

We have developed an efficient route to C_2-symmetric hydrazine **7** and diamine **11**. Initial trials suggest that the bis tertiary amine **11** is too hindered to function as an asymmetric catalyst or ligand. We are currently exploring routes to less hindered C_2-symmetric tricyclic amines that lack the two geminal dimethyl substituents.

Experimental section

General procedures

NMR spectra were recorded at 400 MHz in $CDCl_3$ unless otherwise indicated, chemical shifts are reported in δ, and coupling constants in Hz. The silica gel used for chromatography was deactivated with methanol unless otherwise indicated. IR spectra are reported in cm^{-1}.

(*R*)-Citronellal azine (6)

Anhydrous hydrazine (0.28 mL, 9.0 mmol) was added dropwise to (*R*)-(+)-citronellal (**5**, 3.26 mL, 2.77 g, 18.0 mmol) at 0 °C and the resulting mixture was stirred at 25 °C for 10 min. The mixture was diluted with CH_2Cl_2 (20 mL), dried over $MgSO_4$, and concentrated under reduced pressure to give 2.637 g (98%) of **6** as a 100:20:1 mixture of *E*,*E*-, *E*,*Z*-, and *Z*,*Z*-isomers (7), respectively, as a clear oil. IR (neat): 1651. ^{1}H NMR: 7.88 (t, 2, *J* = 6.1, *E*,*E*-isomer), 7.56 (t, 1, *J* = 5.8, *E*,*Z*-isomer), 7.15 (t, 1, *J* = 5.5, *E*,*Z*-isomer) 7.07–7.02 (t, 2, *J* = 5, *Z*,*Z*-isomer), 5.09 (tq, 2, *J* = 8.5, 1.2), 2.35 (ddd, 2, *J* = 14.0, 8.5, 6.1, *E*,*E*-isomer), 2.19 (ddd, 2, *J* = 14.0, 8.0, 6.1, *E*,*E*-isomer), 2.07–1.95 (m, 4), 1.84–1.76 (m, 2), 1.68 (s, 6), 1.60 (s, 6), 1.45–1.36 (m, 2), 1.30–1.21 (m, 2), 0.97 (d, 6, *J* = 6.7). ^{13}C NMR: 165.0 (2C), 131.5 (2C), 124.3 (2C), 39.6 (2C), 36.8 (2C), 30.9 (2C), 25.7 (2C), 25.4 (2C), 19.6 (2C), 17.6 (2C).

(3*R*,4a*R*,6a*R*,9*R*,10a*R*,12a*R*)-Dodecahydro-3,6,6,9,12,12-hexamethyl-1*H*,6*H*-indazolo[2,1-*a*]indazole (7) and (3*R*,4a*R*,6a*R*,9*R*,10a*S*,12a*R*)-dodecahydro-3,6,6,9,12,12-hexamethyl-1*H*,6*H*-indazolo[2,1-*a*]indazole (8)

TFA (1.4 mL, 18 mmol) was added to a suspension of azine **6** (2.616 g, 8.591 mmol) and 3 Å powdered molecular sieves (1.024 g) in dry CH_2Cl_2 (300 mL) and the resulting suspension was stirred and heated at reflux for 22 h. The suspension was cooled and water (60 mL) was added. The phases were separated and the aqueous layer was extracted with CH_2Cl_2 (3 × 60 mL). The combined organic phases were dried over Na_2SO_4 and concentrated under reduced pressure to give 3.632 g of a yellow oil. Flash chromatography on silica gel (hexanes–acetone, 3:2) and subsequent deprotonation with satd. $NaHCO_3$ solution gave 495 mg (19%) of 60% pure **8** as a clear wax. Elution with MeOH and subsequent deprotonation with satd. $NaHCO_3$ solution gave 975 mg (37%) of **7** as an orange wax. Data for **7**: IR (CH_2Cl_2): 1688. ^{1}H NMR: 2.65 (ddd, 2, *J* = 11.0, 11.0, 3.7, H_{4a}, H_{10a}), 1.84–1.60 (m, 8), 1.44–1.41 (m, 2), 1.19–1.09 (m, 2), 1.14 (s, 6), 0.98–0.87 (m, 4), 0.96 (s, 6), 0.92 (d, 6, *J* = 6.7). ^{13}C NMR: 58.2 (2C), 58.1 (2C), 57.6 (2C), 41.1 (2C), 34.5 (2C), 30.9 (2C), 28.4 (2C), 24.3 (2C), 22.2 (2C), 19.3 (2C). HRMS (EI) calcd. for $C_{20}H_{36}N_2$: 304.2878 (M^+); found: 304.2882

TFA (2 drops, excess) was added to a solution of **7** in $CDCl_3$ to give **7**·TFA: ^{1}H NMR: 2.92 (ddd, 2, *J* = 11.7, 11.4, 4.0, $H_{4a(10a)}$), 2.20 (ddd, 2, *J* = 12.3, 11.4, 3.2, $H_{12a(6a)}$), 1.91 (br d, 2, *J* = 11.7, $H_{4eq(10eq)}$), 1.78 (br d, 2, *J* = 13.2, $H_{2eq(8eq)}$), 1.73 (br dd, 2, *J* = 11.5, 3.2, $H_{1eq(7eq)}$), 1.44–1.38 (m, 2, $H_{3ax(9ax)}$), 1.41 (s, 6), 1.36 (ddd, 2, *J* = 11.7, 11.7, 11.4, $H_{4ax(10ax)}$), 1.15 (s, 6), 1.15 (br ddd, 2, *J* = 12.3, 11.5, 2.9, $H_{1ax(7ax)}$), 1.05 (m, 2, $H_{2ax(8ax)}$), 0.99 (d, 6, *J* = 6.2). A 1D NOESY experiment showed NOEs from $H_{4a(10a)}$ at δ 2.9 to $H_{12a(6a)}$ at δ 2.2 (small), to $H_{4eq(10eq)}$ at δ 1.91 (large), to $H_{3ax(9ax)}$ at δ 1.44–1.38 (small), to $H_{4ax(10ax)}$ at δ 1.36 (small), to $H_{1ax(7ax)}$ at δ 1.15 (small), and to the methyl group at δ 1.15.

Flash chromatography of 495 mg of 60% pure **8** on silica gel (Et_2O) gave 118 mg (5%) of **8** as a clear wax. ^{1}H NMR: 3.01 (ddd, 1, *J* = 8.5, 8.5, 5.5, H_{10a}), 2.17 (ddd, 1, *J* = 11.0, 11.0, 3.1, H_{4a}), 1.94–1.90 (m, 2, H_{6a}, H_{12a}), 1.86–1.78 (m, 2), 1.76–1.69 (m, 1), 1.58–1.48 (m, 3, including H_{10eq}), 1.47–1.39 (m, 1, H_{4eq}), 1.36–1.31 (m, 2), 1.27–1.18 (m, 2, including H_{10ax}), 1.12–1.05 (m, 1), 1.11 (s, 3), 1.10 (s, 3, 12-CH_3), 1.00 (s, 3, 6-CH_3), 0.98–0.86 (m, 1, H_{4ax}), 0.93 (d, 3, *J* = 6.7), 0.90 (d, 3, *J* = 6.1, 9-CH_3), 0.90 (s, 3, 6-CH_3), 0.77–0.72 (m, 1). ^{13}C NMR: 60.7, 58.5, 56.7, 54.2, 50.2, 38.2, 35.3, 34.2, 31.2, 31.1, 28.7, 26.5, 25.2, 25.0, 23.2, 22.42, 22.41, 21.8, 16.7 (one carbon was not observed). A 1D NOESY experiment showed NOEs from H_{10a} at δ 3.01 to H_{6a} at δ 1.94–1.90 (large), to H_{10eq} at δ 1.58–1.48 (small), to H_{10ax} at δ 1.27–1.18 (large), to 12-CH_3 at δ 1.10, and to 9-CH_3 at δ 0.90 (small). A 1D NOESY experiment showed NOEs from H_{4a} at δ 2.17 to H_{12a} at δ 1.94–1.90 (small), to H_{4eq} at δ 1.47–1.39 (large), to 6-CH_3 at δ 1.00 (large), to H_{4ax} at δ 0.98–0.86 (small), and to 6-CH_3 at δ 0.90 (small).

(3*R*,4a*R*,6a*R*,9*R*,10a*R*,12a*R*)-Hexadecahydro-3,5,6,6,9,12,12-heptamethyldibenzo[*b*,*f*][1,5]diazocine (10)

Iodomethane (0.56 mL, 9.06 mmol) was added to a solution of **7** (276 mg, 0.906 mmol) in dry Et_2O (18 mL) and the resulting solution was stirred at 25 °C for 18 h. The solution was concentrated under reduced pressure to give monomethylated iodide **9** as a white residue.

Crude **9** was dissolved in dry THF (12 mL) and the solution was added dropwise to a dark blue mixture of dry NH_3 (30 mL) and lithium metal at –78 °C. More lithium was

© 2006 NRC Canada

added immediately after the solution became lighter blue so that an excess of solvated electrons was always present. After the addition was complete, the mixture was stirred at reflux (–33 °C) for 1 h. NH_4Cl (3 g) was added and the NH_3 was evaporated. The residue was dissolved in water (20 mL) and the aqueous layer was extracted with CH_2Cl_2 (3 × 50 mL). The combined organic phases were washed with 1 mol/L NaOH solution (100 mL) and dried over Na_2SO_4. The resulting solution was concentrated under reduced pressure to give 283 mg (97%) of >95% pure **10** as a red liquid. IR (neat): 3349. ^{1}H NMR: 3.83 (br s, 1, NH), 2.83 (br dd, 1, J = 11.0, 11.0), 2.49 (br dd, 1, J = 10.4, 10.4), 2.37 (s, 3), 2.12–1.93 (m, 4), 1.76–1.64 (m, 4), 1.44–1.18 (m, 5), 1.17 (s, 3), 1.12–1.01 (m, 1), 1.04 (s, 3), 1.00–0.78 (m, 2), 0.96 (s, 3), 0.95 (s, 3), 0.934 (d, 3, J = 6.7), 0.927 (d, 3, J = 6.1). ^{13}C NMR: 68.7, 60.1, 59.8, 56.4, 50.8, 49.0, 43.6, 38.5, 37.0, 36.0, 35.8, 34.6, 34.1, 31.3, 30.6, 29.7, 28.6, 25.4, 23.8, 22.6, 21.9.

(3*R*,4a*R*,6a*R*,9*R*,10a*R*,12a*R*)-Hexadecahydro-3,5,6,6,9,11,12,12-octamethyldibenzo[*b*,*f*][1,5]diazocine (11)

Formic acid (0.17 mL, 4.42 mmol) and 37% formaldehyde in water (0.17 mL, 2.30 mmol) were added in succession to **10** (283 mg, 0.883 mmol) at 0 °C. The resulting solution was heated at reflux for 19 h. The solution was cooled and 2 mol/L HCl (3 mL) was added. The aqueous solution was extracted with Et_2O (2 × 5 mL) to remove less polar impurities and made basic with 2 mol/L NaOH solution. The aqueous solution was saturated with NaCl and extracted with EtOAc (3 × 10 mL). The combined organic phases were dried over Na_2SO_4 and concentrated under reduced pressure to give 205 mg (69%) of **11** as a white wax. IR (CH_2Cl_2): 2956, 2921, 2772. ^{1}H NMR: 2.38–2.27 (m, 2), 2.32 (s, 6), 2.18–1.98 (m, 4), 1.81–1.73 (m, 2), 1.72–1.62 (m, 2), 1.35–1.15 (m, 4), 1.12–0.82 (m, 4), 0.97 (s, 6), 0.92 (d, 6, J = 6.7), 0.89 (s, 6). ^{1}H NMR (CD_3CN): 2.40–2.29 (m, 2), 2.37 (s, 6), 2.25–2.10 (m, 2), 2.09–2.00 (m, 2), 1.82–1.72 (m, 2), 1.71–1.62 (m, 2), 1.38–1.24 (m. 2), 1.22–1.12 (m, 2), 1.11–0.92 (m, 4) 1.00 (s, 6), 0.94 (s, 6), 0.92 (d, 6, J = 6.7). ^{1}H NMR (CD_3OD): 3.07 (ddd, 2, J = 11.6, 11.3, 2.4), 2.67 (s, 6), 2.44 (ddd, 2, J = 11.3, 11.0, 3.1), 2.18 (br dd, 2, J = 11.6, 2.4), 1.90 (br ddd, 2, J = 12.2, 6.7, 3.0), 1.77 (br d, 2, J = 12.2), 1.54–1.40 (m, 2), 1.41 (ddd, 2, J = 11.6, 11.6, 11.6), 1.27 (s, 6), 1.26 (s, 6), 1.31–1.08 (m, 4), 1.03 (d, 6, J = 6.1). ^{13}C NMR: 67.0 (2C), 58.5 (2C), 49.9 (2C), 38.4 (2C), 36.8 (2C), 36.5 (2C), 34.3 (2C), 30.1 (2C), 22.6 (2C), 22.4 (2C), 22.3 (2C). HRMS (EI) calcd. for $C_{22}H_{42}N_2$: 334.3348 (M^+); found: 334.3356.

TFA (120 µL, 10^{-1} mol/L in $CDCl_3$, 12 µmol, 1 equiv.) was added to a solution of 4 mg (12 µmol) **11** in $CDCl_3$ to give **11**·TFA. ^{1}H NMR: 3.00 (br dd, 2, J = 11.9, 11.5), 2.71 (s, 6), 2.27 (ddd, 2, J = 11.5, 10.4, 2.4), 2.16 (br d, 2, J = 11.0), 1.89–1.79 (m, 4), 1.56–1.42 (m, 2), 1.28 (s, 6), 1.23 (s, 6), 1.23 (br ddd, 2, J = 11.9, 10.4, 9.8), 1.16 (br ddd, 2, J = 14.0, 14.0, 11.9), 1.08–0.94 (m, 2), 1.01 (d, 6, J = 6.7). The NMR spectrum did not change on addition of an additional 120 µL of TFA solution.

TFA (2 drops, excess) was added to a solution of **11** in CD_3CN to give **11**·TFA. ^{1}H NMR (CD_3CN): 2.97 (ddd, 2, J = 11.6, 11.3, 2.4), 2.57 (d, 6, J = 3.1), 2.36 (ddd, 2, J = 11.3, 10.6, 3.1), 2.10 (ddd, 2, J = 10.6, 1.8, 1.8), 1.85–1.74 (m, 2), 1.71 (br d, 2, J = 9.2), 1.49–1.30 (m, 4), 1.28–1.02 (m, 2), 1.18 (s, 12), 1.01–0.88 (m, 2), 0.97 (d, 6, J = 6.1).

Determination of the pK_a of 11 in CH_3CN

TFA (3.5 µmol, 0.4 equiv., 2.7 µL of a 1.3 mol/L solution in CD_3CN prepared by diluting TFA (100 µL, 148 mg, 1.3 mmol) to a final volume of 1 mL) was added to a solution of DBU (8.7 µmol, 13 µL of a 6.7×10^{-1} mol/L solution in CD_3CN prepared by diluting DBU (100 µL, 102 mg, 0.67 mmol) to a final volume of 1 mL) and **11** (2.9 mg, 8.7 µmol) in CD_3CN (1.0 mL). The resulting solution was monitored for 4 days at 25 °C by ^{1}H NMR. DBU was calculated to be 14% protonated from the ^{1}H NMR shift (δ 3.155, t, J = 5.5) relative to $DBUH^+$ (δ 3.279, br s) and to the DBU/**5** solution (δ 3.135, t, J = 5.5) prior to adding TFA. Diamine **11** was calculated to be 28% protonated from an integration of **11** at δ 2.09–1.72 (m, 4) and **11**-H^+ at δ 2.97 (ddd, 2, J = 11.6, 11.3, 2.4). Based on the pK_a of DBU (24.34 (17*a*)), the pKa of **11** was calculated to be 24.7. An identical mixture was obtained adding DBU to a solution of TFA and diamine **11** in CD_3CN.

Determination of the pK_a of 11 in DMSO

TFA (3.5 µmol, 0.40 equiv., 2.7 µL of a 1.3 mol/L solution in DMSO-d_6, prepared by diluting TFA (100 µL, 148 mg, 1.3 mmol) to a final volume of 1 mL) was added to a solution of DBU (8.7 µmol, 13 µL of a 6.7×10^{-1} mol/L solution in DMSO-d_6, prepared by diluting DBU (100 µL, 102 mg, 0.67 mmol) to a final volume of 1 mL) and **11** (2.9 mg, 8.7 µmol) in DMSO-d_6 (1.0 mL) and the resulting solution was monitored for 3 h at 25 °C by ^{1}H NMR. DBU was calculated to be 37% protonated from the ^{1}H NMR shift (δ 3.150, br s) relative to $DBUH^+$ (δ 3.248, br s) and to the DBU/**11** solution (δ 3.093, t, J = 5.2) prior to adding TFA. Diamine **5** was calculated to be completely unprotonated. The peaks for **11** at δ 2.12–1.93 (m, 4) were present and those for **11**-H^+ at δ 2.99 (br dd, 2, J = 10.4, 10.4) were absent.

A solution of TFA (3.5 µmol, 2.7 µL of a 1.3 mol/L stock solution in DMSO-d_6) and **11** (2.9 mg, 8.7 µmol) in DMSO-d_6 (1.0 mL) showed the presence of a mixture of **11** and **11**-H^+ (48:52) based on integration of the peaks for **11** at δ 2.12–1.93 (m, 4) and for **11**-H^+ at δ 2.99 (br dd, 2, J = 10.4, 10.4). Addition of DBU (8.7 µmol, 13 µL of a 6.7×10^{-1} mol/L solution in DMSO-d_6) gave a spectrum identical to that described above with DBU absorbing at δ 3.151 and only unprotonated **11**.

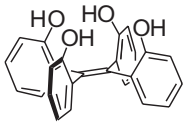
Bis(ether) derivatives of tetrakis(2-hydroxyphenyl)ethene — Direct synthesis of (*E*)- and (*Z*)-bis(2-hydroxyphenyl)-bis(2-methoxyphenyl)ethene via the McMurry olefination reaction[1]

Mee-Kyung Chung, Paul Fancy, and Jeffrey M. Stryker

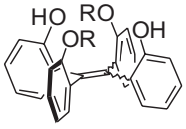
Abstract: The direct synthesis of sterically hindered, partially etherified derivatives of tetrakis(2-hydroxyphenyl)ethene is reported by using the McMurry reductive olefination reaction on a range of differentially substituted 2,2′-dialkoxybenzophenone substrates. Three orthogonal protection strategies are demonstrated, incorporating β-silylethyl, 3-butenyl, and *tert*-butyl protecting groups, respectively, into the starting benzophenones. The latter proved most efficient, with both the McMurry coupling and deprotection steps occurring concomitantly under the McMurry conditions to directly yield the desired bis(2-hydroxyphenyl)-bis(2-methoxyphenyl)ethene as a 1:1 mixture of *E*- and *Z*-diastereoisomers.

Key words: preorganized polyaryloxide ligands, McMurry olefination, titanium trichloride, supramolecular chemistry, tetrakis(2-hydroxyphenyl)ethene, 2,2′-disubstituted benzophenone.



Résumé : On a réalisé la synthèse directe de dérivés stériquement encombrées et partiellement éthérifiés du tétrakis(2-hydroxyphényl)éthène en appliquant la réaction d'oléfination réductrice de McMurry à une large série de 2,2′-alkoxybenzophénones substituées. On a démontré les stratégies de protection orthogonale en incorporant respectivement des groupes protecteurs β-silyléthyle, butén-3-yle et *tert*-butyle dans les benzophénones de départ. Le dernier s'avère le plus efficace alors que les étapes de couplage de McMurry et de déprotection se produisent d'une façon concomitante dans les conditions de McMurry pour conduire directement au bis(2-hydroxyphényl)éthène-bis(2-methoxyphényl)éthène recherche sous la forme de mélange 1 : 1 des diastéréoisomères *E*- et *Z*-.

Mots clés : ligands polyaryloxydes préorganisés, oléfination de McMurry, trichlorure de titane, chimie supramoléculaire, tétrakis(2-hydroxyphényl)éthène, benzophénone 2,2′-disubstituée.



[Traduit par la Rédaction]

Introduction

Structurally preorganized polydentate ligands based on tetrakis(2-hydroxyphenyl)ethene (**I**) constitute a topologically distinct alternative to the ubiquitous calix[4]arene class (1, 2). The roughly square binding array and conformational rigidity imposed by the planarity of the ethylene core allows the construction of highly bridged polymetallic coordination complexes of unusual robustness, providing unique structural and functional models for oxo-surface coordination (1*a*, 3). To expand the potential of this system for applications to coordination chemistry, the preparation of partially etherified tetrakis(2-hydroxyphenyl)ethene ligands (e.g., **II**) has also been reported, both by direct synthesis and by selective dealkylation reactions starting with tetrakis(2-methoxyphenyl)ethene (4).

I

II

The original synthesis of tetrakis(2-hydroxyphenyl)ethene derivatives required a two-step conversion of a 2,2′-dialkoxybenzophenone to the corresponding diaryldiazomethane, followed by acid-catalyzed generation of the tetrakis(2-alkoxyphenyl)ethene. We recently introduced (5) an improved synthesis of tetrakis(2-substituted) tetraphenylethenes by direct conversion of the 2,2′-dialkoxybenzophenone into the corresponding tetraphenylethene using the McMurry reductive olefination reaction (6). Historically, bis(ortho-substituted) benzophenones have been identified as unsuitable for the McMurry reaction, leading instead to competitive reduction of the diarylketone and (or) formation of the

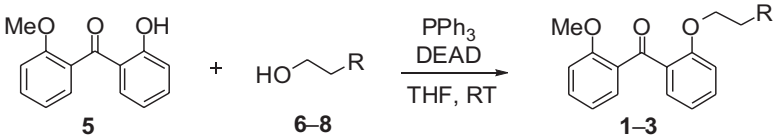
coupled but over-reduced tetrasubstituted ethane (7). 2,2′-Dimethoxybenzophenone itself is reported to produce tetrakis(2-methoxyphenyl)*ethane* nearly exclusively (7*a*), presumably a consequence of the high degree of steric congestion in the vicinity of the carbonyl functionality. Despite this negative precedent, however, meticulous optimization of McMurry reaction conditions has led to a remarkably general McMurry procedure for the preparation of sterically hindered tetrakis(2-substituted) tetraphenylethenes in moderate to excellent yields, a significant expansion in the scope of this important olefination reaction (5). To explain this success, the intervention of a previously unrecognized *substrate-based electronic effect* was postulated, contravening the steric limitations inherent to this substrate class.

To improve upon our syntheses of bis(ether) derivatives of tetrakis(2-hydroxyphenyl)ethene, our McMurry protocol has been challenged by a series of orthogonally protected 2,2′-dialkoxybenzophenones, some of considerable steric encumbrance. In this communication, we report the successful extension of the McMurry olefination protocol to this expanded range of unsymmetrically disubstituted substrates, culminating in a single-step olefination–deprotection procedure for the synthesis of (*E*)- and (*Z*)-bis(2-hydroxyphenyl)-bis(2-methoxyphenyl)ethene.

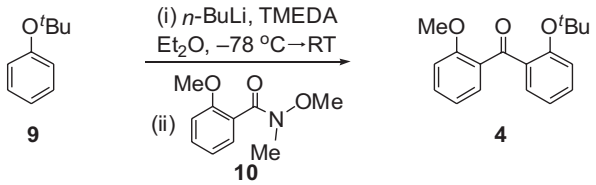
Results and discussion



Thus, four unsymmetrically functionalized 2,2′-dialkoxybenzophenones (**1**–**4**) were selected for investigation, each designed to produce a tetrakis(2-alkoxyphenyl)ethene derivative capable of undergoing selective deprotection to give the targeted bis(2-hydroxyphenyl)-bis(2-methoxyphenyl)ethene. Benzophenones **1**–**3** were directly prepared by the dehydrative etherification of 2-hydroxy-2′-methoxybenzophenone [(2-hydroxyphenyl)(2-methoxyphenyl)methanone] (**5**) (4) and the corresponding functionalized alcohols **6**–**8** (8) under Mitsunobu-type conditions (eq. [1]) (9).[3] The final substrate, 2-*tert*-butoxy-2′-methoxybenzophenone (**4**), was prepared in good yield by the directed ortho-lithiation of *tert*-butoxybenzene (**9**) (*n*-BuLi, TMEDA) (10) followed by condensation with the known Weinreb amide, 2-methoxy-*N*-methoxy-*N*-methyl benzamide (**10**) (eq. [2]) (11, 12).

For each substrate, treatment under the previously optimized McMurry reaction conditions ($TiCl_3$ or $TiCl_3$·1.5DME, Zn(Cu), DME, RT)[3] proceeded in moderate to good yields to give the desired olefination product, albeit as an approximately 1:1 mixture of (*E*)- and (*Z*)-isomers (Table 1). The β-silylethyl and butenyl ethers **1**–**3** were converted to the expected bis(2-methoxyphenyl)-bis(2-alkoxyphenyl)ethene derivatives **11**–**13**, respectively (Table 1, entries 2–4). For comparison, the results obtained from McMurry coupling of the symmetrical 2,2′-dimethoxybenzophenone under the same conditions are also provided in Table 1 (entry 1) (5). Although it was anticipated that the steric bulk of the β-silylethyl protecting groups might produce a diastereoselective McMurry reaction, the reactions were entirely nonselective, suggesting that the silyl substituents are too remote from the reactive carbonyl functionality to influence the stereochemistry of the reaction.

For bis[2-(3-butenyloxyphenyl]-bis(2-methoxyphenyl)ethene (**13**), selective deprotection of the butenyloxy moiety was accomplished using catalytic $RhCl_3$·$3H_2O$ (13) in ethanol (reflux, 24 h).[3] In this way, the readily separable mixture of (*E*)- and (*Z*)-bis(2-hydroxyphenyl)-bis(2-methoxyphenyl)ethene (**14**) (ca. 1:1) was obtained, spectroscopically identical with authentic material (4). With due consideration of the attractive results obtained from the reactions of **4** (vide infra), the deprotection of the β-silylethyl ether derivatives **11** and **12** was not pursued in this investigation.



Among the four substrates, the *tert*-butyl ether derivative **4** provided the most compelling and, not coincidentally, the most synthetically valuable result. Despite our original expectation that the steric bulk of the *tert*-butyl substituent might completely inhibit the McMurry reaction, the desired olefination reaction nonetheless proceeds in good yield, *accompanied by the serendipitous in situ deprotection of the* tert*-butyl ether groups*. Thus, a mixture of (*E*)- and (*Z*)-bis(2-hydroxyphenyl)-bis(2-methoxyphenyl)ethenes (**14**) (ca. 1:1) was obtained *directly* from the McMurry reaction (Table 1, entry 5).[3]

A series of control experiments provides some insight into this unexpected transformation. Although the preparation of the low-valent titanium reagent by reduction of $TiCl_3$ with Zn(Cu) also produces $ZnCl_2$ as a by-product, the Lewis acid-

[c]1,1,2,2-(2′-Methoxyphenyl)ethane was also isolated in 15% yield.

