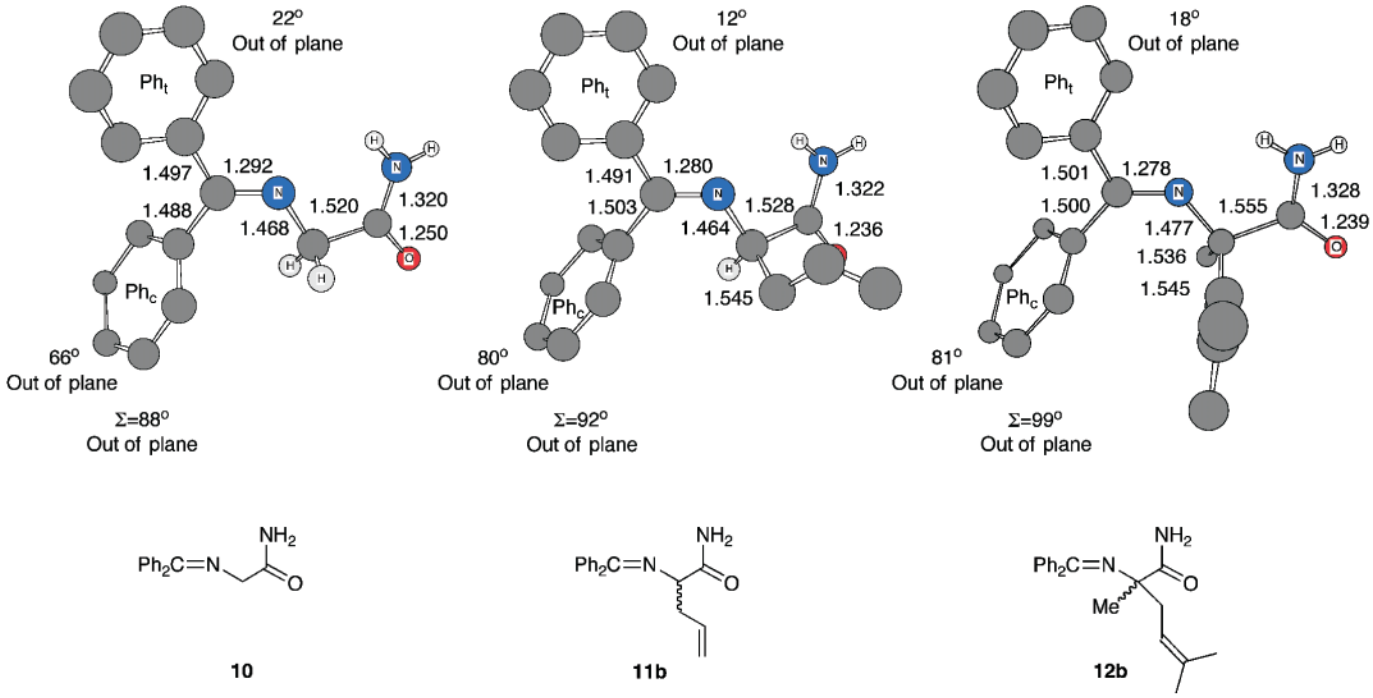
The *cis*-phenyl group (Ph_c) on the imine is considerably farther out of planarity with the imine double bond than is the *trans*-phenyl group (Ph_t). This is due to $A_{1,3}$ strain (6) in the mono- and di-substituted derivatives, where the effect is more pronounced than in the unsubstituted case. Interestingly, the sum of these two values (Σ) increases in going from **10** (Σ = 88°) to **11b** (Σ = 92°) to **12b** (Σ = 99°). As a comparison, in the unsubstituted Schiff base esters ($Ph_2C{=}NCH_2CO_2Et$, **1a**, Σ = 71°; $Ph_2C{=}NCH_2CO_2$-*t*-Bu, **1c**, Σ = 86° (4)) and in the α-benzyl or α-phenyl substituted Schiff base esters ($Ph_2C{=}NCH(CH_2C_6H_4$-4-Cl$)CO_2$-*t*-Bu, **2c**, Σ = 97° (4); $Ph_2C{=}NCH(Ph)CO_2Et$, **2d**, Σ = 82° (7)). The X-ray structure of an α,α-disubstituted Schiff base ester in this series was not determined.

The bond lengths to the quaternary α-carbon in the disubstituted Schiff base amide (**12b**) relative to the other two compounds in the series are also of interest. Three of the four bonds to the α-carbon are the longest in the series: the Cα—N_{imine} bond(1.477 Å), the Cα—Me bond (1.536 Å), and the Cα-C_{CO} bond (1.555 Å), which is a result of the steric congestion about the quaternary α-carbon in **12b**.

Experimental



General

Unless otherwise noted, all manipulations were carried out under an inert atmosphere (argon) in glassware dried

Fig. 5. Crystal structures of representative unsubstituted, α-monosubstituted, and α,α-disubstituted amino amide derivatives.

with a heat gun. THF was freshly distilled before use from sodium benzophenone ketyl. Sure Seal™ bottles of potassium *tert*-butoxide (1.0 mol/L in THF and 1.0 mol/L in *tert*-butyl alcohol), sodium ethoxide (21 wt% in denatured ethyl alcohol), lithium diisopropylamine (2.0 mol/L in heptane–THF–ethylbenzene), potassium bis(trimethylsilyl)amide (0.5 mol/L in toluene), lithium bis(trimethylsilyl)amide (1.0 mol/L in THF), and all solvents other than THF were purchased from the Sigma-Aldrich Chemical Co.

Nuclear magnetic resonance (NMR) spectra were recorded on a 300 MHz Varian Gemini spectrometer. Infrared (IR) spectra were obtained neat in thin films on NaCl plates (oils) using a Matteson Genesis FT-IR. Elemental analyses were performed by Midwest Microlabs, Indianapolis, Indiana. High-resolution mass spectrometry was run in the FAB mode at Indiana University. Melting points were determined in open-end capillaries using a Thomas-Hoover Unimelt melting apparatus and are uncorrected. Thin layer chromatography (TLC) was performed on silica gel 60 F254 aluminum sheets with UV visualization. Column chromatography was performed using silica gel (60 Å, 40–63 μm standard grade gel) with the solvent systems described in the individual procedures. Liquid chromatography – mass spectrometry (LC–MS) was performed on a Waters 2795 liquid chromatograph, a Waters 996 photodiode array, a Sedex 75 light scatterer, and a Waters Micromass ZQ mass spectrometer. The mobile-phase solvent was 90% H_2O – 5% ACN – 5% – 0.2% formic acid buffer at approximately pH 3.0.

X-ray crystallography was performed at the Molecular Structure Center at Indiana University. X-ray diffraction data were collected using a Bruker diffractometer with SMART 6000 CCD detector. Structures were solved via the SHELXTL program suite (29). Further structure determination details are available in CIF form in the Supplementary material.[4]

Preparation of the benzophenone imines of glycinamide and alaninamide by transimination

2-[(Diphenylmethylene)amino]acetamide (10)

Glycinamide hydrochloride (**14**, 5.00 g, 45.2 mmol) and 1,2-dichloroethane (60 mL) were added to a dried 250 mL three-necked round-bottomed flask equipped with a reflux condenser, a magnetic stirrer, and an argon source. Diphenylketimine (7.6 mL, 45.2 mmol), triethylamine (6.93 mL, 49.7 mmol), and 1,2-dichloroethane (20 mL) were added by syringe to a separate dry 50 mL round-bottomed flask equipped with an argon source. The mixture was stirred for 5 min and was added slowly by cannula under argon to the reaction flask. The mixture was refluxed under argon overnight, cooled, filtered, and the solvent was removed under reduced pressure to give a light yellow solid. Recrystallization from hexanes–EtOAc (2:3 by volume) gave **10** as white crystals (7.55 g, 70%); mp 160–163 °C (lit value (22) mp 162 to 163 °C). IR (cm^{-1}): 1681, 3442. ^1H NMR δ: 3.96 (s, 2H, CH_2), 5.55–5.75 (br s, 2H, NH_2), 7.10–7.70 (m, 10H, aromatic). ^{13}C NMR ($CDCl_3$) δ: 58.2, 128.9, 129.8, 130.0, 130.1, 130.5, 130.6, 132.3, 137.6, 140.4, 156.7, 172.0, 175.1.

(±)-2-[(Diphenylmethylene)amino]propanamide (11a)

(±)-Alaninamide hydrochloride (**15**, 1.00 g, 8.03 mmol) followed by anhydr. DMF (50 mL) were added to a dried 250 mL round-bottomed flask equipped with a magnetic stirrer. The solution was stirred at room temperature under argon for 30 min or until the solid was completely dissolved. Benzophenone imine (1.45 g, 8.03 mmol) was added dropwise via syringe to the alaninamide solution under argon at room temperature. The reaction mixture was stirred at room temperature under argon overnight. The solution was

quenched with H_2O (100 mL), Et_2O (100 mL) was added, the layers were separated, and the aqueous layer was extracted with Et_2O (3 × 75 mL). The combined organic layers were washed with H_2O (3 × 100 mL) and brine (50 mL), dried over $MgSO_4$, filtered, and the solvent was removed under reduced pressure. The solid was washed with hexanes (5 × 20 mL) to give **11a** as a white solid (1.94 g, 96%). Recrystallization from CH_2Cl_2–hexanes (1:15) gave the product as a fine white powder (see the following analytical data).

General procedure for the alkylation of the benzophenone imine of glycinamide (10) by IPE to form the α-monosubstituted products 11

Aqueous NaOH (10%, 2.52 mmol) followed by tetrabutylammonium hydrogen sulfate (1.03 mmol) were added to a dried 25 mL round-bottomed flask equipped with a magnetic stirrer and the reaction mixture was stirred for 5 min. The benzophenone imine of glycinamide (**10**, 0.84 mmol) was dissolved in dichloromethane (1.5 mL) and then added dropwise via syringe to the reaction mixture. The solution was stirred for 3 min and then the system was placed under argon. The alkylating agent (4.2 mmol) was added dropwise via syringe and the reaction mixture was stirred at room temperature under argon overnight. The reaction mixture was transferred to a separatory funnel and distilled water (10 mL) and dichloromethane (10 mL) were added. The layers were separated and the aqueous layer was extracted with dichloromethane (3 × 5 mL). The organic layer was washed with distilled water (3 × 10 mL), dried over $MgSO_4$, filtered, and the solvent was removed under reduced pressure to give the crude product. The product was purified by flash column chromatography (SiO_2, first washed with hexanes–EtOAc–Et_3N (90:10:1)) using EtOAc–hexanes (50:50) to EtOAc–hexanes (85:15) gave the purified products **11**.

(±)-2-[(Diphenylmethylene)amino]propanamide (11a)

The general procedure described in the previous section using 10% aq. NaOH (0.9 g, 2.52 mmol), tetrabutylammonium hydrogen sulfate (0.351 g, 1.03 mmol), **10** (0.200 g, 0.84 mmol) in dichloromethane (1.5 mL), and

iodomethane (0.593 g, 4.2 mmol) gave solid product **11a** (177 mg, 84%); mp 120–123 °C. IR (cm^{-1}): 1651, 3451. ^1H NMR δ: 1.35 (d, 3H, J = 7.4 Hz, CH_3), 4.00 (q, 1H, J = 6.9 Hz, CH), 5.30–5.45 (br s, 2H, NH_2), 7.00–7.70 (m, 10H, aromatic). ^{13}C NMR ($CDCl_3$) δ: 22.3, 63.0, 128.9, 129.8, 130.1, 130.3, 130.4, 130.5, 132.2, 137.2, 140.7, 170.5, 178.5. Anal. calcd. for $C_{16}H_{16}N_2O$: C 76.17, H 6.39, N 11.10; found: C 76.36, H 6.50, N 11.14.

(±)-2-[(Diphenylmethylene)amino]-4-pentenamide (11b)

The general procedure described previously using 10% aq. NaOH (11.65 g, 31.5 mmol), tetrabutylammonium hydrogen sulfate (4.38 g, 12.9 mmol), **10** (2.50 g, 10.5 mmol) in dichloromethane (20 mL), and allyl bromide (5.07 g, 42.0 mmol) gave a glassy oil, which was purified by flash column chromatography (SiO_2, first washed with hexanes–EtOAc–Et_3N (90:10:1)) using EtOAc–hexanes (50:50) to EtOAc–hexanes (85:15) to give **11b** as a white solid (2.20 g, 75%); mp 78–80 °C. IR (cm^{-1}): 1686, 3448. ^1H NMR δ: 2.54 (t, 2H, J = 6.6 Hz, CH_2), 4.07 (t, 1H, J = 5.9 Hz, CH), 5.04 (m, 2H, CH_2), 5.44 (br s, 1H, NH), 5.68 (m, 1H, CH), 6.82 (br s, 1H, NH), 7.10–7.66 (m, 10H, aromatic). ^{13}C NMR ($CDCl_3$) δ: 39.8, 65.9, 117.7, 127.8, 128.2, 128.6, 128.7, 128.9, 130.6, 134.0, 135.7, 139.3, 169.8, 175.3. Anal. calcd. for $C_{18}H_{18}N_2O$: C 77.67, H 6.52, N 10.06; found: C 77.36, H 6.52, N 10.00.

(±)-2-[(Diphenylmethylene)amino]-3-(4-chlorophenyl)propanamide (11c)

The general procedure described previously using 10% aq. NaOH (11.6 g, 31.5 mmol), tetrabutylammonium hydrogen sulfate (4.38 g, 12.9 mmol), **10** (2.50 g, 10.5 mmol) in dichloromethane (22 mL), and 4-chlorobenzyl bromide (2.65 g, 12.9 mmol) gave a white solid, which was purified by flash column chromatography (SiO_2, first washed with hexanes–EtOAc–Et_3N (90:10:1)) using EtOAc–hexanes (50:50) to EtOAc–hexanes (85:15) to give the alkylated product **11c** as a white solid (2.74 g, 72%); mp 181 to 182 °C. IR (cm^{-1}): 1681, 3441. ^1H NMR δ: 3.01 (dd, 1H, J = 9.6, 13.2 Hz, CH), 3.15 (dd, 1H, J = 3.3, 12.9 Hz, CH), 4.17 (q, 1H, J = 4.2 Hz, CH), 5.38 (br s, 1H, NH), 6.55 (d, 2H, J = 6.6 Hz, CH), 6.73 (br s, 1H, NH), 6.94–7.59 (m, 14H, aromatic). ^{13}C NMR ($CDCl_3$) δ: 42.4, 69.1, 128.9, 129.8, 130.1, 130.2, 132.3, 132.9, 133.9, 136.8, 137.8, 140.7, 171.9, 176.5. HRMS m/z calcd. for $C_{22}H_{20}N_2OCl$: 363.1186 ($M + Na^+$); found: 363.1252.

(±)-2-[(Diphenylmethylene)amino]butanamide (11d)

The general procedure described previously using 10% aq. NaOH (11.6 g, 31.5 mmol), tetrabutylammonium hydrogen sulfate (4.38 g, 12.9 mmol), **10** (2.50 g, 10.5 mmol) in dichloromethane (25 mL), and iodoethane (2.01 g, 12.9 mmol) gave a light yellow solid, which was purified by flash column chromatography (SiO_2, first washed with hexanes–EtOAc–Et_3N (90:10:1)) using EtOAc–hexanes (50:50) to EtOAc–hexanes (85:15) to give **11d** as a white solid (2.05 g, 73%); mp 116 to 117 °C. IR (cm^{-1}): 1686, 3451. ^1H NMR δ: 0.88 (t, 3H, J = 7.4 Hz, CH_3), 1.78–1.85 (m, 2H, CH_2), 3.93 (q, 1H, J = 3.9 Hz, CH), 5.41 (br s, 1H, NH), 6.80 (br s, 1H, NH), 7.10–7.68 (m, 10H, aromatic). ^{13}C NMR ($CDCl_3$) δ: 11.7, 30.3, 68.8, 129.3, 129.8, 130.2, 130.3, 130.4, 132.2, 137.4, 140.9, 171.0, 177.6. Anal. calcd. for $C_{17}H_{18}N_2O$: C 76.66, H 6.81, N 10.52; found: C 76.94, H 6.84, N 10.55.

General procedure for the alkylation of the benzophenone imines of α-monosubstituted amino amides (11) using KO-*t*-Bu to form the α,α-disubstituted products 12

The benzophenone imine of a monosubstituted α-amino amide (**11**, 1.98 mmol) and anhydr. THF (5 mL) were added at room temperature to a dried 15 mL round-bottomed flask containing a magnetic stirrer and an argon source. The solution was cooled to 0 °C and KO-*t*-Bu (1.0 mol/L in THF, 2.38 mmol) was added dropwise via syringe. The reaction mixture was stirred at 0 °C for 20 min. The alkylating agent (2.38 mmol) was added dropwise via syringe to the reaction mixture at 0 °C and the solution was stirred for 3 h. The reaction mixture was quenched with satd. NH_4Cl (5 mL), H_2O (10 mL), and CH_2Cl_2 (15 mL) were added. The layers were separated, the organic layer was washed with H_2O (2 × 10 mL), and the aqueous layer was extracted with CH_2Cl_2 (3 × 15 mL). The combined organic layers were washed with brine (10 mL), dried over $MgSO_4$, filtered, and the solvent was removed under reduced pressure. The product was purified by flash column chromatography (silica was washed with hexanes–EtOAc–Et_3N, 75:25:1) to give, in most cases, a solid product. Recrystallization from CH_2Cl_2–hexanes (1:15) gave the purified products **12**.

(±)-2-[(Diphenylmethylene)amino]-2-methyl-4-pentenamide (12a) and by-products (16–19)

The general procedure described in the previous section using **11a** (0.500 g, 1.98 mmol) and allyl bromide (0.287 g, 2.38 mmol) gave product **12a** as a white solid (0.35 g, 61%); mp 127–129 °C. R_f 0.39 (hexanes–EtOAc, 7:3). IR (cm^{-1}): 1682, 3438. ^1H NMR δ: 1.23 (s, 3H, CH_3), 2.25 (dd, 1H, J = 6.3, 14.3 Hz, CH), 2.69 (dd, 1H, J = 7.4, 14.7 Hz, CH), 5.05 (m, 2H, CH_2), 5.56 (bs, 1H, NH), 5.71–5.82 (m, 1H, CH), 7.12–7.52 (m, 10H, aromatic). ^{13}C NMR ($CDCl_3$) δ: 24.7, 43.9, 67.8, 117.6, 127.9, 128.0, 128.1, 128.6, 130.3, 133.6, 138.3, 166.9, 179.1. Anal. calcd. for $C_{19}H_{20}N_2O$: C 78.05, H 6.89, N 9.58; found: C 77.94, H 6.93, N 9.62.

Selected analytical data for the by-products

N-Allylated product **16**: R_f 0.62 (hexanes–EtOAc, 7:3). Selected ^1H NMR signals: 1.30 (d, 3H, CH_3), 4.00 (q, 1H, CH), 5.0–6.0 (m, 3H, vinyl of one allyl). LC–MS: 293. Cα,N-Diallylated product **17**: R_f 0.71 (hexanes–EtOAc, 7:3). Selected ^1H NMR signals: 1.23 (s, 3H, CH_3), 5.0–6.0 (m, 6 H, vinyls of two allyls). LC–MS: 333. N,N-Diallylated product **18**: R_f 0.52 (hexanes–EtOAc, 7:3). Selected ^1H NMR signals: 1.30 (d, 3H, CH_3), 4.00 (q, 1H, CH), 5.0–6.0 (m, 6H, vinyls of two allyls). LC–MS: 333. Cα,N,N-Triallylated product **19**: R_f 0.77 (hexanes–EtOAc, 7:3). Selected ^1H NMR signals: 1.23 (s, 3H, CH_3), 5.0–6.0 (m, 9H, vinyls of three allyls). LC–MS: 373.

(±)-2-[(Diphenylmethylene)amino]-2,5-dimethyl-4-hexenamide (12b)

The general procedure described previously using **11a** (0.500 g, 1.98 mmol) and 4-bromo-2-methyl-2-butene (0.355 g, 2.38 mmol) gave product **12b** as a white solid

(±)-2-[(Diphenylmethylene)amino]-2,4-dimethyl-4-pentenamide (12c)

The general procedure described previously using **11a** (0.500 g, 1.98 mmol) and 3-bromo-2-methylpropene (0.320 g, 2.38 mmol) gave product **12c** as a white solid (0.314 g, 52%); mp 122 to 123 °C. IR (cm^{-1}): 1686, 3443. ^1H NMR δ: 1.28 (s, 3H, CH_3), 1.61 (s, 3H, CH_3), 1.96 (d, 1H, J = 16.2 Hz, CH), 2.80 (d, 1H, J = 16.2 Hz, CH), 4.76 (d, 2H, J = 26.5 Hz, CH_2), 5.56 (br s, 1H, NH), 7.21–7.52 (m, 10H, aromatic), 8.13 (br s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 25.7, 28.5, 47.5, 68.8, 114.7, 129.3, 129.5, 129.6, 129.8, 130.1, 131.8, 139.9, 142.8, 143.2, 167.7, 181.3. HRMS *m/z* calcd. for $C_{20}H_{23}N_2O$: 307.1732 for (M + Na^+); found: 307.1797.

(±)-2-[(Diphenylmethylene)amino]-2-methyl-(5E)-phenyl-4-pentenamide (12d)

The general procedure described previously using **11a** (0.500 g, 1.98 mmol) and cinnamyl bromide (0.466 g, 2.38 mmol) gave product **12d** as a white solid (0.423 g, 58%); mp 149 to 150 °C. IR (cm^{-1}): 1686, 3442. ^1H NMR δ: 1.26 (s, 3H, CH_3), 2.40 (dd, 1H, J = 7.0, 13.6 Hz, CH), 2.84 (dd, 1H, J = 7.4, 14.0 Hz, CH), 5.55 (br s, 1H, NH), 6.15 (m, 1H, CH), 6.39 (d, 1H, J = 14.6 Hz, CH), 7.16–7.53 (m, 15H, aromatic), 7.94 (br s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 26.4, 44.8, 69.8, 126.9, 127.8, 128.7, 129.5, 129.7, 129.8, 130.0, 130.3, 131.9, 134.4, 139.2, 140.0, 142.7, 168.7, 180.6. Anal. calcd. for $C_{25}H_{24}N_2O$: C 81.49, H 6.57, N 7.60; found: C 81.29, H 6.61, N 7.63.

(±)-2-[(Diphenylmethylene)amino]-2-(4-chlorophenyl)propanamide (12e)

The general procedure described previously using **11a** (0.500 g, 1.98 mmol) and 4-chlorobenzyl bromide (0.490 g, 2.38 mmol) in anhydr. THF (1 mL) gave product **12e** as a white solid (0.392 g, 53%); mp 147–149 °C. IR (cm^{-1}): 1686, 3444. ^1H NMR δ: 1.14 (s, 3H, CH_3), 2.87 (d, 1H, J = 14.0 Hz, CH), 3.25 (d, 1H, J = 13.2 Hz, CH), 5.39 (bs, 1H, NH), 7.05–7.50 (m, 14H, Ar). ^{13}C NMR ($CDCl_3$) δ: 26.4, 44.8, 69.8, 126.9, 127.8, 128.7, 129.5, 129.7, 129.8, 130.0, 131.9, 134.4, 139.2, 140.0, 142.7, 168.7, 180.6. Anal. calcd. for $C_{23}H_{21}ClN_2O$: C 73.30, H 5.62, Cl 9.41, N 7.43; found: C 73.06, H 5.62, Cl 9.52, N 7.43.

(±)-2-[(Diphenylmethylene)amino]-2-methylbutanamide (12g)

The general procedure described previously using **11a** (0.500 g, 1.98 mmol) and iodoethane (0.371 g, 2.38 mmol) gave of product **12g** as a white solid (0.129 g, 24%); mp 137 to 138 °C. IR (cm^{-1}): 1680, 3436. ^1H NMR δ: 0.87 (t, 3H, J = 7.6 Hz, CH_3), 1.22 (s, 3H, CH_3), 1.45 (m, 1H, CH), 1.96 (m, 1H, CH), 6.20 (br s, 1H, NH), 7.20–7.53 (m, 10H, aromatic), 8.14 (br s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 10.7, 26.7, 33.9, 69.9, 129.3, 129.6, 129.7, 130.1, 131.8, 140.1, 142.8, 167.9, 181.7. Anal. calcd. for $C_{18}H_{20}N_2O$: C 77.11, H 7.19, N 9.99; found: C 76.83, H 7.28, N 9.82.

(±)-2-[(Diphenylmethylene)amino]-2,4-dimethylpentanamide (12h)

The general procedure described previously using **11a** (0.500 g, 1.98 mmol) and 1-iodo-2-methylpropane (0.437 g, 2.38 mmol) gave product **12h** as a white solid (0.150 g, 25%); mp 136–138 °C. IR (cm^{-1}): 1700, 3061. ^1H NMR δ: 0.86 (d, 3H, J = 6.6 Hz, CH_3), 0.93 (d, 3H, J = 6.6 Hz, CH_3), 1.16 (s, 3H, CH_3), 1.42 (dd, 1H, J = 5.1, 14.0 Hz, CH), 1.80 (m, 1H, CH), 1.97 (dd, 1H, J = 8.1, 14.0 Hz, CH), 5.57 (br s, 1H, NH), 7.19–7.53 (m, 10H, aromatic), 8.19 (br s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 24.2, 25.8, 26.9, 28.4, 49.6, 68.9, 129.0, 129.6, 129.7, 129.8, 130.1, 130.2, 131.8, 140.1, 142.8, 167.8, 182.2. HRMS *m/z* calcd. for $C_{20}H_{25}N_2O$: 309.1889 (M + Na^+); found: 309.1961.

2-[(Diphenylmethylene)amino]-2-(2-propenyl)-4-pentenamide (12i)

The general procedure described previously using **11b** (0.500 g, 1.79 mmol) and allyl bromide (0.266 g, 2.16 mmol) gave the product **12i** as a solid (0.119 g, 21%); mp 138–140 °C. IR (cm^{-1}): 1691, 3435. ^1H NMR δ: 2.23 (dd, 2H, J = 6.3, 14.3 Hz, CH_2), 2.67 (dd, 2H, J = 7.4, 13.2 Hz, CH_2), 5.05 (m, 4H, CH_2), 5.73 (m, 2H, CH), 7.26–7.48 (m, 10H, aromatic), 8.72 (br s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 43.6, 72.7, 119.3, 128.9, 129.7, 129.8, 130.5, 131.9, 134.7, 139.9, 142.8, 168.7, 179.4. Anal. calcd. for $C_{21}H_{22}N_2O$: C 79.21, H 6.96, N 8.80; found: C 79.34, H 7.01, N 8.80.

(±)-2-(4-Chlorobenzyl)-2-[(diphenylmethylene)amino]-4-pentenamide (12j) by allylation

The general procedure described previously using **11c** (0.500 g, 1.38 mmol) and allyl bromide (0.196 g, 1.65 mmol) gave product **12j** as a solid (0.139 g, 25%); mp 143 to 144 °C. IR (cm^{-1}): 1686, 2360, 3442. ^1H NMR δ: 2.27 (dd, 1H, J = 5.9, 14.7 Hz, CH), 2.71 (dd, 1H, J = 7.4, 14.7 Hz, CH), 2.89 (d, 1H, J = 14.0 Hz, CH), 3.23 (d, 1H, J = 14.7 Hz, CH), 5.05 (d, 2H, J = 12.5 Hz, CH_2), 5.53 (br s, 1H, NH), 5.72 (m, 1H, CH), 7.09–7.49 (m, 14H, aromatic), 7.93 (br s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 43.3, 45.3, 72.8, 119.7, 128.9, 129.7, 129.8, 129.9, 130.6, 132.1, 132.6, 133.8, 134.4, 137.2, 139.8, 142.6, 168.7, 178.7. HRMS *m/z* calcd. for $C_{25}H_{24}N_2OCl$: 403.1499 (M + Na^+); found: 403.1595.

(±)-2-(4-Chlorobenzyl)-2-[(diphenylmethylene)amino]-4-pentenamide (12j) by benzylation

The general procedure described previously using **11b** (0.250 g, 0.90 mmol) and 4-chlorobenzyl bromide (0.222 g, 1.08 mmol) in THF (1 mL) gave product **12j** as a solid (0.036 g, 10%). See previous analytical data.

(±)-2-[(Diphenylmethylene)amino]-2-ethyl-4-pentenamide (12k)

The general procedure described previously using **11d** (0.500 g, 1.87 mmol) and allyl bromide (0.273 g,

© 2006 NRC Canada

2.25 mmol) gave the product **12k** as a solid (0.075 g, 13%); mp 136 to 137 °C. IR (cm^{-1}): 1679, 3447. ^1H NMR δ: 0.85 (t, 3H, J = 7.4 Hz, CH_3), 1.43 (m, 1H, CH), 1.94 (m, 1H, CH), 2.20 (dd, 1H, J = 6.6, 14.7 Hz, CH), 2.64 (dd, 1H, J = 7.4, 14.7 Hz, CH), 5.03 (m, 2H, CH_2), 5.74 (m, 2H, CH_2), 7.24–7.49 (m, 10H, aromatic), 8.33 (br s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 1.6, 10.3, 32.3, 44.1, 44.2, 119.0, 128.6, 129.6, 129.7, 129.8, 129.9, 130.3, 131.6, 131.8, 133.9, 135.0, 168.2, 187.5. Anal. calcd. for $C_{20}H_{22}N_2O$: C 78.40, H 7.24, N 9.14; found: C 78.28, H 7.26, N 9.13.

Michael addition of the benzophenone imine of alaninamide

1,1-Dimethylethyl (±)-5-amino-4-[(diphenylmethylene)amino]-4-methyl-5-oxopentanoate (20)

2-[(Diphenylmethylene)amino]propanamide (**11a**, 0.500 g, 1.98 mmol) and anhydr. THF (5 mL) were added at room temperature to a dried 15 mL round-bottomed flask containing a magnetic stirrer and an argon source. The solution was cooled to 0 °C and *tert*-butyl acrylate (0.305 g, 2.38 mmol) followed by KO-*t*-Bu (1.0 mol/L in THF, 0.238 mL, 0.238 mmol) were added dropwise via syringe. The reaction mixture was stirred at 0 °C for 3 h. The reaction mixture was quenched with satd. NH_4Cl (5 mL), H_2O (10 mL), and CH_2Cl_2 (15 mL) were added. The layers were separated, the organic layer was washed with H_2O (2 × 10 mL), and the aqueous layer was extracted with CH_2Cl_2 (3 × 15 mL). The combined organic layers were washed with brine (10 mL), dried over $MgSO_4$, filtered, and the solvent was removed under reduced pressure. The product was purified by flash column chromatography (silica was washed with hexanes–EtOAc–Et_3N, 75:25:1) to give product **20** as a white solid (0.242 g, 32%). Recrystallization from CH_2Cl_2–hexanes (1:15) gave the purified product; mp 161 to 162 °C. IR (cm^{-1}): 1686, 3438. ^1H NMR δ: 1.20 (s, 3H, CH_3), 1.38 (s, 9H, *tert*-butyl), 1.77–1.81 (m, 2H, CH_2), 6.10 (br s, 1H, NH), 7.22–7.52 (m, 10H, aromatic), 8.03 (br s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 24.3, 24.9, 28.0, 30.5, 31.1, 33.1, 34.7, 62.1, 66.8, 125.8, 125.9, 127.7, 128.1, 128.2, 128.4, 128.5, 128.6, 130.4, 138.1, 140.9, 145.3, 146.0, 167.3, 172.2, 172.7, 179.4, 179.8. HRMS m/z calcd. for $C_{23}H_{29}N_2O_3$: 381.2100 ($M + Na^+$); found: 381.2187.

Acknowledgements

We thank the National Institutes of Health (R01 GM028193) and Eli Lilly and Company for financial support of this work. We acknowledge helpful discussions with H.E. Schoemaker, Q.B. Broxterman, and B. Kaptein of DSM Research (Geleen, The Netherlands). A generous gift of (±)-alaninamide hydrochloride from DSM Research is gratefully acknowledged.

Cyclotrimerization approach to unnatural structural modifications of pancratistatin and other amaryllidaceae constituents — Synthesis and biological evaluation[1]

Tomas Hudlicky, Michael Moser, Scott C. Banfield, Uwe Rinner, Jean-Charles Chapuis, and George R. Pettit

Abstract: The phenanthridone core of pancratistatin lacking all aromatic oxygenation was prepared by cyclotrimerization of acetylene-containing scaffolds **30** and **41**, reflecting the natural and the C-1 epi configuration, respectively, of the amino inositol moiety. The cobalt-catalyzed formation of the aromatic core led to bisTMS derivatives **39** and **48**, as well as bisacetyl derivative **51**. The effectiveness of cyclotrimerization of the natural or trans series was compared with that of the cis series. In addition, the yields of cyclotrimerization were compared for propargylic amines and propargylic amides. Eleven derivatives, including the fully hydroxylated phenantridone **39**, were tested against seven cancer cell lines. Three of the compounds displayed activities only an order of magnitude less than those of 7-deoxypancratistatin. Full experimental and spectral details are provided for all key compounds and future projections for the preparation of unnatural analogs of Amaryllidaceae constituents are advanced, along with some new insight into the minimum pharmacophore of pancratistatin.

Key words: cyclotrimerization, alkaloids, cobalt catalyst.

Résumé : Faisant appel à une cyclotrimérisation des dérivés acétyléniques **30** et **41** qui reflètent respectivement les configurations naturelle et C-1-épi, on a préparé la phénanthridone, le squelette fondamental de la pancratistatine ne comportant pas d'oxygène aromatique. La formation catalysée par le cobalt du noyau fondamental à conduit aux dérivés bisTMS **39** et **48** ainsi qu'au dérivé bisacétylé **51**. On a comparé l'efficacité de la cyclotrimérisation de la série nature ou trans avec celle de la série cis. De plus, on a comparé les rendements des cyclotrimérisations avec des amines et des amides propargyliques. Onze dérivés, y compris la phénantridone totalement hydroxylé (**39**) ont été évalués contre sept souches de cancer. Trois de ces composés présentent des activités qui ne sont qu'un ordre de grandeur inférieures à celle de la 7-désoxypancratistatine. On rapporte l'ensemble des détails expérimentaux et spectraux relatifs à tous les intermédiaires clés. Les projections relatives à la préparation d'analogues non naturels des constituants de l'Amaryllidaceae sont avancées et l'on possède déjà de nombreuses pistes nouvelles concernant la nature du pharmacophore minimal de la pancratistatine.

Mots clés : cyclotrimérisation, alcaloïdes, catalyseur de cobalt.

Introduction

Pancratistatin (**1**) and its congeners (Fig. 1) have been at the forefront of activities in both synthetic and medicinal communities (1). All four naturally occurring constituents have been synthesized by many creative approaches (2–5), and significant effort has been devoted to the investigation of the mode of action (6), active pharmacophore (7), and more bioavailable agents (8). To date many truncated versions of the key constituents have been prepared (9) and evaluated for activities against several cancer cell lines. From the results of these evaluations, several generalizations

Fig. 1. Amaryllidaceae constituents (**1**–**4**) and some recently synthesized unnatural mimics (**5**–**7**).

have emerged with regard to the structural elements essential to activity. First, the hydroxyphenanthridone moiety is thought to be essential to high activity of pancratistatin and narciclasine; its deletion, as in 7-deoxypancratistatin and lycoricidine, leads to a significant drop in activity (10). Second, the amino inositol motif is also essential, save for small changes at C-1 and C-2; deletion of the hydroxyls at these positions or altering substitution patterns at C-1 does not altogether eliminate activity (7, 11). Various unnatural derivatives with specific deletions in the hydroxylated ring have been tested. A recent article established that the minimum requirement for activity is the 2,3,4-triol pattern found in all active constituents (11). Third, deletion of some of the aromatic oxygenation lowers activity significantly (12). Fourth, recently synthesized lactone mimics **5** and **6**, in both configurations at C-4, were found inactive, suggesting that the phenanthridone unit is essential for retention of activity (13). Finally, an indole mimic of pancratistatin (**7**) recently prepared in our laboratory possessed borderline activity against one cell line (Table 1) (14).

These observations, as well as the bioavailability studies, indicate that the greatest opportunity for structural alterations exists in modifications of the aromatic core of the natural product. To prepare a large number of derivatives, a diversity-oriented synthesis strategy (DOS) is the most efficient way to generate libraries of compounds for testing. Rather than synthesize uniquely functionalized aryl residues for eventual attachment to the amino inositol unit, we have chosen the cyclotrimerization approach portrayed in Fig. 2, which is based on acetylene- and nitrile-containing scaffolds and their cobalt-catalyzed trimerization to aromatic (15) and heteroaromatic (16) variants of the pancratistatin type. This unique transformation was discovered in 1864 by Berthelot (17), who prepared benzene by passing acetylene over hot copper. We note that Berthelot's paper, published in 1866, is usually cited as the event of original discovery (17*b*, 17*c*). This is not the correct citation and for historical interest we include the original description of his 1864 experiment here:

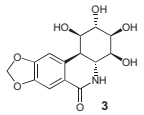
Il est un cas de condensation de l'acetylene naissant très-remarquable et qui mérite un examen particulier, bien que la démonstration en soit plutôt vraisemblable que rigoureusement établie: c'est la condensation de l'acétylène en benzine. Entre la formule de l'acétylène, C^4H^2, et celle de la benzine $C^{12}H^6$, c'est-à-dire entre les poids de ces deux corps ramenés à l'état gazeux et au même volume, il existe une relation très-simple; la deuxième formule est triple de la première :

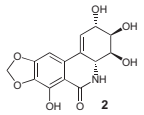
$$3\ C^4H^2 = C^{12}H^6.$$

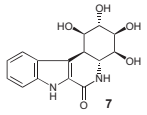
Or cette relation n'existe pas seulement entre les formulas des deux corps; mais on peut admettre que, dans certaines circonstances que nous allons signaler, l'acétylène naissant se transforme réellement en benzine. Voici ces circonstances.

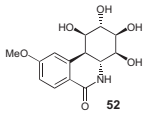
Nous avons vu précédemment (p. 286) qu'en faisant passer un courant de vapeur de formène trichloré (chloroforme), C^2HCl^3, sur du cuivre chauffé au rouge, le chlore est absorbé et l'acétylène prend naissance. Répétons cette expérience avec le formène tribromé (bromoforme), C^2HBr^3, nous obtiendrons de la benzine. Nous sommes donc autorisés à penser que 3 molécules d'acétylène naissant peuvent se condenser en une seule molécule de benzine : la benzine serait alors du triacétylène.

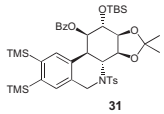
This is an example of condensation of the nascent acetylene that is very remarkable and deserves a close examination, even though the demonstration is rather plausible then rigorously established: it is the condensation of the acetylene into benzene. There is a very simple relationship between the formula of acetylene, C_4H_2, and the formula of benzene, $C_{12}H_6$, specifically between the weight of equal volumes of those two bodies in the gas state: the second formula is triple of the first:

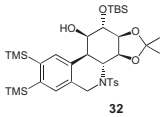












$$3\ C_4H_2 = C_{12}H_6.$$

Now such relation does not just exist between the formulas of the two bodies; but we can admit that under certain particular circumstances that we may point to, nascent acetylene is actually transformed to benzene. We have already seen (p.286) that by passing a stream of gaseous trichlorinated formene (chloroform), C_2HCl_3, over red-hot copper, chlorine is absorbed and acetylene is generated. By repeating this experience with tribrominated formene (bromofrom), C_2HBr_3, we would obtain some benzene. This leads us to think that three molecules of nascent acetylene could combine to form a single molecule of benzene. Thus benzene would be a triacetylene.

The reaction enjoyed moderate attention and, indeed, exhibited moderate yields in most of the documented examples in the literature, including recent applications (18). An ex-

ception to such critique is found in the classic application of cyclotrimerization to the total synthesis of estrone by Funk and Vollhardt in 1977 (19), shown in Fig. 3. Despite the attention this synthesis received, only once more was this technique featured in a total synthesis effort — an approach to morphine also disclosed by Vollhardt and co-workers (20) (Fig. 3). In the estrone synthesis, the initial cyclization furnished a low yield of **13** in addition to the intermediate benzocyclobutane, which, under the conditions of the reaction, underwent [4+2] cyclization to **13** in a total yield of 71%. In the approach to morphine, benzofuran **15** yielded the tetracyclic morphine skeleton as a single diastereomer with C-5, C-9, and C-13 correctly set, indicating the potential for adjustment to the total synthesis of morphine itself, once appropriate substitution parameters for the incipient quaternary center at C-13 were designed. The emphasis on multicomponent reactions and cascade processes, so prevalent in the last decade or so (21, 22), seemed in sharp contrast to the apparent underutilization of cyclotrimerization techniques that satisfy both of these criteria. We reasoned that the modest yields reported in most of the applications could be addressed though appropriate reaction engineering and optimization of conditions. The benefits that would be harvested in the area of structure and activity relationships (SAR) for the analogs of the pancratistatin group of compounds seemed to outweigh the uncertainty and expectations of moderate yields in the construction of aromatic nuclei of the analogs.

In this manuscript we report the successful synthesis of several pancratistatin analogs by a high-yielding cyclotri-

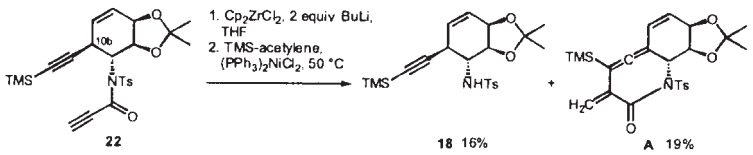
merization protocol from fully functionalized scaffolds of type **9** (23). The biological evaluation of the analogs, also reported herein, provided some surprising results and cast some uncertainty on the previously held views regarding some of the structural features deemed essential for biological function.

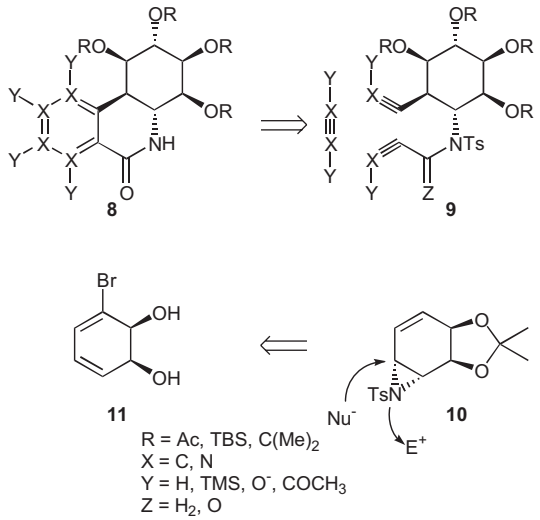


Results and discussion

The original intent of our study was the investigation of a de *novo* approach to pancratistatin (**1**) from scaffold **9** in which the acetylene partners would provide a triply silylated arene that could be converted to the fully oxygenated core of pancratistatin. Portrayed in Scheme 1 are the results of this particular approach, which met with abject failure because of the steric issues associated with multiply silylated sites or perhaps random desilylation processes similar to those observed when Rainier used an iron-based catalyst (24). Only the cobalt-coordinated tetracycle **20** was isolated in low yield from the reactions of bisacetylene **19** (Scheme 1). The final cycloaddition of bis(trimethylsilyl)acetylene (BTMSA) did not lead to the fully silylated arene **21**, presumably because of steric crowding.

When $Ni(COD)_2$ was employed as a catalyst, the cyclotrimerization of **22** gave an interesting dimeric product (**23**) in 47% yield. The use of a zirconium catalyst (25) did not lead to dimeric **23** and gave other products.[3]

Adjustments in the strategic plan led to the construction of simpler scaffolds unencumbered by TMS groups and cyclotrimerization attempts to attain a 7-deoxypancratistatin



[3] The exposure of propargylic amide **22** to a zirconium-based catalyst led to some unusal results. The propargylic amide was lost and tosylamide **18** was recovered, in addition to an unusual structure, tentatively identified as cyclic allene **A**, which may result in an ene reaction between the propargyl group and the hydrogen at 10b.

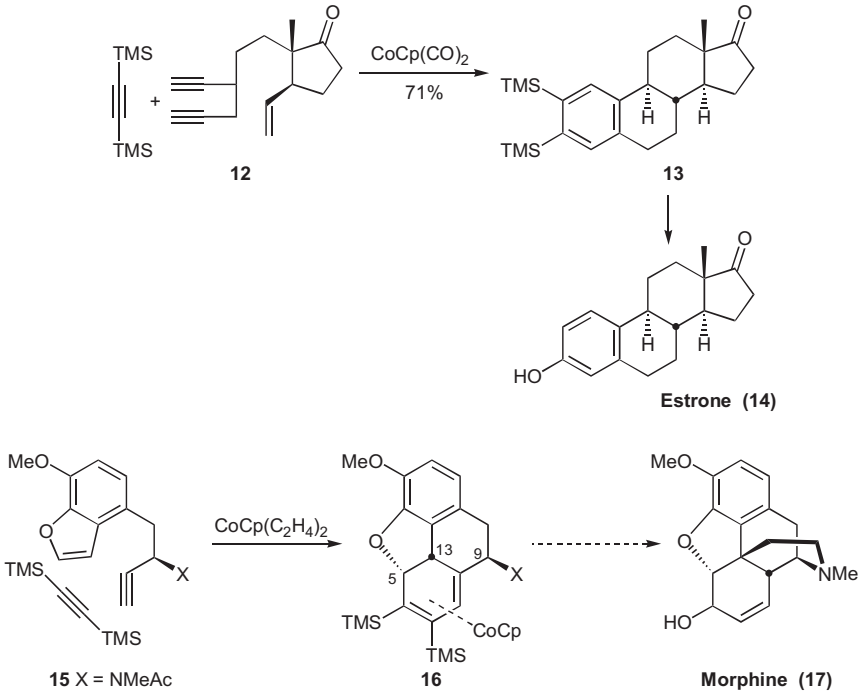
substitution pattern instead. These efforts were divided into three distinct areas: (*i*) synthesis of building blocks exhibiting the stereochemistry of the "natural" or trans series, with respect to stereochemical configuration at C-1 and C-2; (*ii*) synthesis of the corresponding "unnatural" or cis series; and (*iii*) comparison of the overall efficiency of these two approaches with one that would employ propargyl amides vs. propargyl amines. Upon attaining the nucleus of Amaryllidaceae constituents, all of these approaches would be evaluated and the best one chosen for the eventual production of analogs.

Cyclotrimerization of scaffolds in the trans or natural series

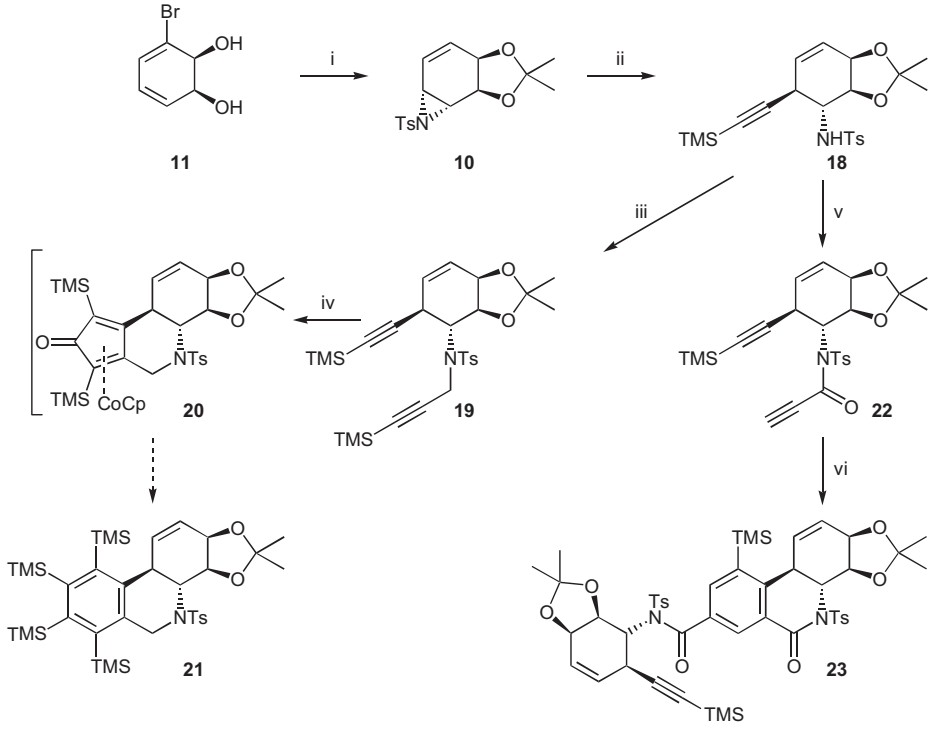
The intermediate reflecting the natural amino inositol configuration was synthesized as shown in Scheme 2 (23). Vinylaziridine **10** (26) was reacted with the aluminum complex prepared from lithium (trimethylsilyl)acetylene to provide **18** in 69% yield. After column chromatography, the product of this reaction was treated with 2,2-dimethoxypropane (DMP) and acetone to reprotect the diol liberated in the portion of the mixture by the action of $AlCl_3$. The reprotected compound was used without further purification. The tosylaziridine **18** was first converted to the cis-diol **24** by the action of OsO_4 and *N*-methylmorpholine-*N*-oxide (NMO) (44% yield, 76% conversion), and the cyclic sulfate **25** was then generated in 82% yield by treatment with SO_2Cl_2 and NEt_3. Cyclic sulfates, whose reactivity resembles that of epoxides (27), are easily opened with weak nucleophiles such as ammonium benzoate. Such opening generates the required trans relationship at C-1/C-2 of pancratistatin, as has been previously demonstrated (27*b*). Treatment of **25** with ammonium benzoate generated, surprisingly, a mixture of the desired **26**, as a minor product accompanied by the elimination product **27**, displaying the substitution parameters of narciclasine or lycoricidine. Investigation of this reaction revealed that **27** does not originate in **26** nor is it derived from **25** by syn elimination. Careful experimentation revealed that the likely source of **27** is the intramolecular elimination of proton at C-10b by the intermediate sulfate anion **25a** as shown in Fig. 4. Further study is required to optimize the production of either **26** or **27**, the latter containing the structural features of narciclasine.

The TMS group was removed with tetrabutylammonium triphenyldifluorosilicate (TBAT) in 84% yield from acetylene **26** to avoid previously encountered problems with steric bulk at the incipient C-10 of the aromatic nucleus. Following the protection of the C-2 alcohol as a TBS ether (89%), tosylamide **29** was alkylated with propargyl bromide to yield the required compound **30** in 79% yield. As mentioned above, the prospects for high yields in the cyclotrimerization were not promising based on the rather modest yields reported throughout the literature. Yet, after optimization, acetylene derivative **30** was converted to tetracyclic tosylamide **31** in 83% yield (slow addition over 36 h of a mixture of **30**, catalyst, and BTMSA to a heated solution of BTMSA, which was recovered by distillation upon completion of the reaction). Tosylamide **31** was converted to fully deprotected tetraol **34** (as shown in Scheme 3) to provide compounds lacking the phenanthridone carbonyl group for biological evaluation. Oxidation of **31** to the state of phenanthridone proved somewhat arduous, proceeding in 15% yield to **35** with $NaIO_4$–$RuCl_3$. Oxidation studies on bisbenzoate **37** led to the same results under these conditions. With the reaction buffered by solid Na_2CO_3, the oxidation occurred more slowly to give **38** in 33% yield. This material was subjected to reductive detosylation with sodium naphthalide, during which a partial loss of the benzoate groups occurred as a result of the basic conditions. The crude material was treated first under stronger basic conditions CH_3ONa in MeOH) then under acidic conditions (Dowex 50WX8-100 in MeOH) to provide the 7-deoxypancratistatin nucleus having TMS groups in place of the aromatic oxygenation. The preparation of this key compound in 14 steps and 0.3% overall yield starting from aziridine **10** signified the successful validation of the cyclotrimerization strategy as an approach to compounds with variations in the aromatic core.



Cyclotrimerization of scaffolds in the cis or unnatural series

The unnatural or cis series intermediate was synthesized as shown in Scheme 4. The purpose of this approach was twofold. First, it would avoid the lack of selectivity in the cyclic sulfate opening encountered with **25**, leaving this reaction for the latter part of the synthesis. Second, it would provide the analogs with unnatural C-1 configuration for biological testing. The bisbenzoate **41** was subjected to cyclotrimerization under the optimized conditions applied to compound **30** in the trans series and provided tetracycle **42** in 87% yield (as shown in Scheme 5).



Deprotection of the benzoate and generation of the cyclic sulfate was accomplished in high yield and *trans*-benzoate alcohol **36** was generated in essentially quantitative yield. Upon exposure of **44** to ammonium benzoate in dimethylformamide (DMF) in this series, the elimination to the narciclasine/lycoricidine manifold was not observed. A possible explanation may lie in the relative acidities of propargylic vs. benzylic protons at C-10b in **25** vs. **44**, respectively. Fully deprotected analogs **34** (lacking the phenanthridone carbonyl) and **39** (containing the amide) were ob-

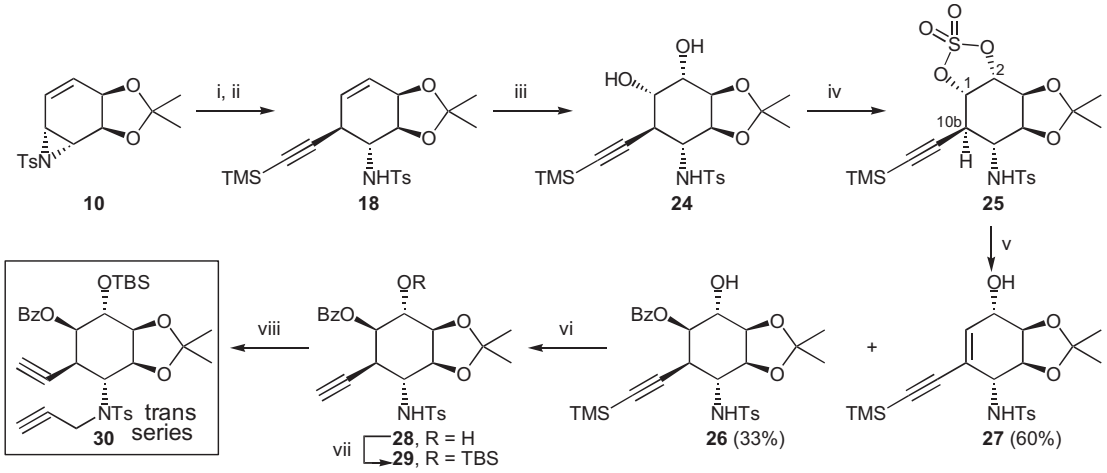

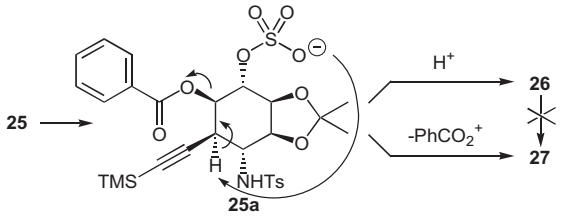

Fig. 4. Generation of enyne **25**.

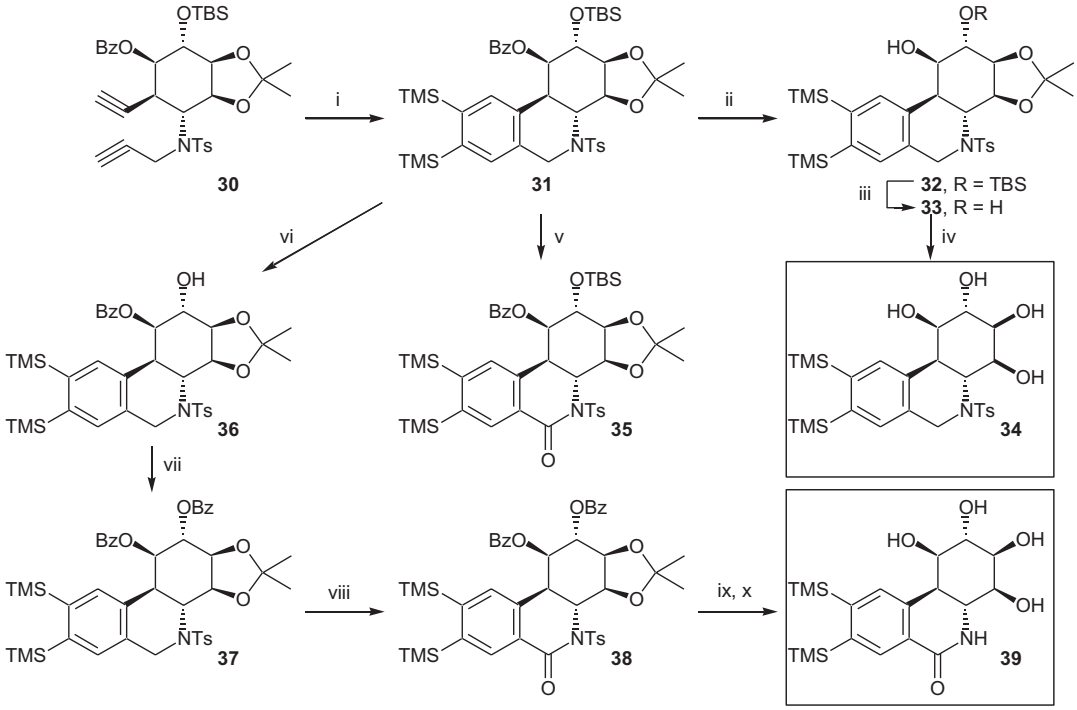
tained in a manner similar to that employed in the trans series. Overall, the cis series synthesis of phenanthridone **48** proved to be three times higher yielding because of higher selectivity in the cyclic sulfate opening. The eventual synthesis of C-1 epimeric analogs would originate in the cis-diol **24**.

Cyclotrimerization of propargyl amides

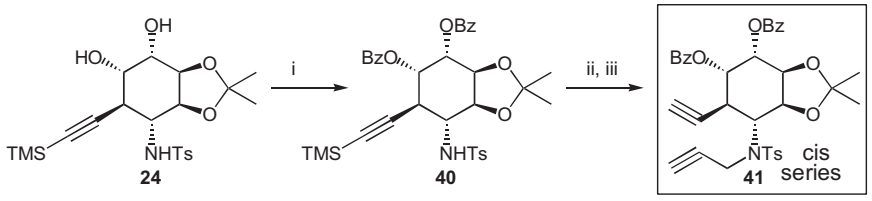
To avoid the modest yields of benzylic oxidation in the tetracycles **31** and **37**, we chose to investigate the cyclotrimerization protocol on propargylic amides, which could be easily generated by acylation of tosylamide **18**. Initially, the enyne **45**, obtained by acylation of **18** with propiolic acid anhydride, was chosen for this purpose (as shown in Scheme 6). Cyclotrimerization of this material furnished metal complex **46** in 11% yield and with apparent isomerization of the olefin to the configuration representing 2-deoxylycoricidine. When **47** was synthesized from **40** in 35% yield over two steps (cis series) and subjected to the same optimized conditions for cyclotrimerization, the tetracyclic phenanthridone **48** was obtained in 5% yield. It remains unclear whether these low yields are a function of unfavorable rotamer population of the imides such as **45** or **47** or whether the additional basic oxygen interferes with the catalytic cycle by complexation with the catalyst. Apparently these issues did not prevent the aforementioned cyclotrimerization of amide **22** to the dimeric phenanthridone **23** obtained in 47% yield (Scheme 1).

Synthesis of the bisacetyl derivative of 7-deoxypancratistatin



As a prelude to a de novo synthesis of one of the Amaryllidaceae constituents, we decided to prepare the bisacetyl derivative **51** shown in Scheme 7. Both arylsilanes and acetophenones should respond to Tamao oxidation (28) or Baeyer–Villiger oxidation (29), respectively, as means of generating the required oxygenation of the aromatic nucleus. Having noticed the experimental difficulties experienced by Vollhardt and Funk (19) in establishing the phenolic unit in estrone from a TMS group, we thought the bis(acetyl)arene would provide an alternative way to accomplish this task. To this end, the cyclotrimerization of bisacetylene **41** (cis series) was performed with hex-3-yne-2,5-diol protected as a bisTBS ether **49**. Tetracycle **50** was obtained as a mixture of diastereomers in 31% yield. The mixture was treated with tetrabutylammonium fluoride (TBAF) and oxidized to the bisacylated tetracycle **51** in 51% yield over two steps. In future endeavors, the oxidation of this compound to acetyl catechols will be pursued as the means of establishing the C-8/C-9 oxygenation of pancratistatin-type constituents.

Biological evaluation



Several of the compounds in both the trans or natural and the C-1 epimeric series were evaluated in the cancer cell line series listed in Table 1. The activity profiles of pancratistatin, 7-deoxypancratistatin, and narciclasine (Table 1, entries 1, 2, and 3, respectively) are shown for comparison, along with two unnatural analogs previously synthesized in our laboratory (Table 1, entries 4 and 5). Some rather surprising and unexpected results were obtained. While the fully protected core of 7-deoxypancratistatin (Table 1, entry 6) is essentially inactive, the partially deprotected intermediates (Table 1, entries 7 and 8), as well as the fully deprotected tetraol (Table 1, entry 9) are quite active, having activities only 10-fold less than those of 7-deoxypancratistatin. This is surprising for several reasons: First, it has been widely held that the phenathridone amide carbonyl is essential for activity, since Chapleur and co-workers (13) demonstrated that

the lactone analogs **5** and **6** are inactive. Second, these compounds represent the first examples of pancratistatin analogs that retain activity despite the absence of all aromatic oxygenation, in addition to lacking the amide moiety. Third, and very surprising, these derivatives have shown greater activity than the fully deprotected bisTMS derivative **39** (Table 1, entry 16) in which the phenanthridone amide is present. This difference in activity may also be ascribed to the fact that a tosyl group is a common pharmacophore and several truncated derivatives of pancratistatin containing tosyl groups were shown to be more active than those lacking it (9*c*). As it has been assumed that the phenolic hydroxyl and the amide may be required as a donor–acceptor pair for hydrogen bonding, our results indicate that these requirements may be offset by other structural features. The only other active compound was the C-1 epimeric diol (Table 1, entry 10), where activity supports the observation that changes at C-1 of the pharmacophore do not drastically alter biological profiles. The fact that four of the intermediates displayed profiles only an order of magnitude lower that those of 7-deoxypancratistatin is promising and will guide us in further design of unnatural analogs with variable functionality in the aromatic core.

Summary and conclusion

The successful synthesis of several analogs of pancratistatin was achieved by the cobalt-catalyzed cyclotrimerization of acetylenic scaffolds with BTMSA and protected 2,5-hex-3-yne. Both configurations at the C-1 hydroxylated aminoinositol unit were examined, with the unnatural, or cis series, being clearly a higher-yielding and more efficient process. The cyclotrimerizations of bisacetylenes with *N*-propargylic substituents were also much higher yielding than the corresponding processes that employed the propargylic amides. The attainment of bisacetyl derivative **51** bodes well for eventual installation of the methylenedioxy unit via the Baeyer–Villiger reaction in a de novo synthesis of 7-

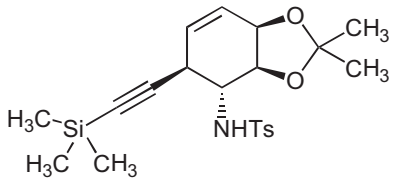
Scheme 5. Cyclotrimerization of the cis scaffold. Reagents and conditions: (*i*) $CpCo(CO)_2$, BTMSA, xylene, 140 °C, 87%; (*ii*) 1% NaOH, MeOH, rt, 99%; (*iii*) SO_2Cl_2, NEt_3, CH_2Cl_2, 0 °C to rt, 70%; (*iv*) $H_5C_6COONH_4$, DMF, 70 °C, 99%; (*v*) BzCl, pyridine, rt, 86%; (*vi*) $NaIO_4$, $RuCl_3$, Na_2CO_3, CH_3CN–CCl_4–H_2O, rt, 33%; (*vii*) Na-naphthalide, THF, –65 °C, then NaOMe, MeOH, rt, 32%; (*viii*) Dowex 50WX8-100, MeOH, 70 °C, 94%; (*ix*) NaOMe, MeOH, rt, 99%; (*x*) Dowex 50WX8-100, MeOH, 70 °C, 79%.

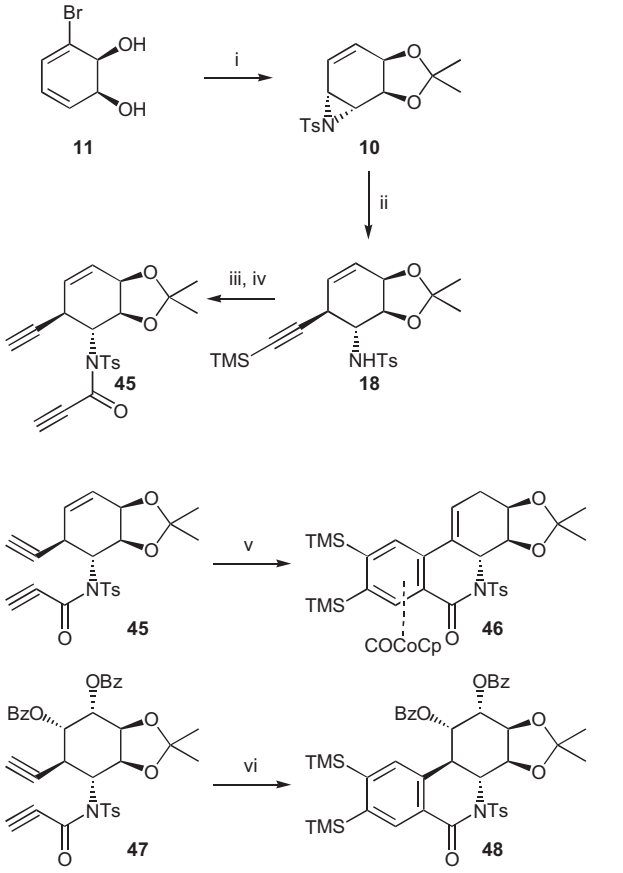


deoxypancratistatin. Based on the surprising and promising results of biological activity, it now seems prudent to proceed further with the preparation of diversely functionalized analogs of Amaryllidaceae constituents.

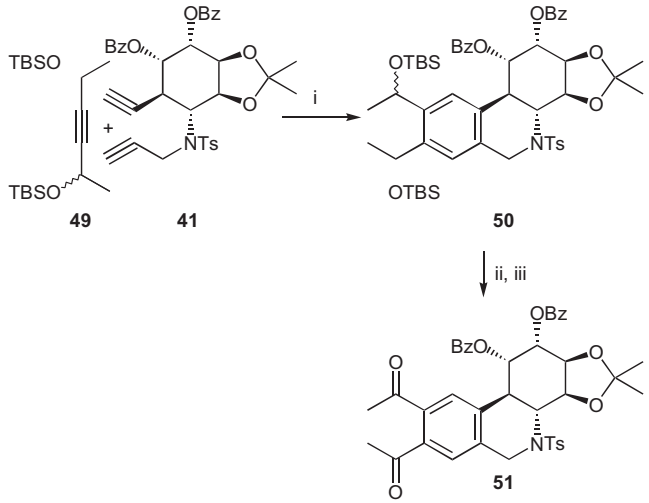
Experimental section

All nonaqueous reactions were conducted in an argon atmosphere using standard Schlenk techniques for the exclusion of moisture and air. Methylene chloride was distilled from calcium hydride; THF and toluene were dried over potassium/benzophenone. Analytical thin-layer chromatography was performed on Silicycle 60 Å 250 μm TLC plates with F-254 indicator. Flash column chromatography was performed using silica gel 60 (230–400 mesh). Melting points were recorded on a Hoover Unimelt apparatus and are uncorrected. IR spectra were obtained on a PerkinElmer One FT-IR spectrometer. Optical rotation was measured on a PerkinElmer 341 polarimeter at a wavelength of 589 nm. ^1H and ^{13}C NMR spectra were recorded on a 300 MHz Brucker spectrometer. All chemical shifts are referenced to TMS or residual undeuterated solvent ($CHCl_3$). The data for the proton spectra are reported as follows: chemical shift (multiplicity, singlet (s), doublet (d), triplet (t), quartet (q), and multiplet (m), coupling constants (Hz), integration). Carbon spectra were recorded with complete proton decoupling and the chemical shifts are reported in ppm (δ) relative to solvent resonance as internal standard. Combustion analysis were performed by Chemisar Laboratories Inc., Guelph, Ontario. Mass spectra and high-resolution mass spectra were performed by the analytical division at Brock University, St. Catharines, Ontario.

_N_-[(1_R_,2_R_,5_R_,6_S_)-2-(2-Trimethylsilylethynyl)-5,6-(isopropylidenedioxy)cyclohex-3-en-1-yl]-4-methylbenzenesulfonamide (18)



$C_{21}H_{29}NO_4SSi$
419.61 g/mol



To a solution of of (trimethylsilyl)acetylene (2.75 g, 28.00 mmol) in 40 mL toluene was added BuLi (1.6 mol/L, 17.50 mL, 28.00 mmol) at 0 °C. During the addition, a heavy white precipitate formed. The reaction mixture was stirred at 0 °C for 10 min before $AlCl_3$ (1.24 g, 9.33 mmol) was added. After stirring for a further 10 min, aziridine **10** (1.00 g, 3.11 mmol), dissolved in 5 mL toluene, was added dropwise. Additional $AlCl_3$ (622 mg, 4.67 mmol) was added and the suspension was allowed to warm to room temperature over 18 h. The reaction was quenched by addition of 1 mol/L HCl (100 mL) and diluted with ethyl acetate (50 mL). The layers were separated and the aqueous layer was extracted with ethyl acetate (3 × 50 mL). The combined organic layers were washed with brine (40 mL), dried over

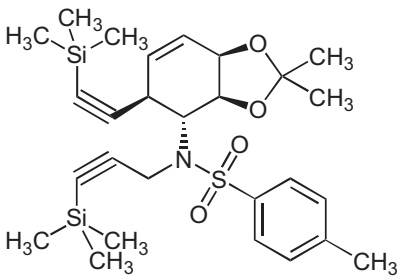
Scheme 6. Propargyl amide series. Reagents and conditions: (*i*) DMP, *p*-TSA, acetone, rt, then PhINTs, $Cu(acac)_2$, H_3CCN, 0 °C to rt, then *n*-Bu_3SnH, AIBN, THF, reflux, 25% over three steps; (*ii*) BuLi, TMS–acetylene, $AlCl_3$, toluene, 0 °C to rt, then DMP, *p*-TSA, acetone, rt, 69% over two steps; (*iii*) BuLi, propiolic acid anhydride, THF, 0 °C to rt, 46%; (*iv*) TBAT, H_3CCN, rt, 61%; (*v*) $CpCo(CO)_2$, BTMSA, xylene, 140 °C, 11%; (*vi*) $CpCo(CO)_2$, BTMSA, xylene, 140 °C, 5%.



Scheme 7. Bisketone approach. Reagents and conditions: (*i*) $CpCo(CO)_2$, xylene, 140 °C, 31%; (*ii*) TBAF, THF, rt, 72%; (*iii*) IBX, DMSO, rt, 71%.

$MgSO_4$, and the solvent was removed under reduced pressure. Flash column chromatography of the residue (hexanes – ethyl acetate, 2:1 to 1:2) afforded the title compound and the corresponding free diol. The diol was dissolved in 40 mL of acetone and protected by addition of 2,2-dimethoxypropane (486 mg, 4.67 mmol) and *p*-TSA (0.2 g). After 15 min the solution was diluted with ethyl acetate (200 mL), washed with satd. aq. $NaHCO_3$ (3 × 40 mL) and brine (40 mL). The organic phase was dried over $MgSO_4$ and the solvent was removed under reduced pressure affording 900 mg of pure acetonide **18** (2.14 mmol, 69%); mp 168 °C. $[\alpha]^{21}_D$ +30.2 (*c* 0.20, CH_2Cl_2). R_f 0.48 (hexanes – ethyl acetate, 2:1). IR ($CHCl_3$, cm^{-1}) ν: 3269, 3020, 2401, 2176, 1600, 1427, 1375, 1330, 1251, 1216, 1159, 1094, 1075, 972, 928, 846, 759, 669. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.83 (d, *J* = 8.0 Hz, 2H), 7.26 (d, *J* = 7.5 Hz, 2H), 5.83 (m, 2H), 4.63 (d, *J* = 8.0 Hz, 1H), 4.50 (m, 1H), 4.05 (dd, *J* = 8.5, 6.1 Hz, 1H), 3.60 (q, *J* = 8.3 Hz, 1H), 3.14 (d, *J* = 8.4 Hz, 1H), 2.41 (s, 3H), 1.34 (s, 3H), 1.26 (s, 3H), 0.14 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 143.2, 138.9, 130.4, 129.4, 127.5, 124.6, 110.1, 103.5, 87.9, 76.5, 71.8, 56.8, 34.6, 27.9, 25.9, 21.6, 0.0. To a solution of diol **24** (150 mg, 0.33 mmol) in 5 mL dry

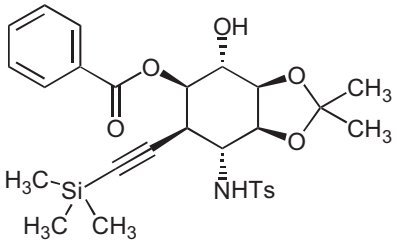
$C_{21}H_{29}NO_8S_2Si$
515.67 g/mol



CH_2Cl_2 was added triethylamine (0.37 mL, 2.65 mmol) at 0 °C. The solution was stirred for 10 min and SO_2Cl_2 (0.99 mL, 1.0 mol/L solution, 0.99 mmol) was added dropwise. After the addition, the solution was allowed to warm to room temperature and was stirred for 3 h. Further addition of triethylamine (0.37 mL, 2.65 mmol) and SO_2Cl_2 (0.99 mL, 1.0 mol/L solution, 0.99 mmol) led to total consumption of the starting material (2 h). The reaction mixture was diluted with CH_2Cl_2 (30 mL) and extracted with water (2 × 10 mL). The organic phase was dried over Na_2SO_4, filtered, and the solvent was removed under reduced pressure. Purification by flash column chromatography (hexanes – ethyl acetate, 2:1) afforded cyclic sulfate **25** (140 mg, 0.27 mmol, 82%); mp 169 °C. $[\alpha]^{26}_D$ –51.5 (*c* 1.40, $CHCl_3$). $C_{35}H_{33}NO_8S$
627.70 g/mol

To a solution of TMS-protected acetylene **40** (976 mg, 1.48 mmol) in dry acetonitrile (35 mL) was added TBAT (1.19 g, 2.21 mmol). The reaction mixture was stirred at room temperature for 1.5 h, quenched with satd. aq. NH_4Cl (50 mL), and extracted with ethyl acetate (3 × 50 mL). The combined organic phases were dried over Na_2SO_4 and evaporated at reduced pressure. Column chromatography (hexanes – ethyl acetate, 4:1 to 2:1) afforded unprotected acetylene (664 mg, 1.13 mmol, 76%) as white crystals. To these crystals (418 mg,0.71 mmol) dissolved in THF (2 mL) was added NaHMDS (1.0 mol/L, 0.85 mL, 0.85 mmol) at –70 °C under argon. The reaction mixture was allowed to warm up to 0 °C over a period of 20 min and was further stirred for 10 min at this temperature. Propargyl bromide (422 mg, 3.54 mmol) and $(n\text{Bu})_4NI$ (262 mg, 0.71 mmol) were added and the solution was allowed to warm to room temperature overnight. The reaction was quenched by addition of satd. aq. NH_4Cl (40 mL) and extracted with ethyl acetate (4 × 40 mL). The combined organic phases were washed with brine (20 mL), dried over $MgSO_4$, and the solvent was removed under reduced pressure. Flash column chromatography of the residue (hexanes – ethyl acetate, 3:2) afforded tosylamide **41** (419 mg, 0.67 mmol, 94%; 71% over two steps) as crystalline foam ; mp 86 °C. $[\alpha]^{23}_D$ –99.0 (*c* 1.40, CH_2Cl_2). R_f 0.29 (hexanes – ethyl acetate, 3:1). IR (CH_2Cl_2, cm^{-1}) ν: 3300, 3064, 2988, 2939, 2593, 2126, 1918, 1732, 1602, 1586, 1494, 1452, 1386, 1374, 1352,

$C_{21}H_{21}NO_5S$
399 46 g/mol

To a solution of acetonide **18** (250 mg, 0.60 mmol) in THF (5 mL) was added BuLi (1.6 mol/L, 0.41 mL, 0.66 mmol) at 0 °C under argon. Propiolic acid anhydride (87 mg, 0.72 mmol) was added and the solution was allowed to warm to room temperature overnight. The reaction was quenched by addition of satd. aq. NH_4Cl (20 mL) and the aqueous phase extracted with ethyl acetate (4 × 20 mL). The combined organic phases were washed with brine (10 mL), dried over $MgSO_4$, and the solvent was removed under reduced pressure. Flash column chromatography of the residue (hexanes – ethyl acetate, 3:1) afforded a bisacetylene (128 mg, 0.27 mmol, 46%) as a slightly yellow foam. To a solution of this bisacetylene (150 mg, 0.32 mmol) in acetonitrile (5 mL) was added TBAT (340 mg, 0.63 mmol). The reaction mixture was stirred at room temperature for 30 h, then diluted with 30 mL ethyl acetate, and washed with satd. aq. NH_4Cl (3 × 10 mL) and with brine (10 mL). The organic phase was dried over $MgSO_4$ and the solvent was removed under reduced pressure. Flash column chromatography of the residue (hexanes – ethyl acetate, 3:1) afforded the bisacetylene **45** (77 mg, 0.19 mmol, 61%) as a colorless oil. $[\alpha]^{21}_D$ +30.3 (*c* 0.25, CH_2Cl_2). R_f 0.40 (hexanes – ethyl acetate, 3:1). (3a*S*,4*S*,5*S*,6*R*,7*R*,7a*S*)-6-(1-Ethynyl)-2,2-dimethyl-7-[4-methylphenyl(propioloyl)sulfonamido]-4,5-di(phenylcarbonyloxy)perhydro-1,3-benzodioxole (47)

To a solution of TMS-protected acetylene **40** (976 mg, 1.48 mmol) in dry acetonitrile (35 mL) was added TBAT (1.19 g, 2.21 mmol). The reaction mixture was stirred at room temperature for 1.5 h, quenched with satd. aq. NH_4Cl (50 mL), and extracted with ethyl acetate (3 × 50 mL). The combined organic phases were dried over Na_2SO_4 and evaporated under reduced pressure. Column chromatography (hexanes – ethyl acetate, 4:1 to 2:1) afforded unprotected acetylene (664 mg, 1.13 mmol, 76%) as white crystals. To a solution of this material (210 mg, 0.36 mmol) in THF (6 mL) was added NaHMDS (1.0 mol/L, 0.43 mL, 0.43 mmol) at –70 °C under argon. The reaction mixture was allowed to warm to 0 °C over a period of 20 min and was further stirred for 10 min at this temperature. Propiolic acid anhydride (130 mg, 1.07 mmol) was added and the solution was allowed to warm to room temperature overnight. The reaction was quenched by addition of satd. aq. NH_4Cl (20 mL) and the aqueous phase extracted with ethyl acetate (4 × 20 mL). The combined organic phases were washed with brine (10 mL), dried over $MgSO_4$, and the solvent was removed under reduced pressure. Flash column chromatography of the residue (hexanes – ethyl acetate, 3:2) afforded an unseparable 3:2 rotamer mixture of tosylamide **47** (128 mg, 0.27 mmol, 46%) as oily white crystals; mp 121 °C. $[\alpha]^{23}_D$ –124.6 (*c* 1.05, CH_2Cl_2). $C_{41}H_{39}NO_{10}S$
737.82 g/mol

To a solution of 2,5-di(*tert*-butyldimethylsilyloxy)-3-hexyne (1.00 g) in $CpCo(CO)_2$ (5 μL), bisacetylene **41** (108 mg, 0.17 mmol) and $CpCo(CO)_2$ (5 μL) dissolved in xylene (5 mL) were added dropwise with a syringe pump at 140 °C over 30 h. During and after this slow addition, extra catalyst was added directly into the reaction mixture in aliquots: 5 μL after 5, 17, 29, and 41 h. The reaction mixture was heated under argon for a further 12 h. Xylene was removed at high vacuum and the residue was purified by column chromatography (hexanes – ethyl acetate, 9:1 to 6:1). All four diastereoisomers of the cyclotrimerized product **50** were isolated as crystalline foam in 31% overall yield (52 mg, 0.05 mmol). MS (EI) *m*/*z* (relative intensity): 954 ($M^+ - CH_3$, 0.1), 912 (10), 526 (12), 253 (12), 179 (12), 147 (11), 106 (12), 105 (100), 91 (16), 77 (17), 75 (27), 73 (33).

The mixture of diastereoisomers was dissolved in THF (0.5 mL), treated with TBAF (1.0 mol/L solution in THF, 0.55 mL) and stirred for 2 h. The reaction mixture was quenched with satd. NH_4Cl solution and extracted three times with diethyl ether. The combined organic phases were dried over $MgSO_4$, filtered, and evaporated to dryness. Column chromatography (hexanes – ethyl acetate, 1:2) gave a mixture of four diastereomeric diols (29 mg, 0.04 mmol, 72%), used immediately in the next step. IR ($CDCl_3$, cm^{-1}) ν: 3417, 3019, 2978, 2929, 2857, 1727, 1601, 1452, 1384, 1375, 1347, 1316, 1276, 1216, 1160, 1092, 1070, 1027, 758, 713, 668.

To the diastereomeric diols (17 mg, 0.02 mmol) dissolved in DMSO (1 mL) was added *o*-iodoxybenzoic acid (IBX, (75 mg, 0.28 mmol). The reaction mixture was stirred for 1 day, diluted with diethyl ether, and washed four times with water. The ether phase was dried over $MgSO_4$, filtered, and evaporated to dryness. The pure product **51** was obtained by column chromatography (ethyl ether – pentane, 2:1) as a white crystalline single diastereomer in 71% yield (12 mg, 0.02 mmol); mp 119 °C. $[\alpha]^{23}_D$ +38.6 (*c* 0.06, CH_2Cl_2). R_f 0.48 (hexanes – ethyl acetate, 1:1). IR ($CDCl_3$, cm^{-1}) ν: 3020, 2926, 2855, 1759, 1727, 1602, 1510, 1452, 1316, 1273, 1216, 1162, 1092, 1068, 1027, 933, 814, 758, 710, 667, 548. ^{1}H NMR (600 MHz, $CDCl_3$, ppm) δ: 7.89 (2m, 4H), 7.62 (d, *J* = 8.3 Hz, 2H), 7.58 (m, 1H), 7.52 (m, 1H), 7.52 (s, 1H), 7.40 (t, *J* = 7.8 Hz, 2H), 7.33 (t, *J* = 7.9 Hz, 2H), 7.15 (d, *J* = 8.1 Hz, 2H), 7.08 (s, 1H), 6.12 (dd, J_1 = 4.8 Hz, J_2 = 8.6 Hz, 1H), 5.74 (dd, J_1 = 4.7 Hz, J_2 = 7.9 Hz, 1H), 5.03 (dd, J_1 = 6.8 Hz, J_2 = 8.8 Hz, 1H), 4.73 (t, *J* = 7.4 Hz, 1H), 4.62 (d, *J* = 16.8 Hz, 1H), 4.53 (d, *J* = 16.7 Hz, 1H), 4.00 (dd, J_1 = 8.9 Hz, J_2 = 12.6 Hz, 1H), 3.43 (dd, J_1 = 8.9 Hz, J_2 = 12.6 Hz, 1H), 2.41 (s, 3 H), 2.35 (s, 3H), 2.20 (s, 3H), 1.54 (s, 3H), 1.36 (s, 3H). ^{13}C NMR (150 MHz, $CDCl_3$, ppm) δ: 201.7, 200.0, 165.4, 165.3, 143.8, 139.3, 138.6, 137.7, 137.4, 136.4, 133.8, 133.5, 129.8, 129.8, 129.4, 128.6, 128.4, 127.5, 126.2, 125.1, 110.8, 96.1, 76.2, 74.1, 70.1, 69.8, 59.4, 48.5, 39.6, 30.3, 29.2, 27.8, 27.7, 25.4, 21.5. Novel electrophilic ipso acylation – detosylation reaction of pyrroles[1]

Erin T. Pelkey and Gordon W. Gribble

Abstract: A pyrrole and two pyrroloindoles that are substituted with a *p*-toluenesulfonyl group undergo an ipso acylation – detosylation reaction with acid chlorides and aluminum chloride to afford the corresponding acyl-substituted pyrroles and pyrroloindoles.

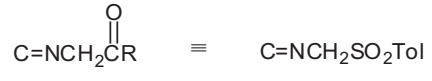
Key words: pyrrole, pyrroloindole, ipso acylation, detosylation, Friedel–Crafts reaction.

Résumé : Sous l'action de chlorures d'acides et de chlorure d'aluminium, un pyrrole et deux pyrroindoles substitués par un groupe *p*-toluènesulfonyle subissent des réactions d'acétylation-détosylation ipso qui conduisent à la formation des pyrroles et pyrroindoles correspondants substitués par un groupe acyle.

Mots clés : pyrrole, pyrroindole, acétylation ipso, détosylation, réaction de Friedel–Crafts.

[Traduit par la Rédaction]

Introduction



Whereas electrophilic ipso substitution (1) of aromatic and heteroaromatic compounds, including organosilanes (2), organostannanes (3), and several other substrates (4), is well-documented, there appear to be no examples of organosulfones undergoing electrophilic ipso substitution. For example, treatment of 3-phenyl-4-(*p*-toluenesulfonyl)furan with acetyl chloride and $AlCl_3$ gives only the expected electrophilic product, 2-acetyl-3-phenyl-4-(*p*-toluenesulfonyl)furan (5). On the other hand, free radical ipso stannylation – detosylation reactions of 1-(phenylsulfonyl)-2-(*p*-toluenesulfonyl) indole and related heterocycles have been described (6).

Results and discussion

In connection with our interest in the closely related Barton–Zard (7), van Leusen (8), and Montforts (9) syntheses of pyrroles (10), we had occasion to examine the Friedel–Crafts acylation of 4-ethyl-2-(*p*-toluenesulfonyl)pyrrole (**4**). This compound was readily prepared by treating either 2-nitrobutyl acetate (**1**) (11) or 2-nitro-1-butene (**2**) (12) with TosMIC (**3**) (13) and DBU in the presence of isopropanol Scheme 1). Treatment of **4** with acetyl chloride in the presence of aluminum chloride affords 2-acetyl-4-ethylpyrrole (**5**) and not the expected 2-acetyl-3-ethyl-5-(*p*-toluenesulfonyl)pyrrole (**6**). The characteristic odor of *p*-toluenesulfonyl chloride (**7**) in the reaction mixture was indicative of this novel transformation. To confirm the regiochemistry of **5**, we synthesized 2-acetyl-3-ethylpyrrole (**8**) by hydrolysis (K_2CO_3, MeOH, reflux, 78%) of the known 2-acetyl-3-ethyl-1-(phenylsulfonyl)pyrrole (14). Direct comparison of these two pyrroles reveals that the product of the acetylation of **4** was clearly **5** and not **8**. We view this ipso acylation – detosylation reaction as involving ipso electrophilic attack at C-5 in **4** followed by chloride attack on the sulfonyl group to give *p*-toluenesulfonyl chloride and pyrrole **5**.

This ipso acylation – detosylation was extended to the synthesis of acylated pyrroloindoles (Scheme 2). Thus, treatment of pyrrolo[2,3-*b*]indole **10** and pyrrolo[3,4-*b*]indole **13** with acetyl chloride and valeryl chloride in the presence of aluminum chloride affords the acylated analogues **11** and **14**, respectively. Pyrroloindoles **10** and **13** were synthesized with TosMIC from indoles **9** and **12**, respectively, according to our earlier method (10).

In summary, we have discovered a novel electrophilic ipso acylation – detosylation reaction of α-tosylpyrroles. In the context of van Leusen and Barton–Zard pyrrole syntheses, the reagent TosMIC (**3**) can be viewed as a synthetic equivalent for α-isocyanoketones (**15**). Compounds related to **15** have previously been generated from α-metalated oxazoles (15), but they have not been employed in these pyrrole ring syntheses.

Scheme 2.

Experimental

Melting points were determined using open capillary tubes and are uncorrected. Thin-layer chromatography (TLC) was performed on regular TLC plates. Visualization of developed plates was achieved with a 254 nm UV lamp and (or) with iodine. Flash chromatography utilized 230–400 mesh silica gel 60. ^{1}H NMR and ^{13}C NMR were run at 300 and 75 MHz, respectively. Chemical shifts (δ) are reported in ppm using the solvent residual proton or carbon signal ($CDCl_3$: H, 7.27, C, 77.23) as an internal reference. The apparent multiplicity (singlet (s), doublet (d), triplet (t), quartet (q), septet (sept), multiplet (m), broad (br)), number of protons, and coupling constants (in Hz) are reported in that order in parenthesis after the chemical shift. Infrared spectra (IR) are reported in reciprocal centimeters and were obtained using neat compounds (neat), solid KBr pellets (KBr), polyethylene IR cards (PE), or polytetrafluoroethylene IR cards (PTFE). High-resolution mass spectrometry (HRMS) was performed at the University of Illinois (Urbana-Champaign, Illinois) mass spectrometry laboratory or by the SOCAL Mass Spectrometry Facility at the University of California (Riverside, California). Elemental analyses were performed by Atlantic Microlabs, Inc. (Norcross, Georgia). Tetrahydrofuran (THF) and diethyl ether (ether) were distilled from sodium-benzophenone ketyl. Diisopropylamine, dichloromethane, xylenes, and triethylamine were distilled from calcium hydride. Acetyl chloride, hexanoyl chloride, trimethylsilyl chloride, and valeryl chloride were distilled from 0.1% quinoline. Unless otherwise indicated, all other reagents and solvents were purchased from commercial sources and were used without further purification. All reactions were performed under a positive nitrogen atmosphere with magnetic stirring unless otherwise noted. All glassware was oven-dried at >130 °C and allowed to cool in a desiccator (Drierite®) before assembly under positive nitrogen.

2-Nitro-1-butanol

A modification of a literature procedure was utilized (11). To a 0 °C stirred solution of sodium hydroxide (4.20 g, 105 mmol) dissolved in distilled water (40 mL) was added 1-nitropropane (8.91 g, 100 mmol) dropwise. The reaction mixture was stirred at 0 °C for 30 min and then at room temperature (rt) for 1 h. Upon recooling to 0 °C, the reaction mixture was treated with an aqueous solution of formalin

© 2006 NRC Canada

(37%, 8.52 g, 105 mmol) dropwise via addition funnel over 10 min and then the reaction mixture was stirred at rt for 7 h. Upon recooling to 0 °C, the reaction mixture was treated with acetic acid (6.60 g, 110 mmol) dropwise and stirred for 3 h. The aqueous solution was extracted with ether (5 × 50 mL) and the combined organic extracts were washed with brine (200 mL) and dried over sodium sulfate. Removal of the solvent in vacuo gave a yellow oil (20 g) that was purified by vacuum distillation through a Vigreux column. The desired product was obtained as a colorless oil. Yield: 6.57 g, 55.1 mmol, 55%; bp 124 to 125 °C at 10 Torr (1 Torr = 133.322 4 Pa) (lit. value (11) bp 90–92 °C at 3 Torr). ^{1}H NMR ($CDCl_3$) δ: 4.51–4.59 (m, 1H) 3.89–4.10 (m, 2H), 1.81–2.06 (m, 3H), 1.02 (t, J = 7.2 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 90.8, 63.1, 23.5, 10.4.

2-Nitrobutyl acetate (1)

A modification of the literature procedure for synthesizing β-nitroacetates was utilized (16). To a 0 °C stirred solution of 2-nitro-1-butanol (5.59 g, 47.0 mmol) dissolved in CH_2Cl_2 (50 mL) was added acetic anhydride (5.72 g, 56.0 mmol) followed by *p*-toluenesulfonic acid monohydrate (380 mg, 2.0 mmol). The reaction mixture was stirred at 0 °C and then at rt for 8 h. Removal of the solvent in vacuo gave a residue (10 g) that was purified by vacuum distillation through a Vigreux column. The desired product **1** was obtained as a light yellow oil. Yield: 6.57 g, 40.1 mmol, 86%; bp 88 to 89 °C at 4 Torr (lit. value (11) bp 70–72 °C at 2 Torr). ^{1}H NMR ($CDCl_3$) δ: 4.62–4.69 (m, 1H), 4.41–4.43 (m, 2H), 2.07 (s, 3H), 1.80–2.06 (m, 2H), 1.03 (t, J = 7.2 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.5, 87.8, 63.8, 23.9, 20.8, 10.2.

2-Nitro-1-butene (2) (Caution: Lachrymator and foul smelling)

A modification of the literature procedure for the synthesis of 2-nitropropene was utilized (17). A round-bottomed flask (100 mL) fitted with a Vigreux column and short-path distillation apparatus was charged with 2-nitro-1-butanol (11.9 g, 0.100 mol) and phthalic anhydride (29.6 g, 0.200 mol) and was partially evacuated (under water aspirator pressure). The reaction mixture was heated in an oil bath to 150 °C for 30 min and then to 200 °C. The desired product **2** distilled over with water into an ice-cooled receiving flask. The aqueous layer was separated and the organic layer was dried over sodium sulfate. The desired product **2** was obtained as a blue-green oil. Yield: 4.48 g, 0.0443 mol, 44%; bp 76–84 °C at 40 Torr (lit. value (12) bp 108 °C at 61 Torr). IR (neat, cm^{-1}) υ_{max}: 3132, 2980, 2942, 2882, 1524, 1465, 1436, 1347, 1258. ^{1}H NMR ($CDCl_3$) δ: 6.44 (s, 1H), 5.55 (s, 1H), 2.64 (q, J = 7.2 Hz, 2H,), 1.18 (t, J = 7.2 Hz, 3H,). ^{13}C NMR ($CDCl_3$) δ: 159.8, 116.3, 23.6, 11.8.

4-Ethyl-2-(*p*-toluenesulfonyl)pyrrole (4)

To a rt stirred solution of 2-nitro-1-butene (**2**) (202 mg, 2.00 mmol) and tosylmethyl isocyanide (**3**) (586 mg, 3.00 mmol) dissolved in THF (3 mL) and 2-propanol (3 mL) was added a solution of DBU (457 mg, 3.00 mmol) dissolved in THF (3 mL) and 2-propanol (3 mL). The reaction mixture was stirred at rt for 20 h. Removal of the solvent in vacuo gave a brown oil (1.8 g) that was purified by flash chromatography (hexanes; CH_2Cl_2–hexanes, 1:1; CH_2Cl_2–hexanes, 3:1). After eluting a brightly colored yellow impurity (R_f 0.38; CH_2Cl_2–hexanes, 3:1), the desired product **4** was obtained as a yellow amorphous solid. Yield: 372 mg, 80% pure by ^{1}H NMR, 1.25 mmol, 63% yield based on NMR integration. Recrystallization (CH_2Cl_2–hexanes, 1:4) gave **4** as off-white needles; mp 94 to 95 °C. R_f 0.15 (CH_2Cl_2–hexanes, 3:1). IR (PTFE, cm^{-1}) υ_{max}: 3306 (NH), 2964, 2924, 2872, 1595, 1494, 1440, 1379, 1301, 1202, 1146. ^{1}H NMR ($CDCl_3$) δ: 8.90 (br s, 1H), 7.80–7.83 (m, 2H), 7.26 (m, 2H), 6.70–6.75 (m, 2 H), 2.45 (q, 2H, J = 7.5 Hz), 2.39 (s, 3H), 1.15 (t, 3H, J = 7.5 Hz). ^{13}C NMR ($CDCl_3$) δ: 143.9, 139.9, 130.0, 129.0, 127.7, 127.0, 121.1, 114.8, 21.7, 20.0, 15.0. MS *m*/*z* (%): 250 (M^+ + 1), 249 (M^+), 234 (100%), 184, 170, 142, 127, 110, 91, 78, 65. Anal. calcd. for $C_{13}H_{15}NO_2S$: C 62.63, H 6.06, N 5.62, S 12.83; found: C 62.57, H 6.05, N 5.56, S 12.95.

2-Acetyl-4-ethylpyrrole (5)

To a 0 °C stirred suspension of aluminum chloride (333 mg, 2.50 mmol) in CH_2Cl_2 (5 mL) was added freshly distilled (from quinoline) acetyl chloride (79 mg, 1.00 mmol) and the mixture was stirred for 15 min and then treated with a solution of 4-ethyl-2-(*p*-toluenesulfonyl)pyrrole (**4**) (125 mg, 0.500 mmol) dissolved in CH_2Cl_2 (5 mL) dropwise. The reaction mixture was stirred at 0 °C for 1 h and then was poured onto ice (20 g). The organic layer was separated and the aqueous layer was extracted with CH_2Cl_2 (3 × 20 mL). The combined organic extracts were washed with brine (60 mL) and dried over sodium sulfate. Removal of the solvent in vacuo gave an orange oil (0.3 g) that was purified by flash chromatography (hexanes; CH_2Cl_2). The title compound **5** was obtained as a yellow oil. Yield: 44 mg, 0.32 mmol, 64%. R_f 0.16 (CH_2Cl_2–EtOAc, 10:1). UV (EtOH) λ_{max} (nm): 208, 250, 302. IR (PTFE, cm^{-1}) υ_{max}: 3257 (NH), 2960, 2920, 2851, 1633 (C=O), 1568, 1479, 1432, 1397, 1322. ^{1}H NMR ($CDCl_3$) δ: 9.82 (br s, 1H), 6.77–6.87 (m, 2H), 2.52 (q, 2H, J = 7.5 Hz), 2.42 (s, 3H), 1.17–1.26 (m, 3H). ^{13}C NMR ($CDCl_3$) δ: 188.1, 132.0, 128.6, 122.8, 116.5, 25.5, 20.0, 15.4. MS *m*/*z* (%): 138 (M^+ + 1), 137 (M^+), 122 (100%), 104, 94, 77, 67. HRMS *m*/*z* calcd. for $C_8H_{11}NO$: 137.0841 (M^+); found: 137.0841.

2-Acetyl-3-ethylpyrrole (8)

To a rt stirred solution of 3-ethyl-2-acetyl-1-(phenylsulfonyl)pyrrole (14) (83 mg, 0.30 mmol) dissolved in methanol (5 mL) was added potassium carbonate (170 mg, 1.2 mmol) and the reaction mixture was heated to reflux for 7 h and then allowed to cool to rt. Removal of the solvent in vacuo gave an orange oil (0.5 g) that was partitioned between distilled water (20 mL) and ether (20 mL). The organic layer was separated and the aqueous layer was extracted with ether (2 × 20 mL). The combined organic extracts were washed with brine (60 mL) and dried over sodium sulfate. Removal of the solvent in vacuo gave a yellow oil (40 mg) that was purified by flash chromatography (hexanes; CH_2Cl_2). The desired product **8** was obtained as a light yellow amorphous solid. Yield: 32 mg, 0.23 mmol, 78%; mp 64 to 65 °C. R_f 0.18 (CH_2Cl_2). UV (EtOH) λ_{max} (nm): 206, 292. IR (PTFE, cm^{-1}) υ_{max}: 3271 (NH), 2967, 1622 (C=O), 1532, 1478, 1407, 1325, 1201, 1136. ^{1}H NMR ($CDCl_3$) δ:

© 2006 NRC Canada

9.43 (br s, 1H), 6.92–6.94 (m, 1H), 6.17–6.19 (m, 1H), 2.82 (q, 2H, J = 7.5 Hz), 2.47 (s, 3H), 1.30 (t, 3H, J = 7.5 Hz). ^{13}C NMR ($CDCl_3$) δ: 187.9, 134.2, 123.3, 111.5, 111.4, 28.0, 21.3, 15.1. MS m/z (%): 138 (M^+ + 1), 137 (M^+), 122 (100%), 94, 80, 67. HRMS m/z calcd. for $C_8H_{11}NO$: 137.0841 (M^+); found: 137.0842.

1,8-Dihydro-4-(phenylsulfonyl)-2-(*p*-toluenesulfonyl)pyrrolo[2,3-*b*]indole (10)

To a stirred solution of 3-nitro-1-(phenylsulfonyl)indole (**9**) (18) (151 mg, 0.500 mmol) dissolved in THF (10 mL) was added a solution of tosylmethyl isocyanide (**3**) (117 mg, 0.600 mmol) dissolved in THF (5 mL) followed by neat DBU (183 mg, 1.20 mmol). The clear yellow reaction mixture was stirred at rt for 22 h. Removal of solvent in vacuo gave a crude orange oil (500 mg) that was purified by flash chromatography (hexanes; CH_2Cl_2–hexanes, 3:1; CH_2Cl_2). The desired product **10** was obtained as a white amorphous solid (150 mg). Trituration (hexanes, 2 × 5 mL) gave **10** as a gray flaky solid. Yield: 142 mg, 0.315 mmol, 63%; mp 212–214 °C (dec). Two recrystallizations (CH_2Cl_2–cyclohexane, 2:1) gave **10** as white crystals; mp 236–238 °C. R_f 0.50 (CH_2Cl_2). UV (EtOH) λ_{max} (nm): 210, 274 (sh), 300, 346 (sh). IR (KBr, cm^{-1}) υ_{max}: 3256 (NH), 2928, 1540, 1528, 1447, 1419, 1374, 1318, 1181. ^{1}H NMR ($CDCl_3$) δ: 9.78 (bs, 1H), 7.88–7.92 (m, 3H), 7.74–7.76 (m, 2H), 7.48–7.54 (m, 2H), 7.22–7.37 (m, 6H), 7.11 (d, 1H, J = 1.8 Hz), 2.41 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 144.3, 139.6, 138.5, 137.6, 136.4, 134.8, 130.2, 129.6, 128.8, 127.2, 126.9, 125.0, 124.6, 124.3, 120.1, 114.8, 113.4, 107.6, 21.8. MS m/z (%): 473.1 $(M + Na)^+$. Anal. calcd. for $C_{23}H_{18}N_2O_4S_2$: C 61.32, H 4.03, N 6.22, S 14.23; found: C 61.35, H 4.04, N 6.23, S 14.36.

2-Acetyl-1,8-dihydro-8-(phenylsulfonyl)pyrrolo[2,3-*b*]indole (11)

To a 0 °C stirred suspension of aluminum chloride in CH_2Cl_2 (5 mL) was added acetyl chloride (79 mg, 1.0 mmol) and the mixture was stirred for 15 min. The reaction mixture was treated with a solution of 1,8-dihydro-2-(*p*-toluenesulfonyl)-4-(phenylsulfonyl)pyrrolo[2,3-*b*]indole (**10**) (225 mg, 0.500 mmol) dissolved in CH_2Cl_2 (5 mL). The reaction mixture was stirred at 0 °C for 2 h and then at rt for 30 min. The reaction was poured onto ice (20 g) and extracted with CH_2Cl_2 (3 × 30 mL). The combined organic extracts were washed with a saturated aqueous solution of sodium bicarbonate (100 mL) and brine (100 mL) and dried over sodium sulfate. Removal of the solvent in vacuo gave a yellow oil (0.6 g) that was purified by flash chromatography (hexanes; CH_2Cl_2–hexanes, 1:1; CH_2Cl_2–hexanes, 3:1). The desired product **11** was obtained as a white amorphous solid. Yield: 82 mg, 0.24 mmol, 48%; mp 222–225 °C. Recrystallization (CH_2Cl_2–hexanes) gave **11** as light brown crystals; mp 230 to 231 °C. R_f 0.18 (CH_2Cl_2). UV (EtOH) λ_{max} (nm): 206, 224, 254 (sh), 332. IR (PTFE, cm^{-1}) υ_{max}: 3304 (NH), 2917, 2851, 1633, 1555, 1488, 1440, 1380, 1285, 1201, 1171. ^{1}H NMR ($CDCl_3$) δ: 9.87 (br s, 1H), 7.93–7.96 (m, 1H), 7.81–7.85 (m, 2H), 7.27–7.59 (m, 6H), 7.11 (d, 1H, J = 1.5 Hz), 2.51 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 187.9, 139.1, 139.0, 136.9, 134.7, 132.9, 129.6, 127.0, 124.9, 124.7, 124.4, 120.0, 114.9, 113.5, 108.2, 25.3. MS m/z (%): 338 (M^+), 197 (100%), 169, 155, 127, 101, 77. Anal. calcd. for $C_{18}H_{14}N_2O_3S$: C 63.89, H 4.17, N 8.28, S 9.47; found: C 64.04, H 4.07, N 8.20, S 9.34.

2-Methyl-1-propyl 2,4-dihydro-3-(*p*-toluenesulfonyl)pyrrolo[3,4-*b*]indole-4-carboxylate (13)

To a rt stirred solution of 2-methyl-1-propyl 3-nitroindole-1-carboxylate (**12**) (18) (1.84 g, 7.00 mmol) and tosylmethyl isocyanide (**3**) (1.56 g, 8.00 mmol) dissolved in THF (50 mL) was added DBU (1.22 g, 8.00 mmol) and the reaction mixture was stirred at rt for 20 h. Removal of the solvent in vacuo gave a brown oil (4 g) that was purified by flash chromatography (hexanes; CH_2Cl_2–hexanes, 3:1; CH_2Cl_2). The desired product **13** was obtained as a brown amorphous solid (615 mg, 1.50 mmol, 21%) that was purified by a second round of column chromatography (hexanes; CH_2Cl_2–hexanes, 1:1). The yellow powder thus obtained was recrystallized (CH_2Cl_2–hexanes) to give **13** as fine yellow needles; mp 177 to 178 °C. R_f 0.23 (CH_2Cl_2). UV (EtOH) λ_{max} (nm): 206, 222 (sh), 254 (sh), 278, 315 (sh), 324. IR (PTFE, cm^{-1}) υ_{max}: 3283 (NH), 2958, 1731 (C=O), 1595, 1515, 1448, 1417, 1379, 1317, 1199, 1139. ^{1}H NMR ($CDCl_3$) δ: 9.60 (br s, 1H), 8.32 (br s, 1H), 8.24–8.26 (m, 1H), 7.89 (d, 2H, J = 8.1 Hz), 7.34–7.49 (m, 2H), 7.24 (d, 2H, J = 8.1 Hz), 7.03 (br s, 1H), 4.23 (d, 2H, J = 4.8 Hz), 2.35 (s, 3H), 2.14 (br s, 1H), 1.06 (d, 6H, J = 6.6 Hz). ^{13}C NMR ($CDCl_3$) δ: 151.4, 144.2, 143.2, 139.7, 131.4, 130.1, 127.4, 126.6, 123.8, 122.8, 121.5, 120.0, 116.1, 115.5, 107.2, 73.1, 28.1, 21.7, 19.3. HRMS m/z calcd. for $C_{22}H_{22}N_2O_4S$: 410.1300 (M^+); found: 410.1294. Anal. calcd. for $C_{22}H_{22}N_2O_4S$: C 64.37, H 5.40, N 6.82, S 7.81; found: C 64.46, H 5.51, N 6.85, S 7.76.

2-Methyl-1-propyl 2,4-dihydro-3-valerylpyrrolo[3,4-*b*]-indole-4-carboxylate (14)

To a 0 °C stirred suspension of aluminum chloride (200 mg, 1.50 mmol) in CH_2Cl_2 (5 mL) was added freshly distilled (from 0.1% quinoline) valeryl chloride (72 mg, 0.60 mmol) and this was stirred for 15 min. The reaction mixture was treated with a solution of 2-methyl-1-propyl 2,4-dihydro-3-(*p*-toluenesulfonyl)pyrrolo[3,4-*b*]indole-1-carboxylate (**13**) (123 mg, 0.300 mmol) dissolved in CH_2Cl_2 (10 mL) dropwise. The reaction mixture was stirred at 0 °C for 15 min and then was poured onto ice (20 g). The aqueous solution was extracted with CH_2Cl_2 (3 × 30 mL) and the combined organic extracts were washed with a saturated aqueous solution of sodium bicarbonate (100 mL) and brine (100 mL) and dried over sodium sulfate. Removal of the solvent in vacuo gave a tan amorphous solid (0.2 g) that was purified by flash chromatography (hexanes; CH_2Cl_2–hexanes, 1:1; CH_2Cl_2–hexanes, 3:1). The desired product **14** was obtained as an off-white amorphous solid (68 mg, 0.20 mmol, 67%, mp 166–168 °C). Recrystallization (EtOAc–hexanes) gave **14** as white needles; mp 173 to 174 °C. R_f 0.48 (H_2Cl_2–MeOH, 98:2). UV (EtOH) λ_{max} (nm): 206, 233 (sh), 246 (sh), 277 (sh), 286, 311 (sh), 344 nm. IR (KBr) υ_{max} (cm^{-1}): 3236 (NH), 2956, 2870, 1728 (C=O), 1627 (C=O), 1506, 1460, 1402, 1390, 1319, 1268, 1219. ^{1}H NMR ($CDCl_3$) δ: 10.04 (br s, 1H), 8.43 (br s, 1H), 8.00–8.02 (m, 1H), 7.43–7.48 (m, 1H), 7.33–7.38 (m, 1H), 7.13 (br s, 1H), 4.27 (d, 2H, J = 6.3 Hz), 3.12 (t, 2H, J = 7.2 Hz), 2.12–2.22 (m, 1H), 1.82–1.92 (m, 2H), 1.48–1.60 (m, 2H), 1.10 (d, 6H, J =

Catalysis with palladium colloids supported in poly(acrylic acid)-grafted polyethylene and polystyrene[1]

David E. Bergbreiter, Andrew Kippenberger, and Zhenqi Zhong

Abstract: Grafts of poly(acrylic acid) on polyethylene powder (PE-*g*-PAA) or polystyrene (PS-*g*-PAA) can be used to support Pd(0) crystallites that function like a homogeneous Pd(0) catalyst in some reactions. These Pd–PE-*g*-PAA catalysts were active in allylic substitution reactions in the presence of added phosphine ligand. A catalyst analogous to the Pd–PE-*g*-PAA powder catalyst on polystyrene (Pd–PS-*g*-PAA) was similarly active for allylic substitution and could also be used in Heck reactions at 80–100 °C in *N*,*N*-dimethylacetamide (DMA). Analysis of the product solutions for Pd leachate and a correlation of the Pd leaching with product formation in the allylic substitution chemistry for both types of catalysts suggests that the active catalysts in these reactions are leached from the support. In the case of the allylic substitution reaction, external triphenylphosphine and substrate together are required for the chemistry and Pd leaching.

Key words: catalysis, palladium, allylic substitution, grafted polystyrene, supported catalysts.

Résumé : Les produits de greffage d'acide polyacrylique sur de la poudre de polyéthylène (PE-*g*-APA) ou de polystyrène (PS-*g*-APA) peuvent être utilizés comme support de cristallites de Pd(0) qui, dans certaines réactions, peuvent fonctionner comme catalyseur de Pd(0). Ces catalyseurs de Pd–PE-*g*-APA mis en présence d'un ligand phosphine sont actifs dans les réactions de substitution allylique. Un catalyseur analogue au catalyseur en poudre Pd–PE-*g*-APA sur du polystyrène (Pd–PS-*g*-APA) est aussi actif pour la réaction de substitution allylique et il peut aussi être utilizé dans les réactions de Heck, à des températures allant de 80 à 100 °C, dans le *N*,*N*-diméthylacétamide (DMA). Une analyse des solutions de produits pour rechercher la présence de Pd qui aurait été lessivé ainsi qu'une corrélation du Pd de lessivage avec la formation de produit dans la chimie de la substitution allylique pour les deux types de catalyseur suggère que les catalyseurs actifs dans ces réactions sont lessivés de leur support. Dans le cas de la réaction de substitution allylique, la présence simultanée de la triphénylphosphine externe et du substrat sont requis pour la chimie et le lessivage du Pd.

Mots clés : catalyse, palladium, substitution allylique, polystyrène greffé, catalyseurs sur un support.

[Traduit par la Rédaction]

Introduction

The use of supported heterogeneous catalysts is well-established. Palladium catalysts are among the most common examples of such species. For example, catalysts like Pd–C are widely used for hydrogenation of alkenes (1). They have the virtue of wide availability, relatively low costs for handling and preparation, and activity that is often as good or better than that of the more "novel" hydrogenation catalysts reported from time to time.

While hydrogenation is an important reaction, other palladium-catalyzed processes, such as allylic substitutions and cross-coupling chemistry, are of more current interest. A variety of palladium catalysts have been developed for these purposes (2). Some years ago we had noted that classical Pd–C catalysts, under relatively mild conditions (i.e., at reaction temperatures <100 °C) (3, 4), exhibit reactivity resembling that of the well-established homogeneous Pd catalyst, tetrakis(triphenylphosphine)palladium(0). Specifically, we found that both a supported Pd(0) species prepared from an organometallic derivative of cross-linked polystyrene (5) and simple Pd–C could effectively catalyze allylic substitution of allyl acetates by nucleophiles like secondary amines. In these cases, catalysis was most effective in the presence of a soluble phosphine with reactions sometimes occurring at room temperature.

The importance of new sorts of catalysts, including adventitiously formed or designed colloidal metal catalysts for various catalytic reactions including cross-coupling reactions, has recently received increased attention (6–11). For example, we and others have noted the exceptional reactivity of Pd(0) colloidal catalysts, presumably generated in situ from Pd(II) palladacycle compounds during cross-coupling chemistry (12–17). These studies suggest that further explo-

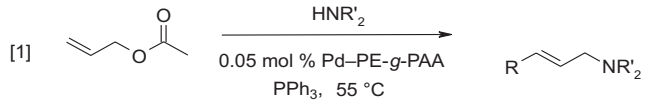
ration of ways to support and use Pd colloids merit attention. Our studies of these putative Pd colloids formed from SCS–Pd(II) precursors noted that those species were more soluble in polar phases than in nonpolar phases (14). Since we recently developed some new sorts of immobilized polar poly(acrylic acid) graft phases on polyethylene powders and on DVB cross-linked polystyrene resins, we have sought to explore these supported phases as supports for catalytically active Pd colloids. We have shown that Pd colloids formed and supported in these poly(acrylic acid) phases are active catalysts. While they are competent catalysts for hydrogenations, their activity is not significantly different then the more readily available and simpler Pd–C catalysts in hydrogenation catalysis.

While catalytic activity, especially reactivity in a reaction as simple as alkene hydrogenation, is often easy to demonstrate and assay, the identity of the actual species that leads to catalysis is not always clear. Indeed, it can even be difficult to determine whether the actual catalyst is soluble or insoluble (18). Such issues are even more complex when the chemistry is carried out with supported palladium colloids. For example, while we assumed a soluble Pd species was generated in our earlier studies (3, 4), a three-phase test using a polymer-supported Pd species (a soluble phosphine) and a second polymer-supported substrate failed to detect a soluble catalyst. We rationalized this result at the time on the basis that the actual phosphine-ligated Pd colloidal catalyst could still be present but could be unreactive to a second insoluble supported substrate (3). More recent work from several laboratories using various procedures, including Rebek's three-phase test (19), has been more successful in showing that homogeneous catalysts are responsible for the catalysis seen in other systems with "heterogeneous" catalysts (12, 19–24).



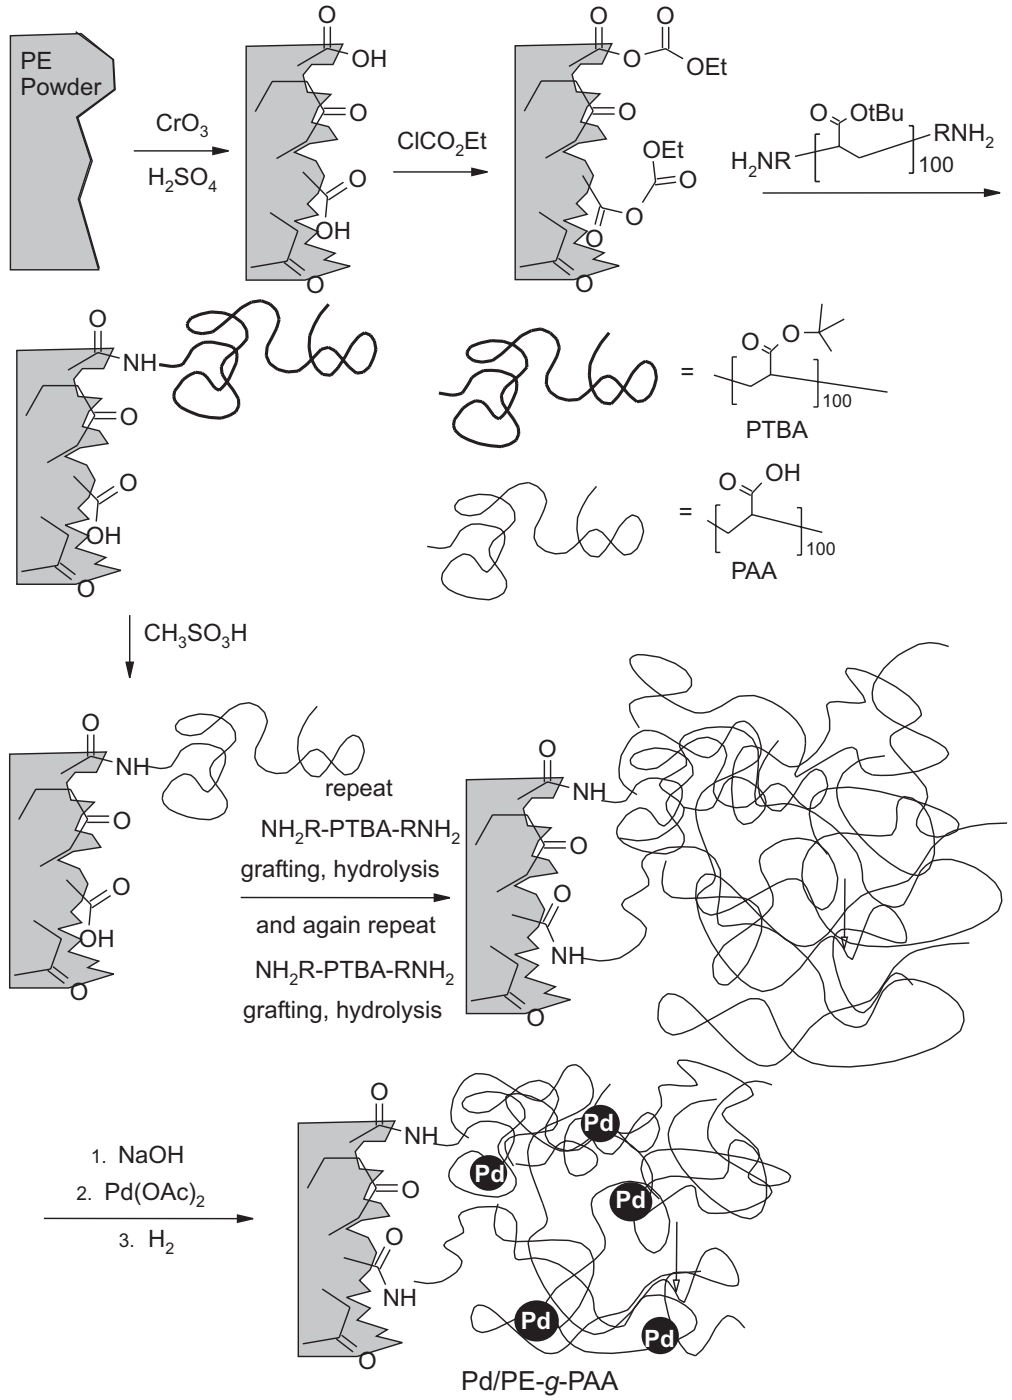
Here we describe work where we have shown that the Pd colloids in poly(acrylic acid) grafted polystyrene, which we used previously in hydrogenation reactions, are active in Heck catalysis and also in allylic substitution chemistry. While the analogous polyethylene-supported catalysts cannot be used in Heck chemistry (the required temperatures are incompatible with the underlying polymer), the polyethylene-bound catalysts exhibit Pd(0)-like reactivity in allylic substitutions of allylic acetates and amines. While we did not achieve the sort of notable reactivity we and others have seen in other putative Pd colloidal catalysts (12–17), we have been able to show that, in the case of these Pd colloids in a grafted polystyrene matrix or supported on polyethylene powder, Pd leaching is associated with the observed Pd(0)-like chemistry. The simplest explanation for these results is that soluble phosphine-free (Heck catalysis) or phosphine-ligated Pd species (allylic substitutions), derived from the interfacially supported Pd colloids in both the poly(acrylic acid)-grafted polyethylene powder and the poly(acrylic acid)-grafted DVB cross-linked polystyrene resin, are the active catalysts.

Results and discussion

We recently described several sorts of supported palladium catalysts using a poly(acrylic acid) graft on polyethylene powder (PE-*g*-PAA) or a poly(acrylic acid) graft within DVB cross-linked polystyrene beads (PS-*g*-PAA) as supports (19, 20, 25). Such colloidal catalysts have precedent both in our earlier work with polystyrene-supported palladium colloids (3, 4) and in other reports where supported thin films or inorganic matrices support analogs of homogeneous catalysts (3, 4, 8, 26–31).

The synthesis and characterization of both the PE-*g*-PAA and PS-*g*-PAA supports and catalysts were previously described, and the syntheses of these catalysts are summarized in Schemes 1 and 2. As shown in both schemes, the formation of a PE-*g*-PAA or a PS-*g*-PAA supported Pd colloid involved ion exchange of palladium acetate onto a PE- or PS-bound carboxylate group with subsequent reduction of the Pd(II) carboxylate ionically attached to the polymer graft. The Pd–PE-*g*-PAA and Pd–PS-*g*-PAA catalysts contained about 0.01 or 1.1 mmol of Pd per gram of support, respectively, based on digestion of the polymers and analysis of the residue for Pd by ICP metal analysis. In the case of the Pd–PE-*g*-PAA catalyst, imaging of the catalyst by XPS spectroscopy showed that the Pd colloids were distributed throughout a 50–100 μm region on the surface of the powder (Fig. 1). In the case of the Pd–PS-*g*-PAA, the Pd colloidal particles were mostly within the polystyrene bead.

The use of the Pd–PE-*g*-PAA and Pd–PS-*g*-PAA catalysts for catalytic hydrogenation reactions were described previously (19, 20). Both catalysts were found to be fully recyclable and no Pd leachate was detected in those studies. Of more interest in this study was that these catalysts also catalyze some Pd(0)-like reactions. Specifically, the PE-bound Pd colloids were effective in promoting allylic substitution reactions between secondary amines and allyl acetate (eq. [1]). Such reactions were not successful if no added phosphine was present in solution, but were successful in the presence of 5 mol% added triphenylphosphine (Table 1).



The reactivity in the presence of added phosphine ligands of the Pd–PE-*g*-PAA catalyst could be due to activation of the Pd colloids within the polymer matrix by the added triphenylphosphine. Alternatively, formation of tetrakis(triphenylphosphine)palladium or formation of some less-defined soluble phosphine-ligated Pd(0) species could explain the observed chemistry. As noted above, we had previously been unsuccessful at using a three-phase test to detect such soluble intermediates in a related system (3). Here we used several other approaches that together provide convincing evidence that a soluble Pd species is formed in these catalytic reactions.

To ascertain the origin of the catalysis, several experiments were performed. First, XPS analysis of Pd crystallites in a hyperbranched graft of Pd–PE-*g*-PAA showed a Pd $3d^{3/2}$ peak at 333.3 eV. This peak was discernibly different than the peak for a previously described immobilized molecular catalyst — a Pd(0) complex prepared using the same polymer that had been further modified to contain aminodiphenylphosphinopropyl ligands (i.e., Pd(0)-DPPA–PE-*g*-PAA; DPPA is diphenylphosphinopropylamide containing a phosphine ligand that was covalently coupled to poly(acrylic

Scheme 1. Synthesis of Pd–PE-*g*-PAA catalysts.

acid)-grafted PE via an amide bond) (25). No evidence was obtained for the presence of phosphine in the recovered PE support after a reaction, suggesting that added phosphine was not sorbed into the resin. Catalysts analogous to the Pd–PE-*g*-PAA could also be prepared by deliberate oxidation of the phosphine ligands in a Pd(0)-DPPA–PE-*g*-PAA catalyst — a process that converted the light yellow Pd(0)-DPPA–PE-*g*-PAA powder into a grey powder and produced a new peak for oxidized phosphine in XPS spectroscopy and a Pd(0) species with a Pd $3d^{3/2}$ peak such as that seen for the Pd crystallites in Pd–PE-*g*-PAA.

While the original Pd(0)-DPPA–PE-*g*-PAA catalyst was active in allylic substitution, after oxidation, both this recovered catalyst, now containing Pd(0) colloids, and the Pd–PE-*g*-PAA catalyst behaved similarly in that they had no activity in allylic substitution unless external phosphine was present (Fig. 2). These reactions catalyzed by Pd(0) colloids were also accompanied by Pd leaching. Using ICP–MS (inductively coupled plasma – mass spectroscopy) analysis, ca. 2% to 3% Pd leaching was seen in the reaction between allyl acetate and diethylamine with external phosphine. Pd leaching was not seen with Pd(0)-DPPA–PE-*g*-PAA catalysts that

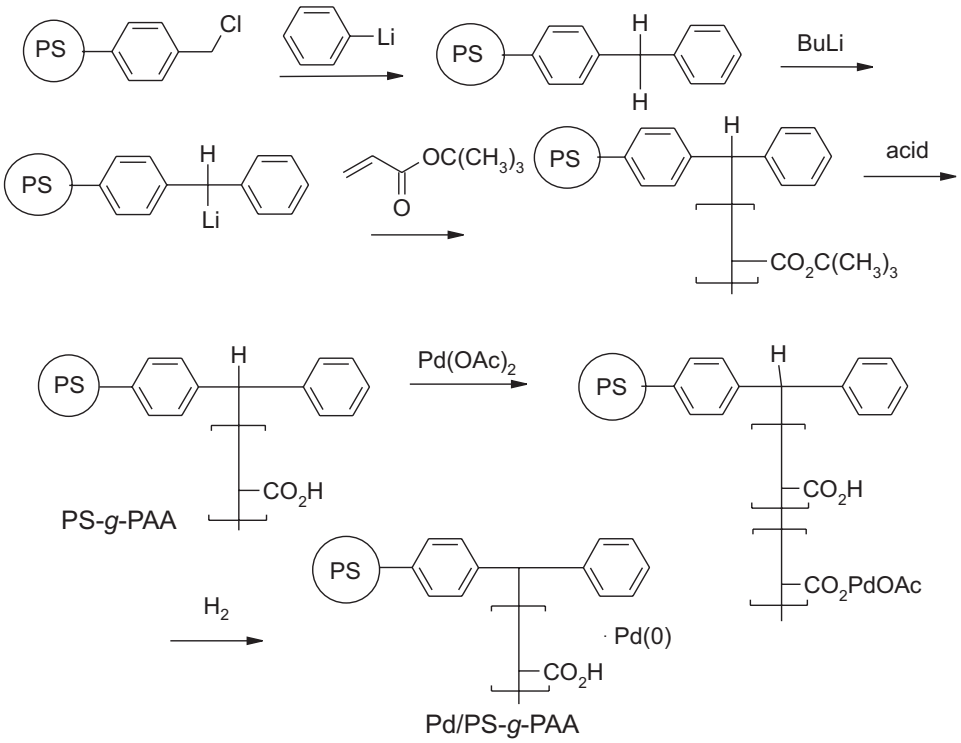

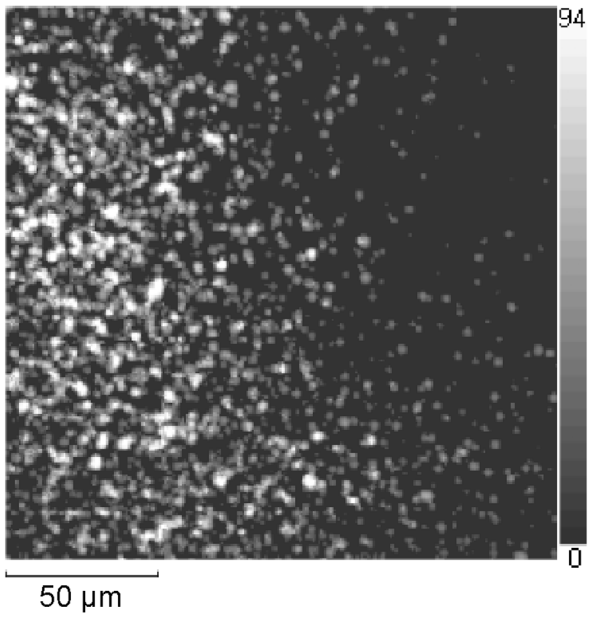

Fig. 1. XPS image of a Pd–PE-*g*-PAA powder. The white regions represent the presence of Pd 3d electrons. The left side of the image is focused on a Pd–PE-*g*-PAA particle, and the edge of the three-dimensional particle roughly transects the photograph.

contained covalently bound phosphine ligands within the functional polymer support that formed analogs of a molecular Pd(0) catalyst (25). Taken together, these results are consistent with an explanation such as that proposed previously (3) for the activity of these Pd–PE-*g*-PAA colloidal catalysts, which is based on leaching of a phosphine-ligated Pd catalyst or a Pd cluster.

Table 1. Allylic substitution reactions of allyl acetate with Pd–PE-*g*-PAA.

-R″	PPh_3 (mol%)	Time (h)	Conversion (%)[a]
Diethylamine	0.00	24	—[b]
Diethylamine	0.05	6/6	99, 99[c]
Pyrrolidine	0.05	20	99

Note: Reactions were carried out at 55 °C on a 20 mmol scale, typically without any added solvent.

[a]GC analysis showed that the conversion of starting material to product was 99%. Isolated yields of allylic amines in similar reactions were typically ca. 90%.

[b]No product was detected.

[c]Conversions for a second cycle using the Pd–PE-*g*-PAA catalyst with a fresh addition of 5 mol% triphenylphosphine.

These PE-bound Pd(0) species could not be used in Heck catalysis. No Heck catalysis was seen at 55 °C, and heating to higher temperatures led to thermal reorganization of the grafted PE powder (melting that produced a material that became inactive in hydrogenation or allylic substitution with or without added phosphine). However, immobilized poly(acrylic acid) grafts on a more thermally robust polymer, which are analogous to the Pd–PE-*g*-PAA powder catalysts described previously, can be prepared on DVB crosslinked polystyrene supports as shown in Scheme 2. Ion exchange of $Pd(OAc)_2$ with the immobilized poly(acrylic acid) followed by reduction, produced immobilized Pd(0) colloids that had hydrogenation activity analogous to that seen with Pd–C or to Pd crystallites immobilized within hyperbranched poly(acrylic acid) grafts on PE powder (20).

While the PE-supported Pd colloids could not be used in Heck catalysis because of temperature limitations, Pd colloids supported on more thermally robust DVB crosslinked polystyrene were active in Heck catalysis (eq. [2]).

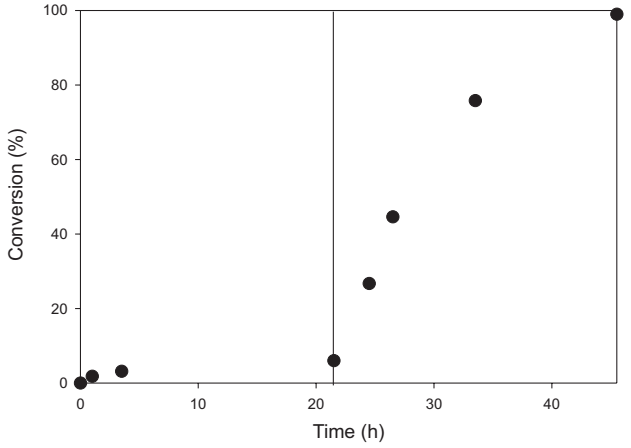
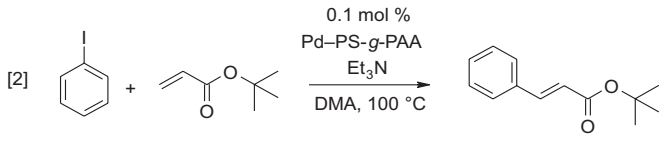
Table 2. Heck catalysis with Pd–PS-*g*-PAA.



Substrate aryl iodide	Heck acceptor	Catalyst	Yield (%)[a]
4-Iodotoluene	*tert*-Butyl acrylate	Pd–PS-*g*-PAA	99
4-Iodotoluene	*tert*-Butyl acrylate	Pd–C[b]	75
Iodobenzene	*tert*-Butylstyrene	Pd–PS-*g*-PAA	100
4-Iodoanisole	*tert*-Butylbenzene	Pd–PS-*g*-PAA	94
4-Iodoanisole	*N*,*N*-Dimethylacrylamide	Pd–PS-*g*-PAA	95
4-Iodoanisole	*N*,*N*-Dimethylacrylamide	Pd–C	36
Iodobenzene	*tert*-Butyl acrylate	Pd–PS-*g*-PAA	100
4-Bromoacetophenone	*tert*-Butyl acrylate	Pd–PS-*g*-PAA	81
4-Bromoacetophenone	*N*,*N*-Dimethylacrylamide	Pd–PS-*g*-PAA	66

Note: Reactions were carried out on a 2 mmol scale in 10 mL of *N*,*N*-dimethylacrylamide using 2.5 mmol of Et_3N as a base at 80 °C for 36 h (or at 100 °C for 24 h). The Heck acceptor was present in 20 mol% excess. The PS-*g*-Pd catalyst contained 0.11 mol% of Pd. The Pd–C species used was 10% Pd–C (Sigma-Aldrich). Yields were measured by GC using dodecane as an internal standard. The catalyst was present at 0.1 mol%.



[a]Isolated yields were typically 10% lower for reactions carried out on a 5 or 10 mmol scale.

[b]The catalyst was present at 0.5 mol%.

Fig. 2. Allylic substitution of allyl acetate using diethylamine with a Pd(0) catalyst containing Pd(0) crystallites and no phosphine ligands within the interface. After 24 h, external PPh_3 was introduced to the reaction mixture, a step that did lead to allylic substitution product formation.

As shown in Table 2, good yields in small scale reactions were obtained with a variety of aryl iodides. However, unactivated aryl bromides and aryl chlorides were not substrates, even if added to a reaction along with a more reactive aryl iodide. The activity of the Pd–PS-*g*-PAA catalysts was also compared to Pd–C — a simple catalyst that also has modest activity in Heck catalysis. The PS-*g*-PAA immobilized Pd colloids were found to be more active. These cross-coupling reactions occurred without any added phosphine ligand present.

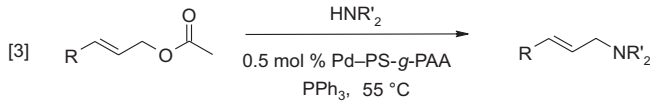
Recycling the Pd species in a polystyrene resin in Heck catalysis was tested using the Heck reaction between iodobenzene and *tert*-butyl acrylate (eq. [2]) as a model reaction. The first cycle was complete in 6 h by GC analysis. The catalyst was recovered by pouring off the reaction solution after centrifugation. Fresh reagents and solvent were then added to the catalyst for the second cycle (Table 3). After 6 h, the reaction had proceeded to 95% conversion by GC analysis. During the third recycling experiment the reaction went to only 46% conversion after 6 h. After washing the catalyst by Soxhlet extraction with MeOH for 24 h, a fourth cycle went to 99% conversion after 9 h. Presumably, the reaction salts had built up in the resin, inhibiting the reaction. Such fouling of a recovered catalyst by salt byproducts is a potential general problem for any recoverable catalyst that employs a relatively polar phase.

Table 3. Recycling experiments using Pd–PS-*g*-PAA in the Heck reaction of *tert*-butyl acrylate and iodobenzene (eq. [2]).

Cycle	Conversion (%)	Time (h)
1	99	6
2	95	6
3	46	6
4	99	9

Note: After the third cycle, the catalyst was recovered and washed in a Soxhlet apparatus with MeOH for 24 h.

Trace metal analysis (ICP–MS) of an acid-digested aliquot from the first reaction cycle showed 2.1% leaching of Pd. This result is in accord with other suggestions that activity of a heterogeneous Pd catalyst involves oxidative addition and formation of a soluble Pd species (2).



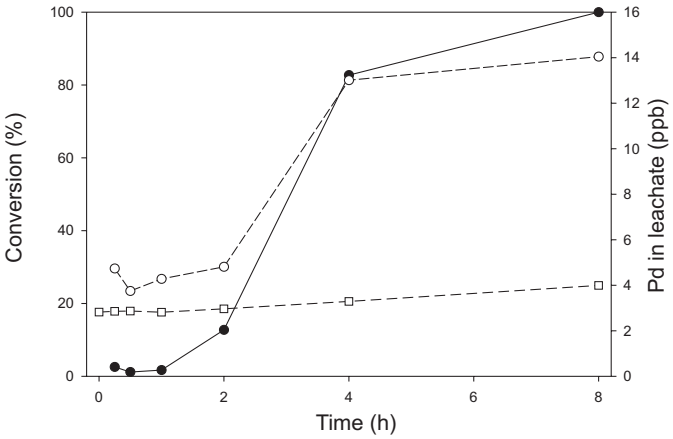
The Pd–PS-*g*-PAA catalyst is also active for allylic substitution chemistry (Table 4). As was true for Pd–PE-*g*-PAA catalysts, the presence of external triphenylphosphine is required for these reactions to proceed. A series of allylic substitution reactions using allyl acetate or cinnamyl acetate reacting with diethylamine or piperidine were performed (eq. [3]). The reaction between allyl acetate and diethylamine went to only 38% conversion in 18 h without the presence of external triphenylphosphine. With external phosphine, the reaction goes to complete conversion in 1 h. The reaction between cinnamyl acetate and diethylamine was even more dependant on external phosphine. After 24 h without any external phosphine, no reaction was seen by GC analysis. A reaction in the presence of added triphenylphosphine was completed within 8 h.

© 2006 NRC Canada

Table 4. Results for allylic substitution reactions with Pd–PS-*g*-PAA.

-R	-R′	PPh_3 (mmol)	Time (h)	Conversion (%)
-H	$-CH_2CH_3$	—	18	38
-H	$-CH_2CH_3$	0.1	1	99
-Ph	$-CH_2CH_3$	—	24	0
-Ph	$-CH_2CH_3$	0.1	8	99
-H	$-CH_2CH_2CH_2CH_2CH_2-$	0.05	1	99

Note: These reactions were carried out in THF at 60 °C on a 10 or 20 mmol scale.



A more detailed study showed that these reactions appear to involve Pd leachates as the active catalyst. An induction period of ca. 2 h was observed for the formation of the cinnamyl acetate and diethylamine product. Interestingly, the progress of these allylic substitution reactions using Pd–PS-*g*-PAA catalysts with added triphenylphosphine were correlated with leaching of palladium into solution. In these studies, the first experiment was designed to monitor the Pd leaching into solution from the Pd–PS-*g*-PAA catalyzed allylic substitution reaction between cinnamyl acetate and diethylamine with triphenylphosphine present. During the course of the 8 h reaction between cinnamyl acetate and diethylamine, aliquots were removed from solution. The aliquots were digested in acid and analyzed by ICP–MS. Figure 3 shows the results from this experiment. The results show very little Pd leaching into solution during the induction period. As product forms, the Pd concentration in the reaction mixture increases. A second control reaction that had only triphenylphosphine and Pd–PS-*g*-PAA catalyst showed almost no palladium leaching for 8 h, the time required for complete conversion of starting materials to product. This suggests that the substrates cause the leaching of Pd and that the active catalytic species is generated with the presence of triphenylphosphine. In this case the Pd–PS-*g*-PAA catalyst serves as a reservoir of Pd for the reaction. These results are in accord with previous results from our group where the three-phase test for a soluble Pd catalyst failed using a polymer-supported allylic ester substrate and Pd–C- and polystyrene-supported Pd(0) catalysts (3). These results showed no reaction between a polystyrene-bound allyl ester and diethylamine using a heterogeneous Pd catalyst with triphenylphosphine in solution. However, as shown here, that result is understandable since in that experiment the substrate and Pd source were both heterogeneous. Assuming that this is also the case presently, the soluble phosphine alone would not cause the Pd leaching and no reaction would occur.

Conclusion

Hyperbranched grafts of poly(acrylic acid) on polyethylene powder or polystyrene can be used to support Pd(0) crystallites that function as a homogeneous Pd(0) catalyst in some reactions. These Pd–PE-*g*-PAA catalysts were active in allylic substitution reactions in the presence of added phosphine ligand. A catalyst analogous to the Pd–PE-*g*-PAA powder catalyst on polystyrene (Pd–PS-*g*-PAA) was similarly active for allylic substitution and could also be used in Heck reactions at 80 °C in *N*,*N*-dimethylacetamide (DMA). Analysis of the solution for Pd and a correlation of the Pd leaching with product formation in the allylic substitution chemistry for both types of catalysts suggests that the active catalysts in these reactions are leached from the support. In the case of the allylic substitution reaction, external triphenylphosphine and substrate together are required for the chemistry and Pd leaching.

Fig. 3. A Pd–PS-*g*-PAA catalyzed allylic substitution reaction between cinnamyl acetate and diethyl amine carried out in the presence of 0.5 mol% of added triphenylphosphine in THF at 60 °C. The various plots show the extent of reaction in the presence of added triphenylphosphine as a function of reaction time (●), the concentration of Pd in the leachate as a function of time (○), and the concentration of leachate in a reaction with the same catalyst and the same amount of triphenylphosphine and amine but no cinnamyl acetate substrate (□). No reaction was observed in the absence of triphenylphosphine over a 24 h period under the same reaction conditions.

Experimental section

General methods

Merrifield Resin (RGEN100) was obtained from the American Peptide Company, Inc. (Sunnyvale, California) as a 100–200 mesh resin and had a loading of 1.05 mmol of $ClCH_2$ groups per gram. Other reagents and solvents were obtained from the Sigma-Aldrich Chemical Company and were used as received unless noted otherwise. X-ray photoelectron spectra were obtained on a Kratos Axis Ultra XPS

© 2006 NRC Canada

(Manchester, UK) using a monochromatic Al K_α source (400 W) in a UHV environment (ca. 5×10^{-9} torr (1 torr = 133.3224 Pa). During acquisition, surfaces were kept from charging by the application of low energy electrons. Surface elemental composition was determined by normalized integration of the resulting peaks using Kratos software (Kratos Analytical, Chestnut Ridge, New York). ^{1}H and ^{13}C NMR spectroscopy experiments were carried out using Mercury 300, Unity 300, or Unity 500 spectrometers. GC analyses were carried out using a Shimazdu Model 2010 GC. All glassware used in the experiments in which trace metal analysis was performed was soaked in a 1 mol/L HNO_3 acid bath for at least 12 h prior to the experiment.

Preparation of Pd–PS-*g*-PAA

A reported procedure was used (20). The product Pd catalyst was prepared on a 12 g scale. The Pd loading of the Pd(II)–PS-*g*-PAA prepared in this manner was 1.27 mmol/g, based on gravimetric analysis of the exchange of $Pd(OAc)_2$ and the sodium salt of the poly(acrylic acid)-grafted polystyrene. Subsequent reduction of this Pd(II) salt in the poly(acrylic acid) graft produces a product (Pd–PS-*g*-PAA) that was used in the catalytic studies. Analysis by ICP–MS of a solution of the residue after combustion and acid digestion of this Pd–PS-*g*-PAA product in triplicate showed that the Pd loading of this polystyrene-supported Pd product was 1.1 mmol of Pd per gram of Pd–PS-*g*-PAA.

Preparation of Pd–PE-*g*-PAA powder

Following a literature procedure (19), a poly(acrylic acid) hyperbranched graft on a PE powder sample (1.3 g) was first stirred with a pH 9 buffer for 2 h to deprotonate the -CO_2H groups of the graft. The resulting carboxylate-containing polymer was then suspended in 25 mL of an acetone–water (4:1) mixture with 20 mg of $Pd(OAc)_2$. This solution was stirred at room temperature for 24 h then filtered and washed with dilute acidic ethanol and ethanol. The yellowish powder was suspended in EtOH and reduced with H_2 in a Parr apparatus to yield the Pd–PE-*g*-PAA catalyst that was used in these studies. To determine the Pd loading, this powder sample was combusted in a crucible at 650 °C for 2 h. The residue was digested in acid and ICP–MS analysis of the residue for Pd showed that Pd loading was ca. 0.01 mmol of Pd per gram of Pd–PE-*g*-PAA powder.

Typical procedure for Heck catalysis with 10% Pd–C or Pd–PS-*g*-PAA

An aryl iodide such as iodotoluene (2.0 mmol), 2.4 mmol (0.3139 g, 98%) of *tert*-butyl acrylate, 2.5 mmol of triethylamine, along with 0.01 mmol of the Pd catalyst (e.g., 9 mg of Pd–PS-*g*-PAA) were added to a 50 mL flask. Then 10 mL of DMA was added to the mixture and the reaction was heated to 80 °C.

Typical procedure for allylic substitutions with Pd–PS-*g*-PAA

A mixture of 2.0 mmol (0.36 g) of cinnamyl acetate, 2.4 mmol (0.21 g) of morpholine, 0.1 mmol (0.264 g) of triphenylphosphine, and 0.01 mmol (9.0 mg) of Pd–PS-*g*-PAA were added to a 50 mL reaction flask along with 10 mL of THF. The reaction mixture was heated to 60 °C and agitated with a wrist-action shaker. The progress of the reaction was checked using GC.

General procedure for Heck catalysis, recycling, and leachate analysis using Pd–PS-*g*-PAA

Iodobenzene (5 mmol), *tert*-butyl acrylate (6 mmol), triethylamine (7.5 mmol), and 0.5 mol% Pd(0)-PAA–PS (0.025 mmol of Pd, 22.5 mg of resin) were added to a 40 mL centrifuge tube along with 25 mL of DMA. This mixture was heated to 100 °C and agitated using a wrist-action shaker until GC analysis showed the reaction was complete. After the reaction was complete, the catalyst was separated by centrifugation and decantation. The catalyst isolated in this manner could then be reused in a subsequent reaction. To analyze for Pd leaching, ca. 25% of the decanted solution from this reaction was evaporated to dryness and then heated on a hot plate with 20 mL of concentrated sulfuric acid for 24 h. The solution was diluted to 50 mL using 1% HCl and analyzed by ICP–MS. In a typical analysis, a reaction that started with 2.65 mg of Pd had 56 μg of Pd in total in this solution corresponding to 2.1% leaching.

General procedure for allylic substitution reactions and leachate analysis using Pd–PS-*g*-PAAC

Cinnamyl acetate (10 mmol, 1.76 g) and diethylamine (24 mmol, 1.75 g) were combined with triphenylphosphine (0.2 mmol, 52.4 mg) and Pd(0)-PAA–PS (0.5 mol%, 45 mg of resin) in 20 mL of distilled THF in a 40 mL centrifuge tube. This mixture was degassed by freeze–pump–thaw cycles three times and then backfilled with N_2. The reaction tube was heated to 55 °C and agitated using a wrist-action shaker. A control reaction was also carried out at the same time using the same amount of catalyst, phosphine, and solvent but without any cinnamyl acetate. GC analysis of aliquots was carried out as the reaction progressed. The remainder of each aliquot was digested by heating in concd. H_2SO_4 for 24 h. The concentrated digest was diluted to 25 mL with 1% HCl and then analyzed by ICP–MS.

Pd–PE-*g*-PAA catalyzed allylic substitution reactions

Allyl acetate (18.8 mmol, 1.8852 g), piperidine (37.8 mmol, 3.2125 g), triphenylphosphine (0.01 mmol, 26.4 mg), and 400 mg of Pd–PE-*g*-PAA powder were combined in a 20 mL flask. This mixture was degassed three times by freeze–pump–thaw, backfilled with N_2, and then heated to 55 °C. After 20 h, the allyl acetate had been completely consumed based on GC analysis.

Design and synthesis of selenonium and sulfonium ions related to the naturally occurring glucosidase inhibitor salacinol[1]

Hui Liu and B. Mario Pinto

Abstract: Four series of analogues of the naturally occurring glucosidase inhibitor salacinol were synthesized for structure–activity studies with different glycosidase enzymes. The target zwitterionic compounds were synthesized by means of nucleophilic attack at the least-hindered carbon atom of the 1,3-cyclic sulfates derived from D-glucose and D-mannose by the isopropylidene-protected 1,4-anhydro-4-thio- and seleno-D-allitols and the 4-thio- and seleno-L-allitols. Deprotection of the coupled products afforded the novel sulfonium and selenonium ions containing polyhydroxylated acyclic chains of four and six carbons, with different stereochemistry at the stereogenic centers and with 1,4-anhydro-4-seleno or 4-thio-D- or L- alditol heterocyclic rings. The compounds showed no significant activity against recombinant human maltase glucoamylase (MGA), a critical intestinal glucosidase involved in the processing of oligosaccharides of glucose into glucose itself.

Key words: glycosidase inhibitors, zwitterionic, selenonium salts, sulfonium salts, cyclic sulfates, L-ascorbic acid, D-gulonic-γ-lactone.

Résumé : Afin de pouvoir faire des études de structure–activité avec divers enzymes glycosides, on a réalisé la synthèse de quatre séries d'analogues du salacinol, un inhibiteur naturel de glucosidase. Les composés zwitterioniques cibles ont été synthétisés par le biais d'une attaque nucléophile au niveau de l'atome de carbone le moins encombré de sulfates 1,3-cycliques obtenus à partir du D-glucose et du D-mannose par des 1,4-anhydro-4-thio- et 1,4-anhydro-4-séléno-D-allitols et des 4-thio- et 4-séléno-L-allitols. La déprotection des produits de couplage fournit des nouveaux ions sulfonium et sélénonium qui contiennent des chaînes acycliques polyhydroxylées de quatre et de six carbones, avec des stéréochimies différentes au niveau des centres stéréogènes et hétérocycles 1,4-anhydro-4-séléno- et 1,4-anhydro-4-thio-D- ou L-alditols. Ces composés ne présentent aucune activité significative contre la maltase glucoamylase humaine recombinante (MGA), une glucosidase intestinale critique dans la transformation des oligosaccharides du glucose en glucose.

Mots clés : inhibiteurs de glycosidase, zwitterion, sels de sélénonium, sels de sulfonium, sulfates cycliques, acide L-ascorbique, γ-lactone de l'acide D-gulonique.

[Traduit par la Rédaction]

Introduction

Glycosidases are responsible for the hydrolysis of poly- and oligo-saccharides into monomers or the cleavage of bonds between sugars and non-carbohydrate aglycons. In recent years, much attention has focused on the synthesis and development of glycosidase inhibitors because of an increasing awareness of the vital role played by sugars in biological processes and because of their therapeutic potential (1, 2). In the case of patients suffering from Type II diabetes, the management of blood glucose levels is crucial since their insulin secretion may be normal, but the entry into cells of glucose (normally mediated by insulin) is compromised (3). Glycosidase inhibitors can be used to inhibit the activity of intestinal glucosidases that break down oligosaccharides to glucose. This enzyme inhibition delays glucose absorption into the blood and results in a lowering or smoothing of the blood glucose levels (4, 5).

There are two generally accepted mechanisms for the enzymatic hydrolysis of a glycosidic bond, proceeding either with the inversion or retention of configuration at the anomeric center (6, 7). In either case, protonation of the exocyclic oxygen leads to cleavage of the glycosidic bond with subsequent formation of an oxacarbenium ion. To generate potent glycosidase inhibitors, an attractive approach is to create compounds that mimic the oxacarbenium ion transition state in the enzyme-catalyzed reaction. Some naturally occurring compounds, such as acarbose (**1**) and voglibose (**2**) (Chart 1), are potent glycosidase inhibitors and presumably mimic the oxacarbenium ion, at least in binding to active site carboxylate residues via the protonated nitrogen atom (8, 9).

Recently, a new class of glycosidase inhibitors, including salacinol (**3**) and kotalanol (**4**) (Chart 2), with an intriguing inner-salt sulfonium sulfate structure was isolated from the roots and stems of the plant *Salacia reticulata* (10–12). The compounds were shown to be inhibitors of intestinal glucosidase enzymes that attenuate the undesirable spike in blood glucose that is experienced by diabetics after consuming a meal rich in carbohydrates. It is postulated that the inhibition of glucosidases by salacinol and kotalanol is due to their ability to mimic both the shape and charge of the oxocarbenium ion-like transition state involved in the enzymatic reactions.

In our current research program, we have undertaken a limited structure–activity study of salacinol and related compounds. The synthesis of salacinol and its ammonium and selenonium analogues have been reported by us and others (13–17). Analogues containing six-membered heterocyclic rings and some chain-extended analogues of salacinol have also been synthesized (18–21). Some of these analogues exhibited inhibitory activities in the micromolar range for recombinant human maltase glucoamylase, an intestinal glucosidase (20, 21). The studies also showed an interesting variation in the inhibitory power of these compounds against glycosidase enzymes of different origin (14–17, 22). In particular, the stereochemistry at the different stereogenic centers as well as the nature of the heteroatom play significant roles in discrimination between glycosidase enzymes. The molecular basis for this selectivity is being investigated through structural studies of the enzyme-bound inhibitors using molecular modeling in conjunction with conformational analysis by NMR techniques (23) and X-ray crystallography (24).

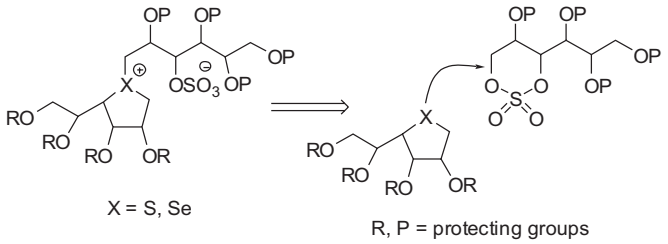
To further understand the enzyme discrimination of related compounds, we now describe the synthesis of new analogues of salacinol analogues **7**–**14** based on novel seleno- and thio-alditols derived from D-gulonic-γ-lactone and L-ascorbic acid (Chart 3).

Results and discussion

The analogues **7**–**14** can be synthesized by alkylation of a protected anhydroalditol at the ring heteroatom with terminal 1,3-cyclic sulfates. The protected anhydroalditols and the cyclic sulfates can be synthesized from the appropriate carbohydrate starting materials (Scheme 1).



The choice of protecting groups for the thio- and selenoanhydroalditols and the cyclic sulfates, however, merited careful consideration, especially in the case of the selenonium analogues. Hydrogenolysis and strongly basic conditions proved to be problematic deprotection steps for similar selenonium analogues; thus, these conditions needed to be avoided (15–17). Therefore, we chose to use isopropylidene and benzylidene acetals as the protecting groups for the thio- and seleno-anhydroalditols **15**–**18** and the cyclic sulfates **19** and **20** since these acetals are both labile to acidic hydrolysis (Chart 4).

Our previous work also suggested that the release of ring strain in the opening of bicyclic sulfates was beneficial (14–17). Therefore, the benzylidene acetal at the 2,4-positions of the cyclic sulfates **19** and **20** played dual roles as protecting groups and reaction facilitators for the coupling reactions with compounds **15**–**18**. After the coupling reactions, the products could then be readily deprotected by simple treatment with trifluoroacetic acid.

The synthesis of the isopropylidene-protected 1,4-anhydro-4-seleno-D-allitol (**15**) and 1,4-anhydro-4-thio-D-allitol (**16**) started from the commercially available D-gulonic-γ-lactone (**21**, Scheme 2). 2,3,5,6-Di-*O*-isopropylidene-D-gulonic-γ-lactone (**22**) (25) was reduced with sodium borohydride to afford the corresponding diol **23**. Compound

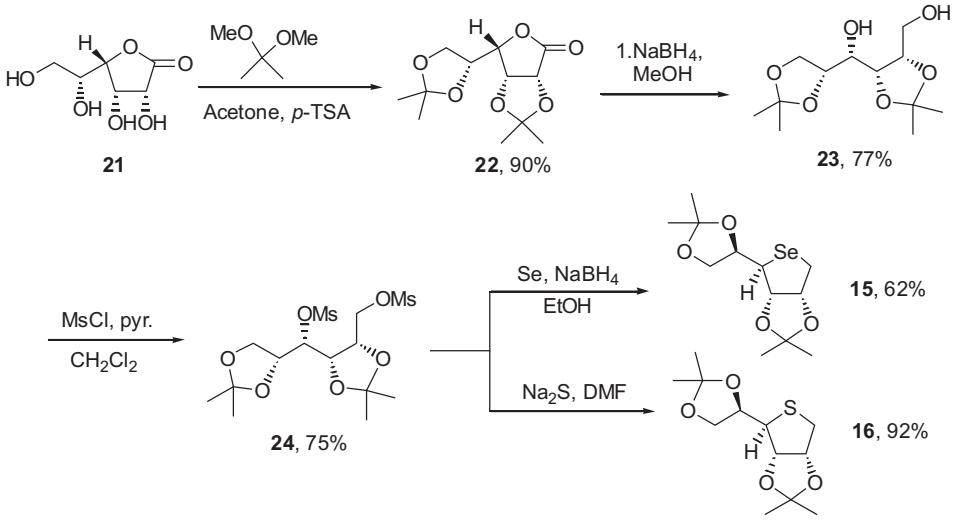
Scheme 2.



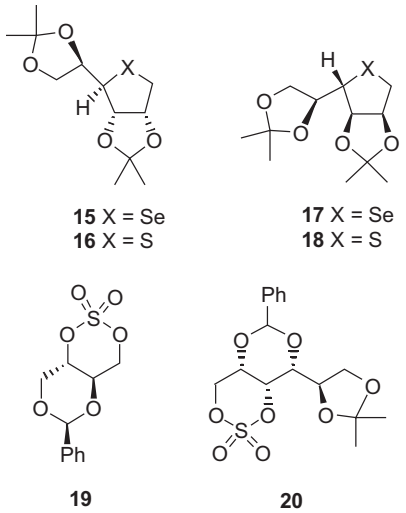


Chart 4.

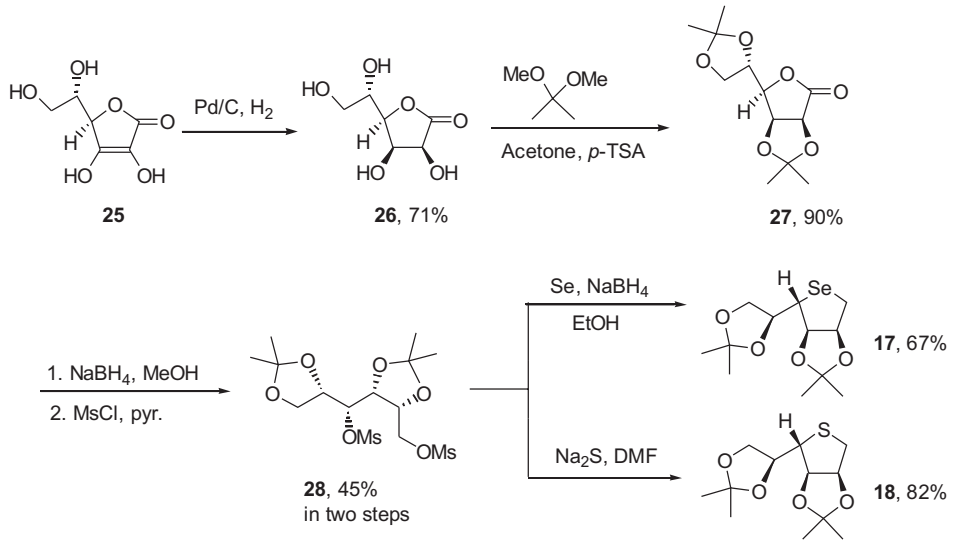
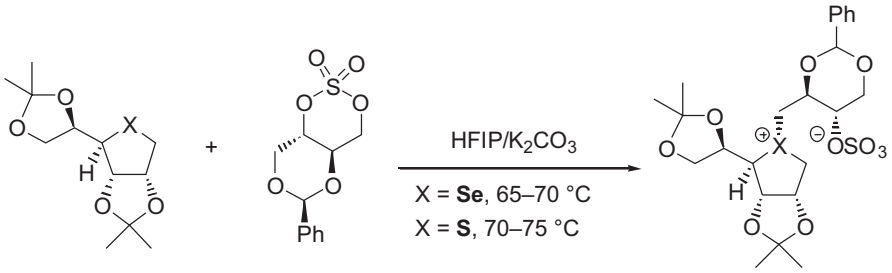


23 was then converted to the dimesylate **24** by treatment with methanesulfonyl chloride and pyridine in 80% yield (26). When the dimesylate **24** was reacted with selenium metal and sodium borohydride in EtOH at 60–65 °C, the isopropylidene-protected 1,4-anhydro-4-seleno-D-allitol **15** was obtained in 62% yield. The isopropylidene-protected 1,4-anhydro-4-thio-D-allitol **16** was prepared in 92% yield by treatment of the dimesylate **24** with sodium sulfide in DMF (Scheme 2).

Although the enantiomeric isopropylidene-protected 1,4-anhydro-4-seleno-L-allitol (**17**) and 1,4-anhydro-4-thio-L-allitol (**18**) could, in principle, be prepared from L-gulonic-γ-lactone, the high cost of this starting material made these syntheses unrealistic. Thus, inexpensive and commercially available L-ascorbic acid (**25**) was used as the starting material to give the L-gulonic-γ-lactone (**26**) in 71% yield (27) (Scheme 3). Compound **26** was then treated with 2,2-dimethoxypropane in dry acetone containing *p*-toluenesulfonic acid as a catalyst to give 2,3,5,6-di-*O*-isopropylidene-L-gulonic-γ-lactone (**27**) (25). The lactone **27** was subsequently reduced with sodium borohydride to afford the corresponding diol that was, in turn, converted to the dimesylate **28** by treatment with methanesulfonyl chloride and pyridine. When the dimesylate **28** was reacted with selenium metal and sodium borohydride in EtOH at 60–65 °C, the isopropylidene-protected 1,4-anhydro-4-seleno-L-allitol **17** was obtained in 67% yield. The isopropylidene-protected 1,4-anhydro-4-thio-L-allitol **18** was prepared in 82% yield by treatment of the dimesylate **28** with sodium sulfide in DMF.



Since salacinol **3** and its selenonium analogue, blintol (**5**) (Chart 2), are the most active, so far, of this class of glycosidase inhibitors against human maltase glucoamylase, we first concentrated on the coupling reactions of **15** and **16** with the cyclic sulfate **19**, which would yield the identical side chain present in salacinol and blintol (Scheme 4). The solvent chosen for the coupling reactions was the unusual solvent 1,1,1,3,3,3-hexafluoroisopropanol (HFIP), which offers significant advantage in these types of coupling reactions compared with other solvents (15–17). The cyclic sulfates **19**, prepared as described previously (16), were reacted with **15** and **16**, to give the corresponding protected

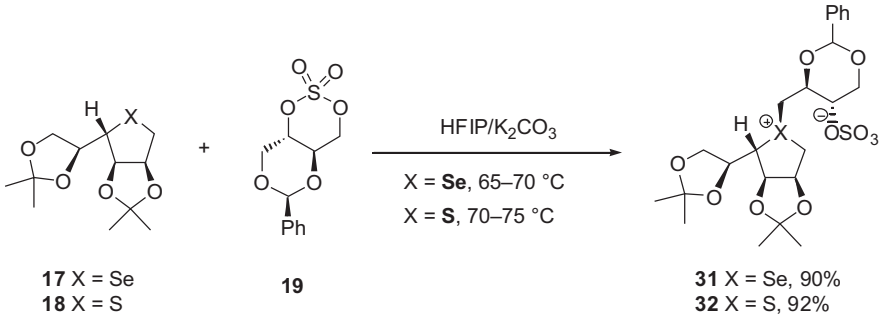
Scheme 3.

Scheme 4.

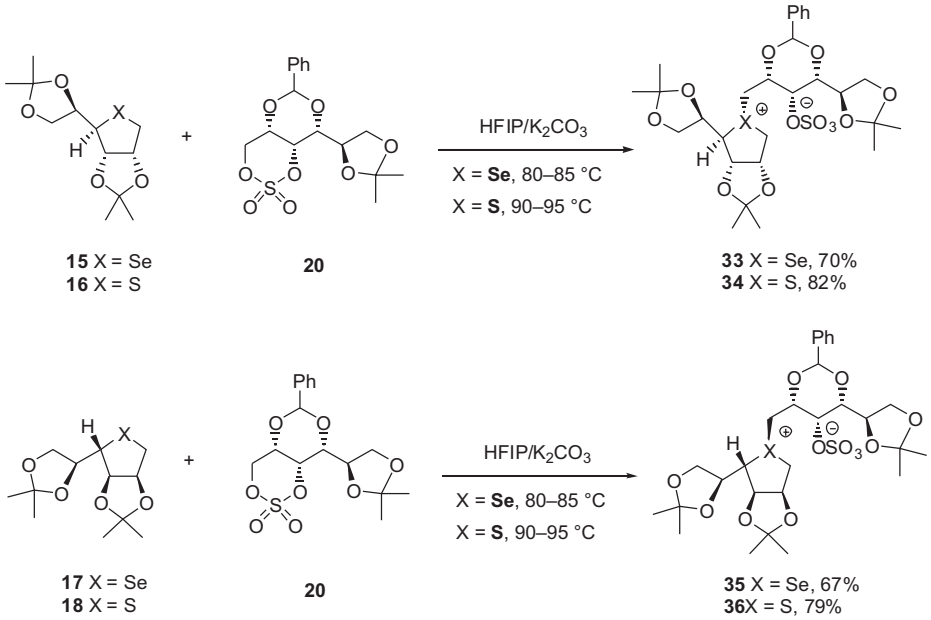
selenonium and sulfonium sulfates **29** and **30**, respectively (Scheme 4).

The coupling reactions of enantiomeric **17** and **18** with the cyclic sulfate **19** were carried out analogously, to give the corresponding protected selenonium and sulfonium sulfates **31** and **32**, respectively (Scheme 5).



We next turned our attention to the possibility of attaching longer side chains to the anhydroalditols **15**–**18**. Our interest in longer side chains stemmed from the fact that kotalanol **4**, which has a seven-carbon side chain instead of four-carbon side chain of the salacinol, exhibits stronger inhibitory activities toward certain glycosidase enzymes. Since the exact stereochemistry of kotalanol **4** is not yet known, it is necessary and important to study the structure–activity relationships of these types of compounds systematically by attaching side chains with different chain lengths and different stereochemistry at the stereogenic centers to the heterocyclic rings of the anhydroheteroalditols. The cyclic sulfate **20**, which consisted of a protected polyhydroxylated six-carbon chain (19), was chosen for this purpose. The cyclic sulfate **20** reacted with **15** and **16** and their enantiomers **17** and **18** in HFIP to give the corresponding protected selenonium and sulfonium compounds **33**–**36**, respectively (Scheme 6).

The reactivity of **15**–**18** with cyclic sulfates **19** and **20** varied slightly. With the same anhydroalditols, the cyclic sulfate **19** was more reactive than the cyclic sulfate **20**, also resulting in higher yields of the coupling reactions. Thus, the coupling reactions with the cyclic sulfate **19** usually proceeded in yields of 90%–95%, while the cyclic sulfate **20** typically gave yields of 70%–80%, with the remainder consisting of starting materials and a small amount of decomposition products. With the same cyclic sulfate, the selenoalditols were slightly more reactive than their sulfur counterparts, as demonstrated by the different reaction temperatures required in the coupling reactions. The reactivities of the enantiomeric pairs, compounds **15**–**17** and **16**–**18** with the cyclic sulfates **19** and **20** were virtually the same. Selectivity for attack at the primary center of the cyclic sulfates **19** and **20** over possible alternative attack at the secondary center by compounds **15**–**18** was invariably excellent, and in no case were isolable quantities of the regioisomers detected. In the case of the coupling reaction of **15** and L-allitol **17** with the cyclic sulfates **19** and **20**, there was a small amount (5%–10%) of the stereoisomer formed through electrophilic attack on the β face of the seleno-D-allitol **15** and the α face of the seleno-L-allitol **17** to give products that were diastereomeric at the selenonium center, but could not be isolated in pure form. However, this type of minor product was not detected in the reactions of the corresponding thioallitols.



The deprotection of the coupled products **29**–**36** was carried out by treatment with trifluoroacetic acid (Scheme 7). After rinsing away the cleaved protecting groups with dichloromethane, the resulting residues were purified by flash

Scheme 5.

Scheme 6.

chromatography to yield compounds **7**–**10** as amorphous, hygroscopic solids. In the cases of compounds **33**–**36**, however, some of the benzylidene acetal protecting group (up to 30% by NMR measurements) remained even after prolonged (up to 48 h) treatment with TFA. The remaining benzylidene acetal was eventually cleaved by hydrogenolysis in 80% acetic acid to give the corresponding deprotected products **11**–**14** as amorphous, hygroscopic solids. The yields of compounds **11**–**14** were low, partly because of the adsorption of the products on the Pd–C catalyst. Compounds **7**–**14** were characterized by spectroscopic methods. The MALDI-TOF mass spectra of compounds **7**–**14** showed major fragmentation peaks ($M + Na^+ - SO_3$) together with the molecular ion peaks ($M + Na^+$) of much lower intensities.

The absolute stereochemistry at the heteroatom center of compounds **7**–**14** was established by 1D-NOE NMR spectroscopy. For example, in the 1D-NOE spectrum of compound **8** (Fig. 1), the H-4 to H-1′b correlation was clearly exhibited, implying that these two hydrogens are syn-facial. Therefore, C-1′ of the side chain must be anti to C-5 of the sulfonium salt ring.

As a final point of interest, compounds **7**–**14** were screened against recombinant human maltase glucoamylase (MGA), a critical intestinal glucosidase involved in the processing of oligosaccharides of glucose into glucose itself. The compounds showed no significant activity.[3]

Conclusions

Four series of analogues of the naturally occurring glucosidase inhibitor salacinol were synthesized. These analogues contained the acyclic chains of salacinol and extended acyclic chains of six carbons, as well as ring heteroatom substitution (Se, S). In addition, the heterocyclic ring bore the D- or L-allitol configuration. These syntheses utilized the 1,3-cyclic sulfates derived from commercially available D-glucose and D-mannose. The isopropylidene and benzylidene acetal protecting groups on the coupled products ensured facile deprotection with TFA to yield the final compounds **7**–**14**. The compounds showed no inhibitory activity against human maltase glucoamylase.

NMR spectra were recorded at 500 and 125 MHz, respectively. All assignments were confirmed with the aid of two-dimensional ^{1}H and ^{1}H (COSYDFTP) or ^{1}H and ^{13}C (INVBTP) experiments using standard Bruker pulse programs. Column chromatography was performed with Merck silica gel 60 (230–400 mesh). MALDI mass spectra were obtained on a PerSeptive Biosystems Voyager DE time-of-flight spectrometer for samples dispersed in a 2,5-dihydroxybenzoic acid matrix. High-resolution mass spectra were obtained by the electrospray ionization (ESI) technique, using a ZabSpec oaTOF mass spectrometer at 10 000 RP.

2,3,5,6-Di-*O*-isopropylidene-1,4-di-*O*-methanesulfonyl-D-gulitol (24)

2,3,5,6-Di-*O*-isopropylidene-1,4-di-*O*-methanesulfonyl-D-gulitol (**24**) was prepared by the literature method (26) with slight variations. To a solution of commercially available D-gulonic-γ-lactone **21** (10.0 g, 56.1 mmol) in dry acetone (200 mL), 2,2-dimethoxypropane (40 mL, 0.32 mmol) was added at RT. To this solution, *p*-toluenesulfonic acid (200 mg) was added as a catalyst. The progress of the reaction was followed by TLC analysis of the aliquots (hexane–EtOAc, 1:1). When the starting material **21** had been essentially consumed, the reaction was stopped by addition of triethylamine (1 mL) to the reaction mixture. The solvent was then evaporated under reduced pressure and the residue was purified by column chromatography (hexane–EtOAc, 1:1) to give compound **22** as a white solid (13.1 g, 90%). The NMR spectrum of compound **22** matched that of the published data (25). The lactone **22** (5.0 g, 19.3 mmol) was dissolved in THF (20 mL) and MeOH (50 mL) was then added. To this solution, $NaBH_4$ was added portionwise at 0 °C. The progress of the reaction was followed by TLC analysis of the aliquots (hexane–EtOAc, 1:1). When the starting material **22** had been consumed, the solvent was evaporated under reduced pressure. The residue was redissolved in EtOAc (50 mL), washed with aqueous tartaric acid solution (2 × 10 mL) and brine (50 mL), and dried over Na_2SO_4. Purification by column chromatography (hexane–EtOAc, 2:1) yielded compound **23** as a colourless syrup (3.9 g, 77%). The NMR spectrum of compound **23** matched that of the published data (26). The diol **23** (5.0 g, 19.1 mmol) was dissolved in CH_2Cl_2 (50 mL) and the solution was added dropwise to a mixture of pyridine (100 mL) and methanesulfonyl chloride (6 mL, 77.5 mmol) and cooled to 0 °C. The reaction mixture was stirred at 0 °C for 30 min and then allowed to warm to RT for 6 h. When TLC analysis of the aliquots (hexane–EtOAc, 1:1) showed total consumption of the starting material, the reaction mixture was poured into ice water, extracted with CH_2Cl_2 (3 × 100 mL), washed with brine (50 mL), and dried over Na_2SO_4. Purification by column chromatography (hexane–EtOAc, 2:1) yielded compound **24** as a colourless syrup (5.9 g, 75%). $[\alpha]^{22}_{D}$ –46° (*c* 1, CH_2Cl_2). ^{1}H NMR ($(CD_3)_2O$) δ: 4.87 (dd, 1H, $J_{3,4}$ = 5.8 Hz, $J_{4,5}$ = 4.7 Hz, H-4), 4.56 (ddd, 1H, $J_{1b,2}$ = 6.0 Hz, $J_{1a,1b}$ = 12.0 Hz, H-1b), 4.56–4.48 (m, 2H, H-2, H-3, H-1a), 4.48 (dd, 1H, H-1a), 4.46 (ddd, 1H, H-5), 4.14 (dd, 1H, $J_{5,6b}$ = 6.8 Hz, $J_{6a,6b}$ = 8.7 Hz, H-6b), 4.02 (dd, 1H, $J_{5,6a}$ = 6.7 Hz, H-6a), 3.23, 3.14 (2 s, 6H, 2 × OSO_2CH_3), 1.51, 1.41, 1.38, 1.34 (4 s, 12H, 4 × CH_3). ^{13}C NMR ($(CD_3)_2O$) δ: 110.1, 109.6 ($(CH_3)_2C(OR)_2$), 79.1 (C-4), 75.6 (C-3), 75.0 (C-2), 74.9 (C-1), 68.7 (C-5), 65.4 (C-6), 38.8, 36.7 (2 × OSO_2CH_3), 26.9, 25.6, 25.1, 25.0 (4 × CH_3). on activated carbon (10%, 1.0 g) was added as a catalyst at RT. The reaction mixture was placed in a steel reaction vessel and underwent hydrogenation (100 psi, 1 psi = 6.894 757 kPa) at 60 °C for 48 h. The progress of the reaction was followed by TLC analysis of the aliquots (EtOAc–MeOH–H_2O, 10:3:1). When the starting material **25** had been essentially consumed, the reaction was stopped and the reaction mixture was filtered under vacuum and washed with water (2 × 50 mL). The filtrate and the wash were combined and the water was then evaporated under reduced pressure. The residue was recrystallized from methanol – ethyl acetate to give compound **26** as a white solid (21.5 g, 71%). The NMR spectrum of compound **26** matched that of the published literature (26). To a suspension of the lactone **26** (10.0 g, 56.1 mmol) in dry acetone (200 mL), 2,2-dimethoxypropane (40 mL, 0.32 mmol) was added at RT. To this mixture, *p*-toluenesulfonic acid (200 mg) was added as a catalyst. The progress of the reaction was followed by TLC analysis of the aliquots (hexane–EtOAc, 1:1). When the starting material **26** had been essentially consumed, the reaction was stopped by addition of triethylamine (1 mL). The solvent was then evaporated under reduced pressure and the residue was purified by column chromatography (hexane–EtOAc, 1:1) to give compound **27** as a white solid. The NMR spectrum of compound **26** matched that of the published data (25). Lactone **27** (5.0 g, 19.3 mmol) was dissolved in THF (20 mL) and MeOH (50 mL) was then added. To this solution, $NaBH_4$ was added portionwise at 0 °C. The progress of the reaction was followed by TLC analysis of the aliquots (hexane–EtOAc, 1:1). When the starting material **27** had been consumed, the solvent was evaporated under reduced pressure. The residue was redissolved in EtOAc (50 mL), washed with aqueous tartaric acid solution (2 × 10 mL) and brine (50 mL), and dried over Na_2SO_4. After evaporating the solvent, the crude diol was used directly in the next step. The crude diol was dissolved in CH_2Cl_2 (50 mL). The solution was added dropwise to a mixture of pyridine (100 mL) and methanesulfonyl chloride (6 mL, 77.5 mmol) and cooled to 0 °C. The reaction mixture was stirred at 0 °C for 30 min, then allowed to warm to RT for 6 h. When TLC analysis of the aliquots (hexane–EtOAc, 1:1) showed total consumption of the starting material, the reaction mixture was poured into ice water, extracted with CH_2Cl_2 (3 × 100 mL), washed with brine (50 mL), and dried over Na_2SO_4. Purification by column chromatography (hexane–EtOAc, 2:1) yielded compound **28** as a colourless syrup (3.6 g, 45% for two steps). $[\alpha]^{22}_D$ +54° (*c* 4, CH_2Cl_2). ^{1}H NMR (($CD_3)_2O$) δ: 4.87 (dd, 1H, $J_{3,4}$ = 6.1 Hz, $J_{4,5}$ = 4.8 Hz, H-4), 4.57 (ddd, 1H, $J_{1b,2}$ = 6.0 Hz, $J_{1a,1b}$ = 12.0 Hz, H-1b), 4.56–4.48 (m, 3H, H-2, H-3, H-1a), 4.45 (ddd, 1H, H-5), 4.13 (dd, 1H, $J_{5,6b}$ = 6.7 Hz, $J_{6a,6b}$ = 8.6 Hz, H-6b), 4.03 (dd, 1H, $J_{5,6a}$ = 6.6 Hz, H-6a), 3.24, 3.15 (2 s, 6H, 2 × OSO_2CH_3), 1.52, 1.41, 1.38, 1.34 (4 s, 12H, 4 × CH_3). ^{13}C NMR (($CD_3)_2O$) δ: 114.3, 113.8 (($CH_3)_2C(OR)_2$), 83.3 (C-4), 79.7 (C-3), 79.0 (C-2), 78.9 (C-1), 72.9 (C-5), 69.6 (C-6), 43.0, 40.9 (2 × OSO_2CH_3), 31.3, 29.9, 29.3, 29.2 (4 × CH_3). General procedure for the preparation of sulfonium and selenonium sulfates 29–36

A mixture of **15**, **16**, **17**, or 1**8**, and the cyclic sulfate **19** or **20** in HFIP (1,1,1,3,3,3-hexafluoroisopropanol) was placed in a reaction vessel and K_2CO_3 (20 mg) was added. The stirred reaction mixture was heated in a sealed tube at the indicated temperature for the indicated time, as given later. The progress of the reaction was followed by TLC analysis of the aliquots (EtOAc–MeOH, 10:1). When the limiting reagent had been essentially consumed, the mixture was cooled, diluted with CH_2Cl_2, and evaporated to give a syrupy residue. Purification by column chromatography (EtOAc to EtOAc–MeOH, 10:1) gave the purified sulfonium salts and selenonium salts **29**–**36**.

1,4-Anhydro-2,3,5,6-di-*O*-isopropylidene-1-[(S)-[(2′S,3′S)-2′,4 -benzylidenedioxy-3′-(sulfooxy)butyl]selenonio]-D-allitol inner salt (29)

The reaction of compound **15** (500 mg, 1.63 mmol) with the cyclic sulfate **19** (530 mg, 1.94 mmol) in HFIP (2.0 mL) for 12 h at 80–85 °C gave compound **29** as a colourless, amorphous solid (850 mg, 90% based on **15**). $[\alpha]^{22}_D$ +12° (*c* 0.5, CH_2Cl_2). ^{1}H NMR ($(CD_3)_2O$) δ: 7.56–7.38 (m, 5H, H-Arom.), 5.74 (s, 1H, C*H*Ph), 5.52 (ddd, 1H, $J_{1b,2}$ = 5.2 Hz, $J_{2,3}$ = 5.7, H-2), 5.27 (dd, 1H, H-3), 4.78 (ddd, 1H, ddd, 1H, $J_{5,6b}$ = 7.3 Hz, $J_{5,6a}$ = 5.2 Hz, $J_{4,5}$ = 3.8 Hz, H-5), 4.62 (dd, 1H, H-4), 4.46–4.37 (m, 4H, H-1′b, H-2′, H-3′, H-4′b), 4.28 (dd, 1H, $J_{1'a,1'b}$ = 13.4 Hz, $J_{1'a,2'}$ = 3.8 Hz, H-1′a), 4.25 (dd, 1H, $J_{6a,6b}$ = 9.5 Hz, $J_{5,6b}$ = 7.3 Hz, H-6b), 4.10 (dd, 1H, $J_{1b,2}$ = 5.2 Hz, $J_{1a,1b}$ = 15.4 Hz, H-1b), 3.97 (dd, 1H, H-1a), 3.96 (dd, 1H, $J_{5,6a}$ = 5.2 Hz, H-6a), 3.78 (m, 1H, H-4′a), 1.64, 1.42, 1.38, 1.32 (4 s, 18H, 4 × CH_3). ^{13}C NMR ($(CD_3)_2O$) δ: 142.3, 133.9, 133.0, 131.1 (C-Ar), 116.9, 115.7 (2 $(CH_3)_2C(OR)_2$), 106.1 (*C*HPh), 89.9 (C-3), 89.8 (C-2), 81.3 (C-2′), 79.0 (C-5), 73.9 (C-4), 73.5 (C-4′), 71.8 (C-6), 71.5 (C-3), 52.8 (C-1), 50.4 (C-1′), 30.3, 30.1, 28.2, 27.1 (4 × *C*H_3). General procedure for the deprotection of the coupled products to yield the final compounds 7–14

The protected coupled products **29**–**36** were dissolved in CH_2Cl_2 (2 mL), TFA (10 mL) was then added, and the mixture was stirred for 6–8 h at RT. The progress of the reaction was followed by TLC analysis of the aliquots (EtOAc–MeOH–H_2O, 7:3:1). When the starting material had been consumed, the TFA and CH_2Cl_2 were removed under reduced pressure. The residue was rinsed with CH_2Cl_2 (4 × 2 mL) and the CH_2Cl_2 was decanted to remove the cleaved protecting groups. The remaining gum was dissolved in water and purified by column chromatography (EtOAc and EtOAc–MeOH, 2:1) to give the purified compounds **7**–**10** as colourless, amorphous, and hygroscopic solids. In the cases of **33**–**36**, the benzylidene groups were not completely cleaved. The residue was then dissolved in 80% AcOH (10 mL) and Pd–C (10%, 200 mg, in two portions) was added and the reaction mixture was subjected to hydrogenolysis for 48 h at RT. After filtering the Pd–C, the filtrate was mixed with water (100 mL) and the solvents were removed under reduced pressure. The remaining gum was dissolved in water and purified by column chromatography (EtOAc and EtOAc–MeOH, 2:1) to give the purified compounds **11**–**14** as colourless, amorphous, and hygroscopic solids.

1,4-Anhydro-1-[(S)-[(2′S,3′S)-2′,4′-dihydroxy-3′-(sufooxy)butyl]selenonio]-D-allitol inner salt (7)

To a solution of **29** (500 mg, 0.86 mmol) in CH_2Cl_2 (2 mL) was added TFA (10 mL) to yield the compound **7** as a colourless, amorphous, and hygroscopic solid (202 mg, 57%). $[\alpha]^{22}_D$ +54° (*c* 2, H_2O). ^{1}H NMR (D_2O) δ: 4.74 (m, 1H, H-2), 4.34 (dd, 1H, $J_{2,3}$ = 9.1 Hz, $J_{3,4}$ = 3.1 Hz, H-3), 4.28 (ddd, 1H, H-3′), 4.25–4.18 (m, 2H, H-2′, H-5), 4.05 (dd, 1H, $J_{4,5}$ = 4.3 Hz, H-4), 3.97 (dd, 1H, $J_{1'b,2'}$ = 3.6 Hz, $J_{1'a,1'b}$ = 12.6 Hz, H-1′b), 3.82 (dd, 1H, $J_{3',4'b}$ = 6.4 Hz, H-4′b), 3.80 (dd, 1H, $J_{1'a,2'}$ = 3.2 Hz, H-1′a), 3.73 (dd, 1H, $J_{3',4'a}$ = 3.3 Hz, 1H, $J_{4'a,4'b}$ = 12.8 Hz, H-4′a), 3.68 (m, 2H, H-6a, H-6b), 3.55 (dd, 1H, $J_{1b,2}$ = 3.7 Hz, H-1b), 3.33 (dd, 1H, $J_{1a,2}$ = 2.1 Hz, $J_{1a,1b}$ = 13.1 Hz, H-1a). ^{13}C NMR (D_2O) δ: 80.8 (C-3′), 76.0 (C-2), 75.9 (C-3), 68.4 (C-5), 66.0 (C-2′), 65.1 (C-4), 63.4 (C-6), 60.1 (C-4′), 48.5 (C-1′), 40.5 (C-1). Synthesis of an 11-*cis*-locked biotinylated retinoid for sequestering 11-*cis*-retinoid binding proteins[1]

Hiroko Matsuda, Shenglong Zhang, Andrea E. Holmes, Sonja Krane, Yasuhiro Itagaki, Koji Nakanishi, and Nasri Nesnas

Abstract: The synthesis of a seven-membered ring locked analogue of 11-*cis*-retinol, tethered to a cross-linking moiety on C-15 and a lysine-extended biotin on the C-3, was accomplished for its utilization as a probe to fish out retinol binding proteins that may be involved in the reisomerization of retinal from all-*trans* to 11-*cis* in the visual cycle.

Key words: retinoids, biotin, 11-*cis*-locked, cross-linking, retinol binding proteins.

Résumé : La synthèse d'un analogue de 11-*cis*-rétinol sous la forme d'un anneau verrouillé, comportant sept membres, attachés en partie, au C-15, avec un groupe ayant la possibilité de se liér aux protéines a été réalisée. En plus, l'analogue est attaché de l'autre côté sur le C-3, avec une lysine biotine étendue. Cette synthèse a été réalisée afin d'utilizer le composé comme agent détecteur des protéines qui portent des rétinols et qui pourraient être impliquées dans la réisomerization du all-*trans* retinal au 11-*cis* dans le cycle de vision.

Mots clés : rétinoides, biotine, 11-*cis*-verrouillé, liés, protéines qui portent des rétinols.

Introduction

The basic process of vision, first elucidated by Wald (1), involves the light-triggered isomerization of retinal (or vitamin A aldehyde) from its 11-*cis* conformation to the all-trans conformation. Retinal, in its 11-*cis* geometry, is bound by the apoprotein opsin, a G-protein coupled receptor, forming a protonated Schiff base with Lys296, present in Helix G of the seven-membered transmembrane protein,which generates rhodopsin, the active photoreceptor unit in the cones and rods of eyes (2, 3). Upon absorption of a photon by 11-*cis*-retinal, the retinoid undergoes an isomerization to the all-trans geometry, resulting in a conformational change in the protein that leads to the activation of the G protein, which ultimately results in vision (4). The all-*trans*-retinal is subsequently hydrolyzed off the lysine residue, freeing the protein for a fresh 11-*cis*-retinal molecule. The completion of the visual cycle is ultimately dependent on the less well-understood proteins that are capable of binding all *trans*-retinoids and converting them to the 11-*cis*-retinal geometry (5). The latter proteins are collectively termed retinol binding proteins (RBPs). Their crucial involvement in the visual cycle warrants the need for the development of tools that enable their isolation and purification for further studies of their detailed function.