[d]Large-scale experiment (4.12 g, 17.0 mmol of ketone).

[e]The corresponding tetraarylethane was isolated in ~5% yield.

[f]1,2-Bis(2′-hydroxyphenyl)-bis(2′-methoxyphenyl)ethane was isolated in 17% yield.

[g]Product identification by comparison to literature data (see ref. 4).

[h]$TiCl_3$·1.5DME was used as the titanium source and the McMurry reagent preparation step was omitted in this procedure.

ity of this compound is significantly moderated by coordination to DME. In independent trials, anhydr. $ZnCl_2$ in DME only slowly mediates cleavage of the *tert*-butyl ether in **4**.[4] Moreover, the reaction of 2-hydroxy-2′-methoxybenzophenone (**5**) with $TiCl_3$–Zn(Cu) under otherwise identical reaction conditions produces no detectable olefination product; the McMurry reaction of **4** clearly involves the reductive coupling of the intact substrate.[5] Steric effects, evidently, do

[4]The conversion of **4** to **5** using equimolar anhydr. $ZnCl_2$ in DME proceeds 12% to completion after being left overnight at ambient temperature.

[5]After standard aqueous work up, **5** was recovered in 87% yield.

not significantly limit the scope of the McMurry reaction for the production of hindered tetraphenylethenes (5). Whether the in situ deprotection of the *tert*-butyl ether occurs on the surface of the low-valent titanium or by subsequent reaction with DME-solvated $ZnCl_2$ remains undetermined. The replacement of unsolvated $TiCl_3$ powder with the $TiCl_3$·1.5 DME complex and elimination of the reagent preparation period (14) provides significantly higher yields of bis(2-hydroxyphenyl)-bis(2-methoxyphenyl)ethene (**14**) (Table 1, entry 5), although the origin of this improvement is not obvious.[6] Finally, despite the close proximity of the sterically bulky *tert*-butyl substituents to the reactive carbonyl functionality, the McMurry olefination of **4** remains inexplicably stereorandom, consistently returning a 1:1 mixture of (*E*)- and (*Z*)-isomers.

Despite this lack of diastereoselectivity, the steric tolerance of this McMurry olefination protocol is quite remarkable, providing unexpectedly general access to sterically encumbered ortho-substituted tetraphenylethenes. Further extension in the scope of this reaction remains under investigation.

Optimized experimental procedure

McMurry reaction of 4 using $TiCl_3$·1.5 DME[3]

All operations were performed under an atmosphere of argon. In a glovebox, an oven-dried, 50 mL Schlenk flask was charged with $TiCl_3$·1.5 DME (0.62 g, 4.0 mmol) and Zn(Cu) (0.13 g, 2.0 mmol). After removal from the glovebox, anhydr. DME (12.0 mL) was added at ambient temperature under an argon flow. An oven-dried 25 mL Schlenk flask was charged with **4** (0.20 g, 0.69 mmol) and anhydr. DME (6.0 mL) under an atmosphere of argon. The resulting solution was transferred to the slurry of low-valent titanium by cannula under a flow of argon and the reaction mixture stirred at ambient temperature for 18 h, with the progress of the reaction monitored by analytical TLC. After completion of the reaction, the reaction mixture was quenched cautiously with 5 mL of water. The resulting suspension was extracted with diethyl ether (3 × 15 mL). The combined organic layers were dried over $MgSO_4$ and the volatiles removed on the rotary evaporator. Flash chromatography of the crude product on silica gel using a gradient solvent system of CH_2Cl_2–hexanes provided 0.220 g of 1,2-bis(2-hydroxyphenyl)-bis(2-methoxyphenyl)ethene (**14**) as a 1:1 mixture of (*E*)- and (*Z*)-isomers (64% yield). Stereochemical assignments and separation of the isomers by selective crystallization or column chromatography has been previously reported (4).

Fabrication of patterned organic thin film by low-energy electron beam lithography and surface-initiated ring-opening metathesis polymerization[1]

Zhebo Ding and Bruce Ganem

Abstract: High densities of immobilized polymer brushes have been created on solid supports in a spatially addressable fashion. Octadecyltrichlorosilane was self-assembled on a silicon substrate to form an inert monolayer. The substrate was then patterned by low-energy electron beam lithography. Finally, the exposed region was back-filled with a second functionalized silane and the pattern was further amplified by surface-initiated ring-opening metathesis polymerization. The patterned substrate was imaged by scanning electron microscopy and atomic force microscopy.

Key words: patterned thin film, e-beam lithography, ring-opening metathesis polymerization, polymer brushes.

Résumé : On a préparé des brosses de polymères de hautes densités immobilisés sur des supports solides dans des arrangements qui peuvent être adressés d'une façon spatiale. On a réalisé un autoassemblage de l'octadécyltrichlorosilane sur un substrat de silicium qui à conduit à la formation d'une monocouche inerte. On a ensuite lithographié le substrat à l'aide de la méthode par faisceau d'électrons de basse énergie. Enfin, on a rempli la région exposée avec un deuxième silane fonctionnalisé et on a amplifié le patron par une polymérisation de métathèse avec ouverture de cycle initiée par la surface. On a obtenu une image du patron du substrat à l'aide de microscopie électronique à balayage et par microscopie des forces atomiques.

Mots clés : film mince avec un patron, lithographie à l'aide d'un faisceau électronique, polymérisation de métathèse avec ouverture de cycle, brosses de polymère.

[Traduit par la Rédaction]

Introduction

The ability to immobilize organic compounds on solid supports in a spatially addressable fashion is of interest in combinatorial chemistry, high-throughput screening, genetic analysis, controlled drug delivery, and trace analyte detection (1). High densities of surface-bound organic substances may be achieved using polymer brushes, which are long polymer chains anchored to the surface that extend away from the attachment sites. Such systems may be assembled either by grafting functionalized polymers onto the surface (2) or by inducing radical (3), cationic (4), or anionic (5) polymerization reactions at surface-bound initiators.

The use of ring-opening metathesis polymerization (ROMP) reactions catalyzed by well-defined and highly active metal alkylidenes (6) represents an attractive alternative approach. The living nature of ROMP reactions provides control of organic thin film thickness and chemical composition. Recently, Weck et al. (7*a*) and Kim et al. (8) reported successful surface-initiated ROMP reactions using an initiator anchored on gold and Si–SiO_2 surfaces, respectively. Pattern generation in polymeric films was achieved by combining microcontact printing (μ-CP) and surface-initiated polymerization (9). Recently, imprint lithography has been demonstrated to fabricate sub-100 nm features (10) for biotechnological applications such as antibody or cell–cell interaction assays (11). Here, we report a simple method for creating high densities of immobilized polymer brushes on solid supports in a spatially addressable fashion as an alternative to imprint lithographic technique.

Electron beam lithography is commonly used in semiconductor manufacturing and can produce precisely aligned, high-resolution patterns. Because direct substrate contact is not required, the method offers advantages over μ-CP or scanned probe lithography (SPL) for patterning surfaces that display complex features (12). Moreover, no mask is needed for electron beam lithography. The creation of features as small as 6 nm in width has been achieved by electron beam

lithography on self-assembled monolayers (SAMs) (13). Low-energy electron beam lithography has recently attracted attention because of its easy operation, low cost, and biological compatibility. Here, we describe a simple and convenient method for fabricating patterned organic thin films using a combination of low-energy electron beam lithography and surface-initiated ROMP.

Methods

A monolayer of octadecyltrichlorosilane (OTS) was self-assembled on a Si–SiO_2 substrate (Fig. 1), then patterned sacrificially by low-energy electron beam lithography. Next, the exposed region was back-filled with a second functionalized silane and the pattern was further amplified by surface-initiated ROMP. Overall, the process is simple and compatible with simple dip and rinse laboratory protocols.

To prepare a hydroxyl group terminated Si–SiO_2 substrate for monolayer deposition, a silicon wafer was first rinsed several times with acetone and 2-propanol. The wafer was then immersed in a boiling solution containing 1:1:5 (by volume) of 30% aqueous hydrogen peroxide, 28%–30% ammonium hydroxide, and deionized water for 10 min, then rinsed with deionized water and dried with flowing argon gas. Self-assembled monolayers of OTS (Sigma-Aldrich) were formed on the clean silicon surface by immersing the cleaned substrate in a 2 mmol/L OTS solution in toluene overnight under argon. The sample was then sonicated in toluene for 5 min, rinsed with toluene, dried with argon, and annealed at 130 °C for 20 min. The contact angle of prepared OTS-modified silicon surfaces was measured to be 113 ± 3°, indicating the complete coverage of the self-assembled monolayers (14). Monolayers were judged to be stable for at least two months when stored in a desiccator at room temperature, since no significant decrease in contact angle was observed.

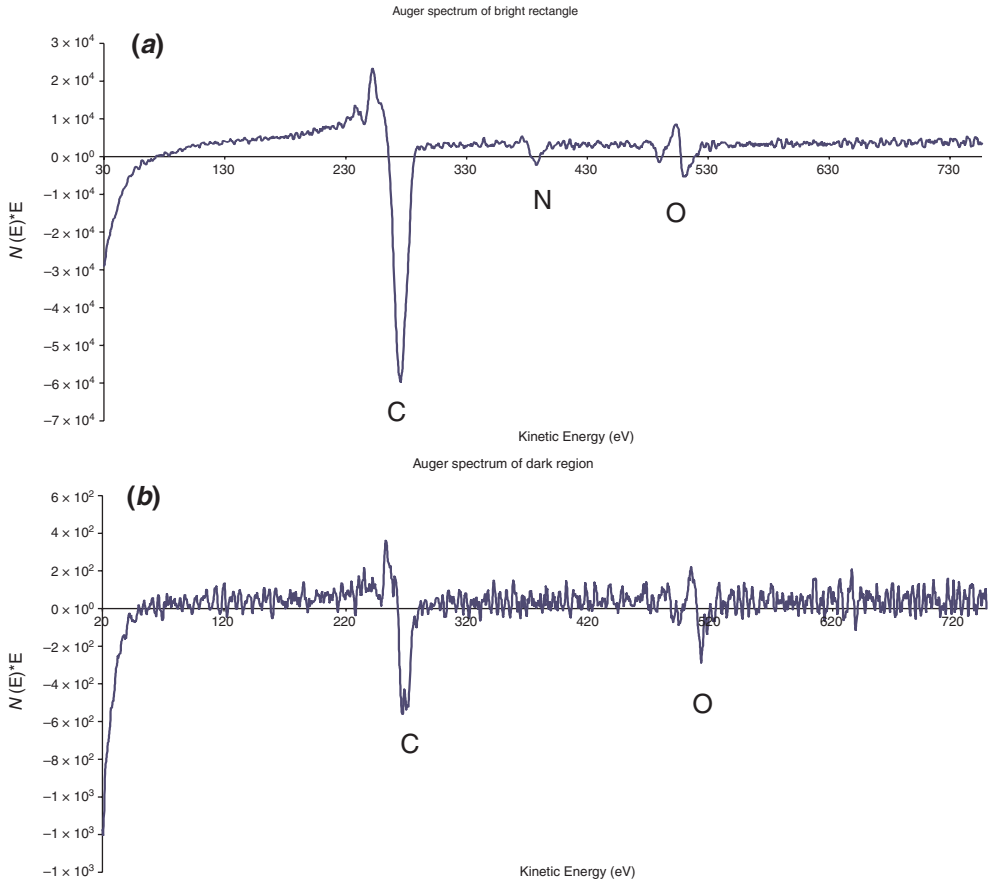

Fig. 2. SEM image of patterned polymer film of **3** on a Si–SiO_2 substrate.

A scanning electron microscope (LEO Electron Microscopy, Inc.Nano Technology Systems Division, Carl Zeiss SMT), equipped with a pattern generator and alignment system (JC Nabity Lithography Systems, Bozeman, Montana), was used for electron beam lithography. Typical electron beam exposures were conducted at an accelerating voltage of 2 kV and doses of 500 µC/cm^2. After electron beam exposure, the sample was further developed in the UV–ozone

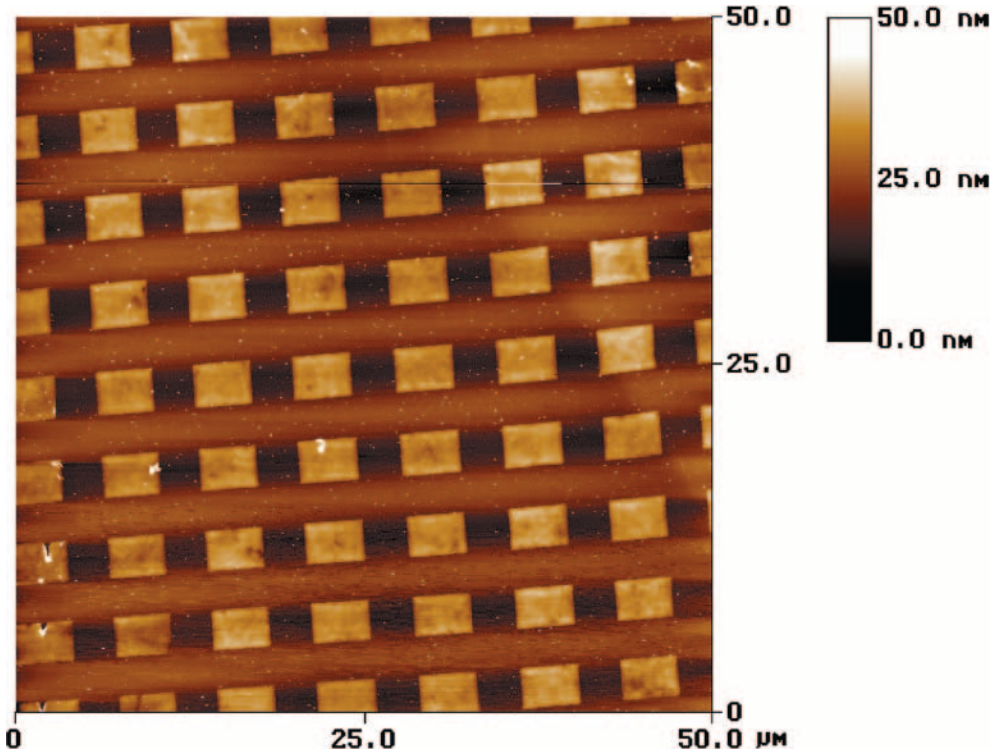
Fig. 3. Auger electron spectra of (*a*) the region modified by polymer film of **3** and (*b*) the OTS-modified region. Spectra were taken at an extraction voltage of 3 kV and an electron current of 20 nA. Samples were tilted at a 60° angle.

cleaner (UVOCS Inc., Montgomeryville, Pennsylvania) for 45 s to remove the decomposed monolayer and to regenerate the chemically active hydroxyl groups. It has been shown (15) that UV–ozone exposure is sufficient to remove damaged monolayers without significantly reducing the hydrophobicity of unexposed areas. After surface cleaning, the substrate was immediately immersed in a toluene solution containing 4% (by volume) styrylethyltrimethoxysilane (**1**, SETS, Gelest Inc., Morrisville, Pennsylvania) and 2% (by volume) triethylamine (Fluka) overnight to back-fill the exposed area. The substrate was then sonicated in toluene for 5 min, rinsed with toluene, and dried with argon. Grubbs catalyst [$(Cy_3P)_2Cl_2Ru{=}CHPh$] (16) (**2**) was then immobilized at the styryl-terminated regions by dipping the patterned substrate into a 33 mmol/L CH_2Cl_2 solution of **2** for 3 h. After extensive rinsing with distilled CH_2Cl_2, the sample was subsequently exposed to a 0.4 mol/L CH_2Cl_2 solution of *exo*-*N*-methyl-7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboximide (**3**) for 16 h to allow the growth of polymer brushes on the surface.

Spatially localized polymer brushes synthesized by surface-initiated ROMP on the patterned functionalized surfaces were imaged by scanning electron microscopy (SEM) and atomic force microscopy (AFM). Figure 2 shows a low-resolution SEM image of the patterned polymer film. The dark rectangles in the image (3 μm × 2 μm) represent regions where polymer brushes were formed, while light regions represent unaffected areas of OTS monolayers.



Insights into the chemical composition of the dark and light regions in Fig. 2 came from Auger electron spectroscopy. A scanning Auger microprobe (SAM) was used to establish unique elemental signatures in each region (Fig. 3). Using this technique, dark regions in the SEM image corresponded to polymer brushes, as confirmed by the carbon, nitrogen, and oxygen elemental signatures in the Auger spectrum (Fig. 3*a*). The Auger spectrum of light regions (Fig. 3*b*) matched spectra of authentic samples of uniform OTS monolayers.

Further analysis of the polymer brushes was carried out using AFM. A 50 μm × 50 μm tapping mode AFM scan of the patterned polymer film (Fig. 4) showed very well-defined boundaries between regions where polymer brushes were formed (bright rectangles) and regions covered with OTS (dark areas). The regions of the surface exposed to the electron beam were covered by uniform polymer films. Estimates from the AFM image indicated that the polymer brush thickness was ~30 nm, which is in good agreement with ellipsometry data.[3]

[3] Ellipsometry results were obtained using uniform polymer films produced under identical experimental conditions.

Fig. 4. Tapping mode AFM image of patterned polymer film of **3** on Si–SiO_2 substrate.

Conclusion

In conclusion, a simple surface chemical process has been developed for fabricating patterned organic thin films using low-energy electron beam lithography and surface-initiated ROMP. All processes were conducted in solution at ambient temperature by simple dip and rinse procedures. The use of low-energy electron beam lithography makes it possible to generate higher resolution patterns on surfaces, while locally varying the density of attached materials. The use of this technique for the site-specific anchoring of concentrated quantities of small-molecule drugs, peptides, or diagnostic proteins as polymer brush deposits on surfaces is currently being explored.

A silyl-mediated [3+2] photochemical cycloaddition[1]

Michael G. Organ and Debasis Mallik

Abstract: The generation of larger rings from intermediate cyclobutanes via a two-step [2+2] photocycloaddition – ring expansion, known as the de Mayo reaction, has been widely applied in synthesis. Herein a one-step synthesis of cyclopentanoids has been developed based on the photochemical irradiation of an enone in the presence of an allylsilane. The ability of the silyl moiety to stabilize the intermediate biradical is believed to be responsible for this unique transformation where one normally expects to see the [2+2] cyclobutane adduct.

Key words: [2+2] photocycloaddition – ring expansion, allylsilanes, cyclopentanoids, photochemical.

Résumé : La génération de cycles plus grands à partir d'intermédiaires cyclobutanes, par le biais d'une séquence en deux étapes comportant une photocycloaddition [2+2] suivie expansion de cycle, connue sous le nom de réaction de de Mayo, est très souvent utilisée en synthèse. Dans ce travail, on décrit une synthèse en une étape de cyclopentanoïdes qui repose sur l'irradiation photochimique d'une énone en présence d'un allylsilane. On croit que la possibilité pour la portion silane de stabiliser l'intermédiaire biradicalaire est responsable de cette transformation unique au cours de laquelle on s'attend normalement à obtenir une addition cyclobutane [2+2].

Mots clés : photocycloaddition [2+2] – expansion de cycle, allylsilanes, cyclopentanoïdes, photochimie.

[Traduit par la Rédaction]

Since the seminal work on the allylation reaction between allyltrimethylsilane and α,β-unsaturated ketones was disclosed by Hosomi and Sakurai (1), there has been a great deal published regarding the expansion of the scope and utility of allylsilanes in such reactions (2). This methodology has been expanded to include ring formation when the allylsilanes involved possess "bulky groups" on silicon to provide cyclobutane and cyclopentane products via Lewis acid catalyzed [2+2] and [3+2] annulation, respectively (3–5). The general addition process for allylsilanes onto unsaturated substrates is illustrated in Scheme 1. Siliranium ion intermediate **3** is central to all possible products of initial conjugate addition. In the case of enone substrates (X = alkyl), if Y is large (e.g., isopropyl) the principal product isolated is the five-membered ring adduct **6**, which appears to be both the thermodynamic and kinetic product (6, 7). When Y is methyl, the allylation product **4**, i.e., the Sakurai product, is the major adduct isolated. In the case of unsaturated ester substrates (e.g., X = OR), the formation of both four- and five-membered rings is also with precedent (8, 9). In these situations, the cyclobutane is typically the kinetic product and the cyclopentane **6** forms from **5** over time in the presence of the Lewis acid, presumably via intermediate **3**.

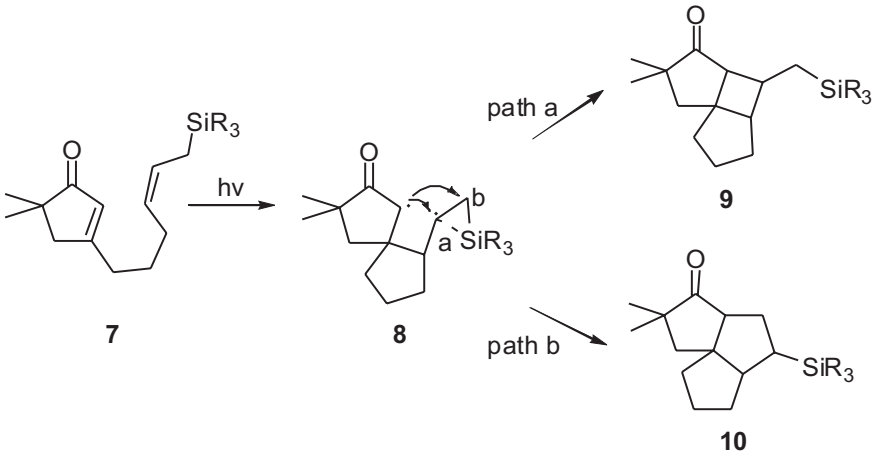
Scheme 1.

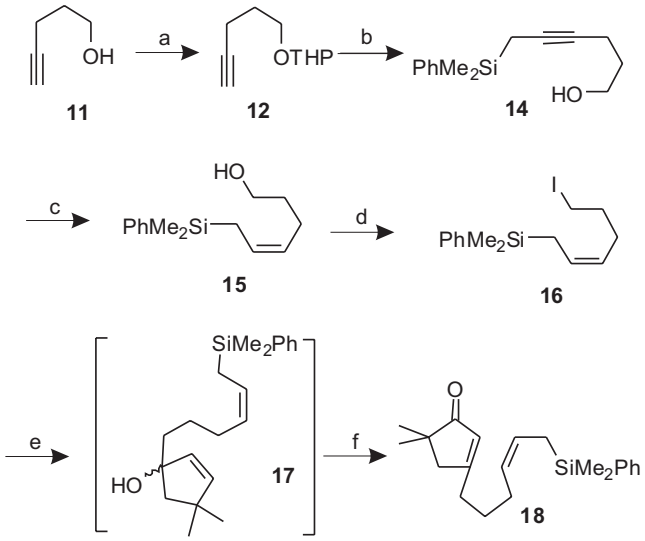


The primary driving force behind nucleophilic reactions involving allylsilanes is the presence of the silicon moiety, which activates the olefin and stabilizes the intermediate carbocation that is generated β to itself during the addition process by strong hyperconjugative effects (see intermediate **3**) (10). Thus, the silyl group is electron-rich and strongly σ-donating. The larger and more electron-rich the ligands on silicon, the more nucleophilic, hence reactive, the allylsilane becomes (11). Further, the larger the ligands on silicon, the more the silyl moiety resists protodesilylation.

It is known that radicals show similar stabilization as do cations when positioned β to silicon, but little has been done with this synthetically. We were interested in trying to exploit this feature of silicon in the development of new cyclization reactions. The photochemical excitation of enones in

 doi:10.1139/V06-077 © 2006 NRC Canada

Scheme 2.

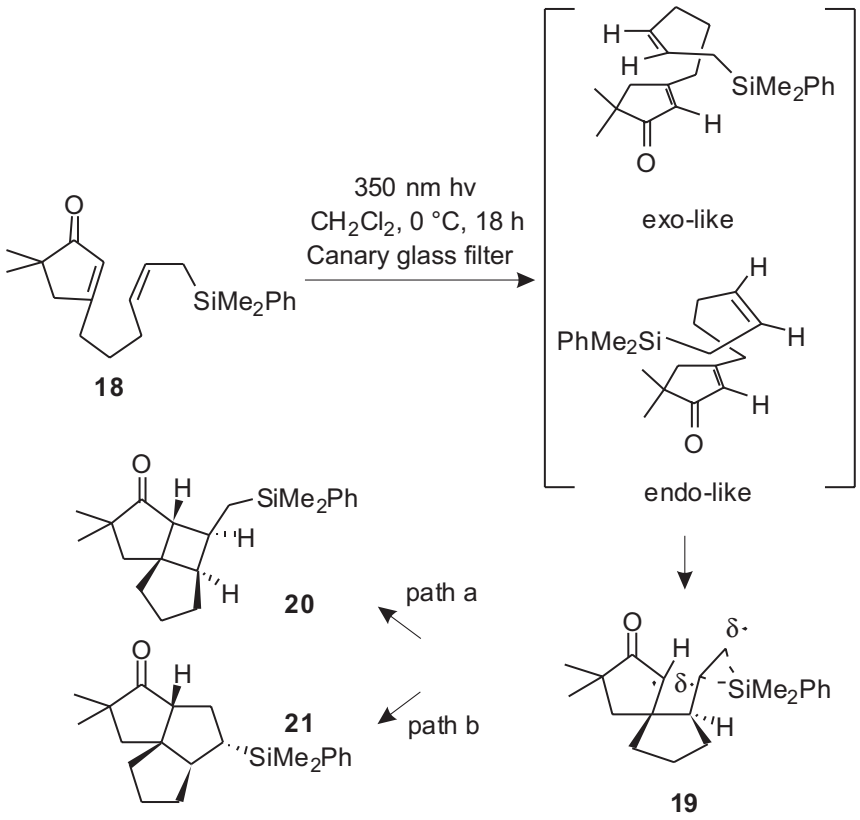


the presence of ground-state alkenes is a reliable and well-established method for the production of radicals. If the alkene was in fact an allylsilane, then the silyl component could become directly involved during the photoaddition itself, thus giving rise to new ringed structures directly upon irradiation. We envisioned that this methodology could be used for the production of five-membered rings and this is demonstrated in our approach to the angular triquinane framework shown in Scheme 2. In this case, it is an intramolecular photoaddition that would lead, presumably, to the intermediate biradical **8**, which would be stabilized by hyperconjugation. This would place radical character at both position *a* and *b*. Closure at *a* would lead to cyclobutane **9**, whereas *b* would provide cyclopentane **10**, which posseses the triquinane ring structure in one overall transformation from **7**.

Our synthetic approach to photoprecursor **18** began with 4-pentyn-1-ol (**11**, Scheme 3). Protection of the alcohol followed by alkyne deprotonation and electrophilic capture with dimethylphenylsilylmethyl iodide provided the corresponding allylsilane. Deprotection (**14**) and controlled hydrogenation with P2 catalyst provided the requisite *cis*-olefin geometry in **15**, which we determined was necessary to deliver the required stereochemistry in the triquinane structure through the ring-forming steps later on (see Scheme 4). Conversion of the alcohol to the corresponding iodide (**16**) provided the substrate for metal–halogen exchange and 1,2-addition to 4,4-dimethylcyclopent-2-en-1-one, yielding **17**. Finally, chromium-mediated [1,3] rearrangement and concomitant oxidation provided photoprecursor **18** cleanly and in good recovery.

The optimized photochemical step is outlined in Scheme 4. Initially, we attempted the reaction under a variety of conditions. In cyclohexane solvent, all other parameters being the same as those in Scheme 4, the Norrish type I cleavage product (i.e., the aldehyde) was the principal one isolated. All reactions attempted using a Hanovia 450 W Hg medium pressure lamp failed to provide any identifiable cycloadducts. However, we did observe isomerization of the allylsilane double bond geometry, which could happen by one of at least two possible mechanisms. The reaction could proceed to the biradical intermediate (**19**), but under these reaction conditions, reversion to starting material is faster than closure to product, thus scrambling olefin geometry.

Scheme 3. Reagents and conditions: (*a*) DHP, PPTS (cat.), CH_2Cl_2, rt, 82%; (*b*) (1*i*) *n*-BuLi, THF, –78 °C, (1*ii*) $PhMe_2SiCH_2I$ (**13**), reflux; (2) H_2SO_4 (cat.), MeOH, rt, 99%; (*c*) H_2 (1 atm, 1 atm = 101.325 kPa), $Ni(AcAc)_2$, $4H_2O$ (cat.), $NaBH_4$ (cat.), Et_3N, EtOH, rt, 75%; (*d*) I_2, PPh_3, Et_3N, MeCN, rt, 76%; (*e*) (*i*) *t*-BuLi (2.2 equiv.), Et_2O, –78 °C, (*ii*) 4,4-dimethylcyclopent-2-en-1-one; (*f*) PDC, CH_2Cl_2, rt, 99%.



Conversely, and more likely, the double bond could be getting excited, either directly or by triplet transfer, and relaxation occurs with olefin scrambling. We reasoned that if we could eliminate light of wavelengths less than 300 nm, at least direct excitation of the allylsilane would be eliminated with certainty. This meant that Pyrex with a 280 nm cutoff was not a suitable filter, so we opted to use uranium (canary) glass that possesses a 314 nm cutoff (12). As mentioned, attempts with the Hg lamp failed, but prolonged irradiation with a low power Rayonet reactor equipped with 350 nm lamps led to two products (**20** and **21**) in equal amounts (yield = 60%) that were purified by preparative HPLC.

Assuming that the intramolecular addition followed the "rule of 5" (13), leading to the linearly fused and not crossfused photoadduct, the trajectory of the olefin to the enone could follow an "endo-like" or "exo-like" arrangement

© 2006 NRC Canada

Scheme 4.

(see Scheme 4). The endo approach would lead to a highly congested transition state, which is exacerbated by the presence of the *gem*-dimethyl moiety that we installed in the photoprecursor, which is present in the general structure of all angular triquinanes and is therefore necessary. Further to this mechanistic assessment, the structures of **20** and **21** were assigned on the basis of 1D and 2D proton NMR spectra, including COSY and nOe that are in the Supporting information.[3]

There are a few examples in the literature pertaining to the use of olefins that are substituted with structural moieties, which can lead to cycloadducts other than the expected [2+2] photoproducts from the biradical intermediates that are presumably formed on the reaction pathway (14). Indeed, vinylcyclopropane and 1,6-hexadiene derivatives have been used to directly produce six- and seven-membered rings during irradiation with suitable enones. These systems were used as mechanistic probes to determine the initial site of bond formation during the addition process itself. Interestingly, when compound **18** was treated with a variety of Lewis acids (i.e., Me_2AlCl, $EtAlCl_2$, and $TiCl_4$), decomposition of the substrate (**18**) was observed, indicating that the ring expansion is a unique photochemical outcome. To our knowledge, no photoaddition has been conducted that directly leads to the formation of a cyclopentane ring. Further, the silyl moiety is a latent alcohol that can be used to modify the photoadduct to deliver the methyl group and unsaturation at the C-9 site, which is common in the structure of triquinanes.

Synthesis and characterization of 2,7-bis(2-pyridyl)-1,8-diazaanthraquinone — A redox-active ligand designed for the construction of supramolecular grids[1]

Rajsapan Jain, Sharon L. Caldwell, Anika S. Louie, and Robin G. Hicks

Abstract: Double condensation of 2-acetylpyridine with 1,3-diaminobenzene-4,6-dicarboxaldehyde affords 2,7-bis(2-pyridyl)-1,8-diazaanthracene, which was subsequently oxidized to the corresponding quinone. Electrochemical studies indicate two reversible reduction processes corresponding to semiquinone and hydroquinonate formation. Electron-withdrawing pyridine groups and the nitrogen atoms make this somewhat more easily reduced than anthraquinone. This compound is redox-active and can be reduced to its radical anion, a potential spin-bearing ligand for the construction of [2 × 2] metallo-grid structures.

Key words: quinone, grid, supramolecular, bistridentate, electrochemistry, metallosupramolecular chemistry.

Résumé : La double condensation de la 2-acétylpyridine avec du 1,3-diaminobenzène-4,6-dicarboxaldéhyde conduit à la formation de 2,7-bis(2-pyridyl)-1,8-diazaanthrène qui s'oxyde subséquemment en quinone correspondante. Des études électrochimiques indiquent qu'il existe deux processus de réductions réversibles qui correspondent à la formation de la semiquinone et de l'hydroquinonate. Par comparaison avec l'anthraquinone, les groupes pyridines et les atomes d'azote électroattracteurs rendent cette réduction plus facile. Ce composé est actif dans un système redox et il peut être réduit en anion radical, un ligand qui pourrait s'avérer utile comme porteur de spin dans la construction de structures en grilles métalliques [2 × 2].

Mots clés : quinone, grille, supramoléculaire, bistridentate, électrochimie, chimie métallosupramoléculaire.

[Traduit par la Rédaction]

Introduction

The designed assembly of metal–ligand architectures — metallosupramolecular chemistry — is an immensely popular contemporary facet of coordination chemistry. Judicious ligand design, coupled with the thermodynamic control that spurs the self-assembly of metal ions and multidentate receptor ligands, has led to a plethora of well-defined geometric shapes (1) as well as coordination polymers (2) and networks. The ultimate product is contingent on ligand topology in addition to its compatibility with different metal ions. This field of research is spurred by the promise of applications based on the potential function (magnetic, optical, catalytic, etc.) of these materials.

One of the more intensively studied classes of discrete metallosupramolecular structures are the so-called "grids" (3). This architectural class is characterized by ligands with multiple polydentate binding sites situated so as to enforce a regular $m \times n$ array of octahedrally or tetrahedrally coordinated metal ions. Figure 1 schematically depicts the assembly of a 2 × 2 grid based on bisbidentate or bistridentate ligands in conjunction with tetrahedrally or octahedrally coordinated metal ions, respectively. A huge number of grids have been prepared, many of which form in high yield simply from reactions of the free ligand and a metal ion source. The structural diversity is impressive and includes larger grids ($n \times n$, $n \geq 3$) (4), rectangular ($n \times m$, $n \neq m$) grids, grids with incompletely filled metal sites (5), and even grids with extraneous (noncoordinated) ligands intercalated into the grid (6).

Beyond their attractive structural features, the properties of grid molecules have been heavily studied. The incorporation of redox-active metals into grid structures can lead to a rich redox chemistry (7), and the magnetic (8) properties of these materials have also been investigated. In all these cases the redox- or spin-active component of the grids are the metal ions; the ligands play an important structural role but can be described as only passive contributors to the electronic functionality of the grids. No examples of metallosupramolecular grids based on redox-active or spin-containing ligands have yet been reported, although we have described the synthesis of a stable radical containing an analogue of **2** designed for such purposes (9).

Herein we present the design and synthesis of a new bistridentate ligand (**5**), which has been designed specifically

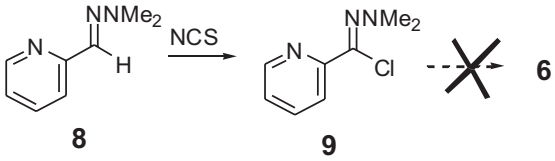
Scheme 1.

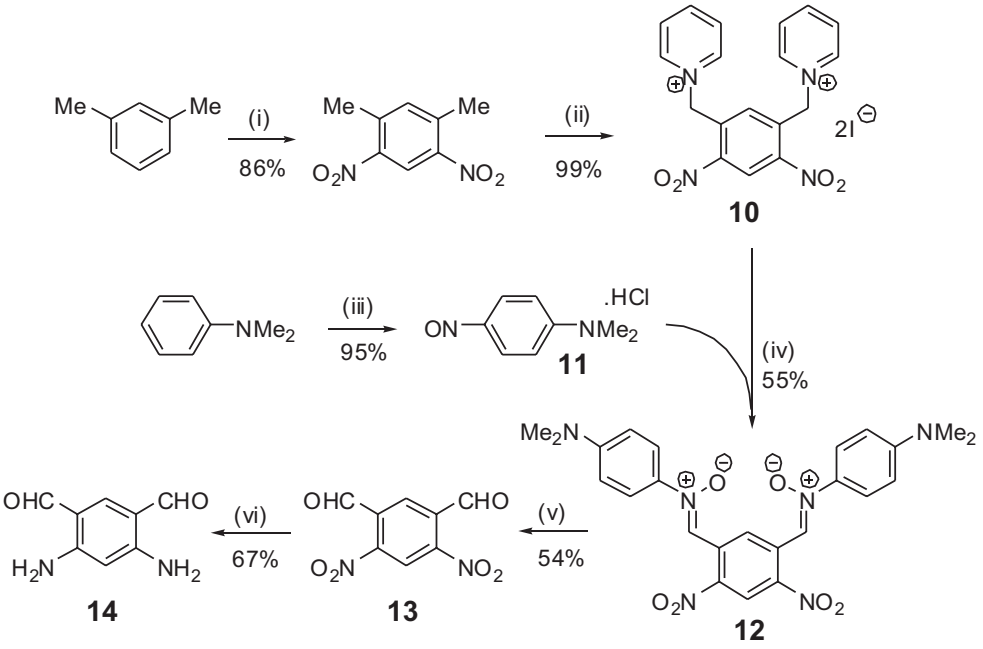
for 2 × 2 grid assembly and has the potential to play an active role in electronic (redox, magnetic, optical, etc.) properties of the assembled grid. The metal-binding sites present in **5** are analogous to those found in **3**, i.e., suited for 2 × 2 grid assembly based on octahedrally coordinated metals. However, **5** is distinguished by the presence of the *p*-(anthra)quinone functional unit embedded in the structure. Quinones are well-known to be redox active and form stable radical anions and dianions. Moreover, metal complexes of *o*-quinones possess a number of very interesting physicochemical properties such as strong magnetic exchange between metal- and semiquinone-based spins and molecular bistability (valence tautomerism) (10). The incorporation of quinone-type functional units into supramolecular assemblies is quite rare (11). The molecular structure of **5** has an appropriate topology of metal binding sites for the formation of 2 × 2 grid structures, and the presence of the *p*-quinone component offers the possibility of magnetically coupled metal–ligand arrays or even grid structures capable of exhibiting valence tautomerism.



5

Synthesis

Diaza-9,10-anthraquinones are commonly prepared through hetero-Diels–Alder reactions of 1,4-benzoquinones or quinoline–diones and azadienes (Scheme 1) (12). Our initial attempts to construct **5** were based on this strategy, for which the azadiene **6** was identified as a key intermediate. However, attempts to prepare this substrate from the reaction of (2-pyridyl) vinyl ketone (**7**), prepared by oxidation of the corresponding secondary alcohol (13) with *N*,*N*-dimethylhydrazine, failed. We then turned to a different strategy to prepare **6**, outlined in Scheme 2. 2-Pyridinecarboxaldehyde-*N*,*N*-dimethylhydrazone (14) was chlorinated with NCS to give **9**. Attempts to convert **9** to azadiene **6** through reactions with vinyl nucleophiles (Grignard, lithium reagents) led to no reaction or extensive substrate decomposition. Addition of late metal catalysts did not improve these reactions. Therefore, a different route was sought.



Scheme 2.

The successful synthesis of **5** is outlined in Schemes 3 and 4. The key intermediate is 4,6-diamino-1,3-benzenedicarboxaldehyde (**14**), which was made by slight modification of literature procedures (Scheme 3) (15). *m*-Xylene was bisnitrated and subsequently refluxed with I_2 for 16 h in pyridine to give the air-sensitive bis(pyridinium)diiodide salt (**10**). This salt was reacted with *p*-nitrosodimethylaniline hydrochloride (**11**) (16) to give the bis(imine) oxide (**12**), which was deprotected to give 4,6-dinitro-1,3-benzaldehyde (**13**). Attempts to reduce **13** to the diamine using the literature method (15) failed in our hands. This problem was solved by adopting the protocol described for the reduction of 6-nitro-

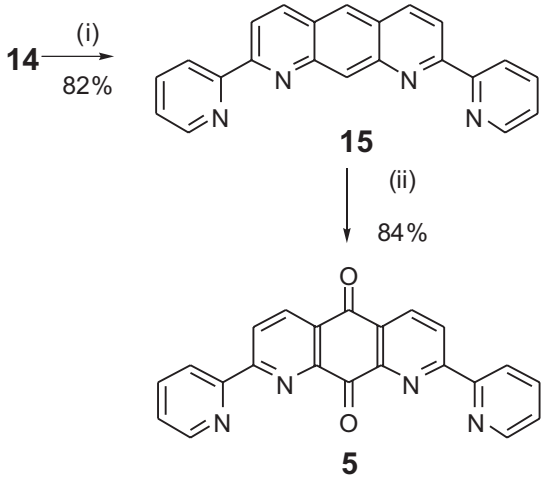
Scheme 3. Reagents and conditions: (*i*) HNO_3 (concd.) O °C to rt; (*ii*) pyridine–I_2, 95 °C; (*iii*) 2HCl, $NaNO_2$; (*iv*) **11**, EtOH – 10% NaOH (–5 to 5 °C); (*v*) H_2SO_4 (6 N), toluene, 65 °C; (*vi*) $FeSO_4{\cdot}7H_2O$, EtOH–H_2O–NH_4OH, 80 °C.

Scheme 4. Reagents and conditions: (*i*) 2-acetylpyridine (20 equiv.), 10% KOH, EtOH, 100 °C; (*ii*) CH_3COOH, CrO_3–H_2O, Δ.



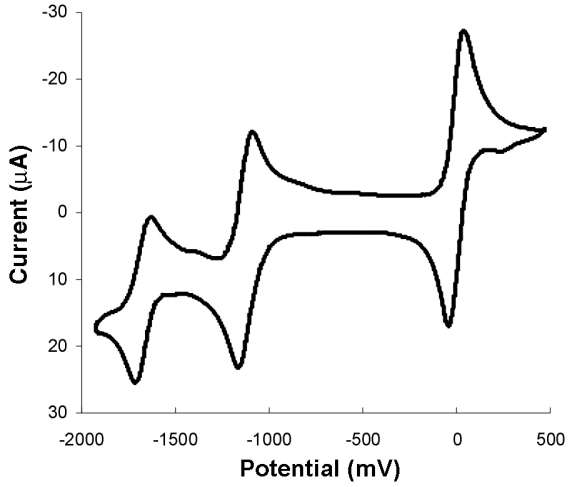


Fig. 2. Cyclic voltammogram of 2,7-dipyridyl-1,8-diaza-9,10-anthraquinone. The redox process at 0 mV is the ferrocene/ferrocenium redox couple, added as an internal reference.

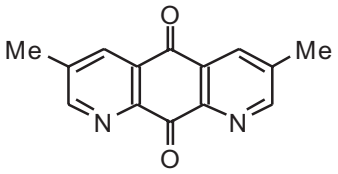

piperinal (17), i.e., aq. $FeSO_4{\cdot}7H_2O$ in EtOH–H_2O followed by addition of 30% NH_4OH at 80 °C. This facilitated formation of **14** in 67% yield.

Dialdehyde **14** then underwent a double condensation reaction with an excess of 2-acetylpyridine to give 2,7-bis(2-pyridyl)-1,8-diazaanthracene (**15**) in excellent yield. We note the potential use of this compound as a bisbidendate ligand in its own right. The oxidation of **15** to target quinone **5** was initially attempted using V_2O_5 and $NaClO_3$, similar to the oxidation of anthracene to anthraquinone (16), but this method was plagued with dismal conversions and recovery of mostly starting material. Aqueous chromium trioxide in glacial acetic acid proved to be a more effective alternative. Upon cooling the reaction after refluxing for 30 min, quinone **5** precipitated and was isolated in 84% yield. The IR spectrum of **5** shows two carbonyl stretches at 1703 and 1662 cm^{-1}. The UV–vis spectrum showed four intense absorptions at 230, 260, 285, and 315 nm. Other spectroscopic and analytical tools confirmed the structure and purity of **5**.

The redox properties of **5** were probed electrochemically. The cyclic voltammogram of **9** (Fig. 2) has two reversible reduction waves at potentials of E_1° = –1.13 V and E_2° = –1.67 V vs. the ferrocene/ferrocenium redox couple. Table 1 presents the reduction potentials of this compound along with corresponding data for several other compounds. 9,10-Anthraquinone is considerably more difficult to reduce (E_1° = –1.39 V, E_2° = –1.86 V) than 1,4-benzoquinone (E_1° = –0.96 V, E_2° = –1.56 V) because of the effects of annelation. The introduction of two nitrogen atoms at the 1,8 positions (i.e., 1,8-diazaanthraquinone (**16**); made according to literature methods (12*b*)) renders this compound slightly more easily

© 2006 NRC Canada

Table 1. Reduction potentials of *p*-quinones in CH_2Cl_2.

16

Compound	E_1° (V)	E_2° (V)
1,4-Benzoquinone	–0.96	–1.56
9,10-Anthraquinone	–1.39	–1.86
16	–1.24	–1.77
5	–1.13	–1.67

reduced (E_1° = –1.24 V, E_2° = –1.77 V) and the title compound has yet still higher reduction potentials (E_1° = –1.13 V, E_2° = –1.67 V) because of the electron-withdrawing 2-pyridyl substituents. Based on this, reduction of **5** should be chemically possible by reaction with cobaltocene (oxidation potential, E_1° = –1.33 V). This was found to be the case as evidenced by a striking color change from pale yellow to deep red on adding cobaltocene to a solution of **5**. However, the presumed cobaltocenium salt of the radical anion of **5** was exceptionally reactive and could not be isolated, as is often the case in *p*-quinones with low reduction potentials. Despite this shortcoming, we anticipate the radical anion of **5** to gain stability upon coordination as observed in other *p*-dioxolene systems (18).

Experimental

General considerations

All reagents were purchased from Sigma-Aldrich and used as received. All solvents were dried and distilled under argon prior to use (ether, Na–benzophenone, CH_2Cl_2, CaH_2). Infrared spectra were recorded on a PerkinElmer FT-IR spectrometer using KBr pellets. NMR spectra were acquired on a Bruker AMX500 spectrometer in $CDCl_3$. Mass spectra were recorded on a Kratos Concept IH mass spectrometer system. UV–vis data were collected on a Cary 100 SCAN spectrophotometer. The electrochemical experiments were performed using a CV-50W voltammetric analyzer (BAS) at room temperature (22 ± 2 °C). Cyclic voltammetry experiments were performed in CH_2Cl_2 containing 0.1 mol/L of *n*-Bu_4NBF_4 under argon. A carbon electrode (BAS, diameter 3.0 mm) was used as the working electrode. Platinum and silver wires were used as the auxiliary and reference electrodes, respectively. The working electrode was polished on alumina before use. *iR* compensations were applied for all experiments. All peak potentials are reported vs. an internal reference (ferrocene/ferrocenium). Elemental analyses were performed by Canadian Microanalytical Services Ltd., Vancouver, British Columbia.

Synthesis of 2-pyridyl-*N*,*N*-dimethylaminochloroimine (9)

A CH_2Cl_2 solution (35 mL) of 2-pyridinecarboxaldehyde dimethylhydrazone (2.03 g, 13.6 mmol) was slowly treated with *N*-chlorosuccinimide in small portions. After stirring overnight, the solvent was removed under reduced pressure and hexanes were added. The succinimide by-product precipitated and was filtered. The yellow-orange filtrate was cooled to afford crystals of **9**. Yield: 1.67 g (67%). ^{1}H NMR ($CDCl_3$, ppm) δ: 8.6 (d, 1H), 7.9 (d, 1H), 7.6 (dd, 1H), 7.2 (dd, 1H), 2.9 (s, 6H). ^{13}C NMR ($CDCl_3$, ppm) δ: 152.1, 149.0, 136.3, 131.9, 124.1, 122.3, 46.7.

Synthesis of 1,3-diamino-4,6-benzenedicarboxaldehyde (14)

A solution of 4,6-dinitro-1,3-benzaldehyde (**13**) (1.6 g, 7.1 mmol) in EtOH–H_2O (50:50, 80 mL) was brought to reflux and then a solution of ferrous sulfate heptahydrate (36.8 g, 0.132 mol) in H_2O (80 mL) was added to the vigorously stirred reaction mixture, followed by ammonium hydroxide (36 mL) while refluxing. The thick black slurry was refluxed for an additional hour. Thereafter, the hot solution was suction filtered using a large Büchner funnel. Finally, hot ethanol (approx. 50 mL) was used to wash the residue to make sure all the product was filtered through. The filtrate was then brought to a boil and refiltered to remove any metallic black residue that may not have been eliminated the first time. The resultant yellow filtrate was boiled to reduce the volume (to approximately one-third) and on cooling, crude **14** (light brown) precipitated, which was isolated by another filtration. The product was recrystallized using a H_2O–EtOH (5:1) mixture. Yield: 0.780 g (67%). Characterization data (^{1}H and ^{13}C NMR) of **14** was the same as reported previously (15).

Synthesis of 2,7-dipyridyl-1,8-diazaanthracene (15)

KOH (10%, 0.4 mL) was added to a solution of 1,3-diamino-4,6-benzenedicarboxaldehyde (**14**, 0.300 g 1.83 mmol) and of 2-acetylpyridine (4.432 g, 36.5 mmol) at 100–110 °C. The solution was stirred for an additional 15 min. Thereafter, 15 mL of ethanol was added to the mixture and boiled for a short time (~2 min). The reaction mixture was cooled, filtered, and the yellow residue washed with EtOH and dried in vacuo to give **15,** which was recrystallized from hot EtOH. Yield: 0.500 g (82%); mp 239 to 240 °C. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.40 (m, 2H, H18, H23), 7.92 (m, 2H, H17, H22), 8.37 (s, 1H, H10), 8.44 (d, 2H, H4, H5, ^3J = 8.8 Hz), 8.61 (d, 2H, H3, H6, ^3J = 8.8 Hz), 8.76–8.80 (m, 4H, H16, H19, H21, H24), 9.07 (s, 1H, H9). ^{13}C NMR ($CDCl_3$, 500 MHz) δ: 119.2 (C3, C6), 122.3 (C18, C23), 124.4 (C16, C21), 126.4 (C10), 127.0 (C11, C14), 129.3 (C9), 136.9, 137.0 (C4, C5, C17, C22), 146.7 (C12, C13), 149.1 (C19, C24), 155.9 (C15, C20), 157.5 (C2, C7). LSIMS: 335 $[M + H]^+$. Anal. calcd. for $C_{22}H_{14}N_4$ (%): C 79.02, H 4.22, N 16.76; found: C 78.73, H 4.23, N 16.74.

Synthesis of 2,7-dipyridyl-1,8-diaza-9,10-anthraquinone (2,7-DIP-DAAQ) (5)

To **15** (0.600 g, 1.80 mmol) in a two-necked flask, mounted by a reflux condenser, was added glacial acetic acid (6 mL), then the flask stoppered. The reaction mixture was brought to reflux, and while that was underway, CrO_3 (4 equiv. mol) were dissolved in H_2O (0.6 mL), followed by glacial acetic acid (3 mL). The heat source was removed from the reaction mixture and the mixture was dropped into the stirring reaction mixture over a course of ~10 min. The

© 2006 NRC Canada

reaction was then refluxed for a further 10–15 min. Pure 2,7-DIP-DAAQ usually precipitates on cooling, but if it did not, the reaction solution at room temperature was precipitated into ice-cold water (30 mL) with continued stirring for another 10–15 min (cold conditions must be maintained). Filtration afforded a crude yellow residue that was washed thoroughly with hot water, cold water, and diethyl ether. Recrystallization from glacial acetic acid afforded **5**. Yield: 0.550 g (84%); mp 316 °C. UV–vis (CH_2Cl_2, nm) λ_{max} (ε): 230 (20 100 (mol/L)$^{-1}$ cm^{-1}), 260 (22 100 (mol/L)$^{-1}$ cm^{-1}), 285 (23 100 (mol/L)$^{-1}$ cm^{-1}), 315 (27 500 (mol/L)$^{-1}$ cm^{-1}). Pertinent IR stetches (cm^{-1}): 1703 (m), 1662 (s), 1589 (s), 1330 (s). ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.46 (m, 2H, H18, H23), 7.96 (m, 2H, H17, H22), 8.76–8.79 (m, 4H, H3–H6), 8.85 (d, 2H, H16, H21, ^3J = 8.1 Hz), 8.97 (d, 2H, H19, H24, ^3J = 8.1 Hz). ^{13}C NMR ($CDCl_3$, 500 MHz) δ: 123.2 (C18, C23), 125.4 (C3, C6, C16, C21), 129.8 (C11, C14), 136.4 (C17, C22), 137.4 (C4, C5), 148.8 (C12, C13), 149.4 (C19, C24), 154.1 (C15, C20), 161.2 (C2, C7), 180.1, 182.0 (C9, C10). HRMS calcd. for $C_{22}H_{12}N_4O_2$: 364.10; found: 364.0955 ± 0.0016. Anal. calcd. for $C_{22}H_{12}N_4O_2$ (%): C 72.52, H 3.32, N 15.38: found: C 72.77, H 3.38, N 15.37.

Synthesis and aldol cyclotrimerization of 4,7-di-*tert*-butylacenaphthenone[1]

Aaron W. Amick, Keith S. Griswold, and Lawrence T. Scott

Abstract: An efficient gram scale synthesis of the previously unknown 4,7-di-*tert*-butylacenaphthenone (**3b**) is reported. The facile isomerization of epoxide **9b** to ketone **3b** occurs simply on stirring a solution of **9b** with silica gel at room temperature. Aldol cyclotrimerization of **3b** with titanium tetrachloride gives 2,5,8,11,14,17-hexa-*tert*-butyldecacyclene (**1b**) in 58% isolated yield. X-ray crystal structures have been obtained for the synthetic intermediates 4,7-di-*tert*-butylacenaphthene (**2b**) and 4,7-di-*tert*-butylacenaphthylene (**8b**).