We have previously synthesized (6) a biotin-linked 11-*cis*-retinol analogue (structure **1** without the trimethylene bridge linking C-10 and C-13), as well as the all-*trans*-retinol analogue, **1a**. The latter derivative, bearing a biotin moiety and a chloroacetate cross-linking unit, enabled us to successfully isolate and characterize certain retinol binding proteins (7). We attempted to use the biotin-linked 11-*cis* analogue in the isolation of RBPs involved in the isomerization of all-*trans*-retinal to 11-*cis*-retinal. Despite the synthetic accomplishment (6), the retinoid was prone to undergoing an inevitable isomerization from 11-*cis* to all-trans upon incubation in the retinal pigment epithelial (RPE) cells, thus losing its affinity toward the RBPs of interest. To circumvent this problem, we resorted to ret7 (Fig. 1), the first of the 11-*cis*-locked analogues, which is comprised of a seven-membered ring locking the double bond at the C-11 position into a *cis*-conformation (8). This retinoid was particularly useful because it retains the full chromophore properties of native 11-*cis*-retinal and readily forms, with bovine opsin, the nonbleachable pigment, rhodopsin 7 or rh7. Both the UV–vis λ_{max} of 490 nm and the CD maxima at 330 and 488 nm

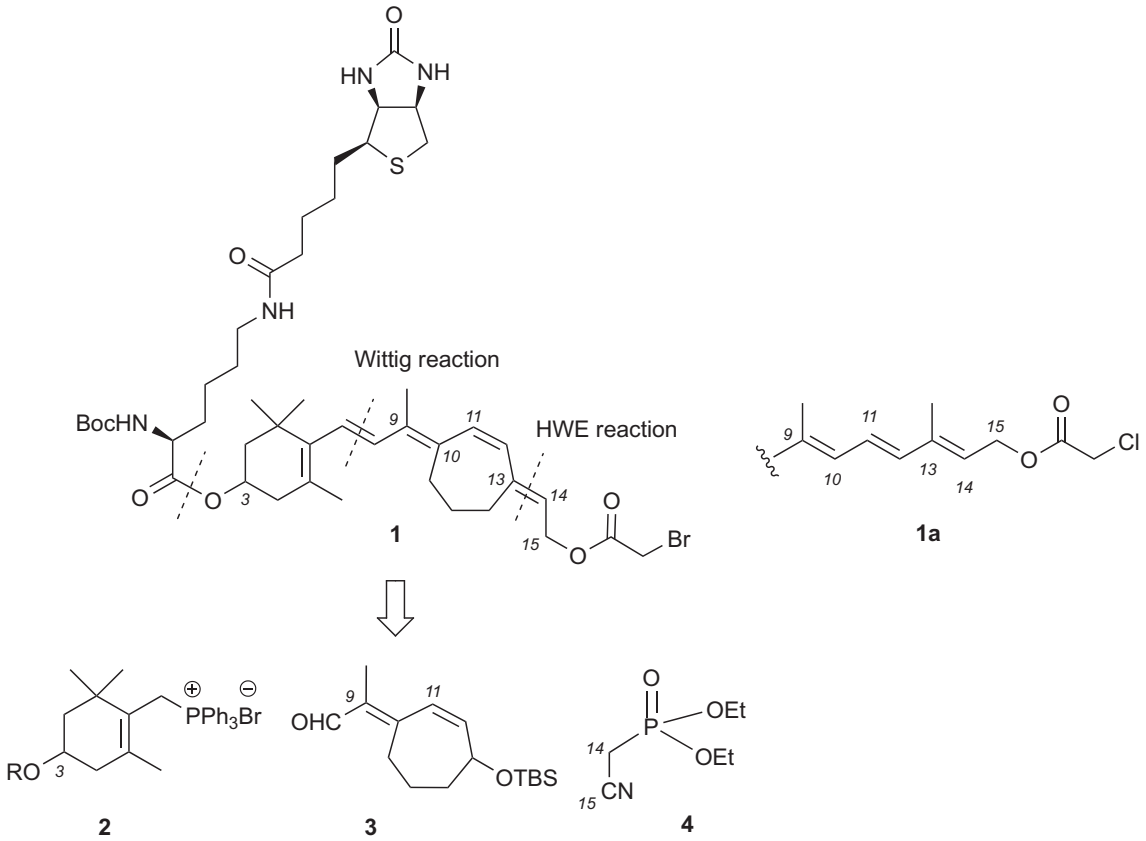
Scheme 1. Retrosynthetic analysis for the biotinylated retinoid **1**.



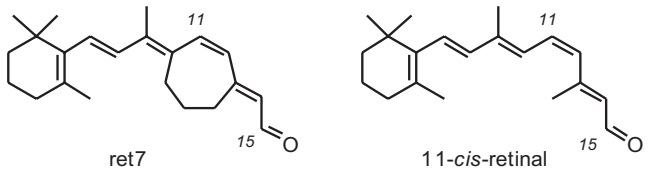


Fig. 1. The structures of ret7 and the native 11-*cis*-retinal.

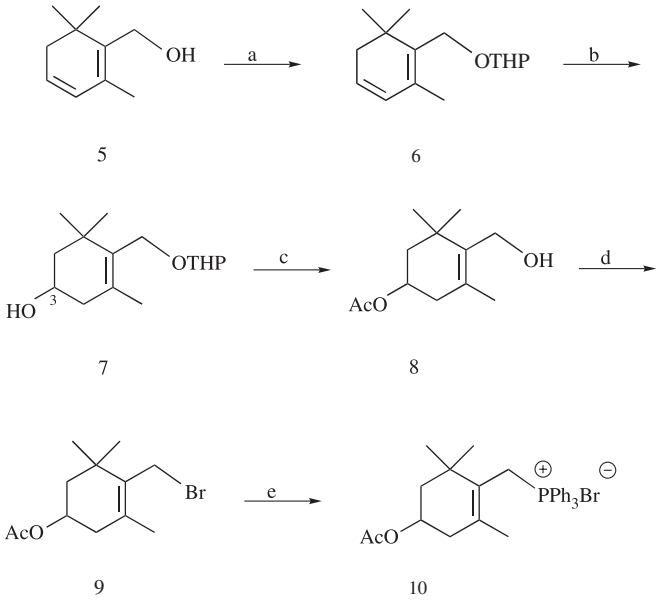
(digitonin–phosphate buffer, pH 7) are similar to those of the native chromophore (UV–vis λ_{max} at 500 nm and CD maxima at 340 and 490 nm), indicating that the binding sites are the same. These aspects have made this pigment a popular substrate for various spectroscopic measurements (9–11).

We hereby report the synthesis of 11-*cis*-locked retinoid **1** bearing an appropriate functionality for isolation through cross-linking and which possesses the additional advantage of resisting isomerization under light conditions as well as in the media of RPE cells.

The target structure **1** has significant features that merit highlighting. It has the basic 11-*cis*-retinoid structure that can bind selectively to certain RBPs involved in the reisomerization of all-*trans*- to 11-*cis*-retinal. It also harbors an active cross-linking unit, the bromoacetate functionality, which can form a stable covalent bond with the RBPs and it also has the (Boc)Lys-biotinyl linker anchored at C-3, which will facilitate isolation of the covalently linked protein via an avidin affinity chromatography. Moreover, the ret7 moiety in the structure ensures its stability against light and (or) the RPE cell medium. Based on our earlier studies, the presence of the seven-membered ring would not prevent the retinoid from binding into the protein (8, 12, 13).

Results and discussion



The retrosynthetic logic for **1** is shown in Scheme 1. It stems from our earlier work conducted on the seven-membered ring unit **3**, synthesized from 2-cyclohepten-1-one in five steps (14). The hydroxylated β-ionone ring structure can be introduced by employing a Wittig reaction between aldehyde **3** and synthon **2**, the latter being prepared from dehydro-β-cyclocitral (also known as safranal) in seven steps as outlined in Scheme 2. The Horner–Wadsworth–Emmons (HWE) reaction can be used to install a nitrile group at the C-14 position with reagent **4**, followed by its reduction to the corresponding aldehyde, which would be subjected to further reduction to the corresponding primary alcohol onto which a bromoester can be esterified in the final stages.

Synthon **3** has been prepared from the commercially available 2-cyclohepten-1-one, according to our earlier report (14). The synthesis featured an allylic oxidation of 2-cyclohepten-1-one, a three-carbon homologation by HWE reaction with the reagent bearing the nitrile functionality, and lastly, a partial reduction of the nitrile to the corresponding aldehyde.

The synthesis of **10** (the synthon **2** unit) is outlined in Scheme 2. Dehydro-β-cyclocitrol (**5**), prepared from dehydro-β-cyclocitral (15), was protected as the tetrahydropyranyl (THP) ether (→**6**, 81%) and subsequently treated

Scheme 2. Reagents and conditions: (*a*) DHP, *p*-TsOH, CH_2Cl_2, 0 °C (81%); (*b*) 9-BBN, THF, Δ, then MeOH, NaOH, H_2O_2, 0 °C → 50 °C (55%); (*c*) (*i*) Ac_2O, pyridine, CH_2Cl_2, rt, (*ii*) *p*-TsOH, MeOH, rt (60%, two steps); (*d*) PPh_3, CBr_4, THF (94%); (*e*) PPh_3, benzene, Δ (quant.).]

with 9-borabicyclo[3.3.1]nonane (9-BBN) to undergo a hydroboration reaction affording the 3-hydroxy **7** in 55% yield. As in the case of the biotinylated all-trans analogue **1a** (6, 7), no attempts were made to resolve the C-3 enantiomers. The 3-hydroxy group was protected as the acetate by treatment with acetic anhydride (Ac_2O) – pyridine. The allylic hydroxy group was then liberated by acidic cleavage of the THP group to give alcohol **8**, which was transformed to the corresponding bromide **9** using triphenylphosphine (PPh_3) and carbon tetrabromide (94% yield). The phosphonium salt **10** was synthesized from **9** by treatment with PPh_3 under reflux conditions.

Scheme 3 shows the critical steps that assemble the retinoid from synthons **3** and **10**. A Wittig reaction between aldehyde **3** and phosphonium salt **10** afforded the desired tetraene **11a** (33%), along with a considerable amount of **11b** (40%). The trans geometry of the olefin thus formed was confirmed from the coupling constant (J = 16 Hz) observed for the H-7 and H-8 protons. The TBS group of **11a** was removed using tetrabutylammonium fluoride (TBAF) to give the free allylic alcohol, which, upon treatment with MnO_2, underwent smooth oxidation to afford the conjugated ketone **12** in 84% yield. A two-carbon extension through HWE reaction was carried out on ketone **12** with cyanomethylphoshonate (**4**) to afford the (*E*)-isomer **13** in 27% yield (the (*Z*)-isomer, 53%). The *E*/*Z* geometry was determined by NOE experiments for the H-12 and H-14 protons. Nitrile **13** was subjected to partial reduction with diisobutylaluminum hydride (DIBAH) to the corresponding aldehyde accompanied by an inevitable reductive cleavage of the acetate group at the C-3 position. After reprotection of the free alcohol with an acetyl group, resulting in **14**, the aldehyde was further reduced to the corresponding primary alcohol by treatment with sodium borohydride and was then protected as a TBS ether to afford **15**. Basic cleavage of the 3-acetyl group gave the corresponding 3-OH followed by esterification with biotinyl-(Boc)Lys-OH to give **16** (78% yield, two steps). The TBS group was deprotected, releasing the primary alcohol, which was eventually subjected to esterification with bromoacetic acid to afford the target structure **1** in 66% yield.

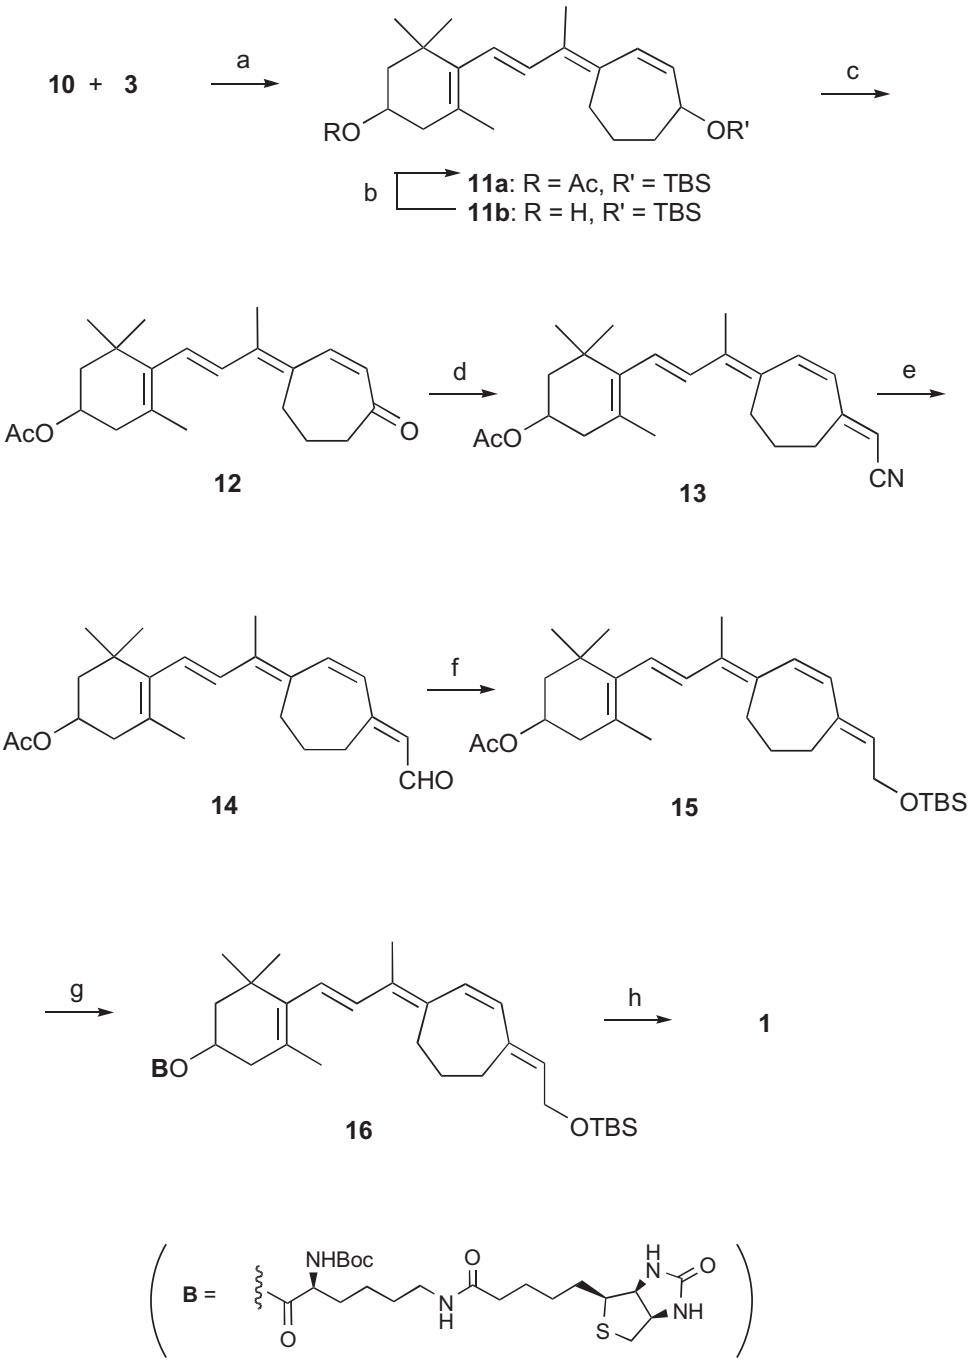
Preliminary studies directed towards isolation and characterization of RBPs employing **1** performed by Rando's group (Harvard Medical School, Boston, Massachusetts) have shown that some RBPs have been sequestered and identified. The results of the isolation and characterization of the RBPs using **1** will be reported in a subsequent manuscript.

Conclusion

The synthesis of biotinylated retinoid **1** was accomplished via a series of Wittig reactions, esterification of a (Boc)Lys-biotin on the 3-hydroxy position of the β-ionone ring, and the final attachment of the active bromoester cross-linking unit. The significance of the seven-membered ring lock is evident as the preliminary biological studies using this molecule have already proven the robust nature of the 11-*cis*-olefin unit. The target structure will be able to cross-link to RBPs that are involved in the crucial isomerization process that regenerates 11-*cis*-retinal. Avidin affinity chromatography will enable facile purification of the sequestered protein, and basic hydrolysis will release the isolated protein from the affinity column by cleaving the ester at the C-15 position. The purified protein can be further studied and characterized for the elucidation of its detailed function.

Experimental section

General considerations



^{1}H NMR spectra were measured on a Bruker DMX 400 or Bruker DPX 300 spectrometer (400 or 300 MHz). The chemical shifts are expressed in ppm downfield from the signal of tetramethylsilane, used as an internal standard in the solvent $CDCl_3$. Splitting patterns are designated as s (singlet), d (doublet), t (triplet), q (quartet), qn (quintet), m (multiplet), and br (broad). High resolution mass spectrometry (HRMS) were measured on a JEOL (Tokyo) JMS-HX110/110 tandem mass spectrometer equipped with a Xe beam FAB gun (6 kV), using 3-nitrobenzyl alcohol as a matrix. Analytical and preparative thin layer chromatography (TLC) was carried out using precoated silica gel plates (Merck silica gel $60F_{254}$). The silica gel used for column chromatography was 230–400 mesh (Merck). All reactions were carried out under an Ar atmosphere using predried solvents. Anhydrous CH_2Cl_2, Et_2O, and THF were obtained from the solvent purification system via passage through an activated alumina cartridge.

Tetrahydropyranyl safranol (6)

To a solution of safranol **5** (7.67 g, 50.4 mmol) in CH_2Cl_2 (100 mL) was added 3,4-dihydro-2*H*-pyran (DHP, 8.48 g, 101 mmol). The mixture was stirred and cooled to –10 °C and *p*-toluenesulfonic acid monohydrate (*p*-TsOH, 190 mg, 1.00 mmol) was then added. After 10 min of stirring, triethylamine (1.0 mL) was added to quench the reaction.

Scheme 3. Reagents and conditions: (*a*) *n*-BuLi, THF, –78 °C → rt, (for **11a**, 33%; for **11b**, 40%); (*b*) Ac_2O, pyridine, DMAP, rt for **11b** (63%); (*c*) (*i*) TBAF, THF, 0 °C → rt (99%), (*ii*) MnO_2, CH_2Cl_2, 0 °C → rt (84%); (*d*) **4**, NaH, THF, 0 °C → rt (*E*:*Z*, 27%:53%); (*e*) (*i*) DIBAH, Et_2O, –78 °C → 0 °C (82%), (*ii*) Ac_2O, pyridine, CH_2Cl_2, 0 °C → rt (50%); (*f*) (*i*) $NaBH_4$, MeOH–$CHCl_3$ (1:10), 0 °C, (*ii*) TBSCl, imidazole, CH_2Cl_2, 0 °C (70%, two steps); (*g*) (*i*) K_2CO_3, MeOH, 0 °C → rt, (*ii*) biotinyl (Boc)lys-OH (**B**-OH), EDC, DMAP, CH_2Cl_2, 0 °C → rt (78%, two steps); (*h*) (*i*) TBAF, THF, 0 °C → rt (60%), (*ii*) $BrCH_2COOH$, EDC, DMAP, 0 °C → rt (66%).

The mixture was poured into water (150 mL) and extracted with Et_2O (3 × 150 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated under reduced pressure. Purification of the residue by silica gel column chromatography (EtOAc–hexanes, 10:90) afforded the THP ether **6** (9.60 g, 40.8 mmol, 81%) as a colorless oil. ^{1}H NMR ($CDCl_3$, ppm) δ: 5.75 (2H), 4.61 (1H, brs), 4.31 (1H, d, *J* = 11.2 Hz), 4.07 (1H, d, *J* = 11.2 Hz), 3.91 (1H, m), 3.52 (1H, m), 2.05 (2H, s), 1.81 (3H, s), 1.81–1.69 (6H), 1.04, 1.01 (each 3H, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 134, 129.9, 129.1, 126, 97.7, 63.4, 62.4, 40.3, 33.5, 31.0, 26.7 (2C), 25.9, 19.9, 18.4. FAB-HRMS calcd. for $C_{15}H_{24}O_2$ *m*/*z*: 236.1776 [M^+]; found: 236.1769.

Tetrahydropyranyl 3-hydroxysafranol (7)

To a solution of THP ether **6** (6.66 g, 28.2 mmol) in THF (40.0 mL), 9-BBN (0.5 mol/L solution in THF, 113 mL, 56.4 mmol) was added slowly over 20 min. The reaction

mixture was heated up to 60 °C and was stirred for 4 h. After the reaction mixture was cooled to room temperature, methanol (68.0 mL) and an aq. NaOH solution (3 mol/L, 9.4 mL) were added to it. Subsequently, H_2O_2 (30% solution, 8.0 mL) was added slowly to the stirring reaction mixture using an ice bath. The reaction mixture was heated for 2 h at 55 °C. The mixture was poured into water (100 mL) and extracted with EtOAc (3 × 100 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated in vacuo. Purification of the residue by silica gel column chromatography (EtOAc–hexanes, 30:70) afforded a diastereomeric mixture of **7** (3.94 g, 15.5 mmol, 55%). The ^{1}H NMR spectra indicated that the sample consisted of a mixture of diastereomers (50:50). ^{1}H NMR ($CDCl_3$, ppm) δ: 4.55 (2 × 0.5H, dt, *J* = 3.2, 8.5 Hz), 4.26, 4.17, 3.80, 3.74 (each 0.5H, d, *J* = 10.7 Hz), 3.93–3.81 (0.5H × 2 × 2), 3.50 (0.5H × 2, m), 2.37 (0.5H × 2, brs), 2.27 (0.5H × 2, brdt), 2.01 (0.5H × 2, brdd), 1.78 (0.5H × 2, m), 1.69, 1.68 (each 1.5H, s), 1.70–1.62 (0.5H × 2 × 2), 1.56–1.40 (0.5H × 2 × 5), 1.06, 1.02, 1.00, 0.993 (each 1.5H, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 134, 133, 131.5, 131.4, 98.9, 98.6, 64.9 (0.5C × 2), 63.5, 63.4, 62.4, 62.3, 48.2 (0.5C × 2), 42.3 (0.5C × 2), 36.8 (0.5C × 2), 30.7 (0.5C × 2), 29.4, 29.2, 28.7, 28.6, 25.5 (0.5C × 2), 19.7 (0.5C × 2), 19.69, 19.63. FAB-HRMS calcd. for $C_{15}H_{26}O_3$ *m*/*z*: 254.1882 [M^+]; found: 254.1891.

3-*O*-Acetoxysafranol (8)

To a solution of hydroxy **7** (1.00 g, 3.93 mmol) in pyridine (7.0 mL), acetic anhydride (3.5 mL) was added at 0 °C. The resultant mixture was stirred at room temperature. After 12 h of stirring, the mixture was azeotropically concentrated with toluene (×3) in vacuo. The crude sample was subjected to the next step without purification. The acetate was treated with a catalytic amount of *p*-TsOH (10.0 mg) in methanol (60.0 mL). The resultant mixture was allowed to stir for 12 h at room temperature. The mixture was neutralized with Et_3N (1.0 mL) and concentrated under reduced pressure. Silica gel purification of the residue (EtOAc–hexanes, 25:75) gave the 3-*O*-acetyl safranol **8** (576 mg, 2.72 mmol, 70%, in two steps). ^{1}H NMR ($CDCl_3$, ppm) δ: 4.97 (1H, m), 4.13, 4.07 (each 1H, d, *J* = 11.5 Hz), 2.35 (1H, dd, *J* = 5.7, 16.9 Hz), 2.04 (1H, dd, *J* = 9.4, 16.9 Hz), 2.00 (3H, s), 1.71 (1H, m) overlapping with 1.72 (3H, s), 1.52 (1H, t, *J* = 11.9 Hz), 1.45 (1H, br, CH_2OH), 1.09, 1.05 (each 3H, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 170, 137, 127, 68.2, 58.2, 43.8, 38.2, 36.4, 29.2, 28.5, 21.5, 19.5.

3-*O*-Acetoxysafranyl bromide (9)

To a solution of alcohol **8** (576 mg, 2.72 mmol) in THF (20.0 mL) at 0 °C, PPh_3 (1.07 g, 4.08 mmol) and CBr_4 (1.35 g, 4.08 mmol) were added. The resultant mixture was stirred at room temperature for 1 h. The mixture was poured into water (50 mL) and extracted with Et_2O (3 × 50 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated in vacuo. The residue was purified with silica gel chromatography (EtOAc–hexanes, 2:98) to afford the allyl bromide **9** (710 mg, 2.55 mmol, 94%). ^{1}H NMR ($CDCl_3$, ppm) δ: 4.99 (1H, m), 4.07, 3.96 (each 1H, d, *J* = 8.2 Hz), 2.43 (1H, dd, *J* = 4.5, 13.8 Hz), 2.11 (1H, dd, *J* = 7.4, 13.8 Hz), 2.02 (3H, s), 1.72 (1H, m) overlapping with 1.75 (3H, s), 1.58 (1H, t, *J* = 9.5 Hz), 1.20, 1.12 (each 3H, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 169, 133.4, 144.2, 67.2, 43.5, 38.4, 36.7, 29.0, 28.6, 28.3, 21.1, 19.6. FAB-HRMS calcd. for $C_{12}H_1{}^{8}{}^{79}BrO_2$ *m*/*z*: 273.0490 [M – H]$^+$; found: 273.0497.

3-*O*-Acetoxysafranyl triphenylphosphonium bromide (10)

To a solution of allyl bromide **9** (710 mg, 2.55 mmol) in benzene (20.0 mL) at room temperature, PPh_3 (670 mg, 2.55 mmol) was added. The resultant mixture was heated up to the reflux temperature (~85 °C bath) for 12 h. After the mixture was cooled to room temperature, the volatiles were evaporated in vacuo. The residue was washed with benzene (×3) and dried under the reduced pressure for 1 day to give **10** (1.37 g, 2.55 mmol, quantitative yield). ^{1}H NMR ($CDCl_3$, ppm) δ: 7.9–7.6 (15H), 4.97 (1H, m), 4.58, 4.42 (each 1H, t, *J* = 14.0 Hz), 2.26 (1H, m), 2.04 (3H, s), 1.95 (1H, m), 1.71 (1H, dd, *J* = 2.0, 12.0 Hz), 1.51 (1H, t, *J* = 12.0 Hz), 1.07 (3H, d, *J* = 4.0 Hz), 0.88, 0.84 (each 3H, s). FAB-HRMS calcd. for $C_{30}H_{34}O_2P$ *m*/*z*: 457.2291 [M – Br]$^+$; found: 457.2285.

3-*O*-Acetyl-13-*O*-TBS (11a)

To a solution of the triphenylphosphonium bromide **10** (657 mg, 1.22 mmol) in THF (7.0 mL) at –78 °C, *n*-BuLi (2.5 mol/L solution in hexanes, 1.4 mL, 3.50 mmol) was added, and the resultant mixture was allowed to warm to room temperature and was stirred at this temperature for 1 h to generate the corresponding ylide. To a solution of aldehyde **3** (460 mg, 1.64 mmol) in THF (10.0 mL), the ylide solution was added. After 14 h of stirring at the same temperature, the mixture was poured into water and extracted with Et_2O (3 × 30 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated in vacuo. Purification of the residue by silica gel column chromatography (EtOAc–hexanes, 5:95 and 20:80) afforded the acetyl **11a** (245 mg, 534 μmol, 33%) and alcohol **11b** (276 mg, 663 μmol, 40%) as a colorless oil. The ratio of diastereomers was not determined and this sample was used as a mixture.

To a solution of 3-hydroxy **11b** (294 mg, 706 μmol) in pyridine (3.0 mL) at room temperature, Ac_2O (1.5 mL) and *N*,*N*-dimethylaminopyridine (DMAP, 5.0 mg) were added, and the resultant mixture was stirred at the same temperature for 12 h. The mixture was poured into a satd. aq. solution of $NaHCO_3$ (30 mL) and extracted with Et_2O (3 × 30 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated in vacuo. Purification of the residue by silica gel column chromatography (EtOAc–hexanes, 2:98) provided the acetyl **11a** (205 mg, 446 μmol, 63%) as a colorless oil. The ratio of diastereomers was not determined, and this sample was used as a diastereomeric mixture. ^{1}H NMR for **11a** ($CDCl_3$, ppm, major signals are only described.) δ: 6.49, 6.09 (each 1H, dd, *J* = 1.8, 16.0 Hz), 6.45, 5.69 (each 1H, dd, *J* = 2.2, 11.8 Hz), 5.06 (1H, m), 4.46 (1H, m), 2.67 (1H, dt, *J* = 5.0, 13.7 Hz), 2.44 (1H, dd, *J* = 5.8, 17.0 Hz), 2.23 (1H, m), 2.10 (1H, dd, *J* = 9.4, 16.6 Hz), 2.04 (3H, s), 1.87 (3H, s), 1.83–1.75 (2H), 1.72 (3H, s), 1.8–1.7 (2H), 1.58 (2H, t, *J* = 12.0 Hz), 1.10, 1.07 (each 3H, s), 0.906 (3H × 3, s), 0.090, 0.081 (each 3H, s). ^{13}C NMR

© 2006 NRC Canada

($CDCl_3$, ppm) δ: 170, 138, 137, 134, 132, 130, 129, 125.8, 125.0, 71.0, 68.4, 43.9, 38.3, 36.6, 35.6, 30.0, 29.8. 28.4, 25.8 (3C), 23.8, 21.4 (2C), 18.2, 14.3, –4.6 (2C). FAB-HRMS calcd for $C_{28}H_{46}O_3Si$ *m/z*: 458.3216 [M^+]; found: 458.3196. ^1H NMR for **11b** ($CDCl_3$, ppm, major signals are only described.) δ: 6.11, 6.49 (each 1H, d, *J* = 16.0 Hz), 5.69, 6.46 (each 1H, d, *J* = 11.9 Hz), 4.46 (1H, m), 4.01 (1H, m), 2.68 (1H, dt, *J* = 5.4, 8.8 Hz), 2.38 (1H, dd, *J* = 5.4, 16.6 Hz), 2.24 (1H, m), 2.04 (1H, m), 1.86 (3H, s), 1.71–1.85 (4H) overlapping with 1.73 (3H, s), 1.65 (1H, brs), 1.48 (1H, t, *J* = 11.9 Hz), 1.07 (3H × 2, s), 0.907 (3H × 3, s), 0.0815, 0.0914 (each 3H, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 138, 136, 134, 132, 130, 130, 125.67, 125.64, 71.0, 64.9, 48.2, 42.4, 37.0, 35.6, 30.2, 29.8, 28.6, 25.8 (3C), 23.8, 21.5, 18.2, 14.4, –4.6 (2C). FAB-MS *m/z* (%, rel. int.): 416 (52, M^+), 398 (25, [M – H_2O]$^+$). FAB-HRMS calcd. for $C_{26}H_{44}O_2Si$ *m/z*: 416.3111 [M^+]; found: 416.3106.

13-Ketone (12)

To a solution of **11a** (205 mg, 446 mmol) in THF (10.0 mL) at 0 °C, tetrabutylammonium fluoride (TBAF, 1.0 mol/L solution in THF, 892 μL, 892 μmol) was added, and the resultant mixture was allowed to warm to room temperature and was continuously stirred at this temperature. After 3 h of stirring, the mixture was poured into water (30 mL) and extracted with Et_2O (3 × 30 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated under reduced pressure. Purification of the residue by silica gel column chromatography (EtOAc–hexanes, 15:85) afforded the 13-hydroxy compound (145 mg, 425 μmol, 99%) as a colorless oil. ^1H NMR ($CDCl_3$, ppm) δ: 6.51, 5.73 (each 1H, d, *J* = 11.8 Hz), 6.47, 6.10 (each 1H, d, *J* = 15.8 Hz), 5.05 (1H, m), 4.47 (1H, m), 2.70 (1H, m), 2.44 (1H, dd, *J* = 5.4, 6.8 Hz), 2.23 (1H, m), 2.12 (1H, m), 2.05 (3H, s), 2.00–1.89 (2H), 1.88 (3H, s), 1.81–1.68 (2H, m), 1.71 (3H, s), 1.58 (2H, t, *J* = 11.9 Hz), 1.10, 1.07 (each 3H, s).

To a solution of the 13-hydroxy (209 mg, 607 μmol) in CH_2Cl_2 (15.0 mL) at 0 °C, MnO_2 (1.60 g, 18.2 mmol) was added, and the resultant mixture was stirred at this temperature. After 40 min of stirring at the same temperature, the mixture was filtered and the volatiles were removed under reduced pressure. Purification of the residue by silica gel column chromatography (EtOAc–hexanes, 20:80) afforded ketone **12** (174 mg, 507 μmol, 84%) as a colorless oil. ^1H NMR ($CDCl_3$, ppm) δ: 7.32, 5.92 (each 1H, d, *J* = 12.0 Hz), 6.55, 6.32 (each 1H, d, *J* = 18.0 Hz), 5.03 (1H, m), 2.63 (2H, t, *J* = 6.6 Hz), 2.57 (2H, t, *J* = 6.6 Hz), 2.45 (1H, dd, *J* = 5.4, 16.9 Hz), 2.11 (1H, dd, *J* = 9.6, 16.9 Hz), 2.04, 2.02 (each 3H, s), 1.87 (2H, qn, *J* = 6.6 Hz), 1.79 (1H, brt), 1.72 (3H, s), 1.58 (1H, t, *J* = 12.0 Hz), 1.10, 1.07 (each 3H, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 203, 170, 143, 137.9, 137.0, 134, 132, 130, 129, 126, 68.1, 43.8, 42.9, 38.3, 36.5, 31.2, 29.9, 28.4, 23.1, 21.4, 21.3, 15.0. FAB–HRMS calcd. for $C_{22}H_{31}O_3^+$ *m/z*: 343.2273 [M + H]$^+$; found: 343.2266.

13-Nitrilemethylene (13)

To a solution of NaH (freshly prepared by washing with hexanes and drying under reduced pressure, 140 mg, 5.84 mmol) in THF (15.0 mL) at 0 °C, $(EtO)_2P(O)CH_2CN$ (**4**, 944 μL, 5.84 mmol) was added, and the resultant mixture was allowed to warm to room temperature and was stirred at this temperature for 1 h to generate the corresponding ylide. To a solution of ketone **12** (174 mg, 507 μmol) in THF (25.0 mL), the generated ylide was added. After 12 h of stirring at the same temperature, the mixture was poured into water (30 mL) and extracted with Et_2O (3 × 30 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated in vacuo. Purification of the residue by silica gel column chromatography (EtOAc–hexanes, 7:93) afforded the (*E*)-nitrile **13** (47.1 mg, 135 μmol, 27%) and the (*Z*)-nitrile (99.3 mg, 265 μmol, 53%) as yellowish oils, respectively. ^1H NMR for (*E*)-isomer **13** ($CDCl_3$, ppm) δ: 6.82, 6.13 (each 1H, d, *J* = 11.3 Hz), 6.52, 6.25 (each 1H, d, *J* = 15.9 Hz), 5.15 (1H, s), 5.04 (1H, m), 2.67 (2H, t, *J* = 6.7 Hz), 2.52 (2H, t, *J* = 6.7 Hz), 2.46 (1H, dd, *J* = 5.9, 17.2 Hz), 2.12 (1H, dd, *J* = 9.5, 17.2 Hz), 2.05, 1.96 (each 3H, s), 1.87 (2H, qn, *J* = 6.7 Hz), 1.79 (1H, m), 1.73 (3H, s), 1.59 (1H, t, *J* = 12.2 Hz), 1.11, 1.08 (each 3H, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 170, 162, 139, 138, 134 (2C), 132, 129, 128, 126, 117, 96.3, 68.2, 43.9, 38.4, 36.6, 33.0, 31.3, 30.0, 28.5, 26.9, 21.5, 21.4, 14.9. FAB–HRMS calcd. for $C_{24}H_{31}NO_2$ *m/z*: 365.2355 [M^+]; found: 365.2354. ^1H NMR for the (*Z*)-isomer ($CDCl_3$, ppm) δ: 6.94, 6.57 (each 1H, d, *J* = 11.4 Hz), 6.50, 6.25 (each 1H, d, *J* = 16.0 Hz), 5.07 (1H, s), 5.04 (1H, m), 2.51 (2H, t, *J* = 6.7 Hz), 2.46 (1H, m) 2.42 (2H, t, *J* = 6.7 Hz), 2.11 (1H, dd, *J* = 9.5, 17.0 Hz), 2.04, 1.97 (each 3H, s), 1.83 (2H, qn, *J* = 6.7 Hz), 1.72 (3H, s), 1.59 (2H, t, *J* = 11.9 Hz), 1.11, 1.08 (each 3H, s).

14-Aldehyde (14)

To a solution of the (*E*)-nitrile **13** (35.7 mg, 97.7 μmol) in Et_2O (3.0 mL) at –78 °C, DIBAH (1.0 mol/L solution in toluene, 900 μL, 900 μmol) was added, and the resultant mixture was stirred at 0 °C. After 40 min of stirring, methanol (0.63 mL) was carefully added, followed by a 30% aqueous solution of Rochelle salt (potassium sodium tartrate) (1.08 mL), the resultant mixture was then stirred for 40 min. The organic layer was washed with a 30% Rochelle salt aqueous solution (2 × 0.45 mL and 1 × 0.23 mL). The combined aqueous layer was back-extracted with Et_2O (3 × 30 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated under reduced pressure. Purification of the residue by silica gel column chromatography (Et_2O–hexanes, 50:50) afforded the aldehyde without an acetyl group at C-3 (26.1 mg, 80.1 μmol, 82%) as an oil. ^1H NMR ($CDCl_3$, ppm) δ: 10.0 (1H, d, *J* = 8.2 Hz), 6.90, 6.24 (each 1H, d, *J* = 11.3 Hz), 6.53, 6.27 (each 1H, d, *J* = 15.9 Hz), 5.93 (1H, d, *J* = 8.2 Hz), 3.97 (1H, m), 2.85 (2H, t, *J* = 6.7 Hz), 2.56 (2H, t, *J* = 6.7 Hz), 2.40 (1H, dd, *J* = 6.2, 17.0 Hz), 2.05 (1H, dd, *J* = 10.0, 17.0 Hz), 1.98 (3H, s), 1.89 (2H, qn, *J* = 6.7 Hz), 1.83–1.74 (1H, m), 1.74 (3H, s), 1.49 (1H, t, *J* = 11.8 Hz), 1.08 (3H × 2, s).

To a solution of the aldehyde (26.1 mg, 80.0 μmol) in a mixture of CH_2Cl_2 (1.0 mL) and pyridine (0.2 mL) at 0 °C, Ac_2O (0.1 mL) and DMAP (2.0 mg) were added, and the resultant mixture was allowed to warm to room temperature and was stirred at this temperature. After 1 h of stirring, the volatiles were removed in vacuo. Purification of the residue by silica gel column chromatography (Et_2O–hexanes, 15:85) afforded the alcohol (14.5 mg, 39.3 μmol, 50%) as an oil.

^{1}H NMR ($CDCl_3$, ppm) δ: 10.0 (1H, d, *J* = 8.2 Hz), 6.90, 6.24 (each 1H, d, *J* = 11.3 Hz), 6.53, 6.25 (each 1H, d, *J* = 15.9 Hz), 5.93 (1H, d, *J* = 8.2 Hz), 5.05 (1H, m), 2.85 (2H, t, *J* = 6.7 Hz), 2.56 (2H, t, *J* = 6.7 Hz), 2.45 (1H, dd, *J* = 5.5, 16.4 Hz), 2.12 (1H, dd, *J* = 9.4, 16.4 Hz), 2.05 (3H, s), 1.98 (3H, s), 1.90 (2H, qn, *J* = 6.7 Hz), 1.79 (1H, m), 1.74 (3H, s), 1.59 (1H, t, *J* = 12.0 Hz), 1.11, 1.08 (each 3H, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 190, 170, 160, 139, 138, 135, 134, 132.4, 132.2, 128.8, 128.5, 126, 68.2, 43.8, 38.4, 36.6, 31.2, 29.9, 29.0, 28.4 (2C), 21.4 (2C), 14.9. FAB–HRMS calcd. for $C_{24}H_{31}O_3$: 367.2273 $[M - H]^+$; found: 367.2271.

15-*O*-TBS (15)

To a solution of the aldehyde **14** (14.5 mg, 39.3 μmol) in a mixture of $CHCl_3$ (0.2 mL) and methanol (1.0 mL) at –10 °C, $NaBH_4$ (8.9 mg, 236 μmol) was added. After 2 min of stirring, a satd. aq. solution of NH_4Cl (20 mL) was added and the resultant mixture was extracted with EtOAc (3 × 20 mL). The organic layers were washed with brine, combined, and dried over $MgSO_4$. ^{1}H NMR ($CDCl_3$, ppm) δ: 6.50, 6.10 (each 1H, d, *J* = 15.9 Hz), 6.47, 6.12 (each 1H, d, *J* = 11.3 Hz), 5.66 (1H, t, *J* = 7.0 Hz), 5.04 (1H, m), 4.25 (2H, d, *J* = 7.0 Hz), 2.52 (2H, t, *J* = 6.7 Hz), 2.44 (1H, dd, *J* = 6.0, 17.6 Hz), 2.36 (2H, t, *J* = 6.7 Hz), 2.11 (1H, dd, *J* = 8.9, 17.6 Hz), 2.05 (3H, s), 1.92 (3H, s), 1.83–1.70 (3H), 1.72 (3H, s), 1.58 (1H, t, *J* = 11.9 Hz), 1.10, 1.07 (each 3H, s).

To a solution of the crude alcohol in CH_2Cl_2 (1.0 mL) at room temperature, imidazole (16.0 mg, 197 μmol) was added. The mixture was cooled to 0 °C, and TBSCl (11.8 mg, 78.6 μmol) was added at this temperature. After 2 h of stirring, the mixture was poured into water (20 mL) and the resultant mixture was extracted with Et_2O (3 × 20 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated in vacuo. Purification of the residue by silica gel column chromatography (EtOAc–hexanes, 7:93) afforded **15** (13.4 mg, 27.6 μmol, 70%, in two steps) as a colorless oil. ^{1}H NMR ($CDCl_3$, ppm) δ: 6.51, 6.08 (each 1H, d, *J* = 16.0 Hz), 6.42, 6.11 (each 1H, d, *J* = 11.4 Hz), 5.57 (1H, t, *J* = 6.4 Hz), 5.05 (1H, m), 4.28 (2H, d, *J* = 6.4 Hz), 2.52 (2H, t, *J* = 6.7 Hz), 2.44 (1H, dd, *J* = 5.5, 17.0 Hz), 2.31 (2H, t, *J* = 6.7 Hz), 2.10 (1H, dd, *J* = 9.3, 17.0 Hz), 2.05, 1.91 (each 3H, s), 1.82–1.73 (3H), 1.72 (3H, s), 1.58 (1H, t, *J* = 12.0 Hz), 1.10, 1.07 (each 3H, s), 0.906 (3H × 3, s), 0.0813 (3H × 2, s). ^{13}C NMR ($CDCl_3$, ppm) δ: 170, 139, 138, 135, 134, 132, 131, 130.4, 130.3, 125.7, 125.0, 68.4, 59.9, 44.0, 38.5, 36.7, 31.3, 30.4, 30.1, 28.9, 28.6, 27.9, 26.1 (3C), 21.6, 18.5, 14.7, –4.80 (2C). FAB-HRMS calcd. for $C_{30}H_{48}O_3Si$ *m*/*z*: 484.3373 $[M^+]$; found: 484.3366.

3-*O*-Biotinyl (Boc)Lys-15-*O*-TBS (16)

To a solution of **15** (5.4 mg, 11.1 μmol) in methanol (1.0 mL) at 0 °C, K_2CO_3 (2.0 mg, 14.5 μmol) was added. The mixture was stirred and allowed to warm to room temperature. After 12 h of stirring, the mixture was poured into a satd. aq. solution of NH_4Cl (20 mL) and the resultant mixture was extracted with EtOAc (3 × 20 mL). The organic layers were washed with brine, combined, dried over $MgSO_4$, and concentrated under reduced pressure. ^{1}H NMR ($CDCl_3$, ppm) δ: 6.51, 6.11 (each 1H, d, *J* = 15.9 Hz), 6.43, 6.11 (each 1H, d, *J* = 11.4 Hz), 5.57 (1H, t, *J* = 6.3 Hz), 4.28 (2H, d, *J* = 6.3 Hz), 4.00 (1H, m), 2.52 (2H, t, *J* = 6.6 Hz), 2.38 (1H, dd, *J* = 5.0, 16.7 Hz), 2.31 (2H, t, *J* = 6.6 Hz), 2.04 (1H, dd, *J* = 9.7, 16.7 Hz), 1.91 (3H, s), 1.77 (1H, m), 1.73 (2H, qn, *J* = 6.7 Hz), 1.73 (3H, s), 1.47 (2H, t, *J* = 11.9 Hz), 1.07 (3H × 2, s), 0.906 (3H × 3, s), 0.0807 (3H × 2, s).

To a mixture of the crude 3-OH compound, biotinyl (Boc)Lys-OH (7.9 mg, 16.7 μmol),1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC, 6.4 mg, 33.3 μmol) at 0 °C, and CH_2Cl_2 (0.7 mL) were added. DMAP (2.0 mg) was also added at this temperature. The mixture was warmed to room temperature and stirred. After 3 h of stirring, the mixture was poured into a satd. aq. solution of $NaHCO_3$ (20 mL) and the resultant mixture was extracted with $CHCl_3$ (20 mL). The organic layer was washed with a satd. aq. NH_4Cl solution, water, and brine, followed by drying over $MgSO_4$. Purification of the residue by silica gel column chromatography (methanol–$CHCl_3$, 7:93) afforded **16** (7.8 mg, 8.69 μmol, 78%, in two steps) as a colorless oil. ^{1}H NMR ($CDCl_3$, ppm) δ: 6.52, 6.11 (each 1H, d, *J* = 16.1 Hz), 6.44, 6.13 (each 1H, d, *J* = 11.3 Hz), 6.24 (1H, brs), 6.18 (1H, brs), 5.59 (1H, t, *J* = 6.5 Hz), 5.45–5.38 (1H, m), 5.37 (1H,brs), 5.20 (1H, d, *J* = 6.5 Hz), 5.10 (1H, m), 4.53 (1H, dd, *J* = 4.8, 7.5 Hz), 4.37–4.28 (1H, m), 4.29 (2H, d, *J* = 6.5), 4.23 (1H, m), 3.23 (2H, qn, *J* = 5.9 Hz), 3.16 (1H, m), 2.92 (1H, dd, *J* = 4.8, 12.6 Hz), 2.75 (1H, d, *J* = 12.6 Hz), 2.52 (2H, t, *J* = 6.4 Hz), 2.44 (1H, m), 2.32 (2H, t, *J* = 7.4 Hz), 2.20 (2H, t, *J* = 7.4 Hz), 2.13 (1H, m), 1.91 (3H, s), 1.85–1.50 (15H), 1.73 (3H, s), 1.45 (3H × 3, s), 1.10, 1.08 (each 3H, s), 0.908 (3H × 3, s), 0.0813 (3H × 2, s). FAB-HRMS calcd. for $C_{49}H_{81}N_4O_7SSi^+$ *m*/*z*: 897.5590 $[M + H]^+$; found: 897.5574. FAB-HRMS calcd. for $C_{49}H_{81}N_4NaO_7SSi$: 920.5493 $[M + H + Na]^+$; found: 920.5489.

3-*O*-Biotinyl (Boc)Lys 15-*O*-bromoacetate (1)

To a solution of **16** (4.1 mg, 4.57 μmol) in THF (1.0 mL) at 0 °C, TBAF (1.0 mol/L solution in THF, 9.2 μL, 9.2 μmol) was added. The mixture was warmed to room temperature and stirred. After 2 h of stirring, the mixture was poured into water (20 mL) and the resultant mixture was extracted with $CHCl_3$ (3 × 20 mL). The organic layer was washed with brine, combined, dried over $MgSO_4$, and concentrated under reduced pressure. Purification of the residue by silica gel column chromatography (methanol–$CHCl_3$, 10:90) afforded the biotinylated alcohol (2.1 mg, 2.68 μmol, 60%) as a colorless oil. ^{1}H NMR ($CDCl_3$, ppm) δ: 6.52, 6.13 (each 1H, d, *J* = 15.3 Hz), 6.49, 6.15 (each 1H, d, *J* = 11.1 Hz), 5.90 (1H, brs), 5.68 (1H, t, *J* = 6.8 Hz), 5.56 (1H, brs), 5.17 (1H, d, *J* = 7.9 Hz), 5.10 (1H, m), 4.90 (1H, brs), 4.52 (1H, m), 4.33 (1H, m), 4.26 (2H, d, *J* = 6.8 Hz), 4.25 (1H, brs), 3.23 (2H, brs), 3.17 (1H, q, *J* = 4.4 Hz), 2.93 (1H, dd, *J* = 4.8, 12.9 Hz), 2.74 (1H, d, *J* = 12.9 Hz), 2.53 (2H), 2.44 (1H, m), 2.37 (2H, t, *J* = 6.6 Hz), 2.28–2.18 (2H), 2.18–2.10 (1H, m), 1.92 (3H, s), 1.85–1.48 (16H), 1.73 (3H, s), 1.45 (3H × 3, s), 1.10, 1.08 (each 3H, s).

To a solution of the biotinylated alcohol (2.1 mg, 2.68 μmol) in CH_2Cl_2 (0.7 mL) at room temperature, $BrCH_2COOH$ (2.0 mg, 14.4 μmol) was added. The mixture was cooled to –10 °C and EDC (3.1 mg, 16.1 μmol) and DMAP (1.0 mg) were added. After 15 min of stirring at the

© 2006 NRC Canada

same temperature, the mixture was poured into a satd aq. solution of $NaHCO_3$ (20 mL) and the resultant mixture was extracted with $CHCl_3$ (20 mL). The organic layer was washed with a satd aq. NH_4Cl solution, water and brine, followed by drying over $MgSO_4$. After concentration in vacuo, purification of the residue by silica gel column chromatography (methanol–$CHCl_3$, 7:93) afforded the biotinylated bromoacetate **1** (1.6 mg, 1.77 μmol, 66%) as a colorless oil. ^{1}H NMR ($CDCl_3$, ppm) δ: 6.53, 6.13 (each 1H, d, J = 11.4 Hz), 6.50, 6.12 (each 1H, d, J = 15.7 Hz), 5.86 (1H, t, J = 5.0 Hz), 5.58 (1H, t, J = 7.3 Hz), 5.51 (1H, brs), 5.16 (1H, d, J = 8.6 Hz), 5.10 (1H, m), 4.87 (1H, brs), 4.77 (2H, d, J = 7.3 Hz), 4.51 (1H, dd, J = 4.7, 7.8 Hz), 4.32 (1H, dd, J = 4.7, 7.6 Hz), 4.23 (1H, m), 3.83 (2H, s), 3.23 (2H, qn, J = 6.1 Hz), 3.16 (1H, m), 2.92 (1H, dd, J = 4.7, 12.6 Hz), 2.73 (1H, d, J = 12.6 Hz), 2.51 (2H, t, J = 7.0 Hz), 2.39 (2H, t, J = 6.5 Hz), 2.10 (1H, m), 2.14 (2H, t, J = 6.5 Hz), 2.10 (1H, m), 1.92 (3H, s), 1.88–1.30 (16H), 1.72 (3H, s), 1.45 (3H × 3, s), 1.10, 1.08 (each 3H, s).

A theoretical and experimental investigation of some unusual intermolecular hydrogen-bond IR bands — Appearances can be deceptive[1]

Grzegorz Litwinienko, Gino A. DiLabio, and K.U. Ingold

Abstract: The IR spectra of the O-H stretch for hydrogen bonds (HBs) arising from complex formation between the HB donor (HBD), 4-fluorophenol, and the HB acceptors, peroxides and ethers, frequently show asymmetry that appears to arise from two incompletely resolved bands from two different complexes, but the O-H HB bands with the HBD methanol are symmetric (M. Berthelot, F. Bessau, and C. Laurence. Eur. J. Org. Chem. 925 (1998)). The present studies show that this difference in O-H HB band shapes also is true for other phenols and alcohols. However with ethylene oxide, 4-fluorophenol gives an almost symmetric O-H HB band with a very broad maximum, while alcohols give symmetric O-H HB bands with well-defined maxima. It is shown by experiment that the unusual O-H HB band shapes for the phenols are not due to Fermi resonance and are unrelated to the enthalpies of HB complex formation. Theoretical exploration of the potential energy (PE) surfaces for complexes of 4-fluorophenol and methanol with *tert*-butyl methyl ether and ethylene oxide reveals that O-H HB band asymmetry or broadness cannot be ascribed to the presence of two different HB complexes. For this ether, the PE surfaces for rotation about the HB and for up-and-down motion of the HBD with respect to the COC plane of the ether are relatively symmetric for methanol, but are strongly asymmetric for 4-fluorophenol, hence the differences in the O-H HB band shapes. The PE surfaces for the epoxide are effectively symmetric, but the PE for rotation about the HB has a single broad minimum for methanol, whereas with 4-fluorophenol there are two minima owing to attractive interactions between the phenyl group and the CH_2 groups of the epoxide. The previously unknown β_2^H values for ethylene oxide and tetramethylethylene oxide are 0.36 and 0.58, respectively.

Key words: asymmetric IR O-H bands, asymmetric potential energy surfaces, hydrogen-bonded complexes, hydrogen bond enthalpy, O-H frequency shift.

Résumé : Les spectres IR de l'élongation O-H des liaisons hydrogènes (LH) découlant de la formation de complexes entre le donneur de liaison hydrogène (DLH), 4-fluorophénol, et des accepteurs de LH, tels les peroxydes et les éthers, présentent fréquemment une asymétrie qui semble découler de la présence de deux bandes pas complètement résolues provenant de deux complexes différents, mais les bandes de LH O-H avec le DLH méthanol sont symétriques (M. Berthlot, F. Bessau, et C. Laurence. Eur J. Chem. 925 (1998)). La présente étude montre que cette différence dans les formes de la bande de LH O-H est aussi vraie pour d'autres phénols et d'autres alcools. Toutefois, avec l'oxyde d'éthylène, le 4-fluorophénol donne lieu à une bande de LH O-H qui est pratiquement symétrique avec un maximum très large alors que les alcools donnent lieu à des bandes de LH OH symétriques avec des maxima bien définis. On a montré sur la base d'expériences que les formes inhabituelles de la bande de LH OH des phénols ne sont pas causées par une résonance de Fermi et qu'elles ne sont pas associées aux enthalpies de formation du complexe de LH. Une étude théorique des surfaces d'énergie potentielle (EP) des complexes du 4-fluorophénol et du méthanol avec l'oxyde de *tert*-butyle et de méthyle et l'oxyde d'éthylène montre que l'asymétrie ou la largeur de la bande de LH O-H ne peut pas être attribuée à la présence de deux complexes différents de LH. Pour cet éther, les surfaces d'EP pour la rotation autour de la LH et pour les mouvements ascendant et descendant du DLH par rapport au plan COC de l'éther sont relativement symétriques pour le méthanol, mais fortement asymétriques pour le 4-fluorophénol; d'où les différences dans les formes des bandes des LH O-H. Les surfaces d'EP pour l'époxyde sont effectivement symétriques, mais l'EP pour la rotation autour de la LH ne présente qu'un seul minimum élargi pour le méthanol alors que pour le 4-fluorophénol on observe deux minima qui résultent d'interactions d'attraction entre le groupe phényle et les groupes CH_2 de l'époxyde. Les valeurs β_2^H qui n'était pas connues antérieurement pour l'oxyde d'éthylène et l'oxyde de

Introduction

During a critical reevaluation of the O—H bond dissociation enthalpy of phenol (1), the relative hydrogen bond acceptor (HBA) activity of di-*tert*-butyl peroxide was required. This is best quantified using the β_2^H scale of HBA relative activities developed by Abraham et al. (2). This is a general, thermodynamically related scale of solute hydrogen bond basicities in CCl_4. Values of β_2^H are calculated from the equilibrium constants for 1:1 complex formation between the HBA and a "calibrated" hydrogen bond donor (HBD), XOH, measured by IR spectroscopy in CCl_4 at room temperature (2)

$$[1] \qquad XOH + HBA \rightleftharpoons XOH\cdots HBA$$

$$[2] \qquad K_{eq} = \frac{[XOH\cdots HBA]}{([XOH]_0 - [XOH\cdots HBA])([HBA]_0 - ([XOH\cdots HBA])}$$

where the subscript 0 refers to the concentrations of XOH and the HBA in the absence of complex formation. Phenol and 4-fluorophenol (4-F-phenol) are often used as the calibrated HBA, the latter being particularly popular because, for 4-F-phenol only, there is a very simple relation between β_2^H and K_{eq} (β_2^H = (log K_{eq} + 1.1)/4.636) (2).[4] Values of β_2^H range from 0.00 for saturated hydrocarbons to 1.00 for hexamethylphosphortriamide, the strongest organic base.

Berthelot et al. (3) had reported a β_2^H value of 0.33 for di-*tert*-butyl peroxide, which we confirmed (1). We also confirmed their report that hydrogen-bond (HB) formation between 4-F-phenol and di-*tert*-butyl peroxide gives an asymmetric O-H HB stretching band in the IR that appears to arise from two incompletely resolved bands. Very reasonably, Berthelot et al. assigned this asymmetry and the asymmetry they found in the O-H HB bands for HB complexes of 4-F-phenol with some, but not all, ethers to the existence of two stereoisomeric hydrogen bonded species. These were suggested to have structures **A** and **B** (Fig. 1).

The asymmetric ether (peroxide)$\cdots HOC_6H_4F$ O-H HB bands discovered by Berthelot et al. (3) are intriguing. Herein, an experimental study of some asymmetric (and symmetric) O-H HB bands, which confirms and extends the earlier report (3), is combined with theoretical calculations on the structures of the species responsible for them.

Experimental

Materials

With one exception, all compounds were purchased from Sigma-Aldrich. Anhydrous solvents and the phenols were of highest purity available (usually 99%+) and were used as received except as noted. Prior to their use, the phenols were kept in a desiccator over P_2O_5 and di-*tert*-butyl peroxide was passed over basic alumina. Gaseous ethylene oxide was dissolved in CCl_4 to obtain a stock solution. The ethylene oxide concentration in the stock solution was determined by ^1H NMR using a sample to which CH_3CN had been added as an internal standard. 1,1,2,2-Tetramethylethylene oxide (purity 98%) was purchased from ChemSampCo Inc., Trenton, New Jersey.

IR spectra

Spectra were measured in CCl_4 at ambient temperatures. Each spectrum was collected on a Shimadzu FTIR 8201PC apparatus using a 1.03 mm CaF_2 cell (20 scans with a resolution of 1 cm^{-1}), and the baseline was corrected using solutions having the same concentration of the HBA as in the HBD–HBA solution. For all HBD–HBA measurements, the HBD concentrations were kept below a level that would lead to HBD self-association.

Theoretical calculations

All calculations were performed using the Gaussian 03 program package (4). Structures, vibration frequencies, and hydrogen bond strengths were computed using B971/6-31+G**(5). This level of theory was shown to predict reasonable hydrogen-bond strengths (6). Hydrogen-bond strengths were corrected for basis set superposition error via the counterpoise technique (7). Additional calculations to generate approximate potential energy surfaces (PESs) were performed with MP2/6-31+G**. This level of theory was used to avoid any uncertainties associated with the use of a density functional theory method to describe effects owing to steric repulsion at the extrema of the PESs.

Results

IR spectra

Figure 2A shows the O-H stretching region with 4-F-phenol (11.5 mmol/L) and concentrations of di-*tert*-butyl peroxide ranging from 109 to 561 mmol/L. The asymmetry of the O-H HB band is very apparent at all HBA concentrations. Deconvolution of this O-H HB band by Berthelot et al. (3) yielded wavenumber differences from the band maximum for the non-hydrogen bonded (i.e., "free") 4-F-phenol (3614 cm^{-1}), $\Delta\nu$(OH) = 145 and 220 cm^{-1}. Additional support for the assignment of this asymmetric band entirely to hydrogen bonding was obtained by measurements using *O*-deuterio-4-F-phenol. The addition of a very small quantity of D_2O to CCl_4 containing 4-F-phenol (16.5 mmol/L) followed by the addition of di-*tert*-butyl peroxide produced the spectra shown in Fig. 2B. The O-H HB band in Fig. 2B has shifted roughly 900 cm^{-1} from that shown in Fig. 2A, but the two bands have the same asymmetric shape. This "makes

[4] From ref. 2, a solute hydrogen bond basicity scale against reference acids is established through the relationship log $K_{eq} = L_A$ log $K_B^H + D_A$. For the reference acid (4-F-phenol), L_A = 1.000 and D_A = 0.000 giving log K_B^H = log K_{eq}.

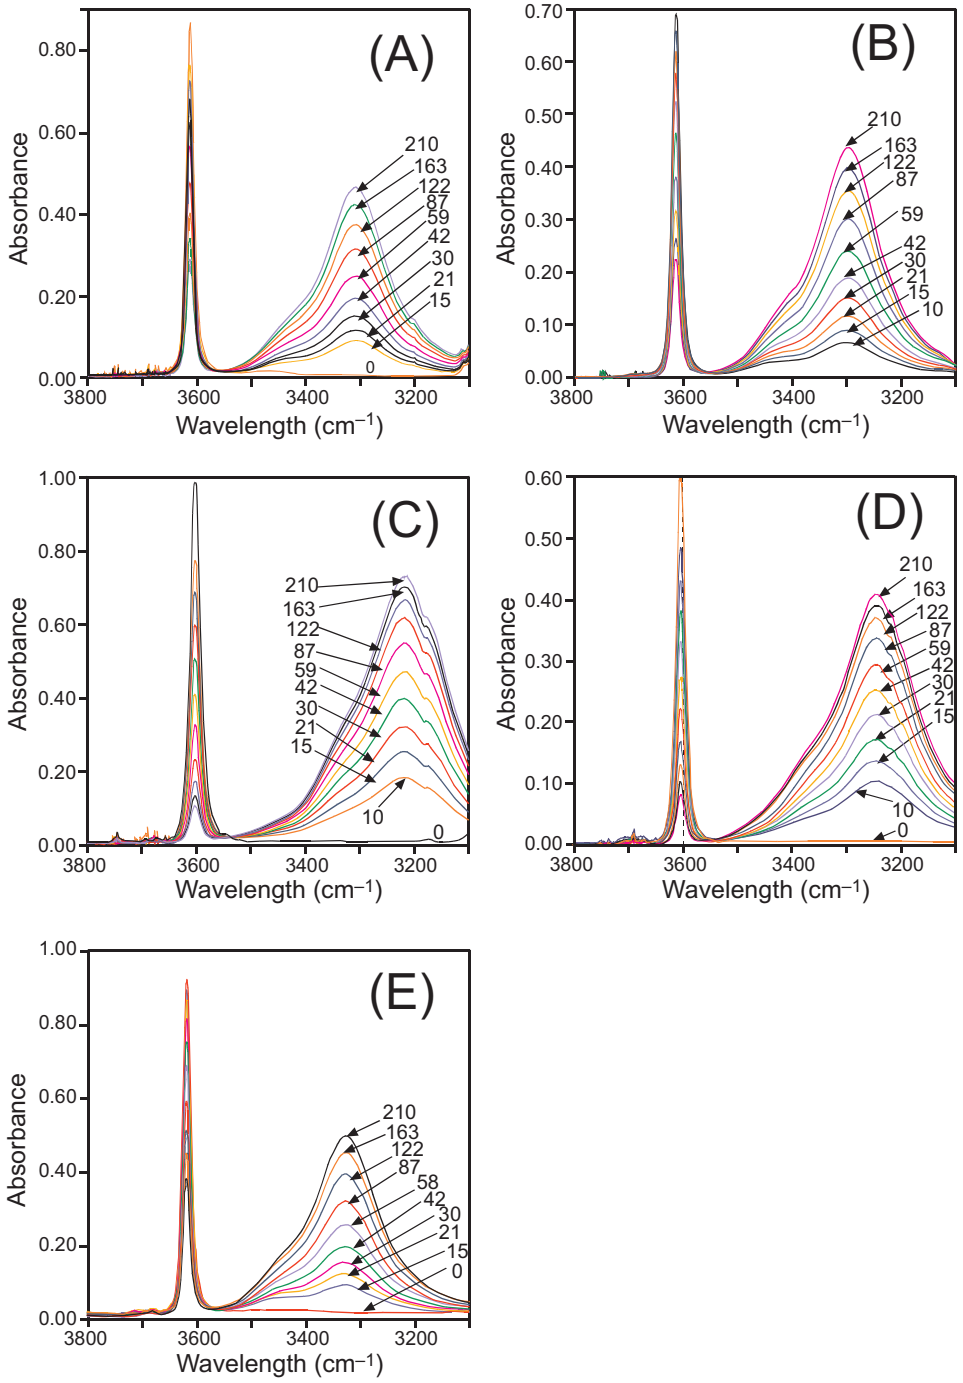
improbable the attribution of the doublet to a Fermi resonance" (3).



Next we demonstrated that asymmetric O-H HB bands are not specific to 4-F-phenol, and furthermore that their shape is more or less independent of the HBD activity of the phenol. Relative HBD activities are best quantified using the α_2^H scale developed by Abraham et al. (8). Like his β_2^H scale, the α_2^H scale is a general, thermodynamically related scale of solute hydrogen bond acidities in CCl_4. Values of α_2^H are also calculated from the equilibrium constants for 1:1 complex formation between the HBD and a calibrated HBA and are measured by IR spectroscopy in CCl_4 at room temperature. Values of α_2^H range from 0.00 for saturated hydrocarbons to nearly 1 for strong organic acids, e.g., 0.951 for CF_3COOH (8). As the HBDs, we chose five phenols covering a range of α_2^H values (Table 1.) As the HBA, we chose *tert*-butyl methyl ether ($\beta_2^H = 0.494$), which had been shown to give an asymmetric O-H HB band with 4-F-phenol that was deconvoluted into two bands with Δν(OH) = 186 and 315 cm^{-1}(3). Our results are presented in Fig. 3 and Table 1. Both the free O-H and O-H HB band maxima shift to higher wavenumbers as the electron-withdrawing ability of the substituents on the phenols decrease, i.e., on going down the list of phenols in Table 1. It has been shown (9) that for phenol

Fig. 3. OH stretching region of the IR spectrum of (A) PhOH (13.6 mmol/L), (B) 4-F-phenol (12.5 mmol/L), (C) 3,5-Cl_2-phenol (15.8 mmol/L), (D) 4-CF_3-phenol (9.2 mmol/L), and (E) 4-MeO-phenol (20.1 mmol/L) in $CC1_4$ containing mmol/L concentrations of *tert*-butyl methyl ether as indicated.

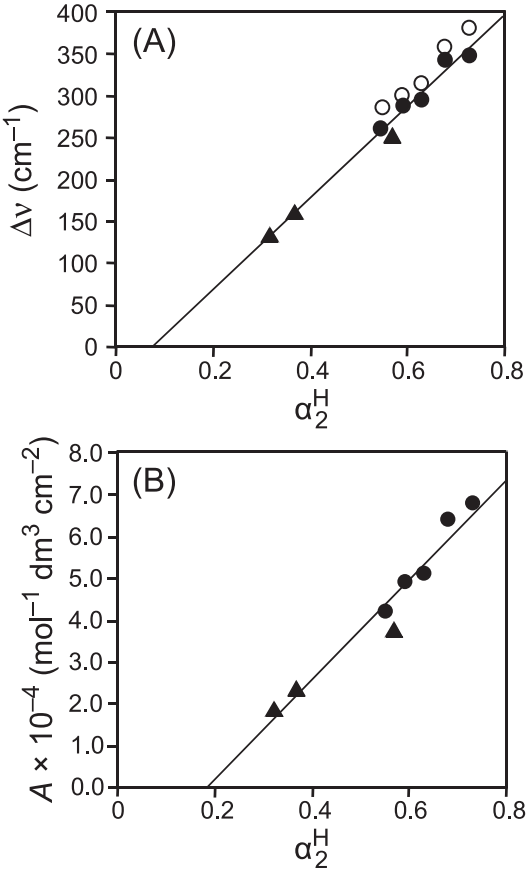
and 17 meta- and para-substituted phenols in CCl_4, the free OH band maximum frequencies (ν(OH)) and the integrated intensities of their bands (*A*) correlate with Σσ where σ is the Hammett substituent constant. In Hammett plots, the frequencies decrease ($\rho = -13.9$ cm^{-1}) and the intensities increase ($\rho = 1930$ $(mol/L)^{-1}$ cm^{-2}) as σ increases (9). The present results on the free O-H stretching band (Table 1) are consistent with this earlier report. The magnitudes of the shifts in the O-H stretching frequencies upon H-bonding to *tert*-butyl methyl ether, $\Delta\nu$ = ν(OH free) – ν(OH HB), are also given in Table 1 using both the O-H HB band maximum and the "center" of those O-H HB bands that are asymmetric. The center is the frequency at which 50% of the area of the O-H HB band is at higher, and 50% at lower, frequencies. B971 calculated values of Δν have also been included.

In earlier work (1), an empirical equation was derived that relates ΔH_1 for 1:1 hydrogen bond complex formation (rxn.

© 2006 NRC Canada

[1]) between an HBD and an HBA to their α_2^H and β_2^H values, respectively. This equation (which is accurate to ±0.4 kcal/mol, 1 cal = 4.184 J) is

$$[3] \qquad \Delta H_1 = -20.56\alpha_2^H\beta_2^H + 0.59 \text{ kcal/mol}$$



Values of ΔH_1 evaluated using eq. [3] and calculated using the B971 functional are included in Table 1.

The three quantities (Δν(OH), α_2^H, and ΔH_1) for each HBD – *tert*-butyl methyl ether combination (Table 1) are obviously interrelated. For example, a plot of experimental Δν(OH) vs. α_2^H yields an excellent straight line for the five phenol and three alcohol HBDs studied in the present work provided that the centers of the ν(OH HB) bands of the phenols are used rather than the band maxima (Fig. 4A). Such linear correlations are not surprising because the O-H and H···O moieties in hydrogen-bonded complexes are coupled oscillators (10). The integrated OH band areas for the free phenols (*A*) also correlate with α_2^H (Fig. 4B).

Asymmetric O-H HB bands have been observed for 4-F-phenol complexes with a number of ethers and peroxides (3) (Figs. 2 and 3). In contrast, methanol has been reported to give a single O-H HB band maximum with all but one of the same substrates (3).[5] Reported differences between the frequencies of the free OH band maxima for methanol and 4-F-phenol and their O-H HB band maxima for their 1:1 complexes with 40 ethers and 3 peroxides (3) reveal that Δν(OH) MeOH]/[Δν(OH) 4-F-phenol ~ 0.5 with all 43 bases. Obviously, methanol forms a weaker hydrogen bond to a particular base than does 4-F-phenol, as is fully consistent with their α_2^H values (0.367 and 0.629, respectively, Table 1). This suggested that HB bond asymmetry might only become obvious for strong HBDs.[6] To check this possibility we again chose *tert*-butyl methyl ether as the HBA and used three alcohols as HBDs: (*i*) methanol, (*ii*) the weaker HBD, *tert*-butanol, and (*iii*) the much stronger HBD, 2,2,2-trifluoroethanol (see α_2^H values in Table 1). The resulting IR spectra are shown in Fig. 5 and the spectral data together with the calculated values of ΔH_1 are collected in Table 1. None of these alcohols give rise to an asymmetric O-H HB band. This allows us to rule out a simple thermodynamic cause (i.e., the magnitude of ΔH_1) for O-H HB band asymmetry.

It was by now clear that an explanation for O-H HB band asymmetry would not come from experiment alone, it would require examination of some of the HBA···HBD complexes that gave asymmetric O-H HB bands by theory, and a simple, preferably fairly rigid, HBA would make high level calculations more practical. We therefore reexamined the data from Berthelot et al. These contain one epoxide[7] in which the epoxide ring plane was also a plane of symmetry for the whole molecule. This was 2,3-diadamant-2-yl oxirane.[8] With 4-F-phenol this epoxide gave an asymmetric O-H HB band

Fig. 4. Values of (A) Δν = ν(OH free) – ν(OH HB) and (B) *A* as functions of the α_2^H parameter of HBD. Alcohols (▲), phenols using ν(OH HB) band maxima (○), phenols using the center of the ν(OH HB) band (●). Note: There is, of course, only a single *A* value for each alcohol and phenol.

that was deconvoluted into two bands (Δν = 234 and 338 cm^{-1}). Unfortunately, this is too large a molecule for high-level calculations to be carried out in any reasonable time. However, this result of Berthelot et al. did encourage us to examine ethylene oxide and tetramethylethylene oxide, neither of which has previously been used in IR studies of hydrogen bonding. In the presence of 4-F-phenol, the spectra (Figs. 6A and 7A) showed O-H HB bands that were almost symmetric, but were very broad with maxima that are wide plateaus rather than the fairly sharp maxima seen for all the other O-H HB bands (Figs. 2, 3, and 5). In contrast, the O-H HB bands formed between alcohols and these two epoxides are not only symmetric, but also show distinct maxima (Figs. 6B, 6C, and 7B).

Deconvolution of the O-H HB bands shown in Figs. 6A and 7A using two Lorentzian functions yields two band

[5] The exception was 2,3-diadamant-2-yl oxirane. Deconvolution of the HB band yielded two band maxima (Δν(OH) = 129 and 180 cm^{-1}, ref. 3).

[6] However, this would not explain why 4-F-phenol does not give asymmetric HB bands with all ethers. That is, if chloroethers and dibenzyl ether are excluded because they contain two HBA moieties (chlorine and an aromatic ring) that could give rise to separate HB bands and hence to asymmetry, only 12 out of 36 ether–4-F-phenol HB bands were deconvoluted into two bands (3).

[7] Four epoxides were employed, but three of them (propylene oxide, cyclohexene oxide, and epichlorhydrin) lack the single plane of symmetry for the epoxide ring and the whole molecule desired to simplify the theoretical calculations.

[8] This is also the only HBA that gave an asymmetric HB band with methanol that was deconvoluted into two bands (Δν = 129 and 180 cm^{-1}, ref. 3).

maxima. However, not only would the implied existence of two HB complexes with different structures be inconsistent with theory (vide infra), but also the two deconvoluted band maximum frequencies vary with the concentration of the epoxide. For example, band maxima are found at 3382 and 3456 cm^{-1} with 41 mmol/L ethylene oxide and at 3392 and

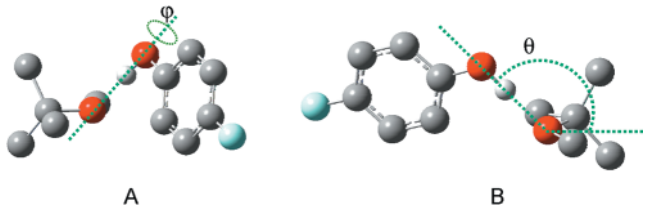
Fig. 7. OH stretching region of the IR spectrum of (A) 4-F-phenol (14.6 mmol/L) and (B) CF_3CH_2OH (16.2 mmol/L) in CCl_4 containing mmol/L concentrations of 1,1,2,2-tetramethylethylene oxide as indicated.



3471 cm^{-1} with 435 mmol/L ethylene oxide (see Supplementary data),[9] a result that can be attributed to differences in the permittivity (dielectric constant) of the two solvent mixtures.

The traces shown in Figs. 6 and 7 can be used to calculate the previously unknown β_2^H values for ethylene oxide (0.36) and tetramethylethylene oxide (0.58) (see Supplementary data).[9] The much larger β_2^H value for tetramethylethylene oxide compared with ethylene oxide is congruent with the β_2^H values for *tert*-butyl alcohol (0.49) vs. methanol (0.41) (2) and is undoubtedly due to the greater inductive electron-donating ability of $(CH_3)_nC$- groups compared with a CH_3 group.

Theoretical calculations

The changes in the potential energy as a function of the dihedral angle defined by R-O-H···O-C(methyl), i.e., as a function of rigid rotations of the molecules about their common hydrogen bond (structure **A**, Fig. 8), are shown in Figs. 9A and 10A, respectively. The results of relaxed

Fig. 8. The rotational potential energy surfaces (shown in Figs. 9A and 10A) were generated by rotation of the dihedral angle (φ) defined by R-O-H···O-C(methyl), as illustrated in structure **A** for the 4-F-phenol – *tert*-butyl methyl ether HB complex. The bending potentials shown in Figs. 9B and 10B were generated by changing the angle (θ) defined by the O—H bond of the HBD and the COC plane of the HBA, as illustrated in structure **B** for the same HB complex. Hydrogen atoms have been removed for clarity.

MP2/6-31+G** potential energy (PE) surface scans as a function of the bending angle (θ) defined by the O-H bond of the HBD and the COC plane of the HBA (structure **B**, Fig. 8) for the same two complexes are shown in Figs. 9B and 10B. This bending motion connects structures **A** and **B** in Fig. 1. These calculations reveal that structure **B** in Fig. 1 (with θ = 180°) is not even a metastable energy minimum. For methanol, but not for 4-F-phenol, the θ = 180° structure is close to the transition state for the shift of the HBD from the "upper" lone pair of electrons on the oxygen atom (structure **A** in Fig. 1) to the equivalent lower lone pair. These PE surfaces demonstrate that these H-bonded complexes must sample a large range of configurations at room temperature.

Discussion

The structures of the HB complexes of 4-F-phenol and methanol with *tert*-butyl methyl ether are similar. In both complexes, the HBDs are aligned so that the plane defined by their COH atoms is roughly perpendicular to and roughly bifurcates the plane defined by the COC atoms of the ether (see structure **A** in Fig. 1). The PE surfaces generated by changes in ϕ (structure **A**, Fig. 8), i.e., by rigid rotation about the HB in both HB complexes, are fairly similar (see Fig. 9A). They reflect repulsive steric interactions between the hydrocarbon moieties of the HBDs and the HBA at rotation angles that substantially deviate from those of the minimum energy structures. The differences in steric bulk of the HBD and HBA hydrocarbon groups (HBD: *tert*-butyl > methyl; HBA: phenyl > methyl) are evident in Fig. 9A.

In contrast, the PE surfaces associated with changes in θ, i.e., with the bending motion of the HBD up and down with respect to the COC plane of the ether (structure **B**, Fig. 8), are very different for the methanol – *tert*-butyl methyl ether and 4-F-phenol – *tert*-butyl methyl ether complexes (see Fig. 9B). For methanol, this PE surface has two degenerate minima that correspond to HB formation to each of the lone pairs of the oxygen atom of the HBA. Note that in the second minimum, the HBA is reoriented to the "trans" position by a 180° rotation about the HB. This reorientation is possi-

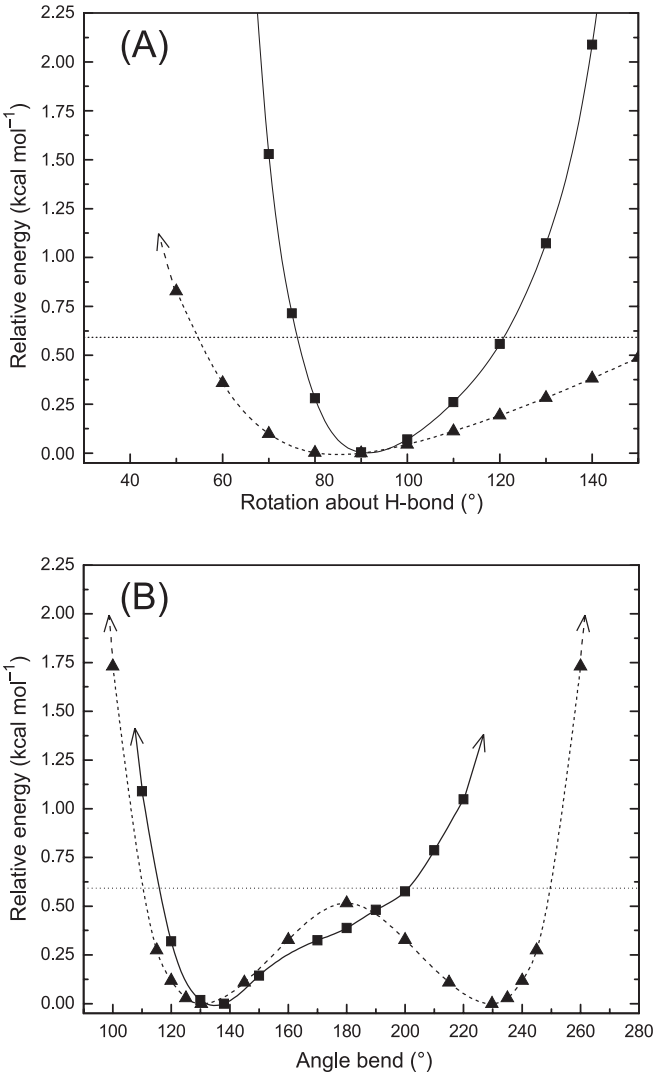
Fig. 9. Potential energy surface (PES) scans at the MP2/6-31+G** level of theory for 4-F-phenol – methyl *tert*-butyl ether (solid line, ■) and for methanol – methyl *tert*-butyl ether (dotted line, ▲). (A) Rigid PE surface associated with changes in φ, i.e., associated with rotation about the hydrogen bond, as illustrated in structure **A** of Fig. 8. The asymmetries of these PE surfaces are due to the different sizes of the methyl and *tert*-butyl groups. (B) Relaxed PE surface associated with changes in θ, the bend angle defined as illustrated in structure **B** of Fig. 8. This second PE surface connects structures **A** and **B** of Fig. 1. The dashed horizontal lines in the plots indicate the value of *RT* at 298.15 K. The arrows indicate that the potential anergies rise steeply toward the HB strength of the complex.



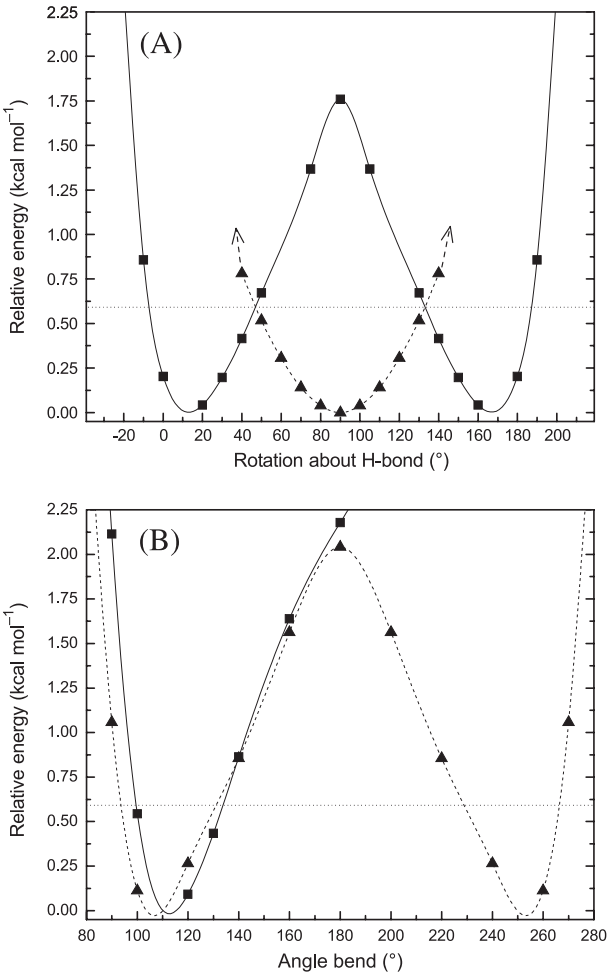


Fig. 10. Potential energy surface (PES) scans at the MP2/6-31+G** level of theory for 4-F-phenol – ethylene oxide (solid line, ■) and for methanol – ethylene oxide (dotted line, ▲). (A) Rigid PE surface associated with changes in φ, i.e., associated with rotation about the hydrogen bond, as illustrated in structure **A** of Fig. 8 for 4-F-phenol – methyl *tert*-butyl ether. (B) Relaxed PE surface associated with changes in θ, the bend angle defined as illustrated in structure **B** of Fig. 8 for 4-F-phenol – methyl *tert*-butyl ether. For methanol, this second PE surface connects structures **A** and **B** in Fig. 1, but for 4-F-phenol the PE continues to increase as θ increases above 180°. The dashed horizontal lines in the plots indicate the value of *RT* at 298.15 K. The arrows indicate that the potential energies rise steeply toward the HB strength of the complex.

ble because of the small size of the methyl group. However, the larger steric bulk of the phenyl ring in the 4-F-phenol complex prevents the facile reorientation of this HBD. Thus, the PE associated with changes in θ in the 4-F-phenol – *tert*-butyl methyl ether HB complex increases continuously from the minimum rather than reaching a local maximum at 180° as is the case for the methanol complex (Fig. 9B). This increase in PE is slow at first, but as the HB approaches the second lone-pair of the oxygen atom of the ether, steric repulsion becomes large and the PE increases more rapidly. A large portion of this asymmetric PE surface can be sampled at room temperature (*RT* = 0.59 kcal/mol at 298 K), and because the coupling between the O-H oscillator of the HBD and the O···H oscillator of the HB changes over this configuration sampling, an asymmetric O-H HB band is produced.

The situation is different for the ethylene oxide HB complexes. Figure 10A shows the PE surface associated with changes in ϕ, i.e., associated with rotation about the HB, in the methanol – ethylene oxide and the 4-F-phenol – ethylene oxide complexes. For the former complex, the COH plane of

© 2006 NRC Canada

the methanol bifurcates and is perpendicular to the plane of the ethylene oxide ring. Rotation about this HB produces a broader, single minimum PE surface analogous to that found for the similar motion in the methanol – *tert*-butyl methyl ether complex (Fig. 9A). In contrast, with 4-F-phenol the PE surface has two minima that are due to attractive interactions between the π electron cloud of the phenyl group and the CH_2 groups of the ethylene oxide.

The θ angle bend PE surface for the methanol – ethylene oxide HB complex has a similar shape to that found for the methanol – *tert*-butyl methyl ether complex (Fig. 10B). That is, two identical HB complexes of equal energy are formed in which the OH group of the HBD interacts with each lone pair on the oxygen atom of the epoxide. The minimum energy structures are transoid with the methyl group pointing away from the epoxide ring and are rather easily interconverted at room temperature. The methanol – ethylene oxide complex therefore yields a symmetric O-H HB band. For the 4-F-phenol – ethylene oxide HB complex, the strong secondary interactions that produce the double minimum shown in Fig. 10A prevent facile changes in the θ angle, i.e., the PE surface for this motion is quite steep. Both of the PE surfaces for the 4-F-phenol – ethylene oxide HB complex are effectively symmetric, which accounts for this complex having a symmetric O-H HB band. In this complex, the broadness of the O-H HB band results from the changes in coupling upon the interconversion of the two structures whose energy minima are shown in Fig. 10A.

Further evidence that two different HB complexes are not formed between *tert*-butyl methyl ether and 4-F-phenol comes from the plots in Fig. 4. The plots of $\Delta\nu$ against α_2^H (Fig. 4A) for the phenols, with their asymmetric O-H HB bands, and for the alcohols, with their symmetric O-H HB bands, yield a single straight line.[10] A least-squares fitting of the data presented in Table 1 gives $\Delta\nu(OH) = 54(-\Delta H) - 9$ cm^{-1} ($R^2 = 0.98$, SD = 11 cm^{-1}). If we now use the two $\Delta\nu$ values given by Berthelot et al. (3) for the deconvoluted 4-F-phenol – methyl *tert*-butyl ether O-H HB band (vide supra), we obtain $-\Delta H$ values of 3.6 ($\Delta\nu$ = 186 cm^{-1}) and 6.0 ($\Delta\nu$ = 315 cm^{-1}) kcal/mol. These HB enthalpies imply that if there really were two different complexes, the ratio of the weaker to the stronger would be ca. 2:98. Such a small population of the weaker HB complex would be unlikely to make an observable contribution to the O-H HB band and hence be the reason for the observed asymmetry.

In conclusion, although the asymmetries of the O-H HB bands for many phenol–ether complexes appear at first sight to be due to two (deconvolutable) overlapping bands that reflect the presence of two distinct HB complex configurations, this is not the true situation. In these cases, as in so many other aspects of science and life, appearances can be deceptive.

Syntheses and characterization of phthalonitriles and phthalocyanines substituted with adamantane moieties[1]

Patrick W. Causey, Igor Dubovyk, and Clifford C. Leznoff

Abstract: The reaction of 3,4,5,6-tetrafluorophthalonitrile with 1-adamantanol, 1-adamantylamine, 1-adamantanemethanol, and 1-adamantaneethanol gave 4,5-di-(1-adamantyloxy)-3,6-difluorophthalonitrile, 4,5-di-(1-adamantylamino)-3,6-difluorophthalonitrile, 4-(1-adamantylamino)-3,5,6-trifluorophthalonitrile, 3,4,5,6-tetra-(1-adamantylmethoxy)phthalonitrile, and 3,4,5,6-tetra-(1-adamantylethoxy)phthalonitrile, respectively. The conversion of these tetrasubstituted phthalonitriles to magnesium, nickel, and metal-free phthalocyanines was demonstrated. These highly hindered phthalocyanines exhibited interesting red shifts in their UV–vis spectra.

Key words: highly hindered adamantane phthalocyanines, adamantylphthalonitriles.

Résumé : La réaction du 3,4,5,6-tétrafluorophtalonitrile avec l'adamantan-1-ol, l'adamantyl-1-amine, l'adamantane-1-méthanol et l'adamantane-1-éthanol conduit à la formation des 4,5-di-(adamantanyl-1-oxy)-3,6-difluorophtalonitrile, 4,5-di-(adamantanyl-1-amino)-3,6-difluorophtalonitrile, 4-(adamantanyl-1-amino)-3,5,6-trifluorophtalonitrile, 3,4,5,6-tétra-(adamantanyl-1-méthoxy)phtalonitrile, 3,4,5,6-tétra-(adamantanyl-1-éthoxy)phtalonitrile respectivement. On a démontré qu'il est possible de transformer ces phtalonitriles tétrasusbstitués en phtalocyanines libre ou complexées avec du nickel ou du magnésium. Les spectres UV–visible de ces phtalocyanines fortement empêchées présentent des déplacements intéressants vers le rouge.

Mots clés : phtalocyanines de l'adamantane fortement empêchées, adamantylphtalonitriles.

Introduction

Phthalocyanines (Pcs) are brilliantly coloured purple, blue, or green macrocyclic compounds that have been extensively studied, initially because of their extensive use as dyes (1), but more recently because of their interesting photochemistry (2), potential applications as chemical sensors (3), nonlinear optics (4), and as medicinal agents in photodynamic therapy (PDT) (5). Recently, red-coloured manganese Pcs for analogs, substituted with highly hindered, bulky hexadecaalkoxyl functional groups, have been reported (6, 7), while other red phthalocyanines bearing alkylthio (8) and phenyl groups (9) have been described. These analogs represent Pcs exhibiting pronounced red shifts. Previously, some highly red-shifted analogs of some Pcs had been prepared with some difficulty owing to insolubility (10) and decomposition problems (11).

A significant bathochromic red shift of the Pc chromophore has long been associated with analogs bearing electron-donating substituents at the 1, 4, 8, 11, 15, 18, 22, and 25 positions (nonperipheral), while less pronounced red shifts of the Q band are associated with substitution on the 2, 3, 9, 10, 16, 17, 23, and 24 positions (peripheral) (12, 13). For analogs fully substituted at both the peripheral and nonperipheral positions with alkoxy moieties, enhanced red shifts of the Q band have also been reported (14). It has been postulated that sterically bulky substituents at the peripheral positions around the Pc exert influence upon the nonperipheral positions, thereby effectively increasing the steric bulk of the nonperipheral substituents and further promoting a shifting of the Q band. Various metallated and nonmetallated Pcs bearing sterically bulky alkoxy moieties have been reported, including both neopentoxy and cyclohexylmethoxy groups (6, 7). In addition to the effect that these substitutions appear to have on the absorption spectra of the resulting Pcs, a disruption of the π stacking among the aromatic macrocycles increases the solubility of the molecule, even in nonpolar solvents.

One particular bulky alkyl moiety that has interested our research group is adamantane. In particular, amine-substituted adamantanes have been approved for treatment as an antiviral agent against influenza A (15) and adamantyl moieties have been investigated for their potential use as carrier groups for anticonvulsant (16) and anticancer drugs

(17). However, it is their more general physicochemical characteristics associated with large steric bulk and their close steric relationship to our favorite bulky group, the neopentoxy group, that have piqued our interest as related to the potential for substitution onto the Pc framework.

The synthesis of substituted Pcs can be accomplished through two distinct approaches, each involving nucleophilic aromatic substitution. A recent approach employed in our research group has focused upon directly reacting metallated hexadecafluorophthalocyanines with various heteroatom nucleophiles (18). A limit to this synthetic approach is the distribution of substituents replacing the fluorine atoms resulting in a range of products that are difficult to separate by flash chromatography. Furthermore, complete replacement of all 16 fluorine atoms is limited to sterically small, strong nucleophiles Alternatively, tetrasubstituted phthalonitriles bearing functionalities, such as the neopentoxy group, can be readily produced by nucleophilic aromatic substitution reactions on 3,4,5,6-tetrafluorophthalonitrile (**1**) despite the steric bulk of the substituents (19).

The general synthetic strategy employed for the synthesis of adamantyl-substituted Pcs follows the production and isolation of substituted phthalonitriles. Subsequent condensation of the adamantyl-substituted phthalonitriles gives the required phthalocyanines. In this research we were interested in systematically varying the bulk of the substitiuents so as to produce a series of hexadecasubstituted phthalocyanines and examining their spectroscopic properties.

Results and discussion

A novel series of phthalocyanine compounds were designed and synthesized bearing bulky adamantane-based substituents. Commercially available 3,4,5,6-tetrafluorophthalonitrile (**1**) was reacted with 1-adamantanol (**2**), 1-adamantylamine (**3**), 1-adamantanemethanol (**4**), or 2-(1-adamantanyl)ethanol (**5**) in the presence of a base to generate 4,5-di-(1-adamantyloxy)-3,6-difluorophthalonitrile (**6**), 4,5-di-(1-adamantylamino)-3,6-difluorophthalonitrile (**7**), 4-(1-adamantylamino)-3,5,6-trifluorophthalonitrile (**8**), 3,4,5,6-tetra-(1-adamantylmethoxy)phthalonitrile (**9**), or 3,4,5,6-tetra-[2-(1-adamantyl)ethoxy]phthalonitrile (**10**). For the synthesis of fully substituted adamantylmethoxyl and adamantylethoxyl (Scheme 1) derivatives, a previously reported synthetic approach was followed in which an excess of alkyl alcohol was combined with 3,4,5,6-tetrafluorophthalonitrile (**1**) in *N*,*N*-dimethylformamide (DMF) at 140 °C in the presence of potassium carbonate (19). Both tetrasubstituted crude products, purified by flash silica gel column chromatography, were eluted with dichloromethane–methanol and reduced to an amber-coloured oil under reduced pressure. These oils solidified under a stream of air yielding the desired final products, which were confirmed by EI mass spectra NMR and IR spectroscopic analysis and microanalyses.

Despite repeated attempts to synthesize the tetrasubstituted analog from 1-adamantanol and **1** using this synthetic approach, the reaction was not successful. Therefore, an alternative synthetic approach for the aromatic nucleophilic substitution of the phthalonitrile fluorine was implemented, in which *n*-butyllithium in tetrahydrofuran (THF) was used to deprotonate **2** (or **3**) to create the desired nucleophile. Although this modified approach did result in fluorine substitution, complete tetrasubstitution was not achieved, presumably because of the high degree of steric bulk associated with the adamantanyl cage. This steric hindrance is not so severe in the adamantanemethanol and adamantaneethanol homologs, thereby enabling complete substitution. An obvious colour change was noted immediately upon addition of 3,4,5,6-tetrafluorophthalonitrile to the activated adamantyloxide nucleophile, and despite allowing the reaction to continue for up to 72 h, substitution of more than two fluorine moieties was not observed (Scheme 1). TLC of the reaction mixture did reveal an additional spot that was presumed to be the monosubstituted analog, although isolation of this species was not achieved. As usual, a sharp intense absorbance at 2239 cm^{-1} was observed in the IR spectra and was attributed to CN stretching. Furthermore, EI mass spectroscopy and microanalysis confirmed that the product from this reaction is a disubstituted phthalonitrile. The ^1H NMR spectra for this compound revealed the expected resonances for the adamantyl protons between δ 1.68 and 2.24 ppm, while the ^{19}F NMR exhibited a singlet at δ –114.9 ppm. The singlet suggests that the two adamantyloxy substituents are positioned at the peripheral position.

The synthesis of derivatives substituted with nitrogen-containing adamantane analogs was accomplished through an approach similar to adamantanol involving the in situ

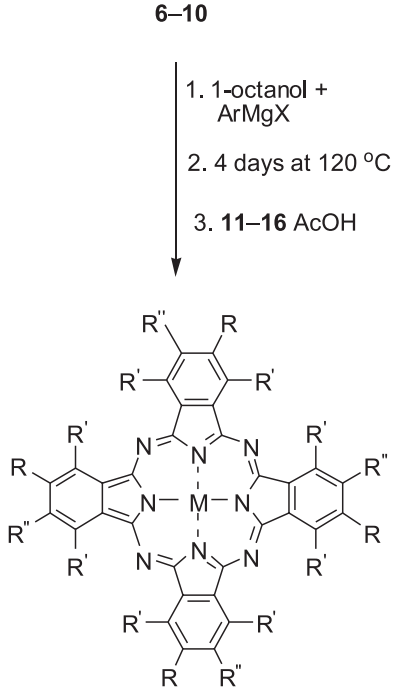
generation of an adamantamide anion from **3**, followed by subsequent addition of **1**. The desired disubstituted product was separated by flash silica gel column chromatography, yielding an amber-coloured oil that solidified under air. EI mass spectroscopy and elemental analysis confirmed the product, while fluorine NMR spectra for the species showed a singlet at $\delta \sim -119$ ppm.



Subsequently, the reaction was repeated with 1 equiv. of adamantylamine (**3**) and **1** to generate the monosubstituted analog, **8**. Three distinct resonances (δ –118.7, –129.7, and –136.8) were identified in the ^{19}F NMR, corresponding to the three inequivalent fluorines from the monosubstituted phthalonitrile. Further characterization by EI mass spectroscopy, FT-IR spectroscopy, and elemental analysis confirm the synthesis of the monosubstituted adamantylamine-substituted analog.

Each of the above phthalonitriles (**6**–**10**) was condensed with 1-octanol and phenyl or 4-methoxyphenylmagnesium bromide to yield the corresponding magnesium phthalocyanine, as outlined in Scheme 2. The formed Pcs were all purified by flash silica gel column chromatography, eluting with a solvent mixture of hexane – ethyl acetate, and subsequently characterized by MALDI mass spectroscopy (MALDI-MS), elemental analyses, UV–vis spectrophotometry, and NMR analyses. The mass spectra of all magnesium phthalocyanines gave the expected parent ion clusters. In addition, daughter ion clusters corresponding to the loss of the adamantanyl fragments cleaved at the alkyl–heteroatom bond were also detected.

The ^{1}H NMR spectra for all magnesium phthalocyanines exhibited resonances for the adamantanyl protons between 1.6 and 2.3 ppm. In the OCH_2 region for the hexadeca-adamantylmethoxysubstituted analog **14**, a broad singlet was observed. A similar nickel phthalocyanine bearing hexadeca-cyclohexylmethoxyl moieties revealed temperature-dependant separation of the peripherally and nonperipherally substituted methylene protons and that at room temperature the two chemically different proton pairs appeared as a broad singlet (19) The peripheral and nonperipheral OCH_2 protons for the hexadecaadamantylethoxyphthalocyanine **15** are chemically inequivalent and appeared as distinct triplets at 4.27 and 4.16 ppm, respectively. As expected, the ^{19}F NMR for the hexadecasubstituted analogs showed no fluorine resonances, while the octaadamantyloctafluoro Pcs **11** and **12** exhibited singlets at approximately –120 ppm. However, the ^{19}F NMR for the tetrasubstituted analog **13**, which consists of a mixture of isomers, revealed multiple fluorine resonances corresponding to the multitude of inequivalent fluorines formed during the phthalocyanine condensation reaction.

A comparison of the UV–vis spectra for the Mg Pcs exhibits the expected red shifts owing to the substitution onto the macrocyclic aromatic ring, as shown in Table 1. Each of the hexadecasubstituted compounds exhibited a pronounced red shift of the Q band, with λ_{max} values similar to those reported in the literature for magnesium hexadecaneopentoxyphthalocyanine (754 nm) (6, 7). The tetrasubstituted derivative **13** was not red-shifted as greatly as the octaadamantylamine derivative, further supporting the association between large, sterically bulky substituents and the red shift of the corresponding UV–vis spectra. As compared

Mg Pc	λ_{max} (log ε)
11	708 (4.83)
12	794 (4.57)
13	714 (4.63)
14	752 (4.91)
15	744 (4.93)

with the tetrasubstituted analog, the octaadamantylamine-substituted derivative exhibited a red shift of 80 nm. It is possible that these bulky adamantylamino groups, even at the peripheral positions, distort the planar Pc ring, causing this red shift. Not surprisingly, a small decrease in the λ_{max} was detected upon insertion of a methylene unit for the hexadecasubstituted analogs **15**, as compared with **14**, as the extra methylene group in **15** will position the bulky adamantyl group further from the core of the Pc.

Metal-free Pcs are useful intermediates for transmetallating synthetically challenging complexes. A metal-free phthalocyanine analog **16** was synthesized after refluxing the magnesium derivative **11** in acetic acid. Purification was achieved by flash silica gel column chromatogra-

phy with hexane – ethyl acetate used as the mobile phase. This compound was characterized by MALDI-MS and again revealed the expected parent ion cluster at 1883 amu. A series of daughter ion clusters were observed separated by 135 amu, corresponding to the loss of an adamantanyl unit ($C_{10}H_{15}$). The complex was further characterized by NMR spectroscopy, elemental analysis, and UV–vis spectrophotometry, with the λ_{max} of the Q band red-shifted by 26–764 nm with respect to the magnesium derivative. Following the isolation and characterization of the metal-free derivative, repeated attempts to introduce manganese into the core of the phthalocyanine were unsuccessful.

Due to the difficulty associated with forming the metal-free phthalocyanines incorporating adamantane-based substituents, a multistep synthesis for transmetalating Pcs was not viable. Therefore, direct condensation of precursor phthalonitriles with nickel as the core metal ion was pursued. As previously described (19), the general synthetic approach is outlined in Scheme 3 in which **6**, **9**, or **10** was heated with $NiCl_2$ in *N*,*N*-dimethylaminoethanol (DMAE) for 4 days at 120 °C to give the nickel phthalocyanines **17**–**19**, respectively. Again, MALDI-MS revealed the expected parent ion clusters, in addition to daughter ion clusters corresponding to fragmentation between the alkyl substituents and oxygen. For the octaadamantyloctafluoro-nickel Pc **17**, the daughter ions were separated by 135 amu, while the daughter ion clusters for the hexadecaadamantylmethoxy-nickel Pc **18** were separated by 149 amu and the daughter ion peaks corresponding to hexadecaadamantylethoxy-substituted analog were separated by 163 amu, as shown in Fig. 1. Similar to the magnesium Pc analogs, the OCH_2 resonances for the adamantylmethoxyphthalocyanine **18** appeared as a broad signal at 4.21 ppm representing both the peripheral and nonperipheral substituents, while two clearly distinct triplet resonances at 4.78 and 4.53 ppm were observed for the peripheral and nonperipheral OCH_2 protons, respectively, of the adamantylethoxyl Pc **19**. UV–vis spectra were recorded for the three nickel phthalocyanines (summarized in Table 2), although the Q bands are not as red-shifted as the corresponding magnesium phthalocyanines. The most sterically congested nickel Pc (**18**) exhibited the greatest red

Table 2. Summary of the UV–vis spectra for the adamantane-substituted nickel phthalocyanines.

Ni Pc	λ_{max} (log ε)
17	708 (4.91), 636 (4.23)
18	750 (4.93), 672 (4.43)
19	736 (4.88), 660 (4.25)

shift, while the octaadamantyloxy-octafluorophthalocyanine **17** was the least red-shifted nickel complex. Perhaps some aggregation in **17**–**19** resulted in somewhat lower log ε values than usual. This reinforces the association between large sterically hindered substitutions onto the aromatic macrocycle and the red shifting of the Q band for phthalocyanines, although the λ_{max} for **18** was slightly less red-shifted as compared with hexadecaneopentoxyphthalocynaninato nickel (750 vs. 758 nm) (19).

Experimental

General methods

Inert atmosphere conditions were maintained using Air Liquide prepurified argon. Magnetic stirring methods were utilized during all reactions. Flash chromatography was performed using silica gel of particle size 40–63 μm, with eluting solvents mixtures as described. Nuclear magnetic resonance (NMR) spectroscopy for proton and fluorine was performed using a Bruker 300 spectrometer at room temperature and was processed using XWIN-NMR 3.5 software. Chemical shifts are reported in parts per million (δ). Infrared (IR) spectra were recorded on a Mattson 3000 FT-IR spectrometer using KBr discs. UV–vis were recorded on a Hewlett-Packard HP8452A diode array spectrophotometer. For all phthalonitriles, low-resolution mass spectra (MS) were recorded in electron ionization (70 eV) mode on a Micromass/Waters GCT time-of-flight instrument. For all phthalocyanines, low-resolution MS were recorded using laser desorption ionization (LDI) on a PE Sciex Q-STAR XL or PerSeptive Biosystems Voyager – DE STR spectrometer. Microanalyses were performed by Guelph Chemical Laboratory Ltd., Guelph, Ontario.

Synthesis of 4,5-di-(1-adamantyloxy)-3,6-difluorophthalonitrile (6)

1-Adamantanol (**2**, 1.50 g, 9.85 mmol, 2 equiv.) was dissolved in 10 mL of THF and the solution was stirred under an argon atmosphere at room temperature. To this solution was added *n*-butyllithium in hexanes (4.94 mL, 2 mol/L, 2 equiv.). The reaction mixture initially turned cloudy and a fine white precipitate was observed. The mixture was stirred for 1 h before a solution of 3,4,5,6-tetrafluorophthalonitrile (**1**, 0.986 g, 4.93 mmol, 1 equiv.) in THF was added dropwise under argon. The reaction mixture turned reddish-purple and was stirred at room temperature for 4 h. After this period, 100 mL of water was added to the reaction mixture and the mixture was extracted with diethyl ether (3 × 50 mL). After drying over sodium sulfate, the solvent was removed under reduced pressure, resulting in an amber-coloured oil. The oil was then dissolved in a minimum of toluene and was passed through a flash silica gel column using toluene as eluant. The first fraction was collected and the solvent was removed under reduced pressure, yielding an oil that solidified upon sitting under a stream of air overnight. Yield: 76% (1.74 g); mp 196–198 °C. TLC (toluene): R_f 0.63. IR (KBr, cm^{-1}) ν: 2911, 2846, 2239 (CN), 1454, 1354, 1295, 1113, 1042. ^{1}H NMR ($CDCl_3$) δ :2.24 (br m, 6H, bridgehead C-H), 1.93 (m, 12H, CH_2), 1.68 (br m, 12H, CH_2). ^{19}F NMR ($CDCl_3$) δ: –114.9 (s). EI-MS *m*/*z* (rel. intensity): M^+ 464 (64). Anal. calcd. for $C_{28}H_{30}O_2N_2F_2$: C 72.39, H 6.51, N 6.03; found: C 72.42, H 6.34, N, 6.11.

Synthesis of 4,5-di-(1-adamantylamino)-3,6-difluorophthalonitrile (7)

1-Adamantylamine (**3**, 1.52 g, 10.1 mmol, 2 equiv.) was dissolved in 15 mL of THF and the solution was stirred under an argon atmosphere at room temperature. To this was added *n*-butyllithium in hexanes (4.0 mL, 2.5 mol/L, 2 equiv.). The reaction mixture initially turned cloudy and a fine white precipitate was observed. The mixture was stirred for 1 h before a solution of 3,4,5,6-tetrafluorophthalonitrile (**1**, 0.986 g, 4.93 mmol, 1 equiv.) in THF was added dropwise under argon. The reaction mixture turned dark red and was stirred at room temperature for 4 h. After this period, 100 mL of water was added to the reaction mixture and was extracted with diethyl ether (3 × 50 mL). After drying over sodium sulfate, the solvent was removed under reduced pressure, resulting in an amber-coloured oil. The oil was then dissolved in a minimum of toluene and was passed through a flash silica gel column using toluene for elution. The first fraction was collected and the solvent was removed under reduced pressure, yielding an oil that solidified upon sitting under a stream of air overnight. Yield: 52% (1.12 g); mp 184–186 °C. TLC (toluene): R_f 0.61. IR (KBr, cm^{-1}) ν: 3377, 2910, 2850, 2225 (CN), 1594, 1515, 1453, 1384, 1359, 1306. ^{1}H NMR ($CDCl_3$) δ: 4.05 (br s, 2H, N-H), 2.20 (br s, 6H, bridgehead C-H), 1.94 (m, 6H, CH_2), 1.85 (m, 6H, CH_2), 1.70(m, 12H, CH_2). ^{19}F NMR ($CDCl_3$) δ: –119.6. EI-MS *m*/*z* (rel. intensity): M^+ 462 (100). Anal. calcd. for $C_{28}H_{32}N_4F_2$: C 72.70, H 6.97, N 12.11; found: C 72.89, H 7.20, N 12.16.

Synthesis of 4-(1-adamantylamino)-3,5,6-trifluorophthalonitrile (8)

1-Adamantylamine (**3**, 0.76 g, 5.0 mmol, 1 equiv.) was dissolved in 15 mL of THF and the solution was stirred under an argon atmosphere at room temperature. To this solution was added *n*-butyllithium in hexanes (2.0 mL, 2.5 mol/L, 1 equiv.). The reaction mixture initially turned cloudy and a fine white precipitate was observed. The reaction was stirred for 1 h before a solution of 3,4,5,6-tetrafluorophthalonitrile (**1**, 0.986 g, 4.93 mmol, 1 equiv.) in THF was added dropwise under argon. It was then stirred at room temperature for 4 h and worked up as for **7**. IR (KBr, cm^{-1}) ν: 3418, 3382, 2912, 2854, 2231 (CN), 1566, 1452, 1382, 1108. Yield: 58% (0.95 g); mp 135–137 °C. TLC (toluene): R_f 0.65. ^{1}H NMR ($CDCl_3$) δ: 3.42 (br s, 1H, N-H), 2.19 (br s, 3H, bridgehead C-H), 1.93 (br s, 6H, CH_2), 1.71 (br s, 6H, CH_2). ^{19}F NMR ($CDCl_3$) δ: –118.7 (m), –129.7 (m), –136.8 (m). Synthesis of 3,4,5,6-tetra-(1-adamantylmethoxy)phthalonitrile (9)

1-Adamantanemethanol (**4**, 5.0 g, 30.1 mmol, 24 equiv.), potassium carbonate (5 g, 36 mmol, 30 equiv.), and 3,4,5,6-tetrafluorophthalonitrile (**1**, 1.0 g, 5 mmol, 1 eq.) were dissolved in 12 mL DMF and the reaction mixture was heated to 120 °C for 4 days. After this period, 100 mL of water was added to the reaction mixture, which was subsequently extracted with diethyl ether (3 × 75 mL). After drying over sodium sulfate, the solvent was removed under reduced pressure, yielding an amber-coloured oil. The oil was dissolved in a minimum of dichloromethane and was passed through a flash silica gel column using dichloromethane–methanol (20:1) as eluant. The first fraction was collected and the solvent was removed under reduced pressure, yielding an amber oil that solidified to an off-white solid under a stream of air overnight. Yield: 78% (3.07 g); mp 173–176 °C. TLC (toluene): R_f 0.66. IR (KBr, cm^{-1}) ν: 2943, 2917, 2230 (CN), 1558, 1489, 1358, 1101. ^{1}H NMR ($CDCl_3$) δ: 3.69 (s, 4H, CH_2), 3.68 (s, 4H, CH_2), 2.04 (m, 12H, bridgehead C-H), 1.71 (m, 24H, CH_2), 1.67 (m, 24H, CH_2). EI-MS *m/z* (rel. intensity): M^+ 784 (41). Anal. calcd. for $C_{52}H_{68}O_4N_2$: C 79.55, H 8.73, N 3.57; found: C 79.14, H 9.07, N 3.59.

Synthesis of 3,4,5,6-tetra-(1-adamantylethoxy)phthalonitrile (10)

1-Adamantaneethanol (**5**, 5.0 g, 27.8 mmol, 8 equiv.), potassium carbonate (4.3 g, 32 mmol, 8 equiv.), and 3,4,5,6-tetrafluorophthalonitrile (**1**, 0.7 g, 3.5 mmol, 1 equiv.) were added to 12 mL of DMF and the reaction mixture was heated to 120 °C for 4 days. The work-up proceeded as for **9**, but dichloromethane–methanol (10:1) was used as eluant. Yield: 81% (2.39 g); mp 166–168 °C. TLC (toluene): R_f 0.68. IR (KBr, cm^{-1}) ν: 2935, 2846, 2231 (CN), 1559, 1448, 1382, 1371, 1244, 1106. ^{1}H NMR ($CDCl_3$) δ: 4.19 (m, 8H, OCH_2), 1.98 (br s, 12H, bridgehead C-*H*), 1.67 (m, 24H, CH_2), 1.56 (m, 32H, OCH_2CH_2 and adamantyl CH_2). EI-MS *m/z* (rel. intensity): M^+ 840 (51). Anal. calcd. for $C_{56}H_{76}O_4N_2$: C 79.96, H 9.11, N 3.33; found: C 79.60, H 9.35, N 3.32.

Synthesis of magnesium 2,3,9,10,16,17,23,24-octa-(1-adamantyloxy)-1,4,8,11,15,18,22,25-octafluorophthalocyanine (11)

4-Methoxyphenylmagnesium bromide (2 mL, 0.5 mol/L in THF) was added to 3 mL of 1-octanol and the mixture was stirred for 0.5 h under argon at room temperature. To this was added 4,5-di-(1-adamantyloxy)-3,6-difluorophthalonitrile (**6**) (0.250 g, 0.53 mmol) and the mixture was heated under argon to 120 °C. Upon heating, the clear, colourless mixture turned green. After heating for 24 h, 50 mL of methanol was added and a green solid precipitated out of solution. The solid was collected by centrifugation and was washed with water and methanol. The crude product was then passed through a flash silica gel column eluting with hexane – ethyl acetate (9:1). The first fraction was collected and the solvent was removed under reduced pressure, yielding a dark green solid. Yield: 34% (0.085 g); mp >300 °C. TLC (hexane – ethyl acetate, 5:1): R_f 0.72. UV–vis (dichloromethane) λ_{max} (log ε) (nm): 708 (4.83), 636 (4.06), 364 (4.43), 318 (4.37). ^{1}H NMR ($CDCl_3$) δ: 2.50 (br s, 24H, bridgehead C-H), 2.31 (m, 48H, CH_2), 2.22 (m, 48H, CH_2). ^{19}F NMR ($CDCl_3$) δ: –119.2. MALDI-MS *m/z* (rel. intensity): 1883 $[M]^+$ (10), 1748 $[M - C_{10}H_{15}]^+$ (21), 1613 $[M - 2(C_{10}H_{15})]^+$ (25), 1478 $[M - 3(C_{10}H_{15})]^+$. Anal. calcd. for $C_{112}H_{120}O_8N_8F_8Mg$: C 71.46, H 6.43, N 5.95; found: C 71.48, H 6.44, N, 6.11

Synthesis of magnesium 2,3,9,10,16,17,23,24-octa-(1-adamantylamino)-1,4,8,11,15,18,22,25-octafluorophthalocyanine (12)

4-Methoxyphenylmagnesium bromide (2 mL, 0.5 mol/L in THF) was added to 3 mL of 1-octanol and the mixture was stirred for 0.5 h under argon at room temperature. To this was added 4,5-di-(1-adamantylamino)-3,6-difluorophthalonitrile (**7**, 0.250 g, 0.53 mmol) and the mixture was heated under argon to 120 °C. Upon heating, the clear, colourless mixture turned red and was worked up as for **11**, yielding a dark green solid. Yield: 17% (0.042 g); mp >300 °C. TLC (hexane – ethyl acetate, 5:1): R_f 0.72. UV–vis (dichloromethane) λ_{max} (log ε) (nm): 794 (4.57), 708 (4.09), 478 (4.04), 358 (4.34), 322 (4.34). ^{1}H NMR ($CDCl_3$) δ: 2.11 (m, 24H, bridgehead C-H), 1.87 (m, 48H, CH_2), 1.68 (m, 48H, CH_2). MALDI-MS *m/z* (rel. intensity): 1872 $[M]^+$ 100. Anal. calcd. for $C_{112}H_{128}N_{16}F_8Mg$: C 71.76, H 6.88, N 11.95; found: C 71.87, H 7.27, N 11.24.

Synthesis of magnesium 2,9,16,23-tetra-(1-adamantylamino)-1,3,4,8,10,11,15,17,18,22,24,25-dodecafluorophthalocyanine (13)

4-Methoxyphenylmagnesium bromide (2 mL, 0.5 mol/L in THF) was added to 3 mL of 1-octanol and the mixture was stirred for 0.5 h under argon at room temperature. To this was added 4-(1-adamantylamino)-3,5,6-trifluorophthalonitrile (**8**, 0.250 g, 0.75 mmol) and the mixture was heated under argon to 120 °C. Upon heating, the clear, colourless mixture turned green. After heating for 24 h, 50 mL of methanol was added and a green solid precipitated out of solution and was worked up as for **11**, yielding a dark green solid. Yield: 21% (0.053 g); mp >300 °C. TLC (hexane – ethyl acetate, 9:1): R_f 0.62. UV–vis (dichloromethane) λ_{max} (log ε) (nm): 714 (4.63), 646 (4.07), 362 (4.37). ^{1}H NMR ($CDCl_3$) δ: 3.82 (br s, 4H, NH), 2.18 (m, 12H, bridgehead C-H), 1.71–1.96 (m, 24H, CH_2), 1.58 (br s, 24H, CH_2). ^{19}F NMR ($CDCl_3$) δ: –128 (m), –138 (m). MALDI-MS *m/z* (rel. intensity): 1348 $[M]^+$ (100), 1213 $[M - C_{10}H_{15}]^+$ (63), 1078 $[M - 2(C_{10}H_{15})]^+$ (53), 943 $[M - 4(C_{10}H_{15})]^+$ (24). Synthesis of magnesium 1,2,3,4,8,9,10,11,15,16,17,18,22,23,24,25-hexadeca-(1-adamantylmethoxy)phthalocyanine (14)

4-Methoxyphenylmagnesium bromide was added (2 mL, 0.5 mol/L in THF) to 3 mL of 1-octanol and the mixture was stirred for 0.5 h under argon at room temperature. To this was added 3,4,5,6-tetraadamantylmethoxyphthalonitrile (**9**, 0.250 g, 0.32 mmol) and the mixture was heated under argon to 120 °C. Upon heating, the clear, colourless mixture turned green. After heating for 24 h, 50 mL of methanol was added and a green solid precipitated out of solution and was worked up as for **11**, yielding a dark green solid. Yield: 15%

Conclusions

Phthalocyanines bearing large bulky substituents have previously shown interesting physicochemical properties, including a red shifting of the Q band. A series of metallated and nonmetallated Pcs have been synthesized incorporating large bulky substituents based upon analogs of adamantane. These complexes exhibit interesting characteristics, notably pronounced red shifting of the Q band.

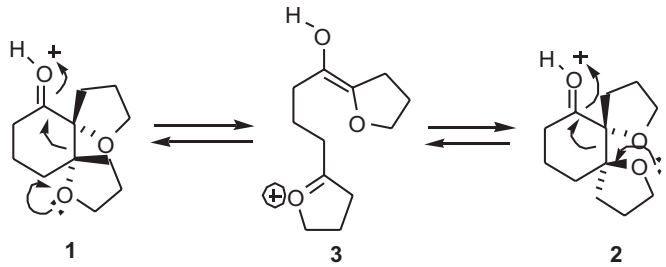
Synthesis and Lewis acid induced isomerization of mono-, di-, and tri-spiro α-keto tetrahydro-furans and -pyrans[1]

David G. Hilmey, Peter R. Selvaraj, and Leo A. Paquette

Abstract: The stereoselectivity of the acid-catalyzed ring expansion of dihydrofuranyl and dihydropyranyl 1,2-adducts to spirocyclic ketones 8 and **9** has been examined. These substrates have become readily available by the utilization of 1,3-dichloroacetone as a synthetic equivalent of cyclopropanone. The kinetically controlled isomerizations result in ring expansion to dispirocyclopentanones. Third-stage conversion to trispirocyclohexanones was shown to be possible in select examples. On a different front, the syn and anti pairs proved capable of interconversion by heating in the presence of boron trifluoride etherate. A push–pull fragmentation of the ketone ring is proposed to account for these epimerizations. Calculations have been performed to simulate transition state energies in the oxonium ion intermediates and to gain some idea of the preferred ground-state geometries of the final products.

Key words: oxonium ion rearrangements, ring expansions, acid-catalyzed epimerizations, cyclopropanone equivalent, spirocyclic ethers.



Résumé : On a étudié la stéréosélectivité de l'expansion de cycle acidocatalysée de 1,2-adduits dihydrofuranyles et dihydropyranyles en cétones spirocycliques **8** et **9**. Ces substrats sont facilement disponibles à partir de la 1,3-dichloroacétone utilisée comme équivalent de synthèse de la cyclopropanone. Les isomérisations sous contrôle cinétique conduisent à une expansion de cycle qui fournit des dispirocyclopentanones. On a démontré la possibilité de réaliser le troisième stade de conversion en trispirocyclopentanones en utilisant des exemples choisis. On a par ailleurs démontré que les paires syn et anti peuvent subir des interconversions par chauffage en présence d'éthérate de trifluorure de bore. On propose une fragmentation de type « push–pull » du cycle cétonique pour expliquer ces épimérisations. Des calculs ont été effectués pour simuler les énergies de l'état de transition dans les ions oxonium intermédiaires et pour mieux comprendre les géométries de l'état fondamental privilégié des produits finaux.

Mots clés : réarrangement d'ion oxonium, expansion de cycle, épimérisation acidocatalysée, équivalent de cyclopropanone, éthers spirocycliques.

[Traduit par la Rédaction]

Introduction

The feasibility of inducing epimerization in molecules constructed of two neighbouring quaternary carbon centers is seldom encountered. One way to drive this process is to suitably position a heteroatom such as an ether oxygen or a divalent sulfur β to a carbonyl group (1, 2). This structural arrangement allows for the operation under acidic conditions of a push–pull fragmentation of the cycloalkanone, with subsequent reconstitution of the original but now stereochemically scrambled substrate (3). The interconversion of **1** with **2** via **3** is illustrative of the process. Since **1** and **2** are chiral and amenable to resolution while **3** is not, the cyclization of this tethered oxonium ion – enol intermediate results in racemization as has been observed experimentally (3). Rotation of either terminus of the chain relative to the other prior to ring closure provides the enabling means for losing stereochemical "memory".

1 3 2

Studies involving such molecular frameworks have previously been limited to di- and tri-spirocyclic cyclohexanone systems because of synthetic constraints. To explore a more representative array of congeners, it became imperative that cyclopropanone replace cyclobutanone as the key building

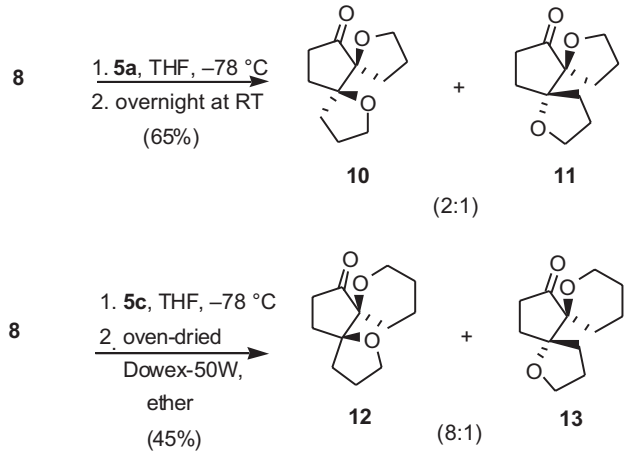
block. However, the highly reactive nature of this compound does not lend itself to being accessible in preparative quantities in a standard laboratory setting (4, 5). Most often, recourse has been made to release of the three-membered cyclic ketone from its ethyl hemiketal (6), 1-acetoxycyclopropanol (7), or a select carbinolamine (8). None of these alternatives was considered to be particularly desirable in the present context.



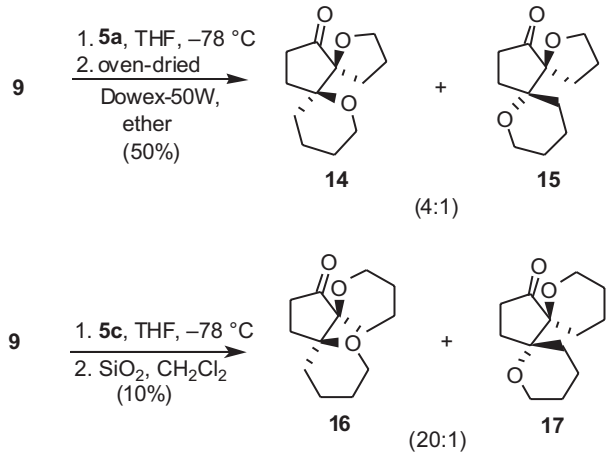
A more promising alternative originated from reports that appeared several decades ago indicating that 1,3-dichloroacetone **4** (Scheme 1) undergoes a straightforward 1,2-addition in the presence of Grignard reagents. Subsequent exposure of these adducts to ethylmagnesium bromide and iron(III) chloride then furnished 1-substituted cyclopropanols (9, 10). At a later date, Barluenga et al. (11) discovered that the initial Grignard adducts are amenable to reductive cyclization when admixed with $MgBr_2$ and lithium powder, or more conveniently with lithium naphthalenide in THF. We have come to favour the latter approach to reactive three-membered carbinols and detail here the advantages that materialize when this chemistry precedes application of the oxonium ion initiated pinacolic ring expansion (12). The use of 1,3-dichloroacetone in this manner offers an experimentally simple and versatile means for varying not only the dimensions of the central ring, but the number of spirocycles attached thereto as well as their individual size (13).

Also addressed herein is the extent to which the end products are subject to solution-phase epimerization in the presence of boron trifluoride etherate. MM3 calculations have also been performed to gauge the relative stabilities of the isomer pairs in the gas phase, and in combination with AM1 semiempirical calculations, the thermodynamically preferred geometry of the putative oxonium ion intermediates.

Scheme 1.

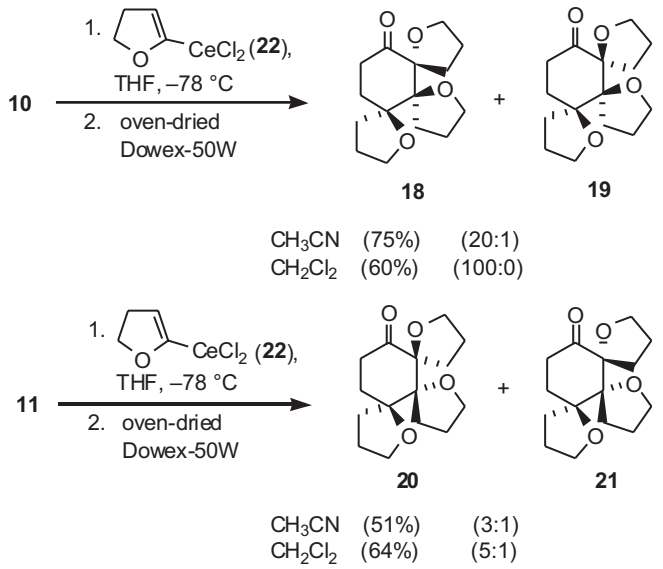
Scheme 2.

Synthetic efforts



The deprotonation of 2,3-dihydrofuran with *tert*-butyllithium (14) proceeds efficiently to produce **5a** whose condensation with **4** gives rise to alkoxide **6a** (Scheme 1). Direct reductive dechlorination of **6a** with a solution of lithium naphthalenide in THF at –78 to 20 °C promoted conversion to cyclopropanol **7a** after workup. Overnight stirring of **7a** with a small quantity of Dowex-50W resin at room temperature resulted in smooth isomerization to the volatile spiro ketone **8**, which was isolated in 65% overall yield from **4**. When comparable direct use was made of 3,4-dihydropyran as the anticipated precursor to organometallic **5c**, a diverse array of products was formed in low yield following exposure to **4**. This situation was remedied by effecting transmetalation instead via stannane **5b** (15). This alternative means for the generation of **5c** and its further processing as in Scheme 1 furnished **9** with an overall efficiency of 75%.

In the case of **8**, second-stage coupling to **5a** led to a diastereomeric mixture of two tertiary carbinols intended to serve as precursors to **10** and **11** (Scheme 2). Fortunately, the pinacol rearrangement of these adducts occurred spontaneously on standing in neat condition at room temperature. Attempts to bring about this isomerization with acid promoters under more customary conditions (3, 16) resulted instead in hydrolysis of the enol ether functionality. Consequently, cyclopentanones **10** and **11** were formed as a chromatographically separable 2:1 mixture in a single laboratory manipulation (65%). The second example, involving the combination of **5c** with **8**, produced carbinols that proved amenable to ring expansion in the presence of oven-dried Dowex-50W resin. The dominance of the more polar syn isomer **12** by the margin of 8:1 is noteworthy.



Our attention was next directed to the acquisition of analogs characterized by the presence of a spirotetrahydropyranyl unit β to the ketone carbonyl. The response of **9** to the action of **5a** and subsequent ring expansion proceeded in a manner closely comparable to the precedent set by **8**. Once again, the syn isomer **14** was more prevalent in the product mixture than **15** (4:1, Scheme 3). A striking difference in behaviour was encountered following preparation of the tertiary carbinol from 1,2-addition of **5c** to **9**. In contrast to its congeners, this intermediate proved to be unusually sensitive to the presence of Dowex-50W. When the targeted ring enlargement could not be brought about in this manner, other promoters were sought and silica gel slurried in CH_2Cl_2

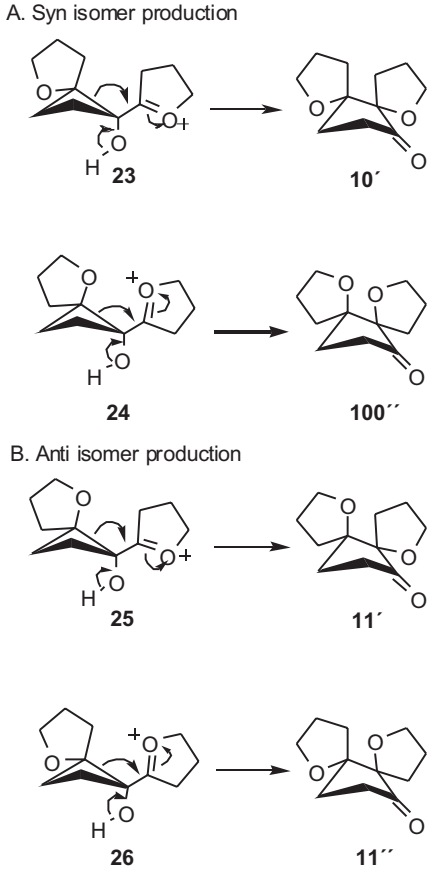
Scheme 3.

Scheme 4.



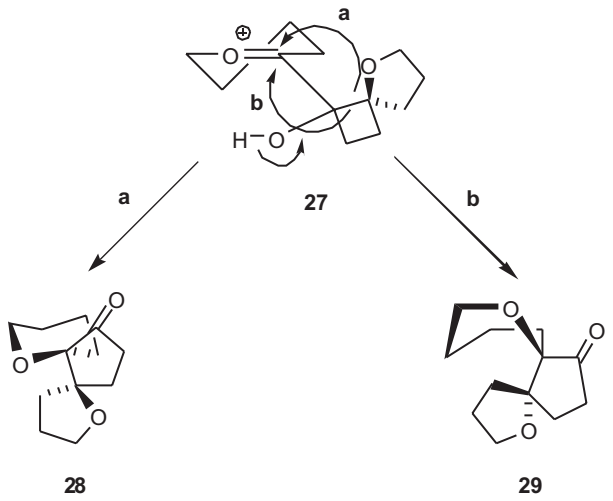
proved to be workable. With this catalyst, isomerization proceeded slowly. After 3 days, a mixture of **16** and **17** richer in the syn isomer was generated and chromatographically separated. The diminished efficiencies of the ring expansions involving **9** are a likely reflection of enhanced steric congestion in the vicinity of the reaction centers. The stereochemical assignments to all of the di- and tri-spiro ketones have been documented elsewhere (13), based on distinctive ^{1}H NMR spectral features and polarity considerations.

Compounds **10** and **11** proved amenable to a third-stage enhancement of the core ring size to the cyclohexanone level provided that the cerate reagent **22** was used to curtail the significant tendency of these cyclopentanones to experience competitive enolization (17, 18). Two important issues emerge from the data compiled in Scheme 4. The more obvious finding is the preference exhibited for introducing the third spirotetrahydrofuran anti to that positioned at the adjacent β-carbon. For **20** and **21**, the stereoselectivity gap is modest (3–5:1) and of comparable magnitude in the two solvents. Where **18** and **19** are concerned, the bias for producing **18** is quite substantial and is particularly dominant when the reaction is performed in CH_2Cl_2. Under the latter conditions, no **19** was observed. In these examples, the trispiro product ratios are reversed relative to those witnessed for the dispiro analogs such as **10/11**, **12/13**, **14/15**, and the like. We also call attention to the brevity with which **18**–**21** can be prepared from 1,3-dichoroacetone, thus doing away with issues surrounding their availability.

Stereoselectivity considerations

In line with ample precedent, the migratory aptitudes associated with 1,2-shifting to the oxonium ion center strongly favour translocation of the more electron-rich neighbouring carbon atom (1, 12, 19, 20). The end result is therefore a preferred migration of that adjacent carbon atom, which is the more highly alkylated. The only restriction is the requirement that the migrating bond be capable of being properly aligned with the pπ orbital, resident at the electrophilic center. In the present examples, the degrees of freedom are such that two modes of structural staging are possible for each product isomer. The conformational facets of the conversion of **8** to **10** and **11** are exemplified in Scheme 5. At issue is the diastereoselectivity of oxonium ion capture, a

Scheme 5.

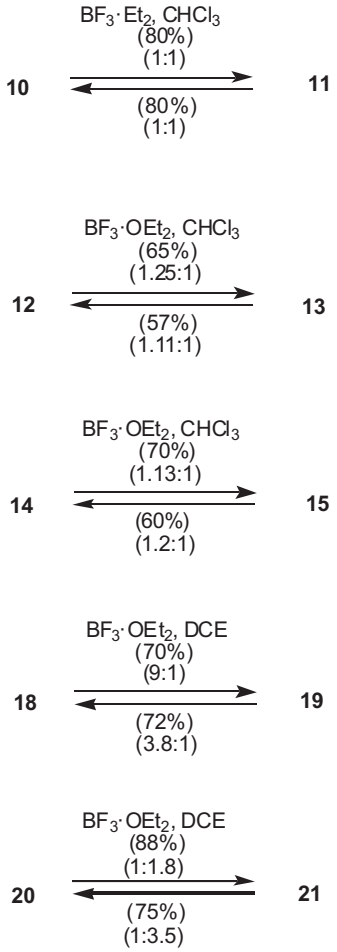


phenomenon that holds considerable fascination (21). One sees that **23** and **24** are capable of arriving at **10′** and **10″**, while **25** and **26** lead instead to **11′** and **11″**, respectively. The possibility exists, of course, that the relative magnitude and direction of stereoselectivity is founded only on steric grounds, an analysis made acceptable by the kinetically irreversible nature of the conversion to products. In this con-

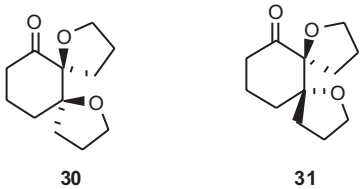
© 2006 NRC Canada

nection, it is perhaps insignificant that the ratio of diastereomeric tertiary carbinols (e.g., the precursors to **23/26** and **24/25**) is not known with precision. The key outcome is the favoured proximal placement of the methylene groups, as in **10′**, or of the ether oxygen atoms, as in **10″**, relative to the pair of alternatives **11′** and **11″** where nonbonded CH_2–O interaction develops.

The change from a flexible envelope arrangement having pseudorotational capability as in tetrahydrofurans to a well-defined axial–equatorial status in tetrahydropyrans, because of the adoption of chairlike arrangements, is a dramatic one. As a result, the diastereoselectivity associated with migrations involving six-membered oxonium ions can be projected to be more pronounced. Thus, the conversion of **27** to **28** should occur more readily and its formation not deterred as in **29** because of the development of boatlike features.



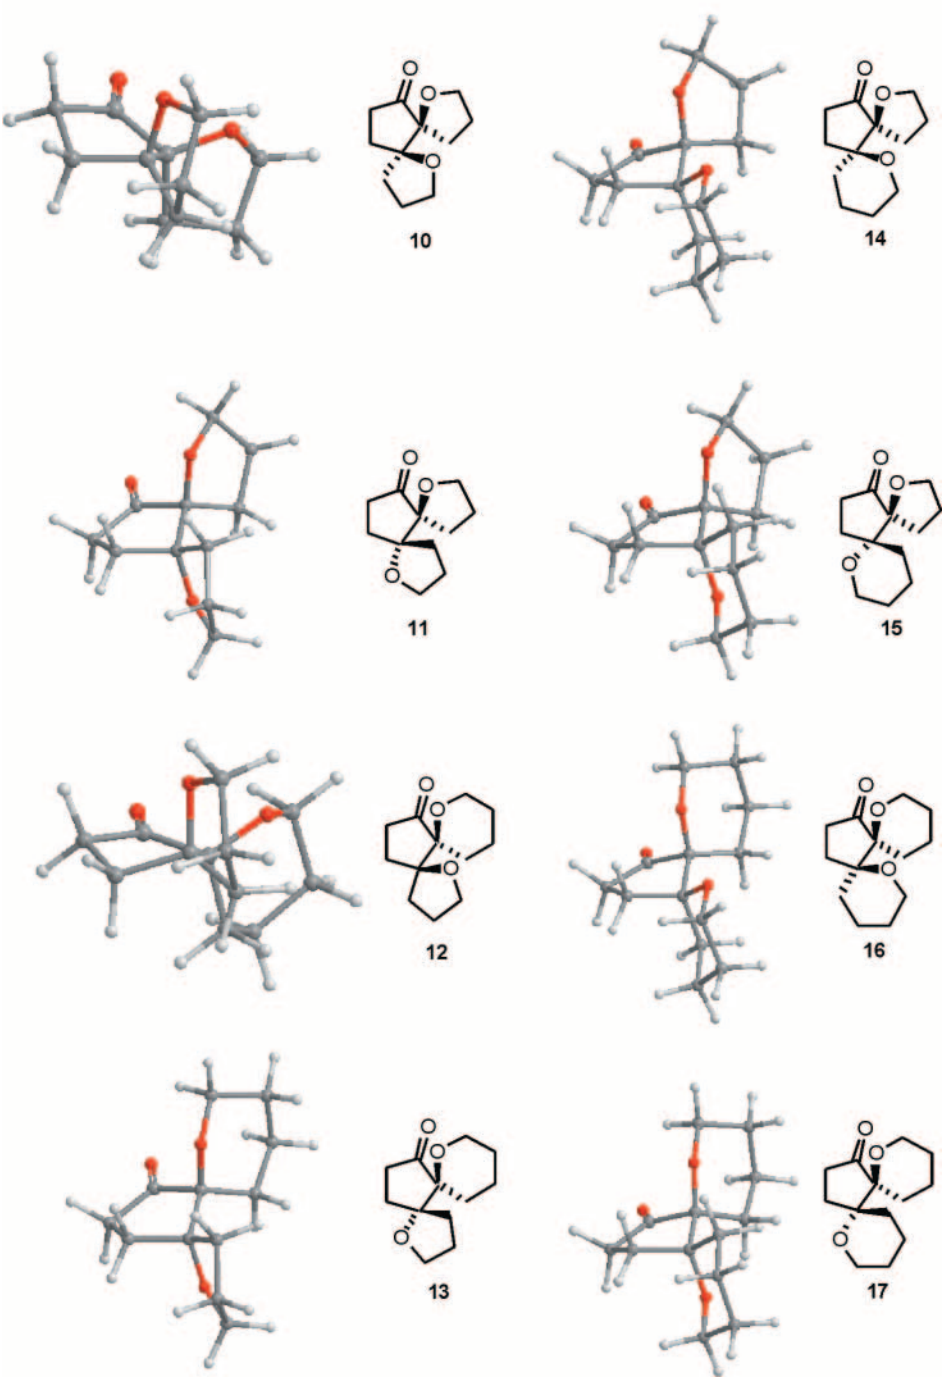
Calculations show that the oxonium functionality preferentially orients its oxygen antiperiplanar to the hydroxyl substituent (22) , as seen in **24**. This conformer will then rearrange to syn isomer **10″**, which would explain, in part, the overall preference for more prevalent formation of dispirocyclopentanones **10**, **12**, **14**, and **16**. On the other hand, the enhanced ability of the oxonium intermediate derived from the chelation-controlled adduct of **10** to adopt a synperiplanar relationship with the hydroxyl group explains the preferences for the formation of **18**. Relevantly, when the addition to **10** is nonchelation-controlled, the preferred conformation of the oxonium unit reverts back to antiperiplanar with respect to the hydroxyl, again giving **18** after ring expansion. These conformational preferences, regardless of the facial selectivity of the addition process, concisely account for the very high selectivity noted in the formation of **18** over **19**.



Lewis acid induced isomerizations

On an allied front, the ability of the various syn–anti isomer pairs to interconvert when heated in the presence of boron trifluoride etherate has been examined. An important distinction to be made regarding isomerizations of the type **1** ⇄ **2** is that kinetic control is not operative. All of the ketones prepared in the course of this investigation were treated in a comparable manner involving either chloroform or 1,2-dichloroethane as solvent. The results are compiled in Table 1. Chlorinated solvents proved most well-suited to these processes, with interconversion being optimal in the indicated medium. Except perhaps for the **10** ⇄ **11** example, complete equilibration was not reached for the majority of the isomerizations. Higher temperatures and longer reaction times only enhanced the extent of the accompanying decomposition. Under no circumstances did **16** and **17** interconvert.

Table 1. BF_3·OEt_2-induced equilibrations.



Molecular mechanics (MM3) calculations were performed on seven sets of isomers, including the **30/31** pair for the sake of completeness. The conformational searching was performed with recourse to the Monto Carlo simulation capability in MacroModel version 5.0 (23). A minimum of 1000 simulations were determined per structure and involved operations featuring one bond closure (1.0–3.0 Å) in all rings. The minimum energy diagrams were visualized with Chem 3D Ultra (24).

Fig. 1. Perspective drawings of the minimal energy conformations of **10**–**31**. Note that the representations for **18**–**21** are enantiomeric to those depicted in the text.

A conformational model of the lowest energy conformation of each of the 14 structures is illustrated in Fig. 1, and the associated steric energy values are compiled in Table 2. These data reveal the cyclopentanone systems **10**–**17** to have rather similar strain energy differences ranging from 2.6–2.8 kcal/mol (1 cal = 4.184 J). These values indicate the anti isomers to be thermodynamically advantaged to the extent of 95:5 at RT. For the cyclohexanone systems, the energy differences between pairs is considerably smaller (ca. 1 kcal/mol), thus reducing the energy gaps to a factor of only three- to six-fold. In addition, the **20/21** pair alone exhibits greater stability for its syn diastereomer.

Whereas **11** has both of its heteroatoms oriented pseudoaxially, isomer **10** projects its α C—O bond in a pseudoequatorial fashion. The latter preference persists when the α-spirocycle is expanded to the tetrahydropyranyl level as seen in **12**. We conclude that the [4.4] and [4.5] dispiro systems, including **14/15** and **16/17**, have lower energy when the capability exists to orient the α- and β-heteroatoms pseudoaxially. In the mixed systems, the

19	74.1	
18	72.9	–1.2
21	72.8	
20	73.8	+1.0

Note: The syn isomer is cited first.

tetrahydropyranyl ring, whether situated α or β to the ketone as in **12** and **14**, likewise prefers to adopt a pseudoaxial orientation placing the tetrahydrofuranyl ring in a seemingly less favourable equatorial position. This conformational dominance by the six-membered heteroring is noteworthy.

The anti isomer of the **30/31** pair is modestly lower in energy (0.7 kcal/mol). This small but significant difference can be traced back to the axial character of the C—O bonds that is adopted twice in **31** and only once in **30**. Finally, in the remaining cyclohexanones **18**–**21**, the spiroannulated tetrahydrofuran rings orient themselves in a fashion opposite to that reflected in the cyclopentanone systems. In these trispirocyclic examples, increased equatorial placement of the C—O bonds serves to lower the level of steric strain in the system, as noted in other contexts (25–27).

At the experimental level, the acid-catalyzed equilibrations of pure samples of **10**–**14** gave rise to product mixtures approximating 1:1. In light of the energy differences determined in the gas phase for these syn–anti isomer pairs, these distributions appear not to be controlled by ground state energetics. We can hypothesize, though, that the final distribution is influenced by solvent effects and more strongly by coordination with the one equivalent of $BF_3{\cdot}OEt_2$. This latter association is likely leveling the energetic differences seen between syn and anti isomers, either through altered conformation or steric and electronic factors. On the other hand, the epimerizations have proven quite utilitarian as a means for funneling one stereoisomer into another. The initial experiments, which were performed with catalytic levels of $BF_3{\cdot}OEt_2$, fared poorly. Subsequently, the use of catalytic

© 2006 NRC Canada

quantities was abandoned in favor of a full equivalent of Lewis acid, despite the possibility that such high levels of promoter could play a role in leveling the relative amounts of isomers in each subset.

For **18**–**21**, it proved possible to make use of 0.3 equiv. of catalyst. This reduced loading resulted in the generation of isomer ratios more reflective of the theoretical equilibrium values. The discrepancies that remain might stem from the tight binding of boron trifluoride to one-third of the respective starting cyclohexanone.

In conclusion, the isomerization of **10**–**15** with stoichiometric amounts of Lewis acid does not adhere to thermodynamic control largely through acid coordination and solvent effects. Ketones **18**–**21** perform better at approaching equilibrium, although very slowly, while **16** and **17** are unresponsive to these conditions. The energetic preference is biased in favour of the anti relationship of the C—O bonds with one exception. The THF and THP spirocycles favour axial oxygen orientations in the dispiro examples regardless of ring size, while an equatorial preference is seen in the trispirocycles.

Experimental

1-Oxaspiro[3.4]octan-6-one (8)

Dry tetrahydrofuran (100 mL) and freshly distilled 2,3-dihydrofuran (7.15 mL, 94.5 mmol) were placed in a 500 mL flame-dried flask, purged with N_2, and cooled to –78 °C. After 15 min, *tert*-butyllithium (55.6 mL of 1.7 mol/L in pentane, 94.5 mmol) was introduced via cannula. After 30 min, the solution was brought to 0 °C (ice bath) and after an additional 30 min introduced into a solution of 1,3-dichloroacetone (10.0 g, 78.8 mmol) in anhydrous ether (200 mL) at –78 °C. The yellow reaction mixture was stirred in the cold for 2 h before a solution of lithium naphthalenide (197 mL of 1 mol/L in THF) was added via cannula. After 4 h, the green solution was allowed to warm to rt and then cooled to 0 °C before being quenched with sat. $NaHCO_3$ solution. The separated aqueous phase was extracted with ether (3 × 150 mL) and the combined organic phases were dried and filtered. The filtrate was admixed with Dowex-50W resin (8 g), stirred overnight, and filtered again. The solvent was removed by bulb-to-bulb distillation to a volume of about 150 mL, followed by rotatory evaporation (no heat) until a solid–oil mixture was seen. Addition of toluene (25 mL), column chromatography on silica gel (elution with 5%–20% ether in petroleum ether), and subsequent fractional distillation to remove solvent afforded **8** as a pale yellow oil (6.4 g, 65%). IR (neat, cm^{-1}): 1790, 1058. ^1H NMR (300 MHz, $CDCl_3$) δ: 3.93 (t, J = 6.6 Hz, 2H), 2.79–2.70 (m, 2H), 2.22–2.05 (m, 3H), 2.02–1.90 (m, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 211.7, 96.8, 70.1, 39.7, 33.8, 26.6, 25.6. EI-MS m/z calcd.: 144.07 [$M^+ - H_2O$]; found: 144.05. Anal. calcd. for $C_7H_{10}O_2$: C 66.64, H 7.99; found: C 66.52, H 8.23.

1-Oxaspiro[3.5]nonan-7-one (9)

A solution of **5b** (14.93 g, 40.0 mmol) in dry THF (150 mL) was blanketed with N_2, cooled to –78 °C, and treated dropwise with *n*-butyllithium (29.2 mL of 1.3 mol/L in pentane, 0.038 mol). Upon completion of the addition, the reaction mixture was stirred in the cold for 30 min prior to being added to a solution of 1,3-dichloroacetone (5.08 g, 0.040 mol) in dry THF (100 mL) at –78 °C. After 1 h at this temperature, a solution of lithium naphthalenide (from lithium (0.69 g, 0.10 mol) and naphthalene (19.22 g, 0.15 mol)) in THF (200 mL) was added. The reaction mixture was maintained at –78 °C for 2 h, quenched with water, diluted with petroleum ether (200 mL), and extracted with ether (3 × 300 mL). The organic extracts were washed with brine, treated with Dowex-50W (3 g), and stirred for 3 h. The resin was separated by filtration, the solvent removed by bulb-to-bulb distillation, and the residue purified by chromatography on silica gel (elution with 4:1 petroleum ether – ether) to furnish 4.0 g (75%) of **9** as a colourless, volatile oil. IR (neat, cm^{-1}): 1732, 1464, 1282. ^1H NMR (300 MHz, $CDCl_3$) δ: 4.18–4.10 (m, 1H), 3.65–3.59 (m, 1H), 2.56–2.32 (m, 2H), 1.90–1.80 (m, 1H), 1.44–1.28 (m, 7H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 208.3, 87.5, 64.9, 39.1, 34.2, 30.1, 29.8, 25.8, 25.4, 20.2. ES-HRMS m/z calcd.: 163.0735 [M + Na]$^+$; found: 163.0735.

Dispirocyclopentanones 10 and 11

A solution of 2,3-dihydrofuran (5.2 mL, 69.0 mmol) in dry THF (75 mL) was cooled to –78 °C under N_2, treated with *tert*-butyllithium (46 mL of 1.5 mol/L in pentane), and stirred for 0.5 h at –78 °C followed by 0.5 h at 0 °C. A solution of **8** (5.8 g, 46.0 mmol) in THF (25 mL) was introduced dropwise at this temperature and the reaction mixture was allowed to warm to rt after 2 h. While being cooled in an ice bath, the mixture was quenched with sat. $NaHCO_3$ solution and diluted with ether. The separated aqueous phase was extracted with ethyl acetate, and the combined organic phases were dried and evaporated. After 2 days, chromatography on silica gel (elution with 25%–50% ethyl acetate in hexanes) afforded 4.17 g of the polar **10** and 2.0 g of **11**, both as colourless oils.

10

IR (neat, cm^{-1}): 1751, 1078. ^1H NMR (300 MHz, $CDCl_3$) δ: 4.10 (m, 1H), 3.95–3.80 (m, 3H), 2.38 (q, J = 9.7 Hz, 1H), 2.23 (ddd, J = 2.8, 9.3, 19.2 Hz, 1H), 2.10–1.65 (series of m, 10H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 216.5, 90.7, 88.6, 70.1, 68.4, 32.2, 31.0, 30.4, 29.9, 25.8, 25.3. ES-HRMS m/z calcd.: 219.0992 [M + Na]$^+$; found: 219.0998.

11

IR (neat, cm^{-1}): 1750, 1067. ^1H NMR (300 MHz, $CDCl_3$) δ: 3.95–3.79 (m, 4H), 2.48–2.23 (m, 2H), 2.20–1.80 (series of m, 9H), 1.70–1.61 (m, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 216.4, 89.7, 88.4, 69.5, 68.5, 33.4, 31.7, 30.8, 27.1, 26.3, 26.1. ES-HRMS m/z [M + Na]$^+$ calcd.: 219.0992; found: 219.0990.

Dispirocyclopentanones 12 and 13

n-Butyllithium (29 mL of 1.54 mol/L, 45 mmol) was added to a solution of **5b** (18.65 g, 50 mmol) in anhydr. THF (100 mL) at –78 °C. After 30 min, the mixture was added to a solution of **8** (5.0 g, 39.7 mmol) in THF (50 mL) and stirring was maintained in the cold for 2 h. Water was slowly added, the products were extracted into ether, and the combined organic layers were washed with brine and dried.

© 2006 NRC Canada

Oven-dried Dowex-50W resin (2 g) was added and ultimately filtered off when isomerization was complete (TLC analysis). The filtrate was evaporated and the residue chromatographed on silica gel (gradient elution with hexanes – ethyl acetate). Ketone **12** eluted with a 2:1 solvent mixture while **13** eluted with a 10:1 solvent system. **12** (3.33 g, 40%) and **13** (0.42 g, 5%) were isolated as colourless oils.

12

IR (neat, cm^{-1}): 1743, 1450. ^1H NMR (300 MHz, $CDCl_3$) δ: 4.33–4.24 (m, 1H), 3.90–3.79 (m, 3H), 2.45–2.32 (m, 1H), 2.22–2.05 (m, 2H), 1.96–1.46 (series of m, 11H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 216.4, 89.9, 81.4, 68.6, 64.2, 33.5, 30.3, 30.1, 26.2, 25.7, 25.3, 18.6. Dispirocyclopentanones 14 and 15

A solution of 2,3-dihydrofuran (2.64 mL, 35 mmol) in anhydr. THF (100 mL) was cooled to –78 °C, treated with *tert*-butyllithium (17.6 mL of 1.7 mol/L, 30 mmol), stirred in the cold for 1 h, and allowed to warm to rt for 30 min. The reaction mixture was returned to –78 °C at which point it was added to a solution of **9** (4.0 g, 28.5 mmol) in dry THF (50 mL). Once TLC analysis indicated the ketone to be consumed, water was slowly introduced and the product was extracted into ether (3 × 100 mL). The combined organic layer was washed with brine and dried. Oven-dried Dowex-50W resin (2.5 g) was added to the filtrate. When the reaction was complete (TLC analysis), the resin was filtered off, the filtrate was concentrated, and the residue was chromatographed on silica gel (gradient elution from hexane to ethyl acetate – hexane) to afford **14** (2.40 g, 40%) and **15** (0.59 g, 10%), both as colourless oils.

14

IR (neat, cm^{-1}): 1752, 1448. ^1H NMR (300 MHz, $CDCl_3$) δ: 4.13–3.92 (m, 2H), 3.82–3.77 (dd, *J* = 10.5, 3.5 Hz, 1H), 3.60–3.52 (dt, *J* = 11, 3.0 Hz, 1H), 2.53–2.44 (ddd, *J* = 3.3, 9.0, 10.3 Hz, 1H), 2.33–2.11 (m, 2H), 2.02–1.54 (series of m, 11H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 216.7, 92.0, 80.3, 70.1, 62.1, 30.8, 29.0, 27.2, 25.5, 25.1, 24.0, 19.2. 15

IR (neat, cm^{-1}): 1750, 1446. ^1H NMR (300 MHz, $CDCl_3$) δ: 3.88–3.54 (m, 4H), 2.45–2.11 (m, 3H), 2.04–1.72 (m, 6H), 1.62–1.46 (m, 5H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 216.1, 89.8, 80.5, 77.5, 77.0, 69.0, 61.6, 32.0, 27.2, 26.5, 26.1, 24.8, 18.9. ES-HRMS *m/z* calcd.: 233.1154 $[M + Na]^+$; found: 233.1156.

Reaction of 5c with 9

n-Butyllithium (20.1 mL of 1.54 mol/L in hexane, 31 mmol) was added to a solution of **5b** (11.94 g, 32 mmol) in anhydr. THF (100 mL) at –78 °C. After being stirred for 30 min, this solution was added to a solution of **9** (2.8 g, 20 mmol) in the same medium (50 mL) and at the same temperature. After the disappearance of **9** (TLC), water was slowly introduced, the products were extracted into ethyl acetate (3 × 200 mL), and the combined organic layers were washed with brine and dried. The residue remaining after solvent evaporation was dissolved in dry CH_2Cl_2 (250 mL). Silica gel (4 g) was added and stirring was maintained at rt for 3 days. After filtration, solvent removal, and chromatographic separation on silica gel (hexane – ethyl acetate, 25–5:1), less polar **17** (20 mg, 0.5%) and more polar **16** (400 mg, 9%) were isolated.

16

Colourless solid, mp 70–72 °C. IR (neat, cm^{-1}): 1745, 1443, 1219. ^1H NMR (300 MHz, C_6D_6) δ: 4.57–4.48 (dt, *J* = 2.8, 11.4 Hz, 1H), 3.83–3.71 (m, 2H), 3.40–3.31 (dt, *J* = 2.7, 8.5 Hz, 1H), 2.29–2.17 (m, 1H), 2.12–2.03 (m, 1H), 1.87–1.76 (m, 2H), 1.63–1.53 (dt, *J* = 4.2, 12.5 H, 1H), 1.49–1.12 (m, 10H), 1.03–0.97 (m, 1H). ^{13}C NMR (75 MHz, C_6D_6) δ: 214.9, 82.6, 80.8, 63.4, 61.8, 32.4, 27.2, 25.8, 25.7,24.8, 23.8, 19.1, 18.8. ES-HRMS *m/z* calcd.: 247.1310 $[M + Na]^+$; found: 247.1308.

17

Colourless oil. IR (neat, cm^{-1}): 1743, 1441, 1094. ^1H NMR (300 MHz, C_6D_6) δ: 3.69–3.64 (m, 2H), 3.50–3.44 (m, 1H), 3.30–3.21 (dt, *J* = 11.6, 2.8 Hz, 1H), 2.56–2.40 (m, 1H), 2.27–2.00 (m, 4H), 1.77–1.21 (m, 11H). ^{13}C NMR (75 MHz, C_6D_6) δ: 214.4, 82.3, 80.3, 63.9, 61.0, 32.6, 27.2, 26.4, 26.2, 23.7, 22.5, 19.1, 18.8. Ring expansion of 10 with 2,3-dihydrofuran

Cerium trichloride heptahydrate (31.3 g, 41.8 mmol) was dried overnight under high vacuum at 140 °C, admixed with dry THF (125 mL), and stirred at rt for 2 h. The resulting slurry was cooled to –78 °C and *tert*-butyllithium (1.6 mol/L in pentane) was added until a pink color persisted at which point a solution of **5a** (from 2,3-dihydrofuran (4.8 mL, 63.4 mmol)) in THF (75 mL) was introduced. Stirring was maintained at –78 °C for 2 h prior to the addition of **10** (8.2 g, 41.8 mmol) dissolved in THF (50 mL) via syringe pump over 45 min. After 2 h of stirring in the cold, the reaction mixture was warmed to 0 °C, quenched with sat. $NaHCO_3$ solution, and filtered through Celite after 30 min. The separated aqueous phase was extracted with CH_2Cl_2 (3×) and the combined organic phases were dried and evaporated. The resulting oil was dissolved in acetonitrile (200 mL), admixed with oven-dried Dowex-50W resin (8 g), and stirred overnight. The mixture was filtered through Celite and freed of solvent to leave a residue that was chromatographed on silica gel (elution with 30% ethyl acetate in hexane) to give 8.0 g of **18** and 0.35 g of **19** (total 75%), both of which were spectroscopically identical with earlier recorded data. When the last step was performed in CH_2Cl_2, a 60% yield of **18**, exclusively, was isolated.

Ring expansion of 11 with 2,3-dihydrofuran

Reaction of cerium trichloride heptahydrate (14.0 g, 37.4 mmol), 2,3-dihydrofuran (1.8 mL, 23.8 mmol), *tert*-butyllithium in pentane (14 mL, 1.6 mol/L), and **11** (2.2 g, 11.2 mmol) in the predescribed manner, and performance of the final step in acetonitrile gave rise to the isolation of 1.5 g of **20** and 0.5 g of **21** for a combined yield of 51% in a ratio of 3:1. Use of CH_2Cl_2 as solvent led to the isolation of **20** and **21** in 64% combined yield in a ratio of 5:1. The spectral features of these products proved identical to those previously reported.

Isomerization of 10 and 11 — Prototypical procedure

Ketone **10** (4.5 g, 22.9 mmol) dissolved in $CHCl_3$ (100 mL) was treated with boron trifluoride etherate (2.9 mL, 23 mmol), refluxed for 6 h, cooled to 0 °C, and quenched with water. The separated organic phase was dried and freed of solvent to leave a residue that was chromatographed on silica gel. Elution with 25%–50% ethyl acetate in hexane furnished 1.7 g of **10** and 1.9 g (80% total) of **11**.

An identical procedure was adopted starting from **11** (500 mg, 2.65 mmol) in $CHCl_3$ (10 mL) and the subsequent introduction of boron trifluoride etherate (0.37 mL, 2.91 mmol). A parallel workup protocol furnished 206 mg of **10** and 1.93 mg of **11** (total of 80%).

Deprotonation of β,β-disubstituted α,β-unsaturated amides — Mechanism and stereochemical consequences[1]

James R. Green, Marek Majewski, and Victor Snieckus

Abstract: A detailed study of the lithium dialkylamide induced deprotonation of β,β-disubstituted α,β-unsaturated amides is presented. The preferential γ-*Z*-deprotonation and stereochemical outcome of substituents on the γ-*Z* carbon atom are rationalized in terms of a cyclic eight-membered transition state, which is supported by DFT calculations. Analogous deprotonations on cyclohexylidenecarboxamides reveal a delicate balance of the preference for the eight-membered cyclic transition state with the effects of existing substituents on the ring and the intervention of a twist-boat transition state.

Key words: dienolate, amide, deprotonation mechanism, transition state, enolization, regioselectivity, stereoselectivity.

Résumé : On a effectué une étude détaillée de la déprotonation induite par les dialkylamides de lithium d'amides α,β-insaturés et β,β-disubstitués. La déprotonation préférentielle en γ-*Z*- et le résultat stéréochimique des substitutions sur l'atome de carbone γ-*Z* sont rationalisés en termes d'un état de transition cyclique à huit chaînons qui est supporté par des calculs de la théorie de la densité fonctionnelle. Des déprotonations analogues sur les cyclohexylidènecarboxamides mettent en évidence la délicate balance de la préférence en faveur de l'état de transition cyclique à huit chaînons avec les effets des substituants déjà présents sur le cycle et l'intervention d'un état de transition en forme de bateau croisé.

Mots clés : diénolate, amide, déprotonation, mécanisme, état de transition, énolisation, régiosélectivité, stéréosélectivité.

[Traduit par la Rédaction]

Introduction

The prediction of the stereochemistry of enolate formation is of fundamental significance to the large number of valuable C—C bond-forming synthetic strategies of which the aldol condensation is arguably the most prominent (1). A body of data (2) on the stereoselection of enolization has been rationalized by the pericyclic chairlike transition state model (structure 1 in Fig. 1) originally proposed by Ireland et al. (3) in which deprotonation occurs perpendicular to the plane of the carbonyl coordinated to the lithium dialkylamide (4). This model is based on allylic strain (5) and stereoelectronic (4, 6) considerations. Compelling kinetic (7, 8) and spectroscopic (9) evidence for lithium base carbonyl complexation associated with proton abstractions has been advanced (10), although the strict cyclohexane-like chair nature of the transition state has required revision in light of computational analysis (11).

In spite of the extensive synthetic use of β,β-disubstituted, α,β-unsaturated carbonyl compounds (**2**) and related derivatives (12, 13), the stereoselectivity aspects of dienolate formation (γ-*Z* or γ-*E* proton abstraction) have not been systematically addressed (14–17). Although the preferential deprotonation of γ-*Z* over equivalently substituted γ-*E* protons has been established (12*a*, 14*a*–14*c*, 18, 19), the scope and limitations of this feature as it pertains to differential substitution at the γ-*Z* and γ-*E* sites, a systematic study of the stereochemical fate of γ-*Z* substituents, and the stereochemical disposition of the proton undergoing abstraction have not been dealt with in depth. Originating with our interest in the synthetic utility of α,β-unsaturated amides (16*k*), we addressed this question (18, 19) and herein present extended detailed studies, which significantly amplify our preliminary results, may have broader application to other α,β-unsaturated functionalized systems (20), and thereby may shed further light on this interesting question, which has considerable synthetic and mechanistic interest.

Concerning the site of deprotonation of senecioamides

Previous work using unsaturated esters does not allow unambiguous generalization concerning the *syn* vs. *anti* γ-H site of deprotonation to analogous systems (14*r*, 14*m*, 14*q*,

Fig. 1. Deprotonation in carbonyls and unsaturated carbonyls.

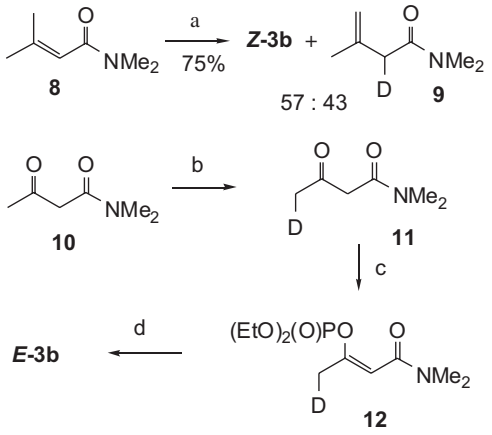
Scheme 1. Reagents and conditions: (*a*) (*i*) LDA, THF; (*ii*) MeI, 0 °C to room temperature.

14*n*, 14*k*, 14*a*–14*d*, 19). We decided to approach this question for unsaturated amides in conjunction with ongoing studies. γ-Silylated carboxamides ***Z*-3a** and ***E*-3b** (Scheme 1), available as a result of our work on amide dienolate reactivity (13*c*, 21), were subjected to LDA deprotonation at room temperature (RT) and the resulting dienolates **4a** and **6a** were quenched with methyl iodide to give products **5a** (*Z*, *E*) and **7a** in 90% and 84% yields, respectively. The products were readily distinguished by ^{1}H NMR spectroscopy (see the Experimental section), which showed that compounds ***Z*-3a** and ***E*-3a** gave exclusively compounds **5a** and **7a**, respectively. The issues of acidifying and steric effects led us to consider replacement of silicon by deuterium as a positional γ marker that would minimally perturb the system under study.

Using conditions previously developed in our laboratories for regio- and stereo-selective introduction of electrophiles into γ-*cis* methyl positions of senecioamdies (16*k*), the dimethyl amide **8** (Scheme 2) was subjected to LDA deprotonation at –78 °C followed by treatment with CuI, according to the protocol of Katzenellenbogen for favoring γ-functionalization, and D_2O in sequence to give a mixture of γ- and α-deuterated products ***Z*-3b** and **9** in a 57:43 ratio. Exclusion of CuI in this sequence led to lower γ:α product ratios. The corresponding ***E*-3b** isomer was prepared according to the excellent and dependable Sum and Weiler procedure (22) involving γ-deuteration of **10** to give **11** followed by stereoselective β-methylation via the enol phosphonate **12**. The location and content of deuterium in the products depicted in Scheme 2 were determined by MS and ^{2}H NMR (see the Experimental section). For compound ***E*-3b**, ^{2}H NMR analysis showed approximately 5% contamination with the ***Z*-3b** isomer.

Deprotonation of ***Z*-3b** and ***E*-3b** under identical conditions (LDA, THF, 0 °C, 0.5 h) and subsequent methylation of the resulting dienolates gave **5b** (78%) and **7b** (68%), respectively. The ^{1}H NMR spectrum of ***Z*-5b** showed significant deuteration in the vinyl site but not in the allylic methyl group, while the corresponding spectrum of ***E*-5b** indicated

Scheme 2. Reagents and conditions: (*a*) (*i*) LDA, THF, –78 °C; (*ii*) CuI; (*iii*) MeOD, –78 °C. (*b*) (*i*) NaH; (*ii*) *n*-BuLi: (*iii*) F_3CCO_2D + D_2O; (*iv*) NH_4Cl. (*c*) (*i*) NaH; (*ii*) $ClP(O)(OEt)_2$. (*d*) (*i*) Me_2CuLi, –78 to –40 °C; (*ii*) NH_4Cl.



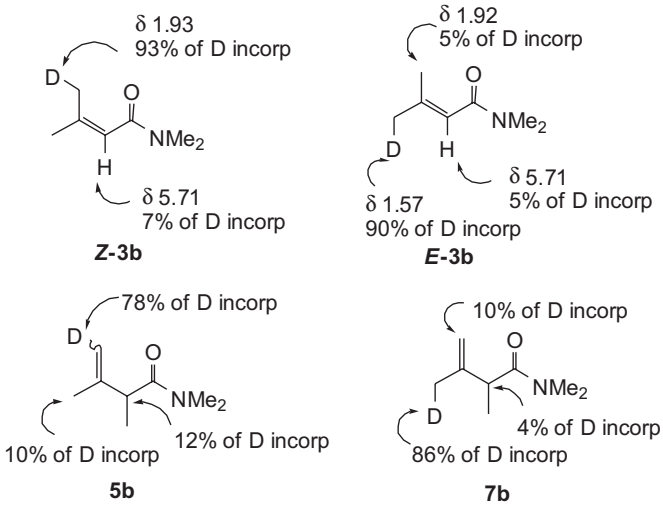


Fig. 2. ^{2}H NMR based relative deuterium incorporation levels.

essentially no deuteration in the vinyl group but significant deuterium incorporation in the allylic methyl group (see the Experimental section and Fig. 2). More conclusive data was obtained from the ^{2}H NMR spectra (Fig. 2), which showed relative deuterium incorporation at the vinyl, α-carbon, and allylic methyl in a ratio of 78:12:10 for **5b** and 10:4:86 for **7b**. These results indicate that γ-*Z* over γ-*E* deprotonation has occurred to the extent of 89% and 96% in the two substrates ***Z*-3b** and ***E*-3b**, respectively, and therefore implicate the intermediacy of the dienolates **4b** and **6b**, respectively. Thermodynamic deprotonation of these systems is ruled out by the observation that ***E*-3a** did not proceed via dienolate **4a**. The results of our studies with ***Z*-3b** and ***E*-3b** mirror the observations of Harris and Weiler (19) on the corresponding carboxylic acids and esters.

Substituent effects on γ-deprotonation

In seeking a more detailed understanding of the factors affecting the geometry of dienolate formation, we investigated

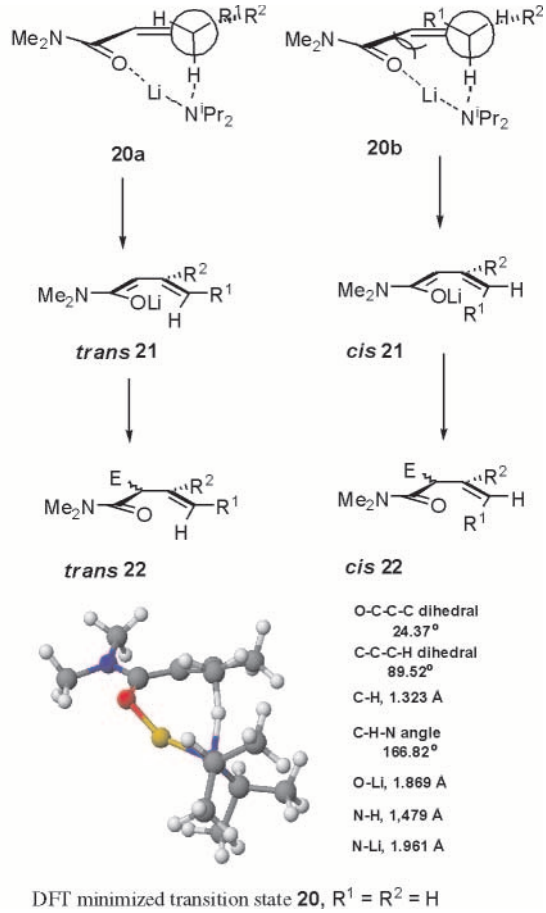
the deprotonation chemistry of a variety of β,γ-disubstituted acrylamides. In particular, we were interested in the effect of substituents anchored at the site of deprotonation. For this purpose, a series of stereochemically homogeneous β,β-disubstituted acrylamides **18** were prepared by adapting cuprate-addition chemistry to ethyl-2-alkynoates (Scheme 3) (23). Condensation of acyl halides **13a**–**13d** with carboethoxymethylene triphenylphosphorane using the procedure described by Hanack et al. (24) as modified by Markl (25) afforded the acyl phosphoranes **14a**–**14d**, which normally were not isolated but directly pyrolyzed to give the 2-alkynoate esters **15a**–**15d**. Treatment of esters **15a**–**15d** with lithium dialkyl cuprates furnished the stereochemically pure α,β-unsaturated esters **16a**–**16f** in variable yields (37%–81%). The conversion of esters **16a**–**16f** into the requisite dimethyl amides **18a**–**18f** was carried out under standard conditions via the intermediate carboxylic acids **17a**–**17f**. Amide **18g** (R^1 = Me, R^2 = Et) was prepared using a Horner–Wadsworth–Emmons procedure (see the Experimental section). The structures and stereochemistry of all amides **18** were assigned by ^1H NMR spectroscopy: with one exception (**18f**), the CH_2 group cis to the amide carbonyl appears as expected downfield (δ 2.3) from the one located trans to the carbonyl (δ 2.15). Furthermore, the *cis*-CH_2 resonances experienced an aromatic solvent-induced shift to lower field (δ 2.47) upon replacement of $CDCl_3$ with C_6D_6 as solvent (26).

Compounds **18a**–**18g** were deprotonated with LDA in THF at room temperature, except for entry 2, and quenched with methyl iodide to give mixtures of products *trans*-**19a**–**19d**, **19f**, and **19g** and *cis*-**19a**–**19d**, **19f**, and **19g**[4] (Scheme 4, Table 1). Attempted deprotonation of **18e** resulted in extensive decomposition and thus was not pursued further. For the sake of completeness, the deprotonation of ***Z*-3a** is included (Table 1, entry 8). The trans to cis ratio was established by integration of the ^1H NMR methine resonance of the two isomers with chemical shifts δ separated by a consistent value of approximately 0.3 ppm (3.3 ppm for trans and 3.6 ppm for cis isomers). Stereochemical assignments at the newly formed double bond were determined by the four-bond vinyl-to-methyl coupling constant in accordance with the literature (Scheme 4) (27). In addition, the stereochemistry of compounds *trans*-**19c** and *trans*-**19f** was confirmed by NOE difference experiments.

Scheme 4. Reagents and conditions: (*a*) (*i*) LDA, THF; (*ii*) MeI, 0 °C to room temperature.



The mechanism of γ-deprotonation

On the basis of the above results, we propose that deprotonation of β,β-disubstitued α,β-unsaturated amides oc-

[4]*Z*/*E* nomenclature is not used because of priority changes in R^2 in the progression of the series.

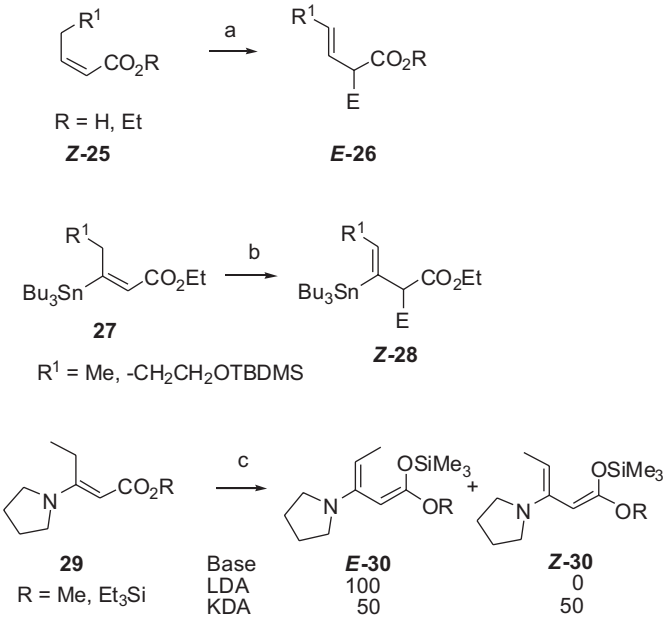
DFT minimized transition state **20**, $R^1 = R^2 = H$

curs through a cyclic eight-membered ring transition state (**20a** and **20b**), which highlights lithium carboxamide oxygen coordination according to the established complex-induced proximity effect (CIPE) (7) (Scheme 5). Since the γ-*Z* carbon is in closer proximity to the amide carbonyl than the γ-*E* carbon atom, deprotonation occurs preferentially from the former leading to dienolates *cis*-**21** and *trans*-**21**, which undergo reaction with the electrophile at the α site to give products *cis*-**22** and *trans*-**22**. To rationalize substitutent effects, we begin with the assumption that deprotonation occurs perpendicular to the plane of the unsaturated amide (3). While semiempirical calculations (MNDO) have indicated a H-C-C-O torsion angle for ketone deprotonation of only about 60° (11), DFT[5] calculations on **20** reveal that the eight-membered ring transition state incorporates an optimal H-C-C-C torsion angle (89.5°) for senecioamide deprotonation, with a minimal twist (24.4°) from coplanarity of the unsaturated carbonyl. With small R^2 substituents, the γ-R^1 group prefers to be oriented away from the carboxamide in transition state **20a**, leading preferentially to dienolate *trans*-**21** and ultimately to alkylated product *trans*-**22**. As the size of the R^2 group is increased (Et < *s*-Bu < *t*-Bu), the steric repulsion between R^1 and R^2 increases, giving rise to greater amounts of deprotonation from transition state **20b**, which cascades to dienolate *cis*-**21** and product *cis*-**22**. Comparison

Fig. 3. Deprotonation transition state for **18f**.

Scheme 6. Reagents and conditions: (*a*) (*i*) LDA, THF, RT; (*ii*) MeI, 0 °C to room temperature.



of entries 4 and 6 (Table 1) suggests that an increase in the size of R^1 enhances the energy difference between transition states **20a** and **20b**. In this context, the result obtained with the TMS (entry 8) shows no size effect in spite of the fact that this group has an A value similar to *i*-Pr (28). The case of the OMe substituent (Table 1, entry 7) is striking in that, on the basis of steric arguments, preferential formation of *trans*-**19f** was expected. The exclusive formation of *cis*-**19f** strongly suggests that lithium–OMe coordination (Fig. 3) in the transition state is significant although the tentative nature of this proposal is recognized in view of reports on the dimeric (29) and tetrameric (30) nature of dienolates in the solid state. Finally, a comparison of the results of deprotonation of **19g** at –78 °C and room temperature (Table 1, entries 1 and 2) shows the expected enhancement in selectivity with decreased temperature consistent with a 0.8–0.95 kcal/mol (1 kcal = 4184 J) difference in activation energy for the respective dienolate isomer formation. To confirm that the products result from kinetic deprotonation and that double bond isomerization about Cβ—Cγ does not occur in the dienolate, the β,γ-unsaturated amide ***Z*-23** was prepared according to Baldwin and co-workers (16*j*) and subjected to the standard LDA deprotonation conditions. The product ***Z*-24** showed retention of double bond geometry, which must stem from the thermodynamically less stable dienolate, thereby providing confirmation of kinetic deprotonation (Scheme 6). Because of the lack of proximity of the carbonyl oxygen and the deprotonation site, our model clearly does not contribute to an understanding of the mechanism of deprotonation of *E*-α,β-unsaturated esters and acids (16*a*, 16*f*, 16*j*).

The earlier observations of Pfeffer and Silbert (16*u*), Krebs (16*r*), and Kende and Toder (16*p*) on the deprotonation of *Z*-unsaturated esters and acids (***Z*-25** to ***E*-26** in Scheme 7) are in agreement with our proposed model of deprotonation (Scheme 5). In all these earlier investigations, compounds with no β-*E* substitutents were employed (Scheme 5, R^2 = H). As a consequence, the R^1 – carbonyl oxygen interaction constitutes the only significant repulsive interaction. A transition state analogous to **20a** is therefore expected, which ultimately leads to the corresponding

[5] DFT calculations were carried out using the B88-PW91 method, and a DZVP basis set, using CAChe® version 6.1.12.33 (see Supporting information). All stationary points were confirmed via frequency calculations.

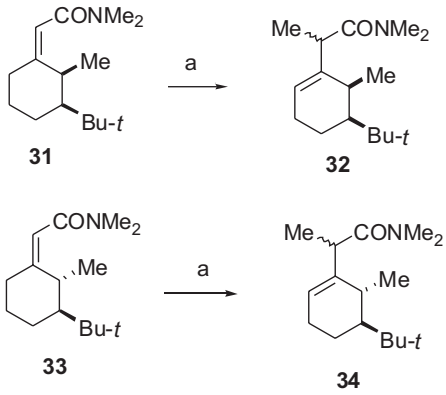
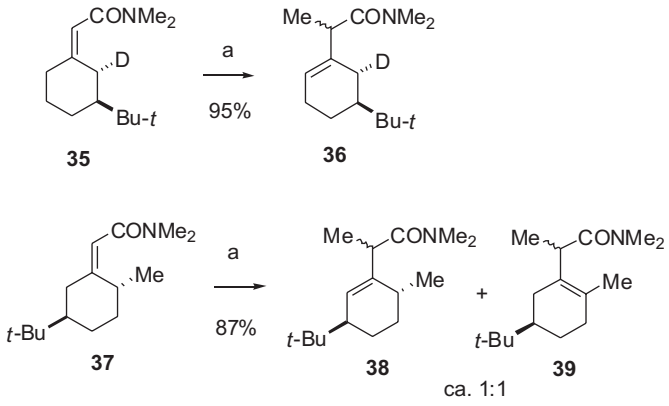
Scheme 7. Reagents and conditions: (*a*) (*i*) LDA, HMPA, THF, –78 °C; (*ii*) E^+. (*b*) (*i*) LDA, THF; (*ii*) H^+, –98 °C. (*c*) (*i*) base, THF, –78 °C; (*ii*) Me_3SiCl.



dienolate *trans*-**21** and product *trans*-**22**. In addition, Piers and Gavai (16*l*) and Schlessinger and co-workers (15*d*) have reported on the low-temperature deprotonation of β-stannyl (**27**) and β-pyrrolidino (**29**) substituted unsaturated esters. Piers and Gavai found that LDA deprotonation of **27** followed by proton quench produced only the ***Z*-28** isomer, which is consistent with the relatively small conformational *A* value of tin (either 0.94 (31)) or 1.06 (32)). Piers and Gavai also observed that the presence of an oxygen function in **27**, R = $CH_2CH_2OTBDMS$, does not alter the stereochemical outcome of deprotonation. This may be due to the oxygen function being too distant to participate in coordination to lithium or the inhibition of coordination by the bulky TBDMS group. In the Schlessinger study, deprotonation of the β-pyrrolidino system **29** with LDA gave exclusively the *cis*-enolate as reflected in the formation of the *O*-silyl dienolate product ***E*-30**, a result in qualitative agreement with our results (Table 1) if one considers the large *A* value (2.1) of a dialkylamino group (33). The lack of selectivity shown by KDA in the deprotonation of **29** to give ***E*-30** and ***Z*-30** may reflect an earlier transition state and weaker metal-to-carbonyl coordination. Our study of the effect of base on the deprotonation of **18g** led to inconclusive results (13*c*).



These arguments concerned with substituent effects on γ-deprotonation appear to be applicable and lead to similar conclusions for α,β-unsaturated systems with other carbonyl acidifying functionality (20), such as phosphonates and phosphine oxides (34) and sulfones (35).

At this point in the study, we were interested in determining whether the requirement for perpendicular C-H orientation would manifest itself in axial proton abstraction in cyclohexylidene carboxamides. For this purpose, we prepared diastereomers **31** and **33** using cuprate conjugate addition and Peterson olefination chemistry (see Supplementary material)[6] and subjected them to the standard LDA deprotonation – methyl iodide quench conditions to give the deconjugated amides **32** and **34**, respectively (Scheme 8). Disappointingly, deprotonation had occurred at the γ-*E* methylene to the exclusion of γ-*Z* methine proton. We considered that the factor responsible for the unwanted γ-*E* deprotonation is the presence of the equatorial γ-methyl or the δ-*t*-Bu groups. Therefore, we prepared (see Supplementary material)[6] γ-deuterated (**35**) and the *t*-Bu γ-methyl (**37**) derivatives and treated these under the normal deprotonation–methylation conditions. Unfortunately, compound **35** also underwent deprotonation at the γ-*E*-methylene site to give deconjugated product **36** (Scheme 9). Furthermore, compound **37** gave a mixture of compounds **38** and **39** (approx. 1:1) indicating γ-*E*-methylene and γ-*Z*-methine deprotonation, respectively. We surmise that the presence of the γ-methyl function in the cyclohexylidene amides either causes the six-membered ring to adopt a twist-boat conformation or prevents the proper orientation of the

amide carbonyl for formation of the required transition state **20** (Scheme 5). In the ^{1}H NMR of cyclohexanones, axial hydrogens resonate at lower fields than the corresponding equatorial hydrogen (36). This is clearly not the case for the corresponding hydrogens H_2 in the cyclohexylidene amides **31** and **33** (Fig. 4). Similarly, the axial hydrogen H_6 in **37** resonates at δ 2.16, but more importantly shows coupling with the adjacent methine hydrogen with J = normal practice 5 Hz. Spectroscopic characterization of **35** does not allow the identification of the conformation of the cyclohexane ring. It appears, however, that the *tert*-butyl function at the position γ to the carbonyl is sufficient to block deprotonation at the γ-*Z* site.

Our difficulties in deprotonating cyclohexylidene amide systems are reminiscent of the results observed by White (14*t*), Gesson (14*o*), and Weiler (14*h*) and their co-workers on cyclohexene carboxylate esters **40** (Scheme 10). Examination of the entries shows that the seemingly trivial modification of substituents of the base (compare entries 2 and 3 or 2 and 4 in Table 1) leads to dramatic changes in ratios of deconjugated products **41** and **42**. Considering that the γ-*Z* deprotonation in the unperturbed cases has been demonstrated by our previous results (Table 1 and Scheme 1), we chose to prepare compound **43** (Scheme 11), which incorporates a *t*-Bu group in a location remote from the site of deprotonation. Treatment of 3-*tert*-butylcyclohexanone **43** with LDA followed by deuteration afforded **44**, albeit with modest incorporation of deuterium (d_1 = 40%, d_2 = 10%) (37). Peterson olefination of **44** with the lithio enolate of α-silyl acetamide gave a mixture of ***Z*-45** and ***E*-45** in a ratio of

66:34, which were separated by column chromatography to give pure ***Z*-45**. The mass spectrum of ***Z*-45** indicated 37% d_1 and 9% d_2 incorporation, while the ^{2}H NMR showed approximately 55%, 25%, and 20% relative deuteration at H_a, H_e, and γ-*E* sites, respectively. When ***Z*-45** was subjected to deprotonation and methylation under normal conditions, compound **46** was obtained in high yield and its ^{2}H NMR spectrum showed relative deuterium incorporation of 65%, 26%, and 9% at H_v, H_a, and H_e, respectively (Scheme 12). This corresponds to an approximately 20:80 ratio favoring equatorial deprotonation. The mass spectrum of **46** showed 27% d_1 and 8% d_2 content, which is consistent with predominant equatorial deprotonation.

We believe that the explanation of these results lies in the classic work of Fraser and Champagne (4) who demonstrated that protonation or deprotonation in conformationally locked systems can occur via perpendicular attack by base through a twist-boat transition state, and in the proposal that these transition states are responsible for equatorial protonation or deprotonation in cyclohexanones (38). The predominant equatorial deprotonation of **Z-45** is due to an analogous twist-boat cyclohexylidene conformation **46** (Scheme 13) in which the axial hydrogen H_e is suitably ori-

Scheme 13. Twist-boat deprotonation model of ***Z*-45**.

ented. DFT calculations[5] on the transition state for the deprotonation of protio-***Z*-45**, employing lithium dimethylamide for simplification of the calculations, support the assertion that H_e deprotonation occurs through a twist-boat transition state (**47**). As the transition state for H_a deprotonation through the chair (**48**) is 2.2 kcal/mol lower in energy relative to **47** according to DFT calculations (again employing lithium dimethylamide), it is entirely possible that the observed results are due to a primary deuterium isotope effect in ***Z*-45** impeding axial H_a deprotonation via **48**; the degree of the contribution of this isotope effect, however, is unknown at this time. Deprotonation of H_a through a complementary twist-boat conformation (**49**) may also be deduced computationally (**50**), with approximately the same energy as **47** (within 0.1 kcal/mol).

Conclusions

We believe that the results reported herein advance our understanding of vinylogous deprotonation reactions in α,β-unsaturated carbonyl systems. The conditions for regio- and stereoselective γ-deprotonation of systems **2** (X = NR_2) followed by simple electrophile quench may be usefully extended to functionalized, and therefore more useful, electrophiles and thereby lead to γ-chain extended intermediates of synthetic value. As one illustration, the construction of terpenoid frameworks could be achieved in a direct manner rather than in several steps. Finally, in view of the progress in the area of enantioselective deprotonation chemistry (39), potentially important results for construction of chiral building blocks may be anticipated.

Experimental section

General methods

Elemental analyses were performed by M-H-W Laboratories, Phoenix, Arizona. Melting points were determined on a Büchi SMP-20 instrument and are uncorrected. Infrared spectra were determined on a PerkinElmer 983 spectrophotometer. ^{1}H NMR spectra were determined with Bruker WP-80 and Bruker AM-250 spectrometers. The spectra were recorded at 80 or 250 MHz in $CDCl_3$ with tetramethylsilane as an internal standard unless otherwise stated. ^{2}H NMR spectra were determined using a Bruker AM-250 spectrometer in C_6H_6 or $CHCl_3$, with C_6D_6 or $CDCl_3$, respectively, as internal standards. Spectral features are tabulated in the following order: chemical shift (δ, ppm); multiplicity (singlet (s), doublet (d), triplet (t), quartet (q), septet (sept), multiplet (m), broad (br)), coupling constant (*J*, Hz); number of protons; assignment. Low-resolution mass spectra were determined on a VG 7070F instrument at 20 eV (1 eV = 1.602 19 × 10^{-19} J) unless otherwise stated. High-resolution mass spectra were determined on a VG ZAB-E spectrometer. Analytical gas chromatography (GC) was performed on either a Hewlett Packard 5840 A instrument or a Varian 6500 instrument using commercially available 10% SE-30 packed and capillary columns, respectively. Preparative HPLC was done on a Waters PREP-500 with an SiO_2 column. Analytical thin layer chromatography (TLC) was performed using Merck precoated silica gel 60F-254 or aluminum oxide 150F-254 neutral (type T) sheets. Preparative TLC was performed using Merck silica gel 60GF-254 with a plate thickness of 1 mm. Column chromatography was carried out using silica gel 60 (0.063–0.20 mm and 0.04–0.063 mm). Flash chromatography refers to the method reported by Still et al. (40).