Key words: aromatic, decacyclene, hydrocarbon, nonalternant, polycyclic.

Résumé : On a mis au point une synthèse efficace au niveau du gramme de la 4,7-di-*tert*-butylacénaphténone, un composé antérieurement inconnu. L'isomérisation facile de l'époxyde **9b** en cétone **3b** se produit simplement en agitant une solution du composé **9b** avec du gel de silice, à la température ambiante. La cyclotrimérisation aldolique du composé **3b** en présence de tétrachlorure de titane conduit au 2,5,8,11,14,17-hexa-*tert*-butyldécacyclène (**1b**) qui a été isolé avec un rendement de 58 %. Faisant appel à la diffraction des rayons X, on a déterminé les structures cristallines des intermédiaires de synthèse 4,7-di-*tert*-butylacénaphtène (**2b**) et 4,7-di-*tert*-butylacénaphtylène (**8b**).

Mots clés : aromatique, décacyclène, hydrocarbure, nonalternant, polycyclique.

[Traduit par la Rédaction]

Introduction

Decacyclene (**1a**), annulated with additional aromatic rings and (or) substituted with strategically placed chlorine atoms, has served admirably in our laboratory for some years now as the core structure of synthetic precursors to geodesic polyarenes ranging from bowl-shaped polycyclic aromatic hydrocarbons to the I_h fullerene, C_{60} (1). The parent decacyclene (**1a**) was first prepared in 1883 (2) by an oxidative trimerization of acenaphthene (**2a**) (3), which, in turn, was isolated from coal tar. Unfortunately, this simple method is not well-suited for the regioselective cyclotrimerization of unsymmetrical acenaphthene derivatives (4). For this purpose, we have relied on the acid-catalyzed head-to-tail cyclic aldol trimerization of compounds related to acenaphthenone (**3a**, Fig. 1) (1).

Other triply annulated benzene rings with threefold symmetry have been prepared by aldol cyclotrimerizations of cyclic ketones since the 19th century (5); however, the success of the reaction depends on the particular system in ways that are still poorly understood. Some cases work spectacularly well, e.g., 1-indanone (**4**), 85% yield (6), whereas closely related systems sometimes fail miserably, e.g., 1-tetralone (**5**), 0% yield (7).

We recently surveyed the literature on such reactions in an attempt to uncover correlations between the outcome of attempted aldol cyclotrimerizations and structural features in the cyclic ketones, and at least one prerequisite for success did emerge (8). Some critical factors that can scuttle these reactions have been identified (8, 9); however, others remain obscure. Thus, it is still not possible to predict with confidence which cyclic ketones will give triply annulated benzene rings in high yield by aldol cyclotrimerizations.

Fortunately for us, the tricyclic and tetracyclic ketones **6** and **7** and certain chlorinated derivatives thereof, provide triply annulated benzene rings in high yield by aldol cyclotrimerizations (9, 10). We have been especially puzzled, however, by the relatively low yield of decacyclene (**1a**) produced under a variety of conditions from acenaphthenone (**3a**), a five-membered ring aromatic ketone that closely resembles both indanone (**4**) and the larger ketones **6** and **7** (11).

By following the buildup and disappearance of the various intermediates involved in this reaction, we hoped to learn more about what makes the aldol cyclotrimerization of acenaphthenone such a comparatively poor reaction. The low solubility of decacyclene and of the two aldol dimers (E and Z) of **3a**, unfortunately, hampered our ability to obtain reliable data, so we decided to incorporate solubilizing groups at the 4 and 7 positions, where they would not impose any steric hindrance to the reactions. The hexa-*tert*-butyldecacyclene (**1b**) expected from cyclotrimerization of 4,7-di-*tert*-butylacenaphthenone (**3b**), in fact, is already a known compound (3, 12) and its solubility in normal organic solvents bodes well for the mechanistic studies we have

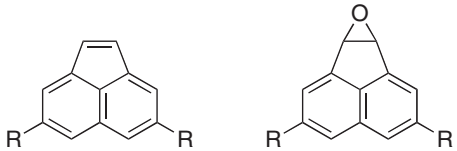
Fig. 1. Decacyclenes (**1**) by oxidative cyclotrimerization of acenaphthenes (**2**) and by aldol cyclotrimerization of acenaphthenones (**3**).



planned. Our purpose is not to compete with the published syntheses of **1b**, which have been achieved both by direct Friedel–Crafts alkylation of **1a** (12) and by oxidative cyclotrimerization of **2b** (3). Rather, we hope to use the alternative synthesis of **1b** from **3b** as a case study with which to probe the factors that influence the interconnected maze of competing pathways involved in aldol cyclotrimerization reactions.

Synthesis and cyclotrimerization of 4,7-di-*tert*-butylacenaphthenone (3b)[3]

The di-*tert*-butylation of acenaphthene (**2a**) under Friedel–Crafts conditions to give 4,7-di-*tert*-butylacenaphthene (**2b**) was first reported by Peters in 1942 (13). The structure of the product was initially misassigned, but Peters corrected the assignment himself in 1950 to the one shown (**2b**) (14).

A further complication in the literature on compounds of this class derives from the intermingling of at least three different numbering schemes for the acenaphthene ring system. Peters consistently refers to compound **2b** as "2 : 5-di-*tert*-butylacenaphthene", in accord with "Richter's numbering of the acenaphthene system",[4] which numbers the carbon atoms of the five-membered ring last. In this paper, we use the *Chemical Abstracts* numbering scheme, which numbers the two carbon atoms of the five-membered ring first.

The unsaturated hydrocarbon, 4,7-di-*tert*-butylacenaphthylene (**8b**), has been prepared from **2b** by dehydrogenation with DDQ in refluxing benzene (15). A third numbering scheme led the authors who first reported this reaction to name the compound "3,6-di-*tert*-butylacenaphthylene", but the structure is the one shown here (**8b**). We have made no significant modifications to the procedures for synthesizing **2b** and **8b**, but report here the UV–vis spectra of both hydrocarbons and the ^{13}C NMR spectrum of **8b** for the first time. Because there are some discrepancies concerning the melting points and NMR chemical shifts of **2b** (13, 14, 16–19) and **8b** (15), we report our melting points and NMR data as well, including copies of the full spectra for the first time in the Supplementary material.[5]

8a R = H

by saponification of the acetate to the alcohol and oxidation to the ketone (17). In the present case, we have found that the readily available epoxide (**9b**) rearranges in high yield to 4,7-di-*tert*-butylacenaphthenone (**3b**) under exceptionally mild conditions (i.e., stirring in solution with silica gel at room temperature).

Preliminary attempts to promote an aldol cyclotrimerization of the substituted acenaphthenone **3b** by treatment with various Lewis acids and Brønsted acids gave only low yields of hexa-*tert*-butyldecacyclene (**1b**). The best conditions found so far (58% isolated yield) entail heating a solution of **3b** and titanium tetrachloride (6 equiv.) in 1,2-dichloroethane to reflux for 4.5 h, with a constant flow of N_2 bubbling through the solvent to sweep out the HCl that is formed.

From a reaction run under other conditions, we isolated and characterized the aldol dimer, 4,7,4′,7′-tetra-*tert*-butyl-1,1′-biacenaphthylenyliden-2-one (**10**), a presumed intermediate in the trimerization. The solubility imparted by the *tert*-butyl groups to all the species present in this reaction has allowed us to begin monitoring these aldol cyclotrimerizations by NMR spectroscopy, and detailed studies that are currently underway with a variety of catalysts, stoichiometries, solvents, temperatures, times, etc., will be reported in due course.

10

X-ray crystal structures of 2b and 8b

Through our ongoing collaboration with the solid-state NMR group of Grant and Pugmire and co-workers in Utah (20), we learned that the motion of individual molecules in crystals of acenaphthylene (**8a**) has prevented the experimental determination of chemical shift tensors for the carbon atoms in this archetypal nonalternant hydrocarbon. We speculated that the *tert*-butyl groups on **8b** should anchor the molecules in the crystal and thereby eliminate the motion. As an added bonus, the incorporation of so many aliphatic hydrogen atoms near the acenaphthylene core would be expected to shorten the relaxation times for the carbon nuclei and allow faster data acquisition. Grant and Pugmire expressed an interest in both the saturated and the unsaturated hydrocarbons, so we supplied them with samples of both **2b** and **8b**.

When we were informed that analysis of the solid-state NMR data would be facilitated by a knowledge of the exact geometries of the molecules, we obtained X-ray crystal structures for both **2b** and **8b** (Fig. 2).[5]

Conclusions

The previously unknown 4,7-di-*tert*-butylacenaphthenone (**3b**) can now be prepared on a gram scale by an efficient three-step synthesis from commercially available acenaphthene (**2a**). The facile isomerization of epoxide **9b** to ketone **3b** occurs simply on stirring a solution of **9b** with silica gel at room temperature. Preliminary efforts to effect the aldol trimerization of **3b** have given the substituted decacyclene **1b** in 58% isolated yield, and the stage is now set for more detailed mechanistic studies. X-ray crystal structures have been obtained for the synthetic intermediates **2b** and **8b**.

4,7-Di-*tert*-butylacenaphthylene (8b)

A 250 mL round bottom flask was charged with 4,7-di-*tert*-butylacenaphthene (**2b**, 5.16 g, 19.3 mmol), DDQ (6.61 g, 29.1 mmol), and benzene (100 mL). The mixture was heated to reflux, and the progress of the reaction was monitored by GC–MS until it reached completion (ca. 4 h). The benzene was evaporated from the reaction mixture under reduced pressure to give a dark blue solid. This solid was then redissolved in dichloromethane and run through an alumina plug to remove any latent DDQ and hydroquinone. This organic solution was evaporated under reduced pressure to give 4.41 g of a yellow crystalline solid (88% yield); mp 114.5–117 °C (lit. value (15) mp 108 to 109 °C). UV–vis (CH_2Cl_2) λ_{max} (log ε): 235 (5.51), 331 (4.39). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.79 (d, *J* = 1.1 Hz, 2H), 7.76 (d, *J* = 1.1 Hz, 2H), 7.08 (s, 2H), 1.46 (s, 18H). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 150.90, 138.84, 129.40, 127.09, 125.26, 122.42, 121.93, 35.61, 31.79. HRMS ESI (*m/z*) calcd. for $C_{20}H_{24}$: 264.1878 $[M]^+$; found: 264.1882.

4,7-Di-*tert*-butylacenaphthenone (3b)

A sample of 4,7-di-*tert*-butylacenaphthylene (2.00 g, 7.60 mmol) was added to a solution of freshly washed *m*-chloroperoxybenzoic acid (2.00 g, 11.4 mmol), dichloromethane (50 mL), and saturated aqueous sodium bicarbonate (50 mL). The reaction mixture was stirred and the reaction progress was monitored by GC–MS. Upon completion of the reaction (2 h), the organic layer was separated, dried over anhydrous magnesium sulfate, filtered, and evaporated under reduced pressure. The product was redissolved in dichloromethane and silica gel (ca. 50 g) was added. This slurry was stirred at 25 °C for approximately 6 h. The silica gel was filtered off and washed with dichloromethane. Evaporation of the organic solvent under reduced pressure gave a reddish-orange, oily solid. This product was dissolved in hexanes and evaporated under reduced pressure yielding 1.70–1.91 g (80%–90% over several runs) of a reddish-orange, crystalline solid; mp 81–83 °C. UV–vis (CH_2Cl_2) λ_{max} (log ε): 234 (5.45), 287 (4.47). IR (KBr, cm^{-1}): 1718 (C=O). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.06 (d, *J* = 1.4 Hz, 1H), 8.02 (d, *J* = 1.4 Hz, 1H), 7.74 (s, 1H), 7.52 (d, *J* = 1.0 Hz, 1H), 3.82 (s, 2H), 1.46 (s, 9H), 1.45 (s, 9H). ^{13}C NMR (125 MHz, $CDCl_3$, ppm) δ: 203.72, 151.90, 151.86, 140.25, 134.14, 134.07, 130.45, 127.16, 119.44, 119.24, 118.72, 42.50, 35.66, 35.64, 31.67, 31.47. HRMS ESI (*m/z*) calcd. for $C_{20}H_{24}O$: 280.1827 $[M]^+$; found: 280.1823.

2,5,8,11,14,17-Hexa-*tert*-butyldecacyclene (1b)

A 100 mL two-necked flask was charged with 4,7-di-*tert*-butylacenaphthenone (0.200 g, 0.714 mmol), dichloroethane (16 mL), and titanium tetrachloride (4.3 mmol, 0.47 mL). The reaction mixture was heated to reflux for 4.5 h with a constant flow of N_2 bubbling through the solvent. When the reaction was complete, as determined by TLC, the mixture was poured into a solution of 10% HCl and ice and extracted with dichloromethane. The organic extracts were dried over anhydrous magnesium sulfate, filtered, and concentrated to dryness under reduced pressure.The dark product thus obtained was purified by column chromatography on neutral alumina with hexane–dichloromethane (75:25) to give 0.097 g of a dark yellow crystalline solid (58%). UV–vis (CH_2Cl_2) λ_{max} (log ε): 234 (5.53), 280 (4.86), 350 (4.70). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.97 (s, 6H), 7.93 (s, 6H), 1.66 (s, 54H). ^{13}C NMR (125 MHz, $CDCl_3$, ppm) δ: 151.00, 137.01, 136.37, 131.37, 129.57, 122.14, 121.80, 35.84, 31.99. HRMS ESI (*m/z*) calcd. for $C_{60}H_{66}$: 786.5165 $[M]^+$; found: 786.5168.

4,7,4′,7′-Tetra-*tert*-butyl-1,1′-biacenaphthylenyliden-2-one (10)

A sample of 4,7-di-*tert*-butylacenaphthenone (0.200 g, 0.714 mmol) and anhydrous ethanol (16 mL) were added to a pressure vessel under N_2 and the mixture was cooled to –78 °C. Titanium tetrachloride (0.034 g, 0.178 mmol) was added via syringe and the vessel was sealed. The reaction mixture was stirred in an oil bath at 90 °C for 1 h and subsequently quenched with 10% HCl. The product was extracted into dichloromethane, which was then dried over anhydrous magnesium sulfate, filtered, and evaporated under reduced pressure. The crude product was purified by preparative TLC on alumina with hexane–dichloromethane (75:25) as the eluent, yielding 0.005 g (2.4%) of a bright yellow solid; mp 246–256 °C (dec). UV–vis (CH_2Cl_2) λ_{max} (log ε): 234 (5.28), 289 (4.56), 440 (4.25). IR (KBr, cm^{-1}): 1692 (C=O). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 10.03 (d, *J* = 1.6 Hz, 1H), 8.19 (d, *J* = 1.6 Hz, 1H), 8.05 (d, *J* = 1.6 Hz, 1H), 8.03 (s, 1H), 7.92 (d, *J* = 1.2 Hz, 1H), 7.82 (d, *J* = 0.8 Hz, 1H), 7.71 (s, 1H), 7.64 (d, *J* = 0.8 Hz, 1H), 4.68 (s, 2H), 1.60 (s, 9H), 1.58 (s, 9H), 1.49 (s, 9H), 1.48 (s, 9H). ^{13}C NMR (125 MHz, $CDCl_3$, ppm) δ: 193.39, 152.27, 151.76, 151.69, 151.18, 150.92, 138.78, 138.27, 138.21, 136.53, 135.94, 133.52, 130.68, 130.33, 129.89, 126.33, 126.30, 123.84, 119.91, 119.88, 119.26, 118.65, 118.06, 41.00, 35.94, 35.88, 35.71, 35.44, 31.88, 31.73, 31.66. HRMS ESI (*m/z*) calcd. for $C_{40}H_{46}O$: 542.3549 $[M]^+$; found: 542.3558.

The stereochemistry around the double bond in this dimer is assigned as (Z) on the basis of ^{1}H NMR chemical shift arguments. Both dimers can be seen in solution, although only this one was isolated and characterized. The lowest field chemical shift for the E-dimer is seen at δ 8.98 ppm, which is very close to lowest field chemical shift for the cyclic trimer (**1b**, 8.90 ppm). The structural similarity between the sterically crowded fjord regions of **1b** and the E-dimer accounts for the near coincidence of their lowest field proton chemical shifts. By contrast, the lowest field chemical shift for the Z-dimer is seen at δ 10.03 ppm, more than 1.00 ppm lower field than that for the E-dimer and for **1b**. The proximity of the fjord region hydrogen in the Z-dimer to the carbonyl group (**10**) accounts for its exceptionally low field chemical shift. Presumably, the E-and Z-dimers interconvert through a common dienol during the aldol trimerization reaction.

Effect of crown ether ring size on binding and fluorescence response to saxitoxin in anthracylmethyl monoazacrown ether chemosensors[1]

Hua Mao, John B. Thorne, Jennifer S. Pharr, and Robert E. Gawley

Abstract: Convenient macrocyclization synthetic routes for the preparation of different-sized monoaza anthracylmethyl crown ether chemosensors (15-crown-5, 18-crown-6, 21-crown-7, 24-crown-8, and 27-crown-9) are described. Evaluation of these crowns as chemosensors for saxitoxin revealed that the larger crowns have moderately higher binding constants, with the 27-crown-9 chemosensor having the largest binding constant (2.29×10^5 $(mol/L)^{-1}$). Fluorescence enhancements of 100% were observed at saxitoxin concentrations of 5 μmol/L, which is close to the detection limit in mouse bioassay.

Key words: anthracene, crown ethers, saxitoxin, paralytic shellfish poison (PSP), binding constants; chemosensors.

Résumé : On décrit des voies de synthèse pratiques à base de macrocyclisations pour la préparation de senseurs chimiques à base des monoaza anthracylméthyl éthers couronnes de tailles différentes, 15-courone-5, 18-couronne-6, 21-couronne-7, 24-couronne-8 et 27-couronne-9. L'évaluation de ces couronnes comme senseurs chimiques pour la saxitoxine révèle que les couronnes les plus grosses présentent les constantes de fixation les plus élevées, alors que le senseur chimique à base de 27-couronne-9 est associée à la constante de fixation la plus élevée, soit $2{,}29 \times 10^{-5}$ $(mol/L)^{-1}$. On a observé des augmentations de la fluorescence de 100 % à des concentrations de 5 μmol/L, valeur qui est proche de la limite de détection dans les bioessais à l'aide de souris.

Mots clés : anthracène, éthers couronnes, saxitonine, intoxication paralysante par les mollusques, constantes de fixation, senseurs chimiques.

[Traduit par la Rédaction]

Harmful algal blooms (HABs) are linked to many cases of human poisoning each year. Economic losses and costs to the fishing industry, public health, and tourism are estimated to be $40 000 000US annually as of the late 1990s (1). The toxins produced by HABs, as well as many other analytes of interest to members of the biomedical community, are "small molecules". Saxitoxin (STX) (Fig. 1) is such a small molecule because of its neurotoxicity and is the most toxic component of the paralytic shellfish poisons (PSPs) (2). Its activity is manifested through the binding of the toxin to voltage-gated sodium channels and blocking sodium ion transport across neuronal membranes. In 1996, saxitoxin was included on the United States government's list of "Select Agents" (potential terrorist weapons). It is one of only three small molecules on the list; the rest are viruses (e.g., Ebola), bacteria (e.g., *Yersenia pestis*), and proteins (e.g., ricin, abrin).

Mouse bioassay is the current method used by government agencies to detect saxitoxin and its derivatives (3), but for both ethical and economic reasons, an alternative would be highly beneficial. We have been working for several years to develop fluorescent chemosensors for the detection of saxitoxin and have recently made significant advances. Specifically, we have shown that arylmethylcrowns are selective for the detection of saxitoxin over sodium, potassium, and calcium ions (4), as well as several organic analytes (5), including tetrodotoxin (Fig. 1) (6). The latter point is clinically relevant since saxitoxin and tetrodotoxin bind, competitively, to the same site on voltage-gated sodium channels and produce the same clinical symptoms (7, 8).

Fig. 1.

Scheme 1.

Until now we have focused on the 18-crown-6 monoaza- or diaza-crown ethers, with anthracene, coumarin, or acridine fluorophores. In early work, Cram and co-workers showed that 27-crown-9 crown ether is the optimum size to host a guanidinium guest (9, 10). Since saxitoxin (Fig. 1) is a bisguanidinium dication, we explored larger crown sizes to determine the effect on binding, using the anthracene fluorophore as sensor. Thus, crown ethers **1**–**5** were prepared and evaluated for fluorescence response to saxitoxin: 15-crown-5 (**1**, n = 1), 18-crown-6 (**2**, n = 2), 21-crown-7 (**3**, n = 3), 24-crown-8 (**4**, n = 4), and 27-crown-9 (**5**, n = 5) (Fig. 1).

Synthesis

Anthracylmethyl crown ethers **1** and **2** were originally prepared by de Silva and co-workers (11). They were made by alkylation of monoazacrowns with 9-(chloromethyl)anthracene. Anthracylmethyl crowns **3**–**5** were similarly prepared by alkylation of monoazacrowns **6**–**8**, as shown in Scheme 1. The diols **9** and **10** are commercially available. Diol **11** was prepared in three steps from diethylene glycol and triethylene glycol according to a literature procedure (12) with some modifications (using benzyl instead of allyl as the protecting group). Ditosylation of polyethylene glycols **9**–**11** afforded ditosylates **12** (13), **13** (14), and **14**, respectively, which were cyclized with *N*-benzyldiol **15** using sodium hydride to afford the *N*-benzyl crowns **16**–**18** in modest yields. Hydrogenolysis of **16**–**18** to crowns **6**–**8** proceeded smoothly and alkylation with chloromethyl anthracene afforded the sensors **3**–**5**. The synthetic steps all proceeded in excellent yields with the exception of the macrocyclization, which is typically low-yielding (10).[3]

Titrations

A solution of each crown ether in methanol was titrated against saxitoxin using the fluorescence response of anthracene at an excitation wavelength of 372 nm and an emission wavelength of 420 nm. The concentration of the crown ethers was held constant at 10^{-6} mol/L, while the

[3] Supplementary data (^{1}H and ^{13}C NMR spectra for compounds **3**–**8** and **12**–**18** and typical binding isotherms for the titration of crowns **1**–**4**) for this article are available on the journal Web site (http://canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 5060. For more information on obtaining material refer to http://cisti-icist.nrc-cnrc.gc.ca/irm/unpub_e.shtml.

© 2006 NRC Canada

concentration of the toxin was varied by successive dilutions with a 10^{-6} mol/L solution of the crown ether. Beginning with 150 µL of a solution of 1 µmol/L crown sensor (**1**–**5**) and a starting STX concentration of 100 µmol/L, binding isotherms were obtained by successive removal of 50 µL aliquots and replacement with 50 µL of a 1 µmol/L crown solution. Fluorescence measurements for each dilution were made after a 4 min equilibration. Binding constants for each anthracylmethyl crown ether were obtained by curve fitting of the intensity at 420 nm to a standard rectangular hyperbolic equation for 1:1 binding (15). The binding constant was determined according to the equation

$$\frac{F}{F_0} = \frac{1 + \left(\frac{k_{11}}{k_{crown}}\right) K_{11}[STX]}{1 + K_{11}[STX]}$$

where F and F_0 are the observed fluorescence intensities in the presence and absence of STX, respectively, k_{crown} and k_{11} are constants related to fluorescence intensities of the crown and the 1:1 crown·STX complex, respectively, K_{11} is the binding constant for the 1:1 complex, and [STX] is the equilibrium concentration of unbound saxitoxin (15). The equation describes a hyperbolic binding isotherm and the binding constant (K_{11}) was obtained by a nonlinear least-squares curve-fitting program. One of the isotherms for saxitoxin binding to **5** is shown in Fig. 2. The binding constants (K_{11}) for the five crown sensors are listed in Table 1. Each value is the average of at least two runs and each run had a correlation coefficient for the least-squares fit of ≥0.98.

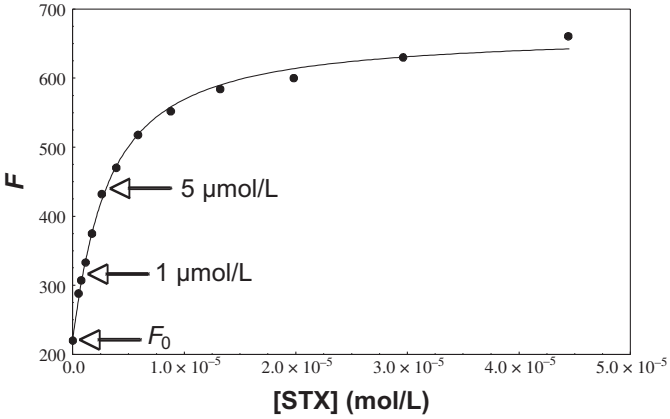
Discussion

The sensing mechanism is illustrated by the following equilibrium

$$\text{Toxin} + \text{Crown} \underset{}{\overset{K_{11}}{\rightleftharpoons}} \text{Toxin·Crown}$$

where K_{11} is the binding (equilibrium) constant for formation of the 1:1 Toxin·Crown complex. In sensors such as **1**–**5**, the fluorescent chromophore having a benzylic nitrogen is only weakly fluorescent owing to photoinduced electron transfer (PET) (16). Upon complexation of the toxin, PET is turned off and the chromophore fluoresces normally. The usual mechanism invoked for this type of PET quenching is complexation of a ligand to the benzylic nitrogen lone pair. The binding model that we believe is operative in saxitoxin sensing involves hydrogen bonding of the crown ether to one of the guanidiniums (C-8, Fig. 1), as shown in Fig. 3 (5). Monte Carlo searching of possible docked structures failed to identify a low energy structure having a hydrogen bond to the benzylic nitrogen (5). Note that the second guanidinium appears to π stack with the anthracene fluorophore. We suggest that this π stacking perturbs the relative energies of the chromophore HOMO and the nitrogen lone pair, thus "turning off" the PET (5). This hypothesis is supported by the fact that sodium, potassium, calcium (4), guanidinium (5, 17), and ammonium ions (5, 17), all of which are known to bind to crown ethers, produce no fluorescence enhancement with these sensors in alcohol solvents containing small amounts of water. Further support is found in the failure of

Fig. 2. Typical binding isotherm for titration of saxitoxin from 10^{-4} mol/L to 5×10−7 mol/L vs. anthracylmethyl 27-crown-9 chemosensor **5** (10^{-6} mol/L). A 50% fluorescence enhancement is observed at 1 µmol/L [STX] and 100% enhancement is observed at 5 µmol/L [STX].



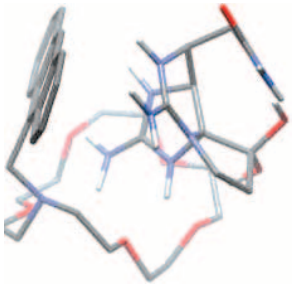


Table 1. Binding constants of saxitoxin to crown sensors **1**–**5** in methanol.