All dry solvents were employed after distillation from the appropriate drying agent (41). Diethyl ether (Et_2O), benzene, and tetrahydrofuran (THF) were distilled from benzophenone-ketyl immediately prior to use. Solutions of *n*-BuLi, *s*-BuLi, and *t*-BuLi were titrated with 2,5-dimethoxybenzyl alcohol (42) as a standard. Diisopropylamine was dried and distilled over CaH_2 and stored in brown bottles over 4 Å mo-

© 2006 NRC Canada

lecular sieves in a dessicator containing $CaCl_2$. All other reagents were purified according to literature procedures (41). All lithiation reactions were carried out under high purity nitrogen or argon.

The term "–78 °C" refers to the temperature of a CO_2–acetone bath (normally –75° to –78 °C). The phrase "workup in the usual manner" or "standard workup" refers to the addition of satd. aq. NH_4Cl to the reaction mixture, followed by evaporation of the organic solvent under reduced pressure, extraction of the residue with CH_2Cl_2 or diethyl ether (Et_2O), drying of the organic extract over $MgSO_4$, filtration, and then evaporation to dryness under reduced pressure to afford the crude product. Subsequent chromatography and (or) recrystallization and (or) distillation of the crude material afforded pure products.

Cuprate reactions were worked up in the following manner. The organic solvent was evaporated under reduced pressure, diethyl ether was added, and the mixture was filtered. The ethereal layer was separated and the remaining aqueous layer was further extracted with diethyl ether. The combined ether layers were then back-extracted with aq. NH_4OH and satd. NaCl, then dried over $MgSO_4$, filtered, and concentrated under reduced pressure.

General procedure for the formation of lithium dienolates

Preparation of LDA

Diisopropylamine (5 mmol, 0.70 mL) was dissolved in THF (25 mL), and cooled to 0 °C. *n*-BuLi (5 mmol) was added by syringe injection over a period of about 30 s. The solution was then stirred for a further 0.5 h at 0 °C.

Lithiation with LDA — Procedure A

The amide in question was added by syringe to 1.05 equiv. of LDA in THF at –78 °C so that the concentration in solution was roughly 0.2 mol/L. This solution was stirred at –78 °C for 1 h prior to electrophile addition.

Lithiation with LDA — Procedure B

The amide in question was added by syringe to 1.05 equiv. of LDA in THF at 0 °C so that the concentration in solution was roughly 0.2 mol/L. This solution was stirred at 0 °C for 0.5 h prior to electrophile addition.

Lithiation with LDA — Procedure C

The amide in question was added by syringe to 1.05 equiv. of LDA in THF at room temperature (RT) so that the concentration of the amide or amide dienolate in solution was roughly 0.2 mol/L. This solution was stirred at RT for 1 h prior to electrophile addition.

Alkylation of lithium dienolates

The temperature of the solution of the lithium dienolate was adjusted to 0 °C at which time an excess of the electrophile was added by syringe. The resulting mixture was allowed to stir for 0.5 h at 0 °C before the ice bath was removed. The mixture was allowed to come to room temperature, after which a standard workup was performed.

***Z*- and *E*-*N*,*N*,2,3-Tetramethyl-4-trimethylsilyl-3-butenamide (*Z*- and *E*-5a)**

Compound ***Z*-3a** (0.9212 g, 4.62 mmol) was lithiated according to procedure C and alkylated with iodomethane (0.4 mL) in the normal manner. After a standard workup, the crude product was subjected to column chromatography (ethyl acetate – hexane, 1:1–2:1) to give a mixture of ***Z*-** and ***E*-5a** (0.8860 g, 90%); bp 40–43 °C at 0.005 Torr (1 Torr = 133.322 4 Pa). IR (neat, cm^{-1}) ν_{max}: 1649, 1611. ^1H NMR (C_6D_6) δ: 0.10 and 0.07 (2s, 9H, $3SiCH_3$), 1.35, 1.38 (2d, J = 7 Hz, 3H, CH_3), 1.75, 1.79 (2d, J = 0.73, 1.17 Hz, 3H, CH_3), 2.40, 2.67 (2s, 6H, $2NCH_3$), 3.04, 3.41 (2q, J = 7 Hz, 1H, CH), 5.26, 5.36 (2m, 1H, vinyl CH). MS *m*/*e* (rel. intensity): 213 (M^+, 9), 199(33), 198(100), 140(24), 101(36), 73(43). Anal. calcd. for $C_{11}H_{23}NOSi$: C 61.91, H 10.86, N 6.56; found: C 62.10, H 11.05, N 6.73.

Preparative HPLC (hexane – ethyl acetate, 3:1) successfully separated small amounts of ***Z*-5a** and ***E*-5a**. The following peaks in the ^1H NMR spectrum were assigned to represent the *E* isomer: 0.10, 1.35, 1.75 (J = 0.73 Hz), 3.04, 5.36. The following peaks in the ^1H NMR spectrum were assigned to represent the *Z* isomer: 0.079, 1.38, 1.79 (J = 1.17 Hz), 3.41, 5.26. By peak heights of the various distinguishable signals and the integrated areas under the δ 3.04 and δ 3.41 peaks, the ratio of ***E*-5a** to ***Z*-5a** in the unseparated mixture was established to be 79:21.

***N*,*N*,2-Trimethyl-3-trimethylsilylmethyl-3-butenamide (7a)**

Compound ***E*-3a** (0.7191 g, 3.61 mmol) was lithiated according to procedure B and alkylated with iodomethane (0.4 mL) in the normal manner. After a standard workup, the crude product was subjected to flash chromatography (CH_2Cl_2–acetone,15:1) to give 0.6993 g (84%) of **7a**; bp 60–62 °C at 0.01 Torr (lit. value (15*k*) bp 65–70 °C at 0.015 Torr).

4-Deuterio-*N*,*N*,3-trimethyl-2-butenanide (*Z*-3b)

N,*N*-Dimethylsenecioamide (1.34 mL, 9.8 mmol) was lithiated according to procedure A. To the resulting dienolate at –78 °C was added CuI (1.822 g, 9.6 mmol). The mixture was stirred for a further 1 h at –78 °C and 1.7 mL (excess) MeOD was added. The reaction was allowed to warm to RT over 6 h, before 2.0 mL of D_2O was added. After a standard workup, the crude product was subjected to column chromatography (ethyl acetate – hexane, 3:2) to give 0.9562 g (75%) of a 57:43 mixture of ***Z*-3b** and its double bond isomer **9**, as determined by the relative areas of vinyl resonances in the ^1H NMR spectrum. Preparative HPLC (CH_2Cl_2–acetone, 10:1) enabled the separation of a small amount of pure ***Z*-3b**; bp 35–40 °C at 0.004 Torr (lit. value (43) bp 62–64 °C at 3.0 Torr). ^1H NMR (C_6D_6) δ: 1.55 (s, 3H, CH_3), 1.96 (s, 2.45H, CH_2D). ^2H NMR (C_6H_6, decoupled) δ: 1.93 (86% of D, CH_2D), 2.84 (7% of D, CHD from **9**), 5.71 (7% of D, CD). MS *m*/*e* (rel. intensity): 129, 128, 127 (M^+, d_2:d_1:d_0, corrected, 1:75:24).

***N*,*N*-Dimethyl-3-oxobutanamide (10)**

Compound **10** was prepared by literature methods (44) in 67% yield; bp 80–83 °C at 0.9 Torr (lit. value (44) bp 109° at 10 Torr).

© 2006 NRC Canada

4-Deuterio-*N*,*N*-dimethyl-3-oxobutanamide (11)

To a suspension of NaH (1.6917 g, 66 mmol) in THF (125 mL) was slowly added **10** (4.2925 g, 33.2 mmol). After stirring for 20 min, the resulting white gel was cooled to 0 °C and *n*-BuLi (36.5 mmol) added. The resulting mixture was stirred for 20 min at 0 °C. In a separate flask, D_2O (3 mL) was added to trifluoroacetic anhydride (7 mL) at 0 °C and the resulting solution was rapidly added to the first flask. After stirring for 15 min at 0 °C, the reaction was worked up in the following manner. Saturated aqueous ammonium chloride was added and the mixture was concentrated under reduced pressure. The resulting mixture was extracted several times with CH_2Cl_2. The combined CH_2Cl_2 layers were washed with saturated aq. $NaHCO_3$, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. The resulting crude product was distilled to give **11** (2.8935, g, 67%); bp 95 to 96 °C at 1.9 Torr. ^{1}H NMR δ: 1.91, 2.24 (2m, 2H, CH_2D), 2.98, 3.00 (2s, 6H, $2NCH_3$), 3.54 (s, 1.15H, CH_2), 4.14 (s, 0.43H, vinyl CH). MS *m*/*e* (rel. intensity): 131, 130, 129 (M^+, d_2:d_1:d_0, corrected, 9:72:19).

Z-4-Deuterio-3-[(diethylphosphoryl)oxy]-*N*,*N*-dimethyl-2-butenamide (12) and *E*-4-deuterio-*N*,*N*,3-trimethyl-2-butenamide (*E*-3b)

To a suspension of NaH (0.5780 g, 26.1 mmol) in THF (125 mL) was slowly added **11** (2.8363 g, 21.8 mmol). After stirring for 20 min, diethyl chlorophosphate (3.40 mL, 22.9 mmol) was added. The resulting yellow suspension was stirred for 0.5 h. A standard workup gave **12**. IR (neat, cm^{-1}) ν_{max}: 1679, 1631, 1275. ^{1}H NMR δ: 1.35 (td, *J* = 7, 1.0 Hz, 6H, $2CH_3$), 2.11 (br s, 2H, CH_2D), 2.96, 3.05 (2s, 6H, $2NCH_3$), 4.18 (dq, *J* = 7, 7 Hz, 4H, $2OCH_2$), 5.42 (s, 1H, CH). MS *m*/*e* (rel. intensity): 267, 266, 265 (M^+, d_2:d_1:d_o, corrected, 14:68:17), 266 (M^+, 20), 222(29), 194(22), 166(44), 156(36), 155(100), 127(72). The crude **12** was not purified, but was carried on directly to the next step.

To a solution of lithium dimethylcuprate (46.4 mmol) in Et_2O (125 mL) at –78 °C was added **12** (6.5361 g). The suspension was stirred for 2 h at –78 °C, then for 1 h at –45 °C and finally warmed to 0 °C for 15 min. After a standard workup, column chromatography of the crude reaction product gave ***E*-3b** (1.8574 g, 67%); bp 45–50 °C at 0.05 Torr. ^{1}H NMR (C_6D_6) δ: 1.54 (br s, 2H, CH_2D), 1.97 (d, *J* = 1.2 Hz, 3H, CH_3), 2.39, 2.70 (2br s, 6H, $2NCH_3$), 5.65 (br s, 1H, CH). ^{2}H NMR (C_6H_6, decoupled) δ: 1.57 (90% of D, CH_2D), 1.92 (5% of D, CH_2D), 5.72 (5% of D, CD). MS *m*/*e* (rel. intensity): 129, 128, 127 (M^+, d_2:d_1:d_0, corrected, 10:71:19), 85, 84, 83 (M^+ – 44, d_2:d_1:d_0, corrected, 8:70:22).

4-Deuterio-*N*,*N*,2,3-tetramethyl-3-butenanide (*E*-5b)

Compound ***Z*-3b** (0.10 mL, 0.72 mmol) was lithiated according to procedure B and the resulting dienolate was alkylated in the normal manner with iodomethane (0.08 mL). After a standard workup, distillation of the crude product gave ***E*-5b** (0.0803 g, 78%); bp 40–50 °C at 0.004 Torr. ^{1}H NMR δ: 1.26 (d, *J* = 7 Hz, 3H, CH_3), 1.73 (s, 3H, CH_3), 2.93, 2.98 (2s, 6H, $2NCH_3$), 3.34 (q, *J* = 7 Hz, 1H, CH), 4.79, 4.86 (2m, 1.3H, CHD). ^{2}H NMR (C_6H_6) δ: 1.60 (t, *J* = 2.2 Hz, 10% of D), 2.93 (s, 12% of D, CD), 4.72 (s, 78% of D, CHD). MS *m*/*e* (rel. intensity): 128, 127, 126 (M^+ – 15, d_2:d_l:d_0, corrected, 4:65:31).

3-Deuteriomethyl-*N*,*N*,2-trimethyl-3-butenanide (7b)

Compound ***E*-3b** (0.4149 g, 3.24 mmol) was lithiated according to procedure B and the resulting dienolate was alkylated with iodomethane (0.30 mL) in the normal manner. Following a standard workup, the crude product was subjected to column chromatography (ethyl acetate – hexane, 4:1) to give **7b** (0.3124 g, 68%); bp 30–35 °C at 0.08 Torr (Kugelrohr). ^{1}H NMR (C_6D_6) δ: 1.26 (d, *J* = 7 Hz, 3H, CH_3), 1.62 (m, 2H, CH_2D), 2.42, 2.67 (2br s, 6H, $2NCH_3$), 3.03 (q, *J* = 7 Hz, 1H, CH), 4.72 (s, 2H, CH_2). ^{2}H NMR (C_6H_6, decoupled) δ: 1.60 (87% of D, CH_2D), 2.97 (4% of D, CD), 4.72 (10% of D, CHD). MS *m*/*e* (rel. intensity): 85, 84, 83 (M^+ – 59, d_2:d_1:d_0, corrected, 11:65:24).

Ethyl 3-oxo-2-triphenylphosphoranylidenepentanoate (14a) and ethyl 2-pentynoate (15a)

Ethyl 3-oxo-2-triphenylphosphoranylidenepentanoate(**14a**) was prepared from the reaction of ethyl phosphoranylidene acetate and propanoyl chloride as described by Hanack et al. (24). Compound **14a** was identified by ^{1}H NMR only. ^{1}H NMR δ: 0.85 (t, *J* = 7 Hz, 3H, CH_3), 1.40 (t, *J* = 8 Hz, 3H, CH_3), 3.17 (q, *J* = 8 Hz, 2H, CH_2), 3.81 (q, *J* = 7 Hz, 2H, OCH_2), 7.71 (m, *J* = 15 Hz, 3H, C_6H_5). The crude **14a** was heated in a flask fitted with a Vigreux column at 260–280 °C and 0.4 Torr for 4 h and the distillate was collected in a flask at –78 °C. The distillate was redistilled under reduced pressure to give **15a** (2.7577 g, 71% based on propanoyl chloride); bp 64–66 °C at 9 Torr (lit. value (45) bp 178.5 °C).

Ethyl *E*-3-ethyl-2-heptenoate (16a)

To a solution of lithium di-*n*-butylcuprate (5.5 mmol) in THF (25 mL) at –78 °C was added **15a** (0.6341 g, 5.03 mmol) in a minimum amount of THF (~2 mL). The mixture was stirred at –78 °C for 1.5 h, after which ethanol and then satd. aq. NH_4Cl were added dropwise. The mixture was then allowed to warm to room temperature overnight. After the normal workup for cuprate reactions, the crude product was purified by distillation under reduced pressure to give **16a** (0.6843 g, 75%); bp 96–98 °C at 8 Torr. IR (neat, cm^{-1}) ν_{max}:1715, 1642. ^{1}H NMR δ: 0.8–1.6 (m, 13H, $3CH_3$ + $2CH_2$), 2.16 (br m, 2H, CH_2), 2.61 (q, *J* = 8 Hz, 2H, CH_2), 4.15 (q, *J* = 7 Hz, 2H, OCH_2), 5.61 (br s, 1H, CH). MS *m*/*e* (rel. intensity): 184 (M^+, 35), 155(59), 142(75), 139(100), 127(23), 114(51). Anal. calcd. for $C_{11}H_{20}O_2$: C 71.70, H 10.94; found: C 71.68, H 11.01.

***E*-3-Ethyl-2-heptenoic acid (17a) and *E*-3-ethyl-*N*,*N*-dimethyl-2-heptenamide (18a)**

To a solution of KOH (0.8695 g) in methanol–water (15 mL, H_2O–MeOH, 10:1) was added ester **16a** (0.6563 g, 3.56 mmol). The reaction mixture was heated under reflux for 5 h, extracted with diethyl ether (50 mL), acidified with HCl, and extracted with CH_2Cl_2 (4 × 25 mL). The combined CH_2Cl_2 extracts were dried over $MgSO_4$, filtered, and concentrated under reduced pressure to give **17a** (0.5091 g, 92%). Compound **17a** was identified spectroscopically by IR ((neat, cm^{-1}) ν_{max}: 1690, 1636 (lit. value (46) ν_{max} 1690, 1640)), then dissolved in benzene (25 mL) and treated with

© 2006 NRC Canada

thionyl chloride (0.9 mL) for 40 h. The excess thionyl chloride and benzene were removed under reduced pressure, the residue dissolved in diethyl ether (25 mL), and dimethylamine bubbled through the solution for 0.5 h at 0 °C. The mixture was made basic with 10% aq. NaOH, the organic layer separated, and the aqueous layer extracted with CH_2Cl_2 (3 × 25 mL). The combined organic extracts were dried over $MgSO_4$, filtered, and concentrated under reduced pressure. Distillation of the crude product gave **18a** (0.5028 g, 84%); bp 78–80 °C at 0.3 Torr. IR (neat, cm^{-1}) ν_{max}: 1628. ^1H NMR δ: 0.8–1.2 (m, 6H, $2CH_3$), 1.3–1.6 (m, 4H, $2CH_2$), 2.12 (m, 2H, CH_2), 2.31 (q, J = 7 Hz, 2H, CH_2), 2.97, 3.01 (2s, 6H, $2NCH_3$), 5.74 (br s, 1H, CH). MS *m/e* (rel. intensity): 183 (M^+, 51), 153(32), 139(100), 72(83). Anal. calcd. for $C_{11}H_{21}NO$: C 72.08, H 11.55, N 7.64; found: C 71.94, H 11.33, N, 7.66.

3-Ethyl-*N*,*N*-dimethyl-2-pentenamide (18g)

To a suspension of NaH (0.6032 g, 25.1 mmol) in benzene (125 mL) was added diethyl 2- (dimethylamino)-2-oxoethylphosphonate (4.92 mL, 25.0 mmol). The mixture was stirred for 45 min and then 3-pentanone (28 mL, 26 mmol) was added. The reaction mixture was heated under reflux for 21 h and the reaction worked up in the normal manner. The crude product was subjected to flash chromatography (ethyl acetate – hexane, 4:1) to give one fraction, which was shown to be **18g** (1.7642 g, 46%); bp 64 to 65 °C at 0.6 Torr. IR (neat, cm^{-1}) ν_{max}: 1630. ^1H NMR δ: 1.05 (m, 6H, $2CH_3$), 2.15 (q, J = 8 Hz, 2H, CH_2), 2.32 (q, J = 8 Hz, 2H, CH_2), 2.98, 3.00 (2s, 6H, $2NCH_3$), 5.73 (br s, 1H, CH). MS *m/e* (rel. intensity): 155 (M^+, 57), 111(100), 72(27). Anal. calcd.for $C_9H_{17}NO$: C 69.63,H 11.04, N 9.02; found: C 69.59, H 11.13, N 9.01.

***Z*- and *E*-3-(1-Butyl)-*N*,*N*,2-trimethyl-3-pentenamide (19a)**

Compound **18a** (0.5028 g, 2.743 mmol) was lithiated according to procedure C and the resulting dienolate was alkylated with iodomethane (0.35 mL) in the normal manner. Following a standard workup, the crude reaction product was subjected to preparative TLC (ethyl acetate – hexane, 95:2) to afford two fractions. The first fraction was shown to be **19a** (0.2925 g, 54%); bp 60–65 °C at 0.2 Torr. IR (neat, cm^{-1}) ν_{max}: 1645. ^1H NMR (250 MHz) δ: 0.85–1.05 (m, 3H, CH_3), 1.21 (d, J = 7 Hz, 3H, CH_3), 1.32 (m, 2H, CH_2), 1.61, 1.66 (2d, J = 7 Hz, 2H, CH_2 from ***E*-** and ***Z*-19a**, respectively), 2.06 (m, 2H, CH_2), 2.90, 2.91, 2.94, 2.97 (2 × 2s, 6H, $2NCH_3$ from ***Z*-** and ***E*-19a**, respectively), 3.28, 3.62 (2q, J = 7 Hz, 1H, CH from ***E*-** and ***Z*-19a**, respectively, relative area 79:21), 5.29 (q, J = 7 Hz, 2H, vinyl CH). MS *m/e* (rel. intensity): 197 (M^+, 5), 182(94), 72(100), 59(100). Anal. calcd. for $C_{12}H_{23}NO$: C 73.04, H 11.75, N 7.10; found: C 72.83, H 11.77, N 7.36. The second fraction proved to be starting **18a** (0.1276 g, 25%).

***Z*- and *E*-3-(2-Butyl)-*N*,*N*,-2-trimethyl-3-pentenamide (19b)**

Compound **18b** (0.1260 g, 0.6784 mmol) was lithiated according to procedure C and the resulting dienolate was alkylated with iodomethane (0.15 mL) in the normal manner. Following a standard workup, the crude reaction product was subjected to column chromatography (hexane – ethyl acetate, 3:1). After a small forerun containing dialkylated material, the one significant fraction proved to be **19b** (0.1212 g, 89%); bp 65–70 °C at 0.2 Torr. IR (neat, cm^{-1}) ν_{max}: 1646. ^1H NMR (250 MHz) δ: 0.7–1.5 (m, 11H, $3CH_3$ + CH_2), 1.66, 1.69 (2d, J = 7 Hz, 3H, CH_3 for ***E*-** and ***Z*-19b**, respectively), 2.06, 2.46 (2m, 1H,CH for ***Z*-** and ***E*-19b**, respectively), 2.92, 2.93 and 2.94, 3.02 (2× 2s, 6H, $2NCH_3$, for ***Z*-** and ***E*-19b**, respectively). MS *m/e* (rel. intensity): 197(M^+, 4), 182(100), 72(45). Anal. calcd. for $C_{12}H_{23}NO$: C 73.04, H 11.75, N 7.10; found: C 73.23, H 11.73, N 6.93.

***E*-3-(1,1-Dimethylethyl)-*N*,*N*-2-trimethyl-3-pentenamide (19c)**

Compound **18c** (0.1160 g, 0.6328 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.20 mL) in the normal manner. Following a standard workup, the crude reaction mixture was subjected to column chromatography (hexane – ethyl acetate, 3:1) to give only one fraction, which was shown to be **19c** (0.0940 g, 75%); bp 60–65 °C at 0.05 Torr. IR (neat, cm^{-1}) ν_{max}: 1648. NMR (250 MHz) δ: 1.09 (s, 9H, $3CH_3$), 1.32 (d, J = 7 Hz, 3H, CH_3), 1.66 (d, J = 7 Hz, 3H, CH_3), 2.93 (s, 6H, $2NCH_3$), 3.56 (q, J = 7 Hz, 1H, CH), 5.54 (q, J = 7 Hz, 1H, CH). MS *m/e* (rel. intensity): 197 (M^+, 2), 182(100), 72(83). Anal. calcd. for $C_{12}H_{23}NO$: C 73.04, H 11.75, N 7.10; found: C 72.89, H 11.51, N, 7.28.

***Z*- and *E*-3-(2-Butyl)-*N*,*N*,2,5-tetramethyl-3-hexenamide (19d)**

Compound **18d** (0.4405 g, 2.084 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.30 mL) in the normal manner. Following a standard workup, the crude reaction product was subjected to preparative TLC (ethyl acetate – hexane, 1:1) to give two fractions. The first fraction was shown to be **19d** (0.2254 g, 54%); bp 60–64 °C at 0.02 Torr. IR (neat, cm^{-1}) ν_{max}: 1643. ^1H NMR (250 MHz) δ: 7.15 (m, 17H, $5CH_3$ + CH_2), 2.03 (m, 1H, CH), 2.65 (m, 1H, CH), 2.94 (m, 6H, $2NCH_3$), 3.25, 3.71 (m, 1H, CH). MS *m/e* (rel. intensity): 225 (M^+, 3), 210(100), 100(23), 72(66). Anal. calcd. for $C_{14}H_{27}NO$: C 74.61, H 12.08, N 6.21; found: C 74.61, H 11.88, N 6.01. The second fraction was found to contain starting material **18d** (0.1657 g, 38%).

***Z*-3-(1-Butyl)-4-methoxy-*N*,*N*,2-trimethyl-3-butenanide (19f)**

Compound **18f** (0.1365 g, 0.6849 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.15 mL) in the normal manner. Following a standard workup, the crude reaction product was subjected to flash chromatography (fine silica, ethyl acetate – hexane, 1:1) to afford **19f** (0.1234 g, 84%); bp 59–62 °C at 0.007 Torr. IR (neat, cm^{-1}) ν_{max}: 1647. ^1H NMR (250 MHz) δ: 0.87 (m, 3H, CH_3), 1.17 (d, J = 7 Hz, 3H, CH_3), 1.29 (m, 4H, $2CH_2$), 1.82 (m, 2H, CH_2), 2.91, 2.94 (2s, 6H, $2NCH_3$), 3.58 (s, 3H, OCH3), 3.90 (q, J = 7 Hz, 1H, CH), 5.76 (m, 1H, CH). Irradiation of the δ 5.76 resonance resulted in a 22% integrated enhancement of the δ 1.82 resonance; irradiation of the δ 1.82 resonance resulted in an 11% integrated enhancement in the δ 5.76 signal. MS *m/e* (rel. intensity):

213 (M^+, 26), 198(27), 141(100), 99(62). Anal. calcd. for $C_{13}H_{23}NO$: C 67.57, H 10.87, N 6.57; found: C 67.68, H 10.76, N 6.63.

_Z_- and _E_-3-Ethyl-_N_,_N_,3-trimethyl-3-pentenamide (19g)

Compound **18g** (0.1220 g, 0.7858 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.20 mL) in the normal manner. Following standard workup, column chromatography (hexane – ethyl acetate, 5:2) afforded one fraction, which was shown to be **19g** (0.1057 g, 80%); bp 58–62 °C at 0.2 Torr. IR (neat, cm^{-1}) ν_{max}: 1645. ^1H NMR (250 MHz) δ: 0.96 (t, J = 8 Hz, 3H, CH_3), 1.18, 1.21 (2d, J = 7 Hz, 3H, CH_3 for ***Z***- and ***E*-19g**, respectively), 1.62, 1.67 (2d, J = 7, 3H, CH_3 for ***E***- and ***Z*-19g**, respectively), 2.10 (q, J = 8 Hz, 2H, CH_2), 2.96 (m, 6H, $2NCH_3$), 3.29, 3.64 (2q, J = 7 Hz, 1H, CH for ***E***- and ***Z*-19g**, respectively, relative area 79:21), 5.27 (q, J = 7 Hz, 1H, CH). MS *m*/*e* (rel. intensity): 169 (M^+, 4), 154(100), 74(69), 72(89). Anal. calcd. for $C_{10}H_{19}NO$: C 70.96, H 11.31, H 8.28; found: C 70.86, H 10.89, N 8.63.

Compound **18g** (0.4156 g, 268 mmol) was lithiated according to procedure C and alkylated at –78 °C with iodomethane (0.4 mL). After allowing the reaction to warm overnight to RT, a standard workup was performed and the crude reaction product was subjected to preparative TLC (ethyl acetate – hexane, 5:2) to yield **19g** (0.3213 g, 71%) as the only isolated fraction. Integration of the δ 3.29 and δ 3.64 resonances in the ^1H NMR spectrum established the ratio of ***E*-19g**:***Z*-19g** as 92:8.

***Z*-_N_,_N_-Dimethyl-3-hexenamide (23)**

Compound **23** was prepared by the method reported by Baldwin and co-workers (16*j*) in 35% yield based on methyl sorbate; bp 46–48 °C at 2 Torr.

***Z*-_N_,_N_,-2-Trimethyl-3-hexenamide (24)**

Compound **23** (0.1394 g, 0.987 mmol) was lithiated according to procedure A and the resulting dienolate alkylated with iodomethane (0.20 mL) in the normal manner. Following a standard workup, column chromatography (hexane – ethyl acetate, 5:2) of the crude product gave, after a forerun that contained a trace amount of dialkylated material, compound **24** (0.1281 g, 84%); bp 75–80 °C at 2.0 Torr. IR (neat, cm^{-1}) ν_{max}: 1643. ^1H NMR (250 MHz) δ: 1.00 (t, J = 8 Hz, 3H, CH_3), 1.81 (d, J = 7 Hz, 3H, CH_3), 2.10 (m, 2H, CH_2), 2.94, 3.01 (2s, 6H, $2NCH_3$), 3.61 (qd, J = 7, 7 Hz, 1H, CH), 5.04 (m, 2H, $2CH_2$); a signal at δ 3.33 (qd, m, CH for ***E*-24**) was barely perceptible and ***E*-24** was therefore estimated to be present to the extent of 5%. MS *m*/*e* (rel. intensity): 155 (M^+, 16), 140(22), 83(100). Anal. calcd. for $C_9H_{17}NO$: C 69.63, H 11.04, N 9.02; found: C 69.63, H 11.16, N 9.08.

_N_,_N_-Dimethyl-2-[*cis*-5-(1,1-dimethylethyl)-6-methyl-1-cyclohexenyl]propanamide (32)

Compound **31** (0.2468 g, 1.04 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.18 mL) in the normal manner. Following a standard workup, the crude product was subjected to column chromatography (hexane – ethyl acetate, 4:1) to give one fraction, which was shown to contain **32** as a pair of diastereomers (0.2480 g, 95%); bp 89–94° at 0.02 Torr. IR (neat, cm^{-1}) ν_{max}: 1646. ^1H NMR (250 MHz) δ: 0.87, 0.89 (2s, 9H, $3CH_3$), 1.03, 1.15 (2d, J = 7 Hz, 3H, CH_3), 1.26 (d, J = 7 Hz, 3H, CH_3), 1.4–2.1 (m, 5H, $2CH_2$ + CH), 2.23 (q, J = 7 Hz, 1H, CH), 2.93, 3.06 and 2.95, 2.97 (4s, 6H, $2NCH_3$), 3.32, 3.37 (2q, J = 7 Hz, 1H, CH), 5.45, 5.73 (2dd, J = 7, 7 Hz, 1H, CH). MS *m*/*e* (rel. intensity): 251 (M^+, 9), 236(33), 194(100), 101(25), 72(136). Anal. calcd. for $C_{16}H_{29}NO$: C 76.44, H 11.63, N 5.57; found: C 76.36, H 11.72, N 5.48.

_N_,_N_-Dimethyl-2-[*trans*-5-(1,1-dimethylethyl)-6-methyl-1-cyclohexenyl]propanamide (34)

Compound **33** (0.198 g, 0.808 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.10 mL) in the normal manner. Following a standard workup, the crude reaction product was subjected to flash chromatography (fine silica, hexane – ethyl acetate, 9:2) to give one major fraction, which contained **34** as a pair of diastereomers (0.1670 g, 82%); bp 90–95 °C at 0.02 Torr. IR (neat, cm^{-1}) ν_{max}: 1646. ^1H NMR δ: 0.84 (s, 9H, $3CH_3$), 0.9–2.3 (m, 12H, $2CH_3$ + $2CH_2$ + 2CH), 2.93, 2.97 (2s, 6H, $2NCH_3$), 3.1–3.6 (m, 1H, CH), 5.34, 5.58 (2br s, 1H, CH). MS *m*/*e* (rel. intensity): 251 (M^+, 12), 236(39), 194(100), 101(38), 72(147). Anal. calcd. for $C_{16}H_{29}NO$: C 76.44, H 11.63, N, 5.57; found: C 76.21, H 11.50, N 5.64.

***trans*-6-Deuterio-5-(1,1-dimethylethyl)-1-cyclohexenyl-_N_,_N_-dimethylpropanamide (36)**

Compound ***Z*-35** (0.1666 g, 0.743 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.15 mL) in the normal manner. Following standard workup, the crude product was subjected to flash chromatography (fine silica, hexane – ethyl acetate, 4:1) to afford one fraction, which contained **36** as a pair of diastereomers (0.1667 g, 95%); bp 90–95 °C at 2 Torr. IR (neat, cm^{-1}) ν_{max}: 1646. ^1H NMR (250 MHz) δ: 0.87 (s, 9H, $3CH_3$), 1.22 (d, J = 7 Hz, 3H, CH_3), 1.0–1.35 (partially obscured m, 1H, CH), 1.65–2.2 (m, 5H, CH_2 + 3CH), 2.95, 2.96, 2.97, 2.98 (4s, 6H, $2NCH_3$), 3.18 (m, 1H, CH), 5.47 (m, 1H, CH). ^2H NMR δ: 1.92 (s, approx. 89% of D), 3.07 (s, approx. 8% of D), 5.49 (s, approx. 3% of D). MS *m*/*e* (rel. intensity): 239, 238, 237 (M^+, d_2:d_1:d_0, corrected, 5:93:22), 238 (M^+, 36), 223(38), 181(100), 167(35), 100(40), 72(173).

_N_,_N_-Dimethyl-2-[*trans*-3-(1,1-dimethylethyl)-6-methyl-1-cyclohexenyl]propanamide (38) and _N_,_N_-dimethyl-2-[5-(1,1-dimethylethyl)-2-inethyl-1-cyclohexenyl]propanamide (39)

Compound **Z-37** (0.1442 g, 0.607 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.15 mL) in the normal manner. Following a standard workup, the reaction product was subjected to column chromatography (hexane – ethyl acetate, 5:1) to give one fraction. The contents of this fraction were shown by GC and ^1H NMR spectroscopy to be a roughly 1:1 mixture of **38** and **39** (0.1328 g, 87%); bp 89–94 °C at 0.05 Torr. IR (neat, cm^{-1}) ν_{max}: 1648. ^1H NMR (250 MHz) δ: 0.83, 0.83 (2s, 9H, $3CH_3$), 1.0–2.3 (m, 12 protons of **38** and 13 protons of **39**, $2CH_3$ + $2CH_2$ + 2CH of **38** and $2CH_3$ + $3CH_2$ + CH

© 2006 NRC Canada

of 39), includes 1.65 (s, CH_3 of **39**), 2.9–3.0 (m, 6H, $2NCH_3$), 3.17, 3.3, 3.57 (q, J = 7 Hz, q, J = 7 Hz and m, 1H, CH), 5.33, 5.57 (2s, 1 proton of **38**, CH). MS *m/e* (rel. intensity): 251 (M^+, 12), 236(52), 194(100), 180(52), 101(36), 84(20), 72(171). Anal. calcd. for $C_{16}H_{29}NO$: C 76.44, H 11.63, N 5.57; found: C 76.56, H 11.75, N 5.56.

***cis*-2-Deuterio-5-(1,1-dimethylethyl)cyclohexanone (44)**

To a solution of LDA (13 mmol) in THF (65 mL) at –78 °C was added 3-(1,1-dimethylethyl)cyclohexanone (0.9988 g, 6.48 mmol) in a minimum amount of THF (~5 mL). The solution was stirred for 1 h at –78 °C. In a separate flask, D_2O (0.25 mL) was added to a stirred solution of trifluoroacetic anhydride (0.92 mL, 13 mmol) at –78 °C and the solution allowed to warm to RT. The contents of the latter flask were then added to the former flask, the mixture was stirred at –78 °C for 10 min, and $MgSO_4$ added. After warming to RT, the mixture was filtered through Celite and concentrated under reduced pressure. Distillation of the crude reaction product gave **44** (0.4614 g, 46%); bp 96–98 °C at 10 Torr. MS *m/e* (rel. intensity): 155, 154, 153 (M^+, d_2:d_1:d_0 = 10:40:50).

***Z*- and *E*-(*cis*-2-Deuterio-5-(1,1-dimethylethyl)cyclohexylidene]-*N*,*N*-dimethylacetamide (*Z*- and *E*-45)**

N,*N*-Dimethyltrimethylsilylacetamide (0.9543 g, 5.99 mmol) was lithiated according to procedure A. To a –78 °C solution of the resulting enolate was added **44** (0.9301 g, 5.99 mmol) in a minimum amount of THF (~3 mL). The reaction mixture was stirred for 3 h at –78 °C, warmed to RT, and two drops of water and $MgSO_4$ were added. After filtration through Celite and concentration of the filtrate under reduced pressure, the crude reaction product was subjected to flash chromatography (fine silica, hexane–Et_2O, 2:1). Four fractions were isolated. The first fraction contained starting material **44** (0.0530 g, 6%). The second fraction proved to be ***E*-45** (6.2084 g, 27% including fraction No. 3, see compound ***Z*-35**) contaminated with a small amount (4%) of ***Z*-45**. The third fraction was a 34:66 mixture of ***E*-45** and ***Z*-45** (0.2084 g). The final fraction was shown to contain ***Z*-45** (0.3805 g, 52% including fraction Nos. 2 and 3); bp 85–90 °C at 0.1 Torr. IR (neat, cm^{-1}) ν_{max}: 1628. ^1H NMR (250 MHz) δ: 0.87 (s, 9H, $3CH_3$), 1.0–1.3 (m, 2H, CH_2), 1.65–2.1 (m, 4.5H, CH_2 + 2CH + CD), 2.30 (d, J = 13 Hz, 1H, CH), 2.93 (obscured d, 1H, CH), 5.71 (s, 1H, CH). ^1H NMR (250 MHz, C_6D_6) δ: 0.79 (s, 9H, $3CH_3$), 0.8–1.8 (m, 6H, $2CH_2$ + 2CH + CD), 2.21 (br d, J = 13 Hz, 1H, CH), 2.24, 2.72 (2s, 6H, $2NCH_3$), 3.57 (br d, J = 11 Hz, 1H, CH), 5.68 (s, 1H, CH). ^2H NMR (C_6D_6, decoupled) δ: 1.60 (55% of D), 2.16 (20% of D), 3.48 (25% of D). MS *m/e* (rel. intensity): 225, 224, 223 (M^+, d_2:d_1:d_0, corrected, 9:37:54), 223 (M^+, 100), 180(69), 166(86), 121(46), 95(87), 81(49), 72(115). Anal. calcd. for $C_{14}H_{25}NO$: C 75.28, H 11.28, N 6.27; found: C 74.98, H 11.24, N 6.25.

2-Deuterio-5-(1,1-dimethyl ethyl)-1-cyclohexenyl-*N*,*N*-2-trimethylacetamide (46)

Compound ***Z*-45** (0.1601 g, 0.714 mmol) was lithiated according to procedure C and the resulting dienolate alkylated with iodomethane (0.15 mL) in the usual manner. Following a standard workup, the crude reaction product was subjected to column chromatography (hexane – ethyl acetate, 1:1) to afford one fraction, which contained **46** as a pair of diastereomers (0.1562 g, 92%); bp 85–90 °C at 0.2 Torr. IR (neat, cm^{-1}) ν_{max}: 1644. ^1H NMR δ: 0.87 (s, 9H, $3CH_3$), 1.0–1.35 (partially obscured m, 1H, CH), 1.6–2.2 (m, 6H, $2CH_2$ + 2CH), 2.95, 2.96, 2.97, 2.98 (4s, 6H, $2NCH_3$), 3.18 (m, 1H, CH), 5.47 (m, 0.65H, CD). ^2H NMR (decoupled) δ: 1.72 (9% of D), 2.28 (26% of D), 3.60 (65% of D). MS *m/e* (rel. intensity): 239, 238, 237 (M^+, d_2:d_1:d_0, corrected, 8:27:65), 237 (M^+, 27), 222(26), 181(100), 166(31), 101(50), 72(38). Anal. calcd. for $C_{15}H_{27}NO$: C 75.90, H 11.46, N 5.90; found: C 76.02, H 11.72, N 6.38.

Material on deposit

The experimental procedures and spectral data for the preparation of **14b–14d**, **15b–15d**, **16b–16f**, **17b–17f**, **18b–18f**, (diethylamino)-2-oxoethylphosphonate, the precursors to **31**, **33**, **35**, and **37**, and the minimized structures, final Cartesian coordinates, and energies for the calculated transition states for senecioamide deprotonation (**47**, **49**, and **50**) have been deposited as Supplementary material.[6]

Acknowledgements

We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for support of our synthetic programs. JRG was a NSERC 1967 Fellowship awardee. We also wish to thank James Gauld for assistance with the DFT calculations on the deprotonation transition states.

Synthesis and characterization of a series of novel phenol- and polyphenol-based glycerolipids[1]

Rolf Schmidt, Joseph G. Carrigan, and Christine E. DeWolf

Abstract: A building block approach was used to design a modular synthetic route for the preparation of novel glycerolipids with phenolic and polyphenolic headgroups. Based on this scheme, it is possible to vary the substitution pattern of the headgroup, the stereochemistry of the backbone, and the length of the sidechains. Five glycerolipids with different headgroups and identical backbone stereochemistry and chain length have been prepared.

Key words: glycerolipid, polyphenol, hydrogen bonding, lipid-protein interaction, self-adhering.

Résumé : On a développé une méthode modulaire de synthèse de nouveaux glycérolipides comportant des têtes phénoliques et polyphénoliques. En se basant sur ce schéma, il est possible de faire varier la nature du groupe de tête, la stéréochimie du squelette et la longueur des chaînes latérales. On a préparé cinq glycérolipides dont la stéréochimie du squelette et la longueur de la chaîne sont les mêmes, mais qui diffèrent par la nature de leur groupe de tête.

Mots clés : glycérolipide, polyphénol, liaison hydrogène, interaction lipide-protéine, autoadhérente.

[Traduit par la Rédaction]

Introduction

It is well-known that polyphenols bind and precipitate proteins and (or) peptides and can act as antioxidants (Handique and Baruah (1) provide a comprehensive review of natural and synthetic polyphenols). Furthermore, poly(phenol) films have been used as protective coatings for proteins immobilized onto electrodes (2). A novel synthetic lipid, 1,2-dipalmitoylgalloylglycerol (DPGG), has been prepared (3) that incorporates a polyphenol as the headgroup. The authors suggest that this lipid has the potential to exhibit comparable protein-binding properties (4) so that Langmuir–Blodgett films of such lipids could prove useful as biocompatible coatings. Pollastri et al. (3) demonstrated the self-adhesive nature of DPGG bilayers and proposed both strong inter- and intra-bilayer hydrogen bonding between gallic acid headgroups. We have recently shown that DPGG monolayers exhibit strong lateral cohesion and high rigidity, which can also be attributed to lateral hydrogen bonding (5). The influence of hydrogen bonding on monolayer and bilayer phase behaviour has been previously documented for lipids such as phosphatidylethanolamines and cerebrosides (3, 6, 7). To probe and understand the lateral cohesion in monolayers due to a hydrogen bonding network requires systematic chemical modification with respect to hydrogen bonding sites. In contrast to phosphatidylethanolamines and cerebrosides, DPGG provides an ideal template for a library of analogous lipids. We have employed a building block approach to design a modular synthetic route for the preparation of this library of novel glycerolipids with phenolic and polyphenolic headgroups. We report here the preparation of DPGG analogues with headgroups varying in number and position of hydroxyl groups (Fig. 1).

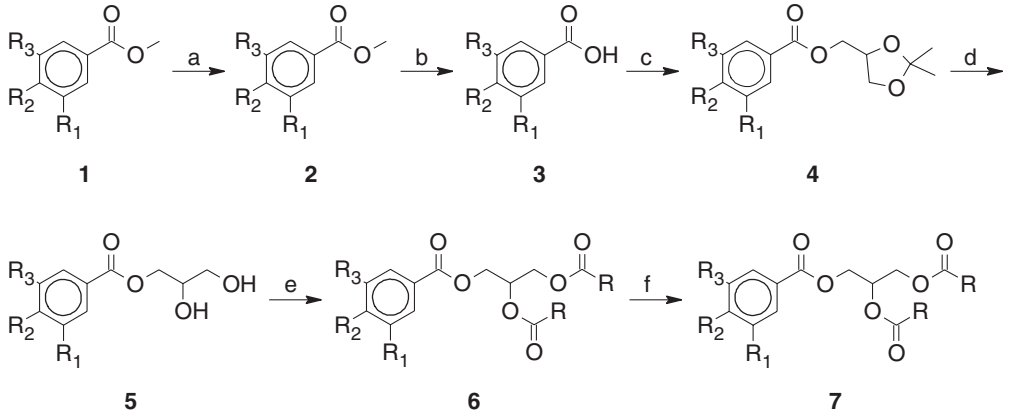
Results and discussion

The preparation of DPGG in two steps from tri-O-benzylgalloyl chloride and dipalmitoylglycerol has been described in the literature (3). The key features of this synthesis are the use of the benzyl protecting group and the introduction of a side chain bearing glycerol moiety. We report a more modular synthetic route to DPGG and some of its analogues, which allows for easy variation not only of the headgroup (number and position of hydroxyl groups) but also the stereochemistry of the backbone (R or S) and the chemical character of the side chains (chain length, units of unsaturation, functionalization, etc.) (Scheme 1). All of these parameters are known to influence monolayer phase behaviour and more generally, lipid self-assembly properties.



Compounds **3a**, **3c**, and **3e** are commercially available in gram quantities. Compounds **3b** and **3d** were prepared by well-known methods from 3-hydroxybenzoic acid methyl ester and 3,4-dihydroxybenzoic acid, respectively. Therefore, it is easy to alter the headgroup structure of the title compounds by varying the substitution pattern of the starting material. In the first step of the synthesis of the title compounds, phenol-bearing benzoic acids **3** are reacted with a racemic mixture of 2,2-dimethyl-1,3-dioxolane-4-methanol (solketal, a protected glycerol) to give compounds **4**. Importantly, the same procedure could be used to prepare the enantiomerically pure analogues starting from commercially

available (*R*)-(-)- or (*S*)-(+)-2,2-dimethyl-1,3-dioxolane-4-methanol instead of the racemic mixture, provided that the pH is held between 7 to 8 to retain optical purity (8). The isopropylidene and benzyl protecting groups were chosen from orthogonal sets to provide selective deprotection of the isopropylidene in step d (Fig. 1). The protected benzoates **4** were not isolated, but the glycerol moiety was deprotected by treatment with wet Amberlyst® 15, a strongly acidic resin that allows for easy removal from the reaction mixture by gravity filtration. The advantage of Amberlyst® 15, aside from easy removal, is the fact that the sulfonic residues bound to the resin beads provide significant steric hindrance to prevent ester cleavage (9). Cleavage of the isopropylidene protecting group with I_2 in methanol (10) or under acidic conditions using aqueous acetic acid (11) was not successful. It has to be noted that a similar approach has previously been employed by Schmidt and Blank (12) for the preparation of compounds **4e** and **5e**. However, reaction times are generally much shorter and workup much simpler for our synthetic scheme with similar yields. In the next step, the palmitoyl side chains were introduced by coupling **5** with palmitic acid in the presence of *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride (EDCI) and 4-dimethylaminopyridine (DMAP) (13, 14). This acylation method was shown to be superior to the coupling of acid chlorides or anhydrides with the corresponding aliphatic acids (15). Furthermore, excess EDCI and the 1-(3-dimethylamino-propyl)-3-ethyl-urea formed during the reaction can easily be removed from the reaction mixture by liquid–liquid extraction because of their good solubility in water. The reaction has also been successfully carried out with the corresponding myristoyl and stearoyl side chains (data not shown). In addition, it is possible to selectively introduce two dissimilar side chains (e.g., palmitoyl and stearoyl) by successive coupling with the respective acids (15, 16).

Diacetylation in the first step as well as 1,2-acyl migration in the second step can be avoided by maintaining the reaction temperature between 0 and 20 °C (15). The benzyl protecting group is removed by catalytic hydrogenation under moderate pressure in the final step. The reaction time in-

creases with the number of benzyl groups to be removed. DPGG and its benzyl-protected precursor were also prepared by this method with comparable yields to the literature (3).

Conclusion

We have prepared a library of phenolic and polyphenolic glycerolipids according to a relatively simple modular reaction scheme. Moreover, the same scheme can be used to prepare glycerolipids that are enantiomerically pure and (or) have dissimilar side chains.

Experimental

All chemicals were purchased from commercial suppliers and used without further purification. 4-Benzyloxybenzoic acid, 3,5-di-benzyloxybenzoic acid, and 3,4,5-tris-benzyloxybenzoic acid were obtained from Tokyo Chemical Industry Co., Ltd. (TCI, Tokyo, Japan). ^{1}H spectra were obtained at 300 MHz and ^{13}C NMR spectra were obtained at 75 MHz in $CDCl_3$ unless otherwise noted using the NMR solvent as an internal reference. Abbreviations used in the descriptions of NMR spectra are singlet (s), doublet (d), triplet (t), multiplet (m), broad signal (br). The coupling constants (*J*) are given in Hertz. Mass spectrometry measurements were carried out on a MALDI mass spectrometer using dithranol as a matrix. IR measurements were carried out using a liquid cell equipped with KBr windows and in $CDCl_3$ unless otherwise noted. All melting points are uncorrected. Silica gel for flash chromatography was acquired from Life Force Inc. (Flushing, New York).

3,4-Dihydroxybenzoic acid methyl ester (1d)

3,4-Dihydroxybenzoic acid (1 g, 6.49 mmol) was dissolved in 40 mL of MeOH. After the addition of 2 drops of concd. H_2SO_4, the solution was refluxed for 7 days. The reaction was stopped by the addition of 300 mL of distilled H_2O. The mixture was extracted with ethyl acetate – hexanes (60:40). The organic layers were combined, dried over Na_2SO_4, and the solvent removed under reduced pressure to give 0.8 g of a light-brown solid in 73% yield.

3-Benzyloxybenzoic acid methyl ester (2b)

Compound **2b** was prepared according to the literature (17) with a reaction time of 6 h. The product was purified by flash chromatography on SiO_2 (hexanes – ethyl acetate, 80:20) to give 0.98 g of a white solid in 61% yield.

3,4-Bis-benzyloxybenzoic acid methyl ester (2d)

Compound **2d** was prepared in a manner analogous to **2b**. However, 2.3 equiv. of benzyl bromide were used and gave 1.19 g of a white solid in 77% yield.

3-Benzyloxybenzoic acid (3b)

Compound **2b** (0.75 g, 3.1 mmol) was dissolved in 35 mL of THF. A solution of KOH (1.04 g, 18.6 mmol, 6 equiv.) in 50 mL of distilled H_2O was added and the reaction was stirred for 24 h. The reaction mixture was added to 250 mL of distilled H_2O and acidified to pH 5 with 2N HCl. The mixture was extracted with diethylether. The organic layers were combined, dried over Na_2SO_4, and the solvent removed under reduced pressure to yield 0.67 g of a white solid in 95% yield.

3,4-Bis-benzyloxy-benzoic acid (3d)

Compound **3d** was prepared in a manner analogous to **3b** with a reaction time of 48 h. The reaction gave 0.67 g of a white solid in 70% yield.

Synthesis of the benzyloxybenzoic acid 2,3-dihydroxypropyl esters (5a–5d)

Typical procedure

Compound **3a** (1.0 g, 4.38 mmol), 1-methyl-imidazole (1.08 g, 13.14 mmol, 3 equiv.), and *p*-toluenesulfonyl chloride (1.17 g, 6.13 mmol, 1.4 equiv.) were dissolved in 45 mL of CH_3CN and stirred for 30 min. After the addition of racemic 2,2-dimethyl-1,3-dioxolane-4-methanol (0.58 g, 4.38 mmol, 1 equiv.), the solution was stirred under inert atmosphere for 3 h. The volume of the solution was reduced to approximately 4 mL under reduced pressure and the solution filtered through Al_2O_3 with 40 mL of CH_2Cl_2. The solvent was removed under reduced pressure to give 1.0 g of a white solid which was used without further purification. Compound **4a** (0.15 g, 0.438 mmol) was suspended in 40 mL of EtOH–H_2O (95:5). Wet Amberlyst® 15 (0.180 g, 1 equiv.) was added to the suspension and the suspension was refluxed for 24 h. The solution was allowed to cool to room temperature and 40 mL of CH_2Cl_2 and 300 mL of brine were added. The mixture was extracted with CH_2Cl_2 (2 × 20 mL). The organic layers were combined, dried over Na_2SO_4, and the solvent removed under reduced pressure. The crude was purified by flash chromatography on SiO_2 (ethyl acetate – hexanes, 70:30) to give 0.105 g of a white solid in 80% yield.

Synthesis of benzyloxybenzoic acid 2,3-bis-hexadecanoyloxypropyl esters (6a–6e)

Typical procedure

Compound **5a** (0.38 g, 1.25 mmol) and hexadecanoic acid (0.73 g, 2.825 mmol, 2.26 equiv.) were dissolved in 20 mL of CH_2Cl_2. A suspension of DMAP (0.35 g, 2.825 mmol, 2.26 equiv.) and EDCI (0.58 g, 3 mmol, 2.4 equiv.) in 10 mL of CH_2Cl_2 was added to the reaction mixture and the mixture was stirred for 4 h. Brine (300 mL) was added and the reaction mixture was extracted with CH_2Cl_2 (2 × 20 mL). The organic layers were combined, dried over Na_2SO_4, and the solvent removed under reduced pressure. The product was purified by flash chromatography on SiO_2 (hexanes – ethyl acetate, 80:20) to give 0.80 g of a white solid in 82% yield.

Synthesis of hydroxybenzoic acid 2,3-bis-hexadecanoyloxypropyl esters (7a–7e)

Typical procedure

Compound **6a** (0.2 g, 0.257 mmol) was dissolved in 20 mL of dry THF. 10% Pd–C (0.07 g, 30 wt%) was added and the reaction mixture was placed in a pressure reactor and stirred under 3.5 atm (1 atm = 101.325 kPa) of hydrogen gas for 4 h. The mixture was filtered through Celite 545 and the solvent removed under reduced pressure to give 0.14 g of a white solid in 80% yield.

Data for 7a

Melting point 69–71 °C. IR (cm^{-1}) ν: 3587, 2927, 2855, 1736, 1610. ^{1}H NMR δ: 7.94 (m, 2H), 6.86 (m, 2H), 5.42 (m, 1H), 5.33 (br, 1H, *OH*), 4.44 (m, 3H), 4.24 (m, 1H), 2.33 (t, 2H, *J* = 7.5 Hz, CH_2COO), 2.32 (t, 2H, *J* = 7.5 Hz, CH_2COO), 1.61 (m, 4H, CH_2CH_2COO), 1.27 (m, 48H), 0.88 (t, 6H, *J* = 6.7 Hz, CH_3). ^{13}C NMR δ: 173.5, 173.1, 165.7, 160.0, 132.1, 122.1, 115.3, 69.0, 62.7, 62.3, 34.3, 34.1, 31.9, 29.7, 29.6, 29.5, 29.4, 29.3, 29.2, 29.1, 24.9, 24.8, 22.7, 14.1. MS *m/z*: 712.0 $[M + Na]^+$.

Data for 7b

Reaction time 6 h, 61% yield, mp 64 to 65 °C. IR (cm^{-1}) ν: 3594, 2927, 2855, 1734, 1593. ^{1}H NMR δ: 7.61 (m, 1H), 7.48 (m, 1H), 7.32 (m, 1H), 7.06 (m, 1H), 5.43 (m, 1H), 5.20 (br, 1H, *OH*), 4.43 (m, 3H), 4.24 (m, 1H), 2.33 (t, 2H, *J* = 7.4 Hz, CH_2COO), 2.32 (t, 2H, *J* = 7.5 Hz, CH_2COO), 1.61 (m, 4H, CH_2CH_2COO), 1.27 (m, 48H), 0.88 (t, 6H, *J* = 6.7 Hz, CH_3). ^{13}C NMR δ: 173.4, 173.1, 165.7, 155.8, 130.1, 129.8, 122.1, 120.5, 116.3, 68.9, 63.0, 62.2, 34.3, 34.1, 31.9, 29.7, 29.6, 29.5, 29.4, 29.3, 29.2, 29.1, 24.9, 24.8, 22.7, 14.1. 29.5, 29.4, 29.3, 29.2, 29.1, 24.9, 24.8, 22.7, 14.1. MS *m*/*z*: 728.0 $[M + Na]^+$.

Data for 7d

Reaction time 7 h, 50% yield, mp 92 to 93 °C. IR (cm^{-1}) ν: 3566, 2927, 2855, 1734, 1616. ^1H NMR δ: 7.07 (d, 2H, *J* = 2.2 Hz), 6.59 (t, 1H, *J* = 2.3 Hz), 5.45 (m, 3H), 4.41 (m, 3H), 4.24 (m, 1H), 2.33 (t, 6H, *J* = 7.6 Hz, CH_2COO), 1.61 (m, 4H, CH_2CH_2COO), 1.27 (m, 48H), 0.88 (t, 6H, *J* = 6.7 Hz, CH_3). ^{13}C NMR δ: 173.7, 173.4, 166.3, 149.8, 146.8, 123.1, 120.9, 115.9, 114.6, 68.9, 62.5, 62.2, 34.3, 34.1, 31.9, 29.7, 29.6, 29.5, 29.4, 29.3, 29.2, 29.1, 24.9, 24.8, 22.7, 14.1. MS *m*/*z*: 728.0 $[M + Na]^+$.

Data for 7e

Reaction time 8 h. The product was then adsorbed to silica in the presence of 1 mL of acetic acid and purified by flash chromatography on SiO_2 using a solvent gradient of hexanes – ethyl acetate from 90:10 to 30:70. The product was then extracted from 200mL of brine with $CHCl_3$ (5 × 20 mL). The organic layers were combined, dried over Na_2SO_4, and the solvent removed under reduced pressure to give 0.050 g of a white solid in 70% yield.

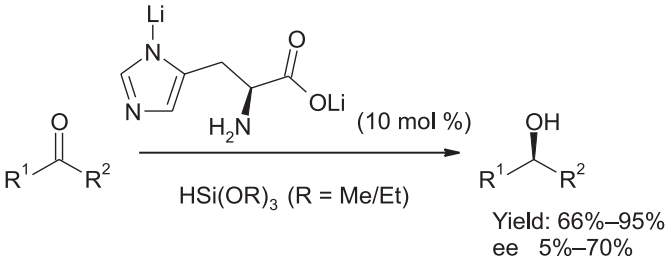
Hydrosilylation of ketones catalyzed by C_2-symmetric proline-derived complexes[1]

Li Gan and Michael A. Brook

Abstract: Extracoordinate chiral hydrosilanes were generated in situ from triethoxysilane and a C_2-symmetric ligand derived from bisproline 7. In the presence of a catalytic amount of ligand **7**, prochiral ketones were reduced in moderate yield with moderate enantioselectivity (up to 64% ee). Alternatively, TiF_4 complexes of **7** were used to provide higher enantioselectivity and with improved yields. The copper complex of ligand **7** and ^{29}Si NMR data provide some guidance as to the key factors responsible for the observed reactivity at the silicon and at the ligand centre.

Key words: extracoordinate chiral silane, C_2-symmetry, enantioselectivity, Lewis acid titanium catalysis.

Résumé : On a effectué une génération *in situ* d'hydrosilanes chiraux extracoordinés à partir du triéthoxysilane et d'un ligand de symétrie C_2 dérivé de la bisproline **7**. En présence d'une quantité catalytique du ligand **7**, les cétones prochirales sont réduites avec des rendements moyens et un énantiosélectivité modérée, allant jusqu'à 64 % d'excès énantiomère. D'une façon alternative, on a utilisé des complexes du tétrafluorure de titane du ligand **7** qui ont fourni une énantiosélectivité supérieure et de meilleurs rendements. Le complexe de cuivre du ligand **7** et les données de la RMN du ^{29}Si donnent des indications sur les facteurs clés responsables au niveau de l'atome de silicium et du centre du ligand pour la réactivité observée.



Mots clés : silane chiral extracoordiné, symétrie C_2, énantiosélectivité, catalyseur de titane agissant comme acide de Lewis.

Introduction

The enantioselective reduction of carbonyl groups remains one of the fundamental operations in organic synthesis (1). Typical catalytic systems utilize a chiral ligand complexed with a transition metal (2). With the exception of boron, such as the well-developed chiral boron catalyst (CBS) (3), the use of chiral catalytic motifs based on main group elements is uncommon (4). However, in a process related to that reported by Shiffers and Kagan (5) and Hosomi and co-workers (6), we previously demonstrated that the complex derived from hydrosilanes and a catalytic amount of amino acids can reduce ketones enantioselectively (Scheme 1) (7).

Scheme 1. Histidine-catalyzed ketone reduction.

These reactions with hydrosilanes occur via extracoordinate silicon in the presence of anionic catalysts. Sakurai and co-workers (8a, 8b) has demonstrated that diastereoselective allylation of carbonyl groups in the presence of pentacoordinate silicon hydrides, for example, can best be explained by invoking six-membered ring transition states (Scheme 2). Coordination of the nucleophile, the carbonyl group, to the extracoordinate silicon is followed by allyl group transfer. As a departure point, we proposed that a related assembly of ketone and carboxylate on an extracoordinate silicon 1 could be used to explain the observed stereoselectivity in the hydrosilane reduction of acetophenone, although related bidentate structures could also be envisaged. While the mechanisms of these reactions have not yet been clearly established, the presence of extracoordinate

It is a great pleasure to dedicate this paper to the superb career of Alfred Bader. I learned about his passion for chemistry and chemists when we met several times when I was a graduate student and postdoctoral fellow. It meant a great deal to me then, and now, that "Please Bother Us" meant anyone interested in chemistry, not just the professors. I thank him for sharing his vision and enthusiasm for chemistry with me then and many times since. The example he set has profoundly affected the way my career has evolved.

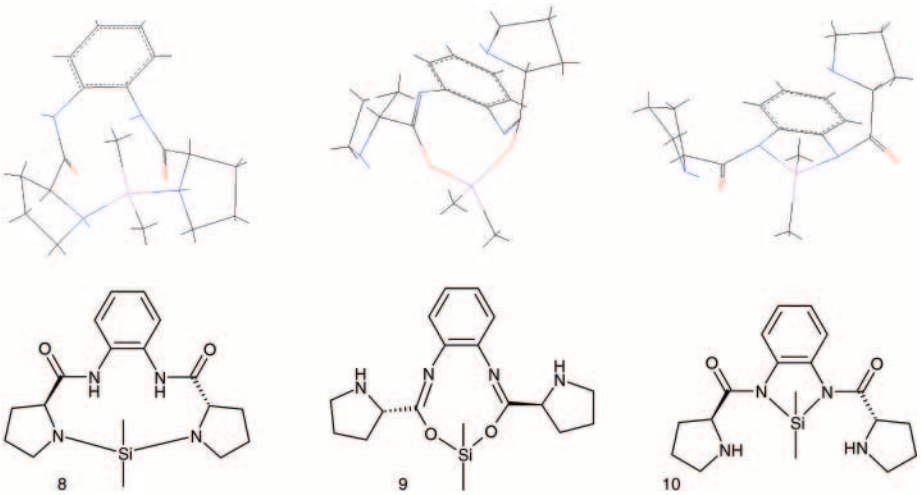
silicon, particularly the pentacoordinate species, is evident from Si NMR.

In an attempt to better understand the processes involved in the reduction, recent research has turned to the utilization of multidentate ligands that, on binding, would have fewer degrees of freedom and, additionally, would be more amenable to structural characterization. The use of C_2-symmetry, in particular, provides a more highly structured environment for enantioselective reactions (9), a strategy we recently utilized with silane-medicated reductions (**2**–**6**, Scheme 3) (10). Unfortunately, only moderate ee were observed in these reactions.

In this study, we developed a C_2-symmetric multidentate ligand that utilizes proline, perhaps the most widely utilized amino acid chiral template (11). We report the synthesis of the C_2-symmetric compound **7** (Scheme 3), the formation of pentacoordinate silicon complexes on reaction of **7** with $HSi(OEt)_3$, as shown by ^{29}Si NMR, the ability of this complex to reduce ketones, and the characterization of its copper complex **13** by an X-ray structure. In addition, the behaviour of the Lewis acidic derivative formed from the reaction of **7** with TiF_4 is described in the same carbonyl reduction process.[3]

Results and discussion



Preparation and characterization of the ligands

A series of molecular modeling experiments were undertaken with C_2-symmetric diamino acid derivatives. Preliminary studies compared the geometries of bidentate

dimethylsilicon complexes based on various amino acid complexes of 1,2-diaminobenzene. Among the amino acids examined (phenylalanine, histidine, alanine, and proline), the latter had a more tightly constrained structure, irrespective of whether the linkages occurred through the proline nitrogen **8**, amide oxygen **9**, or amide nitrogen **10** (Fig. 1). All of the derivatives had more rigid and compact chiral environments than structures based on the structural motifs found in **4** or **5** (Scheme 3). Therefore, the bisproline ligand **7** was prepared by coupling 1,2-diaminobenzene with commercially available N-protected L-proline (Scheme 4). The optically pure ligand was obtained, after deprotection by trifluoroacetic acid, by recrystallization from methanol in an overall yield of 83% and structurally characterized by NMR (^{1}H, ^{13}C), HRMS, and IR.

Mechanistic study

Silicon compounds undergo extracoordination in the presence of silaphilic nucleophiles, particularly oxygen, fluoride, and aromatic amines (12). Coordination expansion is facilitated by electron-withdrawing groups on silicon, especially fluoride and oxygen ligands. Thus, the facility of trialkoxysilanes to undergo extracoordination lies between that of trialkyl- and trihalo-silanes (12). Tacke and co-workers (13), in a beautiful series of papers, demonstrated that bidentate nucleophiles are particularly efficacious in inducing coordination expansion. A broad variety of pentacoordinate amino and hydroxy acid derivatives, exemplified by **11**, have been isolated in crystalline form (Scheme 5) (13, 14).

Complexes of **7** and $HSi(OEt)_3$ were characterized by ^{29}Si NMR. The ^{29}Si NMR of the neutral mixture gave a singlet at

Scheme 5. Formation of extracoordinate silicon with α-hydroxy acids.

–58.68 ppm, consistent with reported data for triethoxysilane (15). Thus, the amine groups are insufficiently basic to engender extracoordination at silicon. By contrast, when the bisproline tetraanion of **7** was mixed with triethoxysilane in a ratio of 1:2 (sensitivity of the NMR precluded lower concentrations of the silicon compound and higher concentration of the bisproline tetraanion led to precipitates) ^{29}Si NMR showed two singlets at –84.27 and –98.83 ppm, respectively.

It is challenging to assign putative structures to compounds with these chemical shifts. Each exchange at silicon of H by O or N leads to an upfield shift, as does each exchange of N by O. For example, the addition of the anionic ligand of **7** to $HSi(OEt)_3$ to give a pentacoordinate species $(HSi(OEt)_3\text{-}N\mathbf{7})^-$ would lead to an upfield shift of about 20 ppm. However, displacement of the EtO^- by the same nitrogen to give a tetracoordinate species $(HSi(OEt)_2\text{-}N\mathbf{7})$ would lead to a downfield shift of about 15 ppm (16). The observed peaks are consistent with a pentacoordinate species ($HSiX_4^-$, –84.27 ppm) and an oxidized pentacoordinate species (SiX_5^-) or a hydrido hexacoordinate species ($HSiX_5^{2-}$,

–98.83 ppm), respectively. Since extracoordinate hydridosiliconates are required to reduce ketones (see later), it is anticipated that these peaks represent penta- and hexacoordinate silicon hydrides; after the ketone reduction, ^{29}Si NMR showed only one peak at –82.39 ppm.

It did not prove possible to prepare crystals of sufficient quality for an X-ray analysis. By contrast, the *N*,*N*-dimethyl derivative **12** gave suitable crystals (Fig. 2, for crystallographic parameters and typical bond lengths and angles see Table 1). To explore complexed ligand structures that would be related to the reduction process, the copper complex **13** of ligand **7** was prepared by the reaction of the ligand with copper(II) chloride in methanol in the presence of excess potassium carbonate (Fig. 2). An X-ray crystal structure of the compound showed a nearly square planar arrangement of the C_2-symmetric nitrogen ligands around copper (Tables 2 and 3). The ligand in **13** forms a compact complex with short Cu—N bond lengths that brings the stereodirecting chiral centres in closer proximity to the metal centre. This structure was very encouraging as it suggests that analogous C_2-symmetric structures, such as **14**, may be formed. Extensive attempts to isolate various silicon complexes of **7** in crystalline form were unsuccessful.

Reductions of acetophenone

Previous work demonstrated that ketone reduction with hydrosilanes could be initiated with carboxylate or other anions to activate the silicon (7). A series of reductions of acetophenone was undertaken to establish the key factors required for efficacy in the presence of **7** (Table 4). Negative controls included a set of reactions in which each of the key ingredients was selectively absent. Notable among the results is the reduction of acetophenone with the proline anion, which resulted in 50% yield and 15% ee (Table 4, entry 3). This is a result that is related to, but less efficient than, reductions in the presence of anions of histidine and particularly phenylalanine that occurred in yields typically of 80% and ee up to 70% (7). A series of experiments demonstrated that the best compromise for yield and ee occurred at 55 °C, higher than would be expected for a reaction run under ki-

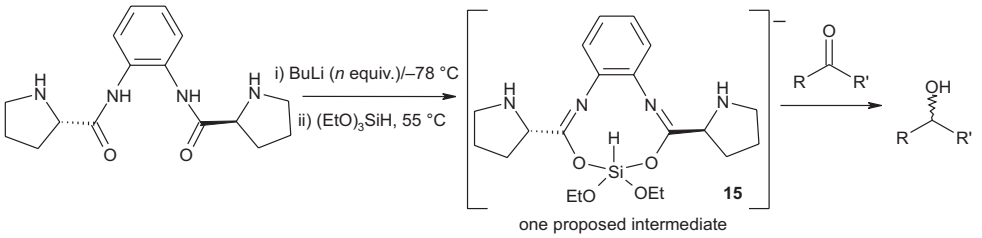
netic control. The reactions further confirmed that extracoordinate hydrosilanes are more reactive towards a variety of electrophiles than their four-coordinate counterparts (12). For example, neutral $HSi(OEt)_3$ is not able to reduce acetophenone in the absence of nucleophilic activation (Table 4, entry 1). Neutral bisproline **7** is similarly unable to activate triethoxysilane to undergo the reduction (Table 4, entry 2) as was also shown by ^{29}Si NMR experiments (see earlier). By contrast, the most effective reduction took place with the tetraanion of **7** (Table 3, entry 4). While the tetraanion of **7** can make a tight complex with silicon, it can do so with loss of chirality because of amino acid epimerization.

While the yields of these reactions were acceptable, the ee were marginal. Although the crystal structure of the copper complex **13** shows that the stereochemistry of the amino acids are maintained in the complex, it is also conceivable that α-amido epimerization occurs under the more basic conditions used for these reductions. To reduce this possibility, the efficacy of the reaction was tested as a function of the equivalents of base added (from 1 to 4 equiv.). The most interesting results came with 2 equiv. of base, which should deprotonate the amide NHs, possibly leading to bidentate complexes **15** (Table 4) and **16** (analogous to **9** and **10**, Fig. 3) without affecting the chiral centres. The reaction was more sluggish and it can be seen that, in one case, the ee improved, but at the expense of reaction yield (Table 4, entries 5–7).

Hydrosilanes are very stable at neutral conditions, but significantly less so away from neutrality, particularly under basic conditions. Exchangeable hydrogens under these conditions serve as excellent electrophiles, with the result that H_2 is normally released (e.g., $R_3SiH + HY \rightarrow R_3SiY + H_2$) (17). This process is particularly favoured when multidentate ligands are utilized (14) and can be exploited as a method for generating H_2 in situ on demand (18).



In the current case, the design of the ligand is challenged by this reactivity. Tetradentate complexation giving compounds such as **14** could also result in loss of chirality through epimerization **17**. By contrast, a bidentate chiral C_2-symmetric complex such as **16** is subject to loss of hydride through the processes just described (**16** → **18**, Fig. 3).

Si-H groups are significantly less reactive to acidic than basic conditions (19). It was reasoned that these problems could be mitigated or avoided by changing from basic to acidic conditions. That is, the same ligand could be complexed by a Lewis acid that would fit into the chiral pocket of the ligand and direct reduction. An important precedent for this approach is the observation by Cozzi and coworkers (20) that Lewis acidic titanium fluoride complexes **19**, based on readily accessible chiral bisoxazoline complexes of Evans, will catalyze carbonyl reductions (Scheme 6). The titanium complex of ligand **7** is expected to be tetradentate (Table 5) based on the structure of the copper complex **13**. Carbonyl complexation will preferentially occur at the more Lewis acidic site (titanium) and the locus of the reduction reaction will be taken away from silicon. These proposals were tested by complexing ligand **7** with titanium-based Lewis acids and examining the reduction reaction in the absence and presence of base (Table 5) in the presence of 5 mol% of the chiral catalyst.

The relative Lewis acidity of simple titanium catalysts follows the order $Ti(OiPr)_4 < TiCl_4 < TiF_4$. Replacement of halides or alkoxy groups with amines will further moderate Lewis acidity. No reduction was observed under any conditions when the first two less acidic compounds were employed as catalysts (Table 5). When 2 equiv. of BuLi were

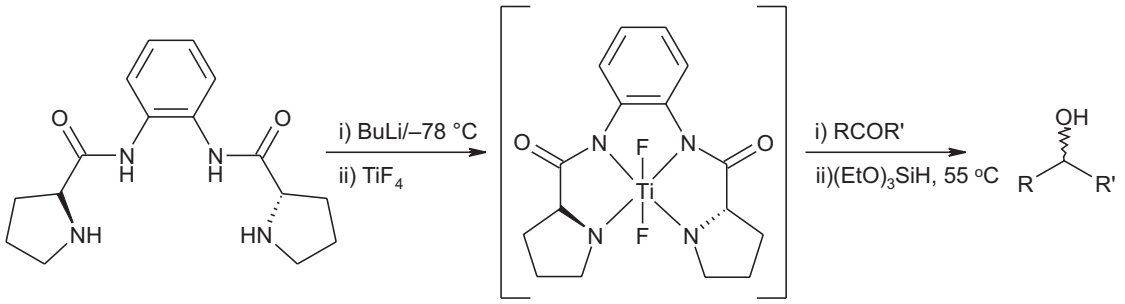
Scheme 6.



used to facilitate formation of the titanium–**7** complex, only marginal reduction yields were observed, in general worse than in the absence of the titanium compound (Table 4). Of the three reducing agents H_2, Ph_2SiH_2, and $HSi(OEt)_3$, only the last was somewhat efficient. H_2 was used as a negative control. Of the two silanes, $HSi(OEt)_3$ is generally more reactive than Ph_2SiH_2. It has a greater facility for coordination expansion, and as discussed earlier, silylhydrides are more reactive as five- rather than four-coordinate silicon. Improved results were obtained when 4 equiv. of base was used to create the titanium–**7** complex. Yields increased as did enantioselectivity as determined using Mosher ester synthesis (21), although not to levels sufficient for practical application.

A bidentate adduct could form from addition of the dianion **20** to TiF_4 (Scheme 7), which will be a less rigid structure than a tridentate complex such as **21** or the C_2-symmetric catalyst tetradentate titanium complex **22** that should form when 4 equiv. of base are added (Scheme 7). The more rigid structures with proximal chiral groups should have improved enantioselectivity, as was observed with the system derived from the tetraanion.

Several observations provide guidance about the role of the titanium complex **20**. Oxophilic titanium will preferentially jettison nitrogen groups to form a complex with the carbonyl oxygen to give a motif such as **21**, which is widely exploited in titanium-catalyzed aldol and related reactions (22), but in doing so will lose C_2-symmetry. The attempt to crystallize **20** or carbonyl complexes of it were unfortunately unfruitful. Hydrosilanes are normally insufficiently reactive

Scheme 7.

to reduce such titanium carbonyl complexes. By contrast, carbocations can be trapped to give C—H bonds (23).

While the specific role of the hydrosilane has not yet been established in the Ti-catalyzed reductions, it seems likely, as with the basic conditions, that extracoordinate silicon is responsible for reduction. The inability of the $TiCl_4$ complex of **7** to catalyze reduction is instructive in this context. The formation of a Lewis acidic chiral complex will liberate the halide Cl^-, which is normally not able to facilitate extracoordination at silicon (12). Thus, while a chiral carbonyl–Ti complex may form, the only reducing agent present is $HSi(OEt)_3$, which is a not viable reducing agent for ketones.

As reported by many researchers, fluoride activates silicon hydrides to reduce carbonyls (24). Formation of compounds such as **22** with TiF_4 serves two purposes. It first provides a chiral Lewis acidic pocket that serves as the locus of reduction and further liberates 2 equiv. of F^-. Fluoride is key, as it can convert the hydrosilane into an active reducing agent, $HSi(OEt)_3F^-$. The obvious disadvantage of this process is that the activated fluoride complex $HSi(OEt)_3F^-$ can directly reduce the ketone outside the sphere of the chiral ligand, leading to a reduction in the overall enantioselectivity of the process.

Of the two very mild approaches examined, the Lewis acidic approach was more efficacious than the extracoordinate hydrosiliconate, with respect to both yields and enantioselectivity. Our current focus is to develop ligands that provide chirality and intramolecular activation to the silicon. Such a system will constrain all reactions to the proximity of the chiral environment.

Conclusion

A C_2-symmetric bisproline ligand can be used as a cata-

© 2006 NRC Canada

lyst to induce enantioselective induction as an anionic extracoordinate silicon complex or after complexation with TiF_4. The Lewis acid catalyzed route led to high yields because side reactions are reduced and showed higher ee.

Experimental section

Reagents and physical methods

The following materials were obtained from Sigma-Aldrich and were used without further purification: acetophenone, *n*-butyllithium (1.6 mol/L solution in cyclohexane), (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride (MTPA-Cl (+)), 2-methoxyacetophenone, *trans*-4-phenyl-3-buten-2-one, sodium sulfate, triethoxysilane, 1,2-diaminobenzene, *N*-BOC-(*S*)-proline, hydroxybenztriazole (HOBt), 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC), rhodium(III) chloride, titanium(IV) fluoride, and titanium(IV) chloride.

All solvents were thoroughly dried before use; THF was dried from Na/benzophenone. All reactions were carried out in flame-dried apparatus under an argon atmosphere with the use of septa and syringes for the transfer of reagents.

^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC-200 (at 200 MHz for protons, 50.32 MHz for ^{13}C) Fourier transform spectrometer. ^{29}Si NMR was performed on a Bruker DRX-300 (at 75.44 and 59.60 MHz for carbon and silicon, respectively). ^{1}H-NMR was also performed on a Bruker DRX-500 (at 500 MHz for hydrogen). ^{1}H chemical shifts are reported either with respect to tetramethylsilane as an external standard set to 0 ppm or $CDCl_3$ as an internal standard set to 7.26 ppm. ^{13}C NMR chemical shifts are reported either with respect to $CDCl_3$ as an internal standard set to 77.26 or THF-d_8 as an internal standard set to 67.57 ppm. Coupling constants (*J*) are recorded in Hertz (Hz). The abbreviations singlet (s), doublet (d), triplet (t), quartet (q), doublet of doublets (dd), doublet of triplets (dt), multiplet (m) are used to report spectra.

Electron impact (EI) and chemical ionization (CI, NH_3) mass spectra were recorded at 70 eV with a source temperature of 200 °C on a Micromass GCT (Waters Corporation, Milford, Massachusetts) mass spectrometer using a heated probe. High-resolution mass spectral (HRMS) data were obtained using the EI method calibrant with perfluorotributyl amine. Molecular modeling calculations were undertaken using the MM2 molecular mechanics parameter set, using Hyperchem 5.01 from Hypercube Inc. (Gainesville, Florida).

X-ray crystallographic data for **7** and **13** were collected from suitable samples mounted with epoxy on the end of thin glass fibers. Data collections were performed at 273 K.

Data for **7** were collected on a Bruker P4 diffractometer equipped with a Bruker SMART 1K CCD area detector (using the program SMART (25)) and a rotating anode utilizing graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å). Data processing was carried out by use of the program SAINT (26), while the program SADABS (27) was utilized for the scaling of diffraction data, the application of a decay correction, and an empirical absorption correction based on redundant reflections. The structures were solved by using the direct methods procedure in the Bruker SHELXTL (28) program library and refined by full-matrix least-squares methods on F^2. All non-hydrogen atoms were refined using anisotropic thermal parameters and hydrogen atoms were added as fixed contributors at calculated positions, with isotropic thermal parameters based on the atom to which they are bonded.

Data for **13** were collected on a three-circle D8 Bruker diffractometer equipped with a Bruker SMART 6000 CCD area detector (using the program SMART (25)) and a rotating anode utilizing cross-coupled parallel focusing mirrors to provide monochromated Cu Kα radiation (λ = 1.541 78 Å). Data processing and structure solving were carried out as noted previously.

Preparation of the bis(L)prolinyl amide of 1,2-diaminobenzene

A solution of 1,2-diaminobenzene (0.36 g, 3.3 mmol) and *N*-(*tert*-butoxycarbonyl)-L-proline (1.5 g, 6.9 mmol) in CH_2Cl_2–DMF (10:1, 30 mL) was treated at 0 °C with HOBt (0.93 g, 6.9 mmol) and EDC (1.35 g, 6.9 mmol). The reaction mixture was stirred at 0 °C for 2 h and allowed to warm up to room temperature (rt) overnight. Solvents were removed under reduced pressure. CH_2Cl_2 (20 mL) was added to the yellow residue and stirred for 2 h. TFA (10 mL) was added dropwise at rt to the solution, which was stirred for another 2 h. Saturated K_2CO_3 solution (20 mL) neutralized the solution (pH 9). The aqueous layer was extracted with CH_2Cl_2 (3 × 20 mL). The combined organic layer was dried over anhydr. Na_2SO_4. After removing the solvents under reduced pressure, the product was recrystallized from methanol and dichloromethane (20:1). The product, a colourless crystal, was formed in 83% yield. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 1.73–1.80 (m, 4H, R_1-C*H*-R_2), 2.02–2.13 (m, 2H, NH), 2.18–2.24 (m, 4H, R_2-C*H*-R_3), 2.95–3.10 (m, 4H, CH_2-NH), 3.86–3.93 (q, 2H, *CH*-NH), 7.13–7.19 (m, 2H, Ph-*H*), 7.65–7.70 (m, 2H, Ph-*H*). ^{13}C NMR (d_6-DMSO, 200 MHz) δ: 33.27, 37.76, 54.07, 67.92, 131.03, 132.11, 137.72, 181.25. LRMS (EI) *m*/*z* (%): 302 (M^+, 13), 232 (62), 205 (53), 188 (100), 91 (92), 70 (83), 45 (87). HRMS (ES) *m*/*z* calcd. for $(C_{16}H_{23}N_4O_2)^+$: 303.1808; found: 303.1821.

Preparation of the *N*,*N*′-dimethyl bis(L)prolinyl amide of 1,2-diaminobenzene (12)

To a stirred solution of **7** (1 g, 3.3 mmol) and 37% aqueous formaldehyde (2 mL, 25 mmol) in 20 mL acetonitrile was added sodium cyanoborohydride (0.8 g, 10 mmol). Glacial acetic acid was added until the solution reached neutrality. The reaction was stirred at ambient temperature for 3 h. The reaction mixture was poured into 50 mL of ether and washed with 3 × 30 mL portions of 1 N KOH and one 30 mL portion of brine. The ether solution was dried (Na_2SO_4) and evaporated under reduced pressure. The desired product was recrystallized from MeOH and ether (1:10). The product, a colourless crystal, was formed in 80% yield, mp 206 °C. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.77–1.80 (m, 4H, R_1-CH_2-R_2), 1.82–1.99 (m, 2H, CH-CH_2-CH_2), 2.25–2.42 (m, 4H, CH-CH_2-CH_2), 2.46 (s, 6H, CH_3-N), 3.02 (q, 2H, *J* = 5.1, 10.2 Hz, CH_2-$NHCH_3$), 3.14–3.19 (m, 2H, CH_2-$NHCH_3$), 3.29–3.32 (m, 2H, C*H*-NCH_3), 7.20–7.25 (m, 2H, Ph-*H*), 7.62–7.67 (m, 2H, Ph-*H*), 9.38 (s, 2H, CON*H*). ^{13}C NMR ($CDCl_3$, 200 MHz) δ: 24.38, 31.15, 41.79, 56.67, 69.23, 124.25, 125.80, 129.77, 173.43. LRMS (ES) *m*/*z* (%): 331.6 (M^+, 100), 147.0 (5), 65 (10). HRMS (ES) *m*/*z* calcd.

for $(C_{18}H_{27}N_4O_2)^+$: 331.2134; found: 331.2139. For X-ray data, see Table 1.

Preparation of the copper complex of the bis(L)prolinyl amide of 1,2-diaminobenzene (13)

Ligand **7** (0.03 g, 0.1 mmol) was dissolved in methanol (5 mL) before the addition of anhydr. K_2CO_3 (0.055 g, 0.4 mmol) and $CuCl_2 \cdot 2H_2O$ (0.017 g, 0.1 mmol). The resulting system was stirred overnight, then the solid was filtered off and the clear blue solution was layered with ether. After 2 weeks, purple crystals were isolated, mp 295 °C (dec.). HRMS (ES) *m/z* calcd. for $(C_{16}H_{21}N_4O_2Cu)^+$: 364.0961; found: 364.0957. For X-ray data, see Tables 2 and 3.

General procedure for the ^{29}Si NMR experiment (example ligand 7–triethoxysilane, 1:2)

To a dry NMR tube was added **7** (0.039 g, 0.13 mmol) and d_8-THF (0.3 mL). This solution was cooled to –78 °C and *n*-butyllithium (0.16 mL, 1.6 mol/L solution in hexanes, 0.26 mmol) was added dropwise. The resulting yellowish solution was warmed to 0 °C for 15 min. To this yellow solution was added triethoxysilane (0.05 mL, 0.26 mmol). The solution was allowed to stand at 0 °C then warmed up to rt for 30 min. ^{29}Si NMR was examined in proton decoupled mode using the Bruker DRX-500.

General procedure for basic reduction of ketone in the presence of 7 (example acetophenone) (Table 4)

To a dry 10 mL round-bottomed flame-dried flask protected by argon was added **7** (0.016 g, 0.05 mmol) and THF (5 mL). This solution was cooled to –78 °C and *n*-butyllithium (0.13 mL, 1.6 mol/L solution in hexanes, 0.2 mmol) was added dropwise. The resulting yellowish solution was stirred for 5 min at –78 °C and then warmed to 0 °C for 15 min at which point $(EtO)_3SiH$ (0.38 mL, 2.06 mmol) was added. The resulting clear solution was stirred for 1 h at rt, then acetophenone (0.12 mL, 1.02 mmol) was added. The solution was stirred at rt and product development was monitored by TLC. The reaction mixture was acidified by adding 1 N HCl at 0 °C and carefully made to pH 6 (29). The organic phase collected. The aqueous phase was extracted with ethyl acetate (3 × 10 mL). The organic layers weree combined, dried over sodium sulfate, and then concentrated to give the crude product, which was purified by column chromatography eluting with hexanes – ethyl acetate (5:1). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 1.56 (d, 3H, *J* = 6.5 Hz, PhCH(OH)*CH*$_3$), 2.76 (bs, 1H, PhCH(*OH*)CH_3), 4.94 (q, 1H, *J* = 6.5 Hz, Ph*CH*(OH)CH_3), 7.32–7.45 (m, $5H_{arom}$). ^{13}C NMR ($CDCl_3$, 200 MHz) δ: 24.97, 69.99, 125.24, 127.14, 128.24, 145.75. MS (EI) *m/z* (%): 122 (M^+, 10), 121 (40), 104 (68), 79 (28), 57 (7), 43 (100). MS (CI) *m/z* (%): 140 ($(M + 18)^+$, 17), 122 (100), 105 (41), 78 (2), 52 (1), 44(1).

General procedure for Lewis acid catalyzed reduction of ketone (example acetophenone) (Table 5)

To a dry 10 mL round-bottomed flame-dried flask protected by argon was added **7** (0.016 g, 0.05 mmol) and THF (5 mL). This solution was cooled to –78 °C and *n*-butyllithium (0.13 mL, 1.6 mol/L solution in hexanes, 0.2 mmol) was added dropwise. The resulting yellowish solution was stirred for 5 min at –78 °C and warmed to 0 °C for 15 min. To this yellow solution was added TiF_4 (6 mg, 0.05 mmol) and the mixture was vigorously stirred until the salt was completely dissolved. The resulting yellow mixture was stirred for 1 h at rt and triethoxysilane (0.38 mL, 2.06 mmol) and acetophenone (0.12 mL, 1.02 mmol) were added. The solution was stirred at 55 °C and product development was monitored by TLC. The reaction mixture was diluted with ethyl acetate (5 mL) and carefully made basic (pH 9) with 1 mol/L of sodium hydroxide (30). The solid was separated by filtration and the organic phase was collected. The aqueous phase was extracted with ethyl acetate (3 × 10 mL). The organic layers were combined, dried over sodium sulfate, and then concentrated to give the crude product which was purified by column chromatography eluting with hexanes – ethyl acetate (5:1).

2-Bromophenethyl alcohol

^{1}H NMR ($CDCl_3$, 200 MHz) δ: 2.69 (bs, 1H, O*H*), 3.69–3.45 (m, 2H, CH_2Br), 4.90 (dd, *J* = 3.5, 8.6 Hz, 1H, Ph*CH*(OH)), 7.36 (s, $5H_{arom}$). ^{13}C NMR ($CDCl_3$, 200 MHz) δ: 40.12, 73.78, 125.95, 128.43, 128.65, 140.31. General experimental procedure for preparation of Mosher esters (example (*S*)-1-phenylethanol)

(*S*)-1-Phenylethanol (2 mg, 0.02 mmol) and MTPA-Cl (+) (4 μL, 0.02 mmol) were mixed with carbon tetrachloride (3 drops) and dry pyridine (3 drops). The reaction mixture was allowed to stand in a stoppered flask for 12 h at ambient temperature. Water (1 mL) was added and the reaction mixture transferred to a separatory funnel and extracted with ether (20 mL). The ether solution, after washing successively with HCl (1 mol/L, 20 mL), saturated sodium carbonate solution (20 mL), and water (20 mL), was dried with sodium sulfate, filtered, and the solvent was removed in vacuo. The residue was dissolved in deuterated chloroform for NMR analysis. The integration of the hydrogen on the carbon bearing the hydroxyl group was used as a measure to assess the enantioselection.

Hydrogen-bonded networks in crystals built from bis(biguanides) and their salts[1]

Olivier Lebel, Thierry Maris, and James D. Wuest

Abstract: Biguanide groups and biguanidinium cations incorporate multiple sites that can donate or accept hydrogen bonds. To assess their ability to associate and to direct the formation of extended hydrogen-bonded networks, we examined the structure of crystals of four compounds in which two neutral biguanide groups or the corresponding cations are attached to the 1,4- and 1,3-positions of phenylene spacers. As expected, all four structures incorporate extensive networks of hydrogen bonds and reveal other reliable features. In particular, (1) neutral biguanide groups favor a roughly planar conformation with an intramolecular hydrogen bond, and they associate as hydrogen-bonded pairs, (2) despite coulombic repulsion, biguanidinium cations can also associate as hydrogen-bonded pairs, and (3) the 1,3-phenylenebis(biguanidinium) dication favors a pincerlike conformation that allows chelation of suitable counterions. However, the precise patterns of hydrogen bonding in the structures vary substantially, limiting the usefulness of biguanide and biguanidinium as groups for directing supramolecular assembly.

Key words: bis(biguanide), bis(biguanidinium), structure, hydrogen-bonded network, noncovalent interaction, supramolecular chemistry, crystal engineering.

Résumé : Des groupes biguanide et des cations biguanidinium incorporent de multiples sites qui peuvent donner ou accepter des liaisons hydrogène. Dans le but d'évaluer la capacité d'associer et de diriger la formation de réseaux étendus de liaisons hydrogène, on a étudié la structure cristalline de quatre composés dans lesquels deux groupes biguanide neutres, ou les cations correspondants, sont attachés aux positions 1,4- et 1,3- de groupes phénylènes. Comme prévu, les quatre structures permettent d'incorporer des réseaux de liaisons hydrogène et mettent en évidence d'autres caractéristiques fiables. En particulier, 1) les groupes biguanide neutres favorisent une conformation pratiquement plane avec une liaison hydrogène intramoléculaire et s'associent sous la forme de paires réunies par des liaisons hydrogène, 2) malgré une répulsion coulombique, les cations biguanidinium peuvent aussi former des paires associées par des liaisons hydrogène et 3) le dication phénylène-1,3-bis(biguanidinium) favorise une conformation en forme de pince qui permet d'effectuer une chélation avec des contre-ions appropriés. Toutefois, les régimes précis des liaisons hydrogène varient d'une façon substantielle, ce qui limite l'utilité des groupes biguanide et biguanidinium comme unités pouvant orienter un assemblage supramoléculaire.

Mots clés : bis(biguanide), bis(biguanidinium), structure, réseau à liaisons hydrogène, interaction non covalente, chimie supramoléculaire, génie cristallin.

[Traduit par la Rédaction]

Introduction

The general family of compounds that includes biguanide (**1**) has been known for over 100 years (1–3).[3] Members of the family have important applications as medicines, as ligands in coordination chemistry, as bases, and as precursors for the synthesis of various heterocyclic compounds (4). In addition, biguanide groups and biguanidinium cations incorporate characteristic patterns of sites that can donate or accept hydrogen bonds, thereby allowing them to associate and engage in supramolecular assembly (4).

A productive strategy for engineering predictably ordered supramolecular materials is to build them from compounds incorporating multiple sticky sites that participate in directional intermolecular interactions (5). These interactions tend to place adjacent molecules in specific positions, leading to the formation of extensive networks with predetermined architectures. In this paper, we assess the potential of multiple biguanide and biguanidinium groups to serve in this way as sticky sites, and we describe the hydrogen-bonded networks present in crystals of bis(biguanide) **2**, its dihydrochloride, and the dihydrochloride and carbonate of isomeric bis(biguanide) **3**. Previous use of such compounds in supramolecular chemistry has been limited to the chelation of metals by ethylenebis(biguanide) (6, 7).

Results and discussion

Crystal structure of bis(biguanide) 2

Bis(biguanide) **2** was prepared by a published method (4) and was crystallized from hot water. X-ray diffraction established that the crystals belong to the triclinic space group *P*-1 and exist as a pair of nonmerohedral twins (8). The crystals have the composition **2**·H_2O and each unit cell contains six molecules of bis(biguanide) **2** and six molecules of H_2O. Crystallographic parameters are given in Table 1, views of the structure appear in Figs. 1 and 2, and additional information is provided as Supplementary data.[4] Multiple symmetry-independent biguanide groups are present in the unit cell, but all correspond to tautomeric form **I** (Scheme 1) and have a roughly planar geometry with internal torsion angles in the range 2.5(3)°–29.8(3)°. This geometry is enforced by an intramolecular NH···N hydrogen bond, with N···H distances of normal values (1.993(5)–2.263(5) Å). Similar features appear in all previous structural studies of neutral biguanides (4, 9–11), so a nearly planar geometry and an intramolecular hydrogen bond appear to be structural features of biguanides that can be used reliably by crystal engineers. The average

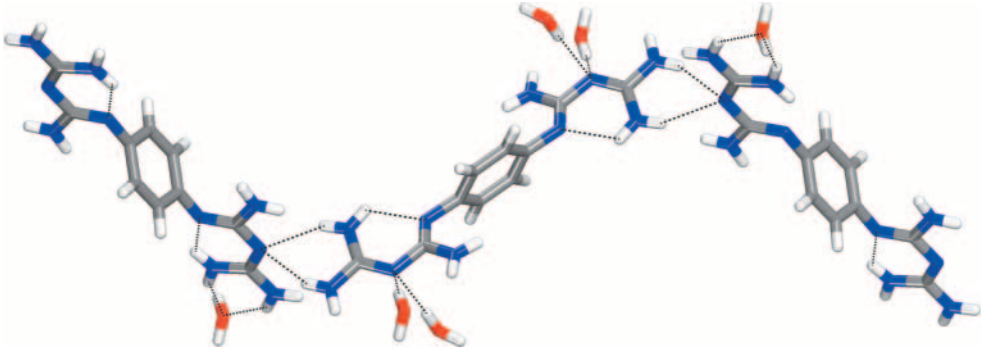
Fig. 1. View of the crstal structure of neutral bis(biguanide) **2** grown from water. The view reveals that each biguanide group incorporates an internal NH···N hydrogen bond and favors tautomeric form **I** (Scheme 1). In addition, the view shows bifurcated intermolecular hydrogen bonds that link compound **2** into continuous ribbons, as well as additional hydrogen bonds involving water. Hydrogen bonds are represented by broken lines. Hydrogen atoms appear in white, carbon in gray, nitrogen in blue, and oxygen in red.



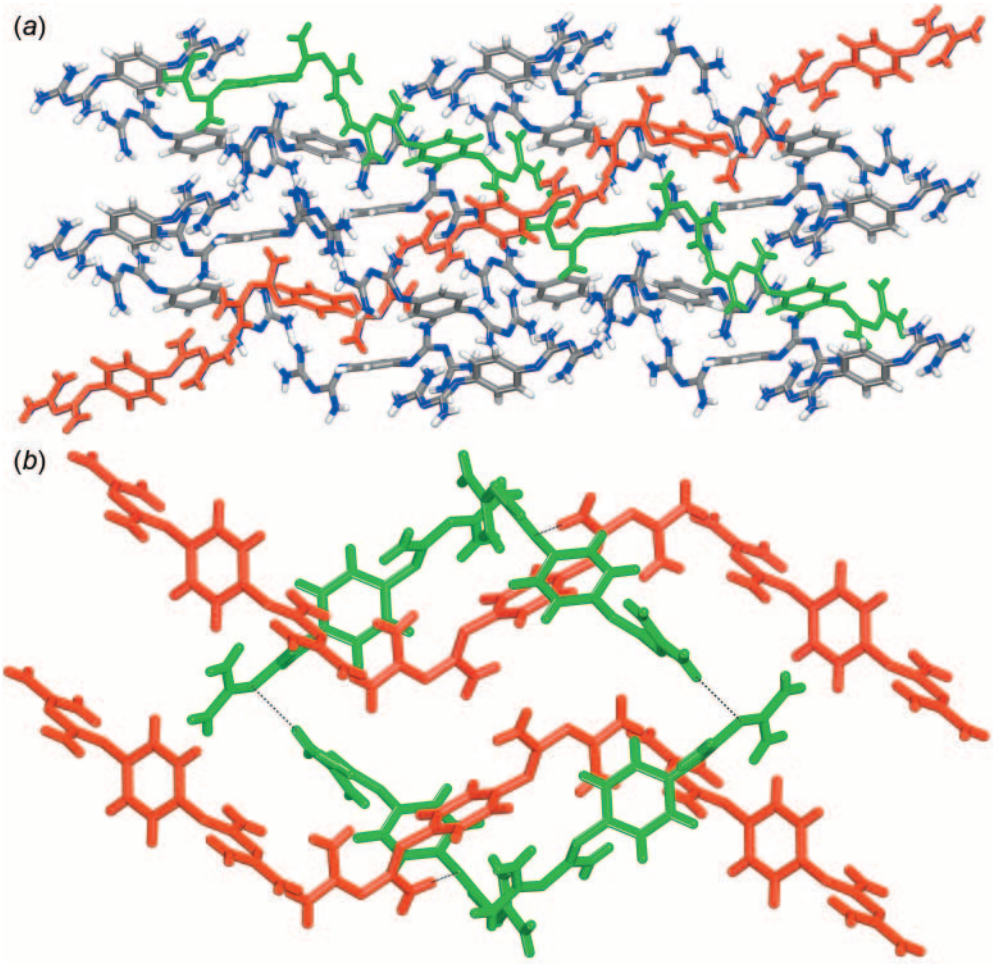


Fig. 2. (*a*) View along the *b* axis of the structure of crystals of neutral bis(biguanide) **2**, with hydrogen atoms shown in white, carbon in gray, and nitrogen in blue. Two hydrogen-bonded ribbons are highlighted in red and green. The two highlighted ribbons run in opposite directions along the *ac* diagonal. (*b*) View along the *a* axis showing secondary hydrogen bonds (represented by broken lines) between the characteristic ribbons. In both views, water molecules are omitted for clarity.

planes defined by the biguanide groups form dihedral angles in the range 67.6(1)°–88.7(1)° with respect to the plane of the central aromatic ring.

Intermolecular hydrogen bonds involving bis(biguanide) **2** and water create a complex network (Figs. 1 and 2), with over 40 hydrogen bonds per unit cell. A primary motif in this network is the ribbon shown in Fig. 1, which links molecules of bis(biguanide) **2** end-to-end by novel bifurcated

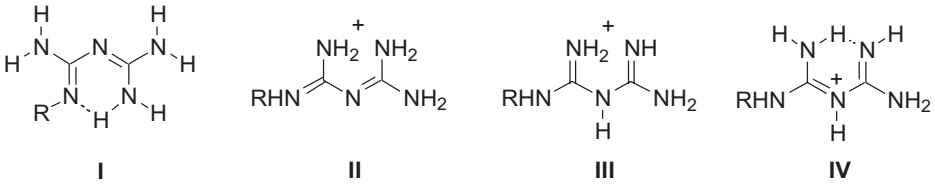
Scheme 1.



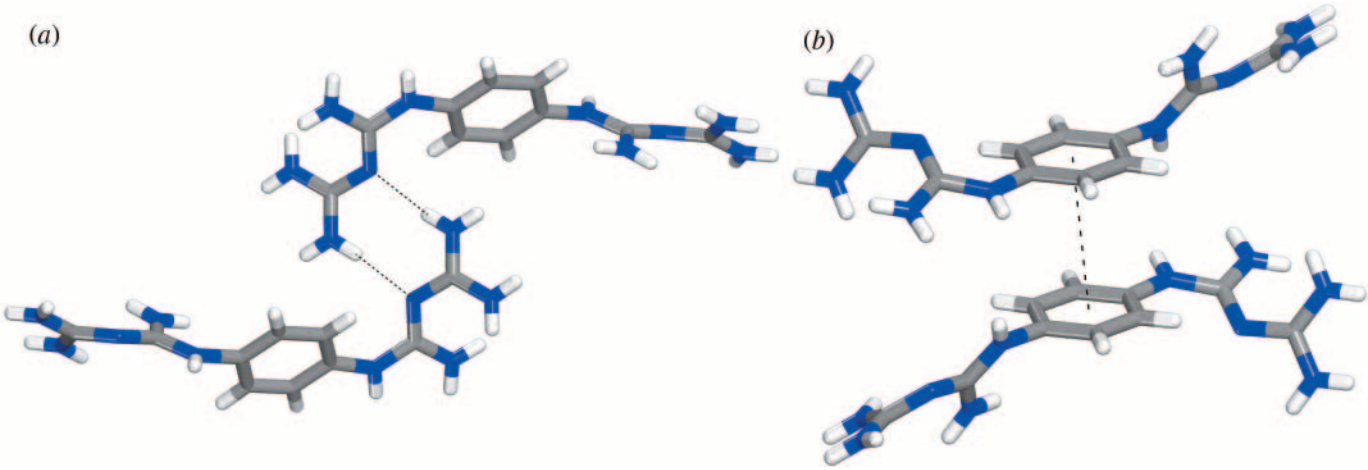


Fig. 3. Views of the crystal structure of the dihydrochloride salt of bis(biguanide) **2** grown from acetone–water. (*a*) The biguanidinium cations favour structure **II** (Scheme 1) and form hydrogen-bonded pairs. (*b*) Additional cohesion is contributed by slightly offset face-to-face aromatic interactions. Hydrogen bonds and the aromatic interaction are represented by broken lines and included water molecules are omitted for simplicity. Hydrogen atoms appear in white, carbon in gray, and nitrogen in blue.

hydrogen bonds. Each molecule in the ribbon serves either as a double acceptor or a double donor of these bifurcated bonds. The resulting ribbons are aligned with the *ac* diagonal and linked by additional hydrogen bonds between biguanide groups, as well as by bridging molecules of water (Fig. 2).

Crystal structure of the dihydrochloride salt of bis(biguanide) 2

Crystals were grown by allowing acetone to diffuse slowly into an aqueous solution of bis(biguanidinium) dichloride (**2**·2HCl), which was prepared by a known method (4). X-ray diffraction demonstrated that the crystals belong to the triclinic space group *P*-1 and have the composition **2**·2HCl·H_2O. Each unit cell contains two symmetry-equivalent molecules of bis(biguanidium) dichloride and two molecules of H_2O. There are four potential sites for H_2O, associated in pairs within van der Waals distances, but only half are occupied. Crystallographic parameters appear in Table 1, views of the structure are shown in Figs. 3 and 4, and additional information is given as Supplementary data.[4] The biguanidinium groups are extensively delocalized, as demonstrated by the similarity of the C-N distances (1.310(3)–1.366(2) Å). Each biguanidinium group can be represented by structure **II** (Scheme 1) and its resonance hybrids, and alternatives in which the central atom of nitrogen is protonated (structure **III**) or in which an intramolecular hydrogen bond is present (structure **IV**) are not favoured in the solid state. Similar conclusions have been reached in all previous structural analyses of biguanidinium cations (4, 10–21), so protonation of biguanides to give structure **II** (Scheme 1) appears to be a fundamental preference, both in solution (2) and in the solid state. Although the biguanidium groups in the dihydrochloride salt of compound **2** can be represented by structure **II**, they are not planar. The two guanidinium subunits that can be considered to be present in each biguanidinium group are individually planar, but their planes define dihedral angles of 39.2(1)° and 45.5(1)° in the two arms of each dication.

The structure of the dihydrochloride salt of bis(biguanide) **2** can be described as a complex network held together in part by hydrogen-bonded pairing of biguanidinium cations (Fig. 3*a*). The N··N distance in these cationic pairs is 3.033(3) Å. Intercationic hydrogen bonding is inhibited by coulombic repulsion and is absent in most biguanidinium salts (4, 11, 14, 15, 17, 19–21), although it has previously been observed in a few cases (12, 13, 18). Slightly offset face-to-face aromatic interactions are also observed in the structure of salt **2**·2HCl (Fig. 3*b*), with a center-to-center separation of 3.879(2) Å. In addition, the structure of the salt reveals multiple ionic hydrogen bonds between biguanidium cations and chloride (Fig. 4). There are two distinct types of chloride ion in the structure, each of which accepts hydrogen bonds from N-H groups provided by neighbouring bis(biguanidium) dications. One type (Cl1) accepts five hydrogen bonds from four dications (Fig. 4*a*) and the other type (Cl2) accepts six hydrogen bonds from four dications, two of which are involved in chelation of chloride (Fig. 4*b*). Each bis(biguanidinium) dication is linked by hydrogen bonding to eight chloride ions, two molecules of water, and one other bis(biguanidinium) dication. The resulting network defines small channels along the *a* axis that are occupied by included molecules of water.

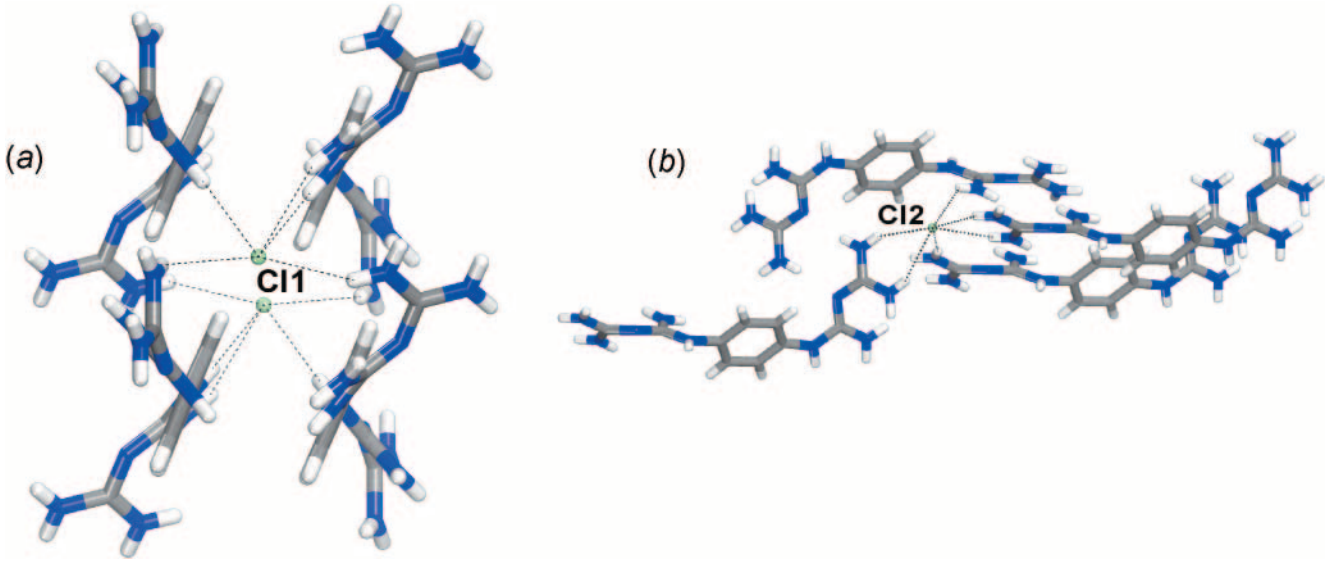
Fig. 4. Views of the crystal structure of the dihydrochloride salt of bis(biguanide) **2** showing ionic hydrogen bonds involving chloride. (*a*) One type of chloride ions (Cl1) accepts hydrogen bonds donated by five N-H groups in four different bis(biguanidinium) dications. (*b*) The other type of chloride (Cl2) accepts six hydrogen bonds (four involving chelation), again contributed by N-H groups in four different bis(biguanidinium) dications. In both views, hydrogen bonds are represented by broken lines. Hydrogen atoms appear in white, carbon in gray, nitrogen in blue, and chlorine in green.



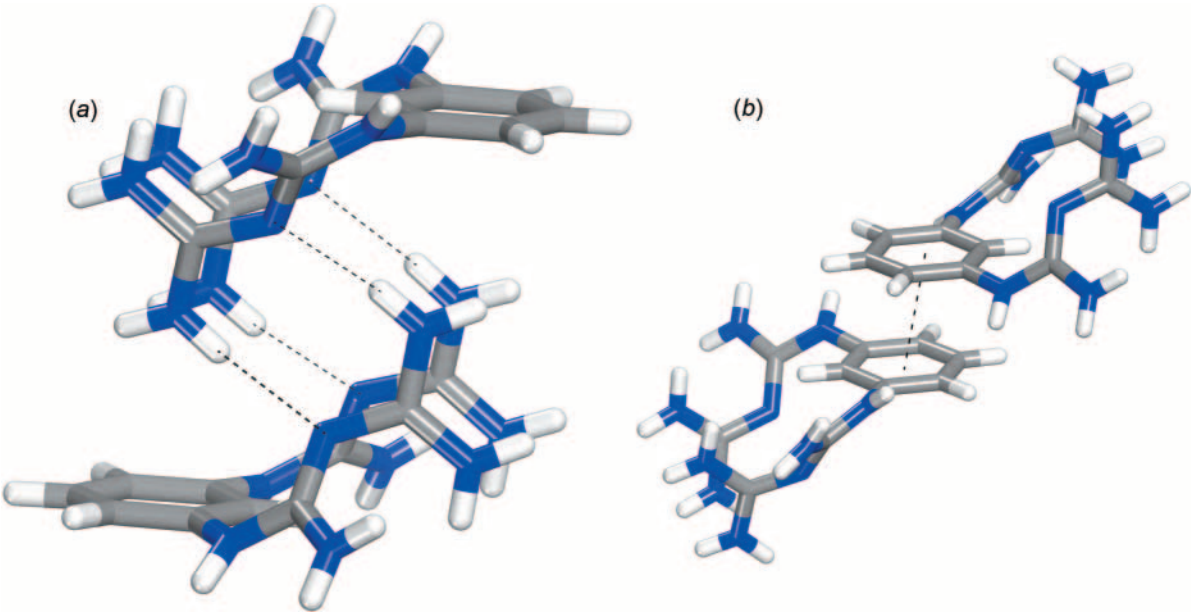


Fig. 5. Views of the crystal structure of the dihydrochloride salt of bis(biguanide) **3** grown from acetone–water. (*a*) The biguanidinium cations favor structure **II** (Scheme 1) and form hydrogen-bonded pairs. (*b*) Additional cohesion is contributed by face-to-face aromatic interactions. Hydrogen bonds and the aromatic interaction are represented by broken lines, and included water molecules are omitted for simplicity. Hydrogen atoms appear in white, carbon in gray, and nitrogen in blue.

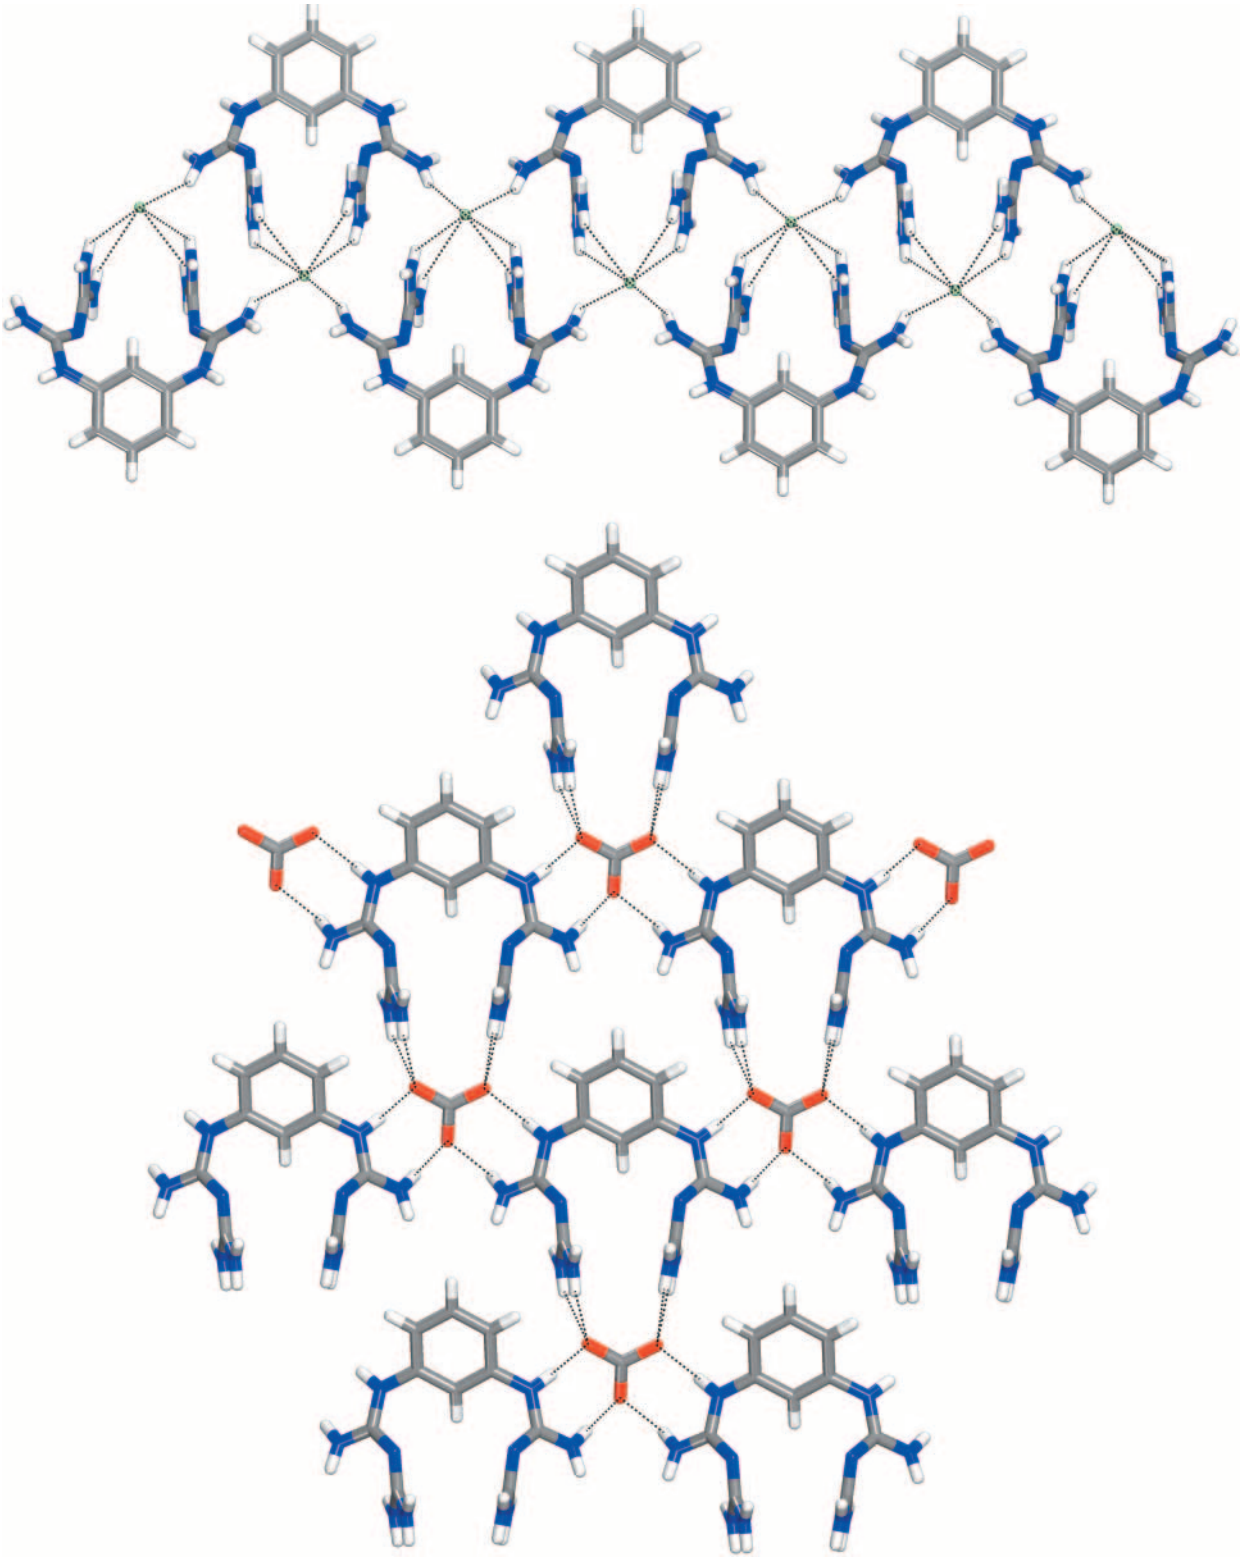

Crystal structure of the dihydrochloride salt of bis(biguanide) 3

Bis(biguanidinium) dichloride **3**·2HCl was prepared by a known method (4) and was crystallized from acetone–water. X-ray diffraction revealed that (*i*) the crystals belong to the triclinic space group *P*-1, (*ii*) their composition corresponds to **3**·2HCl·3H_2O, and (*iii*) each unit cell contains two equivalent molecules of bis(biguanidium) dichloride and six molecules of H_2O. Crystallographic parameters are given in Table 1, views of the structure appear in Figs. 5 and 6*a*, and additional information is provided in the Supplementary data.[4] As noted in other biguanidinium salts, the cations are extensively delocalized, and the C-N distances have similar values (1.320(5)–1.353(5) Å). Again, each biguanidinium

Fig. 6. (*a*) View along the *c* axis of the crystal structure of the dihydrochloride salt of bis(biguanide) **3** grown from acetone–water. The view shows a tape constructed by ionic hydrogen bonding involving one of the two types of chloride ions in the structure. Each bis(biguanidinium) dication adopts a pincerlike conformation that permits chelation of chloride by the simultaneous donation of four hydrogen bonds. (*b*) View along the *c* axis of the closely related structure of crystals of the carbonate salt of bis(biguanide) **3** grown from dioxane–water. In both views, hydrogen bonds are represented by broken lines. Hydrogen atoms appear in white, carbon in gray, nitrogen in blue, oxygen in red, and chlorine in green.

© 2006 NRC Canada

group can be represented by structure **II** (Scheme 1). This further reinforces the conclusion, drawn previously from analysis of salt **2**·2HCl and related compounds (4), that structure **II** is a fundamental preference of biguanidinium cations and can be used dependably by crystal engineers. As in the case of analogue **2**·2HCl, the two biguanidinium groups in each bis(biguanidinium) dication are distinctly nonplanar, and the planes of the guanidinium subunits that can be considered to be present define dihedral angles of 52.6(2)° and 54.8(2)°.

Various important interactions can be identified in the structure of the dihydrochloride salt of bis(biguanide) **3**. As in the structure of the analogous salt **2**·2HCl, a network is formed by hydrogen-bonded pairing of biguanidinium cations (Fig. 5*a*), with N···N distances similar to those observed previously (2.979(4) and 3.028(4) Å). It is noteworthy that this uncommon hydrogen-bonded dimeric motif is observed in the structures of both bis(biguanidinium) salts, despite its coulombic disadvantage. Nevertheless, its absence in the structures of most other biguanidinium salts (4, 11, 14, 15, 17, 19–21) suggests that it does not define a motif that can be used reliably in supramolecular construction.

Additional cohesive forces in the structure of salt **3**·2HCl, also observed in that of analogue **2**·2HCl, are contributed by face-to-face aromatic interactions with a center-to-center separation of 3.687(2) Å (Fig. 5*b*). The structure of salt **3**·2HCl, like that of analogue **2**·2HCl, reveals multiple ionic hydrogen bonds between biguanidium cations and chloride (Fig. 6*a*). Again, there are two distinct types of chloride ion in the structure. One accepts a total of six hydrogen bonds from N-H groups provided by three neighbouring bis(biguanidium) dications (Fig. 6*a*). This type of chloride accepts an additional hydrogen bond from one of the included molecules of water. The dications adopt a pincerlike conformation that favors the binding of chloride by allowing each biguanidinium group to donate two hydrogen bonds to a single chloride, resulting in a characteristic chelation (Fig. 6*a*). Binding of chloride in this way generates tapes that run along the *ab* diagonal. The second type of chloride forms additional ionic hydrogen bonds that help bridge the tapes, and further links between the tapes are created by the hydrogen-bonded pairing of biguanidinium cations (Fig. 5*a*).

Crystal structure of the carbonate salt of bis(biguanide) 3

In contact with air, solutions of bis(biguanide) **3** in dioxane–water yielded crystals of the corresponding carbonate. X-ray diffraction established that (*i*) the crystals belong to the triclinic space group *P*-1, (*ii*) their composition corresponds to **3**·H_2CO_3·H_2O·0.5 dioxane, and (*iii*) each unit cell contains two equivalent molecules of bis(biguanidium) carbonate. Crystallographic parameters are provided in Table 1, a view of the structure appears in Fig. 6*b*, and additional information is given in the Supplementary data.[4] The bis(biguanidinium) dications adopt essentially the same pincerlike conformation observed in dichloride **3**·2HCl, and the two structures are strikingly similar. Chelation of carbonate leads to the assembly of sheets rather than tapes (Fig. 6*b*). Hydrogen-bonded pairing of biguanidinium cations, also observed in the other salts of bis(biguanides) **2** and **3**, then joins the sheets in a three-dimensional network. Each carbonate also accepts an additional hydrogen bond from an adjacent sheet, and molecules of dioxane are held between the sheets by multiple hydrogen bonds.

Conclusions

Biguanides are an intrinsically interesting class of compounds with many known or potential applications. Because biguanides and biguanidinium salts incorporate multiple sites that can donate or accept hydrogen bonds, they are inherently disposed to associate, making them attractive candidates for applications in crystal engineering and other areas of supramolecular chemistry. To evaluate their potential, we have linked two biguanide or biguanidinium groups to rigid aromatic spacers, and we have determined how the resulting bis(biguanides) and bis(biguanidinium) dications interact in the crystalline state. These studies, along with previous structural analyses, have confirmed that the biguanide and biguanidinium groups can be counted on to engage in multiple hydrogen bonds, leading to the formation of extended networks. However, the precise patterns of hydrogen bonding vary significantly, suggesting that other groups are inherently more suitable for fully controlling molecular aggregation.

Experimental

Crystallization of bis(biguanide) 2

Bis(biguanide) **2** was prepared according to a published procedure (4) and crystallized from hot water.

Crystallization of the dihydrochloride salt of bis(biguanide) 2

The dihydrochloride salt of bis(biguanide) **2** was prepared according to a published procedure (4). Single crystals suitable for X-ray diffraction were grown by allowing acetone to diffuse slowly into an aqueous solution of the salt.

Crystallization of the dihydrochloride salt of bis(biguanide) 3

The dihydrochloride salt of bis(biguanide) **3** was prepared according to a published procedure (4). Single crystals suitable for X-ray diffraction were grown by allowing acetone to diffuse slowly into an aqueous solution of the salt.

Crystallization of the carbonate salt of bis(biguanide) 3

Bis(biguanide) **3** was prepared according to a published procedure (4). Single crystals of the carbonate salt suitable for X-ray diffraction were grown by allowing dioxane to diffuse slowly into an aqueous solution of compound **3** in contact with air.

X-ray crystallographic studies

The structures were solved by direct methods using SHELXS-97 (22) and refined with SHELXL-97 (23). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms bonded to nitrogen atoms were located from difference Fourier maps, whereas hydrogen atoms bonded to the carbon atoms of aryl groups were placed in idealized positions. All hydrogen atoms were refined as riding atoms. The structure of bis(biguanide) **2** was refined as a two-

Triazene derivatives of (1,*x*)-diazacycloalkanes. Part VII. Synthesis of a series of 1-aryl-2-[3-(3-[2-aryl-1-diazenyl]-1,3-diazepan-1-ylmethyl)-1,3-diazepan-1-yl]-1-diazenes from the reaction of diazonium salts with mixtures of formaldehyde and 1,4-diaminobutane[1,2]

Reid Tingley and Keith Vaughan

Abstract: A new series of bistriazenes, the 1-aryl-2-[3-(3-[2-aryl-1-diazenyl]-1,3-diazepan-1-ylmethyl)-1,3-diazepan-1-yl]-1-diazenes (**8**), has been synthesized from the reaction of diazonium salts with a mixture of 1,4-diaminobutane and formaldehyde. All new compounds of series **8** have been characterized by IR and NMR spectroscopy, and the elemental composition of selected examples has been verified by elemental analysis. The connectivity of the series has been unequivocally determined by X-ray crystallography. The new bistriazenes are important because the structure contains the novel saturated heterocycle, 1,3-diazepane. The general conclusion of this study is that alkanediamines with three or four carbon atoms in the spacer link between the nitrogen atoms give rise to the linear bicyclic molecules of type **2**, in contrast to the case of ethylenediamine (two carbon atoms in spacer link), which affords molecules of type **3**, which exemplify the cage structure of type **1**.

Key words: diazonium salt, triazene, bistriazene, diazepane, formaldehyde, nuclear magnetic resonance.

Résumé : On a réalisé la synthèse d'une nouvelle série de bistriazènes, les 1-aryl-2-[3-(3-[2-aryldiazén-1-yl]-1,3-diazépan-1-ylméthyl)-1,3-diazépan-1-yl]diaz-1-ènes (**8**) en faisant réagir les sels de diazonium avec un mélange de 1,4-diaminobutane et de formaldéhyde. On a caractérisé tous les nouveaux composés de la série **8** par spectroscopies IR et RMN et on a vérifié la composition élémentaire d'exemples choisis par le biais d'analyses élémentaires. La connectivité dans les produits de la série a été déterminée sans équivoque par diffraction des rayons X. Les nouveaux bistriazènes sont importants puisque leur structure comporte le nouvel hétérocycle saturé, 1,3-diazépane. La conclusion générale de cette étude est que les alcanediamines comportant 3 ou 4 atomes de carbones entre les atomes d'azote conduisent à des molécules bicycliques linéaires de type **2** alors que l'éthylènediamine, qui ne comporte que deux atomes de carbone entre les atomes d'azote, conduit à la formation de molécules de type **3** tel qu'on l'observe dans la structure en cage de type **1**.

Mots clés : sel de diazonium, triazène, bistriazène, diazépane, formaldéhyde, résonance magnétique nucléaire.

[Traduit par la Rédaction]

Introduction

The term "bistriazene" has been coined to describe any molecule that contains two triazene units in the same molecule with a link or spacer in between the triazene moieties. Recent progress in the synthesis of bistriazenes has been reviewed (1). One of the conclusions of recent work is that there are two distinct types of oligomer produced by the interaction of a diazonium salt with a mixture of formaldehyde and a bis-primary amine. The cage-type of bistriazene is exemplified by the general structure **1** (Chart 1) . Examples of this structural type are the bistriazenes (**3**), which arise from ethylene diamine (2) and the 3,7-di-[2-aryl-1-diazenyl]-1,3,5,7-tetraazabicyclo[3.3.1]nonanes (**4**), which are formed by the reaction of a diazonium ion with ammonia/formaldehyde mixtures (3). The alternate type of molecular geometry is the linear bicyclic structure (**2**).

The molecule of type **2** is exemplified by the structure **5a**, which describes the series of products that were obtained from the diazonium coupling reaction with a mixture of formaldehyde and 1,3-propanediamine. The description of the synthesis and characterization of the series **5a** was published in Part IV of this series (4) and the connectivity of one member of series **5a** (with X = *p*-CN) was established

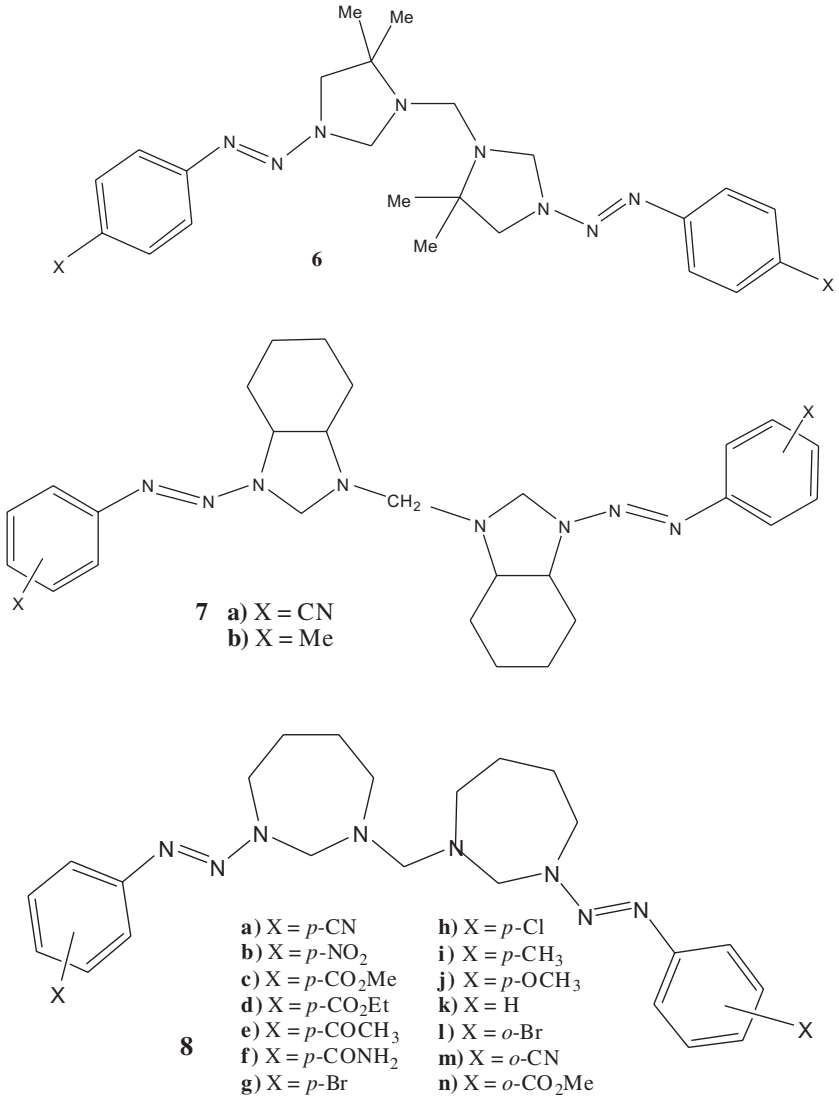
Chart 1.

unequivocally by an X-ray structure determination (5). This work was extended to the dimethyl-substituted series **5b** by the analogous reaction with 2,2-dimethyl-1,3-propanediamine. This work was included in Part IV and an X-ray structure of the methyl benzoate analogue (**5b**, X = CO_2Me) was completed and published (6). The compounds of series **5a** and **5b** are important as new derivatives of the saturated heterocyclic hexahydropyrimidine system, in addition to being illustrations of the linear bicyclic genereal structure **2**.



The linear bicyclic bistriazenes (**5c**) were obtained from the analogous reaction of diazonium salts with formaldehyde and 1,3-pentanediamine, which affords the 6-ethylhexahydropyrimidin-1-yl system. These results have been reported in Part V of this series (7) and an X-ray crystal structure of the *p*-bromo derivative of series **5c** has been published (8). Examples of the linear bicycles of type **2** are not restricted to the six membered ring pyrimidines (**5**). The bistriazene series (**6**) (Chart 2) , which are important and novel derivatives of the rare imidazolidine system, have been obtained from the reaction of diazonium salts with a mixture of formaldehyde and 2-methyl-1,2-propanediamine. The synthesis, characterization and X-ray crystal structure (of **6**, X = CO_2Me) have been published as Part VI of this series (9).

Further examples of imidazolidine-containing molecules of type **2** were found as products of the reaction of diazonium salts with a mixture of formaldehyde and 1,2-cyclohexanediamine. These products have been assigned the structure **7** (Chart 2). The synthesis and characterization of the series **7** has been published (10), and the X-ray structure of the *p*-cyano derivative (**7a**) has been reported (11). The X-ray structure of the second example of this series (**7b**, X = Me) has been published recently (12).

Thus, there seems to be a crossover in behaviour of the alkanediamine going from ethylenediamine to propanediamine and also in the introduction of a branching chain in the ethylenediamine. In the present study, we have extended these reactions with the next further homologue in the diamine series, specifically 1,4-butanediamine, and it is clear that the linear bicyclic molecule of type **2** is formed in preference to the cage structures of type **1**. The products of these

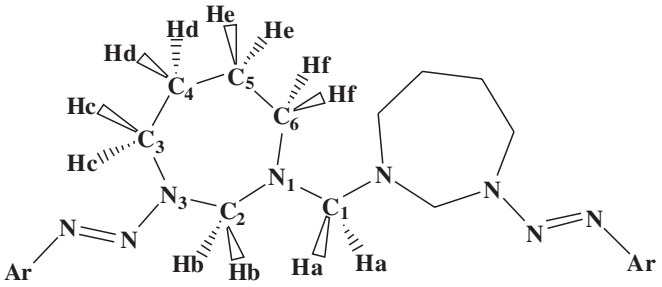
Chart 2.

reactions are seen in Chart 2 (**8a–8n).** In this paper, we report the details of the synthesis of series **8** and their characterization by IR, ^{1}H NMR, and ^{13}C NMR spectroscopy.

Experimental

All reagents were reagent grade materials purchased from the Sigma-Aldrich Chemical Co. Ltd. (Oakville, Ontario) and were used without further purification. Melting points were determined on a Fisher-Johns melting point apparatus and were uncorrected. IR spectra were obtained using Nujol mulls, unless otherwise stated, on a PerkinElmer 299 spectrophotometer or with a Brucker Vector 22 spectrometer. ^{1}H and ^{13}C NMR spectra were obtained using either the Anasazi Instruments 60 MHz EFT spectrometer at Saint Mary's University, or the Bruker 250 MHz spectrophotometer at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University in Halifax, Nova Scotia. Chemical shifts were recorded in $CDCl_3$ or d_6-DMSO solutions at 20 °C, and are relative to TMS as internal standard. Multiplicities are reported as singlet (s), doublet (d), triplet (t), quartet (q), quintet (qu-intet), multiplet (m), and broad (br).

1-Aryl-2-[3-(3-[2-aryl-1-diazenyl]-1,3-diazepan-1-ylmethyl)-1,3-diazepan-1-yl]-1-diazenes (8a–8n)



General procedure

Method A

The appropriate arylamine (0.010 mol) was dissolved in hydrochloric acid (3 mol/L, 40 ml) with heating if necessary to obtain a clear solution. This solution was then cooled in an ice/salt bath. The arylamine hydrochloride solution was diazotized at 0–5 °C with a solution of sodium nitrite (0.011 mol) in water and the resulting mixture was stirred in the cold for 0.5 h. Any insoluble impurities were removed by vacuum filtration. The mixture was brought to pH 7 using a saturated solution of sodium bicarbonate, at which point 37% aqueous formaldehyde solution (5 mL) was added. 1,4-Diaminobutane (0.010 mol) was slowly added to the solution, which was allowed to stir in the cold for a further 0.5 h. Occasionally, a slight precipitate was evident during the period of the addition, but was not removed. The mixture was then adjusted to alkaline pH with additional saturated sodium bicarbonate solution, whereupon the product precipi-

Fig. 1. Proton and carbon labels in **8** for the discussion of NMR assignments.

tated out of solution. Solid precipitates were isolated by vacuum filtration and purified by recrystallization from an appropriate solvent. The oil **8n** was recovered by extraction into dichloromethane (three 20 mL aliquots), dried over anhyd $MgSO_4$, and rotoevaporated under vacuum.

Method B

The procedure of Method A was followed exactly with the exception of the amount of formaldehyde used. A 40:1 molar ratio of formaldehyde–arylamine was used, i.e., approx. 32 mL of 37% aqueous formaldehyde was added at the appropriate time. Application of these procedures afforded compounds **8a–8n**.

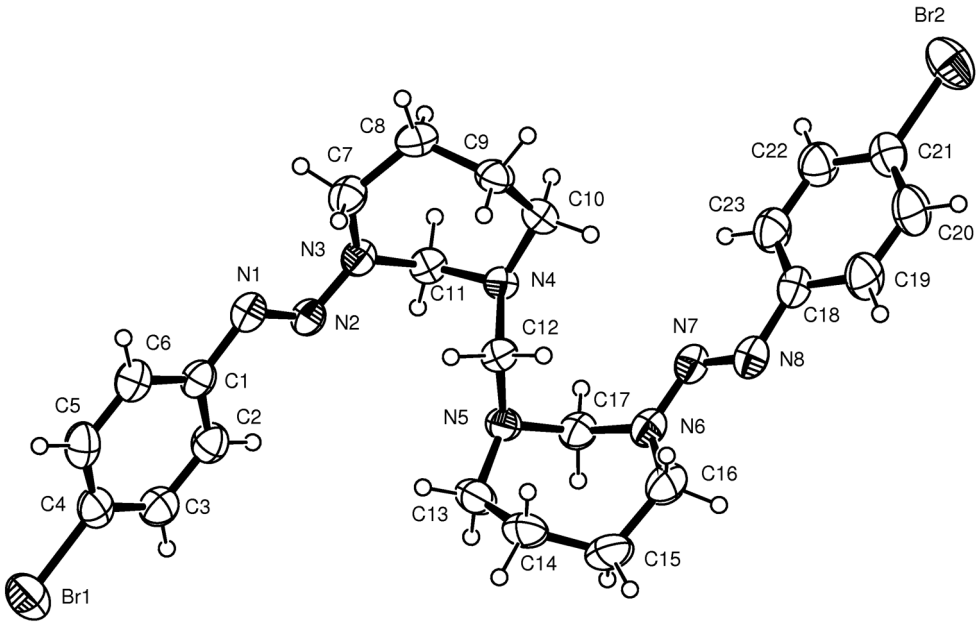
Method A: 18%; oil. IR (cm^{-1}) ν_{max}: 1731 (C=O), 721 (OOP). ^{1}H NMR (60 MHz, $CDCl_3$, ppm): 1.76 (8H, br m, H_d and H_e), 2.90 (4H, br t, J = 4.7 Hz, H_f), 3.32 (2H, br s, H_a), 3.75 (4H, br t, J = 7.5 Hz, H_c), 4.91 (4H, s, H_b), 7.03–7.68 (8H, m, arom.).



Results and discussion

The required diazonium salt, ArN_2^+, was prepared by diazotization of the appropriate arylamine. The diazonium salt solution was then treated with a mixture of formaldehyde and 1,4-diaminobutane ($NH_2(CH_2)_4NH_2$). On the basis of IR and NMR spectroscopic analysis, together with elemental analysis whenever possible, the products of this reaction have been identified unequivocally as the 1-aryl-2-[3-(3-[2-aryl-1-diazenyl]-1,3-diazepan-1-ylmethyl)-1,3-diazepan-1-yl]-1-diazenes (**8a**–**8n**). The connectivity in structure **8** has been established by X-ray crystyallography. The yields of the products are excellent, often in excess of 90%, and the solid products recrystallize in most cases from a mixture of ethanol and ethyl acetate. The pure compounds are generally colourless or pale in colour, crystallizing as needles, prisms, or plates. The IR spectra were recorded mainly to confirm the presence of the particular aryl substituent (X), such as the presence of a carbonyl band in **8c**–**8f** and **8n**, and also to confirm the substitution pattern as ortho or para from the measurements of the OOP bending vibrations.

The ^{1}H NMR spectra of the new bistriazenes are very informative about the structures of these molecules, in particular the presence of two identical 1,3-diazepanyl groups attached to a central methylene group. The detailed structure in Fig. 1 shows the proton labels from H_a to H_e, which is useful to interpret the following discussion. The central methylene group between the heterocyclic rings (H_a) appears universally as a two-proton singlet at ~3.30 ppm, sometimes broadened. The protons (H_b) of the two equivalent methylene groups situated between the N1 and N3 nitrogen atoms of the diazepane rings appear as a four-proton singlet at ~5.0 ppm. The protons (H_c) of the two equivalent *N*-methylene groups of the heterocyclic rings appear at ~3.70–3.80 ppm as a four-proton triplet with coupling constant J_{cd} in the range 5–7 Hz because of the anticipated coupling to the protons of the adjacent methylene group (H_d). Likewise, the protons (H_f) of the other equivalent *N*-methylene groups appear as a four-proton triplet with J_{ef} = ~5.0 Hz because of

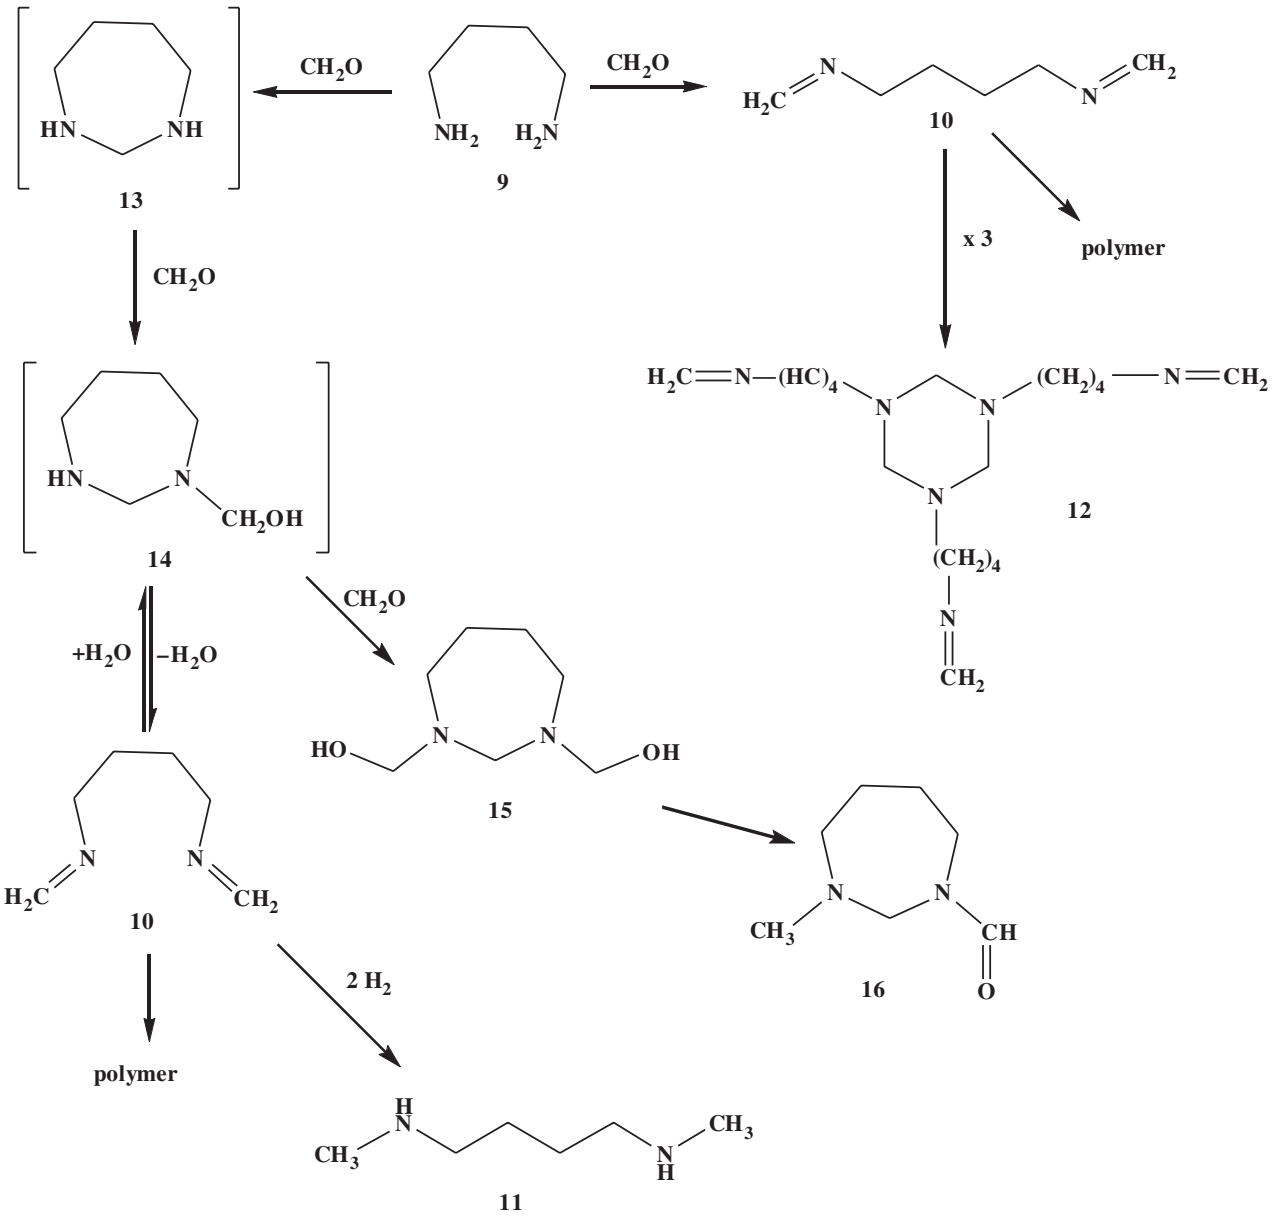
Fig. 2. ORTEP view of 1-(*p*-bromophenyl)-2-[3-{3-[2-(*p*-bromophenyl)-1-diazenyl]-1,3-diazepan-1-ylmethyl}-1,3-diazepan-1-yl]-1-diazene (**8g**) showing the thermal ellipsoids at 40% probability level.

the coupling to H_e. However, the chemical shift of H_f is at a higher field (~2.90 ppm). The proximity of the triazene group to the H_c protons is presumably responsible for this difference. The protons of the other methylene groups of the diazepane rings appear as four-proton multiplets at ~1.6 ppm and 2.0 ppm. Other features of the NMR spectra, such as the AA′BB′ aromatic protons and the proton signals of the aryl substituent (X), are clearly evident.

^{13}C NMR analysis of the series **8a**–**8n** was not possible for all compounds because of the combination of limited solubility and the extreme broadening of carbon signals ubiquitous in triazenes of this type (4). Nevertheless, complete ^{13}C NMR spectral data was acquired for a significant number of these compounds. The assignment of carbon signals is based on the numbering scheme shown in Fig. 1. The carbon of the central methylene group (C1) in **8** is observed at ~64–65 ppm and C2 of the diazepane ring is observed in the narrow range 69.1–69.9 ppm. The assignments of C3, C4, C5, and C6 to the signals at ~53, 28, 25, and 49,respectively, is based on the proximity to the nitrogen atoms N1 and N3, and to the triazene moiety. The ^{13}C NMR data is a strong supporting evidence for the structure **8** assigned to these products.



It should be noted that there is a wide range of stability for the compounds in the series **8a**–**8n**. These stability problems are not new to our experience with similar bistriazenes, such as those of type **5a**–**5c** (4, 7). Several products displayed a limited shelf-life when stored for a couple of years. Samples that were fine powders when fresh are now glass, such as **8d**, **8l**, and **8m**. Others like **8a**–**8c** and **8g** show little if any sign of decay. Compound **8j**, which afforded an X-ray crystallographic structure, is somewhat fickle in this regard. A crude sample that was stored for over two years showed definite signs of decomposition, whereas a purified sample of the same compound showed no sign of decomposition. It is possible that the stability of these bis(aryldiazenyl-1,3-diazepanyl)methanes is prolonged in the crystalline state compared with the amorphous state; however, we have not undertaken a systematic study of this question. This stability problem had a detrimental effect on the results of elemental analysis of several new compounds, which were not universally successful. There is an approximate correlation of the stability of the compounds in this series and either the success or lack of success of elemental analysis. However, elemental analysis of selected compounds in the series **8** did provide further evidence of the assigned structures. Unequivocal evidence of the connectivity of the compounds in series **8** has been obtained from the X-ray crystal structures of three compounds **8a**, **8g,** and **8j**. Full details of the X-ray analysis will be published elsewhere (13)and an ORTEP diagram of the *p*-bromo derivative (**8g**) is shown in Fig. 2.

In consideration of the possible reaction pathways that could be involved in the formation of molecules of type **8**, it is essential to examine the reported work on the reaction of 1,4-diaminobutane with formaldehyde. The earliest work of any consequence is that of Krassig (14), who concluded that the reaction of diaminobutane (**9**) with formaldehyde afforded viscose polymers, described as "poly-bismethylenetetramethylenediamines". He suggested that the initial condensation product (Scheme 1) has structure **10**, which can trimerise to the novel 1,3,5-triazine derivative (**12**). An evidence for the existence of **10** is the isolation and characterization of *N*,*N*′-dimethyl-1,4-diaminobutane (**11**) from the reductive amination of formaldehyde by **9**. Subsequent to Krassig's work, Evans and co-workers (15) investigated the reaction of 1,4-diaminobutane with acetamidine, which resulted in a synthetic method for a variety of substituted diazepines.

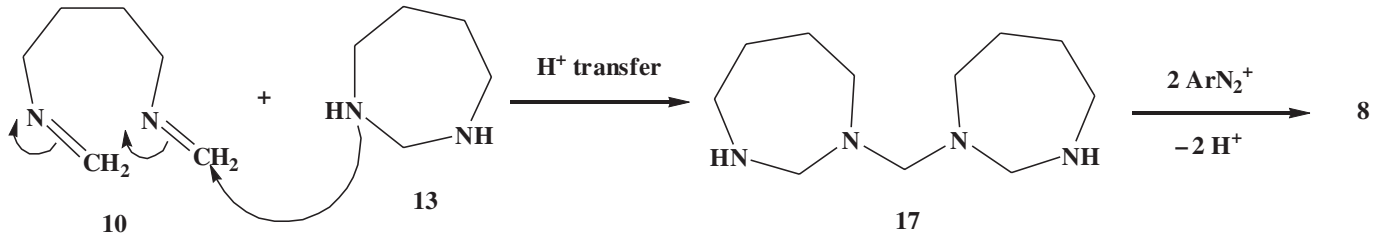
However, the most significant and enlightening work with relevance to the present study is the paper by Dale and Sigvartsen (16). The surprising result in their paper is that the final product after prolonged standing of the reactants is

© 2006 NRC Canada

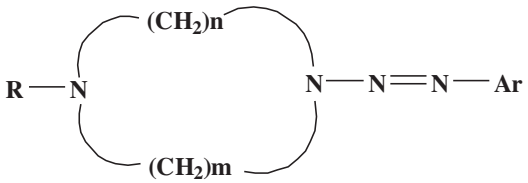
Scheme 1.

the formamide (**16**), together with the initial polymer. They suggest that the formamide (**16**) is produced by the sequence of reactions starting with condensation to give the diazepane (**13**), which can hydroxymethylate to give **14**. This carbinolamine can either: (*i*) dehydrate reversibly to give Krassig's di-imine (**10**), which could be the source of the polymer, or (*ii*) condense further with formaldehyde to give the diol **15**. Cannizzaro-like redox disproportionation of **15** produces the final product **16**.

The work of Dale and Sigvartsen leads to a logical hypothesis (Scheme 2) for the formation of the novel bistriazenes (**8**). Reaction of a molecule of Krassig's diimine (**10**) with a molecule of the diazepane (**13**) affords the bis(1,3-diazepanyl)methane (**17**) by ring-closure dimerization. Reaction of **17** with two equivalents of the diazonium ion followed by deprotonation affords the observed product (**8**).



Conclusion



It appears, from our on-going studies, that the interaction of a diazonium salt with a mixture of formaldehyde and an alkanediamine [$NH_2(CH_2)_nNH_2$] gives rise to two distinct types of oligomer. Bistriazenes of types **3** (2) and **4** (3) are examples of the bridged bicyclic bistriazene, whereas the compounds of series **5** (5, 7) exemplify the linear bicyclic bistriazene. The new compounds of series **8**, reported here, clearly belong to the linear bicyclic class, providing further evidence that there is a crossover in the molecular architecture going from the two-carbon spacer of ethylenediamine to the three- or four-carbon spacer.

This paper is part VII in a series that describes the synthesis of a variety of triazenes and bistriazenes that fit the general classification of 1-aryldiazenyl-(1,x)-diazacycloalkanes described by the general structure **18**, where m = 1 or 2 and

Scheme 2.

18

n = 2, 3, 4 or 5. Previously, we reported new triazenes derived from imidazolidine (m = 1, n = 2) (9, 10), hexahydropyrimidine (m = 1, n = 3) (4), piperazine (m = n = 2) (17, 18), and homopiperazine (m = 2, n = 3) (19). The new diazepanes of series **8** fit to the general structure **18**, where m = 1 and n = 4. Future work in this field of chemistry will endeavour to further extend the family of (1,x)-diazacycloalkanes.

In situ nitrosonium ion generation — α-Oximinylation of enol ethers from steroidal spiroketals: Introduction of C23 (*R*)-OH in cephalostatin intermediates[1]

Seongmin Lee and Philip L. Fuchs

Abstract: Nitrosonium ion generated in situ from the reaction of *t*-$BuNO_2$ and $BF_3{\cdot}Et_2$ is an effective oximinylating agent for enol ethers derived from steroidal spiroketals. The scope and limitations of this method has been studied. The difficult reduction of C23 ketone to C23 (*R*)-alcohol has now been selectively achieved via L-Selectride® reduction. Application to cephalostatin intermediates is discussed.

Key words: oximinylation, nitrosonium ion, steroid spiroketal, cephalostatins.

Résumé : L'ion nitrosonium généré in situ par réaction du *t*-$BuNO_2$ avec le $BF_3{\cdot}OEt_2$ est un agent d'oximinylation efficace pour les éthers énoliques dérivés de spirocétals stéroïdaux. On a étudié la portée et les limitations de cette méthode. Faisant appel à une réduction à l'aide de L-Selectride®, on a maintenant réalisé la difficile réduction stéréosélective de la cétone C23 en alcool-(*R*) C23. On discute de l'application à des intermédiaires de la céphalostatine.

Mots clés : oximinylation, ion nitrosonium, spirocétal stéroïdal, céphalostatines.

[Traduit par la Rédaction]

Introduction

The 45 members of the cephalostatin and ritterazine family, along with analogs, afford the basis for elucidating some of the structure–activity relationships (SAR) of these potent cytotoxins (1). All members of the cephalostatin family possess two steroidal spiroketals connected by a pyrazine. The most active compounds bear a highly oxygenated north unit and a substantially less polar south unit. In terms of bioactivity, cephalostatin **1** (Fig. 1) shows average 1 nmol/L GI_{50}s in 2 day tests in the NCI 60-line screen and 10^{-14} mol/L GI_{50}s in 6day tests in the Purdue 6 line minipanel (2). Cephalostatin **1**, cephalostatin **7**, ritterazine **M**, and ritterazine **K** have been synthesized by our group (3), while we and others (4) have also been active in the synthesis and testing of analogs.

The mechanism of action of the cephalostatins and ritterazines is currently unknown, although recent data indicates that ritterazine **B** is an apoptotic agent like OSW-1 (5) and cephalostatin **7** (6). The role of spiroketals and sugars as hydrogen bond donors and (or) acceptors has been suggested (7). Although it is evident from the NIH 60-cell line COMPARE studies that cephalostatin 1 and OSW-1 are related, significant biological differences[3] and recent bioactivity data of C22 deoxy OSW-**1** analogs (8) suggest that they may have a modified mechanism of action. Correlation of cytotoxicity with energy for E-ring oxacarbenium ion access in cephalostatins and ritterazines has been proposed (9). SAR studies indicate that the hydroxyl groups of both north and south units of the cephalostatin family play an essential role in tumor eradication. Hydroxyl groups provide "polarity match" (10), a requirement for the exhibition of bioactivity, and affect the heat of formation of the E-ring oxacarbenium ion,[4] thus adjusting bioactivity. When the C17 alcohol, for instance, in the north unit of cephalostatin **1** was replaced by a hydrogen, the antitumor activity dropped dramatically.[5] The presence of the C23 hydroxyl group also contributes to the anticancer activity. The recently synthesized C23′-deoxy cephalostatin **1**(11) is about 10 times less potent than cephalostatin **1**.

Our second generation synthesis of cephalostatin **1** (**4**) uses a "redox" strategy(12), requiring a scalable protocol ca-

pable of efficient introduction of the C23 (*R*)-alcohol (Scheme 1). Eighteen of nineteen known cephalostatins possess the north C23 (*R*)-alcohol and seventeen of those bear the south C23 (*R*)-alcohol (Fig. 1).

Many efforts have been made to introduce the C23 (*R*)-alcohol (13), such as the reduction of the C23 carbonyl group (14), sulfinylation of a C22,C23 enol ether with TFAA-activated DMSO followed by allylic rearrangement (15), and addition of allyl stannane to an aldehyde (16). However, none of these methods provided the requisite C23 (*R*)-alcohol in workable excess (de < 30%). At present, the only acceptable method is the dimethyldioxirane (DMDO) oxidation of an enone – vinyl ether to quantitatively achieve stereospecific cyclization to the prized (*R*)-alcohol. However, this method employs 750 mL of DMDO for the production of 15.7 g of C23 alcohol (17) and also requires the use of stoichiometric amounts of toxic selenium and stannyl reagents to prepare **2**. Herein, we describe a scalable pathway leading to C23 (*R*)-OH.

Results and discussion

The known methods for α-oxidation of ketones, enols, and spiroketals (Scheme 2) were initially surveyed to access the desired C23 ketone **7**. We first attempted the synthesis of a masked C23 ketone, such as nitroimine 5 or oxime 6. Although Suàrez and co-workers (18) recently demonstrated that the C14,C15-saturated spiroketal forms the nitroimine in acceptable yield, our attempts to use this procedure on substrate **1** only afforded the C23 nitroimine **5** in very low yield. We also investigated S_N2 chemistry with equatorial C23 bromide **8** and iodide **9**, prepared from **1** with phenyltrimethylammonium bromide (PTAB) or iodine monochloride, respectively. Unfortunately, numerous reagents that convert alkyl halides to alkoxy groups, including superoxide (19), KNO_2 (20), O_2–Bu_3SnH (21), $AgBF_4$–glyme–H_2O (22), AgOAc (23), and CsF–BzOH (24), were either unreactive or severely destructive.

The known methods for α-oximinylation of ketones were not applicable to our substrate (25). Thus, we were delighted that the formation of the desired oxime spiroketal **12** took place smoothly from the reaction of rockogenin diacetate **11** with *t*-$BuNO_2$ and $BF_3{\cdot}Et_2$. Optimization of this new procedure is summarized in Table 1. The choice of Lewis acid is critical for this event, as $BF_3{\cdot}Et_2$ gave the best yields while $FeCl_3$, $TiCl_4$, $SnCl_4$, $ZnBr_2$, $Sc(OTf)_3$, and TMSOTf failed to give reasonable conversions, probably because of their decreased oxophilic character relative to $BF_3{\cdot}OEt_2$.

Minimization of undesired lactone **13**, which comes from oxime spiroketal **12**, requires using excess *t*-BuONO (5 equiv.) and catalytic $BF_3{\cdot}OEt_2$ (0.5 equiv.) in acetic acid at ambient temperature for the minimum time. The use of less *t*-BuONO (Table 1, entries 1–5 and 7) and $BF_3{\cdot}Et_2$ (Table 1, entry 11), solvents other than AcOH (Table 1, entries 1, 3, and 4), lower temperature (Table 1, entry 2), or prolonged reaction time (Table 1, entry 10) results in the formation of significant amounts of lactone **13**.

The proposed mechanism of oximinylation involves nitrosonium ion (26) mediated nitrosylation of the enol ether **11a** formed via Lewis acid opening of the steroid spiroketal (Scheme 3). First, nitrosonium ion ($NO^+BF_4^-$) is generated in situ from a reaction of *t*-$BuNO_2$ and $BF_3{\cdot}OEt_2$. Then, the attack of enol ether **11a** on the nitrogen atom of nitrosonium ion takes place to produce nitroso spiroketal **12a**. Finally, the nitroso spiroketal **12a** is rapidly isomerized to give oxime spiroketal **12**. The presence of a $NOBF_4$ (–141.6 ppm, CD_3CN) peak in the ^{19}F NMR supports this mechanism. The reaction of spiroketal **11** with 3 equiv. of commercial $NOBF_4$ (Table 1, entry 19) in acetic acid affords the same

oxime spiroketal **12** in 82% yield after 10 min, thus exhibiting similar reactivity and product distribution pattern to that observed in the reaction of spiroketal **11** with $BF_3{\cdot}Et_2$ and *t*-BuONO (Table 1, entry 16). The Lewis acid promoted second-order Beckmann fragmentation (27) of α-oxygenated oxime spiroketal **12** appears to account for the formation of lactone **13**. The scope and limitation of the oximinylation of steroid spiroketals was then explored.[6] The results in Table 2 reveal some interesting features. First, C23 oximinylation works for only 5/6 spiroketals, not for 5/5 and 6/5 spiro systems, such as **21** and **22**. Hecogenin acetate (starting material for **15**) containing a C12 ketone, which is diffi-

cult to enolize, smoothly gave oxime spiroketal **15**. The presence of more readily enolized C3 ketone resulted in low yield of **14** because of the formation of by-products. It is notable that olefin moieties (**6** and **22**) are intact under the reaction conditions. Alcohol functionality was converted to nitrite **16a**. Most importantly, employing the new protocol, we were able to obtain a key intermediate (5/6 spiroketal **6**) in reasonable yield.

C23 ketones **23** and **7** were readily prepared by *p*-toluenesulfonic acid catalyzed deoximinylation. We next turned our attention to establishing the requisite C23 (*R*) stereochemistry (Table 3). In the case of C14,C15-saturated C23 ketone **23**, (*S*)-CBS best effected the desired reduction to afford C23 (*R*) and C23 (*S*) in a reproducible ratio of 6.2:1[7] (Table 3, entry 8, C23 (*R*) (78%) and C23 (*S*) (13%), isolated yield, 50 mmol scale; previous results (28) show formation of C23 (*R*) and C23 (*S*) in a ratio of 1.7:1 (72%)). We were pleased that the L-Selectride® reduction of C14,C15-unsaturated ketone **7** (Table 3, entry 9) delivered C23 axial alcohol **2** in a highly sterereoselective fashion.

In conclusion, an efficient and economical in situ method to generate nitrosonium fluoroborate is presented. This chemistry provides a large-scale pathway for the establishment of the C23 (*R*) stereochemistry of steroidal sapogenins. Further research is ongoing regarding the application of this method for the synthesis of the north unit of cephalostatin **1**.

Preparation of enantiopure long chain *threo*-2-amino-3-hydroxyesters via chiral morpholinone-derived azomethine ylids[1]

Victoria A. Brome, Laurence M. Harwood, and Helen M.I. Osborn

Abstract: The synthetic approach to *threo*-2-amino-3-hydroxyesters possessing long alkyl chains outlined herein centres on the generation of chiral azomethine ylids by reaction of (5*R*)-5-phenyl-morpholin-2-one, (*R*)-(**1**), with long chain aldehydes. In the presence of a second equivalent of aldehyde, the azomethine ylid can be trapped to afford a cycloadduct with three new stereodefined centres. Degradation of the cycloadduct allows entry to β-substituted-α-amino acid derivatives, which have potential as building blocks for sphingosine synthesis.

Key words: sphingosine, morpholinone, chiral azomethine ylid, dipolar cycloaddition.

Résumé : On a mis au point une approche à la synthèse de *thréo*-2-amino-3-hydroxyesters d'acides à longues chaînes alkyles qui est centrée sur la génération d'ylures d'azométhines chiraux par la réaction de la (5*R*)-5-phénylmorpholin-2-one, (*R*)-(**1**) avec des aldéhydes à longues chaînes. En présence d'un deuxième équivalent d'aldéhyde, l'ylure d'azométhine peut être piégé pour conduire à la formation d'un cycloadduit comportant trois nouveaux centres stéréodéfinis. La dégradation du cycloadduit permet d'obtenir des dérivés d'acides α-aminés et β-substitués qui peuvent servir de blocs dans la synthèse de sphingosines.

Mots clés : sphingosine, morpholinone, ylure d'azométhine chiral, cycloaddition dipolaire.

[Traduit par la Rédaction]

Introduction

Glycosphingolipids have been isolated from a variety of natural sources, including marine sponge species of *Agelas* and *Axinella* (1, 2). Such compounds demonstrate interesting immunostimulatory activity, for example, the modulation of protein kinase C activities and the regulation of hormone receptors and nerve cells (3). The glycosphingolipid structure may be considered in two parts, namely, a sphingosine-related component and a carbohydrate component (Fig. 1). Generally, throughout the literature, the syntheses of the two constituent units are considered independently.

Developments in the synthesis of the sphingolipid moiety and its analogues have been recently reviewed (4), and since the first nonstere ocontrolled synthesis of sphinganine by Grob and Gadient (5), synthetic strategies have frequently utilized various carbohydrate precursors (6) or serine-derived building blocks for accessing this family of compounds (7).

The sphingosines can be looked upon as 3-hydroxy-2-amino acid derivatives, and detailed examples of enantio- and stereo-selective syntheses of β-hydroxy-α-amino acids have been reviewed by Duthaler (8). Drawing on the findings of Dellaria and Santarsiero's investigation into the alkylation of chiral glycine synthon equivalents in α-amino acid synthesis (9), much work carried out within our group has focused on the use of (*R*)- and (*S*)-5-phenyl-3,4,5,6-tetrahydro-2*H*-1,4-oxazin-2-one (**1**) (referred to herein as 5-phenylmorpholin-2-one) as a chiral relay system and its use as a chiral template in the area of α-amino acid synthesis (10). During the cycloaddition studies in which the ylid was generated using paraformaldehyde, a minor product was sometimes obtained, which neither corresponded to any of the possible cycloadducts nor the diketopiperizine resulting from dimerization of the template. Spectroscopic evidence pointed to the minor product being **2a**, a result of trapping the azomethine ylid by a second equivalent of formaldehyde. Confirmation that this was indeed the case was obtained when reaction between the (*S*)-morpholin-2-one template and excess paraformaldehyde yielded **2a** in essentially quantitative yield. As the trapping of the azomethine ylid with a second equivalent of aldehyde does not compete efficiently with electron deficient alkenes and alkynes, it was concluded that the rate of this reaction is appreciably slower than with carbon–carbon dipolarophiles. When aldehydes other than paraformaldehyde were used, a single adduct was observed in every case, and these adducts (**2b**–**2g**) could be deconstructed to liberate enantiomerically pure *threo*-β-hydroxy-α-

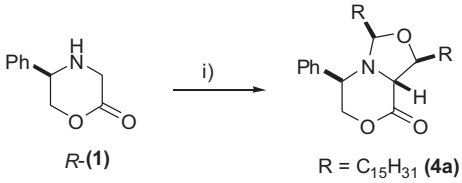
Results and discussion



To extend this methodology to allow preparation of long chain hydroxyamino acids, which could act as precursors to sphingosine analogues, preliminary investigations focused on hexadecanal as a representative substrate, in terms of alkyl chain length. Following our previous protocol, 3 equiv. of the aldehyde were added to (5*R*)-5-phenylmorpholin-2-one ((*R*)-(**1**)) (i.e., 6 mmol aldehyde : 1 mmol (*R*)-(**1**)) in toluene and the mixture was heated to reflux for 48 h, after which time, TLC analysis indicated that all of the morpholinone had been consumed. As the hexadecanal proved to be far less polar than previous aldehydes employed in this reaction, the eluent chosen for chromatographic purification had to reflect this; a system of 19:1 petroleum – diethyl ether proving the most efficient. Unfortunately, only low yields (18%) of pure cycloadduct (**4a**) were isolated under these conditions, with much of the remaining product being contaminated with residual hexadecanal. NOE investigations of cycloadduct **4a** failed to determine conclusively the stereochemistry of the adduct, the very large signal representing the aliphatic protons masking important regions in the ^1H NMR spectrum. Additionally, the pure product was isolated as a waxy solid, which was unsuitable for X-ray analysis. However, as ^1H NMR data were in agreement with those of cycloadducts **2e**–**2f**, derived from lower homologue aliphatic aldehydes (12), the hexadecanal-derived cycloadduct was tentatively assigned as **4a** (Scheme 3). It was clear that use of excess aldehyde in the cycloaddition reaction was not only wasteful but was also hampering isolation and purification of the desired product. The reaction conditions were therefore examined with the objective of achieving higher yields of the pure hexadecanal-derived cycloadduct. To this end, the number of equivalents of hexadecanal to (5*R*)-5-phenylmorpholin-2-one was reduced from 3.0 to 1.5, the rationale being that reduced aldehyde contamination of the crude product could simplify isolation of the cycloadduct. TLC analysis of the reaction mixture after 72 h indicated that the starting material had been almost completely consumed and the crude reaction mixture was therefore purified, resulting in the isolation of 34% of pure cycloadduct. Further reduction to 1.1 equiv. of aldehyde required a reaction time of 5 days before all starting morpholinone had been consumed, but this resulted in a greatly improved yield of 65% of pure cycloadduct (**4a**) after a single purification (Table 1).

Thus, although reducing the number of equivalents of aldehyde in the reaction mixture necessitated an increase in

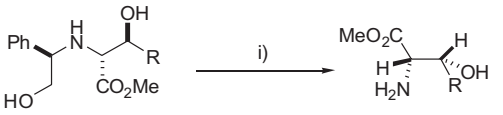
reaction time, it resulted in a greater than three-fold increase in yield and involved less wastage of aldehyde.



With the procedure for preparing the hexadecanal-derived cycloadduct optimized, a range of analogues derived from aldehydes with chain lengths between 14 and 18 carbon atoms was synthesized, utilizing 1.1 equiv. of aldehyde. In each case a single cycloadduct (**4b**–**4e**) was isolated in an acceptable yield after purification by column chromatography (Table 2).

The subsequent step of the synthesis was the opening of the cycloadduct to afford the corresponding amino esters (**5a**–**5e**). The two-step hydrolysis and hydrogenolysis sequence, previously shown to be the optimal procedure for aliphatic aldehyde-derived cycloadducts, was adopted. Previously, the hydrolysis had been carried out in methanol at reflux using 1 mol/L hydrochloric acid to release the amino ester, but when applied to the hexadecanal-derived cycloadduct (**4a**), the conditions failed to effect hydrolysis, leaving the starting material intact. It was observed that the starting material was only sparingly soluble in aqueous methanol at room temperature but was more soluble in hot methanol. Thus, the effect of the addition of 5 mol/L hydrochloric acid to a hot methanolic solution of the cycloadduct was investigated, and this furnished the corresponding methyl ester in 1 h. In the first instance, the lactone-opened products **5a**–**5e** were isolated for characterization purposes and were obtained in moderate to good yield (Scheme 4, Table 3). These derivatives were solids, as opposed to the oils obtained when using the lower homologue aldehydes. The proposed structure for the hexadecanal-derived methyl ester **5a**, (a representative example) was supported by characteristic ^{1}H NMR data, which displayed a multiplet at 7.30 ppm representing the five aromatic protons; a one proton doublet at 3.17 ppm corresponding to the proton α to the amino group and a one proton multiplet at 3.75–3.68 ppm for the methane proton α to the hydroxyl functionality. A set of overlapping multiplets, integrating to 30 protons, due to the aliphatic hydrogens of the long alkyl chain, dominated the spectrum.

Table 4. Hydrogenolysis of the methyl esters (**5a**–**5e**).

Methyl ester precursor (**5**)	Yield of (**hydroxyamino ester**) (**6**) %
5a	53 (**6a**)
5b	60 (**6b**)
5c	54 (**6c**)
5d	66 (**6d**)
5e	69 (**6e**)

Following the previously developed reaction protocol (11*b*), it was envisaged that the crude hydrolysis reaction mixture would be concentrated and subjected directly to hydrogenolysis at 5 bar (1 bar = 100 kPa) using Pearlman's catalyst and TFA in methanol. The first complication encountered was the insolubility of the crude reaction mixture in methanol. Therefore, to aid solubility, a 10:1 ratio of methanol to ethyl acetate was used. Continuing with the standardized conditions, the amino ester was subjected to hydrogenolysis, but after 48 h there was no evidence of reaction. Gratifyingly, when the hydrolysis products (**5a**–**5e**) were purified by column chromatography prior to hydrogenation, the reactions proceeded efficiently. Presumably, components of the crude reaction mixtures were poisoning the catalyst. A further deviation from the original method when applied to the longer aliphatic chain analogues was the final purification procedure. The original method (11*b*) used ion exchange chromatography to afford the free amino acids as colourless solids in near quantitative yields, but the hexadecanal analogue could not be treated in the same way, as the hydrogenolysis product was insoluble in water, and so more conventional silica gel chromatography was implemented. As a result, the final product was isolated as the methyl ester **6a** (Scheme 5), as opposed to the free β-hydroxy-α-amino acid. In this way, all the long chain hydroxyamino esters (**6a**–**6e**) could be isolated in pure form and in acceptable yields (Table 4). In all cases, detailed

Scheme 6. Reagents and conditions: (*i*) *p*-TsCl, imidazole, DMAP, DCM, 43%; (*ii*) $LiBH_4$, THF, rt, 74%.

spectroscopic analysis showed these final products to be homogeneous with a resonance for the proton α- to the amino group, appearing as a doublet between 3.52 and 3.45 ppm, corresponding to the equivalent proton in the pentanal-derived material (3.45 ppm).

In a further illustrative extension of how these long chain hydroxyamino esters could be converted into *N*-protected sphingosine analogues, **6c** was *N*-tosylated to yield **7** in 43% isolated yield, and this was subsequently reduced to diol **8** in 74% yield using lithium borohydride in THF (Scheme 6).

Conclusions

In conclusion, we have developed protocols in which long chain aliphatic aldehydes will undergo 1,3-dipolar cycloadditions with (5*R*)-5-phenyl-morpholin-2-one to furnish cycloadducts containing three newly defined stereocentres in good yield. Degradation of these cycloadducts affords diastereomerically and enantiomerically pure β-substituted-α-amino acid derivatives, and further modification can furnish sphingosine analogues suitable for coupling to appropriate carbohydrate donors.

Experimental section

General techniques

^{1}H NMR spectra were recorded on either a Bruker AMX 400 NMR (400 MHz) or a Bruker DPX 250 (250 MHz) spectrometer in chloroform-*d* or dimethyl sulfoxide-*d* and referenced to the residual solvent residual proton. Signal positions were recorded in δ ppm with the abbreviations s, d, t, q, quint., br, and m denoting singlet, doublet, triplet, quartet, quintet, broad, and multiplet, respectively. ^{13}C NMR spectra were recorded on the same spectrometers listed above at either 100 or 62.5 MHz, respectively, and were referenced to chloroform-*d* or dimethyl sulfoxide-*d*. All NMR chemical shifts are quoted in ppm.

Infrared spectra were recorded on a PerkinElmer 1720-X. Spectra were analysed as either thin films between sodium chloride plates or as potassium bromide disks.

Mass spectra (*m*/*z*) and accurate mass (HR-MS) were recorded under conditions of electron impact (EI) or chemical ionization using ammonia as the ionizing source (CI). The instrument used was a Fisons VG Autospec mass spectrometer.

Specific rotations ($[\alpha]^{20}_D$) were recorded using the sodium D line (589.3 nm) in the appropriate solvent and are quoted in 10^{-1} deg cm^2 g^{-1}. Solution conentrations are given in the units g 100 mL^{-1}. Readings were measured using a PerkinElmer 341 polarimeter.

Melting points were obtained using a Reichert Kofler heated-stage microscope and are uncorrected. Flash column chromatography was performed according to the method of Still (13) with silica gel 60 (Merck 9385) using head pressure by the means of hand bellows. TLC analyses were carried out using 0.25 mm silica gel precoated aluminium or glass-backed plates with fluorescent indicator UV_{254}. Spots were visualized either by the quenching of UV fluorescence or by staining with an acidic ammonium heptamolydate solution.

Reagents obtained from Acros Organics (Loughborough, UK), Aldrich (Gillingham, UK), Avocado (Heysham, UK), Fluka (Gillingham, UK), and Lancaster fine chemicals (Morecombe, UK) suppliers were used directly as supplied or following purification according to standard procedures. Acetonitrile and dichloromethane were dried by distillation from calcium hydride under nitrogen. Tetrahydrofuran was dried by distillation from sodium-benzophenone ketyl under nitrogen. Petrol refers to light petroleum ether in the boiling point range 30–40 °C, which was fractionally distilled through a Vigreux column prior to use. (5*R*)-5-Phenylmorpholin-2-one was synthesized according to the literature procedure (9). The long chain aldehydes were obtained in quantitative yield from the corresponding commercially available alcohols by oxidation using 4-methylmorpholine-*N*-oxide (1.5 equiv.) and tetra-*n*-propylammonium perruthenate (5 mol%) in dichlorormethane at room temperature in the presence of 4A molecular sieves (14).

General method for preparation of cycloadducts (4a–4e)

The requisite aldehyde (2.2 mmol, 1.1 equiv.) was added to a solution of (5*R*)-5-phenylmorpholin-2-one ((*R*)-(**1**), 1.0 mmol, 1 equiv.) in anhydrous toluene (40 cm^3). The flask was fitted with a magnetic stir.bar, a Soxhlet extractor containing 4A molecular sieves, and a condenser. The reaction mixture was heated to reflux under nitrogen for 5 d. The solvent was removed in *vacuo*, and the resulting pale yellow oil was subjected to column chromatography (diethyl ether – petroleum ether, 1:19) to yield the corresponding cycloadduct.

General procedure for the preparation of amino esters (5a–5e)

Cycloadduct **4** (100 mg) was dissolved in methanol (4 cm^3), and 5 mol/L of hydrochloric acid (1 cm^3) was added. The reaction mixture was heated to reflux and left to stir under nitrogen for 2 h. Saturated sodium carbonate solution (5 cm^3) was added, and the aqueous layer separated and extracted with ethyl acetate (5 × 5 cm^3). The organic phases were combined, washed with brine, dried ($MgSO_4$), filtered, and the excess solvent removed in *vacuo* to give a yellow oil, which was subjected to column chromatography (eluent petrol – diethyl ether, 4:1, then 10% methanol) to afford the corresponding amino ester.

Methyl (2R,3S,1′R)-(2N-2′-hydroxy-1′-phenylethylamino)-3-hydroxyoctadecanoate (5a)

*Methyl (2**R**,3**S**,1′**R**)-(2**N**-2′-hydroxy-1′-phenylethylamino)-3-hydroxyicosanoate (5e)*

Yield 56%; colourless solid; mp 59–61 °C. $[\alpha]^{20}_D$ –23.8 (*c* 1.0, $CHCl_3$). IR ($CHCl_3$, cm^1) ν_{max}: 3315 (O-H), 2920 (Ar–H), 2850 (C–H), 1740 (C=O). ^{1}H NMR (250 MHz, MeOD) δ: 0.80 (3H, t, *J* = 6.2, alkyl CH_3), 1.19–1.36 (30H, m, alkyl CH_2), 3.07 (1H, d, *J* = 5.9, $CHCO_2CH_3$), 3.26 (3H, s, CO_2CH_3), 3.48–3.51 (3H, m, CH_2OH and PhC*H*), 3.56–3.62 (1H, m, C*H*OH), 7.13–7.20 (5H, m, Ph-H). ^{13}C NMR (60 MHz, MeOD) δ: 14.9 (alkyl CH_3), 24.2, 27.1, 30.9, 31.0, 31.1, 31.2, 33.5, 35.2 (alkyl CH_2), 52.5 (CO_2CH_3), 67.2, 67.3 ($CHCO_2CH_3$ and *C*HOH), 68.1 (CH_2OH), 74.0 (Ph*C*H), 129.1, 129.4, 129.8, 142.4 (Ar–C), 176.1 (C=O). CI-MS *m/z* (%): 460 ([MH]$^+$-H_2O, 12), 428 (76), 268 (16), 216 (25), 178 (100), 104 (37). HR-MS calcd. for $C_{29}H_{50}O_3N$ ([MH]$^+$-H_2O): 460.3790; found: 460.3799.

General method for the preparation of long chain amino acid methyl esters (6a–6e)

Amino ester (1 equiv.) was dissolved in methanol, and water (10:1) and Pearlman's catalyst were added (weight for weight of amino ester) followed by the addition of trifluoroacetic acid (1 equiv.). The system was degassed and hydrogen introduced. The system was once again degassed and hydrogen re-introduced. The reaction mixture was warmed to 50 °C and left to stir for 16 h. The hydrogen was released, and the reaction mixture filtered through Celite® and the filtrate concentrated in *vacuo*. The residue was subjected to column chromatography (eluent petrol – diethyl ether, 1:1, then 10% methanol) to afford the amino acid methyl ester.

*Methyl (2**R**,3**S**)-2-amino-3-hydroxyoctadecanoate (6a)*

Yield 53%; colourless solid; mp 74–76.5 °C. $[\alpha]^{20}_D$ –10.5 (*c* 1.0, $CHCl_3$). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3355 (N–H), 3130 (O–H), 2915, 2840 (C–H), 1720 (C=O). ^{1}H NMR (250 MHz, D_6 acetone) δ: 0.82 (3H, t, *J* = 6.4 alkyl CH_3), 1.19–1.38 (28H, m, alkyl CH_2), 3.45 (1H, d, *J* = $CHNH_2$), 3.53 (3H, s, $COOCH_3$), 3.62–3.74 (1H, m, C*H*OH). ^{13}C NMR (60 MHz, D_6 acetone) δ: 14.8 (alkyl CH_3), 23.7, 27.3, 29.3, 33.0, 36.2 (alkyl CH_2), 52.9 ($COOCH_3$), 66.2 ($CHNH_2$), 81.5 (*C*HOH), 173.7 (C=O).

*Methyl (2**R**,3**S**)-2-amino-3-hydroxyhexadecanoate (6b)*

Yield 60%; colourless solid; mp 61–63 °C. $[\alpha]^{20}_D$ –14.3 (*c* 1.0, $CHCl_3$). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3345 (O–H), 2920, 2850 (C–H), 1680 (C=O). ^{13}C NMR (250 MHz, D_6 acetone) δ: 0.75 (3H, t, *J* = 6.5, alkyl CH_3, 1.16–1.40 (24H, m, alkyl CH_2), 3.52 (1H, d, *J* = 7.7, $CHNH_2$), 3.60 (3H, s, CO_2CH_3), 3.64–3.72 (1H, m, C*H*OH). ^{13}C NMR (60 MHz, D_6 acetone) δ: 14.8 (alkyl CH_3), 23.7, 27.3, 29.3, 31.1, 33.0, 36.2 (alkyl CH_2),52.9 ($COOCH_3$), 66.1 ($CHNH_2$), 81.5 (*C*HOH), 173.5 (C=O). CI-MS *m/z* (%): 302 ([MH]$^+$, 89), 242 (10), 89 (100). HR-MS calcd. for $C_{17}H_{36}O_3N$ ([MH]$^+$): 302.2695; found: 302.2708.

*Methyl (2**R**,3**S**)-2-amino-3-hydroxyheptadecanoate (6c)*

Yield 54%; colourless solid; mp 75–77.5 °C. $[\alpha]^{20}_D$ –16.8 (*c* 1.0, $CHCl_3$). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3135 (O–H), 2915, 2845 (C–H), 1735 (C=O). ^{1}H NMR (250 MHz, D_6 acetone) δ: 0.75 (3H, t, *J* = 6.4, alkyl CH_3), 1.25–1.45 (26H, m, alkyl CH_2), 3.48 (1H, d, *J* = 7.7, $CHNH_2$), 3.57 (3H, s, $COOCH_3$), 3.59–3.70 (1H, m, C*H*OH). ^{13}C NMR (60 MHz, D_6 acetone) δ: 14.8 (alkyl CH_3), 23.7, 27.3, 28.2, 33.0, 36.3 (alkyl *C*H), 52.8 ($COOCH_3$), 66.4 ($CHNH_2$), 81.7 (*C*HOH), 173.6 (C=O). CI-MS *m/z* (%): 316 ([MH]$^+$, 100), 256 (10), 89 (50). HR-MS calcd. for $C_{18}H_{38}O_3N$ ([MH]$^+$): 316.2852; found: 316.2847.

*Methyl (2**R**,3**S**)-2-amino-3-hydroxynonadecanoate (6d)*

Yield 66%; colourless solid; mp 84–86.5 °C. $[\alpha]^{20}_D$ –6.1 (*c* 1.0, $CHCl_3$). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3130 (O–H), 1720 (C=O). ^{1}H NMR (250 MHz, acetone) δ: 0.75 (3H, t, *J* = 6.2, alkyl CH_3), 1.24–1.53 (30H, m, alkyl CH_2), 2.76 (3H, br s, NH_2 and O*H*), 3.47 (1H, d, *J* = 7.7, $CHNH_2$), 3.62 (3H, s, $COOCH_3$), 3.63–3.67 (1H, m, C*H*OH). ^{13}C NMR (60 MHz, D_6 acetone) δ: 14.7 (alkyl CH_3), 23.7, 27.3, 33.0, 36.3 (alkyl CH_2), 52.8 ($COOCH_3$), 66.3 ($CHNH_2$), 81.6 (*C*HOH), 173.6 (C=O). CI-MS *m/z* (%): 326 ([MH]$^+$-H_2O, 69), 266 (18), 115 (100), 82 (13), 56 (25). HR-MS calcd. for $C_{20}H_{39}O_2N$ ([MH]$^+$-H_2O): 326.3059; found: 326.3043.

*Methyl (2**R**,3**S**)-2-amino-3-hydroxyicosanoate (6e)*

Yield 69%; colourless solid; mp 86 to 87 °C. $[\alpha]^{20}_D$ –7.1 (*c* 1.0, $CHCl_3$). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3140 (O–H), 2915, 2845 (C–H), 1720 (C=O). ^{1}H NMR (250 MHz, D_6 acetone) δ: 0.75 (3H, t, *J* = 6.2, alkyl CH_3), 1.28–1.54 (32H, m, alkyl CH_2), 2.76 (3H, br s, NH_2 and O*H*), 3.47 (1H, d, *J* = 7.7, $CHNH_2$), 3.59 (3H, s, $COOCH_3$), 3.62–3.65 (1H, m, C*H*OH). ^{13}C NMR (60 MHz, D_6 acetone) δ: 14.8 (alkyl CH_3), 23.7, 27.3, 33.0, 36.3 (alkyl CH_2), 52.8 ($COOCH_3$), 66.3 ($CHNH_2$), 81.6 (*C*HOH), 173.6 (C=O). CI-MS *m/z* (%): 358 ([MH]$^+$, 26), 90 (100). HR-MS calcd. for $C_{21}H_{44}NO_3$ ([MH]$^+$): 358.3321; found: 358.3313.

Methyl (2*R*,3*S*)-3-hydroxy-2-(toluenesulfonylamino)heptadecanoate (7)

Amino ester **6c** (74 mg, 0.0.23 mmol) was dissolved in anhydrous dichloromethane (5 cm^3), and freshly recrystallized *p*-toluenesulfonyl chloride (45 mg, 0.23 mmol, 1 equiv.) was added followed by dimethylaminopyridine (2 drops). The reaction mixture was left to stir under an atmosphere of nitrogen for 16 h. Water was added (5 cm^3), the organic layer was separated, and the aqueous phase extracted with dichloromethane (5 × 10 cm^3). The organic fractions were combined, dried ($MgSO_4$), filtered, and the solvent removed in *vacuo*. The residue was purified by column chromatography, eluting with dichloromethane–acetone (10:1), to afford the title compound as a colourless solid (47 mg, 43%), mp 85 to 86 °C. $[\alpha]^{20}_D$ –15.3 (*c* 1.0, $CHCl_3$). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3400 (O–H), 2910, 2840 (C–H), 1710 (C=O), 1165 (SO_2). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.81 (3H, t, *J* = 6.4, alkyl CH_3), 1.19–1.47 (26H, m, alkyl CH_2), 2.22 (1H, br s, O–H), 2.34 (3H, s, Ph–CH_3), 3.45 (3H, s, COOCH_3), 3.80–3.85 (2H, m, C*H*OH, C*H*NHTs), 5.58 (1H, d, *J* = 9.6, N*H*PhCH$_3$), 7.21 (2H, d, *J* = 8.4, *m*-Ph–H), 7.65 (2H, d, *J* = 8.4, *o*-Ph–H). ^{13}C NMR (60 MHz, $CDCl_3$) δ: 14.5 (alkyl *C*H$_3$), 21.9 (Ph–*C*H$_3$), 23.1, 25.8, 29.8, 29.9, 30.0, 30.1, 30.1, 32.3, 34.0 (alkyl *C*H$_2$), 53.0 (COO*C*H$_3$), 59.9 (*C*HNHTs), 72.8 (*C*HOH), 127.6 (*m*-Ar–C), 129.9 (*o*-Ar–C), 137.3 (*p*-Ar–C), 144.0 (*i*-Ar–C), 171.5 (C=O).

(2*S*,3*R*)-2-(Toluenesulfonylamino)heptadecan-1,3-diol (8)

The *N*-protected amino ester **7** (49 mg, 0.098 mmol) was dissolved in anhydrous THF (5 cm^3), and lithium borohydride (2 mg, 0.36 mmol) was added. The reaction mixture was left to stir under nitrogen for 16 h. Water (5 cm^3) was added, the organic phase separated, and the aqueous phase extracted with ethyl acetate (5 × 5 cm^3). The organic fractions were combined, dried ($MgSO_4$), filtered, and the solvent removed in *vacuo*, to afford the title compound as a colourless solid (32 mg, 74%), mp 80 to 81 °C. $[\alpha]^{20}_D$ +10.6 (*c* 1.0, $CHCl_3$). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3415 (O–H), 2910, 2840 (C–H), 1160 (SO_2). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.81 (3H, t, *J* = 6.3, alkyl CH_3), 1.04–1.27 (26H, m, alkyl CH_2), 2.35 (3H, s, Ph–CH_3), 2.87 (1H, br s, O–H), 3.09–3.16 (1H, m, C*H*NHTs), 3.64 (2H, d, *J* = 3.7, CH_2OH), 3.71–3.79 (1H, m, C*H*OH), 5.57 (1H, d, *J* = 7.9, N*H*Ts), 7.22 (2H, d, *J* = 8.2, *m*-Ph–H), 7.71 (2H, d, *J* = 8.2, *o*-Ph–H). ^{13}C NMR (60 MHz, $CDCl_3$) δ: 13.1 (alkyl *C*H$_3$), 20.5 (Ph–*C*H$_3$), 21.7, 24.4, 28.4, 28.5, 28.7, 28.7, 30.9, 32.8 (alkyl *C*H$_2$), 55.7 (*C*HNHTs), 64.4 (*C*H$_2$OH), 72.2 (*C*HOH), 126.1 (*o*-Ph–H), 128.7 (*m*-Ph–H), 136.6 (*p*-Ph–H), 142.5 (*i*-Ph–H). CI-MS *m*/*z* (%): 442 ([MH]$^+$, 100), 410 (15), 213 (15), 91 (7), 60 (10). HR-MS calcd. for $C_{24}H_{44}O_4SN$ ([MH]$^+$): 442.2991; found: 442.2979.

Intramolecular [4 + 3] cycloadditions — Stereochemical issues in the cycloaddition reactions of cyclopentenyl cations — A synthesis of (+)-dactylol[1]

Michael Harmata, Paitoon Rashatasakhon, and Charles L. Barnes

Abstract: Five cyclopentanones were prepared for the purpose of examining the effects of stereogenic centers on the course of the intramolecular [4 + 3] cycloaddition reactions of cyclopentenyl cations. One substrate reacted with very high levels of diastereoselectivity and was converted to (+)-dactylol. The cyclopentenone without stereogenic centers on the tether or the five-membered ring gave two cycloadducts, the endo isomer being only slightly favored over the exo. Other substrates reacted with generally good to poor stereoselectivity. An epimer of the substrate leading to (+)-dactylol afforded all possible isomers of the cycloadduct with relatively poor stereoselectivity.

Key words: cycloaddition, total synthesis, dactylol.

Résumé : On a préparé cinq cyclopentanones dans le but d'examiner les effets des centres stéréogènes sur le cours des réactions de cycloaddition [4 + 3] intramoléculaires des cations cyclopentényles. Un substrat réagit avec des degrés élevés de diastéréosélectivité et conduit à la formation du (+)-dactylol. La cyclopenténone sans centres stéréogènes sur la chaîne latérale ou sur le cycle à cinq chaînons conduit à la formation de deux cycloadduits dans lesquels l'isomère endo est légèrement favorisé par rapport à l'isomère exo. D'autres substrats réagissent avec des stéréosélectivités qui vont généralement de bonnes à mauvaises. Un épimère du substrat qui conduit au (+)-dactylol a permis d'isoler tous les isomères possibles du cycloadduit avec une stéréosélectivité relativement faible.

Mots clés : cycloaddition, synthèse totale, dactylol.

[Traduit par la Rédaction]

Introduction

The intramolecular [4 + 3] cycloaddition reaction of allylic cations and dienes has been shown to be a powerful route to polycyclic compounds (1). One variation on this theme involves the use of cyclic cations in the cycloaddition reaction. Appropriate modifications of the cycloadducts from such reactions can then provide useful routes to natural products (2). We and others realized the potential for this process in the context of the synthesis of cyclooctanoids (3). We recently reported a total synthesis of (+)-dactylol based on this chemistry (2*c*). This report is a more detailed description of that work, including studies to evaluate the effects of various stereocenters on the course of the cycloaddition reaction.

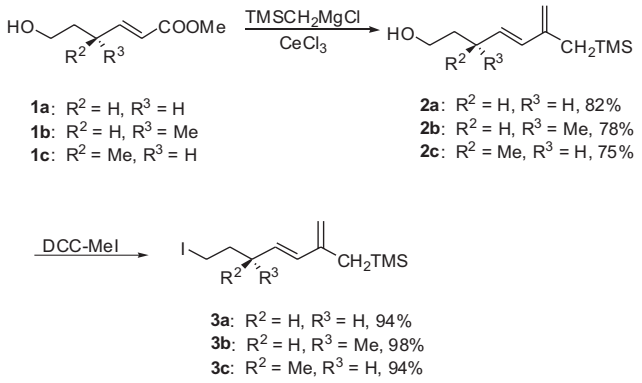
Results and discussion

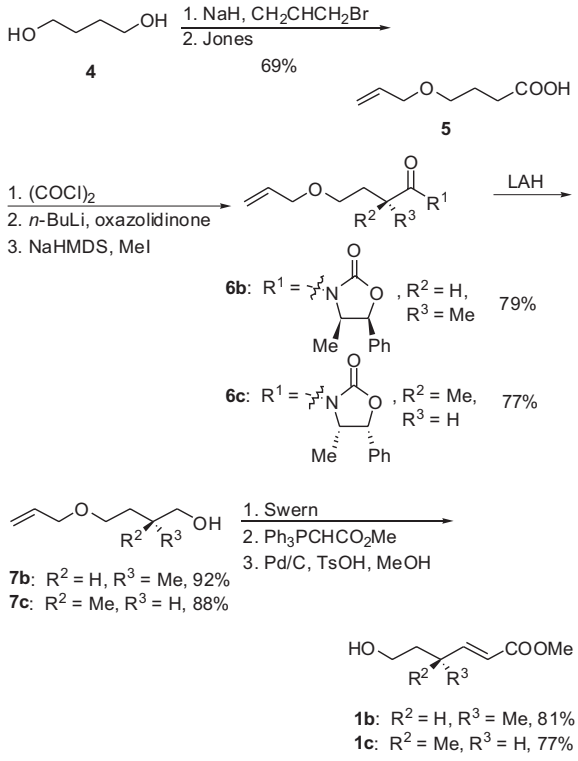
Diene synthesis

The basic approach for the preparation of substrates for this study consisted of the alkylation of cyclopentanone enolates with diene-containing electrophiles. The synthesis of the dienes used is shown in Scheme 1. Treatment of **1a**–**1c** with $TMSCH_2MgCl$–$CeCl_3$ followed by iodide formation afforded **3a**–**3c** in excellent yields (4, 5).



Ester **1a** was prepared by a literature procedure (6). Esters **1b** and **1c** were prepared as shown in Scheme 2. Protection of 1,4-butanediol with allyl bromide followed by oxidation gave the acid **5** in 69% yield from **4**. Oxazolidinones were formed from **5** in standard fashion and alkylated with high stereoselectivity and in good yields to afford **6b** and **6c**. Reduction with LAH gave the alcohols **7b** and **7c** in excellent yields. Swern oxidation, Wittig homologation, and deprotection (7) afforded esters **1b** and **1c** in 81% and 77% yields, respectively.

Preparation of cycloaddition substrates



Cycloaddition substrates were easily prepared by alkylation. For example, the reaction of **8** with potassium carbonate in the presence of **3a** afforded the alkylation product **9** in good yield. This was converted to the ketone **11** in 66% yield via reaction with potassium cyanide in hot DMSO

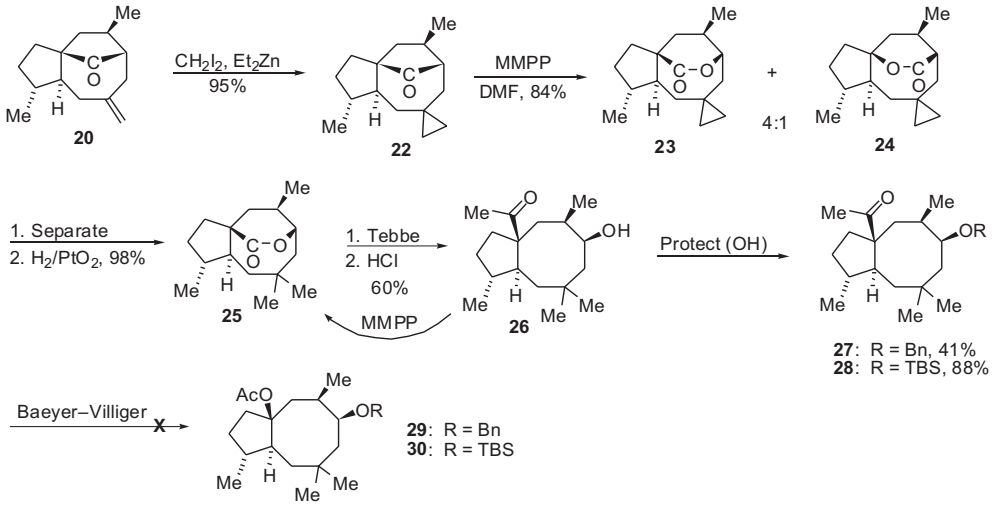
Scheme 5.

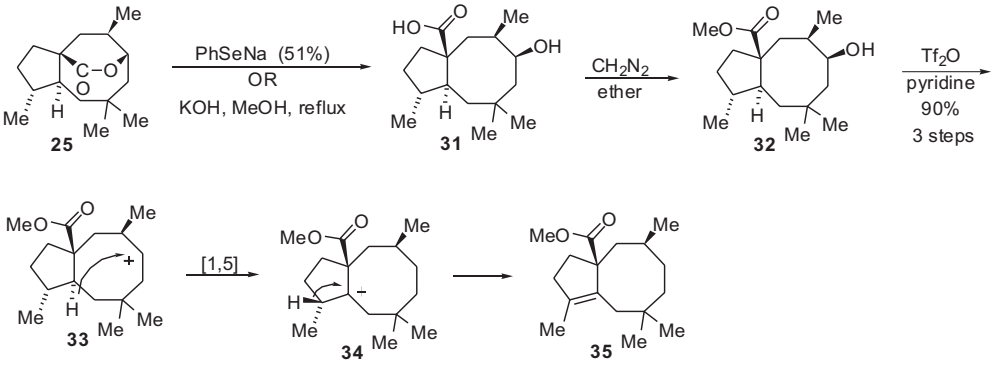
(8). Ketone **12** was prepared in a similar fashion in 73% overall yield (Scheme 3).

The ketoester **13** was readily prepared from (*R*)-pulegone by a known procedure (9). Dianion formation followed by alkylation and decarboalkoxylation afforded cycloaddition substrates **17**–**19**, as shown in Scheme 4.



The synthesis of (+)-dactylol

We begin with the synthesis of dactylol, since that was indeed the first cycloaddition in this series that we examined. Treatment of **18** with Lithium diisopropylamide (LDA) and reacting the resultant enolate with triflyl chloride gave an α-chloroketone. This was not characterized but immediately subjected to typical cycloaddition conditions: stirring at –78 °C to room temperature in a 1:1 mixture of ether and trifluoroethanol in the presence of 3 equiv. of triethylamine (Scheme 5). Even though the purification of the cycloadduct could be carried out at this stage, we found that some desilylation and double bond migration occurred during the chromatography on silica gel.



Therefore, the crude product was subsequently treated with tosic acid to give rise to alkene **20** as a 25:1 mixture of isomers in 74% yield for the three steps. The diastereomeric ratio was determined by GC and integration of the olefinic region of the ^{1}H NMR of a crude product mixture. The minor isomer has not been characterized. The rationalization for the favorable stereochemical outcome is depicted in structure **21**. We anticipated that the diene would approach the dienophile in an endo fashion on the less-hindered face of the dienophile. In addition, the methyl group on the tether

© 2006 NRC Canada

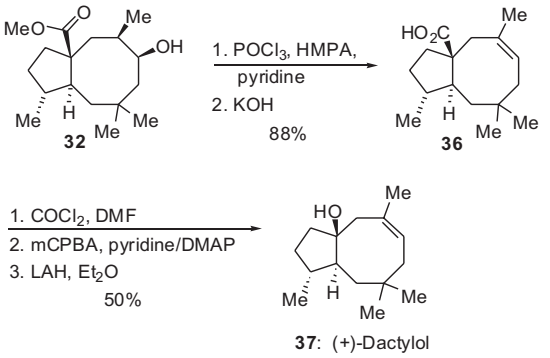
Scheme 6.

Scheme 7.

would occupy a pseudoequatorial orientation on the puckered, incipient five-membered ring with the diene oriented so as to minimize gauche interactions.

The next stage of the synthesis is shown in Scheme 6. Simmons–Smith cyclopropanation of **20** produced **22** in 95% yield. The Baeyer–Villiger reaction of **22** with MMPP in DMF afforded a 4:1 mixture of two regioisomers after purification. Surprisingly, the major product was that resulting from the migration of the less substituted carbon atom. Attempts to alter the regioselectivity using a variety of reaction conditions were unsuccessful, as some reagents gave higher regioselectivity but lower yields of the products.[3] Studies we have conducted suggest that the methyl substituent on the five-membered ring has a major, but not exclusive, influence on the regiochemistry of the reaction (10). The major isomer **23** was separated, and the cyclopropane ring was cleaved by hydrogenolysis to afford **25** in 98% yield. The structure and relative stereochemistry were established by X-ray crystallography.

Our first attempt to convert **25** into dactylol began with a methylenation reaction using Tebbe's reagent (11). Hydrolysis of the resultant enol ether afforded the ketone **26**, whose hydroxy group could be protected with either a benzyl or TBS group. We anticipated that a Baeyer–Villiger oxidation of either of these species would afford the corresponding acetate **29** or **30**.[4] Unfortunately, no reaction occurred between either **27** or **28** and MMPP, *m*-CPBA, or TFAA-H_2O_2 after a 24 h period at room temperature. Treatment of **26** with MMPP afforded lactone **25** (10). We also attempted a reaction between lactone **25** and sodium phenylselenide and expected to obtain a system suitable for further elaboration to (+)-dactylol. However, the hydroxy acid **31** was obtained as the sole product in 51% yield, via an apparent hydrolysis reaction. Even though this result was not satisfactory, it proved the existence and stability of the hydroxycarboxylic acid **31**, which became significant.



Thus, the next sequence to (+)-dactylol began with a hydrolysis of lactone **25** using KOH in refluxing aqueous methanol and esterification of the corresponding hydroxy acid with diazomethane (Scheme 7). The next challenging step was the introduction of the double bond in dactylol by dehydration of **32**. Regioselectivity was a problem, as were side reactions. For example, treatment of **32** with $POCl_3$ in pyridine, Tf_2O in pyridine, or Martin's sulfurane resulted in

[3] Reagent, ratio **23**:**24**, solvent, temperature, time, yield: (*a*) *m*-CPBA–$NaHCO_3$, 6:1, CH_2Cl_2, RT, 5 d, 67%; (*b*) TFAA–H_2O_2, 5:1, CH_2Cl_2, 0 °C – RT, 3 d, 36%; (*c*) *m*-CPBA–TFA, 4:1, CH_2Cl_2, 0 °C–rt, 48 h, 53%; (*d*) peracetic acid – NaOAc, 9:1, AcOH, RT, 48 h, 31%; (*e*) MMPP, 4:1, DMF, RT, 48 h, 84%.

[4] Without protection of the alcohol group, the Baeyer–Villiger reaction proceeded by an unexpected course. See ref. 10.

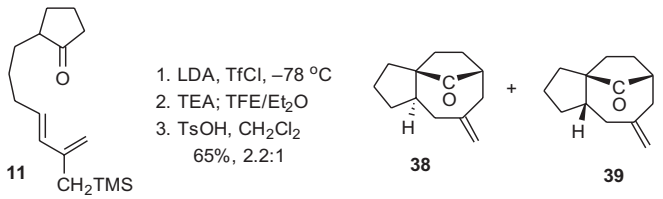
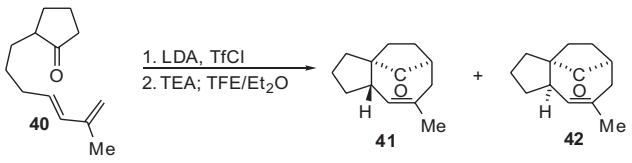
Scheme 8.



the formation of a compound identified as **35**. Presumably, these reagents induced cation formation, which was followed by a 1,5-transannular hydride shift to form **34**, and subsequent elimination to give tetra-substituted alkene **35**, whose structure was determined based on spectroscopic and analytical data. The ^{1}H NMR spectrum showed no signal for olefinic protons. The most downfield peak appeared at 3.59 ppm as a singlet, which corresponded to the methyl ester. There was also a singlet peak that integrated for three protons at 1.65 ppm, suggesting the presence of a methyl substituent on an olefin. The ^{13}C NMR spectrum confirmed the existence of ester and alkene (δ: 177.3, 136.9, 134.7).

By taking advantage of the dehydration procedure developed by Trost and Jungheim (12), we were able to overcome this problem (Scheme 8). Phosphorus oxychloride ($POCl_3$) was added to a solution of **32** in HMPA with slow heating from room temperature to 50 °C. After the white precipitate that formed dissolved, pyridine was added and heating was continued to 100 °C at which point the dehydration was complete. Subsequent hydrolysis of the sterically hindered methyl ester group using KOH in DMSO provided **36** as a single product (based on crude ^{1}H NMR) in 84% yield. At this point, we found that typical acid chloride formation procedures failed to give the acid chloride of the hindered acid **36**.[5] However, upon treatment with DMF and phosgene in refluxing toluene, **36** was cleanly converted to the corresponding acid chloride (13). In a benzene solution containing pyridine and DMAP, this acid chloride reacted with mCPBA to form a mixed anhydride, which rearranged upon stirring for 24 h at room temperature to a mixed carbonate with retention of configuration (14). Reduction of the mixed carbonate with LAH then afforded (+)-dactylol in 50% overall yield from **36**. The spectral, analytical, and optical rotation data were consistent with those reported in the literature (15).



Simple diastereoselectivity

After the successful synthesis of (+)-dactylol, we decided to examine the influence of all stereocenters on the course of the reaction. First, however, we looked at simple diastereoselectivity. Past experience suggested that the intramolecular [4 + 3] cycloaddition reaction of cyclopentenyl cations with tethered butadienes would proceed with only a slight simple diastereoselectivity in favor of the endo product (3*b*). This was indeed the case.

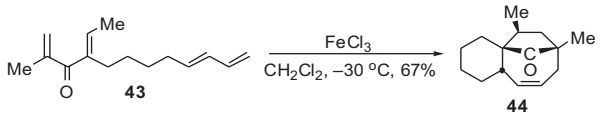
Scheme 9.

Scheme 10.

The ketone **11** was treated with LDA and TfCl to furnish the corresponding α-chloroketone, which was subjected to the [4 + 3] cycloaddition and desilylation reactions (Scheme 9). Two diastereomeric cycloadducts (**38** and **39**) were obtained in 65% yield in a ratio of 2.2:1. The product ratio was determined by gas chromatographic analysis and integration of the crude product ^{1}H NMR spectrum. After purification by flash chromatography on silica gel, the major product was treated with excess $NH_2OH{\cdot}HCl$ and KOH in refluxing ethanol to form an oxime derivative. Recrystallization of this oxime from hexane and EtOAc afforded crystals of suitable quality for single crystal X-ray crystallographic analysis. Thus, the major product was assigned as the endo isomer **38**. It should be noted that cycloadditions of this type appear to take place under kinetic control.

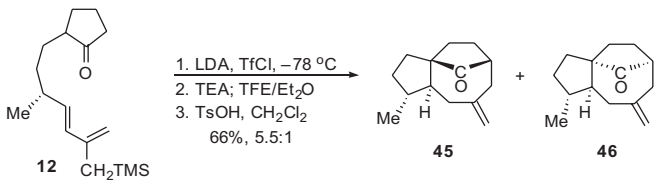
We have examined simple diastereoselectivity computationally for the conversion of **40** to **41** and **42**. We found that while the lowest energy transition state corresponds to the endo product **41**, other transition state structures that lead to the exo product are close in energy, and thus, for unsubstituted systems at least, simple diastereoselectivity should not ever be expected to be substantial (Scheme 10) (16).

It is interesting to note that West and co-workers (3*a*) have reported very high simple diastereoselectivity in the formation of **44** via a domino Nazarov – [4 + 3] cycloaddition process as shown in Scheme 11. It is clear that many new features of this aspect of the intramolecular [4 + 3] cycloaddition reaction of cyclopentenyl cations remain to be uncovered.



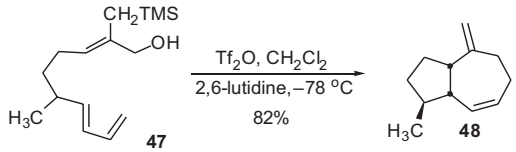
Relative stereoselection I — Cycloaddition of 12

The introduction of a stereogenic center in the tether joining the diene and dienophile in these reactions introduces a new complication. Our goal in pursuing the cycloaddition of **12** was essentially to discover the impact of the stereocenter on the course of the reaction in an effort to elucidate which of the stereocenters in **18** had a more profound impact on the stereochemical outcome on that compound's cycloaddition.



[5] For example, stirring the solution of **36** in hexane with 3 equiv. of oxalyl chloride or heating a hexane solution of **36** with excess thionyl chloride resulted in no change.

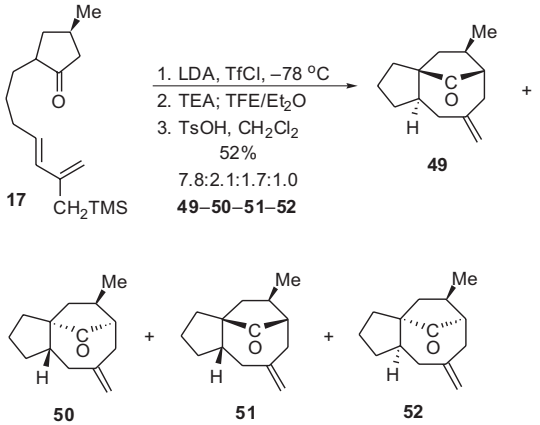
© 2006 NRC Canada



Scheme 11.

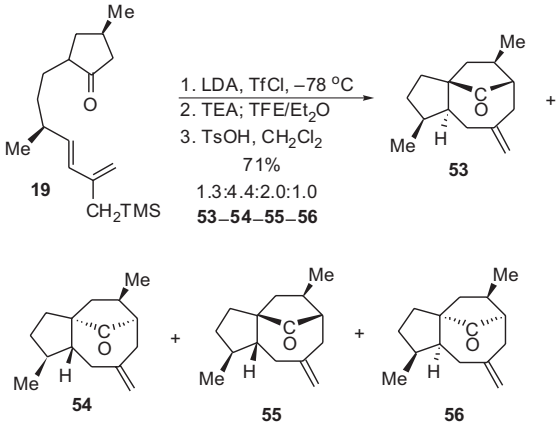
Scheme 12.

Scheme 13.



Cycloaddition of **12** afforded four products, only two of which, **45** and **46**, could be cleanly isolated (Scheme 12). Gas chromatographic analysis of the crude reaction mixture indicated a product ratio of 47.2(**45**):8.1(**46**):1:2.3. The major product of the reaction was **45**, as expected on the basis of the small but real endo preference observed in these systems and a report by Giguere and co-workers (17) on relative diastereoselection in intramolecular [4 + 3] cycloadditions. In that paper, Giguere and co-workers (17) reported that treatment of **47** with triflic anhydride afforded cycloadduct **48** as the major product of the reaction (Scheme 13). Regardless of the mechanistic basis for the outcome, one could assume that stereogenic centers adjacent to dienes would produce similar stereochemical outcomes in other intramolecular [4 + 3] cycloaddition reactions. This is what is observed in the formation of **45** and **46**. The structure of both compounds was established by X-ray analysis of the corresponding oximes.[6]

Relative stereoselection II — Cycloaddition of 17



The cycloaddition reaction of **17** was anticipated to be reasonably selective. Endo–exo selectivity was not expected to be high but facial selectivity was expected to be reasonable, the diene approaching the less hindered face of the dienophile (i.e., on the face opposite the methyl substituent). There is a reasonable amount of precedent for this in the literature (18).

Surprisingly, the reaction produced all four possible isomeric products (**49**–**52**) in 52% yield overall from ketone **17** (Scheme 14). Gas chromatographic analysis of the crude product mixture suggested that the products were formed in a ratio of 7.8:2.1:1.7:1.0. They were separated by flash chromatography on silica gel and individually transformed into their oxime derivatives. Consistent with other data, the major

Scheme 14.

Scheme 15.

products were those derived from the transition states having the diene approaching from the opposite side of the methyl group on the stereogenic center. However, the level of facial selectivity in this reaction was approximately 3:1, while the endo–exo ratio was 3.4:1. The low level of facial selectivity is surprising, but larger substituents at the stereogenic centers should produce a better result.

Cycloaddition of 19 — The mismatched case

The last [4 + 3] cycloaddition in this study was the reaction of ketone **19**. Since the stereogenic center on the cyclopentanone remained the same (*R*) while the one on diene was switched from (*R*) to (*S*) compared with ketone **18**, we expected to see the diastereomer of **20** formed as the major isomer. In fact, the reaction produced all four isomers of cycloadduct (**53**–**56**) in 71% yield in a ratio of 1.3:4.4:2.0:1.0 (Scheme 15). Each product was purified, characterized, and converted into an oxime derivative, and the stereochemical assignment was made using X-ray crystallography. The major isomer (**54**) derived from a transition state having an endo approach of the diene with a tether conformation that minimized gauche interactions. However, at-

[6] The oxime derived from **46** gave poor quality X-ray data. Finding a suitable crystal was problematic and the one found turned out to be racemic, in spite of the fact that the bulk sample was clearly enantiomerically enriched based on optical rotation data. However, the data were sufficient to establish the relative stereochemistry.

© 2006 NRC Canada

tack occurred on what appears to be the more sterically hindered face of the oxyallylic cation intermediate.

Surprisingly, the overall facial selectivity in this case, (**53** + **55**):(**54** + **56**), was 1:1.6 in favor of the products derived from the approach of the diene to the more hindered face of the cyclopentanone. The endo–exo ratio, (**53** + **54**):(**55** + **56**) was 1.9:1 in favor of endo products. The relative stereoselectivity (**53** + **56**):(**54** + **55**) was 1:2.8 in favor of the products having a cis relationship between the angular hydrogen and the methyl group on the newly formed five-membered ring.

Conclusion

The intramolecular [4 + 3] cycloaddition of cyclopentenyl cations to dienes is a useful route to cyclooctanoids. High levels of stereocontrol in this reaction are possible, but it is clear that effects that might appear to be cooperative need not be and that further studies of these cycloadditions will be necessary to achieve results that are more generally suitable for applications in synthesis. This conclusion is true for acyclic dienes tethered to cyclopentenyl cations. High levels of simple diastereoselection are possible with tethered furans (3). Whether this inherent selectivity can be used to produce high levels of relative stereocontrol remains to be seen. We plan to perform further work to solve the problems that exist and continue to apply the methodology to the synthesis of cyclooctanoids. Further results will be reported in due course.[7]

Experimental

General procedure for Peterson olefination: synthesis of 2a–2c

A 500 mL round-bottomed flask was charged with powdered cerium(III) chloride heptahydrate ($CeCl_3$-$7H_2O$, 13.02 g, 34.96 mmol). The flask was immersed in an oil bath and evacuated to a full vacuum (about 0.1 mmHg (1 mmHg = 133.322 4)). The solid was magnetically stirred as the flask was heated at 150 °C for 2 h. After the flask was cooled to room temperature, it was vented to the atmosphere and quickly purged with a steam of argon for 30 s. The flask was capped with a rubber septum and 60 mL of THF was added. The white suspension was stirred at room temperature for 1 h, cooled to –78 °C in a dry ice – 2-propanol bath, and a 1 mol/L solution of trimethylsilylmethylmagnesium chloride (35 mL, 35 mmol) was added over a period of 15 min. After the cold mixture was stirred for an additional 15 min, 9.99 mmol of **1a**, **1b**, or **1c** was added dropwise and the mixture was allowed to warm slowly to room temperature over a period of 3 h. The reaction was quenched with ice-cold 1 mol/L HCl (60 mL) and stirred for 5 min. The layers were separated, and the aqueous phase was extracted with ether. The combined organic layers were washed with saturated sodium bicarbonate solution (100 mL), dried over magnesium sulfate, filtered, and the solvents were removed by rotavap. The crude product was purified by flash chromatography (hexane–EtOAc, 4:1).

6-Trimethylsilylmethyl-hepta-4,6-dien-1-ol (2a)

Yield: 82%, colorless oil. IR (neat, cm^{-1}): 3353 (ms), 2947 (s), 1252 (s), 859 (s). ^1H NMR (250 MHz, $CDCl_3$) δ: 6.09 (d, *J* = 15.6 Hz, 1H), 5.58 (dt, *J* = 7.0, 15.6 Hz, 1H), 4.78 (d, *J* = 1.5 Hz, 1H), 4.66 (s, 1H), 3.68–3.61 (m, 2H), 2.18 (q, *J* = 7.3 Hz, 1H), 1.77 (br t, *J* = 4.5 Hz, 1H), 1.72–1.61 (m, 2H), 1.69 (s, 2H), 0.00 (s, 9H). ^{13}C NMR (62.9 MHz, $CDCl_3$) δ: 143.7, 133.6, 129.7, 112.0, 62.3, 32.3, 29.0, 22.1, –1.2. (3R)-Methyl-6-trimethylsilylmethyl-hepta-4,6-dien-1-ol (2b)

Yield: 78%, colorless oil. $[\alpha]^{20}_D$ –24.42 (*c* 1.0, $CHCl_3$). IR (neat, cm^{-1}): 3334 (m), 2957 (s), 2929 (m), 2898 (m), 1596 (w), 1422 (w), 1250 (m), 1157 (m), 1054 (m), 967 (m), 853 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 6.07 (d, *J* = 15.7 Hz, 1H), 5.45 (dd, *J* = 8.3, 11.3 Hz, 1H), 4.80 (d, *J* = 1.9, 1H), 4.68 (s, 1H), 3.66 (br s, 1H), 2.37 (sept, *J* = 7.1 Hz, 1H), 1.70 (s, 2H), 1.66–1.35 (m, 2H), 1.35 (br s, 1H), 1.05 (d, *J* = 6.7 Hz, 3H), 0.00 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 143.7, 135.7, 132.0, 112.3, 61.2, 39.8, 34.0, 22.1, 21.0, –1.2. Anal. calcd. for $C_{12}H_{24}O_3Si$: C 67.86, H 11.39; found: C 67.92, H 11.47.

(3S)-Methyl-6-trimethylsilylmethyl-hepta-4,6-dien-1-ol (2c)

Yield: 75%, colorless oil. $[\alpha]^{20}_D$ +26.67 (*c* 1.0, $CHCl_3$). IR (neat, cm^{-1}): 3378 (s), 2957 (s), 2877 (s), 1459 (m), 1420 (m), 1380 (m), 1254 (s), 1055 (s), 853 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 6.07 (d, *J* = 15.7 Hz, 1H), 5.45 (dd, *J* = 8.3, 11.3 Hz, 1H), 4.80 (d, *J* = 1.9, 1H), 4.68 (s, 1H), 3.66 (br s, 1H), 2.37 (sept, *J* = 7.1 Hz, 1H), 1.70 (s, 2H), 1.66–1.35 (m, 2H), 1.35 (br s, 1H), 1.05 (d, *J* = 6.7 Hz, 3H), 0.00 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 143.7, 135.7, 132.0, 112.3, 61.2, 39.8, 34.0, 22.1, 21.0, –1.2. HR-MS (EI) calcd. for $C_{12}H_{24}OSi$ (M^+): 212.1596; found: 212.1610.

General procedure for conversion of alcohols to iodides: synthesis of 3a–3c

To a solution of **2a**, **2b**, or **2c** (4.70 mmol) in THF (47 mL) was added 9.42 mmol of DCC-MeI salt. The mixture was stirred in an oil bath at 35 °C for 6 h. The solvent was removed under reduced pressure, and the crude product was purified by flash chromatography (100% hexane). Due to the instability of the products, the characterizations were performed by NMR and IR only.

(7-Iodo-2-methylene-hept-3-enyl)-trimethylsilane (3a)

Yield: 94%, colorless oil. IR (neat, cm^{-1}): 3078 (w), 2945 (s), 2896 (s), 1597 (m), 1423 (m), 1241 (m), 1155 (s), 967 (m), 846 (s). ^1H NMR (250 MHz, $CDCl_3$) δ: 6.12 (d, *J* = 15.7 Hz, 1H), 5.51 (dt, *J* = 7.0, 15.6 Hz, 1H), 4.81 (d, *J* =

2.0 Hz, 1H), 4.69 (s, 1H), 3.19 (t, J = 6.9 Hz, 2H), 2.21 (q, J = 7.0 Hz, 2H), 1.92 (quint, J = 7.0 Hz, 2H), 1.69 (d, J = 0.7 Hz, 2H), –0.48 (s, 9H). ^{13}C NMR (62.9 MHz, $CDCl_3$) δ: 143.6, 134.6, 128.0, 112.5, 33.3, 33.1, 22.1, 6.3, –1.2.

(7-Iodo-(5R)-methyl-2-methylene-hept-3-enyl)-trimethylsilane (3b)

Yield: 98%, colorless oil. $[\alpha]^{20}_D$ –43.94 (c 1.0, $CHCl_3$). IR (neat, cm^{-1}): 3078 (w), 2955 (s), 2927 (m), 2897 (m), 1597 (m), 1422 (m), 1249 (s), 1158 (m), 969 (m), 851 (s). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.12 (d, J = 15.7 Hz, 1H), 5.35 (dd, J = 8.4, 15.6 Hz, 1H), 4.84 (d, J = 1.9 Hz, 1H), 4.71 (s, 1H), 3.23–3.09 (m, 2H), 2.35 (sept, J = 6.8 Hz, 1H), 1.90–1.80 (m, 2H), 1.70 (s, 2H), 1.05 (d, J = 6.7 Hz, 3H), 0.01 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 143.5, 134.0, 132.9, 112.7, 40.6, 38.0, 22.1, 20.3, 4.9, –1.2.

(7-Iodo-(5R)-methyl-2-methylene-hept-3-enyl)-trimethyl silane (3c)

Yield: 94%, colorless oil. $[\alpha]^{20}_D$ +39.71 (c 1.0, $CHCl_3$). IR (neat, cm^{-1}): 3079 (w), 2952 (s), 2927 (m), 2887 (m), 1594 (m), 1421 (m), 1252 (s), 1160 (m), 970 (m), 853 (s). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.12 (d, J = 15.7 Hz, 1H), 5.35 (dd, J = 8.4, 15.6 Hz, 1H), 4.84 (d, J = 1.9 Hz, 1H), 4.71 (s, 1H), 3.23–3.09 (m, 2H), 2.35 (sept, J = 6.8 Hz, 1H), 1.90–1.80 (m, 2H), 1.70 (s, 2H), 1.05 (d, J = 6.7 Hz, 3H), 0.01 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 143.6, 134.0, 132.9, 112.7, 40.6, 38.0, 22.1, 20.3, 4.9, –1.2.

4-(2-Propenyloxy)-butanoic acid (5)

To a solution of 1,4-butanediol (54.0 g, 600 mmol) in dry DMF (400 mL) was added 60% NaH (5.76 g, 240 mmol) portionwise while the solution was stirred in an ice-water bath. After the addition of NaH, the reaction flask was removed from the bath. The mixture was stirred at room temperature for 30 min and cooled in the ice-water bath again. Allyl bromide (17.3 mL, 200 mmol) was added dropwise, and the mixture stirred for 1 h. The reaction was quenched with water (500 mL) and extracted with EtOAc. The organic phase was concentrated on a rotatory evaporator, and the residue dissolved in acetone (400 mL). The solution was cooled in the ice bath and Jones reagent (prepared from 133.6 g of CrO_3, 115 mL of H_2SO_4, and 350 mL of H_2O) was added dropwise with stirring until a red color persisted (approximately 70 mL of Jones reagent was used). Volatile solvents were removed under reduced pressure. The residue was diluted with water and extracted with EtOAc. The combined organic phases were washed with saturated $NaHCO_3$ solution (300 mL × 2), and the organic layer was discarded. The aqueous phase was acidified by addition of 6 mol/L HCl until pH ≤ 4, and extracted with ether (100 mL × 3). The combined organic phase was dried over $MgSO_4$ and filtered. The solvent was removed under reduced pressure, and the product was obtained as a colorless liquid (19.9 g, 69%). NMR and IR data were consistent with those published in literature (19).

(4*R*)-Methyl-(5*S*)-phenyl-3-(4-propenyloxy)butanoyl-oxazolidin-2-one and (4*S*)-methyl-(5*R*)-phenyl-3-(4-propenyloxy)butanoyl-oxazolidin-2-one

Oxalyl chloride (30 mL, 343.34 mmol) was added to a solution of acid **5** (16.5 g, 114.45 mmol) in hexane (220 mL) and the mixture was stirred at room temperature for 3 h. Volatile compounds were removed under reduced pressure, and the crude product was used in the next step without further purification. A solution of (4*R*)-methyl-(5*S*)-phenyl-oxazolidin-2-one or (4*S*)-methyl-(5*R*)-phenyl-oxazolidin-2-one (16.89 g, 95.31 mmol) in dried THF (320 mL) was cooled to –78 °C and 2.2 mol/L n-BuLi (43.3 mL, 95.31 mmol) was added dropwise. After the addition of n-BuLi, 4-(2-propenyloxy)butanoyl chloride (18.6 g, 114.38 mmol) was added in one portion. The reaction flask was moved into an ice-water bath and stirred for 30 min. The reaction was quenched with 1 mol/L K_2CO_3 (200 mL) and extracted with EtOAc. The combined organic phases were dried over $MgSO_4$, filtered, and concentrated. The crude product was purified by flash chromatography (hexane–EtOAc, 4:1) on silica gel.

(4R)-Methyl-(5S)-phenyl-3-(4-propenyloxy)butanoyl-oxazolidin-2-one

Yield: 94%, colorless oil. $[\alpha]^{20}_D$ +41.72 (c 1.0, $CHCl_3$). IR (neat, cm^{-1}): 3072 (w), 2932 (m), 2860 (m), 1783 (s), 1702 (s), 1455 (m), 1349 (s), 1198 (s), 1120 (m). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.45–7.29 (m, 5H), 5.98–5.85 (m, 1H), 5.66 (d, J = 7.30 Hz, 1H), 5.28 (dq, J = 17.2, 1.5 Hz, 1H), 5.17 (dq, J = 10.4, 1.5 Hz, 1H), 4.76 (quint, J = 6.8 Hz, 1H), 3.97 (dm, J = 5.5 Hz, 2H), 3.52 (t, J = 6.3 Hz, 2H), 3.14–2.97 (m, 2H), 1.99 (sept, J = 7.1 Hz, 2H), 0.89 (d, J = 6.6 Hz, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 172.7, 153.0, 134.8, 133.3, 128.7, 128.6, 125.6, 116.8, 78.9, 71.7, 69.1, 54.7, 32.5, 24.4, 14.5. (4*R*)-Methyl-(5*S*)-phenyl-3-(4-propenyloxy-2(*R*)-methyl-butanoyl)-oxazolidine-2-one (6b) and (4*S*)-methyl-(5*R*)-phenyl-3-(4-propenyloxy-(2*S*)-methyl-butanoyl)-oxazolidine-2-one (6c)

To a flame-dried, 1 L, round-bottomed flask was placed 27.1 g (89.33 mmol) of (4*R*)-methyl-(5*S*)-phenyl-3-(4-propenyloxy)butanoyl-oxazolidin-2-one or (4*S*)-methyl-(5*R*)-phenyl-3-(4-propenyloxy)butanoyl-oxazolidin-2-one and freshly distilled THF (350 mL). The solution was cooled to –78 °C, and 2.0 mol/L NaHMDS in THF (53.6 mL, 107.2 mmol) was added dropwise over 20 min. The mixture was stirred at –78 °C for 30 min and MeI (38.0 mL, 268.0 mmol) was added. After stirring at –78 °C for an additional 4 h, the reaction was quenched with half-saturated NH_4Cl solution (300 mL). The organic phase was separated, and the aqueous

© 2006 NRC Canada

phase was extracted with EtOAc (200 mL × 3). The combined organic phases were dried over $MgSO_4$, filtered, and concentrated. The crude product was purified by flash chromatography (hexane–EtOAc, 10:1) on silica gel.

Synthesis of 6-allyloxy-(4*R*)-methyl-hex-2-enoic acid methyl ester and 6-allyloxy-(4*S*)-methyl-hex-2-enoic acid methyl ester

DMSO (9.4 mL, 132.41 mmol) was added to a cooled solution (–78 °C) of oxalyl chloride (5.8 mL, 66.20 mmol) in methylene chloride (460 mL). After 5 min, a solution of **7b** or **7c** (6.80 g, 47.29 mmol) in 10 mL of methylene chloride was added. The mixture was stirred for 30 min at –78 °C, and triethylamine (29.0 mL, 208.08 mmol) was added. After stirring for an additional 1 h at –30 °C, the reaction was quenched and washed with water (200 mL × 2). The organic phase was dried over magnesium sulfate, filtered, and concentrated. The crude product was dissolved in 1,2-dichloroethane (50 mL), $Ph_2PCHCOOMe$ (16.56 g, 47.26 mmol) was added, and it was refluxed for 6 h. Volatile solvents were removed under reduced pressure, and the crude product was purified by flash chromatography (hexane–EtOAc, 4:1) on silica gel.

General procedure for the alkylation of ketoester 8: synthesis of 9 and 10

To a solution of **8** (5 mmol) in acetone (25 mL) was added alkyl iodide **3a** or **3b** (2.5 mmol) and K_2CO_3 (7.5 mmol). The mixture was heated under a reflux condition under N_2 for 12 h. After the mixture was cooled to room temperature, water (30 mL) was added and the mixture was extracted with Et_2O (30 mL × 3). Combined organic phases were washed with brine, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. The crude product was purified by column chromatography (silica gel, pentane–ether, 20:1).

General procedure for the alkylation of ketoester 13: synthesis of 14–16

To a flame-dried, 50 mL, round-bottomed flask equipped with a magnetic bar was placed 0.65 g (17 mmol) of 60% NaH in mineral oil and 27 mL of freshly distilled THF. The mixture was stirred in an ice bath, and a solution of **13** (15 mmol) in 3 mL of THF was added slowly. The mixture was stirred for 5 min, and 2.5 mol/L solution of *n*-BuLi (15 mmol) was added. After stirring for an additional 5 min, a solution of alkyl iodide **3a**, **3b**, or **3c** (10 mmol) in 3 mL of THF was added into the orange-yellow solution. The mixture was stirred and allowed to warm to room temperature overnight. The reaction was quenched with water (25 mL) and extracted with ether (30 mL × 3). The combined organic phases were dried over magnesium sulfate, filtered, and concentrated with a rotatory evaporator. The crude product was purified by column chromatography (silica gel, pentane–ether, 20:1) to give a mixture of diastereomers.

General procedure for decarbomethoxylation: synthesis of 11–12 and 17–19

To a solution of β-keto ester (3.0 mmol) in DMSO (6.0 mL) was added potassium cyanide (6.0 mmol) and water (6.0 mmol). The mixture was heated under reflux for 30 min, allowed to cool to room temperature, diluted with water (20 mL), and extracted with ether (20 mL × 3). The combined organic phases were dried over magnesium sulfate, filtered, and concentrated. The crude product was purified by flash chromatography (silica gel, pentane–ether, 20:1).

α-Chlorination of cyclopentanone, intramolecular [4 + 3] cycloaddition, and desilylation of allylsilane: synthesis of 20

To a cooled solution (–78 °C) of ketone **18** (2.0 mmol) in THF (15 mL) was slowly added a solution of LDA (prepared by adding a 2.5 mol/L solution of *n*-BuLi (2.5 mmol) into a solution of diisopropylamine (3.0 mmol) in THF (5 mL) at 0 °C). The mixture was stirred at –78 °C for 30 min and trifluoromethanesulfonyl chloride (2.5 mmol) was added dropwise. After stirring for 5 min, the reaction was quenched with water (20 mL) and extracted with ether (15 mL × 3). The combined organic phases were washed with water (20 mL), dried over magnesium sulfate, filtered, and concentrated. Volatile solvents were removed under high vacuum. The resulting colorless oil was dissolved in freshly distilled ether (10 mL), cooled to –78 °C, and diluted with trifluoroethanol (10 mL). The mixture was stirred for a few minutes and triethylamine (6.0 mmol) was added dropwise. The reaction was allowed to warm to room temperature overnight, quenched with water (20 mL), and extracted with ether (15 mL × 3). The combined organic phases were dried over magnesium sulfate, filtered, and concentrated. The crude product was dried under high vacuum. The resulting yellow oil was dissolved in methylene chloride (20 mL), and $TsOH{\cdot}H_2O$ (0.2 mmol) was added. The mixture was stirred at room temperature for 6 h and washed with water (20 mL). The organic phase was separated and dried over magnesium sulfate, filtered, and concentrated. The crude product was purified by flash chromatography on silica gel using hexane–EtOAc (30:1) as the eluent. Ketone **20** was obtained as a colorless oil in 74% yield. $[\alpha]^{20}_D$ +44.60 (*c* 1.0, $CHCl_3$). IR (neat, cm^{-1}): 3073 (w), 2952 (s), 2867 (s), 1735 (s), 1643 (w), 1455 (m), 1154 (w). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 4.83 (d, *J* = 13.5 Hz, 2H), 2.46–1.68 (m, 8H), 1.58–0.92 (m,

6H), 1.04 (d, J = 6.4 Hz, 3H), 1.00 (d, J = 6.1 Hz, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 220.8, 146.5, 115.0, 61.1, 58.6, 52.7, 46.9, 43.2, 39.9, 39.4, 35.1, 31.7, 28.0, 21.0, 18.3. Anal. calcd. for $C_{15}H_{22}O$: C 82.52, H 10.16; found: C 82.25, H 10.20.

Simmons–Smith cyclopropanation: synthesis of 22

To a cooled solution (0 °C) of **20** (2.29 mmol) in methylene chloride (5 mL) was added methylene iodide (5.4 mL, 5.8 mmol) and 1.0 mol/L solution of diethylzinc in hexane (23 mL, 23 mmol). The mixture was stirred vigorously for 12 h while it was allowed to warm to room temperature. The reaction was quenched with water (20 mL), 1 N HCl (5 mL) was added, and it was extracted with ether (20 mL × 3). The combined organic phases were dried over magnesium sulfate, filtered, and concentrated using a rotatory evaporator. The crude product was purified by flash chromatography (3:1, hexane–CH_2Cl_2). Ketone **22** was obtained in 95% yield as a colorless oil. $[\alpha]^{20}_D$ +12.63 (*c* 1.0, $CHCl_3$). IR (neat, cm^{-1}): 2956 (s), 2869 (s), 1728 (s), 1457 (m), 1390 (m), 1164 (m), 1114 (m). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 2.63–2.51 (m, 1H), 2.28–2.11 (m, 3H), 1.99–1.94 (m, 4H), 1.84–1.77 (m, 1H), 1.56–1.43 (m, 1H), 1.36–1.13 (m, 5H), 1.03 (d, J = 6.88 Hz, 3H), 0.99–0.95 (m, 1H), 0.91 (d, J = 5.33 Hz, 3H), 0.83–0.75 (m, 1H), 0.51–0.39 (m, 2H), 0.31–0.15 (m, 2H). ^{13}C NMR (62.9 MHz, $CDCl_3$) δ: 220.1, 61.6, 55.0, 41.2, 42.8, 39.1, 35.1, 31.6, 27.3, 21.1, 18.4, 17.0, 14.7, 12.3. Hydrogenolysis of a cyclopropane: synthesis of 25

To a 20 mL hydrogenation vessel was placed 0.90 mmol of cyclopropane **23**, 9.0 mL of glacial acetic acid, PtO_2 (4 equiv.), and NaOAc (4 equiv.). The vessel was connected to a hydrogenation apparatus, and the system was flushed with H_2 gas for a few minutes. The hydrogen pressure was adjusted to 100 psi (1 psi = 6.894 757 kPa), and the mixture was stirred under hydrogen for 12 h. The vessel was vented, and the catalyst was filtered off. The filtrate was partitioned between ether (20 mL) and water (20 mL). The organic phase was separated, and the aqueous phase was extracted with ether (20 mL × 2). The combined organic phases were dried over magnesium sulfate, filtered, and concentrated. The crude product was purified by flash chromatography (hexane–EtOAc, 10:1). Lactone **25** was synthesized in 98% yield as a white crystalline solid. mp 91 to 92 °C. $[\alpha]^{20}_D$ +15.23 (*c* 1.0, $CHCl_3$). Hydrolysis of lactone 25 and esterification of carboxylic acid 31: synthesis of 32

To a 10 mL round-bottomed flask equipped with a reflux condenser was placed **25** (0.05 g, 0.20 mmol), MeOH (2.0 mL), water (1.0 mL), and KOH (0.5 g). The mixture was heated and stirred under a reflux condition for 12 h. The mixture was allowed to cool to room temperature, was diluted with 2 N HCl (5 mL), and extracted with ether (10 mL × 3). The organic phase was dried over magnesium sulfate, filtered, and concentrated. The crude product was dissolved in 5 mL of ether; a solution of diazomethane in ether was added until a yellow color persisted. The mixture was stirred for 5 min, and the solvent was removed under reduced pressure. The crude product was purified by flash chromatography (hexane–EtOAc, 4:1). Ester **32** was obtained as a colorless oil (0.053 g, 95%). $[\alpha]^{20}_D$ –27.08 (*c* 1.0, $CHCl_3$). IR (neat, cm^{-1}): 3424 (m), 2960 (s), 2872 (s), 1720 (s), 1466 (m), 1175 (m). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.80–3.74 (m, 1H), 3.67 (s, 3H), 2.26 (dd, J = 9.3, 15.0 Hz, 1H), 2.04–1.83 (m, 4H), 1.73–1.35 (m, 6H), 1.26–1.15 (m, 3H), 1.03 (d, J = 7.0 Hz, 3H), 0.96–0.93 (m, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 178.6, 72.4, 55.4, 51.4, 49.7, 46.9, 41.4, 39.4, 37.7, 36.8, 35.9, 32.0, 31.9, 31.2, 24.1, 20.2, 19.3. Dehydration of alcohol 32 using $POCl_3$–HMPA–pyridine and hydrolysis of ester: synthesis of 36

A 10 mL round-bottomed flask was charged with 0.053 g (0.19 mmol) of **32**, 2.0 mL of HMPA, and 0.2 mL of $POCl_3$. The resulting white suspension was stirred for 1 h at room temperature and for another 1 h in an oil bath at 50 °C. Pyridine (0.2 mL) was added, and the mixture was stirred at 50 °C for 1 h, at 75 °C for 45 min, and at 100 °C for 30 min. The mixture was allowed to cool to room temperature and was quenched by the dropwise addition of water (2 mL). The mixture was extracted with ether (5 mL × 3). The combined organic phases were washed with water (5 mL), dried over magnesium sulfate, filtered, and concentrated. The volatile compounds were removed under high vacuum, and the residue was dissolved in DMSO (2 mL). A few drops of water and 0.1 g of KOH were added, and the mixture was heated under reflux for 1 h. The reaction was allowed to cool to room temperature, 2 N HCl (5 mL) was added, and the mixture was extracted with ether (10 mL × 3). The organic phase was dried over magnesium sulfate, filtered, and concentrated. The crude product was purified by flash chromatography (hexane–EtOAc, 10:1). Acid **36** was obtained as a white solid (0.04 g, 88%). mp 133–135 °C. $[\alpha]^{20}_D$ +17.78 (*c* 1.0, $CHCl_3$). Carboxy inversion: synthesis of (+)-dactylol (37)

A dried, 10 mL, round-bottomed flask was charged with 0.03 g (0.11 mmol) of acid **36**, 2.0 mL of 20% solution of $COCl_2$ in toluene, and four drops of DMF. The mixture was stirred at room temperature for 1 h, and then heated under reflux for 30 min. The mixture was allowed to cool to room temperature and was diluted with pentane (5 mL), filtered, and concentrated. The resulting colorless oil was dissolved in benzene (2.0 mL). *m*-CPBA (0.019 g, 0.11 mmol), pyridine (0.1 mL, 0.12 mmol), and DMAP (0.005 g) were added. The mixture was stirred at room temperature for 24 h, filtered, and concentrated. The volatile compounds were removed under high vacuum, and the residue was dissolved in ether (2 mL). The solution was cooled in an ice-water bath and 0.013 g (0.33 mmol) of $LiAlH_4$ was added. The suspension was stirred at 0 °C for 2 h and slowly quenched with water, filtered, and the white precipitate washed thoroughly with ether (5 mL × 3). The combined organic phases were concentrated, and the crude product was purified by flash chromatography (hexane–EtOAc, 10:1). (+)-Dactylol (**37**) was obtained as a white solid (0.012 g, 50%). mp 49 to 50 °C (lit. value (15e), mp 50.3–51.5 °C). $[\alpha]^{20}_D$ +21.38 (*c* 1.0, $CHCl_3$) (lit. value (15e)) $[\alpha]^{20}_D$ +22.5). Polycyclic oxonium ylides — Use of cyclic acetals as convenient scaffolds in the construction of fused bicyclic compounds containing a medium ring[1]

Graham K. Murphy, Fredrik P. Marmsäter, and F.G. West

Abstract: Cyclic mixed acetals with pendant diazoketone side chains undergo efficient rearrangement to ether-bridged cyclooctanoid and cycloheptanoid systems upon treatment with $Cu(hfacac)_2$. Stevens [1,2]-shift of an oxonium ylide furnishes the major product, in some cases accompanied by minor amounts of a product resulting from [1,2]-shift of a sulfonium ylide. These results demonstrate that hetero-substituted carbons are suitable migrating groups for the Stevens [1,2]-shift of oxonium ylides. In cases employing a mixed thioacetal, the resulting sulfide served as a trigger for cleavage of the bridging ether through one of two complementary strategies. In the hydrazulene series, the desired bicyclo[5.3.0]heptene was accompanied by the product of novel transannular S_N2' attack on the resulting allylic ketal.

Key words: [1,2]-shift, diazo, medium-sized ring, oxonium ylide, ring expansion.

Résumé : Les acétals cycliques mixtes portant des chaînes latérales diazocétones soumis à un traitement avec du $Cu(hfacac)_2$ subissent un réarrangement efficace en systèmes cyclooctanoïdes et cycloheptanoïdes à pont éther. Un déplacement [1,2] de Stevens d'un ylure d'oxonium conduit à la formation du produit principal qui est dans quelques cas accompagné de quantités mineures d'un produit qui résulte d'un déplacement [1,2] d'un ylure de sulfonium. Ces résultats démontrent que les carbones substitués par des hétéroatomes sont des groupes migratoires appropriés pour le déplacement [1,2] de Stevens d'ylures d'oxonium. Dans les cas où on fait appel à un acétal mixte, le sulfure qui en résulte sert à déclencher le clivage de l'éther de pont par le biais d'une des deux stratégies complémentaires. Dans la série de l'hydroazulène, le bicyclo[5.3.0]heptène est accompagné par le produit d'une nouvelle attaque transannulaire S_N2' sur le cétal allylique qui en résulte.

Mots clés : déplacement [1,2], diazo, cycle de taille moyenne, ylure d'oxonium, expansion de cycle.

Introduction

Stereocontrolled synthesis of medium-sized carbocycles is an important challenge in synthetic organic chemistry. We have had a long-standing interest in the chemical synthesis of natural products such as dactylol, traversianal, and phorbol (Fig. 1). Common structural features among these compounds include the presence of a functionalized medium-sized ring fused to one or more smaller rings, along with bridgehead oxygenation. Efforts towards the chemical synthesis of these compounds have resulted in many new methods (1). For example, use of a preexisting carbocyclic or heterocyclic ring as a scaffold could allow the formation of an intermediate bridged bicyclic compound by closure of a smaller second ring. Fragmentation of the bridge would then reveal a medium-ring skeleton and install a bridgehead hydroxyl group (2), although attempted cleavage of bridging ethers (3) or their carbon analogues (4) is not always a straightforward process.

The Stevens [1,2]-shift of fused bicyclic oxonium ylides can furnish medium-ring ethers or carbocycles with bridging ethers (5). Early examples typically involved the migration of aryl-substituted carbons, and the products were not well suited to synthetic manipulation. In an effort to broaden the synthetic potential of this approach, we have examined various hetero-substituted examples of the oxonium ylide ring expansion (6, 7). By this approach, bicyclic acetals with bridgehead diazoketone side chains could be used as convenient scaffolds for the construction of seven- and eight-membered carbocycles (Scheme 1). The key [1,2]-shift step is believed to involve a stepwise homolytic mechanism, with subsequent recombination of the intermediate biradical (8).

Here we present a full account of this work, an oxonium ylide-based method that permits the concise synthesis of

functionalized fused 5–8 and 5–7 bicyclic ring systems using a novel sulfur- or oxygen-directed Stevens rearrangement of oxonium ylides. In addition, convenient methodology is described for subsequent sulfur-mediated cleavage of the ether bridge to introduce a bridgehead alcohol.

Results and discussion

Substrate synthesis

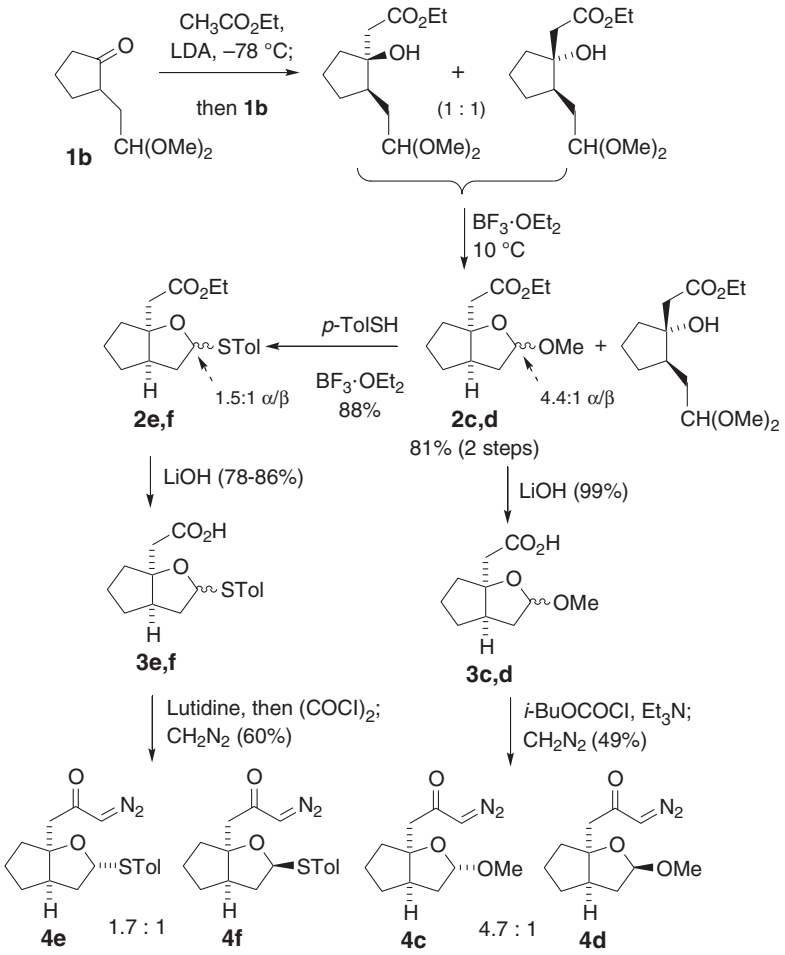
Substrates were prepared in a straightforward fashion via cyclopentanone precursors **1** (Scheme 2). Reformatsky addition of ethyl bromoacetate to the known 2-(3,3)-dimethoxypropyl)-cyclopentanone **1a** (9) was followed by conversion to cyclic acetal **2a** with $BF_3{\cdot}OEt_2$. The methoxy group of the acetal could be exchanged for STol with careful control of temperature and stoichiometry to give mixed thioacetal **2b**. Both **2a** and **2b** were formed as the expected β anomers. Saponification to the acids **3a** and **3b** was uneventful and these intermediates were then converted to the desired diazoketones **4a** and **4b**. Diazoketone **4a** was formed via activation of **3a** as the mixed anhydride, followed by treatment with diazomethane. This method was not suitable in the case of **3b**, as the mixed anhydride was found to be insufficiently reactive. The corresponding acid chloride did furnish some of **4b**, but the process was complicated by the formation of lactone-bridged side product **5**. This material presumably results from acid-catalyzed decomposition of the

Scheme 2.

thioacetal with subsequent trapping by the carboxyl group. We eventually found that careful control of reaction temperature minimized the formation of **5**, allowing access to **4b** in 73% yield.

The lower homologue **1b** (10) was treated with the lithium enolate of ethyl acetate and the diastereomeric adducts were treated with $BF_3{\cdot}OEt_2$ (Scheme 3).[3] This effected cyclization of the cis isomer to the fused bicyclic mixed acetals **2c** and **2d** (4.4:1 mixture of anomers), while leaving the trans diastereomer unchanged. Thio exchange (HSTol, $BF_3{\cdot}OEt_2$) furnished the corresponding mixed thioacetals **2e** and **2f** in good yield. The esters **2c**–**2f** were subjected to saponification to give acids **3c**–**3f**, then converted to diazoketones **4c**–**4f**. As before, the methoxy acetals could be activated via the mixed anhydrides, but the thioacetals required the more reactive acid chlorides. In these cases, the presence of 2,6-lutidine was found to suppress acid-catalyzed decomposition, allowing the formation of **4e** and **4f** in 60% yield.

Finally, two substrates possessing additional carbonyl stabilization at the incipient ylide centre were prepared (Scheme 4). Mixed thioacetals **2b**, **2e**, and **2f** were condensed with ethyl acetate to furnish the corresponding keto esters **6a**–**6c**. Attempts to form **6a** more directly by the addition of the dianion of ethyl acetoacetate to **1a** and **1b**, cyclization to the mixed acetal, and thio exchange encountered a variety of undesired side reactions, so the crossed Claisen approach was followed in all three cases. Standard diazotransfer conditions with *p*-toluenesulfonyl azide (11) were then carried out on **6a** and the major five-membered anomer **6b** to yield the diazoketones **4g** and **4h**.



Oxonium ylide generation and rearrangement — Formation of bicyclo[6.3.0]undecanones and bicyclo[5.3.0]decanones

Substrates **4a**–**4h** were subjected to catalytic carbene transfer conditions to effect generation of the desired

[3] Use of Reformatsky conditions resulted in similar diastereromer ratios and lower yields.

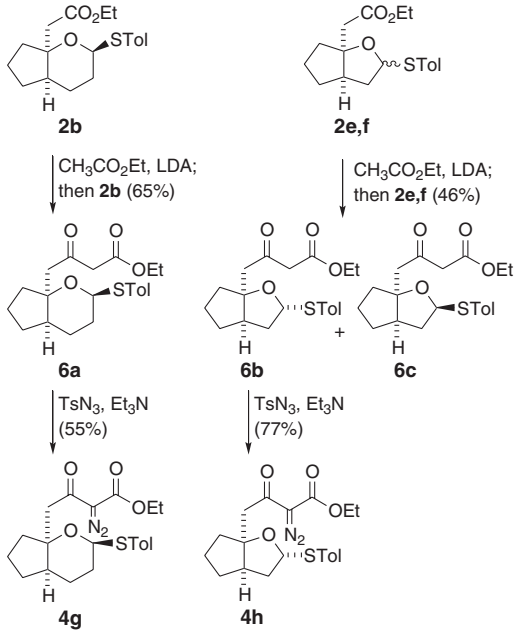
Scheme 3.

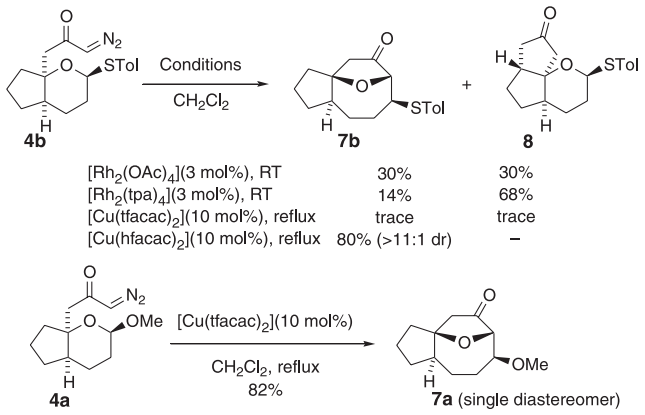
oxonium ylide intermediates. Initial trials with thioacetal **4b** (Scheme 5) were conducted using several transition metal catalysts known to effect oxonium ylide formation (8, 12). Rhodium(II) catalysts were found to be ineffective: both rhodium(II) acetate dimer and the bulkier rhodium(II) triphenylacetate (13) gave a side product tentatively assigned as **8** and only minor amounts of the desired [1,2]-shift product **7b**.[4] There is considerable precedent for poor selectivity for oxonium ylide formation vs. C–H insertion with rhodium carbenoids (5*b*, 8, 12). The optimal conditions ($Cu(tfacac)_2$, CH_2Cl_2, reflux) for the generation and [2,3]-shift of allyl-substituted oxonium ylides (12, 14) gave only low yields of several unidentified products, consistent with the observation that this catalyst is not effective for 1,2]-shift processes (14). In contrast to the above, $Cu(hfacac)_2$ provided **7b** in high yield and with excellent diastereoselectvity. The major diastereomer of **7b** was the result of a [1,2]-shift with retention of configuration at the migrating anomeric centre.[5] Mixed acetal **4a** was also subjected to the optimized conditions found for **4b** and furnished the analogous [1,2]-shift product **7a** in good yield as a single diastereomer, again the result of migration with retention.

The five-membered acetal substrates **4c**–**4f** were next examined (Scheme 6). In each case, the desired ether-bridged bicyclo[5.3.0]octanone system was formed, although the degree of stereochemical retention observed was substantially lower than with **4a** and **4b**. Thus, either the α anomer (**4c**) or the β anomer (**4d**) of the methoxy mixed acetal provided a mixture of **7c** and **7d** in moderate yield, in each case with a small preference for the product of retention. In the case of **4c**, an additional very minor product was isolated and tentatively assigned as structure **9**.[6] Mixed thioacetal **4f** underwent conversion to **7e** and **7f** in excellent yield and with relatively good diastereoselectivity. The corresponding α anomer (**4e**) provided the same products in somewhat lower yield, but in this case a side product, **10e**, was isolated in significant quantities. This compound apparently results from formation of the alternative sulfonium ylide **A**, fol-



[4] Spectral data indicated a newly formed ketone and an intact thioacetal. Evidence for the proposed structure includes the apparent presence of an anomeric acetal-type proton in the ^1H NMR spectrum and a ^{13}C NMR carbonyl chemical shift consistent with a cyclopentanone.

[5] X-ray data confirming the structures of compounds **7b** and **12** can be found in CIF format in the Supporting Information of ref. 7*a*.



[6] Compound **9** may arise from competing formation of the oxonium ylide derived from the OMe group, followed by a 1,4-shift of the methyl substituent. Evidence for the proposed structure of this acid-labile substance includes the presence of both an enol ether and an anomeric carbon, and its silica gel-mediated conversion to an apparent α-methoxy aldehyde.

Scheme 4.

Scheme 5.

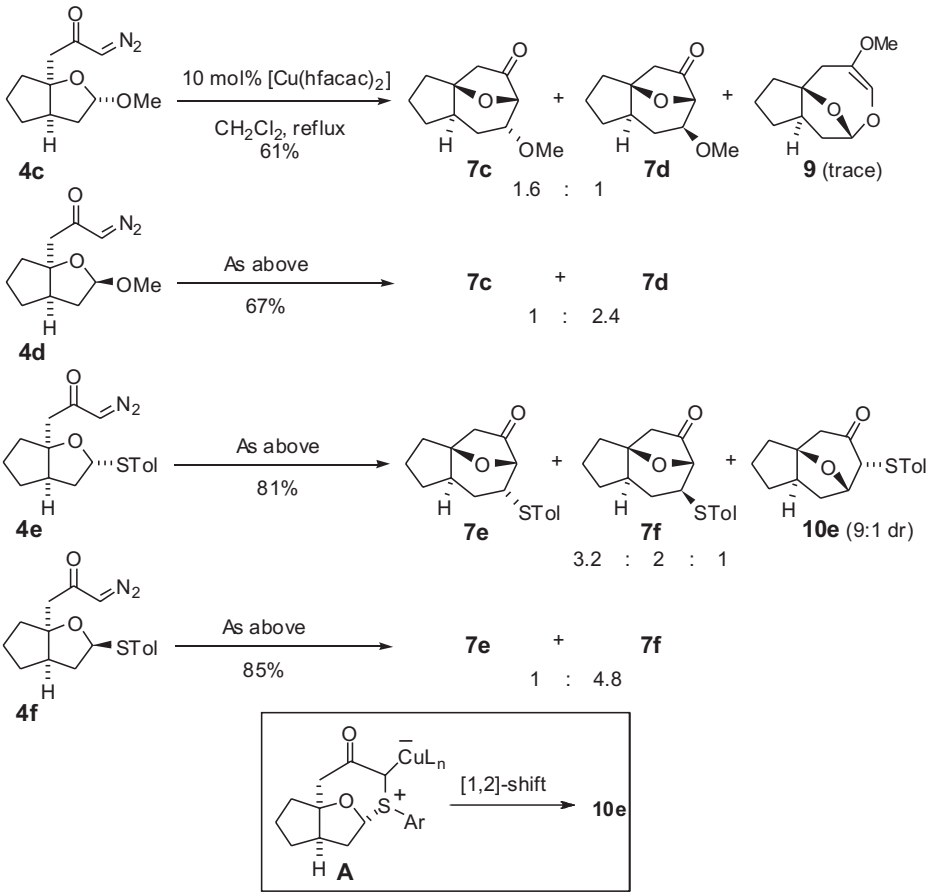
lowed by [1,2]-shift of the anomeric carbon with concomitant ring contraction.

Finally, the doubly stabilized diazoketoester substrates **4g** and **4h** were subjected to $Cu(hfacac)_2$ in refluxing toluene (Scheme 7). Six-membered thioacetal **4g** underwent conversion to **7g** (4.5:1 mixture of diastereomers) in moderate yield. The five-membered thioacetal **4h** gave dramatically different results: only minor amounts of the oxonium ylide-derived products **7h** and **7i** (8:1 dr) were obtained. Instead, the major product was **10h** (ca. 7:1 dr), resulting from selective formation and rearrangement of the sulfonium ylide.

In the key rearrangement steps, it appears that in most cases the oxonium ylide was formed efficiently with $Cu(hfacac)_2$ catalysis and underwent smooth a [1,2]-shift to give the ether-bridged medium-ring products. The exceptions are the doubly stabilized substrates **4g** and **4h**, which did not react in refluxing CH_2Cl_2 and required extended stirring in refluxing toluene to consume starting material. Carbene transfer from diazo compounds substituted with two electron-withdrawing groups is known to be relatively slow.[7] Although the diastereoselectivity varied substantially, in all cases the major product resulted from migration with retention of configuration. Most mechanistic evidence related to ylide [1,2]-shifts points to stepwise rearrangement via radical pair intermediates (8). However, rearrangement with moderate to high degrees of retention in the Stevens rearrangement of both oxonium (5) and ammonium (15) ylides has been observed. One possible explanation for migration with retention is rapid radical recombination as compared with bond rotation (16). However, direct involvement by the transition metal catalyst in the rearrangement step cannot be ruled out (8*b*, 17).

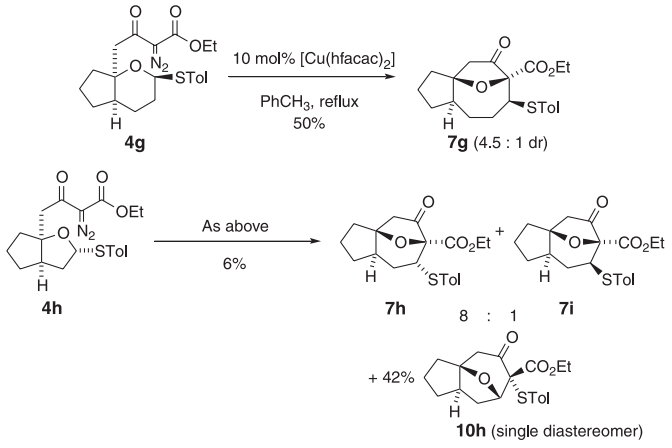
The origin of the lower levels of retention seen for the five-membered acetals **4c**–**4f** as compared with the six-membered substrates **4a**, **4b**, and **4g**, is unclear. Assuming a stepwise mechanism via a radical pair intermediate, this result suggests that the relative rate for recombination vs. bond rotation is greater for six-membered rings despite the presence of an additional freely rotating C–C bond in the side chain. A possible explanation may derive from the relative strain of the angularly fused tricyclic ylide precursors. Homolysis of the more strained 5-5-5 tricyclic ylide **B** could involve greater ring strain release, which might permit a higher amount of randomization by the biradical **C** prior to recombination than in the case of the higher homologues **D** and **E** (Scheme 8; shown for β anomers but also applicable to α anomers **4c**, **4e**, and **4h**). Recombination of **C** may also be slowed relative to that of **E** as a result of increased strain in the cyclization transition state due to the shorter tether. However, since involvement of the catalyst in the [1,2]-shift is also possible (8*b*, 14), this explanation must be viewed as tentative.

Competing formation of the ylide derived from the exocyclic XR group was observed in several cases. This was not seen for six-membered acetal substrates **4a**, **4b**, and **4g** due to the predominant or exclusive formation of the β anomers, with the XR group disposed trans to the diazoketone side chain. On the other hand, the five-membered acetals were formed as anomeric mixtures, and products apparently resulting from the alternative ylides were seen in each case with the α anomers (**4c**, **4e**,and **4h**). Notably, **4h** reacted mainly via the 7-membered sulfonium ylide, possibly as a result of the greater electrophilicity and (or) selectivity of the metallocarbene precursor. Equilibration between the two possible ylides may be possible, based on related competition experiments (4).



Cleavage of the ether bridge

The methodology described above allows for quick entry into a series of ether-bridged fused bicyclic skeletons containing a medium-sized ring. For application to natural product targets, an effective method for cleavage of the bridging ether is needed. We felt that the thioacetal-derived products **7b** and **7e** were well suited to this goal: the thioaryl group, which had effectively mediated the [1,2]-shift of the former anomeric carbon, could now be used as an anionic trigger for eliminative opening of the ether. First, the keto group of



[7] See ref. 11, pp. 64–65.

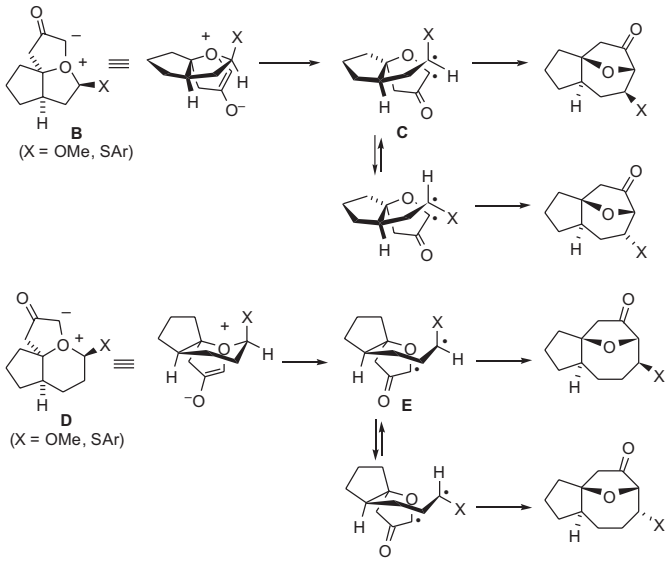
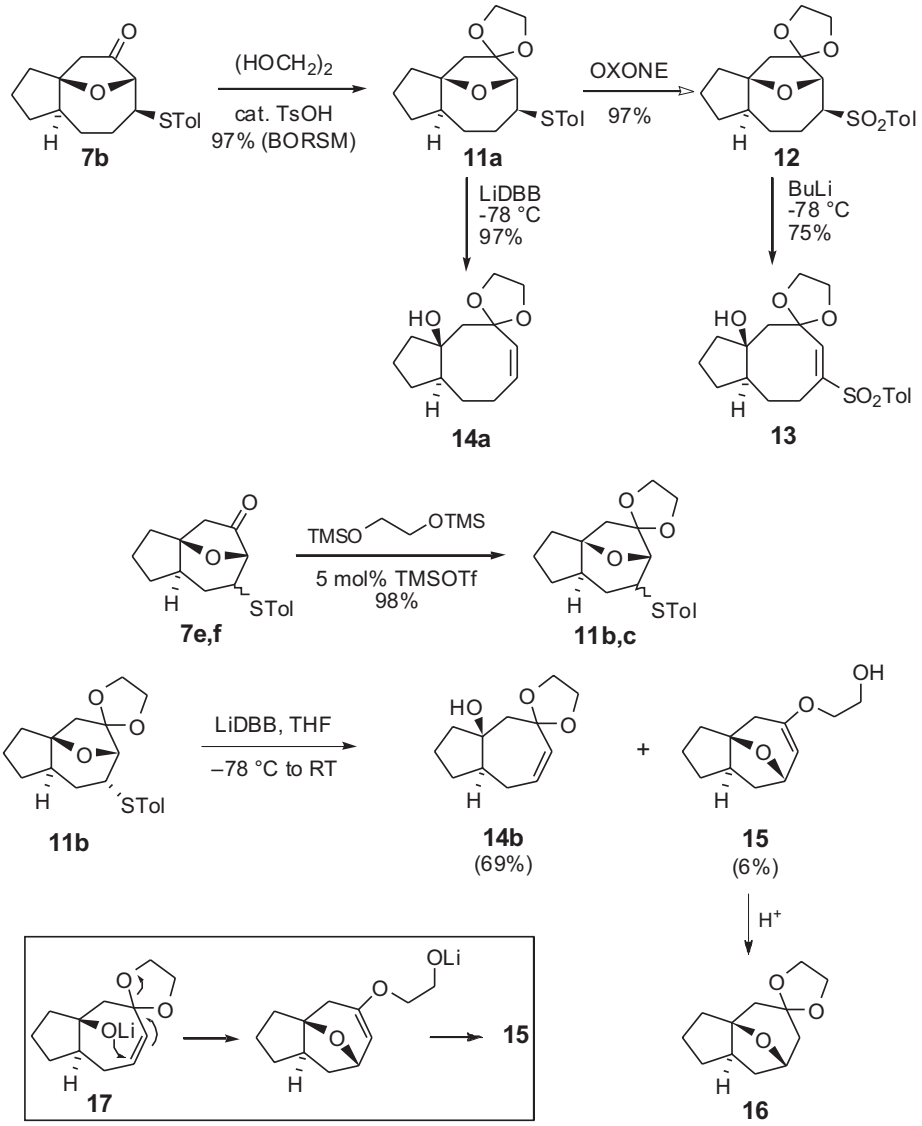


Scheme 6.

Scheme 7.



Scheme 8.

7b was protected as the ethylene ketal to give **11a**, and the thioaryl group oxidized to the corresponding sulfone **12** (18) (Scheme 9). Treatment of this compound with *n*-BuLi at low temperature effected the elimination of the ether to give unsaturated sulfone **13**. Alternatively, **11a** could be subjected to reductive desulfurization with LiDBB (19) to provide cyclooctene **14a** in excellent yield. A mixture of hydrazulenes **7e** and **7f** was converted to ketals **11b** and **11c**, and **11b** was also subjected to the reductive conditions. In this case, cycloheptene **14b** was obtained in good yield, accompanied by minor amounts of enol ether **15**, which underwent slow, acid-catalyzed conversion to ketal **16**. This compound is believed to arise from in situ transannular S_N2' attack by the initially formed lithium alkoxide **17** on the unsaturated ketal. Paquette et al. (20) reported a related case involving

© 2006 NRC Canada

Scheme 9.

transannular cyclization of a medium-ring enolate with concomitant with S_N2' displacement of a methoxy leaving group.

The methodology described here allows for the expeditious construction of fused bicyclic skeletons containing a medium-sized ring, starting with readily available mixed acetals. In cases involving mixed thioacetals, two convenient methods are available for cleavage of the bridging ethers found in the rearrangement products. Interesting reactivity differences are seen, depending upon ring size and anomeric configuration. Application of this chemistry to natural product targets is currently underway and will be reported in due course.

Experimental[8]

General information

Reactions were conducted in oven-dried (120 °C) or flame-dried glassware under a positive nitrogen atmosphere unless otherwise stated. Transfer of anhydrous solvents or mixtures was accomplished with oven-dried syringes or cannulae. Solvents were distilled before use: dichloromethane from calcium hydride; diethyl ether and tetrahydrofuran from sodium benzophenone ketyl. Thin layer chromatography (TLC) was performed on plates of silica precoated with 0.25 mm Kieselgel 60 F_{254}. Flash chro-

matography columns were packed with 230–400 mesh silica gel. Where given, column dimensions include outer diameters. Radial chromatography was performed on plates of silica precoated with 1, 2, or 4 mm silica gel 60 PF_{254} containing gypsum.

Proton nuclear magnetic resonance spectra (^{1}H NMR) were recorded at 300, 400, or 500 MHz on Varian Inova 300, 400, and 500, Mercury 400, or Unity 500 spectrometers, and the chemical shifts are reported on the δ scale (ppm) downfield from tetramethylsilane. Coupling constants (*J*) are reported in Hz. Splitting patterns are designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad; dd, doublet of doublets, etc. Carbon nuclear magnetic resonance spectra (^{13}C NMR) were obtained at 125 MHz and are reported (ppm) relative to the center line of a triplet at 77.23 ppm for deuterochloroform. Infrared spectra (IR) were measured with a Nicolet Magna 750 FT-IR infrared spectrophotometer. Mass spectra were determined on a Kratos Analytical MS-50 (EI) or Applied Biosystems Mariner Biospectrometry Workstation (ESI). Elemental analyses were obtained at the University of Alberta on a Carlo Erba CHNS-O EA 1108 Elemental Analyzer.

Substrate syntheses

Ethyl 2-(2-(3,3-dimethoxypropyl)-1-hydroxycyclopent-1-yl)acetate

To a two-necked flask equipped with a large stir bar and condenser, charged with a mixture of Zn (400 mg, 6.1 mmol) in Et_2O (6 mL), TMSCl (47 μL, 0.36 mmol) was added via syringe (21). The mixture was heated to reflux for 15 min and then stirred at RT for an additional 15 min. Freshly distilled ethyl bromoacetate (0.68 mL, 6.1 mmol) was added dropwise via syringe. The mixture was heated to reflux for 45 min and then stirred at RT for an additional 1 h. During this time, the mixture turned to a yellow tint and most of the solid Zn was consumed. The solution of Reformatsky reagent thus prepared was then transferred via cannula to a second flask, leaving behind any remaining solid Zn. The flask was then cooled to –10 °C (acetone – ice bath) and 2-((3,3)-methoxypropyl)cyclopentanone **1a** (8) (677 mg, 3.61 mmol) was slowly added as a solution in Et_2O (3 mL) via cannula. The reaction was stirred at –10 °C for 1 h and then for an additional 2 h at RT at which time the reaction had consumed the starting material as ascertained by TLC. The reaction was diluted with Et_2O (30 mL) and quenched by addition of satd. NH_4Cl solution (30 mL). The aqueous phase was extracted with Et_2O (3 × 30 mL) and the combined organic phase was dried with $MgSO_4$, filtered, and concentrated. The resulting oil was purified by flash chromatography (silica gel, 3 cm × 24 cm column, solvent ramp: 200 mL each of 20%, 30%, and 40% EtOAc–hexanes) to yield the desired alcohol (856 mg, 87%) as a 3.2:1 cis/trans mixture of diastereomers. R_f = 0.17 (30% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 3516, 2951, 2872, 1731, 1189, 1053. ^{1}H NMR (500 MHz, $CDCl_3$, major diastereomer) δ: 4.35 (t, *J* = 5.7 Hz, 1H), 4.17 (q, *J* = 7.2 Hz, 2H), 3.32 (s, 3H), 3.30 (s, 3H), 2.71 (d, J_{AB} = 15.7 Hz, 1H), 2.33 (d, J_{AB} = 15.4 Hz, 1H), 1.90–1.44 (m, 11H), 1.38–1.31 (m, 1H), 1.28 (t, *J* = 7.2 Hz, 3H). ^{13}C NMR (125 MHz, $CDCl_3$, major diastereomer) δ: 173.6, 105.1, 79.7, 60.9, 53.3, 52.7, 49.5, 40.0, 31.9, 29.9, 23.9, 21.3, 14.4. HR-MS (ESI) calcd. for $C_{13}H_{22}O_4$ (M – MeOH$^+$): 242.1518; found: 242.1521.

Mixed acetal 2a

To a solution of ethyl 2-(2-(3,3-dimethoxypropyl)-1-hydroxycyclopent-1-yl)acetate (812 mg, 2.96 mmol, 3.2:1 mixture of diastereomers) in CH_2Cl_2 (150 mL) cooled to –10 °C (acetone – ice bath), $BF_3{\cdot}OEt_2$ (376 μL, 2.96 mmol) was added via syringe. The reaction was stirred for 15 min at which time the reaction had consumed the starting material as ascertained by TLC. The reaction was quenched by addition of Et_3N (~1 mL) followed by H_2O (50 mL). The aqueous phase was extracted with CH_2Cl_2 (50 mL) and the combined organic phase was washed with brine (200 mL), dried with Na_2SO_4, filtered, and concentrated. The resulting oil was purified by flash chromatography (silica gel, 3 cm × 24 cm column, solvent ramp: 200 mL each of 2.5%, 5%, 10%, and 20% EtOAc–hexanes) to yield the minor (α) anomer of **2a** (99 mg, 18% based on 3.2:1 diastereomer ratio of starting material), major (β) anomer of **2a** (354 mg, 65% based on 3.2:1 diastereomer ratio of starting material), and a mixture of anomers derived from the minor trans diastereomer (131 mg, 77% based on 1:3.2 diastereomer ratio of starting material). Major anomer of **2a**: R_f = 0.49 (30% EtOAc – hexanes). IR (neat, cm^{-1}): 2953, 2870, 1734, 1368, 1225, 1150, 1016. ^{1}H NMR (500 MHz, $CDCl_3$, major anomer) δ: 4.62 (dd, *J* = 8.8, 3.2 Hz, 1H), 4.21 (dq, *J* = 10.8, 7.2 Hz, 1H), 4.09 (dq, *J* = 10.8, 7.2 Hz, 1H), 3.42 (s, 3H), 2.97 (d, J_{AB} = 13.4 Hz, 1H), 2.31 (d, J_{AB} = 13.3 Hz, 1H), 2.10–2.05 (m, 1H), 1.92–1.84 (m, 2H), 1.82–1.65 (m, 5H), 1.63–1.54 (m, 3H), 1.27 (t, *J* = 7.2 Hz, 3H). ^{13}C NMR (125 MHz, $CDCl_3$, major anomer) δ: 171.1, 98.6, 83.8, 60.5, 56.1, 41.1, 40.9, 39.9, 27.9, 25.9, 21.9, 21.8, 14.5. HR-MS (ESI) calcd. for $C_{13}H_{22}O_4$ (M$^+$): 242.1518; found: 242.1516.

Thioglycoside 2b

A solution of **2a** (275 mg, 1.14 mmol) and thiocresol (141 mg, 1.14 mmol) in CH_2Cl_2 (114 mL) was stirred for 10 min to ensure that the thiocresol was completely dissolved. The solution was cooled to –10 °C (acetone – ice bath) and $BF_3{\cdot}OEt_2$ (144 μL, 1.14 mmol) was added dropwise via syringe. The reaction was stirred for 10 min at which time the reaction had consumed the starting material as ascertained by TLC. The reaction was quenched by addition of Et_3N (~1 mL) followed by H_2O (50 mL). The aqueous phase was extracted with CH_2Cl_2 (50 mL) and the combined organic phase was washed with brine (200 mL), dried with Na_2SO_4, filtered, and concentrated. The resulting oil was purified by radial chromatography (4 mm plate, solvent ramp: 100 mL each of 2.5%, 5%, and 10% EtOAc–hexanes) to yield **2b** as a single anomer (313 mg, 82%). R_f = 0.53 (30% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2951, 2869, 1733, 1221, 1044. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.41 (d, *J* = 8.3 Hz, 2H), 7.08 (d, *J* = 7.8 Hz, 2H), 4.90 (dd, *J* = 10.6, 3.6 Hz, 1H), 4.05 (dq, *J* = 11.1, 7.3 Hz, 1H), 3.95 (dq, *J* = 10.9, 7.3 Hz, 1H), 2.88 (d, J_{AB} = 13.6 Hz, 1H), 2.45 (d, J_{AB} = 13.5 Hz, 1H), 2.31 (s, 3H), 2.10–2.05 (m, 1H), 1.92–1.55 (m, 10H), 1.19 (t, *J* = 7.1 Hz, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 170.9, 137.6, 133.4, 130.1, 129.5, 84.6, 79.8, 60.5, 40.1, 39.9, 39.4, 27.7, 25.9, 22.7, 22.0,

21.3, 14.4. HR-MS (ESI) calcd. for $C_{12}H_{19}O_3$ (M – $CH_3C_6H_4S^+$): 211.1334; found: 211.1336.

Acid 3a

To a solution of hemiacetal **2a** (410 mg, 1.69 mmol) in THF (3.0 mL) and methanol (3.0 mL), a 2 mol/L solution of LiOH (1.7 mL) was added. The reaction was stirred for 16 h at RT, during which time the reaction mixture turned slightly yellow. The reaction was diluted with water (15 mL) and Et_2O (15 mL) and transferred to a separatory funnel. The layers were separated and the aqueous layer was washed with ether (15 mL). The aqueous layer was then acidified with 0.5 mol/L HCl to pH ~3, resulting in a cloudy suspension. Ethyl acetate (20 mL) was added to this and the resulting layers separated. The aqueous layer was washed with 3 portions of ethyl acetate (20 mL) and the combined organic extracts were washed with water and then brine, dried over magnesium sulfate, filtered, and concentrated to yield the acid, as a yellow oil (307 mg, 85%). IR (CH_2Cl_2 cast, cm^{-1}): 3500–2400, 2946, 2891, 2680, 1704, 1451, 1408, 1391, 1363, 1335, 1322, 1307. ^1H NMR (500 MHz, $CDCl_3$) δ: 10.90 (br s, 1H), 4.66–4.64 (m, 1H), 3.41 (s, 3H), 2.94 (d, J_{AB} = 14.1 Hz, 1H), 2.35 (d, J_{AB} = 14.1 Hz, 1H), 2.16 (m, 1H), 1.91–1.80 (m, 3H), 1.78–1.72 (m, 4H), 1.66–1.58 (m, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 174.9, 98.9, 83.8, 56.0, 41.2, 41.0, 38.9, 28.1, 26.2, 21.7, 21.5. HR-MS (EI) calcd. for $C_{11}H_{18}O_4$ (M^+): 214.1205; found 214.1192. Anal. calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.73; found: C 61.31, H 8.47.

(1S,3S*,6R*)-3-Methoxy-2-oxabicycl[4.3.0]nonane-1-acetic acid isobutyrylcarbonic mixed anhydride*

To a solution of the acid (100 mg, 0.47 mmol) in Et_2O (2 mL) at 0 °C was added Et_3N (68 μL, 0.49 mmol) followed by isobutyl chloroformate (65 μL, 0.49 mmol). The reaction was stirred for 4 h, resulting in an off-white precipitate. The reaction mixture was filtered through a fritted filter (D), the residue was rinsed with Et_2O (20 mL), and the combined filtrates were concentrated to give the anydride as a yellow oil (149 mg, 100%) used directly in the next step. R_f = 0.66 (30% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2956, 2874, 1819, 1735, 1457, 1392, 1369, 1336, 1307, 1230, 1207. ^1H NMR (500 MHz, $CDCl_3$) δ: 4.60 (dd, J = 8.8, 3.0 Hz, 1H), 4.04 (d, J = 6.7 Hz, 2H), 3.42 (s, 3H), 3.08 (d, J_{AB} = 13.6 Hz, 1H), 2.42 (d, J_{AB} = 13.6 Hz, 1H), 2.16 (m, 1H), 2.01 (sept, J = 6.7 Hz, 1H), 1.94–1.83 (m, 2H), 1.82–1.68 (m, 5H), 1.64–1.53 (m, 3H), 0.97 (d, J = 6.7 Hz, 6H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 165.4, 149.3, 98.7, 83.5, 75.7, 56.2, 41.2, 40.9, 39.7, 28.0, 27.8, 25.9, 21.9, 21.8, 19.0. HR-MS (EI) calcd. for $C_{16}H_{26}O_6$ (M^+): 314.1729; found: 314.1721.

Diazoketone 4a

Into a solution of freshly prepared diazomethane (12 mmol) in Et_2O (40 mL) at –15 °C was added a solution of the mixed anhydride (250 mg, 0.80 mmol) in Et_2O (10 mL), and the resulting mixture was allowed to stir overnight as the cold bath expired. A stream of N_2 was applied to the system to allow for slow evaporation of both excess diazomethane and solvent, and the resulting yellow oil was diluted in ether and passed through a short pad of silica gel in a fritted filter, eluting with ether. This was then concentrated and the resulting oil purified by radial chromatography (2 mm plate, solvent ramp: 100 mL each of 5%, 10% then 15% EtOAc–hexanes until the product was recovered) to yield starting material (152 mg) as well as **4a** (51 mg, 22%; 70% BRSM) as a yellow oil. R_f = 0.33 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 3082, 2953, 2869, 2101, 1733, 1637, 1457, 1364, 1226, 1187. ^1H NMR (500 MHz, –20 °C, $CDCl_3$) δ: 5.50 (s, 1H), 4.64 (dd, J = 8.4, 3.1 Hz, 1H), 3.46 (s, 3H), 2.96 (d, J_{AB} = 13.7 Hz, 1H), 2.33 (d, J_{AB} = 13.7 Hz, 1H), 2.09 (ddd, J = 12.8, 8.2, 4.0 Hz, 1H), 1.86 (m, 2H), 1.82–1.66 (m, 5H), 1.66–1.54 (m, 3H). ^{13}C NMR (125 MHz, –60 °C, $CDCl_3$,) δ: 193.0, 98.2, 83.8, 56.7, 56.6, 46.0, 41.1, 39.2, 26.8, 25.2, 21.4, 21.0. HR-MS (EI) calcd. for $C_{12}H_{17}N_2O_3$ (M – H^+): 237.1239; found: 237.1225.

Acid 3b

To a solution of **2b** (850 mg, 2.54 mmol) in THF (2 mL) and MeOH (4 mL) was added a 2 N solution of LiOH (2.54 mL). The reaction was stirred for about 12 h during which time the reaction turned slightly yellow and the starting material was consumed as ascertained by TLC. The reaction was diluted by addition of Et_2O (50 mL) and H_2O (50 mL). The aqueous phase was washed with Et_2O (50 mL). After the layers were separated, EtOAc (50 mL) was added to the aqueous phase followed by the dropwise addition of 3 N HCl until the pH reached ~2. The cloudy aqueous phase was then extracted with EtOAc (3 × 30 mL), the combined organic phase was dried with Na_2SO_4, filtered, and concentrated to yield the desired acid as a white solid (743 mg, 96%), mp 122–124 °C. IR (CH_2Cl_2 cast, cm^{-1}): 3220, 3030, 2948, 1707, 1042, 979. ^1H NMR (500 MHz, $CDCl_3$) δ: 10.88 (br s, 1H), 7.42 (d, J = 8.1 Hz, 2H), 7.09 (d, J = 8.3 Hz, 2H), 4.89–4.86 (m, 1H), 2.98 (d, J_{AB} = 14.6 Hz, 1H), 2.39 (dd, J = 14.5, 1.9 Hz, 1H), 2.32 (s, 3H), 2.13–2.08 (m, 1H), 1.91–1.59 (m, 10H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 175.7, 138.1, 133.6, 129.6, 129.4, 84.6, 80.3, 40.4, 39.8, 38.9, 27.7, 25.8, 22.7, 21.9, 21.4. HR-MS (ESI) calcd. for $C_{17}H_{22}O_3S$ (M^+): 306.1289; found: 306.1284.

Diazoketone 4b

To a solution of oxalyl chloride (38 μL, 0.44 mmol) and the acid in CH_2Cl_2 (2.4 mL) cooled to –45 °C (acetonitrile – dry ice bath) was added 1 drop of DMF. The reaction was stirred at this temperature for 1 h then allowed to warm to –10 °C (acetone – ice bath; gas evolution was observed during the warming of the reaction) and stirred an additional 1 h at that temperature. The reaction was then directly transferred via cannula to a freshly prepared solution of diazomethane (~4 mmol) in Et_2O (~12 mL) and cooled to –45 °C (acetonitrile – dry ice bath). The bath was allowed to expire, and a stream of N_2 was introduced once the reaction reached RT The crude yellow oil thus obtained was passed through a short pad of silica gel (1 cm in a disposable pipette), eluting with 10 mL of 50% EtOAc–hexanes. The solvents were removed under reduced pressure and the resulting yellow oil was purified by radial chromatography (2 mm plate, solvent ramp: 100 mL each of 10%, 20%, and 30% EtOAc–hexanes) to yield **4b** as a yellow solid (88 mg, 73%), mp 93 to 94 °C. R_f = 0.30 (30% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2949, 2868, 2100, 1635, 1363, 1044. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.48 (d, J = 8.1 Hz, 2H), 7.12 (d, J = 8.2 Hz, 2H),

© 2006 NRC Canada

4.84–4.81 (m, 1H), 4.78 (br s, 1H), 2.97 (d, J_{AB} = 14.6 Hz, 1H), 2.31 (s, 3H), 2.09 (br app d, J_{AB} = 14.6 Hz, 1H), 1.95–1.54 (m, 11H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 193.0, 138.7, 135.1, 129.7, 129.5, 84.6, 80.6, 55.2, 45.7, 42.0, 39.0, 27.8, 25.8, 22.8, 21.9, 21.3. HR-MS (ESI) calcd. for $C_{18}H_{22}N_2O_2NaS$ ($M + Na^+$): 353.1300; found: 353.1295.

Ethyl acetate adducts of 1b

Into a stirring solution of diisopropyl amine (3.66 mL, 26.1 mmol) in THF (30 mL) at –78 °C, *n*-BuLi (10.9 mL of 2.4 mol/L solution, 26.1 mmol) was added and the resulting mixture was stirred at –78 °C for 30 min. This was then warmed to 0 °C over several minutes and stirred for another 30 min before being cooled once again to –78 °C. Ethyl acetate (2.44 mL, 25 mmol) was added dropwise, and the mixture was stirred for 1 h. A solution of 2-[(2,2-dimethoxy)ethyl]cyclopentanone **1b** (9) (4.0 g, 22.7 mmol) in THF (10 mL) was added dropwise to the above mixture and the reaction mixture was stirred at –78 °C until the reaction was complete by TLC analysis (4 h). The reaction mixture was quenched with saturated ammonium chloride (25 mL). After separation of the phases, the aqueous layer was extracted with Et_2O (3 × 15 mL) and the combined organic extracts were washed with water (50mL) and brine (50mL), dried ($MgSO_4$), filtered, and concentrated. The crude product (5.64 g, 95.3%), a 1.7:1 mixture of inseparable cis and trans isomers (ratio determined by ^{1}H NMR integration of methoxy singlets), was carried on without further purification.

Cis isomer

R_f = 0.23 (3:7 EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 3513, 2953, 2830, 1731, 1447, 1371, 1334, 1190, 1125, 1057, 964. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 4.37 (dd, J = 7.8, 3.5 Hz, 1H), 4.14 (q, J = 7.0 Hz, 2H), 3.28 (s, 6H), 3.23 (br s, 1H), 2.66 (d, J_{AB} = 15.5 Hz, 1H), 2.33 (d, J_{AB} = 15.5 Hz, 1H), 1.88–1.65 (m, 5H), 1.60–1.50 (m, 4H), 1.25 (t, J = 7.0 Hz, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 220.7, 103.3, 53.4, 52.8, 45.7, 37.9, 32.7, 30.4, 21.0. LR-MS (ESI) calcd. for $C_{13}H_{24}O_5Na$ ($M + Na^+$): 283.1; found: 283.1. Anal. calcd. for $C_{13}H_{24}O_5$: C 59.98, H 9.29; found: C 59.58, H 10.01. (Data obtained from the inseparable mixture of diastereomers).

Trans isomer

R_f = 0.23 (3:7 EtOAc–hexanes). LR-MS (ESI) calcd. for $C_{13}H_{24}O_5Na$ ($M + Na^+$): 283.1; found: 283.1. Anal. calcd. for $C_{13}H_{24}O_5$: C 59.98, H 9.29; found: C 59.85, H 9.29. (Data obtained from a pure sample of the trans isomer recovered after the formation of **2c** and **2d** from the inseparable mixture of cis and trans isomers).

Mixed acetals 2c and 2d

To a solution of the cis and trans ethyl acetate adducts (11.2 g, 43.3 mmol) in CH_2Cl_2 (1.0 L) at –15 °C (acetone – ice bath), $BF_3{\cdot}OEt_2$ (5.50 mL, 43.3 mmol) was added and the reaction was stirred for 20 min, at which time TLC showed consumption of the cis isomer and a mixture of **2c** and **2d**, together with unreacted trans isomer. The reaction was quenched with Et_3N (6 mL) and water (500 mL) and the resulting phases were separated. The aqueous layer was extracted with CH_2Cl_2 and the combined organic extracts were washed with water and brine, then dried ($MgSO_4$), filtered, and concentrated. The crude product was purified by column chromatography (silica gel; 3:7, EtOAc–hexanes) to afford recovered trans adduct and **2c** and **2d** (3.85 g, 62%; 4.4:1 mixture of α and β anomers; ratio based on integration of OMe singlets) as a yellow oil. R_f = 0.53 (3:7, EtOAc–hexanes). Mixed thioacetals 2e and 2f

To a solution of **2c** and **2d** (50 mg, 0.22 mmol) and *p*-thiocresol (27 mg, 0.22 mmol) in CH_2Cl_2 (22 mL) at –45 °C, $BF_3{\cdot}OEt_2$ (28 μL, 0.22 mmol) was added and the reaction was stirred until deemed complete by TLC. After 2 h only a trace of starting acetals was observed; the reaction was quenched with Et_3N (0.5 mL) and water (15 mL) and the resulting bi-layer was separated. The aqueous phase was extracted with CH_2Cl_2 (15 mL) and the combined organic extracts were washed with water (30 mL), brine (30 mL), dried with magnesium sulfate, filtered, and concentrated. The crude product was first passed through a pad of silica gel in a fritted filter, eluting with Et_2O, and then purified by radial chromatography (silica gel, 2 mm plate, solvent ramp: 100 mL each of 3%, 6%, and then 9% EtOAc–hexanes until the product was recovered) to afford the product, a yellow oil, as a 1:5:1 mixture of partially separable anomers (**2e** and **2f**) in 88% yield (57 mg) based on recovered **2c** and **2d** (4 mg).

Diazoketones 4c and 4d

To a solution of mixed acetals **2c** and **2d** (1.00 g, 4.38 mmol) in THF (8 mL) and methanol (8 mL) was added a 2.0 mol/L solution of LiOH (4.38 mL). The reaction was stirred for 16 h at RT, during which time the reaction mixture turned slightly yellow. The reaction was diluted with water (20 mL) and Et_2O (20 mL) and transferred to a separatory funnel. The layers were separated and the aqueous layer was washed with ether (20 mL). The aqueous layer was then acidified with 0.5 mol/L HCl to pH ~3, resulting in a cloudy suspension. This was then diluted with ethyl acetate (30 mL) and the resulting layers separated. The aqueous layer was washed with three portions of ethyl acetate (20 mL) and the combined organic extracts were washed with water then brine, dried over magnesium sulfate, filtered, and concentrated to give the acids **3c** and **3d** (mixture of anomers) as a yellow oil (870 mg, 99%). IR (CH_2Cl_2 cast, cm^{-1}): 3600–2500, 2949, 1708, 1468, 1440, 1409, 1339, 1300, 1218. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 10.8 (br s, 1H), 4.99 (d, J = 5.2 Hz, 1.0H), 3.30 (s, 2.4H), 3.28 (s, 0.6H), 2.90 (d, J_{AB} = 14.9 Hz, 0.8H), 2.64 (d, J_{AB} = 14.6 Hz, 0.2H), 2.63 (d, J_{AB} = 14.9 Hz, 0.8H), 2.56 (d, J_{AB} = 14.6 Hz, 0.2H), 2.49 (ddd, J = 4.6, 1.2 Hz, 0.2H), 2.27 (ddd, J = 13.6, 9.8, 5.7 Hz, 0.2H), 2.20 (dd, J = 13.3, 9.2 Hz, 0.8H), 1.98–1.80 (m, 1.6H), 1.75–1.55 (m, 5.2H), 1.43 (m, 1.0H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: major anomer: 176.0, 107.1, 93.5, 55.0, 46.5, 46.0, 41.1, 38.9, 33.7, 24.0; minor anomer: 176.0, 107.2, 94.7, 55.1, 44.8, 40.2, 40.1, 34.0, 24.6. HR-MS (EI) calcd. for $C_{10}H_{16}O_4$ (M^+): 200.1049; found: 200.1051.

To a solution of the anomeric acids **3c** and **3d** (800 mg, 4.0 mmol) in Et_2O (50 mL) at 0 °C was added Et_3N (585 μL, 4.4 mmol) followed by isobutyl chloroformate (574 μL, 4.4 mmol) and the reaction was stirred for 2.5 h, resulting in the formation of an off-white precipitate. The reaction mixture was filtered through a fritted filter (D), rinsed with Et_2O (50 mL), and concentrated to give the mixed anhydrides (1.09 g, 91%) as a yellow oil. R_f = 0.62 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2958, 2784, 2831, 1804, 1760, 1470, 1452, 1396, 1370. ^{1}H NMR (500 MHz, $CDCl_3$, major anomer) δ: 5.00 (d, J = 5.3 Hz, 1H), 4.03 (d, J = 7.1 Hz, 2H), 3.31 (s, 3H), 3.03 (d, J_{AB} = 15.3 Hz, 1H), 2.80 (d, J_{AB} = 15.3 Hz, 1H), 2.66 (m, 1H), 2.23 (dd, J = 13.3, 9.2 Hz, 1H), 2.01 (sept, J = 6.8 Hz, 1H), 2.00 (m, 1H), 1.76 (m, 1H), 1.68 (ddd, J = 12.0, 7.5, 5.3 Hz, 1H), 1.63 (m, 2H), 1.46 (m, 1H), 0.95 (d, J = 6.8 Hz, 6H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: major anomer: 165.8, 149.4, 106.9, 93.1, 75.7, 54.8, 46.4, 45.7, 41.3, 38.8, 33.5, 27.8, 24.0, 19.0; minor anomer: 165.6, 149.4, 106.7, 94.4, 75.5, 54.8, 45.6, 44.6, 41.4, 38.9, 34.3, 33.6, 24.5, 19.0. HR-MS (EI) calcd. for $C_{15}H_{23}O_6$ ($M - H^+$): 299.1495; found: 299.1499.

A solution of anomeric mixed anhydrides (624 mg, 2.2 mmol) in Et_2O (10 mL) was added via cannula to a solution of freshly prepared diazomethane (20 mmol) in Et_2O (60 mL) at –15 °C, and the resulting mixture was stirred for 16 h as the cooling bath expired. A gentle stream of N_2 was applied to the system to allow for slow evaporation of both excess diazomethane and solvent, and the resulting yellow oil was diluted in ether (20 mL), passed through a short pad of silica gel in a fritted filter, eluting with copious ether. This was then concentrated and the resulting oil purified by radial chromatography (silica gel, 4 mm plate, solvent ramp: 100 mL each of 3%, 6%, 9%, and then 12% EtOAc–hexanes until the products were recovered) to yield **4c** and **4d**, an inseparable 4.7:1 mixture of anomers (228 mg, 49%) as a bright yellow oil, as well as a trace of starting material (not quantified). R_f = 0.23 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 3087, 2949, 2868, 2829, 2102, 1817, 1735, 1637, 1440, 1361. ^{1}H NMR (500 MHz, –40 °C, $CDCl_3$) δ: 5.67 (s, 0.8H), 5.52 (s, 0.2H), 5.01 (m, J = 5.1 Hz, 1H), 3.36 (s, 2.4H), 3.30 (s, 0.6H), 2.94 (d, J_{AB} = 14.3 Hz, 0.8H), 2.69 (d, J_{AB} = 13.5 Hz, 0.2H), 2.60 (m, 1H), 2.55 (d, J_{AB} = 14.3 Hz, 0.8H), 2.47 (d, J_{AB} = 13.5 Hz, 0.2H), 2.20 (dd, J = 13.5, 9.5 Hz, 1H), 1.90 (m, 1H), 1.70–1.45 (m, 6H). ^{13}C NMR (125 MHz, $CDCl_3$, –60 °C) δ: major anomer: 194.1, 106.4, 93.4, 56.0, 54.9, 52.8, 46.4, 40.3, 38.1, 32.5, 23.4; minor anomer: 194.1, 106.5, 95.4, 56.8, 54.7, 50.8, 44.2, 40.3, 39.9, 33.6, 24.2; HR-MS (ESI) calcd. for $C_{11}H_{16}N_2O_3Na$ ($M + Na^+$): 247.1059; found: 247.1060.

Diazoketones 4e and 4f

Preparation and characterization of individual acid anomers is given below. For convenience, they were usually prepared as a mixture of anomers and converted into the separable diazoketones.

To a solution of mixed acetal **2e** (423 mg, 1.3 mmol) in THF (5 mL) and methanol (5 mL) was added a 2.0 mol/L solution of LiOH (1.3 mL). The reaction was stirred for 16 h at RT, during which time the reaction mixture turned slightly yellow. The reaction was diluted with water (20 mL) and Et_2O (20 mL) and transferred to a separatory funnel. The layers were separated and the aqueous layer was washed with ether (15 mL). The aqueous layer was then acidified with 0.5 mol/L HCl to pH ~3, resulting in a cloudy suspension. This was then diluted with ethyl acetate (40 mL) and the resulting layers separated. The aqueous layer was washed with three portions of ethyl acetate (20 mL) and the combined organic extracts were washed with water (50 mL) and then brine (50 mL), dried over magnesium sulfate, filtered, and concentrated to yield **3e** as a yellow oil (333 mg, 86%). IR (CH_2Cl_2 cast, cm^{-1}): 3500–2400, 2953, 2867,

© 2006 NRC Canada

1708, 1597, 1493, 1443, 1408, 1300, 1231, 1133, 1093. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.34 (d, J = 8.2 Hz, 2H), 7.07 (d, J = 8.2 Hz, 2H), 5.56 (dd, J = 6.0, 6.0 Hz, 1H), 3.03 (d, J_{AB} = 14.8 Hz, 1H), 2.74 (d, J_{AB} = 14.8 Hz, 1H), 2.63 (m, 1H), 2.32–2.25 (m, 1H), 2.29 (s, 3H), 2.14 (ddd, J = 13.4, 6.8, 5.0 Hz, 1H), 1.98–1.92 (m, 1H), 1.88–1.79 (m, 1H), 1.70–1.58 (m, 3H), 1.52–1.46 (m, 1H), (COO*H* peak not measured). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 186.8, 137.9, 132.5, 130.8, 130.0, 94.7, 88.7, 47.5, 44.9, 40.5, 39.0, 33.0, 24.5, 21.3. HR-MS (EI) calcd. for $C_{16}H_{20}SO_3$ (M^+): 292.1133; found: 292.1135.

Following the same procedure as the previous section, **2f** (142 mg, 0.44 mmol) was converted into the corresponding acid **3f** (100 mg, 78%) as a white solid, mp 115 to 116 °C. IR (CH_2Cl_2 cast, cm^{-1}): 3500–2500, 2949, 2865, 1707, 1493, 1439, 1411, 1299, 1232, 1146, 1093. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 9.4 (br s, 1H), 7.34 (d, J = 8.4 Hz, 2H), 7.06 (d, J = 8.4 Hz, 2H), 5.28 (dd, J = 8.2, 5.6 Hz, 1H), 2.69 (d, J_{AB} = 14.8 Hz, 1H), 2.57 (d, J_{AB} = 14.8 Hz, 1H), 2.60–2.51 (m, 2H), 2.29 (s, 3H), 2.10 (m, 1H), 1.78–1.54 (m, 6H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 186.8, 137.7, 132.4, 130.7, 129.9, 94.4, 86.5, 47.6, 43.6, 40.6, 39.0, 33.6, 24.3, 21.3; HR-MS (EI) calcd. for $C_{16}H_{20}SO_3$ (M^+): 292.1133; found: 292.1141. Anal. calcd. for $C_{16}H_{20}O_3S$: C 65.72, H 6.89; found: C 65.21, H 7.07.

To a solution of both anomeric acids (**3e** and **3f**) (1.0 g, 3.42 mmol) in CH_2Cl_2 (140 mL) at –15 °C was added 2,6-lutidine (478 μL, 4.1 mmol) followed by oxalyl chloride (36 μL, 4.1 mmol) and DMF (2 drops, ~10 μL), resulting in the evolution of copious amounts of gas. The reaction was stirred for 4 h, and solvent was removed by rotary evaporation to give a yellow oil entrained in a white precipitate. This material was redissolved in ether (50 mL) and the suspension filtered through a fritted filter (D) and was then washed several times with ether (50 mL). The ethereal solution of the acid chloride was condensed to a lesser volume (~50 mL) and added via cannula to a solution of freshly prepared diazomethane (60 mmol) in Et_2O (200 mL) at –15 °C, and the resulting mixture stirred for 16 h as the cooling bath expired. A gentle stream of N_2 was applied to the system to allow for slow evaporation of both excess diazomethane and solvent, and the resulting yellow oil was diluted in ether (40 mL), passed through a short pad of silica gel in a fritted filter, eluting with copious ether. The filtrate was concentrated and the resulting oil purified by radial chromatography (silica gel, 4 mm plate, solvent ramp: 100 mL each of 3%, 6%, 9%, and then 12% EtOAc–hexanes until the products were recovered) to yield **4e** (410 mg) and **4f** (240 mg), as yellow oils in a combined overall yield of 60%.

Major anomer 4e (α)

R_f = 0.32 (3:7, EtOAc–hexanes). Ethyl acetate adduct 6a

Into a stirring solution of diisopropyl amine (1.44 μL, 10.31 mmol) in THF (7 mL) at –78 °C, *n*-BuLi (4.37 mL of 2.36 mol/L solution, 10.31 mmol) was added, and the resulting mixture was stirred at –78 °C for 30 min. This was then warmed to 0 °C over several minutes and stirred for another 30 min before being cooled once again to –78 °C. Ethyl acetate (968 μL, 9.9 mmol) was added dropwise, and the mixture was stirred for 1 h. A solution of anomer **2b** (662 mg, 1.98 mmol, 1 equiv.) in THF (1 mL) was added dropwise to the mixture and the reaction mixture was stirred overnight, allowing the cooling bath to expire. The reaction was then diluted with ethyl ether (10 mL) and quenched by the addition of saturated ammonium chloride solution (10 mL). After separation of the phases, the aqueous layer was extracted with Et_2O (3 × 10 mL) and the combined organic extracts were washed with water (15 mL) and brine (15 mL), dried ($MgSO_4$), filtered, and concentrated. The crude β-ketoester product was then purified by radial chromatography (4 mm plate, solvent ramp: 100 mL each of 2%, 4%, 8%, and then 15% EtOAc–hexanes until the product was recovered) to afford 424 mg of the product **6a** as a yellow oil in 65% yield, based on recovered **2b** (77 mg). R_f = 0.65 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2952, 2870, 1743, 1712, 1492, 1449, 1366, 1318, 1236, 1152, 1096, 1041. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.40 (d, J = 8.1 Hz, 2H), 7.06 (d, J = 8.2 Hz, 2H), 4.86 (dd, J = 8.0, 5.6 Hz, 1H), 4.12 (q, J = 7.2 Hz, 2H), 3.26 (d, J_{AB} = 14.0 Hz, 1H), 3.19 (d, J_{AB} = 15.8 Hz, 1H), 3.05 (d, J_{AB} = 15.8 Hz, 1H), 2.32 (s, 3H), 2.29 (d, J_{AB} = 14.0 Hz, 1H), 1.92–1.52 (m, 11H), 1.25 (t, J = 7.1 Hz, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 201.8, 167.3, 138.3, 134.5, 129.5, 129.1, 84.5, 80.2, 61.1, 49.8, 46.4, 41.4, 39.0, 27.4, 25.7, 22.6, 21.8, 21.1, 14.1. HR-MS (EI) calcd. for $C_{21}H_{28}O_4S$ (M – $EtOH^+$): 330.1290; found: 330.12943.

Diazoketoester 4g

To a stirred solution of **6a** (91 mg, 0.24 mmol, 1 equiv.) and TEA (34 μL, 0.24 mmol, 1 equiv.) in CH_3CN (2 mL), *p*-TsN_3 (48 mg, 0.24 mmol, 1 equiv.) was added, and the mixture was vigorously stirred at RT for 2.5 h. The CH_3CN was then removed by rotary evaporation and the resulting oil dissolved in 10 mL ether. This solution was washed with 5 mL of 25% aq. KOH, 5 mL of 6% aq. KOH, and then 10 mL

© 2006 NRC Canada

water. The organic layer was then dried over sodium sulfate and concentrated by rotary evaporation. The product was purified by radial chromatography (2 mm plate, solvent ramp: 50 mL each of 1%, 2%, 5%, and then 10% EtOAc–hexanes until the product was recovered) to afford 54 mg (55%) of **4g** as a pale yellow oil. R_f = 0.62 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2948, 2869, 2133, 1712, 1652, 1492, 1371, 1300, 1220, 1145, 1040. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.42 (d, J = 8.1 Hz, 2H), 7.07 (d, J = 8.0 Hz, 2H), 4.93 (dd, J = 8.0, 5.2 Hz, 1H), 4.21 (q, J = 7.2 Hz, 1H), 4.18 (q, J = 7.2 Hz, 1H), 4.01 (d, J_{AB} = 14.4 Hz, 1H), 2.52 (d, J_{AB} = 14.4 Hz, 1H), 2.31 (s, 3H), 2.13 (m, J = 8.5, 4.7 Hz, 1H), 1.98–1.84 (m, 3H), 1.80–1.54 (m, 7H), 1.30 (t, J = 7.1 Hz, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 189.7, 161.2, 137.5, 133.8, 130.0, 129.1, 85.5, 80.2, 61.3, 41.3, 40.8, 40.0, 27.4, 25.7, 22.8, 22.0, 21.0, 14.1, (diazo carbon was not detected for this compound). HR-MS (EI) calcd. for $C_{21}H_{26}O_4S$ ($M - N_2^+$): 374.1552; found: 374.1548.

Ethyl acetate adducts 6b (α) and 6c (β)

Into a stirring solution of diisopropyl amine (409 μL, 2.92 mmol) in THF (1 mL) at –78 °C, *n*-BuLi (1.24 mL of 2.36M solution, 2.92 mmol) was added, and the resulting mixture was stirred at –78 °C for 30 min. This was then warmed to 0 °C over several minutes and stirred for another 30 min before being cooled once again to –78 °C. Ethyl acetate (280 μL, 2.86 mmol) was added dropwise, and the mixture was stirred for 1 h. A solution of anomers **2e** and **2f** (183 mg, 0.57 mmol, 1 equiv.) in THF (1 mL) was added dropwise to the mixture and the reaction mixture was stirred overnight, allowing the cooling bath to expire. The reaction was then diluted with ethyl ether (10 mL) and quenched by the addition of saturated ammonium chloride solution (5 mL). After separation of the phases, the aqueous layer was extracted with Et_2O (3 × 5 mL) and the combined organic extracts were washed with water (15 mL) and brine (15 mL), dried ($MgSO_4$), filtered, and concentrated. The crude β-ketoester product was then purified by radial chromatography (2 mm plate, solvent ramp: 50 mL each of 2%, 4%, 8%, and then 15% EtOAc–hexanes until the product was recovered) to afford the products as yellow oils and as a mixture of separable anomers **6b** (α) and **6c** (β) in 46% yield (51 and 38 mg, respectively), based on recovered **2** (13 mg).

Major anomer 6b (α)

R_f = 0.69 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2955, 2867, 1744, 1713, 1493, 1446, 1366, 1313, 1235 1153, 1094, 1031. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.36 (d, J = 8.2 Hz, 2H), 7.11 (d, J = 8.2 Hz, 2H), 5.62 (dd, J = 6.2, 6.2 Hz, 1H), 4.16 (q, J = 7.1 Hz, 1H), 4.15 (q, J = 7.1 Hz, 1H), 3.51 (s, 2H), 3.26 (d, J_{AB} = 14.7 Hz, 1H), 2.87 (d, J_{AB} = 14.8 Hz, 1H), 2.62 (m, 1H), 2.32 (s, 3H), 2.27 (ddd, J = 12.7, 8.6, 5.6 Hz, 1H), 1.92–1.84 (m, 2H), 1.70–1.60 (m, 3H), 1.48 (m, 1H), 1.25 (t, J = 7.1 Hz, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 202.1, 167.4, 136.8, 131.9, 130.8, 129.7, 95.0, 87.8, 61.1, 52.7, 50.5, 47.4, 40.5, 38.7, 32.7, 24.3, 21.0, 14.1. Carbene transfer reactions of diazo compounds 4a–4h

Catalytic decomposition of diazoketone 4b with Cu(hfacac)$_2$; 8-(p-tolylthio)-12-oxatricyclo[7.2.1.0^{1,5}]undecan-10-one (7b)

To a solution of $Cu(hfacac)_2$ (11 mg, 0.017 mmol, 10 mol%) in CH_2Cl_2 (22 mL, 0.01 mol/L) heated to reflux, was added dropwise via cannula, a solution of diazoketone **4b** (56 mg, 0.17 mmol) in 2 mL of CH_2Cl_2. Following completion of addition, the reaction was stirred at reflux until complete consumption (ca. 30 min) of **4b** (TLC monitoring), after which the reaction was cooled to RT and a solution of 0.5 mol/L K_2CO_3 was added. The aqueous phase was then extracted with CH_2Cl_2 (2 × 15 mL) and the combined organic phase was dried with $MgSO_4$, filtered, condensed, and purified by radial chromatography to yield 41 mg (80%) of **7b** as a white crystalline solid, mp 75 to 76 °C. R_f = 0.53 (30% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2934, 2866, 1753, 1492, 1081, 809. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.35 (d, J = 8.2 Hz, 2H), 7.11 (d, J = 8.2 Hz, 2H), 4.27 (approx. br s, 1H), 3.59 (ddd, J = 6.6, 4.7, 1.4 Hz, 1H), 2.74 (dd, J = 17.5, 1.1 Hz, 1H), 2.38 (dd, J = 17.3, 1.1 Hz, 1H), 2.31 (s, 3H), 2.15–2.10 (m, 1H), 2.02–1.96 (m, 2H), 1.92–1.83 (m, 2H), 1.80–1.64 (m, 4H), 1.60–1.53 (m, 1H), 1.49–1.43 (m, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 216.7, 137.6, 132.5, 130.1, 130.0, 91.1, 83.5, 51.7, 51.2, 49.1, 40.3, 32.1, 27.5, 26.3, 23.4, 21.3. HR-MS (EI) calcd. for $C_{18}H_{22}O_2S$ (M^+): 302.1341; found: 302.1342.

8-Methoxy-12-oxatricyclo[7.2.1.0^{1,5}]undecan-10-one (7a)

To a refluxing solution of $Cu(hfacac)_2$ (9.4 mg, 0.02 mmol, 10 mol%) in CH_2Cl_2 (15 mL) was added a solution of **4a** (46.9 mg, 0.20 mmol) in CH_2Cl_2 (5 mL), and the

© 2006 NRC Canada

resulting mixture was stirred at reflux until consumption of **4a** (~30 min), after which the reaction mixture was cooled to RT and quenched with 0.5 mol/L K_2CO_3 (10 mL). The layers were separated and the aqueous phase extracted with CH_2Cl_2 (2 × 10 mL). The organic extracts were combined and washed with water and brine, dried with magnesium sulfate, filtered, and concentrated. The crude product was purified by column chromatography (30% EtOAc–hexanes) to give **7a**, a yellow solid (34 mg), in 82% yield, m.p. 41 to 43 °C. R_f = 0.44 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2937, 2867, 2823, 1755, 1450, 1403, 1366, 1342, 1299, 1235. ^1H NMR (500 MHz, $CDCl_3$) δ: 4.05 (s, 1H), 3.50 (ddd, *J* = 6.2, 4.2, 1.2 Hz, 1H), 3.35 (s, 3H), 2.73 (d, J_{AB} = 17.7 Hz, 1H), 2.37 (d, J_{AB} = 17.7 Hz, 1H), 2.09 (m, 1H), 2.02–1.92 (m, 2H), 1.89–1.81 (m, 2H), 1.79–1.71 (m, 2H), 1.66 (m, 1H), 1.56 (m, 1H), 1.48 (ddd, *J*= 14.5, 10.2, 4.2 Hz, 1H), 1.37 (ddd, *J* = 13.7, 10.0, 3.2 Hz, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 216.5, 90.9, 83.1, 81.6, 56.6, 51.3, 49.0, 40.4, 32.1, 27.0, 23.9, 23.5. HR-MS (EI) calcd. for $C_{12}H_{18}O_3$ (M^+): 210.1256; found: 210.1249. Anal. calcd. for $C_{12}H_{18}O_3$: C 68.60, H 8.60; found: C 68.20, H 9.06.

Carbene transfer reactions of 4c and 4d

Preparation of 7c and 7d

To a refluxing solution of Cu(hfacac)$_2$ (37 mg, 0.08 mmol, 10 mol%) in CH_2Cl_2 (55 mL) was added a solution of **4c** and **4d** (168 mg, 0.75 mmol, 4.4:1 mixture of anomers) in CH_2Cl_2 (25 mL), and the resulting mixture was monitored by TLC. Upon consumption of diazoketone **4a** (45 min), the reaction mixture was cooled to RT and quenched with 0.5 mol/L K_2CO_3 (25 mL). The layers were separated and the aqueous phase extracted with CH_2Cl_2 (2 × 15 mL). The organic extracts were combined and washed with water (20 mL), pre-dried with brine (20 mL), dried with magnesium sulfate, filtered, and concentrated. The resulting pale oil was purified by gradient column chromatograhy (silica gel; 5%, 10%, 15%, and then 20% EtOAc–hexanes until the products were recovered) to yield **7c** (68 mg) and **7d** (25 mg) as pale yellow oils, in an overall yield of 67%. (This reaction was also carried out on a small scale with pure samples of **4c** and **4d**. **4c** also furnished trace amounts of product **9**.).

Major diastereomer 7c (α)

R_f = 0.40 (3:7, EtOAc–hexanes). ^1H NMR (500 MHz, $CDCl_3$) δ: 6.03 (d, *J* = 2.3 Hz, 1H), 5.56 (d, *J* = 4.5 Hz, 1H), 3.49 (s, 3H), 2.54 (dd, *J* = 14.1, 2.3 Hz, 1H), 2.42 (d, *J* = 14.1 Hz, 1H), 2.33 (dd, *J* = 13.2, 8.9 Hz, 1H), 2.24 (dddd, *J* = 9.8, 8.7, 6.4, 4.0 Hz, 1H), 2.01–1.83 (m, 3H), 1.74 (approx. dt, *J* = 13.2, 4.3 Hz, 1H), 1.70–1.56 (m, 2H), 1.35–1.27 (m, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 136.2, 134.0, 102.9, 93.2, 60.1, 44.1, 40.9, 36.0, 34.2, 33.1, 25.7.

Carbene transfer reaction of 4e

Preparation of 7e, 7f, and 10e

To a refluxing solution of Cu(hfacac)$_2$ (16 mg, 0.03 mmol, 10 mol%) in CH_2Cl_2 (33 mL) was added a solution of **4e** (105 mg, 0.33 mmol) in CH_2Cl_2 (8 mL), and the resulting mixture was monitored by TLC. Upon consumption of diazoketone **4e** (30 min), the reaction mixture was cooled to RT and quenched with 0.5 mol/L K_2CO_3 (25 mL). The layers were separated and the aqueous phase extracted with CH_2Cl_2 (2 × 15 mL). The organic extracts were combined and washed with water (25 mL), pre-dried with brine (25 mL), dried with magnesium sulfate, filtered, and concentrated. The resulting pale yellow oil was diluted in ether (20 mL), and passed through a short pad of silica gel in a fritted filter while rinsing with excess ether. This was then concentrated and the resulting oil purified by radial chromatography (silica gel, 2 mm plate, solvent ramp: 100 mL each of 2%, 5%, 7%, and then 10% EtOAc–hexanes until the products were recovered) to yield a mixture of **7e** and **7f** (59 mg, 68%, ca. 2:1 ratio) as pale yellow oils, as well as **10e** (11 mg, 13%) as a white solid, in an overall yield of 80%. Minor diastereomer **7f** could be obtained as a white solid, mp 64–65 °C.

Diastereomers 7e and 7f

R_f = 0.41 (3:7, EtOAc–hexanes). Carbene transfer reaction of 4f — Preparation of 7e and 7f

Diazoketone **4f** was subjected to the procedure given previously for **4e**, to yield 85% of **7e** and **7f** in a 1:4.8 ratio. None of the isomeric product **10e** was isolated.

Carbene transfer reaction of 4g — Preparation of 7g

To a solution of **4g** (43 mg, 0.11 mmol) in toluene (9 mL) was added Cu(hfacac)$_2$ (9 mg, 0.01 mmol, 10 mol%), and the resulting mixture was heated to reflux. Upon consumption of diazoketone **4g** (14 h at reflux) the reaction mixture was cooled to RT and quenched with 0.5 mol/L K_2CO_3 (15 mL). The layers were separated and the aqueous phase extracted with CH_2Cl_2 (2 × 15 mL). The organic extracts were combined and washed with water (25 mL) and brine (25 mL), dried over $MgSO_4$, filtered, and concentrated. The resulting pale oil was diluted in ether (20 mL), and passed through a short pad of silica gel in a fritted filter while rinsing with excess ether. This was then concentrated and the resulting oil purified by radial chromatography (2 mm plate, solvent ramp: 50 mL each of 2%, 5%, 7%, and then 10% EtOAc–hexanes until the products were recovered) to yield 20 mg (50%) of **7g** as a pale oil, and as a 4.5:1 mixture of isomers by GC. This pale oil crystallized upon standing into a white solid. R_f = 0.42 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2952, 2934, 2867, 1769, 1746, 1492, 1443, 1400, 1269, 1254, 1143. ^{1}H NMR (500 MHz, $CDCl_3$; major diastereomer) δ: 7.34 (d, J = 8.1 Hz, 2H), 7.09 (d, J = 7.9 Hz, 2H), 4.19 (dq, J = 16.4, 7.1 Hz, 1H), 4.15 (dq, J = 16.4, 7.1 Hz, 1H), 4.04 (dd, J = 3.5, 3.5 Hz, 1H), 2.81 (d, J_{AB} = 17.0 Hz, 1H), 2.54 (d, J_{AB} = 17.0 Hz, 1H), 2.35 (m, 3H), 2.32 (s, 3H), 2.18 (dd, J = 11.5, 11.5 Hz, 1H), 2.03 (m, 1H), 1.97–1.84 (m, 3H), 1.80 (m, 1H), 1.63–1.46 (m, 3H), (t, J = 7.2 Hz, 3H). ^{13}C NMR (125 MHz, $CDCl_3$; major diastereomer) δ: 209.1, 166.1, 137.4, 132.4, 131.5, 129.7, 62.3, 55.8, 52.7, 50.8, 41.6, 35.2, 30.1, 26.7, 24.8, 21.1, 13.9. HR-MS (EI) calcd. for $C_{21}H_{26}O_4S$ (M^+): 374.1552; found: 374.1554.

Carbene transfer reaction of 4h — Preparation of 7h, 7i, and 10h

To a solution of **4h** (122 mg, 0.314 mmol) in toluene (31 mL) was added Cu(hfacac)$_2$ (16 mg, 0.03 mmol, 10 mol%), and the resulting mixture was heated to reflux. Upon consumption of diazoketone **4h** (14 h at reflux) the reaction mixture was cooled to RT and quenched with 0.5 mol/L K_2CO_3 (25 mL). The layers were separated and the aqueous phase extracted with CH_2Cl_2 (2 × 15 mL). The organic extracts were combined and washed with water (25 mL) and brine (25 mL), dried over $MgSO_4$, filtered, and concentrated. The resulting pale oil was diluted in ether (20 mL), and passed through a short pad of silica gel in a fritted filter while rinsing with excess ether. This was then concentrated and the resulting oil purified by radial chromatography (2 mm plate, solvent ramp: 50 mL each of 2%, 5%, 7%, and then 10% EtOAc–hexanes until the products were recovered) to yield 7 mg of a mixture of **7h** and **7i** (8:1 diastereomers by GC) and 48 mg of **10h** (single diastereomer by GC and NMR) as pale oils (49% combined yield).

Modification of rearrangement products

Ketal 11a

A flask containing a solution of **7b** (67 mg, 0.22 mmol), ethylene glycol (144 μL, 3.32 mmol), and TsOH (2 mg, 0.01 mmol) in toluene (5 mL) was equipped with a condenser and Dean-Stark trap (pre-filled with toluene), and then heated to reflux for 12 h. The reaction was cooled to RT and the solution was transferred to a separatory funnel and washed with satd. $NaHCO_3$ (10 mL). The organic phase was dried with $MgSO_4$, filtered, and the solvent was removed under reduced pressure. The crude white solid thus obtained was passed through a short pad of silica gel (1 cm in a disposable pipette) while eluting with 10 mL of 30% EtOAc–hexanes. The solvents were removed under reduced pressure and the resulting white solid was purified by radial chromatography (2 mm plate, solvent ramp: 100 mL of hexanes, 2.5%, 5%, and 10% EtOAc–hexanes) to yield recovered **7b** (16 mg, 25%) and **11a** (55 mg, 73%) as a white solid. R_f = 0.18 (5% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2946, 2868, 1319, 1092. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.35 (d, J = 8.1 Hz, 2H), 7.09 (d, J = 7.9 Hz, 2H), 4.11 (approx. br s, 1H), 3.93 (ddd, J = 8.0, 6.6, 4.9 Hz, 1H), 3.85 (approx. q, J = 7.3 Hz, 1H), 3.77 (ddd, J = 6.9, 6.9, 4.9 Hz, 1H), 3.62 (ddd, J = 7.9, 7.1, 7.1 Hz, 1H), 3.62–3.48 (m, 1H),

Tricyclic sulfone 12

To a mixture of **11a** (83 mg, 0.24 mmol) in MeOH (1 mL) cooled to 0 °C was added a mixture of OXONE® (295 mg) in a pH 4 buffer (1 mL) (18). After the addition, the cooling bath was removed and the slurry was stirred at RT for 10 h. The mixture was diluted with water (5 mL) and $CHCl_3$ (5 mL). The biphasic mixture was transferred to a separatory funnel, separated, and the aqueous phase was extracted with $CHCl_3$ (3 × 5 mL). The combined organic phase was washed with brine, dried with $MgSO_4$, and the solvents were removed under reduced pressure. Sulfone **12** was obtained as a white crystalline solid (88 mg, 97%) (homogenous by TLC and ^{1}H NMR analysis), and was used without further purification; mp 191–194 °C. R_f = 0.25 (30% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 2956, 1299, 1145, 1085. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.76 (d, J = 8.4 Hz, 2H), 7.34 (d, J = 7.9 Hz, 2H), 4.46 (approx. d, J = 2.9 Hz, 1H), 4.01 (ddd, J = 8.0, 6.5, 4.4 Hz, 1H), 3.95–3.90 (m, 1H), 3.85 (approx. q, J = 7.0 Hz, 1H), 3.78 (approx. q, J = 7.4 Hz, 1H), 3.51 (dddd, J = 11.6, 3.3, 3.3, 3.3 Hz, 1H), 2.44 (s, 3H), 2.27 (dd, J = 14.3, 0.9 Hz, 1H), 2.10 (d, J_{AB} = 14.3 Hz, 1H), 1.98–1.90 (m, 2H), 1.80–1.50 (m, 9H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 144.7, 135.2, 129.9, 129.4, 117.3, 92.7, 79.5, 67.1, 65.4, 64.8, 47.2, 42.6, 39.7, 28.5, 25.2, 21.8, 20.9, 20.5.

Vinyl sulfone 13

To a solution of **12** (22 mg, 0.058 mmol) in THF (1.16 mL) cooled to –78 °C (isopropanol/dry ice bath) was added dropwise via syringe *n*-BuLi (35 μL, 2.52 mol/L in hexanes). The solution initially turned pale yellow, then dark yellow-orange. The starting material was consumed after 20 min as ascertained by TLC, and the reaction was stirred an additional 30 min. The cooling bath was removed and the reaction was immediately quenched by the addition of satd. NH_4Cl solution (4 mL) and Et_2O (5 mL). The biphasic mixture was transferred to a separatory funnel, separated, and the aqueous phase was extracted with Et_2O (3 × 5 mL). The combined organic phase was then washed with brine (10 mL), dried with $MgSO_4$, filtered, and the solvents were removed under reduced pressure. The resulting crude material was purified by radial chromatography (2 mm plate, solvent ramp: 100 mL each of 20%, 30%, and 40% EtOAc–hexanes) to yield **13** (16 mg, 75%) as a white solid; mp 120–122 °C. R_f = 0.11 (30% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 3534, 2948, 1301, 1143, 1086. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.75 (d, J = 8.4 Hz, 2H), 7.33 (d, J = 8.3 Hz, 2H), 6.92 (approx. br s, 1H), 4.02–3.92 (m, 3H), 3.87–3.83 (m, 1H), 3.30 (br s, 1H), 3.16 (ddd, J = 14.2, 12.3, 6.7 Hz, 1H), 2.44 (s, 3H), 2.31 (ddd, J = 14.8, 7.3, 1.5 Hz, 1H), 2.26 (d, J_{AB} = 14.6 Hz, 1H), 2.06 (d, J_{AB} = 14.6 Hz, 1H), 1.76–1.73 (m, 2H), 1.67–1.57 (m, 3H), 1.51–1.46 (m, 1H), 1.35–1.19 (m, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 144.9, 144.8, 140.1, 136.1, 130.1, 128.7, 108.8, 79.8, 65.5, 63.7, 50.2, 47.1, 44.0, 34.5, 28.8, 23.4, 23.2, 21.9. Cyclooctenone ketal 14a

This procedure was carried out under an argon atmosphere. A large excess of LiDBB solution was prepared according to Cohen's procedure (Li (10 mg), di-*tert*-butylbiphenyl (DBB) (358 mg), THF (4.5 mL)) (19*b*). To a solution of **11a** (14 mg, 0.04 mmol) and a crystal of phenanthroline in THF (0.17 mL) cooled to –78 °C (isopropanol/dry ice bath) *n*-BuLi (~10 μL, 2.52 mol/L in hexanes) was added dropwise until the solution turned a red color (19*c*). LiDBB was then added dropwise via cannula to this solution until a persistent dark green color was observed, indicating an excess of LiDBB (exact volume of LiDBB added not measured). Starting material was consumed within 30 min (TLC). The reaction was allowed to stir for an additional 1 h at –78 °C, the cooling bath was then removed followed by the immediate addition of satd. NH_4Cl solution (5 mL) and Et_2O (5 mL). The mixture was then transferred to a separatory funnel, the aqueous phase was back extracted with Et_2O (5 mL), the combined organic phase was washed with brine (10 mL) and dried with $MgSO_4$, filtered, and the solvents were removed under reduced pressure. The resulting crude material was purified by radial chromatography (2 mm plate, solvent ramp: 100 mL each of hexanes, 5%, 15%, and 30% EtOAc–hexanes) to yield **14a** (9 mg, 97%) as a colorless oil. R_f = 0.32 (30% EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 3542, 3018, 2948, 1061, 757. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 5.78 (ddd, J = 11.5, 9.7, 7.6 Hz, 1H), 5.58 (dd, J = 11.5, 1.2 Hz, 1H), 4.00–3.98 (m, 1H), 3.94–3.90 (m, 3H), 3.39 (br s, 1H), 2.94–2.85 (m, 1H), 2.26 (d, J_{AB} = 14.4 Hz, 1H), 2.08–2.01 (m, 2H), 1.99 (d, J_{AB} = 14.4 Hz, 1H), 1.80–1.56 (m, 6H), 1.49–1.41 (m, 1H), 1.41–1.34 (m, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 133.2, 132.8, 109.6, 80.3, 64.8, 63.4, 50.3, 46.9, 43.9, 34.8, 29.4, 24.3, 23.3. HR-MS (EI) calcd. for $C_{13}H_{20}O_3$ (M^+): 224.1413; found: 224.1412.

Ketalization of 7e and 7f

Formation of 11b and 11c

To a mixture of diastereomers **7e** and **7f** (340 mg, 1.2 mmol, ca. 2.5:1) in CH_2Cl_2 (6 mL) at 0 °C was added 1,2-bis(trimethylsiloxy)ethane (580 μL, 2.4 mmol) followed by TMSOTf (12 μL, 5 mol%), and the resulting mixture was warmed to RT over several hours. This was then heated to reflux for ca. 12 h, after which TLC showed consumption of starting materials. The reaction was quenched with pyridine (1 mL) and saturated aqueous $NaHCO_3$ (5 mL), diluted with Et_2O (10 mL), and the resulting layers were separated. The aqueous layer was washed with three portions of Et_2O (10 mL) and the combined organic extracts were washed with water (30 mL) and then brine (30 mL), dried over magnesium sulfate, filtered, and concentrated, giving the crude product as a yellow oil. This oil was diluted in ether (20 mL) and passed through a short pad of silica gel in a fritted filter while eluting with ether. This was then concentrated and the resulting oil purified by radial chromatography (silica gel, 2 mm plate, solvent ramp: 100 mL each of 3%, 6%, and then 10% EtOAc–hexanes until the products are recovered) to

© 2006 NRC Canada

yield **11b** (283 mg, 72%) as a pale oil and **11c** (102 mg, 26%) as a crystalline solid.

LDBB reduction of 11b

Formation of 14b and 15

A large excess of LDBB was prepared according to Cohen's procedure, using Li (8 mg, 6 equiv.) and di-*tert*-butylbiphenyl (300 mg) in THF (3.2 mL). To a solution of **11b** (57 mg, 0.19 mmol) and a crystal of phenanthroline in THF (0.7 mL) cooled to –78 °C was added *n*-BuLi until the color turned deep red. LDBB was then added dropwise (without quantification) to the reaction mixture until an intense green color persisted, indicating the presence of excess LDBB. The reaction was stirred until consumption of starting material was observed by TLC (ca. 2 h). The reaction was then quenched by addition of saturated aqueous ammonium chloride (5 mL), further diluted in Et_2O (15 mL), and the resulting bilayer was separated. The aqueous layer was back extracted once with Et_2O (10 mL) and the combined organic extracts were pre-dried with brine (30 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The crude product was purified by gradient column chromatography (silica gel, 0%, 20%, and 60% EtOAc–hexanes) to give **14a** (25 mg, 69%) as a pale yellow oil, as well as a trace of isomer **15** (2 mg, 5.5%), in an overall yield of 75%. The ratio of product isomers depended on the time allowed for the reaction: if the reaction was quenched after 30 min, the ratio of the products is **14a** (19%) and isomer **15** (45%).

Alcohol 14b

R_f = 0.36 (3:7, EtOAc–hexanes). IR (CH_2Cl_2 cast, cm^{-1}): 3513, 3025, 2959, 1653, 1445, 1425, 1397, 1344, 1316, 1281. ^1H NMR (500 MHz, $CDCl_3$) δ: 5.89 (ddd, J = 12.2, 8.9, 3.5 Hz, 1H), 5.65 (ddd, J = 12.0, 3.1, 1.3 Hz, 1H), 4.19 (s, 1H) 3.93 (s, 4H), 2.29 (dddd, J = 16.1, 11.8, 3.1, 3.1 Hz, 1H), 2.21 (d, J_{AB} = 14.1 Hz, 1H), 2.04 (ddd, J = 16.0, 8.8, 2.3 Hz, 1H), 1.86 (d, J_{AB} = 14.1 Hz, 1H), 1.80–1.66 (m, 3H), 1.65–1.50 (m, 4H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 133.9, 133.6, 108.6, 78.6, 64.6, 63.9, 47.2, 44.9, 41.9, 30.9, 26.6, 19.8. An examination of VANOL, VAPOL, and VAPOL derivatives as ligands for asymmetric catalytic Diels–Alder reactions[1]

Douglas P. Heller, Daniel R. Goldberg, Hongqiao Wu, and William D. Wulff

Abstract: Several derivatives of the vaulted biaryl ligand VAPOL were prepared and evaluated as chiral ligands for aluminum Lewis acids in the catalytic asymmetric Diels–Alder reactions of methyl acrylate and methacrolein with cyclopentadiene. The substituents on VAPOL were introduced into the 6- and 6′-positions in an effort to further extend the chiral pocket of the major groove, which contains the phenol functions at the 4- and 4′-positions. The set of four new ligands that have been prepared have the following groups introduced into the 6- and 6′-positions of VAPOL: bromide, methyl, phenyl and 3,5-di-*t*-butylphenyl. All of these ligands give lower asymmetric inductions than the unsubstituted VAPOL for the Diels–Alder reactions of both methyl acrylate and methacrolein. The positive cooperativity of added carbonyl compounds on the autoinduction in the Diels–Alder reaction of methyl acrylate and cyclopentadiene were also investigated with the VANOL and VAPOL ligands as well as the 6,6′-dibromo and 6,6′-diphenyl derivatives of VAPOL. Only the reaction with VAPOL showed any significant positive cooperativity. The reaction with VANOL was sluggish at –78 °C, but at higher temperatures, the reaction did exhibit positive cooperativity that was similar to that of VAPOL. Finally, no positive cooperativity was observed with the VAPOL ligand for the reaction of methacrolein and cyclopentadiene.

Key words: Diels–Alder, asymmetric catalysis, vaulted biaryl ligands, VANOL, VAPOL.

Résumé : On a préparé plusieurs dérivés du ligand voûté VAPOL et on les a évalués comme ligands chiraux pour des acides de Lewis dérivés de l'aluminium à utiliser dans des réactions de Diels–Alder asymétrique catalytique de l'acrylate de méthyle et de la méthacroléine avec le cyclopentadiène. On a introduit des substituants sur les positions 6 et 6′ du VAPOL dans le but d'agrandir la poche chirale de la cannelure principale qui comporte les fonctions phénols dans les positions 4 et 4′. Dans l'ensemble des quatre nouveaux ligands qui ont été préparés, on a introduit les groupes suivants dans les positions 6 et 6′ du VAPOL: bromure; méthyle; phényle et 3,5-di-tert-butylphényle. Chacun de ces ligands conduit à des inductions asymétriques inférieures à celle observé avec le VAPOL non substitué, tant pour les réactions de Diels-Alder de l'acrylate de méthyle que celles de la méthacroléine. On a aussi étudié la coopération positive des composés carbonyles ajoutés sur l'autoinduction de la réaction de l'acrylate de méthyle et du cyclopentadiène à l'aide de ligands VANOL et VAPOL ainsi qu'avec les dérivés 6,6′-dibromo et 6,6′-diphényl du VAPOL. Seule la réaction avec le VAPOL a montré une coopération positive significative. La réaction avec le VANOL était lente à –78°C, mais à des températures plus élevées, la réaction présente une coopération positive semblable à celle du VAPOL. Enfin, on n'a observé aucune coopération positive avec le ligand VAPOL pour la réaction de la méthacroléine avec le cyclopentadiène.

Mots clés : Diels–Alder, catalyse asymétrique, ligands biaryles voûtés, VANOL, VAPOL.

This manuscript is dedicated to Dr. Alfred Bader. Dr. Bader is many things to many people and included among them he is an entrepreneur, a lover of the arts, a champion of young scientists, and above all, a generous and gracious human being. When I was a beginning assistant professor in the early 1980s, he awarded me one of his young chemist awards. This was a greatly appreciated and needed boast to my program. A gift of $5000 was a significant sum in those days considering my start-up package was $25 000. His call came out of the blue one day when I was home in bed with a nasty fever. Having failed to reach me at work, he tracked me down at home and what I remember from my delirious state is my wife saying someone named Alfred Bader was on the phone. I think that I thanked him at the time, and if I didn't, I would certainly like to thank him now.

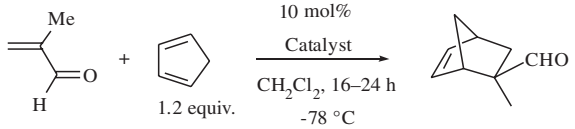
Scheme 1.



Introduction

One of the most widely used and successful ligands in asymmetric catalysis is 1,1′-binaphth-2,2′-ol, or BINOL 1 (1). In most applications, catalysts are generated from BINOL by the formation of covalent bonds to the two phenol functions with either a transition metal or a main group atom. In many applications it has been found that improved induction results from these catalysts if substituents are introduced in the 3- and 3′-positions of BINOL (such as **2**) (2). This is particularly true for catalysts that have only one BINOL ligand bound to the metal center (2). In the absence of substituents at the 3- and 3′-positions, the BINOL ligand provides a much smaller chiral pocket for the metal center since the phenol functions project into the minor groove of BINOL rather than the major groove (Scheme 1). Our approach to this problem is to design biaryls in which the phenol functions are projected into the major groove of the ligand (Scheme 1). To this end, we simply envisioned an extension of the aromatic system of BINOL out into the region of the phenol functions and as a result ultimately synthesized the vaulted biaryl ligands VANOL **3** and VAPOL **4** (3). These ligands have been demonstrated to be particularly successful in catalytic asymmetric Diels–Alder (4), aziridination (5), Mannich (6) reactions, as well as in Baeyer–Villiger oxidations (7) and imine amination reactions (8).

We have reported that a catalyst prepared from VAPOL and diethylaluminum chloride is effective in providing high asymmetric inductions in the reactions of methacrolein and methyl acrylate with cyclopentadiene (Table 1) (4). A comparison of a series of catalysts prepared from diethyl aluminum chloride and ligands **1**–**4** reveals that only the VAPOL-derived catalyst offers significant asymmetric induction in the reaction with methacrolein (Table 1) (4*a*). The data from a corresponding set of boron catalysts prepared from bromoborane dimethyl sulfide complex revealed that these catalysts are slower and that VANOL gave the catalyst with the superior enantioselectivities (4*b*). Based on the data in

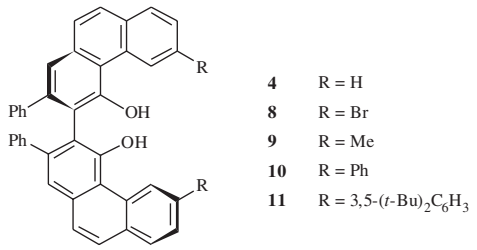
[a]ee% was measured by conversion to chiral acetals as described in the experimental section.

[b]ee% in parentheses was measured by GC as described in the experimental section.

Scheme 2.



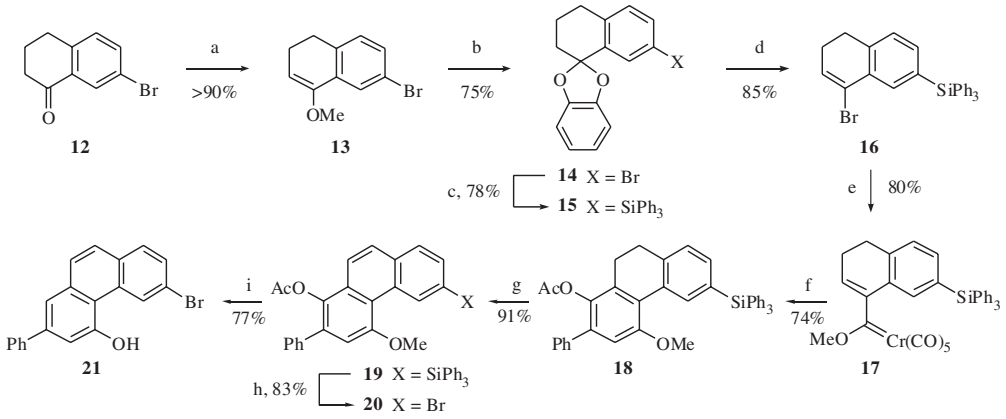


Table 1, we set out to prepare and evaluate the set of 6,6′-disubstituted VAPOL ligands **8**–**11** (Scheme 2) as precursors to aluminum catalysts in the asymmetric catalytic Diels–Alder reaction and to compare their selectivity profile with that of the unsubstituted VAPOL ligand **4**. Substituents in the 6- and 6′-positions would be expected to increase the size of the major groove of the VAPOL ligand (Scheme 1) and as a result, the asymmetric induction observed in reactions mediated by catalysts generated from these ligands. In addition, catalysts generated from the VANOL ligand **3** will be evaluated for the Diels–Alder reactions, given the recent findings that the VANOL ligand is equally as effective as the VAPOL ligand in asymmetric catalytic aziridination reactions and superior to the VAPOL ligand in Baeyer–Villiger reactions (7).

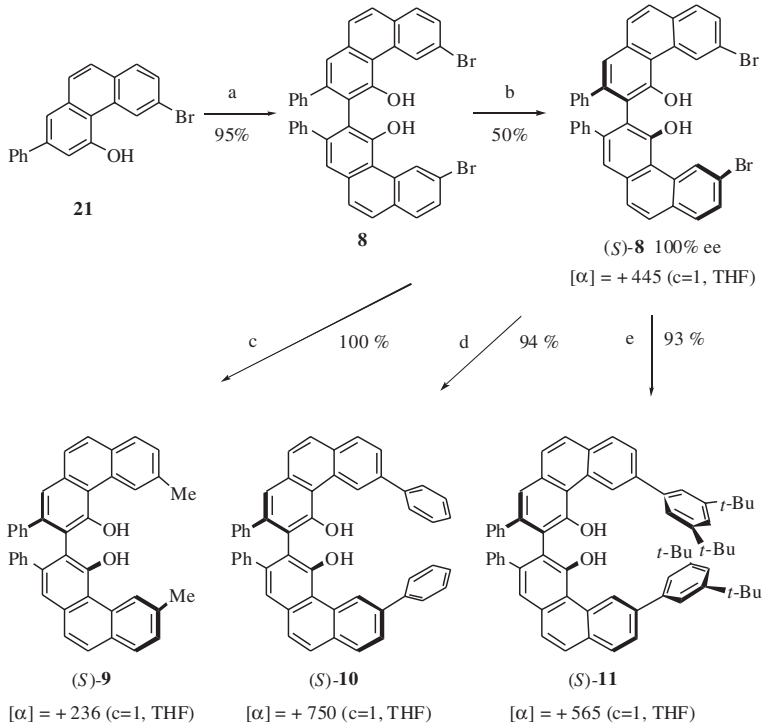

The retrosynthesis of the VAPOL derivatives **8**–**11** was envisioned to involve, first, the initial preparation of the 6,6′-dibromoVAPOL **8** and then after subsequent resolution, the utilization of this dibromo derivative as the intermediate through which the other derivatives will be prepared. The synthesis of the 6,6′-dibromo-VAPOL **8** was modeled after the original method that we developed for the synthesis of the VAPOL ligand (3) and involves the oxidative phenol coupling of the phenanthrol **21** (Scheme 3), whose synthesis in turn would involve the benzannulation reaction of the carbene complex **17** with phenylacetylene as the key step (Scheme 4). The synthesis of the alkenyl bromide **16** neces-

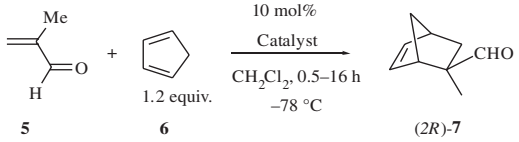
sary for the synthesis of the carbene complex **17** begins with 7-bromo-α-tetralone **12**, as indicated in Scheme 4. After evaluation of several methods for the conversion of ketones to alkenyl bromides, we found that the best procedure for the tetralone **12** was the method reported by Napolitano (9) involving the intermediacy of a catechol ketal, which was reported for α-tetralone in 40% overall yield. As reported by Napolitano for α-tetralone, we found that the direct conversion of 7-bromo-α-tetralone **12** to the catechol ketal **14** was inefficient. On a small scale, the direct reaction of **12** with catechol gave minimal yields of **14** and on a large scale this conversion failed completely. However, excellent yields of **14** could be obtained if **12** was first converted to the methyl enol ether **13**. The bromide function in the alkenyl bromide **16** is necessary for the preparation of the carbene complex **17**, but prior to the formation of the alkenyl bromide **16** by treatment of the ketal with boron tribromide the aryl bromide function in **14** was protected as its triphenylaryl silane **15**. The carbene complex **17** could then be generated by the standard Fischer procedure from **16** and chromium hexacarbonyl in 80% yield. The benzannulation of the carbene complex **17** with phenyl acetylene was carried out in two steps, (*i*) the reaction with phenylacetylene and (*ii*) the protection of the phenol function as its acetate. One attempt to carry out this transformation concurrently by the addition of acetic anhydride and triethylamine at the beginning of the reaction met with failure. Thus, this overall transformation must be carried in sequential steps. In the next step, oxida-



© 2006 NRC Canada

tion of the B ring with NBS under free-radical conditions afforded phenanthrene **19** in 91% yield. Initial attempts at this oxidation with palladium on carbon or DDQ were unsuccessful. One might wonder why we waited until after the benzannulation reaction to aromatize. We could have, for example, oxidized the compound **16** and carried the naphthyl system into the benzannulation. We chose this order because the benzannulation of alkenyl carbene complexes with alkynes is much less susceptible to side-product formation than aryl complexes (10). The triphenylsilyl group was then "deprotected" to the bromide by treatment with bromine, which after considerable optimization was found to be best achieved with two equivalents of bromine to give **20** in 83% yield. The monomer **21** was finally generated by the reaction of **20** with ethanethiol and aluminum chloride (3). It is critical to control the time of this reaction since prolonged times can lead to the reduction of the bromide in the product **21**. Since trace amounts of this reduced monomer would lead to cross-coupled products in the oxidative phenol coupling step, it was necessary to rigorously purify the monomer **21** by column chromatography.

The oxidative phenol coupling follows the procedure developed for the synthesis of VAPOL and VANOL (3). Melting **21** in the presence of air and heating at 195 °C until the monomer **21** was consumed gave racemic 6,6′-dibromo-VAPOL **8** in 95% yield. This compound was deracemized with (–)-sparteine and copper (II) according to a procedure originally reported by Kocovsky (11), which has recently been improved by our laboratory (12). This procedure gave 6,6′-dibromo-VAPOL **8** that was substantially enantioenriched (>90% ee). The optical purity could be easily improved by extracting with hexane. The racemates of VAPOL **4** and Br_2-VAPOL **8** are both substantially less soluble than the optically pure material. Thus, the pure enantiomer of **8** (>99% ee) could be easily obtained by stirring the enantioenriched **8** with enough hexane to leave only a small amount of residue undissolved. The hexane solution is decanted to leave the solid and then the hexane is removed to leave the optically pure ligand **8**. This ligand could also be crystallized from hexane and ethyl acetate to give X-ray quality crystals, which have two molecules of ethyl acetate per molecule of **8**. The conversion of the 6,6′-dibromo-VAPOL ligand **8** to the corresponding dimethyl derivative **9** was accomplished in 100% yield by the nickel-catalyzed coupling of **8** with methyl magnesium bromide (6 equiv.) (13). The two aryl-substituted VAPOL ligands **10** and **11** were prepared from the dibromide **8** by Suzuki coupling reactions in 94% and 93% yields, respectively (14).

The results from the asymmetric catalytic Diels–Alder reactions of methacrolein and cyclopentadiene with catalysts generated from VAPOL **4** and the VAPOL derivatives **8**–**11** are shown in Table 2. All of the VAPOL derivatives with substituents in the 6- and 6′-positions give lower asymmetric inductions than VAPOL. The best of these is the bis-(3,5-di-*t*-butylphenyl) derivative, which gives a 62% ee for the reaction. Interestingly, the diphenyl derivative **10** gives the product **7** with the opposite sense of induction to all of the other ligands. The catalyst was prepared in each case by treating the ligand with 1 equiv. of ethylaluminum dichloride at RT. The completion of catalyst formation was determined by ^{1}H NMR and it was found that for the ligands **4**, **8**, and **9** the

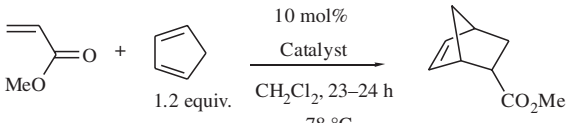
[b]Determined by GC of acetals prepared from (2*R*,4*R*)(–)pentanediol.
[c]Catalyst was prepared at 55 °C for 24 h.



VAPOL was completely consumed within 30 min. However, for the more hindered ligands **10** and **11**, the complete consumption of the ligand required heating at 55 °C for 24 h.

Catalysts prepared from VAPOL-derived ligands **8**–**11** were also examined with the reaction of methyl acrylate and cyclopentadiene (Table 3). These reactions were slower than those with methacrolein but all are complete in 24 h except for the catalyst generated from the VANOL ligand, which only gave a 28% yield of the product **23** after 24 h. As with the reactions with methacrolein, all of the derivatives of VAPOL gave lower asymmetric inductions than VAPOL itself. Thus, for both sets of reactions it appears that the VANOL ligand does not provide a large enough chiral pocket. Furthermore, all of the 6,6′-substituted VAPOL derivatives form aluminum catalysts where either the bound substrate does not exist in a single conformation or the substrate does not have one of its faces sufficiently differentially shielded. The VAPOL ligand seems to be optimal for this particular aluminum catalyst.

The effect of solvents on the reaction of methyl acrylate with cyclopentadiene that is catalyzed by the VAPOL-derived catalyst is shown in Table 4. There was no reaction at all in THF and in ether the reaction was very sluggish giving only a 23% yield after 24 h with 10 mol% catalyst. Clearly, the best solvent for this reaction is toluene, which gives the product in 100% yield and 97% ee, whereas methylene chloride gives 87% yield and 82% ee. It was very curious indeed to find that if the reaction in methylene chloride was stopped after 15 min, the product was isolated with 48% ee. Furthermore, if the reaction was carried out by addition of only 10% of the dienophiles at the beginning of the reaction followed by slow addition of the remaining dienophiles, the asymmetric induction for **23** was higher at the end of the

reaction. We had observed this same type of behaviour for the reaction of methacrolein and cyclopentadiene (4*a*). We interpreted this as an asymmetric autoinduction (15) and have investigated this in some detail for the reaction of methyl acrylate and cyclopentadiene (4*c*). We chose the reaction of methyl acrylate and cyclopentadiene over that of methacrolein and cyclopentadiene since the former reacts much slower and it would be easier to follow the time course of the reaction. Also, the asymmetric induction was lower for the reaction with methyl acrylate and thus changes in induction would be more easily detected and monitored over a greater range. It is also for this reason that we chose to investigate the reaction of methyl acrylate in methylene chloride rather than in toluene.

Our explanation for the autoinductive effect observed for these reactions is illustrated in Scheme 5 for the reaction of methyl acrylate with cyclopentadiene (4*c*). It was proposed that the aluminum in the chiral catalyst could coordinate to the carbonyl group of two molecules of the starting material as in **24**, two molecules of the product as in **26**, or one molecule of each as in **25**. The fact that the particular asymmetric autoinduction we observed involves an increase in the asymmetric induction as the reaction progresses can then be accounted for if the Diels–Alder reaction of the complex **25** with one molecule of methyl acrylate and one molecule of product coordinated to the aluminum occurs with a higher selectivity than complex **24** with two molecules of starting material coordinated to the aluminum. At the beginning of the reaction there was little or no product and thus the great majority of the reaction flux will be through complex **24**. As more and more of the product is formed, more of the flux will occur through complex **25** and thus the asymmetric induction will continue to climb as the reaction progresses. In fact we have previously reported that the asymmetric induction for the reaction of methyl acrylate with cyclopentadiene is 48% ee after 20% completion and slowly rises during the course of the reaction until its culmination at 82% ee when the reaction is complete (Table 4 and ref. 4*c*).

It was reasoned that if complex **25** gives higher induction than **24** because of the greater steric size of the product com-

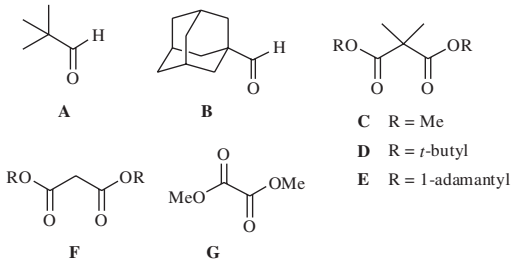
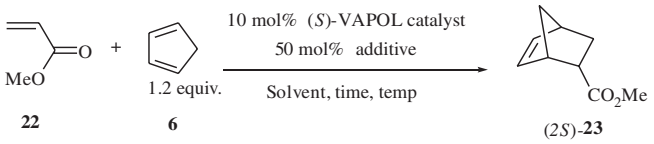


Scheme 5.

pared with that of the starting material, then one might be able to avoid the low asymmetric induction at the beginning of the reaction by the addition of a "dummy" carbonyl compound that is physically larger than methyl acrylate. This expectation was borne out in a series of experiments involving the carbonyl compounds indicated in Scheme 6. This study has been already communicated and some of this data is included in Table 5 (4*c*). As can be seen from the data in the first three entries, the addition of 0.5 equiv. of pivaldehyde at the beginning of the reaction increased the asymmetric induction at the end of the reaction from 82% to 96% ee. The larger adamantyl aldehyde B increased the induction still further to 98.5% ee. It was unexpected to find that 1,3-dicarbonyl compounds were even more effective. The di-*t*-butylmalonate D increased the induction to greater than 99% ee (Table 5, entry 5). These effects were more visible at higher temperatures. For example, the malonate E can increase the induction from 37% ee to 85% ee at 0 °C with 0.5 equiv. of E and to 92% ee with 1.0 equiv. This is quite remarkable when considering that the presence of this additive allows the temperature of the reaction to be increased by 80 °C and at the same time increases the induction from 82% ee to 92% ee. Since our initial report (4*c*) and as mentioned above, we have found that substantially increased asymmetric induction can be achieved in toluene as solvent. The asymmetric induction can be increased from 82% ee in CH_2Cl_2 to 97% ee in toluene at –78 °C (Table 5, entries 1 and 20). However, the additive effect is hardly observable in toluene. The reaction at 0 °C in toluene shows only a slight increase in induction from 46% ee to 58% ee in the presence of 0.5 equiv. of the malonate E.

The phenomenon of increased asymmetric induction with the addition of product mimics was termed "positive cooperativity" (4*c*). The strong effect that carbonyl additives had on the autoinduction for the reaction of methyl acrylate and cyclopentadiene with a catalyst generated from the VAPOL

Scheme 6.



ligand prompted the study outlined in Table 6 to probe the extent to which added carbonyl compounds would exhibit positive cooperativity with the substituted VAPOL ligands **8** and **10** and with the VANOL ligand. These reactions were screened with 0.5 equiv. of the di-*t*-butyl malonate D added at the beginning of the reaction. Remarkably, the addition of malonate D had essentially no effect on the asymmetric induction with catalyst generated from 6,6′-dibromo-VAPOL **8** or from 6,6′-diphenyl-VAPOL **10**. Perhaps the major groove of these ligands (Scheme 1) is too hindered to allow for the coordination of two carbonyl groups at the same time. It was also found that the asymmetric induction from the VANOL-derived catalyst was not sensitive to the addition of the malonate D (Table 6, entries 8 and 9). In this case however, the yields were quite low with and without the additive. At this point we do not know if the structure of the active catalyst is the same from VAPOL and VANOL and, in fact, the ^1H NMR spectrum of the catalyst generated from Et_2AlCl and VAPOL reveals that there appears to be a mixture of several different species. In light of this fact, it is remarkable that very high asymmetric inductions can be achieved with this catalyst mixture for the reaction with methyl acrylate in toluene (Table 5, entry 20) or in CH_2Cl_2 in the presence of additives A-D (Table 5, entries 2–5).

The sluggishness of the reaction with the VANOL catalyst prompted a study of the effect of temperature on this catalyst to find conditions under which the reaction could be driven to completion and at the same time to determine the extent of any positive cooperativity with added carbonyl compounds leading to increased asymmetric induction. As the data in Table 7 shows, it was found that reasonable yields of the product could be observed in 24 h with 10 mol% catalyst if the temperature was raised to –40 °C and that at –20 °C the reaction was complete in the same time period. It is interesting to note that the VANOL and VAPOL ligands gave nearly identical results at –40 °C (Table 7, entry 7 vs. Table 5, entry 7) and at 0 °C (Table 7, entry 11 vs. Table 5, entry 13). In contrast to the VAPOL-derived ligands **8** and **10** (Table 6), the VANOL catalyst was significantly affected by the addition of additives. The degree of the effect of the malonate D was about the same as that on the VAPOL catalyst at 0 °C but the effect was less for the VANOL catalyst at –40 °C.

An investigation of the Diels–Alder reactions of cyclopentadiene with the *t*-butyl, *n*-propyl, and ethyl esters of acrylic acid was undertaken to compare the results with those of methyl acrylate. It was thought that if the steric bulk of the two carbonyls coordinated to the aluminum were important to the asymmetric induction of the Diels–Alder reaction (Scheme 5) then perhaps adjusting the size of the alkoxy group of the acrylate ester could have a similar ef-

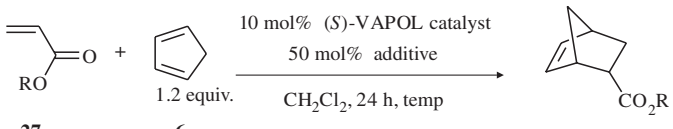
fect. As expected, the asymmetric induction observed for the ethyl and *n*-propyl esters (Table 8, entries 6 and 9) were greater than that for the methyl ester (Table 5, entry 1). However, the trend does not continue to the *t*-butyl ester as the induction with this substrate falls to 9% ee (Table 8, entry 1). While the reaction of the *t*-butyl ester was unresponsive to any positive cooperativity effect with any additive (B–E), it was found that both the ethyl and *n*-propyl esters responded to carbonyl additives to a degree very similar to that of methyl acrylate (Table 8 vs. Table 5).

Finally, the reaction of methacrolein and cyclopentadiene was investigated in the presence of carbonyl additives to look for positive cooperativity effects. The data in Table 9 suggests that this reaction is unaffected by the presence of adamantyl aldehyde B or the di-*t*-butyl malonate D. The asymmetric induction for this reaction in CH_2Cl_2 is higher at –78 °C (93.6% ee) than it is for the same reaction with methyl acrylate (82% ee). Nonetheless, the addition of either B or D to the reaction would have been expected to produce measurable increases in induction if the positive cooperativity effect was in play here. Furthermore, no significant positive cooperativity effect was observed if the reaction temperature was raised to –40 °C or even to 0 °C where the asymmetric induction of the reaction itself was 16.9% and 5.1% ee, respectively. This lack of a positive cooperativity effect for the reaction of methacrolein and cyclopentadiene was surprising since this reaction, like the reaction of methyl acrylate, exhibits autoinduction. The degree of autoinduction for methacrolein is not as strong as that for methyl acrylate. For example, the reaction of methacrolein and cyclopentadiene has been reported to give an 81% ee after 30% conversion under conditions where an 88% ee was observed at the end of the reaction (4*a*).



The results of the present studies suggest that the VAPOL ligand appears to be optimal in forming a catalyst with diethylaluminum chloride to effect asymmetric Diels–Alder reactions with methacrolein and methyl acrylate with cyclopentadiene. Catalyst derived from the 6,6′-disubstituted VAPOL derivatives **8**, **9**, **10**, and **11** all gave reduced enantioselectivities for both of these reactions. The VANOL ligand gave lower enantioselectivities and slower rates as well. Since this is a smaller ligand, the lower rates may be due to a different catalyst structure. It was also found that carbonyl additives displayed positive cooperativity with the VAPOL catalyst on the autoinduction for the reaction with methyl acrylate but not with the substituted VAPOL catalysts derived from **8** and **10** or with the catalyst derived from the VANOL ligand. In contrast, no positive cooperativity with carbonyl additives was observed with the VAPOL catalyst on the autoinduction in the reaction of methacrolein and cyclopentadiene.

Experimental

Syntheses were performed under dry argon unless otherwise stated. THF and ether were distilled from sodium benzophenone ketyl. Methylene chloride, 1,2-dichloroethane, and acetonitrile were distilled from CaH_2. Toluene was distilled from sodium. Methacrolein was distilled from CaO. Methyl acrylate and pivaldehyde were distilled from $MgSO_4$. Cyclopentadiene was freshly cracked from dicyclopentadiene over 4 Å MS. Whatman glass-backed TLC plates (part #4861–820, 250 mm thickness, K6F Silica gel) were used for reported R_f values, except in those noted cases in which Macherey–Nagel plastic-backed TLC plates (Polygram® Sil N-HR/UV_{254}, 250 mm thickness) were used. IR spectra were taken on a Nicolet 20SXB FTIR spectrometer. Melting points were taken on a Hoover Unimelt apparatus and are uncorrected. Mass spectra were run on a VG Analytical 70–70EQ Double Focusing Hybrid MS (EI @ 70 eV).

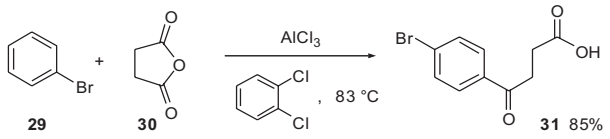
Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tennessee.

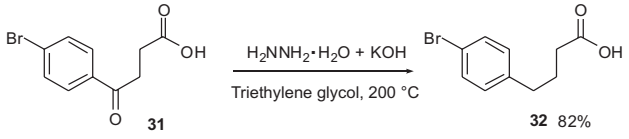


Chiral HPLC was done with a Pirkle covalent D-phenylglycine Rexchrom™ Regis column. Pump: Waters M-45 (ser. # 5615); operating pressure: 3100 psi (1 psi = 6.894 757 kPa); flow rate: 2.0 mL/min; solvent: 7:3 (*v*/*v*) hexane–isopropanol; detector (254 nm): Waters 440 Absorbance detector (ser. #07249); integrator: Spectra-Physics SP4270 (ser. #092–132).

Capillary GC was done on a Varian Star 3600 outfitted with an Alltech Econocap SE-54 column for nonchiral applications and a J & W Scientific Cyclodex-B column for chiral applications using helium carrier gas and FID detection.

Optical rotations were taken on a PerkinElmer Model 141 instrument using the sodium D line (589 nm). For ligand sample preparation, a 20 mg sample was dissolved in 2 mL THF. Concentration: 1 g/100 mL; temperature: 23 °C; path length: 1 dm; $[\alpha]_D = (100)\ a_{obs}$.

Preparation of 7-bromo-α-tetralone 12 (16)

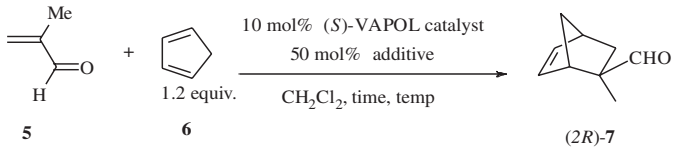


Friedel–crafts acylation of bromobenzene

29 **30** **31** 85%

A 1 L three-necked round-bottomed (RB) flask was fitted with a mechanical stirrer and was connected to an oil bubbler. It was charged with bromobenzene **29** (60.5 mL, 573 mmol), succinic anhydride **30** (37.6, 376 mmol), and *o*-dichlorobenzene (113 mL), and mechanically stirred. Aluminum trichloride (107 g, 804 mmol) was added in portions over 30 min. The solution turned rust red in colour and emitted a whitish smoke. It was warmed to 83 °C for 6 h, cooled to RT, and then poured into a mixture of HCl–ice in a 2 L Erlenmeyer flask whereupon a white curdish precipitate came out of solution. The precipitate was dissolved in ether, the entire contents were transferred in portions to a large separatory funnel, and the aqueous layer was removed. Concentration of the ether layer by distillation afforded crystals of product, which were suction filtered and then finely divided and spread out to dry in a pan in a 110 °C oven for two days. Yield: 82 g white-pinkish solid (85% yield). On a larger scale, it was not practical to dissolve the crude product in ether. In this case, crude product was allowed to oven dry directly, which took longer.

Wolff–Kischner reduction of 31



31 **32** 82%

A 1 L three-necked flask was equipped with a thermometer and a condenser–receiving flask. KOH (45 g, 804 mmol) and triethylene glycol (350 mL) were added and mechanically stirred. The mixture was warmed to 100 °C with a heating mantle to dissolve the KOH. It was then cooled to

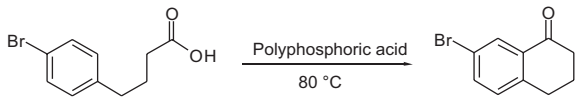
7	D	15 min	0	80	77	10.8



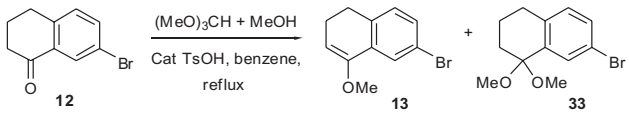
Note: All reactions use 0.5–1.0 mol/L in **5**. Unless otherwise specified the catalyst was prepared as indicated in Table 2.

[a]Determined by ^{1}H NMR with ligand as internal standard.

[b]Determined with a chiral GC column (Astec B-MB column) after reduction to the alcohol with $NaBH_4$.

80 °C, whereupon 68 g (265 mmol) of the keto acid **31** from the previous step and 34 mL of hydrazine monohydrate (702 mmol) were added. After stirring at 90–100 °C for 1 h, the mixture was warmed by a heating mantle to 200 °C and stirred at that temperature for 1 h. Liquid was distilled off into the receiving flask. The solution was cooled to near RT and poured into 400 mL of H_2O. Aq HCl (6 N, 220 mL) was added, which precipitated out a white suspension, and an oil settled on the bottom. On sitting overnight the oil solidified. The solid was filtered, then dissolved in ether (it was exceedingly soluble in ether), dried over $MgSO_4$, filtered, and left to crystallize in a crystallizing dish on air evaporation of ether to afford 52.98 g of **32** as a light tan solid (82% yield). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.96 (quintet, 2H), 2.38 (t, 2H, *J* = 7.4 Hz), 2.64 (t, 2H), 7.04 (d, 2H, *J* = 8.2 Hz), 7.38 (d, 2H, *J* = 8.2 Hz), acid proton not reported.

Cyclization of carboxylic acid (32)

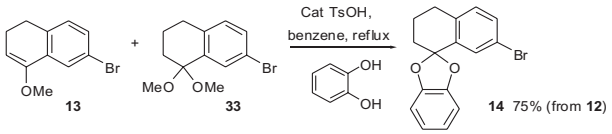


32 **12** 75%

This reaction was run in open air. Polyphosphoric acid (PPA, 250 g) was warmed in a 1 L Erlenmeyer flask to 70 °C. The bromoaryl carboxylic acid **32** (52.98 g, 218 mmol) was melted at 50 °C and then added to the PPA and the mixture was swirled with a glass rod for a few minutes while keeping the temp between 70 and 90 °C. Additional PPA (200 g) was added and the mixture was kept at 80 °C for 1 h and swirled occasionally and it became a dark orange color. Heat was removed and ice was added, which turned the mixture yellowish. The mixture was extracted three times with ether (1 × 200 mL, 2 × 100 mL). The combined ether layers were washed sequentially with 200 mL H_2O, 100 mL 5% aq KOH, 100 mL H_2O, 100 mL 3% aq HOAc, 100 mL 5% aq $NaHCO_3$, and 100 mL H_2O, then dried over $MgSO_4$ and filtered into a crystallizing dish. Air evaporation of ether afforded 36.8 g of clear blocky crystals covered with an orange thin film (75% yield). The product could be crystallized from MeOH to yield colourless crystals: mp 75 to 76 °C (lit. value (16) mp 71–73 °C). R_f = 0.23 (hexane–EtOAc, 9:1). IR (neat film, NaCl, cm^{-1}): 2946 (w), 1676 (s), 1585 (m), 1221 (m), 1190 (m). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.10 (quintet, 2H, *J* = 6.3 Hz), 2.62 (t, 2H, *J* = 6.5 Hz), 2.88 (t, 2H, *J* = 6.0 Hz), 7.12 (d, 1H, *J* = 8.13 Hz), 7.53 (dd, 1H, *J* = 8.2, 1.9 Hz), 8.11 (d, 1H, *J* = 1.8 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.9, 29.0, 38.6, 120.5, 129.8, 130.5, 133.9, 135.9, 143.0, 196.8.

Preparation of the catechol ketal 14 from 7-bromo-α-tetralone (12)

Preparation of methyl vinyl ether (13)

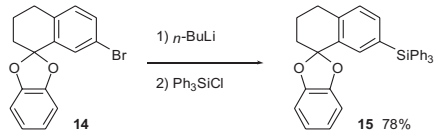


12 **13** **33**

A 250 mL three-necked RB flask equipped with a side arm adapter, to which was connected a condenser and receiving flask, was charged with 7-bromotetralone **12** (20 g, 88.8 mmol), trimethyl orthoformate (25 mL, 228.5 mmol), *p*-toluenesulfonic acid monohydrate (980 mg, 5.15 mmol), methanol (23 mL), and benzene (60 mL). The magnetically stirred solution was warmed under N_2 to gentle reflux for 40 h so that solvent distilled very slowly over into the receiving flask. After cooling to RT, it was partitioned between 500 mL ether and 250 mL satd. aq $NaHCO_3$. The organic layer was removed by separatory funnel and washed with 1 × 150 mL satd. aq $NaHCO_3$ and 1 × 150 mL brine, then dried over $MgSO_4$ and filtered. Solvent was removed in vacuo to afford 22 g of an orange oil, which was used in the next step without purification.

Conversion of 13 to ketal 14

A 250 mL three-necked RB flask equipped as described in the last step was charged with 22 g of the crude starting material **13**, catechol (11.75 g, 106.7 mmol), *p*-toluenesulfonic acid monohydrate (150 mg, 0.79 mmol), and benzene (150 mL) and was brought to reflux under N_2 for 4 h so that



© 2006 NRC Canada

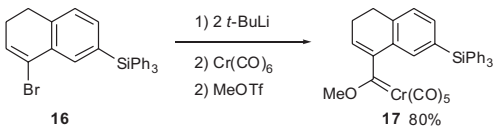
13 33 14 75% (from 12)

solvent distilled slowly into the receiving flask. After cooling to RT, 1.5 mL triethylamine was added. The mixture was partitioned between 200 mL ether and 100 mL water. The organic layer was removed by separatory funnel, washed with 1 × 100 mL H_2O, 2 × 75 mL 10% aq NaOH, 1 × 100 mL brine, then dried over $MgSO_4$, and filtered. The solvent was removed in vacuo to afford 27 g of a light tan crude product. The product was purified in portions by SiO_2 chromatography (hexane eluent) to yield 21 g of the white crystalline product **14** (75% yield): mp 101–104 °C. R_f = 0.45 (hexane–EtOAc, 9:1). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.03–2.10 (m, 2H), 2.22–2.26 (m, 2H), 2.82 (t, 2H, J = 6.3 Hz), 6.81–6.88 (m, 4H), 7.04 (d, 1H, J = 8.3 Hz), 7.41 (dd, 1H, J = 8.3, 2.1 Hz), 7.68 (d, 1H, J = 2.1 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 19.8, 28.4, 34.0, 108.6, 114.4, 120.0, 121.5, 129.3, 130.4, 132.7, 136.4, 137.1, 147.0. EI-MS m/z (%): 318 [M^+] (69, ^{81}Br), 316 [M^+] (69, ^{79}Br), 301 (16), 299 (17), 290 (16), 288 (17), 209 (22), 207 (22), 128 (100), 107 (36). Anal. calcd. for $C_{16}H_{13}O_2Br$: C 60.59, H 4.10; found: C 60.24, H 4.13.

Synthesis of the catechol ketal of 7-triphenylsilyl-α-tetralone (15)

14 15 78%

A 250 mL RB flask was charged with aryl bromide **14** (2.04 g, 6.4 mmol) and covered with Ar. It was dissolved in 50 mL THF and then cooled to –78 °C. *t*-BuLi in pentane (7.8 mL, 1.7 mol/L, 13.2 mmol) was added over 10 min whereupon the solution turned brown. After stirring at –78 °C for 40 min, a solution of triphenylsilylchloride (2.08 g, 7.1 mmol) in 20 mL THF was added dropwise over 5 min. After stirring an additional 1.25 h, the cold bath was removed. Over the next few hours the colour evolved from a dark blue, to a greenish olive, to a light brown, and finally to a clear light orange. The solution was stirred for 20 h at RT. Satd. aq $NaHCO_3$ (3 mL) was added and the THF was removed by rotory evaporator to leave a gummy residue. The residue was partitioned between 100 mL ether and 100 mL satd. aq $NaHCO_3$. The organic layer was washed with brine and then dried over $MgSO_4$. Purification by SiO_2 chromatography (hexanes–EtOAc, 9:1) afforded 2.5 g of a clear, colourless waxy oil, which foamed up under high vacuum (78% yield). On runs of larger scale, a white solid crystallized out on removal of solvent: mp 125.8–128 °C. R_f = 0.375 (hexane–EtOAc, 9:1). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.05–2.09 (m, 2H), 2.25–2.29 (m, 2H), 2.87 (t, 2H, J = 6.2 Hz), 6.64–6.75 (m, 4H, catechol protons), 7.16 (d 1H, J = 7.6 Hz), 7.75 (s, 1H), 7.24–7.63 (m, 16 H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 20.1, 28.8, 34.6, 108.1, 115.0, 121.1, 127.8, 128.2, 129.5, 133.8, 134.1, 136.2, 136.36, 136.44, 137.2, 139.2, 147.2, (one sp^2 C not located). EI-MS m/z (%): 497 [M^++1] (43), 496 [M^+] (100), 416 (27), 339 (22), 259 (38), 181 (17).