Crown sensor	Binding constant (K_b, $(mol/L)^{-1}$)
1	4.93×10^4
2	5.3×10^4
3	4.68×10^4
4	1.07×10^5
5	2.29×10^5

Note: Each K_{11} is the average of at least two runs. Correlation coefficients of ≥0.98 were calculated for each fit.

Fig. 3. Molecular mechanics model of STX docked to anthracylmethyl 18-crown-6 (global minimum) (5). Note the absence of a hydrogen bond to the benzylic nitrogen.

tetrodotoxin (Fig. 1), a toxin having many hydrogen bond donors but only one guanidinium and which binds competitively to saxitoxin in sodium channels to produce any fluorescence enhancement (6).

Three factors can contribute to an increase in fluorescence intensity upon binding of the toxin: (1) a large binding constant, which increases the relative concentration of the fluorescing Toxin·Crown complex over the unbound Crown; (2) a chromophore having a high molar absorptivity (extinction coefficient); and (3) a high fluorescence quantum yield, such that a high fraction of incident light is absorbed and a high fraction of absorbed light is emitted when PET is turned off. Anthracene has one of the highest fluorescence quantum

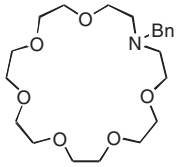
© 2006 NRC Canada

yields known (~0.4–0.8, depending on conditions). The fluorescence enhancement by saxitoxin in these sensors has not shown significant dependence on the chromophore (anthracene (5, 17), coumarin (4), or acridine (6)), so our efforts have focussed primarily on increasing the binding constant by making modifications to the crown ether.

In a full paper (5), we reported the synthesis and binding constants of 11 anthracylmethyl 18-crown-6 ethers, 10 of which were diazacrowns with additional substituents added to the crown ring — opposite the anthracylmethyl group — in the hope of increasing the binding constant. Although replacement of one oxygen with a nitrogen doubled the binding constant, further substitution failed to produce any improvement.

In early work on the binding of guanidinium ions to crown ethers, molecular models were used to postulate six hydrogen bonds between guanidinium ion and 27-crown-9 ethers (9, 10). The hypothesis was supported by the solubilization of (otherwise insoluble) guanidinium ion in chloroform by benzo-27-crown-9. The binding model invoked hydrogen bonding between the six guanidinium N-Hs and six of the nine oxygens of the crown ether. Although this binding model cannot be employed for saxitoxin, the large number of hydrogen bond donors in the toxin prompted the question whether a larger crown might show enhanced binding. Interestingly, neither ammonium ion nor guanidinium ion produced any fluorescence enhancement in **2** in ethanol (5, 17). The results of the current study reveal increased binding as the size of the crown ring increases. A control experiment shows that guanidinium ion fails to enhance the fluorescence of **5**; if anything, a slight suppression is observed in methanol.

Summary

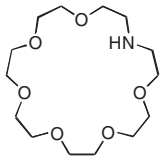


Anthracylmethyl crown ether chemosensors show enhanced binding over smaller crowns. This may be due to the fact that there are more heteroatoms in the crown and (or) that the larger crown is simply more flexible. Either effect could offer more sites for hydrogen bonding to the toxin. Our results show that simple chemosensors such as these could be developed for the detection of saxitoxin and possibly other PSP toxins, at concentrations comparable to those at which mice are sensitive.

Experimental section

General methods

IR spectra were recorded as thin films between NaCl plates or as KBr pellets. ^{1}H and ^{13}C NMR were recorded at 300 MHz for ^{1}H and 75 MHz for ^{13}C. ^{1}H and ^{13}C NMR chemical shifts are reported in ppm relative to residual chloroform; coupling constants are reported in Hz. ESI mass spectra were obtained by flow injection on a quadrupole ion trap mass spectrometer with methanol as the carrier solvent. High-resolution ESI mass spectra (HRMS/ESI) were obtained by using direct flow injection on a 9.4 T Fourier transform mass spectrometer. Dry solvents were freshly distilled before use: dichloromethane was distilled from calcium hydride and THF from sodium–benzophenone. Methanol, acetonitrile, and ethyl acetate were used as received. The hexane used in column chromatography was distilled before use. Water refers to high purity water that was obtained from the Milli-Q purification system. All reactions were performed under a nitrogen atmosphere.

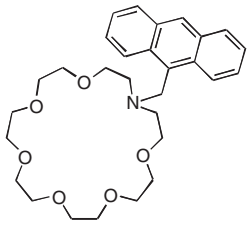


N-Benzyl monoaza-21-crown-7 (16)

To a solution of pentaethylene glycol (5.00 g, 21.0 mmol) in CH_2Cl_2 (120 mL) was added Et_3N (8.8 mL, 63.0 mmol), DMAP (1.28 g, 10.5 mmol), and TsCl (8.41 g, 44.1 mmol) at 0 °C. After stirring at RT for 1 h, NH_4Cl (satd. aq. sol., 50 mL) was added. The reaction mixture was extracted three times with CH_2Cl_2 (3 × 20 mL), the organic phase was dried with $MgSO_4$ and evaporated under reduced pressure. The residue was purified on silica gel using EtOAc–hexane (50%:50%), which gave **12** as an oil (11.2 g, 97%).

To a solution of bistosylate **12** (11.2 g, 20.5 mmol) in anhydr. THF (150 mL) was added *N*-benzyl diol **15** (4.00 g, 20.5 mmol) and NaH (2.46 g, 61.4 mmol; 60% dispersion in mineral oil, the oil was removed from the product chromatographically). The mixture was heated at 65 °C for 18 h. After cooling to RT, NH_4Cl (satd. aq. sol., 100 mL) was added. The reaction mixture was extracted three times with CH_2Cl_2 (3 × 30 mL). The organic phase was dried with $MgSO_4$, evaporated under reduced pressure, and the residue was purified on alumina using EtOAc–hexane (50%:50%), which gave an oil (2.69 g, 33%). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3523, 2870, 1643, 1453, 1124. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.78 (t, 4H, J = 5.8 Hz, CH_2), 3.57–3.68 (m, 26H, CH_2), 7.19–7.33 (m, 5H, CH-Ar). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 53.78 (*C*H_2), 59.66 (*C*H_2-Bn), 70.00, 70.63, 70.78, 70.83, 70.90 (*C*H_2), 126.78, 128.11, 128.83 (*C*H-Ar), 139.71 (*C*-Ar). MS *m*/*e*: 398 [M^+ + 1]. HRMS calcd. for $C_{21}H_{36}NO6$ 398.2542 [MH^+]; found: 398.2531. Anal. calcd. for $C_{21}H_{35}NO_6$: C 63.45, H 8.87; found: C 63.29, H 8.88.

1-Aza-21-crown-7 (6)



A solution of **16** (2.69 g, 6.76 mmol) in MeOH (50 mL) containing Pd-C (10%, 200 mg) was stirred under 1 atm H_2 (balloon, 1 atm = 101.325 kPa) overnight. The catalyst was filtered through Celite and washed with MeOH (5 × 10 mL). After evaporation, the residue was purified on alumina using MeOH–EtOAc (15%:85%), which gave a colorless oil (1.94 g, 93%). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3504, 2874, 1648, 1460, 1353, 1110. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.71

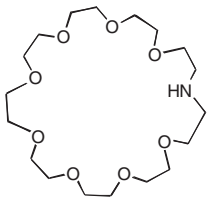
Heptaethylene glycol ditosylate (14)

The bisbenzyl ether prepared above (4.825 g, 9.52 mmol) was dissolved in MeOH (50 mL) containing Pd-C (10%, 300 mg) and stirred under 1 atm H_2 pressure (balloon) overnight. The catalyst was filtered through Celite and washed with MeOH (5 × 20 mL). After evaporation, the product (heptaethylene glycol) was obtained as a colorless oil (2.52 g, 81%) and used without further purification or characterization.



To this heptaethylene glycol (2.52 g, 7.73 mmol) in CH_2Cl_2 (50 mL) was added Et_3N (3.2 mL, 23.2 mmol), DMAP (0.472 g, 3.87 mmol), and TsCl (3.09 g, 16.23 mmol) at 0 °C. After stirring at RT for 1 h, NH_4Cl (satd. aq. sol., 20 mL) was added. The reaction mixture was extracted three times with CH_2Cl_2 (3 × 30 mL) and the combined organic phase was dried with $MgSO_4$, evaporated, and the residue was purified on silica gel using EtOAc to afford a colorless oil (4.71 g, 96%). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3525, 2872, 1598, 1457, 1182. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.43 (s, 6H, CH_3-Ts), 3.56–3.68 (m, 24H, CH_2), 4.12–4.15 (m, 4H, CH_2), 7.32–7.34 (m, 4H, CH-Ts), 7.76–7.79 (m, 4H, CH-Ts). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 21.63 (*C*H_3-Ts), 68.63, 69.28, 70.48, 70.52, 70.54, 70.58, 70.70 (*C*H_2), 127.95 and 129.84 (*C*H-Ar), 132.95 and 144.82 (*C*-Ar). 1,4,8,11-Tetra[2-aryl-1-diazenyl]-1,4,8,11-tetraazacyclotetradecanes — Synthesis, characterization, and X-ray crystallography of the first tetrakistriazenes to be reported[1]

Jeffery D. Clarke, Keith Vaughan, and Valerio Bertolasi

Abstract: The reactions of a series of arene diazonium salts with 1,4,8,11-tetraazacyclotetradecane (cyclam) afford the novel compounds, the 1,4,8,11-tetra[2-aryl-1-diazenyl]-1,4,8,11-tetraazacyclotetradecanes (**1a**–**1f**), which are the first examples of tetrakistriazenes to be reported. The tetrakistriazenes were characterized by IR spectroscopy, proton and carbon NMR, elemental analysis, high resolution electrospray mass spectrometry, and X-ray crystallography. The analogous reaction of a diazonium salt with 1,4,7-triazacyclononane or 1,5,9-triazacyclododecane yields the tristriazenes **2**, **3a**, and **3b**. The structures of compounds **1c** and **1e** were solved by X-ray crystallography at low temperature (150 K). Both molecules display a conformation where the four phenyltriazenyl groups point alternately upwards and downwards with respect to the mean macrocyclic plane.

Key words: triazene, tetrakistriazene, cyclam, tetraazacyclotetradecane, X-ray, NMR, cyclic polyamines.

Résumé : Les réactions d'une série de sels d'arènediazonium avec le 1,4,8,11-tétraazacyclotétradécane (= cyclame) conduit à la formation de nouveaux composés, les 1,4,8,11-tétra[2-aryl-1-diazényl]-1,4,8,11-tétraazatétradécanes (**1a**–**1f**) qui sont les premiers exemples de tétrakistriazènes à être rapportés. On a caractérisé les tétrakistriazènes par spectroscopie IR, par RMN du ^{1}H et du ^{13}C, par analyse élémentaire, par spectrométrie de masse à haute résolution à l'aide d'une ionisation par électronébulisation, et par diffraction des rayons X. La réaction analogue d'un sel de diazonium avec le 1,4,7-triazacyclononane ou le 1,5,9-triazacyclododécane conduit à la formation des tristriazènes **2**, **3a** et **3b**. Les structures des composés **1c** et **1e** ont été résolues par diffraction des rayons X à basse température (150 K). Les deux molécules présentent chacune une conformation dans laquelle les quatre groupes phényltriazényles sont orientés alternativement vers le haut et vers le bas par rapport au plan macromoléculaire moyen.

Mots clés : triazène, tétrakistriazène, cyclame, tétraazacyclotétradécane, rayons X, RMN, polyamines cycliques.

[Traduit par la Rédaction]

Introduction

1,4,8,11-Tetraazacyclotetradecane (cyclam) forms the most stable complexes with transition metal ions from both a thermodynamic and a kinetic viewpoint, among cyclic polyamines of varying ring size (1). The proclivity of cyclam to coordinate to Ni^{II} has been used to advantage in the template synthesis reaction (2), whereas covalent attachment of cyclam to a DNA-intercalator molecule, such as anthraquinone (3), influences interaction with DNA, causing substantially enhanced unwinding of the DNA. Metal complexation to the cyclam portion of the adduct increases the effect still further and metal-binding to DNA can cause sequence selective binding (4). Bicyclam derivatives composed of two cyclam units linked by an aliphatic linker have been identified as potent inhibitors of HIV type 1 and type 2 (5). This is just a fragment of the intense and vast literature dealing with the chemistry and pharmacology of cyclam. Surprisingly, the potential of cyclam to undergo diazo coupling reactions has apparently not been explored previously.

The reaction of a diazonium salt with a simple secondary amine is the conventional way to synthesize a stable triazene, e.g., $ArN{=}N{-}NR_2$ (6). Many triazenes have been shown to possess antitumor properties in experimental models (7) and a few triazenes are used clinically in the treatment of human malignant melanoma (8) and brain tumors (9). Bistriazenes are compounds that contain two triazene units in the same molecule; the chemistry of bistriazenes has recently been reviewed (10). Compounds that contain three or four triazene units per molecule, i.e., tristriazenes and

tetrakistriazenes, are hitherto unknown, so it is with great satisfaction that we report here the synthesis of the first known examples of the classes of tristriazenes and tetrakistriazenes from the diazonium coupling reaction with the cyclic polyamines, 1,4,7-triazacyclononane, 1,5,9-triazacyclododecane, and 1,4,8,11-tetraazacyclotetradecane (cyclam). The potential medicinal chemistry resulting from the combination of the polyamine and triazene units in the same drug molecule is an exciting prospect.

Experimental

Melting points were determined on a hot-stage melting point apparatus and are uncorrected. IR spectra were obtained using Nujol mulls. ^{1}H and ^{13}C NMR chemical shifts were recorded in $CDCl_3$ or d_6-DMSO solutions at 27 °C (unless stated otherwise) and are relative to TMS as internal standard. Accurate mass measurements were performed by ESI-MS. The sample was dissolved in methanol or methanol–chloroform. The solution concentration was approximately 50–100 μmol/L. It was infused at a flow rate of 30 μL/min. For accurate mass measurement of $(M + H)^+$, tetralysine KKKK or Angiotensin III was used as the reference compound. The mass of $(M + H)^+$ from tetralysine was used as the lock mass.

Synthesis of the 1,4,8,11-tetra[2-aryl-1-diazenyl]-1,4,8,11-tetraazacyclotetradecanes (1a–1f)

General procedure

A solution of the aromatic amine (0.005 mol) in 3 mol/L hydrochloric acid (5.0 mL) was cooled to 0 °C and diazotized with a solution of sodium nitrite (0.38 g) in water (1.5 mL). A solution of 1,4,8,11-tetraazacyclotetradecane (0.20 g) in water (2.0 mL), with 3 mol/L HCl (0.5 mL) added, was added slowly with stirring to the cold diazonium salt solution and the mixture was left stirring for 0.5 h. The solution was then neutralized with saturated sodium bicarbonate solution, stirred in the cold for a further 1.0 h, and then filtered by vacuum filtration to afford the following tetrakistriazenes.

*1,4,8,11-Tetra[2-(*p*-cyanophenyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (1a)*

Off-white powder, yield 80%, mp 251–254 °C (ethyl acetate). IR (cm^{-1}) ν_{max}: 2223 (CN), 844 (OOP). ^{1}H NMR (500 MHz, d_6-DMSO) δ: 2.17 (4H, v br), 3.84 (8H, br), 4.15 (8H, br s, H_a), 7.45 (8H, d, J = 6.7 Hz), 7.75 (8H, d, J = 6.7 Hz). MS (ESI+) m/z calcd. for $C_{38}H_{36}N_{16}$: 716 $(M + Na)^+$; found: 739.2.

*1,4,8,11-Tetra[2-(*p*-nitrophenyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (1b)*

Yellow powder, yield 90%, mp 263 to 264 °C (from dimethylsulfoxide). IR (cm^{-1}) ν_{max}: 1514, 1333 (nitro group), 854 (OOP). ^{1}H NMR (500 MHz, d_6-DMSO) δ: 2.18 (4H, br), 3.93 (8H, br), 4.20 (8H, br s), 7.57 (8H, d, J = 9.0 Hz), 8.24 (8H, d, J = 9.5 Hz). Second species (rotamer with 40% relative intensity) δ: 2.94 (br), 3.99 (br), 4.20 (br), 7.42 (br), 8.31 (d, J = 9.0 Hz). Anal. calcd. for $C_{34}H_{36}N_{16}O_8$: C 51.25, H 4.55; found: C 51.14, H 4.57.

*1,4,8,11-Tetra[2-(*p*-methoxycarbonylphenyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (1c)*

Pale yellow prisms, yield 75%, mp 215–217 °C (toluene). IR (cm^{-1}) ν_{max}: 1716 (C=O), 1278 (C-O), 859 (OOP). ^{1}H NMR (500 MHz, 47 °C, $CDCl_3$) δ: 2.19 (4H, quintet, J = 6.7 Hz), 3.79 (8H, t, J = 6.7 Hz), 3.91 (12H, s), 4.11 (8H, s), 7.33 (8H, d, J = 8.5 Hz), 7.92 (8H, d, J = 8.6 Hz). ^{13}C NMR (15 MHz, $CDCl_3$) δ: 30.40, 51.76, 120.21, 130.50, 145.03, 153.61, 166.75. HRMS (ESI) m/z calcd. for $C_{42}H_{49}N_{12}O_8$: 849.3796 $(M + H)^+$; found: 849.3799. Anal. calcd. for $C_{91}H_{104}N_{24}O_{16}$: C 61.07, H 5.82, N 18.79; found: C 61.24, H 5.95, N 18.45.

*1,4,8,11-Tetra[2-(*p*-acetylphenyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (1d)*

Reddish-brown powder, yield 65%, mp 182–184 °C (ethanol). IR (cm^{-1}) ν_{max}: 1672 (C=O), 841 (OOP). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.19 (4H, br), 2.58 (12H, s), 3.80 (8H, br), 4.15 (8H, s), 7.35 (8H, d, J = 8.2 Hz), 7.84 (8H, d, J = 8.2 Hz). Anal. calcd. for $C_{42}H_{48}N_{12}O_4$: C 64.26, H 6.16; found: C 63.84, H 6.31.

*1,4,8,11-Tetra[2-(*p*-methylphenyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (1e)*

White needles, yield 40%, mp 139 to 140 °C (ethanol). IR (cm^{-1}) ν_{max}: 825 (OOP). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.14 (4H, quintet, J = 6.7 Hz), 2.33 (12H, s), 3.73 (8H, t, J = 6.8 Hz), 4.02 (8H, s), 7.07 (8H, d, J = 8.2 Hz), 7.26 (8H, d, J = 8.2 Hz). ^{13}C NMR (125.77 MHz, $CDCl_3$) δ: 21.04, 27.09, 49.54, 120.53, 129.44, 135.37, 148.32. HSQC NMR (125.77 MHz, $CDCl_3$) δ: 51.38 correlates with proton signal at 3.73 ppm. HRMS (ESI) m/z calcd. for $C_{38}H_{49}N_{12}$: 673.4203 $(M + H)^+$; found: 673.4202.

*1,4,8,11-Tetra[2-(*p*-bromophenyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (1f)*

Off-white powder, yield 86%, mp 198 to 199 °C (propanol). IR (cm^{-1}) ν_{max}: 828 (OOP). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.12 (4H, quintet, J = 6.6 Hz), 3.72 (8H, t, J = 6.6 Hz), 4.04 (8H, s), 7.18 (8H, d, J = 8.5 Hz), 7.365 (8H, d, J = 8.5 Hz). ^{13}C NMR (125.77 MHz, $CDCl_3$) δ: 26.99, 49.44, 119.18, 122.15, 131.92, 149.25. Anal. calcd. for $C_{34}H_{36}N_{12}Br_4$: C 43.90, H 3.89, N 18.03; found: C 44.07, H 3.87, N 17.74.

Application of this procedure with 1,5,9-triazacyclododecane in place of cyclam afforded the tristriazene **2**.

*1,5,9-Tri[2-(*p*-cyanophenyl)-1-diazenyl]-1,5,9-triazacyclododecane (2)*

Red-brown powder, yield 57%, mp 172–175 °C (ethanol). IR (cm^{-1}) ν_{max}: 2221 (CN), 844 (OOP). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.32 (6H, br quintet), 3.88 (12H, t, J = 6.0 Hz), 7.47 (6H, d, J = 8.5 Hz), 7.61 (6H, d, J = 8.5 Hz). Anal. calcd. for $C_{30}H_{30}N_{12}$: C 64.50, H 5.41; found: C 64.26, H 5.39.

Application of the general procedure with 1,4,7-triazacyclononane in place of cyclam afforded the tristriazenes **3a** and **3b**.

Crystallography

X-ray diffraction data for compounds **1c** and **1e** were collected at low temperature (150 K) on a Nonius Kappa CCD diffractometer with graphite monochromated Mo Kα radiation (λ = 0.7107 Å).[3] The structures were solved by direct methods (SIR97) (11) and refined (SHELXL-97) (12) by full-matrix least-squares with anisoptropic non-H and hydrogen atoms included on calculated positions riding on their carrier atoms. The methoxy carbonyl moiety C41, O7, O8, C42 in **1c** is disordered and the methyl group $C42H_3$ has been refined over two positions with the respective occupancies of 0.579(9) and 0.421(9). The crystal contains half a molecule of toluene per molecule of **1c**, disordered around a crystallographic centre of symmetry. It has been refined over

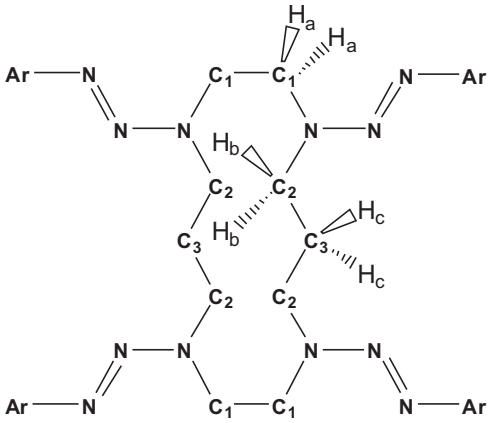
The crystal data and refinement parameters are summarized in Table 1. Selected bond distances and angles are given in Tables 2 and 3.

Results and discussion

1,4,8,11-Tetraazacyclotetradecane (cyclam) reacted favorably in aqueous solution with a variety of diazonium salts to afford the novel 1,4,8,11-tetra[2-aryl-1-diazenyl]-1,4,8,11-tetraazacyclotetradecanes (**1a**–**1f**) in excellent yields, as high as 90%. The diazonium salt was used in 25% excess above the required stoichiometric ratio of 4:1. Raising the amount of diazonium salt to 50% excess had little effect on the yield, with the exception of the *p*-bromo derivative (**1f**) that went from 35% to 86% yield. The 1,4,8,11-tetra[2-aryl-1-diazenyl]-1,4,8,11-tetraazacyclotetradecanes are stable solids that crystallize, mostly from polar solvents, and it was possible to grow small crystals from two of the compounds in the series for X-ray crystallography. The tetrakistriazenes have been identified by spectroscopic methods. The IR spectra display the characteristic bands of the particular aryl substituents, e.g., nitrile, carbonyl, and nitro groups. The ^{1}H NMR spectra are consistent with the assigned structures, although significant broadening of NMR signals was evident

© 2006 NRC Canada

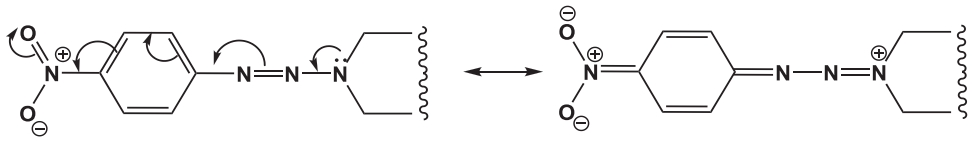


owing to the familiar phenomenon of restricted rotation around the N—N bonds of the triazene moieties (14). The protons attached to the carbon atoms of the 14-membered macrocyclic ring are clearly distinguished (see proton and carbon labelling in Fig. 1 to clarify the following discussion).

The eight equivalent protons of the ethylene spacers, labeled H_a attached to C_1, give rise to a singlet at ca. 4.2 ppm, integrating for 8H as expected, with varying line width from quite sharp in **1e** and **1f** to very broad in **1b**. The multiplicity of the protons of the propylene spacers, H_b and H_c, is resolved in compounds **1c**, **1e**, and **1f**. In these spectra, the H_b protons appear as an eight-proton triplet at ca. 3.8 ppm and the H_c protons are resolved as a four-proton quintet at ca. 2.2 ppm. The analogous signals in the spectra of **1a**, **1b**, and **1d** are too broad for the multiplicity to show. In all compounds (**1a**–**1f**) the aromatic protons give rise to the expected AA′BB′ pattern and the protons of the methyl groups in the X-substituents of **1c**–**1e** are observed at the predicted chemical shifts.

A VT NMR experiment was conducted with compound **1c** in $CDCl_3$ to attempt to slow down the rotational equilibrium in the triazene units so that resolution would be improved. However, lowering the temperature of the solution of **1c** resulted in further broadening of the proton signals, while raising the temperature to 47 °C gave a nicely resolved spectrum with the triplet of H_b and the quintet of H_c clearly evident. Evidently, raising the temperature of the solution causes the faster exchange of rotamers and individual multiplets are observed. A different manifestation of the dynamic rotation is observed in the case of the *p*-nitro derivative (**1b**); this tetrakistriazene affords a proton spectrum with two clear sets

Fig. 1. Proton and carbon labelling in structures **1a**–**1f**.



of broad signals that we ascribe to the rotamers resulting from the restricted rotation around the N—N bond (14). This total doubling of the spectra is only seen in the case of the *p*-nitro compound; the strongly electron-withdrawing nitro group promotes the resonance (eq. [1]) that gives the N—N bond greater double-bond character.

^{13}C NMR analysis was not feasible with compounds **1a**, **1b**, and **1d** owing to the combination of low solubility and the broadening of NMR signals because of rotational dynamics. However, compounds **1c** and **1f** gave partial ^{13}C NMR spectra with not all macrocyclic ring carbons showing. Only compound **1e** gave a complete set of ^{13}C signals, with the aid of HSQC spectroscopy (Fig. 2) to detect the signal from C2. These limited data give the general assignments of C1 at 49.5 ppm, C2 at 51.0 ppm, and C3 at ca. 27.0 ppm, together with the predicted aromatic carbon signals.

Further analytical evidence for the structures of the tetrakistriazenes was obtained from elemental analysis of compounds **1b**–**1f** and from electrospray mass spectrometry with compounds **1a**, **1c**, and **1e**. The molecular ions of these compounds did not survive the conditions of electron ionization mass spectrometry. Unequivocal proof of the novel tetrakistriazene structure is evident in the X-ray crystallography of compounds **1c** and **1e**.

An ORTEP (15) view of the molecule of the tetrakistriazene **1c** is shown in Fig. 3, in which the molecule is viewed more or less through the plane of the cyclam core. The best view of the 14-membered macrocycle (without substituents for the sake of clarity) is shown in the ORTEP diagram of Fig. 4. The molecule of **1c** displays a conformation where the four phenyltriazenyl groups point alternately upwards and downwards with respect to the mean macrocyclic plane. All the phenyltriazenyl groups are almost planar and those on the same side are roughly parallel, but the phenyl ring couples (C11-C16)–(C27-C32) and (C19-C24)–(C35-C40) form angles of 11.0(2)° and 10.2(1)°, respectively. An important point to make regarding this structure is the conjugation degree within the triazene moieties that is greater for

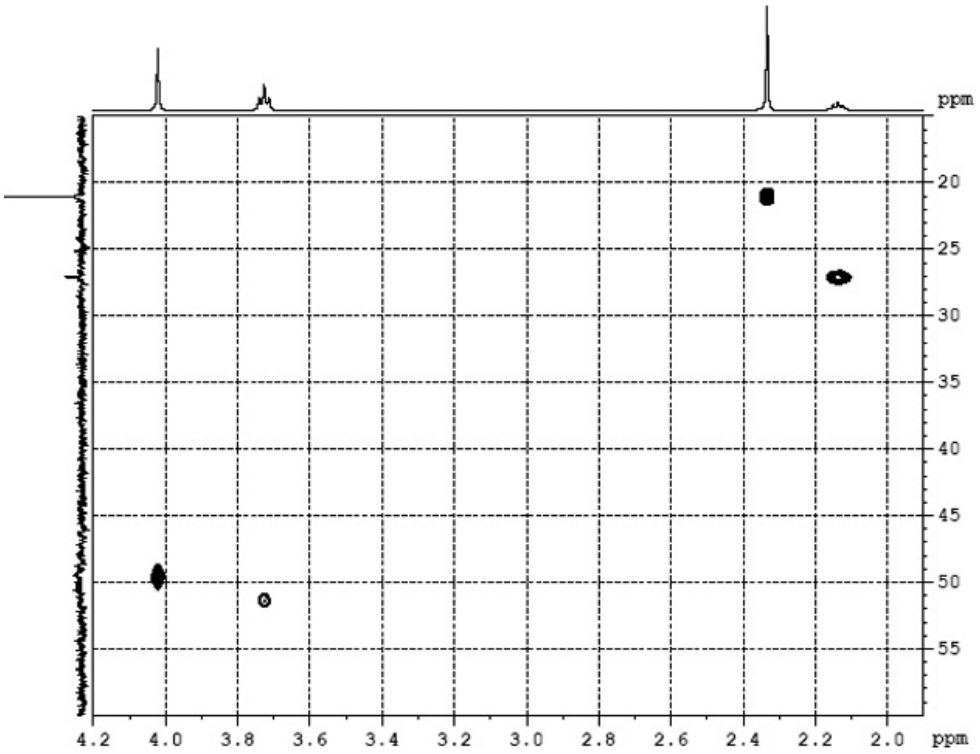
Fig. 2. High-field region of the HSQC ($CDCl_3$) spectrum of 1,4,8,11-tetra[2-(*p*-tolyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (**1e**), showing the correlation of protons H_a, H_b, and H_c with carbons C1, C2, and C3, respectively.



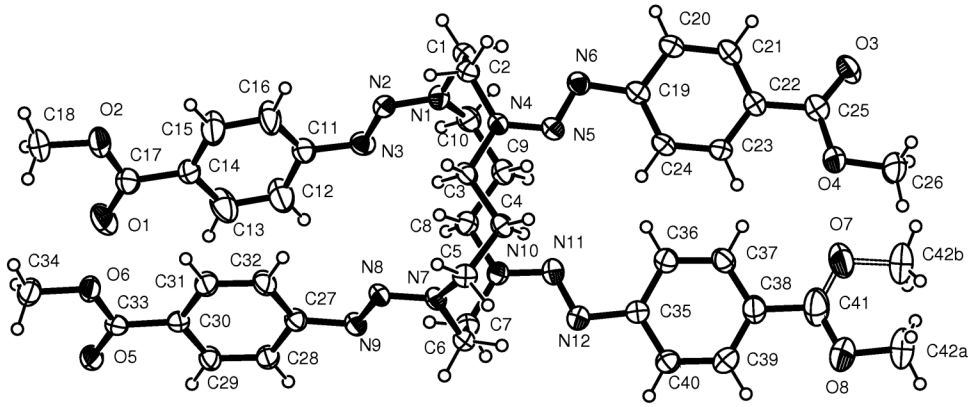


Fig. 3. ORTEP view of 1,4,8,11-tetra[2-(*p*-methoxycarbonyl-phenyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (**1c**), displaying the thermal ellipsoids at 40% probability.

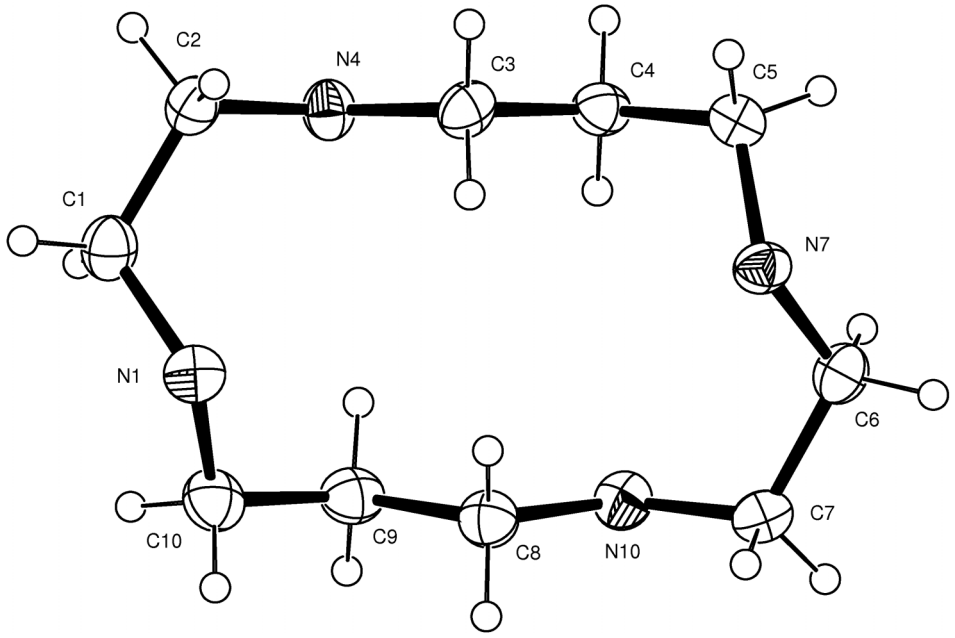

N4-N5=N6 and N10-N11=N12 situated on one side with respect to N1-N2=N3 and N7-N8=N9 on the other side.

Although the N1—N2 and N7—N8 single bonds of 1.340(4) and 1.341(4) Å and the N2=N3 and N8=N9 double bonds of 1.277(5) and 1.277(5) Å indicate significant conjugation within the triazene moieties, the corresponding distances for the other triazenes, N4—N5 = 1.309(4) Å, N5=N6 = 1.287(4) Å, N10—N11 = 1.314(4) Å, and N11=N12 = 1.283(5) Å, show, however, a much more pronounced degree of conjugation. The macrocycle shown in Fig. 3 displays a rectangular cavity with the following internal distances: N1···N7 = 5.311(4) Å, N4···N10 = 4.527(4) Å, N4···C9 = 3.609(5) Å, and N10···C4 = 3.623(5) Å.

The structure of the *p*-tolyl analogue in the series (**1e**) is quite complicated because the asymmetric unit contains two independent molecules; the ORTEP diagrams of these two species are shown in Figs. 5*a* and 5*b*, which clearly support our conclusions that the connectivity in this compound is the tetrakistriazene structure. The best projections of the 14-membered macrocycles (without substituents) are shown in Figs. 6*a* and 6*b*. Both molecules display similar conformations with respect to those observed in compound **1c**, where the four phenyltriazenyl groups point alternately upwards and downwards from the mean macrocyclic plane. All the phenyltriazenyl groups are almost planar and the phenyl groups, on the same sides, form the following dihedral angles: C11-C16-C25-C30 of 15.9(1)° and 3.7(1)° and C18-C23-C32-C37 of 10.4(1)° and 11.8(1)° for molecules A and B, respectively. All the triazene groups display similar conjugations with N—N single bonds in the range 1.32–1.35 Å

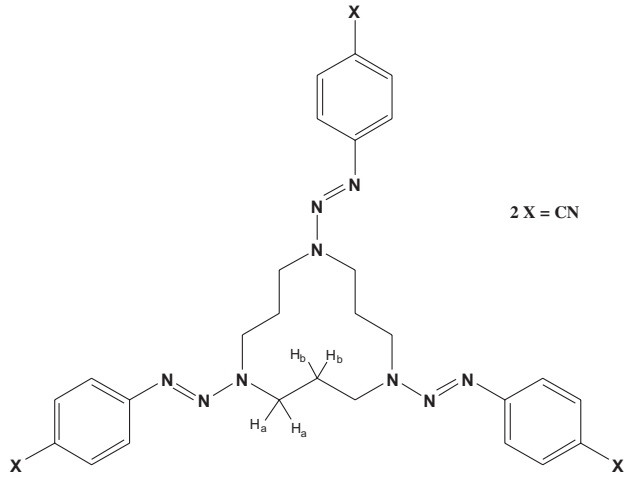

Fig. 4. ORTEP view of the heterocyclic cyclam core of the molecule of **1c**.

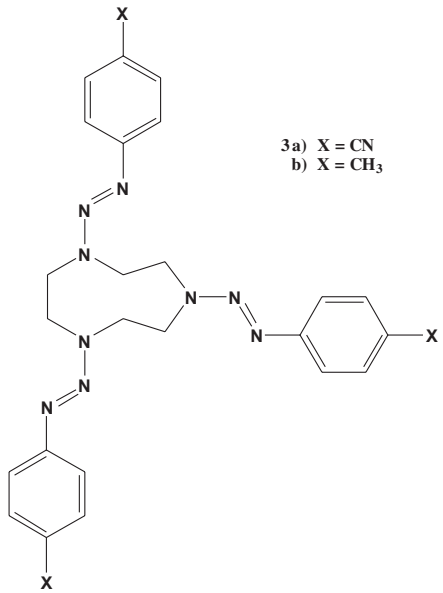
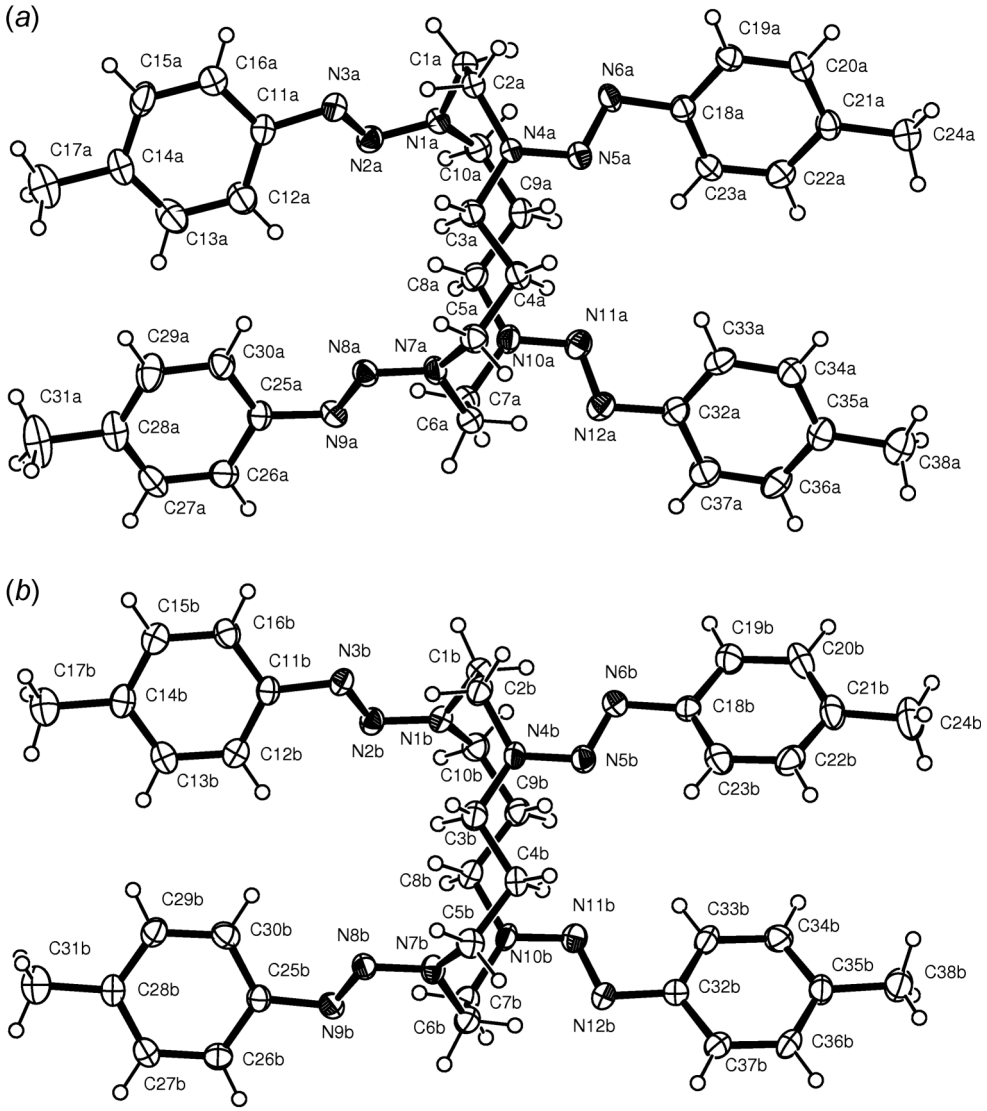


and N=N double bonds in the range 1.27–1.28 Å. The macrocycles, shown in Figs. 6*a* and 6*b*, exhibit slightly different conformations displaying cavities with the following internal distances: N1···N7 = 5.378(4) Å, N4···N10 = 4.470(4) Å, N4···C9 = 3.564(5) Å, and N10···C4 = 3.586(5) Å for molecule A; N1···N7 = 5.346(4) Å, N4···N10 = 4.556(4) Å, N4···C9 = 3.665(5) Å, and N10···C4 = 3.663(5) for molecule B.

This paper represents a major advance in the chemistry of triazenes, moving in one leap from the bistriazene front to the previously unknown tetrakistriazene. Of course, there is a missing link in this picture, which is the tristriazene represented by structures **2** and **3**. Accordingly, we investigated the reaction of 1,5,9-triazacyclododecane with *p*-cyanobenzenediazonium chloride, which afforded the tristriazene, 1,5,9-tri[2-(*p*-cycanophenyl)-1-diazenyl]-1,5,9-triazacyclododecane (**2**). The ^{1}H NMR spectrum of **2** is decidedly simple and consistent with the tristriazene structure. The protons of the three equivalent three-carbon spacers appear as the expected six-proton quintet at 2.32 ppm, assigned to the protons H_b of the central methylene groups, and a 12-proton triplet at 3.88 ppm, assigned to the protons H_a of the N-CH_2 groups.

Reaction of 1,4,7-triazacyclononane with diazonium salts afforded the tristriazenes **3a** and **3b**. However, the NMR spectra of these molecules are not as simple as expected; in principle, the protons of the triazacyclononane methylene groups should be equivalent. In the ^{1}H NMR spectrum of **3b**, the peaks are broad but, significantly, they integrate for the correct number of protons. The tolyl methyl protons resonate at 2.34 ppm with an integration for nine protons and the broadened aromatic AA′BB′ system integrates for 12 protons. The methylene protons of the heterocyclic ring appear as two very broad signals at 3.91 and 4.19 ppm, each integrating for 6H. We suggest that these two methylene signals can be assigned to the axial and equatorial hydrogen atoms



2 X = CN

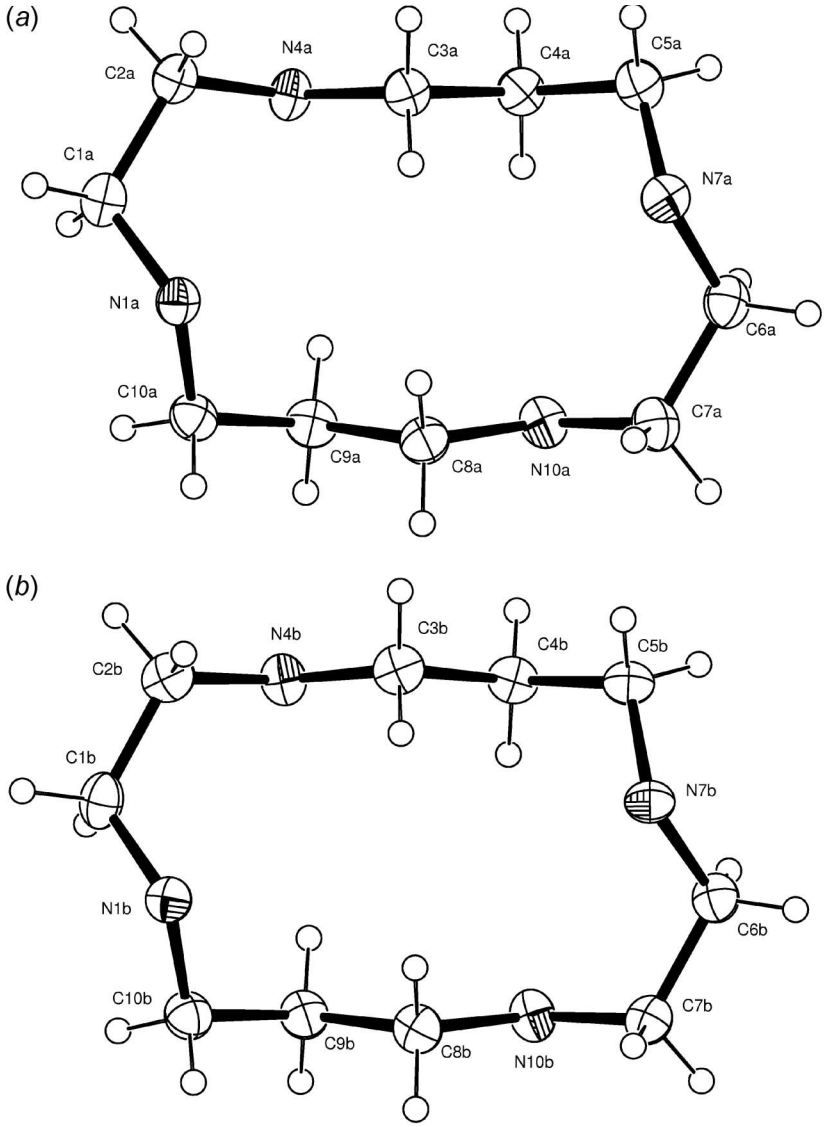
Fig. 5. ORTEP views of the two independent molecules of 1,4,8,11-tetra[2-(*p*-methylphenyl)-1-diazenyl]-1,4,8,11-tetraazacyclotetradecane (**1e**), displaying the thermal ellipsoids at 40% probability.

in the nine-membered ring (see Fig. 7). The broadening of the signals is ascribed to the rotational dynamics of the triazene moieties (14). Indeed, the two rotameric forms of **3b** are clearly seen in the ^{13}C NMR spectrum, and each carbon atom is detected. The relative intensity of the signals from the two rotamers indicates that the major rotamer is present in 60%–70% abundance. Significantly, the equivalent carbon atoms of the heterocyclic ring are detected at 49.28 and 53.18 ppm.

Tristriazene **3a** did not have sufficient solubility to enable ^{13}C NMR analysis, but the ^{1}H NMR spectrum of **3a** showed a complex set of signals for the methylene protons of the heterocyclic ring. The multiplet observed in the range 3.95–4.37 ppm could be interpreted as a group of signals centred around 4.03 ppm and a second group around 4.25 ppm. The two groups are assigned to the axial and equatorial hydrogens (Fig. 6) and the multiple peaks in each group could be assigned to the various rotamers arising from the restricted rotation around the N—N bond in the triazenes (14).

Conclusion



The results reported in this paper clearly show that tristriazenes and tetrakistriazenes can be synthesized and characterized. These results further our extensive research into the synthesis of bistriazenes of various types. Notably, our recent studies have been involved with the general synthesis of triazene derivatives of 1,*x*-diazacycloalkanes. For example, diazonium coupling with piperazine affords the stable bis-1,4-di-(2-aryl-1-diazenyl)-piperazines (**4**) (16). Analogous coupling of diazonium salts with homopiperazines affords the bistriazene series **5** (17).

A chiral auxiliary cleavable by ring-closing alkene metathesis — Efficient synthesis of chiral nonracemic cycloalkenes[1]

Luc Boisvert, Francis Beaumier, and Claude Spino

Abstract: *p*-Menthane-3-carboxaldehyde is a readily available chiral auxiliary used to prepare cycloalkenes and heterocycles bearing a chiral tertiary or quaternary carbon of high enantiomeric purity. The auxiliary is available in both enantiomeric forms and is inexpensive and recyclable. It is cleaved by a ring-closing alkene metathesis reaction directly yielding the cycloalkene.

Key words: chiral auxiliary, cleavage reaction, cyclization, ring-closing alkene metathesis, enantioenriched cycloalkenes.

Résumé : Le *p*-menthane-3-carboxaldéhyde est utilisé comme auxiliaire chiral pour fabriquer des cycloalcènes et des hétérocycles contenant un centre carboné tertiaire ou quaternaire de pureté énantiomérique élevée. L'auxiliaire est disponible dans les deux séries énantiomériques et est peu dispendieux et recyclable. Il est clivé par une réaction de fermeture de cycle par métathèse d'alcènes menant directement au cycloalcène.

Mots clés : auxiliaire chiral, réaction de clivage, cyclisation, fermeture de cycle par métathèse d'alcènes, cycloalcènes énantioenrichis.

Introduction

Chiral auxiliaries are exceptionally useful tools in synthetic organic chemistry because many of them achieve high levels of asymmetric induction on a wide range of substrates (1). One inherent drawback to their use is the need to install and cleave the auxiliary, which adds two chemical steps to the synthesis of the target molecule. This disadvantage can, however, be minimized if one of these two steps consists of a chemical transformation that would have been carried out eventually as part of the synthetic plan. This is not the case for the majority of chiral auxiliaries found in the literature that are cleaved either by addition–elimination reactions on polarized π systems (e.g., hydride reduction of C=O functional groups) or by hydrolysis of acetal-like functionalities (1). In addition, while other auxiliary-specific cleaving reactions have been developed (e.g., ozonolysis of C=C bonds (2) or hydrogenolysis of benzylic groups (3)), there is still a need to widen the arsenal of available methods to cleave chiral auxiliaries.

In this report, we disclose the cleavage of a chiral auxiliary by ring-closing alkene metathesis (RCM) (4) to yield highly enantioenriched cycloalkenes. To the best of our knowledge, this constitutes the first example of a chiral auxiliary cleavable by a RCM reaction (5, 6). Using our strategy, the cleavage of the auxiliary becomes intrinsic to the synthetic strategy and does not add extra steps en route to the final target.

Synthesis of RCM precursors[3]

The sequence of reactions starts with the synthesis of allylic alcohols **7a**–**7e** from *p*-menthane-3-carboxaldehyde **3** (7). These allylic alcohols were prepared by one of three methods (Scheme 1 and Table 1).

Method A involves the $AlMe_3$-promoted addition of vinyllithium reagents **6a** to aldehyde **3** (8). In this manner, a mixture of diastereomeric allylic alcohols, which are easily separated by flash chromatography, is obtained with selectivities ranging from ca. 10:1 to more than 100:1, favouring the Felkin–Ahn adducts (i.e., **7** as illustrated). Method B involves the addition of vinylalanes **6b**, generated by the zirconium-catalyzed methylalumination of alkynes (9) to aldehyde **3**. In Method C, lithium acetylides **2** are added to aldehyde **3** in the presence of dry cerium trichloride to afford a mixture of diastereomeric propargylic alcohols **4** (10).

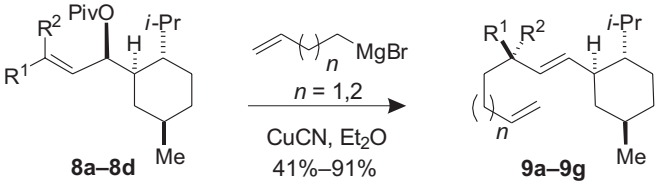
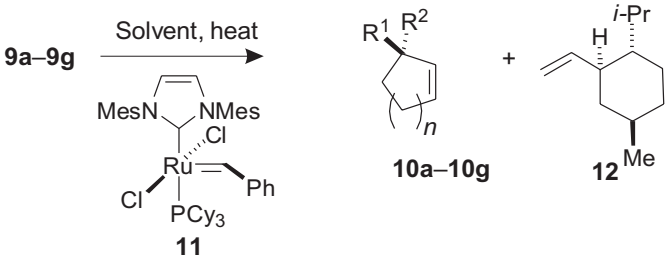
[b]Method A.
[c]Method C (yield of **7** over two steps).
[d]DR of **4** from the addition of **2** to **3**.
[e]Method B.



These propargylic alcohols are easily separated and converted to geometrically pure *E* allylic alcohols **7** by reduction with Red-Al. The alcohols **7a**–**7e** were then converted to the corresponding allylic pivalate esters **8a**–**8e** in excellent yields.

Cyanocuprates, derived from Grignard reagents, displaced the pivalate esters stereospecifically (anti to the leaving group with complete transfer of chirality) with 100% stereoselectivity (reaction on the conformer with minimized $A^{1,3}$ strain, yielding *E* alkenes) and with exclusive S_N2' regioselectivity (no S_N2 adduct detected by GC) (7, 11). Thus, cuprate adducts **9a**–**9g** (precursors to five- and six-membered rings for the subsequent RCM reactions) were prepared from pivalate esters **8a**–**8d** (Scheme 2). It should be noted that both absolute stereochemistries at the newly created chiral center in adducts **9** are accessible since both enantiomers of *p*-menthane-3-carboxaldehyde **3** are available, the double-bond geometry in **8** can be controlled, and the order of introduction of the different substituents on the new chiral center can be varied (7).



RCM reactions

After screening different ruthenium-based metathesis catalysts (see Supplementary data),[3] it was found that the formation of cycloalkenes **10** by a RCM reaction was best performed using the Grubbs–Nolan catalyst **11** (12) (Scheme 3). For precursors of five-membered rings bearing a tertiary carbon center (**9a** and **9c**) very mild conditions (**11** (1 mol%), CH_2Cl_2, 40 °C, 3 h) resulted in smooth transformation to cycloalkenes **10a** and **10c** (Table 2, entries 1 and

Scheme 2.

Scheme 3.

3). The only detectable (^{1}H NMR) products in the crude reaction mixtures were the cycloalkenes **10** and compound **12**.