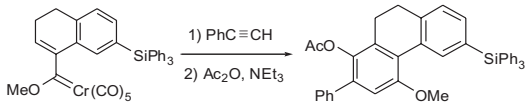


The preparation of vinyl bromide 16 (9)

15 16 85%

A 500 mL RB flask was charged with starting material **15** (5.0 g, 10.08 mmol) and was covered with Ar. Methylene chloride (200 mL) was added to dissolve the solid and the solution was cooled to between –30 and –35 °C. A 1 mol/L solution of BBr_3 (10.25 mL, 10.15 mmol) in CH_2Cl_2 was added over 5 min. The reaction was slowly warmed to –15 °C over 3 h and then to 0 °C over 2 h, after which time it was stored overnight at –15 °C. Satd. aq $NaHCO_3$ (10 mL) was added and the mixture was concentrated until ~50 mL CH_2Cl_2 remained. Hexane (300 mL) was added and the solution was washed sequentially with 1 × 150 mL H_2O, 1 × 100 mL 10% aq NaOH, 1 × 150 mL 5% aq KOH, 1 × 150 mL H_2O, then dried over $MgSO_4$, and filtered. The crude product was purified by SiO_2 chromatography (hexane–EtOAc, 9:1) to give 4.0 g of **16** as a white crystalline solid (85% yield): mp 146–148 °C. R_f = 0.38 (hexane–EtOAc, 9:1). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.36 (dt, 2H, J = 4.8, 8.0 Hz), 2.84 (t, 2H, J = 8.0 Hz), 6.38 (t, 1H, J = 4.8 Hz), 7.05 (d, 1H, J = 7.3 Hz), 7.33 (t, 6H, J = 7.1 Hz), 7.38 (t, 3H, J = 7.0 Hz), 7.50 (d, 1H, J = 7.3 Hz), 7.53 (d, 6H, J = 7.1 Hz), 7.74 (s, 1H). ^{13}C NMR (75MHz, $CDCl_3$) δ: 25.3, 27.6, 121.6, 126.9, 127.9, 129.6, 130.7, 132.38, 132.45, 134.2, 136.3, 136.5, 137.9. EI-MS m/z (%): 469 [M^++1] (33, ^{81}Br), 468 [M^+] (97, ^{81}Br), 467 [M^++1] (36, ^{79}Br), 466 [M^+] (100, ^{79}Br), 391 (83), 389 (86), 312 (30), 259 (55), 181 (40), 105 (30). Anal. calcd. for $C_{28}H_{23}SiBr$: C 71.97, H 4.92; found: C 71.81, H 5.09.

Synthesis of chromium carbene complex (17)

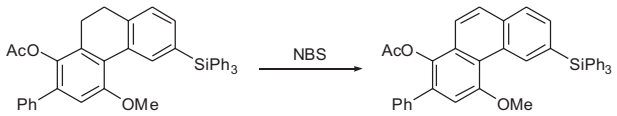


16 17 80%

A 100 mL RB flask with a stir bar was charged with vinyl bromide **16** (3.0 g, 6.42 mmol) and then covered with Ar. THF was added (32 mL) and after the solid dissolved the solution was cooled to –78 °C. A 1.7 mol/L solution of *t*-BuLi in pentane (12.84 mmol, 7.6 mL) was added over 5–10 min. The solution was stirred at –78 °C for 15 min, was warmed to 0 °C for 10 min, and was then transferred by cannula into a separate flask containing a stirred slurry of $Cr(CO)_6$ (1.41 g, 6.42 mmol) in 39 mL of THF under Ar. After stirring at RT for 1.7 h the solvent was removed by rotary evaporator and then high vacuum (19 h) to afford a light brown foam. The foam was dissolved in 45 mL argon-sparged (AS) CH_2Cl_2 under Ar and then cooled to 0 °C. Methyl triflate (1.09 mL, 9.63 mmol) was added over 5 min. The mixture was warmed to RT and stirred for 55 min. The deep red so-

© 2006 NRC Canada

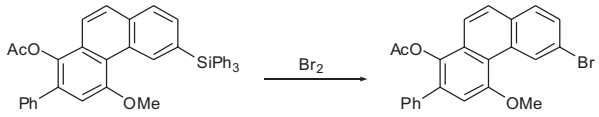
lution was then concentrated down to a few mL of volume by rotary evaporator, applied to the top of a SiO_2 column, and eluted with hexane–EtOAc (9:1), which after removal of solvent afforded 3.2 g of carbene complex **17** as a red solid (80% yield). R_f = 0.275 (hexane–EtOAc, 9:1). IR (neat film, NaCl, cm^{-1}): 2062 (m), 1988 (w), 1940 (s). ^1H NMR (300 MHz, CD_2Cl_2) δ: 2.47 (m, 2H), 2.86 (m, 2H), 4.14 (br s, 3H, methoxy), 5.76 (t, 1H, J = 4.5 Hz), 7.38 (t, 6H, J = 7.0 Hz), 6.78 (s, 1H), 7.52 (d, 6H, J = 7.6 Hz), 7.24–7.57 (m, 5H). ^{13}C NMR (75 MHz, CD_2Cl_2) δ: 22.7, 27.8, 66.1, 123.4, 128.3, 128.6, 129.7, 130.0, 130.1, 132.2, 134.3, 135.9, 136.4, 136.6, 137.8, 216.5 (CO), 225.1 (CO), 358.6 (carbene C). MS (FAB, nitrobenzyl alcohol) *m/z* (%): 622 [M^+] (3), 594 [M^+ – CO] (5), 483 (44), 482 (87), 467 (37), 452 (18), 259 (100).



The benzannulation reaction of complex 17 with phenylacetylene (3)

17 **18** 74%

Carbene complex **17** (3.2 g, 5.15 mmol) was dissolved in 150 mL of THF in a 250 mL single-necked RB flask, which had the joint replaced with a threaded high-vacuum Teflon stopcock. Phenylacetylene (0.85 mL, 7.72 mmol) was added and the solution was deoxygenated by the freeze-pump-thaw method (3 cycles, –196 °C and 20 °C). The flask was charged with Ar at RT and then sealed and warmed at 60 °C for 21 h. After cooling to RT, triethylamine (1.79 mL, 12.87 mmol) and 1.19 mL acetic anhydride (12.6 mmol) were added. The flask was resealed and warmed to 60 °C for 8 h and then stirred at RT overnight. The crude mixture was concentrated down to a few mL of volume by rotorary evaporator, applied to the top of a SiO_2 column, and eluted with hexane–EtOAc 9:1). The product fraction was collected (R_f = 0.22, hexane–EtOAc (9:1)) as well as a more polar yellow band, which was the arene chromium tricarbonyl complex of the product. This yellow compound was dissolved in $CHCl_3$ and stirred overnight in open air to remove the chromium. This was then passed through a short SiO_2 pad to filter off the green flocculent chromium byproduct. The resulting product was combined with the earlier collected product to afford 2.3 g of a white crystalline solid (74% yield); mp 228–229.5 °C. IR (neat film, NaCl, cm^{-1}): 3067 (w), 3048 (w), 2933 (w), 1761 (ms), 1460 (m), 1428 (m), 1367 (m), 1211 (s), 1186 (s), 1108 (ms), 1059 (m), 701 (vs). ^1H NMR (500 MHz, $CDCl_3$) δ: 2.07 (s, 3H), 2.78 (t, 2H, J = 6.4 Hz), 2.50–2.85 (m, 2H), 3.56 (s, 3H), 6.76 (s, 1H), 7.21–7.29 (m, 2H), 7.31–7.39 (m, 14H), 7.58 (d, 6H, J = 7.0 Hz), 8.51 (s, 1H). ^{13}C NMR (75MHz, $CDCl_3$) δ: 20.5, 23.1, 28.9, 55.4, 111.6, 123.8, 127.0, 127.5, 127.8, 128.8, 129.4, 131.1, 131.5, 133.1, 134.1, 134.6, 135.1, 136.5, 136.9, 138.0, 138.5, 139.6, 154.7, 169.4. EI-MS *m/z* (%): 604 [M^+ + 2] (10), 603 [M^+ + 1] (27), 602 [M^+] (51), 562 (15), 561 (48), 560 [M^+ – ketene] (100), 483 (14), 259 Ph_3Si^+ (73), 230 (19), 181 (14). Anal. calcd. for $C_{41}H_{34}O_3Si$: C 81.70, H 5.64; found: C 81.53, H 5.62.

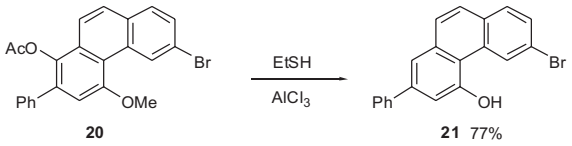


Aromatization of the B-ring of intermediate (18)

18 **19** 91%

A 500 mL RB flask was charged with starting material **18** (2.17g, 3.6 mmol), N-bromosuccinimide (673 mg, 3.78 mmol), benzoyl peroxide (89 mg, 0.36 mmol), and benzene (200 mL). The magnetically stirred solution was refluxed for 9 h. Upon cooling, the solution was filtered through a short plug of Al_2O_3 and then purified by SiO_2 chromatography (hexane–EtOAc, 5:1) to afford 1.97 g of **19** as a white crystalline solid (91% yield); mp 237 to 238 °C. R_f = 0.31 (hexane–EtOAc, 4:1). IR (neat film, NaCl, cm^{-1}): 3066 (w), 3048 (w), 2922 (w), 1763 (m), 1428 (m), 1197 (s), 1108 (ms), 1049 (mw). ^1H NMR (500 MHz, $CDCl_3$) δ: 2.14 (s, 3H), 3.61 (s, 3H), 6.98 (s, 1H), 7.28–7.39 (m, 11H), 7.47 (d, 2H, J = 7.3 Hz), 7.63 (d, 6H, J = 7.2 Hz), 7.73 (m, 4H), 7.83 (d, 1H, J = 7.8 Hz), 9.89 (s, 1H). ^{13}C NMR (75MHz, $CDCl_3$) δ: 20.7, 55.4, 109.6, 120.5, 120.8, 127.6, 127.9, 128.4, 128.8, 129.1, 129.5, 132.0, 132.8, 132.9, 133.0, 133.2, 134.6, 136.6, 136.9, 137.3, 137.8, 138.0, 156.6, 169.7, (1C not located). EI-MS *m/z* (%): 602 [M^+ + 2] (8), 601 [M^+ + 1] (15), 600 [M^+] (30), 560 (21), 559 (45), 558 [M^+ – ketene] (100), 481 (8), 465 (10), 387 (10), 260 (17), 259 Ph_3Si^+ (66,), 230 (19), 181 (14), 220 (15), 181 (8).

Bromo-desilylation of phenanthrene (19)



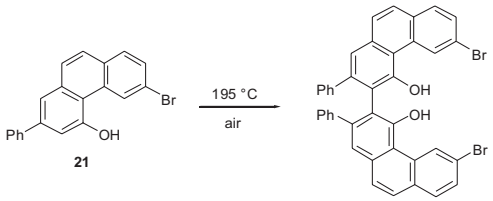
19 **20** 83%

A 100 mL RB flask with a stir bar was charged with phenanthrene **19** (342 mg, 0.57 mmol), CH_2Cl_2 (20 mL), and 5.1 mL of a 0.3 mol/L solution of Br_2 in CH_2Cl_2 (1.54 mmol). The mixture was brought to reflux for 3.5 h and then stirred at RT for 20 h. A small amount of SiO_2 was poured into the reaction mixture. Solvent was removed in vacuo to adsorb the crude reaction material on the silica. This SiO_2 adsorbate was applied to the top of a silica gel column and eluted with hexane–EtOAc (4:1) to afford 199 mg of **20** as a white solid (83% yield). The desired product elutes from the column after an orange impurity elutes. On scaling up the reaction, it was more efficacious to use slightly less Br_2 (~2 equiv.) to avoid this separation. Melting point 203.5–205 °C. R_f = 0.36 (hexane–EtOAc, 4:1). IR (neat film, NaCl, cm^{-1}): 2922 (w), 1761 (ms), 1589 (mw), 1440 (m), 1368 (m), 1212 (m), 1196 (vs), 1048 (m). ^1H NMR (300 MHz, $CDCl_3$) δ: 2.17 (s, 3H), 4.11 (s, 3H), 7.13 (s, 1H), 7.32–7.44 (m, 4 H), 7.56 (d, 1H, J = 7.9 Hz), 7.61 (dd, 1H, J = 7.6, 1.4 Hz), 7.64–7.68 (m, 1H), 7.70 (d, 2H, J = 9.5 Hz), 9.84 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 20.7, 55.9, 109.6, 120.5, 121.1, 127.7, 127.8, 127.9, 128.4, 128.6, 129.0, 129.4, 129.6, 130.0, 131.1, 132.7, 134.9, 136.5, 137.7, 156.4, 169.6. EI-MS *m/z* (%): 423 [M^+ + 1] (5,

© 2006 NRC Canada

^{81}Br), 422 [M$^+$] (18, ^{81}Br), 421 [M$^+$ + 1] (5, ^{79}Br), 420 [M$^+$] (19, ^{79}Br), 381 (23), 380 (99), 379 (25), 378 (100), 365 (14), 363 (14), 300 (19), 298 (14), 284 (32).

Reduction of 20 to the phenanthrol 21 (3)



20 **21** 77%

A 200 mL RB flask with stir bar was charged with freshly sublimed $AlCl_3$ (405 mg, 3.03 mmol), CH_2Cl_2 (100 mL), and ethanethiol (0.475 mL, 6.4 mmol). Caution: flask needs to be openly vented to allow gases to escape on addition of ethanethiol. A gentle stream of N_2 was directed down into the open neck of the flask. After stirring for 5 min at RT, starting material (421 mg, 1.0 mmol) was added, which turned the mixture orange. The flask was then sealed with a septum and punctured with a needle connected to an N_2 bubbler. The mixture was stirred 9 h. The solution turned murky within 2 to 3 h after the addition of the starting material. The solution was carefully quenched with satd. aq $NaHCO_3$ (caution: vent flask to open air) and then partitioned between 50 mL H_2O and 100 mL ether. The aqueous layer was removed by separatory funnel and re-extracted with 50 mL ether. The combined organic layers were washed with 50 mL brine, dried over $MgSO_4$, filtered, and then stripped of volatiles. Trituration from CH_2Cl_2–hexane afforded a white powder that was contaminated with a small amount (ca. 5%) of a compound that resulted from reduction of the bromide in **21**. Repeated trial runs of this reaction indicated that the amount of this impurity increased with reaction times greater than 8 to 9 h. Reaction glassware was deodorized from the stench of EtSH by immersion in dilute aqueous bleach solution. Pure product was isolated by SiO_2 chromatography (hexane–EtOAc, 5:1). It elutes just before the bromine-reduced impurity. Yield: 270 mg (77%) of light peach-coloured powder, which could be crystallized to colourless needles by slow evaporation from ether; mp 178 to 179 °C (ether). R_f = 0.29 (hexane–EtOAc, 4:1). Note: the phenananthrol monomer **21** as well as the phenanthrol dimers described below are prone to decomposition as evidenced by their turning yellow and orange on handling. Chromatography should be done expeditiously. They should not be stored as solutions (especially CH_2Cl_2) open to air. They are more stable as solids. A useful method for crashing out solid is to dissolve the compound in CH_2Cl_2, add hexane, and then slowly remove solvent on a rotory evaporator. IR (neat film, NaCl, cm^{-1}): 3335 (br), 3052 (w), 2921 (w), 1587 (w), 1393 (w). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 5.76–6.10 (variable) (s, 1H, O**H**), 7.20 (d, 2H, J = 5.9 Hz), 7.35 (t, 1H, J = 7.2 Hz), 7.44 (t, 2H, J = 7.5 Hz), 7.61–7.69 (m, 6H), 9.77 (s, 1H). ^{13}C NMR (75MHz, CD_2Cl_2) δ: 112.6, 117.8, 119.7, 121.0, 127.5, 127.9, 128.17, 128.23, 129.3, 129.9, 131.3, 131.5, 131.9, 135.7, 140.2, 155.5 (2C not located). Synthesis of (*S*)-6,6′-dibromo-2,2′-diphenyl-3,3′-bis(phenanthren-4-ol) 8 (3)

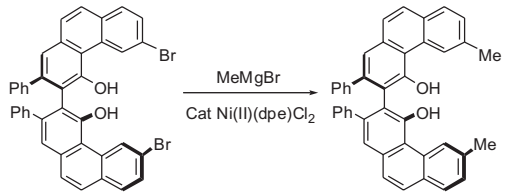
Oxidative coupling of 21

21 **8** 95%

Phenanthrene **21** (310.8 mg, 0.89 mmol) was added to a 25 × 150 mm test tube containing a micro stir bar. It was heated for a total of 14 h at 195 °C during which time it solidified to a dark brown cake. Heating was interrupted briefly after ca. 6 h to wash down sublimed starting material from the sides of the test tube with a small amount of EtOAc. (Care should be exercised in evaporating of the last of this EtOAc as it tends to spray the reaction mixture along the sides of the test tube.) The crude brown product was obtained (303 mg, 97% crude yield), which NMR indicated was the dimerized product **8** contaminated with ~5%–10% unreacted starting material. This material was used in the next step without purification. HPLC retention times for the two enantiomers: 11.33 and 17.45 min.

Deracemization of 8



8 (*S*)-**8**

A sample of $CuCl_2 \cdot 2H_2O$ (73 mg, 0.428 mmol) was dissolved under Ar in 6.7 mL AS MeOH in a 100 RB flask. A solution of 200 mg (–)-sparteine (0.853 mmol) in 13 mL AS MeOH was added by cannula, which turned the solution a murky lime green. The solution was stirred for 0.5 h at RT. In a separate flask, 213 mg of the crude biphenanthrol **8** (–0.31 mmol) was partially dissolved in 10 mL AS CH_2Cl_2. This solution was transferred by cannula into the reaction mixture with concurrent addition of 10 mL AS MeOH. The remaining undissolved starting material was dissolved in 6.5 mL AS CH_2Cl_2 and transferred into the reaction flask with concurrent addition of 6.5 mL AS MeOH. The mixture turned black. It was stirred for 24 h, quenched with 1 mL concd HCl, and then partitioned between 50 mL H_2O and 50 mL CH_2Cl_2. The organic layer was dried over $MgSO_4$ and filtered, then adsorbed onto a small amount of SiO_2 and chromatographed (hexane–EtOAc, 5:1) to afford 108 mg of (*S*)-**8** as a white or pale yellow solid (50% yield). R_f = 0.38 (hexane–EtOAc, 4:1). The optical purity of **8** was determined to be >98% ee by chiral HPLC analysis on Pirkle D-phenyl glycine column with 70:30 mixture of hexane–*i*PrOH at 2 mL/min. The chiral HPLC retention time of (*S*)-**8** was 16.9 min. X-ray quality crystals were grown by dissolving a

© 2006 NRC Canada

sample in a minimum amount of hot EtOAc, allowing this to cool to RT, and then layering with hexane, which produced clear faintly pale green crystals. Crystallography as well as ^{1}H NMR indicated the crystal contained two equiv. of EtOAc. Absolute configuration is assigned to the (*S*)-isomer by analogy with the parent molecule VAPOL, which upon deracemization with (–)-sparteine–$CuCl_2$ affords (*S*)-(+)-VAPOL (12). On scaling up the reaction, the material obtained from the chromatography column was not always enantiopure. In this case the enantiopurity was upgraded by stirring the scalemic powder for 1 h in enough hexane to allow a small amount to remain undissolved. The decanted hexane was found to contain enantiopure material. $[\alpha]_D$ + 445° (*c* 1.0, THF). IR (neat film, NaCl, cm^{-1}): 3482 (s), 3139 (w), 3052 (w), 3027 (w). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 6.60 (s, 2H), 6.64 (d, 4H, *J* = 7.5 Hz), 6.94 (t, 4H, *J* = 7.6 Hz), 7.05 (t, 2H, *J* = 7.3 Hz), 7.40 (s, 2H), 7.65 (d, 2H, *J* = 8.7 Hz), 7.69 (d, 2H, *J* = 8.3 Hz), 7.75 (t, 4H, *J* = 9.5 Hz), 9.91 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 116.0, 117.1, 121.3, 123.2, 126.9, 127.4, 127.6, 128.6, 128.8, 129.4, 129.6, 131.27, 131.35, 131.42, 135.3, 139.5, 142.2, 153.3. Coupling of (*S*)-8 with phenyl boronic acid — Synthesis of (*S*)-10 (14)

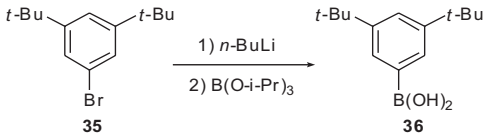
(*S*)-**8** (*S*)-**10**

Ethanol, aq Na_2CO_3 (2 mol/L), and benzene were sparged (>10 min) with inert gas (Ar or N_2) prior to use. A 25 mL RB flask was charged with $Pd(PPh_3)_4$ (2.3 mg, 2.2 μmol) and optically pure (*S*)-**8** (25 mg, 35.9 μmol). The flask was filled with Ar and 1.5 mL benzene and aq Na_2CO_3 (0.75 mL, 2 mol/L) was added by syringe. A solution of phenyl boronic acid (10.9 mg, 89.7 μmol) in 0.5 mL EtOH was added. The mixture was refluxed for 7 h and then stirred overnight at RT. The reaction mixture was diluted with 30 mL ether and washed with 25 mL brine containing a pipette tipful of HCl. The organic layer was dried over $MgSO_4$, filtered, adsorbed onto a small amount of SiO_2, and chromatographed (hexane–EtOAc, 9:1) to afford 23.4 mg of (*S*)-**10** as a white solid film (94% yield). $[\alpha]_D$ 749.5° (*c* 1.0, THF). R_f = 0.25 (hexane–EtOAc, 9:1, plastic plate). Chiral HPLC retention time: 22.4 min. IR (neat film, NaCl, cm^{-1}): 3481 (s), 3058 (w), 2923 (m), 2852 (w). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 6.66 (d, 6H), 6.94 (t, 4H, *J* = 7.6 Hz), 7.04 (t, 2H, *J* = 7.1 Hz), 7.27, (t, 2H, *J* = 7.1 Hz), 7.39 (t, 6H), 7.64 (d, 2H, *J* = 8.7 Hz), 7.76 (d, 4H, *J* = 7.4 Hz), 7.81 (d, 2H, *J* = 8.5 Hz), 7.87 (d, 2H, *J* = 7.5 Hz), 7.96 (d, 2H, *J* = 8.3 Hz), 10.04 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 115.9, 118.2, 123.3, 125.5, 126.8, 127.1, 127.2, 127.5, 128.8, 130.6, 132.0, 135.6, 139.6, 139.7, 141.7, 153.5, (6 C not located). EI-MS *m*/*z* (%): 692 [M$^+$ + 2] (17), 691 [M$^+$ + 1] (57), 690 [M$^+$] (100), 672 (8), 614 (20), 615 (11), 446 (13), 346 (15), 345 (25).

Coupling of (*S*)-8 with 3,5-di-*t*-butylphenyl Grignard reagent — Synthesis of (*S*)-11

Synthesis of 3,5-di-t-butylbromobenzene (17).

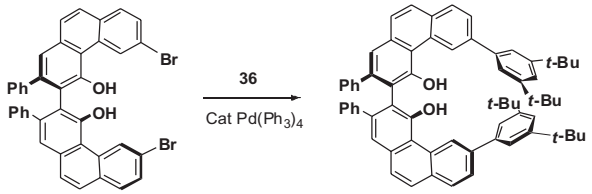


34 **35** 54%

A 25 mL RB flask with stir bar was charged with pulverized $CuBr_2$ (544 mg, 2.43 mmol) and 5 mL freshly distilled CH_3CN. NO gas was bubbled through the mixture for 10 min. The reaction mixture was then cooled to –30 °C, while maintaining NO gas bubbling. A solution of 500 mg of the *tert*-butylated aniline **34** (2.43 mmol) in 1.5 mL CH_3CN was added over 5 min. After stirring 5 additional minutes, the cold bath was removed, NO gas flow was

© 2006 NRC Canada

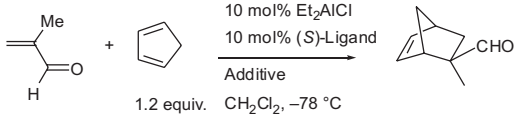
reduced to a trickle, and the solution stirred at RT for 1 h 10 min. The reaction was partitioned between 50 mL H_2O and 100 mL ether. The murky green organic layer was then washed with brine, dried over $MgSO_4$, filtered, and adsorbed onto a small amount of SiO_2. Purification by SiO_2 chromatography (hexane) afforded 355 mg of a clear, colourless oil, which crystallized on sitting at RT (54% yield). R_f = 0.40 (hexane). ^{1}H NMR (500 MHz, CD_3CN) δ: 1.09 (s, 18H), 7.13 (s, 2H), 7.19 (s, 1H). The aryl protons showed the same chemical shift in $CDCl_3$. EI-MS *m/z* (%): 271 (3), 270 [M^+] (24, ^{81}Br), 269 (3), 268 [M^+] (24, ^{79}Br), 256 (15), 255 (99), 254 (10), 253 (100).



Synthesis of boronic acid 36 (18)

35 **36**

A 25 mL RB flask with stir bar was charged with 320 mg of aryl bromide **35** (1.19 mmol) and then covered with Ar. THF (5 mL) was added and after dissolution the flask was cooled to –78 °C, whereupon 0.48 mL of a 2.5 mol/L solution of *n*-BuLi in hexanes (1.2 mmol) was added dropwise. After stirring at –78 °C for 1 h, a solution of 0.68 mL triisopropyl borate in THF (1 mL, 2.9 mmol) was added all at once by syringe to give a clear solution. The cold bath was removed and while warming to RT the solution became cloudy. After stirring 1 h the mixture was poured into a vigorously stirred mixture of 10% aq HCl (30 mL) and ether (40 mL) and stirred a few minutes. Both the aqueous and organic layers were clear and colourless. The organic layer was removed, washed with 30 mL H_2O, dried over $MgSO_4$, and filtered. Rotary evaporation of the solvent yielded **36** as a white solid, which was used in the next step without purification. ^{1}H NMR analysis (500 MHz, $CDCl_3$) of the aryl region suggested a mixture of two compounds; major: δ 7.52 (s, 2H), 8.06 (s, 1H); minor: δ 7.63 (s, 2H), 7.94 (s, 1H). In addition there was a pronounced singlet at δ 4.54, which is attributed to the BOH of the desired product.



Suzuki coupling of (S)-8 with 36 — Synthesis of (S)-11 (14)

(*S*)-8 **(*S*)-11**

Ethanol, aq Na_2CO_3 (2 mol/L), and benzene were sparged (>10 min) with inert gas (Ar or N_2) prior to use. Optically pure (*S*)-**8** (66 mg, 75.9 µmol, based on MW 872.6, containing two equiv. of EtOAc) was dissolved in a minimum of CH_2Cl_2 in a 25 mL RB flask, the solvent was removed by rotory evaporator, and then the ethyl acetate was removed on high vacuum. To the flask was added $Pd(PPh_3)_4$ (6 mg, 5.2 µmol) and the solids were covered with Ar. Benzene (4 mL) and aq Na_2CO_3 (2 mL 2 mol/L) was added. To the vigorously stirred mixture was added a solution of crude boronic acid **36** (89 mg, ~304 µmol, based on 80% purity) in EtOH (2 mL). The mixture was refluxed for 14 h and then stirred at RT for 11 h. The reaction mixture was partitioned between 50 mL ether and 25 mL brine containing a pipette tip of HCl. The organic layer was dried over $MgSO_4$, filtered, and adsorbed onto a small amount of SiO_2. Purification by chromatography on silica gel (hexane–EtOAc, 9:1) afforded 70.0 mg of (*S*)-**11** as a clear, colourless solid film (100% yield). $[\alpha]_D$ 565° (*c* 1.0, THF). R_f = 0.42 (hexane–EtOAc, 9:1). Chiral HPLC retention time: 5.7 min. IR (neat film, NaCl, cm^{-1}): 3486 (m, sharp), 2962 (s, sharp), 2863 (w), 1594 (m, sharp). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.35 (s, 36H), 6.55 (s, 2H), 6.69 (d, 4H, *J* = 7.2 Hz), 6.94 (t, 4H, *J* = 7. 5 Hz), 7.04 (t, 2H, *J* = 6.6 Hz), 7.37 (s, 2H), 7.56 (s, 4 H), 7.43 (s, 2H), 7.64 (d, 2H, *J* = 8.7 Hz), 7.81 (d, 2H, *J* = 8.8 Hz), 7.85 (d, 2H, *J* = 7.7 Hz), 7.96 (d, 2H, *J* = 8.1 Hz), 9.95 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 31.6, 115.8, 118.4, 121.4, 122.3, 123.4, 126.2, 126.9, 127.6, 127.7, 128.8, 128.9, 129.1, 130.6, 131.8, 135.6, 139.8, 141.2, 141.3, 141.8, 151.2, 153.7 (2 C not located). Diels–Alder reaction of methacrolein and cyclopentadiene

5 **6** **(*2R*)-7**

A sample of the desired ligand (45–75 mg) was added to a 5 mL RB flask containing a stirbar and the flask was flushed with Argon. Methylene chloride (1 to 2 mL) was added by syringe followed by 1 equiv. Et_2AlCl (1 mol/L solution in hexane), which turned the solution a deep blood-red color. After stirring at RT for 0.5 h the flask was cooled to –78 °C. Methacrolein (10 equiv. relative to ligand) was then added by syringe. After stirring at –78 °C for 0.5–0.75 h, 12–14 equiv. of cyclopentadiene was added. If an additive was used, it was added 15 min before the cyclopentadiene was added. After 0.5 h at –78 °C, the reaction was quenched by the addition of 1 mL brine. The mixture was then partitioned between 20 mL CH_2Cl_2 and 10 mL H_2O and stirred vigorously. The organic layer was dried over $MgSO_4$, filtered, and then taken to near dryness on the rotory evaporator. The yield of the exo product **7** was determined on this concd CH_2Cl_2 solution by ^{1}H NMR using the ligand as an internal standard. The product was separated from the ligand by bulb-to-bulb distillation under high vacuum into a –78 °C trap prior to the measurement of the exo–endo ratio and the ee%, which were each determined by one of the two methods indicated below. Catalyst formation for ligands **10** and **11** were much slower as indicated by ^{1}H NMR. For these ligands, catalyst formation required heating at 55 °C for 24 h. ^{1}H NMR for *exo*–**7** (500 MHz, $CDCl_3$) δ: 0.76 (d 1H, *J* = 11.9 Hz), 1.00 (s, 3H), 1.38 (s, 2H), 2.23 (dd, 1H, J = 11.9, 3.5 Hz), 2.80 (s, 1H), 2.87 (s, 1H), 6.06 (dd, 1H, J = 5.2, 2.9 Hz), 6.25 (dd, 1H, J = 5.1 Hz, 2.9 Hz), 9.62 (s, 1H).

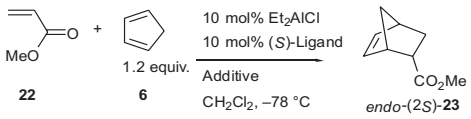
Analysis of exo-adduct 7 by conversion to chiral acetals



This method was originally developed by Yamamoto (20). A pipette tip of product **7** (~20 mg) was mixed with 25–30 mg (2*R*,4*R*)-(–)-pentanediol, 40 mL triethyl orthoformate, a small crystal of $TsOH{\cdot}H_2O$, and 1 to 2 mL benzene and stirred overnight. The de% of the exo product (and hence ee% of the exo product) and the exo–endo ratio were determined by GC on an Alltech Econocap capillary column (cat. #19646, ser. # 2475–9): 0.32 mm i.d., 0.25 mm film thickness, and 30 m in length. Column temperature was 50 °C for 2 min and then ramped up at 4 °C per min. Under these conditions, the following retention times were observed: (*2R*,*2′R*,*4′R*)-**38** (23.15 min); (*2S*,*2′R*,*4′R*)-**38** (23.25 min), **39** (21.98 and 22.93 min, not assigned). It was previously established that (*S*)-VAPOL is selective for (*2R*,*2′R*,*4′R*)-**38** (4*a*). Spectral data for (*2R*,*2′R*,*4′R*)-**38**: IR (neat, cm^{-1}): 3139 (w), 3059 (m), 2979 (s), 2932 (s), 2878 (s), 2700 (w), 1572 (w), 1451 (s), 1398 (m), 1376 (s), 1333 (s), 1289 (m), 1241 (s), 1181 (m), 1158 (s), 1135 (s), 1093 (m), 1081 (m), 1007 (s), 972 (m), 906 (m), 839 (m), 721 (s). ^{1}HNMR ($CDCl_3$) δ: 0.76 (d, 1H, *J* = 12.0 Hz), 0.86 (s, 3H), 1.19 (d, 3H, *J* = 6.2 Hz), 1.29–1.31 (m, 2H), 1.34 (d, 3H, *J* = 7.1 Hz), 1.60 (d, 1H, *J* = 8.4 Hz), 1.74–1.82 (m, 2H), 2.66 (s, 1H), 3.90–3.94 (m, 1H), 4.27–4.66 (m, 1H), 4.66 (s, 1H), 6.01–6.11 (m, 2H). ^{13}C NMR (CDC_3) δ: 17.25, 18.77, 21.96, 36.87, 37.10, 43.07, 45.45, 47.15, 48.06, 67.68, 67.74, 99.48, 135.54, 137.15. Analysis of exo-adduct 7 by reduction to alcohol 40

The aldehyde **7** (71.7 mg) distilled from the reaction described above was dissolved in 1.2 mL of ethanol and treated with $NaBH_4$ (24 mg). After 1 h the reaction was quenched by the slow addition of water. The reaction mixture was partitioned between 10 mL of H_2O and 10 mL of ethanol. The aqueous phase was extracted with ether (2 × 5 mL) and the combined organic layer was washed with 15 mL of brine and dried over $MgSO_4$. Removal of solvent left 77 mg of crude product, which was purified by chromatography on silica gel with a 5:1 mixture of hexanes – ethyl acetate to give 61 mg of **40** as a white solid. The de% of the exo product (and hence ee% of the exo product) and the exo–endo ratio were determined by GC on an Astec B-MB capillary column (Beta-cyclodextrin Dimethyl, *t*-Butyl, ser. # 9606–29) of 0.25 mm i.d. and 30 m in length. Column temperature was isothermal at 140 °C. Under these conditions, the following retention times were observed: (*2R*)-**40** (6.12 min); (*2S*)-**40** (6.01 min); **41** (5.67 and 5.41 min, not assigned).

Diels–Alder reaction of methacrolein and cyclopentadiene

A sample of the desired ligand (45 mg) was added to a 5 mL RB flask containing a stir bar and the flask was then flushed with argon. Methylene chloride (1 to 2 mL) was added by syringe followed by 1 equiv. Et_2AlCl (1 mol/L solution in hexane), which turned the solution a deep blood-red color. After stirring at RT for 0.5 h, the flask was cooled to –78 °C. Methyl acrylate (10 equiv. relative to ligand) was then added by syringe. After stirring 0.5–0.75 h at –78 °C, 12–14 equiv. of cyclopentadiene was added. If an addtive was used it was added 15 min before methyl acrylate. After 24 h at –78 °C the reaction was quenched by the addition of 1 mL brine. The mixture was then partitioned between 20 mL of CH_2Cl_2 and 10 mL of H_2O and stirred vigorously. The organic layer was dried over $MgSO_4$, filtered, and then taken to near dryness on a rotatory evaporator. The yield of *endo*-**23** was determined on this concentrated CH_2Cl_2 solution by ^{1}H NMR using the ligand as an internal standard. The product was separated from the ligand by bulb-to-bulb distillation under high vacuum into a –78 °C trap prior to the measurement of the exo–endo ratio and the ee%, which were

© 2006 NRC Canada

both determined by the method indicated below. Catalyst formation for ligands **10** and **11** were much slower as indicated by ^{1}H NMR. For these ligands, catalyst formation required heating at 55 °C for 24. Spectral data for *endo*-**23**: ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.28 (d, 1H), 1.40–1.45 (m, 2H), 1.88–1.96 (m, 1H), 2.92–2.99 (m, 2H), 3.21 (s, 1H), 3.63 (s, 3H), 5.94 (dd, 1H, J = 5.6, 2.8 Hz), 6.20 (dd, 1H, J = 5.6, 3.0 Hz).

Analysis of endo-adduct 23 by GC

endo-(2*S*)-**23** *endo*-(2*R*)-**23** *exo*-(2*R*)-**42** *exo*-(2*S*)-**42**

The methyl ester **23** distilled from the reaction described above was directly assayed for endo–exo selectivity and for enantioselectivity by chiral GC on a J & W Cyclodex-B capillary column (part #1122532, ser. #5094942) of 0.25 mm i.d., 0.25 mm film thickness, and 30 m in length, and with column temperature 90 °C (isothermal). The oven was baked at 200 °C a few minutes before each run, which improved GC peak resolution. Under these conditions, the following retention times were observed: (*2S*)-**23** (16.43 min), (*2R*)-**23** (15.90 min), **42** (12.79 and 12.98 min, not assigned). It was previously shown that (*S*)-VAPOL gives selectively the *endo*-(*2S*) isomer of **23** (4).

BIOGRAPHY / BIOGRAPHIE

Born in Vienna, Alfred Bader fled to England at the age of fourteen, ten months before the outbreak of World War II. Although a Jewish refugee from the Nazis, he was interned in 1940 along with other 'enemy aliens', and sent to a Canadian prisoner of war camp.

Today, Dr. Bader is one of the most respected men in his field. In this heartwarming book, he tell the fascinating story of how he made good in the land of opportunity, the United States.

It was a case of hard study and hard work. Obtaining release in 1941, he was accepted at Queen's University in Kingston, Ontario, where he studied engineering chemistry. There followed a fellowship in organic chemistry at Harvard. He worked in Milwaukee as a research chemist for the Pittsburgh Plate Glass Company and in 1951 co-founded Aldrich, which today, as Sigma-Aldrich, is the world's largest supplier of research chemicals.

He spent forty years building Aldrich's distinctive reputation and the extraordinary story of how he was eventually thrown off the board of Sigma-Aldrich will be of key interest to people in the chemical industry worldwide, as well as to students of business.

After leaving Sigma-Aldrich, he continued a fruitful career as an art collector and dealer, and he has some very pertinent and amusing things to say about his experiences in the art world.

Alfred Bader and his family have earned a reputation as generous benefactors, notably in the fields of chemistry, education, and Jewish interests. Dr. Bader's personal philanthropy has been particularly directed towards helping students of chemistry and art history. He recently gave £6,000,000 to Queen's University to purchase and renovate Herstmonceux Castle in Sussex (the home of the old Royal Greenwich Observatory) – one more 'thank you' to the Canadian institution that had enabled him to take the first step on the road to success, so entertainly described in this book.

(Alfred Bader, Adventures of a Chemist Collector. Weidenfeld & Nicolson, London, 1995)

Né à Vienne, Alfred Bader s'enfuit en Angleterre à l'âge de 14 ans, dix mois avant qu'éclate la Seconde Guerre mondiale. Réfugié juif des nazis, il est quand même interné en 1940 avec d'autres « ressortissants de pays ennemis » et déporté au Canada dans un camp de prisonniers de guerre.

Aujourd'hui, Bader figure parmi les plus respectés de son domaine. Dans ce récit attachant et émouvant, il retrace les événements qui lui ont permis de faire sa marque dans un pays d'avenir, les États-Unis.

C'est l'histoire d'un solide engagement envers les études et de persévérance. Libéré en 1941, il étudie le génie chimique à l'Université Queen's. Il fait un stage postdoctoral en chimie organique à Harvard. Il travaille à Milwaukee à titre de chimiste de recherche pour la *Pittsburgh Plate Glass Company*. En 1951, il cofonde l'*Aldrich Chemical Company*, aujourd'hui la *Sigma-Aldrich Corporation*, le plus important fournisseur de substances chimiques employées dans la recherche du monde entier.

Malgré le fait qu'il consacre quarante ans de sa vie à cultiver la réputation d'excellence d'Aldrich, il se fait exclure du conseil de Sigma-Aldrich, une histoire qui est sfre d'intéresser tous les intervenants de l'industrie, sans compter les étudiants en administration.

Il quitte donc Sigma-Aldrich pour poursuivre une carrière fructueuse en tant que collectionneur et marchand d'Éuvres d'art. Il a d'ailleurs des anecdotes fort amusantes et très pertinentes à raconter à propos de ses expériences dans l'univers des arts.

La très grande réputation de bienfaisance et de bonté d'Alfred Bader et de sa famille, notamment au profit de la chimie, de la pédagogie et de la culture juive, n'est plus à démontrer. Parmi les plus importants bénéficiaires de leur générosité figurent les étudiants en chimie et en histoire de l'art. Un autre grand bénéficiaire de la philanthropie des Bader est l'Université Queen's, qui s'est vu remettre la somme de 6 000 000 £ pour acquérir et rénover le château Herstmonceux, B Sussex (le site de l'Observatoire royal de Greenwich) – une autre façon de « remercier » l'établissement canadien qui lui a permis de faire un premier pas vers la réussite, tel que décrit de manière si divertissante dans cet ouvrage.

(Alfred Bader, Adventures of a Chemist Collector. Weidenfeld & Nicolson, Londres, 1995)

Unwrapped

for Alfred Bader and a city

by Roald Hoffmann

I didn't expect
to receive it
watching "The Third

Man," to hear it
in Anna's schmal-
tzy lines, in her

black and white walk
down the allée. No,
it would have made

more sense for it
to surface in
the angle of cut

of the vines still
strapped to wires.
Or at night. But

if one is in-
clined to sadness,
it plain takes over --

like an arch, all
of-a-sudden
perceived as off-

center, like the
leaping buck in
my lights. Until...

you realize you
have been granted
a gift, the salty,

loosening gift
of the road in
to the father -

no chance, then,
to mourn; the
time rending

gift, Vienna, her;
The gift I wish
would pass from me.

TRIBUTE / HOMMAGE

It is a great privilege and honour for us to write the dedication for this Special Issue honouring Alfred Bader. Alfred Bader, a true visionary, has had a profound effect on the way chemists do research. But Alfred Bader's influence is much broader than chemistry as he is an entrepreneur, businessman, art collector, Rembrandt expert, and philanthropist.

Throughout his childhood and teenage years Alfred faced great adversity. He was born in Vienna in 1924 and two weeks after his birth, his father died. In November 1938 following the anti-Jewish demonstrations on Kristallnacht, Alfred's mother sent him to the U.K. He lived in Sussex and entered Brighton Technical College in 1939. In May 1940, the British government, given the escalating conflict with Germany, arrested German and Austrian males including Alfred and put them in internment camps. The Canadian government agreed to accept custody of some of the interned individuals comprising prisoners of war and strongly anti-Nazi refugees as well as German civilians. Alfred Bader was one of those interned in Canada and was sent to a fortress on an island on the Richelieu River near Lake Champlain. While there, he and some others were determined to continue their education and Alfred passed both the Junior and Senior Matriculation exams before being released in 1941. Bader applied to several universities and was accepted by Queen's University in Kingston. Alfred enjoyed his studies at Queen's and to earn money to continue university and go on dates, he worked at Murphy Paint Company in Montreal on the formulation of enamels and lacquers. There, he also learned to appreciate industry and entrepreneurship.

Bader recognized the need for a research chemicals business while he was a graduate student at Harvard working with Louis Fieser, a leading organic chemist. At that time nearly all chemicals came from Eastman Kodak, which had a product list of 4000 chemicals. Although others tried to discourage him, Alfred persevered and together with a friend, Milwaukee attorney Jack Eisendrath, incorporated Aldrich Chemical Company on August 17, 1951, each putting up $250. The first home of Aldrich was a garage they rented for $25 per month. They were two part-time employees, their catalogue was a mimeographed sheet with one offering, and sales in the first year was $1705.

The company moved to 1000 square feet of rented space where Bader single handedly carried out all the syntheses. In 1955 Aldrich expanded into medicinal chemistry, which gave Alfred tremendous satisfaction. Alfred's hard work and determination paid off and by 1958 they had a staff of 12 and purchased a three-story building. What was so impressive was the commitment by Alfred to deliver chemicals in a highly efficient manner. It was clear by then that Bader's vision and integrity coupled with his determination and dedication would lead to a highly successful career.

The company continued to grow at a tremendous rate and by 1962 had sales of one million dollars, up from $5,400 a decade earlier. In 1990, Aldrich merged with Sigma to become Sigma-Aldrich, the 80th largest corporation in the US, employing over 4,000 people with subsidiaries in many European countries, Israel, and Japan. After serving as Chair of the Board from 1980 to 1991 he "officially retired" but became chairman emeritus.

One of Bader's key recommendations to those building a business is "listen carefully to your customers". This personal approach was the cornerstone of Alfred's success. The trademark Aldrich advertisement had a picture of Alfred with the heading "Please Bother Us". He and his wife Isabel travelled tirelessly to laboratories throughout North America and around the world where he listened attentively to problems chemists were having with syntheses and offering advice and proposing solutions. Bader comments in his book *Adventures of a Chemist Collector* "Although all of our visits to universities begin in the hope of getting to know our customers and perhaps finding exciting new compounds, they often become pure personal pleasure for Isabel and me". My (Anne's) first encounter with Alfred Bader was in 1966, discussing with him over breakfast in the Windsor Hotel in Montreal, the possibility of making a diazo compound in larger quantities than the few mg I had amassed after a lengthy process. The research went in another direction and Aldrich did not make the compound but I will never forget my first meeting with Alfred and Howard's and my good fortune in getting to know Alfred and Isabel in the years following.

Bader's vision and accomplishments go far beyond chemistry and the chemicals business. Bader calls himself an "inveterate collector" beginning with stamps at 8, drawings at 10, and paintings at 20. When Alfred was a child in Vienna his mother's apartment was filled with paintings, 19th and 20th century Viennese works. He knew he did not like these but became very interested in painting. Bader has been buying selling, trading, and giving away paintings for many years. When Aldrich was on a firm footing and he could give a little more time to what he calls an enjoyable pastime, he established Alfred Bader Fine Arts and since 1992 has devoted more and more of his time to it. Although he now trades in very expensive art including works by Rembrandt and Rubens, he always considered it much more fun to pay a few thousand dollars for a work that might prove great and valuable after cleaning. He loves discoveries not only of material value but also of great beauty. Bader has shared his love of paintings with others. On his visits to universities and at every Aldrich exhibit booth, he distributed prints of some of the paintings in his vast collection. Chemists will remember the Alchemist well and each year a painting appeared on the cover of the Aldrich catalog. He thus served a very important role in art appreciation for the chemical community

In addition to Bader's impact on chemistry and his contributions to art collecting, art history, and art conservation, his generosity of spirit will leave a lasting impact. He gives back to the discipline of chemistry, to Queen's University that accepted him when other universities did not, and to other institutions and foundations. It started with small no strings attached grants to chemists in need of funding around the world. Many of these have become internationally recognized scientists. He has established prizes, scholarships, and awards for students in Canada, the United States, Britain, and the Czech Republic recalling the benefit such awards provided him when he was a student. He established the Alfred Bader Award in Organic Chemistry for the American Chemical Society (now known as the Aldrich award) and the Canadian Society for Chemistry and the Royal Society of Chemistry in the UK. More recently he endowed the ACS Alfred Bader Award in Bioinorganic or Bioorganic Chemistry and supported the ACS Project Seed to enable undergraduate chemistry students to experience laboratory work.

© 2006 NRC Canada

Bader's donations to Queen's have included: Chairs in Organic Chemistry and Art History, outstanding paintings from his collection for the Agnes Etherington Art Centre, and seed money for a new museum. Bader Lane at Queen's connects the Chemistry Building with the Agnes Etherington Art Centre. Perhaps the most unusual gift to Queen's has been Herstmonceux Castle, a moated castle in Sussex England parts of which date from the 15th century. In addition, Bader has supported many Jewish educational projects and set up charitable foundations in Milwaukee.

Alfred Bader has been recognized for his work by a number of Honorary Doctorates from different universities including Simon Fraser University and the University of Ottawa, an honorary Fellowship in the Royal Society of Chemistry, and the ACS Charles Lathrop Parsons Award, given in recognition of outstanding public service by a member of the ACS. He is also a Honorary Fellow of the Chemical Institute of Canada.

Another facet of Alfred, and Isabel, is their remarkably intense romantic relationship. Several years ago, a new book was published by Isabel entitled "A Canadian in Love". It contains some beautifully composed letters by Isabel to Alfred and at the end of the book, a letter from Alfred to Isabel dated April 18, 1975. One paragraph in the letter states:

"You had not written to me from September 11, 1950 until August 11, 1951, your last letter to me for 24 years. I have read that letter so often that I know it by heart and it has torn me apart these many years. What power you have over me! Your last words to me were "God bless you, Alf" and of course you meant this with all your heart. And God has indeed blessed me by giving me you as a beacon in my life. Whatever important I have done, I have thought of you, and done the right thing. As David said-"Whither shall I go from your spirit, or whither shall I flee from your presence? If I ascend into heaven, you are there, and if I make my bed in hell, behold, you are there". All of us have part of God in us, and the great goodness in you is so plain to me".

Following his retirement from Aldrich, Alfred was able to devote nearly all his time and energy to his activities as an art collector, lecturer, and philanthropist. Alfred says that getting to know people involved in art has enriched his life. Those of us who have been fortunate to know Alfred have had our lives enriched by him.

TRIBUTE / HOMMAGE

Nous sommes extrêmement privilégiés et honorés de rédiger la dédicace du présent numéro spécial de la Revue, qui rend hommage à Alfred Bader. Véritable visionnaire, Alfred Bader a certes profondément transformé la façon dont les chimistes réalisent aujourd'hui leurs recherches, mais son influence s'étend beaucoup plus loin puisqu'il est aussi un entrepreneur, un homme d'affaires, un collectionneur d'œuvres d'art, un spécialiste de Rembrandt et un philanthrope.

L'enfance et l'adolescence d'Alfred ont été marquées par l'adversité. Alfred est né à Vienne, en 1924; deux semaines après sa naissance, son père est décédé. En novembre 1938, dans le sillage de la campagne antisémite « Nuit de Cristal », la mère d'Alfred a envoyé son fils au Royaume-Uni. Là-bas, il a vécu au Sussex et est entré au Brighton Technical College en 1939. En mai 1940, aux prises avec un conflit grandissant avec l'Allemagne, le gouvernement britannique a fait arrêter tous les hommes allemands et autrichiens, y compris Alfred, et les a fait placer dans des camps d'internement. Le gouvernement du Canada a accepté de prendre à sa charge quelques-uns de ces détenus, principalement des prisonniers de guerre, des réfugiés antinazis et des civils allemands : c'est ainsi qu'Alfred Bader a été envoyé au Canada, plus précisément dans une forteresse sur une île de la rivière Richelieu, près du lac Champlain. Malgré cet internement, Alfred et quelques autres détenus étaient déterminés à poursuivre leurs études et Alfred est arrivé à obtenir son immatriculation junior et son immatriculation senior avant sa libération, en 1941. Alfred a frappé à la porte de plusieurs universités avant d'être accepté à l'Université Queen's, à Kingston, où il a vécu des jours heureux. Pour financer la poursuite de ses études et ses rendez-vous galants, il a travaillé pour la Murphy Paint Company, à Montréal, où il planchait sur la formulation de peintures-émail et de peintures-laque. C'est auprès de cette société qu'il a nourri un intérêt pour l'industrie et l'entrepreneuriat.

Tandis qu'il était étudiant de troisième cycle à l'Université Harvard, sous la direction de Louis Fieser, chimiste organicien réputé, Alfred a pris conscience de la nécessité de fonder une entreprise de production de produits chimiques spécialisée en recherche. À l'époque, presque tous les produits chimiques provenaient de la société Eastman Kodak, dont le catalogue recensait quelque 4 000 substances. Bien que plusieurs de ses pairs aient tenté de l'en dissuader, Alfred a constitué l'Aldrich Chemical Company le 17 août 1951, avec son ami Jack Eisendrath, un avocat du Milwaukee, chacun ayant investi 250 $ dans le projet. À ses débuts, Aldrich occupait un garage loué à 25 $ par mois; la société comptait deux employés à temps partiel et son catalogue se bornait à une page polycopiée. Ses ventes se sont chiffrées à 1 705 $ la première année.

La société a subséquemment déménagé dans des locaux loués de 1 000 pieds carrés, où Alfred réalisait à lui seul toutes les synthèses. En 1955, Aldrich a étendu ses activités aux produits chimiques médicinaux, ce qui a particulièrement ravi Alfred. L'ardeur et la détermination d'Alfred ont porté fruit et, en 1958, sa société, qui employait 12 personnes, s'est enfin installée dans son propre édifice de trois étages. Une qualité particulièrement admirable chez Alfred était son engagement à fournir des produits chimiques dans la plus grande efficacité. On voyait déjà dans son acuité et son intégrité, conjuguées à sa détermination et à son dévouement, les signes annonciateurs d'une carrière remarquable.

La société a poursuivi son ascension et, en 1962, ses ventes ont atteint le million de dollars, bien loin des 5 400 $ de dix ans auparavant. En 1990, Aldrich a fusionné avec Sigma et est devenue Sigma-Aldrich, la 80e plus importante société américaine, forte de 4 000 effectifs et de filiales dans de nombreux pays d'Europe, en Israël et au Japon. Après avoir occupé la présidence du conseil d'administration de la société de 1980 à 1991, Alfred a « officiellement pris sa retraite », mais est toutefois demeuré président émérite.

Un des principaux conseils qu'Alfred se plaisait à donner aux nouveaux entrepreneurs était le suivant : « Écoutez attentivement vos clients. » Cette attitude était la clé de voûte de son succès. D'ailleurs, toute la publicité d'Aldrich arborait une photo d'Alfred au-dessus de laquelle figurait la phrase « Prière de déranger ». Lui et sa conjointe, Isabel, voyageaient sans relâche d'un laboratoire à l'autre, en Amérique du Nord et partout dans le monde, et Alfred écoutait attentivement les difficultés qu'éprouvaient les chimistes en matière de synthèse, puis leur livrait des conseils ou leur proposait des solutions. Dans son autobiographie *Adventures of a Chemist Collector*, il déclarait : « Bien que toutes nos visites dans les universités soient mues par le désir de mieux connaître nos clients et, peut-être, de découvrir de nouveaux composés prometteurs, elles aboutissent souvent à une délicieuse expérience personnelle pour Isabel et pour moi. » Mon premier contact avec Alfred Bader [c'est Anne qui parle] remonte à 1966, à l'hôtel Windsor de Montréal. À l'occasion d'un petit déjeuner, je m'entretenais avec lui de la possibilité d'accroître ma production actuelle d'un composé diazoïque – à peine quelques milligrammes à la suite d'un long procédé. Les recherches ont pris un autre cours et Aldrich n'est jamais revenu sur la question, mais je n'oublierai jamais notre première rencontre avec Alfred, à Howard et à moi, et la chance qui m'a été donnée de côtoyer ultérieurement Alfred et Isabel au cours des années qui ont suivi.

Le talent et les réalisations d'Alfred vont bien au-delà de la chimie et du commerce des produits chimiques. Alfred se dit un « collectionneur invétéré » : son parcours a commencé avec les timbres, à l'âge de 8 ans, puis s'est poursuivi avec les étampes, à l'âge de 10 ans, et enfin avec les tableaux, à l'âge de 20 ans. Lorsqu'Alfred était enfant, à Vienne, l'appartement de sa mère regorgeait de tableaux, principalement d'œuvres viennoises des XIXe et XXe siècles. Bien que ces écoles ne l'aient pas particulièrement séduit, la peinture a fait vibrer une corde sensible chez lui. Alfred fait le commerce et le don de tableaux depuis nombre d'années. Une fois qu'Aldrich eut été bien établie et qu'il eut davantage de temps à consacrer à ce qu'il estime être un joli passe-temps, Alfred a fondé Alfred Bader Fine Arts et, depuis 1992, il s'emploie de plus en plus à cette activité. Bien qu'il gravite dans les hautes sphères du commerce des œuvres d'art, notamment celui des tableaux de grands maîtres, tels que Rembrandt et Rubens, Alfred tire énormément de plaisir à ne payer que quelques milliers de dollars pour une œuvre d'art qui, au prix de quelques efforts de restauration, est appelée à devenir un objet de grande valeur. C'est non seulement le caractère monnayable des œuvres d'art qui l'anime, mais aussi leur caractère esthétique. Alfred n'hésite jamais à partager son amour de la peinture. Lors de ses visites dans les universités et à tous les

© 2006 NRC Canada

kiosques aménagés par Aldrich, il distribuait des représentations de tableaux tirés de sa vaste collection. Les chimistes ne sauront oublier l'*Alchimiste* et, chaque année, un tableau faisait la page couverture du catalogue d'Aldrich. Alfred a de ce fait beaucoup contribué à l'« éducation artistique » de la collectivité de la chimie.

En plus de ses contributions à la chimie, à la collection et la conservation d'œuvres d'art et à l'enrichissement de l'histoire de l'art, Alfred a fait preuve d'une vaste générosité qui laissera une empreinte indélébile. En effet, il est prodigue avec les membres de la collectivité de la chimie, avec l'Université Queen's, qui lui a ouvert ses portes alors que les autres universités l'avaient repoussé, ainsi qu'avec d'autres institutions et fondations. Tout a commencé par de petites subventions sans condition destinées aux chimistes du monde entier en manque de financement; plusieurs de ces chimistes sont devenus des scientifiques réputés à l'échelle internationale. Alfred a impulsé la création de primes, de bourses et de prix pour les étudiants du Canada, des États-Unis, de la Grande-Bretagne et de la République tchèque, étant reconnaissant de l'aide que de tels appuis financiers lui avaient procurée quand il était lui-même étudiant. Il est le père du prix de chimie organique Alfred Bader de la American Chemical Society (aussi connu sous le nom « Prix Aldrich ») de même que d'autres prix éponymes de la Société canadienne de chimie et de la Royal Society of Chemistry du Royaume-Uni. Plus récemment, il a fondé le prix de chimie bio-inorganique et bio-organique Alfred Bader de l'ACS et financé la fondation de démarrage de l'ACS, qui permet aux étudiants de chimie de premier cycle de se familiariser avec le travail de laboratoire.

Alfred a fait de nombreux dons à l'Université Queen's, dont une chaire en chimie organique, une chaire en histoire de l'art, de superbes tableaux de sa collection privée destinés à l'Agnes Etherington Art Centre et du financement de lancement d'un nouveau musée. (Au fait, la voie Bader, sur le campus de l'Université Queen's, relie la faculté de chimie et l'Agnes Etherington Art Centre). Le don le plus original fait par Alfred à l'Université Queen's est sans contredit le château de Herstmonceux, dans le comté de Sussex, en Angleterre, dont certaines sections datent du XVe siècle. Par ailleurs, Alfred a appuyé plusieurs projets éducatifs pour la communauté juive et a mis sur pied des organisations caritatives à Milwaukee.

Les contributions d'Alfred Bader ont été soulignées par des doctorats honorifiques de plusieurs universités, y compris l'Université Simon Fraser et l'Université d'Ottawa; par un honorariat de la Royal Society of Chemistry de même que par le prix Charles Lathrop Parsons de l'ACS, soulignant l'indéfectible engagement d'un membre de l'ACS au bien public. Alfred est également membre honoraire de l'Institut de chimie du Canada.

Un autre admirable trait d'Alfred et de sa conjointe est leur profonde tendresse l'un pour l'autre. Il y a quelques années, Isabel a publié l'ouvrage, *A Canadian in Love*, dans lequel elle citait de magnifiques lettres qu'elle avait adressées à Alfred. On y retrouvait aussi, en toute fin, une lettre qu'Alfred lui avait écrite le 18 avril 1975. Nous nous permettons d'en traduire un paragraphe :

« Tu ne m'as pas écrit du 11 septembre 1950 au 11 août 1951, ta dernière lettre depuis 24 ans. J'ai tant lu et relu ce mot que je le connais par cœur et cela me bouleverse depuis tout ce temps. Quelle emprise tu as sur moi! Les derniers mots que tu m'as adressés étaient "Que Dieu te bénisse, Alf". Cette imploration, je le savais, venait du creux de ton âme. Et Dieu m'a certes béni en faisant de toi la lumière de ma vie. Tous mes accomplissements, je les sais justes, car continuellement inspirés de toi. Comme l'a dit David "Où irais-je loin de ton esprit; et où fuirais-je loin de ta face? Si je monte aux cieux, tu y es; si je me couche au séjour des morts, t'y voilà." Dieu est présent en chacun de nous et, chez toi, Sa Bonté m'apparaît flagrante. »

Après avoir tiré sa révérence à Aldrich, Alfred a pu consacrer presque tout son temps et son énergie à la collection d'œuvres d'art, à la présentation de conférences et à des activités philanthropiques. Il estime que le fait d'avoir forgé des rapports avec la communauté des arts a enrichi sa vie. Ceux d'entre nous qui ont eu la chance de forger des rapports avec Alfred peuvent aussi affirmer que leur vie en a été enrichie.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

Montreal Medal Award Lecture — Coordination chemistry of molecular bowls: Ligands and their complexes derived from resorcinarenes[1]

Richard J. Puddephatt

Abstract: A review is given of the design, synthesis, structures, and properties of octadentate or tetradentate ligands and their coordination compounds, based on the bowl-like resorcinarene skeleton.

Key words: resorcinarene, coordination, phosphine, thiophosphinate, polymer.

Résumé : On présente une revue du développement, de la synthèse, des structures et des propriétés de ligands octadentates ou tétradentates et de leurs composés de coordination apparentés au squelette de résorcinarène qui a la forme d'un bol.

Mots clés : résorcinarène, coordination, phosphine, thiophosphinate, polymère.

[Traduit par la Rédaction]

Introduction

Calixarenes and resorcinarenes (Chart 1) are bowl-shaped molecules that have a rich host–guest chemistry. Consequently, they have potential uses in sensors, catalysts, and in selective separation or extraction processes (1). Chart 1 shows the molecules in flat projection (above) and in the cone conformation (below).

For many potential applications of the molecular bowls, it is advantageous to decorate the lower or upper rim with extra functional groups. If these functional groups can bind metals, an extensive coordination chemistry can be developed (2, 3). The parent calixarenes (Chart 1) can bind metal ions through the oxygen atoms or through the arene groups, but a much greater variety of donor groups can be added by derivatization. Some examples of metal complexes with ligands derived from calixarenes are shown in Chart 2 (4). Chart 2 shows a silver(I) ion bound directly to atoms of the calixarene skeleton and linear gold(I) or square planar platinum(II) centres bound to appended diphenylphosphinite or alkynyl donor groups (4).

The chemistry of complexes derived from calixarenes is extensive and has been well reviewed (1–4). The coordination chemistry of ligands, and their metal complexes, derived from resorcinarenes is developing rapidly and will be the subject of this review. Because this is primarily a review of work carried out in the author's research group, the important contributions to this area of research from other groups cannot be described adequately. However, some recent references are cited for the interested reader (1, 5–13).

[1]This article is an expanded form of a section of the Montreal Medal award lecture, given in Halifax, Nova Scotia, in May 2006.

Resorcinarene ligands with eight donor groups

The hydroxyl groups of a resorcinarene **1** (Scheme 1, R = CH_2CH_2Ph) can be converted to phosphorus-donor diphenylphosphinite groups by the reaction with diphenylchlorophosphine and a base. Ligands of type **2** can be regarded as octopus-like, with the resorcinarene skeleton as the body and the diphenylphosphinite groups as the arms. Ligand **2** phosphorus-donors can then bind eight gold(I) centers in **3** or, by acting as a tetra(bidentate) ligand, it can bind four platinum(II) centres in complex **4** (Scheme 1) (14). Comparing Scheme 1 with Charts 1 and 2, it is clear that calixarenes and resorcinarenes are naturally functionalized at the lower and upper rims of the bowl, respectively. The octa(diphenylphosphinito) ligands are sterically congested, and thus, no host–guest chemistry has been established (14).

Similarly, the resorcinarene **1** can be converted to the octapropargyl derivative **5** (Scheme 2). Ligand **5** provides a route to the octopus-like organometallic derivatives. Thus, the alkyne units can be deprotonated and act as σ-alkynyl ligands in forming the octagold(I) derivative **6** (Scheme 2). Alternatively, the alkynes can act as π-donor ligands in reactions with dicobalt octacarbonyl to give the derivative **7**, which contains sixteen cobalt atoms (15).

Complex **7** is the most highly metallated resorcinarene complex known, and its sterically congested structure is shown in Fig. 1. The complex adopts a boat conformation of

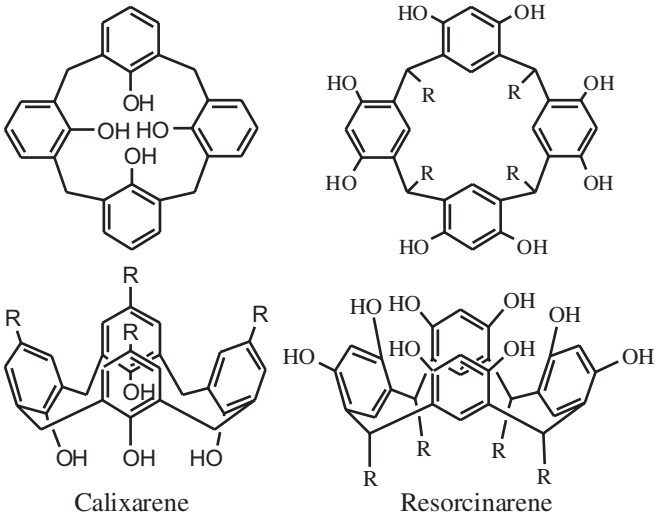
Chart 1.



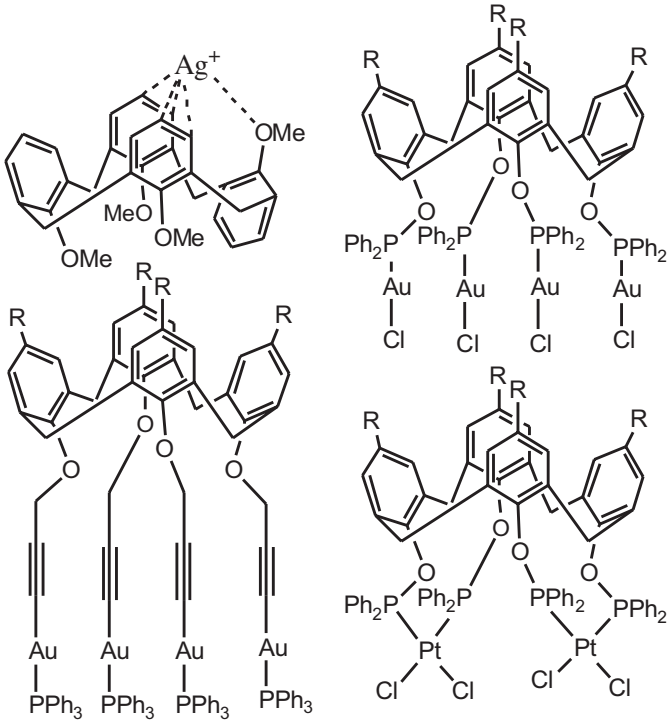


Chart 2.

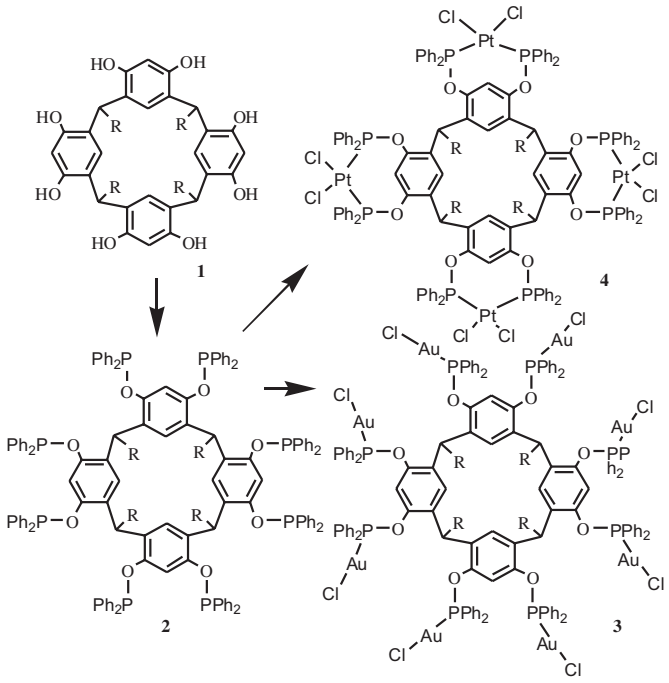
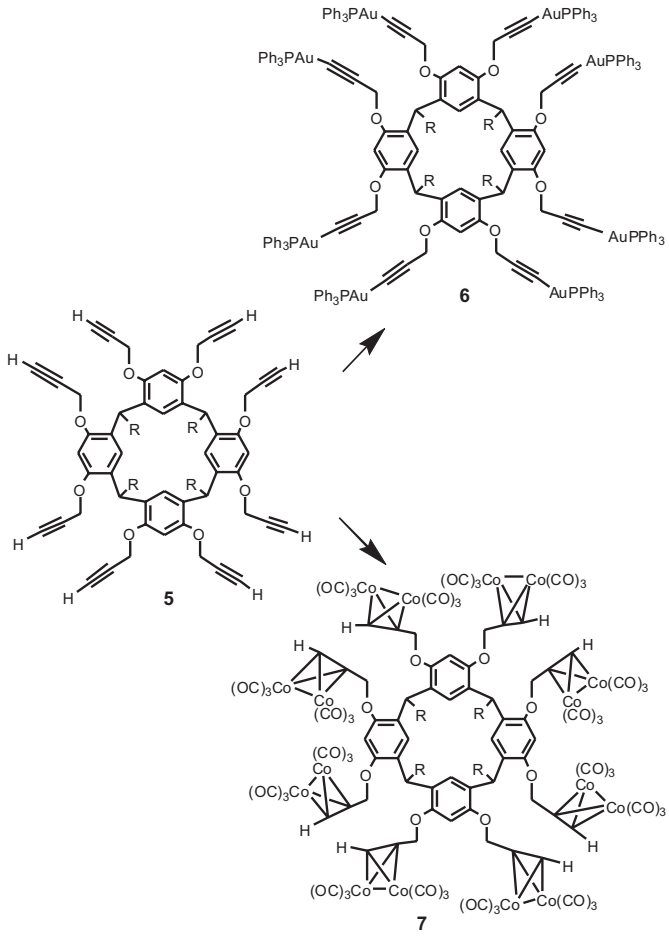


the resorcinarene core in which two opposite aryl rings are flattened to reduce the steric congestion around the upper rim of the original bowl. There is an activation energy in dichloromethane solution of 51 kJ mol^{-1} for the interconversion of the flattened and upright arene rings of complex **7**, as determined by variable temperature NMR of the fluxional complex (15).



Resorcinarene ligands with four phenylphosphonite groups

The reaction of resorcinarene **1** with phenyldichlorophosphine gave the tetrakis(phenylphosphonite) ligand **8** (Scheme 3) (14, 16). The scheme shows the ligand both in flat projection (left) and in the cone conformation

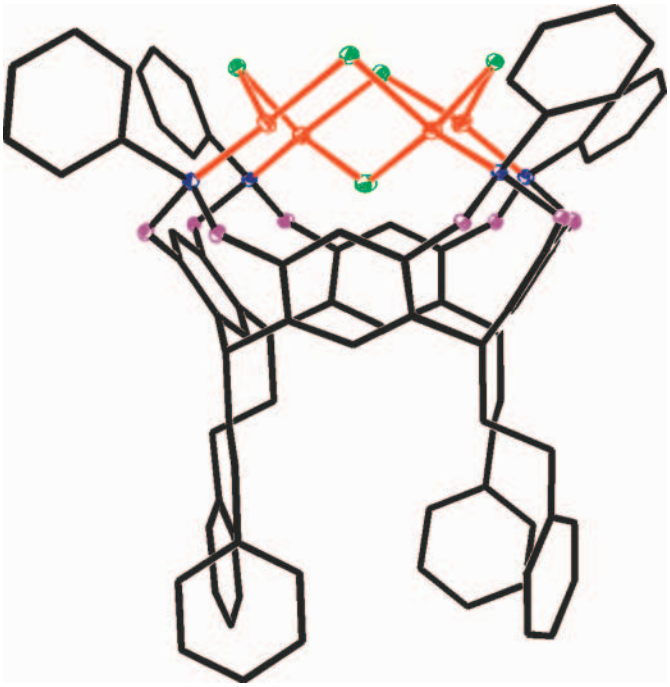

Scheme 4.

(right), which is imposed by the bridging phosphorus atoms. In addition, the ligand **8** adopts a conformation with all phenyl groups directed outwards and all lone pairs on phosphorus directed inwards. When ligand **8** reacts with [AuCl(SMe_2)], the tetragold(I) complex **9** is formed in which three of the AuCl units are directed upwards, extending the depth of the bowl, while the fourth AuCl unit is directed towards the centre of the bowl, occupying the cavity (14, 16). This fourth AuCl unit seems able to move out of the cavity to allow guest molecules, such as primary amines, to enter (14).

The reaction of the tetraphosphonite ligand **8** with precursors to copper(I) or silver(I) halides gave the unusual anionic complexes **10** or **11** (Scheme 4, X = Cl, Br, or I). These complexes contain an $M_4(\mu\text{-}X)_4$ crown unit (M = Cu or Ag) with a more weakly bound halide ion in the centre of the resorcinarene bowl. When X = Cl and M = Cu, the "guest" halide is too small to bind effectively to all copper atoms and tends to bind to two or three copper(I) centres while moving easily among them all. A view of one such complex, in which the guest chloride binds to two copper(I) centres, is shown in Fig. 2. Larger halide ions can bind more strongly in the guest position and can be substituted selectively to

Fig. 2. The structure of one form of complex **10** [M = Cu (red), X = Cl (green)] with the guest chloride weakly bound to two copper(I) centers.

form complexes **12** or **13** (e.g., X = Cl, Z = I) (17, 18). The guest halide could be removed by the reaction of complex **10** with silver(I) ions (18).

Complex **11** (M = Ag, X = Cl) reacts with *t*-BuI or *i*-PrI by overall halide exchange to give *t*-BuCl or *i*-PrCl and complex **13** (Scheme 4, M = Ag, X = Cl, Z = I), and the corresponding reaction with (*S*)-(+)-2-iodooctane occurred with an overall retention of the stereochemistry at the asymmetric carbon centre. It is suggested that a silver(I) centre of complex **11** abstracts the iodide from the alkyl iodide while a chloride ligand is donated to the forming alkyl cation (18).

The anionic complexes **10** and **11** can act as cation receptors by binding primarily through the bridging chloride ligands. Structures of a complex of **10** with cesium(I) ions and of a complex of **11** with mercury(II) ions are shown in Figs. 3 and 4, respectively (19). Overall, these compounds can be considered to form by the inclusion of two units of CsCl or one unit of $HgCl_2$ with the neutral complex [**8**{$M_4(\mu\text{-}Cl)_4$}], with the chloride inside the bowl and the metal ion outside.

Resorcinarene ligands with four diphenylphosphinite groups

It is possible to esterify the hydroxyl groups of opposite arene rings of the resorcinarene **1** and then to introduce diphenylphosphinite groups to the remaining arene rings (as shown in Scheme 5). This reaction sequence gives the tetraphosphinite derivatives **14a**–**14e** (Scheme 5), which, like the tetraphosphonite ligand **8**, have four phosphorus donor groups but are more flexible (20).

Ligands **14** adopt the boat conformation and tend to exist in the conformation with the arene groups having the

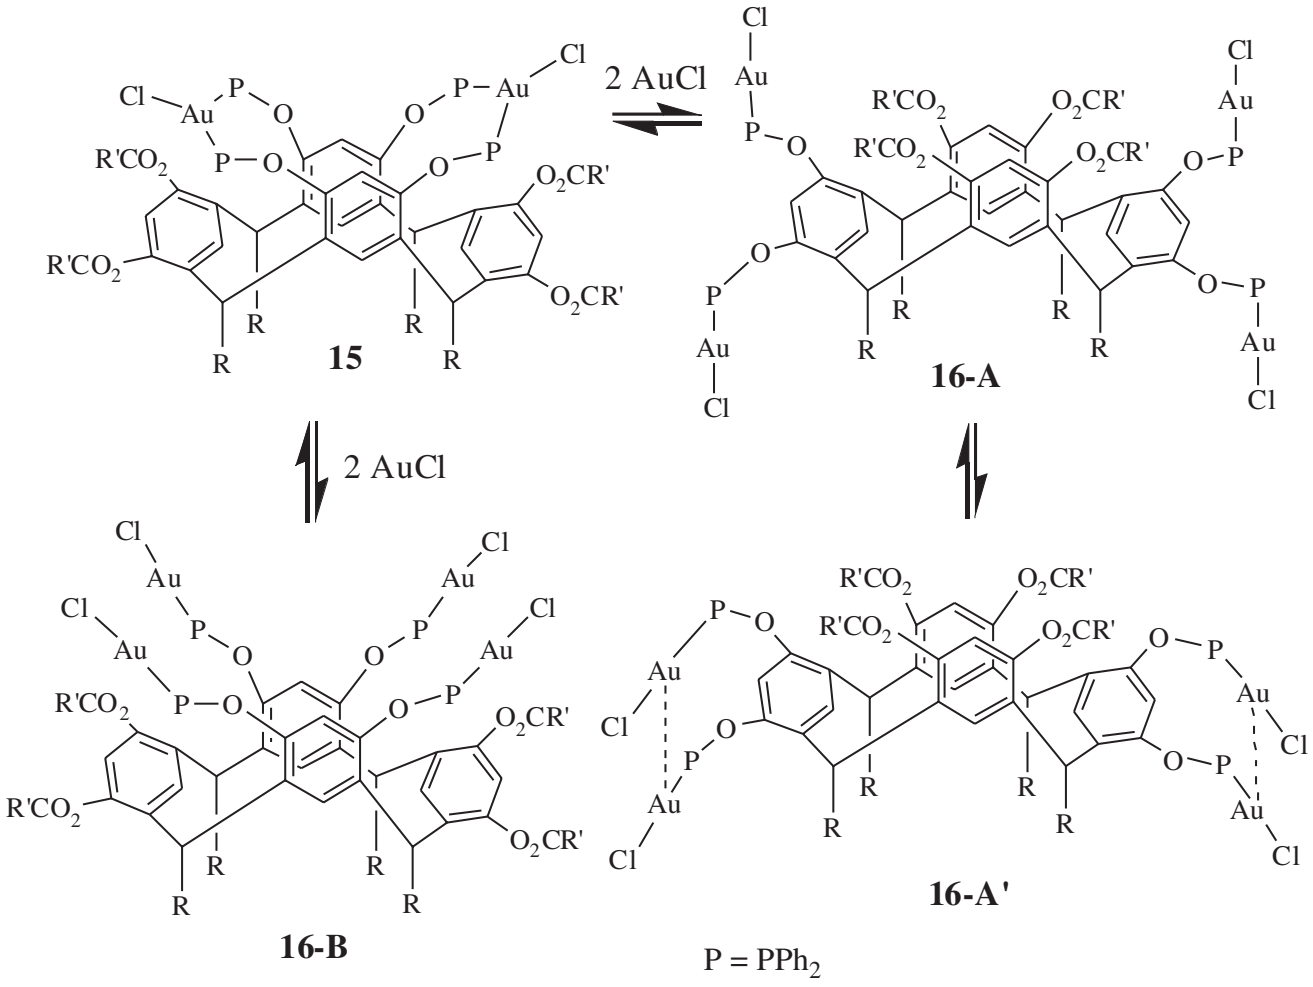
Scheme 5.

Scheme 6.



diphenylphosphinite groups in the flattened position (Scheme 6, conformation **14-A**) (20). However, the conformation **14-B**, with diphenylphosphinite groups on the upright arene rings, is easily accessible, and complexes can be formed with the ligands in either conformation.

Ligand **14** can bind to two AuCl units to give complex **15** or to four AuCl units to give complex **15** (Scheme 7) (21). In complex **15**, the ligand must adopt conformation **B** so that the gold atoms can bind between phosphorus donors from opposite arene rings, but complex **16** is flexible and can exist either in conformation **A** or **B** (Scheme 7) depending on the nature of the groups R′ (Scheme 7). Rotation about the P–O bonds is also possible and can lead to different orientations of the P–Au–Cl units (as illustrated for **16-A** and **16-A′** in Scheme 7). The presence of aurophilic bonding may influence the nature of the preferred conformer **16-A** versus **16-A′** both in the solid state and in solution (21).

The tetraphosphinite ligand **14** reacts with copper(I) or silver(I) halides to give the crown cluster complexes **17** (M = Cu or Ag, X = Cl, Br, or I), as shown in Scheme 8 (22). These crown cluster compounds are related to the tetraphosphonite deivatives **10** and **11**, but they contain one extra copper(I) or silver(I) ion bound to chloride ligands in the $M_4(\mu\text{-}Cl)_4$ crown ; thus, the complexes **17** are neutral. The reaction of **17b** (M = Ag, X = Cl) with triflic acid led to loss of silver(I) and chloride ions to give the corresponding disilver complex **18b**. Both complexes **17** and **18** have the arene groups with diphenylphosphinite substituents in the

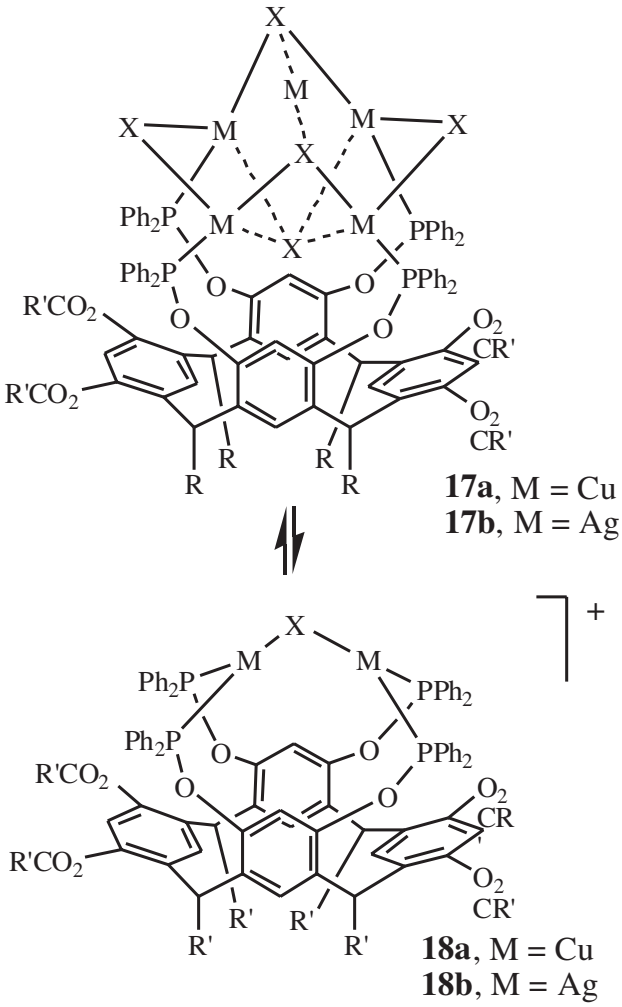
© 2006 NRC Canada

Scheme 7.

upright position so that the cluster or dimer can be accommodated between opposite arene groups (Scheme 8).

When ligand **14** reacts with silver trifluoroacetate or silver triflate, the primary products are the tetrasilver(I) derivatives **19** shown in Chart 3 and Scheme 9, in which the arene groups with the diphenylphosphinite groups are in the flattened position (23, 24). However, with smaller amounts of silver(I) salts, the disilver(I) complexes **20** or the monosilver complexes **21** may be formed. The conversion of **19** to **20** or **21** requires rearrangement of the resorcinarene boat conformation so that the arene groups with the diphenylphosphinite groups are in the upright position.

Complexes **19** can undergo association in the solid state through intermolecular Ag···O(trifluoroacetate) bridging to give the first supramolecular polymers incorporating resorcinarene units (Fig. 5) or they can undergo partial hydrolysis followed by supramolecular association to give capsule complexes formed by tail-to-tail dimerization of resorcinarene units (23, 24).



An interesting property of complexes **17** and **18** (Scheme 8) is that they can bind mercury(II) halides in subtle ways. An example, in which an I–Hg^+ unit is substituted for Ag^+ in **17b** (M = Ag, X = I) to give complex **22**, is shown in Scheme 10. The atoms involved in the substitution step are shown in bold in Scheme 10 (25).

Another example, in which three copper(I) iodide units are displaced for each HgI_2 unit added, is shown in Scheme 11 (25). The complex **23** can be formed by the coordination of a $[Hg_2I_6]^{2-}$ ion between two units of complex **18** (Scheme 8, M = Cu, X = I).

The two phosphorus donors on a given arene group of the ligand **14** do not chelate to a single metal ion acceptor in any known complex because the bite distance is too great. However, they are well suited to bind to two metal centres connected by a bridging ligand. These complexes usually form with the arene groups bearing the diphenylphosphinite donors in the flattened position. The tetrasilver(I) complexes **19** (Scheme 9) are examples of this type of complex, and two further examples are shown in Chart 4 (26, 27). The metal centres can have tetrahedral stereochemistry, as in the tetramercury(II) complexes **24** (X = Cl, Br, or I), or square planar stereochemistry, as in the tetrarhodium(I) complex **25**. In solution, complexes **24** exist as a mixture of two conformers, one of which has the arene groups bearing the diphenylphosphinite groups in the upright position. The stereochemistry of the dimercury(II) and dirhodium(I) units in complexes **24** and **25**, with the *syn* arrangement of the phosphorus donors, is very unusual and is imposed by the geometry of the ligand **14** (26, 27).

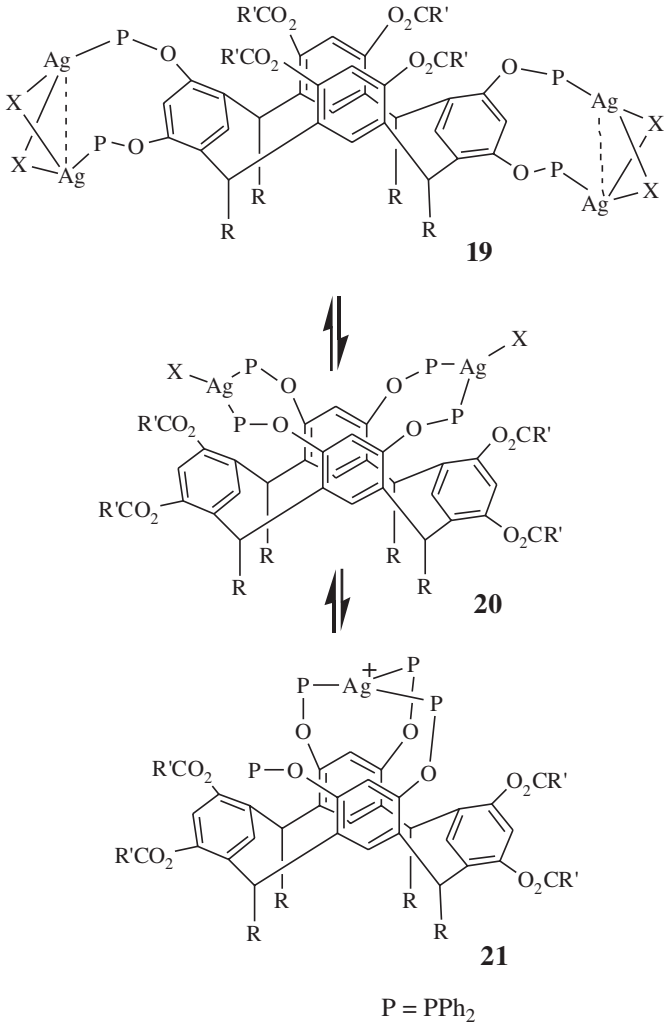
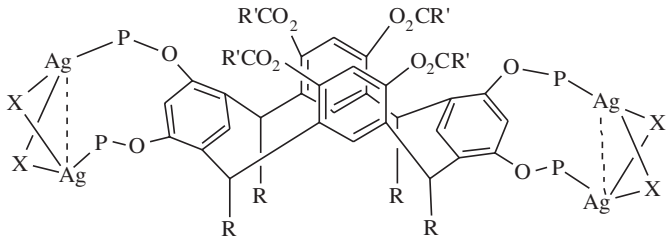
Scheme 8.

Scheme 9.





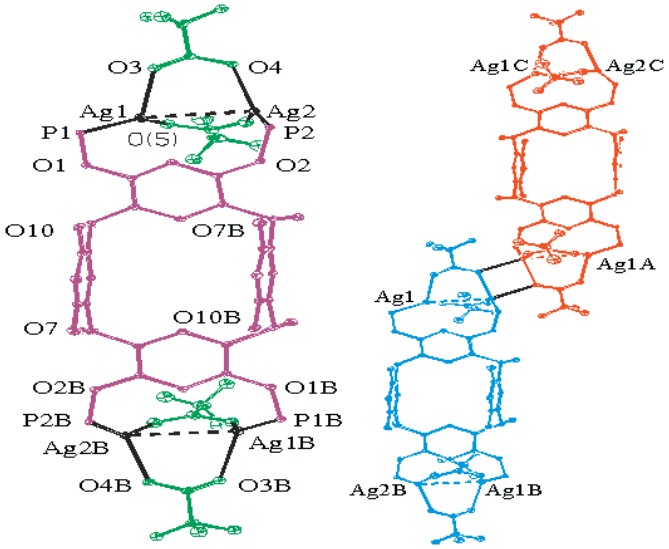


Chart 3.

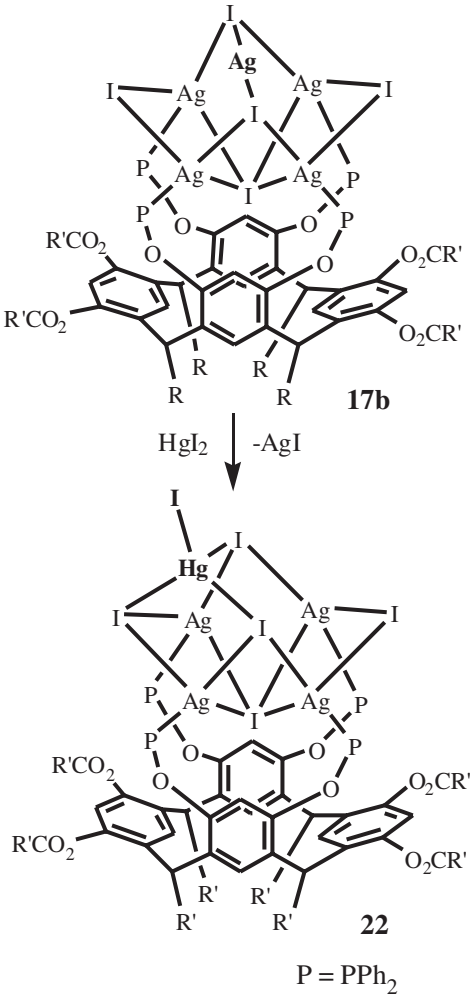
Resorcinarene ligands with four thiophosphinate groups



Ligands **14** react with sulfur to give the corresponding tetrakis(thiophosphonite) ligands **26** (Chart 5) (28). These ligands react with silver(I) or gold(I) compounds to give the corresponding cationic complexes **27** or **28** (Chart 5), provided that the anions present are weakly coordinating. In these complexes **27** and **28**, the arene groups bearing the thiophosphinate groups are in the flattened position of the resorcinarene boat, and the two thiophosphinate donors on a

Fig. 5. The silver trifluoroacetate complex **19** (left) and its supramolecular association through intermolecular Ag···O-bonding to give a side-by-side polymer. The phenyl (Ph) and phenethyl groups (R) have been omitted for clarity.

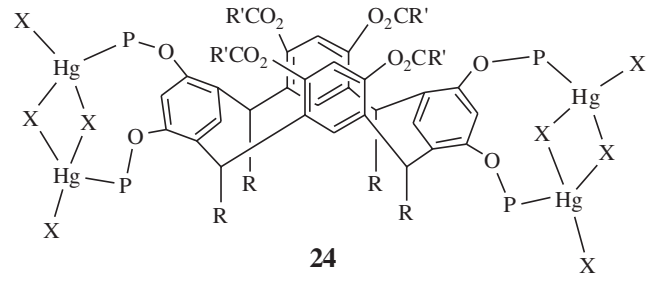
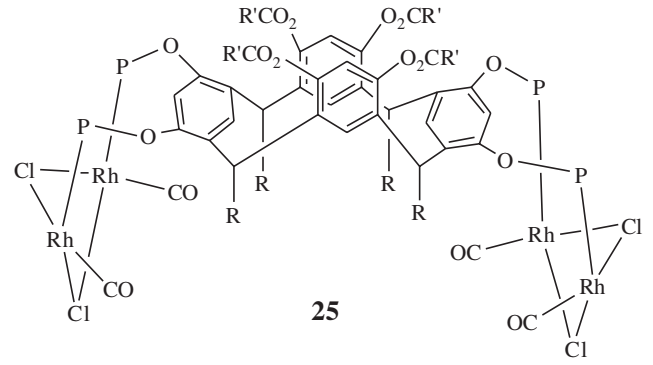
Scheme 10.

Scheme 11.

given arene group chelate to the metal atom to give a 10-membered ring. This behaviour is different from that of the precursor ligand **14**, which cannot form such chelate complexes.



In cases when the anion is more strongly coordinating, there can be an equilibrium between the chelate and monodentate ligation by **26**. Thus, with gold(I) chloride there is a complex equilibrium in solution and crystallization gives a 1:1 mixture of complexes **28** and **29** (Chart 5). In the solid state, these complexes associate through aurophilic bonding to give a supramolecular polymer shown in Fig. 6 (28).



The tetrakis(thiophosphonate) ligand **26** reacts with palladium(II) chloride to give complex **30** (Chart 6). In this complex a $Pd_2Cl_2(\mu\text{-}Cl)_2$ unit is bound to a thiophosphonate donor from two opposite arene groups, which are in the upright position. There are two free thiophosphonate groups. The structure is rigid in solution, and there is no easy exchange between the free and coordinated thiophosphonate groups (28).

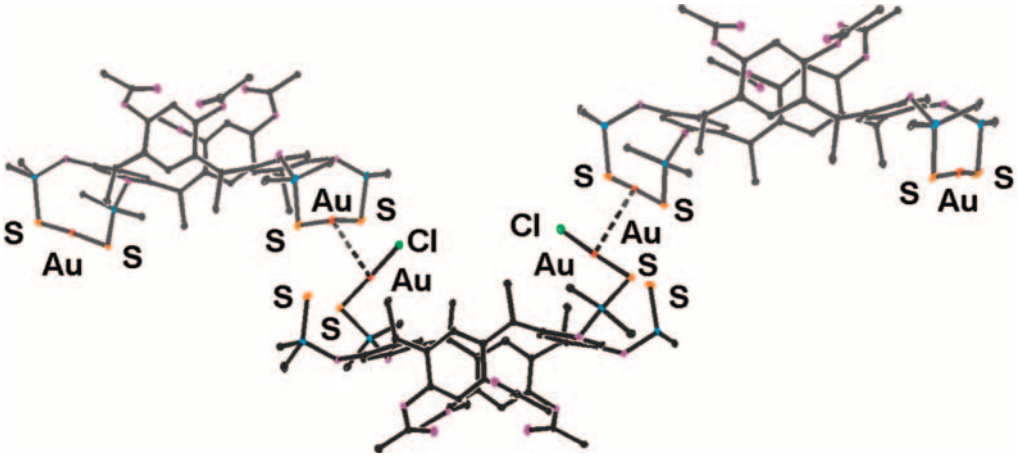
Summary

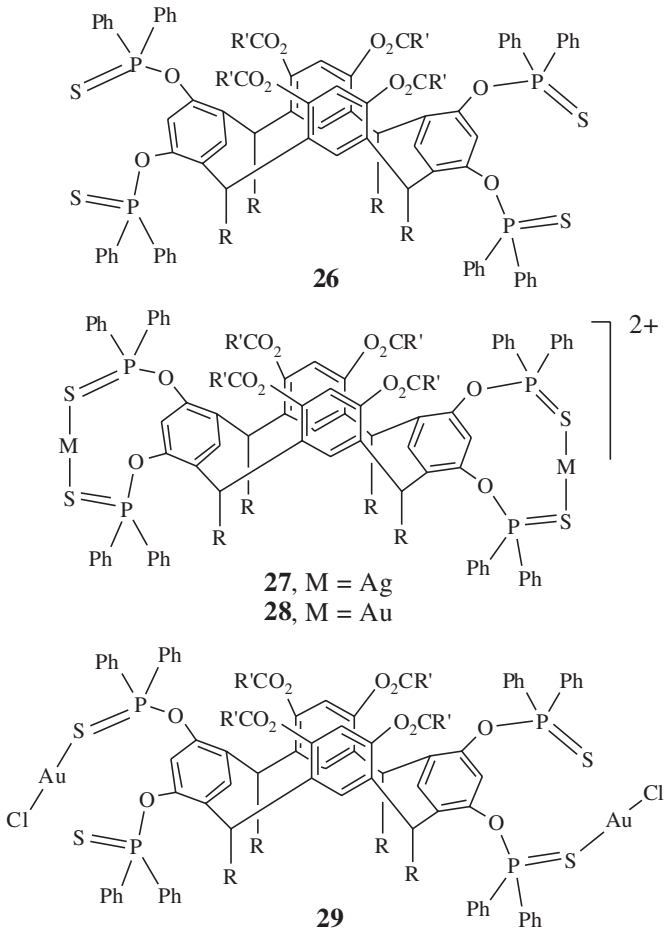
The resorcinarene skeleton has been shown to be an excellent platform for developing new and unusual coordination chemistry of both main group and transition elements. It is

Chart 4.

© 2006 NRC Canada

Fig. 6. The supramolecular polymer formed by Au–Au bonding between units of complexes **28** and **29**. Some substituents on phosphorus atoms and resorcinarene groups are omitted for clarity.





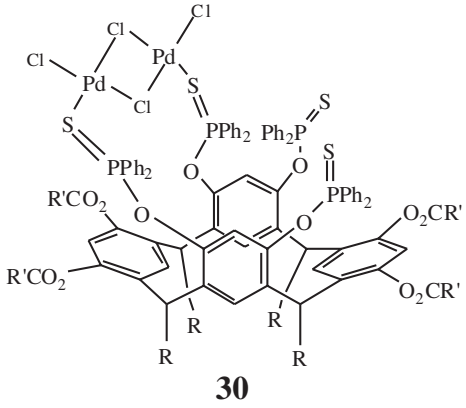


Chart 5.

easy to introduce eight donor groups at the upper rim of the resorcinarene bowl and to coordinate eight, or even 16, metal atoms to these donors. The complexes with eight or more metal atoms are sterically congested, and a more versatile chemistry is found for ligands with four donor groups incorporated. Metal cluster complexes that can act as unusual hosts for anion or salt inclusion have been discovered. Moreover, the unusual bite distances between the donor atoms in the tetradentate ligands leads to very unusual coordination geometries in many of the complexes formed. Clearly, there is a considerable scope for further exploitation of ligands derived from resorcinarenes.

Chart 6.

Acknowledgments

RJP thanks the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support and the Government of Canada for a Canada Research Chair. Particular thanks are due to the excellent students whose names are given in the references. In particular, Jon Rourke began the work, and Wei Xu and Dana Eisler carried it forward, while J.J. Vittal, Ljubica Manojlovic-Muir, and Ken Muir solved challenging X-ray structures.

Synthesis of β-hydroxy dithiocarbamate derivatives via regioselective addition of dithiocarbamate anion to epoxide in water

Azim Ziyaei-Halimjani and Mohammad R. Saidi

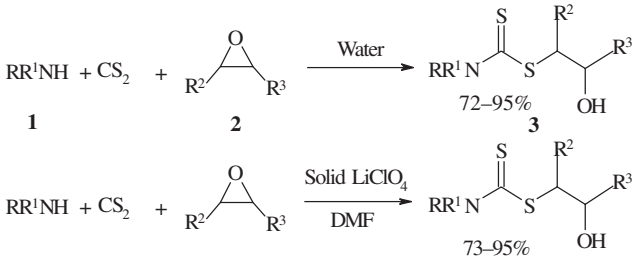
Abstract: The reactions of different dithiocarbamate anions with epoxides were investigated in water. With this method, β-hydroxy dithiocarbamate derivatives were synthesized in high yields. The reaction was also carried out in DMF in the presence of lithium perchlorate with a simple work-up procedure, and the results are compared.

Key words: hydroxy dithiocarbamate, dithiocarbamate anion, epoxide, water.

Résumé : On a étudié les réactions de divers anions dithiocarbamates avec des époxydes dans l'eau. De cette façon, on a réalisé la synthèse de dérivés β-hydroxydithiocarbamates avec des rendements élevés. La réaction a aussi été effectuée dans le DMF, en présence de perchlorate de lithium, en utilisant un traitement conclusif simple et on compare les résultats.

Mots clés : hydroxydithiocarbamate, anion dithiocarbamate, époxyde, eau.

[Traduit par la Rédaction]



Introduction

Dithiocarbonyl-containing compounds such as xanthates and dithiocarbamate have been successful in their role as important synthesis precursors (1, 2), protecting groups (3*a*), and chain transfer agents (3*b*), and are of considerable biological and medical interest (4, 5). Also, the superconductivity of different transition metal complexes of dithiocarbamates makes these compounds more interesting (6–9). The reported procedure for the preparation of these compounds employs harsh reaction conditions, such as the use of a strong base, high temperature, and long reaction times (10, 11). Different modifications have been reported, such as using thiophosgene (12), chlorothioformate, and isothiocyanates, which are costly and toxic (13). The preparation of dithiocarbamate derivatives from the reaction of an amine, inexpensive and readily available CS_2, and a nucleophile acceptor were also investigated using a strong base as an activator (14–18). They were also prepared by the reaction of an amine, CS_2, and alkyl halides (19), and by the addition of amines and carbon disulfide to α,β-unsaturated compounds (20).

Results and discussion

As a result of environmental consideration in recent years, water has become an attractive solvent in the preparation of organic compounds (21). We recently reported a one-pot procedure for the Michael addition of the dithiocarbamate anion to α,β-unsaturated olefins mediated by solid lithium perchlorate (22). As part of our research in organic synthesis in water and under solvent-free conditions (23), we report the ring-opening of epoxides with a variety of dithiocarbamate anions in water at room temperature. To the best of our knowledge, there are no reports for the addition of dithiocarbamate to epoxides for the preparation of β-hydroxy dithiocarbamate derivatives. The reactions were carried out at room temperature without adding any other solvent or catalyst. By mixing amine **1** and CS_2 in water, then adding epoxide **2** into the reaction mixture, the β-hydroxy dithiocarbamates **3** derivatives are formed in high yields. All epoxides showed very high regioselectivity with the exception of styrene oxide. The procedure for these reactions is very simple, and the products were extracted from the aqueous solution after the completion of the reaction (Scheme 1). To show the generality and scope of this new protocol, structurally diverse amines were treated with various epoxides, and the results are shown in Table 1. The role of water as a reaction medium is still unclear. Hydrophobic and hydrogen bonding interactions and polarity are probably the main factors that influence the reactivity and selectivity of the process.

12				**3l**	80
13				**3m**	72

Note: The molar ratio of the amine:CS_2:epoxide is 6:16:8.
[a]Isolated yield.

For comparison, the same reactions were also carried out in an organic solvent. After testing different organic solvents, we found that the best was *N,N*-dimethylformamide (DMF). The preparation of β-hydroxy dithiocarbamates **3** in DMF was accelerated by the presence of anhydrous lithium perchlorate at room temperature, with good to excellent yields in a short reaction time. Without adding lithium perchlorate, the reaction time is much longer. Under these mild conditions, both in water and DMF, the reactions are regioselective, except for styrene oxide. Also, we did not observe any direct addition of amine to epoxide in water or in DMF.

Table 2. Addition of dithiocarbamates to styrene oxide in water and DMF.

Amine	Product	Yield[a] in water (DMF) %
NH	 **4a** 70(12)[b]  **4b** 30(88)[b]	90(81)
NH	 **5a** 78(14)[b]  **5b** 22(86)[b]	85(85)

[a]Isolated yield.
[b]The % of regioisomers in water and (DMF).

Table 1 shows that primary and secondary amines can react with carbon disulfide and different epoxides in water and DMF to give the corresponding β-hydroxy dithioarbamate derivatives. All reactions with aliphatic epoxides are regioselective, and NMR (^{1}H & ^{13}C) spectra of the crude products showed only one regioisomer. The reactions in water were done in one-pot and completed overnight, while the one-pot reaction in DMF and in the presence of anhydrous lithium perchlorate was completed within 1.5 h. In general, the isolated yields are higher in water.

As shown in Table 2, the addition of dithiocarbamate to styrene oxide was not regioselective. In general, the reaction in DMF gave a more S_N2 type reaction (attack of the anion on the β-position of the styrene oxide), while the reaction in water gave a more S_N1 type reaction compared with DMF (attack on the α-position of the styrene oxide). The addition of dithiocarbamate (Table 2, entry 3) with two equivalents of an epoxide gave the corresponding bis(dithiocarbamate) in an excellent yield.

In conclusion, we have shown the first clean, mild, efficient, and neutral method for the preparation of β-hydroxy dithiocarbamate derivatives in water without using any catalyst or in DMF in the presence of solid lithium perchlorate as a catalyst. The procedures for these reactions are very simple, with good to excellent yields, and the work-up system is very easy. Therefore, they can serve as a new method for the preparation of substituted dithiocarbamates and bis(dithiocarbamates).

Experimental

A typical procedure for the synthsis of β-hydroxy dithiocarbamate in water

To a mixture of pyrrolidine (0.43 g, 6 mmol, 0.5 mL) and water (20 mL) in a 50 mL round bottom flask, CS_2 (1 mL, 16 mmol) was added dropwise over 2 min at room temperature, and the mixture was stirred for 20 min. Then, 1,2-epoxybutane (0.58 g, 8 mmol) was added, and the mixture was stirred vigorously at room temperature overnight (18 h). After completion of the reaction, the mixture was extracted with ethyl acetate (2 × 20 mL). The combined organic layers were washed with water (2 × 20 mL), dried over $MgSO_4$, and concentrated under reduced pressure. The resulting residue was purified by flash column chromatography (light petroleum – ethyl acetate, 9:1) if needed. The products were pure in most cases and did not need any further purification.

General procedure for the synthsis of β-hydroxy dithiocarbamate in DMF in the presence of $LiClO_4$

To a solution of an amine (3 mmol), anhydrous lithium perchlorate (0.4 g, 4 mmol), and anhydrous DMF (8 mL), carbon disulfide (0.36 ml, 0.46 g, 6 mmol) was added slowly at room temperature. The mixture was stirred for 30 min, and then an epoxide (4 mmol) was added. The reaction mixture was stirred for about 1.5 h at room temperature, and the reaction was monitored by TLC. After completion of the reaction, the solution was poured into water, and the organic materials were extracted with ethyl acetate (3 × 10 mL). The combined organic layers were washed with water (2 × 20 mL) and dried over Na_2SO_4. The solvent was removed using a rotary evaporator. Flash chromatography of the residue using silica gel (light petroleum – ethyl acetate, 9:1) afforded the pure product.

Reactivity of mesoporous palladium yttria-stablilized zirconia for solution phase reactions

Carl Poulin, Matthew A. Brown, Yamile A. Wasslen, Catherine M. Grgicak, Keith Fagnou, and Javier B. Giorgi

Abstract: A reduced mesoporous 5% Pd-YSZ precatalyst was observed to be very active for the Heck reaction providing up to 770,000 TON. Three-phase tests have experimentally confirmed that a leached homogeneous species is responsible for the activity. Residual Pd concentration in solution is minimal (<0.10 ppm) and therefore this material has potential applications because it can be easily removed by filtration. This paper describes the synthesis, structural characterization, and catalytic activity of the mesoporous Pd-YSZ material. The material was prepared using an amphiphillic surfactant templating method resulting in a homogeneous dispersion of Pd in an ordered mesoporous structure. Material properties were fully characterized using X-ray diffraction, surface area analysis, and electron microscopy.

Key words: mesoporous catalysts, palladium, yttria-stabilized zirconia, Heck reaction, Pd-YSZ.

Résumé : On a observé qu'un précatalyseur 5% Pd-YSZ mésoporeux réduit est très actif pour la réaction de Heck qui peuvent fournir jusqu'à 770,000 TON. Des essais en trois phases ont permis de confirmer expérimentalement qu'une espèce homogène lessivée est responsable pour cette activité. La concentration résiduelle de palladiium dans la solution est minimale (<0,10 ppm); ce matériau a donc des applications potentielles compte tenu du fait qu'il peut être récupéré par filtration. Dans ce travail, on décrit la synthèse, la caractérisation de la structure et l'activité catalytique du matériel mésoporeux Pd-YSZ. Ce produit a été préparé en faisant appel à la méthode de matrice à agent de surface amphiphile qui fournit une dispersion homogène du palladium dans une structure mésoporeuse ordonnée. Les propriétés du matériau ont été complètement caractérisées à l'aide de la diffraction des rayons X, l'analyse de la superficie de la surface et la microscopie électronique.

Mots clés : catalyseurs mésoporeux, palladium, yttrium stabilisé par du zirconium, réaction de Heck, Pd-YSZ.

Introduction

Palladium-catalyzed transformations have become widespread in the construction of new carbon–carbon and carbon–heteroatom bonds (1–5). Recent advances in the development of new homogeneous palladium catalysts have enabled these transformations to be carried out even with very deactivated substrates such as aryl chlorides under mild conditions (6). In the context of product purity, however, the use of homogeneous catalysts has detractions including the fact that the palladium must be removed from the organic product at the end of the reaction (7, 8). This can sometimes be very challenging and costly. With this challenge in mind, chemists have been studying the use of heterogeneous palladium catalyst systems as viable alternatives to the more intensely studied homogeneous catalysts (9). In recent years, a variety of heterogeneous supports have appeared including carbon, silicates, zeolites, and block copolymers (10–16). Alternatively, homogeneous catalysts have been "heterogenized" via immobilization of active homogeneous catalysts on various solid supports (17–26). With all of these heterogeneous catalysts, however, there is debate with respect to the true nature of the active catalyst (27). Some catalysts do appear to function as true heterogeneous catalysts (28, 29), while others have been shown to be catalyst reservoirs (precatalysts) from which an active catalyst leaches into solution (28, 30–38). Analysis of these reactions is further complicated by a third option in which a release and capture mechanism involving catalyst leaching and subsequent readsorption onto the matrix support occurs upon reaction completion. Since the question of catalyst form is of paramount importance, more studies are warranted in this area, particularly when new catalysts and (or) supports are being designed and studied. Simple coupling reactions such as Heck or Suzuki can be used as the standard to test catalyst performance of heterogeneous catalysts.

In the design of heterogeneous catalysts, maximization of the active surface area is the key to performance together with the nature of the catalytic species. Metal catalysts such as palladium have been shown to be in their most active state when speciated as nanoparticles (39). In this state, a maximum of palladium sites are exposed while the catalytic properties are controlled by the electronic structure of the

Fig. 1. Mechanism of formation of mesoporous Pd-YSZ.

nanoparticle and influenced by its support. The optimization of the active surface area was revolutionized with the discovery of mesoporous structures, which provide a maximum total surface area with channels of the appropriate size for reactant transport (40–42). Examples of the improved performance of mesoporous silica-based catalysts date back to their petrochemical origins (43) and enhanced properties continue to surface, as recently demonstrated for ethane hydrogenolysis and ethylene hydrogenation (44), hydrogenation of phenyl acetylene (45), and anti-stokes luminescence of encapsulated dyes (46). A particularly appropriate example has recently used mercaptopropyl modified silica to anchor Pd atoms to the SBA-15 zeolitic framework (16). The modified zeolite is an excellent Pd scavenger and has been used successfully as a Pd catalyst for low-turnover high-yield coupling reactions with minimal Pd leaching.

A considerable effort has been made over the past 15 years to obtain mesoporous metal oxide materials that possess enhanced properties in catalysis, charge transport, and host–guest affinities. Since the family of silicate mesoporous molecular sieves was first synthesized (40–42), efforts have been made toward the synthesis of mesoporous transition metal oxide materials (47–50) and, in particular, mesoporous yttria and zirconia materials have been recently developed (51–53). The general synthetic methodology to prepare mesoporous oxides uses an amphiphillic surfactant as a template. In solution, the surfactant agglomerates into micelles and the inorganic oxide framework grows around it. Upon removal of the organic species, a mesoporous framework remains. In many cases, the mesoporous framework is impregnated with the metal catalyst, however we used this methodology to create not only the support framework but also the homogeneous distribution of the nanoparticle-catalyst within the framework. Coproduction of the catalyst with the support produces a homogeneous distribution of the metal and is particularly suitable for high metal loadings where metallic connectivity and (or) conductivity is desired. For low metal loadings, coproduction ensures a homogeneous distribution of the catalyst in the porous framework. The obstacle of relatively low solubility of the metal precursors can be overcome by the synthesis of yttrium and zirconium glycolates as precursors for the preparation of yttria-stabilized zirconia (YSZ) with mesoporous structure (54–56).

In this paper, we report the synthesis and characterization of a versatile palladium catalyst supported on a mesoporous yttria-stabilized zirconia (YSZ) framework. These materials, which are characterized by a high surface area, have the potential to be used in a liquid–solid regime for the catalysis of organic reactions (57, 58), which has been validated by demonstrating high turn-over numbers in the Heck reaction. Catalyst structure along with reaction kinetics and mechanisms are discussed.

Experimental

Pd-YSZ preparation

The general synthesis involves the formation of yttrium and zirconium glycolates separately by reaction of $ZrCl_4$/$(OEt)_3$ with ethylene glycol. The solutions are combined and a Pd^{+2} source is added in appropriate proportion according to the desired loading. Cetyltrimethylammonium bromide (CTAB) is added as a template to form the mesoporous structure. The solution is allowed to age and finally the resulting precipitate is filtered, washed, and dried. This "as-synthesized" (dried) material consists of the micellar CTAB array around which the Pd-YSZ matrix has been formed. Upon calcination, the organic component is eliminated giving rise to the porous structure (Fig. 1).

Details of the procedure are as follows. Zirconium ethoxide (5.0 g, Strem Chemicals Inc., 99.9+%) and 2.4 equiv. of NaOH (1.8 g) were added to a flask containing excess ethylene glycol (51 mL, spectroscopic grade, Sigma-Aldrich Chemical Ltd.). The resulting mixture was then refluxed at 180 °C under flowing nitrogen for 24 h. Excess ethylene glycol was distilled off leaving a thick yellowish gel (zirconium glycolate). Separately, yttrium glycolate was prepared by adding yttrium acetate tetrahydrate (1.2 g, Alfa Aesar, 99.9%) to ethylene glycol (31 mL) and stirring. The zirconium and yttrium glycolates were then mixed in a dropwise fashion while the zirconium glycolate was still hot (~50 °C). The resulting solution was added to a polypropylene bottle containing a Pd^{+2} source ($Pd(NO_3)_2$, Sigma-Aldrich Chemical Ltd., 99.999%, 2.0 mL solution 10 wt% in

© 2006 NRC Canada

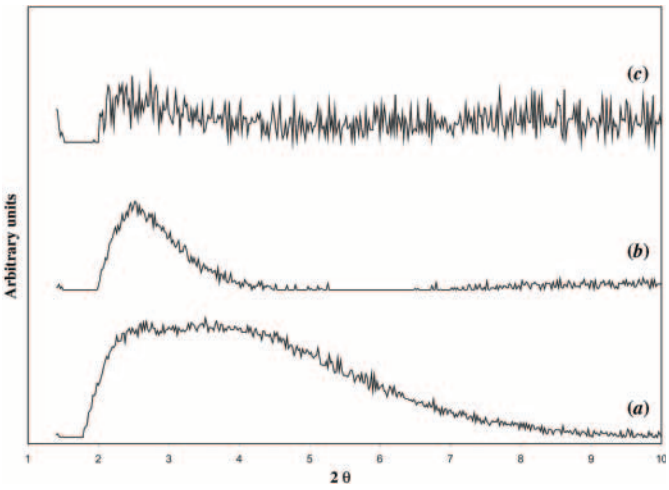
10 wt% nitric acid), cetyltrimethylammonium bromide (CTAB, Sigma-Aldrich Chemical Ltd., 4.1 g), NaOH (1.7 g), and water (120 mL). The mixtures were stirred at RT for 25 min and then put into an oven for 5 days at 80 °C. The solid products obtained were collected by vacuum filtration and washed two times with water to remove residual chlorine and CTAB. Samples were then dried at 120 °C for 6 h and denoted as-synthesized. This procedure produces a Pd loading of 5%; for different loading the Pd concentration is simply adjusted.

Calcination to 600 °C or 950 °C was performed in air for 2 h to ensure the crystallization of the YSZ. The calcination procedure also produces PdO. When reduced Pd is required, reduction was performed at 500 °C under H_2 flow for 2 h for samples previously calcined to 600 °C, and at 800 °C under N_2 flow for 2 h for samples previously calcined to 950 °C. A reduced material containing 5 mol% Pd and calcined to 950 °C prior to reduction shall be denoted as 5%Pd-YSZ950 and one precalcined to 600 °C as 5%Pd-YSZ600.

Pd-YSZ characterization

Powder composition and crystallite sizes were determined by X-ray diffraction (XRD) (Phillips PW1830) using Cu K_α radiation with a wavelength of 1.54 Å. Crystalline phases were assigned using the Powder Diffraction File database (ICCD, 2001). The crystallite size analysis of each phase was performed using the Williamson–Hall methodology, which takes into account crystallite strain (59). Vibrational characterization of the powders prior to calcination was determined using Attenuated Total Reflection Fourier transform IR spectroscopy (ATR-FTIR) (Bruker Equinox 55). The BET surface area of the calcined powders were determined after reduction in flowing H_2 (5% in N_2) at 500 °C for 2 h, using a Quantachrome Autosorb 1-C instrument. A BJH analysis provides pore size information and the average pore size was calculated using the Kelvin equation.

General procedure for the Heck reaction of butylacrylate with iodobenzene



To a round-bottomed flask fitted with a reflux condenser was added iodobenzene (4.0 mmol, 0.45 mL), butylacrylate (4.8 mmol, 0.69 mL), *N,N*-diisopropylethylamine (DIPEA) (8 mmol, 1.4 mL), and *N,N*-dimethylformamide (DMF) (1.4 mL). To this solution was added the precatalyst 5% Pd-YSZ (0.004 mmol, 9.7 mg). The reaction was then heated to 140 °C. Reaction progress was monitored by GC-MS analysis of the crude reaction mixture against a decane internal standard. For all reactions, the mol ratio iodobenzene–butylacrylate–DIPEA was kept at 1:1.2:2.

Triple phase test

Preparation of resin

To a mixture of Wang resin (0.3 equiv.) and iodobenzene (1 equiv.) in DMF (0.1 mol/L) was added dicyclohexylcarbodiimide (1 equiv.) and a few grains of 4-dimethylaminopyridine as catalyst. The reaction mixture was heated at 60 °C for 4 days. The solution was filtered and washed twice with each of the following solvents: water, methanol, dichloromethane (DCM), and diethyl ether.

Fig. 2. Small angle XRD pattern of 20%Pd-YSZ for (*a*) as-synthesized, (*b*) calcined to 600 °C, and (*c*) calcined to 950 °C.

Capping of the unreacted hydroxyls on the resin

To a suspension of the resin (1 equiv.) in dichloromethane (0.1 mol/L) was added acetic anhydride (5 equiv.) and pyridine (5 equiv.). The reaction was stirred for 24 h at RT. The reaction mixture was filtered and washed twice with each of the following solvents: water, methanol, DCM, and ether to afford the acetate protected resin.

Reaction and cleavage of compound from the resin

To a mixture of acetate protected resin (1 equiv.) was added butyl acrylate (3 equiv.), DIPEA (3 equiv.), Pd-YSZ (0.05 equiv.) in DMF (0.16 mol/L). The reaction mixture was heated at 130 °C for 3 h. The resin (1 equiv.) was filtered and washed thoroughly before being stirred in a 1:1 mixture of trifluoroacetic acid and dichloromethane (0.5 mol/L) for 2 h. The resulting mixture was filtered and washed twice with each of the following solvents: methanol, DCM, and ether. The filtrate was put under reduced pressure at 70 °C to remove the volatiles as well as the trifluoroacetic acid. This afforded compound **5** (eq. [1]).

Thiol scavenger test

To a suspension of thiol resin (0.5 equiv.) was added iodobenzene (1 equiv.), butyl acrylate (1.2 equiv.), DIPEA (2 equiv.), and Pd-YSZ (0.01 equiv.) in DMF (2.7 mol/L). The reaction mixture was heated to 130 °C and monitored by GC. After prolonged reaction time, no greater than 2% conversion was detected.

Results and discussion

Pd-YSZ material properties

The as-synthesized material containing the residual hydrocarbon micelles possesses long-range order with d-spacing of 40 Å, as seen by the low-angle peak in the XRD pattern (Fig. 2). Upon calcination in air to 600 °C, the hydrocarbon is eliminated leaving a porous mesostructure with d-spacing of 41 Å. The low-angle peak is decreased in intensity, consistent with a partial disruption of the long-range order. The observed change in d-spacing is consistent with a thickening of the pore walls as the crystals of YSZ become larger (56).

© 2006 NRC Canada

Finally, upon calcination to 950 °C the material is described as having lost its long-range order.

The shape of the low-angle peak for the as-synthesized material is observed as very broad and asymmetrical. Such a shape has been observed by Ozin and coworkers (54–56) in similar materials and discussed in terms of a poor long-range order of the mesoporous structure. An alternative explanation is the superposition of two peaks for different orientations of the long-range order structure (53). Kim et al. (53) assigned their peak at $2\theta \approx 3.9°$ to the (110) reflection of a hexagonal arrangement of meso-zirconyl chloride. In this case, the metastable structure present when the surfactant is still in the pores is disturbed when the organic component is removed, leaving a single peak in the XRD pattern of the calcined samples.

The mesoporous structure of the material calcined to 600 °C is also reflected by the intermediate surface area, typically in the range of 150 $m^2\ g^{-1}$, and a slightly asymmetric pore size distribution that peaks at 19 Å in diameter with an average pore size diameter of 26 Å, as calculated by the Kelvin equation. This value is smaller than those obtained for perfectly structured mesoporous materials such as zeolites, but it is an order of magnitude larger than most commercial YSZ catalyst powders (Maketech Materials 70% NiO/8YSZ, 9.8 $m^2\ g^{-1}$ and 34% NiO/8YSZ, 6.63 $m^2\ g^{-1}$). The surface area decreases to ~10 $m^2\ g^{-1}$ upon calcination to 950 °C indicating the predominant collapse of the porous structure.

Removal of the pore-forming molecule CTAB from the material is achieved during the calcination process and is complete by 600 °C. This is illustrated in Fig. 3, which shows ATR-FTIR spectra of a sample as-synthesized and after calcination. The two peaks present at 2850 and 2916 cm^{-1} in the as-synthesized sample are characteristic of the C–H stretching modes in the CTAB long chain. These peaks are removed upon calcination. The regions around 1500 and 3400 cm^{-1} are characteristic of water and can be seen to decrease substantially upon calcination. Peaks at ~1000 cm^{-1} are associated with yttrium and (or) zirconium species, but their identification is difficult due to the large broadening (60).

It is interesting to note that the CTAB species are not removed at a single temperature and in fact they appear to be partially decomposed and trapped within the porous structure. Thermogravimetric analysis in helium shows weight loss at several distinct temperatures (Fig. 4). Correlation of the weight loss with mass analysis shows that in the temperature range below 60 °C, water is the main component desorbed. The hydrocarbon moieties represented by the ethyl group (*m*/*e* = 29) are desorbed in the subsequent two peaks at 280 and 440 °C. Trapping and decomposition of the CTAB is suggested by the simultaneous observation of zirconium (*m*/*e* = 91) and the tertiary amine group (*m*/*e* = 57), which come out from the matrix at 440 °C. These observations have direct implications on the stability of the mesoporous structure. The binding and (or) trapping of CTAB to the YSZ network is sufficiently strong that the removal of the surfactant disrupts the pores. A more inert surfactant may improve the thermal stability of the YSZ porous structure.

Palladium and YSZ crystallites are present in the material as individual phases as seen from their characteristic powder diffraction pattern. The large width of their peaks suggests extremely small crystallite sizes, particularly for YSZ. Increasing the calcination temperature results in an increase in size of the YSZ crystallites, as observed by a decrease in peak widths in the XRD patterns (Fig. 5).

During the calcination process, the crystallites of palladium originally present (Fig. 5) also increase in size. However, as the temperature rises Pd is oxidized to PdO. At a temperature of 840 °C, PdO is reduced to Pd once again. The reduction of PdO to Pd can be readily observed in the TGA experiment performed in air as a sharp decrease in mass (Fig. 6). It is interesting to note that the reoxidation of Pd to PdO during cooling occurs more gradually around 650 °C, a hysteresis of 190 °C. The observed temperature of PdO reduction in air is high for zirconia-based catalysts, but it is consistent with literature (61–63) for other Pd-oxide catalysts. The ratio of oxidized vs. metallic palladium observed in the XRD (at RT, after calcination to 950 °C, Fig. 5) depends on the sample cooling rate in air. Calcination to

Table 1. Crystallite sizes for selected materials.

Sample composition	Conditions	Pd crystallites (nm±esd)[a]	PdO crystallites (nm±esd)[a]	YSZ crystallites (nm±esd)[a]
5% Pd-YSZ	Calc. 600 °C	Not present	9.3±2.7	5.0±0.5
	Calc. 950 °C	29.8±9.4[b]	21.6±1.4[b]	14.1±0.2
20% Pd-YSZ	As-synthesized	41.8±6.9	Not present	Amorphous
	Calc. 600 °C	Not present	39.6±6.5	4.2±0.1[b,c]
	Calc. 950 °C	133±32	14.8±1.1	21.8±1.1
50% Pd-YSZ	As-synthesized	34.8±4.0	Not present	Amorphous
	Calc. 600 °C	Not present	19.9±2.9	4.7±0.1[b,c]
	Calc. 950 °C	90±16	22.3±2.0	21.1±1.2

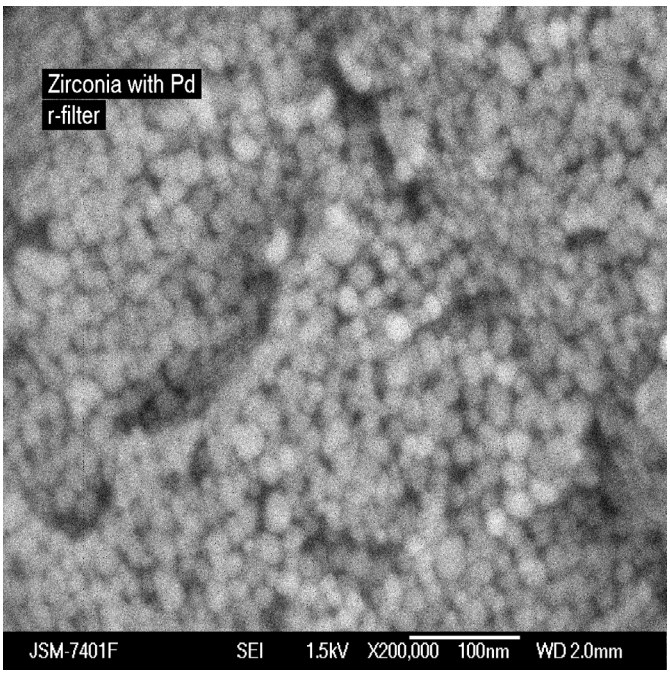
Note: Crystallite sizes were measured by XRD using the Williamson–Hall analysis. Multiple peak analysis consisted of, 4 peaks for Pd, 6 peaks for YSZ, and 4 peaks for PdO.

[a]Estimated standard deviation is based on the peak fitting/refinement routine (JADE diffraction analysis).

[b]Single peak analysis (111) performed by Scherrer method.

[c]Only a few broad peaks are available for analysis. YSZ is mostly amorphous in these samples.

600 °C in air produces only the PdO phase. To obtain metallic Pd exclusively, the samples can be calcined and cooled in an inert atmosphere.



Palladium sintering effects in heterogeneous catalysis are a general concern for temperature treatments above 800 °C because coarsening leads to a decrease in catalytic activity (61–63). In these mesoporous Pd-YSZ materials, palladium crystallites remain constant in size up to ~800 °C during the oxidation and subsequent reduction process. Calcination to higher temperatures does increase the Pd crystallite size, but only to a limited extent (Table 1). The ultimate average crystallite size upon calcination depends on the palladium content with a maximum coarsening of three-fold observed for 20% Pd loading. The observed increase in crystallite size compares very well to increases of over 10-fold for Pd-Al_2O_3 (64, 65) and nanoengineered 3%Pd-YSZ (66) catalysts at similar temperatures. For all samples, the YSZ average crystallite size after calcination to 950 °C is around 20 nm, regardless of Pd loading. The relatively stable mesostructure of the YSZ, which partially survives the calcination process, seems to be responsible for the low degree of sintering of palladium. Figure 7 shows an SEM image of 5%Pd-YSZ950R (reduced palladium) where the homogeneous nature and the small particle size of the material can be assessed.

Application to the Heck Reaction

A 5 mol% material with the highest possible surface area was chosen for catalytic experiments. The mesoporous 5 mol% Pd-YSZ framework possesses long-range order with a d-spacing of 40 Å (by XRD). Crystallites sizes of 10 nm and 5 nm for Pd and YSZ respectively were measured for samples calcined to 600 °C. This highly reactive 5%Pd-YSZ600R has a total surface area of 150 m^2/g with an average pore size diameter of 26 Å. For comparison, a 5% Pd loading material calcinated to 950 °C in the reduced form was chosen (5%Pd-YSZ950R). Higher temperatures during the material preparation process disrupt the long-range order of the mesoporous structure and lead to the overall reduction of surface area to 10 m^2/g. However, up to 1000 °C the increase in the crystallite size of the two components is relatively small, ~2×. Generally, catalytic materials with smaller total surface areas are not expected to perform as well under reaction conditions. However, for selected reactions the

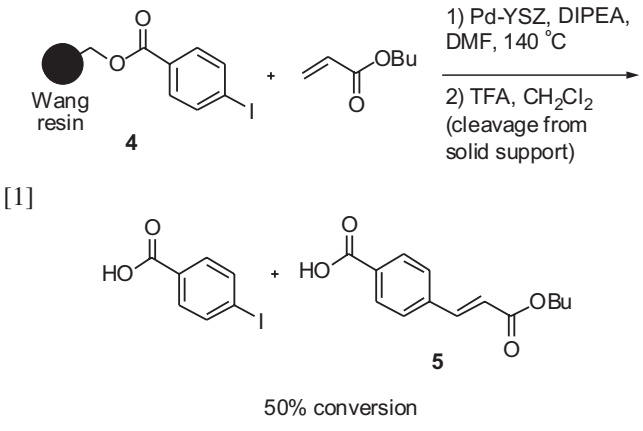
Fig. 7. Scanning electron micrograph of 5%Pd-YSZ950. Image is taken with an r-filter for improved contrast. High palladium concentration areas appear brighter, although Pd is homogeneously distributed in this sample as confirmed by energy dispersion measurements.

high-temperature treatment may be preferred because it adds mechanical, chemical, and thermal stability to the catalysts, which have a direct impact on the reusability of the catalysts.

Preliminary work showed that both of these precatalysts were active for the Heck reaction, even prior to the reduction step. The subsequent sections compare the performance of these two precatalysts and provide a discussion of their effectiveness and the reaction mechanism involved for a standard Heck coupling reaction.

Reaction optimization

With an active catalyst in hand, the reaction conditions were optimized with respect to solvent, base, temperature, and concentration. In early screens, dimethylformamide (DMF) emerged as the optimal solvent. A base scan also revealed that the best outcomes were achieved with organic bases such as diisopropylethylamine (DIPEA). Inorganic bases such as potassium bicarbonate lead to lower turn-over numbers (TONs) and slower reaction. All subsequent optimization studies were performed in DMF with DIPEA as base.

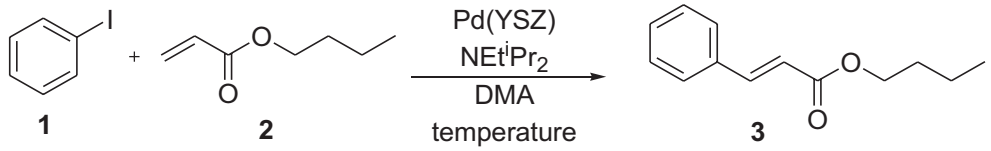


Initial optimization reactions were performed with 5%Pd-YSZ950R (reduced Pd). From three experiments performed at 120, 130, and 140 °C, it was determined that faster reactions and improved TONs were achieved at 140 °C. For example, after 60 min of reaction time less than 10% conversion was observed at 120 °C compared with 47% and 65% conversion at 130 and 140 °C, respectively (Table 2, entries 1–3).

These reactions are very sensitive to concentration as illustrated in Table 2, entries 4–7. Four different iodobenzene concentrations were assayed (0.2, 0.5, 1.0, and 1.2 mol/L) and each of the reactions was analyzed after 30 min. At these intervals, neither reaction at 0.2 and 0.5 mol/L showed any conversion to product. On the other hand, reactions performed at 1.0 and 1.2 mol/L had progressed to 35% and 75% conversion after 30 min, respectively, showing that a faster initial reaction occurs at elevated concentration. It is interesting to note that in Table 2, entries 4–7, the substrate to catalyst ratio (S/C) is kept constant and therefore the effect of concentration is different from the homeopathic effect described by de Vries (27) where a large S/C ratio prevents Pd nucleation and subsequent deactivation of the catalytic species.

A comparison of the two precatalysts 5%Pd-YSZ950R and 5%Pd-YSZ600R was carried out. From these experiments (Table 2, entries 8–11), the 5%Pd-YSZ600R emerges as a superior catalyst as evidenced by the percentage conversion at 30 min (Table 2, entry 10 vs. 8) and 60 min (Table 2, entry 11 vs. 9). With these conditions in hand, reactions were performed to determine the maximal TON that could be achieved with this new catalyst. We were delighted to see that under optimal conditions, up to 770,000 TON could be achieved after approximately 7 days (Table 2, entry 12).

Elucidation of the active species



With an active catalyst in hand, we were interested in determining unequivocally if this was a heterogeneous catalyst or if palladium was leaching off of the support to produce an active homogeneous species. Two different approaches were taken to answer this question based on the three-phase test concept (67–70). In the first case, the aryl halide was anchored to a Wang resin (71). If the true catalyst in these processes was purely heterogeneous then interaction between the supported substrate and the matrix bound catalyst should not be possible, thus preventing reaction. In contrast, if palladium leaching occurs and if this soluble palladium species is catalytically active, then Heck reaction at the solid-supported **4** should be observed. When supported **4** was reacted under standard conditions followed by separation of the solid phase, washing of the Wang resin, and cleavage of the substrate–product mixture from the solid support via treatment with trifluoroacetic acid in dichloromethane (72, 73), approximately 50% conversion to **5** was observed (eq. [1]). This lends strong support to the notion that a homogeneous active catalyst is generated under the reaction conditions via leaching from the YSZ support.

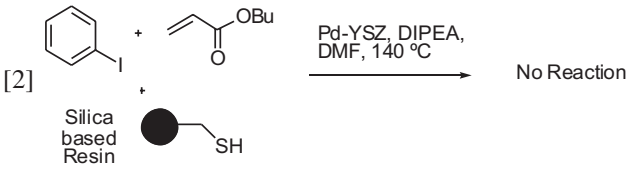
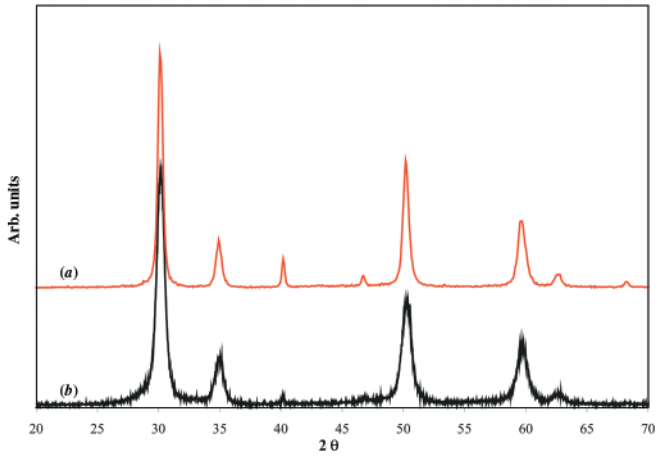
Table 2. Heck reaction optimization.



Entry	Catalyst	Substrate–Catalyst Ratio	Temp (°C)	Conc. [B][a]	Reaction Time (min)	% Conc.[b]
1	A	100	140	0.2	60	65
2	A	100	130	0.2	60	47
3	A	100	120	0.2	60	9
4	A	1 000	140	0.2	30	0
5	A	1 000	140	0.5	30	0
6	A	1 000	140	1.0	30	35
7	A	1 000	140	1.2	30	75
8	A	1 000	130	0.5	30	13
9	A	1 000	130	0.5	60	49
10	B	1 000	130	0.5	30	41
11	B	1 000	130	0.5	60	61
12	B	1 000 000	140	1.0	7 days	77

Note: Catalyst A: 5%Pd-YSZ950R and B: 5%Pd-YSZ600R. Conditions: Iodobenzene, butylacrylate, *N,N*-diisopropylethylamine (DIPEA), and *N,N*-dimethylformamide (DMF) added to a round-bottomed flask followed by the addition of the catalyst and heating to the indicated temperature.

[a]Concentration of iodobenzene.



[b]Determined by GC-MS analysis of the crude reaction mixture against a decane internal standard.

To determine if an active heterogeneous catalyst species was also contributing to the direct arylation reaction, another three-phase test was conducted. In this experiment **1** was reacted under standard conditions in the presence of a silica supported thiol-based scavenger resin. Since thiols are known to have a very high affinity for palladium, the presence of this heterogeneous metal scavenger should sequester the homogeneous catalyst as it is produced. On the other hand, a heterogeneous palladium species that is catalytically active should not be poisoned by the presence of the heterogeneous metal scavenger. After 16 h, less than 5% of the desired product had been formed while an identical reaction run in parallel without the scavenger resin reached 100% conversion (eq. [2]). This indicates that the heterogeneous palladium is not catalytically active on the timescale examined and that the observed reactivity arises from the in situ generation of a homogeneous catalyst.

Having shown that the mechanism of reaction is homogeneous, we investigated how much Pd is lost during the process. As it was not possible to identify Pd in solution, we determined the amount of palladium before and after reaction to obtain an upper limit to the amount of palladium remaining in solution after reaction. Figure 8 shows the XRD pattern of catalysts 5%Pd-YSZ950R before and after undergoing a reaction. XRD was chosen to search for PdO, which could have been formed during reaction, but was not observed. Although XRD is not a traditional quantitative technique, we can clearly see that the ratio of Pd to YSZ has

Fig. 8. Powder XRD pattern of 5%Pd-YSZ950. Diffractograms have been normalized to the peak at 2θ = 30° (the most intense YSZ peak) for (*a*) before undergoing reaction and (*b*) after undergoing reaction.

decreased substantially. Since YSZ is not affected by the reaction, it can be considered as an internal standard for the XRD measurement allowing us to use the intensity ratio of the variable (Pd) to the standard (YSZ) for quantization purposes. A quantitative value can be obtained by measuring the intensity ratio of the most intense peaks for Pd and YSZ (at 40 and 30 °, respectively) and comparing this to a calibration curve obtained for variable amounts of Pd in YSZ. The technique cannot measure atomic Pd in the sample, but after a sintering treatment to allow palladium aggregation, no change was observed. If we consider that all the Pd not present in crystalline form in our sample has remained in solution, we obtain an upper limit to the amount of Pd leached. Estimating that about 80% of the Pd was lost during reac-

© 2006 NRC Canada

tion, this would correspond to ~0.10 ppm of Pd in the final solution (e.g., Table 2, entry 12). This value is consistent with best effort for Pd on activated carbon (0.05 ppm) (74) and only slightly worse than the mercaptopropyl-modified silica (0.003 ppm), which is a Pd scavenger (16).

Structure–reactivity analysis

The activity of different precatalysts can be analyzed in terms of total number of turn-overs and how fast that TON can be achieved, namely kinetics. In fact, the optimization of reaction parameters will be most sensitive to the kinetics of reaction. For these reasons, we chose the lower surface area catalyst, which we expected would be slower, to optimize the other reaction parameters. Table 2 (entries 1–9) shows a subset of the reaction optimization data for the Heck reaction using 5%Pd-YSZ950R.

Our previous work demonstrated that if reactions were allowed sufficient time (24 h), the conversion for 100:1 (substrate–catalyst) reactions was >95% for a wide range of conditions. Therefore, the difference in reactivity for the two catalysts was assessed by comparison of the percentage conversion vs. time for different catalysts and conditions. For example, entries 8–11 in Table 2 for a substrate–catalyst ratio of 1000:1 show that after 0.5 h of reaction 5%Pd-YSZ600R has a TON 3× higher than 5%Pd-YSZ950R. This result is consistent with the heterogeneous catalysis literature since more active catalyst is usually exposed in higher surface area materials. In this case, because of the homogeneous nature of the reaction mechanism the higher surface area and smaller Pd particle size of 5%Pd-YSZ600R facilitate the extraction of Pd to solution, thereby making the reaction faster.

However, the support seems to be playing a more important role than simply controlling the surface area of available palladium. It is interesting to note that the activity of the catalyst is also reflected in the total number of turn-overs. 5%Pd-YSZ600R attains 770,000 turn-overs after 7 days, approximately twice as much as 5%Pd-YSZ950R. This effect may be accounted for by the mesoporous structure of 5%Pd-YSZ600R, which may be preventing the active homogeneous Pd species from diffusing into the bulk of the solution (encapsulation) where it can be easily de-activated (27).

Despite the homogeneous nature of the catalysts due to leaching of Pd into solution, 5%Pd-YSZ600R compares well with other heterogeneous precatalysts discussed in the literature. While TONs for homogeneously catalyzed Heck reactions have been documented in excess of 8.0×10^6 (75), TONs with heterogenous precatalysts are typically much lower. In rare cases, TONs in slight excess of 10^6 have been obtained demonstrating that the Pd-YSZ catalyst examined in these studies compares favourably with other catalyst systems. The highest value we have found in the literature is slightly higher (TON 1,150,000 (29, 76)) for a complex polymer-based ligand-coordinated palladium catalyst. In contrast, palladium supported on activated carbon, with similar cost per gram of catalyst as our precatalyst, has been shown to achieve TONs of 36,000 (74, 77).

Conclusions

Pd-YSZ has been prepared using an amphiphillic surfactant templating method resulting in a homogeneous dispersion of Pd on an ordered mesoporous structure. The Pd particle size and composition properties are easily controllable. The material is resistant to high temperatures, although some coarsening is observed and the long-range order is maintained only up to intermediate temperatures.

Reduced Pd-YSZ showed high activity for the Heck reaction. Up to 770,000 TON were achieved with a 5% Pd-loaded catalyst having a surface area of 150 m^2/g. This result compares favourably with other heterogeneous precatalysts in this reaction. Three-phase tests were conducted to ascertain the nature of the active catalyst species. These tests revealed that a homogeneous catalyst is leaching from the solid support and that the palladium that remains on the matrix is not responsible for the observed reactivity. Despite the homogeneous nature of the active species, the heterogeneous precatalyst remains interesting because it can be easily filtered out leaving behind only residual amounts of Pd (<0.10 ppm).

A highly efficient carbon–sulfur bond formation reaction via microwave-assisted nucleophilic substitution of thiols to polychloroalkanes without a transition-metal catalyst

Yi-Ju Cao, Yuan-Yuan Lai, Hong Cao, Xiao-Ning Xing, Xiang Wang, and Wen-Jing Xiao

Abstract: An efficient carbon–sulfur bond formation reaction has been developed under microwave irradiation. This reaction affords a novel and rapid synthesis of thioacetals and sulfides under mild conditions. This method is particularly noteworthy given its experimental simplicity and high generality, and no transition-metal catalysts were needed under our conditions.

Key words: microwave, sulfide, thiol, nucleophilic substitution.

Résumé : Faisant appel à des irradiations microondes, on a mis au point une méthode efficace pour la formation de liaisons carbone–soufre. Cette réaction fournit une nouvelle méthode rapide de synthèse de thioacétals et de sulfures dans des conditions douces. La méthode est particulièrement remarquable en raison de sa simplicité, de son caractère général et du fait que, dans nos conditions, aucun catalyseur métallique n'est nécessaire.

Mots clés : microonde, sulfure, thiol, substitution nucléophile.

[Traduit par la Rédaction]

Introduction

The formation of a C–S bond is an important organic reaction (1). For example, the formation of thioacetals provides an excellent method to protect the carbonyl group (2) and can serve to generate umpoled carbonyls (3). Furthermore, some 1,3-dithiolane compounds exhibit remarkable biological activities, which include anticonvulsant (4), radioprotective (5), hepatoprotective (6), anti-tumor (7), and anti-HIV activities (8). In addition, sulfides and their derivatives are also biologically active compounds (9), as well as attractive building blocks in the synthesis of sulfur-containing functional monomers (10). Consequently, numerous synthetic methods for dithioacetals and sulfides have been developed. Representative examples for the preparation of thioacetals include the condensation of a carbonyl compound with thiols in the presence of various Lewis acid catalysts (2, 11) and the reaction of thiols with diiodomethane, dibromomethane, or dichloromethane under strongly basic conditions (12). Sulfide formation is generally carried out by the condensation of activated alkyl halides with alkali metal thiolates (13) or by the reduction of sulfones or sulfoxides using strong reducing agents such as DIBAL–H or $LiAlH_4$ (14). However, many of these clasical methods are limited by their moderate yields, harsh reaction conditions, and tedious work up. Thus, methods for the introduction of a carbon–sulfur bond with the use of transition metal catalysts have been recently developed (15, 16). Among them, the most promising and straightforward methods for the preparation of dithioacetals and sulfides are Tanaka's rhodium-catalyzed reaction of polychloroalkanes with thiols (15*a*) and Ogawa's palladium-catalyzed hydrothiolation of alkynes with thiols (15*h*). Although these methods successfully yield versatile dithioacetals or sulfides, they require a long reaction time, use of expensive catalysts, and vigorous conditions. In particular, the use of transition metals leads to the generation of waste and has a number of hazards associated with it (17). Accordingly, the development of more efficient methods is still in demand.

In the past few years, the utilization of microwave irradiation in organic synthesis has become increasingly popular within the pharmaceutical and academic arenas (18). By taking advantage of this efficient source of energy, compound libraries and optimization can be assembled in a fraction of the time required by classical thermal methods (19). Microwave-assisted protocols have been widely applied to the formation of a variety of carbon–heteroatom and carbon–carbon bonds (20). To the best of our knowledge, the direct metal-free substitution of thiols to polychloroalkanes using

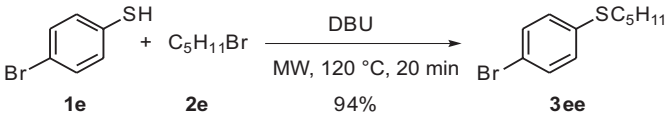
high-speed microwave techniques has not been described. Herein, we would like to report our preliminary investigation on the microwave-assisted C–S bond formation reactions, which constitute one of the most efficient and rapid syntheses of dithioacetals and sulfides. Compared with Tanaka's procedure (15*a*), the superiorities of our method include (1) a shorter reaction time and higher yields, (2) a broader substrate scope, and (3) the exclusion of transition-metal catalysts.



Results and discussion

As a starting point for the development of our microwave-mediated methodology, we chose to study the reaction of thiophenol with dichloromethane for the optimization of reaction conditions, and the results are summarized in Table 1. It was found that the reaction was significantly influenced by the base employed and the temperature (Table 1, entries 1–5 and 9–11). Although both inorganic and organic bases could be used in the reaction, DBU and Cs_2CO_3 are obviously much better than others (Table 1, entries 1–5). Increasing the loading of DBU from 1.0 to 2.0 equiv., based on thiophenol, could dramatically improve the reaction yield (Table 1, entries 4 and 6); however, further increasing the loading of DBU to 4.0 equiv. did not affect the reaction (Table 1, entries 6–8). The reaction temperature is another critical factor for the successful formation of dithioacetals, with the best result being attained at 150 °C (Table 1, entry 6). Decreasing the temperature from this value has been shown to be detrimental to the reaction (Table 1, entries 9–11).

Encouraged by the previous results, we further examined the microwave-assisted reactions of various thiols with polychloroalkanes. From the results shown in Table 2, it can be concluded that both aliphatic and aromatic thiols with an electron-donating or electron-withdrawing group readily undergo this transformation to afford the corresponding dithioacetals or sulfides in good to excellent yiels (Table 2, entries 1–6, 12, and 13). 1,2-Ethanedithiol can also be employed successfully in the reaction (Table 2, entries 7 and 14). In addition to dichloromethane, chloroform, 1,1-dichloropropane, and 1,2-dichloroethane are effective for this microwave-assisted, direct C–S bond formation reaction (Table 2, entries 8–14). 1,3-Dithiolane and 1,4-dithiane can be easily prepared in good isolated yields by the reaction of 1,2-ethanedithiol with dichloromethane and 1,2-dichloroethane, respectively (Table 2, entries 7 and 14).

Next, we investigated the microwave-assisted reaction of *p*-bromothiophenol with pentyl bromide. As expected, the reaction also gave excellent yields and short reaction time in the presence of DBU under microwave irradiation (eq. [1]).

[1]

Conclusions

In conclusion, we established a rapid and efficient method for the synthesis of dithioacetals and sulfides by the direct substitution reaction of thiols with polychloroalkanes without any transition-metal catalyst under microwave irradiation. Particularly, the methodology presented here is attractive because of its shorter reaction time, higher yields, broader substrates scope, and the experimental simplicity. Furthermore, the reaction was developed to meet the increasing demand for green chemistry and environment-friendly chemical processes.

Experimental section

General methods

Unless otherwise noted, materials were purchased from commercial suppliers and used without further purification. Solvents and liquid organic bases were freshly distilled according to the known procedures (21). Column chromatography was performed using 200–300 mesh silica gel. ^{1}H NMR spectra were recorded on Varian Mercury 400 (400 MHz) spectrometers. Chemical shifts are reported in ppm from TMS with the solvent resonance as the internal standard ($CDCl_3$, δ 7.24). Data are reported as follows: chemical

Typical procedure for the microwave-assisted reaction of thiol with polychloroalkane

A 5.0 mL process vial was charged with polychloroalkane (2 mL), thiol (0.5 mmol), and DBU (1.0 mmol). The vial was then capped with a Teflon septum and irradiated with microwave to 150 °C for 20 min. After cooling, the reaction mixture was poured into water and extracted with dichloromethane (3 × 5 mL). The combined organic phase was dried over $MgSO_4$ and then filtered. The solvent was evaporated, and the residue was purified by flash chromatography to give the desired dithioacetals or sulfides in good to excellent yields (72%–95%).

Di(phenylthio)methane (3aa) (22)

White solid; mp 30–34 °C; yield 95%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.43–7.27 (m, 10H), 4.34 (s, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 135.1, 130.8, 129.1, 127.2, 40.5.

Di(p-tolylthio)methane (3ba) (23)

White solid; mp 40–42 °C; yield 94%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.34–7.32 (d, J = 6.4 Hz, 4H), 7.13–7.11 (d, J = 6.8 Hz, 4H), 4.26 (s, 2H) 2.33 (s, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 137.4, 131.5, 131.3, 129.7, 41.9, 21.1.

Di(4-methoxyphenylthio)methane (3ca)

White solid; mp 66–67 °C; yield 95%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.40 (dd, J = 2.4, 6.4 Hz, 4H), 6.85 (d, J = 9.2 Hz, 4H), 4.15 (s, 2H), 3.81 (s, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 159.6, 134.4, 125.2, 114.6, 55.3, 44.5. Anal. calcd. for $C_{15}H_{16}O_2S_2$: C 61.61, H 5.52; found: C 61.69, H 5.48.

Di(4-chlorophenylthio)methane (3da) (23)

White solid; mp 42–43 °C; yield 90%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.33 (d, J = 6.8 Hz, 4H), 7.12 (d, J = 6.8 Hz, 4H), 4.26 (s, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 133.6, 133.0, 132.4, 129.1, 41.2.

Di(4-bromophenylthio)methane (3ea)

White solid; mp 70.5–72.0 °C; yield 93%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.3 (d, J = 8.4 Hz, 4H), 7.26 (d, J = 8.4 Hz, 4H), 4.28 (s, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 133.6, 132.5, 132.1, 121.5, 40.8. Anal. calcd. for $C_{13}H_{10}Br_2S_2$: C 40.02, H 2.58; found: C 40.21, H 2.61.

Di(octylthio)methane (3fa) (15a)

Colorless oil; yield 86%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.64 (t, J = 1.2 Hz, 2H), 2.62 (t, J = 6.8 Hz, 4H), 1.55–1.60 (m, 4H), 1.27–1.38 (m, 20H), 0.88 (t, J = 7.2 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 35.4, 31.8, 30.8, 29.2, 29.2, 28.9, 22.6, 14.0.

1,3-Dithiolane (3ga) (24)

Colorless oil; yield 72%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.86 (d, J = 0.4 Hz, 2H), 3.16 (d, J = 0.8Hz, 4H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 8.0, 34.3.

1,1-Di(phenylthio)propane (3ab)

Pale yellow oil; yield 79%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.47–7.24 (m, 10H), 4.35 (t, J = 6.4 Hz, 1H), 1.88 (m, 2H), 1.13 (t, J = 7.2 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 134.5, 132.8, 128.7, 59.9, 28.8, 11.5. Anal. calcd. for $C_{15}H_{16}S_2$: C 69.18, H 6.19; found: C 69.04, H 6.32.

1-Chloro-2-phenylthioethane (3ac) (25)

Colorless oil; yield 89%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.40–7.24 (m, 5H), 3.61 (t, J = 4.2 Hz, 2H), 3.21 (t, J = 4.2 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 134.3, 130.5, 129.3, 127.1, 42.1, 35.9.

1,2-Di(phenylthio)ethane (3ac′) (26)

White solid; mp 92–93 °C; yield 91%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.32–7.21 (m, 10H), 3.08 (d, J = 2.4 Hz, 4H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 135.0, 130.0, 129.0, 126.5, 33.4.

Tris(phenylthio)methane (3ad)

Pale yellow oil; yield 72%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.49–7.30(m, 15H), 5.41 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 134.1, 133.1, 129.1, 128.5, 64.9. Anal. calcd. for $C_{19}H_{16}S_3$: C 67.02, H 4.74; found: C 67.30, H 4.86.

1,1-Di(4-bromophenylthio)propane (3eb)

Colorless oil; yield 95%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.43–7.28(m, 8H), 4.28 (t, J = 6.6 Hz, 1H), 1.84 (m, 2H), 1.12 (t, J = 7.4 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 137.4, 133.1, 132.0, 122.1, 60.3, 28.8, 11.8. Anal. calcd. for $C_{15}H_{14}Br_2S_2$: C 43.08, H 3.37; found: C 43.29, H 3.30.

1-Chloro-2-(4-bromophenylthio)ethane (3ec)

White solid; mp 134–136 °C; yield 92%. ^{1}HNMR (400 MHz, $CDCl_3$) δ: 7.45–7.23 (m, 4H), 3.60 (m, 2H), 3.20 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 133.5, 132.3, 132.0, 121.1, 42.1, 36.2. Anal. calcd. for C_8H_8BrClS: C 38.19, H 3.21; found: C 38.07, H 3.33.

1,4-Dithiane (3gc) (27)

White solid; yield 81%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.90 (s, 8H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 29.1

4-Bromophenylthiopentane (3ee)

Colorless oil; yield 94%. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.40–7.16 (m, 4H), 2.89 (t, J = 7.4 Hz, 2H), 1.67–1.25 (m, 6H), 0.91 (t, J = 5.4 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 136.3, 131.8, 130.3, 119.3, 33.6, 30.9, 28.7, 22.2, 13.9. Anal. calcd. for $C_{11}H_{15}BrS$: C 50.97, H 5.83; found: C 51.04, H 5.77.

Interaction of dimethyltin(IV)dichloride with 5′-AMP and 5′-GMP

Farrokh Gharib, Elnaz Farzad, and Mostafa Mohammadpour Amini

Abstract: The formation constants of the species formed in the systems H^+ + dimethyltin(IV) + 5′-AMP and 5′-GMP, H^+ + 5′-AMP, and H^+ + 5′-GMP have been determined in aqueous solution in the pH range of 1.5–9 at constant temperature (25 °C) and constant ionic strength (0.1 mol dm^{-3}, $NaClO_4$) using spectrophotometric and potentiometric techniques. ^1H and ^{31}P NMR investigations in aqueous solution confirmed the species formation and led us to propose their structures. The precipitated complexes of AMP and GMP by $Me_2Sn(IV)^{2+}$ at low pH values were characterized by elemental analysis and FTIR spectroscopy, which ruled out purine moiety (N-1 and N-7) coordination and a bidentated coordination of the phosphate group is concluded in both cases.

Key words: dimethyltin(IV)dichloride, guanosine 5′-monophosphate, adenosine 5′-monophosphate, stability and protonation constants.

Résumé : Faisant appel à des techniques spectrophotométriques et potentiométriques et opérant en solution aqueuse, à des pH allant de 1,5 à 9, à température (25 °C) et une force ionique constante (0,1 mol dm^{-3} $NaClO_4$), on a déterminé les constantes de formation des espèces qui se forment dans les systèmes H^+ + diméthyléthain(IV) + 5′-AMP (ou + 5′-GMP) et H^+ + 5′-AMP et H^+ + 5′-GMP. Des études par RMN du ^1H et du ^{31}P en solutions aqueuses ont confirmé la formation de ces espèces et permis de proposer leurs structures. Les complexes qui précipitent par réaction du AMP ou du GMP avec du $Me_2Sn(IV)^{2+}$, à des pH faibles, ont été caractérisés par analyse élémentaire et par des méthodes de spectroscopie IR à transformée de Fourier, ce qui a permis d'éliminer la possibilité de coordination dans les positions N-1 et N-7 de la purine et de conclure que dans les deux cas il y a coordination bidentate du groupe phosphate.

Mots clés : dichlorure de diméthylétain(IV), 5′-monophosphate de guanosine, 5′-monophosphate d'adénosine, constante de protonation, constante de stabilité.

[Traduit par la Rédaction]

Introduction

Many organometallic compounds exhibit antitumour activity against several human cancer cells in vitro (1). The mechanism of the antitumour activity of cisplatin, which has already been used clinically in cancer chromotherapy, is believed to be due mainly to the formation of an internal crosslink with DNA involving the N-7 sites of two guanine residues (2). To find a metal-based anticancer drug with higher activity and lower toxicity, many organometallic compounds have been synthesized and tested (1, 3). Organotin(IV) complexes have been shown to have high antitumour activity in vitro in a wide variety of human tumors (4–5), but the antitumour action of the complexes of these types is not well understood. The activity of these compounds led to the hypothesis that these drugs hydrolyze easily in aqueous media and transport the active part (R_2Sn) inside the cells where it possibly reacts with DNA (6). To obtain more information on the molecular basis of the anticancer activity of organotin(IV) compounds, a number of studies have been performed on their interactions with some amino acids, dipeptides, and nucleotides (7–17). Several investigations of the last group indicated that purine moiety is not involved in the coordination, confirming that the interactions are limited to the phosphate site of the ligand. On the other hand, some authors have suggested that the N-1 or N-7 atoms of the base interact with $(CH_3)_2Sn(IV)^{2+}$. Recently, Surdy et al. (18) performed pH-metric titration and Mössbauer studies of dimethyltin(IV) with two classes of amino acids and dipeptides, having either only nitrogen or nitrogen and oxygen donor atoms. According to their results, for the two imidazol-containing N-donor ligands that do not contain carboxylate groups (histamine and glycyl-histamine), no evidence of complex formation was observed with dimethyltin(IV) cation. However, for the ligands containing carboxylate and nitrogen donor groups, complexation occurred and several species were detected. Interactions between mononucleotides and some dialkyltin(IV) derivatives were also investigated (16). In the solid complexes formed in the physiological pH range, dissociation of the N-donor ligands and nucleotide coordination through only the phosphate group were observed (19). Investigation of the solid complexes of adenosine and related ligands formed by $Bu_2Sn(IV)$ proved the coordination through the sugar moiety and phosphate group of the ligands, but the base moiety did not participate in complex formation (17).

Since water is a crucial part of the cellular organization of all animals, we decided to study dimethyltin(IV) ions with adenosine 5′-monophosphate (AMP) and guanosine 5′-monophosphate (GMP) in aqueous solution. Since the organotin cations are strong Lewis acids, it follows that the hydrolytic equilibria should be examined in the presence of noncomplexing anions prior to the study of the interactions of organotin cations with the ligands.

Accepting the hypothesis that R_2Sn^{2+} is the usual active species for antitumour action of organotins (20), a good antitumour agent should be easily dissociable following administration to animals. This requires weak bonds between tin and the donor atom of the coordinated ligands, which are readily hydrolysable. If the compound is hydrolytically unstable the R_2Sn moiety will be released too quickly, but if it is too stable it may be released too slowly and consequently lower activity will be observed. Therefore, there is a relationship between the stability of the organotin compounds and their antitumour activity.

The present work is concerned with the equilibrium of complex formation between $Me_2Sn(IV)^{2+}$ with AMP and GMP in a wide pH range. The formation of three complex species is proposed, of which two were isolated in solid states and characterized using FTIR spectroscopy. To verify the different donor groups in the complexes, ^{1}H NMR and ^{31}P NMR spectroscopy was used in D_2O–H_2O solutions.

Experimental

Chemicals

Dimethyltin(IV)dichloride, sodium salts of adenosine, and guanosine 5′-monophosphate were obtained from Merck and Fluka, respectively, as reagent grade materials and were used without further purification. Sodium perchlorate was obtained from Merck and was dried under vacuum at RT for at least 48 h before use. NaOH solution was prepared from a titrisol solution (Merck) and its concentration was determined by several titrations with standard HCl solution. Perchloric acid (Merck) was used as supplied. The aqueous stock solutions of the ligands were freshly prepared daily and their concentrations were determined each time by titration with NaOH solution. All dilute solutions were prepared from double-distilled water with conductance equal to 1.3 ± 0.1 μS.

Measurements

All measurements were carried out at 25 °C. The ionic strength was maintained at 0.1 mol dm^{-3} with sodium perchlorate. An Eyela pH meter, PHM 2000, was used for pH measurements. The hydrogen ion concentration was measured with an Ingold UO 3234 glass electrode and an Ingold UO 3236 calomel electrode. The pH meter was calibrated for the relevant H^+ concentration with a solution perchloric acid (0.01 mol dm^{-3}) containing sodium perchlorate (0.09 mol dm^{-3}, for adjusting the ionic strength to 0.1 mol dm^{-3}). For this standard solution, we set $-\log[H^+] = 2.00$ (21). Junction potential corrections calculated from eq. [1]

$$[1] \qquad -\log[H^+]_{real} = -\log[H^+]_{measured} + a + b[H^+]_{measured}$$

where a and b were determined by measuring the hydrogen ion concentration for two different solutions of $HClO_4$ with sufficient $NaClO_4$ to adjust the ionic media.

Procedure

Fifty cm^3 of an acidic solution of dimethyltin(IV)dichloride (2.0×10^{-3} mol dm^{-3}) was titrated with an alkali solution (0.1 mol dm^{-3}, NaOH) of the ligands ($1.91–1.97 \times 10^{-3}$ mol dm^{-3} of GMP and $1.78 –1.87 \times 10^{-3}$ mol dm^{-3} of AMP), both of the same ionic strength. The absorbance and $-\log[H^+]$ were measured after the addition of a few drops of titrant and this procedure was extended up to the required $-\log[H^+]$. To exclude carbon dioxide from the system, a steam of purified nitrogen was passed through a sodium chloride solution and then bubbled slowly through the reaction solution. In all cases, the procedure was repeated at least three times and the resulting average values and corresponding deviations from the average are shown in the text and tables.

Spectroscopy measurements

Spectrophotometric measurements were performed on a UV–vis Shimadzu 2100 spectrophotometer using a Pentium 4 computer and thermostated matched 10 mm quartz cells. The measurement cell was of flow type. A Masterflex pump allowed circulation of the solution under study from the potentiometric cell to the spectrophotometric cell so the absorbance and $-\log[H^+]$ of the solution could be measured simultaneously.

^{1}H NMR spectra of the ligand and the complexes were recorded on a Bruker DRX-300 MHz spectrometer in H_2O–D_2O (1:1 by volume) using TMS as an external reference. ^{31}P NMR spectra were recorded on the same spectrometer in H_2O–D_2O (1:9 by volume) operating at RT. The chemical shifts are given relative to phosphoric acid. The solutions were prepared by mixing $Me_2Sn(IV)$ with Na_2(5′-GMP or AMP) in H_2O–D_2O solution to give a 1:1 mole ratio. The concentration of the NMR samples was 1 mmol/L in both ^{1}H and ^{31}P NMR.

Other methods

FTIR spectra were obtained on a Bruker Bomem 100 spectrometer in the range 4000–500 cm^{-1} using KBr pellets. Samples for microanalysis were dried in vacuum to constant mass. Elemental analysis (C, H, N) was performed with a Fison Instruments CHNSO-1108 elemental analyzer.

The stepwise acidity constants of AMP^{-2} and GMP^{-2}

The results obtained using potentiometric pH titrations for the various acidity constants of the proton donors of the ligands, eqs. [2–5], are listed in Table 1 together with some previously reported values. The nucleosides 5′-monophosphate shown in Scheme 1 may bind with two protons at the phosphate group and one at the purine moiety. It was proposed (22) that $H_3(AMP)^+$ and $H_3(GMP)^+$ release their first proton from $-P(O)(OH)_2$, the second one from H^+(N-1) in the case of AMP and H^+(N-7) from GMP, and the third one again from the phosphate group. A fourth proton is released from H^+(N-1) in GMP in the alkaline pH range and from the ribose group in AMP (pH > 13). The fourth deprotonation of AMP was not considered further in this work. The given

Table 1. Protonation constants of different species of GMP and AMP considered in this work.

Species	log $K^{H}_{H3(NMP)}$	log $K^{H}_{H2(NMP)}$	log $K^{H}_{H(NMP)}$	log $K^{H}_{(NMP)}$	Reference
GMP	—	2.48±0.05	6.28±0.08	9.60±0.09	This work
AMP	—	3.94±0.04	6.31±0.06	—	This work
GMP	0.3	2.48	6.25	9.49	22
AMP	0.4	3.84	6.21	—	22
AMP	—	3.98	6.38	—	23

Note: Measurements made by potentiometric pH titrations in aqueous solution at 25 °C and ionic strength 0.1 mol dm^{-3} ($NaClO_4$).

Scheme 1. Structures of adenosine 5′-monophosphate (AMP) and guanosine 5′-monophosphate (GMP).

acidity constants agree well, as far as available, with those reported in recent compilations (22–23).

[2*a*] $H_3(NMP)^+ \leftrightarrows H_2(NMP) + H^+$

[2*b*] $K^{H}_{H3(NMP)} = [H_2(NMP)][H^+] / [H_3(NMP)^+]$

[3*a*] $H_2(NMP) \leftrightarrows H(NMP)^- + H^+$

[3*b*] $K^{H}_{H2(NMP)} = [H(NMP)^-][H^+] / [H_2(NMP)]$

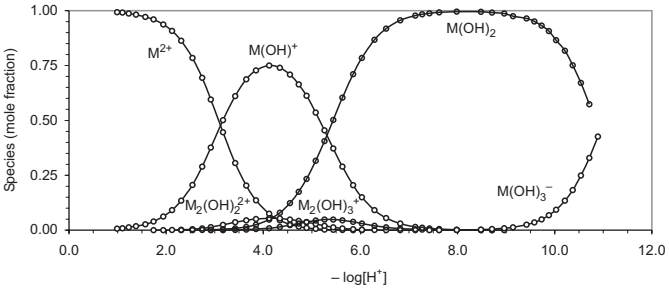
[4*a*] $H(NMP)^- \leftrightarrows (NMP)^{-2} + H^+$

[4*b*] $K^{H}_{H(NMP)} = [(NMP)^{-2}][H^+] / [H(NMP)^-]$

[5*a*] $(NMP)^{-2} \leftrightarrows (NMP\text{-}H)^{-3} + H^+$

[5*b*] $K^{H}_{(NMP)} = [(NMP\text{-}H)^{-3}][H^+] / [(NMP)^{-2}]$

The release of the first proton from $H_3(NMP)^+$ occurs at very low pH. A comparison of the protonation constants listed in Table 1 and those reported by ^1H NMR shift experiments (24) shows that the second proton in H_2(AMP) and H_2(GMP) are released mainly from H^+(N-1) and H^+(N-7), respectively, and the next from the phosphate group; these assignments agree with previous conclusions (25).



Hydrolysis of dimethyltin(IV)dichloride

The hydrolysis of $Me_2Sn(IV)^{+2}$ has been investigated in different media by several authors (26–27). We performed earlier spectrophotometric titrations to obtain these data in various ionic strengths (0.1–1.0 mol dm^{-3}) in $NaClO_4$ and NaCl media (28). The species mole fractions of the observed hydrolyzed species of $Me_2Sn(IV)^{2+}$ in different pH and constant ionic strength (0.1 mol dm^{-3} sodium perchlorate) are shown in Fig. 1. Hydrolysis reactions are (where $M^{2+} = Me_2Sn^{2+}$),

$$M^{2+} + OH^- \Phi M(OH)^+$$

$$M^{2+} + 2OH^- \Phi M(OH)_2$$

Fig. 1. Distribution mole fraction of hydrolytic species of $Me_2Sn(IV)^{2+}$ vs. hydrogen ion concentration at 25 °C and ionic strength 0.1 mol dm^{-3} ($NaClO_4$) ($[Me_2Sn(IV)^{2+}] = 4 \times 10^{-3}$ mol dm^{-3}).

$$M^{2+} + 3OH^- \Phi M(OH)_3^-$$

$$2M^{2+} + 2OH^- \Phi M_2(OH)_2^{2+}$$

$$2M^{2+} + 3OH^- \Phi M_2(OH)_3^+$$

The hydrolysis constants of the hydrolyzed species are determined as before (28) and are listed in Table 2. The detected species and their formation constants are in good agreement with those reported earlier and show the strong tendency of dimethyltin(IV) to hydrolysis in aqueous solution to form various hydrolyzed species (26–28).

Complexation of AMP and GMP by dimethyltin(IV)

One of the main obstacles in studying metal ion systems with nucleotide derivatives in solution is the known self-association of AMP and GMP (29). This means that low concentrations of the ligands must be employed in the experiments, a condition usually fulfilled with UV spectroscopic studies. In similar studies, Sigel and coworkers (22, 30) have demonstrated that in 5 mmol/L and 1 mmol/L solutions, about 95% and 97% of the total GMP or AMP exists in the monomeric form, respectively. With the indicated problems in mind we decided to study the complexes of AMP and GMP with dimethyltin(IV) in aqueous solution by evaluating precise stability data from spectrophotometric titrations.

The complex $M_xH_yL_z^{(2x+y-nz)}$ that formed is characterized by its stoichiometry (x:y:z), where M and L represent the metal ion and AMP or GMP, respectively. To determine the stability constant of the complexation, eq. [6] is defined by β_{xyz} where

[6] $xM^{2+} + yH^+ + zL^{n-} \leftrightarrows M_xH_yL_z^{(2x+y-nz)}$

[7] $\beta_{xyz} = [M_xH_yL_z^{(2x+y-nz)}] / ([M^{2+}]^x[H^+]^y[L^{n-}]^z)$

3.25	8.54	—	5.05	9.81	26
3.12	8.45	19.48	5.2	9.7	27

Note: Measurements of β_{pq} made in aqueous solution at 25 °C and ionic strength 0.1 mol dm^{-3} ($NaClO_4$), where p and q represent $Me_2Sn(IV)$ and hydroxyl ions, respectively. Some literature values are also listed.

The method of determining the stability constant is based on the relation A = f(pH) (21, 31). The absorbance A and $-\log[H^+]$ were measured for a solution containing dimethyltin(IV) and AMP or GMP. Treatments of the spectrophotometric data (each 5 nm) obtained during the titrations, as a function of the H^+ concentration, were analysed by computer program (32). The program calculates the stability constants for different stoichiometry models. The degree of refinement guides the user to a choice between the models.

Considering the protonation constants of the ligands, the predominant species for complexation is H_2L in acidic pH. In this case, the spectrophotometric titration data were analyzed by using the absorbance of AMP or GMP in the presence of dimethyltin(IV) at wavelengths in the UV range that are given by,

$$[8] \quad A = \varepsilon_M[(CH_3)_2Sn(IV)^{2+}] + \Sigma\varepsilon_C[\text{complex}]$$

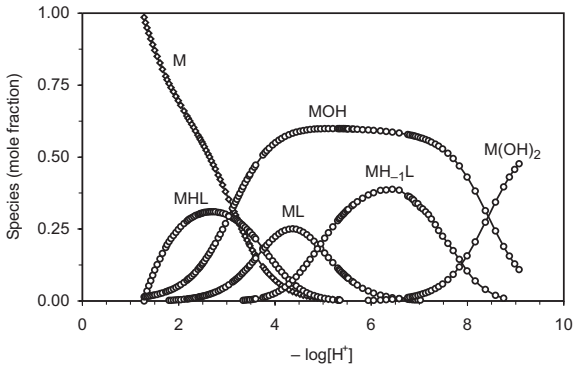
where ε_M and ε_C are the molar absorbance coefficients of the metal ion and each complex, respectively. For the mass balance

$$[9] \quad [(CH_3)_2Sn(IV)^{2+}] = C_M - \Sigma[\text{complex}]$$

$$[10] \quad [H_2L] = C_L - \Sigma[\text{complex}]$$

where C_M and C_L are the total concentrations of the metal ion and each ligand, respectively. Substituting eqs. [7], [9], and [10] into eq. [8] gives the final equation for fitting. Using a suitable computer program (31) we fitted the data to the final equation to estimate the formation constant of eq. [6]. We used the Gauss–Newton nonlinear least-squares method in the computer program to refine the absorbance by minimizing the error squares sum from eq. [11],

$$[11] \quad U = \Sigma(a_i - b_i)^2 \qquad (i = 1, 2, 3, \ldots)$$



Here, a_i is an experimental absorbance and b_i is a calculated one. The computer program used two different kinds of fit, (*a*) graphical and (*b*) numerical. The final selection of the species was based on both graphical and numerical methods and on various statistical criteria, i.e., sums of squared residuals and differences of C_M(exp) and C_L(exp) values from calculated ones.

Different models, including ML, MHL, $MH_{-1}L$, and several polynuclear and protonated species were tested by the program. As expected, polynuclear complexes were systematically rejected by the computer program, as were MH_2L_2, MHL_2, and ML_2 (the charges were omitted for simplicity). A value for the MH_3L species (in both cases of GMP and AMP) was also calculated by the program, but the species was not considered further because the estimated error in its formation constant was unacceptable and its inclusion does not improve the goodness of the fit. The chosen models, formed by MHL, ML, and $MH_{-1}L$ for AMP and GMP, besides the hydrolysis products of $Me_2Sn(IV)^{2+}$, resulted in satisfactory numerical and graphical fits. The calculated average values of the stability constants for various wavelengths are listed in Table 3.

Table 3. Average values of the stability constants for the systems $Me_2Sn(IV)^{2+}$ + AMP and GMP at 25 °C and ionic strength 0.1 mol dm^{-3} ($NaClO_4$).

Species	$\log \beta_{111}$	$\log \beta_{101}$	$\log \beta_{1-11}$
AMP	5.69±0.11	2.56±0.01	8.47±0.05
GMP	5.59±0.09	4.19±0.04	7.75±0.06

Fig. 2. Species distribution diagram of the $Me_2Sn(IV)$-AMP system ($[Me_2Sn(IV)] = 2 \times 10^{-3}$ mol dm^{-3} and [AMP] = 1.87×10^{-3} mol dm^{-3}) at 280 nm, 25 °C and 0.1 mol dm^{-3} $NaClO_4$.

During the spectrophotometric titration of AMP and GMP by dimethyltin(IV), no precipitation was observed (under the conditions of the UV–vis measurements). The species distribution curves depicted in Figs. 2 and 3 reveal similar behaviour for the two ligands towards $(CH_3)_2Sn(IV)^{2+}$ and demonstrate that complexes with a 1:1 ligand to metal ion ratio were formed. There was no evidence of the presence of polynuclear species in solution.

Figures 4 and 5 exhibit the ^1H NMR spectra of methyl signals at different pH values. As can be seen, the $^2J(Sn\text{-}^1H)$ values increase with increasing pH in NMR titration, which indicate that a complex species besides $(CH_3)_2Sn(IV)$ exists in solution. This species is most probably MH_2L, which forms on the monodentate coordination of the ligands through their phosphate groups. At such a low pH value (<1), it was very difficult to fit the species matrix and determine the stability constant of this species. However, at higher pH (pH ≅ 1.5–4.5 for AMP and 1.5–3 for GMP) the MHL species is formed from MH_2L on deprotonation of H^+(N-1) and H^+(N-7) on the purine bases of AMP and GMP, respectively (MH_2L Φ MHL + H^+). The species formed at different pH values were found to be in different protonation

In (*a*) curves a–f represent pH 10.01, 8.05, 6.47, 5.1, 3.39, and 1.96, respectively; in (*b*) curves a–f represent pH 9.01, 8.38, 7.3, 5.95, 4.43, and 1.96, respectively; in (*c*) curves a–f represent pH 8.57, 6.95, 5.81, 4.68, 3.76, and 1.97, respectively.

states. In the acidic and neutral pH range, two deprotonation processes take place for both systems (pH ≅ 2.5–6 and 4–8 for AMP; pH ≅ 2–7 and 4.5–9 for GMP, respectively) resulting in formation of the ML and $MH_{-1}L$ species, MHL Φ ML + H^+, and ML Φ $MH_{-1}L$ + H^+. The first reaction is due to the deprotonation of the second OH of the phosphate group and the second reaction is attributed to the deprotonation of a coordinated H_2O molecule, resulting in the formation of a

Fig. 5. Measured coupling constants, $^2J(Sn\text{-}^1H)$, of Me protons as a function of pH in solutions of (*a*) 1:1 $Me_2Sn(IV)$-AMP system, (*b*) 1:1 $Me_2Sn(IV)$-GMP system, and (*c*) $Me_2Sn(IV)$ alone.

mixed hydroxo complex (Figs. 2 and 3). Evaluation of the titration curves shows that only the hydrolyzed species, $M(OH)_2$, is present at higher pH (pH ≅ 8–9).

Lockhart and Manders studied the correlation of $^2J(Sn\text{-}^1H)$ and the Me–Sn–Me angle in 25 methyltin(IV) compounds (33). They proposed an empirical quadratic expression in terms of $^2J(Sn\text{-}^1H)$ to determine the C–Sn–C angle. It was found that these values provide useful information on the C–Sn–C bond angle of the compounds in a sample and indirectly on the possible coordination numbers and geometry around the Sn atom.

Two-bond coupling, $^2J(Sn\text{-}^1H)$, of the $Me_2Sn(IV)^{2+}$ alone and its complexes with AMP and GMP were determined via the ^1H NMR spectra at different pH. It can be seen (Fig. 4) that the signals of the methyl protons in $Me_2Sn(IV)^{2+}$ are sharp for both systems and have the same chemical shift as in the solution of $Me_2Sn(IV)^{2+}$ alone. The ^1H NMR titration vs. pH of 1:1 mixtures of $Me_2Sn(IV)^{2+}$ and GMP or AMP, on the other hand, do not show any shift of the adjacent to N-1 and N-7 protons of the ligands in the pH range 1.5–9, thus excluding Sn(IV) interaction with the nitrogen of the purine ring. In similar studies, the same results were observed by Yang et al. (34) and Jankovics et al. (19) in ^1H NMR and ^{119}Sn Mössbauer spectra for the systems $Et_2Sn(IV)^{2+}$ + 5′-GMP, 5′-IMP, and $Me_2Sn(IV)^{2+}$+ R5P, GIP, G6P, respectively. At higher pH the $^2J(Sn\text{-}^1H)$ values of $Me_2Sn(IV)^{2+}$ are somewhat smaller than complex systems (Fig. 5), possibly because of a slight distortion of C–Sn–C angle by the coordinated ligand (33). Using the quadratic equation of Lockhart and Manders (33), the average C–Sn–C bond angle at low pH (<2) and higher pH values (>6) for the two species calculated from the coupling constant are 175 and 135 °, respectively. On this basis, $Me_2Sn(IV)^{2+}$ and their complexes with AMP and GMP are proposed to have an octahedral structure at low pH and a distorted trigonal bipyramidal structure at higher pH, as shown in Scheme 2.

Figures 6 and 7 present the ^{31}P NMR chemical shifts (δ) of the $Me_2Sn(IV)^{2+}$ and the complexes with AMP and GMP in 1:1 stoichiometries in aqueous solution as a function of pH. For the free ligand the chemical shifts of P slightly increase with increasing pH up to two and this can be attributed to the deprotonation of P-OH and delocalization of negative charge over the P moiety. Interestingly, a further increase of pH to four has no effect on chemical shifts. However, pH values higher than five facilitate further deprotonation and the delocalization of remaining P-OH and

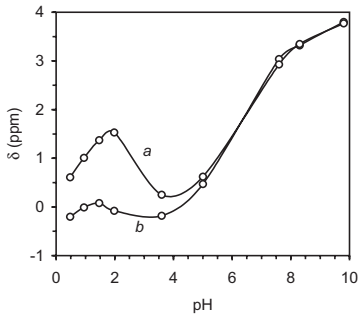

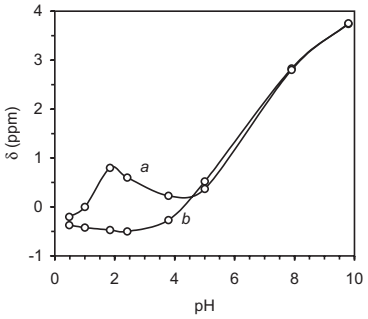

Fig. 7. The ^{31}P chemical shifts vs. pH of (*a*) AMP and (*b*) the mixtures with $Me_2Sn(IV)$.

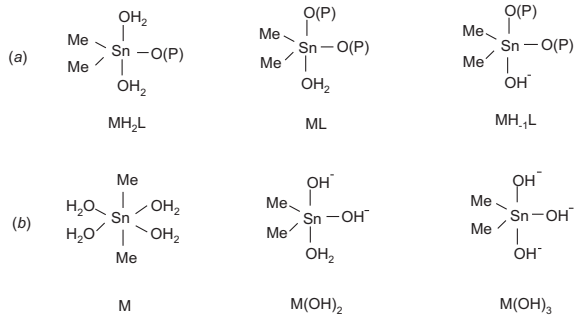

consequently large down field shifts accrue. It is seen that the presence of $Me_2Sn(IV)^{2+}$ causes an upfield shift in ^{31}P NMR signals of AMP and GMP to a maximum of about 1.5–2 ppm at pH ~2 for both systems, indicating a Sn(IV) interaction with the pyrophosphate groups. At about pH 3, precipitation starts at higher concentrations. In aqueous solution, it has been suggested that $Me_2Sn(IV)^{2+}$ reacts with phosphate ions to form solid complexes (11, 34). At pH > 6.5, the ^{31}P NMR chemical shift of the free ligands and their mixtures with $Me_2Sn(IV)^{2+}$ present no significant difference and this leads to the conclusion that no tin–phosphate interaction is taking place.

Characterization of the $Me_2Sn(IV)^{2+}$-AMP and GMP precipitates

When the concentration of the ligands is higher than 0.005 mol dm^{-3}, a white precipitate is formed in the pH range 3–5 during the titration of both GMP and AMP by dimethyltin(IV). The hydrolysis products of dimethyltin(IV) are soluble at this concentration and there was no precipitation during the titration of the ligands alone. So, we concluded that the solid products were attributed to the formation of MHL and ML species. The precipitates were collected by filtration, dried at RT by vacuum, and characterized by means of FTIR. The metal to ligand ratio in $Me_2Sn(IV)^{2+}$-AMP and -GMP were determined by elemental analysis (found C 27.03, H 4.02, N 13.06 and C 26.24, H 3.92, N 12.75 for AMP and GMP, respectively, that were calculated for Me_2Sn-AMP,$2H_2O$ [$C_{12}H_{22}N_5O_9PSn$] C 27.18, H 4.15, N 13.22 and Me_2Sn-GMP,$2H_2O$ [$C_{12}H_{22}N_5O_{10}PSn$] C 26.39, H 4.03, N 12.83). These results indicate the formation of complexes with 1:1 metal to ligand ratio. The characteristic IR bands of GMP, AMP, dimethyltin(IV)-GMP, and dimethyltin(IV)-AMP are listed in Table 4.

Scheme 2. Proposed structure of (*a*) the complexes and (*b*) the hydrolyzed species of dimethyltin(IV).

The intensive and broad band in the region 3500–2600 cm^{-1} due to ν(OH) and ν(NH_2) stretching vibrations of the sugar OH groups and the purine moiety is observed in the spectra of the ligands and the precipitates (19). The intensity of the band is lower in the spectra of the complexes, but their shapes are identical. From this, coordination of the ligands through their sugar moiety can be excluded (19). The skeleton vibrations of the purine rings of the nucleotides in the region 1609–1481 cm^{-1} do not shift in the complexes, indicating the nonexistence of any metal ion with the ring nitrogen atoms interactions (34). On the other hand, considerable changes were observed in phosphate stretching in the range 1200–970 cm^{-1} of the free ligands and the complexes. This can be explained by the binding of tin to the oxygen of the phosphate.

© 2006 NRC Canada

The arrangement mentioned above confirms that the phosphate group in both cases coordinate to dimethyltin(IV) and the ring nitrogen atoms do not participate in the coordination. These findings are in agreement with earlier results for similar systems (6, 9, 17, 34).

Efficient Ru^{III}-catalyzed condensation of indoles and aldehydes or ketones

Khalil Tabatabaeian, Manouchehr Mamaghani, Nosratollah Mahmoodi, and Alireza Khorshidi

Abstract: Synthesis of bis(indolyl)methanes through condensation of indoles and various aldehydes or ketones, using Ru^{III} as catalyst, is reported. It was found that the catalytic system involving Ru^{III} affords the products smoothly under very mild conditions in good to high yields.

Key words: aldehydes, ketones, bis(indolyl)methanes, indoles, ruthenium.

Résumé : Utilisant du Ru(III) comme catalyseur, on a réalisé la synthèse de bis(indolyl)méthanes par le biais de la condensation d'indoles et de divers aldéhydes ou cétones. On a trouvé que le système catalytique impliquant du Ru(III) permet d'obtenir facilement les produits dans des conditions douces et avec des rendements allant de bon à élevés.

Mots clés : aldéhydes, cétones, bis(indolyl)méthanes, indoles, ruthénium.

[Traduit par la Rédaction]

Introduction

Transition metal-catalyzed C–H bond activation has received considerable attention in synthetic organic chemistry since the cleavage of an unreactive C–H bond and subsequent addition of the C–H unit into unsaturated substrates could lead to the formation of a new C–C bond (1). The formation of a C–C bond is one of the most fundamental projects in organic chemistry. Much effort has naturally been devoted to developing more convenient and efficient strategies for the formation of C–C bonds. During the last two decades, many successful applications of catalytic C–H bond activation directed toward the construction of C–C bonds have been reported in synthetic communities (2).

The development of new efficient synthetic methods leading to indole derivatives continues to receive much attention in organic synthesis because of their biological activities (3). Various indole derivatives occur in many pharmacologically and biologically active compounds (4). Among of them, bis(indolyl)methanes possess a wide range of biological activity and their synthesis has received a considerable amount of interest (5, 6). Generally, bis(indolyl)methanes are prepared by the condensation of indoles with various aldehydes or ketones in the presence of either protic (7) or Lewis acids (8–10). On the other hand, Ru^{III} salts are well-known to catalyze many organic transformations, including aldol and Michael reactions (11), oxidation reactions of alkanes (12), oxidative cyanation of amines (13), and many others (14). We found that Ruthenium (III) chloride hydrate is a very effective catalyst for the double addition of indoles to aldehydes or ketones, yielding bis(indolyl) derivatives in high yields. The ruthenium catalyst was used in low concentrations (as low as 1.2 mol%) and a relatively easy work-up affords catalytic formation of a carbon–carbon bond under mild reaction conditions. To the best of our knowledge, this is the first report on the use of Ru^{III} salts as catalyst for the condensation of indoles with various aldehydes or ketones.

Results and discussion

Typical results of the ruthenium-catalyzed condensation of indoles and aldehydes or ketones are shown in Tables 1 and 2 and they indicate the scope of the reaction. Treatment of benzaldehyde (1.2 mmol) with indole (2 mmol) in the presence of $RuCl_3 \cdot nH_2O$ catalyst (1.2 mol%) in methanol (2 mL) at RT for 27 min gave the corresponding 3,3′-bis(indolyl)phenylmethane in 92% yield (product 1a). No attempts were made to characterize byproducts since they are formed in trace amounts (using GLC analysis). The reaction can be used for substituted aromatic aldehydes with either electron-donating or electron-withdrawing groups (Table 1, entries b–e). Furthermore, the reaction of indole with aliphatic aldehydes furnished high yields of the corresponding product class (Table 1, entries f and g).

Encouraged by these results, we studied the condensation reaction between indole and some ketones. The method is highly chemoselective, as ketones do not participate in the reaction in ambient conditions. This selectivity might be useful in the reaction of multifunctional carbonyl compounds with indole since they have both aldehyde and ketone functionalities. However, the method is still effective enough to afford the condensation products of indole and ketones through reflux of the reaction mixture (Table 1, entries h–l) in good yields.

[cde]Identified by comparison with authentic samples (15, 16, 8).