Cyclization of precursors of six-membered rings bearing a tertiary carbon center (**9b** and **9d**) necessitated harsher conditions (**11** (10 mol%), $ClCH_2CH_2Cl$, 83 °C, 3 h) to avoid the formation of the corresponding dimers **13b** and **13d** by a competitive cross-metathesis reaction (Fig. 1). Under these conditions, the RCM reactions occurred smoothly to provide cycloalkenes **10b** and **10d** in good yields (Table 2, entries 2 and 4), with only trace amounts of **13** being detected.

Adducts **9e**–**9g**, bearing a quaternary carbon, presented a greater challenge. Minimizing the production of dimer **13** was crucial because when **13e** (derived from **9e**) was treated under RCM conditions (with or without an atmosphere of ethylene), no useful amount of **10e** could be obtained. Ultimately, it was found that higher dilution and temperatures were efficient in decreasing the amount of **13**. However, these conditions sometimes caused side-reactions, like the well-documented alkene isomerization (13), such that cycloalkenes **10e** and **10g** were contaminated with small amounts of inseparable alkene regioisomers **14e** and **14g**, respectively (Fig. 1).

Many strategies were tried to inhibit the formation of **14** (see Supplementary data),[3] but none gave reproducible results. Although the isomerization could not be completely suppressed, cycloalkene **10e** could be obtained in 79% yield as an acceptable 31:1 mixture of **10e** and **14e** by maintaining strictly anhydrous conditions and limiting the reaction time. In the same manner, **10g** was obtained in 70% yield as a 42:1 mixture of **10g** and **14g**. The fact that the RCM proceeds at all on substrates **9e** and **9g** is very satisfying, given the presence of an allylic quaternary center and a bulky menthyl fragment on each side of the *E* double bond (14).

It is perhaps not surprising, given the above results, that we have not yet succeeded in forming six-membered rings bearing a quaternary carbon. Compound **9f** afforded mostly dimer **13f** and degradation products under various conditions; RCM adduct **10f** was never observed, nor was by-product **12** (Table 2, entry 6).

The enantiomeric purity (determined by GC or HPLC analysis against racemic samples) of each RCM adduct was

found to be excellent. For entries 1 and 7 of Table 2, we were unable to achieve complete resolution of the cycloalkene enantiomers, but their enantiomeric ratios are likely to be equally high. By-product **12** can be easily recovered by flash chromatography in yields of 70%–80% and, if desired, can be recycled back to aldehyde **3** by ozonolysis.

It is possible to envisage the application of our strategy to the preparation of a wide variety of highly enantioenriched cycloalkenes. Among the most interesting candidates, heterocycles are highly desirable (15). As an example, diene **15** (obtained in three steps from pivalate ester **8e**) was submitted to a RCM reaction to furnish dihydropyran **16** in 81% yield and >99% ee (as determined by HPLC analysis) (Scheme 4). *N*-Heterocycles, prepared by a different route (16), were also obtained by a similar RCM cleavage strategy as shown in Scheme 4. Dehydropiperidine **18a** and **18c**, pyrrolidine **18b**, and dihydroquinoline **20** were formed in excellent yield under much milder conditions (1 mol% catalyst in refluxing dichloromethane). Dihydropyran **22** required higher catalyst loading and higher temperature. We are currently embarked on the total synthesis of several alkaloids using this methodology.

Conclusion

We have achieved the first cleavage of a chiral auxiliary by a RCM reaction. This unprecedented method of cleavage has the merit of increasing the complexity of the substrate during the cleavage of the auxiliary, while not adding any extra steps to a synthetic plan aimed at synthesizing cycloalkenes. The sequence described herein allows the synthesis of enantioenriched cycloalkenes bearing a tertiary or quaternary chiral carbon in just four steps starting from readily available starting materials (vinyliodides or alkynes).

Scheme 4.

We are currently expanding the methodology to include more diverse and complex structures.

Triazene derivatives of (1,*x*-)diazacycloalkanes. Part VI. 3-({5,5-Dimethyl-3-[2-aryl-1-diazenyl]-1-imidazolidinyl}methyl)-4,4-dimethyl-1-[2-aryl-1-diazenyl]imidazolidines — Synthesis, characterization, and X-ray crystal structure[1,2]

Keith Vaughan, Shasta Lee Moser, Reid Tingley, M. Brad Peori, and Valerio Bertolasi

Abstract: Reaction of a series of diazonium salts with a mixture of formaldehyde and 1,2-diamino-2-methylpropane affords the 3-({5,5-dimethyl-3-[2-aryl-1-diazenyl]-1-imidazolidinyl}methyl)-4,4-dimethyl-1-[2-aryl-1-diazenyl]imidazolidines (**1a**–**1f**) in excellent yield. The products have been characterized by IR and NMR spectroscopic analysis, elemental analysis, and X-ray crystallography. The X-ray crystal structure of the *p*-methoxycarbonyl derivative (**1c**) establishes without question the connectivity of these novel molecules, which can be described as linear bicyclic oligomers with two imidazolidinyl groups linked together by a one-carbon spacer. This is indeed a rare molecular building block. The molecular structure is corroborated by ^{1}H and ^{13}C NMR data, which correlates with the previously published data of compounds of types **5** and **6** derived from 1,3-propanediamine. The triazene moieties in the crystal of **1c** display significant π conjugation, which gives the N—N bond a significant degree of double-bond character. This in turn causes restricted rotation around the N—N bond, which leads to considerable broadening of signals in both the ^{1}H and ^{13}C NMR spectra. The molecular ion of the *p*-cyanophenyl derivative (**1b**) was observed using electrospray mass spectrometry (ES + Na). The mechanism of formation of molecules of type **1** is proposed to involve diazonium ion trapping of the previously unreported bisimidazolidinyl methane (**13**).

Key words: triazene, bistriazene, imidazolidine, synthesis, X-ray crystallography, NMR spectroscopy.

Résumé : Les réactions d'une série de sels de diazonium avec un mélange de formaldéhyde et de 1,2-diamino-2-méthylpropane conduit à la formation des 3-({5,5-diméthyl-3-[2-aryl-1-diazényl]-1-imidazolidinyl}méthyl)-4,4-diméthyl-1-[2-aryl-1-diazényl]imidazolidines (**1a**–**1f**) avec d'excellents rendements. On a caractérisé les produits par leurs spectres IR et RMN, par analyse élémentaire et par diffraction des rayons X. La structure cristalline ainsi déterminée pour le dérivé *p*-méthoxycarbonyle (**1c**) permet d'établir sans ambiguïté la connectivité dans ces nouvelles molécules qui peuvent être décrites comme des oligomères bicycliques linéaires comportant deux groupes imidazolidinyles reliés par un groupe d'espacement formé d'un atome de carbone, ce qui est un élément moléculaire d'assemblage assez rare. La structure moléculaire est corroborée par les données de la RMN du ^{1}H et du ^{13}C qui permettent d'établir une corrélation avec les données publiées antérieurement au sujet de composés des types **5** et **6** dérivés de la 1,3-propanediamine. Dans les portions triazènes présentes dans la structure cristalline du composé **1c** on retrouve une conjugaison π importante qui donne à la liaison N—N un caractère important de double liaison. Ce caractère provoque une restriction autour de la liaison N—N et, par voie de conséquence, un élargissement considérable dans les spectres RMN du ^{1}H et du ^{13}C. Dans le spectrogramme de masse obtenu en faisant appel à une ionisation par électronébulisation, on peut observer l'ion moléculaire du dérivé *p*-cyanophényle (**1b**). On suggère que le mécanisme de formation des molécules de type **1** implique un piégeage par l'ion diazonium du bisimidazolidinyméthane (**13**) qui n'avait pas encore été rapporté antérieurement.

Mots clés : triazène, bistriazène, imidazolidine, synthèse, cristallographie à l'aide de rayons X, spectroscopie RMN.

Introduction

Imidazolidines are ubiquitous in pharmacology, medicinal chemistry, biochemistry, and various chemical studies. A number of imidazolidine carbonyl derivatives have recently been shown to exhibit antinociceptive activity (1) and several substituted thioxo-imidazolidine compounds have been evaluated for schistosomicidal activity (2). A structure–activity relationship of some new antiarrhythmic 5-arylideneimidazolidine-2,4-diones has been established (3) and the compounds were devoid of significant side effects. In the area of asymmetric synthesis, chiral imidazolidine ligands have been synthesized from *N*,*N*′-dialkylated cyclohexanediamine derivatives with excellent levels of enantiomeric excess (4). A novel imidazolidine derivative is formed spontaneously from the reaction of triethylenetetramine, salicylaldehyde, and benzaldehyde in methanol (5); this reaction has some significance to the chemistry reported in this paper. On a different playing field, a pentamethylimidazolidine embedded in polyethylene has been used as a radical probe to investigate the orientation distribution function of certain anisotropic paramagnetic species (6), and in a theoretical study, structural, electronic, and energetic information has been elucidated for three imidazolidinone derivatives (7).

This paper reports the synthesis and characterization of a series of new bis(imidazolyl)methanes, the novel 3-({5,5-dimethyl-3-[2-aryl-1-diazenyl]-1-imidazolidinyl}methyl)-4,4-dimethyl-1-[2-aryl-1-diazenyl]imidazolidines (**1a**–**1f**), from the diazonium coupling reaction with a mixture of formaldehyde and 1,2-diamino-2-methylpropane. These new bistriazenes exhibit the linear bicyclic structure similar to other bistriazenes derived from 1,3-propanediamines previously reported (8). However, these structures are diametrically different from the molecules of type **2**, obtained by analogous reaction with ethylenediamine (9), which have a distinctly different bridged bicyclic (or "cagelike") structure. Evidently, we have discovered a crossover in the molecular architecture of the products (**2**) derived from ethylenediamine itself (**3**) compared with the products (**1**) derived from the branched chain molecule, 1,2-diamino-2-methylpropane (**4**) (Scheme 1).

Experimental section

All reagents were reagent grade materials purchased from the Sigma-Aldrich Chemical Co. Ltd. and were used without further purification. Melting points were determined on a Fisher-Johns melting point apparatus (Fisher Scientific Inc.) and are uncorrected. Infrared spectra were obtained using Nujol mulls, unless otherwise stated, on a PerkinElmer 299 spectrophotometer or with a Brucker Vector 22 spectrometer. ^{1}H and ^{13}C NMR spectra were obtained using either the Anasazi Instruments 60 MHz EFT spectrometer at Saint Mary's University or the Bruker 250 MHz spectrophotometer at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University, both located in Halifax, Nova Scotia. Chemical shifts were recorded in $CDCl_3$ solutions at 20 °C and are relative to TMS as the internal standard. Elemental analysis was carried out at the Canadian Microanalytical Laboratory, Delta, British Columbia.

Synthesis of the 3-({5,5-dimethyl-3-[2-aryl-1-diazenyl]-1-imidazolidinyl}methyl)-4,4-dimethyl-1-[2-aryl-1-diazenyl]imidazolidines (1a–1f)

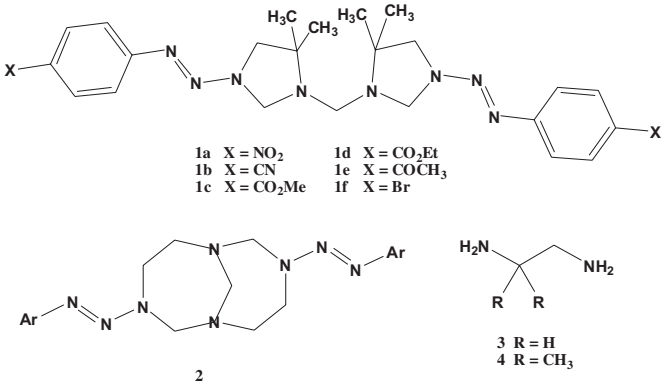
General procedure

The appropriate aromatic amine (0.015 mol) was dissolved in 3 mol/L of hydrochloric acid (20.0 mL) and the resulting solution was cooled to 0 °C. The hydrochloride solution was diazotized with a solution of sodium nitrite (1.15 g) in water (minimum volume) and the diazonium salt solution was left in the cold with stirring for 0.5 h. The solution was neutralized with saturated sodium bicarbonate solution and then 37% aqueous formaldehyde (5.0 mL) was added, while the temperature was kept below 0 °C. An aliquot of 1,2-diamino-2-methylpropane (0.015 mol) was dissolved in water and was then slowly added to the neutralized formaldehyde – diazonium salt mixture. After stirring for a further 0.5 h, the mixture was again basified with saturated sodium bicarbonate and the product that precipitated at this point was isolated by vacuum filtration, dried, and recrystallized from either ethanol, an ethanol – ethyl acetate mixture, or a hexanes – ethyl acetate mixture, to afford the following products.

*3-({5,5-Dimethyl-3-[2-(*p*-nitrophenyl)-1-diazenyl]-1-imidazolidinyl}methyl)-4,4-dimethyl-1-[2-(*p*-nitrophenyl)-1-diazenyl]imidazolidine (1a)*

Yellow crystals; yield 87%; mp 135–138 °C (ethanol – ethyl acetate). IR (Nujol, cm^{-1}) ν_{max}: 848, 1338, 1507. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 1.27 (12H, s), 3.51 (2H, s), 3.88 (4H, br s), 4.59 (4H, br s), 7.48 (4H, d, J = 9.0 Hz), 8.17 (4H, d, J = 9.0 Hz). ^{13}C NMR ($CDCl_3$, 62.9 MHz, ppm) δ: 22.0, 58.2, 120.7, 125.0, 145.0. Anal. calcd. for $C_{23}H_{30}N_{10}O_4$ (%): C 54.1, H 5.9, N 27.5; found: C 53.9, H 5.8, N 27.1.

*3-({5,5-Dimethyl-3-[2-(*p*-cyanophenyl)-1-diazenyl]-1-imidazolidinyl}methyl)-4,4-dimethyl-1-[2-(*p*-cyanophenyl)-1-diazenyl]imidazolidine (1b)*



Cream prisms; yield 97%; mp 198–200 °C (hexanes – ethyl acetate). IR (Nujol, cm^{-1}) ν_{max}: 848, 2219. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 1.26 (12H, s), 3.50 (2H, s), 3.65 (4H, br s), 4.59 (4H, br s), 7.46 (4H, d, J = 8.5 Hz), 7.59 (4H, d, J = 8.4 Hz). ^{13}C NMR ($CDCl_3$, 62.9 MHz, ppm) δ: 22.0 (br), 58.3, 60.0 (br), 68.0 (br), 69.4 (br), 108.5, 119.6, 121.3, 133.3, 154.3. MS (ES$^+$ + Na) m/z: 493 (M$^+$ + 23). Anal. calcd. for $C_{25}H_{30}N_{10}$ (%): C 63.8, H 6.4, N 29.8; found: C 63.7, H 6.3, N 29.8.

*3-({5,5-Dimethyl-3-[2-(*p*-methoxycarbonylphenyl)-1-diazenyl]-1-imidazolidinyl}methyl)-4,4-dimethyl-1-[2-(*p*-methoxycarbonylphenyl)-1-diazenyl]imidazolidine (1c)*

Amber needles; yield 87%; mp 178–181 °C (ethanol – ethyl acetate). IR (Nujol, cm^{-1}) ν_{max}: 860, 1710. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 1.25 (12H, s), 3.49 (2H, s), 3.75 (4H, br s), 3.89 (6H, s, O-Me), 4.67 (4H, br s), 7.46 (4H, d, J = 8.5 Hz), 8.00 (4H, d, J = 8.6 Hz). ^{13}C NMR ($CDCl_3$, 62.9 MHz, ppm) δ: 22.0, 26.7, 58.2, 60.5, 120.5, 125.5, 129.7, 154.7, 197.6. Anal. calcd. for $C_{27}H_{36}N_8O_4$ (%): C 60.4, H 6.7, N 20.9; found: C 59.6, H 6.7, N 20.2.

Crystallography

X-ray diffraction data were collected on a Nonius Kappa CCD diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.7107 Å). Data sets were integrated using the Denzo-SMN package (10) and corrected for Lorentz and polarization effects. The structure was solved by direct methods (SIR97) (11) and refined (SHELXL-97) (12) by full-matrix least-squares with anisotropic non-H and the hydrogen atoms included on calculated positions, riding on their carried atoms. All other calculations were accomplished using the PARST system of programs (13). Crystal data are given in Table 1.[4] Selected bond distances and angles are given in Table 2.

Results and discussion

Reaction of a mixture of 1,2-diamino-2-methylpropane and formaldehyde with an arene diazonium salt afforded the new bistriazene series, the 3-({5,5-dimethyl-3-[2-aryl-1-diazenyl]-1-imidazolidinyl}methyl)-4,4-dimethyl-1-[2-aryl-1-diazenyl]imidazolidines (**1a**–**1f**); in all but one case, the yields are very high, in the range 87%–97%. These new bistriazenes have two 4,4-dimethylimidazolidinyl moieties connected together via a single methylene group bridging

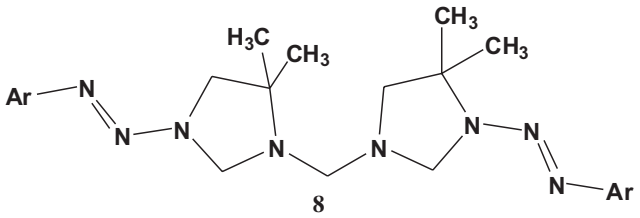
the N3 nitrogens; the available N1 nitrogens are coupled to the aryldiazenyl groups. This is a very similar type of molecular architecture to that previously reported (8) for the hexahydropyrimidine series, **5** and **6**. Molecules of types **1**, **5**, and **6** can be described as linear bicyclic bistriazenes, whereas the contrasting structure (**2**) can be described as a bridged bicyclic bistriazene with a cagelike structure. All compounds in the series **1a**–**1f** are stable crystalline solids, whereas the compounds of series **5** and **6** showed variable stability with a certain tendency to decompose (Scheme 2).

Molecules of type **1**, with two imidazole groups bridged by a single carbon atom are quite rare. Habermeier and Porret (14) reported a series of 1,1′-methylene-bis(hydantoins) (**7**). It is intriguing to note that the dimethyl branching positions in **1** are identical to those in the hydantoin (**7**), which raises the question regarding the possible existence of isomers of the new compounds of series **1**. Such isomers would have the structures shown in **8** and **9**; however, it is clear from the crystal structure elucidation of



Scheme 2.

9

compound **1c** that we do indeed have the novel structure **1** in which the methyl branches essentially face each other in an intuitively unlikely stereochemical combination.

An ORTEP (15) view of compound **1c** is shown in Fig. 1. The compound is built up by two equivalent fragments in the S-cis orientation, with respect to the N4-C14-N5 bridge. The planar phenyltriazenyl groups are mutually slightly rotated by an angle of 39.57(6)° and both the triazene moieties in the anti configuration display significant π conjugation. Both the imidazolidine five-membered rings adopt a twist conformation as shown in Table 3 (16).

The intuitive reasoning that suggests that structure **1c** should be sterically crowded is not supported by the ORTEP diagram in Fig. 1. The molecule of **1c** adopts a folded conformation that brings the triazene moieties fairly close together, but not close enough to invoke π–π stacking interactions. This folding of the molecule, which is similar to the folding observed in the X-ray structures of molecules of types **5** and **6** (17, 18), relieves any steric strain that would build up between the methyl branching groups. The folded conformation is also seen clearly in the crystal packing diagram, as displayed in Fig. 2, which is determined only by

van der Waals interactions. There is an inherent flow to the 3D structure shown in Fig. 2; the crystal is built up of layers of strings of molecules, but each string is like a sine wave. This repeating sine curve is made possible by the inherent curvature of each molecule derived from the folded conformation. It would appear that the ends of the molecules in each string are held together by the van der Waals attraction between the dipole moments of the terminal ester (COOMe) groups.

Further identification of the compounds in the series **1a**–**1f** is based on spectroscopic evidence. In the IR spectra of the new bistriazenes, the functional groups in the parasubstituents give rise to the predicted bands of either nitro, cyano, or carbonyl groups. Discussion of the supporting NMR data will be facilitated with reference to the proton and carbon labels in Fig. 3. In the ^{1}H NMR spectra, the protons of the methyl substituents give rise to a 12-proton singlet at ca. 1.25 ppm and the protons (H_a, H_b) of the bridging methylene group also give a sharp singlet at ca. 3.5 ppm. The equivalent methylene groups (H_c, H_d) give rise to a somewhat broadened singlet at ca. 4.6–4.7 ppm. The singlet

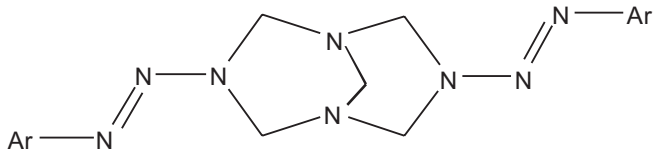
Fig. 3. Labelling of some hydrogen and carbon atoms in structure **1** to assist with the discussion of NMR data.

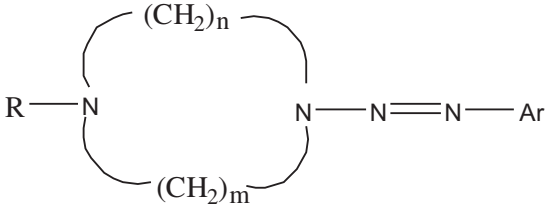
arising from the other methylene protons (H_e, H_f) at ca. 3.7–3.9 ppm is similarly broadened. This broadening of the signals of protons in close proximity to the triazene moiety is quite familiar and is attributed to the restricted rotation around the N—N bond in the triazene because of the partial double bond character of this group (19). The aromatic protons appear as the predictable AA′BB′ patterns.

The ^{13}C NMR spectra also show signs of the rotational dynamics in the triazene units referred to in the preceding paragraph. The carbon signals of carbon atoms C1, C2, and C3 are often so broad as to be impossible to detect. The carbon atom at C4, well away from the triazene units, is clearly seen in all spectra at ca. 58 ppm. The carbon atoms of the methyl substituents are also clearly evident at ca. 22 ppm. The C3 carbon is visible in four out of six spectra and is readily assigned to the chemical shift at ca. 60 ppm. The carbon atoms at C1 and C2 are more difficult to detect and when they are seen, the signals are weak and broad, but we can say with reasonable certainty that C1 occurs at ca. 68 ppm and C2 occurs at ca. 70 ppm. These chemical shift assignments show a strong correlation with the chemical shift assignments previously reported (8) for the compounds of series **5**.



The stability of the compounds of series **1** did not extend to the analysis by mass spectrometry. Attempts to record mass spectra of these compounds by EI instrumentation did not succeed; no molecular ions were observed. However, in one case, that of **1b**, we were successful in seeing the molecular ion under ES^+ conditions with sodium as the charged cation.

Conclusion

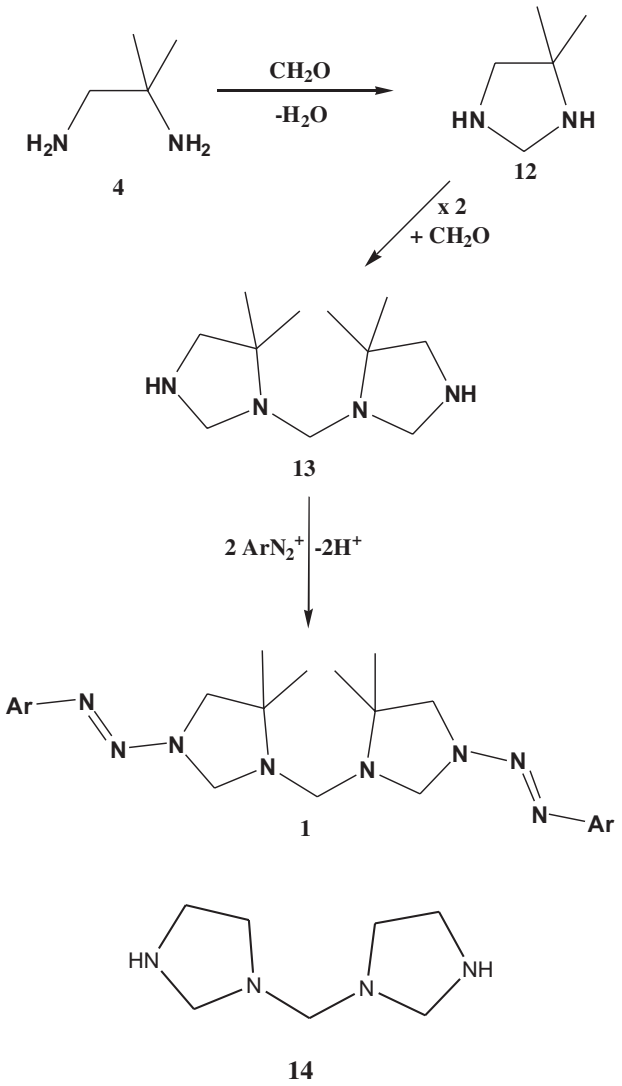


It appears, from our ongoing studies, that the interaction of a diazonium salt with a mixture of formaldehyde and an alkanediamine [$NH_2(CH_2)_nNH_2$] gives rise to two distinct types of oligomer. Bistriazenes of types **2** (9) and **10** (20) are examples of the bridged bicyclic bistriazene, whereas the compounds of series **1** and **5** exemplify the linear bicyclic bistriazene. The new compounds of series **1**, reported here, clearly belong to the linear bicyclic class, providing further evidence that there is a crossover in the molecular architecture going from ethylenediamine (**3**) (two-carbon spacer) to the branched two-carbon spacer (**4**). This type of crossover was also observed in the transition from ethylenediamine to propanediamine in structures **5** and **6** (17, 18) (Scheme 3).

This paper is part VI in a series that describes the synthesis of a variety of triazenes and bistriazenes that fit the general classification of 1-aryldiazenyl-(1,*x*)-diazacycloalkanes

Scheme 3.

10



11

described by the general structure **11**, where m = 1 or 2 and n = 2, 3, 4, or 5. The new compounds of series **1** fit to the general structure **11** where m = 1 and n = 2. Previously, we reported new triazenes derived from piperazine (21, 22) ($m = n = 2$) and homopiperazine (23) (m = 2, n = 3). In future papers in this series, we will report more examples of the linear bicyclic bistriazene derived from other diamines, such as 1,4-diaminobutane and 1,5-diaminopentane. Evidently, the linear bicyclic bistriazene, reported here in the new compounds of series **1**, appears to be the normal type of molecular architecture in this field of chemistry.

However, there may be a more prevailing reason why these new compounds of type **1** are significant and that is the presence of the imidazolidine ring. Although well-known stable molecules like imidazolidine-2,4-dione ("hydantoin") (used to prepare amino acids (24)) and the essential growth factor, biotin, contain a 2-oxoimidazolidine ring in their structure, the parent imidazolidine is not so well-known. Direct hydrogenation of imidazole is difficult and it has been said by no less a figure of heterocyclic chemistry than Adrien Albert (25) that "imidazolidine appears to be unknown". However, the *N*,*N*′-diethyl derivative is readily prepared by reaction of *N*,*N*′-diethylethylenediamine and formaldehyde. This observation, and the work of Bera et al. (5), gives us a clue as to how the molecules of type **1** are formed (Scheme 4). Condensation of **4** with formaldehyde could afford the 4,4-dimethylimidazolidine (**12**), which in turn undergoes a dimerization–condensation to give the dimer **13**. Reaction of **13** with the diazonium ion then affords the observed product **1**. It would seem that the importance of the results reported here lies in the fact that the diazonium coupling reaction "traps out" the elusive intermediate bisimidazolidinyl methane **13**, which has previously not been reported. In fact, it would appear that the central moiety of our new compounds of series **1**, i.e., the saturated bis(imidazolidinyl)-methane unit (**14**), is virtually unknown. Although the CA files contain numerous molecules that contain the skeleton of **14**, all known compounds with this skeleton are either oxo-substituted derivatives, i.e., hydantoin-like molecules, such as **7**, or they are aromatic benzimidazolidine derivatives.