With regard to the indole moiety, the present protocol is noteworthy because substituted indoles underwent smooth reactions with aromatic aldehydes giving excellent yields of products (Table 2). For example, treatment of 1-, 2-, and 5-substituted indoles with various aromatic aldehydes gave corresponding products **2a**–**2f**, most of them insoluble in the reaction media (solvent methanol) and this makes the work-up even easier (see Experimental section). Also, the reaction times for 1- and 2-substituted indoles are much less than those of unsubstituted substrates.

The reaction of indole and benzaldehyde was taken as a representative example and the progress of the reaction was monitored by GLC technique. To examine the influence of the catalyst concentration, we also carried out the reaction of benzaldehyde and indole in different catalyst concentrations. Due to the decomposition of the products under chromatographic conditions, decrease in the corresponding aldehyde peak areas was selected as a measure of reaction coordinate. Also, the peak of methanol was used as internal standard. The results are summarized in Table 3.

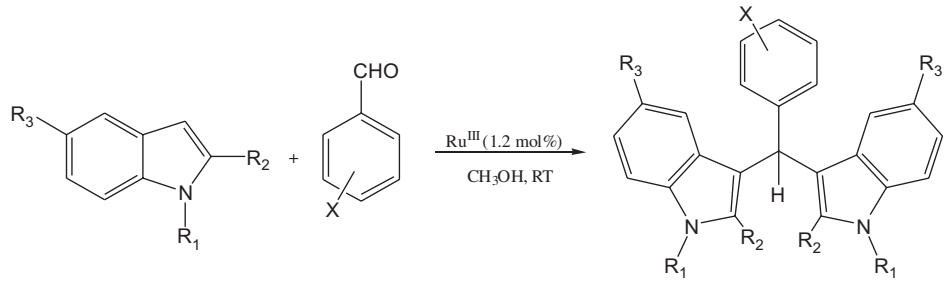
These results reveal that the Ru^{III} system is at least four times more effective than the previously reported catalytic system using Fe^{III} in ionic liquids (15) in terms of utilized catalyst concentration (1.2% vs. 5%). Also, the catalytic activity is nearly ten times greater in terms of reaction time (3 min vs. 30 min in ~5 mol% of catalyst).

Conclusion

In brief, we have developed a convenient method for the synthesis of bis(indolyl)methanes using the condensation reaction of indoles and aldehydes or ketones in the presence of $RuCl_3 \cdot nH_2O$ as efficient catalyst. With regard to the previous works, the present protocol has several advantages. As the reaction solvent, methanol has lower toxicity in contrast to CH_3CN (8–10). In the reaction of substituted indoles with aromatic aldehydes, the products are mainly insoluble in methanol, therefore simple filtration of the reaction mixture and rinsing with methanol provides completely pure products. The unique feature of the reaction is selectivity between ketones and aldehydes at ambient temperature while the other methods catalyze the reaction of both aldehydes and ketones at room temperature (8–10) or only catalyze the reaction of aldehydes (15). Further manipulation of this reaction is underway.

Experimental

General



IR spectra were recorded on a Shimadzu FTIR-8400S spectrometer. ^1H NMR spectra were obtained on a Bruker DRX-500 Avance and ^{13}C NMR spectra were obtained on a Bruker DRX-125 Avance. Chemical shifts of ^1H and ^{13}C NMR spectra were expressed in parts per million downfield from tetramethylsilane. Analytical GLC evaluations of product mixtures were carried out on a Varian CP-3800 chromatograph (using a split/splitless injector, CP Sil 8CB column, FID assembly). Melting points were measured on a BÜCHI Melting Point B-540 and are uncorrected. Elemental analyses were made with a Carlo-Erba EA1110 CNNO-S analyzer and agreed with the calculated values.

Materials

HPLC grade methanol was used as solvent and all other materials were purchased from Merck and used without further purification.

Ruthenium-catalyzed condensation of benzaldehyde and indole

A 20 mL flask equipped with a magnetic stirring bar was charged with methanol (2 mL), benzaldehyde (127.4 mg, 1.2 mmol), and indole (234.4 mg, 2 mmol). $RuCl_3 \cdot nH_2O$ (3 mg, 0.014 mmol) was added into the flask and the reaction mixture was stirred at RT. After 0.5 h, the reaction mixture was purified by preparative TLC (petroleum ether – ethyl acetate, 10:4) providing a pure product (296 mg, 92%). The same procedure was also used for the other products listed in Tables 1 and 2. In the case of entries a–e in Table 2, simple filtration of the reaction mixture and treatment with methanol provided pure products.

3,3′-Bis(indolyl)methyl-4-nitrophenylmethane (1k)

Solid, mp 250 to 251 °C. IR (KBr, cm^{-1}) υ: 422, 457, 551, 582, 636, 700, 744, 770, 808, 862, 1008, 1107, 1245, 1338, 1409, 1458, 1504, 1591, 2923, 2981, 3045, 3409 (NH). ^{1}H NMR (500 MHz, $(CD_3)_2SO$, 25 °C, ppm) δ: 2.04 (s, 3H), 6.42 (d, *J* = 2.42 Hz, 2H), 6.54 (t, *J* = 7.60 Hz, 2H), 6.76 (t, *J* = 7.60 Hz, 2H), 6.87 (d, *J* = 8.07 Hz, 2H), 7.07 (d, *J* = 8.17 Hz, 2H), 7.28 (d, *J* = 8.94 Hz, 2H), 7.75 (d, *J* = 8.87 Hz, 2H), 9.98 (br, s, 2H, NH). ^{13}C NMR (125 MHz, $(CD_3)_2SO$, 25 °C, ppm) δ: 29.16, 44.25, 111.91, 118.64, 121.22, 121.37, 122.24, 123.02, 124.01, 126.16, 129.32, 137.59, 145.99, 156.70. Anal. calcd. for $C_{24}H_{19}N_3O_2$: C 75.57, H 5.02, N 11.02; found: C 75.52, H 5.05, N 11.06.

3,3′-Bis(indolyl)diphenylmethane (1l)

Solid. IR (KBr, cm^{-1}) υ: 426, 487, 580, 607, 624, 702, 742, 815, 1012, 1033, 1101, 1242, 1336, 1373, 1413, 1456, 1485, 1606, 1720, 2850, 2920, 3053, 3407 (NH). ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 6.80–6.85 (m, 4H), 6.87 (d, *J* = 2.47 Hz, 2H), 7.10–7.15 (m, 3H), 7.20–7.27 (m, 5H), 7.34–7.37 (m, 6H), 7.95 (br, s, 2H, NH). ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C, ppm) δ: 54.65, 111.61, 112.30, 119.48, 120.05, 121.96, 122.96, 126.39, 127.89, 128.16, 130.56, 137.26, 146.39. Anal. calcd. for $C_{29}H_{22}N_2$: C 87.41, H 5.56, N 7.03; found: C 87.44, H 5.60, N 6.99.

3,3′-Bis(1-methyl-indolyl)phenylmethane (2a)

Solid, mp 199–201 °C. IR (KBr, cm^{-1}) υ: 428, 518, 572, 702, 742, 769, 800, 1010, 1118, 1130, 1150, 1199, 1224, 1238, 1328, 1369, 1425, 1475, 2933, 3020, 3053. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 3.73 (s, 6H), 5.95 (s, 1H), 6.59 (s, 2H), 7.06 (t, *J* = 7.72 Hz, 2H), 7.21–7.28 (m, 3H), 7.31–7.37 (m, 4H), 7.41 (d, *J* = 5.32 Hz, 2H), 7.44 (d, *J* = 7.90 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C, ppm) δ: 33.11, 40.52, 109.48, 118.70, 119.07, 120.48, 121.85, 126.45, 127.90, 128.63, 128.70, 129.13, 137.85, 144.89. Anal. calcd. for $C_{25}H_{22}N_2$: C 85.68, H 6.33, N 7.99; found: C 85.69, H 6.33, N 8.01.

3,3′-Bis(1-methyl-indolyl)-4-isopropylphenylmethane (2b)

Solid, mp 147–149 °C. IR (KBr, cm^{-1}) υ: 426, 567, 595, 676, 738, 767, 804, 860, 1010, 1105, 1153, 1222, 1261, 1326, 1369, 1421, 1465, 1510, 1548, 1612, 2871, 2925, 2958, 3049. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 1.30 (d, *J* = 6.90 Hz, 6H), 2.95 (sep, *J* = 6.90 Hz, 1H), 3.74 (s, 6H), 5.92 (s, 1H), 6.62 (s, 2H), 7.06 (t, *J* = 7.20 Hz, 2H), 7.18 (d, *J* = 7.90 Hz, 2H), 7.26 (t, *J* = 8.00 Hz, 2H), 7.31–7.35 (m, 4H), 7.46 (d, *J* = 7.90 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C, ppm) δ: 24.50, 33.11, 34.09, 40.09, 109.45, 118.97, 118.99, 120.54, 121.78, 126.63, 127.97, 128.61, 128.90, 137.84, 142.12, 146.76. Anal. calcd. for $C_{28}H_{28}N_2$: C 85.67, H 7.19, N 7.14; found: C 85.70, H 7.20, N 7.15.

3,3′-Bis(1-methyl-indolyl)-3-methoxy-4-hydroxyphenylmethane (2c)

Solid, mp 147–149 °C. IR (KBr, cm^{-1}) υ: 426, 505, 690, 738, 779, 804, 869, 1010, 1026, 1116, 1199, 1220, 1251, 1267, 1326, 1369, 1427, 1508, 1612, 2935, 3490. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 3.74 (s, 6H), 3.84 (s, 3H), 5.56 (s, 1H), 5.88 (s, 1H), 6.59 (s, 2H), 6.86 (d, *J* = 8.14 Hz, 1H), 6.89 (d, *J* = 8.14 Hz, 1H), 6.96 (s, 1H), 7.07 (t, *J* = 7.35 Hz, 2H), 7.27 (t, *J* = 7.21 Hz, 2H), 7.36 (d, *J* = 8.12 Hz, 2H), 7.46 (d, *J* = 7.85 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C, ppm) δ: 33.13, 40.22, 56.35, 109.50, 111.86, 114.41, 118.94, 119.05, 120.51, 121.68, 121.84, 127.88, 128.68, 136.99, 137.85, 144.20, 146.75. Anal. calcd. for $C_{26}H_{24}N_2O_2$: C 78.76, H 6.10, N 7.07; found: C 78.81, H 6.15, N 7.10.

3,3′-Bis(2-methyl-indolyl)-4-isopropylphenylmethane (2e)

Solid, mp 224–226 °C. IR (KBr, cm^{-1}) υ: 451, 493, 582, 599, 740, 784, 833, 1016, 1220, 1244, 1299, 1342, 1423, 1458, 1510, 2920, 2956, 3049, 3396 (NH), 3438. ^{1}H NMR (500 MHz, $(CD_3)_2SO$, 25 °C, ppm) δ: 0.94 (d, *J* = 6.90 Hz, 6H), 1.78 (s, 6H), 2.59 (sep, *J* = 6.90 Hz, 1H), 5.63 (s, 1H), 6.44 (t, *J* = 8.04 Hz, 2H), 6.62–6.65 (m, 4H), 6.77 (d, *J* = 8.12 Hz, 2H), 6.86 (d, *J* = 8.04 Hz, 2H), 6.93 (d, *J* = 8.05 Hz, 2H), 9.50 (br, s, 2H, NH). ^{13}C NMR (125 MHz, $(CD_3)_2SO$, 25 °C, ppm) δ: 12.51, 24.36, 33.72, 38.93, 110.44, 113.13, 118.36, 119.16, 119.96, 126.04, 128.99, 129.03, 132.41, 135.49, 141.68, 146.35. Anal. calcd. for $C_{28}H_{28}N_2$: C 85.67, H 7.19, N 7.14; found: C 85.69, H 7.17, N 7.14.

3,3′-Bis(5-bromo-indolyl)phenylmethane (2f)

Solid, mp 246–248 °C. IR (KBr, cm^{-1}) υ: 420, 487, 584, 609, 659, 703, 732, 750, 771, 800, 858, 871, 881, 979, 1099, 1217, 1334, 1417, 1442, 1460, 1560, 1596, 3417 (NH). ^{1}H NMR (500 MHz, $(CD_3)_2SO$, 25 °C, ppm) δ: 5.14 (s, 1H), 6.11 (d, *J* = 1.94 Hz, 2H), 6.52 (dd, *J* = 8.57, *J* = 10.73 Hz, 2H), 6.59 (t, *J* = 7.00 Hz, 1H), 6.65–6.71 (m, 6H), 6.75 (d, *J* = 1.40 Hz, 2H), 10.13 (br, s, 2H, NH). ^{13}C NMR

Phenolic compounds from *Mammea siamensis* seeds

Surat Laphookhieo, Wisanu Maneerat, and Rattana Kiattansakul

Abstract: The investigation of dichloromethane and acetone extracts of the seeds of *Mammea siamensis* led to the isolation of a novel phenolic compound, siamensone A (**1**), together with three known compounds, suragin B (**2**), mammea E/BB (**3**), and δ-tocotrienol (**4**). The structures of the isolates were characterized by spectroscopic methods, and all compounds were reported for the first time as metabolites of *M. siamensis*.

Key words: Mammea siamensis, siamensone, coumarins.

Résumé : Une étude des produits d'extraction des graines de *Mammea siamensis* par le dichlorométhane et l'acétone a permis d'isoler un nouveau produit phénolique, la siamensone A (**1**), aux côtés de trois composés déjà connus, la suragine B (**2**), la mammea E/BB (**3**) et le δ-tocotriénol (**4**). Les structures des composés isolés ont été déterminées par des méthodes spectroscopiques et tous les composés ont été caractérisés pour la première fois comme métabolites de *M. siamensis*.

Mots clés : Mammea siamensis, siamensone, coumarines.

[Traduit par la Rédaction]

Introduction

Mammea belongs to the family of Guttiferae, typically found in several southeast asian countries. Two species are found in Thailand, *M. siamensis* (syn. *Ochrocarpus siamensis*) and *M. harmandii* (1). The flowers of *M. siamensis* have been used as a heart tonic in local medicine. A number of secondary metabolites have been isolated from both species (2–8). Our previous phytochemical studies of Thai medicinal plants led to the isolation and identification of xanthones (9), triterpenoids (10–12), cardenolide glycosides (13), and diterpenes (14). As a continuation of our studies on Thai medicinal plants, we now report the isolation of a novel chromone, siamensone A (**1**) and three other known compounds (**2**–**4**) from the seeds of *M. siamensis*. In addition, the ^{13}C NMR spectral data of **2** and **3** is also reported for the first time.

Results and discussion

The dichloromethane and acetones extracts of the seeds of *M. siamensis* were subjected to column chromatography to give a new compound (**1**) together with three other known compounds (**2**–**4**) shown in Chart 1. Their structures were elucidated using 1D and 2D NMR spectroscopic data and compared with those reported in the literature.

Siamensone A (**1**), yellowish solid, is a 6,8-dihydroxy-2-*sec*-butyl-4*H*-chromen-4-one. Its molecular formula of $C_{13}H_{14}O_4$ with a molecular ion $[M]^+$ at *m/z* 234.0877 (calc. $C_{13}H_{14}O_4$ *m/z* 234.0892) was established by HR-EIMS analysis. This compound exhibited UV absorption maxima at 225, 248, 300, and 337 nm, suggesting the presence of conjugation in the molecule. The IR spectrum showed absorption bands of OH stretching at 3399 cm^{-1} and C=O stretching at 1714 cm^{-1}. The ^{13}C NMR spectrum also showed the resonance of a carbonyl carbon at δ: 182.7 (C-4). The ^{1}H NMR spectrum (Table 1) displayed the characteristic signals of *meta*-coupled aromatic protons at δ: 6.32 (d, *J* = 2.1 Hz, H-5) and 6.24 (d, *J* = 2.1 Hz, H-7) and a singlet signal of an olefinic proton at δ: 6.00 (*s*, H-3). With combination of the COSY spectrum, a *sec*-butyl moiety was evident from ^{1}H NMR signals at δ: 2.58 (sextet, *J* = 6.9 Hz, H-1′), 1.70–1.80 (m, H-2′a), 1.55–1.65 (m, H-2′b), 1.27 (d, *J* = 6.9 Hz, Me-4′), and 0.93 (t, *J* = 7.5 Hz, Me-3′). The *sec*-butyl moiety was located at C-2 position based on Heteronuclear Multiple Bond Correlations (HMBC) (Table 1). The singlet methine proton signal at δ: 6.00 (H-3) correlated to C-1′ (40.4), and a sextet methine proton at δ: 2.58 (H-1′) correlated to C-2 (174.2) and C-3 (106.7). The other HMBC correlations were summarized in Table 1. Therefore, compound **1** was deduced to be siamensone A.

The remaining compounds were characterized as suragin B (**2**) (15, 16), mammea E/BB (**3**) (16), and δ-tocotrienol (**4**) (17) by the analysis of 1D and 2D NMR data and by comparison with their reported physical and spectroscopic data. In addition, the complete assignments of ^{13}C NMR of

suragin B (**2**) and mammea E/BB (**3**) are also reported here for the first time (Table 2).

Experimental section

General experimental procedures

Melting points were determined using a Fisher–Johns melting point apparatus. The optical rotation $[\alpha]_D$ values were determined with a JASCO P-1020 polarimeter. UV spectra were measured with a UV-160A spectrophotometers (Shimadzu, Kyoto, Japan). The IR spectra were measured with a PerkinElmer FTS FTIR spectrophotometer. The ^{1}H and ^{13}C NMR spectra were recorded using 400 and/or 300 MHz Bruker FTNMR Ultra Shield spectrometers. Chemical shifts were recorded in ppm (δ) in $CDCl_3$ with tetramethylsilane (TMS) as an internal reference. The EIMS was obtained from a MAT 95 XL mass spectrometer. Quick column chromatography (QCC) (18, 19) and column chromatography (CC) were carried out on silica gel 60 H (Merck, Rahway, NJ; 5–40 μm) and silica gel 100 (Merck, Rahway, NJ; 63–200 μm), respectively. Precoated plates of silica gel 60 F_{254} were used for analytical purposes.

Plant material

The seeds of *M. siamensis* were collected from Mae Fah Luang University, Tasud, Muang, Chiang Rai province, northern part of Thailand in August 2005. Plant identification was made by Professor Puangpen Sirirugsa, Department of Biology, Faculty of Science, Prince of Songkla University, and the voucher specimen (No. SC09) was deposited at Prince of Songkla University Herbarium.

Extraction and isolation

The seeds (224.5 g) of *M. siamensis* were extracted with dichloromethane and acetone, respectively, at room temperature (each for 5 days) and evaporated under reduced pressure to provide dichloromethane extract (44.4 g) and acetone extract (30.5 g). The dichloromethane extract (44.4 g) was chromatographed by QCC (column size: 12 × 16 cm) and eluted with EtOAc–hexane mixtures to give seven fractions (F1–F7). Fraction F4 (3.35 g) was separated by CC with EtOAc–hexane (3:17) followed by RP-18 preparative TLC with MeOH–H_2O (4:1) to afford five subfractions (F4a–F4e). Subfraction F4d (1.02 g) was purified by RP-18 CC with MeOH–H_2O (4:1) followed by CC with EtOAc–hexane (1:3) to afford compound **1** (12.7 mg).

The acetone extract (30.5 g) was chromatographed by QCC (column size: 12 × 16 cm) and eluted with hexane–acetone (5:1) to give seventeen fractions (F1–F17), of which fractions F8–F10 (1.5 g) gave compound **2**. Fraction F2 (4 g) was subjected to repeated QCC with hexane–acetone mixtures (95% hexane–acetone to 100% acetone) to afford compound **2** (104 mg) and 5 subfractions (F2-1–F2-5). A portion (450 mg) of subfraction F2-2 (1.05 g) was subjected to repeated CC with 10% EtOAc–hexane to afford fourteen subfractions (F2-2A–F2-2N). Compound **4** (7.7 mg) was ob-

Medium effects on the α-effect in DMSO–H_2O mixtures — Comparative studies of *p*-nitrophenyl benzoate and acetate — Dissection of ground-state and transition-state effects

Ik-Hwan Um, Young-Hee Shin, Jeong-Yoon Han, and Erwin Buncel

Abstract: In a study of the origin of the α-effect and its dependence on the nature of the reaction medium as well as structural effects, we report herein a kinetic study of the reactions of *p*-nitrophenyl benzoate (PNPB) with butan-2,3-dione monoximate (Ox^-, α-nucleophile) and *p*-chlorophenoxide (*p*-$ClPhO^-$, the reference nucleophile) in dimethyl sulfoxide (DMSO)–H_2O mixtures of varying compositions at 25.0 ± 0.1 °C. The second-order rate constants (k_N) decrease modestly on addition of DMSO to the medium up to 10 mol% DMSO but increase significantly beyond that point for both nucleophiles. Ox^- is more reactive than *p*-$ClPhO^-$ in all solvent mixtures studied (i.e., the α-effect). The α-effect increases as the DMSO content in the medium increases up to 40 mol% DMSO and then decreases beyond that point resulting in a bell-shaped α-effect profile. The bell-shaped α-effect profile obtained for the current reaction is similar to that found previously for the corresponding reaction of *p*-nitrophenyl acetate (PNPA), differing notably however, in the magnitude of the α-effect beyond 40 mol% DMSO. The PNPB/*p*-$ClPhO^-$ reaction gains greater rate enhancement than the PNPA/*p*-$ClPhO^-$ reaction in the DMSO-rich region, resulting in the smaller α-effect for PNPB beyond 40 mol% DMSO. It is proposed that the observed modulation of the α-effect by the solvent medium is explicable as a ground-state effect in the H_2O-rich region and a transition-state effect in the DMSO-rich region.

Key words: medium effect, the α-effect, ground state, transition state, solvation, desolvation.

Résumé : Dans le cadre d'une étude sur l'origine de l'effet α et de sa dépendance sur la nature du milieu réactionnel ainsi que des effets structuraux, on a réalisé une étude cinétique des réactions du benzoate de *p*-nitrophényle (BPNP) avec le monoximate de la butane-2,3-dione (Ox^-, α-nucléophile) et le *p*-chlorophénolate (*p*-$ClPhO^-$, le nucléophile de référence), dans des mélanges de diméthylsulfoxyde (DMSO)–eau (H_2O) de compositions variables, à 25,0 ± 0,1 °C. Jusqu'à une concentration de 10 mole %, les constantes de vitesse du deuxième ordre (k_N) diminuent légèrement par addition de DMSO; au-delà de ce point, elles augmentent toutefois d'une façon significative pour les deux nucléophiles. Le nucléophile Ox^- est plus réactif que le *p*-$ClPhO^-$ dans tous les mélanges de solvant étudiés, c'est-à-dire qu'il présente l'effet α. Jusqu'à une concentration de 40 mole % de DMSO, l'effet α augmente avec une augmentation de la concentration de DMSO; au-delà de ce point, il diminue ce qui conduit à un profil d'effet α qui est en forme de cloche. Le profil d'effet α en forme de cloche qui est obtenu pour cette réaction est semblable à celui qui a été observé antérieurement pour la réaction correspondante de l'acétate de *p*-nitrophényle (APNP); il diffère toutefois dans l'amplitude de l'effet α au-delà de la concentration de 40 mole % en DMSO. Dans la région riche en DMSO comportant plus de 40 mole % de DMSO, la réaction du BPNP–*p*-$ClPhO^-$ conduit à une augmentation beaucoup plus grande de la vitesse que celle observée pour la réaction du APNP–*p*-$ClPhO^-$. On propose donc que la modulation observée de l'effet α par la nature du solvant (figure 2) peut être expliquée par un effet de l'état fondamental dans la région riche en eau et un effet de l'état de transition dans la région riche en DMSO.

Mots clés : effet de solvant, effet α, état fondamental, état de transition, solvatation, désolvatation.

Introduction

Nucleophiles possessing one or more nonbonding electron pairs at the position α to the nucleophilic center exhibit enhanced reactivity compared with reference nucleophiles of similar basicity (the α-effect) (1). Various proposals have been advanced to account for the α-effect phenomenon, including destabilization of the ground state (GS) through electronic repulsion between nonbonding electron pairs, stabilization of product (thermodynamic α-effect), stabilization of the transition state (TS), a TS having aromatic or radicaloid character, as well as a solvent medium effect (1–11). However, up to this time there is no general agreement as to which factor(s) are predominant as the origin(s) of this phenomenon. Our studies have been largely directed toward elucidating the role of the solvent medium (7–10).

In the best known protic polar solvent, water, anionic nucleophiles are expected to be highly solvated through H-bonding (12, 13). Transfer to an aprotic polar solvent such as DMSO should result in loss of H-bonding, however, ion–dipole and polarizability interactions could become dominant (12, 13). The generally observed increased nucleophilic reactivity of small (hard) anions in DMSO with respect to water was first highlighted in studies by Parker (13). However, this effect may operate differentially when comparing two nucleophiles, as must be the case when considering the α-effect. Differential solvation could be exhibited in imbalanced transition states as well as in differences in ground state solvation and desolvation (14). To probe such differential effects, we have combined kinetic and thermodynamic studies for α-effect systems as a function of incremental modulation of the solvent medium from pure water to DMSO (7, 9).

The definition of the α-effect adopted recently is a positive deviation exhibited by an α-nucleophile from a Brønsted-type nucleophilicity plot (1*a*, 1*b*). According to this definition, the reference nucleophile is one which possesses the same basicity as the α-nucleophile but does not deviate from the Brønsted-type plot.

Some years ago, we performed nucleophilic substitution reactions of *p*-nitrophenyl acetate (PNPA) with butan-2,3-dione monoximate (Ox^-, α-nucleophile) and *p*-chlorophenoxide (*p*-$ClPhO^-$, the reference nucleophile) in dimethyl sulfoxide (DMSO)–H_2O mixtures at 25.0 ± 0.1 °C (7*a*). The pK_a of the conjugate acids of the two nucleophiles has been reported to vary in a parallel manner in the DMSO–H_2O mixtures studied. Unexpectedly, we found that the α-effect increases as the DMSO content in the medium increases up to ca. 50 mol% DMSO and then decreases on further addition of DMSO, resulting in a bell-shaped α-effect profile (7*a*). Such a bell-shaped α-effect profile cannot be accounted for in terms of basicity changes with solvent variation and was also found for the corresponding reactions of substrates with different electrophilic centers (i.e., *p*-nitrophenyl diphenylphosphinate and benzenesulfonate) and with different leaving groups (i.e., substituted phenyl acetates) (7*c*–7*e*).

However, a contrasting result was reported by Moss et al. (11) for the reactions of PNPA with *o*-iodosylbenzoate as the α-effect nucleophile and *p*-$ClPhO^-$ as reference nucleophile, i.e., the α-effect decreased steadily as the mol% DMSO was increased. Since the basicity of *o*-iodosylbenzoate was not determined in the DMSO–H_2O mixtures, one cannot exclude the possibility that the decreasing α-effect trend could be due to variation in pK_a for the conjugate acid of *o*-iodosylbenzoate with mol% DMSO. In fact, we have recently shown that variation of the basicity of the α-nucleophile is an important factor in determining the magnitude of the α-effect in the reactions of PNPA with Ox^- and *p*-$ClPhO^-$ in MeCN–H_2O mixtures (8). While the α-effect increases continuously as the mol% MeCN in the medium increases, Ox^- becomes more basic than *p*-$ClPhO^-$ with increasing mol% MeCN in the medium. Accordingly, the increasing basicity difference between Ox^- and *p*-$ClPhO^-$ was held responsible for the increasing α-effect in MeCN–H_2O mixtures (8).

There has been an upsurgence of interest in recent years in studies of solvent effects on reaction kinetics, equilibria, and chemistry more generally (12). For example, renewed interest has been engendered by studies into environmentally benign or "green" solvents including ionic solvents and supercritical water (15). Any practical use of such new media will require an in-depth examination of the physical organic chemistry of these systems. DMSO has emerged as the prototypical aprotic solvent of choice for a wide range of reactions (12, 13). One may cite a few landmark studies: those of Cram in the area of stereocontrol in isotopic H exchange and carbanion chemistry more generally (16), Cox and Stewart on the H_- basicity scale (17), and Parker (13) on nucleophilic reactivity, as well as the extensive investigations of Bordwell (18) into acidities in DMSO. Studies of mixed solvent systems have yielded a wealth of information on structure–reactivity relationships (19). In this context, we have focused on DMSO–H_2O mixed media and more recently on MeCN–H_2O media (7–9).

As mentioned above, one key difference between H_2O and DMSO is the enhanced polarizability of the latter solvent, which may be expected to extend to DMSO-rich media as well. To test the significance of this factor we have extended our study to *p*-nitrophenyl benzoate (PNPB) as the substrate. Here, a change of a methyl in PNPA for a phenyl group in PNPB provides a test compound that should exhibit greater polarizability interactions with the DMSO solvent component. The reaction studied is that of PNPB with Ox^- and *p*-$ClPhO^-$ anions (Scheme 1) as part of the α-effect phenomenon, as modulated by systematic change of mol% DMSO in DMSO–H_2O mixtures.

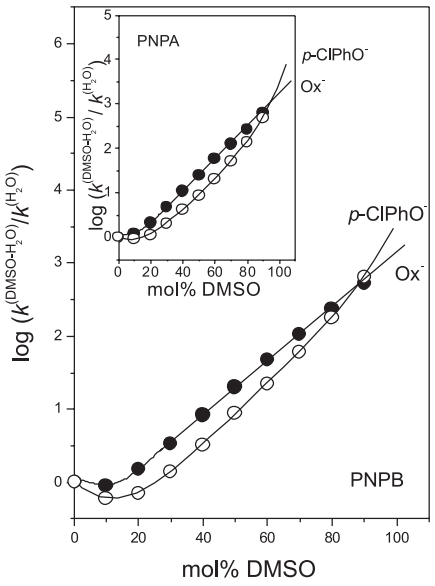
Results

The kinetic study was performed spectrophotometrically under pseudo-first-order conditions with the nucleophile in excess. All the reactions in this study obeyed pseudo-first-order kinetics and pseudo-first-order rate constants (k_{obsd}) were obtained from plots of ln (A_∞–A_t) vs. *t*, which were linear over 90% of the total reaction. Second-order rate constants (k_{Nu}) were determined from the slopes of the linear plots of k_{obsd} vs. the nucleophile concentration. These plots had only small intercept values, indicating that the contribution of hydroxide and (or) water to k_{obsd} is negligible (see Supplementary data for detailed kinetic data).[3] It is estimated from replicate runs that the uncertainty in the rate constants is less than ±3%. The k_{Nu} values determined are summarized in Table 1 for the reactions of PNPB with Ox^- and *p*-$ClPhO^-$ in DMSO–H_2O mixtures of varying compositions.



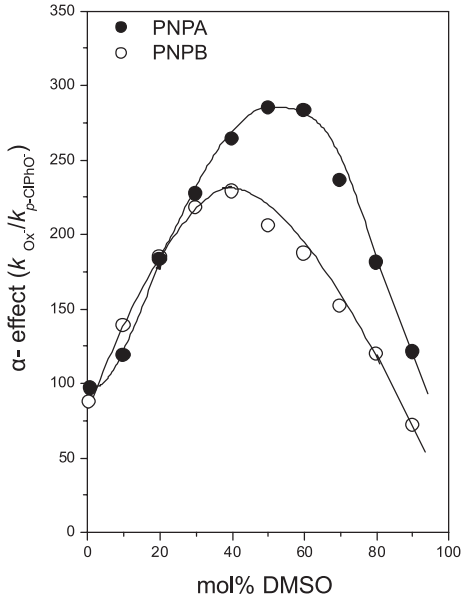
Discussion

Effect of medium on reactivity

The rate data presented in Table 1 and exhibited in Fig. 1 show a nonuniform behaviour as the DMSO content of the medium is varied. Now, it is well-known that the properties of DMSO–H_2O mixtures exhibit anomalous behavior up to 33 mol% DMSO (7, 12, 20). This has been interpreted as resulting from rigidification of water–water H bonding induced by the addition of DMSO or the strong tendency of DMSO to form complexes with two water molecules (7, 12, 20). In the present system we have observed that the reactivity of *p*-$ClPhO^-$ and Ox^- decreases modestly in the low DMSO region (<20 mol% DMSO) but increases significantly in the high DMSO region. This initial decline in reactivity is more significant for *p*-$ClPhO^-$ than for Ox^-.

Focusing on the high DMSO region, it is generally accepted that GS destabilization of anionic nucleophiles is responsible for the rate enhancement in this region relative to pure water (12, 13). Loss of H bonding in going to DMSO-rich media will effectively destabilize the anionic nucleophile (see Introduction). This desolvation of the anion enhances reactivity. For *p*-$ClPhO^-$ and Ox^-, in fact, we have recently found through calorimetric measurements that these anions become desolvated to the extent of 10.2 and 13.2 kcal/mol (1 cal = 4.184 J), respectively, as the medium is changed from pure water to 90 mol% DMSO (7*b*).

Fig. 1. Logarithmic plots of relative rate constants, $\log k^{(DMSO-H_2O)}/k^{(H_2O)}$, vs. mol% DMSO for reactions of PNPB (and PNPA in inset) with Ox^- (●) and *p*-$ClPhO^-$ (○) at 25.0 ± 0.1 °C. The data for reactions of PNPA were taken from ref. 7*a*.



The effect of medium change on reactivity can be expressed as the ratio of the second-order rate constant in DMSO–H_2O mixtures over the corresponding rate constant in pure H_2O, i.e., $k^{(DMSO-H_2O)}/k^{(H_2O)}$. As shown in Fig. 1, this rate constant ratio decreases as the medium changes from H_2O to 10 mol% DMSO with both Ox^- and *p*-$ClPhO^-$. Beyond 10 mol% DMSO the relative rate for Ox^- increases linearly as the mol% DMSO increases, while *p*-$ClPhO^-$ exhibits slightly upward curvature resulting in a crossover.

Fig. 2. Plots of the α-effect ($k_{Ox^-}/k_{p\text{-}ClPhO^-}$) vs. mol% DMSO for reactions of PNPA with Ox^- and *p*-$ClPhO^-$ (●) and PNPB with Ox^- and *p*-$ClPhO^-$ (○) at 25.0 ± 0.1 °C. The data for reactions of PNPA were taken from ref. 7*a*.

Recalling that our calorimetric study has shown that Ox^- is more destabilized than *p*-$ClPhO^-$ throughout the range of DMSO–H_2O mixtures studied, we conclude that destabilization of the anionic nucleophile GS cannot be solely responsible for the rate enhancement in the high DMSO region.

The bell-shaped α-effect

As shown in Table 1, Ox^- exhibits much larger k_N values than *p*-$ClPhO^-$ for the reaction of PNPB in all the medium compositions investigated (i.e., the α-effect). Interestingly, as illustrated in Fig. 2 up to 40 mol% DMSO the magnitude of the α-effect ($k_{Ox^-}/k_{p\text{-}ClPhO^-}$) increases as the DMSO content in the medium increases. Beyond that point there is a decrease in the α-effect, resulting in a bell-shaped α-effect profile. The bell-shaped α-effect profile found for PNPB is similar to that found previously for the comparable reactions of PNPA, differing notably however in the magnitude of the α-effect beyond 40 mol% DMSO; the PNPB system exhibits a much smaller α-effect than the PNPA system in this DMSO-rich region.

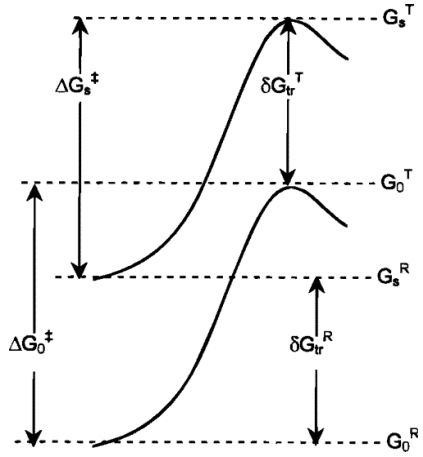
The origin of the bell-shaped α-effect

A further striking aspect of the α-effect plots in Fig. 2 is that up to 30 mol% DMSO the plots for PNPB and PNPA are virtually superimposable but diverge thereafter; the PNPB curve reaches a maximum at 40 mol% DMSO while the maximum for PNPA is found at 50 mol% DMSO. Also the α-effect maximum occurs at 230 for PNPB and at 285 for PNPA. While the advent of the maximum in the bell-shaped α-effect profile at a lower DMSO content with PNPB, relative to PNPA, is concordant with the higher polarizability associated with the change from Me to Ph, the different response of the two systems to medium change beyond 40 mol% DMSO bears further analysis.

Dissection of medium effect into GS and TS contributions

Studies of the relationship between the magnitude of the α-effect, Brønsted basicity, and medium effects have revealed a remarkable behaviour of oximate reactivity that is, however, still not fully understood (2, 21). Terrier et al. (2*a*) studied the reaction of PNPA with a series of pyridinium carbaldoximates in H_2O and found that the Brønsted-type plot is linear for reactions of low basic oximates ($pK_a < \sim 8$), but levels off for more basic oximates ($pK_a \geq 8$). In a study of reactions of PNPB with a series of acetophenone oximates in 20 and 90 mol% DMSO, we observed that in 20 mol% DMSO the Hammett plot is linear with $\rho = +0.20$, but in 90 mol% DMSO $\rho = -0.15$ (21). The positive ρ value obtained for the reactions in 20 mol% DMSO is striking since it corresponds to a decrease in reactivity of the oximate with a stronger base strengthening substituent. A similar result has recently been found by Terrier and coworkers (2*b*) for reactions of bis(*p*-nitrophenyl)phenylphosphonate with a series of oximates in H_2O. The Brønsted-type plot exhibited a negative β_{nuc} value in the region of $pK_a > \sim 9$, indicating that more basic oximates become less reactive.

We have recently reported (7*b*) from a calorimetric study that both Ox^- and *p*-$ClPhO^-$ become desolvated on addition of DMSO to water and the former experiences higher desolvation than the latter. The difference in desolvation energy between Ox^- and *p*-$ClPhO^-$ ($\Delta\Delta H_{sol}$) became large as the DMSO content in the medium increased up to 40 mol% DMSO and then remained nearly constant beyond that point. Thus, $\Delta\Delta H_{sol}$ increased from 0 to 0.6, 1.8, and 3.2 kcal/mol as the medium changes from pure water to 10, 20, and 40 mol% DMSO, in turn, but remained nearly constant on further addition of DMSO (7*b*). The increasing trend in $\Delta\Delta H_{sol}$ up to 40 mol% DMSO was found to parallel the increasing α-effect trend observed over that medium range, indicating that the difference in GS desolvation between Ox^- and *p*-$ClPhO^-$ may be responsible for the increasing α-effect trend for the reactions of PNPA in this solvent region. However, since $\Delta\Delta H_{sol}$ remains constant beyond 40 mol% DMSO the GS effect cannot account for the decreasing α-effect trend in that medium range.



Previously, we introduced a methodology for the dissection of medium effects into GS and TS contributions (see also refs. 12, 13, 22, 23). Figure 3 shows a qualitative two-dimensional energy profile for a reaction carried out in two different media, H_2O and a DMSO–H_2O mixture. δG_{tr}^{T} can be evaluated from the measurable transfer free energies of reactants (δG_{tr}^{R}) and the kinetic activation parameters ($\delta G_{tr}^{\ddagger}$) as given by eq. [1].

$$[1] \qquad \delta\Delta G_{tr}^{\ddagger} = \delta G_{tr}^{T} - \delta G_{tr}^{R}$$

This methodology can be applied to enthalpy and entropy parameters as well. This allows the dissection of the effect of medium on the α-effect into GS and TS effects through the combination of the calorimetrically measured enthalpies of solution (ΔH_{sol}) and the kinetically determined activation parameters. For the reaction of PNPA with Ox^- and *p*-$ClPhO^-$, we have found that in the DMSO-rich region the TS becomes more stabilized for *p*-$ClPhO^-$ than for Ox^- resulting in a smaller α-effect (7*b*). Accordingly, differential solvation of the two TSs was proposed to be responsible for the de-

Fig. 3. Illustration of the relationship between the transfer free energies of reactants (δG_{tr}^{R}) and the transition state (δG_{tr}^{T}) and the free energies of activation for a reaction occurring in the two-solvent systems.

creasing α-effect trend for the reactions of PNPA beyond the break point of 40–50 mol% DMSO (7*b*). For the current PNPB system, one can also conclude that the origin of the increasing and decreasing α-effect trend found with medium change can be attributed to the same factors as for the PNPA system, i.e., dominant GS effect in the H_2O-rich region and TS effect in the DMSO-rich region, which demonstrates the generality of this methodology.

The effect of medium change on reactivity can be illustrated in a different way via Fig. 4, showing a plot of the logarithmic relative rate constants for the reactions of PNPA and PNPB with Ox^- and *p*-$ClPhO^-$ vs. the transfer enthalpies from H_2O to DMSO–H_2O mixtures ($\Delta\Delta H_{tr}$) for the two nucleophiles (Table 2). $\Delta\Delta H_{tr}$ represents the extent of GS desolvation for Ox^- and *p*-$ClPhO^-$ ions as the medium changes from H_2O to DMSO–H_2O mixtures (7*b*). Accordingly, if the GS effect were solely responsible for the relative rate constants one should have observed a linear correlation between $\Delta\Delta H_{tr}$ and $\log k^{(DMSO-H_2O)}/k^{(H_2O)}$. Contrariwise, Fig. 4 exhibits nonlinear correlations, i.e., the increase in the relative rate constant is small on changing $\Delta\Delta H_{tr}$ from 0 to 8 kcal/mol for *p*-$ClPhO^-$ and from 0 to 11 kcal/mol for Ox^-. However, for *p*-$ClPhO^-$ the relative rate constant increases significantly as $\Delta\Delta H_{tr}$ changes from 8 to 10 kcal/mol while for Ox^- the change is from 11 to 13 kcal/mol. These results further emphasize that the GS effect is not solely responsible for the medium effect on reactivity but that a TS effect also contributes to the rate enhancement in the DMSO-rich region.

Notably in Fig. 4, the curved lines for the reactions of PNPA and PNPB with *p*-$ClPhO^-$ cross over those for the corresponding reactions for Ox^- at $\Delta\Delta H_{tr}$ = 6–7 kcal/mol. The points for the reactions of *p*-$ClPhO^-$ lie below those for the reactions with Ox^- up to $\Delta\Delta H_{tr}$ = ~6 kcal/mol but exceed them beyond that point. Such a crossover indicates that in the DMSO-rich region the reactions with *p*-$ClPhO^-$ attain almost the same rate enhancements as those with Ox^- but with smaller $\Delta\Delta H_{tr}$ values.

Interestingly, further scrutiny of Fig. 4 reveals that the points for the reactions of PNPA with Ox^- fall above

Fig. 4. Plots of $\log k^{(DMSO-H2O)}/k^{(H2O)}$ vs. transfer enthalpies ($\Delta\Delta H_{tr}$) for reactions of PNPA (○) and PNPB (●) with Ox^- and *p*-$ClPhO^-$ at 25.0 ± 0.1 °C. The data for reaction of PNPA were taken from ref. 7*b*.

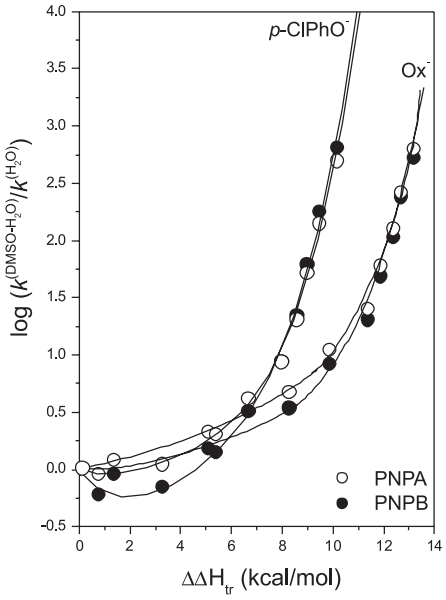

Table 2. Transfer enthalpies ($\Delta\Delta H_{tr}$, kcal/mol) from 0 to 90 mol% DMSO for single ions of *p*-$ClPhO^-$ and Ox^- at 25.0 °C.

	$\Delta\Delta H_{tr}$ (kcal/mol)	
DMSO (mol%)	*p*-$ClPhO^-$	Ox^-
0	0	0
10	0.8	1.4
20	3.3	5.1
30	5.4	8.3
40	6.7	9.9
50	8.0	11.4
60	8.6	11.9
70	9.0	12.4
80	9.5	12.7
90	10.2	13.2

Note: Data were taken from ref. 7*b*.

those for the reactions of PNPB with Ox^- throughout the whole $\Delta\Delta H_{tr}$ range. However, a contrasting result is shown for the reactions with *p*-$ClPhO^-$, i.e., the points for the reactions of PNPA lie above those for the reactions of PNPB up to $\Delta\Delta H_{tr}$ = ~7 kcal/mol, but are situated below beyond that point. This result indicates that the reactions of PNPB with *p*-$ClPhO^-$ gain greater rate enhancement than the corresponding reactions of PNPA with the same $\Delta\Delta H_{tr}$ value in the DMSO-rich medium. The contrasting α-effect behaviour for the PNPB and PNPA systems, as exhibited in Fig. 2 for the DMSO-rich region, is therefore accounted for.

Conclusions

Through the combination of kinetic data with calorimetrically determined GS solvation of Ox^- and *p*-$ClPhO^-$, which allowed dissection of the medium effect on TS and GS con-

© 2006 NRC Canada

tributions, the present study leads to the following conclusions. (*i*) The bell-shaped α-effect profile obtained for the reaction of PNPB with Ox^- and *p*-$ClPhO^-$ is similar to that previously found for the corresponding reaction with PNPA, differing notably however, in the magnitude of the α-effect beyond 40 mol% DMSO; the PNPB system exhibits a much smaller α-effect than the PNPA system in this DMSO-rich region. (*ii*) The dominant GS effect in the H_2O-rich region and TS effect in the DMSO-rich region are proposed to be responsible for the origin of the increasing and decreasing α-effect trends, respectively. (*iii*) The effect of medium change on reactivity is more significant for the reaction with *p*-$ClPhO^-$ than for that with Ox^- in DMSO-rich region. (*iv*) The reaction of PNPB with *p*-$ClPhO^-$ gains greater rate enhancements than the corresponding reaction of PNPA in DMSO-rich region, which is responsible for the smaller α-effect found for the reaction of PNPB beyond 40 mol% DMSO. (*v*) Concordant with the increased polarizability effected on going from PNPA to PNPB with the change Me → Ph, is the advent of the maximum in the bell-shaped α-effect profile (Fig. 2) at a lower DMSO content with PNPB than with PNPA (40 vs. 50 mol% DMSO) and similarly the smaller magnitude of the α-effect (230 vs. 285).

Experimental section

Materials

PNPB was readily prepared from the reaction of benzoyl chloride with *p*-nitrophenol in the presence of triethyl amine in anhydrous ether. Butan-2,3-dione monoxime and phenols used are of the highest quality available and were recrystallized before use. DMSO was refluxed over calcium hydride, distilled, collecting the fraction of bp 64–66 °C (6–7 mm Hg, 1 mm Hg = 133.322 4 Pa) and stored under nitrogen. Doubly glass distilled water was further boiled and cooled under nitrogen just before use.

Kinetics

Kinetic studies were performed with a UV–vis spectrophotometer for slow reactions ($t_{1/2} \geq 10$ s) and a stopped-flow spectrophotometer for fast reactions ($t_{1/2} < 10$ s) with a constant temperature circulating bath at 25.0 ± 0.1 °C. Typically, the reaction was initiated by adding 5 μL of ca. 0.02 mol/L of substrate solution in MeCN by 10 μL gastight syringe to a 10 mm quartz UV cell containing 2.50 mL of the thermostated reaction mixture made up of reaction medium and an aliquot of the nucleophile stock solution. The nucleophile stock solution of ca. 0.2 mol/L was prepared by dissolving 2 equiv. of oxime (or phenol) and 1 equiv. of standardized NaOH solution to make a self buffered solution. Generally, the nucleophile concentration was varied over the range, $1–100 \times 10^{-3}$ mol/L, while the substrate concentration was 4×10^{-5} mol/L. All the solutions were transferred by gastight syringes under nitrogen. The reactions were followed by monitoring the appearance of *p*-nitrophenoxide ions at 410 nm.

Product analysis

p-Nitrophenoxide ion was liberated quantitatively and identified as one of the reaction products in the reactions of PNPB by comparison of the UV–vis spectra after completion of the reactions with those of the authentic samples under the same reaction conditions.

Morphology of surfactant–polymer complexes on mica substrate visualized by atomic force microscopy

Feng Zhao, Yukou Du, Jingkun Xu, and Shufeng Liu

Abstract: The morphology of surfactant–polymer complexes formed in two dimensions has been studied. We found that the morphology of hexadecyltrimethylammonium bromide – modified partially hydrated polyacrylamide (CTAB–MHPAM) complexes transferred to mica from the interface between air and MHPAM aqueous solution shows pearl necklace structures, and it is orientationally aligned. On the addition of salt, this structure is altered to the dendritic fractal structure with a smaller fractal dimension about 1.1 ± 0.01. These structures have potential applications in the fabrication of materials in the nanoscale. The mechanism of the formation of different patterns has been discussed.

Key words: morphology, Surfactant–polymer complexes, Dendritic fractal structure.

Résumé : On a étudié la morphologie des complexes agent de surface–polymère qui se forment en deux dimensions. On a trouvé que la morphologie des complexes du bromure de hexadécyltriméthylammonium – polyacrylamide hydraté partiellement modifié (CTAB–MHPAM) transférés à du mica à partir d'une interface entre de l'air et une solution aqueuse de MHPAM présente des structures en forme de collier de perle et qu'ils ont une orientation alignée. Par addition de sel, cette structure est modifiée en structure fractale dendritique avec une dimension fractale plus petite d'environ 1,1 ± 0,01. Ces structures offrent des possibilités d'application dans la fabrication de matériaux à l'échelle nano. On discute du mécanisme de formation des différents patrons.

Mots clés : morphologie, complexes agent de surface–polymère, structure fractale dendritique.

Introduction

Modification of interfaces is important in a broad range of applications in biotechnology and materials science (1–4). To establish a relationship between the applications and the properties of the surfaces, it is necessary to have additional information about their structures and morphologies. Significant efforts have been made to understand these features (5–9). However, the studies have predominately focused on the relatively simple or ordered structures at interfaces, and little is known about the highly disordered and complicated structures (fractal structures), at least on some length scales. The analysis of these structures is usually a difficult task owing to the complexity of the system. However, such fractal patterns play an important role in many physical processes (10). Campion et al. (11) reported a large enhancement of Raman scattering from the metallic fractal clusters. Safonov et al. (12) reported the formation of silver nanoparticle fractal aggregates with highly localized, laser-excited optical modes. Recently, Kimberly et al. (13) described the synthesis of branching fractal "nanotree". The process involves the self-assembled growth of nanoparticles via the vapor–liquid–solid growth mode followed by the sequential seeding of branching structures. More recently, Lauhon et al. (14) reported a new route to generate the fractal nanowire structure based on the vapor-phase deposition and a self-assembly of a catalyst on the surface of a growing nanowire.

Recently, some fractal patterns are reported at air–liquid and solid–liquid interfaces (15–20). Fractals are often statistically self-similar and defined by an average cluster size and a fractal dimension (21–23). Fractal dimension is a measure of the surface and structural irregularities of a given solid. The value of this dimension can vary from two to three. The lower limiting value of two corresponds to a perfectly regular smooth surface, whereas the upper limiting value of three relates to the maximum allowed complexity of the surface (24). The diffusion limited cluster aggregation (DLCA) model (25) and reaction limited cluster aggregation (RLCA) model (26) are widely used to characterize such irregular patterns at the interface. The corresponding fractal dimensions are 1.45 and 1.55 in two dimension (d = 2). In this study, we report the dendritic fractal pattern of CTAB–MHPAM complex films transferred to mica surface from the interface between the air and aqueous MHPAM solution. Without adding salt to subphase, the pearl necklace structure

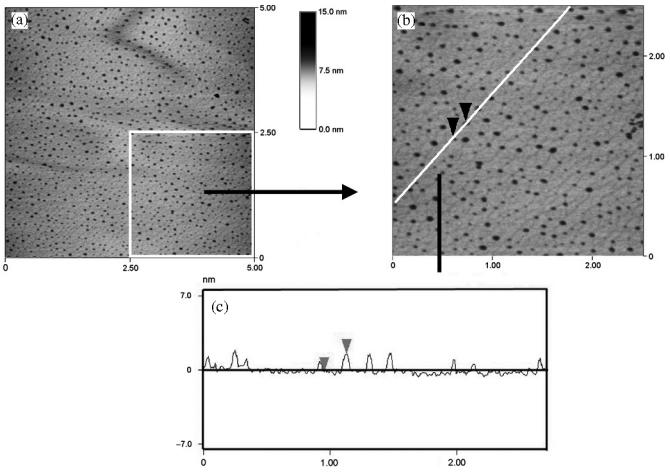
on mica surface was observed. On the addition of salt, a well-defined dendritic fractal structure was formed with a small fractal dimension (D = 1.1 ± 0.02).

Experimental section

Materials

Hexadecyltrimethylammonium bromide (CTAB) was of analytical reagent grade (Beijing Xi Zhong Chemical Factory, Beijing, China) and was purified by extraction with diethylether followed by recrystallization from anhydrous ethanol. After recrystallization, there was no minimum in the plot of surface tension vs concentration.



Modified partially hydrated polyacrylamide (MHPAM) with a weight average molecular weigh of 0.8×10^7g mol^{-1} was obtained from Beijing Hengju Chemical Agent Co. Ltd. (Beijing, China) and used without further purification. The values of the repeated units (m, n, p) are about 109825, 15294, and 7018. The structure of MHPAM is shown in Fig. 1.

Preparation of CTAB–MHPAM complexes

The surface pressure (π) – surface area (A) isotherm of a spread film was obtained using an LB trough (length 700 mm ± width 40 mm, FACE HBM, Japan) equipped with a Wilhelmy plate for monitoring the surface pressure. The entire film balance is placed in a container to avoid contamination and air flows. The accuracy of the surface pressure measurements is ±0.1 mN/m. Before each experiment, the trough was thoroughly cleaned with acetone and dichloromethane. The surface area was compressed by moving a Teflon barrier at the speed of 20–25 cm^2/min.

Owing to the good solubility in water, either CTAB or MHPAM molecules cannot form a stable monolayer at the air–water interface. However, the strong electrostatic interactions between the negatively charged COO$^-$ groups along

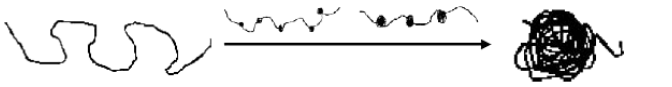
Fig. 3. (a) AFM image of CTAB–MHPAM complexes on mica surfaces transferred from the interface between the air and MHPAM aqueous solution. (b) Enlarged and contrast-enhanced AFM image from (a). (c) Cross-section indicated by arrows on image (b). (Note: to observe the structures more clearly, the above images were treated with nvert function in Adobe Photoshop 6.0; therefore, the brighter regions in AFM images are bare mica substrate, and the darker regions are the complex films, which is different from the conventional AFM images. AFM images in Fig. 6 are also similar).

MHPAM chains and CTA$^+$ headgroups make CTAB–MHPAM complexes form stable film at the air–water interface. The CTAB–MHPAM complex films were prepared as following.

CTAB was dissolved in chloroform to make a 1.0 mmol/L solution and then spread on the subphase MHPAM aqueous solution interface (c = 0.01 mg/mL). Five minutes was allowed for solvent evaporation before compression was started. The π–A isotherm is shown in Fig. 2, which implied co-adsorption of MHPAM and CTAB molecules at the air–water interface and the formation of a stable CTAB–polymer complex films. Then, the CTAB–MHPAM complex films were compressed to the surface pressure of 12 mNm^{-1}. The freshly cleaved mica slide was brought down horizontally by hand to touch the monolayer and lifted carefully after a contact time of a few seconds. This is the so-called "horizontal lifting method (HLM)" described in detail elsewhere (27). Finally, the mica slide was dried in air and imaged with AFM.

Atomic force microscopy (AFM)

CTAB–MHPAM complex films on mica surfaces were characterized using a Digital Instrument Nanoscope IIIa multimode system (Santa Barbara, CA) with the tapping mode. AFM cantilevers were conductive silicon cantilevers with a typical resonance frequency of 300 kHz, spring constant of 35 N m^{-1}. The AFM image is shown in the height mode after flattening.



Results and discussion

the interface between air and MHPAM aqueous solution. Figs. 3*a* and 3*b* clearly confirm the existence of pearl necklace structures. We believe the pearl necklace structure morphology results from the compromise between short-range attraction and long-range repulsion (28) along the polymer chains. The coil-to-globule conformational transition of the polymer chains has been predicted by Dobrynin–Rubinstein–Obukhov (DRO) theory (29). In the process of transition, a sequence of intermediate configurations, which consist of chains bearing individual smaller sub-globules along the chains, similar to a pearl necklace, may be formed (28). In the past, direct visualization of the pearl necklace structure of the polymer chains has been lacking; a few papers (28, 30–31) recently reported direct experimental evidences of such structure. Particularly, Kirwan et al. (30) depicted the coil-to-globule conformational transition of single poly(vinylamine) molecules through a sequence of pearl necklace structures on mica surface. In our experiments, the formation of pearl necklace structures is similar to what they observed. However, it should be noted that the pearl necklace structures visualized by Kirwan et al. formed through single polymer molecule chains,whereas the structures reported here resulted from many polymer molecule chains through the mutual entanglement.

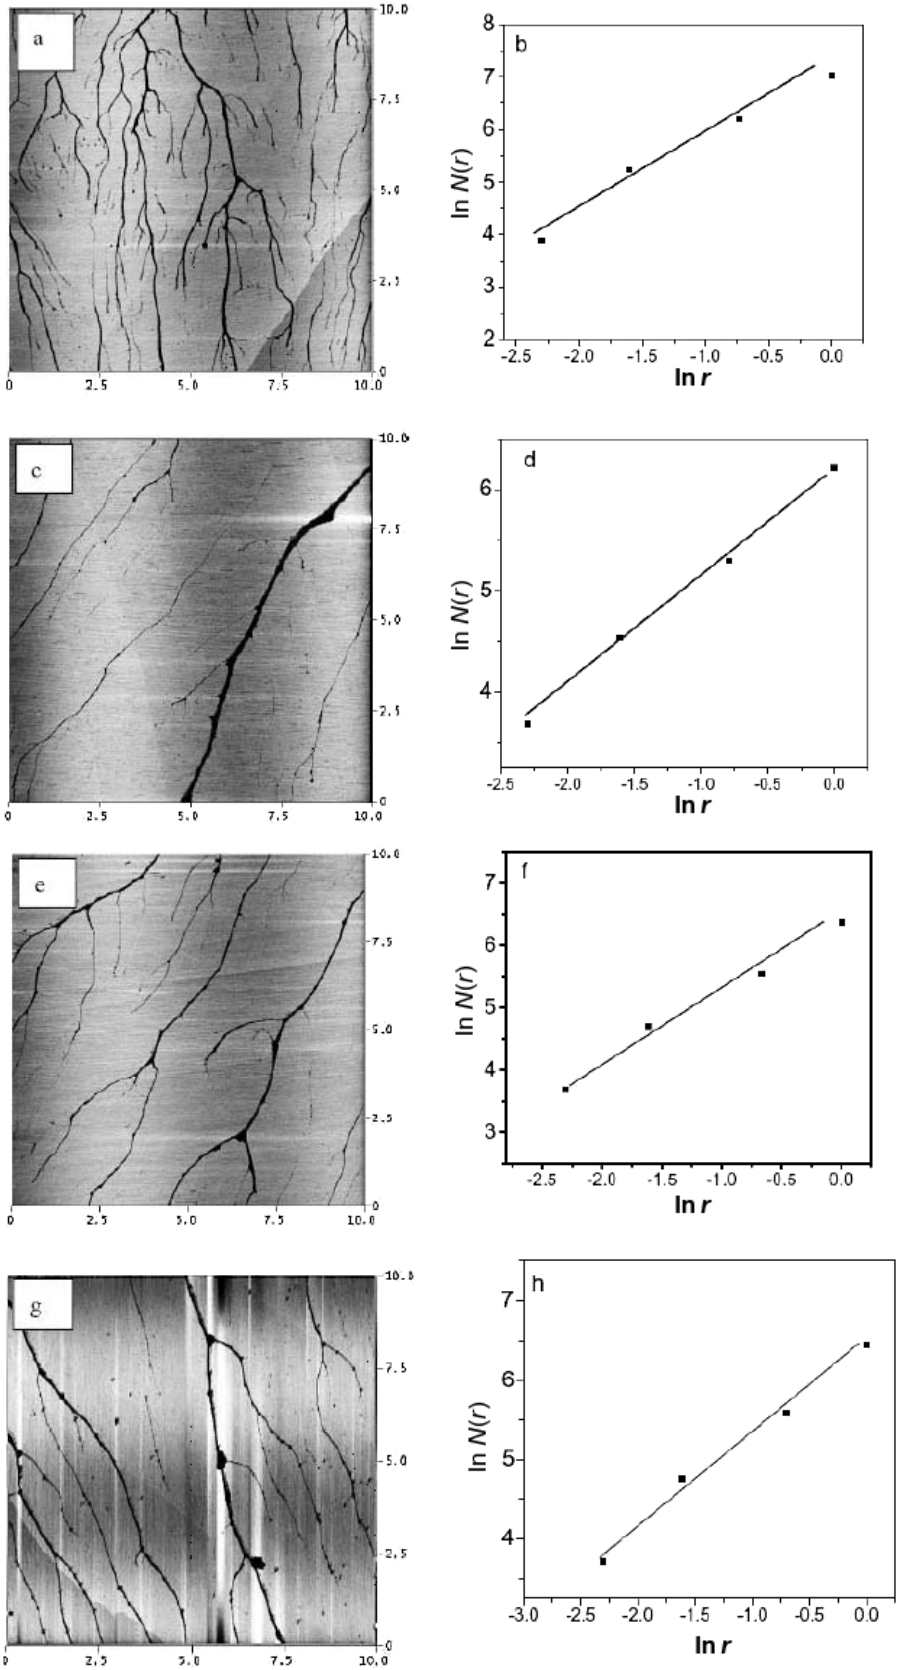
The negatively charged COO^- groups, along each MHPAM long chain complex with CTA^+ ions, and the long-range Coulombic repulsion forces decrease owing to the effect of neutralization of charged groups, analogous to the decrease of the polyelectrolyte density, which results in the collapse of the MHPAM chains. However, the positively charged $CH_2N^+H_2CH_3$ groups (pK_a = 9.1–10.2, in our experiments, pH = 6.18) attached to the MHPAM chains will hinder the collapse of MHPAM, thus the long coil MHPAM chains may form a necklace with compact globules joined by narrow strings (29) because of the equilibrium interaction between short-range attraction and long-range repulsion along the chains. A representative schematic of conformational transition of a polymer is shown in Fig. 4.

In addition, it should be emphasized that one can observe the orientational adsorption of the pearl necklace structure to mica. The phenomenon obtained in the present investigation is related to the combination of the properties of mica surfaces and adsorption behavior of polymer. Mica is a layered aluminosilicate mineral. Each layer is strongly negatively charged due to isomorphism substitution where some silicon atoms are replaced by aluminum. These charges are compensated for by monovalent ions, mostly potassium (32, 33). Mica has crystalline substrate features (Fig. 5). The adsorption behavior of polymer to surface is a two-step process: an initial adsorption in terms of the diffusion-limited adsorption and the slow reorganization of the adsorbed chains to minimize the surface free energy (34). In the case of adsorption of CTAB–MHPAM complexes to mica surfaces, the aggregation of CTAB–MHPAM complex chains with the positively charged $CH_2N^+H_2CH_3$ groups was mainly along the mica crystal axes, and the thermal fluctuations of the complex chains on mica surface eventually resulted in the morphology of orientational adsorption on mica substrate.

Fig 5. A schematic representation of the mica surface crystal axes.

Effect of salt on the morphology of CTAB–MHPAM complex films

Figure 6 shows morphological changes of CTAB–MHPAM on mica at various subphase NaCl concentrations. Here, we show that the addition of salt causes a sequential conformational transition from the pearl necklace structure to the dendritic structure.



The structures in our systems are quite similar to fractal patterns observed in other systems, particularly the metal dendrites grown by electrodeposition (9, 20), two-dimension crystallites grown on a rough surface (35), and dendritic crystal grown (36). As a result, we performed the fractal dimension analysis for the images of Fig. 6 by the box-counting method (21–23), which quantifies the total number of occupied boxes ($N_{(r)}$) (squares containing any portion of the image) at varying box sizes *r*. The logarithm of the number of occupied boxes is plotted against the log of the box sizes. The absolute value of the slope of the resulting line is the fractal dimension *D*, as shown in detail by the early literature (37), and the corresponding results are shown in Figs. 6*b*, 6*d*, 6*f*, and 6*h*.

With the increase of salt concentration, the fractal dimensions of the dendritic structure decrease continuously. It clearly shows that at salt concentration ~0.73 mmol/L, a stable fractal structure is formed, and its fractal dimension is 1.1 ± 0.02 (Fig. 7). In two-dimensional systems, fractal dimensions ranging from 1.2 to 1.74 have been obtained under different experimental conditions (19, 38–39). However, the smaller fractal dimension (D = 1.1 ± 0.02) was obtained in our experiments. The well-refined dendritic fractal structure on mica substrate holds great promise for potential fundamental and technological applications. The fractal dimension *D* of 1.41–1.09 is reasonable compared with the diffusion-limited cluster aggregation (DLCA) (D = 1.45), indicating that the self-complexation and adsorption on mica surfaces seems to be a DLCA process, but the interactions between the adsorbed molecules and mica surfaces also played an important role in the morphology formation.

The driving force for the occurrence of dendritic patterns on mica may be the interaction between the background (mica surface) and the aggregated particles (CTAB–MHPAM complexes) (40, 41). When NaCl is added to the subphase

Fig 7. A plot of fractal dimension versus NaCl concentration.

MHPAM aqueous solution, it screens the electrostatic repulsion barrier between the CTAB–MHPAM complex chains and enhances the aggregation of CTAB–MHPAM complex chains. On the other hand, they cannot grow strictly along the mica crystal axes owing to uncertain conditions, such as liquid convection, and defects of mica crystal axes. Consequently, the aggregation patterns were not very regular orientational lattice-like structures. Similar mechanism had been proposed earlier in several papers to describe the adsorption of other surfactants (33, 42).

Moreover, such fractal dendritic patterns could have potential applications as self-assembly templates for the formation of fractal metallic nanoparticles because the functional group, CH_2NHCH_3, has a high affinity for metal nanoparticles (43). Therefore, it is reasonable to expect that dendritic metallic nanoparticle aggregations can be achieved by applying this pattern as a template.

Conclusions

We demonstrated the morphological formation of surfactant–polymer complexes on mica substrates by AFM. At the air–MHPAM aqueous solution interface, CTAB–MHPAM complexes, adsorbed to mica surfaces, appear as a pearl necklace structure with orientational lattice-like array. On the addition of salt, a well-defined dendritic fractal structure eventually formed with a smaller fractal dimension. Such fractal structures enable the complexes to have potential applications as self-assembly templates for the formation of fractal nanoparticles.

Ytterbium perfluorooctanesulfonate catalyzed synthesis of acylals from aldehydes and acetic anhydride in a fluorous biphasic system

Wen-Bin Yi, Ya-Qing Yin, and Chun Cai

Abstract: Ytterbium perfluorooctanesulfonate [$Yb(OPf)_3$] catalyses the highly efficient synthesis of acylals from aldehydes and acetic anhydride in a fluorous biphase system (FBS) composed of toluene and perfluorodecalin. The fluorous phase containing the fluorous catalyst is easily separated and can be reused several times without significant loss of catalytic activity.

Key words: acylals, ytterbium perfluorooctanesulfonate, fluorous biphasic catalysis.

Résumé : Le perfluorooctanesulfonate d'ytterbium [$Yb(OPf)_3$] catalyse d'une façon très efficace la synthèse d'acylals à partir d'aldéhydes et d'anhydride acétique dans un système fluoré biphasique (SFB) formé de toluène et de perfluorodécaline. La phase fluorée qui contient le catalyseur fluoré se sépare facilement et elle peut être réutilisée plusieurs fois sans perte significative de son activité catalytique.

Mots clés : acylals, perfluorooctanesulfonate d'ytterbium, catalyseur fluoré biphasique.

[Traduit par la Rédaction]

Introduction

Recently, transition metal-catalyzed reactions in a fluorous biphasic system (FBS) have become among the most important methods for facile catalyst separation from the reaction mixture and recycling of the catalyst (1–3). In this catalytic system, the metal catalyst coordinated by perfluoroalkylated ligands can dissolve into the fluorous phase containing the product after the reaction (1). Furthermore, FBS has the advantage of possible use for water-sensitive reactions unlike aqueous biphase systems (4, 5). In our continued interest in the utility of lanthanide perfluorooctanesulfonates-catalyzed reactions in fluorous media (6–8), we report herein our newest results on a successful approach to FBS, i.e., perfluorodecalin–toluene system for the synthesis of 1,1-diacetates (acylals), efficient protecting groups for aldehydes (9) catalyzed by a ytterbium perfluorooctanesulfonate [$Yb(OPf)_3$] complex.

Rare earth (III) perfluorooctanesulfonates ($RE(OPf)_3$, RE = Sc,Y, La, Lu), a novel series of Lewis acids, have been of special interest because of their characteristic features such as low hygroscopicity, ease of handling, robustness for recycling, and high solubility in fluorous solvent (10–12). A catalytic amount of $RE(OPf)_3$ successfully promotes several synthetically useful reactions such as Friedel–Crafts acylation (13) and alkylation (6), aldol condensation (8), nitration (14), Mannich reaction (15), and Diels–Alder reactions (10). The catalyst immobilized in the fluorous phase was recovered by simple phase separation and reused directly for the next reaction without a significant loss of catalytic activity.

The acylals were prepared from aldehydes and acetic anhydride employing fluorous phase technology. The reaction of benzaldehyde with acetic anhydride in a FBS was examined with various Lewis acid catalysts (Scheme 1) and the results are summarized in Table 1. We found that the $Yb(OPf)_3$ and $Sc(OPf)_3$ complexes had similar activity for the reaction with a quantitive conversion to acylal product in the presence of 0.3 mol% catalyst at 80 °C over 2 h, while other lanthanide perflates such as $Eu(OPf)_3$, $Tm(OPf)_3$, or $La(OPf)_3$, yielded desired product in 62%, 51%, or 39%, respectively. This could be ascribed to the higher Lewis acidity of $Yb(OPf)_3$ and $Sc(OPf)_3$ relative to other lanthanide perflates (10). Heptadecafluorooctanesulfonic acid ($C_8F_{17}SO_3H$, PfOH) can itself promote the reaction, but it was found to be less effective than $RE(OPf)_3$. When the reaction was finished, the reaction mixture was cooled to RT. The fluorous phase with $RE(OPf)_3$ catalysts can separate from the organic layer and return to the bottom layer. In addition, based on ^{19}F NMR, UV–vis, and GC-MS data, no loss of catalyst or fluorous solvent to the organic phase was detected and no organic compounds were found in the fluorous phase. There were no significant differences between the UV–vis spectra of the initial and recovered fluorous phases, which may indicate that the fluorous lanthanide catalyst is recovered unaltered after the reaction process has taken place. $RE(OPf)_3$ was completely (>99%) recovered, as determined by atomic emission spectrometry (ICP) and was then reused (Table 1, entries 3 and 4). The separated fluorous phase could be re-

[b]The fluorous phase was run for five consecutive cycles.

used for the next reaction without any specific treatment and the recycling work-up procedure was accomplished by simple phase separation. For example, in the $Yb(OPf)_3$-catalyzed reaction of aldehydes and acetic anhydride, the yields from the first run to the fifth run were 99%, 99%, 98%, 96%, and 97%, respectively.

We decided to use the relatively cheap and similarly active catalyst $Yb(OPf)_3$ for the synthesis of other acylals (Scheme 1). The results are summarized in Table 2. All isolated pure products gave satisfactory spectral analysis for ^1H NMR, IR, and MS. The aromatic aldehydes, cinnamaldehyde and 1-naphthylaldehyde that have an electron-withdrawing group, are worth mentioning as they almost gave quantitative yields in the presence of 0.3 mol% catalyst, which is less than those of the reported methods (21–27). The nature of the substituents on the aromatic ring seems to have no effect on the reaction system. It is worth noting that hydroxyl groups in 2-hydroxy- and 4-hydroxybenzaldehyde were also acetylised to afford the corresponding triacetates under these conditions. Notably, in the cases of 4-hydroxy- and 4-(dimethylamino)-benzaldehyde, only 41% of 4-hydroxy-benzaldehyde was converted to acylals, while 4-(dimethylamino)-benzaldehyde failed to give the expected acylals even though the reaction mixtures were stirred for 24 h. Such reactions may have suffered from the tautomerization that occurred in the catalysis of $Yb(OPf)_3$, which decreased the reactivity of the aldehyde groups (17). However, such tautomerization does not happen in 2-hydroxy-benzaldehyde because the intramolecular hydrogen bond between hydroxyl and aldehyde groups prevents the formation of a quinoid structure (20). The reaction of heterocyclic aldehydes such as furyl aldehyde also gave quantitive conversion to products. Greater reaction times were required for aliphatic aldehydes than aromatic aldehydes to obtain excellent yields, while ketones such as butanone, acetophenone, and benzophenone were practically unchanged in the reaction (Scheme 2). Therefore, the present procedure is a selective preparation of acylals of aldehydes in the presence of ketones.

It was reported that the mechanism of the title reaction could involve either intermolecular or intramolecular transfer of the second acetate group after initial attack by acetic anhydride (Scheme 3) (19). To test this aspect of the conversion in an FBS, we prepared acetic propionic anhydride for the geminal acylation reaction (Scheme 4). Analysis of the products by GC-MS showed a nearly 1:1:2 ratio of geminal diacetate, geminal dipropionate, and mixed acetate–propionate, respectively. This result supports the intermolecular pathway of Scheme 3.

In summary, the efficiency of $Yb(OPf)_3$ as a Lewis acid catalyst in FBS as an ecofriendly reaction system was demonstrated for the conversion of aldehydes into geminal diacetates. The versatility of this reaction system benefits greatly from both the efficient Lewis acidity of $Yb(OPf)_3$ and the unique solution properties of FBS. We believe that the following properties endow the catalytic approach with great potential for synthetic applications: (*i*) the amount of catalyst used is minute, (*ii*) the catalyst, which is completely immobilized in the fluorous phase, can be recovered and reused, and (*iii*) fluorous biphasic catalytic technique allows high yields and purities of the resultant 1,1-diacetates and indeed they can be used directly, without purification, for many reactions.

Experimental section

Melting points were obtained with a Shimadzu DSC-50 thermal analyzer. IR spectra were recorded on a Bomem MB154S IR analyzer. UV–vis spectra were obtained with a UV-1601 apparatus. ^1H NMR and ^{19}F NMR spectra were recorded with Bruker Advance RX300. Mass spectra were recorded on a Saturn 2000GC-MS instrument. Inductively coupled plasma (ICP) spectra were measured on an Ultima2C apparatus. Elemental analyses were performed on a Yanagimoto MT3CHN recorder. The perfluorodecalin (octadecafluorodecahydronaphthalene) and rare earth (III) salts were purchased from Sigma-Aldrich Co. Heptadecafluorooctanesulfonic acid was commercially obtained from ARCOS Co. Commercially available reagents were used without further purification.

Typical procedure for the preparation of rare earth (III) perfluorooctanesulfonates

$RE(OPf)_3$ compounds were prepared according to literature methods (6). In method A, a mixture of a solution of heptadecafluorooctanesulfonic acid (PfOH, 0.77 g, 1.5 mmol) in water (5 mL) and a solution of $YbCl_3{\cdot}6H_2O$ (0.2 g, 0.5 mmol) in water (0.8 mL) was stirred at RT for 18 h. In method B, a mixture of a solution of PfOH (0.77 g, 1.5 mmol) in water (5 mL) and of Yb_2O_3 (0.12 g, 0.25 mmol) powder was stirred at boiling for 3 h.

In both methods, the resulting gelatinlike solid was collected, washed, and dried at 150 °C in vacuum to give a white solid that shrinks at around 380–450 °C. IR (KBr, cm^{-1}) υ: 1237 (CF_3), 1152 (CF_2), 1081 (SO_2), 1059 (SO_2), 747 (S-O), 652 (C-S). ICP (%) calcd. for $C_{24}O_9F_{51}S_3Yb{\cdot}H_2O$: Yb

Typical procedure for synthesis of acylals in FBS

The aldehyde (10 mmol) or ketone (10 mmol) was slowly added into a mixture of $Yb(OPf)_3$ (50 mg, 0.03 mmol), toluene (2 mL), and perfluorodecalin ($C_{10}F_{18}$, cis and trans mixture, 2 mL) containing acetic anhydride (20 mmol). The mixture was stirred at 80 °C for the time indicated in Table 2. The fluorous layer on the bottom was then separated for the next reaction. The reaction mixture (organic phase) was washed subsequently with brine (10 mL), 5% $NaHCO_3$ solution (10 mL), and water (2 × 10 mL), and dried over $MgSO_4$. The solvent was removed under reduced pressure and the residue was purified by a silica gel column chroma-

Expanding the scope of the Newman–Kwart rearrangement — A computational assessment

Heiko Jacobsen and James P. Donahue

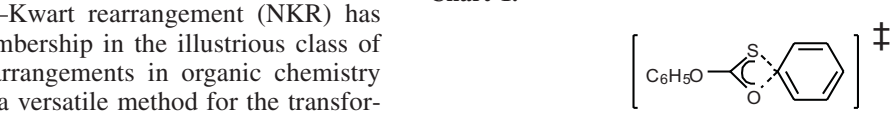
Abstract: The Newman–Kwart rearrangement (NKR) has been studied for a variety of thioncarbamates using density functional (B3LYP) and ab initio (MP2) methodologies. The results confirm and support the generally accepted mechanism that the NKR proceeds through a four-membered cyclic transition state. The presence of a π system connected via an oxygen linkage to a thiocarbonyl functionality is identified as a crucial structural element for the NKR. The calculations further suggest that the NKR might also be feasible for thioncarbamates derived from π system containing groups other than phenols such as ethenol, ethenediol, and butadienol. The NKR is compared with the Schönberg rearrangements of thioncarbonates.

Key words: density functional calculations, localized orbital locator, oxygen–sulfur transposition, thiols.

Résumé : Faisant appel à des méthodologies ab initio (MP2) et de densité fonctionnelle (B3LYP), on a étudié le réarrangement de Newman–Kwart (RNK) d'une variété de thioncarbamates. Les résultats confirment et sont en accord avec le mécanisme généralement accepté selon lequel le RNK se produit par le biais d'un état de transition impliquant un cycle à quatre chaînons. On a identifié que la présence d'un système π lié à une fonctionnalité thiocarbonyle par le biais d'une liaison oxygène est un élément crucial au RNK. Les calculs suggèrent de plus que le RNK pourrait aussi être possible avec des thioncarbamates dérivés de groupes contenant des systèmes π autres que les phénols, tels l'éthénol, l'éthènediol ou le butènediol. On a comparé le RNK aux réarrangements de Schönberg des thioncarbonates.

Mots clés : calculs de densité fonctionnelle, locateur d'orbitale localisée, transposition oxygène–soufre, thiols.

[Traduit par la Rédaction]



Introduction

By now, the Newman–Kwart rearrangement (NKR) has firmly established its membership in the illustrious class of the most well-known rearrangements in organic chemistry (1). The NKR represents a versatile method for the transformation of phenols to the corresponding thiophenols as outlined in Scheme 1.

Phenols **1** are first converted to thioncarbamates **2**. These compounds, when heated, rearrange to the corresponding thiolcarbamates **3**, which then can be easily changed into the desired thiophenols **4**. The key step in NKR is the O→S transposition, which relates this reaction to the Schönberg rearrangement (2) of diaryl thioncarbonates to diaryl thiolcarbonates. Tarbell and coworkers (3) have studied the Schönberg rearrangement in detail, addressing the scope as well as the kinetics (4) of this transformation. He proposed (3) that this first order reaction involves a four-membered cyclic transition state (Chart 1).

When talking about the Schönberg rearrangement, a caveat is in order. This rearrangement should not be mistaken for the Schönberg reaction (5, 6), i.e., the reaction of diarylthioketones with diazomethane at room temperature (7).

Chart 1.

Kwart and Evans (8) have expanded the Schönberg rearrangement and studied the vapour phase rearrangement not only of thioncarbonates but also of thioncarbamates. Newman and Karnes (9) have then established a synthetic protocol for the conversion of phenols to thiophenols via dialkylthioncarbamates, which has evolved into a standard procedure in organic chemistry. The NKR has not only found wide applications in synthetic protocols such as the syntheses of benzothiophenes (10), azulenethiols (11), isoflavons (12), and biaryl dithiols (13), to list but a few representative examples, but has also emerged as key procedure in the field of supramolecular chemistry (14–17). Partly because of its importance in medicinal chemistry, the NKR remains a central focus of ongoing research activities (18–20). Very recently, Moseley and et al. (21) have re-evaluated the NKR employing microwave technology. Microwave heating

Scheme 1.

has proven to be ideal for investigating this high temperature rearrangement and has facilitated the confirmation of many aspects of this valuable reaction.

The NKR is well established for phenols and substituent influences on the kinetics of the reaction have been studied in detail (22–24). Electron-withdrawing groups are known to aid the rearrangement, either by reducing the reaction time or lowering the required temperature. Thus far however, no reports are to be found in the literature as to whether this methodology might be employed for other alcohols as well.

Inspired by the broad potential of the Newman–Kwart rearrangement, we have undertaken a computational study to explore whether and how the scope of the NKR might be expanded. The goals of the present study are twofold. Firstly, we seek to identify structural elements that are essential requirements for the NKR. The computational investigation therefore centers on the mechanism of the O→S transposition step. Secondly, we want to develop an electronic picture of the NKR that provides a deeper understanding of this important reaction. Not only shall we follow the traditional molecular orbital approach to chemical bonding, but we will employ arguments based on the charge density distribution ρ of a molecular system (25). In this context, the newly proposed localized orbital locator LOL (26, 27) will be of special importance in our analysis. We will briefly outline our computational approach before discussing our results in detail.

Computational methodology

Pratt and coworkers (28) have recently proposed a strategy for evaluating barrier heights for gas-phase reactions. Based on an extensive study of representative lithium enolate reactions, they found that transition-state geometry optimization with B3LYP followed by single-point MP2 calculations generally provided acceptable results in comparison with higher level ab initio methods. In this study, we adopt the approach as advocated by Pratt and coworkers. Geometries for reactants, products, and transition states have been optimized in density functional calculations employing the hybrid functional B3LYP. Final energies were determined in Møller–Plesset MP2 single-point calculations.

Regarding the choice of basis set, Truhlar and coworkers (29) have found that the addition of diffuse functions is of importance when calculating reaction energies and reaction barrier heights with density functional theory. It was shown that diffuse basis functions are vital to describe the relative energies between reactants, products, and transition states in isogyric reactions. Therefore, we employed a 6–31+G** basis for all calculations presented in the present work.

Enthalpies H at zero K were obtained as the sum of total electronic energies E_{elec} and zero-point vibrational energies ZPVE. Rate constants k were calculated according to transition-state theory, $k = (k_B \cdot T/h) \times \exp(-\Delta G^{\ddagger}/R \cdot T)$ (30). For calculations at the MP2–B3LYP level of theory, corrections for ZPVE, for H, and for entropy S were calculated from B3LYP frequencies.

The results presented in this work were obtained using the Gaussian03 program system, revision C.02 (31). B3LYP density functional calculations are based on Becke's three parameter hybrid functional (32) together with the correlation functional of Lee et al. (33). Local minima on potential energy surfaces were characterized by real frequencies only, while transition states were characterized by one imaginary frequency corresponding to a molecular displacement along the reaction coordinate.

Topological analyses of molecular electron densities have been carried out with a modified version of the program MORPHY (34). Bond orders have been evaluated using the program FUZZY (35).

Results and discussion[3]

We have studied the O→S transposition step of the NKR for nine representative molecules, **2a**–**2i** (Chart 2). The set of molecules includes phenols, substituted phenols, ethenylic alcohols, alkyl alcohols, as well as thioncarbonates. The molecules were chosen to identify the structural elements required for the NKR and to make a comparison with experimental results to judge the quality of the calculations.

Energetics of NKR

Representative geometries along the reaction coordinate of the O→S transposition of **2a** are depicted in Fig. 1. Of special interest is the geometry of the cyclic transition state and we will return to this aspect at a later point in our discussion.

Reaction enthalpies ΔH_{NKR} for the transformation **2**→**3** are reported in Table 1 and we will base our discussion on the values obtained from MP2–B3LYP calculations. The NKR is calculated to be exothermic with ΔH_{NKR} values ranging from –51 to –76 kJ/mol. The formation of the C=O double bond provides the thermodynamic driving force for this reaction. The enthalpy of activation $\Delta H^{\ddagger}_{NKR}$ for the prototypical substrate **2a** amounts to 151 kJ/mol. Introducing electron-withdrawing substituents like a nitro group into the aromatic ring, compound **2b**, substantially lowers the activation enthalpy by 14 kJ/mol. When the aromatic ring is replaced by a C=C double bond as in **2c**, the activation energy increases by 8 kJ/mol. Expanding the conjugated π system by adding another double bond, as is the case for compound

i	–68	170	–76	167

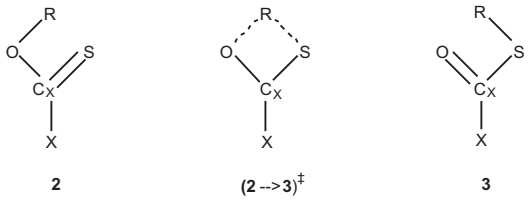
Fig. 1. Optimized geometries of reactant, transition state, and product for the NKR **2a**→**3a**. Selected bond distances are given in pm.

2d, is equivalent to adding an electron-withdrawing substitutent to the C=C double bond. As expected, $\Delta H^{\ddagger}_{NKR}$ decreases by 8 kJ/mol when going from **2c** to **2d**. The activation energy for compound **2d** is comparable to that of the aromatic system **2a**. Adding electron-donating substituents to the conjugated π system now has the opposite effect. Introducing a hydroxyl group to the C=C double bond in **2c** furnishes compound **2e**. This substitution causes an increase in $\Delta H^{\ddagger}_{NKR}$ by 16 kJ/mol.

The presence of a π system connected via an oxygen linkage to a thiocarbonyl functionality appears to be a crucial structural element for the Newman–Kwart rearrangement. When the aryl or ethenyl group is replaced by an alkyl group like methyl or *tert*-butyl as in **2f** and **2g**, the activation enthalpy $\Delta H^{\ddagger}_{NKR}$ increases substantially and takes on values of 225 and 218 kJ/mol, respectively.

The activation enthalpies for thioncarbonates **2h** and **2i** are higher than those for aryl or ethenyl thioncarbamates. The presence of a nitrogen atom couples the π system of adjacent the O- and S-atoms more effectively, and thus facilitates the thiocarbonyl to carbonyl transformation.

The results of B3LYP and MP2–B3LYP calculations are in qualitative agreement and also in good quantitative agreement. An exception is the activation enthalpy $\Delta H^{\ddagger}_{NKR}$ for the alkyl compounds **2f** and **2g**. The density functional approach appears to underestimate the activation barriers by 35–60 kJ/mol.



The **2a**→**3a** rearrangement has also been computationally investigated by Woodward and coworkers (36). The authors employed 6–31G* basis sets and report activation energies E_a of 162 and 160 kJ/mol obtained from B3LYP–MP2 calculations, respectively. These results are in good agreement with values of the present study.

Chart 3.

Next, we turn to the geometries of reactants **2**, products **3**, and transition states $(\mathbf{2}\rightarrow\mathbf{3})^{\ddagger}$ (Chart 3). Here, X represents a dimethyl amide (**a**–**g**) or phenoxy (**h**, **i**) functionality.

Selected bond distances are compiled in Table 2. All transition state structures display O–C_X distances between 126 and 129 pm, and have S–C_X separations between 170 and 175 pm. These bond distances reflect the change of bond character; a C–O single bond is converted into a C=O double bond whereas a C=S double bond transforms into a C–S single bond. The O–C_X and S–C_X distances formally indicate bonds of order 1.5 and characterize the transition state as a resonance structure. The distances O···R and S···R are indicative of a concerted process of bond cleavage and bond formation. Comparing related aryl and ethenyl thioncarbamates, it appears that transition states with lower activation barriers have shorter O···C and S···C distances.

Alkyl compounds **2f** and **2g** undergo the O→S transpositions via transition states with extremely long O–C and S–C separations. The processes of bond cleavage and bond formation do not proceed in a synchronous fashion but constitute a sequential reaction. Since the process of bond cleavage is not supported by additional bond forming interaction, the transition states for compounds **2f** and **2g** are at high energies.

To assess the feasibility of a Newman–Kwart rearrangement for the compounds investigated in this work, we have calculated rate constants k for **2**→**3** transformations at various temperatures. The synthetic protocol developed by Newman and Karnes (9) prescribes temperatures in the range of 170–270 °C, a temperature range that we have adopted in our calculations as well. The values for k at different temperatures are collected in Table 3.

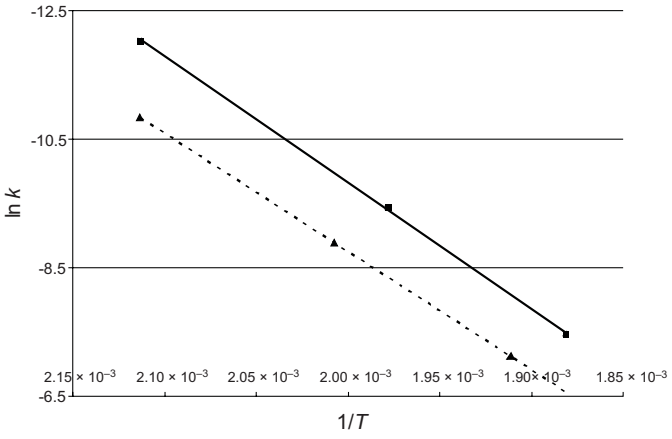
For the nitro compound **2b**, Newman and Karnes (9) report a reaction temperature of 180 °C. From inspection of the data presented in Table 3, we estimate that the rate constant k should have a value of 1.0×10^{-5} s^{-1} or greater for a Newman–Kwart rearrangement to be of synthetic value. The data in Table 3 suggest that thioncarbamates **2c**, **2d**, **2e** derived from ethenol, butadienol, and ethenediol should undergo O→S transpositions at temperatures above 250, 175, and 275 °C, respectively. The data further suggest that alkyl compounds such as **2f** and **2g** cannot be subjected to the NKR.

Although the activation enthalpies for compounds **2h** and **2i** are almost identical, entropic contributions cause slight differences in reaction rates. The chloro compound **2i** displays somewhat smaller k values compared with the unsubstituted compound **2h**. Powers and Tarbell (4) have investigated the gas-phase kinetics of the rearrangement of bis-(4-chlorophenyl)thioncarbonate **2i**. They report values for the rate constant k of 6.2×10^{-5} s^{-1} and 2.08×10^{-4} s^{-1} at 251.4 and 269.3 °C, respectively. The results of our calculations are in good agreement with the experimental data.

Solution kinetics of the NKR have also been investigated. Relles and Pizzolato (22) measured rate constants k (in s^{-1}) for the rearrangement **2a**→**3a** in diphenyl ether solutions (0.3 mol/L) of $8.0 \pm 0.25 \times 10^{-5}$ and $5.70 \pm 0.20 \times 10^{-4}$ at temperatures of 232.3 and 258.2 °C, respectively. For the same reaction in diphenyl ether, Miyazaki and coworkers (24) report a k value of 5.92×10^{-6} at a temperature of 200.5 ± 0.1 °C.

Arrhenius plots of $\ln k$ vs. $1/T$ for measured and calculated rate constants are depicted in Fig. 2. Inspection of Fig. 2 suggests that the main difference between gas-phase and solution kinetics is caused by different pre-exponential factors, which in turn are related to the entropy of activation $\Delta S^{\ddagger}_{NKR}$. An enhanced entropic barrier causes the NKR to proceed somewhat slower in solution than in the gas phase.

Electronic structure of NKR transition states



The nature of the chemical bond constitutes one of the central subjects of chemistry and provides valuable insight and information not only for a chemical molecule but also for the cause of chemical reactions. Since the early days of quantum chemistry this problem has been tackled mainly on the grounds of orbital models, which have evolved into a standard tool in chemistry. We therefore begin with an analysis of the electronic structure of NKR transition states in terms of their relevant frontier orbitals. We will restrict our analysis to compounds **2a**, the prototypical Newman–Kwart reagent, **2c**, in which the migrating phenol group has been

replaced by ethenyl, and **2f**, having a methyl group. A frontier Kohn–Sham (KS) orbital diagram for the corresponding transition states is displayed in Fig. 3.

The lowest unoccupied and the highest occupied orbitals kso1 and kso2 are similar for the three transition states (**2a→3a**)‡, (**2c→3c**)‡, and (**2f→3f**)‡. For kso1, lone-pair p orbitals at oxygen and sulfur interact in antibonding fashion with a p orbital of the migrating group, which is oriented towards the two chalcogen atoms. For kso2, we again see major contributions for chalcogen lone-pair p orbitals; in cases where the migrating ligand binds to the chalcogen atom through an sp_2-carbon atom that contributes to an extended π system, the chalcogen lone-pair orbitals undergo antibonding interaction with the migrating group. This then is the reason that the highest occupied molecular orbitals for the transition states (**2a→3a**)‡ and (**2c→3c**)‡ are higher in energy than for (**2f→3f**)‡. Of special interest is orbital kso3, which contains significant bonding interaction of sulfur lone-pair orbitals with p_π orbitals of the migrating group. For the transition state (**2f→3f**)‡, a kso3-type orbital surface at 0.075 au is not to be found among the frontier orbitals. Instead, we see bonding contributions between a p orbital at oxygen and an sp_3-type orbital of the migrating group, orbital kso4. Similar orbitals are present for (**2a→3a**)‡ and (**2c→3c**)‡. This orbital analysis is in accord with our previous observation that the presence of a π system connected via an oxygen linkage to a thiocarbonyl functionality appears to be a crucial structural element for the NKR.

The conclusions emerging from our orbital analysis are not new. Miyazaki and coworkers (24) already pointed out that a four-membered cyclic transition state is formed by nucleophilic attack of lone-pair electrons of the thiocarbonyl sulfur atom on the migrating ring. However, the question arises as to how well these simple molecular orbital arguments correlate with the nature of the chemical bonds of the transition states in question. Do we indeed have a four-membered cyclic transition state and if so, is this transition state topology also present in systems that have migrating groups without π systems at the chalcogen-bonded atom?

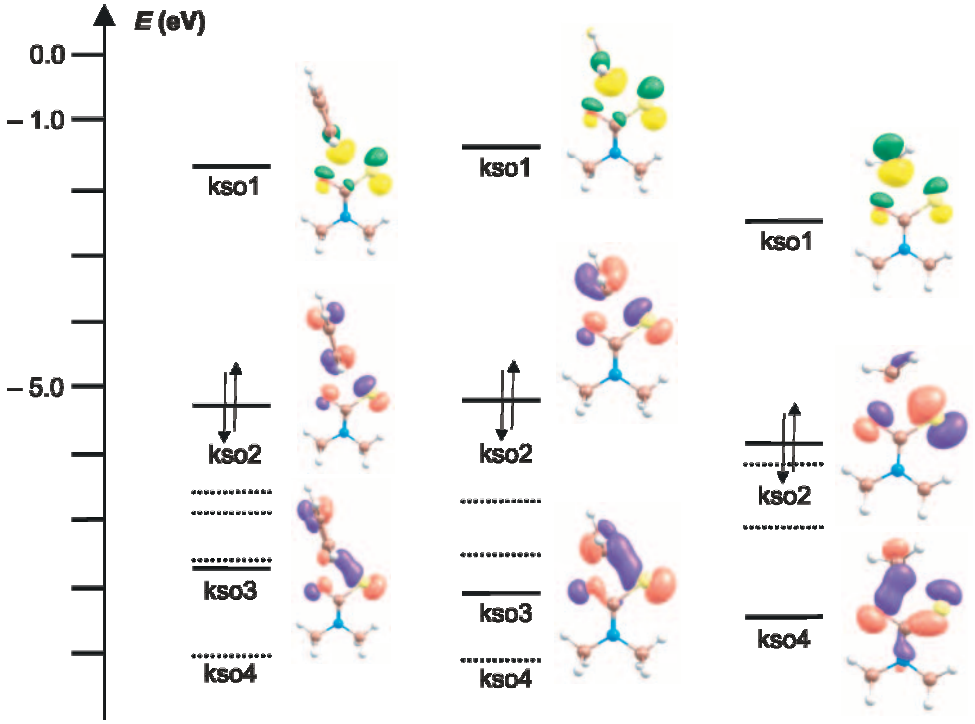
Orbitals are not unique and it is desirable to have orbital-independent descriptions of chemical bonding. One such picture is supplied by the electronic charge density ρ(r) of a chemical system. Bader (25) has revolutionized the field of interpretation of ρ(r) in terms of physical and chemical principles and his theory of "atoms in molecules" (AIM) not only allows for a description of the topology of a chemical system but also for an assessment of the quality of chemical bonds. In a topological analysis of the electronic charge density ρ(r), gradient paths of the gradient vector field ∇ρ(r), which originate at a bond critical point and terminate at the nuclei, might be used to define a chemical bond and to establish a molecular graph (37). Such graphs in the O–C_X–S plane of transition states (**2a→3a**)‡, (**2c→3c**)‡, and (**2f→3f**)‡ are displayed in Fig. 4. We reiterate the fact that the chemical bonds, which define the molecular graph, are derived from the electron density of the calculated molecules and are not based on structural criteria of optimized molecular geometries. The AIM approach provides a clear and unambiguous definition of a chemical bond and is applicable whenever the electron density ρ(r) is known, be it from theory or experiment.

From Fig. 4, it is evident that the three representative transition states all possess a four-membered cyclic ring, which includes the two chalcogen atoms as well as the migrating functional group R. Even for the transition state (**2f→3f**)‡, with long R–O and R–S separations of 208 and 238 pm, we find bond paths connecting the migrating R group with both O and S atoms. The presence of a four-membered ring system is further corroborated by the occurrence of a ring critical point.

When assessing the quality of a chemical bond, Bader advocates the use of the topology of the Laplacian of the electron density $\nabla^2\rho$. The function L, which is the negative of the Laplacian, can be used to map out regions where electronic charge is locally concentrated, $L > 0$, or depleted, $L < 0$ (38). This analysis leads naturally to the identification of covalent bonds and electron lone pairs. Becke and Edgecombe (39) have introduced a different approach to the identification of localized electronic groups in atomic and molecular systems. This function is based on the kinetic energy density τ and is commonly known as electron localization function ELF. Very recently, Schmider and Becke (26) have formulated a localized orbital locator LOL (26,27). LOL is similar in definition and structure to the electron localization function

© 2006 NRC Canada

Fig. 3. KS frontier orbital diagram for transition states (**2a→3a**)‡ (left), (**2c→3c**)‡ (middle), and (**2f→3f**)‡ (right). For orbital energy levels represented by solid lines, a corresponding orbital surface plot at 0.075 au is shown. The occupation of the highest occupied orbitals is designated by a double arrow. The molecular orientation is that of Chart 3.



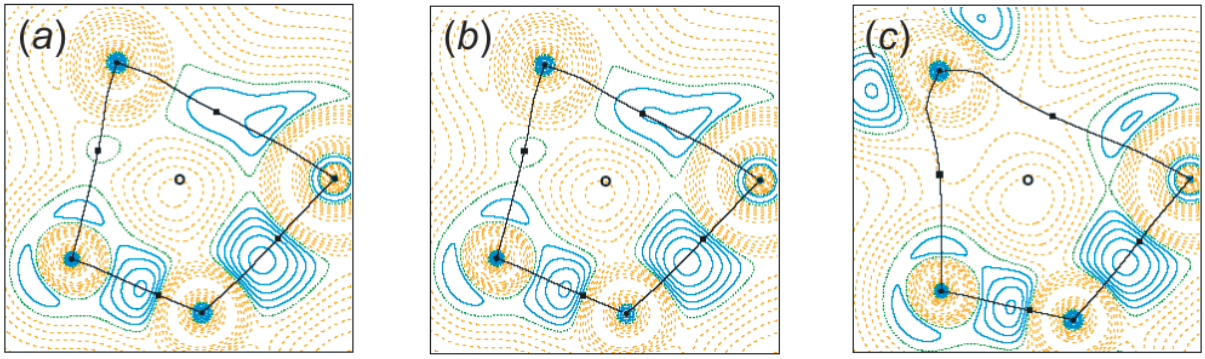


Fig. 4. Molecular graphs and LOL contour maps in the O–CX–-S plane for *a*) (**2a→3a**)‡, *b*) (**2c→3c**)‡, and *c*) (**2f→3f**)‡. Also shown are bond critical points (■) and ring critical points (○). The molecular orientation is that of Chart 3. ν contours are equally spaced by 0.05 units. Contours with ν = 1/2 are plotted as dotted lines (green), with ν > 1/2 as solid lines (blue), and with ν < 1/2 as dashed lines (yellow).

ELF, but is a simpler function and generates simplified pictures that are easier to interpret.

The localized orbital locator ν is a measure of the relative value of the local kinetic energy τ in a mapping onto the finite range [0,1]. A value of $\nu = 1/2$ indicates that the kinetic energy content of the corresponding region is what would be expected from a spin-neutral electron gas of that density and values of ν > 1/2 indicate regions where electrons are localized. Such regions do not only occur in bonds but also at places in the molecule that are usually associated with lone pairs. Only covalent bonds show up as a closed region of large ν values between the bound atoms. Closed-shell interactions do not show that feature.

LOL contour plots are also shown in Fig. 4. For the transition states (**2a→3a**)‡ and (**2c→3c**)‡, we find a region of significant electron localization along the S–R bonds and only marginal electron localization along the O–R bonds. For the transition state (**2f→3f**)‡, on the other hand, no regions of electron localization are to be found along S–R or O–R bonds. This picture supports our previous notion of the course of the NKR. For systems that have migrating groups without π systems at the chalcogen-bonded atom, the steps of O–R bond cleavage and S–R bond formation occur in a sequential matter; in the transition states, the bonds between chalcogen atoms and the migrating group are essentially broken. On the other hand, for systems that have migrating groups with π systems at the chalcogen-bonded atom, the steps of O–R bond cleavage and S–R bond formation occur

Note: The molecular orientation is that of Chart 3.

in a concerted manner, which then leads to a decrease in activation energy.

We recall that the LOL maps out the covalent character of a chemical bond. However, there exist other bonding interactions such as electrostatic attraction. Molecular properties then are often analyzed in terms of charge or electron distribution and in the context of density functional theory one might say that the charge distribution determines all molecular properties (30). The most popular indicators of electron distribution in a molecule are electron population and bond order. Various definitions for bond orders have been suggested and are used in bonding analysis, all of which have their particular advantages and drawbacks. Recently, Mayer and Salvador (40) have proposed bond order indices in terms of fuzzy atoms. The fuzzy bond order (FBO) scheme is based on divisions of the three-dimensional physical space into atomic regions in which the regions assigned to the individual atoms have no sharp boundaries but exhibit a continuous transition from one to another. In a comparative study, Solà and coworkers (41) have analyzed the behaviour of various bond order schemes. They found that, especially for polar bonds, the bond orders obtained with the FBO approach are in good agreement with the formally predicted bond orders. We thus decided to evaluate bond orders using the fuzzy atom approach and the results of an FBO analysis are collected in Table 4. The bond orders presented here are derived from B3LYP calculations.

When we compare the transition state bond orders of molecules with (**2a**, **2b**, **2c**, **2d**, **2e**) and without (**2f**, **2g**) supporting π systems, we see that the latter group shows lower O⋯R and higher O–C_X bond orders. It appears that for the latter group the transition state represents a structure in which the O–R bond cleavage has proceeded to a more complete degree. At the same time, we see that molecules without supporting π system have smaller values for the S⋯R bond order. This observation is in agreement with our conclusions obtained from the LOL analysis: In the absence of a supporting π system, the processes of bond formation and bond cleavage occur in a sequential fashion.

Comparing thioncarbamates and thioncarbonates, we find for the latter somewhat larger FBO values for the O–C_X and S=C_X bonds. Making the simplified assumption that a larger FBO value corresponds to a larger bond strength, the introduction of a carbamate group then reduces the O–C_X and S=C_X bonds. Since these bonds need to be fully or partially broken during the course of the NKR, it follows that introduction of a carbamate group lowers the activation barrier for the NKR.

Conclusion

Our computational studies confirm and support the mechanism of the NKR that was developed in the early kinetic investigations, i.e., the NKR proceeds through a four-membered cyclic transition state. The presence of a π system connected via an oxygen linkage to a thiocarbonyl functionality is identified as crucial structural element for the NKR. This allows the processes of bond cleavage and bond formation to proceed in a synchronous fashion, which in turn lowers the activation energy associated with this reaction. Our calculations further suggest that the NKR might also be feasible for thioncarbamates derived from π system-containing groups other than phenols, such as ethenol, ethenediol, and butadienol. Experimental work is currently under way in our laboratories addressing the question whether the NKR can indeed be expanded according to the predictions that emerged from the present computational assessment.

Metal(II) Schiff base complexes as catalysts for the high-regioselective conversion of epoxides to β-hydroxy nitriles in glycol solvents

Hossein Naeimi and Mohsen Moradian

Abstract: A facile preparation of 3-hydroxy propanenitrile derivatives is described involving ring opening of epoxides with potassium cyanide in glycol solvents in the presence of Schiff base complexes as catalysts. This method occurs under neutral and mild conditions with high yields and high regioselectivity. Thus, several β-Hydroxy nitriles, useful intermediates toward biologically-active molecules, are easily obtained at room temperature.

Key words: β-hydroxy nitrile, Schiff base, epoxide, glycol, catalyst.

Résumé : On décrit une préparation facile de dérivés du 3-hydroxypropanenitrile qui implique l'ouverture d'époxydes à l'aide de cyanure de potassium dans des solvants à base de glycol, en présence de complexes de bases de Schiff comme catalyseurs. Cette méthode implique des conditions neutres et douces et conduit à des rendements et une régiosélectivité élevés. Opérant à température ambiante, on an a ainsi préparé plusieurs β-hydroxynitriles utiles comme intermédiaires dans la synthèse de molécules biologiquement actives.

Mots clés : β-hydroxynitrile, base de Schiff, époxyde, glycol, catalyseur.

[Traduit par la Rédaction]

Introduction

β-hydroxy nitriles are important reagents as well as technical products in organic chemistry. They have been extensively investigated and employed for the preparation of intermediates of many naturally occurring bioactive compounds (1–4).

β-Hydroxy nitriles can be prepared by the reaction of epoxides with the toxic volatile HCN (5), NaCN (6, 7), KCN (8), LiCN (9), cyanide exchange resin (10*b*), and TBAF–TMSCN in CH_3CN (11–13). The reaction of epoxides with NaCN, KCN, or HCN usually requires extended times (6, 7*b*, 7*c*, 8*c*), protic solvents (5–7, 8*a*, 8*b*), or additives (7*a*, 8*c*), e.g., Zr-catalyzed one-pot synthesis of β-cyanohydrins from olefins via epoxidation of the olefins and nucleophilic ring opening of the epoxides (10*a*). Some of these reactions afford mixtures of regioisomers (8*c*, 10*b*, 11) or stereoisomers (5). By using trimethylsilylcyanide (TMSCN) in the preparation of β-hydroxy nitriles, the iso-nitrile has been formed (12, 13*d*) as the main product.

In the literature, ring opening of epoxides with cyanide ion as a nucleophile has been carried out by employing nonvolatile alkali cyanides in the presence of perchlorate salts (14) or $Yb(CN)_3$ (12, 14). Some methods employ acetone cyanohydrin in the presence of various bases (15) or lanthanide alkoxides (16), alkyl aluminum cyanides (17), and $Ce(OTf)_4$ (18). In most methods referred to in the literature, the reaction conditions are usually severe; some reagents are commercially unavailable and have to be prepared from alkali cyanides. In addition, the use of alkyl aluminum cyanides presents difficulty in large scale reactions.

To overcome these limitations, we developed a new approach of oxirane ring opening with potassium cyanide in glycol solvents using Schiff base complexes as catalysts at room temperature to afford β-hydroxy nitriles.

Results and discussion

Metal(II)-salen complexes are promising catalysts for various reactions. These complexes have shown wide applicability and are now used as catalysts for a variety of enantioselective reactions, such as oxidation (19), aziridination (20), cyclopropanation (21), the Diels–Alder reaction (22), and the conversion of 1,2-epoxyethanes to 2-haloethanols with molecular halogen (23).

In this study, the reaction of styrene oxide with potassium cyanide in the presence of some Schiff base complexes of metal(II) was carried out. The preparation and characterization of these complexes were according to the procedure reported in the literature (23–25). On this basis, the syntheses of these metal complexes were essentially the same and involved heating and stirring of stoichiometric amounts of the appropriate tetradentate ligand and metal acetate in a suitable solvent, such as methanol, ethanol, or water–methanol mixtures. The desired complexes crystallized upon cooling and were recrystallized from chloroform. The complexes are easy to prepare and cheap. All of the used metal chelates in this study are insoluble in water but soluble in most organic

 doi:10.1139/V06-158 © 2006 NRC Canada

Scheme 1.

solvents. They are stable in water, even at high pH and temperature.

The IR spectrum of the Schiff base exhibits a band at 1625 cm^{-1} assigned to υ(C=N) of azomethine (26). This band shifts to a lower wavenumber by about 10–15 cm^{-1} on the chelation of the ligand with a metal ion. In the ^1H NMR spectra of the Schiff bases (26), the broad signals around 12.5–13.1 ppm are assigned to the protons of the hydroxyl groups in the free ligands. Protons of CH=N have the same chemical shifts (8.5–8.9 ppm). The signal around 6.0–6.65 ppm is assigned to the protons of the NCHN, and signals around 6.6–7.90 ppm are assigned to the protons of aromatic rings (CH=CH). In the ^1H NMR spectra of the Schiff base complexes, all of these signals exhibit a 0.6 ppm shift to a lower field and the broad signal around 12.5–13.1 ppm disappeared. In the IR spectrum, the appearance of two or three bands in the low frequency region (between 420 and 540 cm^{-1}) indicates the coordination of phenolic oxygen in addition to azomethine nitrogen (24).

To examine the effects of the ligands on the catalyst, a variety of ligands were employed in the reaction (Scheme 1).

After a solution of styrene oxide and a catalyst (molar ratio is 10:1) in ethylene glycol was stirred at room temperature, 1.2 mol of potassium cyanide was added to the flask. In this reaction, 3-hydroxy-3-phenyl propanenitrile was obtained as a product and its yield was determined by GC and TLC analysis. The results of the reactions of styrene oxide with potassium cyanide in the presence of the previously mentioned catalysts are given in Table 1.

As shown in Table 1, in these reactions, β-hydroxy nitriles were prepared as products in good to excellent yields with high regioselectivity. In each case, cleavage of the epoxide ring occurs. After completion of the reaction, by addition of water and work-up with CH_2Cl_2, propanenitriles are obtained.

In comparison, the cleavage behaviour of styrene oxide with potassium cyanide in the absence of the catalyst is given in Table 1 (entry 9). This reaction in ethylene glycol in the absence of the catalyst has afforded the product with very low yield and low regioselectivity even with an extended reaction time to overnight. As seen in Table 1, the yields of the reactions with this new method are quite fair, and the reaction time is short. It is of great importance that the reaction is largely affected by the various ligands of the complexes. The complex catalysts **A** and **B** are the most effective ones in these reactions (Table 1, entries 1 and 2), while the complex catalysts **C**, **D**, and **E** have shown lower catalytic performance. This can be related to the low ability of their ligands to coordinate the metal(II) ions.

Table 1. The reaction of styrene oxide with KCN in the presence of various complex catalysts in ethylene glycol.

8	H	4.5	55
9	–	Overnight	20

Note: The reactions were carried out at room temperature.
[a]GC yield based on epoxide.
[b]The only formed *trans*-isomer.

Because H_2-salen is the most effective ligand for the reaction, we studied the catalytic effect of the first-row transition metal(II) with the ligand of *N*,*N*′-ethylenedisalicylideneamine (H_2-salen) on the formation of 3-hydroxy-3-phenyl propanenitrile (Table 1, entries 1, 6, 7, and 8). On the other hand, because the first-row transition metal(II) complexes of simple Schiff base are known to be sparingly soluble in common organic solvents, the different of the used complexes may be attributed to their own solubility or their adducts with epoxide in the reaction solution.

From the previous studies, the Co(II)-salen **A** was the best catalyst used in this reaction (see Table 1). To study the solvent effect on the reaction, nucleophilic cleavage of styrene oxide with potassium cyanide by catalyst **A** has been carried out in various glycol solvents. The results shown in Table 2 indicated that ethylene glycol is the most convenient solvent in this reaction. It was found that these reactions appeared to be largely dependent on the nature of the solvent.

The results of the reactions of some representative

8			2.3	80
9			2.5	85
10			2.2	82

[a]Isolated yields based on epoxide.

epoxides in the presence of complex **A** as the catalyst are summarized in Table 3. In these reactions, the optimum amount of the catalyst used for all of the epoxides was 0.1 mol for 1 mol of epoxide. As can be seen, at the same amount of the catalyst, the ring opening of various epoxides have been carried out with 80%–93% yields, and the reaction time was 2.2–3.0 h.

As shown in Table 3 (entry 6, in which only the trans isomer is obtained), the reactions are completely anti-stereoselective. As for the regioselectivity, an attack of the nucleophile preferentially occurs at the less-substituted oxirane carbon. An anti-Markovnikov type regioselectivity is generally observed in these reactions. In many cases, this type of regioselectivity appears to be the opposite of that observed in ring opening of the same epoxides with aqueous hydrogen cyanide under classic acidic conditions. The previously mentioned regiochemical mode can be viewed as occurring via a nucleophilic attack by a cyanide ion on the less sterically hindered oxirane carbon. This mechanism closely resembles the S_N2 model for aliphatic nucleophilic displacement.

The structure of β-hydroxy nitrile products has been assigned by spectroscopic data. In the IR spectra, the C–N stretching vibrations of the nitrile groups appear in the region between 2250 and 2274 cm^{-1}. The hydroxyl group O–H bond stretching frequency is found in the region between 3400 and 3477 cm^{-1} as a strong broad band. The C–H stretching vibrations of the alkyl groups appear in the region between 2877 and 2960 cm^{-1}. In the ^1H NMR spectra, OH protons have chemical shifts between 4.20–4.55 ppm as a singlet broad peak. The signals around 6.5–8.4 ppm are assigned to the protons of CH=CH of the aromatic rings.

Conclusion

This new method for the preparation of β-hydroxy nitriles have some advantages, such as high regioselectivity, high yields, short reaction times relative to other procedures, and work-up simplicity. The nucleophilic attack by the cyanide ion on the epoxides occurs at the primary carbon atom. Thus, we have not so far detected secondary cyano derivatives.

Experimental section

Column chromatography was carried out using 100–200 mesh silica gel (Acme India Ltd., Maharashtra, India). TLC analyses were performed on Merck 60 PF254 silica gel plates. Melting points were determined in open capillaries using an Electrothermal Mk3 apparatus. IR spectra were recorded using a PerkinElmer FT-IR 550 spectrometer and values are reported as υ in cm^{-1}. ^1H and ^{13}C NMR spectra were recorded on a Bruker DRX-400 spectrometer for samples as indicated with tetramethylsilane as internal reference. Mass spectra were recorded on a Finnigan MAT 44S with an ionization voltage of 70 eV. The elemental analyses (CHN) were obtained from a Carlo ERBA Model EA 1108 analyzer carried out on PerkinElmer 240c analyzer.

General procedure for the cleavage of epoxide into β-hydroxy nitriles

To a solution of epoxide (20 mmol) in ethylene glycol (30 mL), KCN (22 mmol) was added and the mixture was stirred for 5 min at room temperature. Then, catalyst **A** (as the modified catalyst) (2.0 mmol) was added, and stirring was continued to completion of the reaction as indicated by TLC. Then, 100 mL water and 20 mL CH_2Cl_2 were added to the reaction mixture while stirring. After being stable, the organic phase was collected and concentrated to dry under reduced pressure. The product was washed with brine and dried over anhyd Na_2SO_4. Evaporation and purification by column chromatography employing EtOAc–hexane (3:7) as the eluent afforded the pure β-hydroxy nitriles.

3-Hydroxy-4-phenoxybutanenitrile

Yield: 90%; mp 58–61 °C. IR (Neat, cm^{-1}): 3437, 3066, 2930, 2256, 1228, 1047. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.60–2.84 (2H, m), 3.96–4.12 (2H, m), 4.20 (1H, m), 4.35 (1H, br s), 6.77–7.00 (3H, m), 7.14–7.29 (2H, m). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 21.7, 62.5, 69.1, 113.1, 117.1, 126.6, 130.3, 155.8. MS (70 eV): 177, 119, 107, 94, 77.

3-Hydroxy-4-(4-chlorophenoxy)butanenitrile

Yield: 93%; mp 65–68 °C. IR (KBr, cm^{-1}): 3438, 3098, 2879, 2255, 1242, 1092, 1043. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.55–2.67 (2H, m), 3.86–4.07 (2H, m), 4.37 (1H, m), 4.39 (1H, br s), 6.84 (2H, m), 7.24 (2H, m). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 20.6, 64.1, 68.9, 114.4, 115.3, 124.6, 127.3, 154.9. MS (70 eV): 211, 141, 128, 94.

3-Hydroxy-4-(4-methylphenoxy)butanenitrile

Yield: 88%; mp 54–58 °C. IR (Neat, cm^{-1}): 3477, 3028, 2931, 2254, 1193, 1044. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.22 (3H, s), 2.69–2.88 (2H, m), 3.68–3.81 (2H, m), 4.42 (1H, m), 4.54 (1H, br s), 6.73–6.94 (2H, m), 7.06–7.19 (2H, m). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 20.6, 21.3, 67.1, 73.9, 124.6, 116.1, 128.6, 129.1,158.0. MS (70 eV): 191, 139, 108, 91, 77.

3-Hydroxy-4-(4-nitrophenoxy)butanenitrile

Yield: 93%; mp 71–74 °C. IR (KBr, cm^{-1}): 3401, 3023, 2938, 2274, 1240, 1102, 1052. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.43–2.58 (2H, m), 3.78–3.89 (2H, m), 4.30 (1H, m), 4.62 (1H, br s), 7.24 (2H, m), 8.08 (2H, m). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 21.0, 22.5, 68.1, 74.2, 117.7, 125.3, 132.6, 139.1, 155.0. Anal. calcd. for $C_{10}H_{10}N_2O_4$: C 54.06, H 4.54, N 12.61; found: C 54.02, H 4.49, N 12.49.

2-Hydroxy-1-cyclohexanecarbonitrile

Yield: 84%; liquid. IR (KBr, cm^{-1}): 3425, 2960, 2885, 2254, 1189, 1082, 1038, 948, 870, 790. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.2–1.4 (3H, m), 1.7–1.9 (3H, m), 2.15 (1H, m), 2.3 (1H, m), 2.4 (1H, s), 2.5 (1H, m), 3.6–3.8 (1H, m). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 20.6, 23.3, 24.1, 26.9, 33.4, 60.3, 118.6. Anal. calcd. for $C_7H_{11}NO$: C 67.17, H 8.86, N 11.19; found: C 67.05, H 8.81, N 10.94.

3-Hydroxy-6-heptenenitrile

Yield: 83%; liquid. IR (KBr, cm^{-1}): 3401, 3023, 2938, 2274, 1240, 1102, 1052. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.14 (2H, m), 2.41 (2H, m), 2.67–2.85 (2H, m), 3.91 (1H, m), 4.21 (1H, br), 4.87 (1H, dd, J_1 = 9.6 Hz, J_2 = 2.1 Hz), 4.94 (1H, dd, J_1 = 16.3 Hz, J_2 = 2.1 Hz), 5.69 (1H, m). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 28.3, 30.4, 36.3, 66.16, 114.3, 119.8, 137.0. Anal. calcd. for $C_7H_{11}NO$: C 67.17, H 8.86, N 11.19; found: C 67.15, H 8.70, N 11.02.

3-Hydroxy-4-isopropoxybutanenitrile

Yield: 80%; liquid. IR (KBr, cm^{-1}): 3445, 2924, 2899, 2253, 1602, 1495, 1412, 1329, 1028, 868. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.21 (6H, d, J = 6.1 Hz), 2.64–2.75 (2H, m), 3.24 (2H, m), 3.6 (1H, m), 3.7 (1H, m), 3.98 (1H, br). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 21.9, 22.7, 65.3, 70.6, 72.1, 117.8. Anal. calcd. for $C_7H_{13}NO_2$: C 58.72, H 9.15, N 9.78; found: C 58.62, H 9.08, N 9.57.

4-(Tert-butoxy)-3-hydroxybutanenitrile

Yield: 85% ; liquid. IR (KBr, cm^{-1}): 3432, 2933, 2894, 2258, 1594, 1483, 1440, 1354, 1031, 890. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.14 (9H, s), 2.36–2.48 (2H, m), 3.14 (2H, m), 3.88 (1H, m), 4.14 (1H, br). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 22.1, 27.4, 66.5, 68.5, 73.2, 117.8. Anal. calcd. for $C_8H_{15}NO_2$: C 61.12, H 9.62, N 8.91; found: C 62.01, H 9.55, N 8.78.

3-Hydroxybutanenitrile

Yield: 82%; liquid. IR (KBr, cm^{-1}): 3419, 2916, 2887, 2251, 1519, 1474, 1365, 1033, 890, 745. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.74 (3H, d, J = 5.3 Hz), 2.34–2.47 (2H, m), 4.07 (1H, m), 4.25 (1H, br). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 21.6, 25.3, 63.7, 119.0.

Principal component analysis of solvent effects on equilibria and kinetics — A hemisphere model

Robert A. Stairs and Erwin Buncel

Abstract: Principal Component Analysis (PCA) was applied to 17 selected properties relating to the properties of solvents and their effect on solute spectra and equilibria and rates of reactions in solution. The analysis showed affinities and contrasts among the parameters. Using the first three principal components (PC's) as unit vectors in the Cartesian directions, the properties were represented as vectors in this space with their directions being represented as points on the unit hemisphere; their magnitudes are lost in the process of correlation. Properties that fell into recognizable groups included the following: (*i*) those purporting to measure acidity (**A**) (α, AN, SA, and A_j), closely associated with E_T^N, *Z*, *S*, and $A(^{14}N)$, which are usually considered to be measures of polarity; (*ii*) properties supposed to measure basicity (**B**) (β, SB, and DN); (*iii*) polarity group (**P**), including pure (di-)polarity properties ($\beta_\mu^{1/2}$ and Q_v) and those measuring some combinations of polarity and polarizability (π*, π^*_{azo}, SPP, and $-\chi_R$). The space spanned by the three PCs of the properties provided a frame in which solvent effects on equilibria and on rates of reactions could be represented. Eight equilibria, represented by $\log_{10}(K)$ measured in different solvents, and 10 reaction rates, similarly represented by $\log_{10}(k)$, were correlated with the three PCs of the solvent properties. This enabled plotting of their directions in the hemisphere to show which groups of properties were most strongly correlated with the rate of each reaction. A separate plot showed the magnitudes and sense of the effects. These finding are considered in the light of the mechanisms proposed for the reactions.

Key words: Chemometrics, Principal Component Analysis, solvent effects on equilibria and rates.

Résumé : On a appliqué l'analyse du composant principal à dix-sept propriétés choisies apparentées aux propriétés de solvants et leurs effets sur les spectres ainsi que les équilibres et vitesses de réaction de solutés en solution afin de mettre en évidence les affinités et les contrastes entre les paramètres. Utilisant les trois premiers composants principaux (CP) comme vecteurs unitaires dans les directions cartésiennes, on a représenté les propriétés sous la forme de vecteurs dans cet espace dans lequel leurs directions sont représentées sous la forme de points sur l'hémisphère unitaire; leurs amplitudes sont toutefois perdues dans le processus de corrélation. Les propriétés qui peuvent être regroupées dans groupes reconnaissables sont les suivantes: (*i*) celles qui se rapportent à une mesure de l'acidité (**A**) (α, AN, SA et A_j) avec E_T^N, *Z*, *S* et $A(^{14}N)$, qui sont généralement considérées comme une mesure de la polarité; (*ii*) les propriétés qui sont sensées mesurer la basicité (**B**) (β, SB et DN); (*iii*) le groupe de polarité (**P**), y compris les propriétés de (di-)polarité pure ($\beta_\mu^{1/2}$ et Q_v) et celles qui mesurent des combinaisons de polarité et de polarisabilité (π*, π^*_{azo}, SPP et $-\chi_R$). L'espace couvert par les trois composants principaux des propriétés fournit un cadre dans lequel on peut représenter les effets de solvant sur les équilibres et les vitesses de réaction. On a pu établir une corrélation entre les trois composants principaux des propriétés de solvant et huit équilibres, représentés par $\log_{10}(K)$ mesurés dans différents solvants, et dix vitesses de réaction, représentées principalement par $\log_{10}(k)$. Ceci a permis de tracer leurs directions dans l'hémisphère et de montrer quelle est la nature des groupes de propriétés qui sont les plus reliés aux vitesses de chacune des réactions. Une courbe différente montre l'amplitude et le sens de ces effets. On discute de ces résultats à la lumière des mécanismes proposés pour les réactions.

Mots clés : chimiométrie, analyse du composant principal, effets de solvant sur les équilibres et les vitesses de réaction.

[Traduit par la Rédaction]

Introduction

Buncel et al. (1) described an application of Principal Component Analysis (PCA) to a selected group of properties that have been used to correlate the effects of solvents on spectra and on equilibria and rates of reactions in solution. This paper reports an extension of that study with a modified graphical method of representing the results. The result will first be applied to the consideration of solvent effects on equilibrium constants of a set of reactions, and second, to

Table 1. Summary of the procedure to prepare a hemisphere plot of the solvent property data.

Step	Do	Keep (file name)
1	Enter raw data (file or keyboard): m properties, n solvents	File of raw data n x m: **X** (f$.dat) (f$ is forename for particular data set.)
2	Correlate pairwise	Matrix of correlation coefficients m x m (Stored as lower triangular): **R** (f$.cor)
3	Find eigenfunctions and eigenvalues of correlation matrix	Eigenvalues: λ_i (i = 1, 2, …, n) (f$.lam), First three eigenfunctions: **Q** : m x 3 (f$.q)
4	Prepare table of reduced data (zero mean and unit norm)	File of reduced data: **Y** : n x m (f$.red)
5	Calculate the first three principal components (PCs): **QY** = **Z**. If the data contain gaps, they may not be mutually orthogonal; orthogonalize. Create augmented data matrix adding the three **z** column vectors before the **y** vectors	Augmented data: [**Z**|**Y**]: n x (3 + m) (f$.aug)
6	Correlate again to obtain correlation coefficients between the **y** vectors and the three **z** vectors	Correlation coefficients $r_{j,k}$ (j = 1, 2, …, m; k = 1, 2, 3)
7	Interpret the coefficients $r_{j,k}$ as direction cosines to $\mathbf{z}_1$('N'), $\mathbf{z}_2$('G') and $\mathbf{z}_3$('E') (on the equator at long. 0 and 90° E); calculate latitude and longitude of each **y**, and uncertainties	Lats., Longs., and uncertainties (m x 3) for export for plotting (f$.lat)

Table 2. Analysis of reaction rate data for the hemisphere display.

Step	Do	Keep
1	Enter (from file or keyboard) data on m' reaction equilibrium or rate constants in the same set of solvents as were used for the solvent properties	File of reaction rates (speeds) in solvents. **S**: (n x m')
2	Create table n x (3 + m') of the previous three **z** vectors and the m' **s** vectors	File of **z**'s and rates (n x (3 + m'))
3	Correlate and interpret $r_{j,k}$ as direction cosines	
4	Calculate lats., longs., and uncertainties	Table of lats., longs., and uncertainties for export to plotting program
5	Prepare file of vectors parallel to reaction vectors; calculate magnitudes of solvent effects	

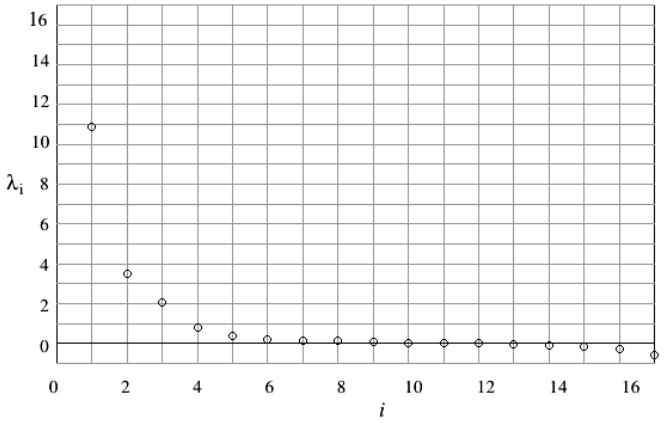
solvent effects on the rate constants of a separate set of reactions.

The properties that are most susceptible to this treatment are those that are considered in the method of *Linear Free Energy Relationship* (LFER) (2, 3), i.e., quantities that have the dimension of energy, or that are proportional to energies, such as changes in spectral frequencies or in the logarithms of rate or equilibrium constants. Some other properties are often included, such as functions of dipole moment or relative permittivity as polarity measures or functions of refractive index as a measure of polarizability.

The list of values of a physical property x_i for a set of n substances can be treated as a vector in n-dimensional space, i.e., we may write $(x_1, x_2, \ldots, x_n) = \mathbf{X}$. Given a data set containing values of m properties of the n substances, the actual number of really distinct properties may be less than m. Among the many parameters that have been introduced over the years to attempt to relate reaction rates in solvents to solvent properties, there is a great deal of redundancy or overlap. Buncel et al. (*loc. cit*. p. 135) list 10 that purport to measure acidity without being nearly exhaustive.

The PCA statistical procedure (4, 5) is a way of finding a minimal set of vectors, *principal components*, that are linear combinations of the original properties such that the first contains the largest portion of the variance of all the data, the second, orthogonal to the first, contains the next largest portion, and so on. If all the various kinds of measurements actually measure only, say, three really distinct properties, only the first three vectors will be important. Part of the remainder of the variance of the data will represent error, though some contribution from properties of less significance will necessarily be lost.

Methodology



The method employed in this study is summarized in Tables 1 and 2. It begins with pairwise correlation of all the m properties, generating the $m \times m$ correlation matrix **R**, which contains the correlation coefficients $r_{j,k}$, defined by eq. [1]. Here, all the summations are over the $n_{j,k}$ substances for which both properties are known. It is symmetric, and all the diagonal elements $r_{j,j}$ are unity.

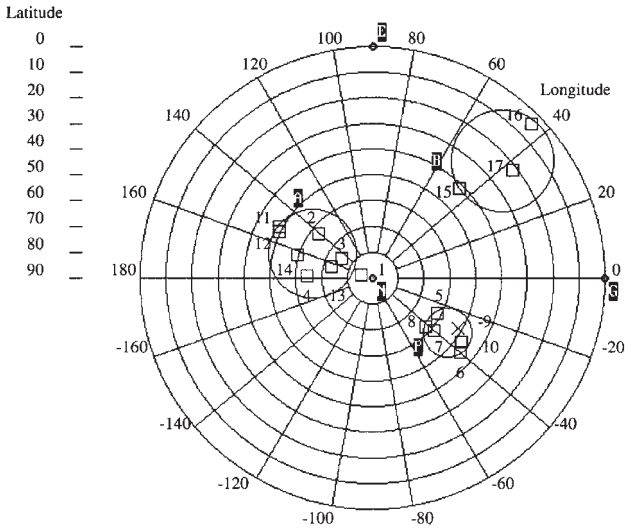
$$[1] \qquad r_{j,k} = \frac{n_{j,k}\sum_i x_{i,j}x_{i,k} - \sum_i x_{i,j}\sum_i x_{i,k}}{\left[\left(n_{j,k}\sum_i x_{i,j}^2 - \left(\sum_i x_{i,j}\right)^2\right)\left(n_{j,k}\sum_i x_{i,k}^2 - \left(\sum_i x_{i,k}\right)^2\right)\right]^{1/2}}$$

The matrix **R** has m eigenvalues λ_j and m eigenvectors $\mathbf{V}_j$, which satisfy eq. [2].

© 2006 NRC Canada

Fig. 1. The scree plot (so called from a fancied resemblance to the pile of debris fallen from a cliff face), the eigenvalues λ_i of the correlation matrix in descending order.

[2] $$\mathbf{R}\mathbf{V}_j = \lambda_j \mathbf{V}_j$$



The m constants λ_j are solutions of the secular equation [3], where **I** is the identity matrix, and are the only values of the constant that permit solutions of eq. [2] to find the eigenvectors $\mathbf{V}_j$.

[3] $$|\mathbf{R} - \lambda \mathbf{I}| = 0$$

Each eigenvector is then used as a set of weighting factors to generate a new variable, a linear combination of the original properties, from the original data set. If the eigenvalues are listed in decreasing order, the first few, with their associated eigenvectors, are all that we need to consider. The magnitude of an eigenvalue shows the portion of the variance of the data that the corresponding new parameter contains. Any eigenvalue whose magnitude is less than unity, i.e., that represents less than one whole "property", is usually considered negligible. Some of the remaining variance is normally experimental error. If the data are complete, in the sense of having no gaps, the eigenvalues will be all positive. Missing data create a problem in that some eigenvalues may be negative. As long as the negative eigenvalues are small in magnitude, this does not do great harm to the analysis; however, it does represent increased error.

Using the eigenvectors corresponding to the largest eigenvalues as weighting functions, we create the first, second, and so forth, PC's as vectors in the n-dimensional space that are linear combinations of the m normalized vectors representing the original properties. If only two eigenvalues are larger than unity, one may expect to be able to represent the properties as vectors in two dimensions. In what follows, it will be seen that we were faced with three eigenvalues larger than unity. A suitable projection may represent an aspect of a three-dimensional figure in two dimensions. Here, we shall use the fact that the variance magnitudes of the different properties have been discarded in the normalization process. In fact, the magnitudes are lost in the correlation process. We set up a coordinate system using the first three PC's, as unit vectors in the *z, x*, and *y* directions, to be the *base vectors*. In geographical terms, we place the first at the North Pole (labelled N in Fig. 2), the second on the equator on the Greenwich meridian (G), and the third on the equator at 90° East longitude (E).[2]

Fig. 2. The 17 properties in the hemispheric projection: *(a)* acid–polar: 1. E_T^N, 2. *Z*, 3. *S*, 4. $A(^{14}N)$; (*b*) dipolar: 5. Q_v, 6. $\beta_\mu^{1/2}$; (*c*) polar–polarizable: 7. π*, 8. π^*_{azo}, 9. χ_R (–ve), 10. SPP; (*d*) acid (HBD): 11. α, 12. SA, 13. A_j, 14. AN; (*e*) base (HBA): 15. β, 16. DN, 17. SB.

The angle α between two vectors $\mathbf{X}_j$ and $\mathbf{X}_k$ is defined by eq. [4]:

[4] $$\cos a = \frac{\mathbf{X}_j \cdot \mathbf{X}_k}{|\mathbf{X}_j||\mathbf{X}_k|}$$

From eq. [1], if both $x_{i,j}$ and $x_{i,k}$ are normalized as above, the norms $|\mathbf{X}_j| = \Sigma x_{i,j}^2$ and $|\mathbf{X}_k| = \Sigma x_{i,k}^2$ are each equal to 1, the sums $\Sigma x_{i,j}$ and $\Sigma x_{i,k}$ are zero, and $\cos \alpha = r_{j,k}$. This means that if the vector representing each property is placed in the coordinate system, its termination will lie on the unit sphere, and the three correlation coefficients with the base vectors will be the direction cosines that define its position. If there is no error, the sum of the squares of the three direction cosines is equal to unity (6). The departure of this sum from unity (eq. [5]) may be taken as a rough indication of uncertainty.

[5] $$s_j \approx \sqrt{\left|1 - \sum_{i=1}^{3} r_i^2\right|}$$

Solvent property parameters

There are many parameters in the literature that relate to solvent properties that are relevant to this work. They include solvatochromic parameters (based on the change in frequency of spectral features), parameters based on changes in equilibrium or rate constants, direct measures of physical properties such as dielectric constant, or parameters derived therefrom. We selected a miscellaneous set, chiefly because

[2] A.A. Milne. Winnie-the-Pooh. Dutton, New York. 1926. p. 133. "There's a South Pole", said Christopher Robin, "and I expect there's an East Pole and a West Pole, though people don't like talking about them."

Table 3. Set of 10 nonspecific solvent property parameters.

Entry	Property		Basis	Reference
1	E_T^N	Polarity	Charge-transfer (CT) absorption frequency of a dye	(7)
2	Z	Polarity	CT frequency of a pyridinium iodide	(8)
3	S	Polarity	composite	(9)
4	$A(^{14}N)$	Polarity	ESR hyperfine splitting	(10)
5	Q_v	Polarity	$(\varepsilon_r - 1)/(\varepsilon_r + 2) - (n^2 - 1)/(n^2 + 2)$	(11)
6	$\beta_\mu^{1/2}$	Dipolarity	$\mu/v^{1/2}$	(12) (Square root of the parameter)
7	π^*	Polarity–polarizability	$\pi\rightarrow\pi^*$ transitions in seven nitroaromatics	(13)
8	π^*_{azo}	Polarity	$n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ transitions in six azo-merocyanine dyes	(14)
9	χ_R	Polarity	$\pi\rightarrow\pi^*$ transition in a merocyanine dye	(15)
10	SPP	Polarity	Differential UV–vis shift between 2-(dimethylamino)- and 2-fluoro-7-nitrofluorene	(16)

Table 4. Acidity (11–14) and basicity (15–17) parameters.

Entry	Property		Basis	Reference
11	α	H-bonding donor strength	Enhanced solvatochromism in HBD solvents of Reichardt's dye 30 relative to 4-nitroanisole	(17)
12	SA	Solvent acidity	Comparison of solvatochromism of an unhindered with a sterically hindered stilbazolium betaine dye	(16)
13	A_j	Acity: anion-solvating tendency	Bilinear correlation (with B_j) of many effects.	(18)
14	AN	Electron pair acceptor number (Lewis acidity)	^{31}P NMR shifts in triethylphosphane oxide	(19)
15	β	HBA strength	Enhanced solvatochromism in HBA solvents of 4-nitroaniline relative to *N,N*-diethyl-4-nitroaniline	(17)
16	DN	Donor number (Lewis basicity)	$-\Delta H$ of adduct formation with SbF_5 in dilute solution in 1,2-dichloroethane	(19)
17	SB	Solvent basicity	Solvatochromism of 5-nitroindoline with *N*-methyl-5-nitroindoline	(16)

they were known for a reasonably large number of solvents, to minimize the number of gaps in data. They are listed in Tables 3 and 4. Similarly, a set of solvents (listed in Table 6) was chosen for which most of the chosen properties had been reported, with the additional criterion that at least some of the equilibria and rates of reactions to be discussed later had been measured in them.

When this set of parameters for the chosen 20 solvents was subjected to PCA, the scree plot (Fig. 1) showed that three components have eigenvalues greater than unity, i.e., there are three distinct properties embodied in the 20 parameters. The first is dominant, representing 64% of the total variance of the data. The next two represent 21% and 12%, respectively, leaving 3% of the variance that we neglect in using only the first three. Some of this is error, but some is undoubtedly lost information. The last few eigenvalues are negative, as expected with a data set containing gaps, but none is large. The plotting errors have not been shown in Fig. 2, the representation of the 17 parameters on the hemisphere as the resulting picture would have been too confusing. Estimates of error are listed in Table 5, with the mean latitudes and longitudes.

The properties fall for the most part into three recognizable groups, which we have labelled **A** for acid, **B** for basic, and **P** for polarity. Polarity measures based on physical

properties (Q_v on dielectric constant, $\beta_\mu^{1/2}$ on dipole moment, and molecular volume) and those based on solvatochromism (π^*, π^*_{azo}, SPP, and so forth) with a different set of solvents and properties (1) were found to form distinct sets, but here they were indistinguishable. Interestingly, Reichardt's E_T^N and Kosower's *Z*, which are usually considered to measure polarity, fell close to the **A** region rather than the **P** region. The theoretical study by Matyushov et al. (20) showed that while π^* contains positive contributions from both dipolarity and polarizability, E_T^N is negatively correlated with polarizability, so it is not surprising that they fall into different groups.

The equilibria

The eight equilibria were discussed by Reichardt (21) (Chapter 4). The processes comprise keto–enol equilibria (*A* and *B*), azo–hydrazone (*C*), spiropyran–merocyanine (*D*), rotational *gauche–cis* (*E*) and valence (*F*) isomerism, host–guest complexation (*G*), and electron-transfer equilibrium (radical disproportionation) (*H*). The original reports for the equilibria and also for the rate processes, discussed later, are supplemented and updated by various cognate references that were provided to facilitate further studies in this area. The equilibria were chosen because their equilibrium constants had been measured in at least four of the solvents listed, and they covered a range of different reaction types. A 20 × 11 table (Table 6) was created, having the first three PC's from the analysis of the 17 solvent properties for columns 1, 2, and 3, and for the remaining columns, the common logarithms of the equilibrium constants were listed. The 20 rows correspond to the 20 solvents. There were many more gaps than data, which was regrettable, as too few data points make the correlation less meaningful (22); two points only lead inevitably to a correlation coefficient $r = \pm 1$ exactly. The correlation coefficients $r_{i,j}$ (i = 1, 2, 3; j = 1, 2, …, 8) between the three PC's and the each of the rates (logarithmic) were treated as before as direction cosines, i.e., as cosines of the angular distances between a particular vector and the vectors in each of the three Cartesian axial directions. One may imagine drawing arcs with these distances, two at a time, with great-circle radii on the spherical surface, and finding three estimates of the position of the vector by their intersections. The best estimate of position lies at the centroid of the resulting triangle (the navigator's "cocked hat"). If any two of these cosines squared sum to more than unity, the angles sum to less than 90°, and the arcs fail to intersect. It was decided, to ensure finding at least approximate positions for the eight points, to divide each triplet of correlation coefficients by the quantity $\sqrt{\sum_i r_{i,j}^2}$. This ensures that all three arcs intersect in a common point. Some of the points so determined are subject to large errors, but all meaning is not lost. Figure 3 shows the positions of the eight reactions, *A–H*, in the frame defined by the 17 solvent properties, in hemispheric projection.

As previously noted, the magnitudes of the effects are lost in the correlation process (Table 7). A unit vector in the same direction as the vector representing a given reaction may be constructed as a linear combination of the three base vectors, weighted by the three correlation coefficients, as in eq. [6].

$$[6] \qquad \mathbf{Z}_j = \sum \mathbf{X}_i \, r_{i,j} \qquad (i = 1, 2, 3)$$

i.e., $\mathbf{Z}_j$ is a unit vector parallel to the vector representing the *j*'th reaction. The slope of the least-squares line representing the plot of the *j*'th reaction (as logarithms of equilibrium or rate constants) vs. the elements of the "parallel" vector was taken as a measure of the sensitivity of the reaction to solvent change. Figure 4 summarises the magnitudes and the senses of the effects on the equilibria, and Fig. 5 shows the individual plots. The effects of solvent change on reactions *B, D*, and especially *H* are strongly positive while on *E* it

[b]Number of points correlated.

Fig. 3. The 8 equilibria, *A–H,* in hemispheric projection. Reactions *B* and *D* fall close to region **B**; *H* and the negative of *G* are in region **A**; the negatives of *F* and *A* are near the polar region, **P**. *E* and the negative of *C* lie between the basic **B** and the polar regions, *C* being almost orthogonal to the **A** region.

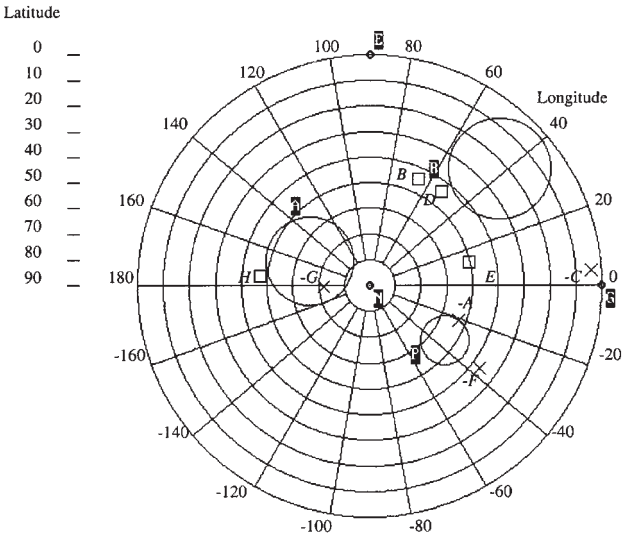

Fig. 4. Magnitude of equilibrium solvent effects: slope of $\log(K_j)$ vs. z_{ij}, the appropriate parallel vector elements, multiplied by the sign of the correlation with the first PC. Error bars are at one standard deviation of slope.

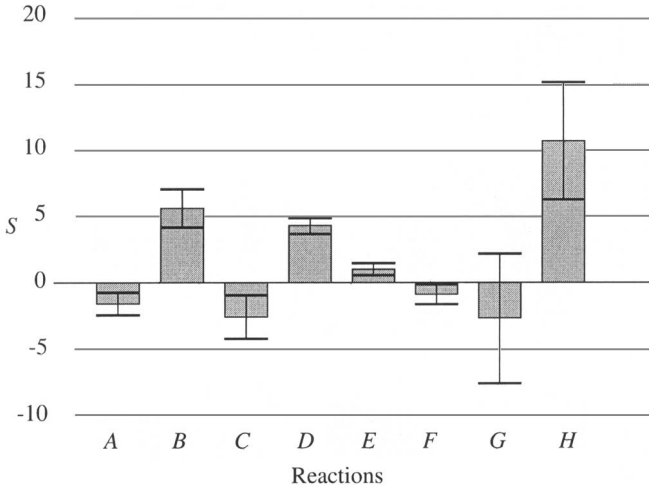

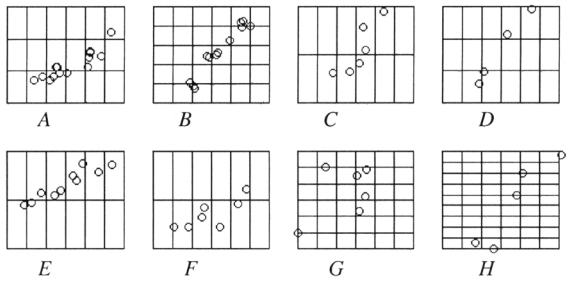

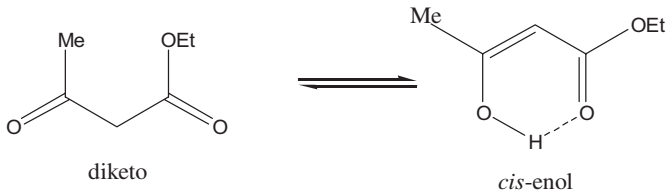

Fig. 5. Logarithms of equilibrium constants vs. the appropriate "parallel" vector components. All the horizontal scales run from –0.6 to 0.6; the vertical scales vary, the grid lines being at one-unit intervals.

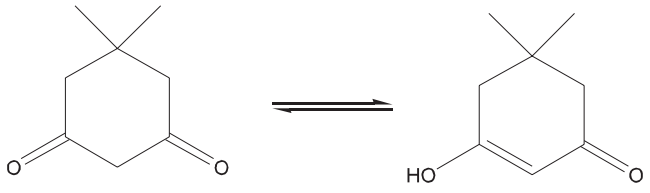
Scheme 1.

was weakly positive but probably real. Reactions *A* and *C* show a reverse effect. The apparently negative effect on *G* is subject to a very large uncertainty. When these values are considered together with the locations of the reactions on the hemisphere, shown in Fig. 3, it becomes possible to discuss the implications. We consider each reaction in turn (Numbers in square brackets [xxx] refer to the page xxx in Reichard) (21).

A. Keto–enol equilibrium of ethyl acetoacetate [107] (23)



K_T = [*cis*-enol]/[diketo]. Increasing polarity of the solvent favours the diketo form (Scheme 1), though not strongly. The overall dipole moment of the diketo form may not be large, but isolated carbonyl groups can act as separate dipoles. The polarity of the *cis*-enol form is reduced by intramolecular H-bond formation.

B. Keto–enol equilibrium of 5,5-dimethylcyclohexane-1,3-dione [107] (23)

K_T'' = [*trans*-enol]/[diketo]. In contrast with *A*, the cyclic enol cannot form an intramolecular H-bond (Scheme 2), so the hydroxyl group is free to interact with basic (H-bond ac-

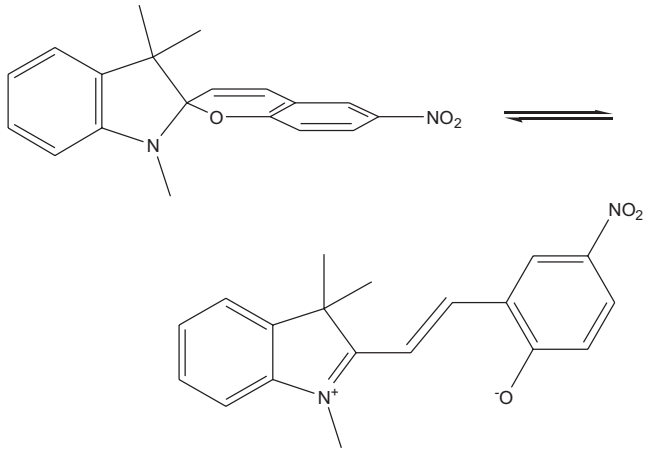
Scheme 2.



diketo *trans*-enol

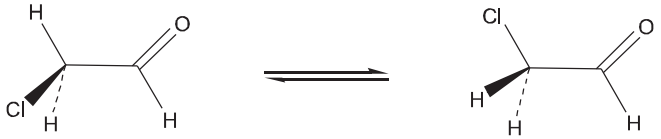
Scheme 3.

Scheme 4.

ceptor, HBA) solvents, as shown by the strong positive effect, in the **B** region of the hemisphere.

C. Azo–hydrazone tautomerism [117] (24)

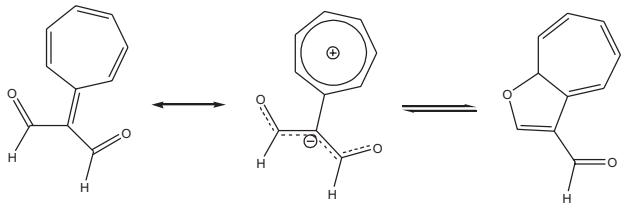
This point is plotted in Fig. 3 as its "antipodes", i.e., inversely. There appears to be a slight positive effect of acidity and negative effects of polarity and basicity. While the hydrazone form may have a larger net dipole moment, the acidic OH group on the azo form carries a local dipole moment (Scheme 3), so that the combined effects of solvent polarity and basicity work to reverse the reaction.



D. Neutral–zwitterion. [124] (25)

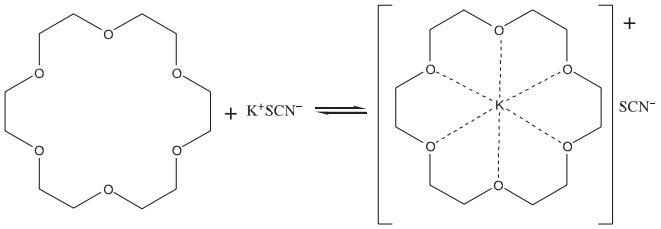
A fairly strong positive effect, favouring the zwitterionic form, as expected. The location of the point on the hemisphere in the **B** region suggests that solvation of the charge-localized positive nitrogen site by basic solvents is more important than solvation of the charge-delocalized negative oxygen by acid solvents (Scheme 4). The uncertainty of position (~35°) is large, but the polar region is 60° away.

E. Gauche–cis rotational equilibrium of chloroacetaldehyde. [126–127] (26)



The more polar *cis* rotamer is favoured by solvent polarity as expected (Scheme 5), and it is also unexpectedly favoured

Scheme 5.



gauche *cis*

Scheme 6.

Scheme 7.

by solvent basicity. Apparently the aldehyde is more acidic in the *cis* form.

F. Valence isomerism equilibrium between 8,8-diformylheptafulvene and 8aH-cyclohepta[b]furan-3-carbaldehyde [136] (27)

Though the uncertainty of position is large, the antipodal position close to the **P** region clearly shows that the former more polar substance is favoured (Scheme 6). The effect is not large but real (see Fig. 4).

G. Host–guest complexation of K^+ (present as thiocyanate) by a crown ether [140] (28)

The antipodal point falls in the **A** region, though with a large uncertainty (27°). If the effect is real, it would be attributable to the coordination of K^+ by EPD (basic) solvents (Scheme 7). The uncertainty of magnitude is so large that the reality of the effect becomes doubtful. K^+ is a weak, hard acid; this analysis did not consider hardness or softness of solvents, and there are perhaps other relevant properties of the solvents in the 3% of the variance previously noted as unaccounted for.

H. Disproportion of 1-ethyl-4-(methoxycarbonyl)pyridinyl radical to form an ion pair [137] (29)

The equilibrium constant is written as K = [ion pair]/[radical] (28), which does not fit the form of the equilibrium reaction: $2R^{\cdot} = (pair)$. Nevertheless, the position of the point in the **A** region (recalling that this region encompasses both the acid parameters and the polar $E_T^{\tilde{N}}$ family) and the strength of the effect show that the ion pair is clearly favoured by increasing solvent polarity reinforced by solvent acidity, owing in part to the basic N in the pyridinyl anion (Scheme 8).

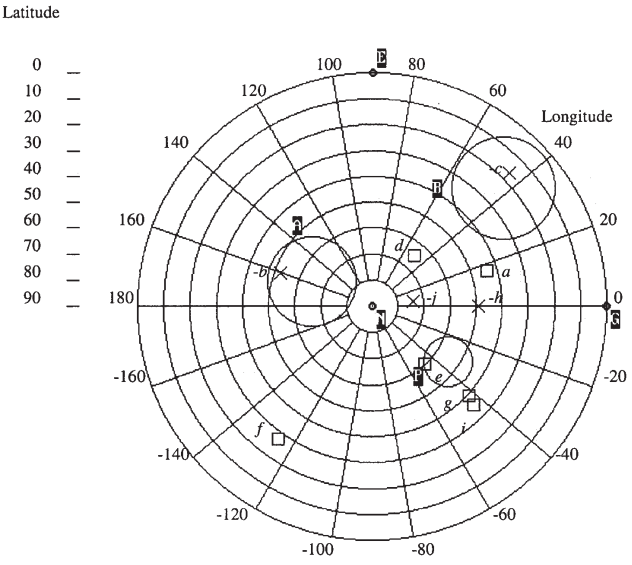
[d]Solvent was *n*-pentane.



Scheme 8.

The reaction rates

In an exactly analogous fashion, we have placed 10 rate processes on the hemisphere defined by the 17 solvent properties. Again, they were chosen somewhat randomly from those discussed by Reichardt (21) (Chapter 5), and the choice was subject to each having been studied in at least four of the solvents in the set of 20, and illustrating a variety of types. These include nucleophilic aromatic substitution S_NAr (*a, b*), electrophilic aromatic substitution S_EAr (*c*), electrophilic aliphatic substitution S_E2 (*d*), electrophilic addition to alkene (*e*), epoxidation of alkene (*f*), alkene cycloaddition (*g*), sulfoxide racemization (*h*), Diels–Alder cycloaddition (*i*), and azoalkane thermolysis (*j*). The reactions and their measured rate constants (in most cases relative to the rate constants in a standard solvent) as common logarithms are listed in Table 8. The ratio of gaps to data is still large, though slightly better than the corresponding ratio for the equilibria. Figure 6 shows their positions on the hemisphere. Again, we did not attempt to show the error circles, the radii of which are listed in Table 9. Figure 7 shows the magnitudes and senses of the effects, and Fig. 8 shows the individual plots. The reactions are labelled with lowercase letters, conforming to the use of lower case for the symbol *k* for rate constants.

Fig. 6. The 10 rates in hemispheric projection. The clear cases: reactions *e, g,* and (slightly) *i* are accelerated by solvent polarity; *c* is retarded by basicity and *b* by acidity. Reactions *a* and *h* are affected by both polarity and basicity, *a* being accelerated and *h* retarded. Reactions *d* and the negative of *j* fall into the space between the three distinguishable regions, so *d* appears to be accelerated by acidity, basicity, and polarity, though the uncertainty of the slope is very large, while *j* is retarded. Reaction *f* lies 130° away from region **B**, meaning that it is retarded by basicity; it is also somewhat accelerated by acidity–polarity.

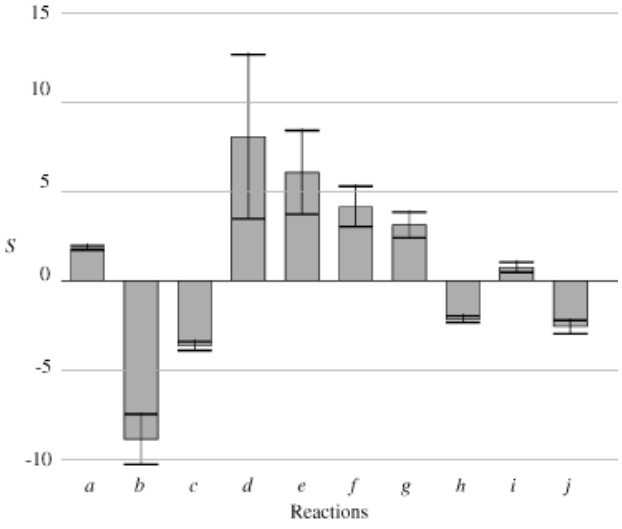
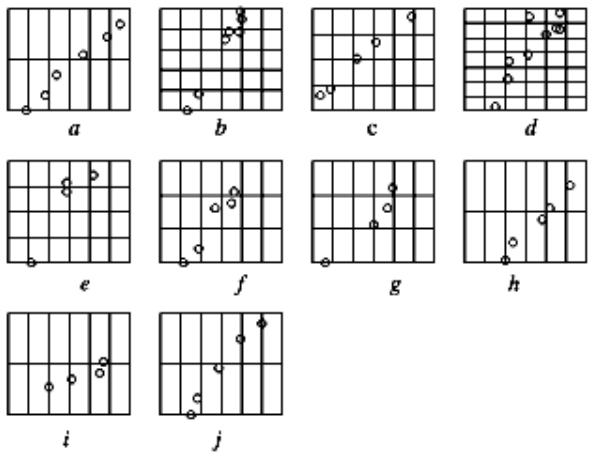
[c]Some of these points were adjusted, see text.

Fig. 7. Magnitude and sense of solvent effects on rates. Slope of the plot of log (*k*) vs. elements of the parallel vector, multiplied by the sign of the correlation with the first PC. Errors bars at one standard deviation of slope.





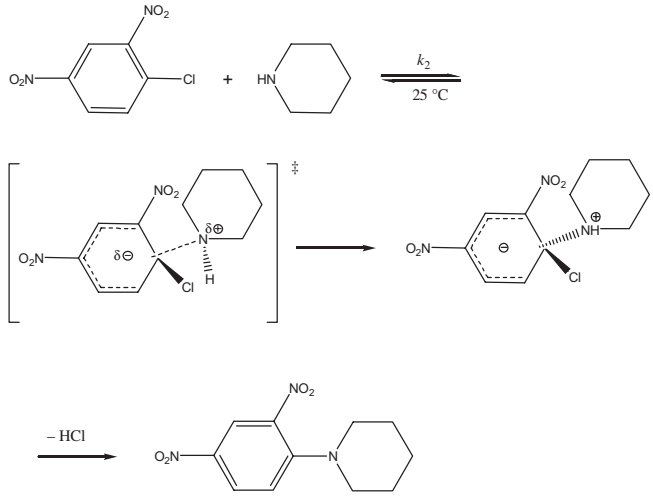


Fig. 8. Kinetic solvent effects: log (*k*) for the 10 reaction rates vs. elements of the appropriate **Z** vectors. Scales are as in

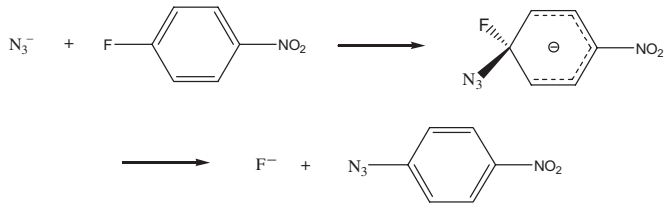
Scheme 9.

a. S_NAr reaction of 1-chloro-2,4-dinitrobenzene with piperidine [174] (30)

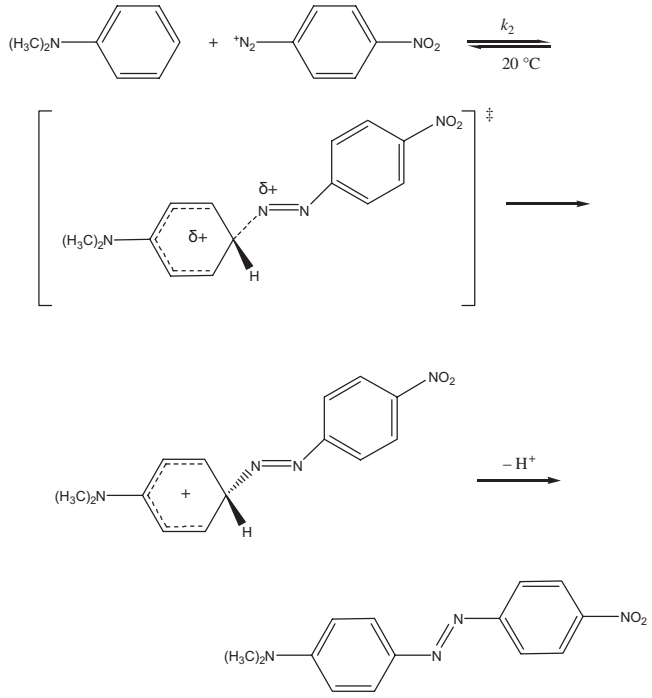
Falling between the **B** and **P** regions with a large uncertainty of the position (48°), this reaction appears to be accelerated by both polarity and basicity. If there is an effect of acidity, it appears small (though the list of solvents used does not include notably acidic ones). The mechanism described (*loc. cit.*) shows a polar transition state agreeing with the effect of polarity (Scheme 9). The influence of solvent basicity is invoked only for the second step.

b. S_NAr reaction of 4-fluoro-1-nitrobenzene with azide ion [249] (31)



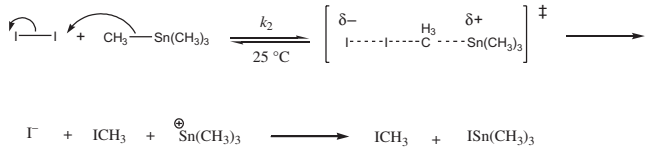
Very strongly retarded by acidity. HN_3 is a weak acid (p*K* in water at 25° is 4.74), so interaction of azide with solvent (HBD) acidity is to be expected (Scheme 10).

c. S_EAr azo coupling of 4-nitrobenzenediazonium tetrafluoroborate with N,N-dimethylaniline [174] (32)



Moderate retardation; the negative point falls in the **B** region with large uncertainty (50°) suggesting coordination of the positive diazonium group by basic solvents. One would have expected a retardation also by polarity, owing to charge dispersal in the transition state (Scheme 11).

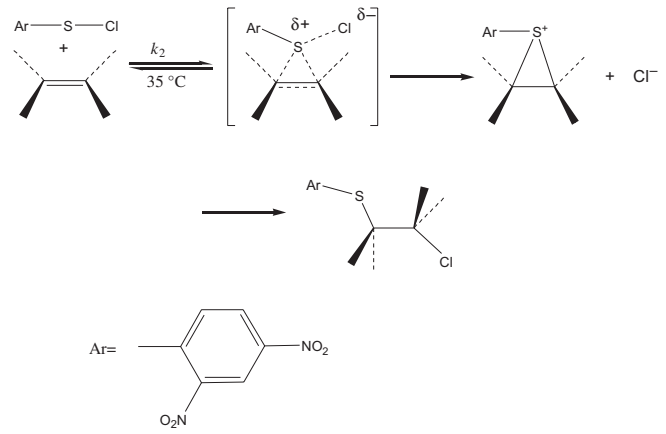
© 2006 NRC Canada



Scheme 10.

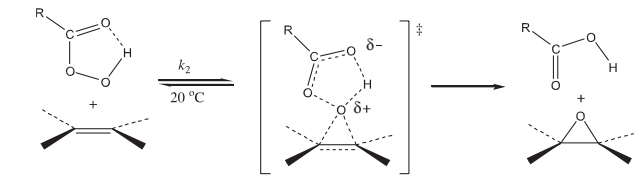
Scheme 11.

Scheme 12.



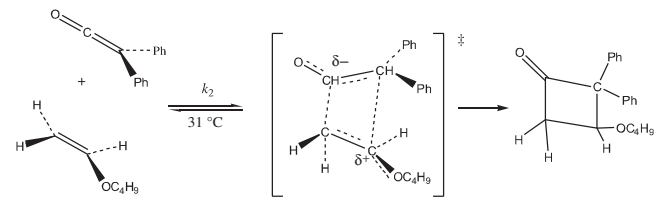
d. S_E2 cleavage of tetramethyltin by iodine [175] (33)

Large but rather uncertain positive effect between **A** and **B** with small position uncertainty. A push–pull effect of acidity on $I^{\delta-}$ and basicity on $Sn^{\delta+}$ is suggested (Scheme 12). To extend the range of solvents, we included the point for tetrachloromethane at 50 °C and four points from Gielen (33*a*) at 20 °C adjusting each to the temperature of Fukuzumi and Kochi's work (33*b*) at 25 °C by using the rule-of-thumb assumption that rates double for each 10 °C rise in temperature. This rough procedure reduced the uncertainty of the slope by half compared with using only the five points at 25 °C.



e. Addition of chloro-2,4-dinitrophenylsulfane to cyclohexene [177] (34)

Precisely located in **P** region with fairly large acceleration. The reactants are relatively non-polar, but there is a considerable charge separation in the transition state (Scheme 13).



Scheme 13.

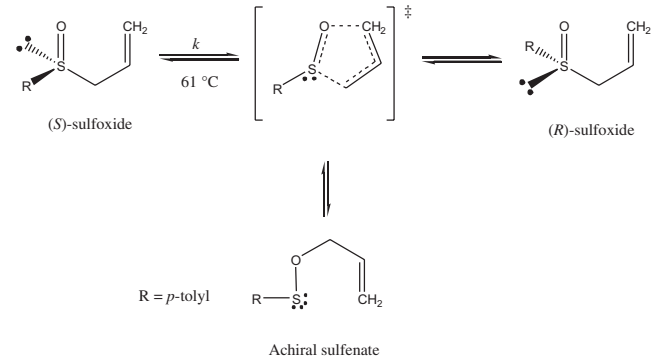
Scheme 14.

Scheme 15.

f. Epoxidation of cyclohexene with peroxybenzoic acid [177] (35)

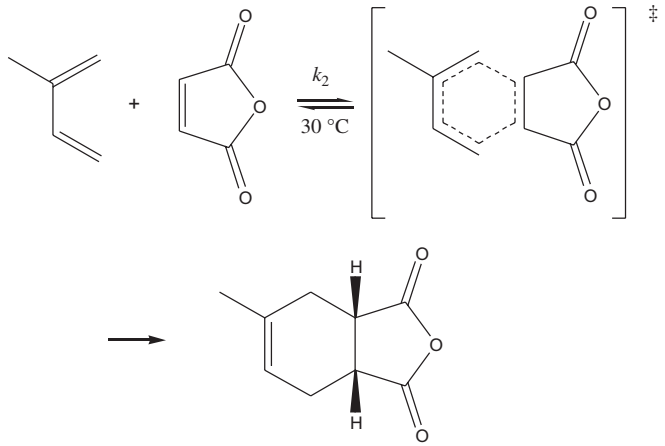
Fairly large acceleration. The position is away from the **B** region but closer to the **A** and **P** regions. Thus, it shows that acidity and polarity have positive effects (the postulated transition state is more polar than the reactants), but basicity (HBA) has a retarding effect owing to interaction with the peroxyacid (Scheme 14).

g. Cycloaddition of diphenylketene to n-butyl vinyl ether [181] (36)



Moderately large acceleration with the point falling on the edge of the **P** region. Although the uncertainty of magnitude is not large, the position uncertainty is very large (66°). The mechanism described shows a substantial charge separation in the transition state (Scheme 15).

h. Thermal racemization of p-tolyl allyl sulfoxide [184] (37)



Moderate retardation with the point falling on the basic side of the polar (**P**) region. The sulfoxide is rather polar, and the proposed intermediate is much less so (Scheme 16). Thus, a decrease of polarity in the transition state is reason-

© 2006 NRC Canada

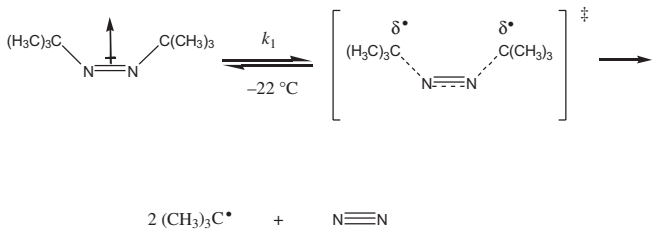
Scheme 16.

Scheme 17.

able. The position uncertainty is enough (30°) to cast doubt on the effect of basicity, but it may be real.

i. Diels–Alder cycloaddition of isoprene and maleic anhydride [188] (38)

A slight, but probably real acceleration by polarity, though the position is very uncertain (60°). Polarizability, which is given scant consideration in this work, may be a factor (Scheme 17).



j. Thermolysis of cis-2,2′-dimethyl-2,2′-azopropane [203] (39)

Moderate retardation with the point falling between the polar, acid, and basic regions. The positive end of the dipole in the starting molecule is accessible to polar solvent molecules in spite of the bulky *t*-butyl groups (Scheme 18), so an effect of solvent polarity is to be expected. Why the point lies towards the acid region is less understandable.

Conclusions

With respect to both equilibria and rate processes, this analysis has largely borne out the conclusions of the authors of the various studies as to the nature and magnitude of solvent effects on the reactions and the probable reasons for them. In some cases, the positions of the points on the hemisphere plot have raised interesting questions. For instance, among the equilibria, the importance of solvent basicity might have gone unnoticed with reactions *C, D*, and *E* but

Scheme 18.

especially with reaction *B*. Among the rates, the importance of solvent basicity emerged with reactions *a* and *b*. In reaction *c*, the possibility of push–pull action by base at one end and acid at the other end of the activated complex was raised. In the case of reaction *b*, the puzzling location of the point, remote from any of the recognised areas, was seen to be due to influences from all three factors, acceleration by acidity, polarity, and retardation by basicity. In short, subtleties that might otherwise have been missed have emerged in several cases at least as possibilities to be further examined.

We suggest that in examining a new reaction, it would be worthwhile to measure its rate or equilibrium in an assortment of solvents of different characters, and to use a suitable set of properties of those same solvents to create the frame in which the reaction is then placed. The nature and strength of the solvent effects on the reaction should immediately emerge pointing the way to further study.

Acknowledgements

This work was supported in part by an institutional grant to Trent University (RAS) and a Discovery Grant (EB) from the Natural Sciences and Engineering Research Council of Canada. The authors wish to thank Ms. Jan Myland and Ms. Jessica Butler for computer assistance, Professors Andrew Vreugdenhil, Errol Lewars, and Raymond March for help and suggestions, and Professor Dr. Christian Reichardt for discussion and insightful comments.

Absolute configuration assignments by experimental and theoretical approaches of *ent*-labdane- and *cis-ent*-clerodane-type diterpenes isolated from *Croton glabellus*[1]

Abraham García, Teresa Ramírez-Apan, J. Antonio Cogordan, and Guillermo Delgado

Abstract: The bioassay-guided fractionation of the moderately cytotoxic extract from *Croton glabellus* resulted in the isolation of bioactive compounds, which were characterized as austroinulin (2), 6-*O*-acetylaustroinulin (**3**), the acetonide artifact of **2** (**4**), and 3-*O*-methylkaempferol (**9**). In addition, a new natural *cis-ent*-clerodane lactone diterpene named marrubiagenin (**1**), *trans*-dehydrocrotonin (**6**), the epimeric mixture of cajucarinolide (**7/8**), and 5,7,3′,4′-tetrahydroxy-3-methoxyflavonoid (**10**) were also characterized and identified as nonbioactive compounds. The structures of all compounds were determined by analyses of their physical and spectroscopic data and by comparison with those reported in the literature. The absolute configuration assignment of **3** was carried out by means of the modified Mosher method and by the experimental and theoretical circular dichroism method establishing that **3** belongs to the *ent*-labdane diterpene series. Furthermore, the absolute configuration of **1** was established by analysis of its chiroptical properties concluding that **1** belongs to the *cis-ent*-clerodane diterpene series.

Key words: Croton glabellus, *ent*-labdane-type diterpenes, *cis-ent*-clerodane-type diterpenes, circular dichroism, TD-DFT.

Résumé : Un fractionnement orienté par des bioessais du mélange modérément cytotoxique extrait de *Croton glabellus* a permis d'isoler et de caractériser des composants bioactifs, dont l'austroinuline (**2**), la 6-*O*-acétylautroinuline (**3**), l'acétonide **4**, un artefact du composé **2** et le 3-*O*-méthylkaempférol (**9**). On a aussi isolé et caractérisé des composés qui ne sont pas bioréactifs, dont une nouvelle lactone diterpénique naturelle de la famille du *cis-ent*-clérodane dénommée marrubiagénine (**1**) ainsi que des produits déjà connus, dont la *trans*-déshydrocrotonine (**6**), un mélange d'épimères du cajucarinolide (**7/8**) et le 5,7,3′,4′-tétrahydroxy-3-méthoxyflavonoide (**10**). Les structures de tous les composés ont été déterminées sur la base d'analyses de données spectroscopiques et physiques et par comparaison avec les données rapportées dans la littérature. L'attribution de la configuration absolue du composé **3** a été faite sur la base de la méthode de Mosher modifiée et par la méthode de dichroïsme circulaire théorique et expérimentale et elle a permis d'établir qu'il appartient à la série diterpénique du *ent*-labdane. De plus, en se basant sur ses propriétés chiroptiques, on a établi que la configuration absolue du composé **1** le situe dans la série diterpénique *cis-ent*-clérodane.

Mots clés : Croton glabellus, diterpène de type *ent*-labdane, diterpènes de type *cis-ent*-clérodane, dichroïsme circulaire, TD-DFT.

[Traduit par la Rédaction]

Introduction

Croton glabellus (Euphorbiaceae) is a plant widely distributed from Mexico to South America whose infusions of leaves and bark are mainly used against cancer and wound infections (1). Previous reports on the chemical constituents of *Croton* species have illustrated the predominance of *cis*- and *trans*-clerodane-type diterpenes (2–4) and some labdane-type diterpenes (5) that are principally confined to the chemistry of *Stevia* (Compositae) (6–9). It has also been reported that some clerodane-type diterpenes possess cytotoxic properties (10).

In the search of new bioactive constituents from the family Euphorbiaceae (11), the CH_2Cl_2–MeOH extract obtained from the leaves of *C. glabellus* was studied because of its moderate cytotoxic properties exhibited against five human tumor cell lines. Chemical investigations of the organic extract led to the purification and characterization of a new natural *cis*-clerodane lactone diterpene (**1**), three *ent*-labdane-type diterpenes (**2**–**4**) (7, 8), three clerodane-type diterpenes (**6**–**8**) (2–4), two 3-*O*-methylflavonoids (**9**, **10**) (12, 13), together with β-sitosterol, β-sitosteryl β-*D*-

glucopyranoside, and sucrose. Compounds **2**–**4** and **9** exhibited moderate cytotoxic properties, with **9** being the most active.

This paper reports the stereostructural determination of **1**, **3**, and **7/8** and the absolute configuration assignments of **1** and **3** by circular dichroism (CD), the application of the exciton chirality method for **3** (14), and the diene helicity rule (quadrant diene rule) for a derivative of **1** (15). The relative configuration of **3** was corroborated by an X-ray analysis and its absolute configuration was established by the application of the empirically modified Mosher method (16) and confirmed by the theoretical simulation of the electronic circular dichroism (ECD) spectrum of its derivative **2b**, using the time dependent density functional theory (TD-DFT) approach. Additionally, the cytotoxic activity of the isolated compounds is reported.

Results and discussion

The bioassay-guided fractionation of the moderately cytotoxic extract from the leaves of *C. glabellus*, using the K562 (leukemia, IC_{50} = 17.79 ± 2.97 μg/mL) and HCT15 (colon cancer, IC_{50} = 31.93 ± 7.3 μg/mL) tumor cell lines as the pilot cells, led to the isolation and characterization of austroinulin (**2**) (8), 6-*O*-acetylaustroinulin (**3**) (7), an acetonide artifact (**4**, formed during the isolation process by reaction of the diol and acetone), and 3-*O*-methylkaempferol (**9**) (12) as the bioactive constituents (Table 1). After the isolation and purification process, a new natural *cis-ent*-clerodane-type diterpene (**1,** previously characterized as the aglycone of marrubiaside), *trans*-dehydrocrotonin (**6**) (2, 3), the epimeric mixture of cajucarinolide (**7/8**) (4), 5,7,3′,4′-tetrahydroxy-3-methoxyflavonoid (**10**) (13), β-sitosterol, β-sitosteryl β-*D*-glucopyranoside, and sucrose were also isolated and characterized. The structures of all compounds were established by means of a careful revision of their physical and spectroscopic properties and by comparison with those reported in literature for related metabolites.

Compound **1** was isolated as optically pure colourless needles ($[\alpha]_D^{25}$ +54.4) and presented the molecular formula $C_{20}H_{28}O_4$, which was established by HRMS–FAB (*m/z*: 333.2076 $[M + H]^+$) and confirmed by 20 carbon signals observed in the ^{13}C NMR spectrum. The IR spectrum exhibited absorption bands for carboxylic acid (HO, 3500–2636 and 1779 cm^{-1}; C=O, 1679 cm^{-1}) and lactone ring functionalities (C=O, 1746 cm^{-1}). The ^1H NMR spectrum (Table 2) showed two vinylic proton signals at δ: 6.82 (t, *J* = 4.0 Hz, H-3) and δ: 5.86 (quint, *J* = 1.5 Hz, H-14), which were positioned β and α to carbonyl groups, respectively; also, a singlet was observed at δ: 4.76 (2H, d, *J* = 2.0 Hz, H-16) that was attributed to two chemically equivalent oxymethylene protons. In addition, the ^1H NMR spectrum exhibited three simple signals at δ: 1.25 (3H, s, H_3-19), 0.83 (3H, s, H_3-20), and 0.78 (3H, d, *J* = 6.5 Hz, H_3-17), which correspond to three methyls. The *cis*-clerodane skeleton of **1** was confirmed by analyses of its HSQC and HMBC spectra, whereas its *cis*-decalin fusion was established by an analysis of the NOESY spectrum, which showed relevant NOE interactions between H-10β (δ: 1.40) and H_3-19 (δ: 1.25). Thus, the OR, MS, IR, and NMR data observed for **1** were quite identical to those reported for the *cis*-clerodane-type diterpenes named marrubiagenin (17, 18) and amphiacric acid (19).

Marrubiagenin was reported at first by Tschesche and Plenio (17) as the acid hydrolysis derivative from the

Fig. 1. Natural products (**2**, **3**, **6–10**) isolated from *C. glabellus*, derivatives **2a–2c** and **4**, and compounds **5** and **5a** taken from ref. 8.

diterpene glucoside marrubiaside isolated from *Leonurus marrubiastrum* and then presumably by Tonn and coworkers (18) as a constituent of *Baccaris sagittalis*. However, the configuration of the substance from *Baccharis* was not determined. Amphiacric acid ($[\alpha]_D^{25}$ – 60.5°) (19) and the substance from *Baccharis* ($[\alpha]_D^{25}$ –58°) (18) exhibited negative optical rotation values, which are opposite to that found for **1** ($[\alpha]_D^{25}$ +54.4°) in this study. The enantiomeric relative configurations reported for amphiacric acid and the substance from *Baccharis* are not consistent with their negative values of optical rotation; therefore, they should be referred to as the same compound. Although the optical rotation for marrubiagenin was not reported by Tschesche and Plenio (17), we compared the observed molar ellipticity (included in the paper) with that found for **1** (this study) and that reported for amphiacric acid (19). Compound **1** ($[\theta]_{242}$ +18 886) and marrubiagenin ($[\theta]_{243}$ +21 054) (17) exhibited first positive Cotton effects in their circular dichroism (CD) spectra, whereas amphiacric acid ($[\theta]_{235}$ –14 900) (19) showed a first negative Cotton effect. These differences confirmed that they are enantiomers. The *cis*-β-decalin fusion of marrubiagenin was established by the analysis of the CD data for its diene derivative **11** and we took those data into account to establish the absolute configurations of **1** and to define the corresponding configuration for amphiacric acid.[3] Diene derivative **11** showed a positive Cotton effect at 293 (Δε +14.8, reported in ref. 17), which can be attributed to the $\pi \rightarrow \pi^*$ electric transition band of the conjugated diene chromophore. Applying the diene helicity rule (15), it can be deduced that the diene derivative **11** contributes to the positive Cotton effect and has the absolute configuration depicted for **1** in Fig. 1. Neither the conformational change of ring B (chair to boat) nor the presence of the alkyl lactone

Fig. 2. Model deduced by application of the diene helicity rule and quadrant diene rule for derivative **11** (Δε value was taken from ref. 17).

fragment bonded to C-9 contribute to the CD properties of **1**, **11**, and several synthetic derivatives from marrubiasid (17); therefore, they do not interfere with the application of the diene helicity rule. Furthermore, the application of the quadrant diene rule (Fig. 2) determines that the allylic hydrogen at C-10 and the helicity of the diene system constitute the main positive contributions to the first Cotton effect. Therefore, it can be established that **1** (this study) and marrubiagenin have the same absolute configuration (5*S*,10*R*), whereas the corresponding configuration for amphiacric acid and the substance from *Baccharis* should be referred as 5*R*,10*S* (see the configuration depicted for

[3] Derivative **11** was obtained by chemical derivatization from the natural product named marrubiasid (17). CD data were taken from the same reference and were analyzed here to establish the absolute configuration of **1**.

© 2006 NRC Canada

amphiacric acid in ref. 19). Therefore, marrubiagenin (**1**) represents a new natural product assigned to the *cis-ent*-clerodane diterpene series (*cis*-β).

Compound **3** showed a positive optical rotation sign ($[\alpha]_D^{25}$ +34.2) and presented the molecular formula $C_{22}H_{36}O_4$, which was deduced from the HRMS–FAB (364 [M^+] (1%); *m/z*: 347.2589, [$M - H_2O + H]^+$) and the ^{13}C NMR and DEPT spectra. All the spectrometric, spectroscopic, and optical data observed for **3** were quite identical to those reported for 6-*O*-acetylaustroinulin whose absolute configuration remains ambiguous (7, 8), notwithstanding that some attempts have been directed towards this challenge. In 1987, Bohlmann and coworkers (8) assigned the absolute configuration of 7-*O*-acetylaustroinulin (**5**), an isomer of **3**, by the CD method and application of the octant rule for its oxidized derivative **5a** (20, 21), which exhibited a negative Cotton effect in the CD spectrum ($\Delta\varepsilon_{295}$ –1.5). The authors concluded that the Cotton effect was principally due to the methyl group at position C-4 and that **5a** belongs to the *ent*-labdane diterpene series; however, they did not analyze the dominant (negative or positive) contribution due to the free rotating conjugated diene fragment at position C-9. Bohlmann's conclusion was contradicted by Ishibashi and coworkers (22) who proposed that **2** belongs to the normal labdane diterpene series according to the results obtained by the application of the modified Mosher method. To clarify these inconsistencies, we attempted three approaches towards the assignment of the absolute configuration of the structural analogue **3** based on the application of the modified Mosher method for its hydrolyzed derivative **2**, followed by the analysis of the experimental CD method for its esterified derivative **2b**, and finally by the theoretical simulation of the ECD spectrum for **2b**.

First, a conformational study of **3** and its structural analogues **2**, **2a**–**2c**, and **4** led to the analysis of CD data for **5a** and allowed us to confirm the previous configurational assignment by Bohlmann and coworkers (8). For this purpose, the solid-state conformation of **3** obtained by an X-ray analysis of a single crystal (Table 3)[4] was compared with its preferred conformation in solution by a NOESY spectrum analysis. Relevant NOE interactions between H-14 and H_2-11, between H-11_a and H_3-20, between H-11_b and H_3-17, and between H-12, H_3-16, and H-9 established that the conformation of **3**, in solution and at room temperature (Fig. 3), is the same as that found in the solid state (Fig. 4, X-ray analysis not previously reported). Analyses of NOESY spectra of compounds **2**–**4** and the synthetic derivatives **2a**–**2c** indicated that the orientation of the planar *trans*-conjugated-diene unit does not change because of the presence or absence of functional groups at C-6 or C-7, which allowed us to establish the same main conformation for all compounds. In this context, the major part of the molecular volume (the diene fragment, the acetoxy group, and part of the decalin skeleton) of the minimum energy structure of **5a** (Fig. 5), which was generated using the MMX force field as implemented in the PCMODEL program (23), is located in negative octants. According to the absolute configuration of **5**, depicted in Fig. 1, a negative Cotton effect is predicted for the $n \rightarrow \pi^*$ ketone transition in the CD curve, which can be corroborated by the sign of the reported molar ellipticity $[\theta]_{295}$ –4 900 (8). This CD analysis supports the proposed absolute configuration for **5** (8) and suggests that **2** and **3**, which were reported as constituents of the same source as that of **5** (8), have the same absolute configuration. To ascertain the latter and to determine whether or not the conclusion of Ishibashi and coworkers (22) should be considered, **3** was subjected to alkaline hydrolysis to give **2**, which was then reacted in situ with the *R*-(+)- and *S*-(–)-α-methoxy-α-trifluoromethylphenylacetyl chloride to obtain its corresponding diastereoisomers according to the modified Mosher method (**2d** and **2e**, Fig. 6) (16). Chemical derivatization of **3**, to furnish **2b** and **2c**, revealed the preferred esterification of the secondary hydroxyl at position

C-7 and the same happened with the formation of Mosher esters. The difference between the chemical shifts of selected hydrogens of the *S*-MTPA (**2d**) and the *R*-MTPA (**2e**) established the 7*R* absolute configuration for **3** (Fig. 6). This result indicates that **3** belongs to the *ent*-labdane diterpene series, as initially proposed by Bohlmann and coworkers (8) and it does not agree with the absolute configuration of **2** proposed by Ishibashi and coworkers (22).

To support our conclusion, **3** was hydrolyzed and esterified to obtain the 7-*p*-bromobenzoylated derivative **2b**, which was then subjected to several unsuccessful crystallization processes where the crystals formed were not suitable for an X-ray diffraction analysis. Nevertheless, considering the *trans*-conjugated-diene and the benzoate chromophores in **2b** and according to the exciton chirality method applied for a diene-benzoate system (14), it was decided to analyze **2b** by the CD method. The CD spectrum of **2b** showed a first positive Cotton effect at 247 nm and a second negative Cotton effect at 231 nm, which were attributed to the $\pi \rightarrow \pi^*$ intramolecular charge transfer bands of the *p*-bromobenzoate and the planar *trans*-conjugated-diene chromophores. According to the exciton chirality method, the CD spectrum of **2b** showed the characteristic exciton-split CD curves due to the interactions between both chromophores (Fig. 7). The exciton splitting was corroborated by an analysis of the CD data of derivative **2c**, which exhibited bisignated CD curves with similar intensities

Fig. 5. Application of the octant rule for the minimum energy structure (PCMODEL) of **5a**.

($[\theta]_{276}$ +6737 and $[\theta]_{266}$ +6961, $[\theta]_{237}$ −15667) (Fig. 7). The positive chirality between the electric transition moments of the benzoate and the *trans*-conjugated-diene chromophores in derivatives **2b** and **2c** allowed us to assign the absolute configuration of **3** as shown in Fig. 1. Thus, it was possible to reinforce that **3** belongs to the *ent*-labdane-type diterpene as was deduced in this work by the application of the modified Mosher method.

The absolute configuration, deduced from experimental CD data, was confirmed by means of the calculated ECD spectrum of the derivative **2b** (24). Following the computational details (described in the experimental section), rotatory strengths were calculated for the velocity and length formalisms. The velocity and length rotatory strengths exhibited similar values. Thus, the computed velocity data were used to reproduce the experimental ECD spectrum. Calculated excitation energies showed a bathochromic shift of ca. 0.4 eV relative to transitions in the experimental CD of **2b**, whereas the intensities of the two Cotton effects are in agreement with the experimental ones (Fig. 8). Our computed ECD spectrum of **2b**, illustrated in Fig. 8, exhibited the characteristic exciton-split CD curves due to the electric dipole – electric dipole interaction of the *p*-bromobenzoate and the *trans*-conjugated-diene chromophores. This exciton splitting can be attributed to the $\pi \rightarrow \pi^*$ transitions of the interacting electric transition moments of the benzoate-diene chromophores of **2b**. The first positive Cotton effect at ca. 274 nm and the second negative Cotton effect at ca. 256 nm from the theoretically computed ECD spectrum of **2b** are in agreement with the experimental CD curves (Fig. 8).

After the isolation and purification process of natural compounds, a white amorphous solid was isolated and characterized by detailed NMR analyses as the acetonide artifact (**4**, formed during the isolation process since acetone was used as a component of the eluting system for chromatographies; see the Experimental section).

Compounds **7** and **8** were isolated as a beige amorphous solid (238–240 °C), which was composed of an epimeric mixture of cajucarinolide as can be deduced from the duplicated pattern of signals in the ^{1}H and ^{13}C NMR spectra (Fig. 9) and their comparison with those reported for cajucarinolide (4). One set of these NMR data was quite identical to those reported for the clerodane-type diterpene named cajucarinolide (4); however, an additional hemiacetal

group (δ: 6.14, H-15 and δ: 97.76, C-15) suggested the presence of its epimer at C-15. This functional group allowed us to establish that the second set of proton signals corresponds to the epimer of cajucarinolide and not to the presence of its isomer named isocajucarinolide (4), which was reported to have a vinylic proton positioned α to carbonyl group at δ: 6.12 (H-14) and an hemiacetal proton at δ: 6.19 (H-16) [data taken from ref. 4]. This vinylic proton (H-14, δ: 6.12) was not observed for the mixture **7/8**; instead, two vinylic protons β to carbonyl group (δ: 7.09 and 7.08) and two hemiacetal protons (δ: 6.24 and 6.14) were found. These spectroscopic data support the epimeric mixture at C-15 of cajucarinolide (**7/8**), which could not be separated because of the minute amounts of substance available.

Conclusions

The bioassay-guided fractionation of the moderately cytotoxic extract from the aerial parts of *C. glabellus* led us to the isolation of the bioactive constituents **2**–**4** and **9**, which exhibited moderate cytotoxicities against the U251, K562, and HCT15 cell lines (Table 1). The leukemia cell line (K562) was the most sensitive to the tested compounds, with **9** being more potent than the *ent*-labdane-type diterpenes. It is interesting to mention that clerodane-type diterpenes (**1**, **6**–**8**) did not show remarkable cytotoxic activities (these compounds were tested at 50 µmol/L and exhibited ca. 20% tumor cell growth inhibition and no further

Fig. 9. ^{13}C and ^{1}H NMR chemical shifts for the epimeric mixture at C-15 of **7/8**.

experiments were carried out), contrary to those exhibited for the *ent*-labdane series (**2**–**4**). In addition, it can be noted that the functional group variation at C-6 or C-7 in the *ent*-labdane-type diterpenes did not modify their cytotoxic properties noticeably.

Additionally, the applicability of the circular dichroism method and its rules in the determination of the absolute configurations of chiral molecules was extended here for the

© 2006 NRC Canada

analysis of **1** and **3** by the diene helicity rule (quadrant diene rule) and the exciton chirality method, respectively. Furthermore, the theoretical ECD simulation of **2b** by TD-DFT/B3LYP/H–W showed that the two Cotton effects between 230 and 280 nm are due to the dipole–dipole coupling of the *p*-bromobenzoate and the *trans*-conjugated-diene chromophores, which is in agreement with the experimental spectrum in that region. The experimental and theoretical ECD results support the *ent*-labdane classification of **3**, which was also determined by the modified Mosher method. These conclusions do not agree with previous assignments (22), which should be re-examined.

Experimental

General experimental procedures

Uncorrected melting points were determined on a Fisher-Johns apparatus. Optical rotations were measured on a PerkinElmer 341 polarimeter. IR spectra were recorded on a Nicolet Magna FT-IR 750 spectrometer. UV spectra were performed on a Shimadzu-UV160 spectrophotometer. Circular dichroism spectra were recorded on a Jasco-J720 spectropolarimeter. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Unity Plus 500 spectrometer (at 500 and 125 MHz) and on a Bruker Avance 300 spectrometer (at 300 and 75 MHz). EI and HR–FAB mass spectra were measured on Jeol JMS-AX505HA and JMX-SX102A mass spectrometers, respectively. Column chromatography (CC) was performed using silica gel 60 (70–230 mesh). Thin layer chromatography (TLC) and preparative TLC (PTLC) were performed using the silica gel 60 F_{254} (Merck) plates.

Plant material

C. glabellus was collected in Los Tuxtlas, Veracruz, México, on April 2003 and authenticated by M. Sc. Verónica Juárez Jaimes (Instituto de Biología, UNAM). A voucher specimen was deposited in the National Herbarium, UNAM, with the register number MEXU-1104456.

Extraction and separation

The leaves (5.5 kg) of *C. glabellus* were dried at RT and extracted with a mixture of CH_2Cl_2–MeOH (1:1) for 48 h, three times. The crude extract was evaluated against five human tumor cell lines showing major bioactivity against K562 and HCT15 cells (IC_{50} = 17.79 ± 2.97 and IC_{50} = 31.93 ± 7.3, respectively). Then, the crude extract (270 g) was dissolved in a mixture of CH_2Cl_2–MeOH (1:1), adsorbed in silica gel 60, and subjected to CC (silica gel 60, hexane, hexane–AcOEt, AcOEt–MeOH, and MeOH). Seventeen main fractions (A–Q) were obtained according to their similarity pattern in TLC. Fractions E–L showed 90%–100% tumor cell growth inhibition; thus, these fractions were processed until the isolation and purification of the bioactive constituents. β-sitosterol (32.9 mg) (CC, Hex–AcOEt 9:1) was obtained from D. Forty-five milligrams of **3** (CC, Hex–AcOEt 7:3) and 32 mg of **6** (PTLC, Hex–AcOEt 75:25) were isolated from E. Nine hundred fifty-two milligrams of **3** (CC, Hex–AcOEt 7:3) were obtained from F. Sixteen milligrams of **2** (CC, Hex–Acetone 3:2 and PTLC, Hex–Acetone 3:2), 4.11 g of **3** (CC, Hex–AcOEt 7:3), 28 mg of **4** (CC, Hex–Acetone 3:2), 3.6 mg of **1** (CC, Hex–Acetone 4:1), and 23 mg of **9** (CC, Hex–Acetone 7:3) were isolated from G. Thirty-five milligrams of **2** (CC, Hex–Acetone 3:2), 436 mg of **3**, 5.3 mg of the epimeric mixture of **7/8** (CC, Hex–Acetone 3:2), and 38 mg of **9** (CC, Hex–Acetone 3:2) were isolated from H and I. Five milligrams of **10** (CC, Hex–AcOEt 1:1) and 57 mg of **2** were obtained from J. β-sitosteryl (1.45 g) β-*D*-glucopyranoside (CC, AcOEt) was isolated from K and L. Four hundred milligrams of sucrose (CC, AcOEt–MeOH 3:2) was obtained from fraction O.

6,7-Diacetylaustroinulin (2a)

Compound **2** (5 mg) was esterified with acetic anhydride and pyridine to afford 4 mg of **2a**. The same procedure was applied to **3** (62.5 mg). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 6.85 (ddd, *J* = 17.2, 10.8, 0.8 Hz, H-14), 5.43 (t, *J* = 7.4 Hz, H-12), 5.29 (dd, *J* = 10.0, 9.8 Hz, H-6α), 5.19 (d, *J* = 16.8 Hz, H-15), 5.10 (dd, *J* = 10.8, 1.5 Hz, H-15), 4.90 (d, *J* = 10.0 Hz, H-7β), 2.45 (m, H-11a), 2.24 (m, H-11b), 2.06 (s, H_3C(2′)-Ac), 2.01 (s, H_3C(2″)-Ac), 1.78 (d, *J* = 1.2 Hz, H-16), 1.70–1.18 (m, H-1a, H-2a, H2b, H-9, H-5, H-3a, H-3b), 1.22 (s, H-17), 0.97 (s, H-18), 0.95 (s, H-20), 0.95–0.97 (m, H-1b), 0.88 (s, H-19).

7-*p*-Bromobenzoylaustroinulin (2b)

Compound **3** (60 mg) was hydrolyzed with KOH–MeOH (10%) to obtain **2** (36 mg). Then **2** was reacted with *p*-bromobenzoyl chloride in anhydrous pyridine to obtain derivative **2b** (29 mg). UV–vis (*c* 1.98 × 10^{-5} mol/L, EtOH) (log ε): 204 (4.48), 215 (4.17), 241 (4.62). CD (*c* 1.98 × 10^{-5} mol/L, EtOH): $[\theta]_{247}$ +9962, $[\theta]_{231}$ –2760, $[\theta]_{208}$ +2987. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.94 (2H, d, *J* = 9.0 Hz, AA′MM′), 7.58 (2H, d, *J* = 8.7 Hz, AA′MM′), 6.86 (ddd, *J* = 17.4, 10.8, 0.9 Hz, H-14), 5.45 (t, *J* = 7.8 Hz, H-12), 5.20 (d, *J* = 17.1 Hz, H-15_{trans}), 5.10 (dt, *J* = 10.8, 1.8 Hz, H-15_{cis}), 5.02 (d, *J* = 9.9 Hz, H-7β), 3.89 (dd, *J* = 11.2, 9.8 Hz, H-6α), 2.50 (dt, *J* = 15.6, 5.1 Hz, H-11a), 2.23 (dt, *J* = 16.2, 6.0 Hz, H-11b), 1.78 (d, *J* = 1.2 Hz, H_3-16), 1.32 (s, H_3-17), 1.27 (d, *J* = 11.1 Hz, H-5), 1.17 (s, H_3-18), 1.01 (s, H_3-20), 0.96 (s, H_3-19). MS–FAB *m/z*: 504 (2, $[M^+]$), 505 (3), 507 (2), 487 (7, 505 – H_2O), 489 (3, 507 – H_2O), 183 (100, $[C_7H_4OBr]^+$), 185 (97, $[C_7H_4OBr]^+$), 81 (67, $[C_6H_9]^+$).

7-(*E*)-Cinnamoylaustroinulin (2c)

Compound **3** (40 mg) was subjected to alkaline hydrolysis to obtain **2** (31 mg), which was further reacted with (*E*)-cinnamoyl chloride in anhydrous pyridine to give **2c** (23 mg). UV–vis (*c* 4.42 × 10^{-5} mol/L, MeOH) (log ε): 238 (4.34), 277 (4.37). CD (*c* 4.42 × 10^{-5} mol/L, MeOH): $[\theta]_{276}$ +6 737, $[\theta]_{266}$ +6 961, $[\theta]_{237}$ –15 667, $[\theta]_{217}$ –10 710. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.74 (d, *J* = 15.9 Hz, AB), 7.53 (m, 2H), 7.39 (m, 2H), 6.87 (ddd, *J* = 17.1, 10.5, 0.6 Hz, H-14), 6.52 (d, *J* = 16.2 Hz, AB), 5.46 (t, *J* = 7.5 Hz, H-12), 5.19 (dd, *J* = 17.1, 0.6 Hz, H-15_{trans}), 5.10 (dt, *J* = 10.8, 1.5 Hz, H-15_{cis}), 4.90 (d, *J* = 9.9 Hz, H-7β), 3.85 (dd, *J* = 11.1, 9.9 Hz, H-6α), 2.50 (dt, *J* = 15.9, 6.0 Hz, H-11a), 2.23 (dt, *J* = 16.2, 5.7 Hz, H-11b), 1.78 (d, *J* = 1.5 Hz, H_3-16), 1.27 (s, H_3-17), 1.17 (s, H_3-18), 1.02 (s, H_3-19), 0.96 (s, H_3-20).

Preparation of the (*S*)-MTPA and (*R*)-MTPA ester derivatives (2d and 2e) of 3

Compound **3** (35 mg) was hydrolyzed with KOH–MeOH (10%) to afford **2** (16 mg). Then, 2.0 mg of **2** were reacted in situ (into a NMR tube) with 6 μL of the (*R*)-(–)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride in 0.5 mL of anhydrous pyridine-d_5 (16). The NMR tube was shaken carefully to mix the sample and the reaction was monitored every 2 h by ^{1}H NMR until the (*S*)-MTPA ester derivative (**2d**) of **2** was formed. ^{1}H NMR (pyridine-d_5, 300 MHz) δ: 7.1784 (ddd, *J* = 17.11, 10.83 Hz, H-14), 5.7429 (t, *J* = 7.6 Hz, H-12), 5.8456 (d, *J* = 9.9 Hz, H-7β), 5.2474 (dd, *J* = 17.13 Hz, H-15 *trans*), 5.1285 (dt, *J* = 10.86 Hz, H-15 *cis*), 4.2793 (dd, *J* = 11.0, 10.83 Hz, H-6α), 2.8732 (m, H.11a), 2.3764 (m, H-11b). The procedure described for **2d** was applied to afford the (*R*)-MTPA ester derivative (**2e**) of **2** from the reaction mixture of (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride (6 μL), anhydrous pyridine-d_5 (0.5 mL), and **2** (2.0 mg). ^{1}H NMR (pyridine-d_5, 300 MHz) δ: 7.2619 (ddd, *J* = 17.31, 10.77, 0.78 Hz, H-14), 5.7948 (t, *J* = 7.64 Hz, H-12), 5.7794 (d, *J* = 9.24 Hz, H-7β), 5.2552 (dd, *J* = 17.46, 2.37 Hz, H-15 *trans*), 5.1547 (dt, *J* = 10.89, 1.59 Hz, H-15 *cis*), 4.0128 (dd, *J* = 10.0, 8.97 Hz, H-6a), 2.9314 (m, H.11a), 2.4171 (m, H-11b).

6,7-Isopropylidendioxy-austroinulin (4)

White powder; mp 106–108 °C. $[\alpha]_D^{25}$ +40° (*c* 0.075, MeOH). IR ($CHCl_3$, cm^{-1}) ν_{max}: 3460 (OH), 2985, 2921, 2874, 1370; 1230 (C-O), 1642, 1091, 896 (C=C). ^{1}H NMR (CD_3COCD_3, 500 MHz) δ: 6.95 (ddd, *J* = 17.5, 11.0, 1.0 Hz, H-14), 5.48 (t, *J* = 7.0 Hz, H-12), 5.13 (dd, *J* = 17.0, 1.0 Hz, H-15), 5.03 (dt, *J* = 10.8, 1.5 Hz, H-15), 3.61 (dd, *J* = 11.0, 9.0 Hz, H-6α), 3.49 (OH), 3.42 (d, *J* = 9.5 Hz, H-7β), 2.50 (m, H-11a), 2.27 (m, H-11b), 1.74 (d, *J* = 0.5 Hz, H-16), 1.64–1.58 (2H, m, H-1a, H-2a), 1.42–1.34 (3H, m, H-2b, H-9β, H-3a), 1.35 (d, *J* = 0.5 Hz, H_3-2′), 1.33 (d, *J* = 0.5 Hz, H_3-3′), 1.26 (d, *J* = 11.5 Hz, H-5β), 1.16 (m, H-3b), 1.18 (s, H-17), 1.04 (s, H-18), 0.97 (s, H-20), 0.96 (s, H-19), 0.93 (d, H-1b). ^{13}C NMR (CD_3COCD_3, 125 MHz) δ: 135.7 (C-12), 135.0 (C-14), 130.5 (C-13), 113.5 (C-15), 108.9 (C-1′), 90.8 (C-7), 76.6 (C-6), 75.0 (C-8), 61.5 (C-9), 56.7 (C-5), 42.7 (C-3), 41.5 (C-10), 40.8 (C-1), 35.3 (C-18), 34.1 (C-4), 27.6 (C-3′), 27.1 (C-2′), 23.0 (C-11), 22.5 (C-19), 20.0 (C-16), 19.0 (C-2), 18.6 (C17), 17.0 (C-20). EIMS *m/z*: 362 (1, $[M^+]$), 361 (1, $[M - H]^+$), 344 (10, $[M - H_2O]^+$), 286 (10), 195 (65), 137 (50), 81 (82), 43 (100), 41 (42), 18 (12). HRMS–FAB *m/z* calcd. for $C_{23}H_{39}O_3$: 363.2899 $[M + H]^+$; found: 363.2889.

***trans*-Dehydrocrotonin (6)**

White solid; mp 135 °C (137 to 138 °C). $[\alpha]_D^{25}$ +13° (*c* 0.075, $CHCl_3$). EIMS, IR, ^{1}H and ^{13}C NMR data were identical to those reported (2, 3).

Epimeric mixture of cajucarinolide (7, 8)

Beige powder; mp 238–240 °C. UV–vis (*c* 2.02 × 10^{-5} mol/L, MeOH) (log ε): 205 (4.15), 235 (4.60). CD (*c* 2.02 × 10^{-5} mol/L, MeOH): $[\theta]_{324}$ –8 399, $[\theta]_{271}$ +2 506, $[\theta]_{243}$ –41 300, $[\theta]_{222}$ +56 754. IR ($CHCl_3$, cm^{-1}) ν_{max}: 3273 (OH), 2962, 2859, 1753 (C=O γ-lactone ring), 1661 (C=O α,β-unsaturated), 1213, 1107 (C-O), 1620 (C=C), 755. ^{1}H NMR ($CDCl_3$–DMSO-*d*6 3:1, 300 MHz) δ: 7.08 (2H, t, *J* = 1.2 Hz, H-14′, H-14), 6.24 (t, *J* = 1.2 Hz, H-15′), 6.14 (dd, *J* = 1.2, 1.8 Hz, H-15), 5.87 (2H, s, H-3′, H-3), 5.19 (2H, m, H-12′, H-12), 3.09 (2H, s, H-5′, H-5), 2.60 (m, H-11a), 2.58 (m, H-1a), 2.51 (m, H-11a′), 2.34 (2H, m, H_2-1′), 2.29 (m, H-11b′), 2.23 (2H, m, H-6a′, H-6a), 2.16 (m, H-11b), 2.12 (m, H-1b), 1.97 (6H, d, *J* = 1.0 Hz, H_3-18′, H_3-18), 1.82 (2H, m, H-7a′, H-7a), 1.77 (2H, m, H-10′, H10), 1.70 (2H, m, H-8′, H-8), 1.68 (2H, m, H-7b′, H-7b), 1.19 (2H, td, *J* = 12.6, 3.3 Hz, H-6b′, H6b), 1.13 (3H, d, *J* = 6.6 Hz, H_3-17), 1.12 (3H, d, *J* = 6.6 Hz, H_3-17′). ^{13}C NMR ($CDCl_3$–DMSO-*d*6 3:1, 75 MHz) δ: 197.5 (C-2′), 197.3

(C-2), 176.5 (C-20′), 176.4 (C-20), 168.5 (C-16′, C-16), 165.9 (C-4′), 165.6 (C-4), 144.7 (C-16′), 144.2 (C-14), 136.2 (C-13′), 136.0 (C-13), 126.6 (C-3′), 126.5 (C-3), 98.4 (C-15′), 98.2 (C-15), 71.5 (C-12′, C-12), 50.9 (C-9′), 50.7 (C-9), 45.5 (C-10′, C-10), 41.5 (C-8′), 41.3 (C-8), 39.6 (C-1′), 39.4 (C-5′, C-5), 39.1 (C-1), 38.6 (C-11′), 38.2 (C-11), 29.9 (C-7′), 29.8 (C-7), 27.9 (C-6′), 27.9 (C-6), 21.8 (C-18′, C-18), 17.3 (C-17′), 17.2 (C-17). MS–FAB: 693 (4, $[2(M) + H]^+$), 347 (82, $[M + H]^+$), 259 (51), 243 (100), 154 (80), 136 (68), 91 (32), 77 (30), 55 (25), 43 (18), 41 (21).

3-*O*-Methylkaempferol (9)

Yellow powder; mp 268–270 °C. MS–FAB, IR, ^{1}H and ^{13}C NMR data were identical to those reported (12).

5,7,3′,4′-Tetrahydroxy-3-methoxyflavonoid (10)

White powder; mp 254–256 °C (252–255 °C). EIMS, IR, ^{1}H and ^{13}C NMR data were identical to those published (13).

Computational details

First, a minimum energy structure of **2b** was obtained using the PCMODEL program. Then, geometry optimization was carried out by means of density functional theory employing the hybrid functional B3LYP. To reduce the computational effort for all our quantum mechanical calculations, we employed the Hay and Wadt (H–W) effective core potentials (ECP) together with their associated double-ζ basis sets (25). The optimized geometry was used to carry out theoretical ECD calculations within the time-dependent DFT formalism.[5] Our TD-DFT computations were calculated for singlet states and solved for 10 states. We only considered the spectrum in the [200, 300] nm interval. Rotatory strengths were calculated in the velocity and length formalisms. All these quantum mechanical computations were carried out with the suite of programs in Gaussian 03 (26). The ECD spectrum was simulated by overlapping Gaussian functions for each transition according to (see ref. 24),

$$\Delta\varepsilon(E) = \left(\frac{1}{2.297^{-39}}\right)\left(\frac{1}{\sqrt{2\pi\sigma}}\right) \times \sum_a (\Delta E_{0a})(R_{0a}) \exp\left[-\left(\frac{(E - \Delta E_{0a})}{2\sigma}\right)^2\right]$$

where σ is the width of the band at 1/*e* height and ΔE_{0a} and R_{0a} are the excitations energies and rotatory strengths for transitions 0 to a, respectively. A σ value of 0.2 eV was used.

Cytotoxicity assay

Colon (HCT-15), breast (MCF-7), leukemia (K-562 CML), central nervous system (U-251 Glia), and prostate (PC-3) human tumor cell lines were supplied by National Cancer Institute (NCI), USA. The cytotoxicity of the tumors cells with the test compounds was determined using the protein-binding dye sulforhodamine B (SRB) in microculture assay to measure cell growth (27). The cell lines were cultured in RPMI-1640 (Sigma Chemical Co. Ltd., St. Louis, Missouri), supplemented with 10% fetal bovine serum, 2 μM L-glutamine, 100 IU/mL penicillin G, 100 μg/mL streptomycin sulfate, and 0.25 μg/mL amphotericin B (Gibco). They were maintained at 37 °C in a 5% CO_2 atmosphere with 95% humidity. For the assay, 5×10^4 cell/mL (K562, MCF-7), 7.5×10^4 cell/well (U251, PC-3), 10×10^4 cell/well (HCT-15), and 100 μL/well of these cell suspensions were seeded in 96-well microtiter plates and incubated to allow the cell attachment. After 24 h, 100 μL of each test compound and positive substance were added to each well. After additional 48 h, adherent cell cultures were fixed in situ by adding 50 μL of cold 50% (*wt*/*vol*) trichloroacetic acid (TCA) and incubated for 60 min at 4 °C. The supernatant was discarded and the plates were washed three times with water and air-dried. Cultures fixed with TCA were stained for 30 min with 100 μL of 0.4% SRB solution. Protein-bound dye was extracted with 10 μmol/L unbuffered tris base and the optical densities were read on an Ultra Microplate Reader (Elx 808, BIO-TEK Instruments, Inc.) with a test wavelength of 515 nm. Results were expressed as inhibitory concentration 50 (IC_{50}) values and they were calculated according to the protocol of Monks (27), where a dose-response curve was plotted for each compound and the concentration giving 50% inhibition (IC_{50}) was estimated from linear regression equations. The IC_{50} values (mean ± standard error) for **2**–**4**, the synthetic derivatives **2a** and **2b**, and **9** are shown in Table 1.

The absolute configuration of a nitroxide spin labeled derivative of podophyllotoxin determined by the crystal structure

Baohan Zhou, Guodong Yin, Xianggao Meng, Yitao Li, and Anxin Wu

Abstract: The crystal structure of the nitroxide spin labeled derivative of podophyllotoxin was first reported. X-ray analysis demonstrated that four contiguous chiral centers in the molecule, C1, C2, C3, and C4, adopt *cis*- (1:2), *trans*- (2:3), and *cis*- (3:4) arrangement.

Key words: crystal structure, synthesis, nitroxyl radical, podophyllotoxin.

Résumé : On a déterminé pour la première fois la structure cristalline d'un dérivé de la podophyllotoxine portant un groupe nitroxyde comme marqueur de spin. Les analyses par diffraction des rayons X ont permis de démontrer que quatre centres chiraux contigus de la molécule, C1, C2, C3 et C4, adoptent des arrangements *cis*- (1,2), *trans*- (2,3) et *cis*- (3,4).

Mots clés : structure cristalline, synthèse, radical nitroxyle, podophyllotoxine.

[Traduit par la Rédaction]

Introduction

Podophyllotoxin (**1**) and its many related derivatives are well known to possess pronounced antitumor and antiviral properties. However, the clinical application of podophyllotoxin and its analogues in the treatment of cancer has been limited by severe toxic side effects during the administration of the drugs (1–4). It was previously found that the introduction of a stable nitroxyl radical into the molecule of podophyllotoxin could result in novel compounds that have significant antitumor activity with marked decrease in toxicity compared with podophyllotoxin itself (5–7). Though the structure of spin-labeled podophyllotoxin derivatives can be indirectly characterized by mp, ESR, IR, MS, and HR-MS spectral analyses, its elaborate structure can't be confirmed by ^{1}H NMR because of its paramagnetic properties. Moreover, there are four contiguous chiral centers in the molecule, and its absolute configuration was not determined until now. In this paper, we synthesized one nitroxide spin labeled derivative of podophyllotoxin (**3**), first reported the crystal structure, and confirmed its absolute configuration.

Experimental section

4-[4″-(2″,2″,6″,6″-tetramethyl-1″-piperidinyloxy)amino]-4′-demethylepipodophyllotoxin (**3**) was prepared as shown in Scheme 1 (8). Podophyllotoxin (**1**), commercial agent (J & K Chemical Ltd., Shanghai, China), was used as a starting material.

The demethylation and bromination of **1** gave 4-bromo-4′-demethyl-epipodophyllotoxin (**2**). 33 g of **1** was suspended in 300 mL of 1,2-dichloroethane and 30 mL of ether and cooled to 0 °C. A current of dry hydrobromide was passed in until an increased mass of 82.5 g was obtained. After standing at 0–2 °C for 20 h, the solvent was removed under vacuum. The residue was recrystallized from acetone to give 12 g of **2**: 36% yield; mp 180–190 °C (dec.). A solution of **2** (2.77 g, 6 mmol) and 2,2,6,6-tetramethyl-1-piperidinyloxy-4-amine (2.57 g, 15 mmol) in 35 mL of dry THF and 2 drops of dry pyridine was refluxed under N_2 for 4 h. After filtering off the insoluble solids and removing the solvent under reduced pressure, the crude product was chromatographed twice through silica gel using CH_2Cl_2–acetone–Et_2NH (40:1:1, *v*/*v*) as an eluent to obtain 1.07 g (32% yield). Crystallization from acetone–hexane afforded the spin-labeled derivative of podophyllotoxin (**3**): red solid; mp 218–220 °C. UV (methanol) λ_{max} (nm): 283, 242, 220. IR (cm^{-1}): 3338 υ(NH), 1757 υ(C=O), 1609 υ(C=C), 1516 υ(C=C), 1479 $\delta_S(CH_3)$. ESR: 3 Lines, A_n = 16.2 G, ΔH_o = 2.66 G, g_o = 2.0061. MS–FAB *m*/*z* (%): 554 (13), 553 (16), 537 (7), 383 (100). Anal. calcd. (%): C 65.08, H 6.74, N 5.06; found: C 65.36, H 6.505, N 4.035.

A red crystal of the synthesized compound **3** was mounted on a glass fiber in a random orientation at 292(2) K. The determination of the unit cell and the data collection were performed with Mo Kα radiation (λ = 0.71073 Å) on a Bruker SMART APEX-CCD diffactometer with a ψ-ω scan mode. The structure was solved by direct methods with SHELXS-97 program and expanded by Fourier technique. The non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were determined by theoretical calculations.

Results and discussion

Figure 1 shows the molecular structure of compound **3**, and the atomic numbering of the same compound is shown in Fig. 2.

Because the tumor-damaging potency of podophyllotoxin and related compounds is closely associated with their stereochemistry (9, 10), the determination of their absolute configuration might shed further light on the mechanism of their action, a question of importance in the search for effective chemotherapeutic agents. Synthetic organic chemists have been attracted to the stereochemical challenge represented by the four contiguous chiral centers of podophyllotoxin, the rigid *trans*-lactone, and the axially locked 1-aryl substituent. The early syntheses (11–14) generated

much new and interesting chemistry but led to the inactive *cis*-lactone.

X-ray analysis demonstrated that four contiguous chiral centers in the molecule, C1, C2, C3, and C4, adopt *cis*-(1:2), *trans*- (2:3), and *cis*- (3:4) arrangement (Fig. 1). The angles of C3–C2–C12, C3–C2–C1, and C13–C3–C2 are 101.2(4)°,108.6(4)°, and 103.6(4)°, respectively, which are less than the normal 109.5° angle. The angles of C12–C2–C1, C13–C3–C4, and C2–C3–C4 are 119.7(4)°, 120.0(5)°, and 113.3(4)°, respectively, which are much larger than the normal 109.5° angle. These results show that C2 and C3 are distorted atoms. Perhaps because the *trans*-lactone is a rigid ring and can not rotate freely. The six-membered ring containing N–O radical adopts a chair conformation, and the bond length of N—O is 1.270(5) Å, which is in the normal range of nitroxyl radicals (1.25–1.31 Å) (15, 16).

The energetics of the $X_2 + X^- \rightarrow X_3^-$ equilibrium (X = Cl, Br, I) in aqueous and nonaqueous solution

Evan Crawford, J. Scott McIndoe, and (the late) Dennis G. Tuck

Abstract: The magnitude of the stability constants (*K*) for the formation of X_3^- from X^- and X_2 (X = Cl, Br, I) in aqueous and nonaqueous solution depends strongly on both X and solvent. Thermodynamic arguments establish that for aqueous solutions this is not the result of differing bond strengths in the X_3^- anion but rather depends on the solvation energies of the relevant anions and halogens. The experimental results for *K* in different organic solvents can also be rationalized in terms which emphasise solvation effects. Electrospray ionization mass spectrometry (ESI-MS) has been used to qualitatively probe relative bond strengths in the absence of solvent.

Key words: trihalides, stability constants, solvation, electrospray ionization, mass spectrometry.

Résumé : En solutions aqueuses ou non aqueuses, l'amplitude des constants de stabilité (*K*) pour la formation de X_3^- à partir de X^- et X_2 (X = Cl, Br, I) dépend fortement de la nature de X ainsi que de celle du solvant. Des arguments thermodynamiques permettent d'établir que, dans les cas de solutions aqueuses, cette situation ne résulte pas de différences dans les forces de liaison dans l'anion X_3^-, mais plutôt des énergies de solvatation des anions et des halogènes appropriés. Les résultats expérimentaux pour les valeurs de *K* dans divers solvants organiques peuvent aussi être rationalisés en fonction d'effets qui mettent l'accent sur la solvatation. On a utilisé la spectrométrie de masse avec ionisation par électronébulisation pour évaluer qualitativement les forces relatives des liaisons en absence de solvant.

Mots clés : trihalogénures, constantes de stabilité, solvatation, ionisation par électronébulisation, spectrométrie de masse.

[Traduit par la Rédaction]

Introduction

Many polyhalide anions have been characterized in recent years and the X_3^- ions (X = Cl, Br, I) have been the focus of special interest. Over the last 100 years, many different techniques have been used in attempts to establish reliable values for the equilibrium constant for the formation of these ions in aqueous and nonaqueous solutions. The related X_2Y^- anions (X ≠ Y = Cl, Br, I, SCN) are also known and their dissociative and redistribution equilibria in solution have been investigated (1).

One feature which has aroused interest is that in aqueous solution the equilibrium constants for

[1] $$X_2 + X^- \rightleftharpoons X_3^-$$

[2] $$K_3 = \frac{[X_3^-]}{[X_2][X^-]}$$

are in the order I > Br > Cl, which has prompted speculation about the bonding in the X_3^- anions. A second point is that in nonaqueous solvents this order is reversed and the numerical values are all higher by several orders of magnitude. A recent paper by Landrum et al. (2) has shown that there is, in fact, little difference between the bonding energies in the three trihalide ions (X = Cl, Br, I) and these results form the basis of a satisfactory analysis of those factors that do affect the value of K_3 in different solvents.

The present paper addresses the energetics of the $X_2 + X^- \rightarrow X_3^-$ equilibrium in three related ways. In the first place, we show that the value reported by Landrum et al. (2) for the binding energy of I_3^- is compatible with related experimental values; secondly, we compare this and other calculated binding energies for X_3^- and X_2Y^- anions (X ≠ Y = Cl, Br, I) with mass spectrometric determinations of the decomposition potential; and finally, the effect of solvent on the stability constants of the X_3^- anions is discussed in terms of the relevant solvation parameters.

The bonding energy of $I_3^-{}_{(g)}$

The bonding in the X_3^- anions has been the subject of a number of theoretical treatments prompted by the fact that X^-, X_2, and X_3^- are all closed shell species. Landrum et al. (2) have reviewed previous attempts at estimating the bonding energy for

for which a range of values have been proposed. Their calculations give –164, –166, and –157 kJ mol^{-1} for Cl_3^-, Br_3^-, and I_3^-, respectively, and this small range of values immediately emphasizes that factors other than bond energy must affect the value of K_3. The authors comment on the lack of experimental data against which these numbers can be tested. Fortunately, it is possible to obtain a value for the iodine system from published information and this provides a starting point for the present discussion. The appropriate thermodynamic cycle is shown in Scheme 1.

The thermodynamic parameters for the formation of I_3^- in aqueous solution (eq. [1], X = I) have been studied by several authors using a variety of experimental techniques, and the results have been reviewed by Ramette and Sandford (3) who recommend the spectrophotometric results of Daniele (4), namely K_3 = 723 at 25 °C, ΔH° = –19.9 kJ mol^{-1}, ΔG° = –16.3 kJ mol^{-1}, ΔS° = –12.0 J K^{-1} mol^{-1}. These values are used in Scheme 1 and later. The enthalpy of solution of I_2 in water reported by Ramette and Sandford is ΔH° = +22.7 kJ mol^{-1} for

$$[4] \qquad I_{2(s)} \rightleftharpoons I_{2(aq)}$$

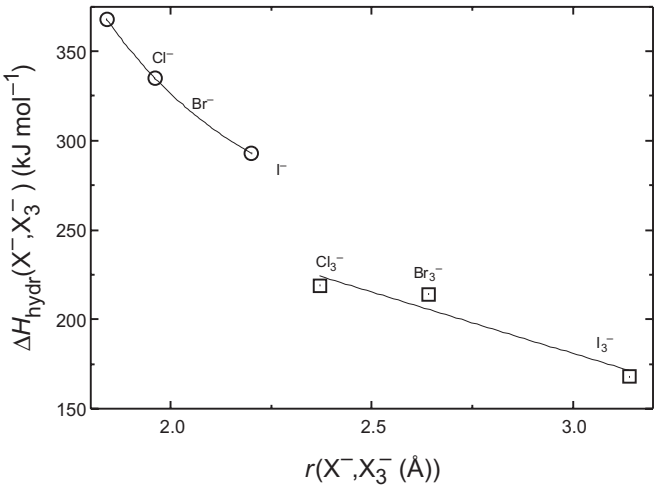
with ΔG° = +16.4 kJ mol^{-1}. Earlier studies by Davies and Gwynne (5) gave ΔH° = +25.7 kJ mol^{-1}; the lower value is used in Scheme 1. The standard enthalpy of formation of $I_{2(g)}$ (i.e., ΔH_{sub}) is +57.5 kJ mol^{-1}. The thermodynamics of the hydration of ions has been reviewed by Marcus (6); the work of Halliwell and Nyburg (7) gives values for the halide ions and for I_3^- (ΔH_{hydr} (I^-) = –293 ± 4 kJ mol^{-1}, ΔH_{hydr} (I_3^-) = –168 ± 20 kJ mol^{-1}).

The resultant value for the dissociation energy of I_3^- is 180 kJ mol^{-1}, ca. 8% higher than the 157 kJ mol^{-1} calculated by Landrum et al. (2). The largest experimental uncertainties are in the enthalpies of hydration; any errors related to the fact that these necessarily depend on ΔH°_{hydr} of the proton fortunately cancel in the summation around the cycle. The largest uncertainty in the calculation of the bond energy relates to the size of the basis set and to possible relativistic effects.[3] In general, the agreement between the two approaches seems satisfactory.

Equilibrium constants in aqueous solution

As noted earlier, there is a wide range of values for K_3 in contrast to the calculated bond energies. For X = I, the value quoted (4) earlier is K_3 = 723. For X = Br, Dubois and Garnier (8) found K_3 = 16.3 at 25 °C, in good agreement with an earlier result (1*a*), which gave ΔH = –12.8 kJ mol^{-1}. The corresponding values (9) for X = Cl are K_3 = 0.191 ± 0.016 and ΔH = –8 kJ mol^{-1}, again in keeping with earlier investigation (1*a*, 10) of this experimentally difficult system.

To identify the reasons for the differences in K_3, it is necessary to use the hydration enthalpies of Cl^- and Br^- and the enthalpies of solutions of $Cl_{2(g)}$ and $Br_{2(g)}$, which are available from the sources used for iodine. The corresponding terms for Cl_3^- and Br_3^- are not available and so must be estimated, which can be done by using a cycle analogous to that in Scheme 1, but now relying upon the calculations of Landrum et al. (2) for the Cl_3^- and Br_3^- dissociation energies. The relevant numerical values are shown in Table 1 and the appropriate summation leads to ΔH_{hydr} ($Cl_3^-{}_{(g)}$) = –219 kJ mol^{-1} and $\Delta H_{hydr}(Br_3^-{}_{(g)})$ = –214 kJ mol^{-1}. The size dependence of the resultant ΔH_{hydr} for X_3^- is shown in Fig. 1, using the calculated X–X distances as a measure of ionic size; the analogous values for X^- are plotted against r(X^-) for comparison.



The value for $\Delta H_{hydr}(Cl_3^-)$ appears to be lower than one would predict from Fig. 1 and this may well be related to the large uncertainty in ΔH_{equil} for the formation of $Cl_3^-{}_{(aq)}$. In what follows, we assume the values of the enthalpy of hydration to be –168, –210, and –225 kJ mol^{-1} for I_3^-, Br_3^-, and Cl_3^-, respectively, derived from Fig. 1.

Table 1 makes it immediately obvious that the $X_3^-{}_{(g)}$ bonding energies are not the dominant terms determining the

[3] Private communications from Prof. Hoffmann and Dr. Goldberg.

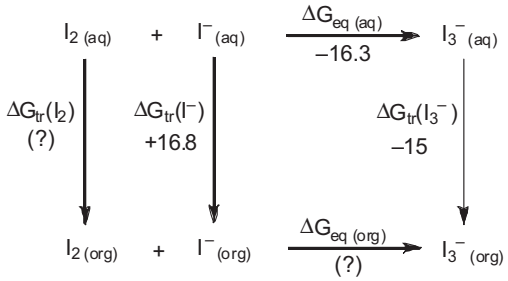
Fig. 1. Size dependence of ΔH_{hydr} for X^- (circles) and X_3^- (squares) anions (X = Cl, Br, I).

value of $\Delta H°_{equil}$ for eq.[1]. The derived parameters given in the last two lines of this Table show that while the differences between the enthalpy of hydration of $X^-_{(g)}$ and $X_3^-{}_{(g)}$ are similar, there is a much larger variation in the enthalpy of solution of the elements from their standard states. In sum, the important enthalpy terms relate to the solution and hydration of the various solute species and do not reflect differences in the bond energy of the X_3^- anions.



This last conclusion is relevant to the purported estimate of the stability of X_3^- based on the thermal stabilities of crystalline $M^+X_3^-$ salts (ref. 1*a*, p. 241). These results are better understood as a reflection of the different lattice energies of the salts in question and must depend only slightly on the bond energy of X_3^-. Equally, they can have little to do with the symmetry of the cation involved (ref. 1*b*) other than to the extent that this affects the lattice energy.

Comparison of aqueous and nonaqueous solutions

As noted earlier, K_3 is substantially larger for all three trihalide anions in nonaqueous solutions, and in the order Cl > Br > I. It is immediately obvious from the previous discussion that neither of these conclusions can be the result of bond energy factors and therefore it is incumbent to examine the solvation energies involved. As in the aqueous solution case, the I_3^- equilibrium is the only case for which adequate data are available and these are free energy rather than enthalpy values. A comparison of aqueous and nonaqueous systems can be made through the cycle shown in Scheme 2.

Where the numerical values refer to acetonitrile, Nelson and Iwamoto (11) have measured K_3 for Cl, Br, and I^- in this and other polar solvents and we use their value of log K_3 = 6.6 for the formation of I_3^-. The free energy of transfer of I^- from H_2O to CH_3CN is given as +16.8 kJ mol^{-1} by Marcus (6) and the corresponding ΔG_{tr} for I_3^- is –15 kJ mol^{-1}. There appears to be no direct measurement of $\Delta G_{tr}(I_2)$ from aqueous solution to acetonitrile, but Hildebrand et al. (12) have published an extensive set of values for the solubility of I_2 in organic solvents and their data show that iodine is more soluble in polar organic solvents than in water by a factor of

Scheme 2.

ca. 10^3. The value of ΔG_{tr} calculated from the result for ethanol at 25 °C is –18.6 kJ mol^{-1} and in the absence of other information this value is used for acetonitrile in the first iteration. The equilibrium constant for K_3 for I_3^- in aqueous solution is 723, with $\Delta G°$ = –16.3 kJ mol^{-1} (see earlier), so that Scheme 2 gives $\Delta G°$ for eq. [1] in acetonitrile as –29.5 kJ mol^{-1} and log $K_3(CH_3CN)$ = 5.2. As noted above, the reported experimental value is log K_3 = 6.6 and the agreement seems reasonable given the uncertainty in ΔG_{tr}. Nelson and Iwamoto do not give values for their equilibrium constants, so that the reality of the difference cannot be explored.

The agreement justifies an extension of the argument to seek an explanation of the order of K_3 in organic solvents. Ideally, a series of cycles analogous to Scheme 2 for each solvent and each halogen would lead to a detailed understanding of the factors involved, but unfortunately the numerical data required for this approach are not available; in particular, there is an absence of results for the solution properties of X_3^-. It is however possible to go some way in comparing the equilibrium constants for the three different trihalides, in acetonitrile in the first place, with the corresponding aqueous systems by using Scheme 2. The appropriate numerical data are in Table 2, in which the final column is the sum

[5*a*] $\Delta G°(CH_3CN) - \Delta G°(H_2O) + \Delta G_{tr}(X^-)$

which from Scheme 2 obviously equates to

[5*b*] $\Delta G_{tr}(X_3^-) - \Delta G_{tr}(X_2)$

The value of K_3 taken for the iodine system is that reported by Nelson and Iwamoto (log K= 6.6) and not that calculated in the paragraph above.

The values for bromine and iodine in the final column of Table 2 are quite close and as noted earlier any conclusions about the value for chlorine are conditioned by the experimental uncertainties. Beyond that, an inspection of the parameters in this table suggests that the single most significant factor predicting the order Cl > Br > I for K in acetonitrile and the change from the reverse order in water is the free energy of transfer of X^- from aqueous to nonaqueous solution.

To further examine this conclusion and its possible application to other solvents (e.g., S), we make the assumption that the term in eq. [5*b*], which equates to the last column of Table 2, is effectively constant within experimental error and lies in the range 0 ± 15 kJ mol^{-1}, corresponding to ±2.6 in

the accumulated errors for log $K(H_2O)$ and log $K(S)$. Experimental values have been reported for K_3 for each trihalide in the solvents acetonitrile, nitromethane, and acetone, and Marcus has published ΔG values for the transfer of X^- from aqueous to nonaqueous solution for these and other solvents. Equation [5] can be rewritten as

$$[6] \quad \Delta G°(H_2O) - \Delta G°(S) = -\Delta G_{tr}(X) - [\Delta G_{tr}(X_2) - \Delta G_{tr}(X_3)]$$

and following the assumption above that the term in square brackets is effectively constant within the uncertainties of the data, we have

$$[7] \quad RT \log [K_3(S) / K_3(H_2O)] = -\Delta G_{tr}(X^-) - \text{constant}$$

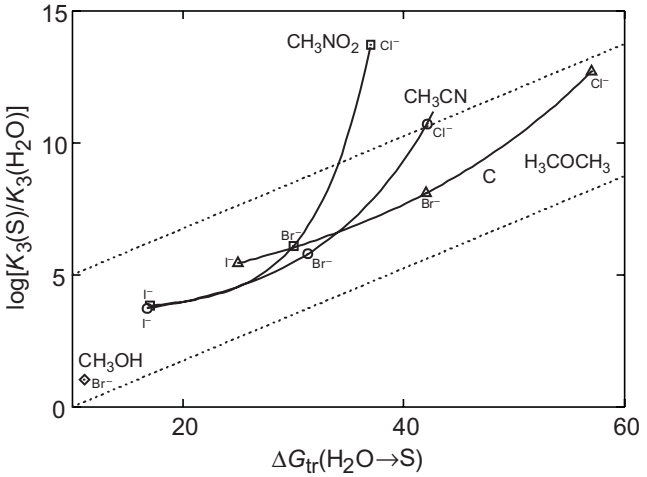

Figure 2 shows a plot of log $[K_3(S) / K_3(H_2O)]$ against $\Delta G_{tr}(X^-)$ for acetonitrile, nitromethane, and acetone, using the data in Table 2, and in refs. 6 and 11.

With one exception, the points fall within a band (indicated with dotted lines on Fig. 2) with a slope of 2.303*RT* on log $[K_3(S) / K_3(H_2O)]$. The exception is for Cl^-–CH_3NO_2 and the value for Cl^-–CH_3CN is barely within the upper limit. Given the experimental problems in measuring K_3 for the Cl_3^- system in aqueous solution and apparently in organic solvents (9), it is not surprising that this is where the largest deviations are found. In spite of the considerable assumptions made in deriving eq. [8], it is reasonable to conclude that the main factor predicting the value of K_3 in organic solvents relates to the free energy of transfer of X^- from H_2O to the solvent in question. In essence, since the X^- anions are much less strongly solvated in organic solvents than in water, equilibrium (3) is driven to the right relative to the situation in aqueous solution. This conclusion is in keeping with that reached earlier that solvation forces are more important than bond energies in both aqueous and nonaqueous systems.

The Br_3^- system in aqueous methanol

Two papers by Dubois and coworkers (8, 14) report results for the Br_2–Br^-–Br_3^- system in water, methanol, and aqueous methanol over the whole range of compositions. The ratio $K_3(MeOH)$–$K_3(H_2O)$ is 176:16.3; ΔG_{tr} for Br^- from H_2O to MeOH is +11.1 kJ mol^{-1}, leading to the point shown in Fig. 2. Dubois and Garnier (8) show that the change in log K_3 with H_2O–CH_3OH mole ratio is a linear function of the reciprocal of the dielectric constant of the solvent mixture. Any comparison of this conclusion with the arguments used in deriving Fig. 2 is negated by the absence of the necessary data (e.g., ΔH_{sol} of Br_2 in H_2O–MeOH mixtures). It is clear, however, that within the limits of the argument the change in K_3 with solvent composition is explicable in terms of the changing free energy of solvation of the Br^- ion, even in a system involving a highly polar nonaqueous solvent.

Fig. 2. Log $(K_3(S) / K_3(H_2O))$ as a function of ΔG_{tr} $(H_2O \rightarrow S)$ for X^- ions (X = Cl, Br, I). The dotted lines have slope = 2.303RT.

Mass spectrometry

We were interested in the speciation of Br_3^- in methanol. One useful technique for the analysis of charged species in polar solvents is electrospray ionization mass spectrometry (ESI-MS) (15). This technique is most prominent in the study of biomolecules (16) but has also become widely used in the analysis of a huge range of inorganic compounds (17). The power of the technique is probably best demonstrated in the analysis of complex mixtures, because the extensive fragmentation common to other mass spectrometric ionization methods is essentially absent from ESI mass spectra. A result of this is that each signal in the spectrum is due to a different parent ion corresponding to a unique solution species. We have already demonstrated the utility of the technique with respect to solutions of polyhalides (1*d*).

Examination of the negative-ion ESI mass spectrum of Br_3^- in methanol revealed rather complicated solution speciation (Fig. 3). While Br_3^- can be observed in the spectrum, it makes up only a small percentage of the total ion current. Close inspection of the isotope patterns revealed a complex series of polybrominated ions. These could not be assigned to simple combinations of Br, solvent, and counterion and so other possibilities were considered. The key to this puzzle was an ion at 517 m/*z* that had the exact

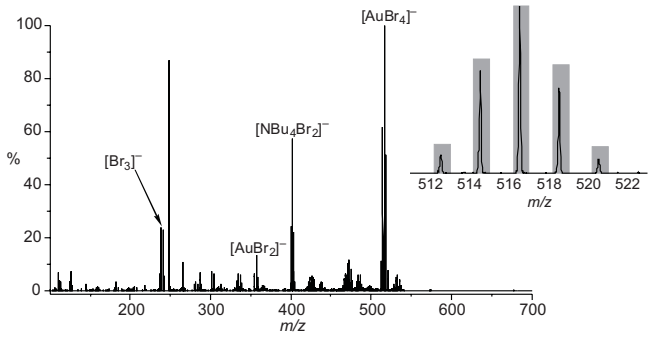

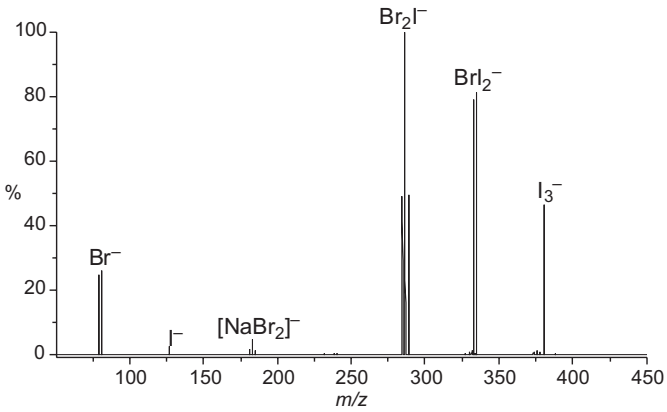

Fig. 4. Negative-ion ESI-MS of NaBr + I_2 in acetonitrile.

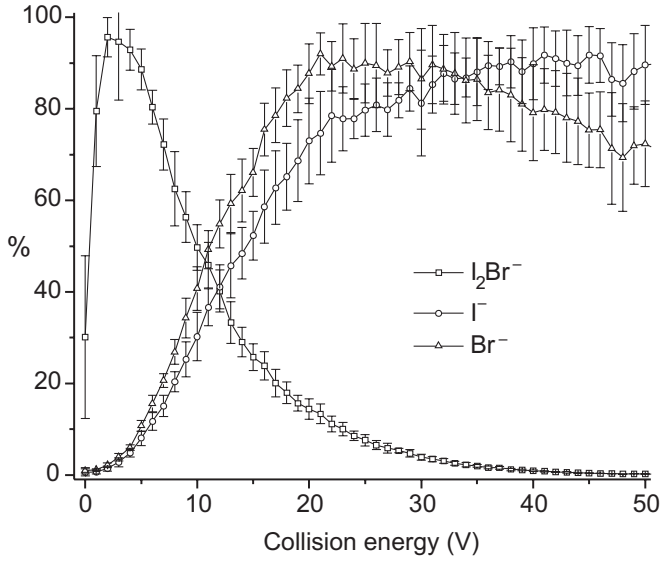
isotope pattern for Br_4, with all other contributors being monoisotopic (see inset pattern in Fig. 3). A single isotope with the correct mass is ^{197}Au and the pattern matches perfectly for $[AuBr_4]^-$. Chemically, this is perfectly reasonable as this complex is quite stable (18), but where did it come from? The answer provided itself when the mass spectrometer stopped functioning and after dismantling the source we found that the stainless steel capillary from which the spray emerges had been completely corroded. $[AuBr_4]^-$ is present in an appreciable quantity; its abundance in the spectrum is surprising and suggests that corrosion elsewhere in the source is an issue because it is unlikely the stainless steel capillary contains sufficient gold to provide the strength of signal observed (the brass components of the ion block assembly are a likely source of the gold; some parts may also be gold-plated, though this information is proprietary). Br_3^- in methanol is clearly too reactive to be studied routinely using ESI-MS and viable conclusions cannot be drawn using this method of analysis.



However, we found ESI-MS of acetonitrile solutions of X_3^- (X = I, Br, Cl, and the pseudohalide SCN) to provide entirely explicable spectra (Fig. 4), with no sign of any species attributable to corrosion of parts of the source. Prominent peaks in the negative-ion mode include X^-, X_3^-, and $[CX_2]^-$ (C = cation) (Fig. 4). The thiocyanates were investigated, but spectra were dominated by $X_2(SCN)^-$ ions and an $X(SCN)_2^-$ ion was detected only in the case of X = I.

All X_3^- species undergo collision-induced dissociation (CID) in the argon-filled collision cell of the mass spectrometer to form X_2 (neutral, so not observed) and X^- in a simple MS–MS experiment. As collision energies may be smoothly varied, this process offers qualitative insight into the relative bonding energy by assessing the voltage required to fragment X_3^-. Table 3 summarizes the results obtained from these experiments. Figure 5 illustrates the type of raw data obtained for each of the species using I_2Br^- as the example (only I_2Br^-, $I_2(SCN)^-$, and $Br_2(SCN)^-$ generated both possible X^- ions upon CID; the remainder exclusively formed the ions listed in Table 3).

Essentially, X_3^- was selected using the first mass analyser (MS1) of a hybrid quadrupole time-of-flight (Q-TOF) mass spectrometer. The ion was fragmented in the collision cell using a collision voltage that increased by an increment of

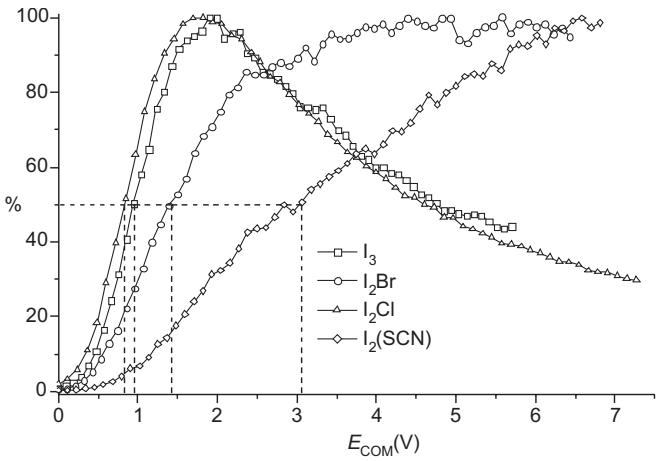
Fig. 5. Breakdown graph of I_2Br^- showing traces for the disappearance of $I_2Br^-$and the appearance of I^- and Br^-. The error bars represent the variability between five independent experiments. The collision energy, E_{LAB} is the value of the offset voltage for the central hexapole.

1 V for each spectrum that was recorded, in exactly the same way as in energy-dependent ESI mass spectra (EDESI-MS) (19). However, the simplicity of the spectra are such that breakdown graphs (20) convey the same information in a readily comprehensible fashion. Half of the maximum intensity of the X_3^- ion was used as a convenient point to assess the relative energy required to break apart the X_2 and X^- fragments (Table 3, 50% decomposition). Half of the maximum intensity of the X^- ion was also recorded (Table 3, 50% appearance; also see Fig. 6). The energies are recorded as centre-of-mass, where $E_{COM} = E_{LAB}(m / (m + M))$, where E_{LAB} is the value of the offset voltage for the central hexapole (the collision energy), m is the mass of the stationary Ar atom, and M is the mass of the precursor ion.

Figure 7 shows a spectrum obtained by summing all spectra used in the collection of the breakdown graphs depicted in Fig. 5 (note that all ions appear monoisotopic because of the fact that the lowest mass isotopomer of X_3^- was selected for fragmentation in all cases). Note that trace amounts of $I_2^{\bullet-}$ and $IBr^{\bullet-}$ are also present; these imply loss of $Br^{\bullet}$ and $I^{\bullet}$, respectively. The radical decomposition channel was always a minor one.

There is sufficient error in the values obtained for appearance and decomposition voltages (ca. ±0.3 V) that in-depth analysis of the values obtained is not prudent; the experiments we describe are very much qualitative. However, two useful general conclusions can be drawn. First, all mixed species X_2Y^- tended to lose XY as the primary neutral fragment, generating X^-. Three examples also lost X_2, namely $I_2(SCN)^-$, $Br_2(SCN)^-$, and BrI_2^-, but in all of these cases this decomposition pathway was in competition with XY loss. On purely statistical grounds, one would expect that X_2Y^- species should produce XY as the neutral fragment twice as often as X_2; the selectivity for the mixed fragment suggests that the XY bond is marginally stronger than the X_2 bond

Fig. 6. Breakdown plots of the appearance of I^- from I_3^-, BrI_2^-, ClI_2^-, and $I_2(SCN)^-$. $E_{COM} = E_{LAB}(m / (m + M))$, where E_{LAB} is the value of the offset voltage for the central hexapole, m is the mass of the stationary Ar atom, and M is the mass of the precursor ion. Dotted lines indicate the 50% appearance potential for each trace. Note that for BrI_2^- and $I_2(SCN)^-$, Br^- and SCN^- were being concurrently generated.



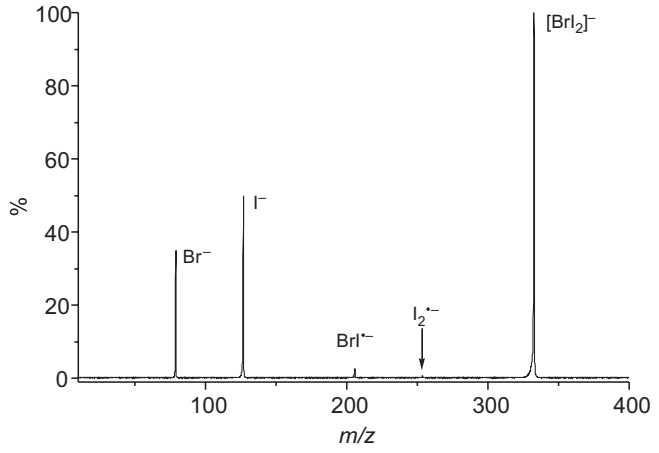


Fig. 7. ESI-MS–MS of BrI_2^- summed over collision voltages of 0–50 V.

(though in the case of BrI_2^-, I-Br, and I-I it must be of comparable strength). Second, the thiocyanate-containing species $I_2(SCN)^-$, $Br_2(SCN)^-$, and $(SCN)_2I^-$ clearly have the lowest bonding energies, being the easiest to decompose. Both $I_2(SCN)^-$ and $Br_2(SCN)^-$ produced both possible decomposition products (SCN^- and the appropriate halide ion), though in the case of $I_2(SCN)^-$, I^- was a very minor product and the spectrum was dominated by the appearance of SCN^-. The remaining species have values that are not dramatically different to one another and accurate quantitative assessments of the bond energies are required, e.g., by guided ion beam tandem mass spectrometry (21), before any firm conclusions can be drawn about the exact ordering of bond strengths.

General conclusion

The variation of K_3 in the Cl, Br, I triad is not a function

© 2006 NRC Canada

of any wide variation in the X_3^- bonding energy, but rather reflects the solvation energies of the solutes in question. Within the limits of the available thermodynamic information, it is possible to rationalize the range of equilibrium constants and the effect of changes of solvent on these constants. ESI-MS–MS studies confirm that bond strengths do not vary wildly between different species and also suggest that for mixed X_2Y^- trihalides the XY bond is marginally stronger than the X_2 bond. Mixed halogen–thiocyanate species exhibit the weakest bonding.

Experimental

Electrospray ionization mass spectra were collected using a Waters Micromass Q-Tof micro with Z-Spray source with the following settings: the nebuliser tip was set at 2900 V and 100 °C and nitrogen was used as the bath gas; samples were introduced directly to the source at 5 μL min^{-1} as acetonitrile solutions via a syringe pump; data collection was carried out in continuum mode. For the breakdown graphs, the cone voltage was set at 15 V and MS1 was set at the appropriate *m*/*z* value for the species of interest. The collision voltage was initially set at 0 V and spectra collected at every 1 V increment until MS2 showed no change in the daughter ion spectrum (typically ~ 60 V). The collision gas was argon at a pressure of 10^{-4} mbar (1 bar = 100 kPa).

All chemicals were purchased from Sigma-Aldrich (99% purity or better) and used as received. Solutions of the trihalides were typically prepared by adding the appropriate potassium or sodium (pseudo)halide salt to an acetonitrile solution of I_2 or Br_2. To get spectra of $[Cl_2Br]^-$ and $[Br_2Cl]^-$, equimolar amounts of Br_2 and $[Et_4N]Cl{\cdot}H_2O$ were heated to complete liquification. The cooled solid was then dissolved in acetonitrile. The spectrum of $[Br_2(SCN)]^-$ was collected by mixing an acetonitrile solution of Br_2 with 0.2 mL of a saturated acetonitrile solution of KSCN. Solution concentrations of each species were of the order of ca. 0.1 mg mL^{-1}.

Carbonate radical anion — Thermochemistry[1]

D.A. Armstrong, W.L. Waltz, and A. Rauk

Abstract: High level ab initio calculations along with isodesmic reactions have been used to derive a set of self-consistent free energies of formation for carbonate and nitrate species in the gas phase and in aqueous solution. The results show that $HCO_3^{\cdot}$ is a strong acid, $pK_a = -4.1$, and that $E°(CO_3^{\cdot-}/CO_3^{2})$ = 1.23 ± 0.15 V.

Key words: carbonate radical anion, theoretical, thermochemistry, acidity, reduction potentials.

Résumé : On a utilizé des calculs théoriques *ab initio* de haut niveau associés à des réactions isodesmiques pour déduire un ensemble d'énergies libres autocohérentes pour les espèces carbonate et nitrate en phase gazeuse et en solution aqueuse. Les résultats montrent que le $HCO_3^{\cdot}$ est un acide fort, $pK_a = -4,1$, et que la valeur de $E°(CO_3^{\cdot-}/CO^{2-})$ = 1,23 ± 0,15 V.

Mots clés : anion radical carbonate, théorique, thermochimie, acidité, potentiels de réduction.

[Traduit par la Rédaction]

Introduction

The production of carbonate radicals by the reaction of $^{\cdot}OH$ with bicarbonate or carbonate ions in aqueous solution has been known for many years and rate constants for its reactions with many inorganic and organic species have been reported (1, 2). During the last decade it has also been shown that carbonate radicals are produced in living cells, where they can cause damage to important constituents, including DNA (3, 4). There is, therefore, a need to understand the structure of the radical and the thermodynamic properties that control its rate of formation and reactivity. Shkrob (5) has recently reviewed earlier work on the structure of $CO_3^{\cdot-}$. He also performed CIS-B3LYP/6-311+G(d) calculations and showed that the experimentally observed optical, Raman, and magnetic properties of carbonate radical in aqueous solution can be accounted for by a trigonally distorted C_{2v} $CO_3^{\cdot-}$ structure, a consequence of a complex with a single water molecule. In terms of the thermochemistry, several experimental studies[3] reported evidence for pK_a in the range of 8–10. This was attributed to the presence of $HCO_3^{\cdot}$ at lower values of pH and its ionization in reaction [1].

[1] $$HCO_3^{\cdot} = H^+ + CO_3^{\cdot-}$$

However, that evidence is not supported by the early ESR work (6) or the recent Raman spectroscopic (7) and optical pulse radiolysis studies (8). These imply that $HCO_3^{\cdot}$ is strongly acidic with pK_a probably below 0.0. Redox equilibrium experiments carried out with $Br_2^{\cdot-}$ and $(SCN)_2^{\cdot-}$ at values of pH above 10 demonstrate that $E°(CO_3^{\cdot-}/CO_3^{2-})$ is 1.58 ± 0.03 V vs. the standard hydrogen electrode (9, 10).[4] In short, at the present time there is considerable information available on the carbonate radical anion with direct spectroscopic observations pointing to $CO_3^{\cdot-}$ as the only significant species in the pH region 0–14. However, while H abstraction appears to be one of the most important reactions of $CO_3^{\cdot-}$ (3, 4), there appears to be no data on the bond dissociation enthalpy (BDE) of HCO_3^-, the parameter that controls the barrier to H-atom abstraction reactions.

The purpose of this study was to use ab initio methods to examine the thermochemical properties of $HCO_3^{\cdot}$ and $CO_3^{\cdot-}$ species in some detail. These include the BDE of HCO_3^- and $\Delta G_{(acid;g)}$ of $HCO_3^{\cdot}$, the free energy of reaction [1] in the gaseous phase. Using corrections to calculated free energies of solution based on the structurally similar nitrate species HNO_3, NO_3^-, and $NO_3^{\cdot}$, values of $\Delta_f G_{(aq)}°$ for $HCO_3^{\cdot}$ and $CO_3^{\cdot-}$ were also derived. These are clearly free of any of the "medium effects" that have created problems in the interpretation of some of the experimental data. The calculated values are found to be in excellent accord with the experimental $E°(CO_3^{\cdot-}/CO_3^{2-})$ cited above. Also, the results indicate unequivocally that the pK_a for $HCO_3^{\cdot}$ is negative.

Computational details

The ab initio calculations were performed with the Gaussian 98 and Gaussian 03 molecular orbital packages

(11–13). Geometry optimizations and vibrational frequency calculations were carried out at the B3LYP-LB level, where LB denotes the large basis set, 6-311+G(3df,2p). Zero-point energies (ZPEs) were scaled with the factor 0.9806 (14). Values of $H° - H_0°$ and entropies were evaluated by standard methods of statistical thermodynamics based on the rigid rotor harmonic oscillator model (15, 16). The electronic energies used to obtain heats of formation were calculated by application of the CBS-RAD procedure (17) to the B3LYP-LB structures. CBS-RAD is a high-level theoretical procedure for obtaining thermochemical values for radicals to experimental accuracy. The CBS-RAD–B3LYP combination employed here has been found to yield good reaction enthalpies and barriers for the addition of C-centred radicals to alkenes (18) and to the β-scission reactions of alkoxy radicals (19). Gaseous phase free energies of formation were obtained from the entropies and heats of formation (16). Free energies of solvation were calculated with the integral equation following a polarizable continuum model procedure implemented as SCRF = IEFPCM in Gaussian 03 (20, 21). The cavity was defined from the united atom Hartree–Fock (UAHF) radii, scaled according to program defaults. The free energy of solvation evaluated in this manner is further subject to correction by reference to experimental values on related systems as described below.

UV–vis spectroscopic properties were calculated by time-dependent density functional theory (22) using the B3LYP Hamiltonian and the LB basis in the polarizable continuum medium implemented as SCRF = CPCM in Gaussian 98 and 03 (23), with the molecular cavity defined by the 0.001 electrons/bohr^3 (1 bohr = 0.529×10^{-10} m) isodensity surface (24).

Results

Structure and IR–Raman spectra of $CO_3^{\cdot-}$

The ground electronic state of $CO_3^{\cdot-}$ is $^1A_1'$, with D_{3h} symmetry and r_{CO} = 1.270 Å. At the B3LYP-LB level of theory, the predicted vibrational modes are (cm^{-1}): E′ 374.6 (O–C–O bend); A_2'' 837.0 (out-of-plane bend); A_1' 1097.4 (sym str); E′ 1278.7 (asym str). At the same level of theory, the presence of a single water molecule coordinated by a single H bond to one of the O atoms reduces the symmetry approximately to C_{2v} (actually C_s), with the unique O–C–O angle contracted to 114.2°. The predicted vibrational modes are (cm^{-1}): 367.2, 506.1 (O–C–O bend); 828.1 (out-of-plane bend); 1097.8 (sym C–O str); 1184.1, 1453.7 (asym C–O str). Thus, in the H-bonded complex, the O–C–O in-plane bends and asymmetric C–O stretches are strongly split, while the out-of-plane umbrella motion and the symmetric C–O stretching motions are hardly perturbed. Given the breadth of the bands in the experimental Raman spectrum, the calculated frequencies agree well with those observed (cm^{-1}): 485, 701, 1063, 1166, 1372, and 1426 (7). The three C–O stretching modes all have high Raman intensities, in units of Å^4 AMU^{-1} (depolarization ratios), 64.4(0.57), 137.7(0.87), and 426.7(0.78), respectively. Thus, the calculations of the IR–Raman spectrum of the single-water complex support the suggestion that the structure of the carbonate radical anion is distorted toward C_{2v} by interaction with water (7).

UV–vis spectra of $CO_3^{\cdot-}$

The electronic spectrum of D_{3h} $CO_3^{\cdot-}$ predicted at the TD-B3LYP-LB level in an aqueous environment shows the following bands (nm, oscillator strength): E″ 828.6, 0.0000; E′ 608.2, 0.0606; A_1'' 205.7, 0.0000. In the lower C_s symmetry environment of the H_2O–$CO_3^{\cdot-}$ complex, one finds in the same spectral range (nm, oscillator strength): A″ 942.5, 0.0000; A″ 699.6, 0.0000; A′ 596.0, 0.0236; A′ 569.3, 0.0403; A″ 360.2, 0.0000; A′ 231.6, 0.0177; A″ 203.62, 0.0000. Thus, the degeneracy of the E″ state is strongly split by the explicit solvation but the transitions, though formally allowed, do not gain any intensity. Both components of the E′ state are blue-shifted but also not much affected in intensity. The calculated absorption spectrum of either the D_{3h} or the C_{2v} form of $CO_3^{\cdot-}$ agrees well with the experimental observation of a broad absorbance at 600 nm (25).

Gas phase heats and free energies of formation

Values of the electronic energies (EEs), zero-point energy levels (ZPEs), thermal corrections ($H° - H_0°$), entropies ($S°$), and $\Delta_f H°$ values derived from the CBS-RAD level EEs are given in Table 1 for $HCO_3^{\cdot}$, $CO_3^{\cdot-}$, and several other species of relevance to this study. The column under the heading $\Delta_f H°$ (Rec.) contains values of $\Delta_f H°$ from the literature for HNO_3, NO_3^-, the formyloxyl radical (HC(O)O$^{\cdot}$), bicarbonate (HCO_3^-), and the recommended values derived here for $HCO_3^{\cdot}$ and $CO_3^{\cdot-}$. It can be seen that the CBS-RAD energies lead to $\Delta_f H°$ being underestimated by 3–8 kJ mol^{-1} for HNO_3 and NO_3^-, but overestimated by 8 kJ mol^{-1} for HCO_3^-. A correction for $HCO_3^{\cdot}$ and $CO_3^{\cdot-}$ is obviously desired but the direction is uncertain. Assuming that the error for $HCO_3^{\cdot}$ is similar to that for $HCO_2^{\cdot}$, 11.6 kJ mol^{-1}, one derives $\Delta_f H°$ of $HCO_3^{\cdot}$ = –365.7 kJ mol^{-1}. Alternatively one can use the isodesmic reaction

[2] $$HCO_3^{\cdot} + CH_4 = HCO_2^{\cdot} + CH_3OH$$

for which $\Delta\Delta H°$ (CBS-RAD) (= $\Delta_f H°(HCO_2^{\cdot}) + \Delta_f H°(CH_3OH) - \Delta_f H°(CH_4) - \Delta_f H°(HCO_3^{\cdot})$ is 110.7 kJ mol^{-1}. Combining this with the values of $\Delta_f H°$ (Rec.) for CH_4, $HCO_2^{\cdot}$, and CH_3OH leads to $\Delta_f H°$ of $HCO_3^{\cdot}$ = –364.1 kJ mol^{-1}, which differs from the CBS-RAD value by 13.2 kJ mol^{-1}. We chose to take the mean of these two corrections, 12.4 kJ mol^{-1}, giving the recommended value of $\Delta_f H°$ ($\Delta_f H°$ (Rec.)) of $HCO_3^{\cdot}$ = –364.9 kJ mol^{-1} in Table 1. One may note here that $\Delta_f H°$ (Rec.) of $HCO_2^{\cdot}$ = –127.0 kJ mol^{-1} reported in our previous study (26) is bracketed by –129.7 ± 12.6 from photoelectron spectroscopy (27) and –126.4 ± 1.7 from a computational coupled cluster study (28).

Proceeding in the same manner, the error for $CO_3^{\cdot-}$ should be similar to that for NO_3^- (8.3 kJ mol^{-1}) and the isoelectronic $NO_3^{\cdot}$ (6.2 kJ mol^{-1}) (29). Use of the isodesmic reaction,

[3] $$HCO_3^{\cdot-} + NO_3^{\cdot} = CO_3^{\cdot-} + HNO_3$$

leads to –3.2 kJ mol^{-1}. The correction is again taken as the mean (3.8 kJ mol^{-1}), giving $\Delta_f H°$ (Rec.) of $CO_3^{\cdot-}$ = –564.8 kJ mol^{-1}. $\Delta_f H°$ (Rec.) of NO_3^- in Table 1 is supported by a calculation from $\Delta_f H^0$ (Rec.) of HNO_3 and the proton affinity (30), as well as from the energy of formation of

[d]Ref. 35.

$NO_3^{\cdot}$ from NO_2 + O ($^3P_2$) (29) and the EA of $NO_3^{\cdot}$ (3.937 eV) (31). The uncertainties in the calculated $\Delta_f H°$ (Rec.) values are taken to be ±5 kJ mol^{-1}.

Bond dissociation enthalpies (BDE)

From the $\Delta_f H^0$ (Rec.) values in Table 1 and using $\Delta_f H°(H^{\cdot})$ = 218.0 kJ mol^{-1}, one finds that BDE(OH) of HCO_3^-, namely $\Delta H_{(rxn)}$ for

[4] $$HCO_3^- = CO_3^{\cdot -} + H^{\cdot}$$

is 397 kJ mol^{-1} (387 kJ mol^{-1} by direct calculation from the CBS-RAD values). This is 30 kJ mol^{-1} lower than BDE(OH) of HNO_3 (426 kJ mol^{-1}) and 83 kJ mol^{-1} lower than BDE(OH) of HCO_2H (470 kJ mol^{-1}). Thus, the formation of $CO_3^{\cdot -}$ as a result of H atom abstraction from bicarbonate anion by hydroxyl radical is exothermic by 100 kJ mol^{-1}.

Aqueous phase free energies of formation

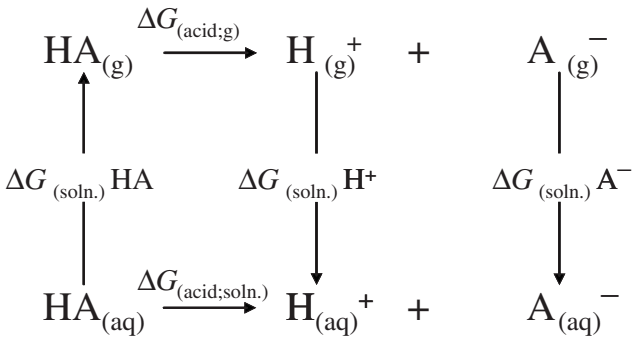

Table 2 summarizes the values of $\Delta_f G_{(g)}$ obtained from the $\Delta_f H°$ (Rec.) in Table 1 and lists $\Delta_f G_{(aq)}°$, and the free energies of solution, $\Delta G_{(soln)}$. The values of $\Delta_f G_{(aq)}°$ for the $HCO_3^{\cdot}$ and $CO_3^{\cdot -}$ radicals were obtained from the gas phase results and the IEFPCM free energies of solution by using corrections derived from the structurally similar HNO_3 and NO_3^- species. The data for other species except HNO_3 are from standard tables (32). $\Delta_f G_{(aq)}°$ for HNO_3 was derived from the value for NO_3^- and pK_a (= –1.37) (33). Comparison with $\Delta_f G_{(g)}{}^0$ of HNO_3 gave a $\Delta G_{(soln)}$ (–34.2 kJ mol^{-1}) 9.6 kJ mol^{-1} more negative than calculated by the polarizable continuum model. Applying the same correction to the IEFPCM result for $HCO_3^{\cdot}$ gave $\Delta G_{(soln)}$ = –42.2 kJ mol^{-1} and hence, from $\Delta_f G_{(g)}°$, $\Delta_f G_{(aq)}°$ = –367.7 kJ mol^{-1}. In a similar vein, $\Delta_f G_{(aq)}°$ for the two anion species NO_3^- and $CO_3^{\cdot -}$ can be derived from their $\Delta_f G_{(aq)}°$ values and the $\Delta G_{(Rxn)}$ for,

[5] $$H^+_{(g)} + A^-_{(g)} = H^+_{(aq)} + A^-_{(aq)}$$

in which A^- is NO_3^- or $CO_3^{\cdot -}$. The result for NO_3^-

© 2006 NRC Canada

Scheme 1.

(–115.6 kJ mol^{-1}) is in error by –6.9 kJ mol^{-1} from the accepted –108.7 in Table 2. Applying this correction to the $CO_3^{\cdot-}$ data leads to $\Delta_f G_{(soln)}$ = –269.4 kJ mol^{-1} and the $\Delta_f G_{(aq)}^\circ$ value in Table 2, –409.4 kJ mol^{-1}. This is 26 kJ mol^{-1} more negative than the estimate based on a review of early data in ref. (34). The $\Delta_f G_{(aq)}^\circ$ value of $HCO_3^\cdot$ in that paper is badly in error because of the erroneous pK_a of 7.6, which was accepted at that time. For $CO_3^{\cdot-}$ and $HCO_3^\cdot$ the uncertainties in the calculated $\Delta G_{(soln)}$ and $\Delta_f G_{(aq)}^\circ$ values are estimated to be ±5 and ±7 kJ mol^{-1}, respectively, the latter being the combination of the uncertainties in $\Delta_f G_{(g)}^\circ$ and $\Delta G_{(soln)}$.

The pK_a of $HCO_3^\cdot$

The pK_a values of the two acid species HNO_3 and $HCO_3^\cdot$ were evaluated using the thermochemical cycle in Scheme 1. IEFPCM free energies of solution were used for the HA and A^- species and –1107 kJ mol^{-1} for H^+ (35). The value of $\Delta G_{(acid;g)}$ for HNO_3 derived directly from our CBS-RAD energies was 3.2 kJ mol^{-1} lower than the experimental value reported in ref. 30 (1330 ± 1 kJ mol^{-1}), which is acceptable for calculations at this level. The value derived from the $\Delta_f H_{(g)}$ (Rec.) data in Table 1 (1339.5 kJ mol^{-1}) was in less good agreement. However, for consistency we used $\Delta G_{(acid;g)}$ from the $\Delta_f H_{(g)}$ (Rec.) values for all species. For HNO_3, the resulting $\Delta G_{(acid;aq)}$ (–7.8 kJ mol^{-1}) was in perfect agreement with the pK_a value, –1.37. $\Delta G_{(acid;g)}$ for $HCO_3^\cdot$ was found to be 1306.9 kJ mol^{-1}. Using this result, $\Delta G_{(acid;aq)}$ for $HCO_3^\cdot$ was found to be –27.2 kJ mol^{-1}, which is similar to the –20.1 kJ mol^{-1} difference between the $\Delta_f G_{(aq)}^\circ$ values of $CO_3^{\cdot-}$ and $HCO_3^\cdot$ in Table 2 and clearly more negative than the experimental value of –7.8 kJ mol^{-1} for HNO_3. $HCO_3^\cdot$ is therefore a very strong acid with pK_a = –4.1 ± 1 and $CO_3^{\cdot-}$ will be the only important form of the radical over the pH range 0–14. This conclusion is in agreement with the conclusions in ref. 8.

Reduction potentials

Because of the very low radical pK_a, reactions [6] and [7] are the important redox half reactions. The E° values calculated from the $\Delta_f G_{(aq)}^\circ$ values in Table 2 are given beside the equations below.

[6] $CO_3^{\cdot-}{}_{(aq)} + H^+{}_{(aq)} + e^- = HCO_3^-{}_{(aq)}$; E° = 1.84 ± 0.1 V

[7] $CO_3^{\cdot-}{}_{(aq)} + e^- = CO_3^{2-}{}_{(aq)}$; E° = 1.23 ± 0.1 V

The E° value for reaction [7] is in modest agreement with the experimental value of 1.58 ± 0.03 V noted above from refs. 8 and 9. The experimental data are therefore consistent with the monomeric $CO_3^{\cdot-}$ form of the radical.

Other equilibria

By using the $\Delta_f G_{(aq)}^\circ$ values in Table 2 and further information in refs. 32–34, we may examine other possible reactions involving $CO_3^{\cdot-}$. These include the reactions for formation by $^\cdot OH$ at different pH values and the decomposition to CO_2 and $O^{\cdot-}$. The reactions are listed below with the $\Delta G_{(Rxn.)}^\circ$ values in kJ mol^{-1} beside them.

[8] $^\cdot OH + CO_2 = H^+ + CO_3^{\cdot-}$; $\Delta G_{(Rxn.)}$ = –49

[9] $^\cdot OH + HCO_3^- = H_2O + CO_3^{\cdot-}$; $\Delta G_{(Rxn.)}$ = –85

[10] $^\cdot OH + CO_3^{2-} = OH^- + CO_3^{\cdot-}$; $\Delta G_{(Rxn.)}$ = –220

[11] $O^{\cdot-} + H_2O + CO_3^{2-} = 2OH^- + CO_3^{\cdot-}$; $\Delta G_{(Rxn.)}$ = –53

[12] $CO_3^{\cdot-} = CO_2 + O^{\cdot-}$; $\Delta G_{(Rxn.)}$ = 117

Formation from carbonate (reaction 10) is clearly the most favoured. The electron transfer is fast with $k_{10} = 3.7 \times 10^8$ (mol/L)$^{-1}$ s^{-1} (36). Formation by hydrogen atom transfer from bicarbonate (reaction 9) is also favoured, although is probably much slower than electron transfer. Lastly, the radical is clearly stable to decomposition to $CO_2 + O^{\cdot-}$.

Self-association

Finally, we examine the possibility of dimerization of $CO_3^{\cdot-}$ according to reaction [13],

[13] $2\ CO_3^{\cdot-} = O_2COOCO_2^{2-}$; $\Delta G_{(Rxn.)}$ = –65

In the gaseous phase, the dimeric dianion is a local minimum with C_2 symmetry. Like hydrogen peroxide, the peroxy link is twisted with C–O–O–C dihedral angle = 140°. The dimer is unstable toward dissociation into two carbonate radical anions by 220 kJ mol^{-1} at the CBS-RAD level.[5] In aqueous solution, however, the much greater free energy of solution of the dianion ($\Delta G_{(soln)}$ = –913 kJ mol^{-1}) compared with the two $CO_3^{\cdot-}$ radicals (IEFPCM value, –276.8 kJ mol^{-1} in Table 2) makes the dimer more stable by 65 kJ mol^{-1} at the uncorrected IEFPCM level. This result suggests that if the $CO_3^{\cdot-}$ radical concentration is higher than nanomolar then the major species at equilibrium would be the dimer dianion. Whether equilibrium could be achieved, given the reactivity of $CO_3^{\cdot-}$, is doubtful however. Although we are not able to determine it, we expect that there will be a substantial barrier to dimerization because of the coulombic repulsion and solvent reorganization that must be overcome. Nevertheless, in the absence of substrates, dimerization would provide a route to the decay of the $CO_3^{\cdot-}$ radical in aqueous solution.

Conclusions

The present ab initio calculations along with isodesmic reactions have been used to derive a set of self-consistent free

[5] The CBS-RAD energy of $O_2COOCO_2^{2-}$ is –526.929 454 hartrees (1 hartree = 2625.5 kJ/mol).

© 2006 NRC Canada

energies of formation for carbonate and nitrate species in the gas phase. By using IEFPCM-calculated free energies of solution and making corrections based on the experimental values for the nitrate system, these have been extended to the aqueous phase. The results show that $HCO_3^{\cdot}$ is a strong acid and that $E^{\circ}(CO_3^{\cdot -}/CO_3^{2-}) = 1.23 \pm 0.15$ V. These findings do not support earlier data indicating a pK_a of $HCO_3^{\cdot}$ in the region of 7–10, but are in excellent agreement with the experimental findings in refs. 7 and 8. Attention is currently being directed toward medium effects, which are likely to be the origin of the conflicting results from earlier studies.

Intramolecular amidation — An efficient synthesis of 3-aryl-2-quinolinones

Yinggang Luo, Feiyan Tao, Yan Liu, Bogang Li, and Guolin Zhang

Abstract: To reveal the scope of the syntheses of 3-aryl-2-quinolinones from 2-nitro-α-phenylcinnamic acids, the isomerization of (*E*)-2-amino-α-phenylcinnamic acids was studied. The results showed that (*E*)-2-amino-α-phenylcinnamic acids were isomerized to its (*Z*)-forms under sunlight in organic solvents. The reaction temperature and the functional groups at both phenyl rings have no effect on the isomerization of (*E*)-2-amino-α-phenylcinnamic acids and the following intramolecular spontaneous amidation of (*Z*)-2-amino-α-phenylcinnamic acids. Various 3-aryl-2-quinolinones prepared in high total yields indicated that the syntheses of 3-aryl-2-quinolinones from Perkin condensation products 2-nitro-α-phenylcinnamic acids via reduction, sunlight-induced isomerization of (*E*)-2-amino-α-phenylcinnamic acids, and the following intramolecular amidation is an efficient procedure.

Key words: 3-aryl-2-quinolinones, isomerization, amidation.

Résumé : Afin d'évaluer la portée des synthèses de 3-aryl-2-quinoléinones à partir d'acides 2-nitro–phénylcinnamiques, on a étudié l'isomérisation des acides (*E*)-2-amino-α-phénylcinnamiques. Les résultats montrent que les acides (*E*)-2-amino-α-phénylcinnamiques en solution dans des solvants organiques s'isomérisent en formes (*Z*) sous l'influence de la lumière du jour, que la température de la réaction et les groupes fonctionnels sur l'un ou l'autre des groupes phényles n'ont aucune influence sur l'isomérisation des acides (*E*)-2-amino-α-phénylcinnamiques et sur l'amidation spontanée intramoléculaire des acides (*Z*)-2-amino-α-phénylcinnamiqued. Les synthèses de 3-aryl-2-quinoléinones à partir des acides 2-nitro-α-phénylcinnamiques qui ont été obtenus comme produits de condensation de Perkin, puis soumis à une réduction, une isomérisation induite par la lumière des acides (*E*)-2-amino-α-phénylcinnamiques et une amidation intramoléculaire s'avèrent efficaces.

Mots clés : 3-aryl-2-quinoléinones, isomérisation, amidation.

[Traduit par la Rédaction]

Introduction

3-Aryl-2-quinolinones could inhibit the migration of tumor cells with no cytotoxicity in vitro or in vivo. The combination of 3-aryl-2-quinolinones and doxorubicin (or etoposide), two drugs routinely used in clinic, led to additive in vivo benefits compared with individual administration of the drugs (1). 3-Aryl-2-quinolinones were also efficient tools in the treatment of osteoporosis (2). They were selective non-competitive antagonists of *N*-methyl-D-aspartate receptors and (or) antagonists of 2-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (3). They could serve as precursors of a new class for nonpeptide gonadotropin releasing hormone receptor antagonists (4).

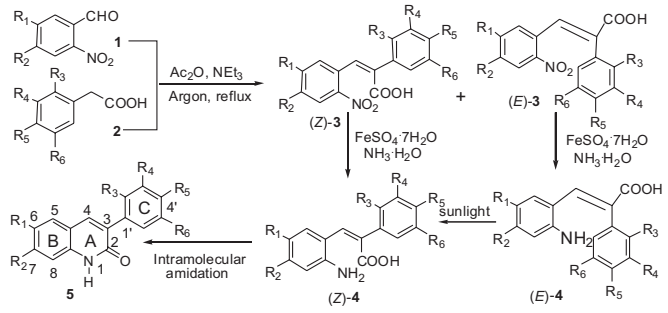
To date, the condensation of anilines with arylmalonate or its analogues (1, 2*a*) and the palladium-catalyzed annulation of *o*-iodoaniline derivatives with aryl substituted terminal alkynes or 2-phenylacrylic acid were introduced into the syntheses of 3-aryl-2-quinolinones (5, 6). The total yields ranged from 9.10 to 40.85% for the former strategy (1, 2) and from 20 to 42% for the latter one (5, 6). Recently, palladium-catalyzed amidation of *o*-carbonyl-substituted aryl halides for quinolinones (7*a*) and a rapid assembly of 4-fluoroquinolinones were reported (7*b*).

3-Aryl-2-quinolinones, a small-amount by-product in Pschorr's phenanthrene synthesis, were obtained from the reduction of (*Z*)-2-nitro-α-phenylcinnamic acids originally formed in Perkin condensation (8). (*E*)-2-Amino-α-phenylcinnamic acids could be converted to 3-aryl-2-quinolinones by treatment with acetic anhydride and concentrated sulfuric acid or zinc chloride (8*a*, 9) or by exposure to ultraviolet (8*a*) or sunlight (10). The methyl esters of (*E*)-2-amino-α-phenylcinnamic acids were converted to 3-aryl-2-quinolinones by heating or by standing at room temperature (10).



However, the scope of the preparation of 3-aryl-2-quinolinones from 2-amino-α-phenylcinnamic acids including the detailed process of the isomerization of the (*E*)-2-amino-α-phenylcinnamic acids, the effect of the functional groups at aryl moieties on the isomerization, and the following spontaneous intramolecular amidation has not been reported.

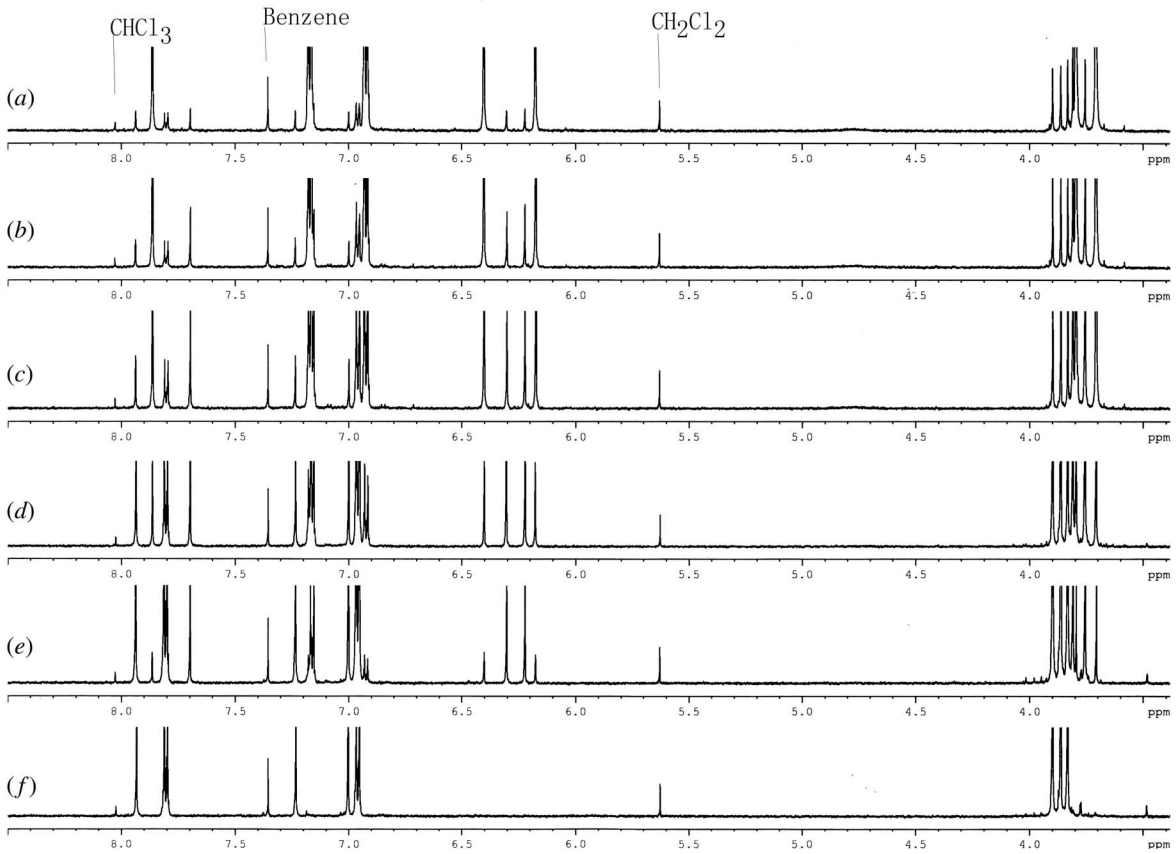
Scheme 1.

Herein, we report our investigations concerning these problems.

Results and discussion

Perkin condensation of 2-nitro-benzaldehydes (**1**) and phenylacetic acids (**2**) gave a mixture of the (*E*)- and (*Z*)-isomers of 2-nitro-α-phenylcinnamic acids (**3**) (Scheme 1). The ratio of (*E*)- and (*Z*)-isomers could be determined by proton integration in the ^{1}H NMR spectra without separation (8*c*). Taken as an example, Fig. 1 shows the ^{1}H NMR spectra of (*E*)-**3d** and (*Z*)-**3d**, which could be separated by silica gel column chromatography or fractional crystallization.



Reduction of the mixture of (*E*)-**3** and (*Z*)-**3** by ferrous sulfate in aq. ammonia led to the formation of (*E*)-**4** and 3-aryl-2-quinolinones (**5**); thus, indicating that (*Z*)-**4** spontaneously cyclized to give the intramolecular amidation products **5**. Roy and Bhaduri (8*c*) suggested that only (*Z*)-**3d** could be converted to 3-aryl-2-quinolinone by reduction. To confirm their conclusion, the (*E*)-**3d** and (*Z*)-**3d** were isolated and characterized on the basis of NMR, IR, UV, and mass spectral data. The stereochemistry of (*E*)-**3d** was confirmed by X-ray crystallographic analysis (Fig. S1, the ORTEP drawing of CCDC 264443, see supplementary data).[2] Reduction of (*Z*)-**3d** by ferrous sulfate in aqueous ammonia with or without exposure to sunlight led to 3-aryl-2-quinolinone (**5d**), whereas the reduction of (*E*)-**3d** under the same conditions afforded only (*E*)-**4d**.

However, 3-aryl-2-quinolinone (**5d**) was obtained when (*E*)-**4d** was dissolved in acetone and was left standing under sunlight at room temperature. Initially, only (*E*)-**4d** was observed in the ^{1}H NMR spectrum, and it was stable without exposure to sunlight. When the acetone solution of (*E*)-**4d**

Fig. 2. Conversion of (*E*)-**4d** to **5d** in acetone-d_6 monitored by ^{1}H NMR spectra: (*a*) 10 min, (*b*) 30 min, (*c*) 60 min, (*d*) 90 min, (*e*) 10 h, and (*f*) 16 h.

was left standing under sunlight, the ratio of (*E*)-**4d**, (*Z*)-**4d**, and **5d** changed from 100:0:0 to 0:0:100 in 16 h (Fig. 2), suggesting that the isomerization of (*E*)-**4d** to (*Z*)-**4d** is a sunlight-induced process and the formation of **5d** from (*Z*)-**4d** is an intramolecular spontaneous amidation.

(*E*)-**4d** kept unchanged in H_2O, 5% HCl (aq.), 5% NaOH (aq.), or 25% aq. ammonia under sunlight, indicating that sunlight could not induce the isomerization of (*E*)-**4d** to its (*Z*)-isomer in acidic, basic, or neutral aqueous media. The conversion of (*E*)-**4d** to **5d** in protic and polar aprotic solvents was very easy and fast (10–18 h), but it was difficult in nonpolar aprotic solvents (>48 h).[2]

To investigate the scope of this method, 26 3-aryl-2-quinolinones with electron-withdrawing and electron-donating groups on the rings B and C were synthesized (Scheme 1 and Table 1). The functional groups have no effect on the isomerization of (*E*)-**4** to (*Z*)-**4** or on the subsequent intramolecular amidation of (*Z*)-**4** to 3-aryl-2-quinolinones in view of the total yields of the title compounds (Table 1). The same conversion rate of (*E*)-**4d** to **5d** was observed when the acetone solution of (*E*)-**4d** was exposed to sunlight with stirring under reflux at room temperature or at 0 °C, indicating that the temperature has no effect on this process.

In the case of **3f**–**3h** and **3n**–**3p**, the hydroxyl groups were acetylated during Perkin reaction. The acetyl groups were removed during reduction, which was concluded from their ^{1}H NMR spectral data (Table 1, entries 6–8 and 14–16).

All 3-aryl-2-quinolinones were identified by ^{1}H and ^{13}C NMR, UV, IR, ESIMS, and HR-ESIMS data. The basic skeleton of 3-aryl-2-quinolinone, compound **5i**, was confirmed by X-ray crystallographic analysis (Fig. S2, the ORTEP drawing of CCDC 264442).[2]

In conclusion, it is an efficient procedure to prepare 3-aryl-2-quinolinones from Perkin condensation products (*Z*)- and (*E*)-2-nitro-α-phenylcinnamic acids via reduction, sunlight-induced isomerization of (*E*)-2-amino-α-phenylcinnamic acids to its (*Z*)-forms, and the spontaneous intramolecular amidation of the latter.

Experimental

General

All reagents were commercial and were used without purification. The 2-nitrobenzaldehydes with electron-withdrawing groups such as 4-bromo (11), 5-bromo (12), 5-chloro (12), and 4-acetyl (13) were prepared according to the literature. 2-Benzyloxyphenylacetic acid was prepared according to the reported procedure (14). Acetic anhydride was obtained by fractional distillation. Triethylamine was refluxed for 6 h with the freshly distilled acetic anhydride, then distilled, refluxed with CaH_2, and distilled again. Melting points were recorded on an X-6 apparatus and were uncorrected. IR spectra were recorded on a PerkinElmer Spectrum One spectrometer using KBr discs, and ν_{max} is given in cm^{-1}. UV spectra were recorded in MeOH (1 mg in

50 mL) on a PerkinElmer Lambda 35 spectrometer. NMR spectra were recorded on a Bruker Avance 600 spectrometer (^{1}H NMR: 600 MHz; ^{13}C NMR: 150 MHz) at room temperature in DMSO-d_6, when not mentioned. The chemical shifts (δ) are reported in ppm relative to tetramethylsilane as an internal standard, and the coupling constants (*J*) are given in Hz. HR-ESIMS spectra were obtained on a Bio TOF IIIQ mass spectrometer. Column chromatography (CC) was performed on self-packed open column with silica gel (200–300 mesh) from Qingdao Ocean Chemical Engineering Company (QOCEC, Qingdao, P.R. China). TLC analyses were carried out on plates precoated with 10–40 μ of silica gel GF_{254} from QOCEC and were visualized under an ultraviolet lamp.

General procedure for preparation of substituted 2-nitro-α-phenylcinnamic acids 3.

Compounds **3** were prepared according to Lebrun et al. (15*a*) with some modifications. A solution of 2-nitrobenzaldehyde (**1**, 0.2 mmol), NEt_3 (0.5 mL), substituted phenylacetic acid (**2**, 0.22 mmol), and Ac_2O (0.5 mL) was refluxed under argon for 30 min (TLC analysis). When the reaction was completed, water (10 mL) was added to the reaction mixture. During the addition, the temperature of the mixture should be maintained at 100–110 °C. Then, the reaction mixture was cooled to room temperature and then to 0 °C. The precipitate from the cold solution was collected by filtration. The mother liquor was partitioned between water and ethyl acetate. The organic layers were combined, washed with brine, dried over anhyd. Na_2SO_4, and concentrated to give a residue. The residue and the precipitate were pure enough for the next step. For compound **3d**, the two isomers can be separated by column chromatography over silica gel and eluted with petroleum ether (bp 60–90 °C) : acetone : acetic acid (5:1:0.025) (the value of $R_{f\text{-}(E)\text{-}\mathbf{3d}}$ > the value of $R_{f\text{-}(Z)\text{-}\mathbf{3d}}$) or by fractional crystallization from ethanol, in which (*E*)-**3d** crystallized from ethanol and (*Z*)-**3d** was left in the mother liquor.

General procedure for preparation of substituted 2-amino-α-phenylcinnamic acids 4

Compounds **4** were prepared according to Bradsher et al. (15*b*) with some modifications. A solution of **3** in 10% aq. ammonia was added dropwise in the course of 3 to 6 min to a solution of 440 mg of $FeSO_4 \cdot 7H_2O$ in 1.3 mL of H_2O and 0.03 mL of 25% aq. ammonia (several drops of *n*-butanol was added to the solution before heating to prevent foaming) under reflux. A total of 0.5 mL of concd. aq. ammonia was added slowly to the mixture within 85 min. When the reaction was completed, the reaction solution was cooled to 40–50 °C and filtered. The dark residue was washed six times with 10% aq. ammonia solution at about 50 °C, then washed 10 times with ethyl acetate. The combined basic solution was acidified carefully with acetic acid to pH = 6.0 and then extracted with ethyl acetate. The combined organic layers were washed with brine, dried over anhyd. Na_2SO_4, and con-

centrated to give a residue. For compound (*E*)-**4d**, the residue was subjected to column chromatography over silica gel and eluted with petroleum ether (bp 60–90 °C) : acetone : acetic acid (2:1:0.025) to give (*E*)-**4d** and **5d**.

General procedure for the preparation of 3-aryl-2-quinolinones 5

The previously obtained residue was dissolved in acetone and was left standing under sunlight at room temperature until (*E*)-**4** was converted to 3-aryl-2-quinolinones (**5**, TLC analysis). Most of the 3-aryl-2-quinolones were crystallized or precipitated from the solution. The mother liquor was subjected to silica gel column chromatography and eluted with petroleum ether (bp 60–90 °C) : acetone (5:2) to give another portion of 3-aryl-2-quinolinones.

Scaled quantum mechanical force fields for trifluoromethyl selenium derivatives. I. The CF_3SeCN and CF_3SeCH_3 molecules

L.E. Fernández and E.L. Varetti

Abstract: Force fields and vibrational properties were calculated for the trifluoromethyl selenium derivatives, CF_3SeCN and CF_3SeCH_3, by means of density functional theory (DFT) techniques. The existing experimental data and assignments for these molecules were confirmed by the theoretical results. These data were subsequently used in the definition of scaled quantum mechanical force fields for such chemical species. The obtained force constants are compared with results previously published for similar compounds.

Key words: trifluoromethyl selenium, force constants, structure, DFT calculation.

Résumé : Faisant appel à des techniques de la théorie de la fonctionnelle de densité (« DFT »), on a calculé les champs de force et les propriétés vibrationnelles de dérivés trifluorométhylsélénium, soit le CF_3SeCN et le CF_3SeCH_3. Les données expérimentales et les attributions pour ces composés ont été confirmées par les résultats théoriques. On a subséquemment utilisé ces données dans la définition d'un champ de force normalisé en mécanique quantique pour de telles espèces. On a comparé les constantes de force obtenues avec les résultats publiés antérieurement pour des composés semblables.

Mots clés : trifluorométhylsélénium, constantes de force, calculs selon la théorie de la fonctionnelle de densité.

[Traduit par la Rédaction]

Introduction

A theoretical study of the vibrational properties of the selenium compounds, CF_3SeX (X = H, D, Cl, or Br), was recently performed in our laboratory (1). Similar calculations are now made on other two simple CF_3Se derivatives, i.e., CF_3SeCN and CF_3SeCH_3. These molecules were prepared from $(CF_3Se)_2Hg$ by Dale et al. (2) and by Emeléus and Welchman (3). The molecular parameters for CF_3SeCN were obtained by the electron diffraction method (4), but no structural study is known for the CF_3SeCH_3 molecule. IR and Raman spectra were reported for these two molecules by Marsden (5) and by Clase et al. (6), and normal coordinate analyses were also published (7).

In the present work, quantum chemical calculations were performed on the mentioned molecules to obtain the corresponding force constants, which were scaled to reproduce the experimental frequencies. Such adjustment was made using the formalism of the scaled quantum mechanical (SQM) force field, as defined by Pulay et al. (8).

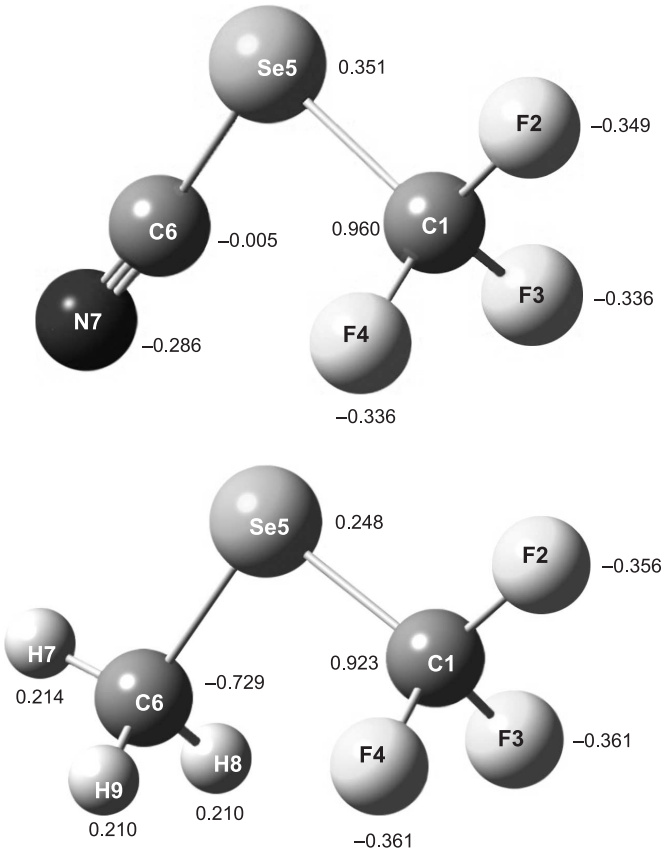
Calculation procedure

Optimized structures and vibrational wavenumbers for CF_3SeCN and CF_3SeCH_3 were obtained with density functional theory (DFT) methods using the B3LYP functional (9, 10) together with the 6-311G* basis set. This theoretical data facilitated the comparison of the results with those obtained in previous work in which the same combination of functional and basis sets was used. The natural bond orbitals (NBO) formalism (11) was used for the calculation of the atomic charges, which appear in Fig. 1. The calculations were made with the Gaussian 98 set of programs (12).



Structural results

The molecular conformations of the two molecules were investigated starting with initial, staggered structures having FCSeC dihedral angles of 180°. The respective CF_3 group was rotated around the Se–C bond from 0° to 60°, in steps of 5°, and the structure was optimized with that dihedral angle frozen. These calculations showed that only a single conformer exists for both compounds, corresponding to the structures of symmetry Cs shown in Fig. 1. The potential energy curve shows maxima for structures in which the trifluoromethyl group is rotated 60° with respect to the most stable conformation.

An additional series of calculations were performed for the CF_3SeCH_3 molecule in which the CF_3 and CH_3 groups

 doi:10.1139/V06-171 © 2006 NRC Canada

Fig. 1. The calculated molecular structure and atomic charges for the molecules CF_3SeCN and CF_3SeCH_3.

were rotated simultaneously in the same or opposite directions in steps of 10°. These calculations confirmed the existence of only one minimum in the potential energy surface.

The most stable conformations predicted for these molecules were fully optimized, and their structures are shown in Fig. 1. As mentioned before, structural geometrical parameters were reported only for CF_3SeCN (4), and these values are shown in Table 1 together with the calculated values. The (mean) calculated and experimental distances and angles do not differ by more than 0.020 Å and 3.4°, respectively. The theoretical tilt angles existing between the C–Se bonds and the ideal symmetry axis of the CX_3 group, with X = F or H, also appear in Table 1; this angle is calculated for the CF_3 groups as $1/3[2\alpha(F3,4–C–Se) – 2\alpha(F2–C–Se)]$ (13). Clearly, CF_3SeCN shows a tilt angle that is considerably larger than those calculated for $SeCF_3$ and $SeCH_3$ in CF_3SeCH_3. This theoretical result could be explained by taking into account the calculated electric charges on the atoms. In fact, the F3, F4, and N7 atoms of CF_3SeCN (Fig. 1) show negative charges of –0.34 (F) and –0.29 (N); whereas, in CF_3SeCH_3 the charges are positive for H8 and H9 (+0.21) and negative for F3 and F4 (–0.36). Therefore, the repulsive forces between the F and N atoms in the former molecule could explain the relatively large tilt angle of the $SeCF_3$ moiety and the predicted value of 176.6° for the Se–C–N angle; whereas, the attractive forces between the mentioned H and F atoms in the latter molecule could be the cause of the notably smaller calculated tilt angles.

Vibrational results

The normal modes of vibration of the CF_3SeCN and CF_3SeCH_3 molecules, with Cs symmetry, are classified as $10A' + 5A''$ and $13A' + 8A''$, respectively.

The atomic displacements calculated for each vibrational mode, represented graphically with the program Moldraw (14), confirmed the assignment of bands proposed by Clase et al. (6) for both molecules. In fact, these authors corrected and completed a previous study made on CF_3SeCN and related molecules by Marsden (5). The experimental wavenumbers for each molecule reported in ref. 6 appear in Tables 2 and 3 together with the corresponding qualitative intensities. In most cases, the observed values agree with the calculated IR and Raman band intensities. That agreement is particularly clear for the bands due to the CF_3 stretching vibrations where the strongly polarized C–F bonds produce very strong IR bands and weak or very weak Raman bands. The agreement between measured and calculated wavenumbers was evaluated by means of the root-mean-square deviation (RMSD), which was equal to 29 cm^{-1} for CF_3SeCN and 55 cm^{-1} for CF_3SeCH_3. After the force field scaling procedure, these values fell to 8 and 7 cm^{-1}, respectively.

Force constants

The force fields in Cartesian coordinates, as generated by the Gaussian programs for the two molecules, were transformed to the set of non-redundant coordinates defined in Tables 4 and 5. Such coordinates consider the local symmetry of the CF_3 and CH_3 groups and follow the proposals of Fogarasi et al. (15). The resulting force constants were sub-

sequently scaled according to the scheme of Pulay et al. (8), in which the main force constants are multiplied by scale factors (e.g., f_i and f_j), and the corresponding interaction constants are multiplied by $(f_i \times f_j)^{1/2}$, adjusting the scale factors to reproduce the experimental wavenumbers as accurately as possible.

The final scaling factors corresponding to each force constant for the two studied species appear in Table 6. Obviously, most of these factors are greater than one. This is the case when heavy atoms (after the second row of the Periodic Table) appear in the molecule. This fact has been reported for many molecules containing non-metallic heavy atoms

(16) as well as for several CF_3SO_2X molecules (17). To prove that the scaling factors are transferable between related molecules, a subsequent calculation was performed using the mean factors for common coordinates previously obtained for the CF_3SeX series (1) and adjusting only the factors that affect the non-common coordinates. In that calculation, the final RMSD values did not differ by more than 1 cm^{-1} from those obtained with the scaling factors of Table 6.

The main force constants in symmetry coordinates as well as some interaction constants for the studied molecules are reproduced in Tables 7 and 8 together with the corresponding values calculated by Wahi et al. (7). Clearly, no large differences appear between both sets of main force constants, based in the same vibrational band assignments. However, there are significant disagreements between the sets of interaction constants, probably because most of these values were fixed in the traditional procedure of refinement performed by these authors. On the other hand, the theoretical approach used in the present work produces a complete force constants matrix. The SQM matrices are available as supplementary data.[3] The SQM force fields were used to calculate the potential energy distributions (PED) that appear in Tables 2 and 3. The PED show that some coordinates are strongly mixed in both molecules, as is the case with S_3 ($\nu(CF_3)$ symm.), S_4 ($\delta(CF_3)$ symm.), and S_8 (ν(C–Se)) for CF_3SeCN and the corresponding S_6, S_8, and S_{11} coordinates for CF_3SeCH_3, which appear to be contributing in different proportions to the modes ν_3 and ν_4 for the first

molecule and ν_6 and ν_8 for the latter. A similar observation was made for the CF_3SeX molecules (1).

The internal force constants calculated from the corresponding SQM force fields for these molecules are shown in Table 9. As expected, these force constants are close to the values previously obtained for other selenium derivates using the same calculation procedure (1).

Regioselective synthesis of biologically interesting pentacyclic polyheterocycles by sequential thio-Claisen and $AlCl_3$ catalyzed oxy-Claisen rearrangement of 4-(4′-aryloxybut-2′-ynylthio)-1-phenyl-1,8-naphthyridin-2(1*H*)-one

K.C. Majumdar and R. Islam

Abstract: A number of 4-aryloxymethyl-6-phenyl-2*H*-thiopyrano[3,2-*c*][1,8]naphthyridin-5(6*H*)-ones were regioselectively synthesized in 82%–95% yields by the thermal Claisen rearrangement of 4-(4′-aryloxybut-2′-ynylthio)-1-phenyl-[1,8]naphthyridin-2(1*H*)-ones. These products were then subjected to a second Claisen rearrangement in the presence of a Lewis acid catalyst, anhyd. $AlCl_3$, to give hitherto unreported pentacyclic heterocycles in 75%–90% yields. The same final products were also obtained in low yield upon refluxing 4-aryloxymethyl-6-phenyl-2*H*-thiopyrano-[3,2-*c*][1,8]naphthyridin-5(6*H*)-ones in *N,N*-diethyl aniline for 12–14 h. This method was found to be more effective than thermal Claisen rearrangement.

Key words: [3,3] sigmatropic rearrangement, regioselective synthesis, phase transfer catalysis, sequential Claisen rearrangement, Lewis acid catalyzed Claisen rearrangement, single crystal X-ray.

Résumé : On a réalisé des synthèses régiosélectives de 4-aryloxyméthyl-6-phényl-2*H*-thiopyrano[3,2-*c*][1,8]naphtyridin-5(6*H*)-ones, avec des rendements allant de 82 % à 95 %, en soumettant des 4-(4'-aryloxybut-2'-ynylthio)-1-phényl[1,8]naphtyridin-2(1*H*)-ones à un réarrangement de Claisen thermique. Ces produits ont ensuite été soumis à un deuxième réarrangement de Claisen, en présence d'un acide de Lewis comme catalyseur, le trichlorure d'aluminium, pour conduire à la formation d'hétérocycles pentacycliques non rapportés jusqu'à maintenant, avec des rendements allant de 75 % à 90 %. On a aussi obtenu ces produits avec de faibles rendements en portant les 4-aryloxyméthyl-6-phényl-2*H*-thiopyrano[3,2-*c*][1,8]naphtyridin-5(6*H*)-ones au reflux dans la *N,N*-diéthylaniline pendant 12 à 14 h. On a trouvé que cette méthode est plus efficace que le réarrangement thermique de Claisen.

Mots clés : réarrangement sigmatropique [3,3], synthèse régiosélective, catalyse par transfert de phase, réarrangements de Claisen séquentiels, réarrangement de Claisen catalysé par un acide de Lewis, diffraction des rayons X par un cristal unique.

[Traduit par la Rédaction]

Introduction

1,8-Naphthyridinones and their derivatives have attracted considerable attention primarily because the 1,8-naphthyridine skeleton is present in many compounds that have been isolated from natural substances and exhibited various medicinal and biological activities (1, 2). 4-Hydroxy-1-phenyl-1,8-naphthyridin-2(1*H*)-one and its derivatives have been used as inhibitors of sulfidopeptide leukotrienes, the major component of SRS-A release (3). 2-Oxo-1,8-naphthyridin-3-carboxylic acid derivatives possess potent gastric antisecretary properties and anti-inflammatory activities (4–6). A series of novel imidazo[4,5-*c*][1,8]naphthyridin-4(5*H*)-ones exhibited potent bronchodilator activity (7). The attractive bioactivities of these 1,8-naphthyidinones, such as the cytoprotective, anti-inflammatory, and antiallergic activity of some 2,3-fused and 3,4-fused furo- and pyrano-tricyclic compounds, justify the great interest in the naphthyridinone moiety as a target in organic synthesis. It is well-documented that the Claisen rearrangement (8) is an excellent method for carbon–carbon bond formation and has been successfully employed for the synthesis of a number of potentially bioactive thieno[3,2-*d*]pyrimidinone and dihydrothieno[3,2-*d*]pyrimidinone derivatives (9). We have previously reported the sequential [3,3] sigmatropic rearrangement of suitably substituted but-2-ynes to give interesting results, e.g., easy access to [6,6] and [6,5] fused polyhetrocycles (10). In view of the medicinal importance of 1,8-

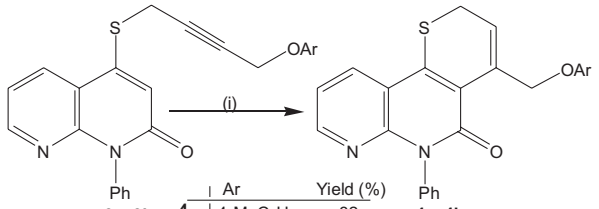
naphthyridine and its derivatives, we became interested in synthesizing a number of polyheterocycles derived from 4-hydroxy-1-phenyl-1,8-naphthyridin-2(1*H*)-one. Here, we report our focused attention on the synthesis of furothiopyrano heterocyclic ring-fused 1,8-napthyridin-2(1*H*)-one by the application of thio-Claisen and oxy-Claisen rearrangement.

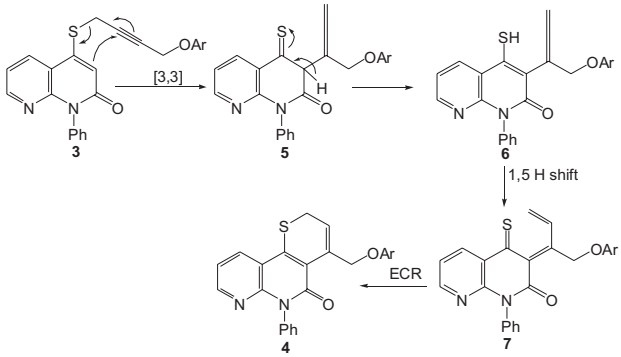
Results and discussion



The starting materials, 4-(4′-aryloxybut-2′-ynylthio)-1-phenyl-[1,8]naphthyridin-2(1*H*)-ones (**3a**–**3h**) were synthesized by phase transfer catalyzed alkylation (11) of 4-mercapto-1-phenyl-1,8-naphthyridin-2(1*H*)-one (**3**) with 1-aryloxy-4-chlorobut-2-ynes (**2a**–**2h**) in 65%–75% yield. 4-Mercapto-1-phenyl-1,8-naphthyridin-2(1*H*)-one (**1**) was prepared according to published procedure (12) (Scheme 1).

The substrates **3a**–**3h** contain the propynylthio-1,8-naphthyridinone moiety as well as the aryl prop-2-ynyl ether moiety, which suggests two different possible [3,3] sigmatropic rearrangements. The aliphatic Claisen rearrangement has the lower activation energy since the aromatic counterpart has to disturb its aromatic sextet in the transition state. Substrate **3a** was heated in chlorobenzene (132 °C) and the reaction was monitored by TLC until complete conversion. Complete conversion was achieved in 4 h giving a white solid in 95% yield. The product **4a** was characterized from elemental analysis and spectroscopic data as 4-(4′-methylphenoxymethyl)-6-phenyl-2*H*-thiopyrano[3,2-*c*][1,8]naphthyridin-5(6*H*)-one. Its ^{1}H NMR spectrum (600 MHz) showed two two-proton doublets at δ: 3.43 (J = 5.4 Hz, -SCH_2), 5.17 (J = 1.2 Hz, -OCH_2) respectively, one proton triple triplet (tt) at δ: 6.28–6.31 (J = 1.8 Hz, 6 Hz, =CH), and a multiplet for twelve aromatic protons at δ: 6.83–8.43. Substrates **3b**–**3h** under similar treatment afforded compounds **4b**–**4h** in 82%–90% yield (Scheme 2).

The formation of products **4a**–**4h** from the substrates **3a**–**3h** is easily rationalized by the initial [3,3] sigmatropic rearrangement of the sulfides **3a**–**3h** to give **5.** This was followed by enolization to **6** and subsequent [1,5] hydrogen shift and electrocyclic ring closure (ECR) to give products **4a**–**4h** (Scheme 3).



Compounds **4a**–**4h** contain allyl aryl ether moieties favourable for a further [3,3] sigmatropic rearrangement. Compounds **4a**, **4d**, and **4f** were refluxed in *N*,*N*-diethyl aniline to perform Claisen rearrangement of allyl aryl ether to

afford the cyclized products in 25% to 30% yields. The products were characterized as **8a**, **8d**, and **8f** from their elemental analyses and spectroscopic data (Scheme 4).

The thermal rearrangement required very high temperature and afforded products in poor yield because of decomposition, so we attempted Lewis acid catalyzed Claisen rearrangement. Among different catalysts reported in literature (13), $AlCl_3$ and its derivatives are known to be efficient for Claisen rearrangement.

Substrate **4a**, upon treatment with anhyd. $AlCl_3$ in dry dichloromethane at RT for 1 h, afforded the cyclized product **8a** in 90% yield. Compound **8a** was characterized from elemental analysis and spectroscopic data. The ^{1}H NMR (500 MHz) spectrum showed δ_H: 1.86 (s, 3H, CH_3 of ring junction), 2.31 (s, 3H, $ArCH_3$), 2.84–2.89 (t, 1H, J =

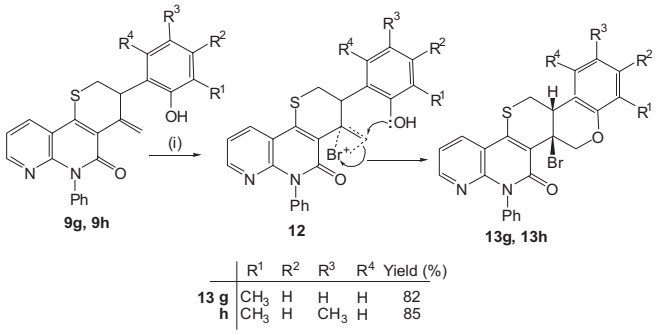
12.3 Hz, SC**H**$_2$), 3.11–3.15 (dd, 1H, *J* = 3.7 Hz, 13.2 Hz, SCH_2), 3.46–3.49 (dd, 1H, *J* = 3.7 Hz, 11.2 Hz, ring juncture H), 6.84–6.85 (d, 1H, *J* = 8.1 Hz, ArH), 6.97–6.99 (d, 1H, *J* = 7.9 Hz, ArH), 7.09 (s, 1H, ArH), 7.14–7.16 (dd, 1H, *J* = 4.6 Hz, 7.8 Hz, ArH), 7.29–7.30 (d, 2H, *J* = 7.5 Hz, ArH), 7.44–7.47 (t, 1H, *J* = 7.4 Hz, ArH), 7.53–7.55 (m, 2H, ArH), 8.26–8.27 (d, 1H, *J* = 7 Hz, ArH), 8.43–8.44 (d, 1H, *J* = 3.3 Hz, ArH). Compounds **4b**–**4h** were also similarly treated to give products **8a**–**8f**, **9g**, and **9h** in 75%–90% yields (Scheme 5). The products were characterized from their elemental analyses and spectroscopic data.

We also examined whether the charge accelerated [3,3] sigmatropic rearrangement is applicable to the sulfides **3a**–**3f**. The substrates **3a**–**3f**, when treated with anhyd. $AlCl_3$ in dichloromethane at RT, showed a tendency to decompose and no traceable product was obtained, although they are quite stable in dichloromethane at RT.



The formation of products **8a**–**8f**, **9g,** and **9h** from **4a**–**4h** is shown in Scheme 6. The isolation of the intermediate **9g** and **9h** indicates that the formation of both the thermal and catalytic rearrangement may follow the [3,3] sigmatropic rearrangement pathway. The use of a Lewis acid catalyst avoids the problem of high temperature that led to decomposition. The formation of products **8** from **4** can be rationalized by a series of steps involving an initial charge accelerated [3,3] sigmatropic rearrangement to give **10,** an ether–oxygen–$AlCl_3$ complex that may pass through a charge-delocalized transition state followed by rapid tautomerization to intermediate **11**, and proton exchange to give the intermediate **9**, which on *5-exo*-cyclization gives the products **8**, analogous to the product usually obtained in the thermal rearrangement (Scheme 6). The single crystal X-ray analysis of **8a** showed the cis stereochemistry at the ring juncture (Fig. 1).

The compounds **9g** and **9h**, upon treatment with pyridine hydrotribromide in chloroform, afforded compounds **13g** and **13h**. The formation of products **13g** and **13h** is thought to occur through the intermediate bromonium ion followed by a "6-endo" attack of the phenolic OH on the bromonium ion **12** (Scheme 7) (10*b*).

In summary, it has been possible to successfully perform the sequential Claisen rearrangement of 4-(4′-aryloxybut-2′-

ynylthio)-1-phenyl-1,8-naphthyridin-2(1*H*)-ones. The method is facile, operationally simple, and allows rapid access to two complex biologically significant heterocyclic systems.

Experimental[2]

Melting points were determined in an open capillary and are uncorrected. IR spectra were recorded on a PerkinElmer L 120–000A spectrometer (ν_{max} in cm^{-1}) on KBr disks. UV absorption spectra were recorded in EtOH on a Shimadzu UV-2401PC spectrophotometer (λ_{max} in nm). ^1H NMR (300 MHz, 400 MHz, 500 MHz, 600 MHz) and ^{13}C NMR (75.5 MHz, 125.7 MHz) spectra were recorded on a Bruker DPX-300, Varian-400 FT-NMR, Bruker DPX-500, and Varian-600 MHz spectrometers in $CDCl_3$ (chemical shifts in δ) with TMS as internal standard. Elemental analyses and mass spectra were recorded on a Leco 932 CHNS analyzer and on a JEOL JMS-600 instrument, respectively. ^1H NMR and ^{13}C NMR spectra were recorded at the Indian Institute of Chemical Biology, Kolkata, and Bose Institute, Kolkata. Silica gel [60–120 mesh, Spectrochem, India] was used for chromatographic separation. Silica gel G [E-Merck, India] was used for TLC. Petroleum ether refers to the fraction boiling between 60–80 °C.

The 1-aryloxy-4-chlorobut-2-ynes (**2a**–**2f**) were prepared according to published procedures (14–16).

Single crystal X-ray study was performed on a Bruker APEX CCD diffractometer equipped with an Oxford Instruments low-temperature attachment. Data were collected using monochromated Mo Kα radiation (λ_a = 0.710 69 Å). The frames were integrated in the Bruker SAINT Software package and the data were corrected for absorption using the SADABS program. The structure was solved and refined with the SHELX suite of programs. ORTEP-III was used to produce the diagram. Pertinent crystallographic data for compound **8a** is summarized in Table 1.

General procedure for the preparation of 4-(4′-aryloxy-2′-but-ynylthio)-1-phenyl-1,8-naphthyridin-2 (1*H*)-one (3a–3f)

To a mixture of 4-mercapto-1-phenyl-1,8-naphthyridin-2(1*H*)-one **1** (0.50 g, 2 mmol) and 1-aryloxy-4-chloro-2-butyne **2a**–**2f** (2.4 mmol) was added a solution of benzyl triethyl ammonium chloride (BTEAC) in 1% aq. NaOH (50 mL) and the mixture was stirred at RT for 8–10 h. The reaction mixture was then diluted with water (100 mL) and the organic layer was extracted with chloroform (3 × 25 mL). The organic layer was repeatedly washed with saturated brine and dried (Na_2SO_4). The solvent was removed and the viscous mass was chromatographed over silica gel using petroleum ether – ethyl acetate (3:1) as eluant to afford the products **3a**–**3f.**

Compounds **3d**–**3h** have already been reported (12).

General procedure for the preparation of compounds 4a–4h

Compounds **3a**–**3h** (1 mmol) were refluxed in chlorobenzene (5 mL) for 4–6 h. The reaction was monitored by TLC. The chlorobenzene was removed at reduced pressure and the residual mass was chromatographed over silica gel. Elution of the column with petroleum ether removed residual chlorobenzene and the rearranged products **4a**–**4h** were obtained by eluting the column with petroleum ether – ethyl acetate (4:1).

Compound 4c

Yield 90%; solid; mp 180–182 °C. UV–vis (EtOH) λ_{max} (nm): 204, 226, 344. IR (KBr, cm^{-1}) ν_{max}: 2928, 1645, 1578, 1508, 1442. ^1H NMR (400 MHz, $CDCl_3$) δ_H: 3.43 (d, 2H, *J* = 6 Hz, SCH_2), 3.73 (s, 3H, OCH_3), 5.14 (d, 2H, *J* = 2 Hz, OCH_2), 6.28–6.31 (t, 1H, *J* = 6 Hz, =CH), 6.76–6.79 (dd, 2H, *J* = 2.4 Hz, 6.8 Hz, ArH), 6.86–6.88 (dd, 2H, *J* = 2.4 Hz, 6.8 Hz, ArH), 7.17–7.20 (dd, 1H, *J* = 4.4 Hz, 7.6 Hz, ArH), 7.25–7.27 (m, 2H, ArH), 7.46–7.50 (t, 1H, *J* = 8 Hz, ArH), 7.55–7.58 (t, 2H, *J* = 8 Hz, ArH), 8.29–8.31 (dd, 1H, *J* = 1.6 Hz, 7.6 Hz, ArH), 8.42–8.43 (dd, 1H, *J* = 1.6 Hz, 4.4 Hz, ArH). MS *m/z*: 428 (M^+). Anal. calcd. for $C_{25}H_{20}N_2O_3S$: C 70.09, H 4.67, N 6.54; found: C 69.91, H 4.91, N 6.76.

Compound 4d

Yield 95%; solid; mp 212–214 °C. UV–vis (EtOH) λ_{max} (nm): 204, 223, 343. IR (KBr, cm^{-1}) ν_{max}: 2924, 1651, 1579, 1485, 1444. ^1H NMR (600 MHz, $CDCl_3$) δ_H: 3.46 (d, 2H, *J* = 6 Hz, SCH_2), 5.26 (d, 2H, *J* = 1.8 Hz, OCH_2), 6.43–6.45 (tt, 1H, *J* = 1.8 Hz, 6 Hz, =CH), 6.84–6.87 (dt, 1H, *J* = 1.2 Hz, 7.8 Hz, ArH), 6.98–6.99 (dd, 1H, *J* = 1.2 Hz, 8.4 Hz, ArH), 7.13–7.16 (dt, 1H, *J* = 1.8 Hz, 8.4 Hz, ArH), 7.18–7.20 (dd, 1H, *J* = 4.2 Hz, 7.8 Hz, ArH), 7.28–7.29 (m, 2H, ArH), 7.33–7.34 (dd, 1H, *J* = 1.2 Hz, 7.8 Hz, ArH), 7.48–7.50 (t, 1H, *J* = 7.8 Hz, ArH), 7.56–7.59 (m, 2H, ArH), 8.31–8.32 (dd, 1H, *J* = 1.8 Hz, 7.8 Hz, ArH), 8.43–8.44 (dd, 1H, *J* = 1.8 Hz, 4.8 Hz, ArH). MS *m/z*: 432, 434 (M^+). Anal. calcd. for $C_{24}H_{17}N_2O_2SCl$: C 66.58, H 3.93, N 6.47; found: C 66.80, H 3.68, N 6.26.

Compound 4e

Yield 85%; solid; mp 186–188 °C. UV–vis (EtOH) λ_{max} (nm): 206, 222, 337. IR (KBr, cm^{-1}) ν_{max}: 2921, 1655, 1574, 1443. ^1H NMR (400 MHz, $CDCl_3$) δ_H: 3.43 (d, 2H, *J* = 6 Hz, SCH_2), 5.19 (s, 2H, OCH_2), 6.28–6.31 (t, 1H, *J* = 6 Hz, =CH), 6.91–6.94 (m, 3H, ArH), 7.17–7.27 (m, 5H, ArH), 7.46–7.50 (t, 1H, *J* = 8 Hz, ArH), 7.54–7.58 (t, 2H, *J* = 8 Hz, ArH), 8.29–8.31 (dd, 1H, *J* = 1.6 Hz, 8 Hz, ArH), 8.42–8.43 (dd, 1H, *J* = 1.6 Hz, 4.4 Hz, ArH). MS *m/z*: 398 (M^+). Anal. calcd. for $C_{24}H_{18}N_2O_2S$: C 72.36, H 4.52, N 7.03; found: C 72.57, H 4.35, N 7.22.

Compound 4f

Yield 85%; solid; mp 165–167 °C. UV–vis (EtOH) λ_{max} (nm): 206, 224, 341. IR (KBr, cm^{-1}) ν_{max}: 2913, 1663, 1583, 1448. ^1H NMR (600 MHz, $CDCl_3$) δ_H: 2.25 (s, 6H, CH_3), 3.44–3.45 (d, 2H, *J* = 6 Hz, SCH_2), 5.15 (d, 2H, *J* = 2 Hz, OCH_2), 6.31–6.33 (t, 1H, *J* = 6 Hz, =CH), 6.57 (s, 1H, ArH), 6.58 (s, 1H, ArH), 7.18–7.20 (dd, 1H, *J* = 4.8 Hz, 7.8 Hz, ArH), 7.27–7.28 (m, 3H, ArH), 7.48–7.50 (t, 1H, *J* = 7.2 Hz, ArH), 7.56–7.59 (t, 2H, *J* = 7.8 Hz, ArH), 8.30–8.31 (dd, 1H, *J* = 1.2 Hz, 7.8 Hz, ArH), 8.42–8.43 (dd, 1H, *J* = 1.2 Hz, 4.8 Hz, ArH). MS *m/z*: 426 (M^+). Anal. calcd. for $C_{26}H_{22}N_2O_2S$: C 73.23, H 5.16, N 6.57; found: C 73.04, H 5.39, N 6.78.

Compound 4g

Yield 90%; solid; mp 195–197 °C. UV–vis (EtOH) λ_{max} (nm): 204, 223, 339. IR (KBr, cm^{-1}) ν_{max}: 2924, 1653, 1575, 1492, 1443. ^1H NMR (600 MHz, $CDCl_3$) δ_H: 2.26 (s, 3H,

© 2006 NRC Canada

CH_3), 3.45–3.46 (d, 2H, J = 6 Hz, SCH_2), 5.20 (d, 2H, J = 1.2 Hz, OCH_2), 6.34–6.36 (tt, 1H, J = 1.8 Hz, 6 Hz, =CH), 6.81–6.87 (m, 1H, ArH), 7.07–7.12 (m, 2H, ArH), 7.18–7.20 (dd, 1H, J = 4.8 Hz, 7.8 Hz, ArH), 7.26–7.28 (m, 3H, ArH), 7.48–7.51 (m, 1H, ArH), 7.56–7.59 (m, 2H, ArH), 8.31–8.32 (dd, 1H, J = 1.8 Hz, 7.8 Hz, ArH), 8.43–8.44 (dd, 1H, J = 1.8 Hz, 4.8 Hz, ArH). MS m/z: 412 (M^+). Anal. calcd. for $C_{25}H_{20}N_2O_2S$: C 72.81, H 4.85, N 6.79; found: C 72.55, H 5.02, N 7.02.

Compound 4h

Yield 85%; solid; mp 178–180 °C. UV–vis (EtOH) λ_{max} (nm): 200, 226, 341. IR (KBr, cm^{-1}) ν_{max}: 2918, 1651, 1579, 1503, 1444. ^1H NMR (300 MHz, $CDCl_3$) δ_H = 2.22 (s, 3H, CH_3), 2.26 (s, 3H, CH_3), 3.43 (d, 2H, J = 6 Hz, SCH_2), 5.16 (s, 2H, OCH_2), 6.32–6.36 (t, 1H, J = 6 Hz, =CH), 6.74–6.93 (m, 3H, ArH), 7.16–7.28 (m, 3H, ArH), 7.47–7.60 (m, 3H, ArH), 8.30–8.32 (d, 1H, J = 7.8 Hz, ArH), 8.42–8.44 (dd, 1H, J = 1.2 Hz, 4.4 Hz, ArH). MS m/z: 426 (M^+). Anal. calcd. for $C_{26}H_{22}N_2O_2S$: C 73.23, H 5.16, N 6.57; found: C 73.49, H 5.40, N 6.38.

General procedure for the preparation of 8a–8f, 9g, and 9h

Compound **4a**–**4f** (0.5 mmol) was dissolved in dry dichloromethane (10 mL) and anhyd. $AlCl_3$ (0.06 g, 0.5 mmol) was added. The reaction mixture was stirred at RT for 0.5–2.0 h. Crushed ice was added to the reaction mixture and was extracted with dichloromethane. The combined extracts were washed with water (20 mL), brine (20 mL), and dried (Na_2SO_4). The solvent was removed and the residual viscous mass was chromatographed over silica gel using petroleum ether – ethyl acetate (3:1) as eluant to afford the products **8a**–**8f**, **9g**, and **9h**.

Compound 8a

Yield 90%; solid; mp 150–152 °C. UV–vis (EtOH) λ_{max} (nm): 206, 224, 296, 320, 332. IR (KBr, cm^{-1}) ν_{max}: 2924, 1655, 1583, 1488, 1441. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 1.86 (s, 3H, CH_3 of ring junction), 2.31 (s, 3H, $ArCH_3$), 2.84–2.89 (t, 1H, J = 12.3 Hz, SCH_2), 3.11–3.15 (dd, 1H, J = 3.7 Hz, 13.2 Hz, SCH_2), 3.46–3.49 (dd, 1H, J = 3.7 Hz, 11.2 Hz, ring juncture H), 6.84–6.85 (d, 1H, J = 8.1 Hz, ArH), 6.97–6.99 (d, 1H, J = 7.9 Hz, ArH), 7.09 (s, 1H, ArH), 7.14–7.16 (dd, 1H, J = 4.6 Hz, 7.8 Hz, ArH), 7.29–7.30 (d, 2H, J = 7.5 Hz, ArH), 7.44–7.47 (t, 1H, J = 7.4 Hz, ArH), 7.53–7.55 (m, 2H, ArH), 8.26–8.27 (d, 1H, J = 7 Hz, ArH), 8.43–8.44 (d, 1H, J = 3.3 Hz, ArH). ^{13}C NMR (125.7 MHz, $CDCl_3$) δ_c: 21.26, 24.75, 29.28, 52.04, 86.05, 111.26, 114.83, 118.30, 125.10, 127.08, 128.68, 128.81, 129.68, 129.71, 130.14, 130.38, 134.30, 137.53, 145.85, 149.45, 151.03, 155.71, 160.56. MS m/z: 412 (M^+). Anal. calcd. for $C_{25}H_{20}N_2O_2S$: C 72.81, H 4.85, N 6.79; found: C 72.58, H 4.64, N 6.98.

Compound 8b

Yield 88%; solid; mp 260–262 °C. UV–vis (EtOH) λ_{max} (nm): 205, 224, 301, 321, 332. IR (KBr, cm^{-1}) ν_{max}: 2921, 1652, 1583, 1470, 1442. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 1.88 (s, 3H, CH_3 of ring junction), 2.85–2.90 (t, 1H, J = 12.2 Hz, SCH_2), 3.12–3.15 (dd, 1H, J = 2.6 Hz, 13 Hz, SCH_2), 3.52–3.54 (d, 1H, J = 8.5 Hz, ring juncture H), 6.87–6.88 (d, 1H, J = 8.3 Hz, ArH), 7.13–7.17 (m, 2H, ArH), 7.25–7.30 (m, 3H, ArH), 7.41–7.55 (m, 3H, ArH), 8.25–8.27 (d, 1H, J = 7.4 Hz, ArH), 8.45–8.46 (m, 1H, ArH). ^{13}C NMR (125.7 MHz, $CDCl_3$) δ_c: 24.75, 29.03, 51.92, 86.99, 112.72, 114.70, 118.39, 124.77, 125.71, 126.55, 128.63, 128.74, 129.49, 129.69, 130.62, 134.30, 137.42, 145.97, 149.45, 151.22, 156.58, 160.44. MS m/z: 432, 434 (M^+). Anal. calcd. for $C_{24}H_{17}N_2O_2SCl$: C 66.58, H 3.93, N 6.47; found: C 66.84, H 4.14, N 6.69.

Compound 8c

Yield 80%; solid; mp 226–228 °C. UV–vis (EtOH) λ_{max} (nm): 204, 224, 333. IR (KBr, cm^{-1}) ν_{max}: 2938, 1650, 1582, 1484, 1441. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 1.87 (s, 3H, CH_3 of ring junction), 2.86–2.91 (dd, 1H, J = 11.5 Hz, 13 Hz, SCH_2), 3.13–3.16 (dd, 1H, J = 3.8 Hz, 13 Hz, SCH_2), 3.48–3.51 (dd, 1H, J = 3.8 Hz, 11.3 Hz, ring juncture H), 3.78 (s, 3H, OCH_3), 6.71–6.71 (dd, 1H, J = 2.5 Hz, 8.7 Hz, ArH), 6.86–6.92 (m, 2H, ArH), 7.14–7.16 (dd, 1H, J = 4.6 Hz, 7.9 Hz, ArH), 7.29–7.30 (d, 2H, J = 7.4 Hz, ArH), 7.44–7.47 (t, 1H, J = 7.4 Hz, ArH), 7.50–7.60 (m, 2H, ArH), 8.25–8.27 (dd, 1H, J = 1.4 Hz, 7.9 Hz, ArH), 8.43–8.44 (dd, 1H, J = 1.4 Hz, 4.5 Hz, ArH). ^{13}C NMR (125.7 MHz, $CDCl_3$) δ_c: 24.72, 29.12, 52.35, 56.45, 86.18, 111.08, 111.69, 114.35, 118.30, 126.94, 127.05, 128.68, 129.67, 129.74, 134.27, 137.51, 145.76, 149.45, 151.04, 151.91, 154.65, 160.53. MS m/z: 428 (M^+). Anal. calcd. for $C_{25}H_{20}N_2O_3S$: C 70.09, H 4.67, N 6.54; found: C 69.85, H 4.48, N 6.72.

Compound 8d

Yield 85%; solid; mp 162–164 °C. UV–vis (EtOH) λ_{max} (nm): 206, 224, 290, 321, 332. IR (KBr, cm^{-1}) ν_{max}: 2926, 1655, 1584, 1444. ^1H NMR (600 MHz, $CDCl_3$) δ_H: 1.92 (s, 3H, CH_3 of ring junction), 2.90–2.94 (dd, 1H, J = 11.4 Hz, 13.2 Hz, SCH_2), 3.13–3.16 (dd, 1H, J = 3.6 Hz, 13.2 Hz, SCH_2), 3.58–3.61 (dd, 1H, J = 3.6 Hz, 11.4 Hz, ring juncture H), 6.84–6.86 (t, 1H, J = 7.8 Hz, ArH), 7.13–7.16 (dd, 1H, J = 4.8 Hz, 7.8 Hz, ArH), 7.17–7.19 (m, 2H, ArH), 7.29–7.30 (d, 2H, J = 6.6 Hz, ArH), 7.45–7.48 (t, 1H, J = 8.4 Hz, ArH), 7.55–7.57 (t, 2H, J = 8.4 Hz, ArH), 8.24–8.25 (dd, 1H, J = 1.8 Hz, 7.8 Hz, ArH), 8.43–8.44 (dd, 1H, J = 1.8 Hz, 4.8 Hz, ArH). MS m/z: 432, 434 (M^+). Anal. calcd. for $C_{24}H_{17}N_2O_2SCl$: C 66.58, H 3.93, N 6.47; found: C 66.32, H 4.15, N 6.66.

Compound 8e

Yield 85%; solid; mp 214–216 °C. UV–vis (EtOH) λ_{max} (nm): 203, 224, 287, 332. IR (KBr, cm^{-1}) ν_{max}: 2919, 1644, 1583, 1461, 1443. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 1.88 (s, 3H, CH_3 of ring junction), 2.85–2.89 (t, 1H, J = 12.3 Hz, SCH_2), 3.13–3.16 (d, 1H, J = 10.5 Hz, SCH_2), 3.52 (d, 1H, J = 8.8 Hz, ring juncture H), 6.90–6.97 (m, 2H, ArH), 7.15–7.20 (m, 2H, ArH), 7.25–7.30 (m, 3H, ArH), 7.46–7.55 (m, 3H, ArH), 8.26–8.27 (d, 1H, J = 7.5 Hz, ArH), 8.44 (d, 1H, J = 2.1 Hz, ArH). MS m/z: 426 (M^+). Anal. calcd. for $C_{26}H_{22}N_2O_2S$: C 73.23, H 5.16, N 6.57; found: C 73.09, H 5.33, N 6.71.

General procedure for the preparation of compounds 8a, 8d, and 8f

A mixture of compounds **4a**, **4d**, and **4f** (1 mmol) in *N,N*-diethylaniline (5 mL) was refluxed for 12–14 h. The reaction mixture was cooled, poured into ice-cold 6 (N) HCl (30 mL), and extracted with $CHCl_3$ (3 × 20 mL). The $CHCl_3$ layer was washed with water and dried over Na_2SO_4. Removal of $CHCl_3$ gave a viscous liquid, which was chromatographed over silica gel. Elution of the column with petroleum ether – ethyl acetate (4:1) furnished products **10a**, **10d**, and **4f**.

General procedure for the cyclization of the compounds 9g and 9h

The brominating agent, solid pyridine hydrobromide perbromide (0.16 g, 0.5 mmol), was added to a chloroform solution (20 mL) of the compounds **9g** and **9h** (0.5 mmol). The reaction mixture was then stirred for 1 h on a magnetic stirrer at 0–5 °C. After the completion of the reaction (monitored by TLC), the mixture was washed with 5% aq. $NaHCO_3$ (3 × 25 mL) and water (3 × 25 mL), and dried (Na_2SO_4). The residual mass after removal of the solvent was subjected to column chromatography over silica gel using petroleum ether – ethyl acetate (6:1) as eluant to give cyclized products **13g** and **13h**.

Compound 13g

Yield 82%; solid; mp 146–148 °C. UV–vis (EtOH) λ_{max} (nm): 207, 224, 286, 323, 334. IR (KBr, cm^{-1}) ν_{max}: 2923, 1651, 1584, 1443. ^1H NMR (300 MHz, $CDCl_3$) δ_H: 2.22 (s, 3H, $ArCH_3$), 2.82 (t, 1H, J = 12.6 Hz, SCH_2), 3.18–3.23 (dd, 1H, J = 4 Hz, 13 Hz, SCH_2), 3.54–3.57 (d, 1H, J = 9.5 Hz, OCH_2), 3.97–4.02 (dd, 1H, J = 4 Hz, 13 Hz, ring juncture H), 4.89–4.92 (d, 1H, J = 9.5 Hz, OCH_2), 6.58–6.90 (t, 1H, J = 7.3 Hz, ArH), 7.01–7.04 (d, 1H, J = 7.3 Hz, ArH), 7.14–7.33 (m, 4H, ArH), 7.49–7.61 (m, 3H, ArH), 8.30–8.33 (d, 1H, J = 8.1 Hz, ArH), 8.46–8.47 (d, 1H, J = 2.8 Hz, ArH). Electrocatalytic hydrogenation of catechol on Rh–Al_2O_3 in different media — pH-Dependent reduction mechanism for intermediate formation

Anne Brisach-Wittmeyer, Nicolas-Alexandre Bouchard, Raymond Breault, and Hugues Ménard

Abstract: The electrocatalytic hydrogenation of catechol was carried out in aqueous media in different pH ranges with Rh–Al_2O_3 powder catalyst. The reactions were conducted in an H-cell used as a dynamic cell, with a reticulated vitreous carbon electrode in contact with the catalyst powder as the working electrode. It was shown that the final product is 1,2-cyclohexanediol (cis and trans isomers) and that several intermediates are detected depending on the pH of the solution. Different media, from pH 5 to 13, were studied. One of the intermediates is 1,2-cyclohexanedione, detected at all pH values. The other is 2-hydroxycyclohexan-1-one, only observed at pH ≤ 7. To determine the mechanism of the reactions involved, the electrocatalytic hydrogenation of these intermediates to form the final 1,2-cyclohexanediol product was also conducted, and their UV spectroscopy and cyclic voltammetry data recorded. The influence of the nature of the solution was screened by measuring the Henry constant of each molecule.

Key words: electrocatalytic hydrogenation of catechol, pH-dependent reduction mechanism, UV–vis spectroscopy, cyclic voltammetry, Henry constants.

Résumé : L'hydrogénation électrocatalytique du catéchol a été menée en milieu aqueux à différents pH sur des poudres de Rh–Al_2O_3 comme catalyseur. Les réactions ont été réalisées dans une cellule en H utilisée en mode dynamique avec des électrodes de carbone vitreux réticulé en contact avec le catalyseur comme électrodes de travail. Il a été montré que le produit final est le 1,2-cyclohexanediol (isomers cis et trans) et que plusieurs intermédiaires sont détectés dépendamment du pH de la solution. Divers milieux de pH 5 à 13 ont été étudiés. Un des intermédiaires est la 1,2-cyclohexanedione, formée quel que soit le pH. L'autre est la 2-hydroxycyclohexan-1-one, uniquement observée à pH ≤ 7. Afin de déterminer le mécanisme des réactions impliquées, l'hydrogénation électrocatalytique de ces intermédiaires en 1,2-cyclohexanediol a été réalisée ainsi que la spectroscopie UV-visible et la voltampérométrie cyclique. L'influence de la nature du milieu a été évaluée en mesurant les constantes de Henry pour chacune de ces molécules.

Mots clés : hydrogénation électrocatalytique du catéchol, mécanisme de réduction dépendant du pH, spectroscopie UV–vis, voltampérométrie cyclique, constantes de Henry.

Introduction

Catechol is known to inhibit gibbsite precipitation (1–4). The scope of this work was to investigate the use of electrocatalytic hydrogenation (ECH) (Fig. 1, I) to transform catechol into an inactive molecule by hydrogenation of its aromatic ring. Since gibbsite crystal growth occurs in alkaline media in the Bayer process, the hydrogenation of catechol at high pH was of particular interest.

Several papers have been devoted to the electrocatalytic hydrogenation of phenol (5–12). It was shown that the addition of six electrons per molecule leads to cyclohexanol via cyclohexanone as intermediate product. It was also shown that catechol, a benzyl group bearing two adjacent hydroxyl groups, can be reduced to 1,2-cyclohexanediol (Fig.1, IV) in H_3BO_3 on Rh–Al_2O_3 (13). Similar electrochemical techniques to the one used for ECH of phenol (14) and catechol (13) were used here with various catalysts. The highest efficiency was observed with 5% Rh–Al_2O_3 as the catalyst, and all the results presented here were obtained using this catalyst.

In sodium hydroxide (1 mol/L), good conversion rates from catechol to 1,2-cyclohexanediol by total reduction with six electrons were obtained in this work, and the formation of the 1,2-cyclohexanedione (Fig. 1, II) intermediate was detected. However, the final molecule presented two forms, cis and trans (Fig. 1, IVa and IVb). This suggested that the catechol hydrogenation occurred via more than one intermediate. To study its mechanism, the ECH of catechol was investigated at different pH values to try to detect intermedi-

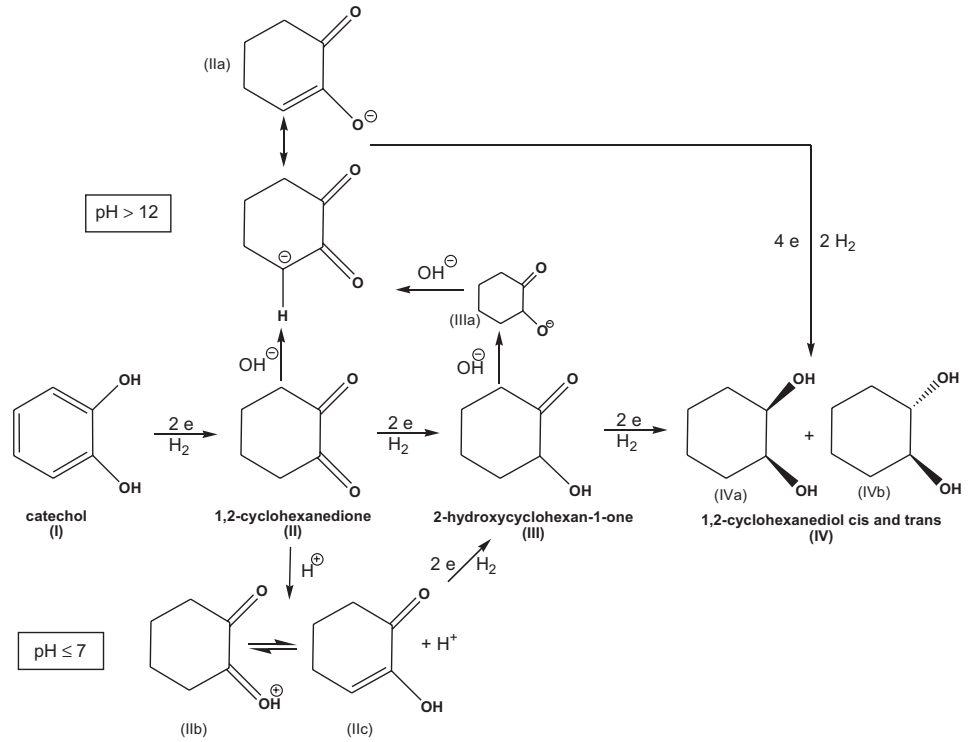
Fig. 1. Proposed ECH mechanism for the reduction of catechol into 1,2-cyclohexanediol depending on the pH of the media.



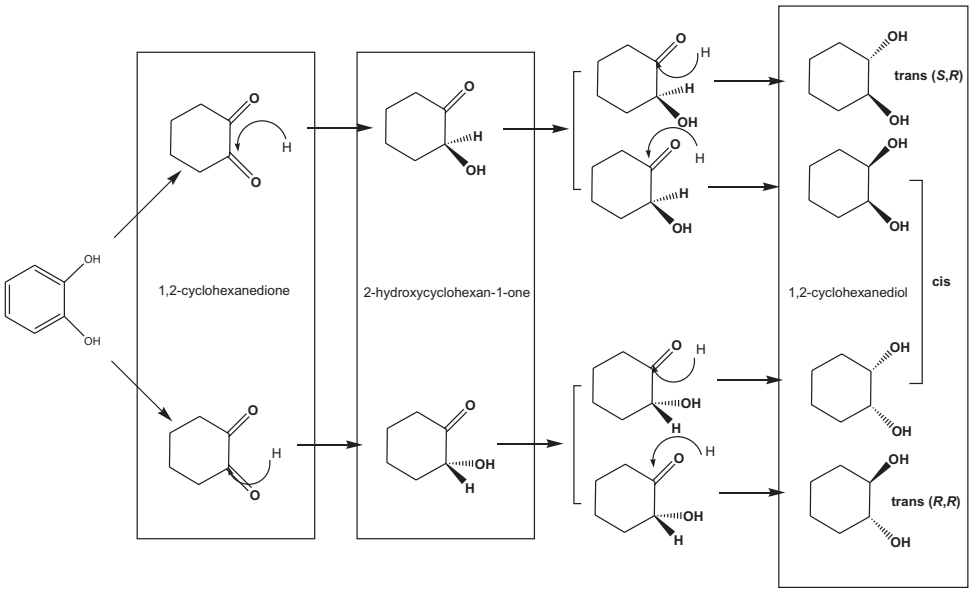


Fig. 2. Possible pathway for the formation of the different isomers of 1,2-cyclohexanediol. For clarity, only the protons involved in the formation of the isomers are indicated.

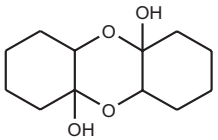

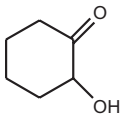

ates as performed in earlier work on molecules such as 2-methyl-1-hydroxybenzene (15). The influence of solution pH on the reactivity appears to be of great importance (16) and was also investigated. Three pH zones were investigated: pH 13 with NaOH (1 mol/L), pH 7 with phosphate buffer (0.5 mol/L), and pH 5 with acetate buffer (0.5 mol/L).

An additional intermediate was observed in media with pH ≤ 7 and was identified as 2-hydroxycyclohexan-1-one (Fig. 1, III). Its presence explains the formation of cis-trans, (*S*-*R*), and (*R*-*R*) isomers of 1,2-cyclohexanediol (17) as depicted in Fig. 2. To determine the role of reaction kinetics in the different media, the direct ECH of 1,2-cyclohexanone and 2-hydroxycyclohexan-1-one into 1,2-cyclohexanediol was also studied.

The stability of these intermediates was examined using UV absorption spectra (18, 19) and voltammetric data (18, 20–22) in the different media. To understand the influence of the solution medium on reactivity, a newly improved method developed by our group (23, 24) was used to determine the adsorption strength by evaluating Henry constants.

Experimental

Electrolysis

The electrolysis was carried out in a two-compartment glass H-cell having a Nafion-117 membrane (Dupont de Nemours) as the separator. The cathodic compartment was filled with 28 mL of NaOH (1 mol/L), phosphate buffer (0.5 mol/L of KH_2PO_4 and 10 mol/L of NaOH) or acetate buffer (0.5 mol/L of CH_3COOH and 10 mol/L of NaOH). Catalyst powder (5% Rh–Al_2O_3, 200 mg) was added to the catholyte. The solution was stirred to force the catalyst to pass through the RVC electrode. A N_2 flow was maintained over the solution. The anodic compartment was filled with the corresponding electrolyte; the counter electrode was a platinum grid. The working electrode was conditioned before starting the ECH process by polarization with 50 C. The chemisorbed hydrogen radicals formed during this time are immediately usable by unsaturated molecules, so some efficiencies may depend on the ECH mechanism and on the quantity of hydrogen available. After polarization, 2 mL of catechol (0.15 mol/L), 1,2-cyclohexanedione (0.15 mol/L) or 2-hydroxycyclohexan-1-one (0.05 mol/L) solution in water was added to the catholyte, giving a total volume of 30 mL. The electrocatalytic hydrogenation was performed under galvanostatic control (i = 10 or 5 mA) using an EG&G Princeton Avanced Research power supply model 273. The commercial 5% Rh–Al_2O_3 powder was purchased from Alfa Aesar and used as received.

During the ECH reaction, aliquots of 200 μL were withdrawn from the catholyte, acidified to pH 5 with HCl (2 mol/L) and filtered with Millipore filters (0.45 μm). The solution analyses were performed on an HPLC Agilent 1100 series liquid chromatograph equipped with a model G1362 refractive index detector.

UV spectroscopy and cyclic voltammetry

UV–vis spectra were recorded on an Agilent 845x UV spectrophotometer. Voltammetric measurements were performed under a nitrogen atmosphere at RT in a three-electrode cell connected to a potentio–galvanostat (EG&G Princeton Avanced Research model 273). Data were quantified on a personal computer using Echem software, version 4.23 (eDAQ Inc., Colorado Springs, Colorado). The working electrode was a hanging mercury drop, the auxiliary electrode was a platinum grid, and the reference electrode was a saturated calomel electrode (SCE).

Quantification

The 1,2-cyclohexanediol cis and trans isomers were quantified by HPLC analysis and compared with available commercial molecules. With this technique, it was not possible to distinguish the (*S*-*R*) and (*R*-*R*) stereoisomers. All other molecules involved in the ECH process (catechol, 1,2-cyclohexanedione, and 2-hydroxycyclohexan-1-one) were analysed by comparison with commercially available molecules.

Henry's Law constants (k_H)

The chromatographic parameters were obtained using an Agilent 1100 series HPLC equipped with a diode array detector (G1315B). The dead volume τ_0 was determined by injecting 5 μL of deuterium oxide (D_2O). The mobile phases were 0.01 mol/L NaOH, 0.05 mol/L phosphate buffer or 0.05 mol/L acetate buffer, filtered through 0.45 μm Milipore filters. The flow rate was 1.00 mL/min. The columns (15 cm) were filled with the sieved Al_2O_3, whose average particle size was between 25 and 35 μm. The parameters used to determine the dynamic adsorption isotherms were collected from the HPLC elution chromatograph and the Henry constants were calculated from the well-known equation, $Q_e = k_H C_e$, according to previous works (23, 24).

Characterization

The isolated 2-hydroxycyclohexan-1-one intermediate was characterized by comparison with the commercially obtained dimer using IR spectroscopy (Bomen MB 104 spectrometer in HATR mode) and Mass Spectroscopy (electrospray MS Agilent G1946A). Solid IR spectrospcopy (Table 1) showed that 2-hydroxycyclohexan-1-one is dimeric in its solid state, proved by the absence of a C=O stretch (25). Liquid-phase IR spectra under the ECH conditions with NaOH in solution showed that the 2-hydroxycyclohexan-1-one dimer reforms to the monomer under these conditions. The MS experiments confirmed these assumptions. Previous synthesis work showed that the 2-hydroxycyclohexan-1-one monomer is liquid at RT whereas the dimer is solid (26–28), and that the monomer easily dimerizes at RT (29).

Results

Preliminary remarks

As demonstrated by the reaction mechanism shown in Fig. 1, 6 F (faraday where 1 F = 96 495.7 C) are necessary to totally hydrogenate one mole of catechol. In the same

© 2006 NRC Canada

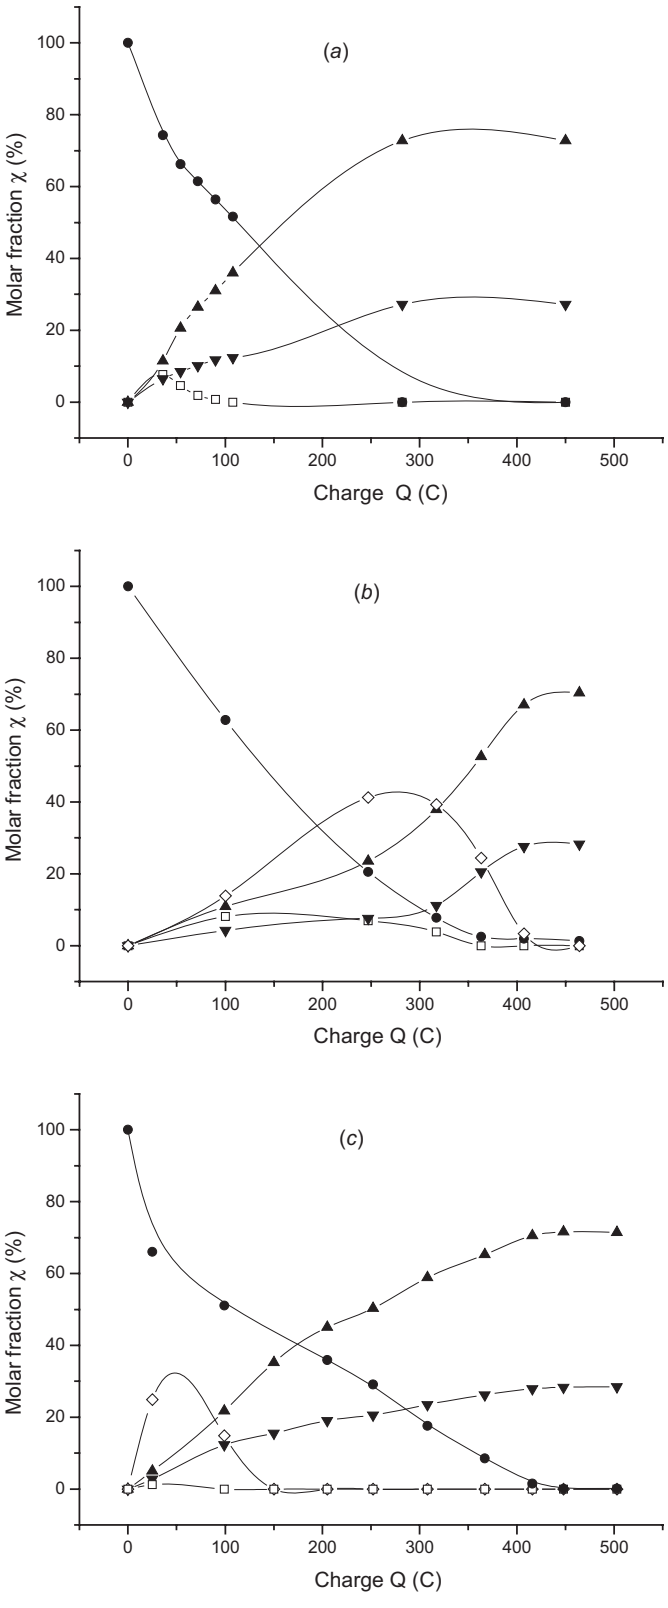
way, it takes 4 F to transform one mole of 1,2-cyclohexanedione into one mole of 1,2-cyclohexanediol and 2 F for the conversion of one mole of 2-hydroxycyclohexan-1-one. Under the conditions used in the present study, it was calculated that it takes 174 C (Coulombs) for the total conversion of 3.00×10^{-4} mol of catechol, 116 C for 3.00×10^{-4} mol of 1,2-cyclohexanedione, and 19 C for 1.00×10^{-4} mol of (i.e., 58 C for 3.00×10^{-4} mol) 2-hydroxycyclohexan-1-one. The relative efficiencies of the ECH processes in the different media were evaluated by comparing the residual concentration of the starting material at the designated value of the current.

In addition, since the charge used is a function of time ($Q_{(C)} = i_{(A)} \times t_{(s)}$) and the applied current is a constant, the slopes of the curves ($\chi = f(Q)$) have been used to indicate the reaction rate in the ECH processes.

ECH of catechol at pH 13

The electrochemical hydrogenation of catechol in an alkaline medium was conducted in NaOH (1 mol/L). The initial and final pH values were 13. After 6 F (Fig. 3*a*), 68% of the catechol was reduced. The intermediate product is 1,2-cyclohexanedione. The low quantity detected indicates that it is a transient species, and that it is not necessary to transform all the catechol into 1,2-cyclohexanedione to form the final product.

ECH of catechol at pH 7



The electrochemical hydrogenation of catechol was conducted in phosphate buffer (0.5 mol/L) with the initial and final pH being 7. After 6 F were passed (Fig. 3*b*), 62% of the catechol was completely reduced. The intermediate products were 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one. Both molecules seemed to form together. That is, 2-hydroxycyclohexan-1-one forms immediately after 1,2-cyclohexanedione is produced without any separation of the two steps. The low quantities detected for 1,2-cyclohexanedione indicate that this product is a transient species with a very short lifetime. The formation and disappearance of 2-hydroxycyclohexan-1-one could clearly be detected, allowing preparation and characterization of this molecule. It was not necessary to transform all the catechol into 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one to form the final 1,2-cyclohexanediol product.

ECH of catechol at pH 5

The electrochemical hydrogenation of catechol was conducted in acetate buffer (0.5 mol/L); the initial and final pH values were 5. After a charge of 174 C was passed (Fig. 3*c*), 60% of the catechol had completely disappeared. The intermediate products were 1,2-cyclohexanedione (a trace detected) and 2-hydroxycyclohexan-1-one, as observed at pH 7. The low quantities of 1,2-cyclohexanedione detected indicate that this product is a transient species in this medium with a very short lifetime compared with that of 2-hydroxycyclohexan-1-one. In this case, 2-hydroxycyclohexan-1-one is rapidly formed and also very rapidly transformed into 1,2-cyclohexanediol. It can be assumed that 1,2-cyclohexanedione is also quickly converted to 2-hydroxycyclohexan-1-one.

The next main question was to determine if 1,2-cyclohexanedione effectively transforms into 2-hydroxycyclohexan-1-

Fig. 3. ECH of catechol (0.01 mol/L) in (*a*) NaOH (1 mol/L), (*b*) phosphate buffer (0.5 mol/L, pH 7), (*c*) acetate buffer (0.5 mol/L, pH 5). Working electrode: RVC 80 PPI packed with 5% $Rh–Al_2O_3$, polarized at 10 mA for 50 C; auxiliary electrode: Pt grid; i = 10 mA. Catechol (–●–); 1,2-cyclohexanedione (–□–); 2-hydroxycyclohexan-1-one (–◇–); *trans*-1,2-cyclohexanediol (–▼–); *cis*-1,2-cyclohexanediol (–▲–).

© 2006 NRC Canada

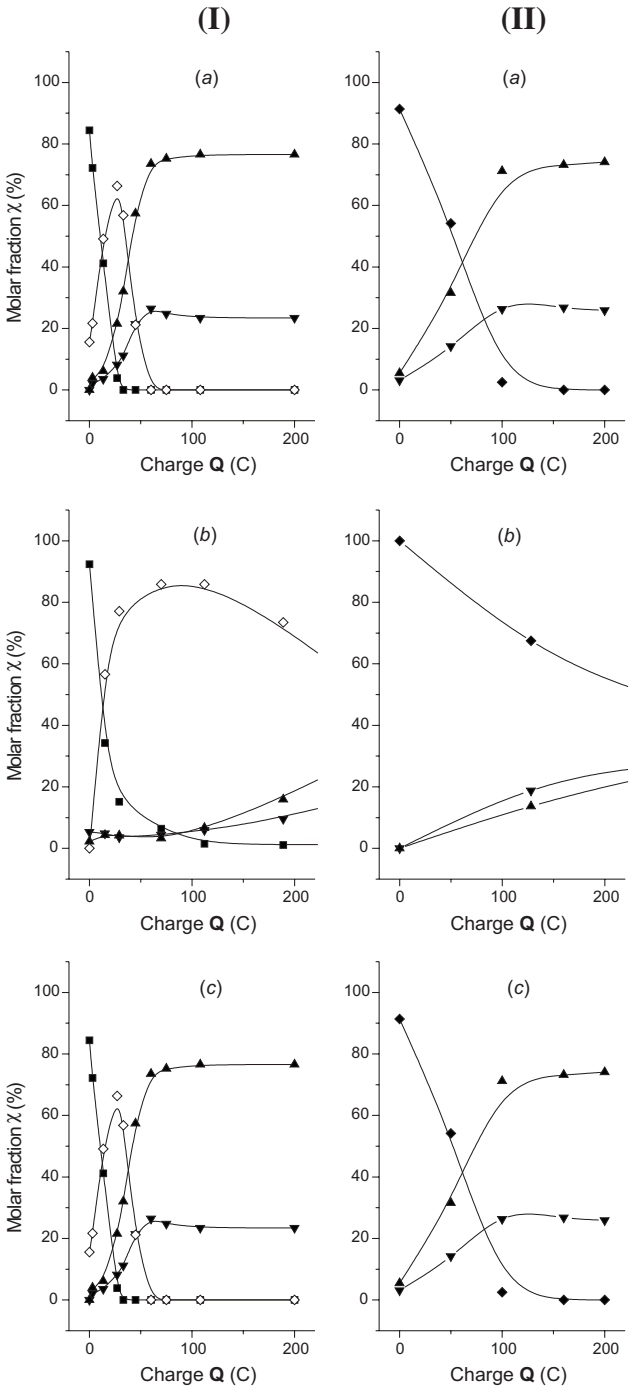
one in alkaline medium, as suggested by the formation of different isomers of 1,2-cyclohexanediol. It was also of interest to discover the role of formation kinetics for the different products in the global mechanism. The reactivity of 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one in the different media was therefore examined.

ECH of 1,2-cyclohexanedione and 2-hydroxycyclohexanone at pH 13

1,2-cyclohexanedione transforms into 2-hydroxycyclohexan-1-one and afterwards into *cis*- and *trans*-1,2-cyclohexanediol in NaOH (Fig. 4, I*a*). These reactions are very fast. It is obvious that all the 1,2-cyclohexanedione must be transformed into 2-hydroxycyclohexan-1-one to allow the formation of 1,2-cyclohexanediol, but this step takes place in a very short time (38 C). The reaction needs less than 2 F; this can be explained by the presence of reactive H adsorbed on the catalyst during the cathodic polarization of 50 C performed before electrolysis. In addition, 58% of 2-hydroxycyclohexan-1-one was consumed after 58 C (Fig. 4, I*a*).

ECH of 1,2-cyclohexanedione and 2-hydroxycyclohexanone at pH 7

At pH 7, 2-hydroxycyclohexan-1-one is also formed very rapidly, and 1,2-cyclohexanediol appears in solution when all 1,2-cyclohexanedione is consumed (Fig. 4, I*b*). Moreover, the reaction is very efficient, with 98% of the 1,2-cyclohexanedione transformed after 4 F. But in this case the transformation of 2-hydroxycyclohexan-1-one into 1,2-cyclohexanediol is much slower than in the other media (Fig. 4, II*a* compared with II*b* and II*c*). The direct transformation from 2-hydroxycyclohexan-1-one into 1,2-cyclohexanediol correlates with results observed for the direct reduction of 1,2-cyclohexanedione (Fig. 4, I*b* and II*b*), and its reduction when formed from catechol (Fig. 3*b*). That is, the reaction is very slow.



ECH of 1,2-cyclohexanedione and 2-hydroxycyclohexanone at pH 5

At pH 5, 2-hydroxycyclohexan-1-one is, once again, formed very rapidly from 1,2-cyclohexanedione, and 1,2-cyclohexanediol appears in solution when all 1,2-cyclohexanedione is consumed (Fig. 4, I*c*). The process is again very efficient with 99% of 1,2-cyclohexanedione consumed after 4 F. 2-Hydroxycyclohexan-1-one is also very rapidly hydrogenated into 1,2-cyclohexanediol in this process (Fig. 4, II*c*). Its direct transformation into 1,2-cyclohexanediol is the fastest among the experiments done on this molecule in the different media (Fig. 4, II*c* compared with II*b* and II*c*). It is particularly interesting to note that the reaction is much more efficient in an acetate than a phosphate buffer, considering that the pH conditions are comparable taking into account the pK_a of catechol (pK_{a1} = 9.45) (30).

UV spectroscopy

The UV spectra of 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one in the three media showed typical behaviour. In sodium hydroxide, both 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one present a band at 300 nm (Fig. 5) that corresponds to carbanion-enolate (Fig. 1, IIa) (18). In phosphate and acetate buffers, i.e., at pH ≤ 7, 1,2-cyclohexanedione exibits a band near 260 nm corresponding to its protonated form (Fig. 1, IIb) in equilibrium with the

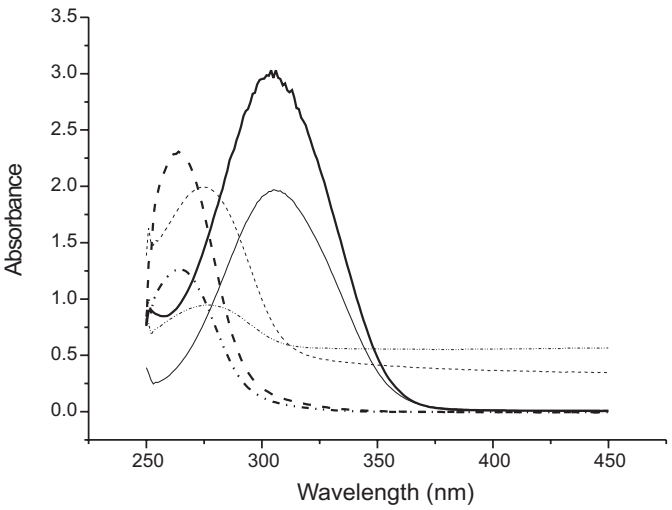
Table 2. Henry constants of catechol, 1,2-cyclohexanedione, 2-hydrocyclohexan-1-one and 1,2-cyclohexanediol in NaOH (0.01 mol/L), phosphate buffer (0.05 mol/L), and acetate buffer (0.05 mol/L).

	NaOH (±0.01)	Phosphate buffer (±0.01)	Acetate buffer (±0.01)
Catechol	0.12	0.12	7.14
1,2-Cyclohexanedione	0	0.01	0.40
2-Hydroxycyclohexan-1-one	0	0	0.40
1,2-Cyclohexanediol	—	—	0.07

Note: All values in (L g^{-1}). The Henry constants for 1,2-cyclohexanediol in sodium hydroxide and phosphate buffer could not be determined because of the detection limit of the RID detector used.

Fig. 5. UV spectra of 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one respectively in, NaOH, pH 13 (—) and (—); phosphate buffer, pH 7 (——) and (——); acetate buffer, pH 5 (–···) and (–···).



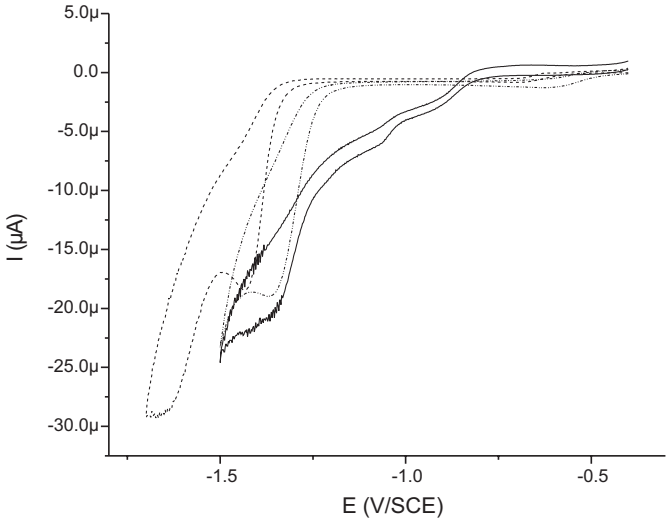


Fig. 6. Voltammetric curves of 1,2-cyclohexanedione in NaOH, pH 13 (—), phosphate buffer, pH 7 (——), and acetate buffer, pH 5 (–···). Working electrode : Hg; auxiliary electrode: Pt grid; reference electrode: Ag–AgCl. Scan rate: 100 mV s^{-1}.

enol form (Fig. 1, IIc) in solution (18). 2-Hydroxycyclohexan-1-one shows a band near 270 nm. The difference of 10 nm between the enol forms of 1,2-cyclohexanedione (Fig. 1, IIc) and 2-hydroxycyclohexan-1-one (Fig. 1, III) could be explained by the slight difference in their structure (Fig. 1).

Cyclic voltammetry

Because of the low solubility of 2-hydroxycyclohexan-1-one in the solutions (in particular in acidic media), it was not feasible to record results for this product. However, the cyclic voltammetry curves of 1,2-cyclohexanedione recorded in the different media fit well with those reported in the literature (Fig. 6) (18). In sodium hydroxide solutions, three reduction waves were observed at –0.81, –1.05, and –1.25 V/SCE. The first and second waves correspond to electron transfers onto 1,2-cyclohexanedione, whereas the third is a reduction process occurring onto the enol form (Fig. 1, IIc). In the phosphate buffer, two reduction waves were observed at –1.39 and –1.59 V/SCE, corresponding to electron transfers onto the protonated form (Fig. 1, IIb) and the enol form (Fig. 1, IIc) in solution equilibrium. In the acetate buffer, only one wave was observed at –1.30 V/SCE, as expected for the reduction of the protonated form (Fig. 1, IIb). All the reported electron transfers were irreversible.

Henry constants

The influence of the bulk chemical nature on the adsorption of the intermediates onto the catalyst surface was investigated by measuring the Henry constants (Table 2). These values, given in L g^{-1}, reflect adsorption of the target molecule on a given support for a given eluent.

It was observed that catechol is most highly adsorbed, whatever the solvent, whereas 1,2-cyclohexanediol is the least adsorbed among the products (Table 2). The adsorption propensity of 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one follows the order, acetate buffer > phosphate buffer > sodium hydroxide. The medium having the highest adsorption (acetate buffer) also shows the fastest reduction of 2-hydroxycyclohexan-1-one into 1,2-cyclohexanediol (Fig. 4, II*c*).

Discussion

It was clearly shown that the final product of the total ECH of catechol consists of two forms of 1,2-cyclohexanediol: the cis and the trans isomers. This result

© 2006 NRC Canada

indicates that the catechol is transformed into 1,2-cyclohexanedione and then is hydrogenated into 2-hydroxycyclohexan-1-one. 2-Hydroxycyclohexan-1-one gives the cis and trans isomers, regardless of the medium (Fig. 2). On the contrary, when varying the medium, changes in the transformation rate of 2-hydroxycyclohexan-1-one were observed. In sodium hydroxide, only 1,2-cyclohexanedione was detected, whereas in media with pH ≤ 7, 2-hydroxycyclohexan-1-one was detected, although 1,2-cyclohexanedione was poorly observed because of its rapid hydrogenation. These differences are explained by the pH variations. Indeed, the pK_a of 1,2-cyclohexanedione is equal to 9.7 (22), so in NaOH (1 mol/L, pH 13) the carbanion-enolate (Fig. 1, IIa) is easily formed from 1,2-cyclohexanedione and from 2-hydroxycyclohexan-1-one. However, when the ECH is conducted at pH ≤ 7, the enol (Fig. 1, IIc), with pK_a equal to 10.3 (22), is rapidly formed. Subsequently, it easily transforms into 2-hydroxycyclohexan-1-one (31), which remains the most stable molecule in solution in these pH ranges (Fig. 1). These results are supported by the UV spectroscopic data (Fig. 5), which show the highest stability for carbanion-enolate (Fig. 1, IIa) at pH 13. At pH ≤ 7, the coexistence of two species (with enol (Fig. 1, IIc) clearly identified) was observed.

The cyclic voltammetry data for 1,2-cyclohexanedione (Fig. 6) are consistent with the UV results (Fig. 5) for pH ≤ 7, as they show in these media that the reducible species are the protonated and enol intermediates (Fig. 1, IIb and IIc). It is also clear that at pH 5, the most stable species in solution is the enol form (Fig. 1, IIc). In sodium hydroxide solutions, both the neutral (Fig. 1, II) and the anionic form (Fig. 1, IIa) can be reduced. All these observations fit well with the ECH results.

The kinetics of the first step in the electrohydrogenation of catechol indicate that the process is pH-independent, as its efficiency is similar in all the media. In all cases, 35% of catechol remains in solution above 200 C. Then, the reduction mechanism kinetics are governed by the formation of the intermediates. At pH 13, the first hydrogenation step of catechol is as fast as the conversion of the intermediate 1,2-cyclohexanedione (or its stable form IIa in Fig. 1), and this intermediate is consumed as soon as it is produced to form 1,2-cyclohexanediol directly. At pH ≤ 7, the transformation of catechol into the enol form (Fig. 1, IIc), then into 2-hydroxycyclohexan-1-one seems to be faster than that of 2-hydroxycyclohexan-1-one into 1,2-cyclohexanediol, because a large quantity of this intermediate can be detected. This difference in kinetics can also be explained by the pH of the solution. Indeed, at pH ≤ 7, the most stable form of 1,2-cyclohexanedione is the enol form (Fig. 1, IIc) (or the protonated form IIb), which can react very fast to give 2-hydroxycyclohexan-1-one (31).

However, great variations are observed in the kinetics of intermediate formation between phosphate and acetate buffers. These are explained by the difference in adsorption in these media. Comparing the Henry constants (Table 2), it is remarkable that the intermediates 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one are more highly adsorbed on alumina covered by acetate than by phosphate. Their hydrogenation is also favoured in the acetate media (Fig. 4). This effect has been pointed out and further explained in recent papers (32, 33).

Conclusions

The work presented in this paper clearly shows that catechol can be hydrogenated by an electrochemical process into 1,2-cyclohexanediol, particularly at high pH values. The pH of the electrolyte plays an important role in the ECH process. It has been demonstrated that the rate of the primary conversion of catechol into 1,2-cyclohexanedione is independent of the pH of the media, although pK_{a1} of the catechol is reached in the basic medium. However, the pH of the medium plays a key role in the conversion mechanism of the identified intermediates 1,2-cyclohexanedione and 2-hydroxycyclohexan-1-one. In some cases (phosphate and acetate buffers, pH ≤ 7), it was even possible to isolate one of the intermediates (2-hydroxycyclohexan-1-one). Its formation explains the cis–trans and the (*S*-*R*) and (*R*-*R*) forms of the final product 1,2-cyclohexanediol. UV spectroscopy and cyclic voltammetry enable the determination of which species coexist in the different media. It has also been demonstrated that adsorption of the different molecules on the catalyst support depends on the nature of the bulk solution. Hydrogenation of the intermediates is fastest in acetate buffer coinciding with the medium where they adsorb most.

Dynamic NMR spectroscopy of 2,2′-dimethyl-1-picrylhydrazine in various solvents

K.C. Brown, M. El-Bermani, Y. Upadrashta, and J.A. Weil

Abstract: We have studied the ^{1}H NMR spectra of 2,2′-dimethyl-1-(2,4,6-trinitrophenyl)hydrazine at 300 and 500 MHz in seven liquid solvents, with a view to learning details of the internal conformational changes taking place as a function of temperature and of the solvent. These molecules in liquid solution occur as interconverting enantiomorphic pairs (atropisomers). Advanced techniques for obtaining the correct activation energies and pseudo-thermodynamic parameters have been utilized, and these parameters are listed and discussed. Our results point to a transformation between the pair of atropisomers that is not quite as complicated as one might have encountered in that the solvent does not affect $\Delta G^{\ddagger}$ in any major fashion. Molecular orbital calculations clarified some of the chemical shifts observed for both ^{1}H and ^{13}C. One goal of this study was to enable a detailed comparison with similar results available for 2,2′-diphenyl-1-(2,4,6-trinitrophenyl)hydrazine.

Key words: dynamic NMR, dimethylpicrylhydrazine, hindered rotation, atropisomers, activation parameters.

Résumé : A fin de préciser les détails des changements conformationnels qui se produisent en fonction de la température et du solvant, on a étudié les spectres de résonance magnétique nucléaire du proton de la 2,2′-diméthyl-1-(2,4,6-trinitrophényl)hydrazine à 300 et 500 MHz, dans sept solvants liquides. En solution dans des liquides, ces molécules existent sous la forme de paires énantiomorphes (atropisomères) qui s'interconvertissent. On a utilisé des techniques avancées afin d'obtenir les énergies correctes d'activation et les paramètres pseudo-thermodynamiques qu'on rapporte et qu'on discute. Les résultats obtenus tendent à montrer qu'il se produit une transformation entre la paire d'atropisomères qui n'est pas tout à fait aussi compliquée que celle attendue; en effet, le solvant n'affecte pas le $\Delta G^{\ddagger}$ d'une façon importante. Des calculs d'orbitales moléculaires ont permis de clarifier quelques-uns des déplacements chimiques observés, tant pour le ^{1}H que pour le ^{13}C. Un des buts de ce travail était d'établir une comparaison détaillée avec des résultats semblables disponibles pour la 2,2′-diphényl-1-(2,4,6-trinitrophényl)hydrazine.

Mots clés : RMN dynamique, diméthylpicrylhydrazine, rotation empêchée, atropisomères, paramètres d'activation.

[Traduit par la Rédaction]

Introduction

The dynamic internal motions of organic amines have been a source of interest leading to numerous NMR spectroscopic studies since the beginnings of that research field in the 1950s. For instance, see the recent review by Bain (1). In particular, various substituted diacyl and diaryl-2,4,6-trinitrophenyl (picryl) hydrazines have yielded detailed information derived from thermal NMR studies (2–8). With these molecules, the NMR spectra of the protons 3 and 5 in the picryl ring have been used as fine probes for the internal conformational changes, in various solvents (4). Similar work has also been published utilizing the ^{13}C NMR spectra of the picryl carbon nuclei (6).

The molecule of interest in the present work, 2,2′-dimethyl-1-picrylhydrazine, is denoted as DMPH-H herein. The notation emphasizes the importance of the hydrazinic proton. This hydrazine was chosen in part to investigate the effect of size and internal steric interaction reduction in going from 2,2′-diphenyl (DPPH-H) to 2,2′-dimethyl hydrazines on the internal conformation rates and barrier energies. Figure 1 depicts the molecular structures of one of the pair of atropisomers of DMPH-H, as obtained from our recent X-ray diffraction studies (9).

The unique property of the molecule of prime interest herein is that the two nitro groups located at ring positions 2 and 6 have different orientations, one out-of-plane (phenyl) and the other (close to being) in-plane because of the H-bonding between hydrazinic nitrogen atom N1 and an oxygen ion on either nearby nitro group. The two non-superimposable enantiomers (atropisomers), which interchange dynamically and can be labeled with (*R*) and (*S*) chirality at N1, have equal energies. The planes of the two nitro groups are far from being orthogonal.

The stability of each DMPH-H molecule towards transforming to its conformer is of course the result of several

Fig. 1. A stereoscopic view of the molecular structure of one of the atropisomers of DMPH-H (configuration (*R*) at N1), as obtained from X-ray diffraction data taken at 123(2) K.

factors. We believe that the presence of the hydrogen-bond between the N1 proton and an oxygen anion from the adjacent nitro group (on C2 or C6) is vital. Another important factor is the partial double-bond nature of the C1–N1 bond. This can be estimated qualitatively from the known C–N bond lengths via the empirical relation:

$$\mathrm{DB} = 100\ (D_s - D_x)/(D_s - D_d),$$

where D_s is a typical single-bond length (0.147 nm), D_d is a typical double-bond length estimated to be 0.127 nm, and D_x is the observed value of 0.134 nm (9). This yields DB ≈ 60%. The corresponding value of DB for DPPH-H is just slightly smaller, as D_x is 0.135 nm in that case (10).

More correctly, there are various possible isomers with asymmetric centres at the picryl hydrazinic nitrogen, local mirror-plane symmetry at the dimethyl nitrogen, and two situations for the out-of-plane nitro groups. Thus, 2^c isomers would exist, where c is the number of asymmetric centres in the molecule. Note that when transforming from (*R*) to (*S*) configuration at the hydrazinic nitrogen N1, other important atropisomer characteristics (the HN–O bond direction and nitro group planes) also switch.