The regioselective α-alkylation of the benzophenone imine of glycinamide, alaninamide, and related derivatives[1]

Martin J. O'Donnell, Jeremy D. Keeton, Vien Van Khau, and John C. Bollinger

Abstract: The benzophenone imine of glycinamide was alkylated using ion pair extraction (RX, 10% aq. NaOH, Bu_4NHSO_4 (1 equiv.), CH_2Cl_2, rt) to give the α-monosubstituted products, which were then alkylated a second time using stronger basic conditions (KO-*t*-Bu, THF, 0 °C, RX). Crystal structures of the Schiff bases of glycinamide, an α-monosubstituted and an α,α-disubstituted product were reported.

Key words: benzophenone imines, Schiff bases, alkylation, ion pair extraction (IPE), phase-transfer catalysis (PTC), anhydrous base, X-ray crystal structures.

Résumé : L'alkylation de la benzophénone imine du glycinamide par extraction par paire d'ions (RX, NaOH aqueux à 10%, Bu_4HSO_4 (1 équiv.), CH_2Cl_2, température ambiante) conduit à des produits α-monosubstitués qui sont alkylés une deuxième fois dans des conditions plus basiques (KO-*t*-Bu, THF, 0 °C, RX). Les structures cristallines des bases de Schiff du glycinamide, d'un produit α-monosubstitué et d'un produit α,α-disubstitué ont été déterminées.

Mots clés : imines de la benzophénone, bases de Schiff, alkylation, extraction par paire d'ions (EPI), catalyse par transfert de phase (CTP), base anhydre, structures cristallines par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

The development of new methods for the synthesis of unnatural α-amino acids has been the focus of our research for many years. The first general synthesis of α-amino acids by phase-transfer catalysis (PTC) was reported in 1978 (1). On treatment with base, the benzophenone imines of glycine alkyl esters (**1**) function as glycine anion equivalents for reaction with electrophiles to yield higher amino acid derivatives **2** (Scheme 1, pK_a experimental (calculated), refs. 2 and 3)) (4). A key tenet in this chemistry is the ability to achieve selective monoalkylation of **1** to give **2** under mild ("normal") PTC conditions, although a second alkylation to form **3** can be accomplished using stronger basic conditions (5). The possibility of stopping the reaction at the monoalkylation stage is attributed to $A_{1,3}$ strain in products **2** (6). The lower acidity of the monoalkylation product **2** compared with starting material **1** (2) has also been applied for the selective monophenylation of **1** (7), in the catalytic enantioselective alkylation for the synthesis of monoalkyl products without concomitant racemization under basic PTC conditions (8–10), and in the regioselective solution (**1**, OR = amino acid ester (11)) and on-resin (**1**, R = Merrifield, Wang, Rink, or Weinreb resin (l2)) monoalkylation of a benzophenone-protected glycine residue in a peptide without either N-alkylation or alkylation of a C-terminal glycine or higher amino acid residue. Additionally, the on-resin enantioselective syntheses of α-alkyl amino acids have been achieved by both alkylation and Michael addition reactions (13).

While monoalkylations of the aldimines of glycine esters ($ArCH{=}NCH_2CO_2R$, **4a**, Ar = 4-ClC_6H_4, R = Et; pK_a (DMSO) 18.8 (19) (refs. 2 and 3)) are possible (14), the similar acidities of the unsubstituted (e.g., **4a**) and monosubstituted (e.g., **5a**) derivatives (2) can lead to overalkylation and (or) racemization of products **5** by deprotonation–reprotonation. In contrast, PTC alkylation of the aldimine of a monoalkyl amino ester is generally the method of choice to prepare α,α-dialkylated amino acid derivatives (Scheme 2) (15). Similarly, the aldimine activating group has been used for preparation of α-phenyl-α-alkyl amino acid derivatives by phenylation of the α-alkyl derivatives (16) and the regioselective solution (11) and on-resin (17) N-terminal α-carbon alkylation of peptides containing an N-terminal non-

Scheme 1. Selective monoalkylation of benzophenone imine glycinates.

glycine residue. A limitation of this methodology for the preparation of α,α-dialkyl amino acids from their glycine counterparts is the need to change activating groups from ketimine (Ph_2C=N-) (Scheme 1, **1** to **2**) to aldimine (ArCH=N-) (Scheme 2). As noted earlier (5), stronger base may be used to prepare the α,α-dialkylated products (Scheme 1, **2** to **3**). Additionally, on-resin tandem alkylations of benzophenone imine protected glycinates have been achieved by initial alkylation under PTC-like conditions followed by introduction of a second group at the α-carbon using stronger base (18).

The successful alkylation chemistry of the Schiff bases of glycine alkyl esters (**1**) and higher amino acid esters (**5**) prompted us to extend this methodology to the selective α-carbon alkylations of amino amides as a route to α-substituted and α,α-disubstituted amides (19). Reports of the enantioselective synthesis of monosubstituted amino amides by PTC have recently appeared (20).

Enzymatic resolution of racemic α-substituted and α,α-disubstituted amino acid amides has been developed by the DSM group (21) for preparing these important compounds and their associated α-amino acids in optically pure form from the racemic or optically enriched products. One synthetic route involves alkylation of **1b**, hydrolysis of the monoalkylated benzophenone imine of glycine methyl ester (**2**, R = Me, R_1 = alkyl), and conversion to the amide by treatment with ammonia (21*g*). A route to the α,α-disubstituted derivatives involved preparation of the aldimine of a monosubstituted amino acid amide (**7**) followed by alkylation under PTC conditions to give **8** (Scheme 3) (21*c*).

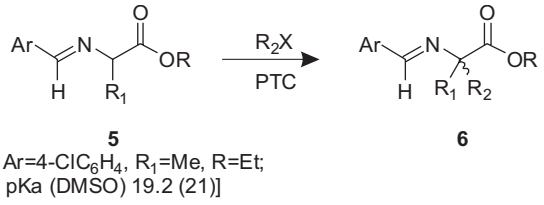
A more efficient route to the α,α-disubstituted derivatives of amino acid amides would be to start with the benzophenone imine of glycinamide (**10**) (prepared from benzophenone imine (**9**) and glycinamide), carry out a selective monoalkylation to (**11**), and then, *without changing the imine-protecting group*, do a second alkylation to give **12**. In this paper we report the successful accomplishment of this goal (Scheme 4).

Results and discussion

Prediction of the acidities of the benzophenone imines of glycinamide and their monoalkylated derivatives

Although the experimental acidities of the imines of glycinamide and their monoalkyl derivatives are not available, it was possible to use CAMEO to obtain qualitative theoretical acidities (DMSO) of these compounds (Fig. 1).[3]

Scheme 2. Alkylation of a higher amino acid derivative by PTC.



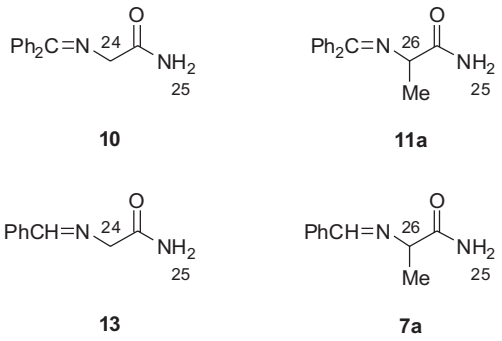


Fig. 1. Calculated acidities (pK_a in DMSO) using CAMEO for the benzophenone imines of glycinamide and alaninamide.

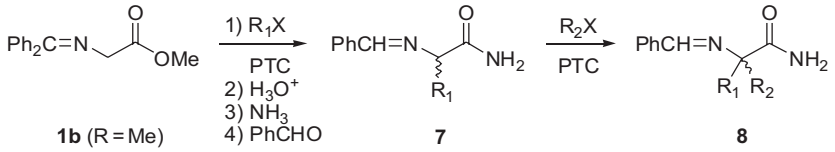

The predicted acidities of the α-protons in glycinamide imines (**10** or **13**, α-CH pK_a = 24) are only an order of magnitude greater than the acidities of the NH protons on the unsubstituted amides (**10** or **13**, NH pK_a = 25). This small effect is certainly not, by itself, sufficient to predict selective α-monoalkylation over N-alkylation. Additionally, as in the amino acid ester cases (2*a*), both the benzophenone imines and aldimines were predicted to have the same acidities and the monoalkyl derivatives were both predicted to be 10^2 less acidic than their glycinamide counterparts. As in the ester cases, the potential major acid-weakening effect in the benzophenone imine of alaninamide (**11a**) was not predicted. If this effect were taken into account, one would predict that the α-proton in **11a** would be even less acidic (higher pK_a) than those in **10**. Thus, it would be expected that the second alkylation of **10** would occur at nitrogen rather than at the α-carbon. Even though these qualitative theoretical predictions do not bode well for achieving the desired selective mono- and di-alkylations in the amino acid amide imines, we proceeded with experimental studies of these alkylation reactions.

[3] Previous alkylation and Michael addition studies of three active methylene derivatives (cyanoacetamide, acetoacetamide, and malonamide) containing an unsubstituted amide and the predicted pK_as (DMSO) of these compounds are summarized in the Supplementary material.

Preparation and monoalkylation of the benzophenone imine of glycinamide

The benzophenone imine of glycinamide (**10**) (22, 23) was prepared from glycinamide hydrochloride **14** and benzophenone imine by transimination following a protocol similar to that developed for preparation of the related imines of glycine and monoalkyl amino acid esters (Scheme 5) (24). Since glycinamide hydrochloride is relatively insoluble in dichloromethane, the reaction was refluxed overnight in 1,2-dichloroethane with triethylamine (1 equiv.). Removal of solvent followed by recrystallization gave **10** (70%) as white crystals. An X-ray crystal structure, which will be discussed later, was obtained for **10**.

Alkylations of the Schiff base of glycinamide **10** were accomplished by ion pair extraction (IPE) using representative active (methyl, allyl, or benzyl) or less active (ethyl) halides, 10% aq. NaOH, and tetrabutylammonium hydrogen sulfate (TBAH, 1.2 equiv.) in dichloromethane at room temperature overnight (Scheme 6) (1*a*, 25). After work-up, the crude products were purified by column chromatography (silica gel was prewashed with 1% triethylamine because of the acid lability of the imine). Notably, under these mild alkylation conditions, the Cα-monoalkylated products (**11a**–**11d**) were obtained in good yield (72%–84%). An X-ray crystal structure, to be discussed later, was obtained of the α-monoalkylated product **11b**.

Alternatively, **11a** was prepared in 96% yield by transimination of alaninamide hydrochloride with benzophenone imine (DMF, rt, overnight).

Model study — Allylation of the benzophenone imine of alaninamide

A model alkylation study for the proposed regioselective Cα-alkylation of the Schiff base of alaninamide (**11a**) to prepare the α,α-dialkylated product was conducted using allyl bromide as the alkylating agent with a variety of bases and reaction conditions (Scheme 7). In addition to the desired C-monoalkylated product **12a**, four other alkylation products are possible in this reaction (**16**–**19**) (Fig. 2). The calculated pK_a values (CAMEO) of the α-CH and NH protons in these products are given for reference (see Fig. 1 for predicted pK_a values of **10** and **11a**).

The reactions were conveniently monitored by TLC (Fig. 3). The optimized TLC system provides for separation of the starting material (**11a**), the desired C-allylated target (**12a**), the N-allylated product (**16**), the two possible diallylated derivatives (**17** and **18**), and the triallylated compound (**19**), as well as the hydrolysis product, benzophenone. Identities of the various spots were determined using mass spectral analysis and ^{1}H NMR.

Allylation of Schiff base **11a** was studied using a variety of bases and reaction conditions (Table 1). The alkylation was first conducted using IPE conditions, however no reaction was observed (Table 1, entry 1) (1*a*, 25). IPE conditions using 50% aq. NaOH gave only trace amounts of desired

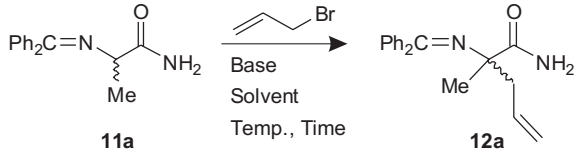
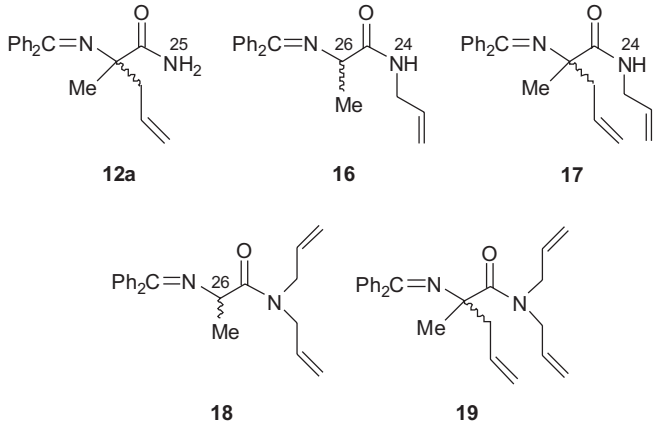
Scheme 7. Model study for regioselective α-C alkylation of the Schiff base of alaninamide (**11**a).





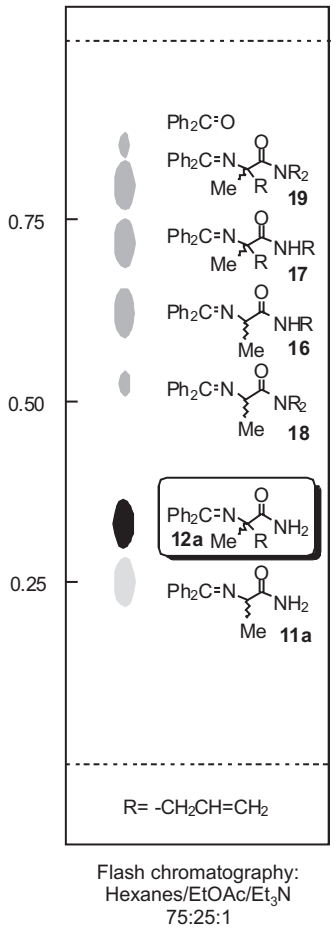


Fig. 2. Possible products from the alkylation of the Schiff base of alaninamide (**11a**) with allyl bromide.

product (**12a**) (Table 1, entry 2). Next, alkylation was performed under nonaqueous conditions using the Schwesinger base BTPP (*tert*-butylimino-tri(pyrrolidino)phosphorane, 0.9 equiv.) to again give only trace amounts of product. BTPP is a relatively strong, organic soluble, nonionic base used successfully for the α-alkylation of resin-bound Schiff base derivatives of amino acids and peptides (26). From these first experiments, it was apparent that stronger conditions were needed to effect α-alkylation. Thus, alkylation was next attempted using sodium ethoxide (in EtOH) in the presence of catalytic TBAB in anhydrous acetonitrile (Table 1, entry 4) (5). In this case, no reaction was observed because of the insolubility of **11a** in acetonitrile. In a second set of reactions using the same reagents, the EtOH was first removed from NaOEt and then acetonitrile was added, but again the reaction was unsuccessful because of the insolubility of the starting Schiff base (Table 1, entry 4). LDA in anhydr. THF gave only trace amounts of product (Table 1, entry 5). The same conditions were applied using LiHMDS, but again only trace amounts of desired product were observed (Table 1, entry 6) (27). With KHMDS, the target α-monoalkylated product (**12a**) was obtained in 24% yield (Table 1, entry 7). The final and most effective base used was KO-*t*-Bu (Table 1, entries 8–10) (27). When the reaction was carried out at ambient temperature or –78 °C, 42%–46% and 34%–48% yields, respectively, of **12a** were obtained (Table 1, entries 8 and 9). Optimal conditions were obtained using Schiff base **11a** (1 equiv.), KO-*t*-Bu (1.2 equiv.), and allyl bromide (1.2 equiv.) in THF at 0 °C for 3 h to give product **12a** in 55%–61% yield (Table 1, entry 10). The addition of LiCl (5 equiv.), which has often proven to be an effective additive in alkylation and other anionic reactions (28), using the KO-*t*-Bu conditions at rt, 0 °C, or –78 °C gave only trace amounts of product as did other solvents (DMF or *tert*-butyl alcohol) with KO-*t*-Bu (TLC, LC–MS, and ^{1}H NMR).

Fig. 3. TLC data for products from the allylation of the Schiff base of alaninamide (**11a**).

The reaction conditions were studied further by using 0.9 equiv. of both allyl bromide and KO-*t*-Bu to understand which of the various possible alkylations was occurring and in what order. Hopefully, selective monoalkylation at the α position to form **12a** would occur first and further alkylation would not be problematic when less than 1 equiv. of base and alkylating reagent was used. If more than 1 equiv. of base and alkylating agent was used, selective Cα-monoalkylation (**12a**) could occur followed by N-alkylation (to **17**), and possibly N,N-dialkylation (to **19**).

The results from the model experiment showed that, even when less than 1 equiv. of base and alkylating reagent were used, the reaction gave mixtures of mono-, di-, and trialkylation products (Fig. 2). From the earlier experimental results (Table 1), in which the desired C-allylated product was obtained in up to 61% yield, it is apparent that the predicted pK_a values (Figs. 1 and 2) provide only a very qualitative estimate of the various pK_as.

Finally, the alkylation reaction of **11a** with allyl bromide was examined after 5 min by TLC to see if the product distribution was affected by time. At this time, all of the products shown in Fig. 3 were present.

[b] *tert*-Butylimino-tri(pyrrolidino)phosphorane.
[c] Bu_4NBr (cat.).
[d] Starting material insoluble.

Alkylation of the Schiff base of monosubstituted amino amides to give α,α-disubstituted derivatives

Using the optimized results from the model alkylation study described previously, several target molecules were made by following the general procedure for alkylation of the benzophenone imine of a monosubstituted amino amide. Further alkylations included benzylation and alkylation with less reactive alkyl halides as well as a Michael addition. The model conditions used, unless otherwise noted, were as follows: KO-*t*-Bu (2.38 mmol) was added to the benzophenone imine of a monosubstituted α-amino amide (1.98 mmol) dissolved in anhydr. THF at 0 °C and the reaction mixture was stirred at 0 °C for 20 min. The alkylating agent (2.38 mmol) was added and the reaction mixture was stirred at 0 °C for an additional 3 h. After work-up, the crude product was purified by flash chromatography using silica that was prewashed with hexanes–EtOAc–triethylamine (75:25:1). The product was then recrystallized from dichloromethane–hexanes (1:15). Four monoalkylated starting materials (**11a**–**11d**, Scheme 6) were used to prepare 10 new α,α-disubstituted products (**12a**–**12e** and **12g–12k**, Fig. 4).

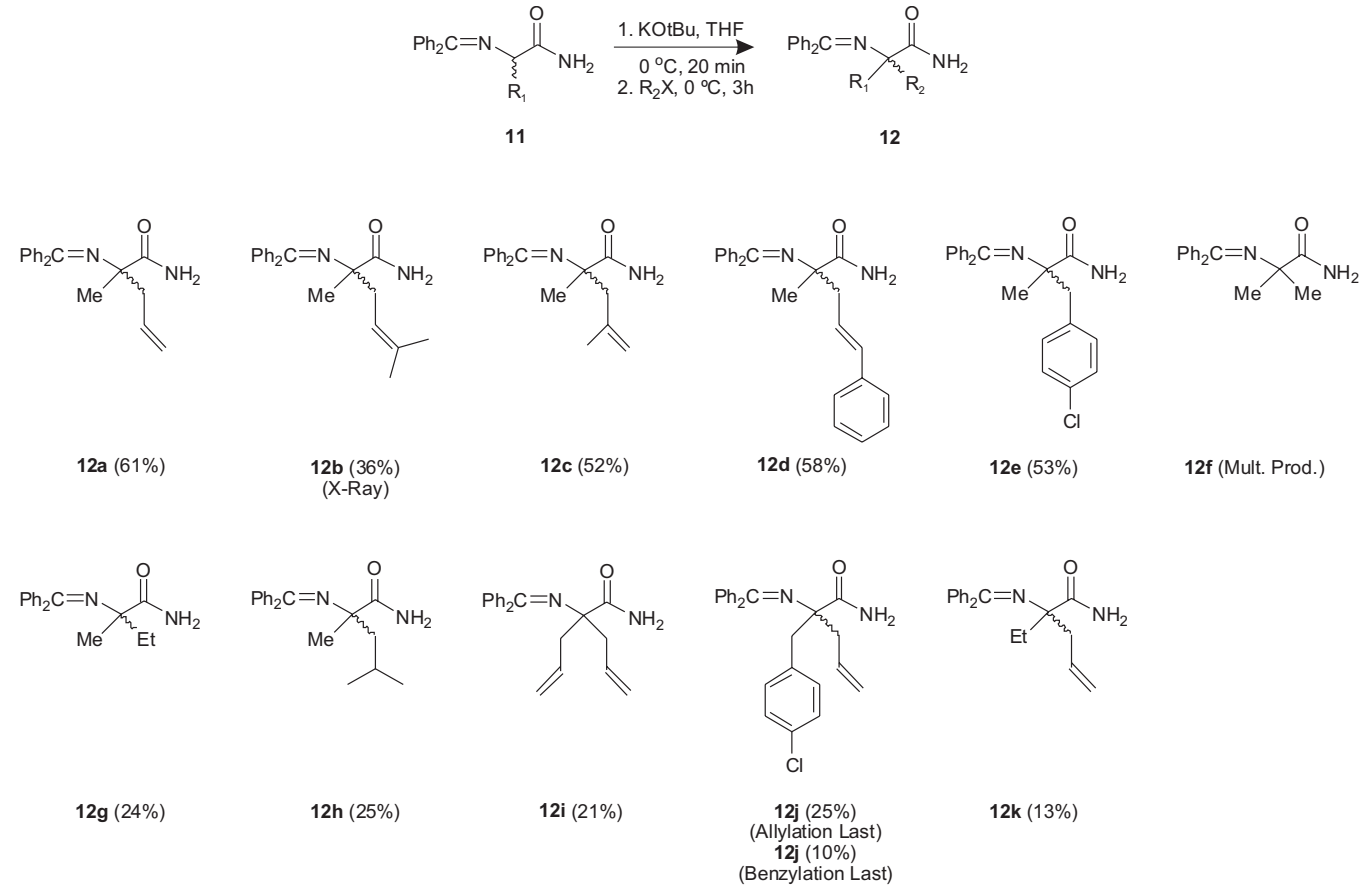
The alkylation of **11a** with allyl derivatives gave the highest yields for all alkylations studied (Fig. 4, products **12a**–**12d**). Alkylation of Schiff base **11a** with allyl bromide, 4-bromo-2-methyl-2-butene, 3-bromo-2-methylpropene, and cinnamyl bromide, gave the respective Schiff bases (**12a**–**12d**) in 36%–61% isolated yield. An X-ray crystal structure, which will be discussed later, was obtained for dialkylated product **12b**.

The alkylation of Schiff base **11a** using non-allylic halides was examined next (Fig. 4, products **12e**–**12h**). Alkylation with 4-chlorobenzyl bromide gave the Schiff base **12e** (53%) while methylation gave a complex mixture of products, likely owing to the reactivity and small size of the methyl group. Alkylation of **11a** with iodoethane gave **12g** (24%) while 1-iodo-2-methylpropane gave **12h** (25%). Alkylation with two α-haloesters, methyl bromoacetate, and *tert*-butyl bromoacetate, did not give the desired α-alkylated products (LC–MS and ^{1}H NMR).

Alkylation of the Schiff base of higher amino amides using the general procedure for the alkylation of **11a** was also studied (Fig. 4, products **12i**–**12k**). The Schiff base starting materials (**11b**–**11d**) were prepared earlier by IPE from the Schiff base of glycinamide (**10**, Scheme 6). These three monoalkylated Schiff base glycinamides (**11b**–**11d**) were then subjected to allylation and benzylation. In all cases, the allylation of the benzophenone imines of these higher amino amides did yield the desired products, although in low yields. Allylation of Schiff base **11b** gave **12i** (21%), **11c** yielded **12j** (25%), and **11d** gave **12k** (13%). For the synthesis of Schiff base **12j**, the addition of 4-chlorobenzyl bromide to Schiff base **11b** gave only a 10% yield of product. This compared with the higher yield (25%) of the same product (**12j**) obtained by allylation of the benzylated starting material **11c**.

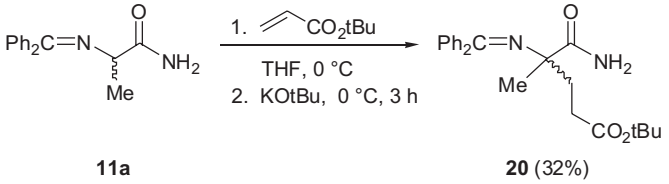
Methylation of Schiff bases **11b** and **10** gave a mixture of products (TLC and LC–MS) and it was not possible to isolate the desired α-alkylated product, which was present only in trace amounts, from the crude reaction mixture. Methylation of **11d** gave the N-monoalkylated product (45%) and methylation of **11c** yielded less than 10% of product **12e**, compared with the 53% yield for the reverse order of alkylation of the Schiff base alaninamide **11a** using *p*-chlorobenzyl bromide.

Michael addition of the Schiff base of alaninamide



The Schiff base of alaninamide (**11a**) was reacted with the Michael acceptor (*tert*-butyl acrylate) to give the Schiff base **20** (32%) (Scheme 8). Schiff base **11a** (1.98 mmol) was dissolved in anhydr. THF, then *tert*-butyl acrylate (2.38 mmol) was added, followed by KO-*t*-Bu (0.238 mmol), and the reaction mixture was stirred at 0 °C for 3 h. This reaction was optimal with 0.12 molar equiv. of KO-*t*-Bu rather than the normal 1.2 equiv. in the case of alkylation. Attempted Michael addition with methyl acrylate did not give the desired product as monitored by LC–MS, while use of acrylonitrile gave the N,N-dialkylated product (^{1}H NMR and LC–MS) and only trace amounts of monoalkylated product (LC–MS).

X-ray crystal structures of the benzophenone imine of amino amides



The X-ray crystal structures of the benzophenone imines of the unsubstituted (**10**), a monosubstituted (**11b**), and a disubstituted (**12b**) amino amide were obtained (Fig. 5). A