Mathematical model of the dynamic lineshape

Previously, we have been quite successful in modeling the NMR absorption lineshapes over the whole range of temperatures in which the conformation effect displays itself, beginning from a low-temperature limit showing a sharp-lined AB quartet to a high-temperature limit of a single narrow peak (2, 4, 5, 11, 8, 12). All five limiting lines are Lorentzian in shape. The mathematical expression, $V_\tau(\nu)$, for the lineshape is a function of the mean first-order rate constant k_T, which equals the inverse of the mean lifetime τ_T, both varying with temperature. The relation, derived from density-matrix considerations (2, 13) is

$$[1] \qquad V_\tau = C\left(\frac{r_+ b_+ - s a_+}{a_+^{\,2} + b_+^{\,2}} + \frac{r_- b_- - s a_-}{a_-^{\,2} + b_-^{\,2}}\right)$$

$$[1a] \qquad a_\pm = 4\pi^2\,(\nu_o - \nu \pm J/2)^2 - (\tau^{-1} + \tau_2^{-1})^2 - \pi^2(\nu_A - \nu_B)^2 - \pi^2 J^2 + \tau^{-2}$$

$$[1b] \qquad b_\pm = 4\pi(\nu_o - \nu \pm J/2)\,(\tau^{-1} + \tau_2^{-1}) \mp 2\pi J\tau^{-1}$$

$$[1c] \qquad r_\pm = 2\pi(\nu_o - \nu \pm J)$$

$$[1d] \qquad s = 2\tau^{-1} + \tau_2^{-1}$$

Thus, the parameters required include: ν_o, τ_2, and coupling constant J. Note that the chemical shift difference $\nu_A - \nu_B$ between peaks A (picryl proton 3) and B (picryl proton 5) is proportional to the frequency ν_o of the excitation magnetic field. For the circumstances holding herein, the value of J (taken in frequency units, hertz) is small compared with $\nu_A - \nu_B$, and it affects V_τ less and less as τ (as well as T) increases. Parameter τ_2 is taken to be the inverse of πw, where w (alias $w_{1/2}$ and w_T) is the total width (in hertz) at half-height of the individual line for the limit $\tau \to \infty$, as well as of the single line occurring at $\tau = 0$. The question arises: Should the parameters $\nu_A - \nu_B$, τ_2, and J be taken as a function of temperature in fitting the spectral data to find the kinetic parameter $\tau = k^{-1}$? Unfortunately, a common assumption in the literature has been to take all three to be independent of T. We have investigated this point (see later) and found it to be important. We shall emphasize this functionality by writing the parameters as $\nu_A - \nu_B \equiv \delta_T$, and w_T. We assume that these do not depend on the mean lifetime τ of the molecular configuration.

The τ_T values obtained by lineshape fitting are used to attain tables of τ_T vs. T for each solvent. From these data, Arrhenius-type plots were constructed, from which (slope and intercept) the relevant pseudo-thermodynamic parameters $\Delta H^\ddagger$, $\Delta S^\ddagger$, and $\Delta G^\ddagger$ were estimated via equations given in ref. 5. Similarly, Eyring-type plots were made and used.

It is informative to define the coalescence of the line set to be the particular τ and also the particular T yielding the point at which the central minimum in function V_τ becomes a maximum. Note that this point depends on ν_o, so the choice of ν_o affects the feasibility of any given study (via the melting and boiling points of the solvent used) and also affects the potential accuracy of the dynamic analysis. The mean lifetime at coalescence has been shown to obey the relation

$$[2] \qquad \tau_{coa} = 4\tau_2\,[(1 + 8\sigma^2)^{1/2} - 1]^{-1}$$

where auxiliary parameter $\sigma \equiv \pi\tau_2\,\delta = \delta/w$ is dimensionless (8).

It has also been of some interest to enquire whether the area under the total absorption lineshape indeed is independent of τ_T. The actual experimental area is proportional to the concentration of molecules in the solution studied. As shown explicitly in ref. 8, contour integration of the normalized lineshape function, eq. [1] with $C = 1$, demonstrates that the area is indeed constant, independent of all the parameters,

© 2006 NRC Canada

with the value unity. Thus, the lineshapes at different temperatures can be directly compared (see later).

Experimental

The DMPH-H was prepared as described in ref. 9. Among the solvents used for the NMR studies were tetrachloromethane (carbon tetrachloride), trichloromethane-d_1 (chloroform-d_1), dichloromethane-d_2 (methylenechloride-d_2), toluene-d_8, ethanenitrile-d_3 (acetonitrile-d_1), 2-propanone-d_6 (acetone-d_6), and tetrahydrofuran-d_8 as well as *N*,*N*-dimethylformamide-d_7. These were used partly to reach down to ~200 K and also because they differ appreciably in H-bonding capability. Tetramethylsilane (TMS) was used as a line-position standard.

The ^{1}H NMR experiments were carried out on a Bruker AMX-300 spectrometer operating at 300.13 MHz and a Bruker Avance DRX System (located at the Saskatchewan Structural Sciences Centre on the University of Saskatchewan campus) working at 500.13 MHz. Some ^{13}C NMR experiments were also performed using the Avance machine. Our ^{1}H spin-lattice relaxation time (τ_1) measurements were carried out with the usual inversion-recovery pulse scheme (14), for DMPH-H at selected temperatures and in two solvents.

A computer program incorporating the above theoretical results (see eq. [1]) and others has been written by us and is called DYNAMAP. This program, written in the Maple V (Release 5) language, simulates the magnetic resonance spectra arising from a two-spin system (denoted by AB in NMR language). The program is equally applicable to frequency-swept and magnetic-field-swept spectra. DYNAMAP is available upon request, from us. The spectral scanning variable is the ordinary frequency ν, rather than the angular frequency $2\pi\nu$ that is sometimes used. A well-known computer program that can accomplish spectral simulation of the Master equation is available, and it is called DNMR (Windows version: WinDNMR) (5, 15). The results from DYNAMAP are consistent with it.

Much of the matching of the experimental and simulated spectra was done visually, using a Porta-Trace Model 1012–1 light-box (Gagne Inc., Johnson City, NY, USA) to superimpose and best-fit the pairs of spectra. This turned out to be sufficiently accurate and the most convenient method.

Fittings of the chemical-shift, linewidth, and rate-constant thermal data were accomplished by using the commercial scientific graphing program OriginLab, Version 7.5 (16) (see Figs. 2*a,* 3–5). This yields some indication of the data quality, for instance, χ (goodness of fit) and R (multiple correlation coefficient).

Some modest modeling calculations applying molecular orbital techniques, using Hartree–Fock bases performing geometry optimizations at the 6-311G* level, were carried out with the commercial program Spartan′04, Quantum Mechanics Module, Release 123 (17).

The various statistical curve fittings and error analyses performed were done in accordance with the treatise by Bevington (18), which also defines the symbols used.

NMR parameters

Of course, the computed line positions depend on the level of sophistication of the theory programmed. We found that the program Spartan yielded mediocre chemical-shift data when we utilized inadequate basis sets. A case in point is restricted Hartree–Fock calculations using basis 3-21G* (single-point) on a trial basis and following with 6-311G* (geometry-optimized) predictions. The latter yielded results far closer to our observed ^{1}H NMR data and thus proved to be quite informative, as discussed later in this paper. No J splittings were included.

Methyl protons

The six lines occurred within the chemical-shift range 2.2–2.9 ppm, relative to 0 for TMS. One methyl proton was predicted to be sufficiently close to an oxygen (see Fig. 1) so as to be shifted away from the other methyls and from TMS. Because we observed a single methyl peak, we concluded that in reality both methyl groups are rotating sufficiently to yield only a single line, even at our lower temperatures, experimentally at 2.10 ppm in acetonitrile-d_3 and 2.19 in chloroform-d_1. The average predicted by Spartan was 2.37 ppm.

Hydrazinic proton

The predicted location for the single peak was 7.23 ppm, while our data yielded 9.0 ppm for both of the previously mentioned solvents. Thus, less shielding should have been predicted by the theory.

Picryl protons

The chemical shift difference for the two picryl protons (labeled 3 and 5 in Fig. 1) was predicted to be 10.265 – 9.278 = 0.987 ppm, with an average center at 9.7725 ppm. Experimental work gave differences and centers at 0.66 and 8.90 ppm, respectively, for acetonitrile and 0.75 and 8.85 ppm for chloroform. The agreement is sufficiently good that the identification of proton 3 (peak A) as being adjacent to (between) two nitro groups "in-plane" with the picryl ring and proton 5 (peak B) as being adjacent to the one out-of-plane nitro group is meaningful (see Fig. 1). This identification was previously suggested by us (4). We note then that the existence of the chemical-shift difference is very successfully predicted by molecular orbital (MO) theory.

Turning now to the ^{13}C NMR spectra calculated via Spartan, we find that a pleasing consistency with experiment values is also attained. The shifts, relative to TMS, are found to be at δ 157.35, 129.39, 141.46, 131.96, 142.46, and 140.00 ppm, and they can be attributed to the ring carbons C (i = 1, …, 6; see Fig. 1). Two methyl peaks are predicted to occur at 42.87 and 41.62 ppm. These data are to be compared with the measured values.

We plan for further results, including energetics and molecular geometric configurations, obtained from Spartan and other programs to appear in a future publication, incorporating results both for several relevant hydrazines and their corresponding hydrazyl free radicals.

From the experimental picryl ^{1}H NMR spectra taken at temperatures sufficiently low that intramolecular motions are too slow to manifest themselves, one can arrive at the picryl chemical shifts δ 3–5 ppm, proton coupling constants J 3–5 Hz, and individual linewidths (full widths at half-height) w, using standard techniques, including lineshape fitting of the AB quartet. Such shift data are to be found in Table 1 of ref. 7

© 2006 NRC Canada

for the various solvents at one temperature (300 K).[2] Careful investigation has disclosed that δ 3–5 ppm and w depend quite appreciably on sample temperature and on the solvent, as discussed later.

Long-range coupling between the N–H and one picryl proton

The presence of a very small long-range (five-bond) coupling between the N–H and one (peak B) of the picryl protons is discernible (4) in some solvents (e.g., acetone) at low temperatures, but that did not appear to interfere with our dynamic measurements.

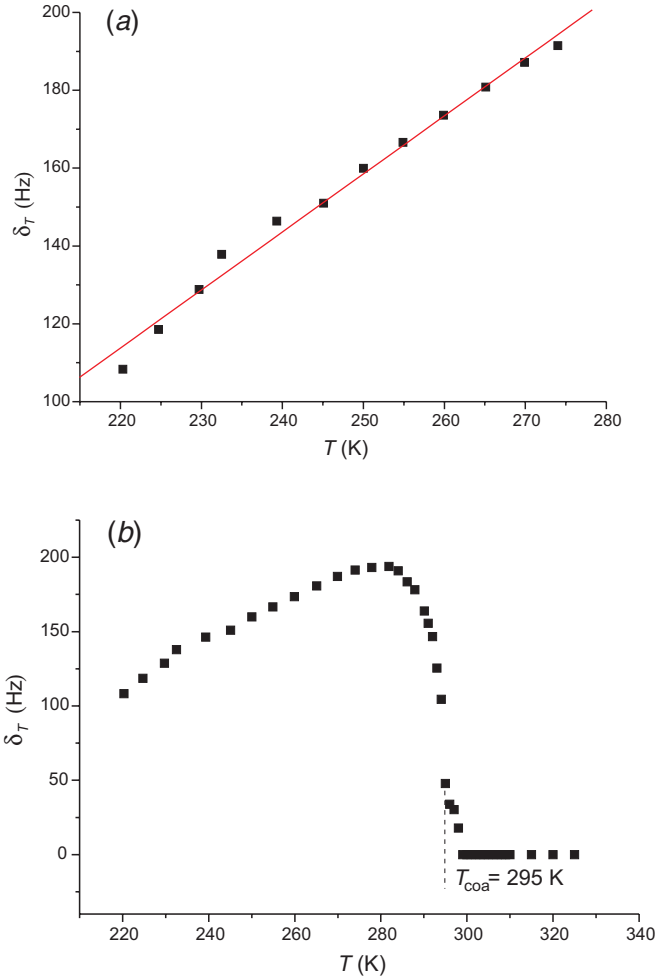
Measurements of τ_1

The inversion-recovery results show that the τ_1 values at lower temperatures (~240 K) are appreciably longer for the picryl protons than for the methyl protons of DMPH-H. We assume that this is explainable via the considerable rotational motion of the methyls even at the lowest temperatures used.

We discerned no dramatic shortening of the τ_1 times away from their typical (order of magnitude is 1–10 s) values for the picryl protons as the temperature was raised towards and through the coalescence region.

^{13}C NMR results

At a sufficiently low temperature (216 K) and in $CDCl_3$, DMPH-H molecules show six sharp picryl carbon peaks that can be attributed to C1–C6 at 141.90, 139.42, 127.02, 134.82, 126.20, and 131.62 ppm, respectively, as well as a single CH_3 peak at 48.05 ppm from TMS. At a higher T (320 K), C1 occurs at 141.42 ppm, C2 and C6 are broadened out of sight, C3 and C5 merge to give a sharp peak at 125.73 ppm, C4 at 135.84 ppm, and CH_3 at 48.68 ppm. These data are consistent with those reported for the analogous molecule diphenylpicrylhydrazine (DPPH-H) (19). At an intermediate temperature (e.g., 296 K), one finds C2 and C6 as a broad line at ~132 ppm and C3 and C5 as a broad doublet (close to coalescing) centered at 125.64 ppm. Modeling the latter lineshape using the previously mentioned formalism yields results consistent with the kinetic data derived from the ^{1}H measurements.



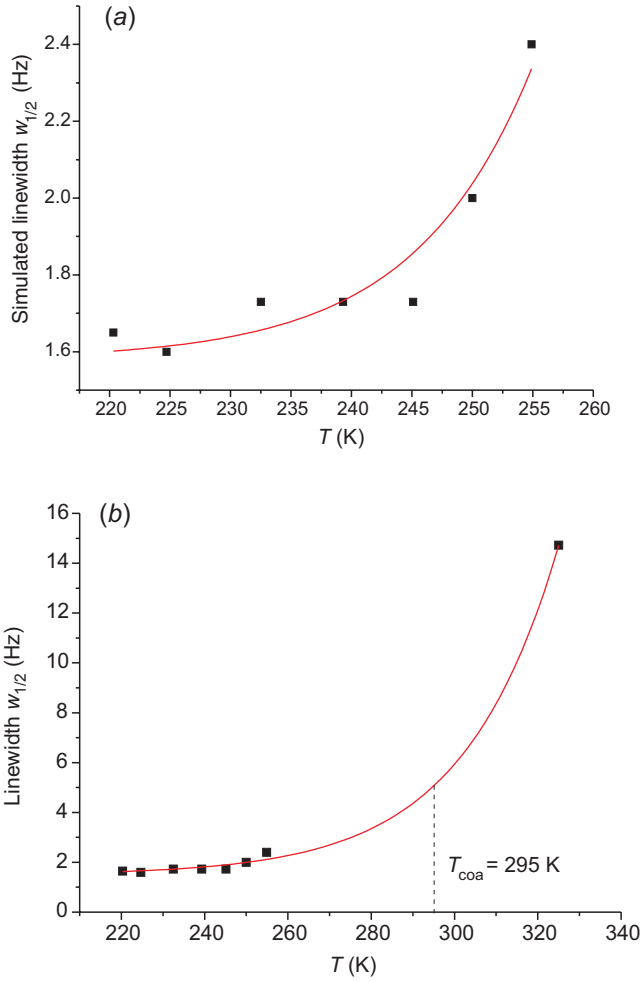
Thermal properties of the parameters

As previously discussed, parameters $\nu_A - \nu_B = \delta_T$ and $w_T = (\pi\ \tau_{2T})^{-1}$ depend on the temperature. The possible dependence of J on T is of no appreciable import for our work and will not be considered herein. We note recent papers (11, 12), other than the present one, which report tackling evaluation of such thermal effects in DNMR.

The picryl chemical-shift difference

We have prepared for the demands of the present work by studying the ^{1}H chemical shift difference δ_T, already discussed in a previous publication (7), as a function of solvent, using temperature ranges well below T_{coa}. We found a substantial dependence on temperature, which allowed extrapolation into the dynamic region for use in accurately evaluating the kinetic parameters obtained by fitting (e.g., see Fig. 2*b*, which shows the course of the AB splitting collapse with increasing temperature, and Fig. 2*a*, which shows only the portion of these data kept for shift extrapolation). Furthermore, the dependence of δ_T was found to correlate well with the Kamlet–Taft solvolytic parameter β, which measures the proton-acceptor basicity of the solvent. The slopes are positive for some solvents and negative for others (see ref. 7, Table 1). Thus, the shift parameter δ_T is markedly affected by the hydrogen-bonding capabilities of the solvent molecules.

Fig. 2. Temperature-dependent nominal chemical-shift difference between picryl proton lines A and B. The NMR spectra were measured at 500.13 MHz for DMPH-H in 2-propanone-d_6. (*a*) No. of data points shown is 12 (T range is limited to 220–280 K). (*b*) No. of data points is 42. Linear regression parameters: slope = 1.49 ± 0.05 Hz/K, intercept $\delta_{T=0}$ = –214 ± 13 Hz, SD = ±3.1 Hz, r = 0.9940.



The inherent picryl-peak linewidths

The thermal variation of w_T has been estimated by lineshape fitting (using the program DYNAMAP) at a limited set of lowest liquid-phase temperatures (see Figs. 3*a* and 3*b*) as well as by measuring the linewidths (the full

[2] Note the difference in definition for the shift-difference symbol δ.

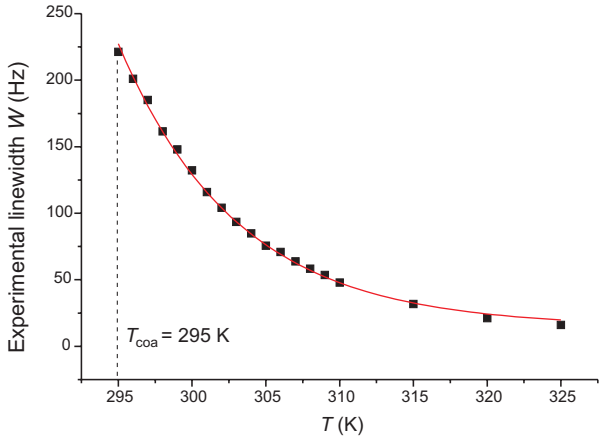
Fig. 3. Temperature-dependent linewidth curves $w_{1/2}$ (Hz). The NMR spectra were measured at 500.13 MHz for DMPH-H in 2-propanone-d_6. The curve fitting is to a first-degree exponential growth equation $w = w_e + w_f \exp(T/T_e)$. (*a*) No. of data points is 7, $w_e = 1.580 \pm 0.081$ Hz, $w_f = (3.320 \pm 31.29)10^{-12}$ Hz, $T_e = 9.75 \pm 3.50$ K, $\chi^2 = 0.0074$, $R^2 = 0.9370$. (*b*) High-T limit value included. No. of data points is 8, $w_e = 1.49 \pm 0.17$ Hz, $w_f = (9.14 \pm 16.8)10^{-6}$ Hz, $T_e = 22.9 \pm 3.0$ K, $\chi^2 = 0.0240$, $R^2 = 0.9992$.



widths $W_T = \Delta\nu_{1/2}$ at half-height of the coalesced line) as a function of T to obtain the limiting high-T value W_∞ of widths W_T. As the mean lifetime τ moves towards zero, the limit W_∞ turns out to be just the (fixed) input parameter w.

In fact, the actual thermal data for W can be nicely represented by a descending exponential function, as shown in Fig. 4. One can derive an analytic functional expression obtained from eq. [1] for $W = \Delta\nu_{1/2}$ (see ref. 8 and eq. [4]).

The values of w_T actually used for the dynamic analysis were taken from a non-linear plot connecting the low-T values of w_T and limiting high-T value W_∞. Typically, w_T increased by a factor of ~5 with increasing temperature in the ranges of interest.

Fig. 4. Experimental temperature-dependent linewidth W (Hz). The NMR spectra were measured at 500.13 MHz for DMPH-H in 2-propanone-d_6. The curve fitting is to a first-degree exponential decay equation $W = W_\infty + W_F \exp(-T/T_E)$. No. of data points is 19. Parameters: $W_\infty = 14.72 \pm 2.19$ Hz, $W_F = (1.61 \pm 1.67)10^{18}$ Hz, $T_E = 8.07 \pm 0.23$ K, $\chi^2 = 7.2682$, $R^2 = 0.9983$.

Some typical values of widths w, W, and W_∞ are to be found in Tables 1 and 2 for the various solvents employed. Figures 3–4 give visual indications.

Sensitivity considerations

All the points given in Tables 3*a*–3*b* have been given equal weighting factors in arriving at the slopes and intercepts of the Arrhenius (Fig. 5) and Eyring plots. This is routine in the literature, using the equation

$$[3] \qquad \ln(k_T) = \ln(k_\infty) - \Delta E/(RT)$$

where the first-order rate constant is $k_T = 1/\tau_T$, and ΔE is the molar activation energy.

However, it is true that the sensitivity of the points to the value of τ_T derived at each temperature varies greatly, with maximum sensitivity in the region where line coalescence occurs. We have herein attempted to take this consideration into account to discover how important this might be.[3] Ideally, one would wish to utilize expressions for the first derivatives $dV_\tau/d\tau$ at each temperature for this purpose.

In Arrhenius and Eyring fittings, it is tempting to try to obtain useful weighting factors given by a normalized Gaussian distribution function

$$[4] \qquad \Sigma \equiv \exp\{-[(T^{-1} - T_{coa}^{-1})/T_o^{-1}]^2\}$$

centered at the coalescence temperature (see the discussion and Fig. 2 in ref. 8). However, the choice of the appropriate drop-off factor T_o is not obvious.

[3] Perhaps another tractable way to accomplish this is to computer-generate lineshapes using a set of appropriate input parameters, and do so at a convenient set of values of $k_T = 1/\tau_T$ chosen over the fitting range. Then, at each k_T value, increment and also decrement by some suitably small value δ_k, and find the difference in fit by subtracting the lineshape at k from that at $\pm\delta_k$. Such curve needs to be integrated somehow (remove negative contributions by shifting and taking the magnitude, …) to produce a number. Average these two numbers to yield a non-negative number Δ. This is a measure of the sensitivity but needs to be normalized by dividing it by the largest $= \Delta_{max}$ of the set to yield the desired sensitivity factors $\Sigma \equiv \Delta/\Delta_{max}$.

[f]Incomplete data since T_{coa} occurs above this solvent's boiling point for 500 MHz ^{1}H NMR.
[g]These spectra have been measured at 300.13 MHz.

We have constructed and tried out an intuitively derived and thus empirical relation

$$[5] \qquad T_o^{-1} = \left\{3n/[10(\ln(2))^{1/2}(n-1)]\right\}(T_1^{-1} - T_n^{-1}),$$

where $2([\ln(2)]^{1/2}T_o^{-1}$ is the full width at half height of the Gaussian (eq. [4]), and n is the total number of points used, e.g., in the Arrhenius plot of $\ln(k_T)$ vs. T^{-1} (Fig. 5). The Eyring plot of $\ln(k_T/T)$ vs. T^{-1} looks much the same as Fig. 5. Quantities T_1 and T_n are the temperatures of the first and last points used ($T_1 < T_n$).

Arrhenius and Eyring activation energies, and pseudo-thermodynamic parameters

The rate constants fitted (20) to the quite general semi-empirical relation

$$[6a] \qquad k_T \approx k_b\, h^{-1}T^\alpha \exp[-\Delta G^\ddagger(RT)^{-1}]$$

$$[6b] \qquad \approx k_b\, h^{-1}T^\alpha \exp(\Delta S^\ddagger R^{-1}) \exp[(-\Delta H^\ddagger (RT)^{-1}]$$

where k_b and h are the Boltzmann and Planck constants, and α is a small ($\alpha < 3$) non-negative number. In the simplified version termed the Arrhenius model,

$$[6c] \qquad k_T = k_\infty \exp[-\Delta E (RT)^{-1}]$$

where α is taken to be unity, and $\Delta E = \Delta H^\ddagger - RT$ (see ref. 5).

It is evident from Table 3*a* that the activation energy ΔE_{Ar} depends on the Kamlet–Taft β parameter, i.e., it is quite appreciably affected by hydrogen-bonding between the DMPH-H molecules and the solvent molecules. Similarly, the energy quantities $\Delta H^\ddagger$ and $T\Delta S^\ddagger$ depend on β in a linear fashion, as may be seen in Fig. 6 and Table 3*a*. These energies can be derived from our data by standard techniques (5).

We have, for good measure, also carried out analysis of some of our data using Eyring plots, $\ln(k_T/T)$ vs. $1/T$, as was done, for instance, by Olsen et al. (11). As seen from Tables 2 and 3, all the resulting activation energies ΔE_{Ey} (Table 3*b*) turn out to be approximately identical to their Arrhenius equivalents with much the same dependence on β. The Gibbs free activation energies $\Delta G_{Ey}^\ddagger$ too are very close to the $\Delta G_{Ar}^\ddagger$ values and independent of β.

Enthalpy–entropy cancellation

Previously, we have already observed that the Gibbs isothermal energy change

$$[7] \qquad \Delta G^\ddagger = \Delta H^\ddagger - T\Delta S^\ddagger$$

for the kinetic process is the most reliable among these three pseudo-thermodynamic quantities (5, 11, 13). Furthermore, it is close to constant for the picrylhydrazines so far investigated in various solvents. On the other hand, the enthalpy change $\Delta H^\ddagger$ and the entropy change $\Delta S^\ddagger$ vary appreciably with β (see Fig. 6) but in the same fashion. Thus, our systems appear to display cancellations of some of the active internal and environmental parameters, and thus, the errors in these, i.e., $\Delta H^\ddagger$ and $T\Delta S^\ddagger$ seem to be proportional to these parameters with virtually identical coefficients. Such "isokinetic" effects are well-known and have been previously detailed in the literature (21–23).

Fig. 5. Arrhenius plot of $\ln(k_T)$ against T^{-1} (K^{-1}). The NMR spectra were measured at 500.13 MHz for DMPH-H in 2-propanone-d_6. No. of data points is 32. Parameters: slope m = –9.13 ± 0.10 K, intercept b = 37.23 ± 0.32, SD = ±0.09, r = –0.9983. The analogous Eyring plot (not shown) of $\ln(k_T/T)$) against T^{-1} has linear-fitting parameters: slope $-\Delta E_{Ar}/R$ = –9.41 ± 0.10 K, intercept $\ln(k_\infty)$ = 36.96 ± 0.34, SD = ±0.09, r = –0.9983.

In summary, because of the cancellation of terms as described above, the Gibbs free energy does not vary appreciably with the hydrogen-bonding capabilities of the solvents used, as is evident in Fig. 7 and Tables 3*a* and 3*b*.

Discussion

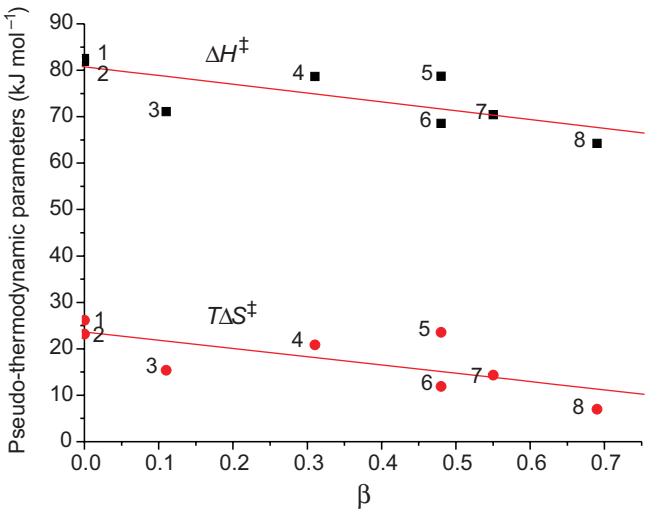
The data-fitting performed to obtain the thermal dependence of the parameters (chemical shift difference δ and linewidth w) seem adequate for our purposes. However, we note that some of the resulting parameters are not all that well characterized (see the captions for Figs. 2 and 3).

We wished to compare the values of ΔE_{Ar} and the other pseudo-thermodynamic energies for the two cases of fittings of the lineshapes done: (*i*) keeping the values of δ and w fixed at their low-T values, as compared with (*ii*) using δ and w values evaluated at each temperature. We used the data taken for DMPH-H in acetone-d_6 (32 points) for this purpose and obtained the Arrhenius results set out in Table 3*a*. A substantial increase (3.4%) in the activation energy was obtained. Thus, our efforts to use thermally varying input parameters appear worthwhile, yielding more accurate ΔE_{Ar} values (Table 3*a*).

Using the weighting factors derived as previously discussed (see eqs. [4] and [5]), we also did linear fittings (OriginLab) incorporating these. For the acetone-d_6 data cited above, we found ΔE_{Ar} = 76.58 kJ mol^{-1}, with the use of T_o = 386.7 K, as compared with 75.91 kJ mol^{-1} unweighted. This constitutes a 0.9% increase. With the DMF-d_7 data, a 4.4 % increase was obtained. The complete set of results is available in Table 4.

We note a couple of aspects of the data recorded in Table 4: (*i*) the values of ΔE_{Ar} are increased appreciably by applying the weighting-factor scheme, as is $\Delta H^{\ddagger}$ (of course) and $T\Delta S_{Ar}{}^{\ddagger}$, by equal amounts, and (*ii*) thus, $\Delta G_{Ar}{}^{\ddagger}$ is not affected by weighting the Arrhenius points (cancellation effect). However, it is lowered by ~1.5 kJ mol^{-1} (2.8%, acetone data) when the temperature dependence of δ and w are not neglected.

Fig. 6. Plot of the Arrhenius molar enthalpy change $\Delta H^{\ddagger}$ and the entropy parameter $T\Delta S^{\ddagger}$ against the Kamlet–Taft parameters β of the solvents at standard temperature T_o = 298.15 K. Numbering of the data points is according to the solvent order in Tables 2 and 3.



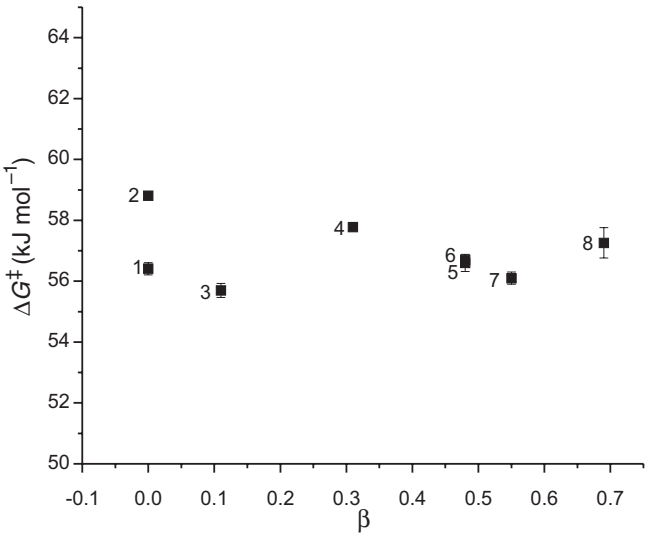


Fig. 7. Plot of the Arrhenius molar Gibbs free energy change $\Delta G^{\ddagger}$ against the Kamlet–Taft parameters β of the solvents at standard temperature T_o = 298.15 K. Numbering of the data points is according to the solvent order in Tables 2 and 3.

The choice of ν_o optimal for dynamic studies is sometimes affected by the physical properties of the solvent to be studied. Thus, CCl_2D_2 boils at such a relatively low temperature that T_{coa} at 500 MHz is above T_{boil} (see Table 4). Hence, increasing the chemical-shift difference δ by going to a higher ν_o is not always beneficial.

Judging from the single example we have, ^{1}H NMR spectra of DMPH-H in acetone-d_6 taken at 300 and 500 MHz, the energies $\Delta H^{\ddagger}$ and $T\Delta S^{\ddagger}$ may contain frequency-

dependent contributions that cancel (see Tables 3*a* and 3*b*). This point should perhaps be investigated further.

Among the solvents used, one (DMF) itself undergoes conformerization between two atropisomers, as is discernible via ^{1}H NMR (13). It would be amusing to know whether the solvent molecules surrounding any given solute molecule transfer configurations in concert with the transformation of the latter.

Comparisons of DPPH-H and DMPH-H

Comparison with the hydrazine DPPH-H (4) shows clearly that $\Delta G_{Ar}^{\ddagger}$ does depend on the Kamlet–Taft β, whereas this is not the case with DMPH-H. Thus, the latter appears to be less effectively hydrogen-bonded to solvents. For the three solvents (CCl_4, CH_3CN, and CH_3COCH_3) measured for both solutes, $\Delta G_{Ar}^{\ddagger}$ is 9 kJ mol^{-1} lower in case of CCl_4 but 6–7 kJ mol^{-1} greater for the other two (CH_3-containing) solvents.

DMPH-H has been reported to be quite inert and not to yield the corresponding (unknown) hydrazyl free radical, DMPH$^{\bullet}$ on providing strong oxidation conditions (24). This is in contradistinction to the well-known result of easily oxidizing 2,2′-diphenyl-1-picrylhydrazine DPPH-H to yield the ubiquitous stable free radical DPPH$^{\bullet}$. Thus, the presence of the aromatic groups and the resulting electron delocalization appears to be essential for stability of the hydrazyl species. We can now confirm the previously mentioned situation and plan to do further work in this area.

One simple way to understand this result qualitatively is to consider the unpaired electron to be confined in a "box". The smaller the box, the higher the energy.

Summary

In this work, we have taken into account, as best as we could, the thermal behavior of the parameters entering into the analysis throughout the dynamic region. Thus, we have used different values of δ_T and W_T at each temperature at which lineshape simulation using eq. [1] was carried out. This approach should become universal in the area of dynamic NMR measurements. Similarly, giving weighting factors to the various points utilized for an Arrhenius plot seems to be uncommon. We can summarize by stating that both the two improvements cited appear to be of modest import, amounting to 1–5 kJ mol^{-1} in the activation-energy parameters.

Acknowledgments

We thank the University of Saskatchewan, including the Saskatchewan Structural Sciences Centre, for the use of its facilities, and we are grateful to Professor J.W. Quail for his assistance in producing Fig. 1. We also wish to thank D.F. Howarth and R.J. Clark for their help with parts of this project. Effect of *N*-cetyl-*N*,*N*,*N*-trimethylammonium bromide and orthophenylenediamine on the corrosion inhibition of carbon steel in 1 mol/L HCl

B. Ramesh Babu, A.K. Parande, and P.L. Ramasamy

Abstract: Inhibition studies of *N*-cetyl-*N*,*N*,*N*-trimethylammonium bromide (CTAB) and orthophenylenediamine (OPD) have shown that they were effective inhibitors of corrosion of carbon steel in HCl. The inhibitive behaviour of OPD with CTAB on the corrosion of carbon steel in 1 mol/L HCl was studied by gravimetric weight loss, potentiodynamic polarization, and electrochemical impedance measurements. Inhibition efficiency (IE) was found to increase with the increase in concentration of CTAB and it was also found that CTAB was effective only when used above a concentration of 100 mmol/L. Furthermore, the addition of 20 mmol/L of OPD to CTAB slightly increased the IE. The adsorption of these compounds on carbon steel in 1 mol/L HCl obeyed Langmuir's adsorption isotherm. These inhibitors reduced the permeation current. The IE was observed as high for 200 mmol/L of CTAB with 20 mmol/L of OPD in all the techniques studied. Scanning electron microscopy clearly showed that the inhibition was due to a polymolecular film formed by the physical adsorption of the inhibitor on the metal surface.

Key words: carbon steel, corrosion, inhibitors, impedance, potentiodynamic polarization.

Résumé : Des études d'inhibition ont permis de montrer que le bromure de *N*-cétyl-*N*,*N*,*N*-triméthylammonium (BCTA) et de l'orthophénylènediamine (OPD) sont des inhibiteurs efficaces de corrosion de l'acier au carbone dans l'acide chlorhydrique. On a étudié le comportement inhibiteur de l'OPD en présence de BCTA sur l'inhibition de la corrosion de l'acier au carbone dans de l'acide chlorhydrique 1 mol/L à l'aide de mesures gravimétrique, galvanostatique et d'impédance. On a trouvé que l'efficacité de l'inhibition (EI) augmente avec une augmentation de la concentration du BCTA et on a aussi observé que le BCTA n'est efficace que lorsque sa concentration est supérieure à 100 mmol/L. De plus, l'addition de 20 mmol/L d'OPD au BCTA augmente aussi l'efficacité de l'inhibition. L'adsorption de ces composés sur de l'acier au carbone dans de l'acide chlorhydrique 1 mol/L obéit à une isotherme d'adsorption de Langmuir. Ces inhibiteurs réduisent le courant de perméation. Dans toutes les techniques étudiées, on a observé une efficacité d'inhibition jusqu'à des valeurs de 200 mmol/L de BCTA avec 20 mmol/L d'OPD. La microscopie électronique à balayage a montré clairement que l'inhibition est due à un film polymoléculaire qui se forme par une adsorption physique de l'inhibiteur sur la surface métallique.

Mots clés : acier au carbone, corrosion, inhibiteurs, impédance, galvanostatique, polarisation.

Introduction

Corrosion of steel in acidic solutions has practical importance (1–7). For example, corrosion is of significant concern in the acid pickling of iron and steel, chemical cleaning of scale in metallurgy and other industries, and in oil recovery and other petrochemical processes. One of the most important means of corrosion protection is the use of organic inhibitors (8–15). Surfactants are used as corrosion inhibitors. These surfactants can be used either alone or in mixtures with other compounds. *N*-Cetyl-*N*,*N*,*N*-trimethylammonium bromide (CTAB), a cationic surfactant, has been used in controlling the corrosion of carbon steel in an aqueous solution containing chlorine ions (16). Orthophenylenediamine (OPD), a nonionic surfactant, has been used as inhibitor for the corrosion of carbon steel in HCl (17). Several studies of surfactant mixtures focused on synergism in both micelle and monolayer formation at the air–water interface (18, 19). Surfactants have been used as corrosion inhibitors either alone (20) or in combination with other compounds to improve their performance as inhibitors (21, 22). CTAB is a cationic surfactant, whereas OPD is a nonionic surfactant. The aim of the present investigation was to study the combined effect of cationic (CTAB) and nonionic (OPD) surfactants on the corrosion inhibition of carbon steel in 1 mol/L HCl. The present work was carried out to investigate the following: (*i*) the inhibition effect of CTAB alone in the corrosion of carbon steel in 1 mol/L HCl and (*ii*) the combined

inhibition effect of OPD with CTAB in the corrosion of carbon steel in 1 mol/L HCl. The results are reported and discussed.

Experimental

Materials used

Carbon steel specimens

The chemical composition (wt%) of the carbon steel used in these tests was C 0.07%, P 0.08%, Mn 0.034%, S 0.04%, with the remainder being iron. Test specimens of size 5 cm × 3 cm × 0.2 cm were used for gravimetric studies. The specimens, embedded in epoxy resins with an exposed area of 1 cm^2 were used for potentiodynamic and impedance measurements. The specimens were polished with different grades of emery paper and degreased with trichloroethylene before use.

Reagents

AR chemicals of HCl, orthophynylenediamine, and *N*-cetyl-*N*,*N*,*N*-trimethyl ammonium bromide were used for this study. Table 1 shows the structures of CTAB and OPD.

Techniques adopted

Gravimetric test

The weighed specimens were exposed in 150 mL of 1 mol/L HCl containing different concentrations of inhibitor for a period of 3 days. After 3 days of exposure, the specimens were removed, washed, dried, and weighed. The experiments were conducted at 30 ± 1 °C using a temperature control bath (Siskin Juloba, India). The inhibition efficiency (IE) was calculated using the formula,

$$[1] \qquad IE = 100\ [1 - W_2 / W_1]\%$$

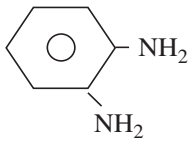
where W_1 = the initial weight of the specimen and W_2 = final weight of the specimen.

Potentiodynamic polarization

A three-electrode cell assembly, consisting of a carbon steel electrode with an exposed area of 1 cm^2 as working electrode, a saturated calomel electrode as reference electrode, and a platinum foil as counter electrode, was used for potentiodynamic polarization studies. The scan range was –650 to –400 mV; the scan rate was 1 mV sec^{-1} and an Electrochemical Analyzer (IM6) was used to generate the scans. From the polarization curves, b_a, b_c, E_{corr}, and I_{corr} values were calculated for carbon steel in uninhibited and inhibited hydrochloric acid. The corrosion IE was calculated using the equation,

$$[2] \qquad IE = 100\ [1 - I_{corr(W)} / I_{corr(WO)}]\%$$

where $I_{corr\ (W)}$ = corrosion current in the presence of inhibitor and $I_{corr\ (WO)}$ = corrosion current without inhibitor.



Electrochemical impedance spectroscopy

Electrochemical impedance spectroscopy (EIS) measurements were carried out using the three-electrode cell assembly, as mentioned in polarization studies, after 15 min of immersion. Experiments were carried out using Solartron SI 1287 in the frequency range of 60 KHz to 10 MHz. The applied sinusoidal wave voltage was 5 mV. Nyquist plots were drawn from these results. From the plots, values of polarization resistance, R_p, were calculated. After substituting R_p values in the Stern–Geary equation, the corrosion rate was calculated using,

$$[3] \qquad I_{corr} = \frac{b_a b_c}{2.303\,(b_a + b_c)} \left(1/R_p \right)$$

The IE was calculated using the value of I_{corr} for various systems studied.

Table 1. Structures of CTAB and OPD.

Compound	Structure
N-Cetyl-*N*,*N*,*N*-trimethyl ammonium bromide	$CH_3(CH_2)_{15}N^+ (CH_3)_3\ Br$
Orthophenylenediamine (OPD)	

Hydrogen permeation studies

The hydrogen permeation studies were carried out using a Devanathan and Stachurski two-compartment cell as described elsewhere (23). Permeation current was obtained for a concentration of 1 mol/L HCl, 1 mol/L HCl with 200 mmol/L CTAB, and 200 mmol/L CTAB and 20 mmol/L OPD in 1 mol/L HCl.

Scanning electron microscopy

Micrographs were made of carbon steel specimens using an Hitachi Model-S-3000 H. Carbon steel specimens of size 1 cm^2 were dipped in 1 mol/L HCl with and without inhibitors for surface analysis.

Results and discussion

Mechanism of corrosion inhibition

It has been hypothesized that the mechanism of iron dissolution occurs in two consecutive steps and involves the participation of a species $(FeOH)_{ads}$ as shown here,

$$[4] \qquad Fe + H_2O \leftrightarrow (FeOH)_{ads} + H^+ + e$$

$$[5] \qquad Fe(OH)_{ads} \xrightarrow{rds} (FeOH)^+ + e$$

where rds refers to rate determining step, and

$$[6] \qquad (FeOH)^+ + H^+ \rightarrow Fe^{2+} + H_2O$$

The dissolution of iron in HCl solution has been studied extensively. One of the mechanisms of breakdown of passivity involves the diffusion of Cl^- through the protective oxide layer. The reaction sequence is supposed to involve the following steps,

$$[7] \qquad Fe + Cl^- + H_2O \leftrightarrow (FeClOH)^-_{ads} + H^+ + e^-$$

$$[8] \qquad (FeClOH)^-_{ads} \xrightarrow{rds} FeClOH + e$$

$$[9] \qquad FeClOH + H^+ \leftrightarrow Fe^{2+} + Cl^- + H_2O$$

© 2006 NRC Canada

where $(FeClOH)^{-}_{ads}$ was treated as per Langmuir's isotherm.

It is well-known that the passive film consists of hydrated iron oxides, $Fe_2O_3 \cdot H_2O$. When the aggressive Cl^- anion attacks the passive film, the Cl^- ions tend to diffuse towards the metal (they meet with bound water molecules, which are the cementing elements of the passive layer) and form chloride-containing iron complexes, which in turn increase the dissolution rate. It has also been confirmed that the presence of chlorides accelerates the formation of corrosion products because of the corresponding cyclic processes of rusting.

In the case of chlorides, the process (Fig. 1) takes place in three phases, reactions [10–12], with the net formation of ferric hydroxide iron with water and oxygen in the presence of acid.

[10] $FeCl_3 + 3H_2O \rightarrow Fe(OH)_3 + 3HCl$

[11] $Fe + 2HCl \rightarrow FeCl_2 + H_2$

[12] $FeCl_2 + HCl + \frac{1}{4}O_2 \rightarrow FeCl_3 + \frac{1}{2}H_2O$

The circle of ongoing corrosion is closed, as the ferric chloride consumed in reaction [10] reappears in reaction [12]. The net reaction, which is the sum of reactions [10–12] is

[13] $Fe + 2.5H_2O + 0.25O_2 \rightarrow Fe(OH)_3 + H_2$

Inhibition efficiency by gravimetric method

The IE calculated for 50, 100, 150, 200, and 250 mmol/L concentrations of CTAB alone in 1 mol/L HCl and the addition of 20 mmol/L OPD with different concentrations of CTAB were reported in Table 2. From the table, it is seen that the IE increases from 50 to 200 mmol/L of CTAB alone and similarly from 50 to 200 mmol/L of CTAB with 20 mmol/L of OPD. The optimum concentration of CTAB and OPD was found to be 200 mmol/L. A further increase in inhibitor does not show any increase in the IE, and there is a decrease in IE at 250 mmol/L of CTAB both alone and with OPD.

Inhibition efficiency by potentiodynamic polarization

Figures 2 and 3 show the polarization curves for carbon steel in 1 mol/L HCl with and without inhibitors. The corrosion parameters such as b_a, b_c, E_{corr}, I_{corr}, and IE collected for 1 mol/L HCl containing different concentrations of CTAB with and without OPD were reported in Table 3. The addition of CTAB and OPD influence the b_c values with less potential difference. Similarly, the E_{corr} values are found to be little changed when compared with blank. This indicates that the studied compounds are of mixed type of inhibitor. From the table it was found that as the concentration of the inhibitor increased from 50 to 200 mmol/L, the IE increased markedly compared with using CTAB alone. The addition of OPD in different concentrations of CTAB increased IE, but no further improvement was found with the addition of OPD to 250 mmol/L CTAB.

Because CTAB has a long chain molecule, the surface coverage area, θ, also leads to an increase in IE when used alone. Hence, it is a good inhibitor. The addition of OPD increases the IE to a lesser extent. The availability of an electron in the benzene ring in OPD and a nitrogen atom plays a vital role in the adsorption of the inhibitor to the steel surface. The nitrogen atoms present in OPD enhance its efficiency. The combination of both has a synergistic effect.

The value of the anodic Tafel slope was reduced from 130 mV dec^{-1} to 110 mV dec^{-1}. The value of the cathodic Tafel slope was between 70 mV dec^{-1} and 60 mV dec^{-1}. These data show that the inhibitors, CTAB and OPD, inhibit the corrosion of carbon steel acting as mixed inhibitors.

	200	89.2
	250	85.6
CTAB and 20 mmol/L OPD	50	64.3
	100	72.5
	150	81.9
	200	92.3
	250	91.4

Electrochemical impedance spectroscopy (EIS) studies

AC impedance technique has been widely used as a tool in the investigation of the protective properties of organic inhibitors for metals. The technique is based on the measurement of the impedance of the double layer at the metal–solution interface. The charge transfer resistance, R_t, and the double layer capacitance, C_{dl}, are calculated by determining the equivalent electrical circuit of the metal–solution interface. In general for a corrosion system, the equivalent circuit diagram is as given in Fig. 4. C_{dl} is the double layer capacitance, R_t the charge transfer resistance, and R_s is the solution resistance.

The impedance of the circuit given in Fig. 4 can be calculated using,

[14] $$Z = R_s + \frac{R_t}{1 + j\omega C_{dl} R_t}$$

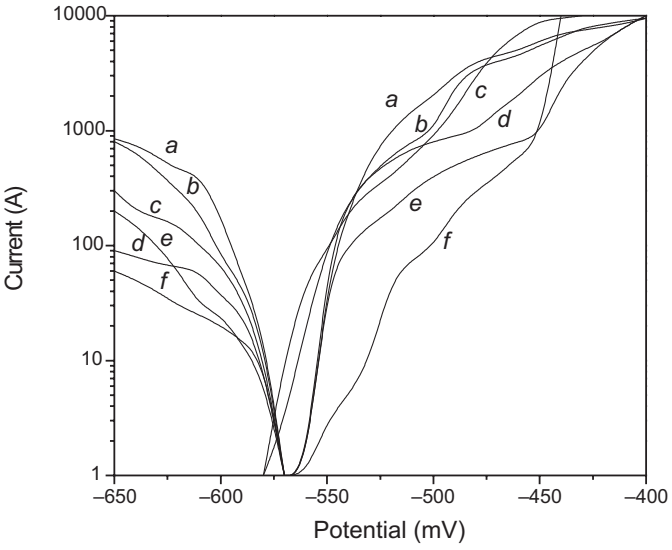
	250	–500	0.52	124	66	83.7

Fig. 2. Polarization curves for carbon steel in blank and in different concentrations of CTAB. (*a*) Blank, (*b*) 50 mmol/L, (*c*) 100 mmol/L, (*d*) 150 mmol/L, (*e*) 200 mmol/L, and (*f*) 250 mmol/L C.



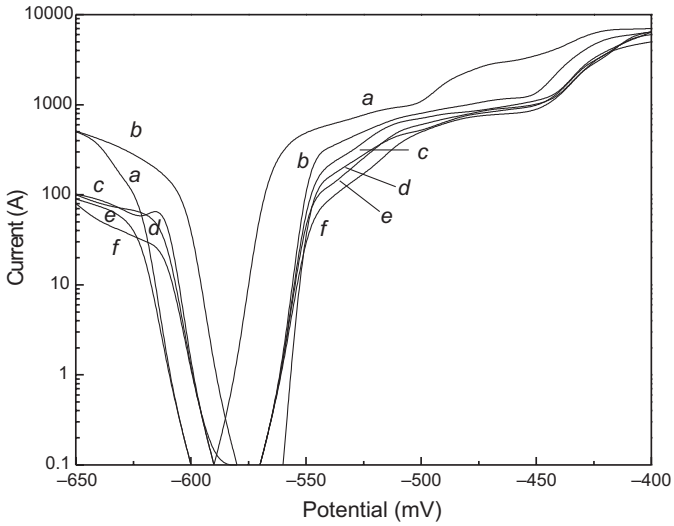


Fig. 3. Polarization curves for carbon steel in blank and in different concentrations of CTAB with OPD. (*a*) Blank, (*b*) 50 mmol/L CTAB and 20 mmol/L OPD, (*c*) 100 mmol/L CTAB and 20 mmol/L OPD, (*d*) 150 mmol/L CTAB and 20 mmol/L OPD, (*e*) 200 mmol/L CTAB and 20 mmol/L OPD, and (*f*) 250 mmol/L CTAB and 20 mmol/L OPD.

$$[15] \quad Z = R_s + \frac{R_t}{1+\omega^2 C_{dl}^2 R_t^2} - \frac{j\omega C_{dl} R_t^2}{1+\omega^2 C_{dl}^2 R_t^2}$$

where R_s is the solution resistance, R_t the charge transfer resistance, j is the imaginary unit ($\sqrt{-1}$), ω is the angular frequency ($\omega = 2\pi f$), and C_{dl} is the double layer capacitance. Equation [15] can be expressed as

$$[16] \quad Z = Z' - jZ''$$

where

$$[17] \quad Z = Z' - jZ''$$

$$[18] \quad Z' = R_s + \frac{R_t}{1+\omega^2 C_{dl}^2 R_t^2}$$

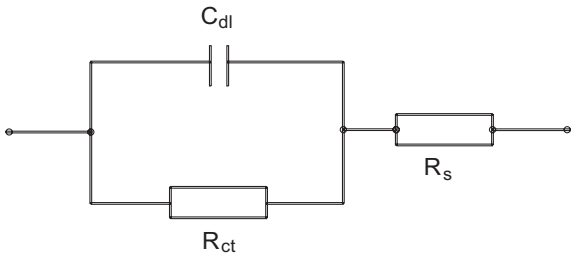
Eliminating ω between eqs. [17] and [18] gives the following equation for a semicircle,

$$[19] \quad \left[Z' - \left(\frac{R_s + R_t}{2}\right)\right]^2 + (Z'')^2 = \left(\frac{R_t}{2}\right)^2$$

According to eq. [19], the experimental data should give a Nyquist plot in the shape of a semicircle. In a real corrosion system, semicircular Nyquist plots can be obtained only with a few metals, and most of the experimental plots deviate from a semicircle.

The value of R_t will be determined from the following equation,

$$[20] \quad I_{corr} = \frac{b_a b_c}{2.3(b_a + b_c)} \frac{1}{R_t}$$



The values of C_{dl} and R_p derived from Nyquist plots, which have been shown in Fig. 5 for CTAB with and without OPD systems, were reported in Table 4.

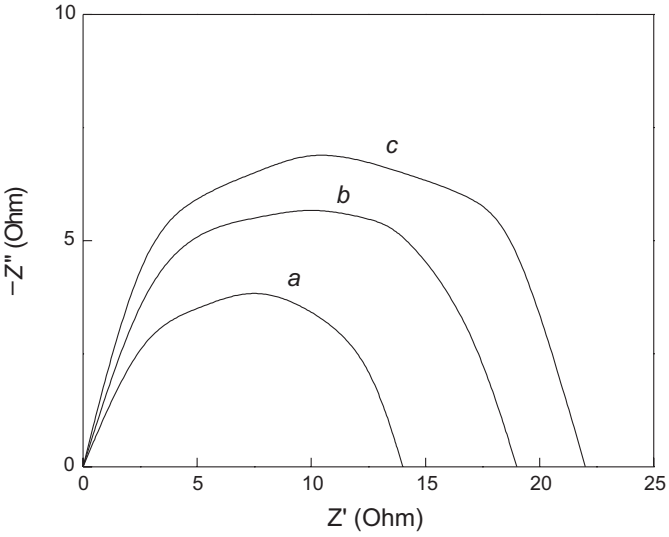
	200	22.1	110	0.78
	250	21.8	113	0.84

Fig. 4. Equivalent circuit diagram for the corrosion system.

The C_{dl} value decreased with the addition of CTAB and it was further reduced by the addition of OPD. The data show that the greater the adsorption of inhibitor, the smaller C_{dl} values that were obtained. C_{dl} indirectly measures the water uptake by the passive film. From the data, 200 mmol/L of CTAB with 20 mmol/L of OPD showed the smallest values of C_{dl} when compared with other concentrations studied. This was explained by the presence of the cations present in the surfactant, which have better adsorption properties than a neutral surfactant.



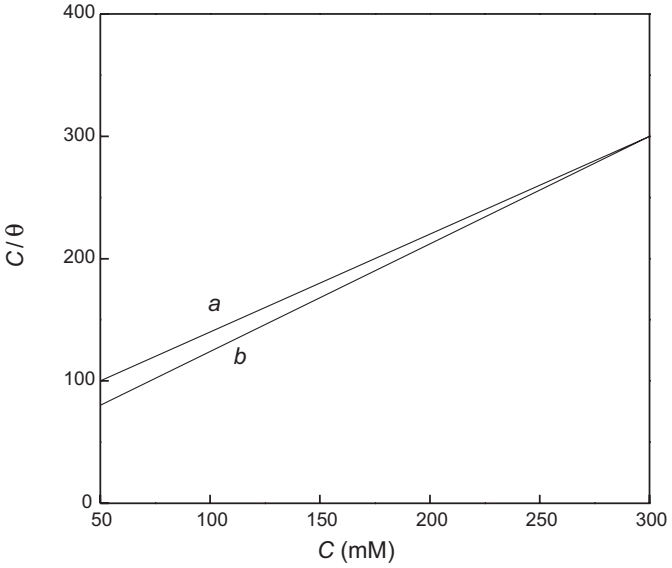
The R_p value for blank was reported as 4.3 Ω cm^2. The addition of CTAB increased the R_p values by 4–5 times in different concentrations. Furthermore, the addition of 20 mmol/L of OPD with different concentrations of CTAB increased the R_p values from 14.2 to 22.1 Ω cm^2. This data showed that the greater the surface coverage of the adsorbed inhibitor, the greater R_p values that were obtained.

The I_{corr} value measured for blank was 4.59 mA cm^{-2}. The I_{corr} values were decreased drastically from 1.34 to 0.87 mA cm^{-2} for different concentrations of CTAB alone. The addition of OPD in CTAB decreased the I_{corr} values further. From the Table 4, the C_{dl} value for the blank was reported as 318 μF cm^{-2}.

Adsorption isotherm

The interaction between the inhibitors and the steel surface can be described by the adsorption isotherm. During corrosion inhibition of metals, the nature of the inhibitor on the corroding surface has been deduced in terms of the adsorption characteristics of the inhibitor. The adsorption of organic inhibitors at an electrolyte–electrode interface may take place through displacement of adsorbed water molecules. The steel electrode is corroding uniformly and the corrosion rate in the absence of inhibitors is representative of the total number of corroding sites. Therefore, the corrosion rate in the presence of inhibitors may be assumed to represent the number of potentially corroding sites that remain after blockage because of inhibitor adsorption.

Fig. 5. Typical Nyquist plots for carbon steel in blank, CTAB, and OPD. (*a*) Blank, (*b*) 150 mmol/L CTAB, and (*c*) 150 mmol/L CTAB and 20 mmol/L OPD.



The surface coverage suggests that a chemical bond is formed between the metal atoms and the inhibitor molecules. The surface coverage is the function of the electronic density of the functional atom of the organic inhibitor; the molecules may be adsorbed on the metal–solution interface by the formation of either electrostatic or covalent bonds between the adsorbates and the metal surface atoms. Surface coverage data (θ) was used in determining inhibitor adsorption characteristics, which resulted in fitting the data to different isotherm type models, including Frumkin, Temkin, and Langmuir.

The simplest adsorption isotherm, the Langmuir isotherm, is based on the assumption that all adsorption sites are equivalent and that particle binding occurs independently from nearby sites, whether occupied or not. The degree of

© 2006 NRC Canada

Fig. 6. Langmuir's adsorption isotherm for carbon steel in HCl with inhibitors, (*a*) CTAB alone and (*b*) CTAB with 20 mmol/L OPD.

surface coverage (θ) for different concentrations of the inhibitor in 1 mol/L HCl has been evaluated from weight loss measurements. The plot of C/θ against C yields a straight line (Fig. 6), clearly suggesting that the inhibitors obey Langmuir's adsorption isotherm.

Hydrogen permeation studies

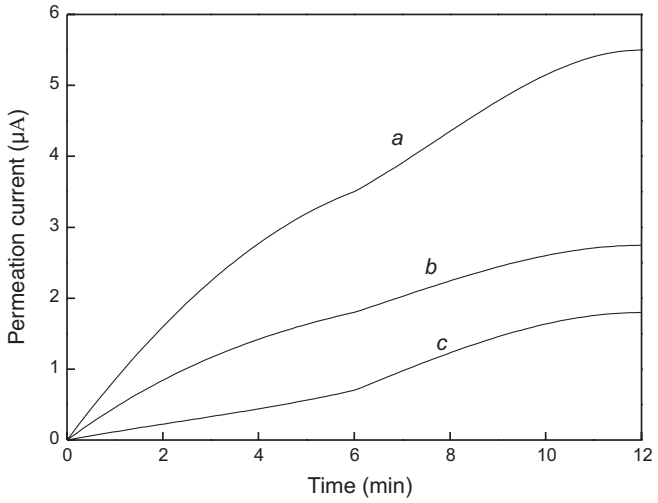
Plots of hydrogen permeation current vs. time for carbon steel in 1 mol/L HCl in the presence and absence of inhibitors are shown in Fig. 7.

In acid solutions, hydrogen permeation through metals takes place in the following manner,

[21] $M + H_3O^+ + e^- \rightarrow H_2O + MH_{ads}$ (discharge step)

where M is the cathode metal surface, followed either by

[22] $MH_{ads} + MH_{ads} \rightarrow 2M + H_2 \uparrow$



or electrochemical desorption by

[23] $MH_{ads} + H_3O^+ + e^- \rightarrow M + H_2O + H_2 \uparrow$

When the metal is immersed in acidic solutions, hydrogen gas is liberated on the steel surface. Some of the atomic hydrogen liberated during the process permeates through the metal (while the remainder is evolved as a fraction of the diffused hydrogen atoms – gas) and becomes occluded in the metal crystal lattice defects. The fraction of the diffused hydrogen atoms – gas that enters the metal produces some detrimental effects on the mechanical properties of steel, such as a decrease in ductility and loss of mechanical strength, leading to hydrogen embrittlement. Thus, the selection and design of inhibitors should take into account these detrimental effects. Inhibitors should either prevent hydrogen adsorption or favour H–H recombination.

The hydrogen permeation was controlled by the diffusion of hydrogen through the metal and the adsorption of the organic compound on the surface of the metal. The attainment

Fig. 7. Plots of hydrogen permeation current against time for carbon steel in HCl with CTAB and OPD inhibitors. (*a*) 1 mol/L HCl, (*b*) 1 mol/L HCl with 200 mmol/L CTAB, and (*c*) 1 mol/L HCl with 200 mmol/L CTAB and 20 mmol/L OPD.

of steady-state hydrogen permeation current density indicated a stable hydrogen surface coverage on the cathodic side of the membrane and saturation of the hydrogen traps present in the metal and a stable hydrogen concentration within the metal. The organic compounds were investigated for their ability to inhibit the rate at which hydrogen permeates through carbon steel in 1 mol/L HCl.

The transient curve shown in Fig. 7 for hydrogen permeation was controlled by the diffusion of hydrogen through the metal and the adsorption of the organic compound on the surface of the metal. The addition of CTAB alone reduces the permeation current compared with the blank. A further slight reduction in the permeation current was achieved by the addition of 20 mmol/L OPD with CTAB. This corresponds to higher IE values of the inhibitors and lesser permeation of hydrogen through the metal. It is expected that a system that induces maximum cathodic polarization will show lesser permeation current. Hence, CTAB with OPD exhibited a reduced permeation current.

The organic compounds possess high IE and, in addition, they reduce hydrogen permeation through the metal. This is to be expected since hydrogen arises from a corrosion reaction and any inhibition of this will necessarily lead to reduced hydrogen production and, therefore, reduced hydrogen uptake by the metal.

Scanning electron microscopy

Micrographs were made of carbon steel specimens in 1 mol/L HCl in the presence and absence of inhibitors and are shown in Figs. 8 and 9. The morphology of the specimen surface shows a characteristic corrosion pitting of mild steel in hydrochloric acid. These areas are highly oxidized. It was found that an uncovered surface of mild steel in acid corroded severely. Deep pits were observed throughout the specimen surface, which was immersed in HCl only, as clearly shown in Figs. 8*a*–8*c*. There was less pit formation in Fig. 9, which was made with CTAB alone in HCl. The addition of CTAB and OPD in HCl controlled the formation of

pits and protected the carbon steel from corrosion as shown in Fig. 10. These figures clearly show that the corrosion was less pronounced in the presence of inhibitors.

The increase in IE in all the techniques can be explained in the following way. Inhibition of corrosion can be attributed to the strong adsorption of the compound on the metal surface by the electron transfer from the organic molecule to the metal surface to form a coordinate type of link. This process is facilitated by the presence of low-energy vacant electron orbitals present in iron, as observed in the metals of the transition group.

As far as the inhibition process is concerned, it is generally assumed that the adsorption of the inhibitors at the metal solution interface is the first step in the action mechanism of inhibitors in aggressive acid media. Inhibition of corrosion of mild steel in HCl solution by the inhibitors can be explained on the basis of adsorption. Four types of adsorption may take place involving organic molecules at the metal solution interface: (*i*) electrostatic attraction between charged molecules and the charged metal, (*ii*) interaction of unshared electron pairs in the molecule with the metal, (*iii*) interaction of π electrons with the metal, and (*iv*) a combination of the above. It is apparent that the adsorption of these organic inhibitors on the metal surface could occur directly on the basis of donor acceptor interaction. Moreover, the presence of inhibitors in the organic structures makes the

© 2006 NRC Canada

formation of dπ–dπ bond which enhances the adsorption of the compounds on the metal surface. These compounds inhibit the corrosion by controlling both the anodic and cathodic reactions. In an acidic solution, these compounds can exist as protonated species. These protonated species may adsorb on the cathodic sites of the mild steel surface and decrease the evolution of hydrogen. The adsorption of these compounds on anodic sites may decrease anodic dissolution of mild steel.

The formation of positively charged species in an acidic medium also facilitates the adsorption of the compound on the metal surface through electrostatic interactions between the organic molecule and the metal surface. Adsorbed molecules of the organic compound decrease the anodic and cathode reaction sites, resulting in a decrease in the active surface area, an increase in polarization resistance R_p, and a decrease in the rate of diffusion of ions to or from the metal surface. In addition, the organic compound may react with adsorbed corrosion intermediates of the steel forming products that passivate the steel surface. This indicates an increase in the energy barrier for proton discharge, leading to less gas evolution.

The mechanism of inhibition in CTAB may be attributed to the the micelles that are formed at these concentrations of CTAB, a cationic surfactant. Above a certain concentration range, these surfactant molecules aggregate in aqueous solution to form particles of colloidal dimensions called micelles. At concentrations of less than 100 mmol/L, CTAB does not effectively inhibit corrosion. However, it shows excellent corrosion inhibition properties at concentrations greater than 100 ppm. This is due to the fact that the micelle concentration takes place over a narrow range of surfactant concentration, the critical micelle concentration, and is accompanied by distinct changes in various physical properties such as surface tension, light scattering, electrical conductivity, solubility capacity, viscosity, and osmotic pressure for a wide variety of solutes. Below and up to the critical micelle concentration, the monomeric surfactant acts as a strong electrolyte, fully dissociated and aggregated. Aggregation begins at the critical concentration, at first with the formation of relatively small micelles that grow rapidly over a very limited concentration range to a size, which for a given surfactant remains approximately constant with further increase in surfactant concentration. Micelles are pictured as liquidlike, spherical in shape, their interior approximating that of liquid hydrocarbons but with hydrophilic end chains constrained to micelle surface. Above the critical micelle concentration, increases in the surfactant concentration lead to an increase in the number of micelles with little, if any, increase in the number of monomer surfactants (23).

With the hydrocarbon chains forming the inner hydrophilic core of the spherical micelles, the polar head groups of ionic micelles align together in a compact manner at the micelle surface. The ionic head groups of the surfactants and a portion of the counter ions form a compact "Stern" layer at the micelle surface at which about 60%–75% of the micelle charge is believed to be neutralized. The remaining ions form a diffuse Guoy–Chapman layer (24).

The addition of OPD in CTAB increases the IE in all the tests and this is due to adsorption of amines through electrostatic interaction between the positively charged amine and the negatively charged metal surface. In addition, in the case of aromatic amines the π electron interaction between the aromatic molecules and the positively charged metals may also play a role.

The concentration of inhibitor has a very great influence on the corrosion of carbon steel. This may be due to the formation of Fe^{2+} and Fe^{3+} complex species with ions like OH^- and Cl^-. For example, Fe^{2+} and Fe^{3+} ions formed from the metal dissolution should be able to form a corrosion product but the film of inhibitor on the surface prevents them. At low concentrations of these additives, the Fe^{2+} and Fe^{3+} ions resulting from metal dissolution should have formed an insoluble protective film of the type $Fe(OH)_3 – FeCl_3$ on the steel surface, but this is converted to a soluble one only at higher currents and temperatures.

The strong influence of the H^+ ion in this medium also helps in the oxidation of Fe^{++}. On the other hand, the solubility of a protective $Fe(OH)_3 – FeCl_3$ film is able to incorporate the inhibitor molecules to form a protective stable film. This incorporation of inhibitor molecules in the protective layer stabilizes the protective layer on the steel surface and decreases the corrosion rate.

Conclusions

The following conclusions can be made: (*i*) the IE calculated by gravimetric and potentiodynamic methods revealed that the combined inhibition effect of OPD and CTAB is better than the CTAB alone; (*ii*) potentiodynamic polarization data showed that the values of E_{corr} decreased using CTAB alone and decreased further with the addition of OPD; (*iii*) CTAB and OPD influence the b_c values but not specific changes in b_a values, showing that inhibitors are of mixed type; (*iv*) the R_p values obtained from EIS studies showed that the addition of OPD in CTAB increases R_p values; (*v*) the adsorption isotherm data showed that inhibitors obey Langmuir's adsorption isotherm; (*vi*) the IE was observed as high for 200 mmol/L of CTAB with 20 mmol/L of OPD in all the techniques studied; and (*vii*) micrographs clearly indicate that these inhibitors control the corrosion of carbon steel in 1 mol/L HCl.

Synthesis and coordination chemistry of the diamido-arsine ligand [NAsN] (NAsN = $PhAs(CH_2SiMe_2NPh)_2$))

Christopher D. Carmichael, Michael P. Shaver, and Michael D. Fryzuk

Abstract: The preparation and characterization of the diamido-arsine ligand $[NAsN]Li_2(THF)$ (**1**) (where NAsN = $PhAs(CH_2SiMe_2NPh)_2$), the protonated ligand precursor $[NAsN]H_2$ (**2**), and its coordination chemistry with tantalum is presented. The complex $[NAsN]TaMe_3$ (**3**) can be synthesized from **1** and $TaMe_3Cl_2$. Hydrogenation of **3** did not produce the desired tetrahydride $([NAsN]Ta)_2(\mu\text{-}H)_4$, instead, activation of Ta–N bonds in the complex produced a modest yield of the free ligand **2**. In an attempt to understand the unusual reactivity of **3**, a density functional theory investigation of the model complexes 'NAsN'$Li_2(OMe_2)_2$ (**4**) and 'NAsN'$TaMe_3$ (**5**) (where 'NAsN' = $MeAs(CH_2SiH_2NMe)_2$) and their phosphine analogs 'NPN'$Li_2(OMe_2)$ (**7**), 'NPN'$TaMe_3$ (**8**), and a related niobium complex 'NPN'$NbMe_3$ (**10**) (where 'NPN' = $MeP(CH_2SiH_2NMe)_2$) was undertaken. The difference between the chemistry supported by the As and P ligands originates from the poor binding of As to Ta in these systems and is likely due to a mismatch of the soft As donor and the hard Ta(V) metal centre.

Key words: arsine ligand, tridentate, tantalum, hydrogenation, DFT calculations.

Résumé : On a décrit la synthèse et la caractérisation du coordinat diamido-arsine $[NAsN]Li_2(THF)$ (**1**) [dans lequel NAsN= $PhAs(CH_2SiMe_2NPh)_2$], de son précurseur protoné $[NAsN]H_2$ (**2**) et sa chimie de coordination avec le tantale. On a synthétisé les complexes $[NAsN]TaMe_3$ (**3**) par réaction du composé **1** avec le $TaMe_3Cl_2$. L'hydrogénation du composé **3** ne conduit pas à la formation de l'hydrure recherché de formule $([NAsN]Ta)_2(\mu\text{-}H)_4$; on observe plutôt une activation des liaisons Ta–N dans le complexe qui conduit à la formation du coordinat libre (**2**) avec un faible rendement. Dans le but d'essayer de comprendre la réactivité inhabituelle du composé **3**, on a entrepris une étude basée sur la théorie de la fonctionnelle de la densité des complexes modèles 'NAsN'$Li_2(OMe_2)_2$ (**4**) et 'NAsN'$TaMe_3$ (**5**) [dans lesquels 'NAsN' = $MeAs(CH_2SiH_2NMe)_2$], des phosphines analogues 'NPN'$Li_2(OMe_2)_2$ (**7**) et 'NPN'$TaMe_3$ (**8**) et d'un complexe du niobium apparenté 'NPN'$NbMe_3$ (**10**) dans lesquels 'NPN' = $MeP(CH_2SiH_2NMe)_2$. La différence entre la chimie supportée par les coordinats de As ou de P tire son origine de la faible liaison du As au Ta dans ces systèmes qui est probablement causée par mauvaise adaptation du donneur doux As et du centre métallique dur du Ta(V).

Mots-clés : coordinat arsine, tridentate, tantale, hydrogénation, calculs sur la base de la théorie de la fonctionnelle de la densité.

[Traduit par la Rédaction]

Introduction

Our interest in small molecule activation has centered around the design, synthesis, and coordination chemistry of a variety of mixed donor ancillary ligands in an attempt to generate reactive metal complexes (1–3). One of the key design criteria has been to utilize multidentate ligand sets that can support changes in oxidation state of the central metal. For this reason, we have concentrated on combinations of hard and soft donors, in particular, amido- and phosphine-based systems as shown in Chart 1 (4, 5).

Recently, we have disclosed the use of the [NPN] system shown (Chart 1) (where NPN = $PhP(CH_2SiMe_2NPh)_2$) as an ancillary ligand for the activation and functionalization of molecular nitrogen by early transition metals (6). In particular, the side-on end-on bound dinitrogen complex $([NPN]Ta)_2(\mu\text{-}H)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}N_2)$ and its reactivity with boranes, alanes, and silanes has been extensively studied (7–9). Reactivity patterns in the [NPN] system can be altered by changing the substituents at both nitrogen and phosphorus (10, 11). Presumably, a change in the neutral donor atom in the ligand from phosphorus to arsenic should also affect reactivity patterns of the resultant complexes. Previously, we have reported profound changes in reductive stability of the $[As_2N_2]$ analogue (12) of the macrocyclic $[P_2N_2]$ system shown in Chart 1.

In comparison with phosphines, arsines are known to be modest σ donors and π acceptors (13). From an NMR spectroscopic point of view ^{75}As (I = 3/2), unlike ^{31}P, is not a

Chart 1. Related amido-phosphine ligand systems with different ratios of phosphine to amido donors.

useful nucleus because of its quadrupolar nature (14). Although the majority of arsine coordination chemistry has been limited to the late transition metals by the modest electron-donating and -accepting properties of arsenic, there are examples of both monodentate and bidentate arsine ligands bound to early transition metals (15, 16), and in particular there are a few reports of arsine–tantalum complexes (17–19).

In this paper, the successful synthesis of a diamido-arsine ligand, [NAsN] (where NAsN = $PhAs(CH_2SiMe_2NPh)_2$), its coordination chemistry to Ta(V) to generate $[NAsN]TaMe_3$, and attempts to hydrogenate this trimethyl complex are reported. We also include the results of a density functional theory (DFT) investigation of the model complexes '$NAsN'Li_2(OMe_2)_2$ and '$NAsN'TaMe_3$ (where 'NAsN' = $MeAs(CH_2SiH_2NMe)_2$). The results are compared with the analogous series of model complexes using the 'NPN' ligand, '$NPN'Li_2(OMe)$ (**6**), '$NPN'TaMe_3$ (**7**), and the related niobium complex '$NPN'NbMe_3$ (**8**) (where 'NPN' = $MeP(CH_2SiH_2NMe)_2$).

Results and discussion

Synthesis

The synthesis of $[NAsN]Li_2(THF)_2$ (**1**) is shown in eq. [1] and is analogous to that described for $[NPN]Li_2(THF)_2$. Thus, the addition of 4 equiv. of BuLi to a mixture of 2 equiv. of $PhNHSiMe_2CH_2Cl$ and 1 equiv. of $PhAsH_2$ in diethyl ether leads to the formation of the dilithiated diamidophosphine as a diethyl ether adduct. Addition of 4 equiv. of THF to a hexanes slurry of the first species and subsequent precipitation affords the bis THF adduct **1** in 78% yield.

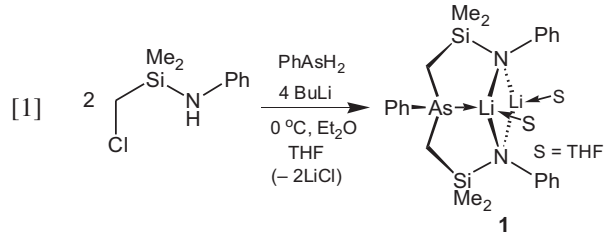

Fig. 1. Molecular structure (ORTEP) of $[NAsN]Li_2(THF)_2$ (**1**). Ellipsoids are drawn at 50% probability.

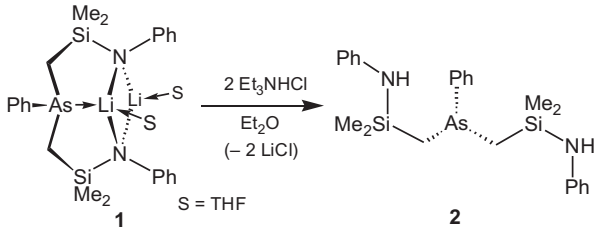
Li(1)–N(2)–Li(2)	75.5(4)



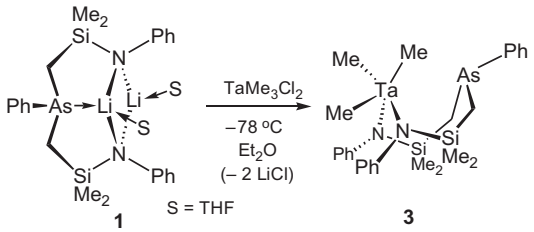
X-ray quality crystals of **1** were grown from a saturated THF solution at –40 °C. X-ray diffraction studies determined the crystal to be a two-component twin; the two orientations of the lattice are related by a rotation of 7.77° normal to 0.03, –1.00, and –1.39. The solid-state molecular structure of **1** is presented in Fig. 1, and selected bond distances and angles are given in Table 1. The structure contains a Li_2N_2 core, like the similar $[NPN]Li_2(THF)_2$ (20) and macrocyclic $[E_2N_2]Li_2$(1,4-dioxane) (E = P, As) complexes (12, 21), and the bond distances and angles of the core agree well with these complexes. The Li(1)–As(1) bond distance of 2.686(6) Å agrees well with the macrocyclic $[As_2N_2]Li_2$(1,4-dioxane) (12) and other similar molecules (22–24).

The ambient temperature ^1H NMR spectrum of **1** displays resonances due to two types of silyl methyl protons, and the

© 2006 NRC Canada

CH_2 ring proton signals appear as a pair of AB doublets, as expected from the solid-state structure. However, the $^7Li\{^1H\}$ spectrum is comprised of a narrow singlet indicating there is only a single lithium environment in solution, whereas two distinct lithium environments would be expected on the basis of the X-ray structure. Substituted variations of the $[NPN]Li_2$ system with only one coordinated solvent donor also show only a single environment in the $^7Li\{^1H\}$ NMR spectrum (10, 11); a fluxional process that exchanges the lithium environments through migration of the phosphine and donor solvent from one lithium to another has been postulated to explain this behaviour (11). Complex **1** is the first observation of a $^7Li\{^1H\}$ singlet in the $[NEN]Li_2$ (E = P, As) ligand family with two coordinated solvent molecules. It is possible that a fluxional process involving arsenic migration can exchange the lithium environments, however, variable temperature ^1H NMR experiments performed on **1** (290–190 K) did not show decoalescence of any resonances. Another possibility for the observed singlet is that arsenic may not be coordinated to either of the lithium ions in solution.

The synthesis of the protonated ligand precursor $[NAsN]H_2$ (**2**) is outlined in eq. [2]. Reaction of **1** with 2 equiv. of NEt_3HCl affords **2** in 96% yield as a colourless oil. Allowing the oil to stand for several weeks produced X-ray quality crystals of **2**.



[2] 

Selected bond distances and angles are collected in Table 2. The asymmetric unit contains two independent molecules, one of which is shown in Fig. 2. The hydrogen atoms bound to N(1) and N(2) were located within the diffraction pattern and refined isotropically. Delocalization of the nitrogen lone pair into the aromatic ring is evidenced by the planarity around the nitrogen atoms ($\Sigma(°)$ 360°). This is also reflected in the short C–N bonds (1.412(4) and 1.401(4) Å) (25–27), compared with nonconjugated examples (28, 29) and indicates partial double bond character. The acute angles about the central arsenic atom have also been observed in solid-state structures of other arsine molecules (30–32). In solution, the silylamine arms are equivalent, and the compound assumes C_s symmetry with the silylmethyl proton resonances appearing as two singlets in the ^1H NMR spectrum, the signals due to methylene protons as a pair of AB doublets, and the NH resonances as a broad singlet.

The synthesis of $[NAsN]TaMe_3$ (**3**) is outlined in eq. [3]. Reaction of dilithio **1** with $TaMe_3Cl_2$ affords **3** as a pale yellow solid in 63% yield after washing with minimal pentane. The product is quite soluble in pentane, and the necessity of removing soluble coloured by-products contributes to the modest yield. Solutions of **3** are photochemically and thermally sensitive, and appropriate precautions must be taken during the reaction; however, the isolated and dried solid

can be stored for extended periods of time in the dark at –40 °C.

Crystals of **3** suitable for X-ray diffraction experiments were grown by slow evaporation of a concentrated benzene solution. The solid-state molecular structure of **3** is presented in Fig. 3, and selected bond distances and angles are detailed in Table 3. The most striking feature of the structure is that arsenic is not coordinated to tantalum (Ta···As = 4.55 Å), which makes the tantalum five-coordinate. The geometry about the tantalum center is a distorted square pyramid with N(1) in the apical position, and the methyl groups are all cis disposed. There is a distinct lack of symmetry in the molecule; this can be observed in the phenyl amido groups and the phenyl group bound to arsenic. Comparing the bonding to the structurally characterized $[NPN]TaMe_3$ complex (20), the Ta–N and Ta–C bonds are slightly shorter on average, perhaps because of the five-coordinate nature of **3**. The Ta–N distances are, however, not significantly different from other [NPN]Ta complexes (33–35), and both Ta–N and Ta–C match those of similar complexes in the literature (36–41). Very few coordination complexes containing tantalum arsenic interactions have been characterized in the solid state. There are two examples using the diars ligand (o-$C_6H_4(AsMe_2)_2$) (17, 42) and three examples of tantalum arsenic clusters (19, 43). The absence of nonchelating examples suggests that interactions between arsenic and tantalum are weak and a stabilizing force is necessary for coordination. The fact that arsenic does not coordinate in **3**, despite the chelating nature of the ligand, confirms the poor coordinating ability of arsenic donors to high oxidation state metal centres such as Ta(V).

NMR data provide some insight into the structure of **3** in solution. The ambient temperature ^1H NMR spectrum of **3**

shows only two silyl methyl resonances, and the methylene resonances appear as a pair of AB doublets, consistent with a C_s symmetry. A single resonance is observed for the three tantalum-bound methyl groups, indicating that a fluxional process must be exchanging the methyl groups in solution. If the complex is five-coordinate in solution and approximates the distorted square pyramid of the solid-state structure, the Ta-methyl groups can be made equivalent through a standard Berry pseudo rotation.

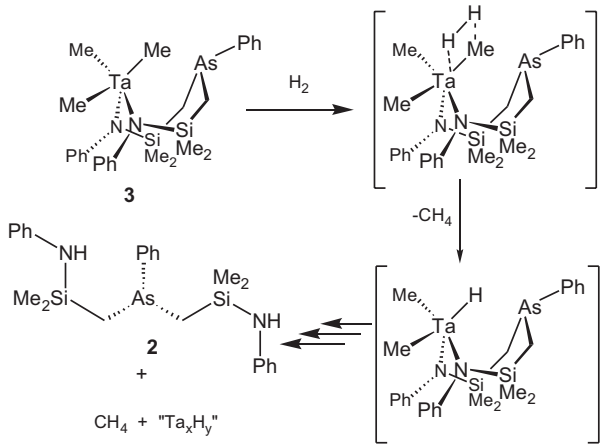
Variable temperature ^{1}H NMR experiments performed in d_8-toluene show that, at 195 K, two resonances are observed for the tantalum-bound methyl groups at δ 1.36 and 1.03, in a 2:1 ratio. A similar 2:1 ratio of methyl resonances has been observed at low temperature in the octahedral complex $[NPN]TaMe_3$, but at significantly different shifts of δ 0.40 and –0.05 (20). This was attributed to cis and trans conformation of the methyls in relation to the phosphine donor. The difference in the shift of the methyl resonances is as pronounced in the RT spectra, where $[NPN]TaMe_3$ has a doublet at δ 0.55 because of phosphorus coupling, and the resonance in **3** is a singlet at δ 1.09. The low temperature ^{1}H spectrum of $[NPN]TaMe_3$ also shows hindered rotation of the amido phenyl groups; however, **3** shows no evidence of this, even at 185 K. There are significant differences in the chemical shifts of the methylene resonances of these two complexes, with $[NPN]TaMe_3$ displaying two multiplets at δ 1.23 and 1.18 and **3** having AB doublets at δ 1.82 and 1.25. The spectral differences suggest that **3** may be five-coordinate in solution; lowering the temperature slows the Berry pseudo rotation and results in the two Ta-methyl signals. However, a six-coordinate structure where the low temperature methyl signals are due to cis and trans conformations relative to the arsine donor cannot be definitively ruled out.

Reaction of **3** with donating solvents such as THF, pyridine, and PMe_3 does not produce solvent adduct complexes, which would be expected if **3** were five-coordinate in solution. This is not conclusive, however, because it is possible that the phenylarsine unit, while not coordinated to the tantalum center can still effectively block access to the open coordination site for a potential ligand.

Hydrogenation of **3** performed under one or four atmospheres (1 atm = 101.325 kPa) of hydrogen in the absence of light does not produce the dinuclear tetrahydride analog of $([NPN]Ta)_2(\mu\text{-}H)_4$, namely $([NAsN]Ta)_2(\mu\text{-}H)_4$. When a diethyl ether solution of **3** is exposed to H_2 (4 atm), a subtle

© 2006 NRC Canada

colour change from pale yellow to pale tan is observed over 24 h, and a colourless solid is deposited on the sides of the flask. In contrast, hydrogenation of [NPN]$TaMe_3$ results in a deep purple-red solution and formation of the dinuclear tetrahydride (20). Evaporation of the solvent from the reaction of **3** with H_2 leaves an oily brown residue, and examination of the soluble material by ^{1}H NMR indicates that a single material displaying two resonances in the silylmethyl region, a pair of doublets in the methylene region, and a broad resonance at δ 3.1 is the major product. The spectrum closely matches that of the protonated ligand precursor [NAsN]H_2 (**2**). No resonances attributable to tantalum hydrides are observed, nor are resonances due to the starting material **3**. ^{1}H NMR spectra obtained in the presence of an internal standard (ferrocene) indicates a 33% yield of **2**.



Reaction of **3** with 4 atm of deuterium (D_2) produces the same colour change and precipitate; however, a ^{1}H NMR spectrum of the soluble material indicates the broad N–H resonance is present, although with significantly smaller integration relative to the methylene and silylmethyl resonances. Integration of the spectrum against an internal standard shows a 32% yield of deuterated **2** (D_2-**2**). The trace amount of **2** is due to thermal decomposition of **3**. A solution of **3** in benzene or THF produces approximately 1% of **2** by integration over the course of 24 h at RT. Although the reaction of **3** with adventitious water cannot be completely ruled out, the degree of deuteration suggests the product is formed by reaction of **3** with H_2–D_2 exclusively.

Hydrogenations performed under lower pressure (1 atm) of hydrogen primarily produce unidentified products from which small amounts of **2** (<5%) can be identified, while deuterations produce similar small amounts of D_2-**2** and a trace of **2** from thermal decomposition of **3**. Following the reaction by ^{1}H NMR spectroscopy does not show any intermediates; the formation of **2** is complete in the first 24–48 h of the reaction, and no resonances attributable to tantalum hydrides are observed. Further reaction time leads to decomposition of the remaining **3**. It is not known why the reaction stops producing **2**, as dissolved hydrogen remains visible in ^{1}H NMR spectrum.

Elemental analyses of the isolated materials, while not reproducible from reaction to reaction, are consistently low in carbon and hydrogen relative to the trimethyl complex **3**, suggesting possible loss of methane. Methane gas can be detected in the headspace of four atmosphere hydrogenations by GC-MS; however, it could not be quantified because of limitations in the four-atmosphere apparatus. Methane was not detected in the one-atmosphere experiments, presumably because not enough methane is produced in such small-scale reactions to permit detection.

Monitoring the hydrogenation reaction of **3** by ^{1}H NMR spectroscopy does not reveal any hydride containing intermediates. However, the detection of methane suggests that the hydrogenation of **3** begins with a σ-bond metathesis of Ta–C bonds producing methane and a tantalum hydride, as shown in Scheme 1. This type of mechanism follows directly from that postulated previously for the hydrogenation of [NPN]$TaMe_3$; however, in that case, further hydrogenation results in the evolution of two additional equivalents of methane and the eventual formation of the dinuclear tetrahydride ([NPN]Ta)$_2$(μ-H)$_4$. The hydrogenation of **3** follows a different reaction pathway leading to the free ligand **2**. It is possible that the amide could be removed from the metal center by reductive N–H formation followed by tantalum amine dissociation affording a Ta(III) dihydride species containing a dangling amine. However, the absence of intense colours in this reaction, typical of low valent tantalum complexes, suggests that any Ta(III) is present only as a transient species. It seems more probable that the mechanism parallels that of [NPN]$TaMe_3$ with further metathesis of tantalum methyl bonds to produce a transient trihydride. At this point, it is possible that a partially open coordination site permits coordination of an additional equivalent of H_2 followed by hydrogenation of the Ta–N bonds. This is supported by the H_2 pressure dependence of the reaction, which suggests that it may be necessary to force the H_2 into the tantalum coordination sphere, perhaps by fully displacing the arsenic donor. However, this steric argument is not supported by previous work with the macrocyclic [P_2N_2] ligand, which has shown that a sterically congested seven-coordinate alkyl complex, [P_2N_2]$TaMe_3$, can be cleanly hydrogenated to yield the dinuclear tetrahydride ([P_2N_2]Ta)$_2$(μ-H)$_4$ (44). Another possibility is the direct hydrogenation of Ta–N bonds in preference to the Ta–C bonds. The fact that Ta–N bonds are significantly stronger than Ta–C bonds suggests that this would not be the preferred reaction (45–48).

Scheme 1.

Previous work in the Fryzuk group performed using ruthenium has shown that the Ru–N bond can activate H_2 to generate Ru-H and N-H moieties (49), including a system supported by the [NPN] ligand (50). The hydrogenation of metal-amide bonds has also been implicated in the regeneration of the active catalytic species for the hydrogenation of ketones and imines via the metal-ligand bifunctional mechanism (51–53). However, this chemistry is virtually unknown for the early transition metals. There are examples of imide hydrogenation in substituted cyclopentadienyl titanium systems (54, 55) and a molybdenum system that formally adds molecular hydrogen across the Si–N bond of a diamido ligand via transfer of H from a coordinated dihydrogen complex (56).

DFT calculations

The observation that the simple substitution of arsenic for phosphorus in the ancillary ligand leads to such a profound difference in the hydrogenation reactivity between

© 2006 NRC Canada

[NAsN]$TaMe_3$, **3**, and [NPN]$TaMe_3$ was unexpected. In an attempt to probe this chemistry further, density functional theory (DFT) calculations were performed on model complexes of **1**, **3**, and their phosphine analogs along with the niobium complex [NPN]$NbMe_3$.

The literature contains many examples of theoretical investigations conducted on transition metal complexes, including reactivity studies (57). Comparative studies have been performed on the activation of methane C–H bonds via oxidative addition and σ-bond metathesis in platinum and rhodium systems (58, 59). Generally, σ-bond metathesis reactions have been studied for high oxidation state early transition metals and lanthanides because oxidative addition is not possible. Investigations conducted on the reaction of Cp_2LnH complexes with H–H (60) and Si–H bonds (61) have shown the reactions proceed via σ-bond metathesis. Similarly, DFT studies on zirconium systems have suggested that a variety of bond activation processes progress through the same mechanism (62–64).

Geometry optimizations and DFT calculations were performed with the Gaussian 98 software package (65) using the B3LYP hybrid functional (66) and the LANL2DZ basis set (67, 68). While care must be taken with DFT calculations of systems with phosphines to incorporate the role of d-type functions in correlated wave functions to account for extra polarization (69), the effect of phosphorus atom d-type functions on the calculated M–P bond distances in diamidodiphosphine systems was studied systematically and found to have a negligible influence (70, 71). For the arsenic systems, the LANL2DZ basis set was augmented with diffusion and polarization functions (denoted LANL2DZdp) (72) to better account for the filled 3d-orbitals of arsenic. Recent results using these additional functions have illustrated their utility in modeling arsenic ligands bound to main group elements (73). Rather than use the [NPN] or [NAsN] framework, a simplified version of the ligand, 'NEN' (where 'NEN' = $MeE(CH_2SiH_2NMe)_2$ and E = P, As), was utilized to reduce calculation complexity. This simplified ligand uses methyl groups on amide and neutral donors and a secondary silane backbone instead of a bis(methylsilyl) backbone.

The model complex 'NAsN'$Li_2(OMe_2)_2$ (**4**) is depicted in Fig. 4 with selected optimized bond distances; 'NPN'$Li_2(OMe_2)$ (**5**) is depicted in Fig. 5 along with bond data. The bond distances and angles of **4** compare well to the solid-state structure for **1**, while those of **5** compare well with [NPN]$Li_2(THF)_2$ (20) and the variant ^{CyMes}[NPN]Li_2(THF) (11) with a cyclohexyl phosphine and the bulky mesityl amide. The N_2Li_2 cores are more square in the model complexes, with distances up to 0.1 Å longer and angles closer to 90°; they differ only slightly despite the fact that the [NPN] derivative has two donor solvent molecules and the model complex only has one. This suggests that the presence or absence of the second solvent molecule does not greatly influence the structure of the ligand. Comparing E–Li distances finds that both are longer in the model complexes with the P–Li distance of **7** marginally longer and the As–Li distance of **4** approximately 0.4 Å longer than in **1**. The longer Li–As distance in the model complex could be due to limitations in the DFT method for modeling the bonding of a soft ligand like arsenic with a hard metal such as lithium. Alternatively, the longer distance in the model complex could be due to the removal of the silylmethyls in the 'NAsN' ligand. It is possible that the silylmethyl groups of **1** could force the arsenic closer to the lithium ion by tightening the angle between the methylene and amide attached to silicon.

and Ta–C bond distances and angles of model complex **6** compare very well with **3**; the Ta(1)–As(1) distance is 0.07 Å longer in the model complex. This reinforces the five-coordinate nature of **3** and indicates that the lack of interaction between tantalum and arsenic is not a solid-state phenomenon. The bond distances and angles of the model complex **7** also compare well with the solid-state structure of [NPN]TaMe$_3$ (20) with the Ta–P length of the model complex slightly elongated from the solid-state structure. Comparing bond angles of the ligands surrounding tantalum for **6** and **7** reveals great similarity. This is surprising given the difference in coordination number and suggests that even in the ^{R}[NPN]TaMe$_3$ complexes, the interaction between the tantalum and phosphorus is weak and the interaction has little influence on the geometry of the other ligands about the metal center. The favorable comparison of model complex distances and angles to solid-state structures for the tantalum trimethyl complexes indicates that the level of calculation employed can adequately model the interaction of phosphorus and, more importantly, arsenic with tantalum.

Fig. 8. Calculated geometry for 'NPN'NbMe$_3$ (**10**) with selected optimized bond distances (Å).

Ligand dissociation is not restricted to the [NAsN] tantalum trimethyl complex. Hydrogenation of niobium trimethyl complexes supported by different versions of the [NPN] ligand failed to produce the corresponding dinuclear tetrahydride complex of niobium, ([NPN]Nb)$_2$(μ-H)$_4$ (11). This was initially attributed to the thermal instability of the niobium trimethyl species. However, a DFT calculation on a model complex as part of this work shows that other factors may be involved. The model complex 'NPN'NbMe$_3$ (**8**) is depicted in Fig. 8 along with selected optimized bond distances. The Nb–N and Nb–C bond distances compare well with the 'NPN'TaMe$_3$ and 'NAsN'TaMe$_3$ model complexes, other ^{R}[NPN]Nb complexes (10), and to the literature (74–77). The Nb–P distance clearly indicates that there is no interaction between the niobium and phosphorus.

While not definitive, there is a correlation between the reactivity of the three trimethyl complexes and their structures determined by DFT optimization. In the case of

© 2006 NRC Canada

[NPN]$TaMe_3$, the reaction with H_2 produces the dinuclear tetrahydride species ([NPN]Ta)$_2$(μ-H)$_4$, for which the model complex 'NPN'$TaMe_3$ shows phosphine ligand binding. In the arsine analog [NAsN]$TaMe_3$ and the niobium congener [NPN]$NbMe_3$ the analgous reaction with H_2 does not generate hydride species, and free ligand is observed. For both of these latter examples, DFT analysis shows that the neutral donor does not coordinate to the metal. Such coordinative unsaturation may facilitate side reactions that exclude formation of the anticipated dinuclear hydride species.

Conclusions

In this report, the synthesis of a mixed donor diamidoarsine ligand [NAsN] and our attempts to utilize this ligand in dinitrogen coordination are described. The lithium complex [NAsN]$Li_2(THF)_2$ (**1**) is a useful reagent for the generation of the tantalum trimethyl [NAsN]$TaMe_3$ (**3**). The solid-state structure of **3** shows that the arsine donor does not interact with the Ta(V) center. Unfortunately, solution NMR spectroscopy does not provide definitive evidence to support the solid-state structure. However, DFT studies on simplified models of the dilithio precursor 'NAsN'$Li_2(THF)_2$ and 'NAsN'$TaMe_3$ show good correlations with the solid-state structures. Hydrogenation of **3** performed under four atmospheres of hydrogen did not produce the anticipated dinuclear tetrahydride ([NAsN]Ta)$_2$(μ-H)$_4$; instead, a modest yield of the protonated ligand precursor [NAsN]H_2 (**2**) was obtained. The observation of methane in the reaction mixture suggests that the reaction may proceed through the anticipated σ-bond metathesis mechanism but was perhaps followed by hydrogenation of the tantalum amide bonds leading to the release of the ligand from the metal center as **2**.

Density functional theory calculations carried out on the trimethyl model complex **5** reveal a five-coordinate complex similar to the solid-state structure. Since the arsenic donor does not bind to the tantalum(V) centre, it is proposed that this is the reason that hydride formation does not occur. The fact that the DFT calculations reproduce the same structure observed in the solid-state was incentive to examine the trimethylniobium(V) complex that incorporates the NPN ligand system; this complex also does not undergo hydrogenation, and this is correlated to the fact that the phosphine donor is not bound to the metal. Although these are only two examples, they exemplify the possibility that σ-bond metathesis processes of group 5 alkyl complexes depend on the ancillary ligand set present.

Experimental

General procedures

All manipulations were performed under an atmosphere of dry oxygen-free dinitrogen or argon by means of standard Schlenk or glovebox techniques (Vacuum Atmospheres HE-553–2 glovebox equipped with a MO-40–2H purification system and a –40 °C freezer) unless specified. Anhydrous hexanes and toluene were purchased from Sigma-Aldrich, sparged with dinitrogen, and further dried by passage through a tower of silica followed by passage through a tower of Ridox (or Q-5) catalyst prior to use (78). Anhydrous pentane, benzene, tetrahydrofuran, and diethyl ether were purchased from Sigma-Aldrich, sparged with dinitrogen, and passed through an Innovative Technologies SPS Pure-Solv 400-4 apparatus. All organic solvents were tested with the addition of sodium benzophenone ketyl prior to use to ensure absence of oxygen and water. Alternatively, anhydrous diethyl ether was stored over sieves and distilled from sodium benzophenone ketyl under argon. Tetrahydrofuran was refluxed over CaH_2 prior to distillation from sodium benzophenone ketyl under argon, and pentane was stored over sieves and distilled from sodium benzophenone ketyl solubilized by tetraglyme under dry dinitrogen prior to storage over a potassium mirror. Nitrogen gas was dried and deoxygenated by passage through a column containing activated molecular sieves and MnO.

Deuterated benzene was dried by refluxing with molten sodium–potassium alloy in a sealed vessel under partial pressure, then trap-to-trap distilled, and freeze-pump-thaw-degassed three times. Deuterated tetrahydrofuran and toluene were dried by refluxing with molten potassium metal or sodium–potassium alloy in a sealed vessel under vacuum, then trap-to-trap distilled, and freeze-pump-thaw-degassed three times. ^1H, $^{13}C\{^1H\}$, and $^7Li\{^1H\}$ NMR spectra were recorded on either a Bruker AMX-500 instrument operating at 500.13 MHz for ^1H spectra, a Bruker AVA-400 instrument operating at 400.13 MHz for ^1H spectra, or a Bruker AVA-300 instrument operating at 300.13 MHz for ^1H spectra. ^1H NMR spectra were referenced to residual protons in deuterated solvent as follows: C_6D_5H (δ 7.15), C_4D_7HO (δ 3.58), and C_7D_7H (δ 2.09) with respect to tetramethylsilane at δ 0.0. $^{13}C\{^1H\}$ NMR spectra were referenced to $^{13}CC_5D_6$ (δ 128.4). $^7Li\{^1H\}$ NMR spectra were referenced to external LiCl (0.3 mol/L solution in MeOH at δ 0.0). Elemental analyses were performed by Mr. M. Lakha, and mass spectrometry by Mr. M. Lapawa, all at The University of British Columbia, Department of Chemistry.

Materials

The compounds $PhAsH_2$ (12), $PhNHSiMe_2CH_2Cl$ (33), and $TaMe_3Cl_2$ (79) were prepared according to literature procedures. Et_3NHCl was prepared by the reaction of triethylamine and aqueous hydrochloric acid and recrystallized from ethanol. Solutions of BuLi (1.6 mol/L) in hexanes were purchased from Acros Chemicals (Geel, Belgium) and used as received. High purity hydrogen gas was purchased from PRAXAIR (Danbury, Conn.) and used as received. Deuterium gas was purchased from Cambridge Isotopes (Andover, Mass.) and used as received. All other reagents were obtained from a commercial source and purified by appropriate methods (80).

Synthesis of [NAsN]$Li_2(THF)_2$ (1)

To a solution of $PhAsH_2$ (2.0 g, 13.0 mmol) and $PhNHSiMe_2CH_2Cl$ (5.2 g, 26.0 mmol) in Et_2O (100 mL) at 0 °C was added a 1.6 mol/L solution of BuLi in hexanes (32.5 mL, 52.0 mmol) dropwise. The solution was warmed to ambient temperature, stirred for 2 h, and then evaporated to dryness. The residue was extracted into toluene (50 mL), the solution filtered through Celite, and the toluene removed. The colourless residue was slurried in hexanes (20 mL), THF was added (3.7 g, 52 mmol), and the solution cooled to

© 2006 NRC Canada

–40 °C. The resultant colourless crystals were collected, rinsed with a small amount of hexanes, and dried under vacuum. Yield 6.50 g (78%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C) δ: 7.71 (d, $^3J_{HH}$ = 7.1 Hz, 2H, *o*-AsPh), 7.23 (m, 6H, *m*-AsPh and *m*-NPh), 7.15 (t, $^3J_{HH}$ = 7.3 Hz, 1H, *p*-AsPh), 6.86 (d, $^3J_{HH}$ = 7.9 Hz, 4H, *o*-NPh), 6.74 (t, $^3J_{HH}$ = 7.2 Hz, 2H, *p*-NPh), 3.35 (m, 8H, THF-OCH_2CH$_2$), 1.27 (AB d, $^2J_{HH}$ = 13.7 Hz, 2H, CH_2), 1.20, AB d, $^2J_{HH}$ = 13.7 Hz, 2H, CH_2), 1.11 (s, 8H, THF-OCH$_2$CH_2), 0.49 (s, 6H, SiCH_3), 0.42 (s, 6H, SiCH_3). ^{1}H NMR (500 MHz, d_8-THF), 25 °C) δ: 7.59 (d, $^3J_{HH}$ = 7.3 Hz, 2H, *o*-AsPh), 7.29 (t, $^3J_{HH}$ = 7.3 Hz, 2H, *m*-AsPh), 7.23 (t, $^3J_{HH}$ = 7.3 Hz, 1H, *p*-AsPh), 6.85 (t, $^3J_{HH}$ = 7.8 Hz, 4H, *m*-NPh), 6.53 (d, $^3J_{HH}$ = 7.7 Hz, 4H, *o*-NPh), 6.33 (t, $^3J_{HH}$ = 7.7 Hz, 2H, *p*-NPh), 3.62 (m, 8H, THF-OCH_2CH$_2$), 1.77 (m, 8H, THF-OCH$_2$CH_2), 1.15 (AB d, $^2J_{HH}$ = 13.7 Hz, 2H, SiCH_2As), 1.07 (AB d, $^2J_{HH}$ = 13.7 Hz, 2H SiCH_2As), 0.15 (s, 6H, SiCH_3), 0.13 (s, 6H, SiCH_3). ^{7}Li{^{1}H} NMR (155.5 MHz, C_6D_6, 25 °C) δ: –1.47 (s). MS (EI) *m*/*z*: 492 (20) [M – (THF)$_2$]$^+$; 387 (45) [M – NPh(THF)$_2$]$^+$. Anal. calcd. for $C_{32}H_{47}AsN_2O_2Si_2Li_2$: C 60.36, H 7.44, N 4.40; found: C, 60.00, H 7.46, N 4.73.

Synthesis of [NAsN]H$_2$ (2)

To a mixture of **1** (1.0 g, 1.5 mmol) and Et$_3$NHCl (0.43 g, 3.11 mmol) was added Et$_2$O (50 mL). The solution was stirred for 12 h and then evaporated to dryness. The residue was extracted into toluene (25 mL), the resulting solution was filtered through Celite, and the solvent removed under vacuum to yield a colourless oil that solidified upon extended standing, producing X-ray quality crystals of **2**. Yield 0.69 g (96%). ^{1}H NMR (400 MHz, C_4D_8O, 25 °C) δ: 7.61 (m, 2H, *o*-AsPh), 7.28 (m, 3H, *m*/*p*-AsPh), 6.98 (m, 4H, *m*-NPh), 6.54 (m, 6H, *o*/*p*-NPh), 4.22 (br s, 2H, N*H*), 1.24 (AB d, $^2J_{HH}$ = 13.6 Hz, 2H, SiCH_2As), 1.17 (AB d, $^2J_{HH}$ = 13.6 Hz, 2H, SiCH_2As), 0.17 (s, 6H, SiCH_3), 0.07 (s, 6H, SiCH_3). ^{1}H NMR (300 MHz, C_6D_6, 25 °C) δ: 7.57 (m, 2H, AsPh *o*-*H*), 7.19 (m, 7H, AsPh *m*/*p*-*H* and NPh *m*-*H*), 6.82 (m, 2H, NPh *p*-*H*), 6.58 (m, 4H, NPh *o*-*H*), 3.09 (br s, 2H, N*H*), 1.13 (AB d, $^2J_{HH}$ = 13.6 Hz, 2H, SiCH_2As), 1.02 (AB d, $^2J_{HH}$ = 13.6 Hz, 2H, SiCH_2As), 0.23 (s, 6H, SiCH_3), 0.18 (s, 6H, SiCH_3). MS (EI) *m*/*z*: 387 (55) [M – NHPh]$^+$. Anal. calcd. for $C_{24}H_{33}AsN_2Si_2$: C 59.98, H 6.92, N 5.83; found: C 60.14, H 7.15, N 6.06.

Synthesis of [NAsN]TaMe$_3$ (3)

A solution of TaMe$_3$Cl$_2$ (0.47 g, 1.57 mmol) in Et$_2$O (10 mL) was added dropwise to a stirred solution of **1** (1.00 g, 1.57 mmol) in Et$_2$O (25 mL) at –78 °C in the dark. The solution was stirred for 20 min at –78 °C, warmed to –20 °C, and then evaporated to dryness. The residue was extracted into toluene (15 mL), the resulting solution was filtered through Celite, and the solvent removed under vacuum. The resulting solid was washed with a minimal amount of cold pentane and further dried to give **3** as a pale yellow solid that was stored in the dark at –40 °C. Yield 0.69 g (63%). Crystals of **3** suitable for X-ray diffraction experiments were grown by slow evaporation of a concentrated benzene solution. ^{1}H NMR (300 MHz, C_6D_6, 25 °C) δ: 7.62 (d, $^3J_{HH}$ = 6.8 Hz, 2H, *o*-AsPh), 7.21 (m, 11H, *m*/*p*-AsPh and *o*/*m*-NPh), 7.03 (t, $^3J_{HH}$ = 6.8 Hz, 2H, *p*-NPh), 1.82 (AB d, $^2J_{HH}$ = 14.1 Hz, 2H, SiCH_2As), 1.25 (AB d, $^2J_{HH}$ = 14.1 Hz, 2H, SiCH_2As), 1.24 (s, 9H, TaCH_3), 0.37 (s, 6H, ring SiCH_3), 0.02 (s, 6H, ring SiCH_3). ^{1}H NMR (500 MHz, C_4D_8O, 25 °C) δ: 7.63 (d, $^3J_{HH}$ = 7.0 Hz, 2H, *o*-AsPh), 7.33 (m, 2H, *m*-AsPh), 7.28 (m, 5H, *p*-AsPh and *m*-NPh), 7.16 (m, 2H, *p*-NPh), 7.07 (d, $^3J_{HH}$ = 7.3 Hz, 4H, *o*-NPh), 1.87 (AB d, $^2J_{HH}$ = 14.2 Hz, 2H, SiCH_2As), 1.40 (AB d, $^2J_{HH}$ = 14.2 Hz, 2H, SiCH_2As), 0.69 (s, 9H, TaCH_3), 0.27 (s, 6H, ring SiCH_3), –0.02 (s, 6H, ring SiCH_3). ^{13}C{^{1}H} NMR (75.4 MHz, C_6D_6, 25 °C) δ: 144.8 (s, NPh *i*-*C*), 141.4 (s, AsPh *i*-*C*), 132.1 (s, AsPh *o*-*C*), 129.9 (s, AsPh *p*-*C*), 129.5 (s, NPh *p*-*C*), 129.2 (s, AsPh *m*-*C*), 128.6 (s, NPh *m*-*C*), 126.1 (s, NPh o-C), 63.6 (s, Ta*C*H$_3$), 13.2 (s, Si*C*H$_2$As), 2.1 (s, Si*C*H$_3$), 1.5 (s, Si*C*H$_3$). MS (EI) *m*/*z*: 689 (100) [M – Me]$^+$, 673 (92) [M – HMe$_2$]$^+$. Anal. calcd. for $C_{27}H_{40}AsN_2Si_2Ta$: C 46.02, H 5.72, N 3.98; found: C 46.22, H 5.62, N 4.29.

Hydrogenation of [NAsN]TaMe$_3$

Hydrogen gas was admitted to a Kontes valve equipped thick-walled bomb fully immersed in liquid nitrogen containing a freeze-pump-thaw degassed solution of **3** (35 mg, 0.050 mmol) in diethyl ether (10 mL). The bomb was sealed and allowed to warm to RT. The solution was stirred for 48 h during which a colour change from pale yellow to pale tan was noted and a colourless precipitate was deposited on the side of the flask. Removal of the solvent under vacuum gave an oily brown residue. ^{1}H NMR (300 MHz, C_6D_6, 25 °C) showed resonances attributable to **2** in 33% yield relative to an internal standard (ferrocene). Elemental analysis of the isolated material returned data indicating the solids were depleted in carbon and hydrogen relative to **3**; a representative analysis found: C 43.33, H 5.20, N 4.32. Deuteration experiments were conducted using the same procedure.

Calculations

Calculations were performed using the Gaussian 98 suite of programs on either a dual 450MHz Pentium II workstation using G98 Rev. A.9 (65) or a dual 1.0 GHz Pentium III workstation using G98 Rev. A.11.4 (81). Calculations were performed using the B3LYP functional (66). The basis functions and effective core potentials were those of the LANL2DZ basis set (67), augmented with polarization functions (p,d) developed for arsenic (72). No geometric constraints were set in the optimization of the complexes. Geometric illustrations were created using ORTEP-III for Windows (82). Orbital depictions were created using the Molden program (83). The Supplementary data for this article contains further details on the calculations including pictures of orbitals, calculated bond distances, and archival output summaries.[2]

[2] Supplementary data for this article are available on the Web site or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON K1A 0S2, CANADA. DUD 5114. For more information on obtaining material refer to http://cisti-icist.nrc-cnrc.gc.ca/irm/unpub_e.shtml. Crystallographic data for this manuscript are contained in CCDC 621660, 621661, and 621662. These data can obtained, free of charge, via www.ccdc.cam.ac.uk/conts.retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk.

Crystallography

In all cases, suitable crystals were selected and mounted on a glass fibre using Paratone-N oil or an acceptable substitute and freezing to –100 °C. Data collection for **1** was made on a Rigaku ADSC CCD area detector with graphite monochromated Mo Kα radiation. Data for **2** and **3** were collected on a Bruker X8 area detector with monochromated Mo Kα radiation. Crystallographic data[2] appear in Table 4. Data for **1** was determined to be a two-component twin (components related by a rotation of 7.77° normal to 0.03, –1.00, and –1.39) using the Twinsolve module of the CrystalClear software package, version 1.3.6 SP0 (84), and corrected for Lorentz and polarization effects and absorption. Data for **2** and **3** was processed and integrated using the Bruker SAINT software package (85) and corrected for absorption effects using the multiscan technique (SADABS) (86). Neutral atom scattering factors for all non-hydrogen atoms were taken from Cromer and Waber (87). Anomalous dispersion effects were included in F_{calc} (88); the values for $\Delta f''$ and $\Delta f'''$ were those of Creagh and McAuley (89). The values for the mass attenuation coefficients are those of Creagh and Hubbell (90).

All structures were solved by direct methods using the program SIR97 (91). All non-hydrogen atoms were refined anisotropically by least-squares procedures on F^2 using SHELXL-97 (92). Hydrogen atoms were included but not refined; their positional parameters were calculated with fixed C–H bond distances of 0.99 Å for sp^2 C, 0.98 Å for sp^3 C, and 0.95 Å for aromatic sp C, with U_{iso} set to 1.2 times the U_{eq} of the attached sp or sp^2 C and 1.5 times the U_{eq} values of the attached sp^3 C atom. Methyl hydrogen torsion angles were determined by electron density. Structure solution and refinements were conducted using the WinGX software package, version 1.64.05 (93). Structure illustrations were created using ORTEP-III for Windows (82).

Acknowledgement

Dr. B.O. Patrick is gratefully thanked for crystallography assistance. We thank the Natural Sciences and Engineering Research Council (NSERC) of Canada for generous financial support.

Reactions of α-isobutyl-α-(methylthio)methylene Meldrum's acid with primary amines in aqueous DMSO

Supriya Biswas, Mahammad Ali, Zvi Rappoport, and Hatim Salim

Abstract: The aminolysis of α-isobutyl-α-(methylthio)methylene Meldrum's acid **7** with primary amines, namely, *n*-butylamine, glycinamide, and methoxyethylamine in DMSO–H_2O (50:50, *v/v*) at 20 °C is overall second-order but first-order in both **7** and amines. The reaction with aminoacetonitrile (AA) is overall third-order, first-order in substrate, and second-order in amine at low amine concentration, while at high amine concentration and high pH the dependence on amine is first-order. A general three-step mechanism has been proposed for all these reactions. For the former group of amines, the first step is a rate-limiting attack of the amine to form the tetrahedral intermediate ($\mathbf{T_A^{\pm}}$), followed by a fast acid–base equilibrium and a fast RNH_3^+- or H_2O-assisted leaving group expulsion. For AA, general base catalysis was confirmed from the dependence of k_A on $[AA]_f$ and on $[OH^-]$. For all four amines, a good Brønsted plot of log k_1 vs. pK_a^{AH} in DMSO–H_2O (50:50, *v/v*) with $\beta_{nuc} = 0.34 \pm 0.02$ was observed. These observations are consistent with the suggested mechanism.

Key words: nucleophilic vinylic substitution reactions, primary amines, α-isobutyl-α-(methylthio)methylene Meldrum's acid, three-step mechanism.

Résumé : L'aminolyse du dérivé α-isobutyl-α-(méthylthio)méthylène de l'acide de Meldrum (**7**) avec des amines primaires telles la butylamine, le glycinamide et la méthoxyéthylamine, dans des solutions contenant 50% de DMSO et 50% d'eau, à 20 °C, est une réaction globalement du deuxième ordre, du premier ordre en composés **7** et du premier ordre en amines. À faible concentration d'amine, la réaction avec l'aminoacétonitrile (AA) est globalement du troisième ordre, soit du premier ordre en substrat et du deuxième ordre en amine; à des concentrations plus élevées d'amine et à des pH plus élevés, la dépendance sur l'amine est toutefois du premier ordre. D'une façon générale, on suggère que la réaction se produit par un mécanisme en trois étapes. Pour le premier groupe d'amines, la première étape est une attaque cinétiquement limitante de l'amine qui conduit à la formation de l'intermédiaire tétraédrique ($\mathbf{T_A^{\pm}}$) et qui est suivie par un équilibre acide-base rapide et une expulsion rapide du groupe partant assistée par RNH_3^+ ou H_2O. Dans le cas de l'aminoacétonitrile, on a confirmé l'existence d'une catalyse basique générale à partir de la dépendance de k_A sur les $[AA]_f$ et $[OH^-]$. Pour les quatre amines, dans des solutions contenant 50% de DMSO et 50% d'eau, on a observé une bonne corrélation de Brønsted entre log k_1 et pK_a^{AH} avec $\beta_{nuc} = 0{,}34 \pm 0{,}02$. Ces résultats sont en accord avec le mécanisme suggéré.

Mots clés : réactions de substitution vinylique nucléophile, amines primaires, dérivé α-isobutyl-α-(méthylthio)méthylène de l'acide de Meldrum, mécanisme en trois étapes.

[Traduit par la Rédaction]

Introduction

The mechanism of the addition–elimination variant of nucleophilic vinylic substitution (S_NV) reactions of electrophilic alkenes (**1**), where X and Y are the activating substituents (1), with anionic nucleophiles (Nu^-) may occur either in a single-step (concerted type) process via a transition state (**2**) or in a two-step process via an intermediate (**3**, $\mathbf{T_{Nu}^-}$), which expels the leaving group (LG^-) to form the product **4** (Scheme 1). Whereas the concerted route is relatively rare (1*h*), reactions with most anionic nucleophiles proceed by a two-step mechanism (1).

The reactions with amine nucleophiles go through a two-step route with the involvement of acid–base equilibrium as an additional step, as depicted in Scheme 2 (2).

In the reactions of **6-SMe-Z** (Chart 1) with a series of secondary amines (2), it was shown that general-acid-catalyzed MeS^- departure (k_3^{AH}, $k_3^{H_2O}$) from $\mathbf{T_A^-}$ is rate-limiting for piperidine, while with piperazine, 1-(2-hydroxyethyl-piperazine), and morpholine deprotonation of $\mathbf{T_A^{\pm}}$ to $\mathbf{T_A^-}$ is

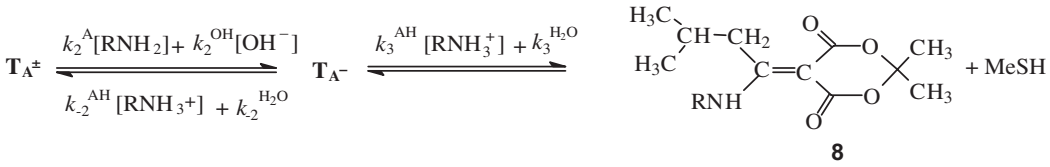
rate-limiting. This conclusion is based on the k_3^{OH}/k_3^{A} ratios of 18:36, indicating the independence of k_1 values on the amine pK_a^{AH} for the former, while for the latter, the ratio was 179, higher than the observed limit of 5:25 (2, 3) manifesting the dependence of k_3^{OH}/k_3^{A} ratio on pK_a^{AH} of the amines.

In the present paper, we examine how the change from a substituted phenyl group in **6-SMe-Z** (**Z** = **H**) to the isobutyl group in **7** (see Chart 1) affects the rate-limiting step(s) and how the overall reactivity changes in the reactions with a series of primary amines.

Results and discussion

General features

All reactions were conducted in DMSO–H_2O (50:50, *v*/*v*) at 20 °C, at an ionic strength of 0.5 mol dm^{-3} maintained with KCl. Pseudo-first-order conditions were applied throughout, with the substrate being the minor component. Rates were measured for the reactions of **7** with *n*-butylamine, glycinamide, methoxyethylamine, and aminoacetonitrile. The representative Fig. 1 shows time-resolved spectra of the reaction with aminoacetonitrile. The presence of an isosbestic point indicates a clean reaction. As observed in the literature, the formation of amine-substituted product **8** produces a blue shift in the UV–vis spectrum (2), and the spectrum of the reaction mixture at infinite time is identical with that of the synthetically prepared **8**. This was further supported by ^{1}H NMR and HR-MS studies.



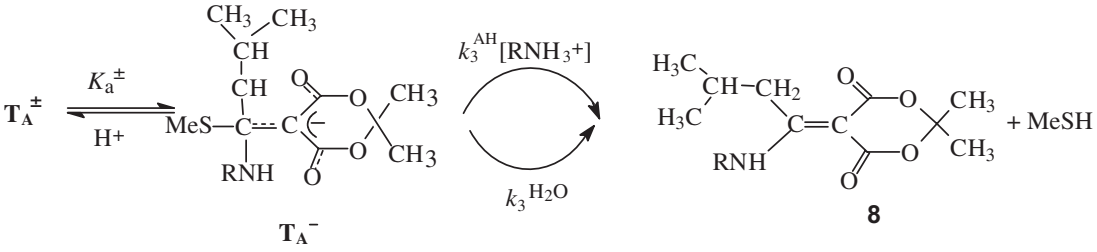
Based on the observations from the reaction of aliphatic primary (4) and alicyclic secondary amines with **6-SMe-Z** (2), we adopt Scheme 3 for the reactions of primary aliphatic amines (RNH_2) with **7**.

As the intermediate does not accumulate to a detectable level, a steady-state approximation to $\mathbf{T_A}^{\pm}$ leads us to derive an expression for the second-order rate constant, k_A, as given by eq. [1].

$$[1] \qquad k_A = \frac{k_1\left(\frac{k_3^{A}}{k_{-1}}[RNH_2] + \frac{k_3^{OH}}{k_{-1}}[OH^-]\right)}{1 + \left(\frac{k_3^{A}}{k_{-1}}[RNH_2] + \frac{k_3^{OH}}{k_{-1}}[OH^-]\right)}$$

The rate constants corresponding to the conversion of $\mathbf{T_A}^{\pm}$ via $\mathbf{T_A}^{-}$ and then to product **8** are shown in eq. [2].

© 2006 NRC Canada



[2] 

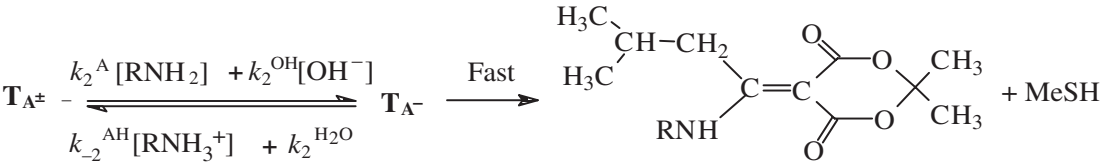
Three cases may arise:

(*i*) When the acid-catalyzed conversion of $\mathbf{T_A^-}$ to $\mathbf{T_A^{\pm}}$ is much faster than its reversal, eq. [3] applies.

[3] $$k_{-2}^{AH}[RNH_3^+] + k_{-2}^{H_2O} \gg k_2^{A}[RNH_2] + k_2^{OH}[OH^-]$$

The interconversion of $\mathbf{T_A^-}$ and $\mathbf{T_A^{\pm}}$ can be treated as a rapid pre-equilibrium followed by a rate-limiting MeS^- departure (eq. [4]) and eqs. [5] and [6] hold, where K_a^{AH} is the acidity constant and K_w is the ionic product of the solvent (pK_w = 15.89 in DMSO–H_2O (50:50, *v*/*v*) at 20 °C, μ = 0.50 mol dm^{-3} KCl) (5).

[4] 



[5] $$k_3^{A} = k_3^{AH}K_a^{\pm}/k_a^{AH}$$

[6] $$k_3^{OH} = k_3^{H_2O}K_a^{\pm}/K_w$$

(*ii*) When the inequality in eq. [7] holds, $\mathbf{T_A^{\pm}}$ deprotonation is the rate-limiting step for the conversion

[7] $$k_{-2}^{AH}[RNH_3^+] + k_{-2}^{H_2O} \ll k_3^{AH}[RNH_3^+] + k_3^{H_2O}$$

of $\mathbf{T_A^{\pm}}$ to **8**, and eq. [8] and relationships [9] and [10] then hold.

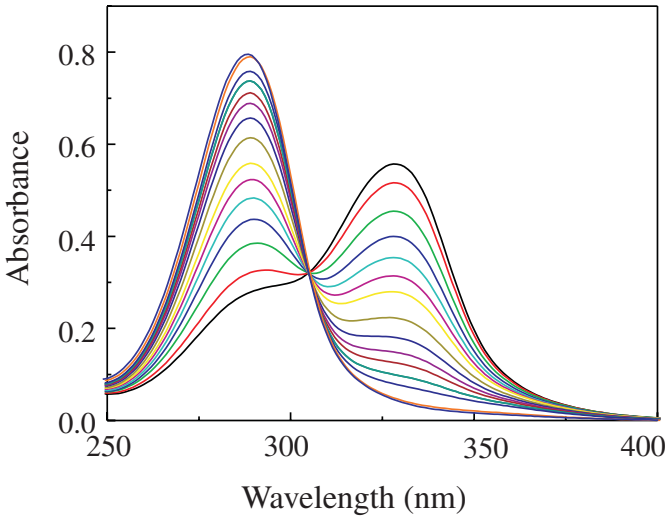
[8] 

[9] $$k_3^{A} = k_2^{A}$$

[10] $$k_3^{OH} = k_2^{OH}$$

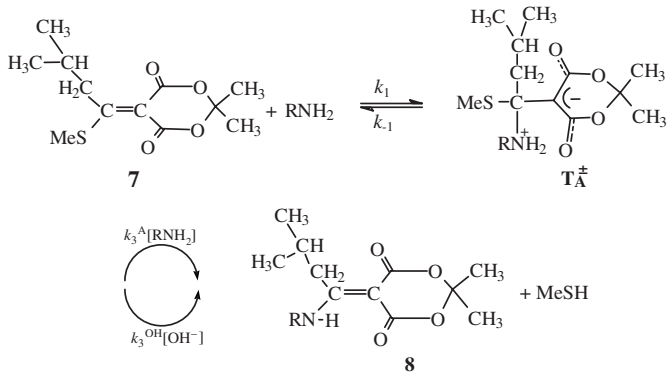
(*iii*) The nucleophilic attack becomes the rate-limiting step either via a concerted route or through the formation of $\mathbf{T_A^{\pm}}$ (Scheme 2) with subsequent faster steps. For reactions with amines, it is generally accepted that the nucleophilic vinylic substitution (S_NV) occurs through the formation of $\mathbf{T_A^{\pm}}$ (2, 6–7), and eqs. [11] and [12] hold (at high pH, this condition is easily met).

[11] $$\left(\frac{k_3^{A}}{k_{-1}}[RNH_2] + \frac{k_3^{OH}}{k_{-1}}[OH^-]\right) \gg 1$$



[12] $$k_A = k_1$$

Reactions of *n*-$BuNH_2$, $MeOCH_2CH_2NH_2$, and $NH_2COCH_2NH_2$



For the reactions of these three primary amines, a strict second-order kinetics (eq. [12] with $k_A = k_1$) was observed under all conditions. All the plots of k_{obs} vs. $[RNH_2]_f$ at pH ~ pK_a of the amines, where $[RNH_2]$:$[RNH_3^+]$ is 1:1, are linear with negligible or no intercept on the rate axis (Fig. 2). A contribution from H_2O or OH^--catalyzed hydrolysis ($k_1^{H_2O}$, k_1^{OH}) of **7** was excluded by the small values of the independently determined k_1^{OH} = 3.27 ± 0.01 dm^3 $mol^{-1}s^{-1}$ and $k_1^{H_2O}$ = (5.52 ± 0.03) × 10^{-6} dm^3 $mol^{-1}s^{-1}$.

Fig. 1. Time resolved spectra generated from a kinetic trace for the reaction between **7** and H_2NCH_2CN in DMSO–H_2O (50:50, *v*/*v*) with $[H_2NCH_2CN]$ = 0.02 mol dm^{-3} at pH 5.30 and 20 °C.

Scheme 3.

[13] $k_{obs} = k_A[RNH_2]$

Consequently, experimental eq. [13] fits the previously mentioned situation (*iii*), and k_A can be identified as k_1 according to eq. [12].

In few cases, reactions were carried out at pH where $[RNH_2]$:$[RNH_3^+]$ ~ 9:1, and no significant changes were observed in slope (k_A) values. Consequently, k_A is pH-independent, showing no general base catalysis.

Reaction with H_2NCH_2CN

The kinetics were performed under pseudo-first-order conditions with **7** as the minor component. A plot of the observed pseudo-first-order rate constants, k_{obs}, vs. $[H_2NCH_2CN]_f$ showed upward curvatures with an increasing slope (Fig. 3), while a plot of k_A ($k_A = k_{obs}/[H_2NCH_2CN]_f$) showed an initial rapid increase in k_A with the increase in [amine] followed by leveling off at higher amine concentration (Fig. 4), which is reminiscent of the reactions of **6-SMe-Z** with secondary amines (2). To check for a general base catalysis in this reaction, a variation of $[NMM]_f$ (NMM is *N*-methylmorpholine) in the range of 0.0005–0.10 mol dm^{-3} at pH 7.40 with $[H_2NCH_2CN]_f$ = 0.002 mol dm^{-3} and pH variation in the range of 6.70–8.45 at constant $[NMM]_f$ = 0.002 mol dm^{-3} and $[H_2NCH_2CN]_f$ = 0.002 mol dm^{-3} were carried out. The k_A value remained almost independent of $[NMM]_f$ with a value 2.26 ± 0.04 dm^3 mol^{-1} s^{-1}, while it increased with $[OH^-]$ at the low $[OH^-]$ region and became independent at high $[OH^-]$ (Fig. 5). This behaviour seems to be a special case of Scheme 2, where only OH^- catalysis but not amine catalysis occurs, particularly at high pH. This can be understood if eqs. [14] and [15] hold throughout the whole concentration ranges used, and if simultaneously the ratio ($k_3^{H_2O}K_a^{\pm}/k_{-1}K_w$) $[OH^-]$ changes from <1 to >1 as $[OH^-]$ is increased and eq. [3] changes to eq. [16].

[14] $$\frac{k_3^{AH}K_a^{\pm}}{k_{-1}k_a^{AH}}[RNH_2] << 2$$

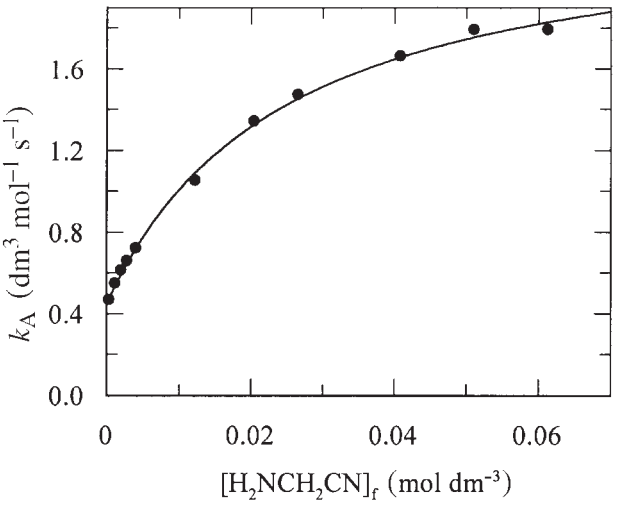
Table 1. Comparison of rate constants for the nucleophilic attack on **6-SMe-H** and **7** by nucleophiles in DMSO–H_2O (50:50, *v*/*v*) at 20 °C.

Amine or other nucleophile	pK_a^{AH}	k_1 (**7**) ($dm^3\ mol^{-1}\ s^{-1}$)	k_1 (**6-SMe-H**) ($dm^3\ mol^{-1}\ s^{-1}$)	k_1(**7**)/k_1 (**6-SMe-H**)
n-Butylamine	10.61	138.4	5.36	25.8
Methoxyethylamine	9.63	65.0	2.63	24.7
Glycinamide	8.28	26.1	1.30	22.9
Aminoacetonitrile	5.39	2.38	0.12	20.3
OH^-	17.30	3.27	0.63	5.2
H_2O	17.33	5.52×10^{-6}	2.80×10^{-6}	2.0

Fig. 4. Plot of k_A vs. $[aminoacetonitrile]_f$ for the reaction of **7** with aminoacetonitrile in DMSO–H_2O (50:50, *v*/*v*) at 20 °C.



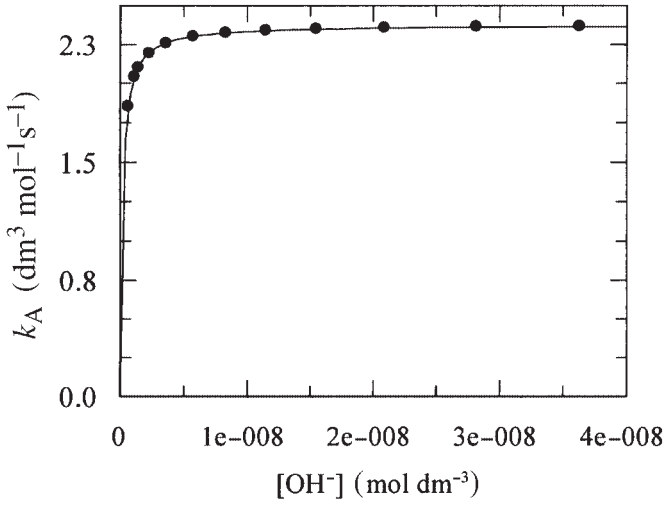


Fig. 5. Plot of k_{obs} vs. $[OH^-]$ for the reaction of **7** with aminoacetonitrile with $[H_2NCH_2CN]_f$ = 0.002 mol dm^{-3} in DMSO–H_2O (50:50, *v*/*v*) at 20 °C.

$$[15]\quad \frac{k_3^{AH}K_a^{\pm}}{k_{-1}k_a^{AH}}[RNH_2] << \frac{k_3^{H_2O}K_a^{\pm}}{k_{-1}K_w}[OH^-]$$

$$[16]\quad k_A = \frac{k_1\left(\frac{k_3^{H_2O}K_a^{\pm}}{k_{-1}K_w}[OH^-]\right)}{1+\left(\frac{k_3^{H_2O}K_a^{\pm}}{k_{-1}K_w}[OH^-]\right)}$$

A non-linear least-squares fit of the data to eq. [3] for $[H_2NCH_2CN]_f$ gives k_1 = 2.37 ± 0.07 $dm^3\ mol^{-1}\ s^{-1}$ and k_3^A/k_{-1} = 50.8 ± 5.15 s^{-1}. Similar treatment for the change in $[OH^-]$ (eq. [16]) yields k_1 = 2.48 ± 0.05 $dm^3\ mol^{-1}\ s^{-1}$ and k_3^{OH}/k_{-1}= 8.13 ± 0.78 × 10^8 s^{-1} (Table 1). The k_1 value obtained from the variation of $[H_2NCH_2CN]_f$ at constant pH is almost the same as that obtained from the variation of $[OH^-]$ at constant $[NMM]_f$ and $[H_2NCH_2CN]_f$, thus confirming the proposed mechanism.

The rate-limiting step

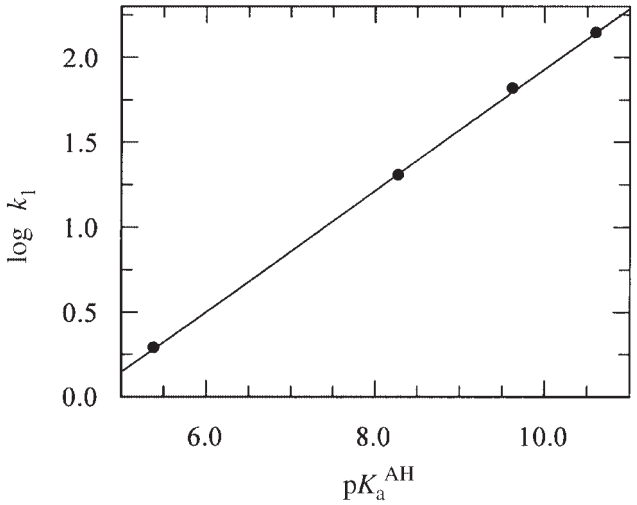
The catalysis by both OH^- and H_2NCH_2CN demonstrates a general base catalysis, which is most likely accounted by Scheme 2. The lack of NMM catalysis may be attributed to its bulkiness, which precludes its closer approach to $\mathbf{T_A^{\pm}}$ in the transition state. Either the conversion of $\mathbf{T_A^{\pm}}$ to $\mathbf{T_A^-}$ or LG departure from $\mathbf{T_A^-}$ is rate-limiting. The very high k_3^{OH}/k_3^A ratio (3.28×10^8) implies a rapid acid–base equilibrium between $\mathbf{T_A^{\pm}}$ and $\mathbf{T_A^-}$ followed by a rate-limiting, general-acid-catalyzed LG departure (2). Similar observations were encountered in the aminolysis of the electrophilic β-methoxy-α-nitrostilbene (**9-OMe**) (see Chart 1) where the deprotonation of the corresponding zwitterionic intermediate (**10**) is fast, and methoxide ion departure is rate determining (7).

Based on the reaction in eq. [8], the reaction of OH^- is expected to be a diffusion-controlled proton transfer with a k_2^{OH} value around 10^{10} $dm^3\ mol^{-1}\ s^{-1}$ (8); hence, k_2^{OH} should be independent of the amine basicity. k_2^A is also expected to be essentially independent of the amine basicity irrespective of whether the reaction is diffusion-controlled ($K_a^{AH} >> K_a^{\pm}$) or diffusion-separation-controlled ($K_a^{BH} < K_a^{\pm}$) (9). In the latter case, k_2^A is independent of the amine basicity because the pK_a *difference* ($K_a^{\pm} - K_a^{AH}$) should be constant. Furthermore, if $K_a^{AH} < K_a^{\pm}$ of $\mathbf{T_A^{\pm}}$, the proton transfer from $\mathbf{T_A^{\pm}}$ to RNH_2 will be thermodynamically favorable and close to diffusion controlled limit. Hence, k_3^{OH}/k_3^A ratios should be independent of the amine basicity and have values of 5–25 (3). Because this contrasts our experimental observation, we ascribe the very high k_3^{OH}/k_3^A value for the H_2NCH_2CN reac-

© 2006 NRC Canada

tion to a rate-limiting leaving group departure rather than to a rate-limiting proton transfer from $\mathbf{T_A^{\pm}}$.

The nucleophilic attack step (k_1)



The good linearity of a Brønsted plot of $\log(k_1)$ vs. pK_a^{AH} ($\beta_{nuc} = 0.34 \pm 0.004$) for the reaction of **7** with the four primary amines is shown in Fig. 6. The corresponding β_{nuc} for k_1 values for the reaction of secondary amines with **6-SMe-H** is 0.41. It was found that the k_1 values for the reactions with secondary amines are smaller than those for the primary amines of comparable basicity. For example, for the **11-H**–HEPA (HEPA is *N*-(2-hydroxyethyl)piperazine) reaction ($pK_a^{AH} = 9.51$), k_1 is 1.06 ± 0.34 dm^3 mol^{-1} s^{-1}, while for **11-H**–$MeOCH_2CH_2NH_2$ reaction ($pK_a^{AH} = 9.63$), k_1 is 2.63 ± 0.05 dm^3 mol^{-1} s^{-1}. These results reflect a strong steric effect that reduces the reactivity of the bulkier secondary amines. When steric effects are absent, secondary amines generally react faster than primary amines of comparable basicity (9, 10).

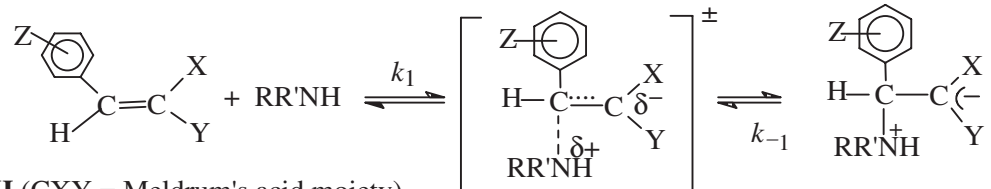
The substitution reactions of **7** are 20–26 times faster than the **6-SMe-H**–RNH_2 reactions. Hence, the formation of $\mathbf{T_A^{\pm}}$ with RNH_2 is thermodynamically more favorable for **7** than for **6-SMe-H**. However, based on both inductive and steric effects a reverse trend is expected. We ascribe this discrepancy to an additional effect, i.e., π-donation by the phenyl group (Ph), which may reduce the reactivity of **6-SMe-H** (11). A similar reactivity trend, which was observed for the reactions of H_2NCH_2CN and morpholine with the Fischer carbene complexes **12** and **13** (see Chart 1) was attributed to a different π-donation effect of the Ph group which lowers the reactivity of **13** over **12** (12–15).

The higher β_{nuc} value for **6-SMe-H**–RR′NH (0.41 ± 0.01) compared with that for the **6-SMe-H**–RNH_2 reactions (0.32 ± 0.01) (4) implies that at the transition state, C–N bond formation is more advanced with the secondary amines. Similarly, the β_{nuc} value for the **7**–RNH_2 reaction (0.34 ± 0.02) is almost the same as that for **6-SMe-H**–RNH_2 reaction and manifests the fact that the bond formations in the transition states progress equally in both reactions.

In the reaction of **14-H** with piperidine or morpholine (16) (eq. [17]), $\beta_{nuc}(k_1) = 0.14$, suggesting that the C–N bond is less advanced than in the reaction of **11-H** and **7** with both primary and secondary amines. This is again consistent with the Hammond–Leffler (17, 18) principle, because **14-H** (19) and **15-H** (16) are much more reactive, e.g., k_1 for the **14-H**-morpholine reaction (3.19×10^5 dm^3 mol^{-1} s^{-1}) is much higher than k_1 for the addition of morpholine to **11-H** (0.49 dm^3 mol^{-1} s^{-1}), and K_1 for the same reaction is also higher for **15-H** (7.76×10^4 dm^3 mol^{-1}) than for **11-H**, which is ~1.9×10^{-8} dm^3 mol^{-1}. The inverse correlation between β_{nuc} and the reactivity of electrophilic olefins (PhCH=CXY) appears to be quite general and has been observed before (20).

Fig. 6. Brønsted Plot for the reaction of **7** with primary amines.

Conclusions



(1) In the reactions of **7** with the more basic amines, namely, $H_2NCH_2CONH_2$, $MeOCH_2CH_2NH_2$, and *n*-$BuNH_2$, no base catalysis is observed; thus, implying a rate-limiting k_1 step because of the strong electronic push from the nitrogen lone pair in the product leading to the stabilization of the transition state resulting from the developing product resonance. For the less basic amine, H_2NCH_2CN, general base catalysis is observed as the electronic push is not so prominent here.

(2) The k_1 values for **6-SMe-H**–RNH_2 reactions are lower than those for the **7**–RNH_2 reactions, suggesting that a strong π-donation by the phenyl group reduces the reactivity of **6-SMe-H**.

Experimental section

Compound **7** was synthesized by following the literature method (20). DMSO was refluxed over CaH_2 and distilled under vacuum. Reagent grade amines were purchased from Aldrich chemicals (USA). The solid amines were recrystallized from a water–ethanol solution, and the liquids were distilled over CaH_2 before use.

Synthesis of α-isobutyl-α-(*n*-butylamino)methylene Meldrum's acid (6)

Compound **7** was prepared analogous to the procedure reported for the synthesis of 2,2-dimethyl-5-[piperidino(*p*-methoxyphenyl)methylene-1,3-dioxane-4,6-dione (21). $CaCl_2$-protected MeCN solution (15 mL) containing 1 mmol of each of **7** and *n*-butylamine was stirred for 48 h at room temperature. The solvent was evaporated, and the remaining solid was recrystallized from EtOH to give α-isobutyl-α-(*n*-butylamino)methylene Meldrum's acid in 35% yield. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 1.00 (2Me of *i*-Bu), 1.02 (Me), 1.24 (CH_2), 1.41 (CH_2), 1.67 (2Me of Meldrum's acid moiety), 2.04 (CH_2 of *i*-Bu), 2.58 (NH), 2.68 (CH of *i*-Bu), 3.45 (CH_2 α- to NH). ES-MS *m*/*z*: 284 (MH^+), 241 ($MH^+ - CMe_2$), 226($MH^+ - OCMe_2$), 197 ($MH^+ - HCMe_2$–$CH_3(CH_2)_2$), 171 (MH^+ – *i*-BuN–CMe_2), 114 (M – MA–CH_2–CH_2, MA is Meldrum's acid moiety).

Kinetics and pH measurements

Details of the kinetic and pH measurements are reported elsewhere (2, 4). Most reactions were followed by monitoring the disappearance of the substrates around 330 nm using a Hewlett-Packard 8453 Agilent UV–vis spectrophotometer. The pH in DMSO–H_2O (50:50, *v*/*v*) at an ionic strength of 0.50 mol dm^{-3} KCl at 20 °C was determined by a digital pH-meter (Systronics–335, India) equipped with a glass electrode and a reference electrode calibrated with standard aq. buffers in DMSO–H_2O (50:50, *v*/*v*) before use. Stock solutions of the substrates were prepared in anhyd. acetonitrile. The pseudo-first-order rate constants (k_{obs}, s^{-1}) were obtained by fitting the kinetic traces with a suitable computer-fit program and the results were within an error limit of ±5%.

Chlorine atom initiated reactions of selected tropospheric halocarbons — Kinetic and product studies

Anisha Garib, Qadir K. Timerghazin, and Parisa A. Ariya

Abstract: Halogens are suggested as important atmospheric oxidants in the marine boundary layer. The room-temperature kinetics of the chlorine-initiated reactions of three biogenic brominated hydrocarbons and four anthropogenic chlorinated ethenes was investigated by gas chromatography with flame ionization detection (GC–FID) at a pressure of 1 atm (1 atm = 101.325 kPa) in air, using the relative rate technique. The rate constants ($\times 10^{13}$ cm^3 molecule^{-1} s^{-1}) for CH_2Br_2, $CHBr_2Cl$, and $CHBr_3$ reactions at 298 ± 2 K were found to be 4.25 ± 0.65, 2.03 ± 0.31, and 2.81 ± 0.41, respectively, using methane as a reference compound. Room temperature rate constants ($\pm 10^{11}$ cm^3 molecule^{-1} s^{-1}) obtained for 1,1-dichloroethene, *cis*-dichloroethene, *trans*-dichloroethene, and trichloroethene using ethene as a reference are 13.4 ± 3.3, 9.1 ± 2.3, 7.4 ± 1.8, and 7.7 ± 1.9, respectively. The rate constants of chlorine-atom reactions with various hydrocarbons obtained in this work and taken from literature were correlated with corresponding rate constants of the OH radical available in the literature. The temperature dependences for the reactions of chlorine atoms with chlorinated ethenes were studied within the 298–358 K range. The corresponding Arrhenius expressions for the rate constants are (cm^3 molecule^{-1} s^{-1}): ln k = (–25.26 ± 0.17) – (758 ± 55)/T for 1,1-dichloroethene, ln k = (–25.79 ± 0.10) – (799 ± 34)/T for *cis*-dichloroethene, ln k = (–26.74 ± 0.09) – (1018 ± 28)/T for *trans*-dichloroethene, and ln k = (–26.10 ± 0.26) – (846 ± 83)/T for trichloroethene. In addition, product studies for the chlorine-initiated gas phase oxidation reactions of $CHBr_3$ and $CHBr_2Cl$ were performed using gas chromatography with mass spectrometric detection (GC–MS). The only identified product for the reaction of $CHBr_3$ with Cl reaction was $COBr_2$, while for the $CHBr_2Cl$ + Cl reaction, COBrCl and $COCl_2$ were observed, indicating the possibility of halogen atom release. The atmospheric implications of the results obtained are discussed.

Key words: tropospheric reactions, kinetics, chlorine atoms, chlorinated hydrocarbons, brominated hydrocarbons.

Résumé : Il a été suggéré que les halogènes sont des oxydants atmosphériques importants dans les interfaces marines. Faisant appel à la chromatographie en phase gazeuse avec détection à ionisation de flamme (CG–DIF), à une pression de une atmosphère dans l'air et utilisant la technique de la vitesse relative, on a étudié la cinétique, à la température ambiante, de réactions initiées par le chlore de trois hydrocarbures bromés biogéniques et de quatre éthènes chlorés anthropogéniques. Utilisant le méthane comme composé de référence, on a établi que les constantes de vitesse ($\times 10^{13}$ cm^3 molécule^{-1} s^{-1}), à 298 ± 2 K, pour les réactions du CH_2Br_2, du $CHBr_2Cl$ et du $CHBr_3$ sont respectivement de 4,25 ± 0,65, 2,03 ± 0,31 et 2,81 ± 0,41. Utilisant l'éthène comme produit de référence, les constantes de vitesse à la température ambiante ($\times 10^{11}$ cm^3 molécule^{-1} s^{-1}) pour les réactions du 1,1-dichloroéthène, du *cis*-1,2-dichloroéthène, du *trans*-1,2-dichloroéthène et du trichloroéthène sont respectivement de 13,4 ± 3,3, 9,1 ± 2,3, 7,4 ± 1,8 et 7,7 ± 1,9. On a établi une corrélation entre les constantes de vitesses des réactions des atomes de chlore avec les divers composés étudiés dans ce travail ou tirées des travaux publiés dans la littérature et les constantes de vitesse correspondantes des réactions du radical HO tirées de la littérature. Opérant entre 298 et 358 K, on a étudié les relations entre les constantes des vitesses de réactions des atomes de chlore avec les divers dérivés halogénés. Les expressions d'Arrhenius correspondantes pour les constantes de vitesses sont (cm^3 molécule^{-1} s^{-1}): ln k = (–25,26 ± 0,17) – (758 ± 55)/T pour le 1,1-dichloroéthène, ln k = (–25,79 ± 0,10) – (799 ± 34)/T pour le *cis*-1,2-dichloroéthène, ln k = (–26,74 ± 0,09) – (1018 ± 28)/T pour le *trans*-1,2-dichloroéthène et ln k = (–26,10 ± 0,26) – (846 ± 83)/T pour le trichloroéthène. De plus, faisant appel à la chromatographie en phase gazeuse avec détection par spectrométrie de masse (CG–SM), on a réalisé une étude des produits obtenus lors des en réactions en phase gazeuse initiées par le chlore du $CHBr_3$ et du $CHBr_2Cl$. Le seul produit identifié pour la réaction de $CHBr_3$ avec le chlore est le $COBr_2$ alors que pour

Introduction

Analysis of ozone-depletion events (1) along with concomitant decreases of the C_2–C_6 hydrocarbon concentrations observed in the Arctic marine boundary layer (MBL) during polar sunrise studies provided convincing evidence of the involvement of chlorine chemistry in these processes (2, 3). The abundance of active chlorine in the marine troposphere and its important role as an atmospheric oxidant has been intensively studied during the last decade (4–6). The OH radical is considered to be a major oxidant and a natural "cleanser" of the troposphere during daytime (6). Its concentration in the MBL is estimated to be approximately 100 times higher than that of active chlorine (7). However, the concentration of Cl atoms may significantly increase during sunrise (8), and for most of the non-methane hydrocarbons (NMHCs) the reaction rates of oxidation by chlorine atoms are about two orders of magnitude larger than the corresponding reactions with OH radicals. Hence, even if [Cl] is lower than [OH], the role of Cl atoms as oxidants for hydrocarbons might still be significant (4).

The mechanism of active chlorine release in the troposphere is still a matter of debate; several proposed mechanisms suggest that heterogeneous reactions are responsible for the formation of Cl atoms. These include reactions of sea-salt aerosols with NO_x species (4), sulfur-containing compounds (9), or the release of halogens through the cycles involving halide ions (10). Various forms of chlorine-containing compounds, such as HOCl, BrCl, and Cl_2, have been repeatedly observed in the atmosphere (11–13). Whereas the concentration of chlorine atoms in the troposphere was estimated to be 10^4–10^5 atoms cm^{-3} during the day in the MBL (14), the molecular chlorine concentration is suggested to be as high as 150 parts per trillion (ppt) (13). Impey et al. (11) reported measurements of photolyzable chlorine of 100 ppt in the boundary layer at Alert (82.5°N, 62.3°W) using a photo-halogen detector (PHD) during the Polar Sunrise Experiment. Thus, photolysis of molecular chlorine or BrCl by sunlight at the Arctic dawn is also believed to form Cl atoms (15).

There is a great variety of biogenic and anthropogenic hydrocarbons emitted into the troposphere, including a large number of chlorinated and brominated species. Whereas the latter compounds are mostly of anthropogenic source, most of the brominated hydrocarbons are of biogenic origin. Trichloroethene, one of the most abundant chlorinated ethenes (emission rate of 197×10^9 g $year^{-1}$) (16), is used industrially as a degreasing, dry-cleaning agent, and solvent (17). It is also emitted by fossil fuel production and combustion. Dichloroethenes, on the other hand, are used in the manufacturing of various plastics (18). The major biogenic bromine-containing species is bromoform ($CHBr_3$) (19) with a concentration in the troposphere within 10–20 ppt (19, 20). Other important brominated hydrocarbons include dibromomethane (CH_2Br_2) and chlorodibromomethane ($CHBr_2Cl$). These compounds are mainly emitted by marine organisms such as algae and phytoplankton (16). According to a recent estimate, marine algae are responsible for up to 70% of global bromoform production (19).

Although a number of experimental and theoretical papers on the chlorine atom initiated oxidation of halocarbons (e.g., see refs. 21–24) have been published, there is still a lack of information on the kinetics of these reactions, especially at the conditions relevant for tropospheric chemistry. The goal of the current work is to provide a self-consistent set of kinetic data for chlorine-initiated reactions of seven halocarbons at an atmospheric pressure of ~760 torr (1 torr = 133.3224 Pa) and over a temperature range of 298–358 K. Product studies of chlorine-initiated reactions of selected brominated hydrocarbons were performed to assess the possibility of regeneration of the halogen atoms as well as their importance in the chemistry of the troposphere.

Experimental

Kinetic studies

Rate constants were determined using the relative rate technique, in which rate constants of two reactions are measured simultaneously and one of the reaction rate constants (a reference) is known.

[1] Cl + reactant → product

$$\frac{-\mathrm{d[reactant]}}{\mathrm{d}t} = k[\mathrm{Cl}][\mathrm{reactant}]$$

[2] Cl + reference → product

$$\frac{-\mathrm{d[reference]}}{\mathrm{d}t} = k_{\mathrm{ref}}[\mathrm{Cl}][\mathrm{reference}]$$

Provided that the reference and the reactant are lost solely by reactions [1] and [2], and there are no significant secondary reactions leading to the reformation of reference and reactant, the following equation applies

$$[3] \qquad \ln\left(\frac{[\mathrm{reactant}]_{t_1}}{[\mathrm{reactant}]_{t_2}}\right) = \frac{k}{k_{\mathrm{ref}}} \ln\left(\frac{[\mathrm{reference}]_{t_1}}{[\mathrm{reference}]_{t_2}}\right)$$

where t_1 and t_2 refer to initial and final concentrations, respectively. Hence, a plot of $\ln([\mathrm{reactant}]_{t_1}/[\mathrm{reactant}]_{t_2})$ against $\ln([\mathrm{reference}]_{t_1}/[\mathrm{reference}]_{t_2})$ is expected to yield a straight line with slope k/k_{ref} and zero intercept. Since k_{ref} is known, the rate constant k for the molecule or atom of interest can be calculated.

All reactants were injected using Hamilton microsyringes into an evacuated (~10^{-3} torr) 3 L double-walled Pyrex glass flask. To avoid undesired side-reactions at the surfaces of the

© 2006 NRC Canada

reaction vessel, the inner walls were deactivated by dimethyldichlorosilane (DMDCS) (25, 26). DMDCS was deposited on the flask walls via a toluene solution, and the toluene was removed by drying and subsequent pumping. The flask was then filled to 760 torr with Ultra Pure air as a diluent. The concentrations of organic reactants ranged from 50 to 150 ppm (where 1 ppm = 2.46×10^{13} molecules cm^{-3}), while that of molecular chlorine was approximately twice as much. Also, 200–500 ppm benzene was added to all reaction flasks to act both as an OH scavenger ($k_{OH} = 1.3 \times 10^{-12}$ cm^3 $molecule^{-1}$ s^{-1}) (27) and an internal reference. Under our experimental conditions, no significant change in the benzene signal was observed throughout the course of the experiments. The reaction mixtures were mixed in the dark using a magnetic stirring bar until all hydrocarbon concentrations were stable.

The reactants were monitored using a gas chromatograph equipped with a flame ionization detector (GC–FID), model HP 6890 equipped with a 5% phenyl-methyl siloxane DB1 capillary column (30 m × 25 mm × 25 μm). Irradiations of reaction mixtures ranging from a few minutes to 30 min were performed in a 0.75 m^3 photolytic box equipped with nine UV tubes (GE Black Light, model F20T12-BL) positioned vertically on the sides of the box. Molecular chlorine was photolyzed to yield two chlorine atoms

$$[4] \qquad Cl_2 + h\nu\ (300 \le \lambda \le 400\ nm) \rightarrow 2\ Cl$$

Immediately following the irradiation, 100 μL of the gas mixture was introduced into the injection port of the GC–FID. For the reactions of the brominated hydrocarbons, the chosen reference molecule was methane, and in the case of chlorinated ethenes, ethene was used as a reference molecule. The reaction flask was thermostated (±1 K) by means of a water circulator (Neslab RTE 111). Identical conditions were maintained for temperature-dependence studies carried out within 298–358 K. Reported experimental uncertainties include a calculated uncertainty of ±2σ. We evaluated an accumulative error of about 12%, which includes uncertainties associated with kinetic plots (~5%–10%), as well as concentration measurements (<5%), and instrument and human errors (~10%).

Product studies

The gas-phase products of the chlorine-initiated reactions of CH_2Br_2, $CHBr_2Cl$, and $CHBr_3$ were investigated using a gas chromatograph with a mass selective detector (GC–MSD, model HP 6890/5973) equipped with a cross-linked 5% phenyl-methyl siloxane HP-5MS (30 m × 0.25 mm × 1.00 μm) capillary column. The experimental setup was identical to the procedure described in the *Kinetic studies* section. Each Cl reaction system was treated separately. Typical concentrations of reactants were 50–200 ppm, while $[Cl_2] \approx 2 \times$ [reactant]. All GC–MS runs were performed in SCAN mode.

Materials

Unless otherwise indicated, all reactants were used as received. Benzene (99.9+%), bromoform (99+%), molecular chlorine (99.5+%), chlorodibromomethane (98%), *cis*-1,2-dichloroethene (97%), dibromomethane (99.6%), 1,1-dichloroethene (99%), ethene gas (99+%), methane gas (99+%), *trans*-1,2-dichloroethene (98%), and trichloroethene (98%) were supplied by Sigma-Aldrich (Oakville, Canada). Ultra Pure air (containing <1 ppm hydrocarbons) was obtained from Matheson Tri-Gas (Newark, USA). Carrier gases for GC (hydrogen, helium, and air) were also supplied by Matheson Tri-Gas. Dimethyldichlorosilane (5% DMDCS in toluene) was obtained from Supelco (Oakville, Ontario, Canada).

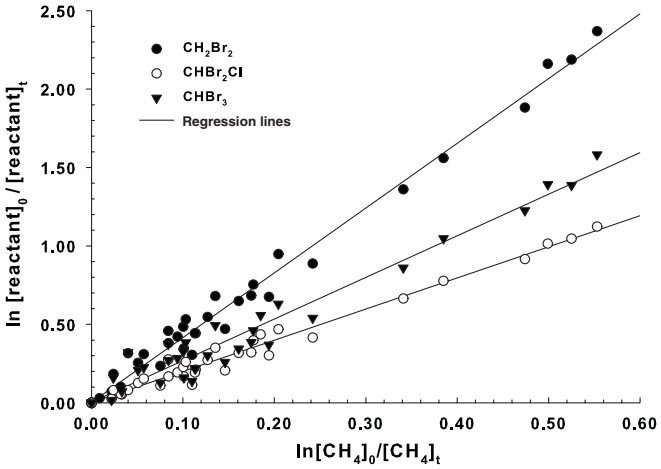

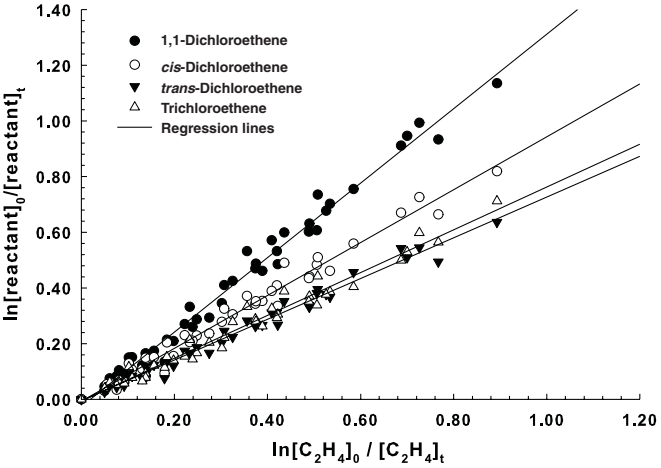

Fig. 2. Relative rate plots for the chlorinated ethenes and the reference compound (ethene) at 298 ± 2 K.

Results and discussion

Reaction rate constants

Prior to starting the kinetic studies, we carried out a series of experiments to verify that "dark" reactions are not significant; no such reactions were observed within experimental uncertainties. Also, aging the gas samples after irradiation for up to 1 h showed that no observable reformation of reactants occurred. To evaluate possible surface catalysis reactions, selected experiments were carried out in 2 to 5 L flasks. However, no change outside experimental errors was

observed. Each kinetic experiment was repeated several times at different reactant concentrations. Conversions of reactants ranged from 30% to 50%. Kinetic plots in Figs. 1 and 2 show the combined results from several experiments. The good linearity of the plots ($r^2 \geq 0.98$) confirms that secondary reactions are negligible. The rate constants for chlorine atom initiated reactions of chlorinated ethenes were measured within the 298–358 K temperature range and at an approximate pressure of 760 torr. The kinetic experiment at each temperature was repeated at least twice. The experimental rate constant ratios have been put on an absolute basis using respective reference rate constants.

Reactions of brominated methanes

For the reactions of bromomethanes, the generally accepted value for the room-temperature rate constant of the reference Cl + CH_4 reaction ($k_{methane}$ = (1.0 ± 0.2) × 10^{-13} in cm^3 molecule^{-1} s^{-1}) was used (28, 29). The room-temperature rate constants for the reactions of bromomethanes are presented in Table 1. The kinetics of the reaction of CH_2Br_2 with chlorine atoms at room temperature is relatively well studied (Table 1), and its rate constant obtained in this work agrees well with the previously published values (23, 29–32), within the uncertainty limits. For the reaction of bromoform, our value is also in agreement with the rate constants from the literature (23, 29, 33). The only value available in the literature for the Cl + $CHBr_2Cl$ reaction rate constant, measured by Bilde et al. (34), is in good agreement with the value reported in the present work.

Reactions of chlorinated ethenes

For the reactions of chlorinated ethenes, the Arrhenius expression for the reference C_2H_4 + Cl reaction rate constant from our previous work (26) (k_{ethene} = (0.39 ± 0.22) × 10^{-11} exp[(966 ± 180)/T] (cm^3 molecule^{-1} s^{-1})) has been used. It should be noted that this Arrhenius expression was obtained at very similar conditions to those used in this work, with both air and N_2 as diluent gases (no considerable differences were found for the rate constants measured in air and N_2) (26). For the room-temperature measurements, the rate constant of k_{ethene} = (10.0 ± 4.0) × 10^{-11} cm^3 molecule^{-1} s^{-1}, calculated from this expression, was used for consistency; it agrees well with the recommended value of k_{ethene} = (10.6 ± 0.3) × 10^{-11} (28, 35).

The relative rate constants (k/k_{ethene}), obtained at room temperature in this work (Table 2), are in good agreement (within the accumulated error bars) with the data reported by Atkinson and Aschmann (21), who also employed the relative rate technique with ethene as a reference compound; the slight disagreements in the absolute values are mainly due to the different reference rate constants used (21). The only case where our rate constant does not agree with the value found by Atkinson and Aschmann (21) is for the *trans*-dichloroethene: the value measured in this work appears to be lower than the literature value. For the trichloroethene reaction, the rate constant measured in the present work is also consistent with the results of Catoire et al. (24).

Chlorinated alkenes are highly reactive toward chlorine atoms: the rate constants of the chlorine-initiated reactions of chlorinated ethenes are greater than those of brominated hydrocarbons by about two orders of magnitude. Radical reactions with unsaturated hydrocarbons proceed via the addition of a radical (Cl in our case) to the double bond forming a carbon-centered radical. This chlorinated alkyl radical formed in the addition reaction rapidly reacts with molecular oxygen to form a peroxy radical, and subsequent reactions lead to the formation of oxygenated chlorine-containing products (6). It should be stressed, however, that the reactions involving unsaturated hydrocarbons are pressure dependent (25, 36, 37); therefore, our results are valid at or near atmospheric pressure.

The temperature dependence studies (Table 2) show that the reactions of chlorinated ethenes have small negative activation energies from approximately –1.5 to –2.0 kcal mol^{-1} (i.e., E_A/R from appoximately –750 to –1000 K^{-1}, Table 3, Fig. 3). Similar small activation energies were observed previously for chlorine-atom reactions with other alkenes, such as ethene (–1.9 kcal mol^{-1}), propene (–1.7 kcal mol^{-1}),

[a]Estimation from three-point temperature dependence.
[b]The values presented are recalculated using the relative rate data from refs. 51 and 52, and the IUPAC recommended (28) (1.4 × 10^{-10} cm^3 molecule^{-1} s^{-1}, T = 200–700 K) value for the reference Cl + C_3H_8 reaction rate.
[c]Estimation from the four-point temperature dependence.

1-butene (–2.0 kcal mol^{-1}), 1-pentene (–1.5 kcal mol^{-1}) (26), and cyclic diene γ-terpenine (–4.2 kcal mol^{-1}) (38). Temperature-dependence studies of the rate constants for chlorine-atom reactions with *cis*-dichloroethene, *trans*-dichloroethene, and trichloroethene were reported in early works by Knox and co-workers (39, 40). The Arrhenius parameters estimated from three- (*cis*-dichloroethene, *trans*-dichloroethene) and four-point (trichloroethene) temperature dependencies taken from refs. 39 and 40 are given in Table 3. It should be noted that the absolute rate constants were recalculated from the relative rate data by Knox and co-workers using a revised rate constant for the reference reaction C_3H_8 + Cl (1.4 × 10^{-10} cm^3 molecule^{-1} s^{-1}, T = 200–700 K) (29). As in the present work, the results of these early studies show negative activation energies for the reaction of chlorine atoms with chlorinated ethenes; however, the absolute values of the activation parameters are significantly different from our results.

As was shown in the case of OH radical addition to unsaturated compounds, the negative activation energies can be explained by reversible formation of a pre-reactive complex

Fig. 3. Arrhenius plots for the reactions of chlorinated ethenes with Cl atoms (298–358 K).

(41). Indeed, the existence of a π-complex formed by the chlorine atom with a C=C double bond has been predicted by quantum-chemical calculations (42). If the reaction mechanism involves the formation of a pre-reactive π-complex at the first step

[5]

then the net rate of the reaction, ν_{net}, is given by

[6] $$\nu_{net} = k_b K_C[\text{alkene}][\text{Cl}] = k_{eff}[\text{alkene}][\text{Cl}]$$

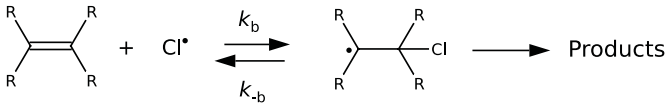
where K_C is the equilibrium constant of the π-complex formation, k_b is the rate constant of the formation of the chlorinated alkyl radical from the pre-reactive complex, and k_{eff} is the effective rate constant. Thus, the dependence of the effective rate constant on the temperature can be expressed as follows (38);

[7] $$k_{eff} = k_b K_C = A\ \exp(-E_A/RT)\ \exp(-\Delta G_C/RT)$$

where ΔG_C is free energy change of the formation of π-complex from the reagents and E_A is the activation energy for the transformation of the π-complex into the chlorinated alkyl radical. Therefore,

[8] $$k_{eff} = A\ \exp(-E_A/RT - \Delta H_C/RT + \Delta S_C/R)$$

where ΔS_C and ΔH_C refer to the entropy and enthalpy change of the formation of the π-complex, respectively. The effective rate constant and activation energy can be described as



[9] $$k_{eff} = A\ \exp[-(E_A + \Delta H_C)/RT + \Delta S_C/R] = A'\ \exp(-E_{eff}/RT)$$

[10] $$E_{eff} = E_A + \Delta H_C$$

[11] $$A' = A\ \exp(\Delta S_C/R)$$

Consequently, depending on the magnitudes of E_A and ΔH_C values, the effective activation energy (E_{eff}) can become negative (eq. [10]). Braña et al. (42) estimated the binding energy of the chlorine–ethene π-complex from quantum-chemical calculations to be in the range of 3 to 7 kcal mol^{-1}, which makes a negative temperature dependence of the effective rate constant possible, if the activation energy of the π-complex transformation into carbon-centered radical is sufficiently low. Unfortunately, no reliable theoretical data on this reaction are available at the moment because the correct treatment of this transformation requires high-level, multi-reference calculations (43).

[12]

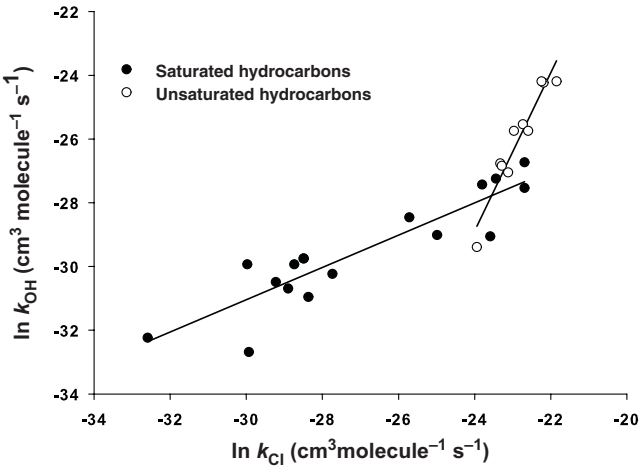
Alternatively, the reversible formation of an unstable radical adduct can account for the negative activation energies in a similar way as the formation of a pre-reactive complex because the enthalpy of formation of a chloroalkyl radical adduct from the reaction of a chlorine atom with an alkene is relatively small (15–20 kcal mol^{-1}) (38).

However, this is less likely because of the high reactivity of chloroalkyl radicals, which would be readily scavenged in reactions with O_2 and (or) other molecules.

Correlation between the reaction rate constants of Cl and OH radicals

We attempted to correlate available experimental rate constants, k_{Cl} (obtained in this work and taken from the literature), for the reactions of chlorine atoms with various hydrocarbons (halogenated or not) with the corresponding rate constants for the OH radical, k_{OH}, (Table 4 and Fig. 4). For the two sets of compounds, saturated and unsaturated, we obtained fairly good correlations: the r^2 values are 0.90 and 0.96, respectively. Obviously, these two sets of rate constants give different correlations because of the different reaction mechanisms: the hydrogen-atom abstraction mechanism for saturated hydrocarbons and the addition to the double bond for unsaturated hydrocarbons (44). Linearity of correlation plots suggests that the reaction mechanism does not change within each series and that the mechanisms of the Cl and OH reactions are similar. It should be mentioned that Bierbach et al. (45) reported very similar correlations among the rate constants for bromine atom reactions and the corresponding reactions of OH, NO_3, and oxygen atoms.

Product studies of chlorine-initiated oxidation of brominated hydrocarbons



For the reaction of chlorine atoms with $CHBr_3$ (Scheme 1), the only product observed is carbonyl dibromide ($COBr_2$) (Fig. 5). A plausible mechanism involves the initial abstraction of the hydrogen atom from bromoform to yield a brominated alkyl radical (CBr_3). Calculations by McGivern et al. (46) have shown that the reaction of the CBr_3 radical with molecular oxygen to form a peroxy radical (CBr_3O_2) is exoergic (–16.7 kcal mol^{-1}), and its barrier is very small. The initial Br atom abstraction by a chlorine atom from $CHBr_3$ is unlikely because this process is quite endothermic (17 to 18 kcal mol^{-1}) (34). Eventual re-

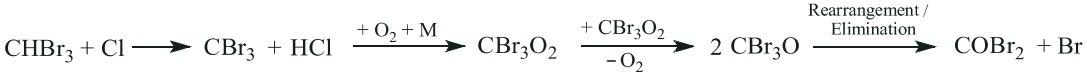
Fig. 4. Correlation plots between room temperature rate constants for the reactions of Cl and OH radicals with saturated and unsaturated hydrocarbons.

action of two brominated peroxy radicals yields a brominated alkoxy radical (CBr_3O), which later decomposes into a carbonyl dibromide molecule and a bromine atom. Therefore, our results suggest that the reaction of a chlorine atom with a $CHBr_3$ molecule in atmosphere may lead to the formation of a bromine atom.



In previous studies of the reaction of a chlorine atom with $CHBr_3$ using FTIR spectroscopy by Kamboures et al. (33) and Weller et al. (47), the formation of $COBr_2$ was also confirmed. In the study performed by Kambanis et al. (23) using a quadrupole mass spectrometer, the experiments were done in a very low pressure reactor in the absence of molecular oxygen; therefore, no $COBr_2$ was observed. However, quantitative production of HCl was reported in this case, which supports the hydrogen-abstraction mechanism as the first step of the reaction.

Our GC–MS study of the chlorine-atom initiated reaction of $CHBr_2Cl$ in the air shows the formation of two products: carbonyl bromochloride (COBrCl), as the main product, and phosgene ($COCl_2$) in small amounts (Fig. 6). The first step of the reaction can involve either hydrogen- or bromine-atom abstraction, with subsequent reaction of the haloalkyl radicals with O_2 and recombination of peroxy radicals, leading to the CBr_2ClO or CHBrClO alkoxy-radicals, respectively (Scheme 2).

Further elimination of a bromine atom from the CBr_2ClO radical leads to the formation of CBrClO, which is the main product observed in this work. The reasons for the formation of small amounts of phosgene ($COCl_2$) detected in our experiments are not clear at the moment. It is possible that side reactions of the radicals formed during the reaction with some impurities in the starting compounds, which are unde-

tectable with the GC–MS setup used in this study, are responsible for the $COCl_2$ formation. We also can not exclude side reactions of the radicals between each other.

It should be noted that in the FTIR study by Bilde et al. (34), carbonyl bromochloride was the only product observed for the $CHBr_2Cl$ + Cl reaction. Also, the absence of HCOCl among the products led Bilde et al. (34) to conclude that the bromine-atom abstraction mechanism is not operational because it is has been shown that the CHBrClO alkoxy radical decomposes quickly and quantitatively to HCOCl (48). However, under the experimental conditions used in both studies, HCOCl would probably not be observed because of its thermal instability toward the decomposition into CO and HCl. Therefore, we cannot completely rule out the bromine-atom abstraction route, although it does not seem to play an important role in the reaction, at least at atmospheric conditions.

We also attempted gas-phase product studies for the CH_2Br_2 + Cl reaction, but no visible product peaks were detected even for high (~80%) conversions of CH_2Br_2. This can be explained by the formation of HCOBr as the main product of the reaction, as observed in ref. 31, which also reports that HCOBr easily undergoes thermal decomposition to give CO and HBr, which are not detectable at our experimental conditions. Therefore, the lack of observable products in our work indirectly supports the formation of HCOBr.

Table 5. Tropospheric lifetimes of studied halocarbons.

Compound	τ_{Cl}	τ_{OH}
CH_2Br_2	7–70 years	0.7–7 years
$CHBr_2Cl$	14–140 years	0.3–3 years
1,1-Dichloroethene	1–14 days	7–75 days
cis-Dichloroethene	6–65 days	10–100 days
trans-Dichloroethene	5–50 days	14–140 days
Trichloroethene	5–55 days	13–130 days

Atmospheric implications

Tropospheric lifetimes of the halogenated hydrocarbons with respect to removal by chlorine atoms can be estimated from the reaction rate constants measured in our study and the chlorine-atom concentration (2) of 10^3–10^4 atoms cm^{-3}. Table 5 shows calculated lifetimes for the hydrocarbons studied in this work in the reactions with Cl and OH (assuming OH concentration (31, 49–51) of 10^5–10^6 radical cm^{-3}). Reaction with OH radicals seems to be the major sink for

© 2006 NRC Canada

the brominated hydrocarbons. In the case of chlorinated ethenes, the chlorine-initiated reactions become as important as the OH-initiated reactions. In the MBL, chlorine atoms can indeed act as a potentially important tropospheric oxidant, which also can lead to release and (or) regeneration of halogen atoms.

Concluding remarks

Rate constants of the chlorine-initiated reactions of several saturated and unsaturated halogenated hydrocarbons were measured within the 298–358 K temperature range. Generally, our kinetic results are in agreement with literature values. The reactions of chlorinated ethenes appear to proceed by chlorine-atom addition to the double bond via the formation of a pre-reactive complex, which leads to negative activation energies for the overall process. The product studies are in agreement with the hydrogen-atom abstraction as the first step of the reactions of the brominated hydrocarbons with chlorine atoms and suggest regeneration of halogen atoms, confirming that these reactions may be important in regulating the tropospheric ozone budget. Chlorine-initiated reactions of the halocarbons studied may only become important sinks in the MBL depending on the relative concentrations of Cl with respect to OH.

Diastereoselective addition of chlorotitanium enolates of *N*-acyl thiazolidinethione to activated imines — A novel synthesis of β-lactams[1]

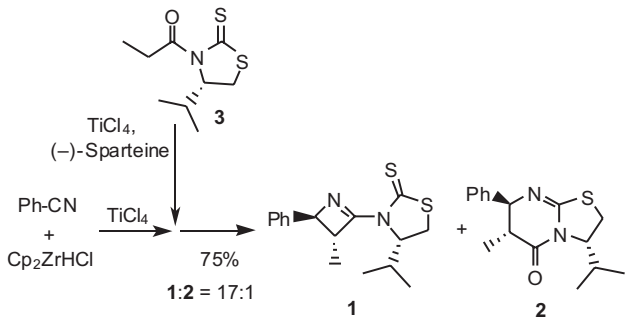
Marike Herold-Dublin and Dennis C. Liotta

Abstract: We report a novel methodology for preparing enantiomerically pure β-lactams, starting from nitriles in diastereomeric ratios up to 10:1. The power of the methodology was demonstrated by the efficient synthesis of the cholesterol absorption inhibitor **SCH 48462**.

Key words: β-lactam, *N*-metalloaldimine, titanium Lewis acids, cholesterol absorption inhibitor.

Résumé : Nous rapportons une nouvelle méthode de préparation des β-lactames énantiomériquement pures à partir de nitriles avec des rapports diastereomériques allant jusqu'à 10 : 1. L'efficacité de la méthode a été démontrée par la synthèse de l'inhibiteur d'absorption du cholestérol **SCH 48462**.

Mots clés : β-lactame, *N*-metalloaldimine, acides de Lewis à base de titane, inhibiteur d'absorption du cholestérol.



[Traduit par la Rédaction]

Introduction

The biological importance of β-lactams has been clearly demonstrated over the last five decades, particularly regarding the central role they play as antibiotics (1). The search continues for new β-lactams that exhibit a broader spectrum of antibacterial activity and a better resistance profile. Furthermore, the relevance of β-lactams in many important non-antibiotic uses, such as cholesterol absorption inhibitors (2) or a variety of enzyme inhibitors (3–6), continues to expand at a surprising rate.

Recently, our research group reported a diastereoselective, one-pot procedure for preparing novel azetine derivatives (**1**) from readily accessible nitriles (Scheme 1) (7). The diastereoselective additions of chlorotitanium enolates of *N*-propionyl-thiazolidine-2-thione (**3**) to various metalloaldimines, derived from the hydrometallation of the corresponding nitriles, resulted in the preferred formation of azetine **1** over tetrahydropyrimidinone derivatives (**2**) for both enolizable and non-enolizable substrates. Here, we describe an efficient, diastereoselective one-pot procedure for preparing β-lactams starting from nitriles.

Scheme 1. Diastereoselective synthesis of azetine derivatives, starting from nitriles.

Results and discussion

In the synthesis of azetine derivative **1**, a β-lactam side-product could be detected in a low percent. The formation of a β-lactam can mechanistically be explained as follows (Scheme 2).

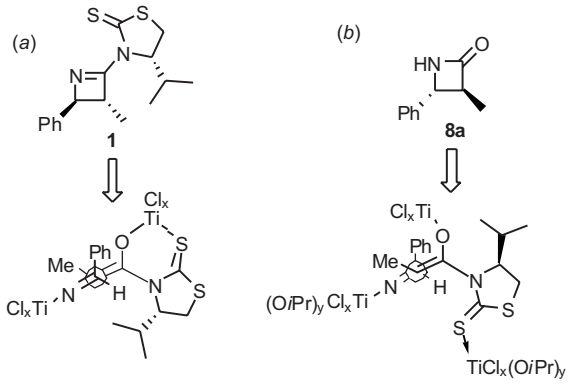
Scheme 2. Proposed mechanism for the formation of lactam **8** and azetine **1**.



The nitrile is converted in situ to the *N*-metalloaldimine species (**4**), thereby activating it for attack by the titanium enolate. After the C–C bond formation, the resulting zwitterion (**5**) undergoes ring closure by nitrogen attack at the carbonyl group (8).[3] When the oxygen in intermediate (**6**) coordinates with a second titanium Lewis acid, it becomes the preferred leaving group, leading to the formation of the azetine **1** (path A). Alternatively, Lewis acid coordination with the chiral auxiliary converts it to a reasonable leaving group, resulting in the production of the β-lactam (**8**) (path B). In principle, redirecting the reaction to favor the lactam over the azetine could be achieved by employing a Lewis acid that is more thiaphilic than oxaphilic (i.e., one that would preferably coordinate to the thiocarbonyl group of the chiral auxiliary). In this way, the thiazolidine-2-thione could be activated as a leaving group, thereby leading to lactam formation.

In our initial investigation, we chose the thiaphilic Lewis acid, titanium trichloroisopropoxide, and were gratified to find that a mixture of *syn* and *anti* β-lactams was formed in a 70% yield (Table 1, entry 1). Each of these isomers was produced in an enantiomerically pure form as confirmed by chiral HPLC studies. The absolute stereochemistry of the β-lactams was elucidated using X-ray crystallography. The yields (but not the diastereomeric ratios) could be improved by increasing the isopropoxide content of the Lewis acid (Table 1, entries 2 and 3). To increase the diastereoselectivity of the lactam formation, a screening of other titanium Lewis acids was conducted. Although the use of pentamethylcyclopentadienyl titanium trichloride increased the ratio of the lactam diastereoselectivity (Table 1, entry 4),

[3]Consistent with literature results from both Crimmins laboratory (see ref. 8) and our own, we have never observed any stereoinduction resulting from the use of sparteine in titanium addition reactions. We use it primarily because we obtain better chemical yields relative to other tertiaty amines, e.g. triethylamine and Huenig's base.

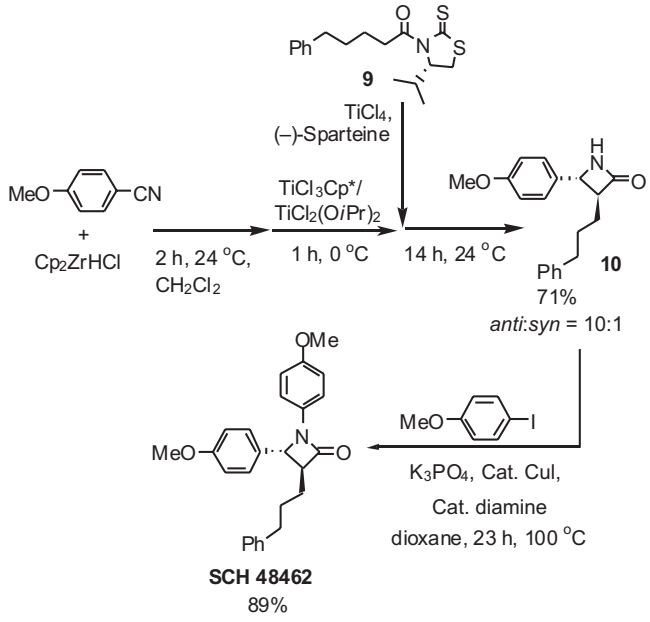
Scheme 3. Proposed transition-states for the formation of (*a*) azetine and (*b*) lactam.



dihydropyrimidinone **2** was also produced in significant quantities (**8**:**2** ratio was 2:1). Because we observed high lactam yields and only traces of dihydropyrimidinone (Table 1, entries 1–3), we speculated that the 6-membered ring formation might be suppressed by adding titanium trichlorodiisopropoxide to the reaction mixture. Indeed, a combination of the Lewis acids, pentamethylcyclopentadienyl titanium trichloride and titanium trichloride isopropoxide, resulted in an efficient formation of the mixture of lactams in a good diastereomeric ratio with nearly complete suppression of dihydropyrimidinone (Table 1, entry 5). The process works well with other non-enolizable nitriles (Table 1, entries 6–9) but resulted in poor yields (0–20%) when attempted with several enolizable nitriles. The diastereoselectivity is highly dependent on the electronic properties of the nitriles, favoring *syn*-lactam fromation for nitriles with electron withdrawing substituents (Table 1, entry 8).

Interestingly, the absolute stereochemistries observed in the formation of *anti*-azetine derivatives are opposite to those observed in the *anti*-lactams (Scheme 3). To explain the difference in the stereochemical outcome, we propose the competing transition-states shown in Scheme 3 as our models. In the azetine formation, we postulate an open transition-state that minimizes dipole interactions (9) between the (*Z*)-titanium enolate (10–12) and the titanium imine.[4] As a consequence, the thiazolidinethione blocks the *re* side of the enolate, and the imine must approach from the *si* side. Diastereomeric transition-states presumably create larger dipole and steric interactions. In case of the lactam formation; however, the coordination of an additional thiaphilic Lewis acid to the thiocarbonyl group of the chiral auxiliary eliminates chelation, thereby allowing it to rotate 180° to minimize dipole effects of the thiocarbonyl group and the carbonyl group of the enolate. As a consequence, the thiazolidinethione blocks the *si* side of the enolate and the imine has to attack from the *re* side. The *syn*-lactam is presumably formed by attack on the other face of the imine.

To probe the scope of this newly developed methodology, we applied it to the synthesis of the cholesterol absorption inhibitor **SCH 48462** (Scheme 4) (2, 13–15). Using the combination of titanium dichlorodiisopropoxide and pentamethyl cyclopentadienyl titanium trichloride, the reaction proceeded in 71% yield and gave improved diastereoselectivity (an *anti* to *syn* ratio of 10:1). In the second step of the synthesis, the β-lactam **10** was readily *N*-arylated (89% yield) by using copper catalysis as described by Klapars et al. (16) (63% overall yield for the two-pot process).

Scheme 4. Synthesis of the cholesterol inhibitor **SCH 48462**.

Conclusions

In summary, we have developed a novel methodology for the preparation of enantiomerically pure β-lactams, starting from nitriles in diastereomeric ratios up to 10:1. The power of the methodology was demonstrated by the efficient synthesis of the cholesterol absorption inhibitor **SCH 48462**.

Experimental section

General procedure for β-lactam formation

The nitrile (1.72 mmol) and Cp_2ZrHCl (445.00 mg, 1.72 mmol) were dissolved in dry dichloromethane (2 mL) in a 50-mL flask and stirred for 2 h under argon at room temperature. The respective titanium Lewis acid (3.45 mmol) was added, and the reaction mixture was stirred for 1 h at 0 °C. During this time, titanium enolate of compound **3** or **9** was generated by dissolving **3** or **9** (1.15 mmol) in dry dichloromethane (5 mL) at 0 °C under argon, then dropwise addition of titanium tetrachloride (0.13 mL, 1.15 mmol), stirring for 5 min, and the addition of (–)-sparteine (0.66 mL, 2.87 mmol). The brown solution was stirred 40 min at 0 °C and then added to the first reaction mixture via a cannula. The reaction mixture was stirred for 14 h at room temperature. It was then quenched with 20 mL saturated aq. ammonium chloride solution with continuous stirring, and dichloromethane (30 mL) and distilled water

[4] We considered and rejected Zimmerman–Traxler-like transition-states primarily because the absolute stereochemistries of the newly formed stereogenic centers would have been derived from an unfavorable *trans* diaxial substituent pattern.

© 2006 NRC Canada

(30 mL) were added. The organic phase was separated, and the aq. phase extracted with dichloromethane (2 × 30 mL). The combined organic phases were washed with saturated aq. sodium bicarbonate solution, then with brine, dried with anhyd. magnesium sulfate, and finally concentrated under vacuum. The product mixture was purified by silica gel flash chromatography (EtOAc:hexanes was 1:10 – 1:3).

For spectroscopic and physical data of **8a**, **8b**, **9**, **10**, and **SCH 48462**, refer to the supplementary data.[5]

Acknowledgments

We would like to thank Dr. Kenneth Hardcastle (Department of Chemistry, Emory University) for obtaining the X-ray structures.
